راهنمای نصب آخرین نسخه آپتودیت آفلاین

۱. برای نصب اپلیکشین درگوشی آیفون، برنامه App Store و درگوشی اندروید Play Store را اجرا کرده سپس عبارت Mehrsys medical library را جستجو کنید و برنامه را نصب کنید.

۲. بعد از نصب و اجرای اپلیکیشن در صفحه اول برنامه **برای دریافت** Username و Password به **به تلگرام پشتیبانی و فروش که در زیر تصویر اشاره شده است پیغام دهید.**

۳. در مرحله بعد حساب کاربری خود را بسازید.

۴. بعد از ورود به برنامه در قسمت یا منوی Download روی آیکون سه نقطه آبی رنگ که رو به روی UpToDate قرار دارد کلیک کنید و گزینه دانلود Download را انتخاب کنید با این عمل می توانید دانلود را به آسانی از طریق اینترنت انجام دهید.

قابلیتهای برنامه

- دسترسی به آخرین نسخه آپتودیت آفلاین با قابلیت بروز رسانی
- امکان جستجو بسیار سریع مطالب بدون نیاز به اینترنت
- امکان مشاهده **abstract** رفرنسهای داخل مقالات آپتودیت
- قابل نصب بر روی گوشی و کامپیوتر
- دسترسی به دیگر منابع پزشکی و دارویی به صورت رایگان
- امکان انتخاب متون، کپی و ارسال آن به برنامه های دیگر
- هایلایت کردن متون در برنامه به رنگهای مختلف
- ذخیره کردن مقالات و عکسهای آپتودیت
- تولید شده توسط شرکت معتبر نرم افزاری و مورد تایید نظام صنفی رایانه ای کشور و شورای عالی انفورماتیک

Contents

Preventive Medicine 1

Learning Objectives

- ❏ Describe appropriate screening methods as they apply to neoplasms of the colon, breast, and cervix
- ❏ Describe epidemiological data related to incidence and prevention of common infectious disease, chronic illness, trauma, smoking, and travel risks

CANCER SCREENING

A 39-year-old woman comes to the clinic very concerned about her risk of developing cancer. Her father was diagnosed with colon cancer at age 43, and her mother was diagnosed with breast cancer at age 52. She is sexually active with multiple partners and has not seen a physician since a motor vehicle accident 15 years ago. She denies any symptoms at this time, and her physical examination is normal. She asks what is recommended for a woman her age.

Screening tests are done on seemingly healthy people to identify those at increased risk of disease. Even if a diagnostic test is available, however, that does not necessarily mean it should be used to screen for a particular disease.

- Several harmful effects may potentially result from screening tests.
- Any adverse outcome that occurs (large bowel perforation secondary to a colonoscopy) is iatrogenic.
- Screening may be expensive, unpleasant, and/or inconvenient.
- Screening may also lead to harmful treatment.

Finally, there may be a stigma associated with incorrectly labeling a patient as "sick."

For all diseases for which screening is recommended, effective intervention must exist, and the course of events after a positive test result must be acceptable to the patient. Most important, the screening test must be valid, i.e., it must have been shown in trials to decrease overall mortality in the screened population. For a screening test to be recommended for regular use, it has to be extensively studied to ensure that all of the above requirements are met.

The 4 malignancies for which regular screening is recommended are **cancers of the colon, breast**, **cervix,** and **lung**.

Colon Cancer

In the patient with no significant family history of colon cancer, screening should begin at age 50. The preferred screening modality for colon cancer is colonoscopy every 10 years. Other choices include annual fecal occult blood testing and sigmoidoscopy with barium enema every 5 years.

In the patient with a single first-degree relative diagnosed with colorectal cancer before age 60 or multiple first-degree relatives with colon cancer at any age, colonoscopy should begin at age 40 or 10 years before the age at which the youngest affected relative was diagnosed, **whichever age occurs earlier.** In these high-risk patients, colonoscopy should be repeated every 5 years. The U.S. Preventive Services Task Force (USPSTF) does not recommend routine screening in patients age >75.

Note

Tamoxifen prevents cancer by 50% in those with >1 family member with breast cancer.

Breast Cancer

The tests used to screen for breast cancer are mammography and manual breast exam. Mammography with or without clinical breast exam is recommended every 1–2 years from age 50–74. The American Cancer Society no longer recommends monthly self breast examination alone as a screening tool. Patients with very strong family histories of breast cancer (defined as multiple first-degree relatives) should consider prophylactic tamoxifen, discussing risks and benefits with a physician. Tamoxifen prevents breast cancer in high-risk individuals.

Note

Prostate Screening

USPSTF concludes that the current evidence is insufficient to assess the balance of benefits/risks of prostate cancer screening in men age <75. It recommends against screening in men age >75.

For USMLE, do not screen for prostate cancer.

Cervical Cancer

The screening test of choice for the early detection of cervical cancer is the Papanicolaou smear (the "Pap" test). In average risk women, screening with Pap smear should be started at age 21, **regardless of onset of sexual activity**. It should be performed every 3 years until age 65. As an alternative, women age 30-65 who wish to lengthen the screening interval can do co-testing with Pap and HPV testing every 5 years. In higher risk women, e.g., HIV, more frequent screening or screening beyond age 65 may be required.

Lung Cancer

Current recommendations for lung cancer screening are as follows:

- Annual screening with low-dose CT in adults age 55-80 who have a 30-pack-year smoking history and currently smoke or have quit within past 15 years
- Once a person has not smoked for 15 years or develops a health problem substantially limiting life expectancy or ability/willingness to have curative lung surgery, screening should be discontinued

TRAVEL MEDICINE

A 44-year-old executive comes to the clinic before traveling to Thailand for business. He has no significant past medical history and is here only because his company will not let him travel until he is seen by a physician. The patient appears agitated and demands the physician's recommendation immediately.

It is important to set up a pretravel counseling session 4–6 weeks before the patient's departure.

Hepatitis A infection is travelers' most common vaccine-preventable disease. Hepatitis A infection is possible wherever fecal contamination of food or drinking water may occur. Infection rates are particularly high in nonindustrial countries. If a patient is leaving within 2 weeks of being seen, both the vaccine and immune serum globulin are recommended. A booster shot given 6 months after the initial vaccination confers immunity for approximately 10 years.

All travelers to less-developed countries should get hep A vaccine.

Hepatitis B vaccination is recommended for patients who work closely with indigenous populations. Additionally, patients who plan to engage in sexual intercourse with the local populace, to receive medical or dental care, or to remain abroad for >6 months should be vaccinated.

Malaria: Mefloquine is the agent of choice for malaria prophylaxis. It is given once per week; it may cause adverse neuropsychiatric effects such as hallucinations, depression, suicidal ideations, and unusual behavior. Doxycycline is an acceptable alternative to mefloquine, although photosensitivity can be problematic. For pregnant patients requiring chemoprophylaxis for malaria, chloroquine is the preferred regimen.

Rabies vaccination is recommended for patients traveling to areas where rabies is common among domesticated animals (India, Asia, Mexico). Chloroquine can blunt the response to the **intradermal** form of rabies vaccine. Therefore, in patients who require malaria prophylaxis, in addition to rabies prophylaxis the **intramuscular** form of the vaccine should be administered. Rabies vaccination is not considered a routine vaccination for most travelers.

Typhoid vaccination is recommended for patients who are traveling to developing countries and will have prolonged exposure to contaminated food and water. Typhoid vaccination comes in 2 forms, an oral live attenuated form and a capsular polysaccharide vaccine given parenterally. The live attenuated form (1) needs to be refrigerated, and (2) is contraindicated in patients who are HIV positive. The polysaccharide vaccine is given intramuscularly as a single injection. Side effects include irritation at the injection site. Fever and headache are rare adverse reactions to the vaccine. The polysaccharide vaccine is the preferred form for almost all subjects as it is well-tolerated and convenient (no need for refrigeration). It is safe for HIV patients.

Polio: Adults who are traveling to developing countries and have never received a polio vaccine should receive 3 doses of the inactivated polio vaccine. Patients who have been previously immunized should receive a one-time booster. The live attenuated polio vaccine is no longer recommended because of the risk of vaccine-associated disease.

Patients traveling to areas where **meningococcal meningitis** is endemic or epidemic (Nepal, sub-Saharan Africa, northern India) should be immunized with the polysaccharide vaccine. Additionally, Saudi Arabia requires immunization for pilgrims to Mecca. Patients with functional or actual asplenia and patients with terminal complement deficiencies should also receive the vaccine. Meningococcal vaccine is now routinely administered at age 11.

To prevent **traveler's diarrhea**, patients should be advised to avoid raw and street vendor salads, unwashed fruit, and tap/ice water. Patients who experience mild loose stools without fever or blood can safely take loperamide. Treatment with a fluoroquinolone or azithromycin is reserved for patients with moderate to severe symptoms.

IMMUNIZATIONS

A 52-year-old man comes to the clinic for a health maintenance evaluation. His recent colonoscopy showed no evidence of carcinoma. Recent serum fasting glucose, serum cholesterol, and blood pressure measurements are all within normal limits. The patient has a history of smoking, continues to smoke 2 packs per day, and was diagnosed with COPD 3 years ago.

Note

Patients must get pneumovax, meningococcal, and Haemophilus vaccines 2 weeks before a splenectomy.

Immunization is the best method available to prevent serious infectious disease. Between 50,000 and 70,000 adults die every year from preventable infectious diseases (influenza, invasive pneumococcal disease, and hepatitis B). Surveys have shown that among patients who have an indication for any vaccination, very few actually receive it (pneumococcal vaccination 20%, influenza 40%, hepatitis B 10%). It is for this reason that the American College of Physicians recommends that every patient's immunization status should be reviewed at age 50. Risk factors that would indicate specific vaccinations should be evaluated at that time.

Most patients received a primary immunization against tetanus and diphtheria as children. Adults who were never vaccinated should receive a total of 3 doses, the first 2 of which are given 1 to 2 months apart, with the third dose given 6 to 12 months later. The principle is that adults require a total of 3 vaccinations against tetanus and diphtheria. A booster vaccination should be given every 10 years for life. One of the boosters should use Tdap instead of Td booster. If the wound is dirty, revaccinate after 5 years.

Influenza Vaccine

Recommended annually for all adults regardless of age. Patients who have a history of cardiopulmonary disease, diabetes mellitus, or hemoglobinopathy, or are age 50+ residents of chronic care facilities derive the greatest benefit from an annual influenza vaccination. Pregnant women who will be in their second or third trimester during the influenza season should also receive the vaccine.

Pneumococcal Vaccine

Indicated for all adults age ≥65. Additionally, patients with a history of sickle-cell disease or splenectomy, those who have a history of cardiopulmonary disease, alcoholism, or cirrhosis, and Alaskan natives and certain Native American populations should receive the vaccine regardless of age. Immunocompromised patients (patients with hematologic malignancies, chronic renal failure, or nephrotic syndrome; HIV-positive patients; or patients receiving immunosuppressive medications) should also receive the vaccine at any age. Revaccination should be performed in healthy patients who received their initial vaccination age <65 and were age <60 at the time of primary vaccination. Patients with a high risk of fatal infection (CKD, asplenic patients, immunocompromised patients) should be revaccinated once after 5 years. No one gets >1 booster shot per lifetime.

Hepatitis B Vaccine

Recommended when there is a history of IV drug abuse, male homosexuality, household or sexual contact with hepatitis B carriers, or frequent exposure to blood or blood products. Additionally, patients with a history of chronic liver disease should receive the vaccine.

Immunity is confirmed serologically. Also recommended for all children through age 18, those with STIs, those who are sexually active but not monogamous, workers with occupational exposure to blood, and prison inmates.

Hepatitis A Vaccine

The vaccine against hepatitis A protects against the virus in >95% of cases. There are 2 types of vaccine; both types stimulate active immunity against a future infection.

- One contains inactivated hepatitis A virus
- One contains a live but attenuated virus

For the best protection, the vaccine should be given in 2 doses; a booster should follow up the initial dose 6-12 months later. Protection against hepatitis A begins approximately 2-4 weeks after the initial vaccination. Those who miss the follow-up booster dose should receive only the remaining booster dose.

In the United States, the vaccine is strongly recommended for all children age 12-23 months in an attempt to eradicate the virus nationwide. There are also recommendations that the following populations should be vaccinated:

- All children age >1 year
- People whose sexual activity puts them at risk
- People with chronic liver disease
- People who are being treated with clotting factor concentrates
- People who are living in communities where an outbreak is present

Hepatitis A is the most common vaccine-preventable virus acquired during travel, so people travelling to places where the virus is common (Indian subcontinent, Africa, Central America, South America, the far East, and Eastern Europe) should be vaccinated.

Varicella Vaccine

A live attenuated vaccine recommended for use in all adults who lack a history of childhood infection with varicella virus. Being a live attenuated vaccine, varicella vaccine should not be given to immunocompromised patients, HIV-positive patients when symptomatic or <200 CD4 cells, or pregnant women.

Patients age ≥60 are recommended to receive the varicella zoster (shingles) vaccine, which has been shown to reduce the risk of zoster and its associated pain (post-herpetic neuralgia). It is indicated regardless of whether there is a history of shingles, as it is possible to have a second herpes zoster infection.

Measles, Mumps, Rubella (MMR) Vaccine

A live attenuated vaccine usually given in childhood. Healthy adults born after 1956 should receive one dose of the vaccine. Pregnant women and immunocompromised patients should not be vaccinated. HIV-positive patients who are asymptomatic may receive the vaccine.

Meningococcal Vaccine

Recommended for everyone at age 11 visit. Also recommended for young adults living in dormitories or barracks, people exposed to outbreaks, those with asplenia or terminal complement deficiencies, those who travel to endemic regions (traveling to Mecca), and those exposed to *Neisseria menigitidis*.

Human Papillomavirus (HPV) Vaccine

Recommended for women age 9-26, regardless of sexual activity. Do not use in pregnancy. Regimen is in 3 doses: 0, 2, and 6 months.

Herpes Zoster Vaccine

The zoster vaccine is a live vaccine that has been shown to reduce the incidence of shingles by 50%. It has also been shown to reduce the number of cases of post-herpetic neuralgia, as well as the severity and duration of pain/discomfort associated with shingles. The vaccine is, basically, a larger-than-normal dose of the chicken pox vaccine, as both shingles and chickenpox are caused by the same virus, varicella zoster (VZV).

The shingles vaccine (Zostavax) is recommended for adults age ≥60, whether they have already had shingles or not. The shingles vaccine is a live vaccine given as a single injection. Some people report a chickenpox-like rash after receiving it. The vaccine should NOT be given to:

- Those with a weakened immune system due to HIV/AIDS or another disease that affects the immune system
- Those who are receiving immune system-suppressing drugs or treatments, such as steroids, adalimumab (Humira), infliximab (Remicade), etanercept (Enbrel), radiation or chemotherapy
- Those who have neoplasia, which affects the bone marrow or lymphatic system, such as leukemia or lymphoma

SMOKING CESSATION

A 25-year-old man comes to the clinic for evaluation of a stuffy nose and fever. Over the course of the interview the patient states that he smokes 3 packs of cigarettes per day and has been doing so for the last 7 years.

Smoking is responsible for 1 in every 5 deaths in the United States. Smoking cessation is the most preventable cause of disease. Physicians can take the following steps to assist:

ASK about smoking at every visit.

ADVISE all smokers to quit at every visit.

ATTEMPT to identify those smokers willing to quit.

ASSIST the patient by setting a quit date (usually within 2 weeks) and using nicotine patches/gum, the oral antidepressant bupropion or varenicline as supportive therapy. Varenicline and bupropion are more effective than patches.

ARRANGE follow-up. Provide positive reinforcement if the quit attempt was successful. If the quit attempt was not successful, then determine why the patient smoked and elicit a recommitment to smoking cessation. Most patients will require several attempts before being successful.

Monotherapy treatment for smoking cessation includes nicotine replacement therapy (transdermal nicotine patches, gum, lozenges, inhalers), bupropion, and varenicline. Bupropion lowers the seizure threshold so do not use in cases of alcohol abuse. With varenicline, screen first for depression since it causes increased rate of suicidal thoughts.

Place a follow-up call 1-2 weeks after quit date. The use of pharmacotherapy doubles the effect of any tobacco cessation intervention.

Note

Varenicline should not be used in patients with a history of psychiatric disease.

OSTEOPOROSIS

All women age >65 should be given DEXA bone density scan. Screening should begin at age 60 if there is low body weight or increased risk of fractures. A bone density test uses x-rays to measure how many grams of calcium and other bone minerals are packed into a segment of bone. The bones that are tested are in the spine, hip and forearm. Bone density test results are reported in 2 numbers: T-score and Z-score.

The **T-score** is the bone density compared with what is normally expected in a healthy young adult of the same sex. The T-score is the number of units—standard deviations—that bone density is above or below the average. T-score >2.5 SD indicates the likelihood of osteoporosis and increased risk of fracture. The diagnosis of osteoporosis by DEXA scan also means that treatment should be initiated with bisphosponates, oral daily calcium supplementation, and vitamin D.

The **Z-score** is the number of standard deviations above or below what is normally expected for someone of the same age, sex, weight, and ethnic or racial origin. Z-score ≤-2 may suggest that something other than aging is causing abnormal bone loss (consider drugs causing osteoporosis such as corticosteroids). The goal in this case is to identify the underlying problem.

ABDOMINAL AORTIC ANEURYSM

U/S should be done once in men age >65 who have ever smoked. There are no screening recommendations for male nonsmokers and women, regardless of smoking history.

HYPERTENSION, DIABETES MELLITUS, AND HYPERCHOLESTEROLEMIA

> A 45-year-old man comes to the physician anxious about his health. Five years ago his mother was diagnosed with diabetes and high cholesterol. He is worried about his health and risk for heart disease. Physical examination is within normal limits.

Cholesterol screening should commence at age 35 in men who have no risk factors. In both men and women with risk factors for coronary artery disease, screening should be done routinely after age 20. Management should not be determined by an isolated reading because cholesterol levels may fluctuate between measurements. Repeat in 5 years in low-risk individuals.

Screening for diabetes mellitus should be considered only for patients with hypertension (>135/80 mm Hg). Diabetes mellitus is diagnosed when:

- 2 fasting glucose measurements are >125 mg/dL, HbA1c > 6.5%, or
- random glucose >200 mg/dL accompanied by symptoms

There is insufficient evidence for or against routine screening. The strongest indication is for those with hypertension and hyperlipidemia.

Screening is recommended for elevated blood pressure in those age >18, at every visit. Screening is not recommended for carotid artery stenosis with duplex.

ALCOHOL ABUSE

A 55-year-old man comes to the office for evaluation of a sore throat. The patient admits that he was recently fired from his job and is having marital problems at home. The patient has no significant past medical history, and physical examination is within normal limits. He attests to drinking 3 shots of whiskey every day after work.

Physicians should screen for alcohol abuse by using the CAGE questionnaire:

Have you ever felt the need to:	**C**ut down on your drinking?
Have you ever felt:	**A**nnoyed by criticism of your drinking?
Have you ever felt:	**G**uilty about your drinking?
Have you ever taken a morning:	**E**ye opener?

A positive screen is 2 "yes" answers. One "yes" should raise the possibility of alcohol abuse.

PREVENTION OF VIOLENCE AND INJURY

A 27-year-old woman presents to the emergency department complaining of right-arm pain. When asked how she sustained the injury, she states that she fell down the steps in front of her house. The patient appears anxious and nervous. On physical examination there are various 2 cm wide lacerations on her buttocks.

Injuries are the most common cause of death in those age <65. The role of the physician is to advise patients about safety practices that can prevent injury, e.g., using seat belts, wearing bicycle helmets, and not driving after drinking alcohol.

Identifying women who are at increased risk of physical or sexual abuse is an essential role for physicians. Simply asking women if they have been hit, kicked, or physically hurt can increase identification by >10%.

Endocrinology 2

Learning Objectives

- List presenting signs and therapeutic approaches to disease of the anterior pituitary, posterior pituitary, thyroid, parathyroid, and adrenal glands
- Describe disorders that cause hypogonadism or affect the testes
- Describe disorders of carbohydrate metabolism

DISEASES OF THE PITUITARY GLAND

The pituitary is surrounded by the sphenoid bone and covered by the sellar diaphragm, an extension from the dura mater. It lies in the sella turcica near the hypothalamus underneath the optic chiasm.

The pituitary is divided into 2 lobes—the adenohypophysis or anterior lobe, which constitutes 80% of the pituitary, and the neurohypophysis or posterior lobe, which is the storage site for hormones produced by the neurosecretory neurons (supraoptic and paraventricular nuclei) within the hypothalamus. The 2 hormones stored in the posterior lobe are ADH (antidiuretic hormone or vasopressin) and oxytocin.

There is a very close relationship between the hypothalamus and the pituitary. The hypothalamus regulates the release of hormones from the anterior pituitary by different hypothalamic releasing and inhibiting hormones (hypothalamic–pituitary axis).

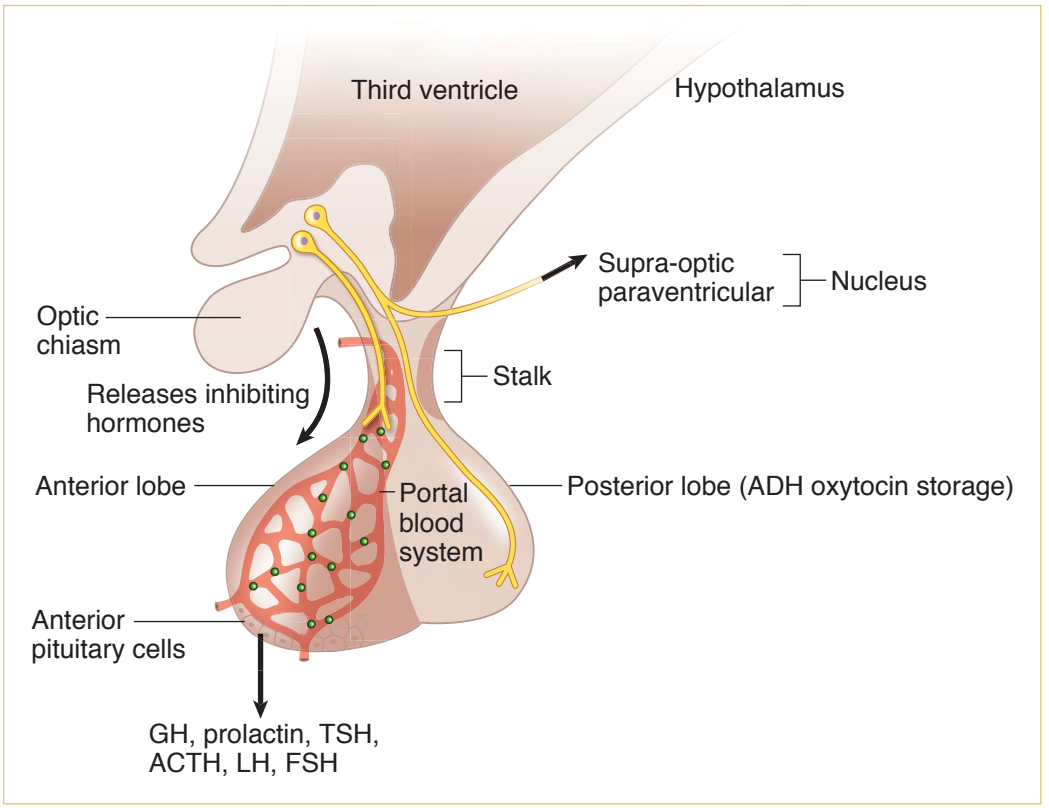

Figure 2-1. Pituitary Gland

As a sample summary, the hypothalamus secretes releasing factors for each respective pituitary stimulatory hormone. Each pituitary hormone stimulates release of the active hormone from the final target gland. The active hormones then inhibit release of releasing factors and stimulatory hormones from the hypothalamus and pituitary gland, respectively. This is feedback inhibition, and it leads to a steady state of both respective hormones involved in the axis.

Clinically, disease states involving overproduction of target hormones lead to suppressed levels of pituitary hormones, while those involving underproduction of target hormones lead to increased levels. We use this physiology to screen and diagnose these diseases.

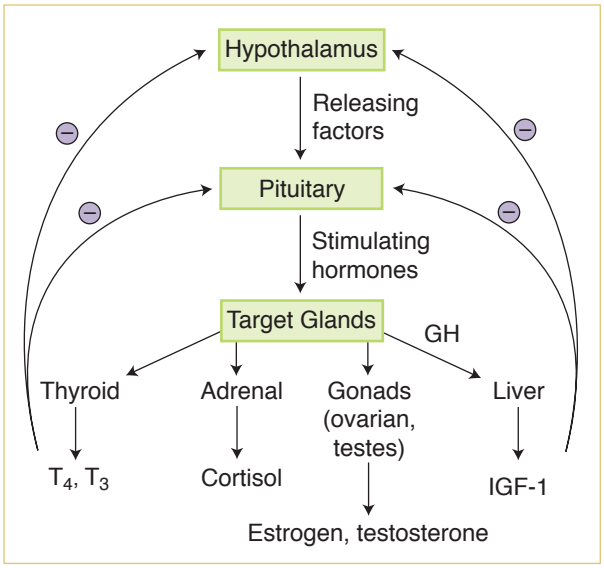

Figure 2-2. Summary of Action

DISEASES OF THE ANTERIOR PITUITARY

Syndromes causing excess production of hormones usually arise from benign tumors only of a single cell type.

Microadenomas are defined as tumors <1 cm in diameter. Macroadenomas are tumors >1 cm in diameter. Larger tumors can occasionally compress the optic chiasm and can cause visual deficits. Microadenomas are more common than macroadenomas.

Table 2-1. Pituitary Adenomas by Function

Prolactin	50–60%
Growth hormone (GH)	15–20%
ACTH	10–15%
Gonadotroph	10–15%

Hyperprolactinemia

A 32-year-old woman comes to your office because she has noticed milk-like discharge from her breasts the past 4 weeks. She also states that she has not menstruated in 2 months. The examination reveals galactorrhea but is otherwise normal.

Note

Cabergoline is used more often than bromocriptine because of a better side-effect profile. It should be considered the preferred medical treatment for galactorrhea.

Definition. Excess prolactin secretion is a common clinical problem in women and causes the syndrome of galactorrhea-amenorrhea. The amenorrhea appears to be caused by inhibition of hypothalamic release of gonadotropin-releasing hormone (GnRH) with a decrease in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion. Prolactin inhibits the LH surge that causes ovulation. The LH/FSH-producing cells are not destroyed, just suppressed. Although hyperprolactinemia is also seen in men, gynecomastia and especially galactorrhea are very rare. The most common presenting symptom in men is erectile dysfunction and decreased libido.

Etiology. Hyperprolactinemia can be seen in natural physiologic states such as pregnancy, early nursing, hypoglycemia, seizure, exercise, stress, sleep, cirrhosis, nipple stimulation, and chronic renal failure (due to PRL clearance).

Autonomous production of prolactin occurs with pituitary adenomas; these so-called prolactinomas are the most common functioning pituitary adenomas, accounting for 60% of all pituitary tumors. They are usually microadenomas when they occur in women and macroadenomas in men, usually presenting with visual field deficits, etc. Macroadenomas can obstruct the pituitary stalk, increasing prolactin release by blocking dopamine transport from hypothalamus (stalk effect). Other examples are tumors, such as craniopharyngioma, meningioma, and dysgerminoma; empty sella; and trauma.

Hyperprolactinemia can also occur with decreased inhibitory action of dopamine. This occurs with the use of drugs that block dopamine synthesis (phenothiazines, metoclopramide) and dopamine-depleting agents (α-methyldopa, reserpine). Tricyclic antidepressants, narcotics, cocaine, SSRIs, and risperidone can also cause increased prolactin.

Stimuli that overcome the normal dopamine inhibition can also lead to hyperprolactinemia. An example of this is primary hypothyroidism (resulting in an increase in thyrotropin-releasing hormone [TRH]) and subsequently an increase in prolactin release.

Always check TSH in patients with elevated prolactin.

Clinical. Hyperprolactinemia presents with galactorrhea, menstrual abnormalities amenorrhea/oligomenorrhea, osteopenia and osteoporosis in long-standing cases, infertility, and gynecomastia in women; men present with hypogonadism, erectile dysfunction, decreased libido, gynecomastia, and infertility. Men typically do not develop galactorrhea. Women are detected earlier because of menstrual symptoms. Hence, microadenomas are more common in women.

Diagnosis. Always exclude states such as pregnancy, lactation, hypothyroidism and medications before starting the work-up of hyperprolactinemia. Prolactinomas may co-secrete growth hormone (GH).

Prolactin levels >100 ng/mL suggest probable pituitary adenoma. Prolactin level should be commensurate with tumor size, with prolactin levels of 100 ng/mL correlating with tumor approximately 1 cm, of 200 ng/mL correlating with tumor approximately 2 cm, etc.

Note

A basal, fasting, morning PRL level >100 to 200 mg/L (normal <20 mg/L) in a nonpregnant woman indicates a need for an MRI of the pituitary.

Management. For prolactinomas, initially treat with cabergoline or bromocriptine (a dopamine agonist), both of which reduce prolactin levels in almost all hyperprolactinemic patients. Dopamine normally inhibits prolactin release. Surgery is reserved only for adenomas not responsive to cabergoline or bromocriptine, or if the tumor is associated with significant compressive neurologic effects. Surgery is more effective for microadenomas than macroadenomas. Only 30% of macroadenomas can be successfully resected (long-term recurrence >50% in macroadenoma). About 90% of patients treated with cabergoline have a drop in prolactin to <10% of pretreatment levels. Radiation therapy is used if drug therapy and surgery are ineffective in reducing tumor size and prolactin levels.

Acromegaly

Definition. Acromegaly is a syndrome of excessive secretion of growth hormone. In children this is called gigantism. Acromegaly is an insidious, chronic debilitating disease associated with bony and soft tissue overgrowth, and increased mortality.

Wikimedia, Philippe Chanson and Sylvie Salenave

Figure 2-3. Acromegaly Facial Features

Etiology. Acromegaly is caused by pituitary adenomas, usually a macroadenoma in 75% of the cases that produce growth hormone. Rarely ectopic tumors can produce GH or growth hormone releasing hormone (GHRH) and cause this syndrome. Less than 1% are malignant. Growth hormone is produced by 20% of pituitary tumors.

Clinical Findings. Growth hormone excess occurs most frequently between the third and fifth decades of life.

- Various skeletal and soft tissue changes occur.
- Enlargement of the hands and feet, coarsening of facial features, and thickened skin folds occur. Shoe, hat, glove, and ring sizes increase.
- The nose and mandible (prognathism and separation of teeth) enlarge, sometimes causing underbite.
- The voice becomes deeper.
- There is increased sweating.
- Obstructive sleep apnea can also develop.
- Internal organs are enlarged, including heart, lung, spleen, liver, and kidneys.
- Interstitial edema, osteoarthritis, and entrapment neuropathy (carpal tunnel syndrome) are seen.
- Menstrual problems are common because prolactin is co-secreted by the GH-producing tumor.
- About 10-20% of patients develop cardiac anomalies such as hypertension, arrhythmias, hypertrophic cardiomyopathy, and accelerated atherosclerosis.

Metabolic changes include impaired glucose tolerance (80%) and diabetes (13–20%). Hypertension is seen in one third of patients. Headaches and visual field loss can also occur. Articular cartilage proliferates and causes severe joint disease.

Diagnosis. Patients with acromegaly have symptoms for an average of 9 years before the diagnosis is made. The best initial test is IGF-1 level. A significantly elevated IGF level compared to the average IGF-1 for age-matched equivalents is a positive screen for acromegaly.

Note

The most common cause of death in acromegaly is cardiovascular mortality.

Confirmatory testing involves the measurement of GH after 100 g of glucose is given orally; this test is positive if GH remains high (>5 ng/mL) and suggests acromegaly. Normally a glucose load should completely suppress levels of GH.

Measurement of insulin-like growth factor (IGF) or somatomedin correlates with disease activity.

Radiologic studies such as CT scanning and MRI are used to localize the tumor but should be done only after GH excess is documented biochemically. MRI is superior to CT scan. MRI will show a tumor in 90% of people with acromegaly.

Management. The objectives are to decrease GH levels to normal, stabilize or decrease tumor size, and preserve normal pituitary function. Transsphenoidal surgery provides a rapid response. Hypopituitarism can result in 10–20%. Primary treatment is surgery.

Somatostatin analogues are the drugs of choice. Octreotide and lanreotide reduce GH values in around 70% of patients and cause partial tumor regression in 20–50% of patients. Octreotide is the best medical therapy for acromegaly. The main side effect of concern with somatostatin analogues is cholestasis, leading to cholecystitis.

Dopamine agonists such as bromocriptine and cabergoline are used if surgery is not curative. 10% of patients respond to these drugs.

Pegvisomant is a growth hormone analogue that antagonizes endogenic GH by blocking peripheral GH binding to its receptor in the liver. Important to note, pegvisomant is a second-line agent.

Radiotherapy, used only if surgery and drug therapy do not work, results in slow resolution of disease and hypopituitarism in 20% of patients.

Complications. Complications of acromegaly can arise from pressure of the tumor on the surrounding structures or invasion of the tumor into the brain or sinuses. Other complications include cardiac failure (most common cause of death in acromegaly), diabetes mellitus, cord compression, and visual field defects.

Hypopituitarism

Definition. Hypopituitarism is partial or complete loss of anterior function that may result from any lesion that destroys the pituitary or hypothalamus or that interferes with the delivery of releasing and inhibiting factors to the anterior hypothalamus. GH and gonadotropins (FSH, LH) are typically lost early.

Etiology. Large pituitary tumors, or cysts, as well as hypothalamic tumors (craniopharyngiomas, meningiomas, gliomas) can lead to hypopituitarism. Pituitary adenomas are the most common cause of panhypopituitarism. The mass compresses the gland, causing pressure, trauma, and necrosis.

Pituitary apoplexy is a syndrome associated with acute hemorrhagic infarction of a preexisting pituitary adenoma, and manifests as severe headache, nausea or vomiting, and depression of consciousness. It is a medical and neurosurgical emergency.

Inflammatory diseases can lead to hypopituitarism: granulomatous diseases (sarcoidosis, tuberculosis [TB], syphilis), eosinophilic granuloma, and autoimmune lymphocytic hypophysitis (usually associated with other autoimmune diseases such as Hashimoto thyroiditis and gastric atrophy). Trauma, radiation, surgery, infections, and hypoxia may also damage both the pituitary and hypothalamus.

Vascular diseases such as *Sheehan postpartum necrosis* (initial sign being the inability to lactate) and infiltrative diseases including hemochromatosis and amyloidosis may induce this state as well.

Stroke can also damage these cells. Stroke can cause central diabetes insipidus due to damage of hypothalamus and/or posterior pituitary.

Clinical Findings. The following hormones will appear in the order in which they are lost in hypopituitarism.

- Gonadotropin deficiency (LH and FSH) can occur in women and lead to amenorrhea, genital atrophy, infertility, decreased libido, and loss of axillary and pubic hair.
- In men, decreased LH and FSH results in impotence, testicular atrophy, infertility, decreased libido, and loss of axillary and pubic hair.
- GH deficiency occurs next and is not clinically detectable in adults, though it may manifest as fine wrinkles and increased sensitivity to insulin (hypoglycemia). GH deficiency gives an asymptomatic increase in lipid levels and a decrease in muscle, bone, and heart mass. It also may accelerate atherosclerosis, and it increases visceral obesity.
- GH deficiency in children results in growth failure and short stature.
- Thyrotropin (TSH) deficiency results in hypothyroidism with fatigue, weakness, hyperlipidemia, cold intolerance, and puffy skin without goiter.
- Adrenocorticotropin (ACTH) deficiency occurs last and results in secondary adrenal insufficiency caused by pituitary disease.
- There is decreased cortisol, which results in fatigue, decreased appetite, weight loss, decreased skin and nipple pigment, and decreased response to stress (as well as fever, hypotension, and hyponatremia).

Electrolyte changes like hyperkalemia and salt loss are minimal in secondary adrenal insufficiency because aldosterone production is mainly dependent on the renin-angiotensin system. ACTH deficiency does not result in the salt wasting, hyperkalemia, and death that are associated with aldosterone deficiency.

Diagnosis. The first step in diagnosing pituitary insufficiency is to measure GH, TSH, LH, and IGF-1. The most reliable stimulus for GH secretion is insulin-induced hypoglycemia. After injecting 0.1 μ/kg of regular insulin, blood glucose declines to <40 mg/dL; in normal conditions that will stimulate GH levels to >10 mg/L and exclude GH deficiency. Random GH and IGF levels are not sensitive enough to diagnose GH deficiency. This is why a provocative test is used.

Arginine infusion can also stimulate growth hormone release. Measure GH levels after infusing arginine. This is less dangerous because it does not lead to hypoglycemia.

To diagnose ACTH deficiency, basal cortisol levels may be preserved (the problem could be only in response to stress). Insulin tolerance test is diagnostic and involves giving 0.05–0.1 U/kg of regular insulin and measuring serum cortisol; plasma cortisol should increase to >19 mg/dL. Metyrapone tests for decreased ACTH production. Metyrapone blocks cortisol production, which should increase ACTH levels. A failure of ACTH levels to rise after giving metyrapone would indicate pituitary insufficiency. Cosyntropin (ACTH) stimulation may give abnormally low cortisol output if pituitary insufficiency has led to adrenal atrophy.

To diagnose gonadotropin deficiency in women, measure LH, FSH, and estrogen. In males, gonadotropin deficiency can be detected by measuring LH, FSH, and testosterone. To diagnose TSH deficiency, measure serum thyroxine (T_4) and free triiodothyronine (T_3), which are low, with a normal to low TSH.

Management. Management of hypopituitarism involves treating the underlying causes. Multiple hormones must be replaced, but the most important is cortisol replacement.

Empty Sella Syndrome (ESS)

ESS is in the differential diagnosis of enlarged sella caused by pituitary tumors. In ESS, the sella has no bony erosion. It is caused by herniation of the suprasellar subarachnoid space through an incomplete diaphragm sella. No pituitary gland is visible on CT or MRI. The syndrome can be primary (idiopathic) and is also associated with head trauma and radiation therapy. *Most patients with these syndromes are obese,* multiparous women with headaches; 30% will have hypertension; endocrine symptoms are absent. Therapy is reassurance.

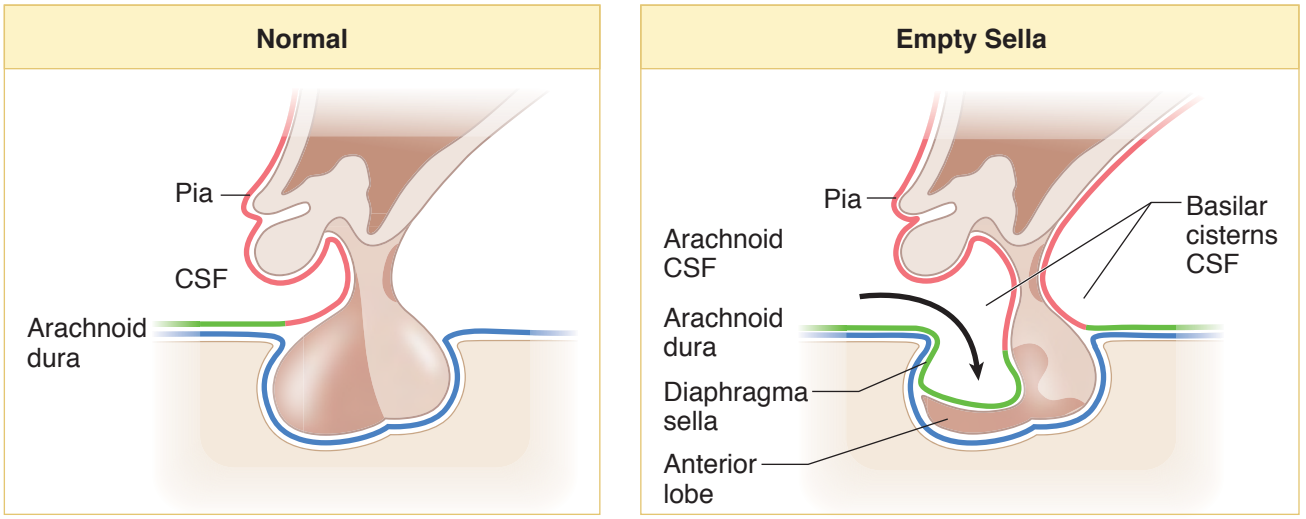

Figure 2-4. Empty Sella Syndrome

DISEASES OF THE POSTERIOR PITUITARY LOBE

Vasopressin or ADH and oxytocin are synthesized in neurons of the supraoptic and paraventricular nuclei in the hypothalamus, then transported to the posterior pituitary lobe to be released into the circulatory system. The syndrome associated with an excess secretion of ADH is called SIADH (syndrome of inappropriate secretion of ADH), and the syndrome associated with a deficiency of ADH is called diabetes insipidus (DI).

Central and Nephrogenic Diabetes Insipidus

Definition. Central diabetes insipidus (CDI) is a disorder of the neurohypophyseal system caused by a partial or total deficiency of vasopressin (ADH), which results in excessive, dilute urine and increased thirst associated with hypernatremia. Nephrogenic DI is caused by renal resistance to the action of vasopressin.

Etiology. DI frequently starts in childhood or early adult life and is more common in men than women. DI caused by ADH insufficiency is called central diabetes insipidus and DI caused by renal unresponsiveness to ADH is nephrogenic diabetes insipidus.

The causes of central DI include neoplastic or infiltrative lesions of the hypothalamus or pituitary (60% also have partial or complete loss of anterior pituitary function); in the hypothalamus these lesions can be secondary to adenomas, craniopharyngiomas, etc.; in the pituitary gland, adenomas, leukemias, or sarcoid histocytosis can lead to DI. Other causes of central DI include pituitary or hypothalamic surgery, radiotherapy, severe head injuries, anoxia, hypertension, and meningitis. Idiopathic DI starts in childhood. Encephalitis, TB, and syphilis may affect the pituitary as well.

Nephrogenic DI can be idiopathic or it can be secondary to hypercalcemia, hypokalemia, sickle cell disease, amyloidosis, myeloma, pyelonephritis, sarcoidosis, or Sjögren syndrome. Drugs (lithium, demeclocycline, colchicine) are among the most common causes of nephrogenic DI.

Clinical Findings. Clinical findings of DI include polyuria, excessive thirst, polydipsia (16–20 L/d), hypernatremia with high serum osmolarity and coexisting low urine osmolarity and urine specific gravity <1.010. Nocturia is expected. Hypertonicity is not usually present if the patient has an intact thirst mechanism and can increase water intake to keep up with urinary loss.

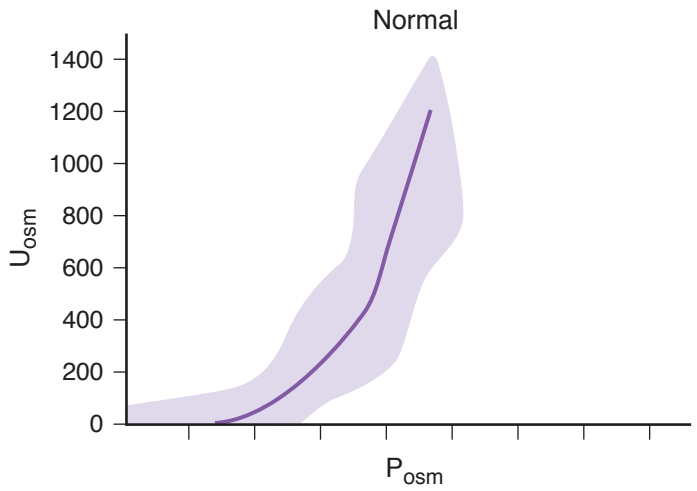

Figure 2-5. P_{osm} versus U_{osm} during Dehydration in Normal Subjects

Diagnosis. The water deprivation test compares U_{osm} after dehydration versus U_{osm} after vasopressin. In a normal person, the response to fluid restriction is to increase urine osmolality and decrease urine volume. In DI, the urine volume remains high despite volume depletion. ADH levels will be low in central DI and high in nephrogenic DI. If they fall to the right of the shaded area, the patient has DI (see Figure 2-5).

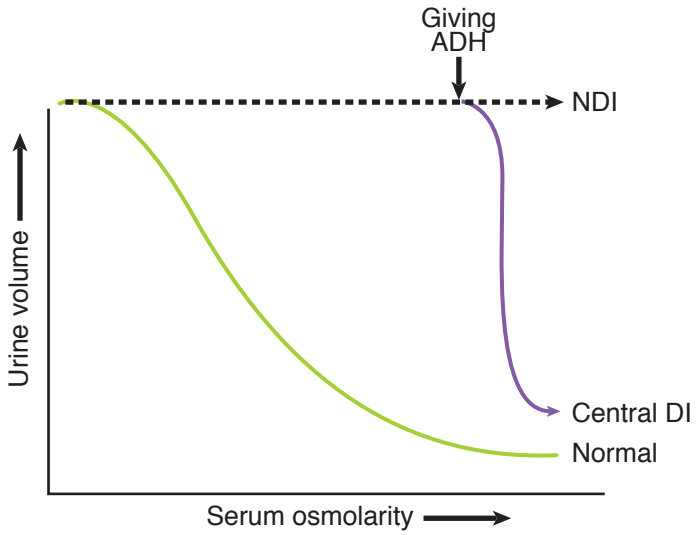

Figure 2-6. Water Restriction Test

Differential Diagnosis. The differential diagnosis of DI includes primary disorders of water intake (psychogenic polydipsia, drug-induced polydipsia from chlorpromazine, anticholinergic drugs, or thioridazine) and hypothalamic diseases.

Management. The management for central DI includes hormone replacement with vasopressin subcutaneously or desmopressin subcutaneously, orally, or intranasally. Some drugs can be used that stimulate the secretion of ADH or increase release (chlorpropamide, clofibrate, or carbamazepine).

For nephrogenic DI, HCTZ or amiloride may be used, which enhances the reabsorption of fluid from the proximal tubule. Chlorthalidone is effective as well. Abnormalities of calcium and potassium should be corrected as well.

Syndromes Associated with Vasopressin (ADH) Excess

Syndromes associated with ADH excess involve a mechanism of defense against hypovolemia or hypotension. This includes adrenal insufficiency, excessive fluid loss, fluid deprivation, and probably positive-pressure respiration.

Excessive release of ADH from the neurohypophysis is associated with drugs or diseases (SIADH).

Syndrome of Inappropriate Secretion of ADH (SIADH)

Etiology. The etiology of SIADH includes malignancies such as *small cell carcinomas,* carcinoma of the pancreas, and ectopic ADH secretion. Nonmalignant pulmonary diseases such as TB, pneumonia, and lung abscess can also lead to SIADH. CNS disorders including head injury, cerebral vascular accident, and encephalitis are other etiologies. Drugs such as chlorpropamide, clofibrate, vincristine, vinblastine, cyclophosphamide, and carbamazepine can induce SIADH.

Clinical Findings. In general, increased ADH causes water retention and extracellular fluid volume expansion without edema or hypertension, owing to natriuresis. The water retention and sodium loss both cause hyponatremia, which is a key feature in SIADH. Hyponatremia and concentrated urine (U_{osm} >300 mOsm) are seen, as well as no signs of edema or dehydration. When hyponatremia is severe (sodium <120 mOsm), or acute in onset, symptoms of cerebral edema become prominent (irritability, confusion, seizures, and coma).

Diagnosis. Laboratory findings in diagnosis of SIADH include hyponatremia <130 mEq/L, and P_{osm} <270 mOsm/kg. Other findings are urine sodium concentration >20 mEq/L (inappropriate natriuresis), maintained hypervolemia, suppression of renin–angiotensin system, and no equal concentration of atrial natriuretic peptide. Low blood urea nitrate (BUN), low creatinine, low serum uric acid, and low albumin will also be seen.

Management. Management of SIADH involves treating underlying causes when possible. Fluid restriction to 800–1,000 mL/d should be obtained to increase serum sodium. Demeclocycline can be used in chronic situations when fluid restrictions are difficult to maintain. Demeclocycline inhibits ADH action at the collecting duct (V2). Conivaptan and tolvaptan are V2 receptor blockers indicated for moderate to severe SIADH. For very symptomatic patients (severe confusion, convulsions, or coma), hypertonic saline (3%) 200–300 mL intravenously in 3–4 h should be used. The rate of correction should be between 0.5–1 mmol/L/h of serum Na.

DISEASES OF THE THYROID GLAND

Generalities. The normal function of the thyroid gland is directed toward the secretion of L-thyroxine (T_4) and L-3,5,5′-triiodothyronine (T_3), which influence a diversity of metabolic processes.

Diseases of the thyroid could be quantitative or qualitative alterations in hormone secretion, enlargement of thyroid (goiter), or both. Insufficient hormone secretion results in hypothyroidism; excess secretion results in hyperthyroidism. Focal enlargement of the thyroid can be associated with tumors (benign or malignant). Generalized enlargement can be associated with increased, normal, or decreased function of the gland depending on the underlying cause.

Laboratory Tests in Thyroid Disease. The most sensitive test in thyroid diseases is the TSH. If the TSH is normal, then the patient is euthyroid.

Total T_4 and T_3 do not always reflect actual thyroid function. For example, increased TBG levels are seen in pregnancy and the use of oral contraceptives. This will increase total T_4 but free or active T_4 level is normal. Decreased TBG levels are seen in nephrotic syndrome and the use of androgens. This will decrease total T_4 but free or active T_4 level is normal with the patient being euthyroid.

Clinical Pearl

Always check **free** T4 to assess thyroid function.

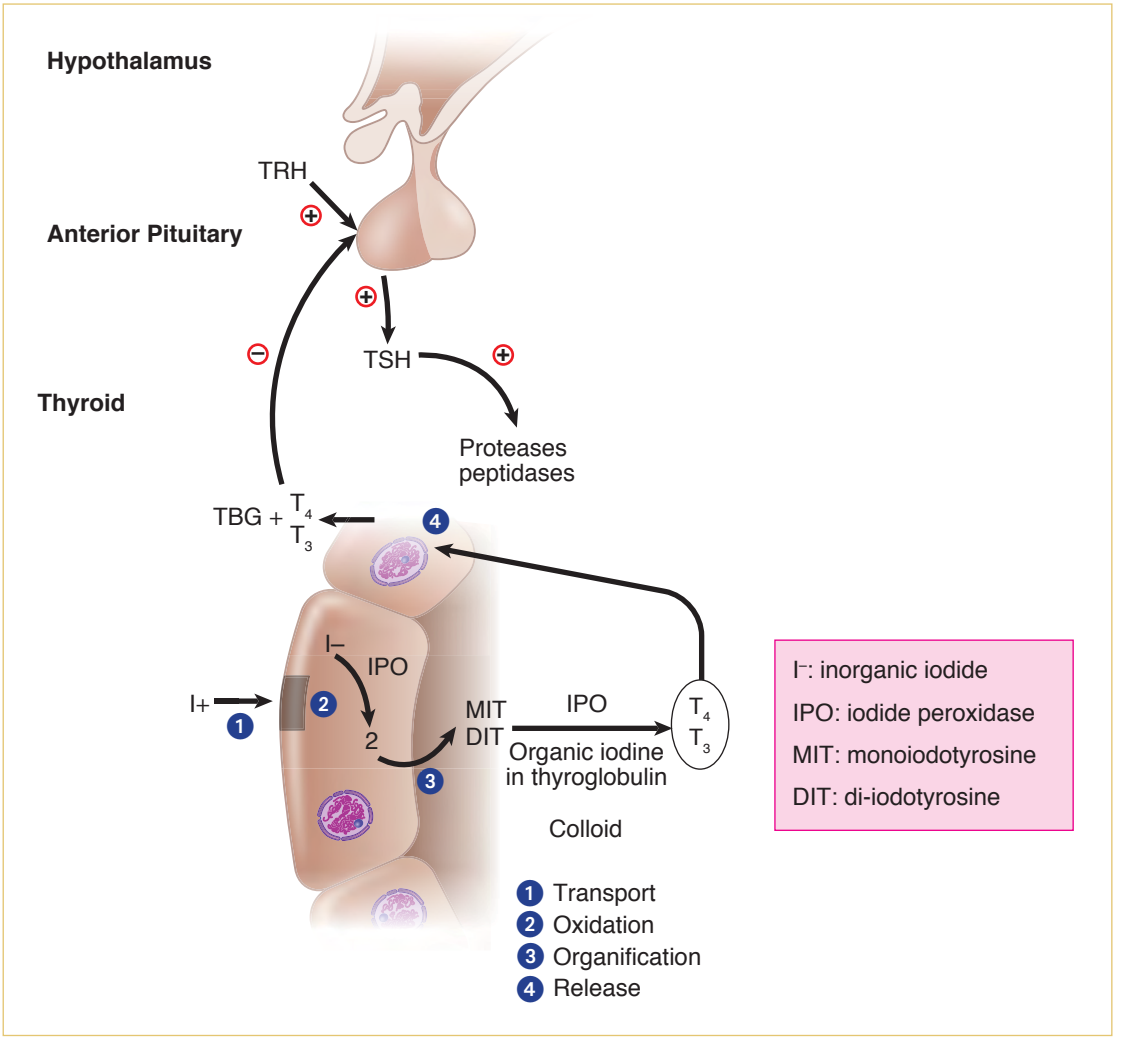

Figure 2-7. Pathways for Synthesis and Secretion of Thyroid Hormones

RAIU (thyroid-reactive iodine uptake) varies directly with the functional state of the thyroid. After 24 hours, normal uptake is 5–30% of administered dose. RAIU is **increased** in Graves' disease or toxic nodule and **decreased** in thyroiditis or surreptitious ingestion of thyroid hormone.

Note

The answers to Diagnosis column can be found at the end of the chapter.

Table 2-2. Evaluating Thyroid Function

Thyroid Hormones and TSH	RAI Uptake Scan	Diagnosis
↓ TSH; free ↑ T_4, ↑ T_3	↑ RAIU	
↓ TSH; free ↑ T_4, ↑ T_3	↓ RAIU	
↓ TSH; free ↓ T_4, ↓ T_3	↓ RAIU	

Other tests include antimicrosomal and antithyroglobulin antibodies, which are detected in Hashimoto thyroiditis. In Graves' disease, thyroid-stimulating immunoglobulin (TSI) is found. Serum thyroglobulin concentration can be used to assess the adequacy of treatment and follow-up of thyroid cancer, and to confirm the diagnosis of thyrotoxicosis factitia.

Hyperthyroidism (Thyrotoxicosis)

A wide range of conditions can cause hyperthyroidism; **Graves' disease**, an autoimmune disorder, is the most common. Graves' causes the production of antibodies (thyroid stimulating immunoglobulin [TSI]), which stimulate the thyroid to secrete T4 and T3**.**

Intrinsic thyroid autonomy can also result from a hyperfunctioning adenoma (toxic adenoma) or it can be caused by toxic multinodular goiter (Plummer disease), a non-autoimmune disease of the elderly associated commonly with arrhythmia and CHF and sometimes the consequence of simple goiter.

Transient hyperthyroidism results from subacute thyroiditis (painful) or lymphocytic thyroiditis (painless, postpartum). For treatment purposes, it is important to distinguish primary hyperthyroidism (Grave's disease or toxic adenoma) from thyroiditis.

Drugs such as amiodarone, alpha interferon, and lithium can induce thyrotoxicosis. Excess iodine, as may occur in people taking certain expectorants, or iodine-containing contrast agents for imaging studies may cause hyperthyroidism. Extrathyroid source of hormones include thyrotoxicosis factitia and ectopic thyroid tissue (struma ovarii, functioning follicular carcinoma). Rarely, hyperthyroidism can result from excess production of TSH (secondary hyperthyroidism).

Figure 2-8. Pretibial Myxedema, a Manifestation of Graves' Disease

Clinical Pearl

Physical Examination of the Hyperthyroid Patient

Painless & diffuse enlargement = **Graves'**

Painless & nodules = **Plummer**

Painful & diffuse enlargement = **subacute thyroiditis**

No thyroid enlargement or thyroid not palpated = **factitious**

Graves' disease

Graves' disease (toxic diffuse goiter = hyperthyroidism + diffuse goiter + exophthalmos + dermopathy) deserves a special mention. In Graves' there is formation of autoantibodies which bind to the TSH receptor in thyroid cell membranes and stimulate the gland to hyperfunction (TSI).

- Commonly affects patients age <50
- Women > men
- Significant genetic component, i.e., a person is more likely to be affected if they have family member with the disease
- Commonly triggered by stress, infection, and pregnancy
- Patients with another autoimmune disease such as type 1 diabetes or pernicious anemia are more likely to be affected
- Smoking causes increased risk of disease and may make the exopthalmos worse

Figure 2-9. Proptosis and Lid Retraction from Graves' Disease

Clinical Findings. Graves' is associated clinically with diffuse painless enlargement of the thyroid. Nervous symptoms predominate in younger patients, whereas cardiovascular and myopathic symptoms are more common in older patients. Atrial fibrillation can also be seen. Other clinical findings include emotional lability, inability to sleep, tremors, frequent bowel movements, excessive sweating, and heat intolerance. Weight loss (despite increased appetite) and loss of strength also are seen. Proximal muscle weakness may be a prominent symptom in many cases and can be the primary reason why the patient sees a physician. Dyspnea, palpitations, angina, or cardiac failure may occur. The skin is warm and moist, and palmar erythema is present along with fine and silky hair in hyperthyroidism. Ocular signs include staring, infrequent blinking, and lid lag. Menstrual irregularity such as oligomenorrhea occurs. Osteoporosis and hypercalcemia can occur from increases in osteoclast activity.

Diagnosis. The diagnosis of Graves' is made on history and physical examination. Lab studies include suppressed TSH and high serum free T4 and T3 (Note, in secondary hyperthyroidism, TSH is elevated). The RAIU is increased (Note, in subacute thyroiditis and factitious hyperthyroidism, RAIU is decreased). TSI, antithyroglobulin and antimicrosomal antibodies are elevated.

Treatment. Treatment involves relief of symptoms and correction of the thyrotoxic state. Adrenergic hyperfunction is treated with beta-adrenergic blockade (propranolol). Correcting the high thyroid hormone levels can be achieved with an anti-thyroid medication (methimazole or propylthiouracil) which blocks the synthesis of thyroid hormones and/or by treatment with radioactive iodine. Methimazole is preferred, as it has a longer half-life, reverses hyperthyroidism more quickly, and has fewer side effects than propylthiouracil.

- Methimazole requires an average of 6 weeks to lower T4 levels to normal and is often given before radioactive iodine treatment; it can be taken 1x/ day.
- Because of its potential for liver damage, propylthiouracil is used only when methimazole is not appropriate; it must be taken 2–3x/ day.

Antithyroid drugs during pregnancy. Propylthiouracil was the traditional drug of choice during pregnancy because it is associated with less severe birth defects than methimazole. But experts now recommend that propylthiouracil be given during the first trimester only. This is because there have been rare cases of liver damage in people taking propylthiouracil. After the first trimester, women should switch to methimazole for the rest of the pregnancy. For women who are nursing, methimazole is probably a better choice than propylthiouracil (to avoid liver side effects). Both drugs can cause agranulocytosis.

The most commonly used 'permanent' therapy for Graves' disease is **radioactive iodine**. Indications for its use (overusing antithyroid agents alone) include:

- Large thyroid gland
- Multiple symptoms of thyrotoxicosis
- High levels of thyroxine
- High titers of TSI

Because of the high relapse rate (>50%) associated with antithyroid therapy, many physicians in the United States prefer to use radioactive iodine as first-line therapy. Patients currently taking antithyroid drugs must discontinue the medication at least 2 days prior to taking the radiopharmaceutical since pretreatment with antithyroid drugs reduces the cure rate of radioiodine therapy in hyperthyroid diseases. With radioactive iodine, the desired result is hypothyroidism due to destruction of the gland, which usually occurs 2-3 months post-administration, after which hormone replacement treatment is indicated.

Subtotal thyroidectomy (and rarely total thyroidectomy) is indicated only in pregnancy (second trimester), in children, and in cases when the thyroid is so large that there are compressive symptoms.

Thyroid Storm

Thyroid storm is an extreme form of thyrotoxicosis. This is an endocrine emergency. It is precipitated by stress, infection, surgery, or trauma. It is manifested by extreme irritability, delirium, coma, tachycardia, restlessness, vomiting, jaundice, diarrhea, hypotension, dehydration, and high fever.

Treatment. The treatment of thyroid storm involves supportive therapy with saline and glucose hydration, glucocorticoids, and oxygen cooling blanket. Therapy for hyperthyroidism is also used and includes first, propylthiouracil. Next, iodine should be given to inhibit hormone release. This should be followed by adrenergic antagonists (e.g., β-adrenergic blockers). Finally, dexamethasone is given to provide adrenal support. Antithyroid drugs should be

Clinical Pearl

Wolff–Chaikoff Effect

When large quantities of iodide are ingested by patients with hyperthyroidism, the result is thyroid hormone suppression (Wolff-Chaikoff effect).

stopped several days (1–2 weeks) before and after the RAI treatment. The antithyroid medications, such as PTU, block the uptake of the radioactive iodine.

Hypothyroidism

Etiology. The etiology of hypothyroidism results from the thyroid in 95% of cases (primary). Primary hypothyroidism can occur secondary to chronic thyroiditis (Hashimoto disease); this is the most common cause of goitrous hypothyroidism and is associated with antimicrosomal antibodies. Postablative surgery or radioactive iodine, heritable biosynthetic defects, and iodine deficiency can lead to primary hypothyroidism. Drugs such as lithium and acetylsalicylic acid can elicit primary hypothyroidism. Amiodarone, interferon, and sulfonamides can cause hypothyroidism.

Suprathyroid causes of hypothyroidism include pituitary induced (secondary hypothyroidism) or hypothalamic induced (tertiary hypothyroidism).

Amiodarone, an antiarrhythmic drug used in the treatment of ventricular and supraventricular tachyarrhythmia, is structurally similar to T4 and contains approximately 40% iodine. It is highly lipid-soluble and is concentrated in the adipose tissue, muscle, liver, lung, and thyroid gland. Its elimination half-life is high (50–100 days) and thus total body iodine stores can remain increased for up to 9 months after discontinuation of the drug. Thyroid abnormalities have been noted in up to 20% of patients receiving long-term amiodarone therapy. However, a meta-analysis suggested that with the lower doses of amiodarone, incidence of thyroid dysfunction is around 4%. The effects range from abnormal thyroid function test findings (without clinical hyper- or hypothyroidism) to overt thyroid dysfunction, which may be amiodarone-induced thyrotoxicosis or amiodarone-induced hypothyroidism (both can develop in apparently normal thyroid glands or in glands with preexisting abnormalities).

- Amiodarone-induced thyrotoxicosis
  - **Type 1** occurs in patients with underlying thyroid pathology such as autonomous nodular goiter or Graves'; treatment is anti-thyroid therapy
  - **Type 2** is a result of amiodarone causing a subacute thyroiditis, with release of preformed thyroid hormones into the circulation; treatment is a trial of glucocorticoids
- Amiodarone-induced hypothyroidism due to inhibition of peripheral conversion of T4 to T3

Clinical Findings. In the newborn, signs and symptoms of hypothyroidism include cretinism (in 1/5,000 neonates) and juvenile hypothyroidism. Persistent physiologic jaundice, hoarse cry, constipation, somnolence, and feeding problems are also seen. In later months, delayed milestones and dwarfism, coarse features, protruding tongue, broad flat nose, widely set eyes, sparse hair, dry skin, protuberant abdomen, potbelly with umbilical hernia, impaired mental development, retarded bone age, and delayed dentition are also seen.

Signs and symptoms of hypothyroidism in the adult in the early stages include lethargy, constipation, cold intolerance, stiffness and cramping of muscles, carpal tunnel syndrome, and menorrhagia. Later in the course of disease intellectual and motor activity slows, appetite decreases and weight increases, hair and skin become dry, voice gets deeper and hoarse, and deafness may occur. Slow deep tendon reflexes with prolonged relaxation phase are noted on examination. Cholesterol levels in the blood may be elevated. Ultimately, myxedema appears with an expressionless face, sparse hair, periorbital puffiness, large tongue, and pale, cool skin that feels rough and doughy. Hyponatremia and anemia also occur.

Diagnosis. Diagnosis of hypothyroidism is made by symptoms and physical findings. Laboratory tests are also used to confirm diagnosis (Table 2-3).

Table 2-3. Confirmation of Hypothyroid Diagnosis*

Primary Hypothyroidism	2° or 3° Hypothyroidism
↑ TSH	Normal or ↓ TSH
↓ T_4, ↓ FT_4	↓ T_4, ↓ FT_4
T_3 decreases in lesser extent	Accompanied by decreased secretion of other hormones

*Also seen: hypercholesterolemia, elevation of CPK, AST, hyponatremia, LDH; 12% associated to pernicious anemia

Management. The goal in management of hypothyroidism is to restore metabolic state with levothyroxine. This has to be done gradually in the elderly and patients with coronary artery disease. Levothyroxine (T4) should be administered with monitoring of TSH/T3, T4 levels (it takes 6 weeks after dosing changes for TSH to equilibrate).

- If there is a strong suspicion of suprathyroid hypothyroidism of hypothalamic or pituitary origin, give hydrocortisone with thyroid hormones.
- In patients with suprathyroid hypothyroidism, T4 level rather than TSH is used to guide treatment.
- Levothyroxine should be taken on an empty stomach with no other drugs or vitamins; multivitamins, including calcium and iron, can decrease its absorption.
- If a patient has coronary heart disease that needs intervention, do the intervention (CABG or stent placement) before thyroid hormone replacement is initiated.

During pregnancy, demand for thyroid hormones may increase and thus close monitoring of TSH and T4 should be done. Hypothyroidism during pregnancy should be treated with levothyroxine, with serum TSH goal to be kept in the lower reference range. Serum TSH should be measured at 4–6 weeks' gestation, then every 4–6 weeks until 20 weeks' gestation.

Myxedema coma can result if severe, long-standing hypothyroidism is left untreated. Patients develop a hypothermic, stuporous state that is frequently fatal. It is associated with respiratory depression (CO_2 retention). Myxedema coma is precipitated by cold exposure, trauma, infections, and CNS depressants. Treatment includes very high doses of T4 along with T3.

Thyroiditis

Thyroiditis includes disorders of different etiologies characterized by inflammation of the thyroid. They have different clinical courses, and each can be associated at one time or another with euthyroid, thyrotoxic, or hypothyroid state.

Subacute Thyroiditis. Subacute thyroiditis includes granulomatous, giant cell, or de Quervain thyroiditis. This can occur at any age, although most commonly in the fourth and fifth decades. Subacute thyroiditis is probably of viral origin and follows upper respiratory infection symptoms including malaise, fever, pain over the thyroid, and pain referred to the lower jaw, ears, neck, or arms. The thyroid gland is enlarged and firm in this setting. Laboratory

Clinical Pearl

- Hashimoto thyroiditis presents more commonly as **hypo**thyroidism.
- Subacute (de Quervain) thyroiditis presents more commonly as **hyper**thyroidism.

findings in subacute thyroiditis include elevated erythrocyte sedimentation rate (ESR), decreased radioactive iodine uptake, initial elevation in T_4 and T_3 (caused by leak of hormone from the gland), followed by hypothyroidism as the hormone is depleted.

The differential diagnosis of subacute thyroiditis includes mostly Graves' disease. Treatment is symptomatic with NSAIDs, prednisone, and propranolol. The disorder may smolder for months but eventually subsides with return to normal function.

Hashimoto Thyroiditis. Hashimoto thyroiditis is a chronic inflammatory process of the thyroid with lymphocytic infiltration of the gland, and is thought to be caused by autoimmune factors.

- **Etiology.** Hashimoto thyroiditis is a common disorder occurring most frequently in middle-aged women, and is the most common cause of sporadic goiter in children. Autoimmune factors are implicated as evidenced by lymphocytic infiltration, presence of increased immunoglobulin, and antibodies against components of thyroid tissue (antithyroglobulin Abs).
- **Clinical findings.** Clinical findings include a *goiter that is painless,* which is the main feature of this disease. The goiter is rubbery and not always symmetrical. Hypothyroidism occurs.
- **Diagnosis.** The diagnosis of Hashimoto thyroiditis is suggested by finding a firm, nontoxic goiter on examination. Laboratory values in the early stages are metabolically normal, then TSH increases, and T_4 and T_3 decrease. High titers of antithyroid antibodies, namely antimicrosomal antibodies, are present. Histologic confirmation is made by needle biopsy, but it is usually not needed. Antithyroperoxidase antibodies are found as well.
- **Management**. Hashimoto thyroiditis is managed by replacement with L-thyroxine.

Lymphocytic (Silent, Painless, or Postpartum) Thyroiditis. Lymphocytic thyroiditis is a self-limiting episode of thyrotoxicosis associated with chronic lymphocytic thyroiditis. It is more common in women of any age. The thyroid is nontender, firm, symmetrical, and slightly to moderately enlarged. T_4 and T_3 are elevated, RAIU is low, and ESR normal. If antithyroid antibodies are present, they are only in a low titer. Etiology and pathogenesis of lymphocytic thyroiditis is unclear. This disease may last for 2–5 months and be recurrent (as in postpartum thyroiditis). Treatment is symptomatic with propranolol.

Reidel Thyroiditis. Reidel thyroiditis results from intense fibrosis of the thyroid and surrounding structures (including mediastinal and retroperitoneal fibrosis).

Neoplasia of the Thyroid

Classification. Thyroid adenomas may be nonfunctioning or hyperfunctioning. They are slow growing over many years. Management for hyperfunctioning adenomas includes ablation with radioactive iodine. The types of thyroid adenomas are follicular (which is most common and highly differentiated, autonomous nodule), papillary, and Hürthle.

Types of thyroid carcinomas

Papillary Carcinoma. Papillary carcinoma is the most common thyroid cancer. It is associated with history of radiation exposure. 60–70% of all thyroid cancers are papillary. Women are affected by papillary carcinoma 2–3 times more than men. There is a bimodal frequency and peaks occur in the second and third decades and again later in life. This tumor is slow growing

and spreads via lymphatics after many years. The treatment is surgery when the tumor is small and limited to a single area of the thyroid. TSH suppression therapy with levothyroxine is also used. With large tumors, radiation therapy is used with surgery.

Follicular Carcinoma. Follicular carcinoma accounts for 15–20% of all thyroid cancers. It is more common in the elderly and in women rather than men. This tumor is more malignant than papillary carcinoma. Follicular carcinoma spreads hematogenously with distant metastasis to the lung and bone. Treatment requires near total thyroidectomy with postoperative radioiodine ablation.

Anaplastic Carcinoma. Anaplastic carcinoma accounts for 1–2% of all thyroid cancer. It occurs mostly in elderly patients. Women are affected more than men with this tumor. Anaplastic carcinoma is highly malignant with rapid and painful enlargement. Eighty percent of patients die within 1 year of diagnosis. This cancer spreads by direct extension.

Medullary Carcinoma. Medullary carcinoma accounts for 5% of all thyroid cancers. It occurs as a sporadic form or familial form. This tumor arises from parafollicular cells of the thyroid and is more malignant than follicular carcinoma. The tumor often produces calcitonin. Medullary carcinoma is the component of two types of MEN (multiple endocrine neoplasia). In type IIa (Sipple syndrome), pheochromocytoma, medullary thyroid carcinoma, and (in one-half of cases) parathyroid hyperplasia occur. In MEN type IIb, pheochromocytoma, medullary carcinoma, and neuromas occur. Medullary carcinoma may also occur in families without other associated endocrine dysfunctions. The only effective therapy is thyroidectomy. Calcitonin levels can also be increased from cancer of the lung, pancreas, breast, and colon. The only thyroid cancer with an elevated calcitonin level is medullary cancer.

Clinical Pearl

RET mutations are the mutations associated with MEN2 and familial medullary thyroid carcinomas.

When to suspect a thyroid carcinoma

Suspect a thyroid carcinoma when there is recent growth of thyroid or mass with no tenderness or hoarseness. Patients with a history of radiation therapy of the head, neck, or upper mediastinum in childhood average 30 years to develop thyroid cancer. The presence of a solitary nodule or the production of calcitonin are also clues to malignancy. Calcifications on x-rays such as psammoma bodies suggest papillary carcinoma; increased density is seen in medullary carcinoma. Do thyroid function tests first; cancer is never hyperfunctioning.

Diagnostic approach to solitary nonfunctioning nodule

Fine-needle aspiration (FNA) for cytology is the initial procedure of choice in the evaluation of most patients. Five percent of nonfunctioning thyroid nodules prove to be malignant; functioning nodules are very seldom malignant. The first test to do in a patient with a thyroid nodule is TSH; if this is normal, then proceed to FNA. U/S is useful to distinguish cysts from solid nodules.

PARATHYROID GLANDS

Generalities. The function of parathyroid hormone (PTH) is to maintain extracellular fluid calcium concentration. PTH acts directly on the bone and kidney, and indirectly on intestine (through its effects on synthesis of 1,25-dihydroxycholecalciferol [$1,25(OH)_2D_3$]) to increase serum calcium. It is closely regulated by the concentration of serum-ionized calcium. PTH increases osteoclast activity, which releases calcium. PTH also inhibits phosphate reabsorption in the kidney tubule. This also favors bone dissolution and calcium release from bones. PTH activates vitamin D, which increases the GI absorption of calcium.

Calcium Regulation—Overview. Calcium regulation involves 3 tissues, namely, the bone, kidney, and intestine. It involves 3 hormones: PTH (hypercalcemic), calcitonin (hypocalcemic), and activated vitamin D (hypercalcemic).

Hypercalcemia

Hypercalcemia represents an increase in the total or free calcium level. About 98% of calcium is stored in bone. Calcium is absorbed from the proximal portion of the small intestine, particularly the duodenum. About 80% of an ingested calcium load in the diet is lost in the feces, unabsorbed. Of the 2% that is circulating in blood, free calcium is 50%, protein bound is 40%, with only 10% bound to citrate or phosphate buffers.

Etiology. The most common cause of hypercalcemia is primary hyperparathyroidism. Hyperparathyroidism, which is usually asymptomatic, comes to light because of routine office-based testing. The hypercalcemia of malignancy is due to a PTH-like protein produced by squamous cell carcinoma of the lung or metastatic disease to the bone. Granulomatous diseases such as sarcoidosis, tuberculosis, berylliosis, histoplasmosis, and coccidioidomycosis are all associated with hypercalcemia. Neutrophils in granulomas have their own 25-vitamin D hydroxylation, producing active 1,25 vitamin D. Rare causes include vitamin D intoxication, thiazide diuretics, lithium use, and Paget disease, as well as prolonged immobilization. Hyperthyroidism is associated with hypercalcemia because there is a partial effect of thyroid hormone on osteoclasts. Acidosis results in an increased amount of free calcium. This is because albumin buffers acidosis. Increased binding of hydrogen ions to albumin results in the displacement of calcium from albumin.

Familial hypocalciuric hypercalcemia (FHH) is a benign form of hypercalcemia. It presents with mild hypercalcemia, family history of hypercalcemia, urine calcium to creatinine ratio <0.01, and urine calcium <200 mg/day (hypocalciuria). Most cases are associated with loss of function mutations in the CaSR gene, which encodes a calcium sensing receptor (expressed in kidney and parathyroid tissue). The perceived lack of calcium levels by the parathyroid leads to high levels of parathyroid hormone. FHH is indicated by the presence of hypercalcemia at the same time with hypocalciuria. (**In all other causes of hypercalcemia, elevated calcium levels in the blood are correlated with elevated calcium urine levels, as a properly sensing kidney works to excrete calcium.**) No treatment is generally required, since patients are most commonly asymptomatic.

Clinical

- Neurologic: Hypercalcemia results in decreased mental activity such as lethargy and confusion.
- GI: Hypercalcemia results in decreased bowel activity such as constipation and anorexia but commonly gives nausea and vomiting as well. Pancreatitis occurs because of the precipitation of calcium in the pancreas. Severe pancreatitis, however, is associated with hypocalcemia because of binding of calcium to malabsorbed fat in the intestine. Ulcer disease is caused by hypercalcemia for unclear reasons.
- Renal: Hypercalcemia results in polyuria and polydipsia because of the induction of nephrogenic diabetes insipidus. Calcium also precipitates in the kidney, resulting in both kidney stones as well as nephrolithiasis.
- Cardiovascular: Hypertension occurs in 30–50% of patients with hypercalcemia. The EKG will show a short QT.

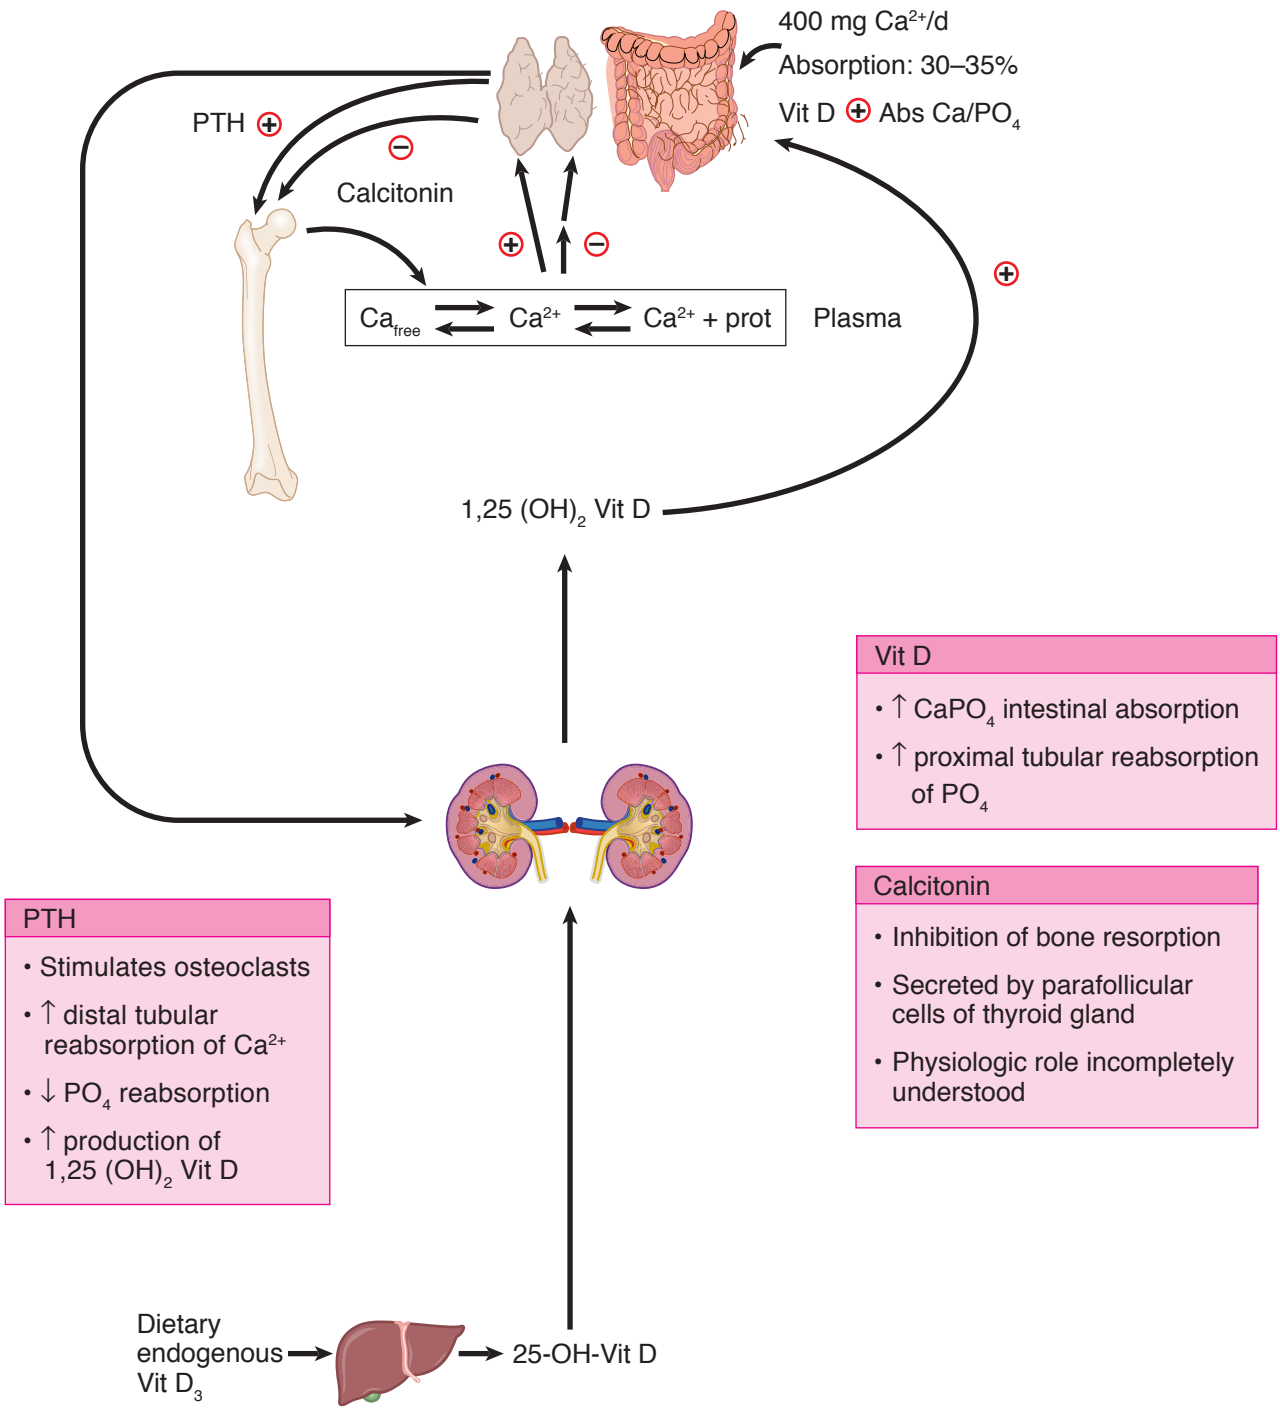

Figure 2-10. Calcium Regulation

Treatment. Severe, life-threatening hypercalcemia is treated first with vigorous fluid replacement with normal saline or half-normal saline. This may be followed by the use of loop diuretics, such as furosemide, which promote calcium loss from the body. Loop diuretics are used **only after hydration in very severe cases**. IV bisphosphonates such as zoledronate and pamidronate inhibit osteoclasts and stimulate osteoblasts. The maximum effect of bisphosphonates takes 2–3 days. If fluid replacement and diuretics do not lower the calcium level quickly enough and you cannot wait the 2 days for the bisphosphonates to work, calcitonin can be used for a more rapid decrease in calcium level. Calcitonin inhibits osteoclasts.

Primary Hyperparathyroidism

Primary hyperparathyroidism represents 90% of mild hypercalcemias.

Etiology. It is most commonly due to one gland adenoma (80%), but hyperplasia of all 4 glands can lead to primary hyperparathyroidism (20%). Parathyroid cancer is a rare cause of this disease (<1%). Primary hyperparathyroidism can occur as part of MEN. In MEN type I, hyperparathyroidism, pituitary tumors (3 "Ps"), and pancreatic tumors are seen. In MEN type II, hyperparathyroidism, pheochromocytoma, and medullary carcinoma of the thyroid are seen.

Clinical Findings. One half of patients with hyperparathyroidism are asymptomatic. Osteitis fibrosa cystica with hyperparathyroidism occurs because of increased rate of osteoclastic bone resorption and results in bone pain, fractures, swelling, deformity, areas of demineralization, bone cysts, and brown tumors (punched-out lesions producing a salt-and-pepper-like appearance). Urinary tract manifestations of hypercalcemia include polyuria, polydipsia, stones, and nephrocalcinosis with renal failure. The polyuria and polydipsia are from nephrogenic diabetes insipidus. Neurologic manifestations include CNS problems, mild personality disturbance, severe psychiatric disorders, mental obtundation or coma, neuromuscular weakness, easy fatigability, and atrophy of muscles. GI manifestations include anorexia, weight loss, constipation, nausea, vomiting, thirst, abdominal pain with pancreatitis, and peptic ulcer disease. Cardiovascular findings include hypertension and arrhythmias (short QT).

Diagnosis. Diagnosis can be made by laboratory findings of serum calcium >10.5 mg/dL, with elevated PTH level. Urine calcium elevation is common, but because of the calcium-reabsorbing action of PTH, there may be normal levels in one-third of patients. Serum phosphate is usually low (<2.5 mg/dL). The differential diagnosis includes all other causes of hypercalcemia, especially hypercalcemia of malignancy. In every other cause of hypercalcemia the PTH level will be low. In primary hyperparathyroidism, PTH is always elevated.

Imaging studies such as CT, MRI, sonography, and nuclear scans are not used to diagnose hyperparathyroidism. A nuclear parathyroid scan (sestamibi) can be used to localize the adenoma. When combined with a neck sonogram, specificity rises significantly.

Note

Calcitonin is an intermediary measure while waiting for IV bisphosphonate to act.

Management. Surgical removal of the parathyroid glands is effective. Medical treatment, used if surgery is contraindicated or if serum calcium ≤11.5 mg/dL and the patient is asymptomatic, includes bisphosphonates (pamidronate). The dietary calcium should be reduced to 400 mg/d. Oral hydration with 2–3 L of fluid is very effective. Phosphate supplementation with phospho-soda should be given. Estrogen may be indicated in hyperparathyroidism in postmenopausal women. Imaging studies may help localize the site of the affected gland prior to surgery.

Parathyroidectomy should be performed if there are symptoms of hypercalcemia, bone disease, renal disease, or if the patient is pregnant. Asymptomatic mild increases in calcium from hyperparathyroidism do not necessarily need to be treated.

In primary hyperparathyroidism, surgery is indicated if any of the following are present:

- Symptomatic hypercalcemia
- Calcium >11.5 mg/dL
- Renal insufficiency
- Age <50 years
- Nephrolithiasis
- Osteoporosis

Emergency treatment for severe hypercalcemia includes IV normal saline to restore volume and rarely furosemide after hydration. Everyone gets IV bisphosphates such as pamidronate. Bisphosphonates are useful only temporarily for hyperparathyroidism and may take 2–3 days to reach maximum effect.

Hungry bones syndrome is hypocalcemia that occurs after surgical removal of a hyperactive parathyroid gland, due to increased osteoblast activity. It usually presents with rapidly decreasing calcium, phosphate, and magnesium 1–4 weeks post-parathyroidectomy.

Cinacalcet is a calcimimetic agent that has some effect in hyperparathyroidism by shutting off the parathyroids. This increases the sensitivity of calcium sensing (basolateral membrane potential) on the parathyroid. Cinacalcet is used as treatment of secondary hyperparathyroidism in hemodialysis patients. It is also indicated for the treatment of hypercalcemia in patients with parathyroid carcinoma and in moderate-to-severe primary hyperparathyroidism unamenable to surgery.

Note

Primary hyperparathyroidism results from a hyperfunction of the parathyroid glands themselves. Most commonly, there is oversecretion of PTH due to a parathyroid adenoma. The elevated PTH then causes elevated serum calcium and low serum phosphate.

Secondary hyperparathyroidism is due to physiologic (i.e., **appropriate**) secretion of PTH by the parathyroid glands in response to hypocalcemia (resulting vitamin D deficiency, chronic kidney disease, etc.). Serum calcium level is low (that is what causes the elevated PTH) and serum phosphate is low (because of elevated PTH). In the case of chronic kidney failure and anuria, the phosphate–in this form of secondary hyperparathyroidism–is elevated (the kidney is unable to 'trash' phosphate).

Tertiary hyperparathyroidism is seen with **long-term secondary hyperparathyroidism**, which can lead to hyperplasia of the parathyroid glands and a loss of response to serum calcium levels. It is most often seen in patients with chronic renal failure, and is an autonomous activity of the parathyroid glands. Treatment is sometimes surgical removal.

Hypocalcemia

Etiology. Hypocalcemia is most commonly caused by hypoparathyroidism, renal failure, hyperphosphatemia, and hypomagnesemia. Drugs such as loop diuretics, phenytoin, alendronate, and foscarnet will also lower calcium levels. Renal failure causes hypocalcemia because of the loss of activated 1,25-dihydroxy-vitamin D. This leads to decreased calcium absorption from the gut. In addition, hyperphosphatemia will cause the precipitation of calcium in tissues. Low magnesium levels from malnutrition of alcoholism prevent the release of parathyroid hormone from the

parathyroid glands. Alkalosis decreases free calcium levels by causing increased binding of calcium to albumin. Pseudo hypocalcemia occurs with low albumin levels. The free calcium level remains normal, while the total calcium level decreases.

To correct for albumin, add 0.8 to calcium level for every 1 gram below 4 of albumin. Massive blood transfusion gives hypocalcemia because of binding of the calcium to the citrate in the transfused units of blood.

Clinical Findings. Hypocalcemia results in increased neural hyperexcitability such as seizures, tetany, circumoral numbness, and tingling of the extremities. Arrhythmias may develop because of a prolonged QT. Cataracts develop for unclear reasons.

Treatment of hypocalcemia is IV or oral calcium replacement, and vitamin D replacement as necessary.

Hypoparathyroidism

Etiology. The most common cause of hypoparathyroidism is surgical removal of the thyroid. Low PTH levels are also seen in hereditary hypoparathyroidism, acquired hypoparathyroidism (surgical removal), and hypomagnesemia. Magnesium deficiency prevents release of PTH from the gland. Hypomagnesemia occurs from decreased GI absorption or alcoholism. High PTH levels are seen in chronic renal failure, and decreased levels of active vitamin D, which is caused by decreased dietary intake or defective metabolism (secondary to anticonvulsant therapy or vitamin D-dependent rickets, type I). Ineffective vitamin D can also lead to high PTH levels; this is seen in intestinal malabsorption and vitamin D-dependent rickets, type II. Low or ineffective vitamin D is also associated with low calcium levels.

Clinical Findings. Clinical findings depend on the level of calcium, duration, acid-base disorder, and age at onset of disease.

Neuromuscular irritability is seen, such as tetany, laryngospasm, cramping, seizures, and impaired memory function. Chvostek sign may be positive (percussion of the facial nerve in front of the ear, which elicits a contraction of the facial muscles and upper lip). Trousseau sign may be positive (inflation of a blood pressure cuff on the arm to a pressure higher than the patient's systolic pressure for 3 min elicits flexion of the metacarpophalangeal joints and extension of the interphalangeal joints). Ocular findings such as cataracts and soft tissue calcifications can occur. The cardiovascular system may be affected, seen as QT prolongation, refractory CHF, and/or hypotension. Hypocalcemia frequently results in circumoral tingling as well as tingling of the hands and feet. Hyperventilation worsens symptoms of hypocalcemia because the alkalosis decreases free calcium levels.

Diagnosis. Diagnosis is suggested when the serum calcium is low; it is important to check an **albumin** and make the correction in calcium level. A low calcium may be due to low albumin; for a 1.0 g/dL drop in albumin, the total calcium will decrease by 0.8 mg/dL. It is better to measure ionized calcium. Depending on the etiology, PTH can be low (hypoparathyroidism) or high. Low calcium with high phosphorous can be due to renal failure, massive tissue destruction, hypoparathyroidism, and pseudohypoparathyroidism. Low calcium with low phosphorous is due to absent or ineffective vitamin D.

Management. In the acute stage of hypocalcemia, calcium gluconate can be given IV. Maintenance therapy includes oral calcium 2–4 g/d, vitamin D, and if there is hyperphosphatemia, diet restriction and phosphate binders ($CaCO_3$ or aluminum hydroxide).

DISORDERS OF CARBOHYDRATE METABOLISM

Diabetes Mellitus

Definition. A disorder of carbohydrate metabolism caused by relative or absolute deficiency of insulin, hyperglycemia, and end-organ complications, including nephropathy, retinopathy, neuropathy, and accelerated atherosclerosis. Diabetes affects approximately 6% of the population in the United States, and approaches 20% of patients over age 65.

Classification

- **Type 1 IDDM (insulin-dependent or juvenile onset)** accounts for 5–10% of diabetes worldwide, with males = females. The age of onset is usually age <30. Genetically, <10% of first-degree relatives are affected with a 50% occurrence in identical twins.
- There is an increased prevalence of autoantibodies to islet cells, glutamic acid decarboxylase (GAD), and other tissues with IDDM. Type 1 diabetes is associated with HLA-B8, HLA-B15, HLA-DR3, and HLA-DR4. Patients usually have a lean body build and are prone to ketosis owing to absent insulin production.
- **Type 2, or NIDDM (non-insulin-dependent or maturity onset)**, is the most common type of diabetes, accounting for 90% of cases, with males > females. Age of onset is usually age 40. Genetically >20% of first-degree relatives are affected with 90–100% occurrence in identical twins.
- No autoantibodies are associated with NIDDM. The body build of these patients is usually obese with >80% being >15% above ideal body weight. NIDDM patients are ketosis-resistant, and insulin levels may be high, normal, or low. About 90% of diabetes is type 2.

Pathophysiology. For IDDM, by the time the condition appears, most of the beta cells in the pancreas have been destroyed. The destructive process is most likely autoimmune in nature.

For NIDDM, there are 2 clear physiologic defects: abnormal insulin secretion and resistance to insulin action in target tissues.

Clinical Findings. Manifestations of symptomatic DM vary from patient to patient. Most often symptoms are associated with hyperglycemia, and polyuria, polydipsia, and polyphagia can be seen. The first event may be an acute metabolic decompensation, resulting in coma (ketoacidosis for IDDM and hyperosmolar coma for NIDDM). Occasionally the initial expression of DM is a degenerative complication like neuropathy.

Diagnosis. Symptomatic patients will have polyuria, polydipsia, ketonuria, and weight loss. Plasma glucose >200 mg/dL in these patients is sufficient for diagnosis with no further testing needed. A random glucose >200 mg/dL is diagnostic.

In asymptomatic patients, an elevated plasma or urine glucose during routine screening does not establish diagnosis but indicates a need for further evaluation. Patients who have DM will have a fasting plasma glucose ≥126 mg/dL on 2 occasions. The oral glucose tolerance test is rarely required. DM is diagnosed when plasma glucose ≥200 mg/dL at 2 h and on at least one of the earlier samples. HbA_{1c} >6.5% is diagnostic of diabetes.

Glycosylated hemoglobin A_{1c} (HbA_{1c}) is produced by nonenzymatic condensation of glucose molecules with free amino groups on the globin component of hemoglobin. It is used both for diagnosis and to follow compliance of the treatment and glucose control in diabetic patients.

HbA_{1c} is high in diabetics with chronic hyperglycemia during the preceding 8–12 weeks.

Management. The objectives of diabetic therapy are to control symptoms, prevent acute complications, and limit long-term complications. Several steps should be considered, such as patient education, weight loss, low-fat diet, physical activity, and pharmacologic therapy with oral hypoglycemic drugs or insulin.

Weight reduction of as little as 4–7% body fat has an enormous effect on peripheral insulin sensitivity and on reduction of postprandial hyperglycemia. Exercise lowers glucose levels. Exercising muscle needs no insulin for glucose to enter. Resting muscle, in comparison, needs insulin for glucose entry. As many as 25% of diabetic patients can be kept off of medication with diet and exercise alone.

The effects of diet, exercise, and weight loss can last for many years. When diet and exercise do not keep the HbA1c <7%, medications are introduced.

Oral hypoglycemics should be prescribed for all type 2 diabetics. Metformin is the drug of choice and along with lifestyle intervention should be used in all newly diagnosed patients. One major advantage of metformin is that it does not cause hypoglycemia. Another is that it does not cause weight gain. (Metformin is contraindicated in those with renal insufficiency.)

- If a patient is initiated on metformin yet the diabetes does not become well-controlled, add a sulfonylurea.
- If a patient is already on sulfonylurea but the diabetes is not well-controlled, add metformin.
- If a patient is already taking both metformin and a sulfonylurea yet there is still poor glycemic control, then either switch to insulin or add a glitazone.
  - Glitazones can lead to fluid retention.
  - If one drug is not sufficient, a second or third oral agent may be combined to keep the patient off insulin.
- If metformin cannot be used, use a new glucagon-like peptide (GLP-1) agonist (exenatide or liraglutide). GLP-1 agonists are second-line agents that can be added to metformin or used individually if metformin cannot be used.

In all cases, metformin is clearly the "best initial therapy" for type 2 diabetes. After metformin, the choices are less clear.

- Sulfonylureas (glyburide, glipizide, glimepiride): increase weight, cause hypoglycemia; sulfa drugs
- Thiazolidinediones (rosiglitazone or pioglitazone): can worsen CHF
  - Thought to act by decreasing the resistance of tissues to insulin
  - Recent studies suggest pioglitazone may be linked to bladder cancer
  - Rosiglitazone only available through a special assessment program
- Incretin mimetics (exenatide, liraglutide): must be given by injection
  - Augment the naturally occurring hormones that are secreted from the GI tract in response to food; when food enters the intestine, incretins are released
  - Increase the release of insulin from the pancreas
  - Also called gastric inhibitory peptide or glucose-dependent insulinotropic peptide (both abbreviated as GIP); GIP increases insulin release and slows gastric motility

The other incretin is "glucagon-like peptide" or GLP. Though "glucagon-like," GLP does **not raise glucose levels** or mimic the effect on glucagon in terms of breaking down glycogen or increasing gluconeogenesis. The term "glucagon-like peptide" is very confusing because the effect of GLP is strictly to LOWER glucose levels. GLP also raises insulin levels and slows gastric motility. GLP is normally released from the small bowel but in the native form lasts only for 2 minutes.

The "incretin mimetic" drugs exenatide and liraglutide are direct analogues of GIP and GLP, except that their actions last much longer. The problem with these drugs is that they must be given by injection. They have an outstanding effect on slowing gastric motility and promoting weight loss, but because they are given by injection they are not used as one of the first 3 classes of medications to treat type 2 diabetes.

- Dipeptidyl peptidase IV (DPP-IV) inhibitors (sitagliptin, saxagliptin, linagliptin): natural hormones which prevent the metabolism of the incretins GIP and GLP
  - Increase insulin release from the pancreas and slow stomach emptying
  - Can be given orally

Only after therapy with multiple oral hypoglycemic fails should an insulin regimen be considered. When starting insulin, divide 50% into long-acting and 50% into pre-meal short-acting. This regimen is usually given as glargine insulin 1x/day injection along with 2–3×/day ultra-short-acting insulin such as lispro or aspart before meals. Glargine causes fewer episodes of hypoglycemia compared with NPH. Levemir is a newer, long-acting insulin, lasting 16–18 hours.

Table 2-4. Oral Hypoglycemic Drugs

Class	Generic Name	Brand Name	Doses/Day
Sulfonylureas	Glyburide, glipizide, glimepiride	Micronase, Diabeta, Amaryl	1–2
Biguanides	Metformin	Glucophage	2–3
Thiazolidinediones	Rosiglitazone, pioglitazone	—	1
Glucosidase inhibitors	Acarbose, miglitol	Precose	With every meal
Meglitinides	Repaglinide, nateglinide	—	—
DPP-IV inhibitors	Sitagliptin, saxagliptin, linagliptin	Januvia, Onglyza, Tradjenta	—
Subcutaneous agents			
GLP-1	Exenatide, liraglutide	Byetta, Victoza	2/day, 1/day

Table 2-5. Insulin Preparations

Type	Peak Action (Hours)	Duration of Action (Hours)
Ultra-short-acting		
Insulin lispro	30–60 min	4–6
Insulin aspart	20–30 min	3–5
Rapid		
Regular	2–4	6–8
Semilente	2–6	10–12
Intermediate		
NPH	6–12	12–18
Lente	6–12	12–18
Long-acting		
Glargine	2	24
Levemir	18–24	36

Complications of diabetes mellitus

Acute Complications. Diabetic ketoacidosis (DKA) is a result of severe insulin insufficiency. It occurs in type 1 diabetics and may be the presenting manifestation. Precipitating factors of DKA include insufficient or interrupted insulin therapy, infection, emotional stress, and excessive alcohol ingestion.

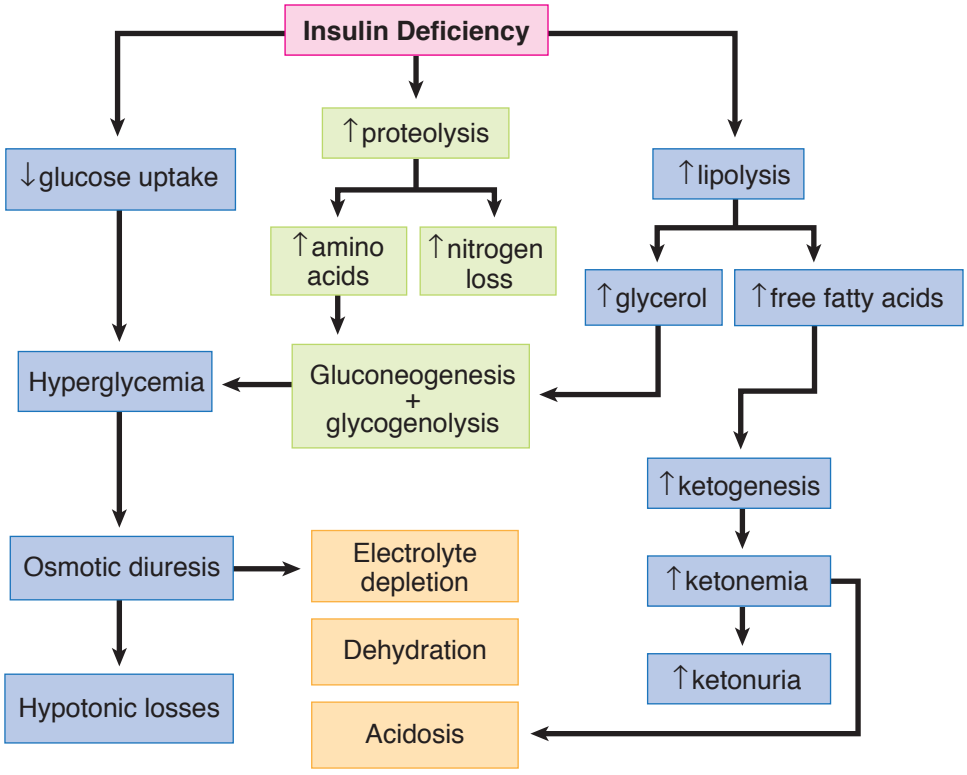

Figure 2-11. Pathophysiology of DKA

The main problems in DKA stem from acidosis with increased anion gap and dehydration. Clinical findings include anorexia, nausea or vomiting, abdominal pain, rapid breathing (Kussmaul respiration), "fruity" breath odor of acetone, signs of dehydration (dry skin and mucous membranes and poor skin turgor), and altered consciousness to coma. Acidosis can result in fatal rhythm disturbance.

The diagnosis of DKA can be made by finding elevated blood glucose, increased serum levels of acetoacetate, acetone, and hydroxybutyrate, metabolic acidosis (low serum bicarbonate and low blood pH), and increased anion gap (sodium – [bicarbonate + chloride]). DKA is managed with insulin, fluids, and electrolyte replacement. Normal saline should be given in high volume with insulin replacement. Bolus with 5–10 units of regular insulin. Acutely, DKA is associated with hyperkalemia. The total body level of potassium is depleted because of the urinary loss of potassium. As soon as the potassium level falls to ≤5 mEq/L, potassium replacement should be given.

Clinical points in the management of DKA

- Begin management with IV insulin, then switch to subcutaneous insulin when the anion gap normalizes and serum bicarbonate levels are normal.
- Do not stop the IV insulin before starting subcutaneous insulin; instead, overlap them both for 6–8 hours.
- Add 5% dextrose to the normal saline as blood glucose reaches 200–250 mg/dL, and continue IV insulin until the anion gap normalizes.

Hyperosmolar nonketotic coma (HONK) is a syndrome that occurs predominantly in patients with type 2 diabetes and is characterized by severe hyperglycemia in the absence of significant ketosis. Precipitating factors include noncompliance with treatment plus the inability to drink sufficient water to keep up with urinary losses. This is common in elderly diabetics living in nursing homes. Infections, strokes, steroids, immunosuppressant agents, and diuretics are other precipitating factors. HONK can occur after a therapeutic procedure such as peritoneal/hemodialysis, tube feeding of high-protein formulas, or high-carbohydrate infusion. The pathophysiology involved is profound dehydration resulting from a sustained hyperglycemic diuresis. Clinical findings are weakness, polyuria, polydipsia, lethargy, confusion, convulsions, and coma.

The diagnosis of HONK is suggested by elevated blood glucose (typically ≥700 mg/dL) and extremely high serum osmolality.

Serum osmolality in mOsm/L = 2[sodium] + [glucose/18] + [BUN/2.8]

A high BUN (prerenal azotemia) and mild metabolic acidosis (bicarbonate ~20 mEq/L) is also seen without ketosis.

Management of HONK involves high-volume fluid and electrolyte replacement, and insulin.

Chronic Complications. Chronic complications of diabetes involve the macro- and microvasculature, and are a major result of disease progression. These complications reduce patients' quality of life, incur heavy burdens to the health care system, and increase diabetic mortality. Microvascular disease of diabetes includes diabetic nephropathy, neuropathy, and retinopathy. Macrovascular disease contains coronary artery disease, peripheral arterial disease, and stroke. The effect of glycemic control is much more evident on the morbidity and mortality associated with microvascular complications.

Cardiovascular Complications. The number 1 cause of death in patients with diabetes is cardiovascular disease. About 75% of all deaths in diabetes are from myocardial infarction, congestive failure, or stroke.The central pathological mechanism in macrovascular disease is atherosclerosis, which leads to narrowing of arterial walls throughout the body. Atherosclerosis is thought to result from chronic inflammation and injury to the arterial wall in the peripheral or coronary vascular system.

Lipid testing should be performed in patients with diabetes at least annually. Diabetes is considered the equivalent of coronary disease in terms of management of hyperlipidemia. Lipid goals for adults with diabetes are as follows:

- LDL <100 mg/dL (or <70 mg/dL in cases of overt CVD)
- HDL >50 mg/dL
- Fasting triglycerides <150 mg/dL
- If LDL >100 mg/dl, patient should implement lifestyle modification (diet, exercise) along with drug therapy (statin). Combination therapy of statin plus another drug such as a fibrate or niacin may be necessary to achieve ideal lipid control, but monitor patients closely for possible adverse reaction to therapy.
- Coronary artery bypass should be performed in a diabetic patient even if there is only 2-vessel coronary disease.

Note

The most common pattern of dyslipidemia in patients with type 2 diabetes is elevated triglyceride and decreased HDL cholesterol.

Diabetic nephropathy. Nephropathy affects 30–40% of type 1 diabetics and 20–30% of type 2 diabetics. Hyperproliferation, proteinuria, and end-stage renal disease can develop. The pathology can be diffuse, which is more common, and lead to widening of glomerular basement membrane and mesangial thickening. Nodular pathology can occur and results in hyalinization of afferent glomerular arterioles (Kimmelstiel-Wilson syndrome). Management of nephropathy involves strict control of diabetes, ACE-inhibitors, and dialysis or renal transplantation.

All diabetics should be screened for proteinuria annually. Proteinuria is detectable on a standard dipstick when the level >300 mg per 24 hours. **Microalbuminuria** is defined as a level 30–300 mg. All those with proteinuria should receive therapy with an ACE inhibitor or angiotensin receptor blocker. Diabetes is the most common cause of end stage renal disease in the United States.

Diabetic retinopathy. The retina is affected, and diabetes is the leading cause of blindness in middle-aged patients. Simple/background, or proliferative (microaneurysms, hemorrhages, exudates, retinal edema) damage can occur.

- For type 2 diabetic patients, screen at diagnosis, then annually.
- For type 1 diabetes, the first screening should take place 5 years after diagnosis, then annually.

Proliferative retinopathy is defined as the presence of vitreous hemorrhages or neovascularization; treatment is with laser photocoagulation. Nonproliferative or background retinopathy can only be prevented with tight control of glucose levels.

Diabetic neuropathy. Neuropathy is another complication of diabetes, and it has various types.

- **Peripheral neuropathy** (most common) is symmetrical, with symptoms of numbness, paresthesia, and pain being prevalent. Physical exam reveals absent reflexes and loss of vibratory sense. Podiatric exam (microfilament testing) should occur annually to look for early signs of neuropathy since it leads to increased injury from trauma. Diabetes is responsible for 50% of all nontraumatic amputations in the United States.

- **Mononeuropathy** affects a single nerve or nerve trunk (mononeuritis multiplex) and is vascular in origin; patients will have sudden foot drop, wrist drop, or paralysis of CN III, IV, or VI.
- **Autonomic neuropathy** can be devastating; patients will have orthostatic hypotension and syncope as main manifestations. Gastrointestinally, patients may have difficulty swallowing, delayed gastric emptying (gastroparesis), constipation, or diarrhea. The diagnostic test of choice for gastroparesis is the gastric emptying scintigraphy study. Bladder dysfunction or paralysis can lead to urinary retention. Impotence and retrograde ejaculation can occur; the prevalence of erectile dysfunction is as high as 50% in patients with 10 years of diabetes.

Wikimedia, Jonathan Moore

Figure 2-12. Diabetic Foot Ulcer

As with other microvascular complications, prevention of neuropathy in diabetes is by tight glycemic control. Management once it occurs depends on the type. For peripheral neuropathy, analgesics, gabapentin, pregabalin, amitriptyline, and carbamazepine are used (gabapentin and pregabalin are the best). For gastroparesis, metoclopramide or erythromycin can be used. Erectile dysfunction is treated with sildenafil and similar drugs.

Additional Concepts. The "honeymoon" period (in IDDM patients) is an initial episode of ketoacidosis followed by a symptom-free interval during which no treatment is required. Presumably stress-induced epinephrine release blocks insulin secretion, causing the syndrome. In normal individuals insulin reserve is such that hormone release is adequate even in the face of stress.

The Somogyi effect is rebound hyperglycemia in the morning because of counterregulatory hormone release after an episode of hypoglycemia in the middle of the night.

The Dawn phenomenon is an early morning rise in plasma glucose secondary to a rise in counter-regulatory hormones cortisol, epinephrine, and GH requiring increased amounts of insulin to maintain euglycemia.

Hypoglycemia

Glucose is the primary energy source of the brain. Symptoms of hypoglycemia are divided into 2 groups and can occur because of excessive secretion of epinephrine, leading to sweating, tremor, tachycardia, anxiety, and hunger. Hypoglycemia can also occur because of dysfunction

of the CNS, leading to dizziness, headache, clouding vision, blunted mental activity, loss of fine motor skills, confusion, abnormal behavior, convulsions, and loss of consciousness. There is no uniform correlation between a given level of blood sugar and symptoms. Major symptoms in normal persons may not be seen until blood sugar is 20 mg/dL.

Classification. Postprandial hypoglycemia (reactive) can be secondary to alimentary hyperinsulinism (after gastrectomy, gastrojejunostomy, pyloroplasty, or vagotomy), idiopathic, and galactosemia.

Fasting hypoglycemia can result from conditions in which there is an underproduction of glucose, such as hormone deficiencies (panhypopituitarism, adrenal insufficiency), enzyme defects, substrate deficiency (severe malnutrition, late pregnancy), acquired liver disease, or drugs (alcohol, propanolol, salicylates). Fasting hypoglycemia can also occur in conditions related to overutilization of glucose such as hyperinsulinism. Hyperinsulinism can occur secondary to insulinoma, exogenous insulin, sulfonylureas, drugs (quinine), endotoxic shock, and immune disease with insulin receptor antibodies. Overutilization of glucose can also occur in states in which there are appropriate insulin levels, such as extrapancreatic tumors and rare enzyme deficiencies.

Insulinoma (pancreatic B-cell tumor) can cause hypoglycemia. Ninety percent of these tumors are single and benign. Clinical findings include symptoms of subacute or chronic hypoglycemia such as blurred vision, headache, feelings of detachment, slurred speech, and weakness. Symptoms occur in the early morning or late afternoon or after fasting or exercise.

Diagnosis. This is made by finding a serum insulin level ≥8 mg/mL in the presence of blood glucose <40 mg/dL (i.e., inappropriately high serum insulin level when glucose is low), noted either spontaneously or during a prolonged fast (72 hours). CT scan, U/S, and arteriography may also be useful in detecting the tumor(s). Management of insulinoma is by surgery, diet, and medical therapy.

Factitious hyperinsulinism is caused by self-administration of insulin or ingestion of Equal or oral sulfonylureas. It is common and exceeds the incidence of insulinomas. Most often, these patients are associated with the health professions or have access to these drugs by a diabetic member of the family. A triad of hypoglycemia, high immunoreactivity, insulin, and suppressed plasma C peptide is pathognomonic of exogenous insulin administration.

Ethanol-induced hypoglycemia can also occur with prolonged starvation, when glycogen reserves become depleted in 18–24 hours and hepatic glucose output depends completely on gluconeogenesis. Ethanol at a concentration of 45 mg/dL can induce hypoglycemia by blocking gluconeogenesis.

Table 2-6. Differential Diagnosis of Insulinoma and Factitious Hyperinsulinism

Test	Insulinoma	Exogenous Insulin	Sulfonylureas
Plasma insulin	High (usually <200 μU/mL)	Very high (usually >1,000 μU/mL)	High
Proinsulin	Increased	Normal or low	Normal
C peptide (insulin connective peptide) 1:1	Increased	Normal or low	Increased
Insulin antibodies	Absent	+/– Present	Absent
Plasma or urine sulfonylurea	Absent	Absent	Present

DISEASES OF THE ADRENAL GLAND

The adrenal gland is divided into 2 areas, the cortex and medulla. The cortex is divided into 3 areas, the outer zone (glomerulosa), which is the site of aldosterone synthesis; the central zone (fasciculata), which is the site of cortisol synthesis; and the inner zone (reticularis), which is the site of androgen biosynthesis. The disorders of hyperfunction of the gland are associated with the following specific hormones: increased cortisol is seen in Cushing syndrome; increased aldosterone in hyperaldosteronism; and increased adrenal androgens with virilization in women.

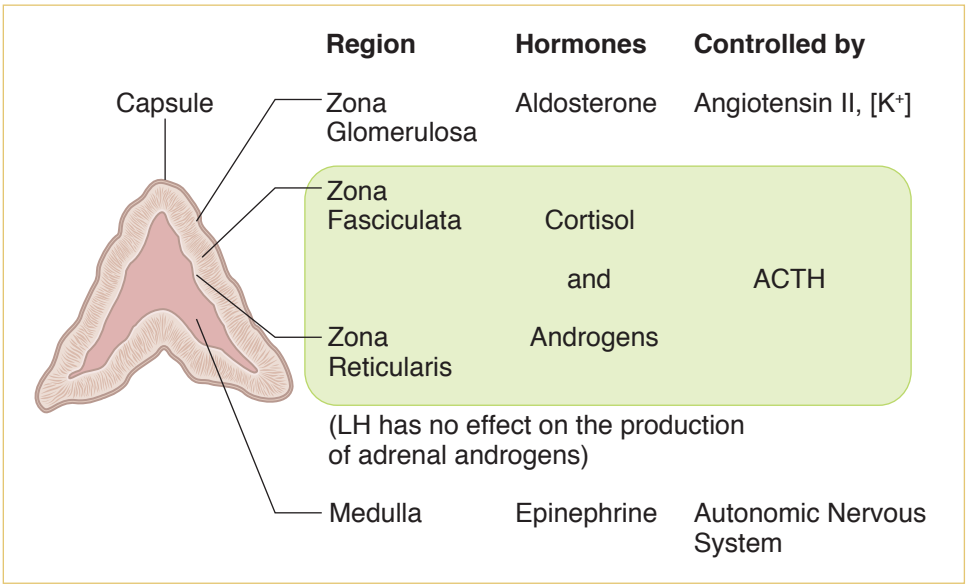

Figure 2-13. Adrenal Cortex Regions

Hyperfunctioning of the Gland

Cushing syndrome

Definition. A group of clinical abnormalities caused by prolonged exposure to increased amounts of cortisol or related corticosteroids.

Etiology. Exogenous, iatrogenic causes are the most common overall causes of Cushing syndrome and can be secondary to prolonged use of glucocorticoids.

The etiology of Cushing syndrome includes adrenal hyperplasia. This can be secondary to pituitary ACTH production, which occurs in pituitary-hypothalamic dysfunction, and pituitary ACTH-producing adenomas (microadenoma, e.g., Cushing disease). ACTH-producing pituitary adenomas cause about 60–80% of Cushing cases. Adrenal hyperplasia can also be secondary to ACTH or corticotropin-releasing hormone (CRH), produced by nonendocrine tumors (bronchogenic carcinoma, carcinoma of the thymus, pancreatic carcinoma, and bronchial adenoma). Adrenal neoplasia, such as adenoma or carcinoma, and adrenal nodular hyperplasia account for about 30% of Cushing cases. Excessive cortisol production by an autonomous adrenal results in a low ACTH level. About 15% of Cushing cases are from ACTH from a source that cannot be located.

Clinical Findings. The clinical findings of Cushing syndrome include deposition of adipose tissue in characteristic sites such as upper fat, moon facies; interscapular buffalo hump; and mesenteric bed, truncal obesity. Other clinical findings include *hypertension*, muscle weakness, and fatigability related to mobilization of peripheral supportive tissue; osteoporosis caused by increased bone catabolism; cutaneous striae; and easy bruisability. Women may have acne, hirsutism, and oligomenorrhea or amenorrhea resulting from the increased adrenal androgen secretion. Emotional changes range from irritability or emotional lability to severe depression or confusion; even psychosis can occur as well. Glucose intolerance is common in Cushing disease, with 20% of patients having diabetes.

Cushing and glucocorticoid use are also associated with hypokalemia and leukocytosis. Hypokalemia occurs because of the mineralocorticoid effect of the steroids.

Clinically significant hypokalemia is uncommon.

Other manifestations are delayed wound healing, renal calculi from increased calcium levels, and glaucoma. Polyuria is from hyperglycemia. There is increased susceptibility to infections because neutrophils exhibit diminished function because of high glucocorticoid levels.

Diagnosis. The diagnostic tests used to establish the syndrome of cortisol excess are the 1-mg overnight dexamethasone suppression test and the 24-hour urine-free cortisol. The tests used to establish a precise etiology of the cortisol excess are the ACTH level, high-dose dexamethasone suppression test, CT and MRI scanning, and occasionally sampling of the petrosal venous sinus, which drains out of the pituitary.

The 1-mg overnight dexamethasone suppression test is used to rule out the diagnosis of Cushing syndrome or glucocorticoid excess. If you give a milligram of dexamethasone at 11 P.M., the cortisol level at 8 A.M. should come to normal if there is the normal ability to suppress ACTH production over several hours. The problem with this test is that there can be falsely abnormal or positive tests. Any drug that increases the metabolic breakdown of dexamethasone will prevent its ability to suppress cortisol levels. Examples of drugs increasing the metabolism of dexamethasone are phenytoin, carbamazepine, and rifampin. Stress increases glucocorticoid levels. The 1-mg overnight dexamethasone suppression test can be falsely positive in stressful conditions such as starvation, anorexia, bulimia, alcohol withdrawal, or depression.

An abnormality on the 1-mg overnight test should be confirmed with a 24-hour urine-free cortisol. The 24-hour urine-free cortisol is more accurate and is the gold standard for confirming or excluding Cushing's syndrome.

A third screening test for Cushing is the midnight salivary cortisol. In normal patients, cortisol is at its lowest at midnight. In Cushing patients, cortisol is abnormally elevated at midnight.

The precise etiology of the Cushing syndrome is established by using ACTH levels, sometimes in combination with high-dose dexamethasone suppression testing. ACTH levels are elevated with either a pituitary source of ACTH such as an adenoma or with an ectopic source. High-dose dexamethasone suppression testing can distinguish the difference. The output of a pituitary adenoma will suppress with high-dose dexamethasone. The output of an ectopic source will not suppress with high-dose dexamethasone.

If the ACTH level is low, then the etiology is most likely from an adrenal tumor such as an adenoma, cancer, or from adrenal hyperplasia. When the adrenal gland is the source of increased cortisol production, there is feedback inhibition on the pituitary and the ACTH level is suppressed.

When there is a low ACTH level, the precise etiology is confirmed with a CT scan of the adrenals.

When there is a high ACTH level, the precise etiology is confirmed with an MRI of the pituitary looking for an adenoma or a CT scan of the chest looking for an ectopic focus. If neither of these show a lesion or the MRI of the brain is equivocal, then inferior petrosal sinus sampling should be done to see if there is increased ACTH coming out of the brain.

Single random cortisol levels are not reliable.

- High plasma ACTH levels = pituitary or ectopic source
- Low plasma ACTH levels = adrenal tumors or hyperplasia

Management. Depends on the etiology, and can be surgical or medical. Unresectable adrenal tumors are treated with ketoconazole or metyrapone.

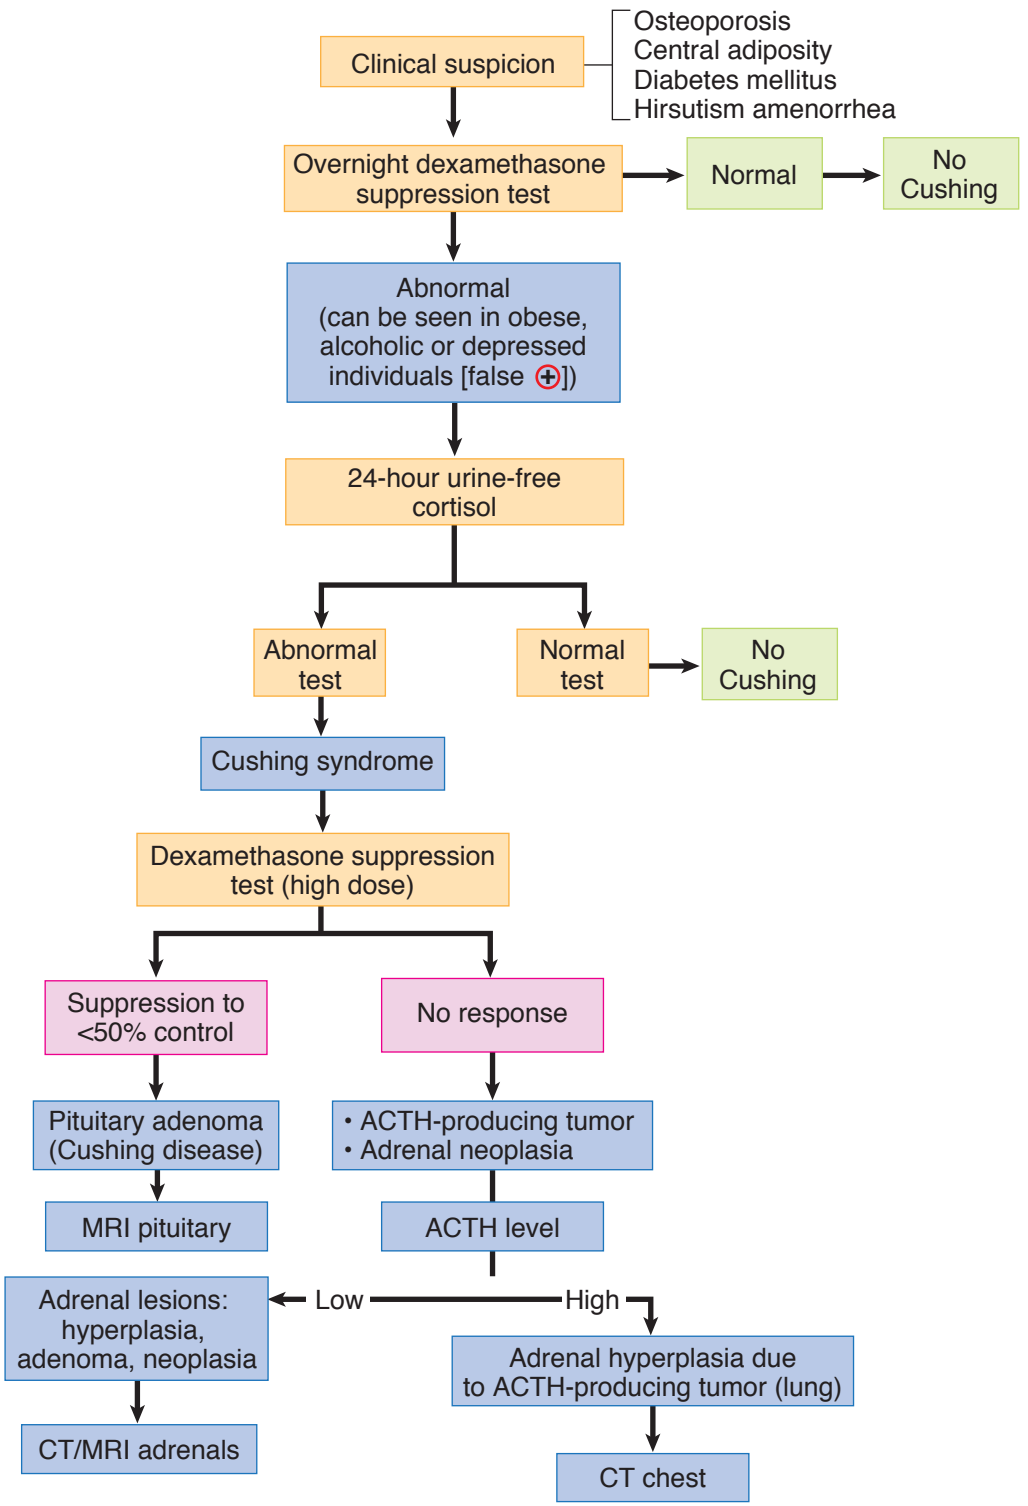

Figure 2-14. Evaluating a Patient with Presumed Cushing Syndrome

Hyperaldosteronism

Hyperaldosteronism is a syndrome associated with hypersecretion of the major adrenal mineralocorticoid, aldosterone. The normal function of aldosterone is to reabsorb sodium and excrete potassium and acid (H^+). Hyperaldosteronism can be divided into the following:

- **Primary aldosteronism**, in which the stimulus for the excessive aldosterone production is within the adrenal gland
- **Secondary aldosteronism**, in which the stimulus is extraadrenal

The most common cause of primary hyperaldosteronism is a unilateral adrenal adenoma (70%). Bilateral hyperplasia accounts for 25–30%. Excessive black licorice ingestion can mimic this effect. Licorice has aldosterone-like qualities.

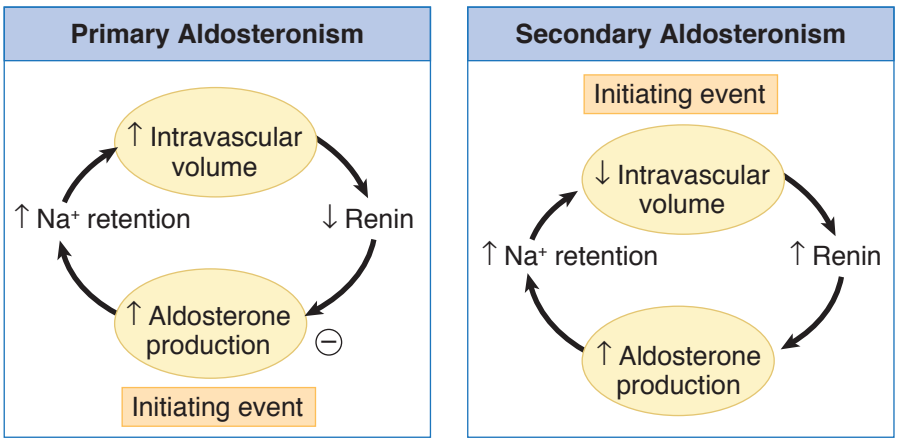

Figure 2-15. Mechanism of Hyperaldosteronism

Clinical. Primary hyperaldosteronism is characterized by hypertension and low potassium levels. Most of the other symptoms, such as muscle weakness, polyuria, and polydipsia, are from the hypokalemia. Metabolic alkalosis occurs because aldosterone increases hydrogen ion (H+) excretion. Aldosterone causes alkalosis. Edema is uncommon with primary hyperaldosteronism because of sodium release into the urine.

Table 2-7. Clinical and Laboratory Findings in Primary and Secondary Aldosteronism

	Primary Aldosteronism	Secondary Aldosteronism
Diastolic hypertension	+	–
Muscle weakness	+	+/–
Polyuria, polydipsia	+	+/–
Edema	–	+/–
Hypokalemia	+	+
Hypernatremia	+	–
Metabolic alkalosis	+	+

Diagnosis. The preliminary screen for hyperaldosteronism is a plasma aldosterone concentration (PAC) and plasma renin activity (PRA). A positive screen is a PAC/PRA ratio >20:1 and a PAC >15. To confirm hyperaldosteronism, an NaCl challenge is required. This can be via normal saline, NaCl tabs, or fludrocortisone. After an NaCl challenge, PAC should be suppressed as in a normal individual. If PAC is still elevated, this confirms the diagnosis.

Management. Adrenal adenomas are removed surgically. Bilateral hyperplasia is treated with spironolactone, which blocks aldosterone.

Bartter Syndrome. The exception of secondary hyperaldosteronism without edema or hypertension is Bartter syndrome. Bartter syndrome is caused by a defect in the loop of Henle in which it loses NaCl. This is due to a defect in the Na-K-2Cl cotransporter. This is like having a furosemide-secreting tumor.

In Bartter syndrome there is juxtaglomerular hyperplasia, normal to low blood pressure, no edema, severe hypokalemic alkalosis, defect in renal conservation of sodium or chloride, and renal loss of sodium, which stimulates renin secretion and aldosterone production.

Syndromes of adrenal androgen excess

Syndromes of adrenal androgen excess result from excess production of dehydroepiandrosterone (DHEA), and androstenedione, which are converted to testosterone in extraglandular tissues. The elevated testosterone accounts for most androgenic effects.

Clinical Signs and Symptoms. Hirsutism, oligomenorrhea, acne, and virilization. Etiology includes congenital adrenal hyperplasia, adrenal adenomas (rare), and adrenal carcinomas.

Congenital adrenal hyperplasia (CAH)

Definition. Congenital adrenal hyperplasia is a syndrome associated with increased adrenal androgen production because of enzymatic defects.

Etiology. CAH is the most common adrenal disorder of infancy and childhood. CAH arises from autosomal recessive mutations, which produce deficiencies of enzymes necessary for the synthesis of cortisol.

Common Enzymatic Defects Associated with CAH. Enzymatic defects include C-21 hydroxylase deficiency in 95% of all cases. C-21 hydroxylase deficiency is associated with reduction in aldosterone secretion in one-third of patients. Adrenal virilization occurs with or without an associated salt-losing tendency, owing to aldosterone deficiency, which leads to hyponatremia, hyperkalemia, dehydration, and hypotension.

Patients are female at birth with ambiguous external genitalia (female pseudohermaphrodism), enlarged clitoris, and partial or complete fusion of the labia. Postnatally CAH is associated with virilization. Patients may be male at birth with macrogenitosomia; postnatally this is associated with precocious puberty.

C-11 hydroxylase deficiency can also occur. The mineralocorticoid manifestations in C-11 deficiency can be 'biphasic.' In early infancy, despite having excessive mineralocorticoid hormones, patients sometimes present with relative 'salt wasting' (aldosterone deficiency). This is because some infants have inefficient salt conservation as well as immature aldosterone production. During this phase, infants can present with hypotension and hyperkalemia (very similar to 21 hydroxylase deficiency). Later in life (childhood and adulthood), there is better

Note

The 'biphasic' presentation is rare. When you think about 11 deficiency, think mineralocorticoid excess (hypertension and hypokalemia) with low cortisol production (remember you need C-11 for the final step in converting to cortisol).

ability to hold onto salt, so the patient develops the typical C-11 deficiency syndrome: hypertension and hypokalemia.

C-17 hydroxylase deficiency can occur as well, and is characterized by hypogonadism, hypokalemia, and hypertension resulting from increased production of 11-deoxycorticosterone.

Diagnosis. CAH should be considered in all infants exhibiting failure to thrive, especially those with episodes of acute adrenal insufficiency, salt wasting, or hypertension. The most useful measurements are of serum testosterone, androstenedione, dehydroepiandrosterone, 17-hydroxyprogesterone, urinary 17-ketosteroid, and pregnanetriol.

Management. Treatment is glucocorticoid (hydrocortisone) replacement.

Hypofunctioning of the Gland

Adrenal insufficiency

Definition. Adrenal insufficiency can be divided into **primary adrenocorticoid insufficiency** (**Addison disease**) and **secondary failure in the elaboration of ACTH**. Primary adrenocortical insufficiency is a slow, usually progressive disease due to adrenocorticoid hypofunction.

Etiology. The etiology of Addison disease can be secondary to anatomic destruction of the gland (chronic and acute). Idiopathic atrophy is the most common cause of anatomic destruction, and autoimmune mechanisms are probably responsible. Autoimmune destruction accounts for 80% of cases. Anatomic destruction can also be secondary to surgical removal, infection (TB, fungal, cytomegalovirus), hemorrhagic, trauma, and metastatic invasion. Metabolic failure in hormone production can also lead to Addison disease and can be secondary to CAH, enzyme inhibitors, and cytotoxic agents (mitotane).

Clinical Findings. The clinical findings in Addison disease include weakness, paresthesias, cramping, intolerance to stress, and personality changes such as irritability and restlessness. Chronic disease is characterized by a small heart, weight loss, and sparse axillary hair. Hyperpigmentation of the skin can occur and appears as diffuse brown, tan, or bronze darkening of both exposed and unexposed body parts. Arterial hypotension is seen and is often orthostatic owing to lack of effect of cortisol on vascular tone. Abnormalities of GI function are found, and symptoms vary from mild anorexia with weight loss to nausea, vomiting, diarrhea, and abdominal pain. Acute Addisonian crisis is characterized by fever and hypotension. A low sodium with a high potassium level and mild acidosis are also present.

Diagnosis. The diagnosis of Addison disease is made through rapid ACTH administration and measurement of cortisol. Laboratory findings include white blood cell count with moderate neutropenia, lymphocytosis, and eosinophilia; elevated serum potassium and urea nitrogen; low sodium; low blood glucose; and morning low plasma cortisol.

The definitive diagnosis is the cosyntropin or ACTH stimulation test. A cortisol level is obtained before and after administering ACTH. A normal person should show a brisk rise in cortisol level after ACTH administration.

Differences between primary and secondary adrenal insufficiency:

- Hyperpigmentation (occurs only with primary insufficiency)
- Electrolyte abnormalities
- Hypotension

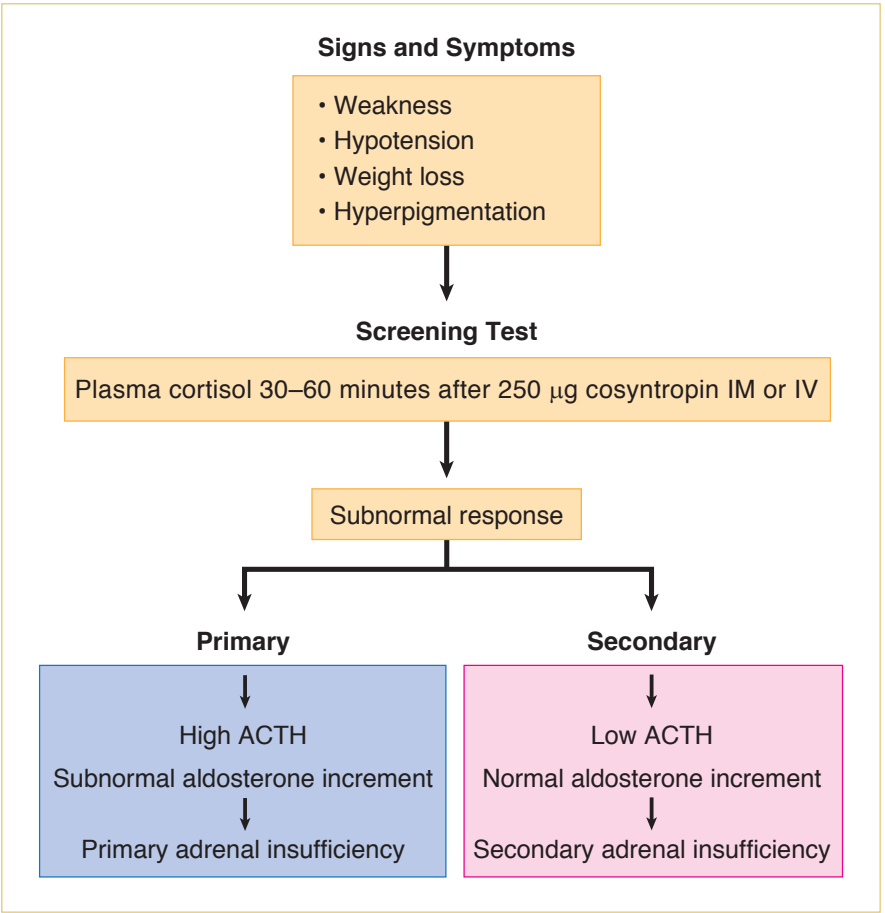

Figure 2-16. Diagnosis of Adrenal Insufficiency

Management. The management of Addison disease involves glucocorticoid, mineralocorticoid, and sodium chloride replacement, in addition to patient education.

Adrenal Crisis. In an adrenal crisis, fever, vomiting, abdominal pain, altered mental status, and vascular collapse may occur. Get a cortisol level, then rapidly administer fluids and hydrocortisone. This may occur in:

- Previously undiagnosed patient with adrenal insufficiency who has undergone surgery, serious infection, and/or major stress
- Bilateral adrenal infarction or hemorrhage
- Patient who is abruptly withdrawn from chronic glucocorticoid therapy

Pheochromocytoma

Definition. A rare, usually benign, tumor that arises from the chromaffin cells of the sympathetic nervous system. The **rule of 10%** applies in pheochromocytoma with 10% being extraadrenal, 10% malignant, 10% in children, and 10% bilateral or multiple (>right side). Also, 10% are not associated with hypertension.

Epidemiology. Pheochromocytoma occurs in approximately 0.1% of the hypertensive population. Familial pheochromocytoma occurs in 5% of cases, and is transmitted as an autosomal dominant trait alone or in combination with MEN type II or III, von Recklinghausen neurofibromatosis, or von Hippel-Lindau retinal cerebellar hemangioblastomatosis.

Pathology. In adults, 80% of pheochromocytomas occur as a unilateral solitary lesion with 10% being bilateral and 10% extraadrenal. In children, 25% of the tumors are bilateral and 25% are extraadrenal. Solitary lesions favor the right side. Extraadrenal pheochromocytomas are mostly located within the abdomen and near the celiac, superior mesenteric, and inferior mesenteric ganglia.

Catecholamine Secretion. Secretion of dopamine occurs more in familial syndromes and is not associated with hypertension. Epinephrine secretion causes tachycardia, sweating, flushing, and hypertension. Norepinephrine is secreted by all extraadrenal tumors.

Clinical Findings. Clinical findings of pheochromocytoma include paroxysms or crisis. This accounts for the typical manifestations occurring in >50% of patients. The attack has a sudden onset, lasting from a few minutes to several hours or longer. Headache, profuse sweating, palpitations, and apprehension are common in this setting. Pain in the chest or abdomen may be associated with nausea and vomiting. Blood pressure is elevated with tachycardia in crisis. Forty percent of patients have blood pressure elevation only during the attack, and 60% have stable hypertension. Anxiety, tremor, and weight loss are also found.

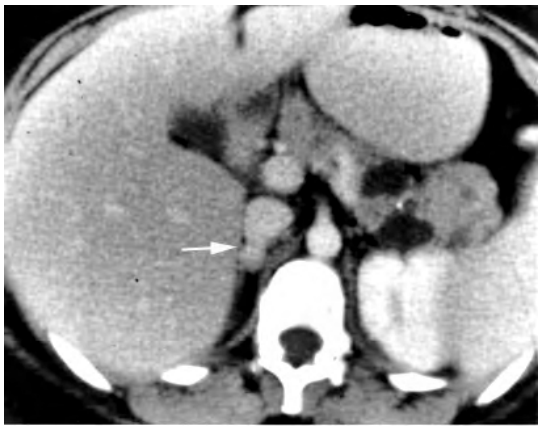
>33% of pheochromocytomas cause death prior to diagnosis; death is often due to cardiac arrhythmia and stroke.

Other clinical features include orthostatic hypotension and glucose intolerance. The hyperglycemia is only found in about 33% of patients and is mild.

Diagnosis. Diagnosis is established by demonstrating increased amounts of catecholamines or catecholamine metabolites in a 24-hour urine collection. Urinary-free catecholamines, urinary metanephrines, vanillylmandelic acid, and plasma catecholamines are tests of choice. Metanephrines are catecholamine metabolites. A 24-hour urinary VMA, metanephrines, and free catecholamines are the best initial tests. Recently, plasma metanephrine levels have been used in conjunction with urinary tests. Overall, metanephrines are the most sensitive and specific individual test. Smoking can increase plasma-free metanephrines. The patient must not smoke at least 4 hours before the test.

Clonidine should suppress epinephrine levels. Failure of epinephrine levels to fall after clonidine administration is highly suggestive of pheochromocytoma. A clonidine-suppression test is used when the above screening tests are equivocal.

When the catecholamine or metanephrine levels are abnormal, the tumor is confirmed with CT or MRI scan. MIBG (metaiodobenzylguanidine) scanning is used to locate a pheochromocytoma not found on a CT scan. If the biochemical tests (catecholamines, metanephrines) are positive and the CT scan does not show the location of the pheochromocytoma, then do an MIBG scan.



National Institutes of Health

Figure 2-17. Pheochromocytoma

Differential Diagnosis. The differential diagnosis of pheochromocytoma includes essential hypertension, anxiety attacks, factitious crisis, intracranial lesions, and autonomic epilepsy.

Management. Alpha-adrenergic blockade, phentolamine, and/or phenoxybenzamine, is required to control BP and prevent a hypertensive crisis, since high circulating catecholamine levels stimulate alpha receptors on blood vessels and cause vasoconstriction.

- Beta blockers are used if significant tachycardia occurs **after** alpha blockade; beta blockers are not administered until adequate alpha blockade has been established, since unopposed alpha-adrenergic receptor stimulation can precipitate a hypertensive crisis.
- Noncardioselective beta blockers (propranolol, nadolol) are the usual choice, though cardioselective agents (atenolol, metoprolol) may be used.
- Labetalol has been associated with paradoxic episodes of hypertension thought to be secondary to incomplete alpha blockade.

Curative surgical removal of the pheochromocytoma is performed only after BP has been stabilized; during surgery, IV phentolamine—a rapid-acting alpha-adrenergic antagonist—is used for controlling BP.

DISEASES OF THE TESTES, HYPOGONADISM

In hypogonadism there is decreased function of the testes or ovaries, resulting in the absence or impairment of secondary sexual characteristics and infertility.

Etiology

- **Primary hypogonadism** (hypergonadotropic: increased LH, FSH) can result from Klinefelter syndrome (small testes, eunuchoid, 47XXY), anorchia, surgical or accidental castration or radiotherapy, infections (mumps, TB, leprosy), or chemotherapeutic agents.
- **Secondary hypogonadism** (hypogonadotropic: low LH, FSH) can result from hypopituitarism secondary to idiopathic causes or tumors, hypothalamic lesions, and Kallmann syndrome (hypogonadic hypogonadism, associated with decreased sense of smell).

Clinical Findings. Clinical findings include prepubertal hypogonadism, most often caused by a specific gonadotropic deficiency of the pituitary. External genitalia are underdeveloped, voice is high-pitched, beard does not grow, and the patient lacks libido and potency. As an adult, the patient has a youthful appearance, with obesity, disproportionately long extremities, lack of temporal recession of the hairline, and a small Adam's apple. Gynecomastia is sometimes seen. The skin is fine-grained, wrinkled, and free of acne. The testes may be absent from the scrotum. Bone age is retarded. Urinary 17-ketosteroid is low to normal, and serum testosterone is below normal. Serum FSH and LH are low in hypothalamic or pituitary origin and elevated in primary testicular failure. Treatment is with testosterone.

Klinefelter syndrome is the most common primary developmental abnormality causing hypogonadism (testicular damage). This syndrome affects 1 of every 400–500 males. It is caused by one or more supernumerary X chromosomes. Eighty percent of patients have a 47,XXY karyotype. Gynecomastia is found with elevated levels of LH and FSH. Sterility and lack of libido are present. The testes are small and thin. Mental retardation may be present. Urinary 17-ketosteroids are low normal or normal, serum testosterone is low to normal, LH and FSH are elevated, and serum estradiol is elevated. Treatment is testosterone replacement.

Note

Males affected by Klinefelter syndrome have a **20× increased risk of breast cancer**.

Answers

Following are the answers for Table 2-2 seen earlier.

Evaluating Thyroid Function

Thyroid Hormones and TSH	RAI Uptake Scan	Diagnosis
↓ TSH; free ↑ T_4, ↑ T_3	↑ RAIU	De novo synthesis of hormone (primary hyperthyroidism)
↓ TSH; free ↑ T_4, ↑ T_3	↓ RAIU	Factitious hyperthyroidism or inflammation or destruction of the gland releasing preformed hormone into the circulation (subacute thyroiditis)
↓ TSH; free ↓ T_4, ↓ T_3	↓ RAIU	Secondary or tertiary hypothyroidism

Rheumatology 3

Learning Objectives

- List the steps for evaluating a patient with arthritis
- Differentiate between autoimmune arthritis, seronegative arthritis, osteoarthritis, crystal-induced arthritis, and septic arthritis
- Differentiate and describe the treatment approaches to rheumatoid arthritis, systemic lupus erythematosus, drug-induced lupus, scleroderma, Sjögren syndrome
- Differentiate and describe treatment approaches to seronegative arthropathies, including ankylosing spondylitis, reactive arthritis, psoriatic arthritis, and enteropathic arthritis
- Answer questions about the management of osteoarthritis, crystal-induced arthropathies, and septic arthritis
- Describe the diagnosis and management of vasculitis syndromes and inflammatory myopathies

EVALUATING A PATIENT WITH ARTHRITIS

When a patient presents with joint swelling, a differential diagnosis is generated based on the answers to the following questions:

1. What is the distribution of joint involvement and how many joints are involved?

Polyarticular symmetric involvement is characteristically seen with rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), parvovirus B19, and hepatitis B. On the other hand, monoarticular arthritis is consistent with osteoarthritis, crystal-induced arthritis (gout, pseudogout), septic arthritis (gonococcus), trauma, and hemarthrosis.

Migratory arthropathy (inflammation and pain migrates from joint to joint, while the previous involved joints improve) is caused by rheumatic fever, disseminated gonococcal infection, and Lyme disease. Oligoarticular asymmetric arthritis is common with the spondyloarthropathies (ankylosing spondylitis) and osteoarthritis involving the small joint of the upper extremities and rarely as a presentation of polyarticular gout.

2. Are the symptoms acute or chronic?

Osteoarthritis is a chronic disease; the patients have symptoms for months to years. Patients with septic arthritis or crystal-induced arthropathies have short-lived symptoms, commonly only a few days.

3. Does the patient have systemic symptoms (beyond the arthritis)?

SLE presents with lung (pleural effusions), kidney (proteinuria and renal failure), CNS (vasculitis, strokes, and change in personality), skin (malar and photosensitivity rash), and hematologic (immune-mediated anemia, thrombocytopenia) manifestations.

Sjögren syndrome has keratoconjunctivitis sicca (dry eyes/mouth) and parotid enlargement.

Systemic sclerosis has skin involvement and Raynaud phenomenon.

Wegener granulomatosis presents with upper respiratory (sinusitis and rhinitis), lower respiratory (lung nodules and hemoptysis), and renal (necrotizing glomerulonephritis) involvement.

OA, on the other hand, presents with absence of systemic symptoms.

4. Is there evidence of joint inflammation?

Evidence of joint inflammation includes: joint stiffness in the morning >1 hour, joint erythema and warmth, and elevated erythrocyte sedimentation rate (ESR) and C-reactive protein. An example of inflammatory arthritis is rheumatoid arthritis, while OA is typically noninflammatory.

Do not go further into a history unless you have answered the above 4 questions.

Examples

- A 62-year-old man presents with right knee pain.
- A 24-year-old woman presents with bilateral wrist, MCP, PIP joint swelling, and pain.
- A 32-year-old man presents with knee swelling after you had seen him one week ago for left wrist pain and swelling, which has now resolved.
- A 29-year-old man has right knee pain and swelling and left hip pain.

TESTS IN RHEUMATOLOGIC DISEASES

Joint Aspiration

If there is fluid in the joint, it needs analysis immediately.

The basic tests to run on the synovial fluid are the 3 Cs (cell count, crystals, and cultures) and the Gram stain.

Synovial fluid may be stratified according to the number of cells:

- OA and traumatic arthritis have 200–2,000 WBCs/mm^3 in the synovial fluid
- Inflammatory diseases (RA, gout) have 5,000–50,000 WBC/mm^3
- Septic arthritis has >50,000 WBC/mm^3

Table 3-1. Synovial Fluid Analysis in Different Rheumatologic Diseases

Disease	WBCs	Crystals/Polarization
DJD	<2,000	Negative traumatic
Inflammatory	5,000–50,000	Gout: needle-shaped, negative birefringent Pseudogout (CPPD): Rhomboid-shaped, positive birefringent
Septic	>50,000	Negative (Gram stain and culture usually negative for GC but positive in *Staph*, strep, and gram-negatives)

There are a few exceptions to the above:

- Septic arthritis may sometimes present with <50,000 WBC/mm^3 in the joint aspirate if antibiotics are given before the joint aspiration. Septic arthritis should be considered a possibility in a patient with >5,000 WBC/mm^3 in the synovial fluid, monoarticular arthritis, but absence of crystals.
- Gout and pseudogout uncommonly present with >50,000 WBC/mm^3 in the absence of infection. Consider this possibility if there is evidence of crystals in the aspirate.
- Culture of joint fluid is positive in only 50% or less of gonococcal arthritis.

Antinuclear Antibodies

Antinuclear antibodies (ANA) are antibodies that have the capability of binding to certain structures within the nucleus of the cells. ANAs are found in patients whose immune system may be predisposed to generate antibodies against their own body tissues. This is referred to as autoimmunity.

Although ANAs are found in patients with SLE, Sjögren syndrome, and systemic sclerosis, they may also be found in approximately 5% of normal people. When ANAs are present in normal people, they are usually in low titers (<1:80).

The ANA test is performed by exposing the antibodies in the serum of the blood to the laboratory test cells. It is then determined whether or not antibodies are present that react with various parts of the nucleus. Fluorescent techniques are now more frequently used, thus the test may be referred to as a fluorescent antinuclear antibody test (FANA).

ANAs present in different patterns depending on the staining of the cell nucleus: homogeneous, speckled, nucleolar, and peripheral (or rim). While these patterns are not specific for any one disease, certain diseases can more frequently be associated with one pattern or another. For example, the peripheral (rim) pattern may be seen with SLE, while the nucleolar pattern is more commonly seen in systemic sclerosis. The speckled pattern is more commonly seen in normal people.

Also, subsets of ANAs are associated with specific autoimmune diseases and are thus used to further diagnose these diseases. For example, anti ds-DNA and anti-SM antibodies are found in patients with SLE; anti-histone antibodies are found in patients with drug-induced lupus. (*See* Tables 3-2 and 3-3.)

Table 3-2. ANA Patterns

Peripheral (Rim)	SLE
Diffuse	Nonspecific
Speckled	Nonspecific
Centromere	CREST
Nucleolar	Systemic sclerosis

Table 3-3. Specific ANAs

Anti-ds-DNA (native DNA)	SLE only (60%); an indicator of disease activity and lupus nephritis
Anti-SM	SLE only (25–30%)
Anti-histone	Drug-induced lupus (95%)
Anti-Ro (SSA)	Neonatal lupus, Sjögren and in the 3% of ANA-negative lupus
Anti-LA (SSB)	Sjögren
Anti-centromere	CREST
Anti-RNP	100% mixed connective tissue disease (MCTD)

Clinical Correlate

Overall, >95% of SLE patients have positive ANA test results, which makes a negative ANA result a good rule-out test for SLE.

Interpret a positive ANA test in the context of the clinical symptoms, i.e., a positive ANA in an asymptomatic patient with no other abnormal tests is likely to be a false–positive (5% of the population); a positive ANA in a patient with arthritis, proteinuria, and pleural effusion is likely to be associated with SLE.

Rheumatoid Factor

Rheumatoid factor (RF) is an autoantibody against the Fc portion of IgG. Rheumatoid factors are found in approximately 70% of patients with RA. However, these antibodies are not specific for RA and are found in 5% of healthy adults (the prevalence increases with age, sometimes seen in up to 20% of people >65 years of age).

Therefore, RF is neither sensitive nor specific for the diagnosis of RA.

The presence of RF can be of prognostic significance, since patients with high titers tend to have more aggressive disease with extraarticular manifestations.

Antineutrophil Cytoplasmic Antibodies

Antineutrophil cytoplasmic antibodies (ANCAs) are antibodies directed against certain proteins in the cytoplasm of neutrophils. The cytoplasmic (c) ANCA refers to the diffuse staining pattern observed when serum antibodies bind to indicator neutrophils; it is seen in >90% of patients with Wegener granulomatosis. Perinuclear (p) ANCA refers to a localized staining pattern observed on the indicator neutrophils, the major target of these antibodies being the enzyme myeloperoxidase; it is found in PAN and Churg-Strauss but is a nonspecific test.

Antiphospholipid Antibody Syndrome

Antiphospholipid antibody syndrome (lupus anticoagulant or anticardiolipin antibodies) is a hypercoagulable state associated with a group of antibodies that are directed against phospholipids or cardiolipins. It is unclear whether the antibodies are directly involved in the etiology of the clotting disorder associated with this syndrome. The nature of these antibodies causes the common laboratory abnormalities associated with the syndrome, i.e., elevated partial thromboplastin time (PTT) and false-positive RPR or VDRL. Clinically, it presents with spontaneous abortions in otherwise healthy women or thromboembolism (pulmonary embolism, DVT) in other patients. Two first-trimester spontaneous abortions suggest antiphosolipid antibodies.

RHEUMATOID ARTHRITIS

A 26-year-old woman with no prior medical history presents with a 3-week history of joint swelling and stiffness. She informs you that she has had stiffness for about 2 h every morning since these symptoms started and that the symptoms improve as the day progresses. She denies back stiffness or back pain. She has fatigue and low-grade fever. On the examination the wrist, MCPs, and PIPs are red and swollen on both hands. The DIPs are not involved. There is fluid in the wrist joints. Otherwise the examination is normal.

Definition. RA is a chronic inflammatory multisystemic disease with the main target being the synovium. The hallmark of RA is inflammatory synovitis that presents in a symmetric distribution. The intense joint inflammation that occurs has the potential to destroy cartilage and cause bone erosions and eventually deform the joint.

Anti-CCP (cyclic citrullinated peptide) is also positive in RA and carries a very high specificity.

Etiology/Epidemiology. The cause of RA is unknown. RA may be triggered as a reaction to an infectious agent (mycoplasma, parvovirus) in a susceptible host.

Of the environmental factors, only cigarette smoking seems to be associated with RA. Women are affected 3× more than men, and in 80% of cases the age of onset is between 35 and 50 years.

Pathogenesis. An initiation phase of nonspecific inflammation occurs, followed by an amplification phase resulting from T-cell activation, and finally the stage of chronic inflammation and tissue injury.

The predominant infiltrating cell is the **T lymphocyte**. Diseases like human immunodeficiency virus (HIV), in which T cells are decreased, will characteristically improve preexisting RA; this is also the reason why **RA is very rare in patients with HIV**.

Recent studies have shown that excessive amounts of the pro-inflammatory cytokines—tumor necrosis factor alpha (TNF-a), interleukin-1, and interleukin-6 (IL-6)—mediate most of the pathogenic features of rheumatoid arthritis. This underscores the focus of new treatment modalities on inhibiting these cytokines (see TNF inhibitors on following pages).

Presentation. Diagnostic criteria—need 4 of the following diagnostic criteria.

- Morning stiffness (>1 h) for 6 weeks
- Swelling of wrists, MCPs, PIPs for 6 weeks
- Swelling of 3 joints for 6 weeks
- Symmetric joint swelling for 6 weeks
- RF positive or anti-cyclic citrullinated peptide
- CRP or ESR

X-ray abnormalities and nodules are not necessary for the diagnosis of RA.

Criteria. RA is a chronic inflammatory symmetric arthropathy. There needs to be involvement of multiple joints, but some joints are *never* involved in RA:

- DIPs
- Joints of the lower back

Because RA is a systemic disease, ~70% of patients present with constitutional symptoms—fatigue, anorexia, weight loss, generalized weakness—before the onset of the arthritis.

Extraarticular Manifestations

- Damage to the ligaments and tendons
  - Radial deviation of the wrist with ulnar deviation of the digits
  - Boutonnière deformity
  - Swan-neck deformity
- Rheumatoid nodules
  - Initial event caused by focal vasculitis
  - 20–30% of patients with RA; usually occur in areas of mechanical stress (olecranon, occiput, Achilles tendon)
  - Methotrexate may flare this process
- Felty syndrome (RA + splenomegaly + neutropenia)
- Caplan syndrome (RA + pneumoconiosis)

Laboratory Findings

- RF or anti-CCP
- Anemia
- ESR or C-reactive protein (CRP)
- X-rays
- Synovial fluid analysis

Diagnosis. The diagnosis is based on the use of clinical criteria; there is no single test or finding that will diagnose RA. Anti-CCP is more specific than RF.

Treatment. None of the nonsteroidal antiinflammatory drugs (NSAIDs) have been shown to be better than aspirin in RA, but they have fewer GI side effects.

There is no single NSAID superior to other agents, and the newer agents have not been shown to have a decreased incidence in toxicity (GI, renal, etc.).

Note

In 2010, a new set of criteria was proposed by the American College of Rheumatology and the European League against Rheumatism which focuses more on serologies, acute phase reactants, number of joints involved, and duration of joint involvement over 6 weeks. This leads to a point system.

For the moment, the 1987 criteria are not obsolete.

Cyclooxygenase 2 (COX-2) inhibitors are a type of NSAID which selectively blocks the COX-2 enzyme at the site of inflammation. The benefit of COX-2 inhibitors is that they do not inhibit COX-1, an enzyme that helps with the production of the protective stomach lining. The nonselective (traditional) types of NSAIDs block both COX-2 and COX-1, which can lead to increased risk for GI side effects (bleeding, etc.).

Because of the increased risk of MI, both rofecoxib and valdecoxib have been recalled; currently only celecoxib is available.

Other drugs in RA:

- Glucocorticoids (usually for short courses only)
- Disease-modifying agents: antimalarials, gold, sulfasalazine, methotrexate (MTX), and tumor necrosis factor (TNF) receptor inhibitors

Disease-Modifying Anti-Rheumatic Drugs

The best initial DMARD is methotrexate (MTX). If MTX does not control disease, an anti-TNF medication is added to treatment.

Table 3-4. Adverse Effects of DMARD

Drug	Profile/Side Effects	Screening Tests for Toxicity
Hydroxychloroquine	Retinopathy	Regular eye examination
MTX (methotrexate; most utilized agent and mainstay of treatment)	Rapid onset of action; hepatitis and hepatic fibrosis; pneumonitis; may flare rheumatoid nodules	CBC and liver enzymes every 4–8 weeks

Hydroxychloroquine and sulfasalazine are used in early, mild disease. Steroids are used briefly to control disease while waiting for methotrexate to work.

Biologic Agents. Tumor necrosis factor (TNF) inhibitors. Tumor necrosis factor alpha (TNF-α) is a pro-inflammatory cytokine produced by macrophages and lymphocytes. It is found in large quantities in the rheumatoid joint and is produced locally in the joint by synovial macrophages and lymphocytes infiltrating the joint synovium. TNF inhibitors relieve the signs and symptoms of RA, and slow or halt radiographic damage. These drugs have been shown to be effective in patients who were thought to be resistant to all methotrexate.

Latent assessment and treatment for TB is required before use of any of these agents.

Note

Screen for TB before using TNF inhibitors.

There are 3 TNF inhibitors approved for the treatment of RA:

- Infliximab (Remicade) is a monoclonal antibody to TNF-α that binds to TNF-α in the joint and in the circulation. The combination of infliximab and methotrexate is very effective in reducing clinical manifestations of disease. Infliximab is given as an IV infusion. Cases of sepsis, disseminated tuberculosis, and other opportunistic infections have been reported for patients treated with infliximab or other anti-TNF therapy.
- Adalimumab (Humira) is an anti-TNF mAb that differs from infliximab in that its sequences are entirely human.
- Etanercept (Enbrel) is a human fusion protein that is entirely human, and anti-etanercept antibodies are relatively uncommon.

Clinical Pearl

Consider atlantoaxial subluxation in patients with RA who complain of occipital headaches and upper extremity tingling and numbness.

Always rule out subclinical subluxation in patients with RA who are undergoing surgery and intubation electively.

Complications/Follow-Up. Aggressive disease is likely to occur with the following features: high titers of RF, diffuse rheumatoid nodules, early joint erosions, late age of onset, and certain subtypes of the HLA-DR4.

Atlantoaxial subluxation may occur in patients with RA when there is excessive movement at the junction between the atlas (C1) and axis (C2), due to either a bony or ligamentous abnormality. In RA, the incidence of cervical involvement has been reported to be 25–80% and results from pannus formation at the synovial joints between C1 and C2. Neurologic symptoms occur when the spinal cord is involved (paraplegia, quadriplegia). Commonly, patients have subtle symptoms, which include neck pain (occipital), C2 radicular pain (paresthesias of the hands and feet), and myelopathy.

Consider this diagnosis in patients who have RA and neck pain, paresthesias, etc. The first test to do when considering the diagnosis is an x-ray of the cervical spine (order multiple views of the cervical spine, including an open-mouth view). You may further investigate with a CT scan or an MRI. Refer always to a spine surgeon (orthopedic specialist or neurosurgeon) if the radiologic testing is positive. All patients with RA should be screened with a plain x-ray for C1–C2 subluxation before intubation or anesthesia is performed.

If a patient with RA presents with a swollen painful calf, consider a ruptured Baker cyst. Baker cyst is the extension of inflamed synovium into the popliteal space.

SYSTEMIC LUPUS ERYTHEMATOSUS

> A 35-year-old woman is brought for the evaluation of confusion lasting 1 day. Her friends and family inform you that "she did not know how to come home from work" and that lately "she has not been herself." You find that the patient has elevated blood pressure, decreased air entry on the right lung base with dullness to percussion, and symmetrical joint swelling of the wrists and MCPs. A chemistry profile shows an elevated creatinine of 2.4 mg/dL, and there is protein in the urine on the urinalysis.

Definition. SLE is a systemic disease in which tissues and multiple organs are damaged by pathogenic autoantibodies and immune complexes.

Etiology/Pathogenesis. SLE is of unknown etiology.

- Ninety percent of cases are women.
- The abnormal immune response probably depends on interactions between a susceptible host and environmental factors.

Ultraviolet (UV)-B light is the only environmental factor known to cause flares.

Presentation. Diagnostic criteria—need 4 to diagnose.

- Malar rash
- Discoid rash
- Photosensitivity
- Oral ulcers

- Arthritis
- Serositis (pleuritis or pericarditis)
- Renal involvement
- Neurologic disorder (seizures or psychosis)
- Hematologic disorder (hemolytic anemia, leukopenia, thrombocytopenia)
- Immunologic disorder (anti-ds DNA, anti-SM, and other ANAs)

Summary of Criteria

- Arthritis is identical to that of RA except that it is non-erosive.
- Both the malar rash and photosensitivity rash (diffuse, maculopapular) flare with exposure to UV-B light (thus are considered photosensitive) and resolve with no scarring of the skin. The discoid lupus (DLE) is a circular rash with a raised rim that occurs over the scalp and face; it can be disfiguring because of central atrophy and scarring. Only 5% of patients with DLE will go on to develop SLE.
- All patients with renal involvement must undergo renal biopsy before treatment is initiated.
- Change of personality and psychosis may be manifestations of CNS lupus. Seizures, paralysis, and aphasia may follow.
- Libman-Sacks endocarditis is a noninfectious endocarditis that is occasionally seen in lupus patients.

Diagnosis

- A positive ANA supports the diagnosis but is not specific for SLE.
- Complement levels (C3, C4) are_____in patients with active lupus.
- Elevated levels of ds-DNA antibodies are seen with active lupus.

Treatment. Since there is no cure for SLE, treatment is aimed at controlling symptoms. NSAIDs are used to treat arthritis and pleurisy. Corticosteroid creams are used to treat skin rashes. Antimalaria drugs (hydroxychloroquine) and oral corticosteroids may also be used for skin and arthritic symptoms. Cytotoxic drugs (azathioprine, cyclophosphamide) are used with severe symptoms (lupus nephritis, heart and lung involvement, hemolytic anemia, central nervous system involvement, etc.), along with corticosteroids. Mycophenolate is often used to treat lupus nephritis.

All patients should be advised to wear protective clothing, sunglasses, and sunscreen when in the sun. Belimumab is an inhibitor of B-cell activation. Belimumab is an IgG monoclonal antibody given intravenously to prevent B-cell activation.

Prognosis. The prognosis of patients with SLE has improved significantly in recent years with a 10-year survival rate >85%. People with severe involvement of the CNS, kidney, heart, and lungs have a worse prognosis in terms of overall survival and disability. Lupus nephritis is probably the most common cause overall of disability in patients with SLE.

Pregnancy and SLE

- Fertility rates are normal in patients with SLE, but spontaneous abortions and still-births are more common when compared with normal patients.
- One reason for the spontaneous abortions in these patients may be anti-phospholipid antibodies, which cause placental infarcts. This is treated with low-molecular weight heparin (LMWH) during pregnancy.

- It is unclear whether lupus worsens with pregnancy. In the case of a lupus flare during pregnancy, steroids may be used safely to suppress the disease.
- All pregnant patients with lupus need to be screened for SSA/anti-Ro antibodies. These antibodies cross the placenta and are passively transferred to the fetus, causing neonatal lupus and heart block.

DRUG-INDUCED LUPUS

Drug-induced lupus erythematosus is a side effect of use of certain medications. There are over 40 drugs that are implicated to cause drug-induced lupus, but the drugs most commonly associated are: hydralazine, isoniazid, procainamide, and quinidine. The most common symptoms are: arthritis, fatigue, fever, and rarely pleurisy. Acute onset SLE is usually not confused with drug-induced lupus, due to the lack of skin disease, kidney disease, and the milder symptoms seen in the latter. Also, photosensitivity, hair loss, and central nervous system disease are uncommon in drug-induced lupus.

Answer to question on previous page

decreased

Patients with drug-induced lupus develop ANAs, although those with drug-induced lupus related to quinidine often are ANA-negative. The ANAs in drug-induced lupus are autoantibodies that react with a histone-DNA complex, which is the major component of the nucleus (anti-histone antibodies).

Anti-histone antibody testing is a sensitive marker for the diagnosis of drug-induced lupus. Hydralazine is the exception, as only about one-third of patients will have positive anti-histone antibodies.

Once the suspected medication is stopped, symptoms resolve within one to two weeks. This confirms the diagnosis of drug-induced lupus with certainty.

SCLERODERMA

A 36-year-old woman comes to you because of skin tightness and painful fingertips with exposure to cold for >1 year. The physical examination discloses a BP of 165/100 and diffuse shiny, thickened skin. The examination is otherwise normal. The laboratory tests reveal an elevated serum creatinine.

Definition. Systemic sclerosis (SSc) is a chronic multisystem disease characterized clinically by thickening of the skin caused by accumulation of connective tissue and by involvement of visceral organs (GI, lungs, kidneys).

Presentation. All patients have Raynaud phenomenon and skin thickening. The Raynaud phenomenon occurs because of vascular damage and diminished blood flow to the extremities.

GI features include esophageal dysmotility, hypomotility of the small intestine with bacterial overgrowth and malabsorption, and dilatation of the large intestine with formation of large diverticula.

Pulmonary features include pulmonary fibrosis with restrictive lung disease and cor pulmonale. Pulmonary involvement is now the leading cause of death in SSc.

Renal features include the scleroderma renal crisis in which malignant hypertension develops and causes acute renal failure. This was the most common cause of death but now is easily treated with angiotensin-converting enzyme (ACE) inhibitors.

The term "scleroderma renal crisis" has been used to characterize the renal involvement in scleroderma, in which malignant hypertension occurs over days to weeks and is associated with acute renal failure (rapid rise in creatinine and proteinuria). The ACE inhibitors (enalapril, lisinopril, etc.) have been effective in reducing the devastating consequences of renal crisis in patients where treatment is initiated before the onset of renal failure.

Figure 3-1. Shiny Skin of Scleroderma

CREST syndrome, a variant of scleroderma, is now called limited scleroderma or limited cutaneous systemic sclerosis. The acronym CREST represents the hallmarks of the disease: **C**alcinosis, **R**aynaud, **E**sophageal dysfunction, Sclerodactyly, and Telangiectasias. Calcinosis is a condition in which calcium deposits occur in soft tissues usually in the fingers (especially proximal inter-phalangeal joints), knees, and elbows. These deposits occur near the skin surface and may ulcerate and become infected. Sclerodactyly refers to skin thickening, primarily affecting the fingers and toes.

Note

Remember, CREST is now called limited scleroderma.

Patients with limited scleroderma generally have skin involvement that does not extend above the elbow or above the knee. Rarely in some patients, the face may be affected. Limited disease generally progresses slowly compared to the diffuse cutaneous form of scleroderma, which is more likely to affect internal organs, although pulmonary arterial hypertension may occur in 25–50% of persons with limited scleroderma. Interstitial lung disease may occur in 10% of this population.

In patients with limited scleroderma, the ANA test is positive, showing a pattern of anticentromere antibodies in up to 90% of patients. Antibodies to Scl-70 are usually negative in limited scleroderma and positive in diffuse scleroderma.

Raynaud phenomenon is defined as episodes of pallor or cyanosis in response to cold or emotional stimuli. The pallor is caused by vasoconstriction of blood vessels (arteries and arterioles) that results in reduced blood flow, while cyanosis is created by deoxygenation of slow-flowing blood. After rewarming the hands, the blood flow will rebound (hyperemia) and the skin will appear reddened or blushed.

It is common for patients with Raynaud phenomenon to complain of cold sensitivity and to have other areas of the skin involved, including the ears, nose, and lower extremities. Episodes come as sudden attacks and are most often triggered by rapid changes in ambient temperature. Attacks may begin in one or two fingers but typically involve all fingers and/or toes symmetrically and bilaterally.

Primary Raynaud phenomenon (Raynaud disease) denotes a patient without an associated underlying disease. Secondary Raynaud phenomenon is used to describe patients with a defined secondary or associated disease (e.g., scleroderma). One test that allows the differentiation between primary and secondary Raynaud is the nailfold capillaroscopy test (done by placing a drop of oil on the patient's nailfold at the base of the fingernail). Examination of this area under a microscope is then conducted to look for any capillary changes. Enlarged, dilated, or absent nailfold capillaries are noted among patients with scleroderma and other autoimmune diseases.

About 5% of the general population has symptoms and signs consistent with Raynaud phenomenon. It is more common among young women, about 30% have a first-degree relative with Raynaud, and most have primary Raynaud phenomenon without any defined cause or associated systemic disease.

Treatment. There is no cure for SSc. For the skin manifestations, D-penicillamine may be used. For severe Raynaud phenomenon, use calcium-channel blockers, specifically nifedipine; for hypertension, angiotensin-converting enzyme inhibitors are the drugs of choice.

SJÖGREN SYNDROME

> A 42-year-old woman presents to your office with some peculiar symptoms lasting 1 year. She feels there is constantly something in her eyes–like dust or sand–and that dry and solid foods are painful to swallow. You are perplexed by her complaints but decide to examine her and find that she has bilateral parotid enlargement The exam is otherwise unremarkable. An ANA test is positive. What specific ANAs would you expect to be positive in this patient?

Definition. Sjögren syndrome is a chronic autoimmune disease characterized by lymphocytic infiltration of the exocrine glands, resulting in xerostomia and dry eyes. Sjögren may be seen alone (primary) or with other autoimmune diseases (secondary) such as RA, primary biliary cirrhosis, or SLE.

As Sjögren syndrome progresses, it becomes a systemic disease involving major organs (lungs, kidneys, etc.) and may eventually evolve into a lymphoproliferative disease—malignant lymphoma.

Presentation. Patients complain of itchy eyes, sandy feeling under their eyes (because of decreased lacrimal production and destruction of the corneal epithelium—keratoconjunctivitis sicca), and difficulty swallowing food.

Also look for increase in dental caries and parotid enlargement.

Diagnostic Tests. Schirmer's test will show decreased tear production, and the rose Bengal stain will document corneal ulcerations. ANAs will be positive and specifically anti-Ro (SSA) and anti-La (SSB).

Lymphocytic infiltration of the salivary glands will be noted on the biopsy.

Treatment. There is no cure for this disease. Symptomatic treatment includes artificial tears.

Pilocarpine and cevimeline increase acetylcholine and increase tear and saliva production.

All of the diseases we just reviewed have an arthritis that is symmetric and polyarticular. RA is a disease that involves mostly the joints; the others—SLE, SSc, and Sjögren syndrome—usually have arthritis plus multiple organ involvement.

For the rheum wizards: There are a few other diseases that may cause symmetrical polyarthropathy—know Parvovirus B19 and hepatitis B.

SERONEGATIVE ARTHROPATHIES, SPONDYLOARTHROPATHIES

A 27-year-old man presents with complaints of severe lower back stiffness and pain that have been bothering him for the past 5 years. The stiffness is most apparent in the morning when he wakes up, lasting sometimes >2 h. The only thing improving these problems is exercise. On examination he has a 2/6 murmur over the second right intercostal space and decreased range-of-motion of the lumbar spine.

Definition. The spondyloarthropathies are a group of disorders that share certain clinical features and an association with the B-27 allele. The similarities among these diseases suggest that these disorders share pathogenic mechanisms.

There are 4 diseases that have 4 similar clinical and laboratory characteristics:

Table 3-5. Seronegative Arthropathies

Diseases	Characteristics
Ankylosing spondylitis Reactive arthritis Psoriatic arthritis Enteropathic arthropathy	• Seronegative (ANA negative, RF negative) • Involve lower back and sacroiliac joints • HLA-B27 • Extraarticular manifestations

All of the above diseases have most of the 4 characteristics plus a few others that are disease-specific.

Ankylosing Spondylitis

Definition. Ankylosing spondylitis (AS) is an inflammatory disorder of unknown etiology that affects primarily the axial skeleton and peripheral joints. AS usually starts by the second to third decade (very rare age >40).

Prevalence in men is 3–4 times that of women—this is one of the few collagen vascular diseases that affects men more than women. 90% of patients are positive for HLA B-27.

Presentation. AS will usually present with **chronic lower back pain** in a young man (in his late twenties to early thirties). The giveaway is the **morning stiffness** lasting at least **1 h** that **improves with exercise**.

The cervical spine is rarely if ever affected and only late in the disease.

Extraarticular manifestations are common in AS: anterior uveitis, aortic insufficiency sometimes leading to CHF and third-degree heart block.

On examination there will be evidence of decreased spine mobility: positive Schober test (measures spine flexion) and sometimes obliteration of the lumbar lordosis. Because of this, spine fractures are sometimes seen in patients with AS after minimal trauma (know that spine fractures occur with insignificant stress in older people with osteoporosis and young people with long-standing inflammatory disease of the spine, e.g., AS).

X-rays show evidence of sacroiliitis (this is the earliest finding) and eventual fusing of the sacroiliac joint. Chronic spine inflammation will eventually cause the bamboo spine and squaring of the vertebral bodies.

SIU BIOMED COMM 2007—Custom Medical Stock Photo.

Figure 3-2. X-ray of Pelvis in AS Demonstrating Sacroiliitis

Diagnosis. The diagnosis of AS is based on clinical and x-ray findings. The HLA-B27 is not commonly used as a diagnostic test.

Treatment. NSAIDs, physical therapy, and exercise. The most promising medications used in the treatment of AS and other spondyloarthropathies are the TNF blockers (infliximab, adalimumab, etanercept). These biologic agents are recommended for axial disease.

Unlike RA, anti-TNF medications are used first and methotrexate used later. Anti-TNF drugs work better for axial disease.

Reactive Arthritis

Reactive arthritis (ReA) is a seronegative arthropathy that occurs as a complication from an infection somewhere in the body. There are 2 types of infection causing 2 different syndromes.

- One (Reiter syndrome) occurs after a nongonococcal urethritis (chlamydia, ureaplasma). These patients have distinct mucocutaneous manifestations: keratoderma blennorrhagica, circinate balanitis, oral or genital ulcers, conjunctivitis, and arthritis.
- The other ReA occurs after an infectious diarrhea caused by *Campylobacter*, *Shigella*, or *Salmonella* organisms (think of the organisms that cause enteroinvasive diarrheas; these are the same ones that cause ReA). The most common is *Campylobacter*.

Diagnosis is based on clinical criteria. X-ray findings will be consistent with a seronegative spondyloarthropathy.

Treatment. Treatment is the same as for AS. There are studies that support an accelerated recovery of Reiter syndrome caused by a chlamydial infection from prolonged tetracycline use (~3 weeks' duration). There are also studies to support the notion that prompt antibiotic use in urethritis will decrease the chance of Reiter syndrome (this is the only exception to the rule that the seronegative arthropathies are untreatable diseases).

A severe form of Reiter syndrome and reactive arthritis has been described in HIV patients. The skin manifestations are particularly aggressive in these patients and improve with antiretroviral medications.

phil.cdc.gov.

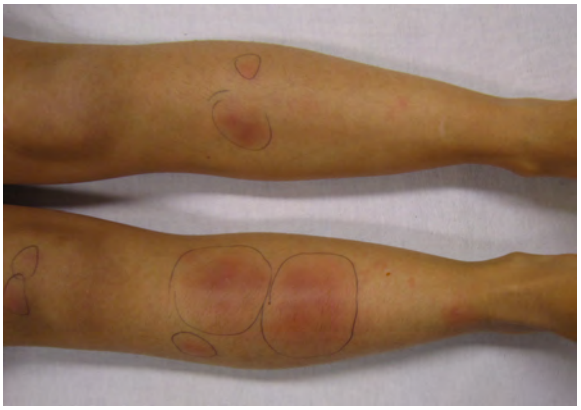
Figure 3-3. Keratoderma Blenorrhagica Sometimes Seen with Reiter Syndrome

Psoriatic Arthritis

Commonly involves the DIP joints when associated with psoriatic nail disease (pitting of the nails); this involvement may sometimes cause the characteristic sausage-shaped digit. Here, the peripheral arthritis is deforming.

Enteropathic Arthropathy

Occurs with ulcerative colitis and Crohn's disease; sometimes the arthritis occurs with flares of the inflammatory bowel disease. Patients sometimes develop characteristic skin lesions: pyoderma gangrenosum and erythema nodosum.



Wikipedia, James Heilman, MD

Figure 3-4. Erythema Nodosum, Characteristic of Some Rheumatic Disorders

OSTEOARTHRITIS

A 64-year-old man comes to you for the evaluation of knee pain. He tells you that he has had right knee pain for many years but recently it has gotten worse. He denies constitutional symptoms and other joint pain except for his left second and third DIPs. He has not noticed stiffness in the morning. On examination you hear crepitations as you move his right knee, but otherwise there is no evidence of swelling, warmth, or erythema of the knee. Laboratory testing is unremarkable.

Definition. Osteoarthritis (OA) is the most common joint disease in humans. The target tissue in OA is articular cartilage. There is destruction of cartilage along with secondary remodeling and hypertrophy of the bone. OA, unlike RA, is not an inflammatory disease.

Knee OA is the leading cause of chronic disability in the elderly.

Major risk factors for OA include age, female sex, genetic factors, major joint trauma, repetitive stress, and obesity (the last 3 factors are potentially modifiable).

The classification involves stratification of OA into idiopathic—the most common form and where no predisposing factor is evident—and secondary, which is attributable to an underlying cause, e.g., other arthropathies (gout), endocrine diseases (diabetes mellitus, acromegaly), deposition diseases (hemochromatosis), and mechanical factors (valgus or varus deformity, unequal lower extremity length). (Remember that any disease that will cause stress or trauma to a joint may eventually cause secondary OA.) Secondary OA is pathologically indistinguishable from idiopathic OA.

The most common joint to be affected is the knee; the second most common joint affected is the base of the thumb.

Presentation. The major joints involved in OA are the weight-bearing joints (hip and knee) and the small joints of the fingers (PIPs and DIPs). These joints are affected in an oligoarticular-asymmetric or monoarticular pattern. The joint involvement is very slow, progressive, and irreversible. Because the cartilage fails and there is increased pressure on articular bone, joint pain increases with exercise and is relieved by rest. Morning stiffness is always <20–30 min. Crepitations may be noted with movement of the joint. There are no systemic manifestations in OA.

Laboratory Tests. These are always normal, especially indices of inflammation. Thus, ESR and C-reactive protein are always normal in OA. (Remember, if ESR is elevated, some other process is complicating OA, e.g., septic joint, or it's not OA.) X-ray findings include osteophytes and unequal joint space. Osteophytes (spurs) are the reparative efforts by the bone; when these occur in the PIPs they are called Bouchard's nodes, whereas similar changes occurring in the DIPs are called Heberden's nodes.

Diagnosis. Made on clinical and x-ray findings.

Treatment. Aimed at reducing pain and maintaining mobility, since there is no cure for OA.

Nonpharmacologic Measures. Reduction of joint loading can be achieved by correction of poor posture and weight loss. Physical therapy and exercise programs should be designed to maintain range of motion, strengthen periarticular muscles, and improve physical fitness.

Drug Therapy. Therapy is palliative because no agent has been shown to change the natural course of the disease. Although limited studies have claimed a chondroprotective effect of certain NSAIDs, well-done studies have not documented such an effect. NSAIDs should only be used to alleviate pain.

In double-blinded placebo trials, there was no difference in relief of joint pain among acetaminophen (4,000 mg/d), analgesic doses of ibuprofen (1,200 mg/d), and antiinflammatory doses of ibuprofen (2,400 mg/d). Although the first drug to use for pain in OA is acetaminophen, it is reasonable to add on analgesic doses of NSAIDs if there is no relief. Cautious dosing should be prescribed in elderly patients because they are at highest risk for the side effects associated with NSAIDs, especially GI (ulcers, hemorrhage, etc.). COX-2 inhibitors may be used in patients who are at high risk for GI complications (only available agent is celecoxib).

Another modality that has been shown to benefit patients with OA is the use of capsaicin cream, which depletes local sensory nerve endings of substance P. Some patients do feel local burning.

Orthopedic surgery and joint arthroplasty are reserved for cases in which aggressive medical treatment has been unsatisfactory, especially if the patient's quality of life has been decreased.

Note

There are rare cases of erosive OA, polyarticular OA, and OA with inflammatory features. These are exceptions, and you do *not* need to know them.

Intraarticular injection of hyaluronic acid has been approved for treatment of knee OA that hasn't responded to pharmacologic treatment. Despite this, the efficacy of hyaluronic acid has been questioned since a large clinical trial failed to demonstrate superiority over intraarticular injections of saline. Similarly glucosamine and chondroitin sulfate are not routinely used in the treatment of OA since in 4 recent randomized, double blind trials both of these agents were no more effective than placebo.

Also, clinical trial results based on analysis of x-rays suggested the possibility of glucosamine being chondroprotective. Since the radiologic methods employed in the trial were limited, there was concern about the interpretation of such data. A current multicenter trial sponsored by the National Institutes of Health is under way in order to address this question.

CRYSTAL-INDUCED ARTHROPATHIES

Definition. The crystal-induced arthropathies, monosodium urate (MSU), calcium pyrophosphate (CPPD), calcium oxalate (CaOx), and calcium hydroxyapatite (HA), are caused by microcrystal deposition in joints. In spite of differences in crystal morphology, they have identical clinical presentations and can only be distinguished by synovial fluid analysis.

Gout

Gout is a disease that affects middle-aged men and presents most commonly with acute monoarthritis (women represent only about 5–15% of all patients with gout; premenopausal women make up 17% of all women with gout). As gout becomes chronic, multiple joints may be involved, and deposition of urate crystals in connective tissue (tophi) and kidneys may occur.

The metatarsophalangeal joint of the first toe is commonly affected (podagra), but other joints like the knee, ankle, PIPs, or DIPs may be initially involved. The first episode commonly occurs at night with severe joint pain waking the patient from sleep. The joint rapidly becomes warm, red, and tender (it looks exactly like cellulitis). Without treatment the joint pain goes away spontaneously within 3–14 days.

Certain events that precipitate gout sometimes precede the attack: excessive alcohol ingestion, red meat intake, trauma, surgery, infection, steroid withdrawal, drugs (diuretics, such as HCTZ [hydrochlorothiazide] and furosemide; anti-TB medicines, such as pyrazinamide and ethambutol), and serious medical illnesses.

MSU deposition causes an intense inflammatory process—red, warm joint. Thus, on an x-ray of a joint that has been involved in multiple gouty attacks you would expect to find _____.

Diagnosis. The serum uric acid during the acute attack may be normal or low. On the other hand, many people have elevated serum uric acid levels and never develop gout. Thus, the serum uric acid level is of no value in the diagnosis of acute urate arthropathy. This is why the diagnosis is made by the analysis of synovial fluid.

On synovial fluid analysis, the MSU crystals are_____ birefringent and_____ shaped. The number of WBCs should be between_____.

Treatment

Acute gouty arthritis: The goal is to decrease inflammation and thus prevent erosions and joint destruction; also in this stage it is very important to avoid any fluctuations in serum uric acid levels.

- NSAIDs
- Steroids, oral, rarely intraarticular, in elderly patients who cannot tolerate NSAIDs or colchicine or in patients with renal impairment
- Colchicine is rarely to be used in acute gout but is still available.

Chronic hypouricemic therapy: The goal here is to decrease uric acid levels. This is usually required for life and initiated in patients who have had recurrent gouty attacks that cannot be corrected by low-purine diet, limitation of alcohol, avoiding diuretics, etc. Unlike acute gout, here the uric acid level may be helpful in following the effect of hypouricemic treatment.

- Allopurinol can be used in overproducers, undersecretors, or patients with renal failure or kidney stones
- Febuxostat is used in those intolerant of allopurinol.
- Pegloticase dissolves uric acid: used in refractory disease
- Probenecid can be used in the undersecretors (>80% of adults) only. Rarely used today.

A 32-year-old man comes with a history of right ankle swelling that occurred the night before. He has noticed that his ankle has been red, warm, and very painful. He occasionally drinks alcohol. On examination you find a red swollen ankle with evidence of an effusion. The range of motion is restricted.

What is the first step in this patient? *Aspiration*

What do we do after confirming the diagnosis? *Treat with NSAIDs*

Six months after the first episode he comes back to your office with left knee swelling. A red, warm knee is noted on examination.

What is the first step now? *Aspiration again*

What do you do after confirming the diagnosis? *NSAIDs*

On a routine visit the same patient has had 4 documented episodes of gout despite limiting alcohol and diet.

What would be the appropriate next step here? *Consider allopurinol or probenecid*

You have decided to place him on allopurinol. He does very well for more than 2 years with no gouty attacks. He then experiences another episode of right ankle swelling.

Note

Allopurinol should not be initiated during an acute crisis. However, if a patient has been taking allopurinol and an acute attack occurs, it should not be discontinued.

Clinical Pearl

Use primarily allopurinol in the chronic treatment of gout.

erosive calcifications

negative; needle; 5,000 and 50,000

Clinical Pearl

Always investigate patients with pseudogout for systemic disease, especially hemochromatosis.

Pseudogout

Definition and Pathogenesis. CPPD crystal deposition is more common in the elderly population and in people who have preexisting joint damage.

A small percentage of the patients have metabolic abnormalities that are associated with CPPD deposition (secondary). Remember the 4 Hs: hyperparathyroidism, hemochromatosis, hypophosphatemia, hypomagnesemia. The presence of pseudogout in a patient <50 years of age should raise suspicions about one of these metabolic abnormalities.

Clinical Manifestations. Pseudogout may have an acute presentation like gout. It may also present in an asymptomatic and chronic form. The knee is the most commonly affected joint; other joints commonly affected are the wrist, shoulder, and ankle.

Diagnosis. Definitive diagnosis requires the typical rectangular, rhomboid, positive birefringent crystals on synovial fluid evaluation.

Radiographs may reveal linear radiodense deposits in joint menisci or articular cartilage (chondrocalcinosis). (Do not forget to look at an x-ray of chondrocalcinosis before going to the exam.)

Treatment. The treatment is the same as gout. Prevention of frequent recurrences may be treated with low doses of colchicine.

SEPTIC ARTHRITIS

> A 67-year-old woman with history of RA for many years presents with right shoulder pain and swelling for 2 days. She has low-grade fever. The examination reveals decreased passive and active range of motion of the right shoulder joint, as well as erythema. She asks you if this is related to an RA flare and if she should start steroids to decrease the pain.

What is the next step? *Do an arthrocentesis*

The most common cause of infectious arthritis is gonorrhea, and gonococcal arthritis accounts for 70% of episodes in patients age <40. Women are at greater risk during menses and pregnancy and are 2–3 times more likely than men to develop disseminated arthritis.

In older patients, *Staphylococcus aureus* is a common cause of infectious arthritis and occurs in patients with preexisting joint destruction from other rheumatic diseases. Patients with RA have the highest risk because of chronic inflamed or destroyed joints, steroid therapy, and frequent skin breakdown over deformed joints.

Acute bacterial infection may cause rapid cartilage destruction, and thus a patient presenting with monoarticular arthritis needs prompt diagnosis. This is done by arthrocentesis. Further, *Staph* or *Strep* must be cleaned out of the joint space by arthocentesis or arthroscopy.

Remember that most infected joints with gonococcal will not have positive cultures, and the Gram stain will be negative.

Treatment. Treatment should focus on the likely etiology. For example, a 30-year-old woman with acute monoarticular arthritis who is found to have >50,000 WBCs in the synovial fluid

without crystals should be treated with ceftriaxone. A 72-year-old man with RA with the same findings should be treated with nafcillin or vancomycin.

This disease is discussed further in the Infectious Diseases chapter.

VASCULITIS SYNDROMES

Definition. Vasculitis is an inflammatory process involving the blood vessels that results in decrease of the lumen diameter and eventual ischemia of the tissues supplied.

The vasculitis syndromes are stratified according to the types of vessels involved.

Wegener Granulomatosis

Wegener granulomatosis is a small vessel vasculitis that can involve any organ system but mainly affects the respiratory tract (sinuses, nose, trachea, and lungs) and kidneys.

The most common sign of Wegener granulomatosis is involvement of the upper respiratory tract, which occurs in nearly all patients. Symptoms include rhinitis, sinusitis, and, rarely, nasal ulcers. A common sign of the disease is chronic rhinitis that does not respond to usual treatment and that becomes increasingly worse.

The lungs are affected in most people despite lack of symptoms. If symptoms are present, they include cough, hemoptysis, and dyspnea. Kidney involvement occurs in >80% of people with this disorder and is a major cause of morbidity and mortality. Arthritis occurs in about 60% of the cases.

Patients with Wegener granulomatosis usually have the presence of antineutrophil cytoplasmic antibodies (C-ANCA). Although a positive ANCA test is useful to support a suspected diagnosis of Wegener granulomatosis, it is never diagnostic. Also, the C-ANCA test may be negative in some people with active Wegener. The only way to confirm the diagnosis is by performing a biopsy of an involved organ (usually the nasal septum), which demonstrates the presence of vasculitis and granulomas.

The standard treatment consists of a combination of a glucocorticoid and an immunosuppressive agent (cyclophosphamide). In a study of 158 patients who were treated with prednisone and cyclophosphamide at the National Institutes of Health (NIH), 90% markedly improved; after years of follow-up, 80% of the patients survived.

Polyarteritis Nodosa (PAN)

PAN is a multisystem disease that may present with nonspecific complaints such as fever, malaise, weight loss, anorexia, and abdominal pain. The disease can affect nearly any site in the body, except the lungs. It has a predisposition for organs such as the skin, kidney, nerves, and GI tract. Peripheral neuropathies are very common (70%). This includes tingling, numbness, and/or pain in the hands, arms, feet, and legs, and mononeuritis (e.g., foot drop). GI manifestations are also common, such as abdominal pain and GI bleeding (occasionally is mistaken for inflammatory bowel disease). A minority of patients with PAN have an active hepatitis B infection.

Clinical Pearl

In patients with PAN, exclude co-existing chronic active viral hepatitis.

The diagnosis is made by biopsy of involved organs, taken more commonly from skin, symptomatic nerves, or muscles. The diagnosis is confirmed by a biopsy showing pathologic changes in medium-size arteries. An angiogram of the abdominal vessels may also be very

helpful in diagnosing PAN since aneurysms affecting the arteries of the kidneys and/or GI tract are found.

Before the availability of effective therapy, untreated PAN was usually fatal within weeks to months. Most deaths occurred as a result of kidney failure, or heart or GI complications. Effective treatment is now available for PAN and consists of high doses of corticosteroids, along with immunosuppressive drugs (cyclophosphamide).

Churg-Strauss Syndrome

This syndrome shares many of the clinical and pathologic features of PAN and can involve any organ. The cardinal manifestations of Churg-Strauss syndrome are asthma, eosinophilia, and lung involvement (for the sake of remembering this syndrome, you may consider this Churg-Strauss as PAN in an asthmatic patient). The typical patient with Churg-Strauss is a middle-aged individual with new-onset asthma. Asthma symptoms may begin long before the onset of vasculitis. Other symptoms include: mononeuropathy (mononeuritis multiplex similar to PAN), transient pulmonary infiltrates on chest x-rays, paranasal sinus abnormalities, nasal polyps, and allergic rhinitis.

Diagnosis is made by biopsy and treatment is similar to PAN (combination of prednisone and cytotoxic agent).

PAN and Churg-Strauss syndrome both involve the small- and medium-sized arteries.

Temporal Arteritis (TA)

TA, also known as giant cell arteritis, is a vasculitis affecting the large arteries that supply the head, eyes, and optic nerves. New-onset headache in any patient age >50 prompts consideration of this diagnosis, which if left untreated may result in permanent vision loss.

The most common symptoms of giant cell arteritis are headache and pain that usually occurs in one or both temples. Other common symptoms include scalp tenderness (pain when combing hair), jaw claudication (jaw pain when chewing), decreased vision or blurry vision, tongue numbness, or, rarely, sudden loss of vision. Sometimes the patient may have proximal stiffness (neck, arms, hips) due to polymyalgia rheumatica, a coexisting condition with TA. Over 25% of patients with TA also have polymyalgia rheumatica.

Clinical Pearl

Always consider TA in patients with new-onset headache who are age >50–60.

The erythrocyte sedimentation test (ESR) is the first test to do in patients suspected to have TA. Since the ESR is always increased in TA, all patients will have an elevated ESR (100% sensitive). The diagnosis is always confirmed by biopsy of the temporal arteries in which the characteristic giant cells are demonstrated. In the patient whom you suspect to have TA, if the ESR is elevated, corticosteroids should be started immediately, before the temporal artery biopsy is performed. Do not withhold treatment waiting for the biopsy to be done.

> A 72-year-old woman comes to you because she has been bothered by a right-sided headache for the past 4 weeks. She has never had migraine headaches and denies blurry vision, nausea, or vomiting. The headache does not get worse any specific time of the day. She has noticed a feverish feeling and hip stiffness along with the headache.

What is the first step? *Do an ESR; if elevated, start prednisone*

INFLAMMATORY MYOPATHIES

A 42-year-old woman is admitted to your service with severe proximal weakness for 2 months. Her examination shows a diffuse lilac rash over the sun-exposed areas. The motor strength is 3/5 in the upper and lower proximal muscle groups.

Definition. The inflammatory myopathies are inflammatory muscle diseases that present with progressive muscle weakness. They include polymyositis, dermatomyositis, and inclusion body myositis.

Clinical Findings. Patients report difficulty with tasks that involve the proximal muscles: lifting objects, combing hair, getting up from the chair, etc. Fine-motor tasks that involve the distal muscles, e.g., writing, are only affected late in the disease. Ocular muscles are never involved; this feature differentiates the inflammatory myopathies from myasthenia gravis and Eaton-Lambert syndrome.

Dermatomyositis will also have skin involvement; the heliotrope rash is a purple-lilac discoloration of the face, eyelids, and sun-exposed areas of the body. Gottron's papules are the scaly lesions seen sometimes over the knuckles.

Laboratory Findings. The inflammatory destruction of muscles causes an elevation of the muscle enzymes (sometimes up to 50-fold), creatine phosphokinase (CPK), and aldolase. These are the most sensitive tests to perform in patients suspected of inflammatory myopathies.

Autoantibodies (anti-Jo-1) occur in patients with inflammatory myopathies, which supports the possible autoimmune origin of these diseases.

Diagnosis. Electromyography shows evidence of myopathic potentials characterized by short-duration, low-amplitude units. Diagnosis is confirmed by muscle biopsy.

Treatment. Steroids are useful in polymyositis and dermatomyositis. Inclusion body myositis is resistant to immunosuppressive therapy.

Gastroenterology 4

Learning Objectives

- ❑ List diseases that should be considered for presenting complaints of epigastric pain, diarrhea, or constipation
- ❑ Describe the presentation and management of a patient with GI bleed
- ❑ Describe the epidemiology and management of diseases of the esophagus, liver, pancreas, and colon including cirrhosis, acute pancreatitis, and colon cancer
- ❑ Describe the types of malabsorption syndrome, their causes, and treatment
- ❑ Differentiate diverticular disease and different forms of IBD in terms of their presentation and treatment

DISEASES OF THE ESOPHAGUS

The majority of diseases of the esophagus result in dysphagia. Dysphagia refers specifically to difficulty swallowing. Only a few of the diseases of the esophagus result in pain on swallowing, called odynophagia. Both dysphagia and odynophagia will result in weight loss if the symptoms persist for more than a few days. The mere presence of dysphagia or odynophagia is not sufficient to help one establish a diagnosis. The basic questions are, What additional information has to be added to this presentation to sufficiently answer the question, and, Which of the following is the most likely diagnosis?

In general, a barium swallow or barium esophagram is a good answer to questions asking for the best initial test. This is not an absolute answer, however, and if there are clear signs of obstruction, then the answer could also be upper endoscopy as the best initial test.

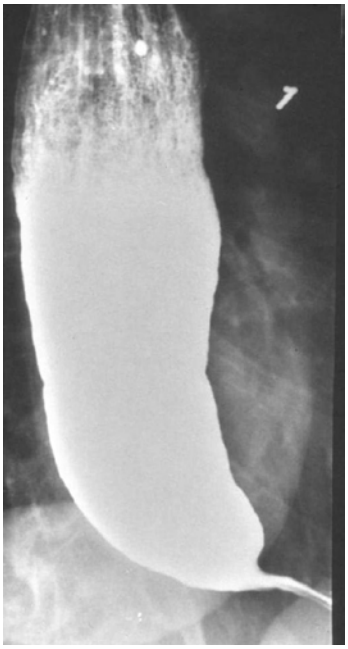
Achalasia

A 32-year-old woman with no past medical history comes to your office for the evaluation of "difficulty swallowing" foods. She has had this problem for almost a year, and it is most difficult for her to eat solids. Her symptoms have not worsened at all over this time period, and her weight has been stable. Physical examination is unremarkable. What is the next step in evaluation?

Pathogenesis. Achalasia is the idiopathic loss of the normal neural structure of the lower esophageal sphincter (LES). The LES is usually contracted to prevent the acidic gastric contents from refluxing backward into the esophagus. For swallowing to occur, there is normally a relaxation process of the LES in order to allow food to pass into the stomach. Inhibitory neurons are stimulated, blocking the impulses that cause constriction. In achalasia, these inhibitory neurons have been lost, as well as the ability to relax the LES. The vast majority of cases are of unknown etiology. A very small number can be from Chagas disease, gastric carcinoma, or diseases that can infiltrate into the area, such as lymphoma.

Clinical Presentation. Achalasia presents with progressive dysphagia to both solids and liquids simultaneously and can have regurgitation several hours after eating. There can also be weight loss. Achalasia has no relationship with alcohol or tobacco use. This is different from esophageal cancer, which not only usually presents with dysphagia to solid foods that progresses to difficulty swallowing liquids, but also is more common in older patients with a long history of alcohol and tobacco use.

Diagnosis. Esophagogastroduodenoscopy (EGD) is done for alarm symptoms: onset after age 60, anemia, heme-positive stools, >6-month duration of symptoms, and weight loss. Although a chest x-ray may show an air-fluid level in the dilated esophagus, plain radiography is insufficiently accurate to be very useful. Barium esophagography is very accurate and shows dilation of the esophagus, which narrows into a "bird's beak" at the distal end. The most accurate test overall (gold standard) is esophageal manometry. Manometry shows increased lower esophageal (LES) resting pressure.



Wikimedia, Farnoosh Farrokhi and Michael F. Vaezi

Figure 4-1. Achalasia

Treatment. The best initial therapy is pneumatic dilation or surgery. Pneumatic dilation should be effective in 80–85% of patients. The procedure gives a 3–5% risk of perforation. Botulinum toxin injections into the LES are used in those patients not willing to undergo pneumatic dilation, or in whom it has failed. Although the botulinum toxin is relatively benign, the main limiting factor in its use is a need for additional injections in a few months. Fifty percent will relapse in 6–9 months, and all patients will need reinjection after 2 years. Botulinum toxin is also used in patients who are poor surgical candidates, e.g., the elderly with multiple comorbid conditions who would not tolerate surgery. If both pneumatic dilation and botulinum toxin injections fail, then surgical myotomy is performed. Myotomy is performed laparoscopically and results in reflux in 20% of patients as a complication of therapy.

Esophageal Cancer

A 62-year-old man comes for evaluation of progressive "difficulty swallowing solids and, recently, semisolids" for 4 months. He has noticed a 20-lb weight loss. His past medical history is significant for reflux esophagitis for 15 years and a 40-pack-year smoking history. On the physical examination, a 1.5-cm, left supraclavicular lymph node is found. The remainder of the physical examination is unremarkable.

Pathogenesis. Esophageal cancer is linked to the synergistic, carcinogenic effect of alcohol and tobacco use for cases of squamous cell cancer in the proximal two-thirds of the esophagus. Adenocarcinoma is found in the distal third of the esophagus and is associated with long-standing gastroesophageal reflux disease and Barrett esophagus. The rate of development of cancer from Barrett esophagus is between 0.4 and 0.8% per year. Squamous and adenocarcinoma are now of equal frequency.

Clinical Presentation. Esophageal cancer presents with progressive dysphagia first for solid food, then for liquids. Weight loss is prominent. Rarely, halitosis, regurgitation, and hoarseness occur. Hypercalcemia may arise, as it can with most cancers.

Diagnosis. Although a barium swallow can be done first, endoscopy is mandatory because this is a diagnosis that requires a tissue biopsy. CT scanning detects the degree of local spread, and bronchoscopy detects asymptomatic spread into the bronchi. Endoscopic U/S is performed for staging.

Treatment. The only truly effective therapy for esophageal carcinoma is surgical resection if the disease is sufficiently localized to the esophagus. Only 25% of patients are found to be operable. Five-year survival is 5–20%. Chemotherapy with a 5-fluorouracil-based chemotherapy is combined with radiation to control locally metastatic disease.

Scleroderma (Progressive Systemic Sclerosis)

Pathogenesis. As many as 80 to 90% of patients with scleroderma will develop diminished esophageal peristalsis from the atrophy and fibrosis of the esophageal smooth muscle.

Clinical Presentation. Although there is dysphagia, the main clue to the diagnosis is simply the presence of gastroesophageal reflux symptoms in a person with a history of scleroderma. The LES will neither contract nor relax and basically assumes the role of an immobile open tube.

Diagnosis. Barium studies are generally unnecessary. The most accurate diagnostic test is motility studies.

Treatment. Therapy is with proton-pump inhibitors, such as omeprazole. Metoclopramide is a promotility agent that has some modest efficacy.

Diffuse Esophageal Spasm and Nutcracker Esophagus

A 34-year-old man complains of "crushing" chest discomfort for 1 hour. He has no significant medical history. The ECG is normal. He is given sublingual nitroglycerin in the emergency room that improves his chest pain almost immediately.

Pathogenesis. Esophageal spastic disorders are idiopathic abnormalities of the neural processes of the esophagus. Fundamentally, diffuse esophageal spasm and nutcracker esophagus are the same disease. The only difference may be in the manometric pattern.

Clinical Presentation. These patients present with intermittent chest pain and dysphagia. The pain can simulate that of a myocardial infarction, but it bears no relationship with exertion. There is no relationship with eating, ruling out odynophagia. The pain can be precipitated by drinking cold liquids.

Diagnosis. Barium studies may show a "corkscrew"' pattern at the time of the spasm. The most accurate test is manometric studies, which will show high-intensity, disorganized contractions. Because the contractions are disorganized, they do not lead to the forward flow of food and peristalsis.

Treatment is with calcium-channel blockers, such as nifedipine, and nitrates.

Rings and Webs

Pathogenesis. Schatzki's ring and Plummer-Vinson syndrome reveal thin, epithelial membranes made out of squamous epithelial cells. Neither of them is progressive in nature, distinguishing both of these conditions from achalasia.

Schatzki's ring is more common and leads to intermittent dysphagia and is not associated with pain. It is also more distal and located at the squamocolumnar junction proximal to the lower esophageal sphincter.

Plummer-Vinson syndrome (PVS) is more proximal and is located in the hypopharynx. The dysphagia is sometimes with liquids as well. Plummer-Vinson syndrome is associated with iron-deficiency anemia and squamous cell cancer; it most often occurs in middle-aged women.

Diagnosis. Both disorders are best diagnosed with a barium swallow or barium esophagram.

Treatment. Plummer-Vinson syndrome may respond to treatment of the iron deficiency. Both are treated with dilation procedures.

Esophagitis

Pathogenesis. Esophagitis refers to either infection or inflammation of the esophagus. The most common infection is from *Candida albicans*. When *Candida* esophagitis occurs, it is almost exclusively in patients who are HIV positive with a CD4 count <200/mm^3, usually even <100/mm^3. Diabetes mellitus is the second most common risk for developing *Candida* esophagitis. Much rarer infectious etiologies of esophagitis are herpes simplex, cytomegalovirus, and aphthous ulcers. Medications and the ingestion of caustic substances are associated with the development of esophagitis. Alendronate and other bisphosphonates are most common.

Clinical Presentation. *Candida* esophagitis presents with progressive odynophagia. Although the swallowing is painful, food is still able to pass until the disease is extremely advanced. The major difference between the pain of esophagitis and the pain of spastic disorders is that in esophagitis, the pain is only on swallowing, whereas with spastic disorders the pain occurs intermittently without even needing to swallow. Esophagitis pain is simply from the mechanical rubbing of food against an inflamed esophagus as it passes by.

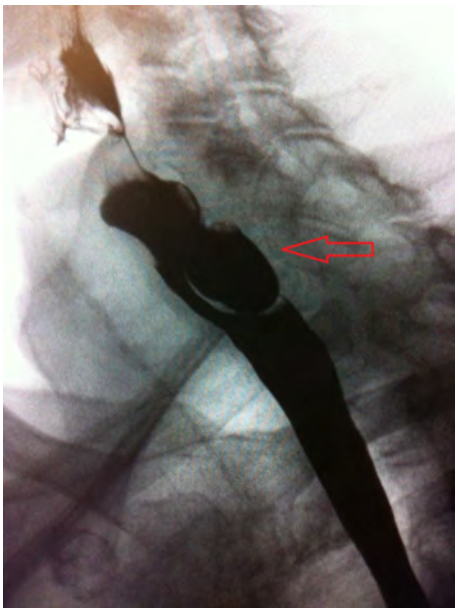
Diagnosis and Treatment. If the patient is HIV positive, *Candida* esophagitis is assumed and fluconazole is started. An improvement of symptoms with empiric fluconazole confirms the diagnosis. If the fluconazole doesn't work, perform endoscopy and biopsy to exclude other causes such as HSV, CMV, etc.

Because esophagitis can also result from ingestion of medications and caustic substances, the direct effect of contact between the mucosa and the pill causes inflammation rather than infection. As with most other toxin-mediated damage to an organ, the diagnosis is based on the presentation and finding the toxin in the history. The most common pills that cause esophagitis are alendronate, quinine, risedronate, vitamin C, potassium chloride, doxycycline, NSAIDs, and iron sulfate. Pill esophagitis is managed by simply swallowing pills in the upright position and drinking enough water to flush them into the stomach. Consider pill esophagitis in a young patient who is taking medications for acne with the acute onset of odynophagia.

Zenker Diverticulum

> A 25-year-old medical student comes to seek your help because he thinks he "has bad breath." This past weekend, a most disturbing event occurred while he was watching a football game: He coughed up the chicken teriyaki he ate 2 days earlier. He claims to brush his teeth every night. The physical examination is normal. What is the next step in the evaluation of this patient?

Pathogenesis. Zenker diverticulum is the outpocketing of the posterior pharyngeal constrictor muscles at the back of the pharynx.



Wikipedia, James Heilman, MD

Figure 4-2. Zenker Diverticulum

Clinical Presentation. This is generally a very slowly developing problem that occurs in older patients. These patients have bad breath and difficulty initiating swallowing because it is such a proximal lesion. Patients also complain of having to repeatedly clear their throats and waking up with undigested, regurgitated food on their pillow. This is particularly unpleasant because the food was usually eaten several days ago.

Diagnosis. The diagnosis is made on barium studies.

Treatment. Endoscopy and the placement of nasogastric tubes are contraindicated because of the risk of developing perforation of the pharynx. Patients with Zenker diverticulum are treated with surgical resection.

Mallory-Weiss Syndrome

Pathogenesis. Mallory-Weiss syndrome is a nontransmural tear of the lower esophagus that is related to repeated episodes of retching and vomiting.

Clinical Presentation. Although Mallory-Weiss syndrome is an esophageal disorder, the presentation is markedly different from the other problems described above. Mallory-Weiss does not present with dysphagia or odynophagia. It presents with painless upper GI bleeding. Patients develop black stool from melena if the volume of bleeding is >100 mL or with hematemesis if there is continued vomiting.

Diagnosis. These patients are diagnosed by direct visualization on upper endoscopy.

Treatment. Most of the time, Mallory-Weiss tears require no direct therapy and will resolve spontaneously. Sometimes, injection of the tear with epinephrine or performing cauterization is necessary.

EPIGASTRIC PAIN

Pathogenesis. There is no definite way to determine the etiology of epigastric discomfort or pain simply by examining the history in the majority of cases. Epigastric pain can be from ulcer disease, pancreatitis, gastroesophageal reflux disease (GERD), gastritis, and, occasionally, gastric cancer. *Helicobacter pylori* is most strongly associated with the development of duodenal ulcers, gastric ulcers, and gastritis.

Pancreatitis is the most common reason for epigastric *tenderness* and pain. Ulcer disease is associated with epigastric tenderness in <20% of patients.

Despite these diagnostic possibilities, the most common etiology of epigastric pain is, in fact, never truly determined. This is referred to as nonulcer dyspepsia, a functional disorder in which there is persistent pain in the epigastric area but all the tests are found to be normal.

Diagnosis. The hardest question is when to perform endoscopy, which is often required for a definitive diagnosis. Barium studies of the stomach, such as the upper GI series, are always less accurate than is endoscopy for problems in the stomach.

Endoscopy is indispensable in the diagnosis of cancer. Essentially, one performs endoscopy to exclude gastric cancer, as well as to determine whether a person is developing dysplasia in their lower esophagus as a result of long-standing reflux or Barrett esophagus.

H. pylori can be diagnosed with noninvasive means, such as serology, urea breath testing, and stool antigen detection. Endoscopy is not needed to determine who has *Helicobacter*, although biopsy and histology are the single most accurate tests. Make sure the patient is off proton-pump inhibitors (PPI)/Abx for 1–2 weeks prior to the test (can give false negative). *H. pylori* ELISA is not affected by PPIs. When testing for eradication, do not use ELISA. Use breath test or stool antigen.

All patients with epigastric pain and alarm symptoms, such as weight loss, dysphagia, odynophagia, or heme-positive stool, should undergo endoscopy. In addition, endoscopy is recommended for those age >45–55, essentially to exclude gastric cancer. Endoscopy is also indicated for those whose symptoms have not resolved with the use of antisecretory therapy, such as PPIs, or histamine 2 (H_2)–receptor blockers, such as ranitidine or cimetidine. H_2 blockers are only effective in two-thirds of patients.

Treatment. Although endoscopy is the most accurate means of diagnosing an ulcer, one can empirically treat ulcers, reflux disease, and gastritis. Patients who do not have duodenal or gastric ulcers or gastritis should not be treated for *H. pylori*. Young, generally healthy patients can be treated empirically with H_2 blockers, liquid antacids, or PPIs, and then undergo endoscopy in the future if there is no improvement.

Note

All patients with epigastric pain should undergo endoscopy, except those age <45–55 with no alarm symptoms, such as bleeding, weight loss, or difficulty swallowing.

Note

There is no point in treating *H. pylori* without evidence of disease, such as gastritis or ulcer disease.

Gastroesophageal Reflux Disease

A 32-year-old man comes to the emergency department for substernal chest pain of 2 hours' duration. He says that he sometimes gets this pain while lying in bed at night. He is otherwise free of symptoms, except for a nonproductive cough that he has had for the past month or so. His physical examination is unremarkable. His ECG is normal. He is given sublingual nitroglycerin and notes that his chest discomfort is worsened.

Pathogenesis. Gastroesophageal reflux disease, or GERD, is caused by the abnormal flow of the acid gastric contents backward from the stomach up into the esophagus. The lower esophageal sphincter (LES) is not a true anatomic sphincter; you can't find it in a cadaver. The LES is created by the different response of the smooth muscle cells in the distal esophagus.

A number of factors can cause decreased tone or loosening of this sphincter, such as nicotine, alcohol, caffeine, peppermint, chocolate, and anticholinergics. We also know that calcium-channel blocking agents and nitrates also lower the sphincter pressure. When the tone of the LES decreases, acid is more likely to reflux backward into the esophagus, particularly when the patient is lying flat. GERD can still occur in the absence of these precipitating factors and can often simply be idiopathic in origin.

Clinical Presentation. Dyspepsia or epigastric pain can be caused by GERD, ulcer disease, pancreatitis, gastritis, and nonulcer dyspepsia. GERD can be differentiated from the others by the presence of a sore throat; a bad, metal-like taste in the mouth; hoarseness; and cough and wheezing. In addition, GERD is the one most likely to be associated with pain in the substernal area.

Diagnosis. Specific diagnostic testing is not necessary when the patient's symptoms are those described in the clinical presentation. In clear cases of epigastric pain going under the sternum and associated with a respiratory complaint or a bad taste in the mouth, therapy should be initiated immediately with antisecretory medications, such as proton-pump inhibitors (PPIs). The most accurate diagnostic test is a 24-hour pH monitor, but this is only necessary when the patient's presentation is equivocal in nature and the diagnosis is not clear. An electrode is placed several centimeters above the gastroesophageal junction, and a determination is made of what the average pH is in that area. Normal endoscopy does not exclude reflux disease.

Treatment. Therapy for GERD is primarily with PPIs, all of which are essentially equal in efficacy. Omeprazole, esomeprazole, lansoprazole, pantoprazole, and rabeprazole will all reliably increase the pH of the gastric contents to a level above 4.0. Do motility studies prior to surgery to avoid iatrogenic dysphagia.

A small number of persons, usually <5%, will not respond to PPIs and will need to undergo surgery to tighten the sphincter. Traditionally, this has been a Nissen fundoplication, which is done laparoscopically. Another method is simply placing a circular purse-string suture in the LES to tighten it.

H_2 blockers should only be used if the patient has very mild, intermittent symptoms. H_2 blockers are not as effective as PPIs. Prokinetic drugs, such as metoclopramide, have an equal efficacy to H_2 blockers and less than that of PPIs, and they are rarely used.

All patients should modify their lifestyle to diminish the frequency of GERD symptoms. This means avoiding nicotine, alcohol, caffeine, chocolate, and late-night meals. It also means elevating the head of the bed 6 to 8 inches with blocks to use gravity to help keep the acid in the stomach.

Indication for surgery:

- Refractory side effects with PPIs, e.g., headaches, diarrhea
- No response to PPIs

Barrett Esophagus

Pathogenesis. Barrett esophagus is a complication of long-standing reflux disease. After several years of GERD, the epithelium of the lower esophagus undergoes histologic change from a normal squamous epithelium to a columnar epithelium.

Diagnosis. Patients with Barrett esophagus should have a repeat endoscopy every 2 to 3 years to see whether dysplasia or esophageal cancer has developed. Patients with low-grade dysplasia should undergo repeat endoscopy in 3 to 6 months to see if the lesion has progressed or resolved. Patients with high-grade dysplasia should have a distal esophagectomy or an endoscopic mucosal resection because of its very high rate of progression to invasive esophageal carcinoma. The usual rate of progression to cancer is about 0.5% per year.

Barium studies are typically normal. Endoscopy should be performed if the patient has GERD and if there are alarm symptoms, such as dysphagia, odynophagia, weight loss, anemia, or heme-positive stool. It is not clear when endoscopy should be done when there is a history only of GERD.

Treatment. All patients with Barrett esophagus should receive PPIs.

Peptic Ulcer Disease

Peptic ulcer disease is the term applied to both duodenal ulcers and gastric ulcers. The term is the archaeologic remnant of a misnomer from the early part of the 20th century, in which it was mistakenly believed that the enzyme pepsin caused ulcer disease.

Etiology. Tobacco smoking, alcohol, and the use of steroids by themselves do *not* cause ulcer disease. Tobacco and alcohol use can delay healing and are associated with the development of gastritis, but they do not cause ulcers. The strongest causal relationship for the development of ulcers is the use of NSAIDs, *Helicobacter pylori* infection, cancer of the stomach, Zollinger-Ellison syndrome, Crohn's disease, burns, head trauma, and prolonged intubation and mechanical ventilation.

NSAIDs lead to ulcer formation because they decrease the normal production of the mucous barrier that protects the epithelial cells of the gastric mucosa. Prostaglandins, the major stimulant for mucous production that forms this protective barrier, are inhibited by NSAIDs and hence diminish the protective barrier of the stomach lining. The presumptive mechanism of the formation of stress ulcers from burns and head trauma is that there is an intense vasoconstriction of the vasculature that supplies the gastric mucosa, leading to the sloughing of these cells and ulceration. Steroid use by itself does not lead to peptic ulcer disease and is therefore not a routine indication for stress ulcer prophylaxis.

Parietal cells in the stomach produce acid. The 3 stimulants to the production of acid from the parietal cells are gastrin, acetylcholine, and histamine. Gastrin is produced by G cells in the stomach, and its release is stimulated by distention of the stomach, the presence of amino acids, and vagal stimulation. Vagal stimulation also releases acetylcholine and gastrin-releasing peptide. However, the single most important stimulant to gastrin release is distention of the stomach.

Histamine is released by enterochromaffin-like cells present in the same glandular elements of the stomach that have the parietal and chief cells. Chief cells release pepsinogen, which is converted to pepsin by the acid environment of the gastric lumen. Histamine directly stimulates the parietal cells to both release acid and potentiate the effects of acetylcholine and gastrin on the parietal cells. This is why H_2 blockers such as cimetidine, famotidine, and ranitidine inhibit acid release.

Zollinger-Ellison syndrome is the excessive production and release of gastrin from G cells. Somatostatin is the counterbalance to this system. Somatostatin inhibits the release of gastrin and histamine, as well as having a direct inhibitory effect on the production of acid from the parietal cells. Secretin is released from the S cells of the duodenal lining. The main stimulant to the release of secretin is the presence of acid in the duodenum. Secretin inhibits the production of gastrin, as well as stimulates pancreatic and biliary bicarbonate production and release.

The most common cause of ulcer disease is *Helicobacter pylori* followed by the use of NSAIDs; 80–90% of duodenal ulcers and 70–80% of gastric ulcers are associated with *H. pylori*. Overall, 10–20% of ulcers are idiopathic, and no clear etiology is ever identified.

Clinical Presentation. The most common presentation of ulcer disease is midepigastric pain. There is no definite way to distinguish between duodenal and gastric ulcers simply by symptoms. The only way to be certain is with endoscopy or, occasionally, radiographic studies with barium, such as an upper GI series. Traditionally, gastric ulcers have been associated with pain on eating, and duodenal ulcers were thought to be relieved by eating. Because gastric ulcers were thought to be associated with pain on eating, this more frequently led to weight loss. This description is only a rough approximation, and it is still necessary to perform endoscopy if a definite diagnosis is required.

Tenderness of the abdomen is unusual with ulcer disease. More than 80% are not associated with abdominal tenderness in the absence of a perforation. Nausea and vomiting are occasionally found with both of them.

Diagnosis. Ulcer disease is best diagnosed with upper endoscopy. Barium studies are inferior. In generally healthy patients age <45–55 with epigastric pain, endoscopy can be deferred in favor of a trial of H_2 blockers or proton-pump inhibitors (PPIs). If the symptoms persist, then endoscopy can be performed. In those age >45–55 or those with alarm symptoms (weight loss, anemia, heme-positive stools, or dysphagia), endoscopy should be performed.

The diagnosis of *H. pylori* is based on either serology, urea breath testing, stool antigen testing, or biopsy with histology. Knowing which diagnostic test to perform first for *Helicobacter* is not definitively clear. Serology is the least expensive, is the least invasive, and has a very high degree of sensitivity. This means a negative test for the *Helicobacter* antibody effectively excludes this agent as an etiology of the ulcer disease. The drawback to serology is that it does not reliably distinguish between old disease and new disease and therefore lacks specificity.

In addition, neither serology nor breath testing nor stool antigen tests can exclude the presence of gastric cancer. The advantage of both breath testing and stool antigen detection methods is that they have the same sensitivity as serology and are able to easily distinguish new versus old disease. When *H. pylori* has been treated, both the breath and stool tests readily become negative. This means they can be used to evaluate eradication of the organism post treatment and can test for cure of the infection.

Note

Gastric ulcers must be biopsied to exclude cancer.

Biopsy with histology is the most sensitive and specific test. Further, it can exclude cancer. Four percent of patients with gastric ulcer disease have cancer. In addition, there is a rapid test on the biopsy, known as a CLO test, that can exclude *Helicobacter*. The CLO is performed to see if the organisms present in the biopsy specimen can produce urease, demonstrating the presence of the bacterium.

Treatment. The treatment of ulcer disease centers largely on the treatment of *H. pylori*. Use a PPI combined with clarithromycin and amoxicillin. Omeprazole, lansoprazole, pantoprazole, rabeprazole, and esomeprazole are all equal in efficacy.

The other 2 choices of antibiotic are tetracycline and metronidazole. Bismuth subsalicylate is not necessary. Regimens that contain PPIs are superior to those that use H_2 blockers, such as ranitidine or cimetidine. The PPI/clarithromycin/amoxicillin regimen should be effective in >90% of patients. Duration of therapy is 10 to 14 days, but sometimes the PPI is continued for a few months in order to heal the gastric mucosa. Repeat endoscopy is essential after treatment for gastric ulcer. The only way to be sure there is no cancer is to document resolution of the ulcer.

In those who fail therapy, a urea breath test should be performed to see if the reason for failure was the inability to eradicate the organism. If the organism was not eradicated, then retreat with different antibiotics plus bismuth subsalicylate. In addition, sensitivity testing for the organism should be explored. If the organism was eradicated and the ulcer persists, recurs, or worsens, the patient may need evaluation for Zollinger-Ellison syndrome.

Ordinary ulcers not related to *Helicobacter* can be treated with PPIs alone. Misoprostol is a prostaglandin analog that was developed to prevent the development of NSAID-induced ulcers. It is rarely used because it is not very effective. Cyclooxygenase 1 (COX-1) is the enzyme that produces the prostaglandins that protect the gastric mucosa. COX-2 is the enzyme implicated in the development of pain. COX-2 inhibitors were developed to relieve pain without damaging the gastric lining as much as NSAIDs. COX-2 inhibitors have no effect on platelets.

Indications for surgery in PUD:

- UGI bleeding not amenable to endoscopic procedures
- Perforation
- Refractory ulcers
- Gastric outlet obstruction (can change endoscopic dilation)

Gastritis

Etiology. Gastritis is the term applied to describe inflammation, erosion, or damage of the gastric lining that has not developed into an ulcer. Unlike ulcer disease, gastritis can be caused by alcohol, as well as NSAIDs, *Helicobacter*, head trauma, burns, and mechanical ventilation. The type of gastritis from these factors is referred to as type B, which is by far the most common type of gastritis. It is also associated with increased gastric acid production.

Type A gastritis is from atrophy of the gastric mucosa and is associated with autoimmune processes, such as vitamin B12 deficiency. Type A is also linked to diminished gastric acid production and achlorhydria. All patients with achlorhydria will have markedly elevated gastrin levels because acid inhibits gastrin release from G cells. MALT (mucosal-associated lymphoid tissue) leads to metaplasia as well as possible dysplasia and then to gastric cancer.

Clinical Presentation. Most patients with gastritis present with asymptomatic bleeding. When the gastritis is severe and erosive, patients will have abdominal pain in the same area that patients with ulcer disease feel theirs. Nausea and vomiting may also occur. The bleeding can present either as hematemesis or melena.

Diagnosis and Treatment. The diagnosis and treatment of *Helicobacter* is the same as that for gastritis (described for ulcer disease above). Vitamin B12 deficiency and pernicious anemia are initially diagnosed with a low vitamin B12 level and an increased methylmalonic acid level. The diagnosis of pernicious anemia is confirmed by the presence of antiparietal cell antibodies and anti-intrinsic factor antibodies. It is treated with B12 replacement, as are all cases of vitamin B12 deficiency.

Zollinger-Ellison Syndrome

A 42-year-old woman comes to your office with complaints of diarrhea for 6 months. She has stopped all dairy products but there has been no improvement. There is no blood or pus with the stools. She takes maximum doses of omeprazole daily, along with famotidine, and still has ulcer symptoms. She has a mild hypercalcemia. What is the next step in the evaluation of this patient?

Zollinger-Ellison syndrome (ZES) is hypergastrinemia caused by cancer of the gastrin-producing cells. There is no known cause for gastrinoma or ZES. Half of these gastrinomas are located in the duodenum, and a quarter are located in the pancreas. A small percentage (<20%) are associated with multiple endocrine neoplasia type 1 (MEN-1) or parathyroid, pituitary, and pancreatic tumors.

Note

The presence of hypercalcemia is the clue to detecting MEN-1. This is because of the hyperparathyroidism.

Clinical Presentation. More than 95% of patients with ZES present with ulcer disease. Less than 1% of people with ulcer disease has an underlying ZES or gastrinoma. How will you recognize the nature of the case in which you should test for gastrin levels to exclude a gastrinoma? ZES presents with ulcers that are recurrent after therapy, multiple in number, and occur in the distal portion of the duodenum or resistant to routine therapy. Routine peptic ulcers usually are <1 cm in size, occur within 2 to 3 cm of the pylorus, are single, and promptly resolve after therapy for *Helicobacter pylori*. Diarrhea occurs in two-thirds of patients. This can be ordinary watery diarrhea, or it can be steatorrhea. Steatorrhea occurs because lipase is inactivated by the large volume of acid passed into the duodenum. Diarrhea may precede the ulcer in 20% of patients. Metastatic disease is evident at the time of diagnosis in 30% of patients at presentation. An additional 20% of patients later develop metastatic disease.

Diagnosis. Although an elevated gastrin level is indicative of ZES, it is critical to remember that all patients on H_2 blockers or PPIs have high gastrin levels. This is because the main stimulus to the suppression of gastrin release is acid. If acid production is suppressed, then gastrin levels go up. To diagnose ZES, the gastrin level must be found elevated while the patient is off antisecretory therapy for several days. Another way to diagnose ZES is to find an elevated gastric acid output while concurrently finding an elevated gastrin level. The secretin stimulation test is positive (abnormal) if there is a rise in gastrin level after the injection of secretin. Normally, secretin should suppress gastrin release. Other causes of increased gastrin are:

- Pernicious anemia
- Chronic gastritis
- Renal failure
- Hyperthyroidism

After confirming a diagnosis of gastrinoma, the most important step is to determine if the lesion is localized or metastatic. Localized lesions can be surgically removed and essentially cured. Metastatic disease can only be suppressed with the use of PPIs. U/S, CT scanning, and MRI have between 60 and 80% sensitivity for the presence of metastatic disease. These tests are specific enough to prove the presence of tumor if they are positive, but not sensitive enough to safely exclude disease if they are negative. A nuclear test, somatostatin-receptor scintigraphy, is 90% sensitive for the detection of metastatic disease. The single most sensitive test is the endoscopic U/S. Typically, both tests are done.

Treatment. Localized disease is surgically resected and metastatic disease is treated with the long-term administration of PPIs simply to block acid production.

Gastroparesis

Pathogenesis. Gastroparesis, also called delayed gastric emptying, is a disorder that results in delayed movement of food from the stomach to the small intestine. The most common association for gastroparesis is diabetes. Electrolyte problems with potassium, magnesium, and calcium can also weaken the musculature of the bowel wall.

Clinical Presentation. Patients present with early satiety, postprandial nausea, and a general sense of increased abdominal fullness. This is from decreased motility of the stomach and the accumulation of food there. Gastroparesis generally occurs in those presenting with abdominal pain and bloating and who have a long-standing history of diabetes, along with retinopathy, neuropathy, nephropathy, and history of poor glycemic control.

Diagnosis. Although gastroparesis is often diagnosed clinically, the gastric-emptying study is the confirmatory test. This study utilizes ingestion of radioisotope-labeled food to measure transit time throughout the stomach. The diagnosis of diabetic gastroparesis is generally obvious as the cause of bloating, vomiting, and nausea in a long-term diabetic, after endoscopy excludes other diseases.

Treatment. Treatment is with agents that will increase motility of the stomach, such as erythromycin or metoclopramide. Emptying from the stomach is faster when there is less food to empty, so smaller, more frequent portions of food are recommended.

Dumping Syndrome

Pathogenesis. This is an increasingly rare disorder because of the rarity of the necessity for surgery in the treatment of ulcer disease. It was far more common in the past, when vagotomy and gastric resection were performed to treat severe ulcer disease.

Dumping syndrome is caused by 2 phenomena.

- First, there is the rapid release of hypertonic chyme into the duodenum, which acts as an osmotic draw into the duodenum, causing intravascular volume depletion.
- Next, there is a sudden peak in glucose levels in the blood because of the rapid release of food into the small intestine. This is followed by the rapid release of insulin in response to this high glucose level, which then causes hypoglycemia to develop.

Clinical Presentation. Patients present with sweating, shaking, palpitations, and lightheadedness shortly after a meal.

Treatment. There is no cure. Management is to eat multiple, small meals.

Nonulcer Dyspepsia

When all the causes of epigastric pain have been excluded and there is still pain, the diagnosis is functional or nonulcer dyspepsia. There is no specific therapy for nonulcer dyspepsia known to cure the disorder. Antacids of various types from H_2 blockers to liquid antacids to PPIs are tried until something is found to relieve the discomfort. The cause of nonulcer dyspepsia is unknown.

Treatment of *Helicobacter pylori* in nonulcer dyspepsia is of equivocal value. If there is no response to anti-secretory therapy with a PPI, you can try to treat *H. pylori* by adding clarithromycin and amoxicillin. Treating *H. pylori* will improve symptoms in another 10–20% of patients.

INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) is a term comprising 2 disease entities: **Crohn's disease (CD)** and **ulcerative colitis (UC)**. They can be discussed simultaneously because of the large degree of overlap in terms of presentation, testing, and treatment.

- Both CD and UC are idiopathic disorders of the bowel associated with diarrhea, bleeding, weight loss, fever, and abdominal pain.
- Both are most accurately diagnosed with endoscopy and sometimes with barium studies, "string sign" on small bowel follow through after barium meal in CD.
- Both are treated with anti-inflammatory medications, such as mesalamine, azathioprine, and 6-mercaptopurine (6MP).
- Steroids are used for acute exacerbations of both diseases.

Clinical Presentation. IBD presents with fever, diarrhea, weight loss, and, occasionally, abdominal pain and bleeding. The extraintestinal manifestations of IBD are episcleritis, scleritis and iritis, sclerosing cholangitis, joint pains, and skin manifestations, such as pyoderma gangrenosum or erythema nodosum.

Crohn's disease is more likely to be associated with a palpable abdominal mass because CD has granulomas in the bowel wall that are transmural in nature. This can lead to the different loops of bowel being inflamed and sticking together, forming a mass. The abdominal masses of CD can be palpated and cause pain. CD is not necessarily continuous, and one hallmark of the disorder is that there are "skip lesions," or areas of normal tissue in between the areas of disease.

Note

Sclerosing cholangitis does not correlate to disease activity.

UC is limited exclusively to the large bowel. It is exclusively a mucosal disease, and although it can cause bleeding, it does not result in fistula formation. UC has no skip lesions, no fistula formation, and no oral or perianal involvement. UC is more likely to cause bloody diarrhea.

Both forms of IBD can lead to colon cancer after 8–10 years of involvement of the colon. If the CD does not result in colonic involvement, then it will not lead to cancer. Complications of Crohn's disease are calcium oxalate kidney stones, diarrhea, and cholesterol gallstones.

Diagnosis. IBD is diagnosed with endoscopy and sometimes with barium studies. (CD can result in deficiency of vitamin B12, calcium, vitamin K, and iron because of malabsorption.) Anti–*Saccharomyces cerevisiae* antibodies (ASCA) are associated with CD, and antineutrophil cytoplasmic antibody (ANCA) is associated with UC. If a patient is ASCA positive and ANCA negative, he has a >90% chance of having CD. If the patient is ASCA negative and ANCA positive, he has a >90% chance of having UC.

Prothrombin time may be prolonged in CD because of vitamin K malabsorption. Kidney stones form more often in CD because the fat malabsorption results in a low calcium level and an increased absorption of oxalate, which forms kidney stones.

Treatment. Mesalamine derivatives are the mainstay of therapy for IBD in all of its forms. Pentasa is a form of mesalamine released in both the upper and lower bowel; hence, it is used in CD. Asacol is a form of mesalamine released in the large bowel, and it is most useful for UC. Rowasa is used exclusively for rectal disease. Sulfasalazine was used in the past for the same effect. The difficulty with sulfasalazine is that the high load of sulfa delivered causes a number of adverse effects, such as rash, hemolysis, and allergic interstitial nephritis. Sulfasalazine also causes reversible infertility in men and leukopenia by its sulfapyridine group.

Acute exacerbations of IBD are treated with high-dose steroids. Budesonide is a form of steroid that is ideal for IBD. It has a strong local effect when used orally, but is largely cleared by the liver in a first-pass effect. This limits the amount of systemic toxicity. Azathioprine and 6-mercaptopurine are associated with drug-induced pancreatitis, but are still used on a long-term basis to try to keep patients off steroids. Ciprofloxacin and metronidazole are used for CD in those with perianal disease. Infliximab is used for CD in those who form fistulae or have disease refractory to the other forms of therapy. There has been re-activation of tuberculosis with infliximab, and it is important to test for latent tuberculosis with a purified protein derivative (PPD) prior to treatment. If the PPD is positive, then patients should receive isoniazid. The most common side effect of infliximab is arthralgias. Balsalazide and olsalazine are other forms of mesalamine that are only active in the colon and are used occasionally.

Surgery is curative in UC; almost 60% of patients will require surgery within 5 years after diagnosis due to refractory symptoms or severe disease. Surgery is not very effective in CD and disease tends to reoccur at the site of anastomosis.

DIARRHEA

Diarrhea is increased frequency or volume of stool per day; stool can also be defined as diarrhea if the number of stools per day is few, but their consistency is watery.

Pathogenesis. The most common causes of diarrhea are of an infectious, antibiotic-associated, or lactose-intolerance etiology or from irritable bowel or carcinoid syndrome.

Clinical Presentation. The patient is often hypotensive, febrile, and experiencing abdominal pain.

Diagnosis. The first thing to do in the evaluation of diarrhea in terms of direct patient care is to see if there is hypovolemia as defined as hypotension or orthostasis. This is more important than determining the specific etiology because of the chance that the patient may die while waiting for the results to come back.

Treatment. No matter the etiology, if the patient is hypotensive, febrile, and having abdominal pain, he or she should be admitted to the hospital and given IV fluids and antibiotics. The presence of blood in the stool is especially serious and is probably the single strongest indication for the use of antibiotics, such as ciprofloxacin.

Note

With management of diarrhea, determine **when to admit** the patient and **when to use IV fluids and antibiotics**. That is more important than determining the precise causative agent.

Infectious Diarrhea

For all patients, assume that new-onset diarrhea has an infectious etiology. After an infectious cause is excluded, then the other possible causes can be systematically ruled out.

In general, to exclude infection, stool should be evaluated for the presence of white cells or "fecal leukocytes," as well as culture and ova and parasite examination. *Clostridium difficile* toxin and stool *Giardia*-antigen testing are done when there are clues to these diagnoses in the history.

The most common causes of infectious diarrhea are *Campylobacter* and *Salmonella*, especially in patients with sickle cell and achlorhydria. One can only make a definitive determination of the etiology with a stool culture.

Clinical presentation

Table 4-1. Clues to the Diagnosis of Infectious Diarrhea Prior to Results of Culture

Causative Agent	Patient Symptoms or History	Additional Comments
Bacillus cereus	Ingestion of refried Chinese food and the spores from *Bacillus* that it contains. Vomiting is prominent. Blood is never present.	Short incubation period (1–6 hours)
Campylobacter	Reactive arthritis, Guillain-Barré syndrome	Most common cause of bacterial gastroenteritis
Cryptosporidia, Isospora	Found in HIV-positive patients with $<100/mm^3$ CD4 cells	—
E. coli 0157:H7	Associated with the ingestion of contaminated hamburger meat. The organism can release a Shiga toxin, provoking hemolytic uremic syndrome.	Hemolytic uremic syndrome happens when the organism dies; that is why antibiotics are contraindicated. Platelet transfusions are also contraindicated, even if the platelet count is low because the new platelets may only make it worse.
Giardia	The ingestion of unfiltered water, as on a camping trip or in the mountains, or in drinking fresh lake water. *Giardia* never gives blood in the stool. There is abdominal fullness, bloating, and gas.	*Giardia* can also simulate celiac disease in terms of causing fat and vitamin malabsorption if it is not eradicated.
Salmonella	Ingestion of chicken and eggs, dairy products	—
Scombroid	Patients who ingest contaminated fish experience vomiting, diarrhea, flushing, and wheezing within minutes of eating it.	Organisms invade, producing and then releasing histamine into the flesh of fish, such as tuna, mahi mahi, and mackerel.
Shigella, Yersinia	No clues strong enough to point to the etiology until the results of the stool culture are known.	*Yersinia* can mimic appendicitis. Also common in people with iron overload, e.g., hemochromatosis.
Vibrio parahaemolyticus	Ingestion of raw shellfish, such as mussels, oysters, and clams	Typically presents as severe systemic gastroenteritis in patients with underlying disease (esp. chronic liver disease)
Vibrio vulnificus	Also in raw shellfish, but has a particularly high incidence in people with underlying liver disease or disorders of iron metabolism. Also associated with the development of skin bullae.	Typically presents as severe systemic gastroenteritis in patients with underlying disease (esp. chronic liver disease)
Viral	Children in day-care centers; the absence of blood and white cells	No systemic manifestation
Staphylococcus aureus	Ingestion of dairy products, eggs, salads. Upper GI symptoms (nausea/vomiting) predominate; rarely diarrhea.	Short incubation period (1–6 hours)
Ciguatera-toxin	2–6 hours after ingestion of large reef fish (grouper, red snapper, and barracuda). Also neurological symptoms → paresthesia, weakness, and reversal of heat and cold.	—

Diagnosis. Stool for fecal leukocytes is the most useful test that can be done immediately. Fecal leukocytes are only found when there has been invasion of the intestinal mucosa, as in dysentery, which is a bacterial infection of the bowel, producing diarrhea and bloody stool.

Invasive organisms need 24 to 36 hours to produce their effect and never give blood in the stool within the first few hours of their ingestion. (The only exception is the protozoan *Entamoeba histolytica*, which can give blood or white cells in stools.) The invasive organisms are *Salmonella, Shigella, Campylobacter, Vibrio parahaemolyticus, Yersinia*, *Escherichia coli,* and *Vibrio vulnificus* (think people drinking sea water). The most definitive test for these bacterial organisms is a stool culture.

Cryptosporidiosis is diagnosed with a unique test, a modified acid-fast test. The routine ova and parasite examination does not reliably detect cryptosporidiosis.

Giardia is best diagnosed with an ELISA stool antigen test. A single stool antigen test has 90% sensitivity. Three stool ova and parasite examinations have only 80% sensitivity.

Treatment. Most cases of food poisoning and infectious diarrhea will resolve spontaneously and will not need specific antimicrobial therapy. Even when they cause severe disease, as defined by high-volume stools with dehydration, antibiotics generally do not help. Antibiotics are used if there is abdominal pain, blood in the stool, and fever. The decision to use antibiotics is always made prior to knowing the result of the stool culture, so the treatment is always empiric and then modified when the culture results are known. The best empiric therapy for infectious diarrhea is ciprofloxacin or the other fluoroquinolones ± metronidazole.

Scombroid poisoning is treated with antihistamines, such as diphenhydramine. *Giardia* is still treated primarily with metronidazole. A newer agent for *Giardia* is tinidazole, which is effective in a single dose. Cryptosporidiosis is treated with nitazoxanide, although it has limited efficacy. The truly effective therapy for cryptosporidiosis is to raise the CD4 count to >100/mm^3 with antiretrovirals. Nitazoxanide is superior to paromomycin for cryptosporidium.

There is no specific therapy for viral diarrhea. Patients are managed with fluid and electrolyte support until the infection resolves.

Note

- TMP/SMX for *Isopora*
- Doxycycline for *Vibrio vulnificus*
- Rifaximin for travelers' diarrhea

Note

Prophylactic antibiotics for traveler's diarrhea is never a correct approach.

Antibiotic-Associated and *C. difficile*-Associated Diarrhea

The term *antibiotic-associated diarrhea* (AAD) refers usually to a benign, self-limited diarrhea following the use of antimicrobials. Typically, no pathogens are identified and the diarrhea is caused by changes in the composition and function of the intestinal flora as well as increased motility (as occurs with agents like erythromycin). Most patients respond to supportive measures and discontinuation of antibiotics.

On the other hand, ***Clostridium difficile* diarrhea** (*C. diff*) refers to a spectrum of diarrheal illnesses caused by the toxins produced by this organism, including severe colitis with or without the presence of pseudomembranes. For exam purposes, this discussion will focus on *C. diff*.

Pathogenesis. Any antibiotic can lead to diarrhea with *C. diff*, although antibiotics that are broad spectrum are more likely to do so. Clindamycin may have one of the highest frequencies of association, as do fluoroquinolones and cephalosporins.

C. diff diarrhea is largely a nosocomial disease and is the most frequent cause of diarrhea in hospitalized patients. Its occurrence in the outpatient setting, other than in patients confined to nursing homes, is much less common. Recent meta-analysis suggests a significant association between *C. difficile* and the use of proton pump inhibitors.

- Epidemiologic studies have shown that *C. difficile* is often isolated in hospital wards, including the floors, door handles, and furniture, even weeks after patients with it have been removed from the area.
- Because of the sporulating properties of this organism, all these observations have suggested an important role for cross-contamination between patients, contact with environmental surfaces, and transmission via hands of medical personnel.
- During the past few years, there has been renewed interest in *C. diff* diarrhea reflecting a form of disease that is more frequent, more severe, and more refractory to standard treatment. These observations are explained by the presence of a new strain of *C. diff*, designated NAP-1, which produces more toxins A and B and is resistant.

Both *C. difficile* toxins A and B exhibit potent enterotoxic and cytotoxic effects that are responsible for the clinical manifestations. The mechanism of action is by toxin binding on intestinal receptors, leading to disruption of the cellular skeleton and intracellular junctions. Protein synthesis and cell division are inhibited. Important inflammatory mediators attract neutrophils and monocytes, increasing capillary permeability, tissue necrosis, hemorrhage, and edema.

Clinical Presentation and Diagnosis. The clinical manifestations of *C. diff* may vary from mild diarrhea to fulminant colitis. If a patient develops diarrhea several days to weeks (even up to 8 weeks) after using antibiotics, evaluate for *C. diff*. Marked leukocytosis and systemic symptoms are evident in severe cases.

Until a few years ago the diagnostic method of choice for *C. difficile* colitis was the enzyme-linked immunosorbent assay (ELISA), based on toxin detection in the stool. While ELISA is fast, relatively inexpensive, and has excellent specificity, its sensitivity is variable (ranging 75–85%). The newest preferred method of diagnosis is the nucleic acid amplification (LAMP, loop-mediated isothermal amplification) assay, which may include the real-time polymerase chain reaction (PCR) or loop-mediated isothermal amplification test, both of which detect the toxin A and B genes responsible for the production of toxins. They have a sensitivity of 90–100% and a specificity of 94–100%. There is no benefit to testing multiple stool specimens or repeat testing following a positive test.

Treatment. Metronidazole is the drug of choice along with discontinuation of antibiotics (if feasible) and supportive therapy. If the diagnosis is highly likely and the patient is seriously ill, metronidazole may be given empirically before the test results. Oral vancomycin is reserved for the following conditions:

- Failed therapy with metronidazole
- Organisms resistant to metronidazole
- Patient is allergic to or cannot tolerate metronidazole
- Patient is pregnant or a child age <10
- Patient is critically ill

If the symptoms resolve but there is a recurrence (~ 30% in some studies), then retreat with metronidazole. Also, IV metronidazole can be used to treat *C. difficile* colitis if the patient is unable to use oral medications. (This is not true of vancomycin. IV vancomycin will have no effect in the bowel because it does not pass the bowel wall. Similarly, oral vancomycin will have no systemic effect.)

A new drug, fidaxomicin, is not more effective than vancomycin or metronidazole for the first episode. Fidaxomicin seems to decrease the number of episodes of recurrent *C. difficile* colitis.

Lactose Intolerance

Pathogenesis. Lactose intolerance is perhaps the single most common potential cause of diarrhea because of the enormously high prevalence of lactase deficiency. This is a disorder so common that the testing and treatment are generally empiric.

Clinical Presentation. The diarrhea produced is associated with gas and bloating, but never has blood or leukocytes in it. Despite the malabsorption of lactose, weight loss does not occur.

Diagnosis and Treatment. A precise diagnosis can be established by finding an increased stool osmolality and increased osmolar gap. The osmolar gap means that the difference between the osmolality measure in the stool and the osmolality calculated from the sodium and potassium levels is >50 mOsm/kg. In other words, the measured stool osmolality is greater than would be expected just by the level of sodium and potassium. The extra osmoles are from lactose. Other causes of an increased stool osmolar gap are magnesium and polyethylene glycol in the stool, also nutrient malabsorption → pancreatic insufficiency, celiac sprue, and bacterial overgrowth.

The routine way to diagnose lactose intolerance is simply to remove milk, cheese, ice cream, and all other dairy products (except yogurt) from the diet and observe for resolution of symptoms, which should occur within 24 to 36 hours. (This is quite different from celiac disease, in which resolution of diarrheal symptoms make take weeks after stopping the ingestion of gluten-containing foods.)

If resolution of symptoms does occur within 24 to 36 hours, then dietary changes are the best therapy. The patient can use lactase supplements.

Irritable Bowel Syndrome

Pathogenesis. Although it is often described at the same time as diarrheal illnesses, irritable bowel syndrome (IBS) is predominantly a pain syndrome of unknown etiology. IBS is an idiopathic disorder in which there is increased frequency of the normal peristaltic and segmentation contractions of the bowel. Pain is often relieved by a bowel movement.

Clinical Presentation. Twenty percent of patients with IBS have constipation only. A large number have diarrhea alone or diarrhea alternating with constipation. Everyone has pain.

No nocturnal symptoms. The majority are women with history of childhood abuse.

Diagnosis. There is no specific diagnostic test for IBS. The physician must first exclude lactose intolerance, inflammatory bowel disease, celiac disease, carcinoid, *Giardia* infection, and anatomic defects of the bowel as the cause.

The diagnostic criteria, called Rome criteria, must occur for at least 3 months:

- Pain relieved by a bowel movement or by a change in bowel habit (e.g., when you develop diarrhea, the pain goes away)
- Fewer symptoms at night
- Diarrhea alternating with constipation

No constitutional signs or symptoms, such as fever, weight loss, anorexia, or anemia.

Treatment. There is no clear definitive therapy for IBS. All patients should be placed on a high-fiber diet in an attempt to increase the bulk of the stool. Those with diarrhea-predominant disease should receive antidiarrheal agents, such as loperamide or diphenoxylate.

Antispasmodic agents are used on a trial-and-error basis until the most effective agent is found. Examples of antispasmodics are hyoscyamine, dicyclomine, and the belladonna alkaloids. The presumptive mechanism of these agents is that they will relax the bowel wall musculature and diminish the pain.

Resistant cases may respond to tricyclic antidepressants. The presumptive mechanism is that the tricyclics are anticholinergic and will relax the bowel. There is also a high frequency of depression in many of these patients, and it is assumed that the tricyclics have an analgesic effect with neuropathic pain.

A newer agent is tegaserod, which is used in constipation-predominant IBS. The major complication of therapy with tegaserod is diarrhea. Another newer agent is alosetron. Alosetron is used in diarrhea-predominant IBS, and it slows motility. Both of these agents work by manipulating serotonin levels in the bowel.

Carcinoid Syndrome

Pathogenesis. Carcinoid syndrome describes tumors of the neuroendocrine system. They are most often located in the appendix and the ileum. Bronchial carcinoids are rare but are highly symptomatic because the serotonin produced from a bronchial carcinoid does not get detoxified in the liver and is released directly into the circulation. With the exception of bronchial carcinoid, carcinoid syndrome by definition implies metastatic disease. Until there is an enormous tumor burden, the liver is able to neutralize all of the serotonin released by the carcinoid in the bowel. This usually does not happen until the metabolic capacity of the liver has been overwhelmed by metastatic disease.

Clinical Presentation. The presentation of carcinoid syndrome is with diarrhea, flushing, tachycardia, and hypotension. A rash may develop from niacin deficiency, which is a direct result of the carcinoid. Serotonin and niacin are both produced from tryptophan. If there is an overproduction of serotonin, it produces a tryptophan deficiency, which leads to a deficiency of niacin. Endocardial fibrosis also occurs because of a constant exposure of the right side of the heart to the serotonin. This leads to tricuspid insufficiency and pulmonic stenosis.

Diagnosis. The diagnosis is confirmed with a urinary 5-hydroxyindolacetic acid level (5-HIAA).

Treatment. Therapy is generally based on controlling the diarrhea with octreotide, which is a somatostatin analog. Very few carcinoids are sufficiently localized to be amenable to surgical resection. If a tumor does happen to be localized, then it should be resected. This is most often possible with bronchial carcinoid. Surgery is also used to relieve obstruction of the bowel.

MALABSORPTION SYNDROMES

Pathogenesis. The major causes of fat malabsorption are celiac disease and chronic pancreatitis, although tropical sprue and Whipple disease are extremely rare but possible causes. What they all have in common is the production of diarrhea characterized as greasy, oily, floating, and fatty, with a particularly foul smell, as if fat were fermenting. This type of diarrhea with fat is referred to as steatorrhea.

All malabsorption syndromes are characterized by weight loss because fat has the highest caloric content of all the foods. In addition, there is malabsorption of the fat-soluble vitamins A, D, E, and K. This can lead to hypocalcemia and easy bruising, as well as prolongation of the prothrombin time.

Iron malabsorption occurs if there is involvement of the duodenum where iron is normally absorbed. Iron deficiency anemia is evident in all patients with celiac sprue. Macrocytic anemia results from folate being malabsorbed. Vitamin B12 malabsorption is from damage or loss of the mucosal surface of the terminal ileum.

Clinical Presentation. All of the malabsorption syndromes present with chronic diarrhea. The only unique feature of celiac disease is dermatitis herpetiformis. This is a vesicular skin rash on the extensor surfaces of the body seen in approximately 10% of patients. Even without dermatitis herpetiformis, celiac disease is the most likely etiology of fat malabsorption because it is the most common.

Patients with chronic pancreatitis will give a history of repeated episodes of pancreatitis from alcohol or gallstones. Tropical sprue is suspected when there is a history of being in a tropical country. Whipple disease is by far the rarest. In addition to the usual presentation of a fat malabsorption, Whipple disease is characterized by dementia (10%), arthralgias (80%), and ophthalmoplegia.

Diagnosis. Celiac disease is first diagnosed by testing for the presence of antiendomysial and antitransglutaminase antigliadin antibodies. The most accurate test is a small bowel biopsy, which shows flattening of villi. Even if the antibody tests confirm the diagnosis of celiac disease, the bowel biopsy should be done anyway to exclude small bowel lymphoma. And because there is very little that is unique about tropical sprue, it is yet another reason to always do a small bowel biopsy.

Just removing gluten (wheat, rye, and oats) from the diet is not a very accurate way of establishing the diagnosis because the circulating antibodies will continue to be present for weeks after stopping the ingestion of gluten.

Chronic pancreatitis is diagnosed from the history of repeated episodes of pancreatitis and is confirmed by finding calcification of the pancreas on x-ray and CT scan. The most accurate test, although rarely done, is a secretin test, or finding a low trypsin level. Secretin normally causes a voluminous release of bicarbonate and other pancreatic enzymes into the duodenum. If you place a nasogastric tube into the duodenum and inject secretin into the blood, the pancreas will not release bicarbonate or enzymes into the duodenum in a patient with chronic pancreatitis.

D-xylose testing was performed in the past to help distinguish between celiac disease and chronic pancreatitis. D-xylose is a monosaccharide that requires no digestion to be absorbed. If there is no absorption of D-xylose, it means there is a bowel-wall abnormality. D-xylose was absorbed and excreted in chronic pancreatitis, but not in celiac disease, Whipple disease, or tropical sprue, in which there is a bowel-wall abnormality. Antibody testing has largely replaced D-xylose testing. In addition, the presence of the deficiency of iron, folate, and carotene also point to a mucosal defect because they do not need pancreatic enzymes to be absorbed. Vitamin B12 is malabsorbed in pancreatic insufficiency and celiac disease. Pancreatic enzymes are necessary to absorb B12. Vitamin K and calcium are malabsorbed because of fat malabsorption.

Tropical sprue and Whipple's disease are diagnosed by finding organisms on a bowel-wall biopsy. The single most sensitive test for Whipple's disease is a polymerase chain reaction (PCR) of the bowel biopsy. A positive *Tropheryma whippelii* biopsy shows foamy macrophages that are PAS positive.

Clinical Pearl

Antibodies Seen in Celiac Disease

- IgA endomysial antibody
- IgA tissue transglutaminase antibody
- IgG tissue transglutaminase antibody
- IgA deamidated gliadin peptide
- IgG deamidated gliadin peptide

Anti-tissue transglutaminase antibody (IgA) is the most sensitive and specific. In patients with **IgA deficiency**, IgA endomysial and transglutaminase antibodies are **falsely normal**.

Treatment. Celiac disease is managed by adhering to a gluten-free diet (no wheat, oats, rye, or barley). Dapsone is used when celiac patients have dermatitis herpetiformis. Chronic pancreatitis can be managed by orally replacing all the deficient enzymes. Amylase, lipase, and trypsin can all be taken in a single combination pill. Tropical sprue is treated with trimethoprim/sulfamethoxazole or doxycycline for 6 months. Whipple's disease is also treated with trimethoprim/sulfamethoxazole or doxycycline, but it can also be treated with ceftriaxone for 1 year.

Although all malabsorption syndromes are associated with multiple deficiencies, note some complications:

- Celiac disease is associated with GI lymphoma and adenocarcinoma; patients are at risk for adenocarcinoma of the intestine.
- Celiac sprue is associated with lymphoma (enteropathy-associated T cell lymphoma) (10-15% of cases); it is unclear whether therapy with gluten-free diet decreases incidence of lymphoma.

DIVERTICULAR DISEASE

Diverticulosis

Diverticulosis is so common in older populations in the Western world as to almost be considered simply a normal part of aging rather than a disease. Diverticulosis is presumably caused by a lack of fiber in the diet to give bulk to stool. There is a subsequent rise in intracolonic pressure, leading to outpocketing of the colon. It is prevalent in 50% of persons age >50, with even higher rates in older populations.

Clinical Presentation. Most of the time, these patients are asymptomatic. When they have symptoms, it is of left lower quadrant abdominal pain that can be colicky in nature.

Diagnosis. Diverticulosis is diagnosed with colonoscopy. Endoscopy is superior to barium studies, particularly when bleeding is present. Diverticula are more common on the left in the sigmoid, but bleeding occurs more often from diverticula on the right because of thinner mucosa and more fragile blood vessels. When bleeding occurs from diverticula, it is painless.

Treatment. Diverticulosis by itself is managed only with increasing fiber in the diet with products like Metamucil®, dietary fiber in bran, or bulking agents, such as psyllium husks.

Diverticulitis

Diverticulitis is from an infection occurring in one of the diverticula. This occurs more frequently when there is a blockage of the diverticular entrance in the colon from nuts or corn.

Clinical Presentation. Diverticulitis is distinguished from uninfected diverticula by the presence of fever, tenderness, more intense pain, and an elevation of the white blood cell count in the blood.

Diagnosis. Diverticulitis is confirmed by CT scanning. Barium studies and endoscopy are relatively contraindicated in diverticulitis because there is a slightly higher risk of causing perforation. There is no risk of perforation with CT scan.

Treatment. Diverticulitis is treated with antibiotics such as ciprofloxacin and metronidazole. The other choices are ampicillin/sulbactam, piperacillin/tazobactam, or the combination of cefotetan or cefoxitin with gentamicin. Mild disease can be treated with oral antibiotics, such as amoxicillin/clavulanic acid (Augmentin®).

CONSTIPATION

A 72-year-old woman has a history of upper GI tract bleeding and iron-deficiency anemia, for which she has recently been started on oral ferrous sulfate iron replacement. She also has a history of diabetes with peripheral neuropathy, for which she is on amitriptyline. She has untreated hypothyroidism, but is treated for hypertension with nifedipine. Currently, she has constipation, and when the stool does pass, it is very dark in color, almost black.

Pathogenesis. The most common cause of constipation is generally a lack of dietary fiber and insufficient fluid intake. Calcium-channel blockers, oral ferrous sulfate, hypothyroidism, opiate analgesics, and medications with anticholinergic effects, such as the tricyclic antidepressants, all cause constipation. In the case of the patient described above, the most likely cause of the constipation is the ferrous sulfate.

Clinical Presentation. As written in the case, this patient's stool is dark. This only occurs with bleeding, bismuth subsalicylate ingestion, and iron replacement. However, GI bleeding gives diarrhea and not constipation because blood acts as a cathartic. Blood causes diarrhea, and iron tablets cause constipation.

Treatment. The general management is to stop medications that cause constipation, and then to make sure the patient consumes 20–30 grams of fiber daily and is well hydrated. Bulking agents, such as those used to manage diverticular diseases, are also helpful. Drug treatment of constipation includes milk of magnesia, cascara, bisacodyl, and docusate (Colace®). Enemas can be used for acute and serious constipation. Lactulose and polyethylene glycol (GoLYTELY®) can also be very effective.

COLON CANCER

Pathogenesis. The lifetime risk of colon cancer is >6%. Most cases occur sporadically, which is to say there is no clearly identified etiology. Diets that are high in red meat and fat lead to an increased risk for colon cancer, and smoking also increases the risk for colon cancer.

Clinical Presentation. Patients present with heme-positive, brown stool and chronic anemia when the cancer is in the right side of the colon. Left-sided lesions and cancer of the sigmoid colon are more often associated with symptoms of obstruction and with narrowing of stool caliber. This is because the right side of the colon is wider, and the stool is more liquid in that part of the bowel, making obstruction less likely on the right. Endocarditis by *Streptococcus bovis* and *Clostridium septicum* is often associated with **colon cancer**. Any patient presenting with endocarditis due to one of these organisms requires a GI work-up.

Diagnosis. Colonoscopy is clearly the most accurate diagnostic test. Sigmoidoscopy will only reach the lesion within the distal 60 cm of the colon. If the lesion is there, then the sensitivity of sigmoidoscopy is equal to colonoscopy. Only 60% of cancer occurs in this distal area. Barium studies are less accurate than colonoscopy. You also cannot biopsy with barium enema.

Treatment. The treatment of colon cancer depends on the stage of disease and the extent of its spread. Cancer that is localized to the mucosa, submucosa, and muscularis layers can easily be resected and cured. However, once the disease has penetrated the serosa and has spread into the surrounding tissues and lymph nodes, surgical resection will not be effective in eradicating the disease. Widespread disease is treated with chemotherapy. The mainstay of chemotherapy for GI malignancies, such as colon cancer, is 5-fluorouracil (5FU). Treatment for a single liver metastatic lesion is surgical resection.

Screening. The standard screening recommendation for colon cancer is annual fecal occult blood testing or colonoscopy every 10 years. Screening should occur in the general population after age 50. The most effective screening method is colonoscopy. False-positive stool guaiac tests can be caused by aspirin, NSAIDs, red meat, and poultry. False-negative tests can be caused by vitamin C. Sigmoidoscopy misses 40% of cancers which are proximal to the sigmoid colon.

If adenomatous polyps have been found on a previous colonoscopy, repeat colonoscopy in 3–5 years. In those who have a family history of colon cancer, screening should begin at age 40, or 10 years earlier than the family member, whichever is younger (also see Preventive Medicine chapter).

Hereditary Nonpolyposis Syndrome (Lynch Syndrome)

There are certain families who carry a genetic defect with a high degree of penetrance for causing colon cancer. The genetic defect does not cause polyps, however. By definition, the syndrome consists of having 3 family members in at least 2 generations with colon cancer. As a matter of definition, one of these cases should be premature, which is to say that it occurred in someone age <50. There is a very high incidence of ovarian and endometrial cancer in this syndrome as well. Up to 30% of patients develop endometrial cancer.

Screening. The recommendation for screening this population is to start at age 25 and undergo colonoscopy every 1 to 2 years.

Hereditary Polyposis Syndromes

Familial adenomatous polyposis has a very clear genetic defect. The adenomatous polyposis coli gene (APC) confers 100% penetrance for the development of adenomas by age 35 and of colon cancer by age 50. Polyps can usually be found as early as age 25.

Screening. Flexible sigmoidoscopy for familial adenomatous polyposis should be done every 1 to 2 years beginning at age 12. As soon as polyps are found, a colectomy should be performed, and a new rectum should be made from the terminal ileum.

By contrast, **juvenile polyposis syndrome** confers about a 10% risk of colon cancer. There are only a few dozen polyps, as opposed to the thousands of polyps found in those with familial polyposis. In addition, the polyps of the juvenile polyposis syndrome are hamartomas, not adenomas. Hamartomas confer very little risk of developing into cancer.

Cowden syndrome is another polyposis syndrome with hamartomas that gives only a very slightly increased risk of cancer compared with the general population. These polyposis syndromes can present with rectal bleeding in a child.

Screening. There is no recommendation for increased colon cancer screening with juvenile polyposis.

Other Polyposis and Colon Cancer Syndromes

Gardner syndrome is the association of colon cancer with multiple, soft-tissue tumors, such as osteomas, lipomas, cysts, and fibrosarcomas. The osteomas have a particular predilection for the mandible. The test question may ask, "What would you do if an x-ray finds osteomas as an incidental finding?" The answer would be to do colonoscopy.

Peutz-Jeghers syndrome is the association of hamartomatous polyps in the large and small intestine with hyperpigmented spots. These are melanotic spots on the lips, buccal mucosa, and skin. The risk of cancer is slightly increased above the general population. Most common presentation is with abdominal pain due to intussusception/bowel obstruction.

Turcot syndrome is simply the association of colon cancer with central nervous system malignancies.

Screening. There is no recommendation to perform increased cancer screening in any of these patients. These syndromes are not common enough to warrant a clear recommendation for uniform early screening. There is an association of endocarditis from *Streptococcus bovis* and colon cancer; therefore, if a patient has endocarditis from *S. bovis*, the patient should undergo colonoscopy.

Note

If an exam question asks, "What do you do if an x-ray finds osteomas as an incidental finding?," the answer would be to perform a colonoscopy.

GASTROINTESTINAL BLEEDING

A 72-year-old man with a history of aortic stenosis is brought to the emergency department with red/black stool several times today. His blood pressure is 94/60 mm Hg, and his pulse is 110/min.

What should you do first? The first thing to consider for a patient with GI bleeding is the treatment, not the etiology.

Treatment. The most important step in the **initial management** of severe GI bleeding is to begin fluid resuscitation with normal saline or Ringer's lactate. A complete blood count, prothrombin time, and type and crossmatch should be done, but if the patient is having a high volume bleed, such as in the case described above, you should never wait for the results of the tests to begin fluid resuscitation.

If the prothrombin time is elevated above the control, also give fresh frozen plasma. Vitamin K works too slowly, and if there is liver disease, it will not work at all. Platelets should be transfused if the platelet count $<50{,}000/mm^3$ and if the patient is actively bleeding.

A nasogastric tube is only useful to determine the site of bleeding to guide endoscopy. There is no direct therapeutic benefit to nasogastric tube placement. Saline or ice water lavage through the nasogastric tube is of no benefit. If the patient has a history of cirrhosis of the liver, or if there is occult cirrhosis (as found in a long-term alcoholic), octreotide should be added to this initial management plan to decrease portal hypertension.

All of the management described above is more important than performing endoscopy to determine a specific etiology. Fluids, blood, platelets, and plasma are indicated in all forms of severe GI bleeding if there is a coagulopathy. More than 80% of GI bleeding cases will stop spontaneously with appropriate fluid resuscitation, irrespective of the etiology. Endoscopy is performed later to determine the etiology.

Note

In >80% of cases, GI bleeding will resolve spontaneously with supportive management, irrespective of etiology.

Acute Bleeding. For acute bleeding, fluid resuscitation should be performed as described above. The hematocrit should be maintained at ≥30% in older patients and those who may have coronary artery disease. Younger patients will form their own reticulocytes and make their own blood over a few days and do not need to be transfused, unless their hematocrit is closer to 20%. Patients with gastritis or the possibility of ulcer disease should be treated with PPIs empirically until a definitive diagnosis can be made. H_2 blockers have no efficacy in acute GI bleeding.

Esophageal varices are treated with octreotide during acute episodes of bleeding in order to lower portal pressure. If this is ineffective, emergency endoscopy should be performed to place bands around the bleeding varices. Sclerotherapy will also stop acutely bleeding varices, but there is a much higher complication rate later on, such as stricture formation. If banding is not effective in stopping an acutely bleeding esophageal varix, then TIPS (transjugular intrahepatic portosystemic shunting) should be performed. A catheter is placed into the jugular vein and guided radiographically through the liver to form a shunt between the systemic circulation in the hepatic vein and the portal circulation through the portal vein. TIPS has largely replaced the need to surgically place the shunt. The most common, long-term complication of TIPS is worsening of hepatic encephalopathy.

A Blakemore tube to tamponade the site of bleeding in the stomach or esophagus is rarely used and is only a temporary bridge to surgery.

Propranolol is a nonselective beta-blocker used in the long-term management of portal hypertension to decrease the frequency of bleeding. Everyone with varices from portal hypertension and cirrhosis should be on a beta-blocker.

Note

Consider the treatment, not the etiology, first when a patient is experiencing GI bleed.

Pathogenesis. The most common causes of **upper** GI bleeding are ulcer disease, gastritis, Mallory-Weiss syndrome, esophagitis, and gastric cancer. Variceal bleeding is common in those with portal hypertension from cirrhosis. By definition, upper GI bleeding is defined as bleeding occurring proximal to the ligament of Treitz, which anatomically separates the duodenum from the jejunum. If there is a history of abdominal aortic aneurysm repair in the past 6 months to a year, think about an aortoenteric fistula.

Lower GI bleeding is most commonly caused by diverticulosis, angiodysplasia (also know as AVM or vascular ectasia), hemorrhoids, cancer, and inflammatory bowel disease.

Clinical presentation. Generally, lower GI bleeding presents with red blood in the stool, and upper GI bleeding presents with black stool, or melena.

Note

Lower GI bleeding presents with red blood in the stool, whereas upper GI bleeding presents with black stool or melena.

Upper GI bleeding can also give hematemesis if the volume of bleeding is high enough. About 10% of cases of red blood from the rectum can be from an upper GI source. This can happen if the volume of bleeding is so high that the blood is rapidly transported to the bowel without the time for it to oxidize and turn black. In upper GI bleeding, occult blood–positive brown stool can occur with as little as 5 to 10 mL of blood loss. The same is true of "coffee-ground" emesis. Melena develops when at least 100 mL of blood have been lost.

Orthostasis is defined as a >10-point rise in pulse when the patient goes from the supine to the standing or sitting position. It is also defined as a >20-point drop in systolic blood pressure on a change in position. There should be at least a minute in between the position change and the measurement of the pulse and blood pressure to allow time for the normal autonomic discharge

to accommodate to the position change. Orthostasis is when the rise in pulse or drop in blood pressure persists after the position has been changed. It indicates a 15 to 20% blood loss. The measurement of orthostatic changes is not necessary in the patient described in this case because a pulse >100/min or a systolic blood pressure <100/min already indicates a >30% blood loss.

Diagnosis. Endoscopy is the most accurate test to determine the etiology of both upper and lower GI bleeding. Barium studies are always less accurate. You also cannot biopsy unless endoscopy is performed.

Occasionally, in lower GI bleeding, endoscopy will not reveal the etiology even when there is active bleeding. A nuclear bleeding scan can detect low volume bleeds 0.1–0.5 mL/min. Red cells from the patient are tagged with technetium and reinjected back into the patient. These tagged cells are then detected to determine the site of bleeding.

Angiography is rarely used in the evaluation of lower GI bleeding because it needs a higher volume of blood loss >0.5 mL/min compared with the tagged nuclear scan. Angiography, however, is useful in extremely high-volume bleeding in which so much blood is coming out that endoscopy cannot see the source. It may then be used prior to either embolization of the site of the bleeding or hemicolectomy. Angiography can also help guide the occasional use of a local vasopressin injection in the control of severe lower GI bleeding.

Despite all of these methods, an etiology of GI bleeding cannot be determined in about 5% of patients. This is often because the upper endoscope only goes as far as the ligament of Treitz, and the lower endoscope only reaches just past the ileocecal valve. When both of these modalities are unrevealing, the most likely source of the bleeding is in the small bowel. The small bowel is very difficult to visualize, and barium studies are inaccurate. The newest modality to visualize the small bowel is capsule endoscopy, in which a patient swallows a capsule with an electronic camera that can transmit thousands of images to a receiver near the patient. This will allow anatomic localization of the lesion.

Virtual endoscopy is a CT scan used to try to detect cancer without the need of endoscopy. Virtual endoscopy lacks both sensitivity and specificity to detect causes of GI bleed, and therefore should not be ordered for this purpose.

ACUTE PANCREATITIS

Pathogenesis. The majority of cases of pancreatitis are due to alcoholism and gallstones. Other causes are as follows:

- Medications such as pentamidine, didanosine (DDI), azathioprine, and sulfa derivatives, like sulfamethoxazole/trimethoprim and thiazide diuretics
- Hypercalcemia
- Hypertriglyceridemia, in which elevated triglycerides are broken down to fatty acids, causing inflammation of the biliary tract and eventual pancreatitis
- Endoscopic retrograde cholangiopancreatography (ERCP), presumably because of back pressure from injection of the contrast material into the ductal system. Most people who have pancreatic injury from ERCP just have an asymptomatic increase in amylase. Only 2–8% of patients actually develop symptomatic pancreatitis.
- Trauma and various viruses, such as mumps
- Premature activation of trypsinogen into trypsin while still in the pancreas (common pathway of most causes of pancreatitis). This results in autodigestion of the pancreas.

Clinical Pearl

Always consider gallstone pancreatitis and rule it out by U/S, even in patients with history of alcohol use.

Clinical Presentation. Midepigastric pain with tenderness, nausea, and vomiting has always been the presentation of acute pancreatitis in the majority of cases. The pain of pancreatitis classically radiates straight through to the back. When pancreatitis is extremely severe, it can mimic many of the features of septic shock, such as fever, hypotension, respiratory distress from ARDS, elevation of the white cell count, and a rigid abdomen.

Diagnosis. The initial tests remain as amylase and lipase. Lipase is more specific to the pancreas than is the amylase. An increased severity of disease and a worse prognosis are indicated by the presence of decreased serum calcium, elevated white cell count, hypoxia, and elevated glucose, LDH, and AST. The glucose will go up in the most severe forms of pancreatitis because of the loss of both endocrine function and insulin production. Calcium decreases because the malabsorption of fat allows the fat to bind with calcium in the bowel and diminish its absorption. The BUN goes up because of intravascular volume depletion. Hypertriglyceridemia can give a falsely normal amylase level.

The most accurate test to determine the severity of pancreatitis is the CT scan, which is more accurate than a sonogram for the presence of inflammation, as well as for detecting necrosis, pseudocysts, abscesses, and the presence of ductal stones. The APACHE score is also used to stratify acute pancreatitis.

The single most accurate test for the detection of biliary and pancreatic ductal pathology is the ERCP.

Treatment. There is no specific therapy to reverse pancreatitis. The inflammation and auto-digestion of the pancreas must resolve on its own over time. For most pancreatitis cases, the management is only supportive, with IV fluids, bowel rest, and pain medication. ERCP is sometimes necessary to remove a stone in the pancreatic duct or to dilate a stricture.

When pancreatitis is very severe, such as when there is >30% necrosis visible on the CT scan, the risk of infected and hemorrhagic pancreatitis markedly increases. For this reason, necrosis on a CT scan is an indication for starting antibiotics, such as imipenem or meropenem, which will diminish both the risk and severity of hemorrhagic and infected pancreatitis. Severe necrosis, particularly when there is a persistent fever, is also an indication to perform a percutaneous needle biopsy of the pancreas. If there is infection of the pancreas in addition to necrosis, urgent surgical debridement is indicated. (This is before the development of an abscess, which does not begin for 4 to 6 weeks after the onset of pancreatitis.)

Pseudocysts develop only 2 to 4 weeks after the episode of pancreatitis. Pseudocysts should be drained if there is pain, fistula formation, and rupture or if the pseudocyst is expanding in size. Asymptomatic pseudocysts do not need to be drained unless there is concern.

Note

Signs of Severe Necrotizing Pancreatitis

Cullen sign: blue discoloration around umbilicus → due to hemoperitoneum

Turner's sign: bluish purple discoloration of the flanks → tissue catabolism of Hb.

Note

IV fluid intake in large volumes is the most important management of acute pancreatitis.

Other Complications of Pancreatitis

- Ascites (high in amylase)
- Pleural effusion (transudate, ↑ amylase)
- Splenic vein thrombosis (think when there are gastric varices but no esophageal varices)

Wikipedia, James Heilman, MD

Figure 4-3. Pancreatic Pseudocyst

LIVER DISEASE AND CIRRHOSIS

Pathogenesis. Cirrhosis develops when there is chronic and severe inflammation of the liver for an extended period of time. The regenerative capacity of the liver is enormous; however, over a long time, fibrosis develops. And when at least 70 to 80% of liver function has been lost, the synthetic capacity of the liver is diminished.

The most common cause of cirrhosis in the United States is alcohol. (However, the most common reason to need a liver transplantation is chronic hepatitis C.) The other causes of cirrhosis are primary biliary cirrhosis, sclerosing cholangitis, alpha-1 antitrypsin deficiency, hemochromatosis, and Wilson disease.

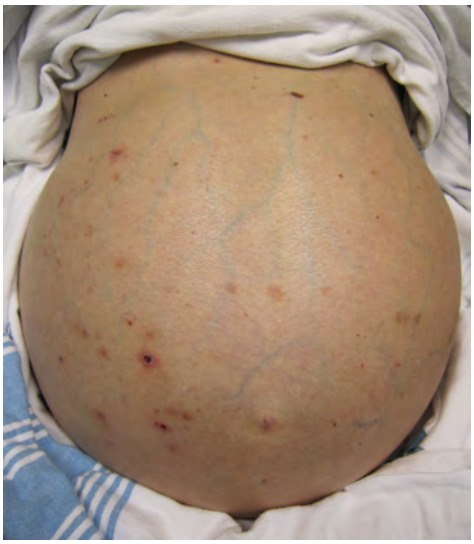
Clinical Presentation/Laboratory Abnormalities. The features common to all forms of cirrhosis, despite the etiology, are a low albumin level, portal hypertension, esophageal varices, ascites, peripheral edema, an elevated prothrombin time, spider angiomata, palmar erythema, asterixis, and sometimes, encephalopathy. Jaundice can develop in any form of cirrhosis or liver disease. The prothrombin time is prolonged because of the loss of ability to synthesize clotting factors. (All of the clotting factors are made in the liver, with the exception of factor VIII and Von Willebrand factor, which are made in the vascular endothelial cells.)

Ascites is the result of portal hypertension. A paracentesis is a sample of the ascitic fluid obtained by needle through the anterior abdominal wall. A paracentesis is used to exclude infection, as well as to determine the etiology of the ascites if it is not clear from the history.

Spontaneous bacterial peritonitis (SBP) is an idiopathic infection of ascites. The Gram stain is rarely positive because the density of microorganisms is so low. Although culture of the fluid is the most specific test, we cannot wait for the results of the culture to make a decision as to whether to give antibiotics. A total white cell count >500/mm^3 or the presence of >250/mm^3 neutrophils are the criteria to determine the presence of infection. Cefotaxime and ceftriaxone are the drugs of choice for SBP and albumin infusion decreases risk of hepatorenal syndrome.

Note

Although a culture of the ascitic fluid is the most specific test for SBP, one cannot wait for the culture results when determining whether to give antibiotics.



Wikipedia, James Heilman, MD

Figure 4-4. Ascites

Serum-Ascites Albumin Gradient. Normally, the ascitic fluid albumin level is less than the serum level. The **difference between them** is referred to as the serum-ascites albumin gradient, or SAAG.

- When this gradient, or SAAG, is >1.1, portal hypertension, as from cirrhosis, is generally the cause.
- When the SAAG is <1.1, it means the ascitic fluid albumin level is high. Cancer and infections generally give a SAAG <1.1.

Clinical Pearl

Remember to subtract the lower number (ascites albumin) from the higher number (serum albumin) when calculating SAAG.

Treatment. There is no specific therapy to reverse cirrhosis. (A complication to consider is hepatocellular carcinoma.) One can only manage the complications of cirrhosis and treat the underlying causes. Edema and fluid overload in third spaces, such as ascites, are managed with diuretics. The diuretic most useful in cirrhosis is spironolactone. This is because cirrhotics have intravascular volume depletion, which results in a high aldosterone state.

Portal hypertension and varices are managed with propranolol to prevent bleeding. Encephalopathy is managed with neomycin or lactulose, a nonabsorbed disaccharide that bacteria metabolize in the colon, making it more acidic. This converts the NH_3 to NH_4^+, or ammonia to ammonium. Ammonium is not absorbed very well, and this leads to an overall increased excretion of ammonia from the body.

Although vitamin K is often given because of the elevated prothrombin time, it is not effective because the liver is not able to synthesize clotting factors, no matter how much vitamin K is present.

Primary Biliary Cirrhosis

Pathogenesis. Primary biliary cirrhosis is an idiopathic autoimmune disorder that occurs more often in middle-aged women. Bilirubin levels do not elevate until the disease is extremely far advanced, which is usually after 5 to 10 years. Primary biliary cirrhosis has

a strong association with other autoimmune diseases, such as Sjögren syndrome, rheumatoid arthritis, and scleroderma.

Clinical Presentation. The most common symptoms are fatigue and pruritus. At least a third of patients, however, are asymptomatic but are found to have an elevated alkaline phosphatase level when measured for other reasons. Osteoporosis and hypothyroidism are found in 20 to 30% of patients.

Diagnosis. The transaminases are often normal. The most common abnormality is an elevation of alkaline phosphatase and gamma glutamyl transpeptidase (GGTP). Total IgM levels are also elevated. The most specific blood test is the antimitochondrial antibody.

Biopsy is always the best way to diagnose liver disease. It is the only test more specific than antimitochondrial antibodies.

Treatment. There is no specific therapy for primary biliary cirrhosis. Steroids will not help. Bile acid medication, such as ursodeoxycholic acid and cholestyramine, are used with variable success. Ultraviolet light is recommended to treat the pruritus. Also liver transplant for late stage PBC may also be considered.

Primary Sclerosis Cholangitis

Pathogenesis. This is an idiopathic disorder of the biliary system most commonly associated with inflammatory bowel disease (IBD). Although it is more often found with ulcerative colitis, it can also occur with Crohn's disease. Cancer of the biliary system can develop in 15% of patients from the chronic inflammation.

Clinical Presentation and Diagnosis. The presentation and general laboratory tests are generally the same as those for primary biliary cirrhosis, except that the antimitochondrial antibody test will be negative. The most specific test for primary sclerosis cholangitis is an ERCP or transhepatic cholangiogram. This is the only chronic liver disease in which a liver biopsy is not the most accurate test.

Treatment. Therapy is the same as for primary biliary cirrhosis, with ursodeoxycholic acid. Also, liver transplant may be considered.

Note

Primary sclerosis cholangitis is the only chronic liver disease in which a liver biopsy is not the most accurate test.

Hemochromatosis

Pathogenesis. Hemochromatosis is one of the most common inherited genetic diseases. There is an overabsorption of iron in the duodenum, leading to iron buildup in a number of tissues throughout the body. This leads to chronic hepatic inflammation and fibrosis.

Clinical Presentation. Cirrhosis is the most common finding. Hepatocellular cancer develops in 15 to 20% of patients. Restrictive cardiomyopathy develops in approximately 15% of patients. Arthralgias, skin hyperpigmentation, diabetes, and hypogonadism are also common. *Vibrio vulnificus* and *Yersinia* infections occur with increased frequency because of their avidity for iron.

Diagnosis. Screening for the disorder is by finding an elevated iron level and diminished iron-binding capacity. The ferritin is also elevated. The most accurate test is a liver biopsy and abnormal C282Y gene; MRI can eliminate the need for biopsy if both are present.

Treatment. Phlebotomy is used to remove large amounts of iron from the body—it removes far more iron than do the chelating agents deferoxamine and deferasirox. Deferoxamine and deferasirox are used only in those who cannot undergo phlebotomy.

Wilson Disease

Pathogenesis. Wilson disease is an autosomal recessive disorder leading to the diminished ability to excrete copper from the body. There is also increased copper absorption from the small intestine.

Note

A patient presenting with choreoathetoid movements and psychosis gives the clue to perform the slit-lamp examination. Kayser-Fleischer rings are then found, confirming the diagnosis of Wilson disease.

Clinical Presentation. Copper builds up in the liver, brain, and cornea. Basal ganglia dysfunction contributes to the movement disorder that develops. Ten percent of patients have a psychiatric disturbance. Kayser-Fleischer rings are found in the eye on slit-lamp examination. Tremor and Parkinson's occur in one-third of all patients. Fanconi syndrome and type II proximal renal tubular acidosis develop because of copper deposition in the kidney.

Diagnosis. The most specific blood test is a low ceruloplasmin level, but a low ceruloplasmin level alone is not enough. There is also a high urinary copper level. But again, the single most specific test is a liver biopsy, which will demonstrate increased copper deposition in the liver. Occasionally, there is a hemolytic anemia when the copper levels go high and are toxic to the red cells.

Treatment. Penicillamine and trientine are copper chelators. Oral zinc interferes with copper absorption. Liver transplantation is curative, and steroids will not help.

Alpha-1 Antitrypsin Deficiency

Pathogenesis. Alpha-1 antitrypsin deficiency (AATD) is an autosomal recessive condition which causes low levels of—or no—alpha-1 antitrypsin (AAT) in the blood. The condition is found in all ethnic groups but occurs most often in whites of European ancestry. AAT protects the lungs so they can have normal function. AAT is made in the liver; without enough of it, the lungs become damaged, leading to emphysema.

- Everyone has 2 copies of the gene for AAT and receives 1 copy of the gene from each parent.
- Patients with AATD have 1 normal copy and 1 damaged copy, or they have 2 damaged copies.
  - Most patients with 1 normal gene can produce enough AAT to live healthy lives, especially if they do not smoke.
  - Those with 2 damaged copies of the gene are generally not able to produce enough AAT, leading them to have more severe symptoms.

Clinical Presentation. The most prominent finding is emphysema developing at a young age in a nonsmoker. Approximately 15% of those with AATD develop cirrhosis. Large amounts of abnormal AAT are made in the liver; nearly 85% of this protein accumulates in the liver causing inflammation and eventually, fibrosis.

Diagnosis. Testing for AATD, using a blood sample from the individual, is simple, quick and highly accurate. Three types of tests are usually done on the serum sample:

- Alpha-1 genotyping, which examines a person's genes and determines his genotype
- AAT PI type of phenotype test, which determines the type of AAT protein a person has
- AAT level test, which determines the amount of AAT in a person's blood

Treatment. There is no specific therapy for the liver disease. Those with emphysema should receive replacement of the enzyme and stop smoking.

Chronic Hepatitis B and C

Pathogenesis. Hepatitis B and C are transmitted by blood products, needlestick injury, and sexual contact. Injection drug use is also strongly associated with both viruses.

- Hepatitis C virus causes 60–70% of cases of chronic hepatitis; at least 80% of acute hepatitis C cases become chronic
- About 10% of hepatitis B cases, sometimes with hepatitis D coinfection, become chronic; hepatitis D does not occur by itself but rather only as a coinfection with hepatitis B
- Rarely, hepatitis E virus causes chronic hepatitis in those with weakened immune systems (organ transplant treatment, chemotherapy for cancer, HIV infection)
- Hepatitis A virus does not cause chronic hepatitis

Hepatitis C is the most common cause of chronic hepatitis in the United States; it is also the most common cause of cirrhosis and hepatocellular carcinoma.

Clinical Presentation. Most patients are asymptomatic until the disease is very far advanced.

Diagnosis.

- To **confirm hepatitis B**: persistence of hepatitis B surface antigen >6 months (though it takes years for cirrhosis to develop)
  - Remember, in **chronic hepatitis B, the hep B surface antibody is negative**.
- To confirm hepatitis C: finding an antibody to hepatitis C, and then finding an elevation of the viral load by PCR methods
  - Single most accurate test to diagnose the extent of liver disease is liver biopsy

Treatment. Chronic hepatitis B is treated with interferon, lamivudine, entecavir, telbivudine, or adefovir. Combining these agents does not lead to increased efficacy.

Chronic hepatitis C is now cured with the new combination antiviral drugs. The most commonly used is **ledipasvir/sofosbuvir** (trade name **Harvoni**), a 2-drug combination. It is administered as a 1x/ daily pill containing the viral NS5A inhibitor ledispavir and a nucleotide inhibitor of the viral RNA polymerase, sofosbuvir. Taken daily for 8–12 weeks, it provides cure rates of 94–99% in those infected with genotype 1 (the most common form of hepatitis C in the United States and some European countries), irrespective of the presence or absence of liver cirrhosis or prior unsuccessful treatment. It has also been evaluated for the treatment of infection with other hepatitis C genotypes and has shown promising results in genotypes 3 and 4.

Cardiology 5

Learning Objectives

- Outline a differential diagnosis and diagnostic plan for patients with acute chest pain or chest discomfort
- List the causes of and treatment for heart rate and rhythm disturbance
- Describe the physiology of valvular disease and CHF, and describe the mechanism of action of appropriate treatments
- Give an overview of presentation, epidemiology, and management of ischemic heart disease, acute coronary syndrome, myocardial disease, and pericardial disease
- Describe the most common medications used to treat cardiovascular disease and their most serious or common side effects

ACUTE CHEST PAIN/CHEST DISCOMFORT

Chest pain is one of the most common complaints for which a patient comes to the physician's office or the emergency department. Patients presenting with chest pain or chest discomfort may have an underlying cause that is benign and requires only moderate analgesic medication, or they may have a life-threatening condition such as acute myocardial ischemia or aortic dissection that mandates prompt diagnosis and treatment. In the evaluation of chest pain, the focus should be on excluding the more serious conditions.

History

Assessing the setting in which the chest pain occurs is one of the most important aspects of the evaluation. The 26-year-old medical resident with chest pain that occurred after on-call and who is otherwise healthy is unlikely to have cardiovascular disease, no matter the quality or duration of chest pain. Consider the 58-year-old man with type 2 diabetes and dyslipidemia with chest discomfort of any type; now the probability for cardiac-related chest pain increases dramatically.

Overall, the chest pain history is more useful than the physical examination. Important aspects of the history include duration, quality, location, radiation, frequency, alleviating or precipitating factors (especially exercise), and associated symptoms.

- For both stable angina and acute coronary syndromes, the quality of chest pain is described by the patient as "tightness," "heaviness," or "pressure," but symptoms which resemble acute abdomen (pain in the upper abdomen, nausea) are not uncommon. Nausea and vomiting are sometimes the main symptoms in inferoposterior wall ischemia (also, vagal reflexes may cause bradycardia and hypotension, presenting as dizziness or fainting).
- "Sharp" or "knife-like" chest pain and pain which the patient can pinpoint to an "exact area" are less likely to be related to ischemia or infarction, especially if the chest pain is reproduced by changes in position or palpation.
- Myocardial infarction is associated with pain that lasts >20–30 minutes in duration.
- Response of chest pain to nitroglycerin (within a few minutes) is most consistent with transient ischemia or esophageal spasm. Chest pain that worsens with nitroglycerin sometimes occurs with gastroesophageal reflux disease. The response to nitroglycerin is not enough to confirm coronary disease as the cause of chest pain.
- Acute coronary syndromes in women present with atypical symptoms: dyspnea, shortness of breath, fatigue. This may be due to the older age group in which myocardial ischemia and infarction occur in women.

Physical Examination

One of the most important parts of the examination of the chest pain patient is the "initial impression." Diaphoresis, tachypnea, and anxious expression should alert the clinician to a potentially life-threatening process. Tachycardia and tachypnea are both nonspecific but occur in almost all cases of pulmonary embolism.

- Blood pressure should be checked in both arms: a difference of >20 mm Hg systolic suggests aortic dissection and is present in ~70% of cases.
- Hypotension may suggest massive pulmonary embolism or cardiac shock.
- Fever may suggest pneumonia or mediastinitis (esophageal rupture) as the cause of chest pain.
- Evidence of atherosclerosis (corneal lipid rings, narrowed retinal arteries, and pigment and hair changes in the legs) is commonly seen in patients with coronary syndromes.

The chest wall should be inspected for tender areas, respiratory motion, respiratory retractions, or accessory muscle use. If the tender area corresponds to the location of the patient's pain and palpation exactly reproduces the pain, consider musculoskeletal chest pain as the cause of chest pain.

Abnormal heart sounds and new murmurs are commonly found in certain chest pain syndromes. Wide physiologic splitting of the second heart sound (splitting wider with inspiration) can be found in right bundle branch block or in right ventricular infarction. New paradoxical splitting is most often due to left bundle branch block (LBBB), or anterior or lateral infarction. A new fourth heart sound can occur with angina or infarction. An S3 is more likely due to underlying heart failure. A new murmur may be significant: aortic regurgitation occurs in over half of patients with aortic dissection, while mitral regurgitation can occur in patients with angina or infarction and is due to papillary muscle dysfunction.

The lungs should be auscultated for crackles and asymmetrical breath sounds. Asymmetry of breath sounds may be found in patients with spontaneous pneumothorax. Absent lung sounds also may occur in pneumothorax and pleural effusions.

The extremities should be examined for pulses, edema, calf tenderness, and signs of atherosclerotic vessel disease. Absence of pedal pulses may occur in aortic dissection. Any swelling of the legs, especially if unilateral, raises the odds of pulmonary embolism as the cause of chest pain.

Testing

All patients with chest pain should have a 12-lead **electrocardiogram** (**ECG**) since the **ECG is the single most important test** for the evaluation of the cause of chest pain. The ECG should be done immediately after initial stabilization and taking of vital signs. Most patients with myocardial infarction will have an abnormal initial ECG: 50% with acute MI will have diagnostic findings (ST elevation or Q waves), while 35% will have findings consistent with ischemia (ST depression and/or T wave inversion). In patients presenting with acute chest pain who have **normal ECG**, the chance of acute MI is much less than 10% (in some studies 1–2.6%). An abnormal ECG can be seen in many non-cardiac conditions (pulmonary embolism, electrolyte abnormalities, aortic dissection).

In interpreting the ECG, every effort must be made to obtain previous ECGs, so that the abnormalities can be compared with those on the old tracing. Any ECG finding is assumed to be new unless proven otherwise by an old ECG (if one is available). Also, in patients with acute coronary syndromes, the ECG is the sole test required to select patients for emergency reperfusion.

Serum **cardiac biomarker** determinations play a vital role in the evaluation of patients who present with acute chest pain and in the diagnosis of acute myocardial infarction. Serum markers such as aspartate transaminase, lactate dehydrogenase, and lactate dehydrogenase subforms no longer are used because they lack cardiac specificity and their delayed elevation precludes early diagnosis. Creatine kinase (CK) is found in striated muscle and tissues of the brain, kidney, lung, and GI tract. This widely available marker has low sensitivity and specificity for cardiac damage. Furthermore, CK levels may be elevated in a number of noncardiac conditions, including trauma, seizures, renal insufficiency, hyperthermia, and hyperthyroidism. Currently, the CK marker largely has been replaced by cardiac troponins and CK-MB.

CK-MB isoenzyme: CK-MB is cardiac specific and is useful for the early diagnosis of acute myocardial infarction. CK-MB typically is detectable in the serum 4–6 hours after the onset of ischemia, peaks in 12–24 hours, and normalizes in 2–3 days (*see* Figure 5-1).

Like the CK level, the peak CK-MB level *does not predict infarct size*; however, it can be used to *detect early reinfarction*. Serial CK-MB levels commonly are obtained at admission to the emergency department and are repeated in 6–12 hours.

CK-MB subforms: CK-MB may be further characterized into subforms (or isoforms). CK-MB2 is found in myocardial tissue, and CK-MB1 is found in plasma. The CK-MB subform is not routinely used.

Cardiac troponins: Troponins (T, I, C) are found in striated and cardiac muscle. Because the cardiac and skeletal muscle isoforms of troponin T and I differ, they are known as the "cardiac troponins." They are the *preferred markers* for the diagnosis of myocardial injury. Troponin T and I generally have similar sensitivity and specificity for the detection of myocardial injury. Unlike troponin I levels, troponin T levels may be elevated in patients with renal disease, polymyositis, or dermatomyositis.

The cardiac troponins typically are measured at emergency department admission and repeated in 6–12 hours. Patients with a normal CK-MB level but elevated troponin levels are

considered to have sustained *minor myocardial damage,* or microinfarction, whereas patients with elevations of both CK-MB and troponins are considered to have had *acute myocardial infarction*. The cardiac troponins may remain elevated *up to two weeks* after symptom onset, which makes them useful as late markers of recent acute myocardial infarction.

An elevated troponin T or I level is helpful in identifying patients at increased risk for death or the development of acute myocardial infarction. Increased risk is related to the high serum troponin levels. The troponins also can help identify low-risk patients who may be sent home with close follow-up. Those with a normal or nearly normal ECG and a normal troponin I test 6 hours after admission had a very low risk of major cardiac events (0.3%) during the next 30 days.

Myoglobin: Myoglobin levels begin to rise as early as 1–4 hours after the onset of pain. Normal myoglobin at 4 hours has a very high negative predictive value.

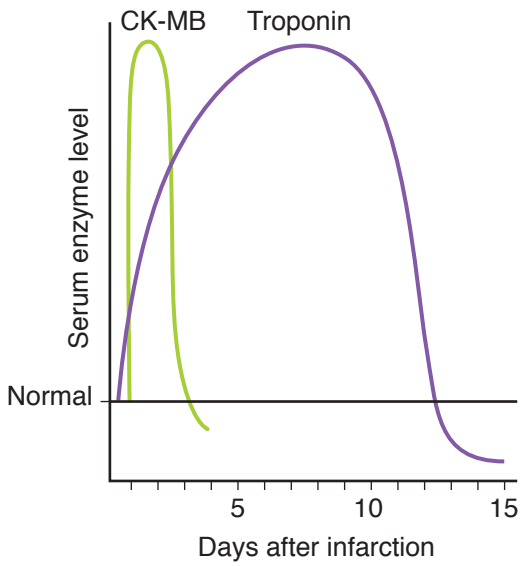


Figure 5-1. Progression of Cardiac Enzyme Serum Levels

A **chest x-ray** should be obtained on patients with chest pain. The x-ray may show pneumothorax, pneumomediastinum (such as from esophageal rupture), pleural effusion, or infiltrates. Aortic dissection can cause widening of the mediastinum. Subtle findings such as loss of lung volume or unilateral decrease in vascular markings may suggest pulmonary embolism.

Especially if the clinician suspects a noncardiac diagnosis, other tests may be helpful in the evaluation of patients presenting with acute chest pain. Some of the most common ones used are: arterial blood gases, BNP (see pulmonary and heart failure section), CT angiogram.

Causes of Chest Pain

Aortic Dissection. Pain is sharp, tearing, and extremely severe; typically radiates to back; loss of pulses or aortic insufficiency often develop; mediastinum is widened on chest x-ray; MI may occur if dissection extends into coronary artery; diagnosis confirmed by MRI, CT scan, or transesophageal echocardiogram.

Pulmonary Embolism. Dyspnea, tachycardia, and hypoxemia are prominent; pain is usually pleuritic, especially when pulmonary infarction develops; EKG is usually nonspecific but may show S wave in lead I, Q wave in lead III, or inverted T wave in lead III; diagnosis confirmed by CT angiogram.

Pericarditis. May be preceded by viral illness; pain is sharp, positional, pleuritic, and relieved by leaning forward; pericardial rub often present; diffuse ST elevation occurs without evolution of Q waves; CK level usually normal; responds to anti-inflammatory agents.

Table 5-1. Differential Diagnosis of Conditions Causing Chest Pain

Noncardiovascular Disorders	Differentiating Features
Costochondritis	Pain exacerbated with inspiration; reproduced with chest wall palpitation
Hiatal hernia	Reflux of food; relief with antacids
GERD	Acid reflux; relief with antacids
Peptic ulcer	Epigastric pain worse 3 h after eating
Gallbladder disease	Right upper quadrant abdominal pain and tenderness
Cardiovascular Disorders	**Differentiating Features**
Myocardial infarction	Pain more severe, usually >20 min in duration
Aortic stenosis	Typical systolic ejection murmur
Myocarditis	Pain is usually vague and mild if present
Pericarditis	Pain is sharper, pain worse with lying down and relieved by sitting up
Dissecting aortic aneurysm	Pain is sharp, tearing, often occurs in back
Mitral valve prolapse	Transient pain, midsystolic click murmur, and young female with no risk factors
Pulmonary Disorders	**Differentiating Features**
Pulmonary embolus-infarction	Tachypnea, dyspnea, cough, pleuritic pain, hemoptysis
Pulmonary hypertension	Signs of right ventricle (RV) failure
Pneumothorax	Sudden onset of pain and dyspnea

Myocarditis. May be preceded by viral illness; pain is generally vague and mild if present; total CK and MB fraction of CK (CK-MB) are often elevated; conduction abnormalities and Q waves may occur.

Musculoskeletal Disorders. Most common cause of chest pain. Includes costochondritis, cervical osteoarthritis, radiculitis; pain is atypical, stabbing, localized, may be pleuritic; reproduced by motion or palpation; EKG changes absent.

GI Disorders. Esophageal reflux is often made worse with recumbency or after meals, may be associated with regurgitation and relieved by antacids; episodes of spasm may be brought on by cold liquids, relieved by nitroglycerin, and may closely resemble angina or infarction; diagnosis may be confirmed by upper endoscopy or esophageal manometry. Peptic ulcer disease, pancreatitis, and cholecystitis may occasionally mimic infarction; abdominal tenderness is present, with radiation to back and elevated amylase in pancreatitis; sonography can confirm cholecystitis.

Pneumothorax. Onset abrupt with sharp pleuritic chest pain and dyspnea; breath sounds absent; chest x-ray confirms.

Pleuritis. Pain is sharp and increases on inspiration; friction rub or dullness may be present; other respiratory symptoms and underlying pulmonary infection usually present.

ISCHEMIC HEART DISEASE

Ischemic heart disease (IHD), also known as coronary heart disease, refers to an imbalance in coronary oxygen demand and supply resulting from insufficient blood flow. In nearly all cases, the reduction in blood flow is caused by coronary atherosclerotic disease. When the atherosclerotic plaque ruptures, there is superimposed thrombus formation that acutely occludes the artery; this is the most common cause of life-threatening acute coronary syndromes.

Rarely, other abnormalities may occur, including coronary artery embolism, coronary artery spasm, coronary arteritis, and coronary artery dissection (*see* section on nonatherosclerotic acute coronary syndromes) that may cause ischemic heart disease in the absence of atheroma formation.

IHD is one of the most prevalent diseases in society, and those affected are likely to die from their disease (though age-specific deaths have declined over the past 30 years). IHD, as part of a systemic process that involves all arteries in the body, is an insidious process that begins in early adulthood with fatty streaks; these lesions progress into plaques and thrombus formation in middle age.

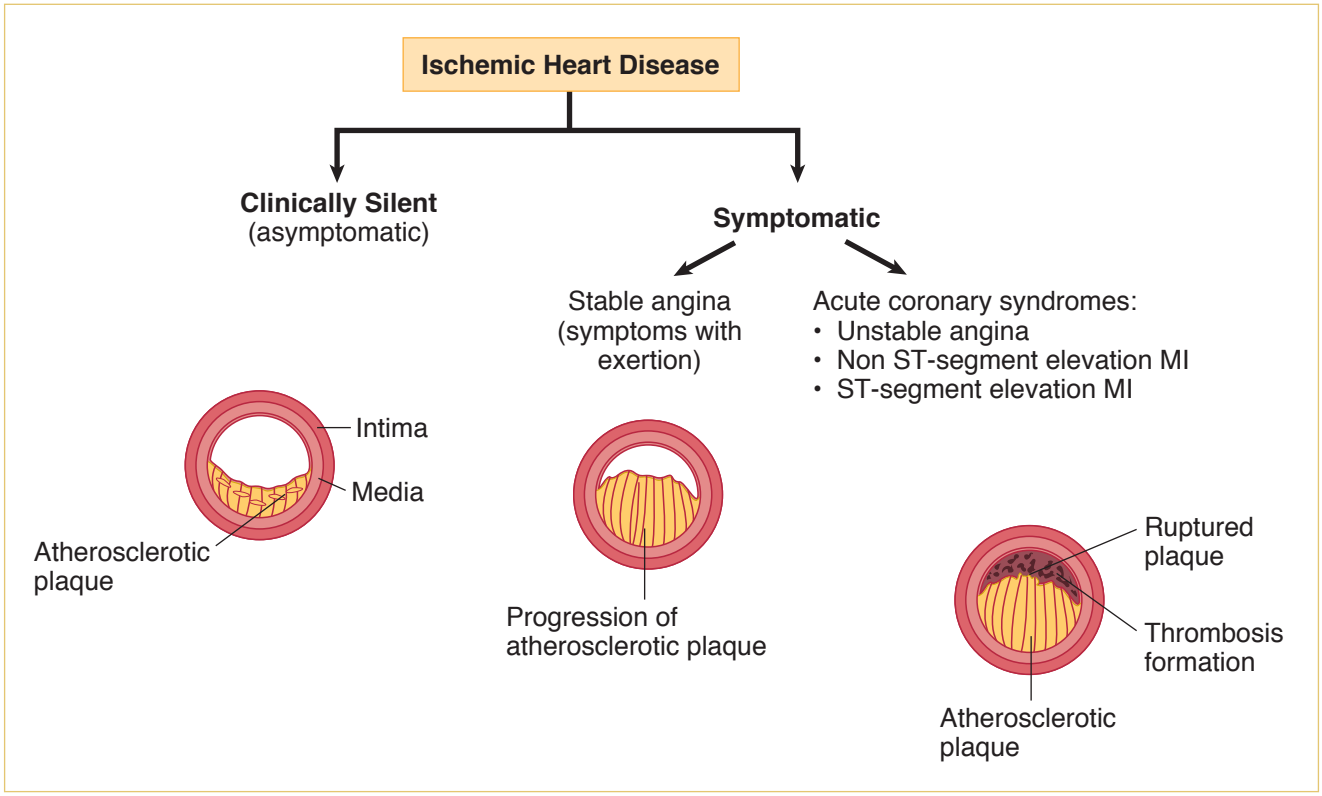

Figure 5-2. Ischemic Heart Disease

The more risk factors a person has, the greater the chance that he will develop heart disease. Also, the greater the level of each risk factor, the greater the risk. For example, a person with total cholesterol 260 mg/dL has a greater risk than someone with total cholesterol 220 mg/dL, even though all people with total cholesterol ≥220 are considered high risk.

Major Modifiable Risk Factors

Elevated cholesterol levels: The risk of IHD rises as blood cholesterol levels increase. The concentrations of lipid fractions, especially low-density lipoprotein (LDL) and high-density lipoprotein (HDL), are also important. LDL cholesterol is the **single most important subgroup** that carries risk for IHD, although there are several other abnormalities that increase coronary risk: low HDL cholesterol, hypertriglyceridemia, increased total-to-HDL-cholesterol ratio and increased lipoprotein A. When other risk factors (such as high blood pressure and tobacco smoke) are present, this risk increases even more.

Proof of the importance of serum cholesterol has come from randomized trials, which showed that reductions in total LDL levels reduce coronary events and mortality.

Tobacco: Cigarette smoking is an important factor for IHD because a smoker's risk of heart attack is >2x that of a nonsmoker. Cigarette smoking also acts with other risk factors (hypertension, dyslipidemia) to greatly increase the risk for IHD.

- Cigar or pipe smokers have a higher risk of death from IHD, though less than cigarette smokers.
- Secondhand smoke or passive smoking increases the risk of heart disease, even for nonsmokers.
- The risk for myocardial infarction in those who quit smoking was reduced to that of nonsmokers within 2 years of cessation; the benefits were seen regardless of how long or how much the patient smoked.

Hypertension (HTN): HTN is a well-established risk factor for increase in risk of myocardial ischemia, stroke, kidney failure, and heart failure. Studies in the general population have shown that the risk for cardiovascular events increases at BP >110/75 mm Hg. Systolic BP is as important as diastolic BP in terms of risk for IHD, especially in older patients.

Treatment of HTN to optimal levels reduces the risk of IHD and all cardiovascular events. In fact, data from recent randomized trials suggest that reducing BP below previously recommended levels is beneficial in high-risk patients.

Physical inactivity and exercise: Inactivity and sedentary lifestyle are risk factors for IHD. Exercise of moderate degree has a protective effect against IHD and cardiovascular events. More vigorous activities are associated with more benefits. Physical activity can help increase HDL cholesterol and control diabetes and obesity, as well as help to lower blood pressure.

Obesity: Patients with increased body fat (elevated body mass index), especially if a lot is in the waist area, are more likely to develop heart IHD and stroke. Excess weight raises blood pressure, blood cholesterol, and triglyceride levels, and it lowers HDL cholesterol levels. It can also increase risk for type 2 diabetes by causing insulin resistance.

Studies have shown that loss of as little as 10–20 lb can significantly reduce the risk of cardiovascular disease.

Diabetes mellitus: Elevated blood glucose levels and insulin resistance are associated with IHD and overall cardiovascular events. All-cause mortality in diabetic patients is comparable to that of all-cause mortality in patients with prior myocardial ischemia; hence, diabetes is now considered an "IHD equivalent." Even when glucose levels are under control, diabetes greatly increases the risk of IHD. Almost 75% of patients with diabetes die of some form of cardiovascular disease.

There is compelling evidence that aggressive treatment of HTN and cholesterol, as well as tight glycemic control, reduces the risk of cardiovascular events in these patients significantly.

Major Uncontrollable Risk Factors

Age: Four out of 5 people who die of IHD are age ≥65. Also, women who develop myocardial ischemia at older ages have a higher mortality than men within the first few weeks of the cardiac event.

Sex: Men have a greater risk of IHD than women, and overall they develop cardiovascular disease earlier in life.

Heredity: Family history is a significant independent risk factor if there is a family history of premature disease (age <55 in male relative and <65 in female relative).

Minor Contributing Factors

Sex hormones: Men have more heart attacks than women before menopause. Several population studies show that the decrease of natural estrogen as women age may contribute to a higher risk of heart disease after menopause.

Stress: Various studies have shown relationship between IHD risk and stress in a person's life. This may be a true association or just a secondary correlation: for example, people under stress may overeat, start smoking, or be less active than people who are not under stress.

Myocardial Ischemia As a Manifestation of IHD

During ischemia, an imbalance occurs between myocardial oxygen supply and demand. Ischemia may manifest in any of the following ways:

- Anginal chest discomfort
- ST-segment deviation on ECG
- Reduced uptake of tracer during myocardial perfusion scanning
- Regional or global impairment of ventricular function

Myocardial ischemia can occur as a result of increased myocardial oxygen demand, reduced myocardial oxygen supply, or both. In the presence of coronary obstruction, an increase of myocardial oxygen requirements caused by exercise, tachycardia, or emotion leads to a transitory imbalance. This condition is frequently termed **"demand ischemia"** and is responsible for most episodes of chronic stable angina.

In other situations, the imbalance is caused by acute reduction of oxygen supply secondary to marked reduction or cessation of coronary flow as a result of platelet aggregates or thrombi. This condition, termed **"supply ischemia,"** is responsible for myocardial infarction (MI) and most episodes of unstable angina (UA). In many circumstances, ischemia results from both an increase in oxygen demand and a reduction in supply.

Angina (Stable Angina)

> A 62-year-old man presents with substernal chest pain that occurs with exertion and is relieved by rest. He has been having this on and off for 8 months, and the last episode occurred 3 days ago while he was running to the bus. He has a history of well-controlled diabetes and dyslipidemia. Vital signs, physical examination, and ECG are normal. An exercise stress test shows a 2-mm ST depression.

Stable angina occurs when the myocardium becomes ischemic. This occurs during periods of increased demand for oxygen, such as exercise, or decreased supply, such as hypotension or anemia (*see* demand ischemia, above). Stable angina is typically a substernal pressure lasting 5–15 minutes. It may be accompanied by radiation to the jaw, neck, shoulders, or arms. It is less likely to have the symptoms often associated with MI: sweats, nausea, and shortness of breath. Anginal pain is not typically affected by respiration or by position. Typically, patients with stable angina will have pain after a predictable amount of exertion and will have identical symptoms with each attack.

In certain patients, symptoms other than pain may occur. For example, a profound sense of weakness and breathlessness may be an "angina equivalent." Atypical symptoms are more likely to occur in the elderly and in diabetics.

The physical exam is usually normal. A new S4 may be heard, suggesting a stiff ventricle due to ischemia.

Most patients with angina will have ECG changes **during an attack**. Most commonly, ST segment depression is seen. ST segment elevation occurs in variant angina (Prinzmetal angina) where coronary artery spasm is responsible and rarely during ischemia caused by stable angina (where atherosclerotic disease is responsible).

Diagnosis. The **exercise treadmill test (exercise stress test)** is the most useful test for evaluating the cause of chronic chest pain when there is concern about IHD (stable angina). Exercise stress testing provides a controlled environment for observing the effects of increases in the myocardial demand for oxygen. In order to do an appropriate analysis, a target heart rate must be reached.

- Target heart rate is 85% of predicted maximum heart rate: **85% × (220 – patient's age)**
- Reaching target heart rate makes test more accurate than if lower heart rate is achieved

Significant fixed stenoses of the coronary arteries will result in ECG evidence of ischemia. Low-grade stenoses (<50%) may not produce sufficient impairment of blood flow to affect the ECG; in these cases the stress test will be normal.

An exercise stress test is considered positive for myocardial ischemia when large (>2 mm) ST-segment depressions or hypotension (a drop of >10 mm Hg in systolic pressure) occur either alone or in combination. In general, the earlier the angina or ECG abnormalities occur, the more significant they will be. The exercise stress testing can help to do the following:

- Determine the severity of IHD and the need for further intervention, i.e., severe symptoms (hypotension) early in the test usually occur in those with triple-vessel disease
- Assess the effectiveness of treatment, i.e., coronary artery disease patients who have undergone surgical intervention or are receiving medical therapy have an exercise stress test when they are medically stable and symptom-free
- Determine functional capacity and identify any ECG changes or symptoms during (low level) exercise for patients who are post-MI

Exercise stress testing is contraindicated when it may place the patient at increased risk of cardiac instability, as in the following settings:

- Aortic dissection
- Acute myocardial infarction
- Unstable angina
- Severe CHF
- Uncontrolled sustained ventricular arrhythmias
- Symptomatic supraventricular arrhythmia
- Significant aortic stenosis
- Hypertrophic cardiomyopathy
- Severe uncontrolled hypertension

Patients who are unable to exercise or walk should be considered for **chemical stress testing**, such as dipyridamole (Persantine) or dobutamine stress test. Presence of baseline ECG abnormalities such as bundle branch block, left ventricular hypertrophy, or with a pacemaker, may make it more difficult to interpret test results. In those cases patients should be evaluated by nuclear stress imaging instead of the exercise stress test. These tests may also be used in patients who are taking digoxin.

In most cases, medications should not be withheld in preparation for an exercise stress test. Certain medications require special consideration:

- Beta blockers may blunt the heart rate during exercise and thus should be held 24 hours prior to the test. While patients receiving beta blockers may perform the exercise required for the test, the usual age-adjusted target heart rate may not be a realistic end point for them.
- Also, the antihypertensive effect of beta blockers, alpha blockers, and nitroglycerin may cause significant hypotension during exercise.

Digoxin may depress the ST segments, so if ST-segment depression of ≥1 mm is present on baseline ECG, the stress test results will be difficult to interpret.

A number of other situations or conditions may reduce the validity of the exercise stress test. Exercise testing in **asymptomatic, young women** yields an increased number of false-positive results, while exercise testing in patients with known CAD may result in an unacceptably high false-negative rate (e.g., a negative stress test in a 64-year-old man with diabetes, hyperlipidemia, and typical stable angina is likely to be a false-negative result).

> A 29-year-old woman has a routine stress test done that shows a 1-mm ST depression. She has no history of chest pain, and she exercises routinely (runs 2–3 miles per day, 3 times per week). Her physical examination is unremarkable.

The **most likely** cause of her abnormal stress test? **False-positive test.**

Other types of stress tests include:

- **Nuclear stress test:** A radioactive substance is injected into the patient and perfusion of heart tissue is visualized. The perfusion pictures are done both at rest and after exercise. An abnormal amount of thallium will be seen in those areas of the heart that have a decreased blood supply. Compared to regular stress tests, the nuclear stress tests have higher sensitivity and specificity (92% sensitivity, 95% specificity vs. 67% sensitivity, 70% specificity). These tests are also not affected by baseline changes in the ECG (LBBB, ST-segment depression at baseline, etc.).
- **Dobutamine or adenosine stress test:** Used in people who are unable to exercise. A drug is given to induce tachycardia, as if the person were exercising.
- **Stress echocardiogram:** Combines a treadmill stress test and an echocardiogram (ECHO). The latter can recognize abnormal movement of the walls of the left ventricle (wall motion abnormalities) that are induced by exercise.

Invasive techniques: Cardiac catheterization is also used in patients with stable angina for (*1*) diagnosis and (*2*) prognosis/risk stratification. Angiography is an appropriate diagnostic test when noninvasive tests are contraindicated or inadequate due to the patient's illness or physical characteristics (e.g., morbid obesity, COPD). Cardiac angiography is also used after conventional stress tests are positive to identify patients that will benefit from stent placement or bypass surgery.

Treatment. For individual episodes of angina, nitroglycerin (NTG) sublingual tablets typically alleviate the pain within 3 minutes. Long-term management is with long-acting nitrates and/or beta blockers. Other medications patients with stable angina should be taking, unless contraindicated, include aspirin and statins (for lipid lowering). Also, modify the risk factors (tobacco cessation, exercise, control of hypertension, etc.).

All patients with stable angina need evaluation of the severity of IHD (cardiac angiography or stress testing, *see* above), and those who will benefit from revascularization (stent or bypass surgery) need to be identified.

Lipid lowering treatment for secondary prevention is important in IHD patients who should be treated aggressively. Most patients will require both pharmacologic and nonpharmacologic interventions to reach target goals. Target goals for hyperlipidemic patients with coronary artery disease include:

- LDL <100 mg/dL
- HDL ≥40 mg/dL
- Triglycerides <150 mg/dL

The optimal LDL-cholesterol goal is considered to be <70 mg/dL for patients considered to be **very high risk**. These are patients with established cardiovascular disease plus diabetes and patients with acute coronary syndromes. Bottom line: almost all patients with chronic stable coronary artery disease will likely need to be on statin therapy, unless contraindicated.

Every effort should be made to ensure that patients with coronary artery disease receive optimal lipid therapy. Statin medications are strongly supported as first-line medications due to compelling evidence of mortality reduction from multiple clinical trials. If patients are intolerant to a statin, consider other statins in reduced doses.

Better medical therapy with aspirin, beta blockers, ACE inhibitors, and statins are decreasing the need for all revascularization procedures.

Coronary bypass graft

Coronary artery bypass graft surgery (CABG) is recommended for patients with obstructive coronary artery disease whose survival will be improved compared to medical therapy or percutaneous coronary intervention. Typically, this means patients with left main disease or triple-vessel disease and low ejection fraction. In addition, patients with angina refractory to medical therapy qualify for CABG.

CABG is more efficacious in diabetics and in those who have a low ejection fraction. The procedure involves the construction of 1 or more grafts between the arterial and coronary circulations. (Many patients receive both arterial and venous grafts.) Long-term graft patency is significantly better with the arterial graph (e.g., internal mammary artery). Potential consequences of graft failure (loss of patency) include the development of angina, myocardial infarction, or cardiac death.

Percutaneous coronary intervention (PCI)

- Stent placement now standard
- Most cases of stable angina do not need PCI
- PCI is most useful in acute coronary syndrome (ACS)

ACUTE CORONARY SYNDROME

Acute coronary syndrome (ACS) is used to describe a range of thrombotic coronary diseases, including unstable angina (UA), non-ST elevation myocardial infarction (NSTEMI), and ST-elevation myocardial infarction (STEMI). Collectively, they represent one of the most common causes of acute medical admission to U.S. hospitals.

The term ACS is clinically useful because the initial presentation and early management of unstable angina, STEMI, and NSTEMI are frequently similar. ACS should be distinguished from stable angina, which develops during exertion and resolves at rest.

ACS is due to coronary vessel atherosclerotic obstruction with superimposed thrombotic occlusion. The natural course of coronary atherosclerotic plaque development and subsequent occlusion does not proceed in a step-wise, uniform manner, gradually progressing to luminal obstruction (and symptoms) over many years. This process is characterized by plaque disruption and mural thrombosis. Angiographic data support the concept that noncritical lesions account for the majority of the ACS. Thus, the pathogenic rate-limiting mechanism of the ACS appears to be acute thrombosis and the resultant obstruction of the coronary lumen.

An operational classification is clinically helpful since it allows the simple distinction of the different types of ACS. In this classification, the ECG is the most important clinical tool. The initial ECG findings, in particular, the presence or absence of ST-segment elevation, will further define the patient's condition and dictate treatment options.

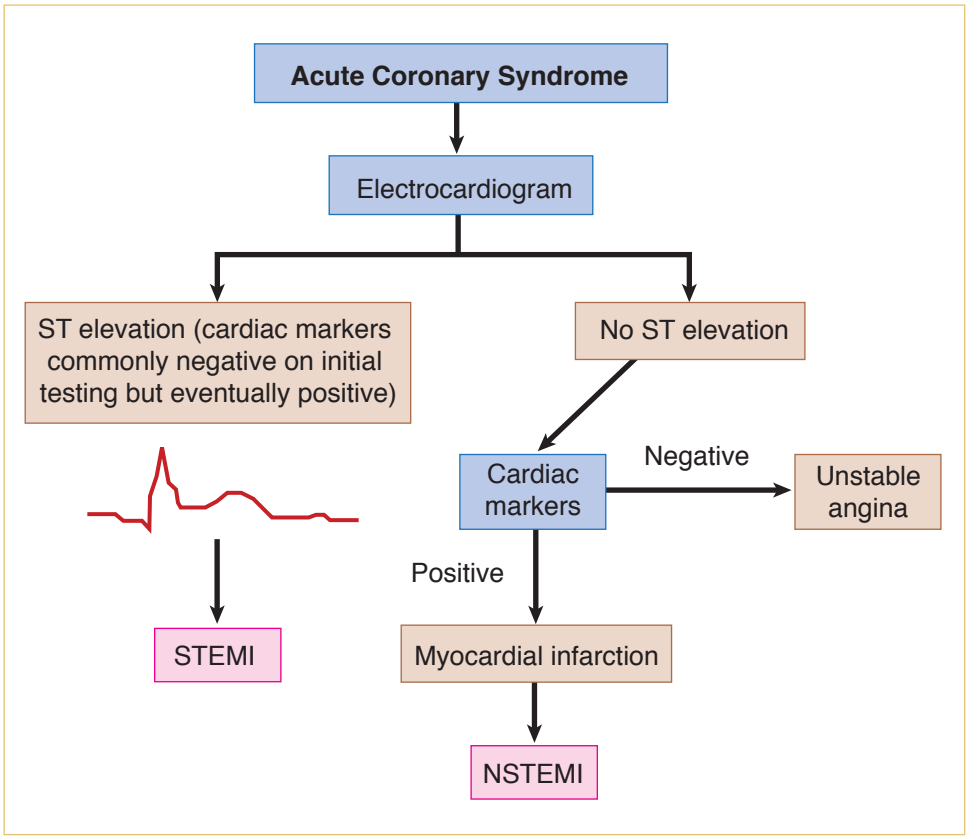

Figure 5-3. Acute Coronary Syndromes

Unstable Angina and NSTEMI

UA and NSTEMI are closely related in terms of clinical presentation and pathogenesis, but patients with these conditions have widely varying risks. Both are usually caused by atherosclerotic CAD and present an increased risk for death and MI.

- NSTEMI is more severe than UA, and is considered to have occurred if ischemia produces damage detectable by biochemical markers of myocardial injury (troponin I or CK-MB).
- If there are no detectable serum markers of myocardial injury 12–18 hours after symptom onset, the patient should be diagnosed with UA.
- At the time of presentation, UA and NSTEMI may be indistinguishable and can be identically managed.
- Therefore, in establishing the diagnosis of NSTEMI, cardiac troponins (elevated enzymes show evidence of infarction) should be used to distinguish this entity from UA.

Outcomes in UA/NSTEMI are generally better than in STEMI, but certain UA/NSTEMI patients are at high risk for MI or death, and it is important to identify these patients at initial screening because they may require intensive monitoring and management.

Thrombolytic therapy is beneficial in patients with STEMI, but is not effective in UA or NSTEMI and may be harmful.

Unstable angina is sometimes referred to as "crescendo" or "preinfarction" angina. Typically, it is defined as angina of increasing severity, frequency, duration; angina showing increasing resistance to nitrates; or angina occurring at rest. Experts also regard *any new-onset angina* as unstable. Sudden change in the pattern of angina usually means a physical change within the coronary arteries, such as hemorrhage into an atherosclerotic plaque or rupture of a plaque with intermittent thrombus formation.

About 35% of patients with the clinical syndrome of UA will already have coronary thrombosis on catheterization. In fact, untreated UA progresses to MI in 50% of cases, thus the patient with new-onset or unstable angina should be hospitalized for intensive medical treatment.

Most patients with NSTEMI have a normal physical examination. An abnormal ECG, particularly dynamic ST-segment deviation (≥0.5 mm), or new T-wave inversion (≥2 mm), will confirm the diagnosis, but the ECG may be normal or show minor changes in up to 50% of cases.

High-risk features for patients with presumed UA/NSTEMI include:

- Repetitive or prolonged chest pain (>10 min)
- Elevated cardiac biomarkers
- Persistent ECG changes of ST depression ≥0.5 mm or new T-wave inversion
- Hemodynamic instability (SBP <90)
- Sustained ventricular tachycardia
- Syncope
- LV ejection fraction <40%
- Prior angioplasty or prior CABG
- Diabetes
- Chronic kidney disease

General management

Aspirin is recommended (unless contraindicated) in all patients. High-risk patients should be treated with aggressive medical management and arrangements should be made for coronary angiography and possible revascularization, except in those with severe comorbidities. Age alone should not be a barrier to aggressive therapy.

Medical management

Antiplatelet therapy (beyond aspirin): Early treatment should be initiated with aspirin and clopidogrel or prasugrel, with the following considerations:

- Avoid clopidogrel in patients likely to require emergency coronary bypass surgery. Prasugrel and ticagrelor are alternatives to clopidogrel.
- If possible, discontinue clopidogrel 5 days before coronary bypass surgery.
- Use ticagrelor in addition to aspirin for acute coronary syndromes. It is not clearly better than clopidogrel or prasugrel.
- Give heparin along with the recommended antiplatelet therapy for UA/NSTEMI.

Antithrombin therapy: Give unfractionated heparin or subcutaneous enoxaparin until angiography or for 48–72 hours. The enoxaparin dose must be reduced in patients with impaired renal function.

Glycoprotein (GP) IIb/IIIa inhibitors: This class of antithrombotic agents inhibits platelet function by blocking a key receptor involved in platelet aggregation. The use of these agents provides a more comprehensive platelet blockade than the combination of aspirin and heparin.

- These drugs take advantage of the fact that platelets play an important role in the development of ischemic complications that may occur in patients with UA/NSTEMI.
- Tirofiban or eptifibatide is particularly recommended in high-risk patients in whom an invasive strategy is planned.
- Concomitant tirofiban is particularly beneficial and recommended in patients with diabetes.
- Complications include bleeding and thrombocytopenia (occurs with all GP IIb/IIa agents; incidence ranges 1–5.5% in clinical studies; an immune mechanism is likely responsible; all patients receiving parenteral GP IIb/IIa antagonsists should be monitored for 24 hours for development of thrombocytopenia).

Other: A beta blocker should be given unless contraindicated. IV nitroglycerin (NTG) can be given for refractory pain.

In patients with diabetes, good glycemic control should be targeted in the hospital and after discharge. This may require considering an insulin-based regimen in hospital.

Invasive management

Early coronary angiography (within 48 hours) and revascularization are recommended in patients with NSTEMI and high-risk features, except in patients with severe comorbidities. Pain or ischemia refractory to medical therapy and high-risk features on early exercise testing can also identify patients suitable for early invasive therapy.

Note

The strongest indication for PCI is an acute coronary syndrome.

ST Elevation MI

The pain of typical MI (STEMI; in the past referred to as Q wave MI) is substernal, diffuse with a pressure quality. It may radiate to the neck or jaw, shoulders, or arms. Often, the pain is accompanied by additional symptoms, such as dizziness (lightheadedness), nausea or vomiting, diaphoresis, or shortness of breath (dyspnea).

The symptoms of MI last >20 minutes and do not respond completely to nitroglycerin. The duration of the pain is variable. Pain may resolve completely after a few hours or may persist for over a day.

Elderly or diabetic patients are prone to atypical symptoms such as nausea or dyspnea as the sole symptoms of infarction. As many as 20% of MI are "silent"—that is, whatever symptoms were present did not impress the patient enough for them to seek medical care or even to remember the incident.

The exam usually shows the patient to have anxiety and pain. Diaphoresis is often present. Pulse rate may be normal, but often bradycardia is present in inferior infarction. Tachycardia is often seen with large infarctions. Blood pressure is often elevated.

Cardiac exam will usually be normal. Large infarctions may cause signs of ventricular failure or valve dysfunction. A fourth heart sound (S4) is common due to a stiffened ventricle. Mitral regurgitation may occur if papillary muscles malfunction. The second heart sound may be paradoxically split as the left ventricular contraction time increases due to LBBB and weakened left ventricle.

Later in the course of MI, other findings may be present: mild fever, pericardial friction rub, ventral septal defect murmur due to septal rupture, or severe mitral regurgitation due to papillary muscle rupture.

STEMI is defined as clinical symptoms consistent with ACS and ECG features including any of these:

- Persistent ST-segment elevation of ≥1 mm in two contiguous limb leads
- ST-segment elevation of ≥2 mm in two contiguous chest leads
- New LBBB pattern

Initially, you don't need increased cardiac biomarkers (troponin, CPK-MB, etc.) to make the diagnosis of STEMI (although these are usually eventually positive at some point during the course of the disease).

Initial nonspecific management for all patients with possible MI (anyone with a compatible chest pain history) is to keep them on a cardiac monitor. Oxygen therapy and an IV line should be established as quickly as possible. Aspirin should be given unless contraindicated, as early as possible. Nitroglycerin and pain control (morphine) should be given as required.

Patients with STEMI usually have a completely occluded coronary artery with thrombus at the site of a ruptured plaque. This eventually leads to myonecrosis. Restoring coronary patency (emergency reperfusion) as promptly as possible is a key determinant of short-term and long-term outcomes.

Patients with STEMI **who present within 12 hours of the onset of ischemic symptoms** should have a reperfusion strategy implemented promptly. Reperfusion may be obtained with fibrinolytic therapy or percutaneous coronary intervention (PCI).

Patients presenting with NSTEMI will not benefit from thrombolytics.

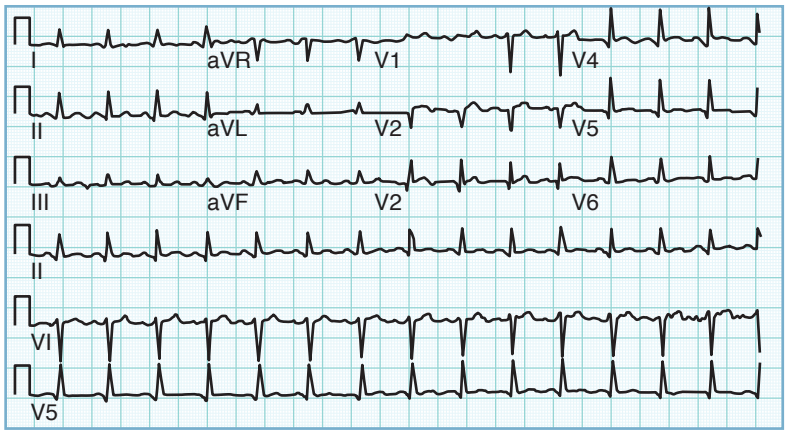

Figure 5-4. Anteroseptal STEMI with Changes in V_1–V_3

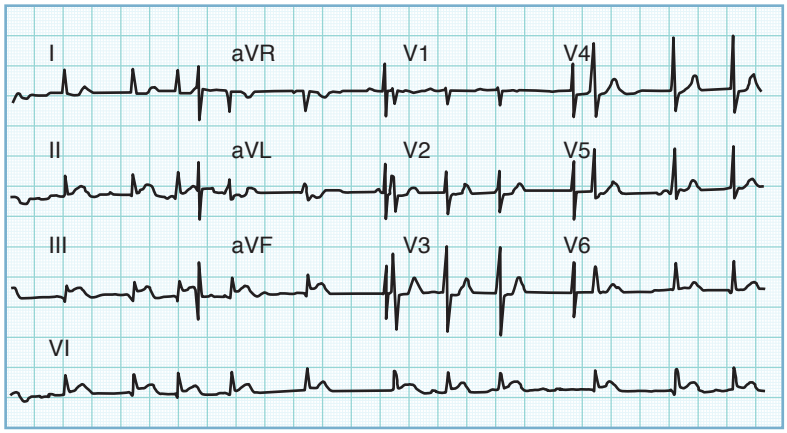

Figure 5-5. Inferior STEMI with Changes in II, III, and aVF

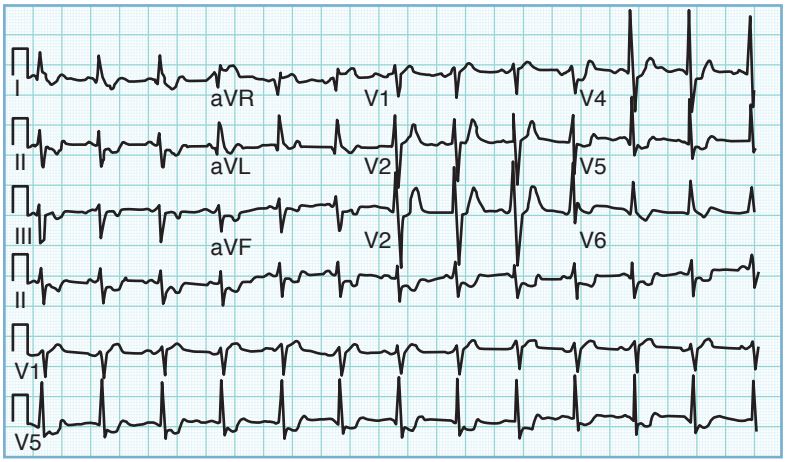

Figure 5-6. NSTEMI Affecting Leads II, III, and aVF

Table 5-2. Localization of STEMI

Area of Infarction	EKG Changes (Q Waves, ST Elevation, T Wave Inversions)	Artery Involved
Inferior	II, III, aVF	Right coronary
Anteroseptal	V_1–V_3	Left anterior descending
Anterior	V_2–V_4	Left anterior descending
Lateral	I, aVL, V_4, V_5, and V_6	Left anterior descending or circumflex
Posterior	V_1–V_2: tall broad initial R wave, ST depression, tall upright T wave; usually occurs in association with inferior or lateral MI	Posterior descending

Table 5-3. Typical Electrocardiographic Evolution of a STEMI

EKG Abnormality	Onset	Disappearance
Hyperacute T waves (tall, peaked T waves in leads facing infarction)	Immediately	6–24 hours
ST-segment elevation	Immediately	1–6 weeks
Q waves longer than 0.04 seconds	One to several days	Years to never
T wave inversion	6–24 hours	Months to years

Emergent reperfusion therapy

The choice of reperfusion therapy is between PCI and thrombolysis therapy. PCI is the best available treatment if provided promptly. PCI improves short-term and long-term outcomes (reduction of deaths and MI) in patients with STEMI presenting within 12 hours when compared with thrombolytic therapy. This benefit over thrombolysis may occur only if the additional time delay associated with PCI is <1 hour. In general, a time delay of 90 minutes from first medical encounter to PCI is the maximum desirable. For patients presenting with STEMI at a facility without PCI access, transfer to another facility capable of performing PCI usually takes too long. Where PCI is delayed or not available, reperfusion with thrombolytic therapy should occur unless contraindicated.

Thrombolytics (Fibrinolytics)

Thrombolytics such as streptokinase or tissue-type plasminogen activator (tPA) restore perfusion to the ischemic area by lysing the clot, thereby reducing infarct size and improving survival.

Thrombolysis benefits patients with all types of ST elevation infarction, but the benefit is several times greater in those with **anterior infarction**. The earlier the treatment is given, the greater the absolute benefit. The greatest benefit is in patients with ST elevation or new left bundle branch block who have had symptoms for <12 hours.

Streptokinase and alteplase are given by IV infusion. Reteplase and tenecteplase can be given by rapid bolus injection. tPA is the most common agent used in the U.S. Prolonged persistence of antibodies to streptokinase may reduce the effectiveness of subsequent treatment; therefore, streptokinase should not be used if used within the previous 12 months in the same patient. Complexity of administration differs among the different thrombolytics: tenecteplase and reteplase are ready in about one minute; for streptokinase or tPA, the typical time from physician order to administration is 12 to 15 minutes.

Bottom line: consider a thrombolytic agent as an alternative to primary PCI in suitable candidates with:

- ST-elevation MI (>1 mm ST elevation in 2 contiguous leads)
- New LBBB

Contraindications to thrombolytic therapy:

- Absolute contraindications:
- Active bleeding or bleeding diathesis
- Significant closed head or facial trauma within 3 months
- Suspected aortic dissection
- Prior intracranial hemorrhage
- Ischemic stroke within 3 months

Relative contraindications:

- Recent major surgery (<3 weeks)
- Traumatic or prolonged cardiopulmonary resuscitation
- Recent (within 4 weeks) internal bleeding
- Active peptic ulcer
- Severe, poorly controlled HTN
- Ischemic stroke (<3 months)

Late presentation (>12 hours after symptom onset): Reperfusion therapy with either PCI or fibrinolysis is not routinely recommended in patients who are asymptomatic and hemodynamically stable, and who present >12 hours after symptom onset.

Other interventions may include coronary artery bypass grafting (CABG). CABG surgery may occasionally be more appropriate—particularly in patients who have suitable anatomy and are not candidates for fibrinolysis or PCI. CABG surgery may also be considered in patients with cardiogenic shock or in association with mechanical repair.

Adjuvant therapy used together with reperfusion

Antiplatelet Therapy

Aspirin should be given to all patients with presumed STEMI unless contraindicated, and, in the absence of significant side effects, low-dose therapy should be continued in the long term.

Clopidogrel or prasugrel should be prescribed in addition to aspirin for patients undergoing PCI with a stent. Ticagrelor is an alternative to clopidogrel or prasugrel.

In patients selected for fibrinolytic therapy, clopidogrel should be given in addition to aspirin, unless contraindicated. Note, however, that if it is thought that the patient is likely to require CABG acutely, clopidogrel should be withheld.

Clopidogrel should be continued for at least a month after fibrinolytic therapy, or for up to 9–12 months after stent implantation, depending on the type of stent used.

Antithrombin Therapy
With PCI: Antithrombin therapy should be used in conjunction with PCI. The dose of unfractionated heparin therapy will depend on concomitant use of glycoprotein (GP) IIb/IIIa inhibitors. It may be advisable to give a bolus of heparin while the patient is in transit to the catheterization laboratory.

The role of enoxaparin in acute STEMI in conjunction with PCI remains to be fully determined, but it appears to be safe and effective.

With fibrinolysis: Antithrombin therapy should be used with fibrin-specific fibrinolytic agents.

IV unfractionated heparin should be given as an initial bolus, adjusted to attain the activated partial thromboplastin time (APTT) at 1.5 to 2 times control. IV unfractionated heparin is used when rapid reversal is needed. The half-life is shorter with unfractionated heparin.

Glycoprotein IIb/IIIa Inhibitors
It is reasonable to use abciximab with primary PCI. Epifibatide and tirofiban are the other GPIIb/IIIa inhibitors. Full-dose GP IIb/IIIa inhibitors should be avoided with fibrinolytic therapy as there is evidence of excessive bleeding (including intracranial hemorrhage) with this combination.

The combination of GP IIb/IIIa inhibitors with reduced doses of fibrinolytic therapy is not recommended. There is no significant advantage over full-dose fibrinolytic therapy alone, and the risk of bleeding is increased, particularly in the elderly.

Cardiac surgery

Emergency bypass surgery should be considered in patients with STEMI and: (*1*) failed PCI with persistent pain or hemodynamic instability and coronary anatomy suitable for surgery or (*2*) persistent or recurrent ischemia refractory to medical therapy and suitable anatomy.

Recommended discharge medications after ACS

1. Aspirin: All patients should take daily unless contraindicated.
2. Clopidogrel: There is evidence that clopidogrel or prasugrel should be prescribed for up to 9–12 months after acute myocardial infarction, particularly after stent placement. Clopidogrel may also be prescribed as an alternative when aspirin is contraindicated, or to those intolerant to aspirin, in patients with recurrent cardiac events.
3. B-blocker: These drugs should be prescribed for all patients after an ACS unless contraindicated, and continued indefinitely. Metoprolol and carvedilol particularly should be used in patients after ACS who have heart failure.
4. ACE inhibitors: Should be given in patients with ACS in CHF, left ventricular dysfunction (ejection fraction <40%). Its use should be reviewed later on the course of the patient and discontinued if the heart failure resolves.
5. Statins: Statin therapy should be *initiated in the hospital* in all patients with ACS (the exception is the rare ACS that is not related to atherosclerosis).
6. Nitrates: Long-acting nitrates (isosorbide) should be reserved for the patients with persistent chest pain.
7. Warfarin: It is recommended after ACS *only* for those at high risk of systemic thromboembolism because of atrial fibrillation or mural thrombus.

Note

To remember issues that need to be considered at the time of discharge, remember **"ABCDE"** (aspirin and antianginals, beta blockers and blood pressure, cholesterol and cigarettes, diet and diabetes, education and exercise).

Secondary prevention through the control or elimination of known risk factors for coronary artery disease (e.g., hyperglycemia in patients with diabetes mellitus, HTN control, tobacco cessation, physical inactivity) also should be part of discharge planning.

> You are asked by your patient, who has a history of ischemic heart disease, about drug treatments that have been shown to decrease mortality in his case. (It doesn't matter if he has stable angina or prior history of acute coronary syndrome.)

Answer: **Lipid lowering agents (statins), ASA, B-blocking agents and CABG in patients with triple vessel disease or left main disease.**

Other testing in ACS

Exercise ECG testing: Increasingly, submaximal testing is performed 4–7 days after infarction. A maximal test can be performed at 3–6 weeks postinfarction. It is used to assess prognosis and to identify those patients with reversible ischemia who should then have an angiogram (if one has not been done) to assess the need for coronary artery bypass graft.

Myocardial perfusion imaging can be performed before hospital discharge to assess the extent of residual ischemia if the patient has not already undergone cardiac catheterization and angiography.

Complications of ACS

Electrical disturbances dysrhythmias

- Bradycardia: sinus, atrioventricular junctional, idioventricular. These are treated acutely with atropine and temporary pacing if severe.
- Premature beats: atrial, ventricular. No treatment is needed for ectopy such as these.
- Tachyarrhythmias (supraventricular): atrial tachycardia, atrial fibrillation, atrial flutter, AV junctional; are seldom caused by ischemia
- Tachyarrhythmias (ventricular): ventricular tachycardia, accelerated idioventricular rhythm, ventricular fibrillation

Conduction Abnormalities

- Atrioventricular nodal: first-, second-, and third-degree block
- Intraventricular: hemiblocks (left anterior, left posterior), bundle branch block, third-degree atrioventricular block

Pump dysfunction

- Contractile dysfunction: left ventricular, right ventricular, and biventricular failure; true ventricular aneurysm; infarct expansion
- Mechanical disruption: acute mitral regurgitation (papillary muscle dysfunction or rupture), ventricular septal rupture, free wall rupture, pseudoaneurysm; treated with emergency surgical repair
- Electromechanical dissociation

Ischemia

- Postinfarction ischemia: ischemia in the infarct and ischemia distant to the infarct
- Early recurrent infarction or infarct extension
- *Postinfarction angina* after thrombolytics or PCI should be treated with *bypass surgery*

Pericarditis—Dressler syndrome (late)

Treated with aspirin, NSAIDs, and later steroids if there is no response.

Thromboembolic

- Mural thrombus with systemic embolism
- Deep vein thrombosis with prolonged immobilization

Sudden cardiac death

Most often due to arrhythmia.

- Ventricular fibrillation (most commonly)
- Ventricular tachycardia

Right ventricular infarction

Accompanies 30% of inferior MIs. It is diagnosed with RV leads and treated with fluids.

Non-Cardiac Complications of ACS

Depression is 3x more common in those who have had a heart attack than in the general population, with 20% of heart attack victims qualifying for a diagnosis of major depressive disorder, and a far greater proportion experiencing increased levels of depressive symptoms. Beyond the accompanying emotional distress and suffering, depression also increases one's risk of having another heart attack or dying over the ensuing months and years.

There is reliable evidence that both antidepressant medications and certain forms of psychotherapy are effective in reducing depression in the post-MI state. Selective serotonin reuptake inhibitors (SSRIs) such as sertraline and citalopram have been found to be both effective in reducing depression and relatively safe for use in patients with coronary heart disease. Cognitive behavior therapy has also been found to be effective in treating depression.

Erectile dysfunction (ED) is prevalent among patients with CAD and post-MI (in some series ~ 40%).

- ED complicates the recovery of those post-MI.
- Treatment of post-MI patients includes management of depression, reassurance, and modification of medications that may cause ED.
- Sildenafil should be used cautiously in men post-MI who are taking nitrates of up to 55 mm Hg, because it can cause a drop in BP. Due to this synergistic effect, it is therefore contraindicated in patients taking nitrates.
- ED is a complication of the conditions that are primary risk factors for developing CAD, in particular, diabetes, hypertension, dyslipidemias, and arteriosclerosis.
- Smoking and stress are implicated in the development of ED.

In evaluating risk of MI associated with intercourse in patients with cardiac disease, it has been estimated that <1% of MIs occur during sexual activity. Although sexual activity can trigger MI, the relative risk is low with a slight increase in risk within 2 hours of sexual activity. However, even in high-risk individuals with previous MI the annual risk is 1.10% vs. 1.0% in the population at large. This risk appears to apply equally to men and women.

Patients can therefore be risk-stratified and counseled about safely returning to or continuing sexual activity:

- **Low risk:** asymptomatic patients with fewer than 3 risk factors for CAD, stable angina, recent uncomplicated MI, mild valvular heart disease, mild CHF, controlled hypertension, or post successful revascularization; patients can generally be managed medically and followed at regular intervals
- **Intermediate risk:** those with recent MI (but beyond 2 weeks), moderate CHF (New York Heart Association class II) and those with >3 risk factors for CAD; patients may benefit from functional testing, i.e., exercise treadmill tests (ETT), echocardiography, or nuclear imaging study with re-stratification based on results of testing
  - ETT can assist in gauging cardiac risk of sexual activity, both for induction of ischemia or arrhythmia. In general, if a patient can achieve 5 METs on ETT without demonstrable ischemia or significant arrhythmia, he is not at high risk to resume normal sexual activities
  - Similarly, if echocardiography does not yield evidence of more than moderate left ventricular dysfunction, resumption of sexual activity is probably safe

High-risk: those with unstable angina, MI within 2 weeks, poorly controlled hypertension, severe CHF (New York Heart Association class III/IV), significant arrhythmias, severe cardiomyopathies; patients should be referred for cardiovascular evaluation and stabilization prior to recommending resumption of sexual activity.

Nonatherosclerotic Acute Coronary Syndromes

Although thrombotic complications of the atherosclerotic process account for most cases of acute coronary syndromes, there are a few rare etiologic factors that have been proposed as causes of or contributors to acute coronary occlusion. These causes include coronary artery spasm, spontaneous coronary dissection, coronary artery embolization, coronary arteritis, and hypercoagulability states such as factor V gene mutation, deficiencies of proteins C and S, antithrombin III deficiency, antiphospholipid antibody syndrome, and prothrombin gene mutation. Cocaine use has been documented to induce coronary vasoconstriction in nondiseased coronary segments but is more pronounced in atherosclerotic segments.

Prinzmetal angina, or variant angina, is a very uncommon condition in which episodes of severe angina are triggered when one of the major coronary arteries suddenly goes into spasm. These episodes are accompanied by ST-segment elevation on the ECG. Although the spasm almost always terminates spontaneously, Prinzmetal angina may be associated with acute MI, serious ventricular arrhythmias, and sudden death.

As opposed to typical angina, Prinzmetal angina usually occurs during periods of rest, most often at night and in the early morning hours. Frequently, episodes appear in clusters. In men, Prinzmetal angina is often associated with atherosclerosis; in women it is not. Women with Prinzmetal tend to have few risk factors for CAD, though many have a history of migraine headaches (another condition associated with arterial spasm).

Exercise testing and routine coronary angiography usually give normal results. Ergonovine has been used to trigger coronary artery spasm in susceptible patients, confirming the diagnosis. Treatment with calcium channel blockers or nitrates eliminates spasm in most of these patients. Once adequately treated, their prognosis is good.

During an acute episode of pain and ST segment elevation, you cannot tell who has Prinzmetal variant angina and who has an acute ST elevation MI. Therefore, you must initially treat everyone with chest pain and ST elevation as if they were having an acute MI. Prinzmetal angina can be confirmed only after coronary angiography.

Causes of MI without Coronary Atherosclerosis

- Vasculitis
  - Systemic lupus erythematosus
  - Polyarteritis nodosa
  - Takayasu arteritis
  - Mucocutaneous lymph node syndrome (Kawasaki)
- Anomalous origin of coronary artery
- Coronary spasm
  - Variant angina
  - Cocaine abuse
- Coronary artery embolus
  - Atrial myxoma
  - Atrial or ventricular thrombus
- Hypercoagulable states
  - Polycythemia vera
  - Thrombocytosis
  - Factor V Leiden
  - Protein C deficiency
  - Antiphospholipid antibodies

CONGESTIVE HEART FAILURE (CHF)

Heart failure (HF) arises from the inability of the ventricle to efficiently pump blood throughout the circulation. Clinically HF presents with symptoms of breathlessness, exercise intolerance, and fatigue.

Case 1:

A 62-year-old man with hypertension and dyslipidemia presents with dyspnea and lower-extremity edema for 2 months. On exam there is jugular venous distention (about 9 cm.), an S3 gallop, and the apical impulse is displaced to the left of the mid-clavicular line at the 6th intercostal space. The chest x-ray shows enlarged cardiac silhouette. The echocardiogram shows a dilated left ventricle with an ejection fraction of 35%.

Case 2:

A 57-year-old man with history of multiple myeloma presents with dyspnea and lower-extremity edema for 2 months. On exam there is jugular venous distention (about 8 cm.), an audible S4, and the apical impulse is non-displaced at the 5th intercostal space. The chest x-ray shows normal cardiac silhouette. The echocardiogram shows a thickened left ventricle with an ejection fraction of 65%.

As HF evolves, changes in vascular function, blood volume, and neurohumoral status occur throughout the body. These changes serve as compensatory mechanisms to help maintain cardiac output (primarily by the Frank-Starling mechanism) and arterial blood pressure (by systemic vasoconstriction). However, these compensatory changes over time can worsen cardiac function. Cardiac changes during HF include increased end-diastolic volume; ventricular dilatation or hypertrophy; decreased stroke volume and cardiac output; reduced ejection fraction (systolic dysfunction) or impaired filling (diastolic dysfunction). Compensatory mechanisms during HF include:

- **Cardiac:** Frank-Starling mechanism, tachycardia, ventricular dilatation
- **Neuronal:** increased sympathetic adrenergic activity, reduced cardiac vagal activity
- **Hormonal:** activation of angiotensin-aldosterone system, vasopressin, catecholamines, and natriuretic peptides

In clinical practice, HF is commonly categorized by whether the abnormality is due to contraction or relaxation of the heart. **Systolic HF** (systolic dysfunction) is due to a loss of contractile strength of the myocardium accompanied by ventricular dilatation. This type of HF is also accompanied by a decrease in normal ventricular emptying (usually ejection fraction <45%). Examples of systolic HF include ischemic cardiomyopathy and dilated cardiomyopathy (Case 1 in this section).

Heart failure with preserved ejection fraction (diastolic dysfunction) occurs when the filling of one or both ventricles is impaired while the emptying capacity is normal (echocardiogram confirms that the ejection fraction is normal). The infiltrative cardiomyopathies (amyloidosis) are typical examples (Case 2 in this section).

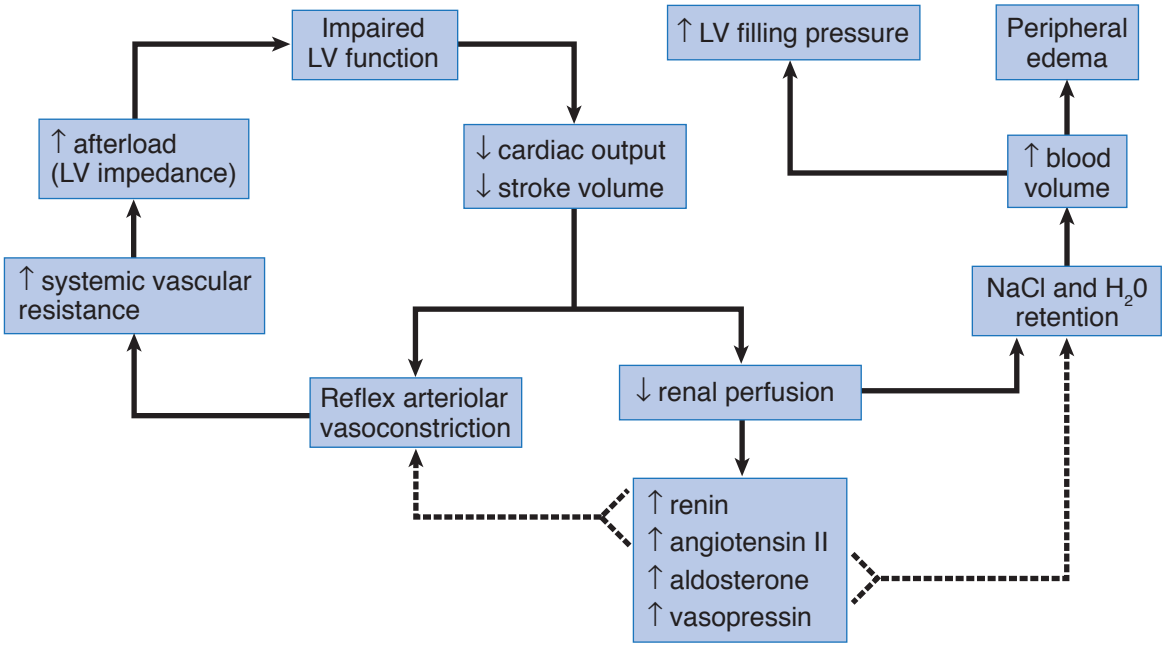

Figure 5-7. Inter-related Cycles in Congestive Heart Failure

Congestive HF indicates a clinical syndrome of dyspnea and fatigue as well as evidence of features of circulatory congestion (peripheral edema, elevated jugular venous pressure [JVP]). In heart failure, intravascular congestion occurs with elevation of left ventricular diastolic and pulmonary venous pressures that eventually causes transudation of fluid from the pulmonary capillaries into the interstitial space. **Pulmonary edema** develops when the rate of fluid accumulation goes above the rate of lymphatic absorption. Pulmonary edema is detected by audible crackles, increased JVP and edema on exam, and chest x-ray findings.

Wikipedia, James Heilman, MD

Figure 5-8. Elevated JVP

Decompensated HF or exacerbation of HF denotes worsening of symptoms and clinical findings in pre-existing HF. This can be due to precipitating factors such as non-adherance to medication, increase in dietary salt, acute ischemia, tachycardia, or pulmonary infection.

In evaluating patients with HF or worsening of pre-existing HF, it is also important to exclude precipitating factors. Commonly, HF manifests for the first time when a precipitating factor places additional burden on the heart. Such factors include:

- Cardiac ischemia and myocardial infarction
- Infections (especially pulmonary infections)
- Arrhythmias (especially atrial fibrillation)
- Excessive dietary salt (commonly after holiday meals)
- Uncontrolled hypertension (especially after abrupt cessation of anti-hypertensive medication)
- Thyrotoxicosis
- Anemia

HF may occur as a consequence of most causes of heart disease, but ischemic heart disease is responsible for over 70% of all cases in the western world. Other common causes include: hypertensive heart disease, the cardiomyopathies (idiopathic, alcohol related, etc.), and valvular and congenital heart diseases.

Symptoms of HF include dyspnea (differentiate from pulmonary dyspnea), orthopnea, paroxysmal nocturnal dyspnea, and fatigue/weakness.

Table 5-4. Most Common Causes of Acute Pulmonary Edema

Ischemia
Arrhythmia
Non-adherence with medication
Dietary indiscretion
Infection

Physical findings in HF:

- Pulmonary rales
- Peripheral edema, ascites
- Hepatomegaly
- Jugular venous distention
- Displaced apical impulse (systolic HF)

Clinical Pearl

In the work-up of patients with new-onset HF, always try to identify potentially reversible causes.

Clinical Pearl

In the work-up of patients with exacerbation of HF, always:

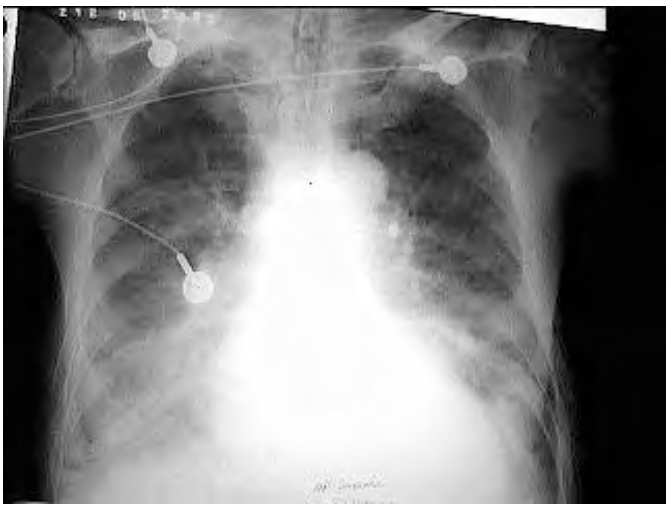
- Check cardiac enzymes to exclude myocardial ischemia or infarction
- Do a chest x-ray to exclude infection

Wikipedia, James Heilman, MD

Figure 5-9. Pitting Edema

The severity of heart failure is commonly classified by using a HF staging system. The New York Heart Association Functional Classification (NYHA staging system) relates symptoms to everyday activities and the patient's quality of life:

- **Class I:** patients have no limitation of activity; they suffer no symptoms from ordinary activities
- **Class II:** patients with slight, mild limitation of activity; they are comfortable with rest or with mild exertion
- **Class III:** patients with marked limitation of activity; they are comfortable only at rest
- **Class IV:** patients are confined to bed or chair; any physical activity brings on discomfort and symptoms occur at rest



Copyright 2007 Gold Standard Multimedia Inc.

Figure 5-10. Chest X-ray Demonstrating Acute Exacerbation of Congestive Heart Failure

Diagnosis. Echocardiography is the test-of-choice to confirm the diagnosis of HF and to classify the type (systolic vs. diastolic). With the echocardiogram, the clinician is able to determine ejection fraction and identify valvular heart disease as well as other cardiac anomalies (dilated ventricle, thickened ventricle, etc.).

Chest x-rays are also used to aid in the diagnosis of heart failure. They may show cardiomegaly, vascular redistribution, Kerley B-lines, and interstitial edema.

Electrocardiogram is used to identify ventricular hypertrophy and/or the presence of ischemic heart disease, arrhythmias, or conduction delays which may cause or precipitate HF.

Brain Natriuretic Peptide (BNP) is a polypeptide secreted by the heart in response to excessive stretching of the myocytes. It is a valuable tool in the evaluation of patients with presumed HF or decompensated HF in the acute setting. The BNP is almost always elevated (97% sensitivity) in patients with decompensated HF. Normal BNP excludes CHF as the cause of dyspnea.

Management. The treatment goals in HF are to improve hemodynamics, relieve symptoms (improve quality of life), and prolong survival. Remember, always evaluate for reversible causes at the same time.

Non-pharmacologic treatment includes primarily reduction of salt intake.

For pharmacologic treatment, ACE inhibitors are the basis of therapy and recommended for all patients with HF (especially systolic HF), irrespective of blood pressure status. They improve survival and reduce ventricular hypertrophy—and eventually, symptoms. ACE inhibitors through vasodilation reduce preload and afterload, thereby reducing right atrial, pulmonary arterial, and pulmonary capillary wedge pressures. All ACE inhibitors have been studied and are considered equal in terms of HF treatment. Angiotensin receptor blockers (ARB) are acceptable alternatives if the patient is unable to tolerate ACE inhibitors (cough, angioedema).

Diuretic therapy, especially loop diuretics, is the treatment of choice for the relief of acute pulmonary edema symptoms. Several classes are used but the loop diuretics (furosemide) class is the most commonly used. Thiazide diuretics (hydrochlorothiazide) are useful only in mild HF. Spironolactone and eplerenone (aldosterone antagonists) have been used as add-on therapy to ACE inhibitors in severe heart failure to prolong survival by presumed aldosterone inhibition.

Clinical Pearl

The single best test for the **evaluation and diagnosis of heart failure** is the **echocardiogram**.

Note

BNP is used acutely if the cause of dyspnea is not clear.

Note

ACE inhibitor (any) and a diuretic are considered first line for all patients with HF. Once the patient is stable, add carvedilol or metoprolol. Don't substitute β-blockers in HF since not all β-blockers have the same efficacy.

Table 5-5. Vasodilators Used in Congestive Heart Failure

Drug	Site of Action	Route of Administration	Complications
Captopril Enalapril Lisinopril	Arteriolar and venous ACE inhibitor	Oral	Rash, nonproductive cough, proteinuria, renal failure, taste disturbance, agranulocytosis, hypotension
Nitroprusside	Arteriolar and venous	IV	Thiocyanate toxicity, methemoglobinemia
Nitroglycerin	Venous (arteriolar at high doses IV)	SL, IV, cutaneous ointment, or patch	Headache, postural hypotension, methemoglobinemia
Isosorbide dinitrate	Venous	Oral or SL	Headache, postural hypotension
Hydralazine	Arteriolar	Oral	Positive ANA, SLE-like syndrome (10–20% if >400 mg/d) drug fever, rash

Chronic adrenergic activation has been implicated in the pathogenesis of HF and thus **β-adrenergic blocking** agents are an important part of HF therapy. Along with ACE inhibitors, beta blockers have been demonstrated to decrease mortality, reduce hospitalizations, improve functional class, and improve ejection fraction in several large-scale, randomized, placebo-controlled trials.

Start patients on beta blockers after stabilization of symptoms with diuretic and ACE inhibitor therapy, irrespective of blood pressure status. Beta blockers such as carvedilol, metoprolol, and bisoprolol have demonstrated survival benefits in trials.

Table 5-6. Commonly Used Diuretics in Heart Failure

Drug	Site of Action	Complications
Thiazides (inhibits NaCl cotransport); used mostly for treatment of hypertension • Hydrochlorothiazide • Chlorothiazide	Distal tubule	Hyponatremia, hypokalemia, hypercalcemia, metabolic alkalosis, hyperuricemia, allergy, agranulocytosis, leukopenia, pancreatitis, glucose intolerance
Indapamide	Distal tube (direct vasodilator)	As above, but hypokalemia and lipid abnormalities less common
Loop diuretics (inhibitors Na/K, 2Cl cotransport); most commonly used diuretics in heart failure • Furosemide • Ethacrynic acid • Bumetanide	Loop of Henle	Hyponatremia, hypokalemia, hypocalcemia, metabolic alkalosis, hyperuricemia, interstitial nephritis, ototoxicity, thrombocytopenia, agranulocytosis, leukopenia
Potassium-sparing diuretics • Spironolactone (aldosterone antagonist)	Distal tubule	Hyperkalemia, gynecomastia (spironolactone only)

Other vasodilators, such as a combination of hydralazine and isosorbide, may be used when ACE inhibitors and ARBs are not tolerated or contraindicated (renal failure). There is a reduction in death and a decrease in hospitalization when a combination of hydralazine and isosorbide is used.

In severe HF and especially if there is no improvement of symptoms while the patient is on standard therapy (diuretic, ACE inhibitor, and beta blocker), the **addition of spironolactone** may be of benefit. The addition of spironolactone in patients with severe CHF significantly reduces (about 30% relative risk) death and hospitalizations among treated patients. Spironolactone is used in patients with NYHA class III-IV. Once the patient is started on spironolactone, serum potassium levels have to be monitored closely.

Eplerenone is an alternative to spironolactone that does not cause gynecomastia.

The addition of inotropic agents to patients with severe HF improves symptoms and quality of life and reduces hospitalizations but does not improve survival. The most commonly used inotropic agent is **digitalis**. Digitalis inhibits Na+/K+ - ATPase pump which results in increased intracellular concentration of Na+ and decreased exchanges of intracellular Ca2+. The end result is an increase in intracellular concentration of Ca2+ which results in improved cardiac contractility.

Note

Agents which lower mortality in systolic dysfunction

- ACE (ARB)
- Beta blockers
- Spironolactone (or eplerenone)

Cardiac glycosides work by inhibition of Na^+/K^+-ATPase pump, which results in:

- Increased intracellular concentration of Na^+
- Decreased exchange of intracellular Ca^{2+} for extracellular Na^+
- The end result is an increase in the intracellular concentration of Ca^{2+}, which gives the (+) inotropic effect characteristic of glycosides

Remember that K^+ and digitalis compete for myocardium binding sites. Hyperkalemia will decrease digitalis activity, whereas hypokalemia results in toxicity.

Digitalis will increase both the force and the velocity of the myocardial contraction. It will also promote a more complete emptying of the ventricles.

It is used for the treatment of:

- CHF
- Atrial fibrillation/flutter
- Paroxysmal atrial tachycardia/SVT

Note

Agents which improve heart failure symptoms but do not reduce mortality

- Digoxin
- Diuretics

Conditions which predispose to digitalis toxicity are:

- Renal insufficiency
- Electrolyte disturbances (hypokalemia, hypercalcemia, hypomagnesemia)
- Advanced age
- Sinoatrial and atrioventricular block
- Thyroid disease, especially hypothyroidism

Table 5-7. Drug Interactions Associated with Digoxin

Drug	Effect*	Mechanism
Quinidine	Increase	Decreases renal clearance of digoxin
Verapamil, diltiazem	Increase	Decreases renal clearance of digoxin
Cholestyramine, colestipol	Decrease	Binds digoxin in GI tract; interferes with enterohepatic circulation
Spironolactone	Increase	Inhibits tubular secretion of digoxin
Thiazides, furosemide	Increase	Diuretic-induced hypokalemia and/or bumetanide hypomagnesemia potentiates digitalis action

*Increase enhances digitalis effect; decrease diminishes digitalis effect.

Toxic Effects of Digitalis

- Nausea and vomiting
- Gynecomastia
- Blurred vision
- Yellow halo around objects
- Arrhythmias—commonly paroxysmal atrial tachycardia (PAT) with block, PVCs (premature ventricular contractions), and bradycardia

Treatment for Intoxication

- Stop drug
- Lidocaine and phenytoin (for arrhythmia)
- Digibind only for acute overdose

Sympathomimetic amines (dopamine, doputamine) and phosphodiesterase inhibitors (amrinone, milrinone) are sometimes used in the management of severe **acute** HF (hospitalized patients). They must be administered by IV infusion and need continuous monitoring of the blood pressure and cardiac rhythm.

Monitoring of patients with HF includes calculation of fluid intake and excretion (in the hospital) as well as monitoring body weight (in the out-patient setting).

In refractory HF (defined as progression of HF despite standard treatment), the patient may be considered for: biventricular pacing, implantable defibrillator, and heart transplantation.

Clinical Pearl

Diastolic HF may worsen when diuretics and vasodilators are used excessively. The goal in diastolic HF is to slow the heart rate with beta blockers and calcium channel blockers (verapamil, diltiazem) in order to allow adequate diastolic filling.

Medical Devices for Systolic Dysfunction

The automatic implantable cardioverter/defibrillator (AICD) is a standard therapy for ischemic dilated cardiomyopathy. Since the most common cause of death in CHF is an arrhythmia, it is logical that a device which interrupts arrhythmia will lower mortality. A biventricular pacemaker will "resynchronize" the heart when there is dilated cardiomyopathy and a QRS >120 mSec. When there is a wide QRS, the 2 ventricles do not beat or depolarize in synchrony. When you put a biventricular pacemaker into the heart, this will "resynchronize" the 2 ventricles, resulting in an immediate decrease in symptoms.

When do I answer AICD?

- Dilated cardiomyopathy with a persistent ejection fraction <35%

When do I answer biventricular pacemaker?

- Dilated cardiomyopathy with a QRS wider than 120 mSec

Summary of therapy for dilated cardiomyopathy

The following classes of medications lower mortality:

- ACE inhibitor or ARBs; use one or the other, not both
- Beta blockers
- Spironolactone (or eplerenone)
- AICD
- Biventricular pacemaker (if QRS >120 mSec)

ACE inhibitors are a class effect; there is no difference in efficacy between the drugs. There is no benefit to adding an ARB to an ACE inhibitor. With beta blockers, not all the drugs are equal; those that benefit mortality in CHF are metoprolol, carvedilol, and bisoprolol. Biventricular pacemakers and cardiac resynchronization therapy also have implantable defibrillator function.

Pulmonary Edema

Pulmonary edema is considered a medical emergency and requires hospitalization. It leads to impaired gas exchange and may cause respiratory failure. There are non-cardiogenic causes of pulmonary edema but in this section we will discuss only cardiogenic pulmonary edema. Cardiogenic pulmonary edema is caused by an acute increase in left ventricular pressure due to ventricular dysfunction which leads to fluid accumulation in the pulmonary interstitium.

Signs and Symptoms

- Increased respiratory rate
- Cough with expectoration (pink frothy sputum)
- Cyanosis
- Nocturnal dyspnea
- Rales, rhonchi, wheezing

Chest X-ray Findings

- Prominent pulmonary vessels
- Effusions
- Enlarged cardiac silhouette
- Kerley B lines

EKG is used to determine if an arrhythmia is contributing to the development of the pulmonary edema.

Treatment

- Oxygen
- Diuretic therapy (furosemide) reduces preload
- Morphine sulfate; side effects include respiratory depression and rarely hypotension
- Sitting the patient upright
- Nitroglycerin to reduce preload
- Digoxin if in atrial fibrillation
- IV ACE inhibitors

VALVULAR HEART DISEASE

Mitral Stenosis

Definition. Most common lesion caused by rheumatic fever consisting of thickened mitral valve leaflets, fused commissures, and chordae tendineae. It may result in right ventricular failure. It often becomes clinically symptomatic during pregnancy.

Etiology. Most cases of mitral stenosis are secondary to rheumatic fever. Rarely, it is caused by a congenital defect, calcification of the valve, or post-radiation treatment to the chest.

Pathogenesis

Mitral valve stenosis impedes left ventricular filling. Increased left atrial pressure is referred to the lungs, causing pulmonary congestion. Forward cardiac output becomes reduced, secondary pulmonary vasoconstriction occurs, and eventually right ventricular failure results.

Clinical Symptoms. Usually manifest slowly over years.

- Dyspnea
- Orthopnea
- Paroxysmal nocturnal dyspnea
- Fatigue
- Wasting
- Hemoptysis (due to rupture of pulmonary vessels)
- Systemic embolism (due to stagnation of blood in an enlarged left atrium)
- Hoarseness (due to impingement of an enlarged left atrium on the recurrent laryngeal nerve)
- Right-sided heart failure
  - Hepatomegaly
  - Ascites
  - Peripheral edema

Physical Signs

- Atrial fibrillation (irregular cardiac rhythm)
- Pulmonary rales
- Decreased pulse pressure
- Loud S_1
- Opening snap following S_2
- Diastolic rumble (low-pitched apical murmur)
- Sternal lift (due to right ventricular enlargement)

Diagnosis

EKG

- May show signs of right ventricular hypertrophy
- May show left and right atrial abnormalities
- Atrial fibrillation often occurs

Chest X-ray

- Large left atrium (indicated by a double-density right heart border, posterior displacement of esophagus, and elevated left mainstem bronchus), straightening of the left heart border
- May show signs of pulmonary hypertension, including Kerley B lines and increased vascular markings
- Large pulmonary artery

Echocardiography

- Shows thickening of mitral valve leaflets and a reduction in the excursion and area of the valve leaflets
- May also show left atrial enlargement

Treatment

Medical Therapy

- Diuretics and salt-restricted diet
- Digitalis to control the ventricular rate in patients with AF
- Anticoagulants in patients with AF
- Balloon valvulotomy is the standard of care for MS

Surgical Management

- Indicated when patient remains symptomatic (functional class III) despite medical therapy
- Mitral commissurotomy or valve replacement, if balloon dilation fails
- Pulmonary hypertension is not a contraindication for surgery

Mitral Regurgitation

Definition. Backflow of blood from the left ventricle into the left atrium, due to inadequate functioning (insufficiency) of the mitral valve. Most commonly from ischemia.

Etiology. Due to abnormalities of the mitral leaflets, annulus, and chordae tendineae.

- Common causes are hypertension, CHF, ischemic heart disease, rheumatic fever, and any cause of dilation of the left ventricle
- Occurs more commonly in men

Table 5-8. Acute versus Chronic Etiologies of Mitral Valve Regurgitation

Acute	Chronic
• Rupture chordae tendineae (permits prolapse of a portion of a mitral valve leaflet into the left atrium) • Papillary muscle rupture • Endocarditis (may lead to valvular destruction) • Trauma	• Rheumatic heart disease (causing scarring and retraction of valve and leaflets) • Papillary muscle dysfunction • Mitral valve prolapse (click-murmur syndrome, Barlow syndrome, floppy mitral valve) • Endocarditis • Calcification of the mitral valve annulus • Accompanying hypertrophic obstructive cardiomyopathy • Congenital endocardial cushion defect, corrected transposition • Endocardial fibroelastosis • Severe left ventricular dilatation

Pathogenesis

- A portion of the left ventricular stroke volume is pumped backward into the left atrium instead of forward into the aorta, resulting in increased left atrial pressure and decreased forward cardiac output.
- Volume overload occurs, increasing preload.
- Afterload is decreased as the left ventricle empties part of its contents into the relatively low-pressure left atrium.
- This helps to compensate for the regurgitation by augmenting ejection fraction.
- Left ventricular dysfunction occurs after prolonged compensation.

Clinical Manifestations

Left ventricular failure is manifested by:

- Dyspnea
- Orthopnea
- Paroxysmal nocturnal dyspnea

Severe and chronic mitral regurgitation lead to right-sided failure presenting with:

- Edema
- Ascites
- Anorexia
- Fatigue

May also have pulmonary hypertension as a late finding.

Physical Signs

- Hyperdynamic and displaced (downward and to the left) left ventricular impulse
- Carotid upstroke diminished in volume but brisk
- Holosystolic apical murmur radiating to the axilla and often accompanied by a thrill
- S_3 heard with a soft S_1 and widely split S_2
- Distended neck veins when severe or acute

Diagnosis

- EKG shows signs of left ventricular hypertrophy and left atrial enlargement.
- Chest x-ray shows cardiac enlargement, with vascular congestion when the regurgitation has led to heart failure.
- Echocardiography: The mitral valve can prolapse into the left atrium during systole in cases of a ruptured chordae or mitral valve prolapse. Regardless of the cause, left atrial and left ventricular enlargement occurs if the condition is chronic.
- Catheterization is the single most accurate test.

Treatment. With medical therapy, the goal is to relieve symptoms by increasing forward cardiac output and reducing pulmonary venous hypertension.

- ARBs or hydralazine
- Arteriolar vasodilators (ACE inhibitors)
- Digitalis
- Diuretics

With surgery, mitral valve replacement is used. Guidelines for selecting patients with mitral regurgitation for operation:

- With significantly limiting symptoms and severe mitral regurgitation, surgery is usually indicated. The risk of surgery rises in chronic heart failure.
- In patients with regurgitation who have few or no symptoms, surgery should be deferred. Their condition may remain stable for years.
- Surgery is indicated when symptoms persist despite optimal medical management.
- Criterion is an ejection fraction <60% or left ventricular end systolic diameter >40 mm.
- Repair is preferable to replacement.

Mitral Valve Prolapse

Definition. The most common congenital valvular abnormality (2–3% population) typically seen in young women. Mitral valve prolapse may occur with greater frequency in those with Ehler-Danlos syndrome, polycystic kidney disease, and Marfan syndrome.

Presentation. Most patients are asymptomatic. Lightheadedness, palpitations, syncope, and chest pain may occur. These symptoms are often due to arrhythmias, which may occur.

Auscultation

- Mid-to-late systolic click and a late systolic murmur at the cardiac apex
- Worsens with Valsalva or standing
- Improves with squatting or leg raise

Complications (all very rare)

- Serious arrhythmias
- Sudden death
- CHF
- Bacterial endocarditis (but does not mean routine dental prophylaxis is indicated)
- Calcifications of valve
- Transient cerebral ischemic attacks

Laboratory

Two-Dimensional/Doppler Echocardiography: Marked systolic displacement of mitral leaflets with coaptation point at or on the left atrial side of the annulus; moderate systolic displacement of the leaflets with at least moderate mitral regurgitation.

Treatment. No specific treatment is needed in the majority of cases.

Medical Management: Beta blocker for chest pain and palpitations

Surgical Management: Mitral valve replacement, rarely

Aortic Stenosis

Etiology

- Calcification and degeneration of a congenitally normal valve; more common in the elderly population. This is the most common cause.
- Calcification and fibrosis of a congenitally bicuspid aortic valve.
- Rheumatic valvular disease: If the aortic valve is affected by the rheumatic fever, the mitral valve is also invariably affected.

Pathophysiology

Aortic stenosis results in elevation of left ventricular systolic pressure, and the resultant left ventricular hypertrophy maintains cardiac output without dilation of the ventricular cavity. Therefore, the stroke volume is normal until the late stages of the disease.

Forceful atrial contraction augments filling at the thick, noncompliant ventricle and generates a prominent S_4 gallop that elevates the left ventricular end-diastolic pressure.

Left ventricular hypertrophy and high intramyocardial wall tension account for the increased oxygen demands and, along with decreased diastolic coronary blood flow, account for the occurrence of angina pectoris.

As the myocardium fails, mean left ventricular diastolic pressure increases, and symptoms of pulmonary congestion ensue.

Clinical Manifestations

- Classic symptoms are angina, syncope, and dyspnea from CHF
- Pulsus tardus et parvus
- Carotid thrill
- Systolic ejection murmur in aortic area, usually with thrill, harsh quality, radiates to carotids
- S_4 gallop
- A_2 decreased, S_2 single or paradoxically split
- Aortic ejection click

Diagnosis

- EKG will often show left ventricular hypertrophy.
- Chest x-ray may present with calcification, cardiomegaly, and pulmonary congestion.
- Echocardiography shows thick aortic valve leaflets with decreased excursion and LVH.

Treatment

- Endocarditis prophylaxis is no longer recommended.
- Surgery (valve replacement) is advised when symptoms develop, which is when the valve area is reduced below 0.8 cm^2 (normal aortic orifice, 2.5–3 cm^2). Generally, if patient has symptoms from stenosis, surgery is the treatment of choice.
- Balloon valvuloplasty may be useful in those too ill to tolerate surgery.

Clinical Pearl

Look for AS in older patients presenting with syncope related to exertion.

Table 5-9. Differential Diagnosis of Aortic Valve Stenosis

Disease Entity	Differentiating Features
Aortic valve sclerosis of the elderly, without stenosis	Systolic murmur does not peak late Carotids do not have delayed upstrokes No left ventricular hypertrophy by EKG Echocardiographic visualization of excursion of valve leaflets usually normal or mildly reduced, but valves may not be visualized No hemodynamically significant aortic valve gradient by cardiac catheterization
Hypertrophic obstructive cardiomyopathy	Brisk bifid carotid upstrokes Murmur usually does not radiate into neck Characteristic change in murmur with various maneuvers Pseudoinfarct pattern (large septal Q waves) on EKG Characteristic echocardiographic features
Mitral regurgitation	Murmur is holosystolic and radiates to axilla and not carotids Carotid upstroke may be normal Dilated left ventricle Aortic valve normal on echocardiogram unless there is associated aortic valve disease
Pulmonic stenosis	Murmur does not radiate into neck; loudest along the left sternal border; increases with inspiration Physical examination, chest x-ray, and EKG may reveal enlarged right ventricle Echocardiogram reveals right ventricular enlargement and hypertrophy

Note: All of the above have a systolic murmur that can be confused with aortic stenosis.

Table 5-10. Effect of Various Maneuvers on Systolic Murmurs

	Valsalva	Phenylephrine Handgrip	Squatting	Amyl Nitrite	Leg Raising
Aortic stenosis	Decrease	Decrease	Increase or decrease	Increase	Increase
Hypertrophic obstructive cardiomyopathy	Increase	Decrease	Decrease	Increase	Decrease
Ventricular septal defect	Decrease	Increase	No change	Decrease	Increase
Mitral regurgitation	Decrease	Increase	Increase	Decrease	Increase

Aortic Regurgitation

Etiology. Systemic hypertension and ischemic heart disease are the most common causes of aortic regurgitation.

- It may occur after infectious endocarditis.
- Conditions that may affect the ascending aorta and cause aortic regurgitation:
  - Syphilis
  - Ankylosing spondylitis
  - Marfan syndrome
  - Rheumatic fever
  - Aortic dissection
  - Aortic trauma

Pathophysiology

Aortic regurgitation results in a volume overload of the left ventricle.

- The ventricle compensates by increasing its end-diastolic volume according to the Frank-Starling mechanism.
- The left ventricular dilation is thought to overstretch the myofibrils, leading to less actin–myosin interaction and decreased contractility.
- In acute severe aortic regurgitation, the left ventricle has not had the opportunity to dilate, its compliance is relatively high, and the aortic regurgitation therefore leads to very high left ventricular end-diastolic pressure.

If mitral regurgitation ensues, the elevated left ventricular diastolic pressure is reflected back to the pulmonary vasculature, and acute pulmonary edema may occur.

Acute aortic regurgitation results in a lower cardiac output, narrower aortic pulse pressure, and a smaller left ventricle than does chronic aortic regurgitation.

Aortic diastolic pressure decreases in chronic aortic regurgitation because of both the regurgitation of blood into the left ventricle and a compensatory decrease in systemic vascular resistance to maintain forward cardiac flow to the periphery. The increased pulse pressure in chronic aortic regurgitation is due to the large stroke volume, causing increased systolic and decreased diastolic pressure.

Clinical Manifestations

- Dyspnea is the most common complaint.
- Diastolic decrescendo murmur is the most typical.
- Systolic flow murmur
- Duroziez sign: Systolic and/or diastolic thrill or murmur heard over the femoral arteries
- S_3 in early left ventricular decompensation
- Austin-Flint murmur
- Remember: Aortic regurgitation can cause 3 different murmurs.

Diagnosis

- **EKG:** LV hypertrophy often with volume overload pattern (narrow deep Q waves in left precordial leads)
- **Chest x-ray:** LV and aortic dilation
- **Echocardiography:** Dilated LV and aorta; left ventricular volume overload; fluttering of anterior mitral valve leaflet

Treatment. Endocarditis prophylaxis is no longer recommended.

- Salt restriction, diuretics, after load reduction (e.g., ACE inhibitors)
- Aortic valve replacement when symptoms worsen or ejection fraction decreases.
- Vasodilators such as an ACE, ARB, or nifedipine are the standard of care.
- Perform surgery when the ejection fraction is <55% or left ventricular systolic diameter is >55 mm.

MYOCARDIAL DISEASE

Cardiomyopathy

Definition. A disease involving the heart muscle itself.

Classification. Cardiomyopathies can be classified according to morphologic and hemodynamic characteristics.

Table 5-11. Morphologic and Hemodynamic Characteristics of Cardiomyopathies

	Dilated	Hypertrophic	Restrictive
	Biventricular dilatation	Marked hypertrophy of left ventricle and occasionally of right ventricle; can have disproportionate hypertrophy of septum	Reduced ventricular compliance; usually caused by infiltration of myocardium (e.g., by amyloid, hemosiderin, or glycogen deposits)
Cardiac output	↓	Normal or ↓	Normal to ↓
Stroke volume	↓	Normal or ↑	Normal or ↓
Ventricular filling pressure	↑	Normal or ↑	↑
Chamber size	↑	Normal or ↓	Normal or ↑
Ejection fraction	↓	↑	Normal to ↓
Diastolic compliance	Normal	↓	↓
Other findings	May have associated functional mitral or tricuspid regurgitation.	Obstruction may develop between interventricular septum and septal leaflet of mitral valve.	Characteristic ventricular pressure tracing that resembles those recorded in constrictive pericarditis, with early diastolic dip-and-plateau configuration

Dilated (congestive) cardiomyopathy

Characterized by diminished myocardial contractility, usually involving both ventricles; most common cause for heart transplants.

Etiologies of Dilated (Congestive) Cardiomyopathy

- Idiopathic: most common
- Alcoholic
- Peripartum
- Postmyocarditis due to infectious agents (viral, parasitic, mycobacterial, Rickettsiae)
- Toxins (cobalt, lead, arsenic)
- Doxorubicin hydrochloride, cyclophosphamide, vincristine
- Metabolic: chronic hypophosphatemia, hypokalemia, hypocalcemia, uremia

Clinical Manifestations. Symptoms and signs of left and right ventricular failure. Typical symptoms of systolic dysfunction.

Diagnosis

- X-ray: cardiomegaly with pulmonary congestion
- EKG: sinus tachycardia, arrhythmias, conduction disturbances
- Echo (key diagnostic study): dilated left ventricle, generalized decreased wall motion, mitral valve regurgitation; transesophageal echo is more sensitive and specific than transthoracic
- Catheterization: dilated hypocontractile ventricle, mitral regurgitation

Treatment. Patients are treated as those with systolic heart failure. ACE, beta blockers, and spironolactone lower mortality. Diuretics and digoxin decrease symptoms. Implantable defibrillator may decrease risk of sudden death when the ejection fraction is <35%.

Hypertrophic Obstructive Cardiomyopathy

Etiology. Although hypertrophic obstructive cardiomyopathy (HOCM) can apparently develop sporadically, it is hereditary in >60% of cases and is transmitted as an autosomal dominant trait.

- An abnormality on chromosome 14 has been identified in the familial form of the disease.
- The distinctive hallmark of the disease is unexplained myocardial hypertrophy, usually with thickening of the *interventricular septum*.

Pathophysiology. As a result of the hypertrophy, left ventricular compliance is reduced, but systolic performance is not depressed. Diastolic dysfunction is characteristic, resulting in decreased compliance and/or inability for the heart to relax.

- The heart is hypercontractile, and systole occurs with striking rapidity.
- Ejection fractions are often 80–90% (normal is 60%, ±5%), and the left ventricle may be virtually obliterated in systole.
- The ability to provoke obstruction or increase/decrease already existing obstruction is influenced by several factors.

Table 5-12. Factors That Modify Obstruction in Hypertrophic Obstructive Cardiomyopathy

Increase Obstruction		Decrease Obstruction	
Mechanism	**Physiologic or Pharmacologic Factors**	**Mechanism**	**Physiologic or Pharmacologic Factors**
Increase in contractility	Tachycardia Digitalis glycosides β-adrenergic stimulation (e.g., epinephrine, exercise) Premature beats	Decrease in contractility	β-adrenergic blockade Heavy sedation and general anesthesia Calcium channel blockers, disopyramide, and other drugs that depress myocardial function
Reduction in preload	Valsalva maneuver Decrease in intravascular volume Standing Nitroglycerin Vasodilator drugs Tachycardia	Increase in preload	Intravascular volume expansion Squatting Bradycardia β-adrenergic blockade
Reduction in afterload	Hypovolemia (diuretics) Nitroglycerin and related drugs Vasodilator drugs	Increase in afterload	Intravascular volume expansion Squatting α-adrenergic stimulation (e.g., phenylephrine) Handgrip

Clinical Manifestations

- Dyspnea, angina, presyncope, syncope with exertion, and palpitations
- Large jugular A wave, bifid carotid pulse, palpable S_4 gallop, systolic murmur and thrill, mitral regurgitation murmur
- Sudden death can sometimes be the first manifestation.

Diagnosis

- EKG: left ventricular hypertrophy, pseudo Q waves (often seen V_1–V_3), ventricular arrhythmias
- **Echocardiogram** is the mainstay of diagnosis. It typically shows hypertrophy, systolic anterior motion of mitral valve, and midsystolic closure of aortic valve

Clinical Pearl

With HOCM, avoid the following:

- Digitalis
- Diuretics
- Vasodilators
- Exercise

Treatment

- Beta-blockers
- Calcium channel blockers that reduce heart rate: diltiazem, verapamil
- Disopyramide, occasionally
- Use implantable defibrillator if there is syncope
- Surgery in severe cases—septoplasty

Restrictive Cardiomyopathy

Restrictive cardiomyopathy is the least common of the causes of cardiomyopathy. It is myocardial disorder characterized by rigid noncompliant ventricular walls.

Etiologies

- Infiltrative: sarcoidosis/amyloidosis; hemochromatosis; neoplasia
- Scleroderma
- Radiation

Pathophysiology. The myocardium is rigid and noncompliant, impeding ventricular filling and raising cardiac filling pressures from abnormal diastolic function. Systolic performance is often reduced, but the overriding problem is impaired diastolic filling, which produces a clinical and hemodynamic picture that mimics constrictive pericarditis.

Clinical Manifestations

- Dyspnea, exercise, intolerance, weakness
- Elevated jugular venous pressure, edema, hepatomegaly, ascites, S_4 and S_3 gallop, Kussmaul sign

Diagnosis

- X-ray: mild cardiomegaly, pulmonary congestion
- EKG: low voltage, conduction disturbances, Q waves
- Echo: characteristic myocardial texture in amyloidosis with thickening of all cardiac structures
- Catheterization: square root sign; elevated left- and right-sided filling pressures

Treatment. There is no good therapy; ultimately results in death from CHF or arrhythmias; consider heart transplantation.

PERICARDIAL DISEASE

Acute Pericarditis

Definition. Inflammation of the pericardial lining around the heart.

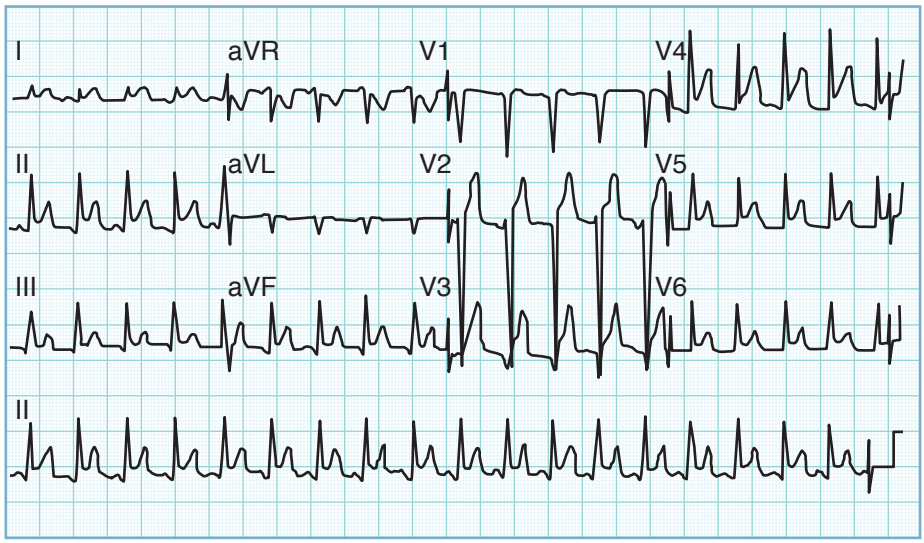


Figure 5-11. Acute Pericarditis with Diffuse ST Segment Elevation

Etiology

- Idiopathic
- Infections (viral)
- Vasculitis—connective tissue disease group
- Disorders of metabolism
- Neoplasms
- Trauma
- Inflammation—uremia

Clinical Manifestations. Chest pain, often localized substernally or to the left of the sternum, is usually worsened by lying down, coughing, and deep inspiration (which helps in the differential diagnosis with MI) and is relieved by sitting up and leaning forward.

Pericardial friction rub (diagnostic of pericarditis) is a scratchy, high-pitched sound that has 1 to 3 components corresponding to atrial systole, ventricular systole, and early diastolic ventricular filling. The ventricular systole component is present more consistently. The rub is often transient and is best heard with the diaphragm of the stethoscope as the patient sits forward at forced-end expiration.

Diagnosis. EKG may be diagnostic and reveals a diffuse ST-segment elevation with upright T waves at the onset of chest pain. PR segment depression is very specific.

Differential Diagnosis. The diffuseness of the ST-segment elevation, absence of reciprocal leads, and absence of the development of Q waves distinguish the characteristic pattern of acute pericarditis from the pattern seen in acute MI.

Treatment of the patient with acute pericarditis involves treating its etiology. In idiopathic pericarditis, treatment with anti-inflammatory medications (NSAIDs, aspirin, corticosteroids) is appropriate. Adding colchicine to an NSAID decreases recurrence.

Pericardial Effusion

Etiology. Fluid may accumulate in the pericardial cavity in virtually all forms of pericardial disease. The fluid may be a transudate, as are the serous cavity effusions that develop in patients with CHF, overhydration, or hypoproteinemia. More often, however, the pericardial effusion is an exudate, reflecting the presence of pericardial injury.

- Serosanguineous pericardial fluid is a classic sign in tuberculosis and neoplastic diseases.
- Frank blood in the pericardial space may occur in cases of aortic aneurysm or aortic dissection.
- Hemopericardium may also be produced by closed or penetrating trauma, rupture of the heart in acute MI, and bleeding caused by coagulation defects.
- When fluid accumulates slowly, the pericardium expands to accommodate it. When fluid accumulates rapidly, however, it compresses the heart and inhibits cardiac filling (cardiac tamponade).

Diagnosis. Echocardiography is the most effective laboratory technique available. The presence of pericardial fluid is recorded as a relatively echo-free space between the posterior pericardium and the posterior left ventricular epicardium in patients with small effusions. In patients with large effusions, the heart may swing freely within the pericardial sac, and this motion may be associated with electrical alternans.

Chest x-ray may show a "water-bottle" configuration of the cardiac silhouette.

Treatment

- Fluid aspiration
- Management of acute pericarditis etiology

Cardiac tamponade

Definition. A life-threatening condition in which a pericardial effusion has developed so rapidly or has become so large that it compresses the heart.

Etiology

- Neoplasia
- Idiopathic (usually viral) pericarditis
- Nonviral infection
  - Tuberculous
  - Suppurative
- Intrapericardial hemorrhage with or without pericarditis

- Wounds, including surgery of
  - Chest
  - Heart
  - Pericardium
- Postpericardiotomy syndrome
- Uremia
- Mediastinal and juxtamediastinal radiation therapy
- Vasculitis–connective tissue disease group

Clinical Manifestations. Most patients with cardiac tamponade complain of dyspnea, fatigue, and orthopnea.

- Pulsus paradoxus, characterized by a decrease in systolic blood pressure >10 mm Hg with normal inspiration, frequently is present. The paradoxical pulse often can be noted by marked weakening or disappearance of a peripheral pulse during inspiration. Paradoxical pulse is not diagnostic of cardial tamponade and can occur in chronic lung disease, acute asthma, severe CHF, and in some cases of hypovolemic shock.
- Neck vein distension with clear lung
- Shock (hypotension)
- Decreased heart sounds
- Beck's triad is associated with acute tamponade; it includes low blood pressure, distended neck veins, and decreased heart sounds

Diagnosis. Clinical manifestations followed by echocardiography and cardiac catheterization, which confirms that left and right atrial pressures are equal.

Treatment

- Pericardiocentesis
- Subxiphoid surgical drainage

Constrictive Pericarditis

Definition. The diffuse thickening of the pericardium in reaction to prior inflammation, which results in reduced distensibility of the cardiac chambers.

- Cardiac output is limited and filling pressures are increased to match the external constrictive force placed on the heart by the pericardium.
- The fundamental hemodynamic abnormality is abnormal diastolic filling.

Etiologies

- Idiopathic, unknown
- Following open-heart surgery
- Following thoracic radiation
- Postviral infection

Clinical Manifestations. Most patients complain of dyspnea on exertion due to limited cardiac output. Orthopnea occurs in about 50% of patients. Symptoms and signs related to systemic venous hypertension are often reported and include ascites, edema, jaundice, hepatic tenderness,

and hepatomegaly (manifestations of right-side failure). Jugular venous distension that increases with inspiration (Kussmaul sign). Heart sounds are distant, and an early diastolic apical sound, or "pericardial knock," is often present and can be confused with an S_3 gallop.

Diagnosis

- EKG: Findings include low-voltage and nonspecific T-wave changes.
- Chest x-ray: The heart usually is normal in size.
- Chest CT or MRI: Shows thickened pericardium; pericardial calcifications may be seen in tuberculous constriction.
- Cardiac catheterization: A marked "y" descent is present in the right atrial pressure tracing. Left and right ventricular pressure tracings demonstrate a characteristic "dip and plateau" or "square root" sign. There is equalization of end-diastolic pressures in all 4 chambers and the pulmonary artery.

Differential Diagnosis. It is sometimes difficult to distinguish constrictive pericarditis from restrictive cardiomyopathy. Left ventricular ejection fraction is more likely to be decreased in patients with restrictive cardiomyopathy. Computed tomography is the procedure of choice to demonstrate the thickened pericardium.

Treatment. Patients may be treated conservatively at first with mild sodium restriction and diuretics. Pericardiectomy may be needed.

RATE AND RHYTHM DISTURBANCES

Disorders of Sinus Node Function

Sinus bradycardia

Ventricular complexes are normal width, evenly spaced, rate <60/min.

Etiology

- Excessive vagal tone causes:
  - Acute MI, particularly diaphragmatic
  - Carotid sinus pressure
  - Vomiting
  - Valsalva maneuver
  - Phenothiazines
  - Digitalis glycosides
- Depression of the sinus node automaticity:
  - Beta-adrenergic blocking agents
  - Calcium blocking drugs
- Marathon running and swimming
- Hypothyroidism
- Normal variant

Treatment

- None necessary in the absence of symptoms
- Atropine acutely if symptoms are present
- Pacemaker if symptoms and bradycardia persist despite atropine

Atrioventricular (AV) block

May be classified in two ways:

- Anatomical, based on the site of block as determined by His bundle electrocardiography.
- Clinical, based on the routine ECG. The 3 classic clinical types are first-, second-, and third-degree (or complete) AV block.

First-Degree AV Block

Definition. Pulse rate (PR) interval >0.20 s at a heart rate of 70 beats/min.

Etiology

- Degenerative changes in the AV conduction system caused by:
  - Aging
  - Digitalis
  - Exaggerated vagal tone
  - Ischemia (diaphragmatic infarction)
  - Inflammation (myocarditis, acute rheumatic fever)
- Cardiomyopathies

Second-Degree AV Block

See Table 5-13.

Table 5-13. Type I versus Type II Second-Degree AV Block

	Type I (Mobitz I, Wenckebach)	Type II (Mobitz II)
	 Progressive prolongation of the PR interval until a P wave is completely blocked and a ventricular beat is dropped. PR interval of the next conducted beat is shorter than preceding PR interval.	 Blocked beat occurs suddenly and is not preceded by a change in duration of the PR interval. Patient is equipped with a pacemaker, which cuts in to sustain a regular ventricular rhythm.
Site of block	Usually AV nodal (supra-Hisian)	Infranodal (intra- or infra-Hisian)
QRS complex	Usually normal in width	Usually wide (bundle branch block) with infra-Hisian block; narrow with intra-Hisian block
Causes	Degenerative changes in AV node; diaphragmatic myocardial infarct; digitalis toxicity; myocarditis; rheumatic fever; increased vagal tone	Extensive anterior myocardial infarct; degenerative changes in His-Purkinje system; massive calcification of mitral or aortic valve anulus
EKG	PR interval lengthens progressively until ventricular beat is dropped PR interval shortens after dropped beat RR interval lengthens progressively up to the dropped beat	PR interval is usually normal in duration and constant in length if PR interval is prolonged, the duration of prolongation is fixed Blocked beats occur suddenly without progressive lengthening of the PR interval RR interval of conducted beats is constant or a multiple of a basic RR interval cycle length
Effect of carotid sinus pressure	May increase degree of block	No effect
Effect of atropine	Frequently shortens PR interval and increases AV conduction	No effect
Consequences of progression to complete heart block	Escape focus usually junctional; narrow QRS complex; rate >45 beats/min; Adams-Stoke attacks uncommon	Escape focus infrajunctional (usually ventricular) wide QRS complex; rate <45 beats/min; Adams-Stoke attacks common
		Junctional escape may be present with intra-Hisian block

Third-Degree (Complete) AV Block

In third-degree, or complete, heart block, all atrial beats are blocked, and the ventricles are driven by an escape focus distal to the site of block.

Figure 5-12. Third-Degree AV Block

Etiology

- Most common cause in adults is simple fibrous degenerative changes in the conduction system that results from aging (Lenègre disease)
- Inferior or posterior infarction
- Infectious and inflammatory processes, such as abscesses, tubercles, tumors, infiltrative disease of the myocardium, sarcoid nodules, and gummas, myocarditis, and rheumatic fever
- Drugs like digitalis
- Ankylosing spondylitis

Clinical Manifestations

- Symptoms are associated with Adams-Stoke attacks and occasionally CHF.
- Adams-Stoke attacks are caused by either sudden asystole or the development of ventricular tachyarrhythmias, such as transient ventricular tachycardia or ventricular fibrillation, that lead to circulatory arrest.
- The bradycardia associated with complete heart block may lead to congestive heart block in patients with myocardial disease.

Treatment. Pacing.

Supraventricular arrhythmias

Sinus tachycardia is defined as a normal rhythm with a rate of >100 beats/minute. In sinus tachycardia, the ventricular complexes are of normal width, evenly spaced, and a P-wave precedes a QRS complex. It usually represents a physiologic response to fever, hypotension, volume depletion, anxiety, and pain. Other causes include thyrotoxicosis, anemia, and some drugs.

Transient sinus tachycardia is occasionally the result of a rebound phenomenon following the discontinuation of beta-adrenergic blocking drugs.

Paroxysmal supraventricular tachycardia is a group of ectopic tachyarrhythmias characterized by sudden onset and abrupt termination. They are usually initiated by a supraventricular premature beat (includes paroxysmal atrial tachycardia)

- 80% are caused by re-entry, mainly in the AV node.
- Manifests as an absolutely regular rhythm at a rate 130–220 beats/min (average 160).
- Initial therapy consists of maneuvers aimed at increasing vagal tone, particularly right carotid sinus massage. Carotid sinus massage is followed by adenosine.
- IV adenosine is effective in >90% of cases.
- IV propranolol or esmolol, verapamil
- IV digitalis
- Synchronized external cardioversion if patient is unstable

Multifocal atrial tachycardia is characterized by an irregular supraventricular rhythm, at rates 100–200 beats/min.

- The morphology of the P waves (at least 3 different P wave forms) varies from beat to beat, as does the PR interval. Each QRS complex, however, is preceded by a P wave.
- Generally seen in elderly patients or those with chronic lung disease who are experiencing respiratory failure
- Use diltiazem, verapamil, or digoxin; avoid beta blockers because of lung disease

Atrial flutter generally presents as an absolutely regular rhythm with a ventricular rate of 125–150 beats/min and an atrial rate of 250–300 beats/min (i.e., 2:1 block).

It has been associated with:

- Chronic obstructive lung disease
- Pulmonary embolism
- Thyrotoxicosis
- Mitral valve disease
- Alcohol
- Atrial flutter may occur as a paroxysmal arrhythmia in persons with normal heart.
- Therapy is cardioversion if hemodynamically unstable (e.g., hypotension), digitalis, verapamil, diltiazem, and beta-blockers.

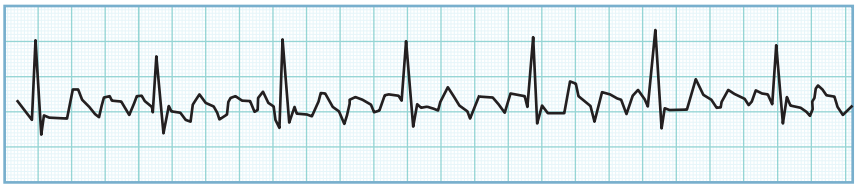

Figure 5-13. Atrial Flutter

Atrial Fibrillation

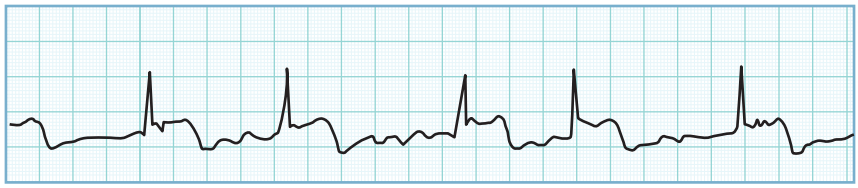

Figure 5-14. Atrial Fibrillation

Atrial fibrillation (AF) is the most common sustained cardiac rhythm disturbance. AF is associated with heart disease but also occurs with no detectable disease. Thromboembolic events occur with AF and can cause significant morbidity and mortality.

AF is a supraventricular tachyarrhythmia characterized by uncoordinated atrial activation with subsequent decline of atrial function. On the ECG, there is replacement of consistent P waves by fibrillatory waves that vary in size, shape, and timing, associated with an irregular, frequently rapid ventricular response (irregularly, irregular). The ventricular response to AF depends on electrophysiologic properties of the AV node, the level of vagal and sympathetic tone, and the action of drugs. Extremely rapid rates (>200 bpm) suggest the presence of an accessory pathway (W-P-W syndrome), which may manifest as AF. The rate of ischemic stroke among patients with nonrheumatic AF averages 5% per year, which is 2–7 times the rate for people without AF.

- The CHADS score is a clinical prediction rule for estimating the risk of stroke in patients with atrial fibrillation. It is used to determine whether treatment is required with anticoagulation or antiplatelet therapy.
- A high CHADS score corresponds to a greater risk of stroke (**C** for CHF; **H** for hypertension; **A** for age over 75; **D** for diabetes; **S** for prior stroke or TIA).
- Each condition receives 1 point except prior stroke, which gets 2.

CHADS Score	Treatment
0	• Give aspirin
1	• Give aspirin or warfarin
≥2	• Give warfarin

When AF is compared with atrial flutter, atrial flutter is found to be more organized than AF, with a sawtooth pattern of regular atrial activation called flutter (f) waves on the ECG, particularly visible in leads II, III, and aVF.

The diagnosis of atrial fibrillation should be considered in elderly patients who present with complaints of shortness of breath, dizziness, or palpitations. The arrhythmia should also be suspected in patients with acute fatigue or exacerbation of CHF. In some patients, atrial fibrillation may be identified on the basis of an irregularly irregular pulse or an ECG obtained for the evaluation of another condition.

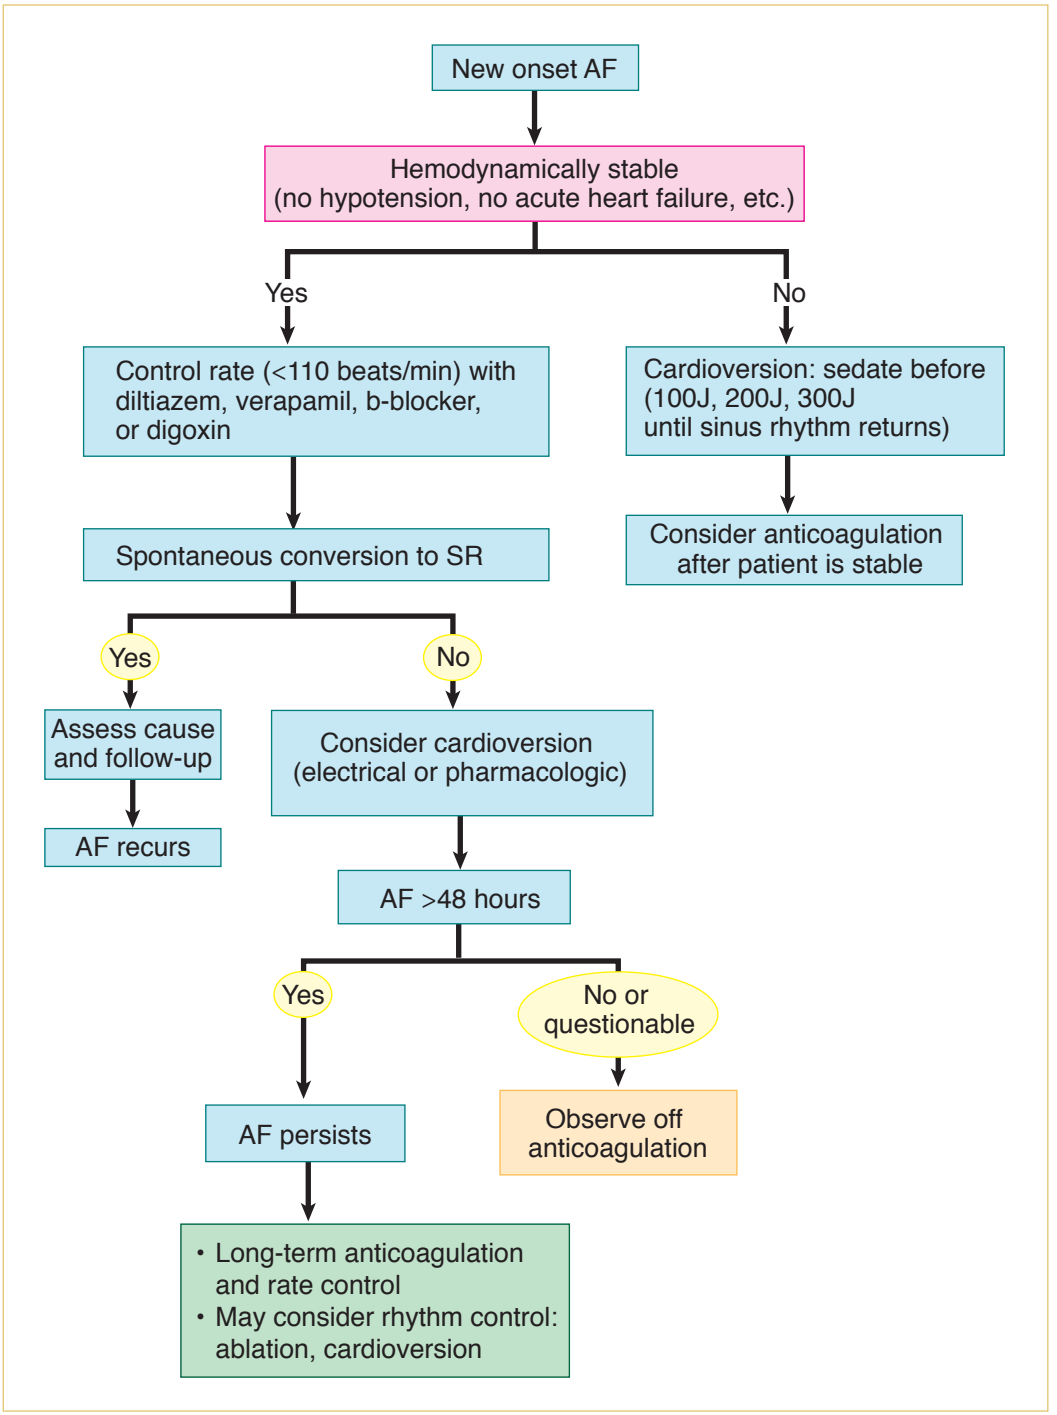

Figure 5-15. Management of Atrial Fibrillation (AF)

Cardiac conditions commonly associated with the development of AF include rheumatic mitral valve disease, coronary artery disease, CHF, and hypertension (cause atrial structures to dilate). Noncardiac conditions that can predispose patients to develop atrial fibrillation include hyperthyroidism, hypoxemia, and alcohol intoxication.

Evaluation of Patients with AF (Minimum Workup):

- **H and P:** identifies the severity of symptoms associated with AF as well as the clinical type (paroxysmal, persistent, first episode); also allows the assessment of frequency and duration of AF, as well as identification of precipitating factors and presence of underlying heart or lung disease.
- **ECG:** verifies the rhythm as well as identifies LVH, pre-excitation, prior MI.
- **Chest x-ray:** allows evaluation of the lung parenchyma and identifies coexisting lung disease.
- **Echocardiogram:** identifies LVH, valvular disease, atrial size, and possible left atrial thrombus.
- **Thyroid function tests:** excludes hyperthyroidism as a cause of AF.

Management. Two general approaches are used for managing AF: (*1*) ventricular **rate control**, and (*2*) **rhythm control** (attempts to convert to and maintain sinus rhythm). There is little difference in mortality between rate control and *pharmacologic* rhythm control. Studies confirm the importance of anticoagulation to reduce the risk of stroke in patients with AF. Interestingly, <25% of patients on an antiarrhythmic regimen remained in sinus rhythm at the end of 1 year. The standard of care is to slow the rate and anticoagulate if the CHADS score is >1.

As a general concept, rate control alone is considered for the patient who notices very little of the symptoms of the arrhythmia, while rhythm control is more likely to be applied to the patient who immediately notices the arrhythmia and is experiencing consequences of the arrhythmia, such as shortness of breath, or development of heart failure.

Cardioversion (rhythm control)—mechanical cardioversion: Involves an electrical shock synchronized with the intrinsic activity of the heart. The synchronization ensures that electrical stimulation does not occur during the vulnerable phase of the cardiac cycle. Mechanical cardioversion may be performed electively to restore sinus rhythm in patients with persistent AF. On the other hand, the need for mechanical cardioversion can be immediate, when the arrhythmia is the main factor responsible for hemodynamic instability (acute heart failure, hypotension, or angina). Since mechanical cardioversion carries a risk of thromboembolism, in cases of elective cardioversion, anticoagulation should be initiated before the procedure.

Cardioversion (rhythm control)—pharmacologic cardioversion: Cardioversion can be achieved by drugs. Pharmacologic cardioversion is less effective than electrical cardioversion, but the latter requires conscious sedation or anesthesia, whereas the former does not. The risk of thromboembolism or stroke does not differ between pharmacologic and electrical cardioversion. Thus, recommendations for anticoagulation are the same for both methods. Drugs proven *effective for pharmacologic cardioversion* of atrial fibrillation include: amiodarone, dofetilide, flecainide, ibutilide, propafenone, and quinidine. Drugs used to *maintain sinus rhythm* in patients with atrial fibrillation include amiodarone, disopyramide, dofetilide, flecainide, propafenone, and sotalol. Rate control is the standard of care for most patients.

Catheter ablation of AF foci is sometimes used as one of the nonpharmacologic therapies for eradicating AF. The techniques evolved with the demonstration that most AF is initiated by ectopic beats from focal areas that may be targeted for ablation. These foci arise more commonly from the 4 pulmonary veins. Thus, techniques have focused on the identification and elimination of these foci.

Note

Routine rhythm control for atrial fibrillation is not indicated. It is an exception.

Ventricular **rate control** to achieve a rate of <100–110 beats/min is one of the first steps in managing AF. Beta blockers, calcium channel blockers, and digoxin are the drugs most commonly used for rate control. These agents *do not* convert atrial fibrillation to sinus rhythm and should not be used for that purpose. Beta blockers and calcium channel blockers are effective in reducing the heart rate at rest and during exercise in patients with AF. Digoxin, because of the inotropic effects, is the drug of choice in patients with coexisting systolic heart failure. Factors that should guide drug selection include the patient's medical condition and the presence of concomitant heart failure. The following drugs are recommended for their demonstrated efficacy in rate control at rest and during exercise: diltiazem, atenolol, metoprolol, and verapamil.

Other key points: Rate control with chronic anticoagulation is the recommended strategy for the majority of patients with chronic AF. Rhythm control has not been shown to be superior to rate control (with chronic anticoagulation) in reducing morbidity and mortality.

Control the heart rate, then anticoagulate. Use aspirin for those with CHADS 0 or 1, and dabigatran, rivaroxaban, or warfarin for CHADS 2 or more. Heparin is not necessary prior to starting oral anticoagulants.

Patients with AF should receive chronic anticoagulation with dabigatran, rivaroxaban, or adjusted-dose warfarin, unless they have a specific contraindication.

Initial management: The goals are hemodynamic stabilization, ventricular rate control, and prevention of embolic complications. When AF does not terminate spontaneously, the ventricular rate should be treated to slow ventricular response and anticoagulation started.

Pre-excitation syndrome

Wolff-Parkinson-White Syndrome (WPW)

- Pre-excitation has been defined as a condition in which all or some portion of the ventricle is activated by atrial impulses earlier than if the impulses were to reach the ventricles by way of the normal cardiac conduction pathways. This is achieved by the use of accessory pathways (Kent bundle).
- Classically, the EKG shows a short PR interval followed by a wide QRS complex with a slurred initial deflection, or delta wave, that represents early ventricular activation.
- WPW is associated with:
  - Paroxysmal supraventricular arrhythmias alternating with ventricular arrhythmias
  - Atrial fibrillation and flutter

Treatment

If the patient is hemodynamically **unstable**, then immediate electrical cardioversion is indicated (synchronized cardioversion). If the patient is hemodynamically **stable**, then procainamide is the best medication. **Avoid digoxin, beta blockers and calcium-channel blockers**, as they can inhibit conduction in the normal conduction pathway. This will potentially increase the likelihood of developing ventricular or supraventricular tachycardia. If conduction is inhibited in the normal pathway, this will increase conduction in the aberrant conduction pathway. Ablation is used as definitive treatment.

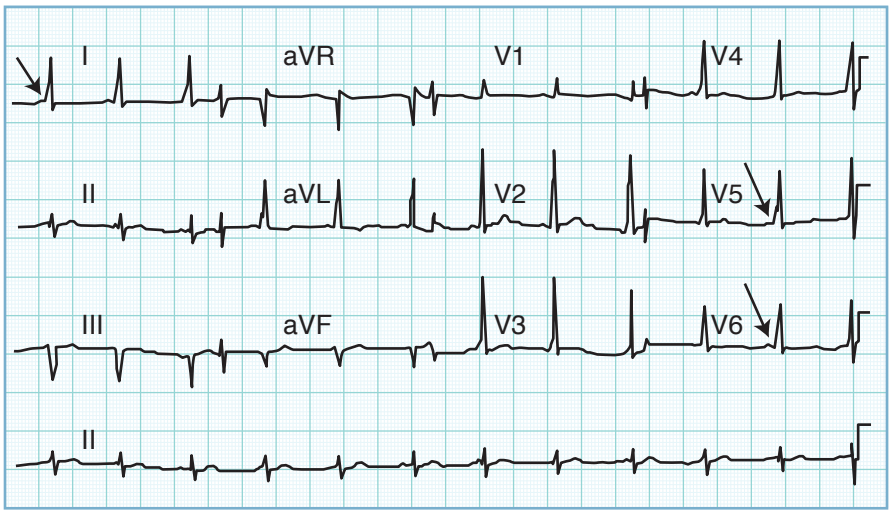

Figure 5-16. Wolff-Parkinson-White Syndrome

Ventricular arrhythmias

Ventricular tachycardia (VT) is defined as 3 or more consecutive beats of ventricular origin at a rate >120 beats/min. QRS complexes are wide and often bizarre.

Etiology

- Particularly after an acute MI
- Cardiomyopathies and rarely seen in patients with mitral valve prolapse
- Metabolic derangements, such as hypokalemia, hypercalcemia, hypomagnesemia, and hypoxia
- Digitalis toxicity and thioridazine drugs

Clinical Manifestations

- Patients with VT often present with concomitant hypotension, CHF, syncope, or cardiac arrest.
- Independent and asynchronous atrial and ventricular contractions produce the following signs. These signs are absent when atrial fibrillation is present.
  - Variation in systolic blood pressure, as measured peripherally
  - Variation in the intensity of the heart sounds
  - Intermittent cannon A waves in the jugular venous pulses caused by the simultaneous contraction of the atrium and the ventricles
  - Extra heart sounds
- Because of asynchronous activation of the right and left ventricles, the first and second sounds are widely split.

Diagnosis and differential diagnosis: *See* Table 5-14.

Table 5-14. QRS Complex

Wide (≥0.12 s)		Narrow (≤0.12 s)	
Regular	**Irregular**	**Regular**	**Irregular**
Ventricular tachycardia	Atrial fibrillation (rarely)	Sinus tachycardia	Atrial fibrillation
Supraventricular tachycardia (aberration)		Paroxysmal supraventricular tachycardia	Multifocal atrial tachycardia
Wolff-Parkinson-White syndrome		Atrial flutter	

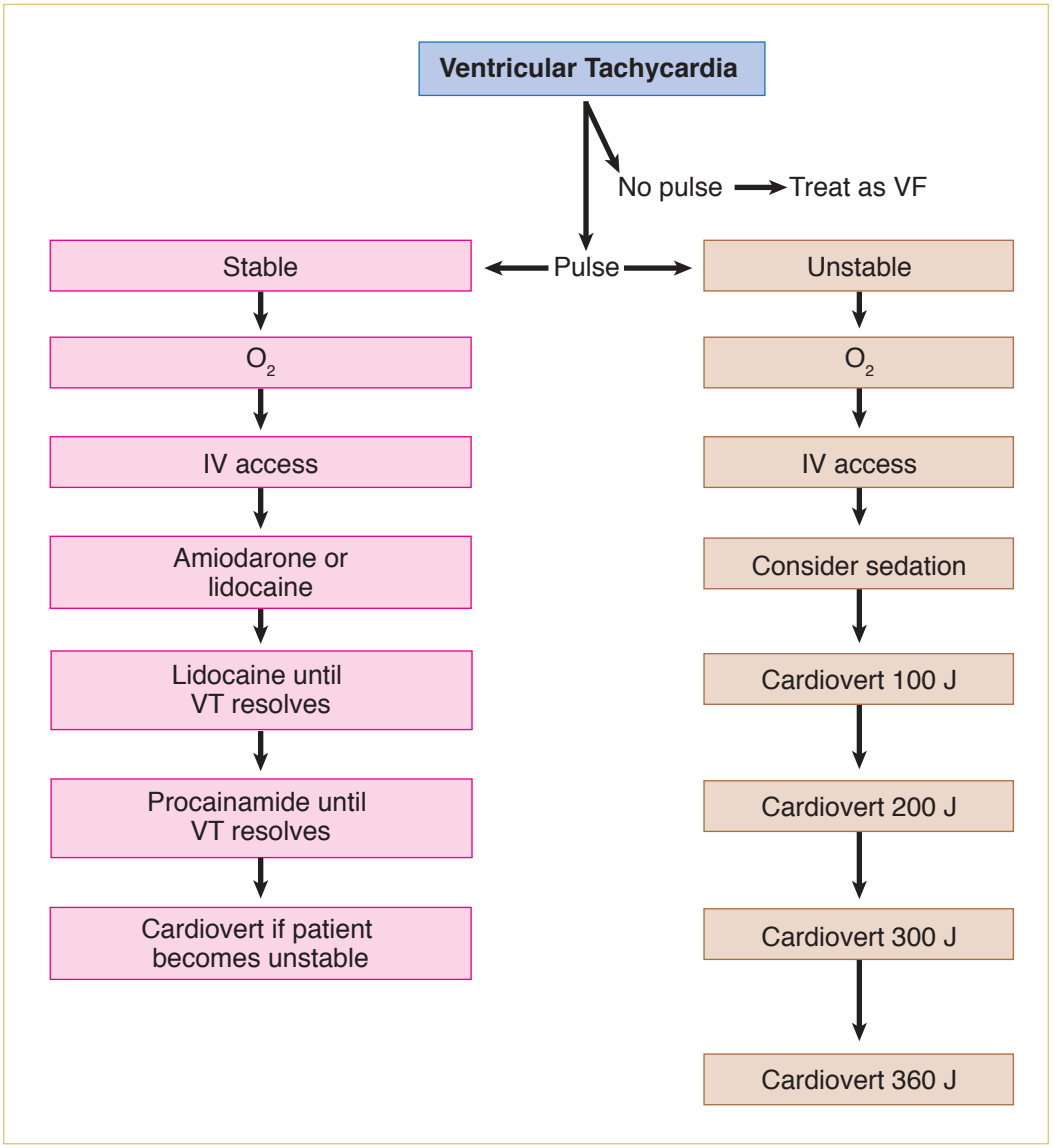

Figure 5-17. Management of VT

Torsade de Pointes

Definition. Characterized by undulating rotations of the QRS complexes around the electrocardiographic baseline.

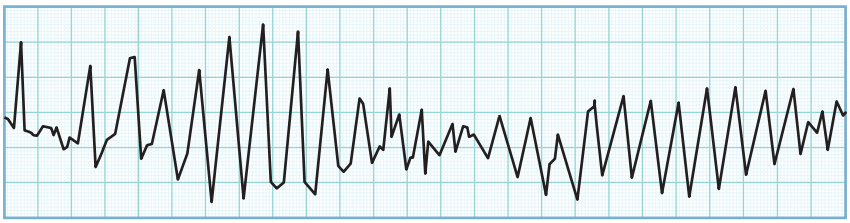

Figure 5-18. Torsade de Pointes

Arrhythmias initiated by a ventricular premature beat in the setting of abnormal ventricular repolarization characterized by prolongation of the QT interval.

Etiology. Antiarrhythmic drugs that prolong ventricular repolarization include:

- Quinidine
- Procainamide
- Disopyramide
- Psychotropic drugs, such as:
  - Phenothiazines
  - Thioridazine
  - Tricyclics
  - Lithium
  - Electrolyte imbalances, especially hypokalemia and hypomagnesemia
  - Central nervous system lesions, such as subarachnoid or intracerebral hemorrhage

Clinical manifestations. Patients with long QT interval are prone to recurrent dizziness or syncope from the ventricular tachycardia.

Sudden auditory stimuli, such as the ringing of the telephone at night, may initiate Torsade de Pointes in a vulnerable individual with a long QT interval syndrome.

Treatment. Treat the underlying disorder. In the case of the antiarrhythmics, use a drug such as lidocaine.

- With electrolyte imbalance disorders, repletion with potassium and magnesium is needed.
- Cardiac pacing or an isoproterenol infusion may suppress episodes of tachycardia and may be useful for emergency treatments.
- If hemodynamically unstable (e.g., hypotension), consider cardioversion, but this dysrhythmia often reoccurs.

Ventricular Fibrillation

See the Emergency Medicine section.

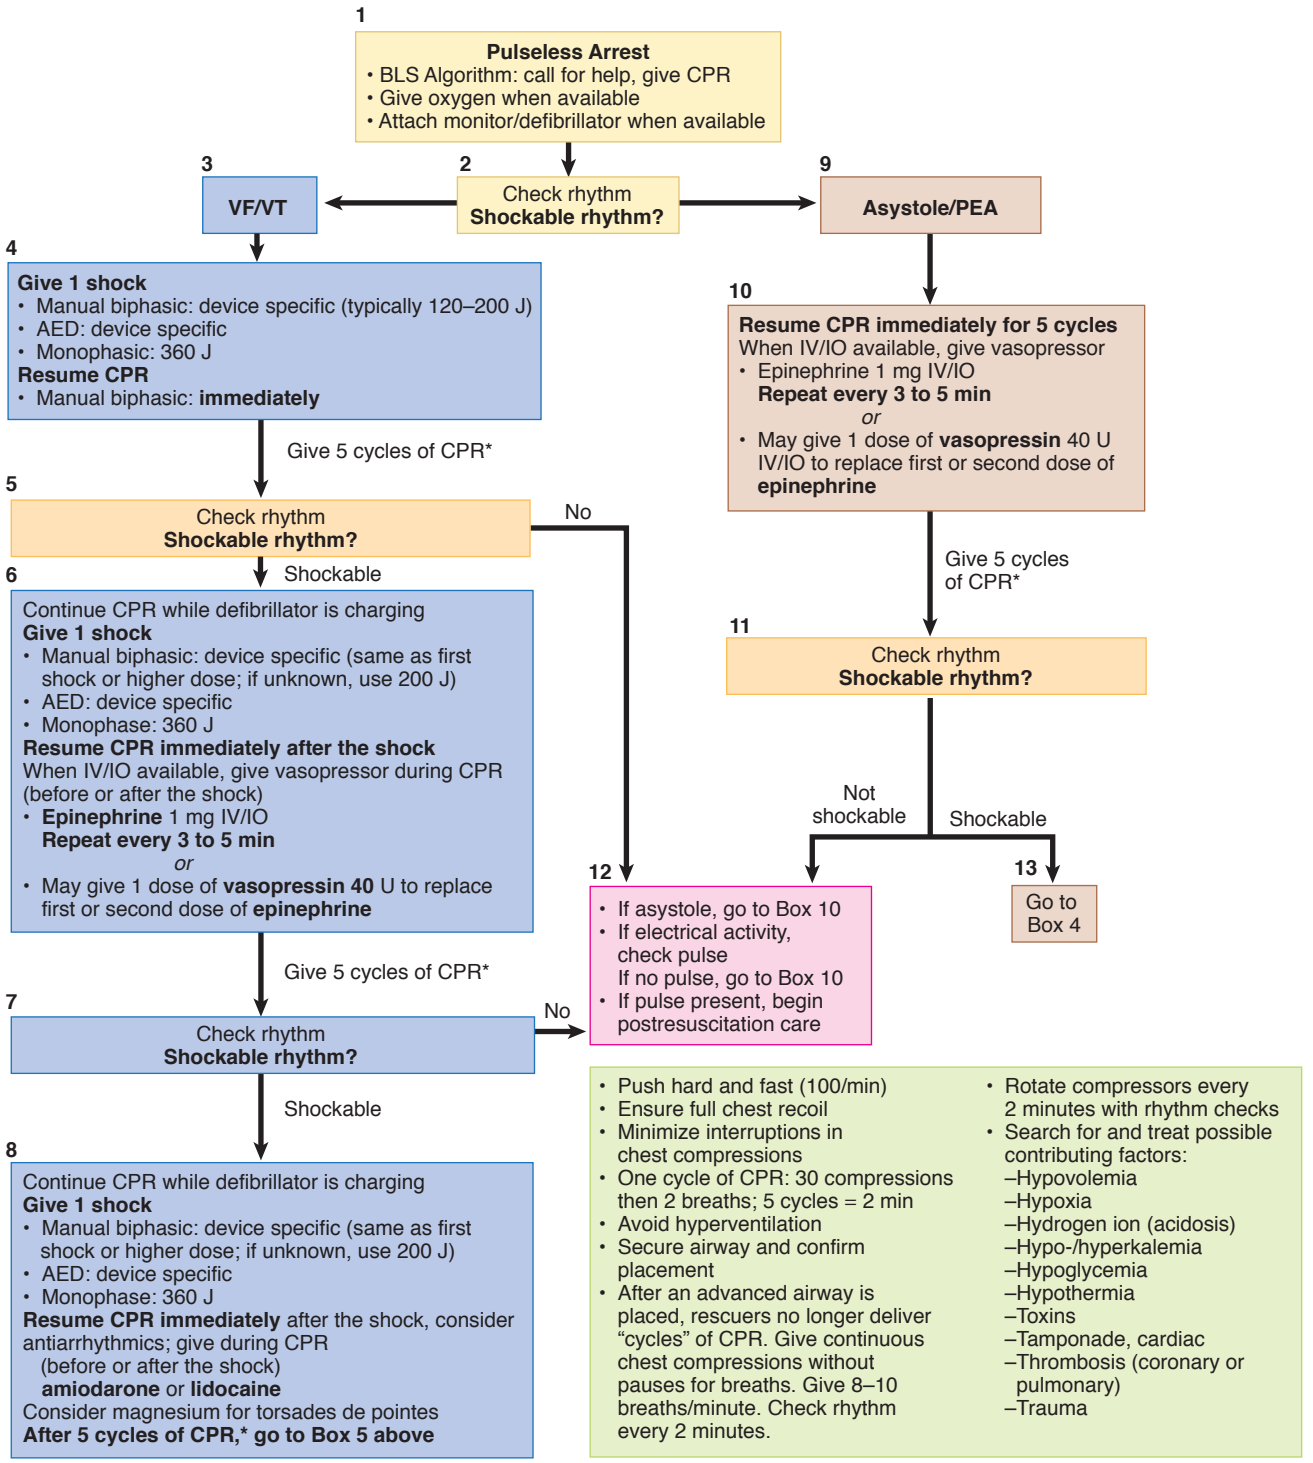

Figure 5-19. ACLS Pulseless Arrest Algorithm

DRUGS USED TO TREAT CARDIOVASCULAR DISEASE

Amiodarone

Amiodarone is a very effective antiarrhythmic drug, and can be used in ventricular tachycardia, AF, and atrial flutter. Because it has a very long half-life (>50 days), drug interactions are possible for weeks after discontinuation.

The most severe side effects of amiodarone therapy are related to the lungs and present as cough, fever, or painful breathing. These reactions can be fatal. About 20% of patients who receive amiodarone experience some form of nerve toxicity. Symptoms may include imbalance or changes in gait, tremor, numbness in the fingers or toes, dizziness, muscle weakness, or loss of coordination. Thyroid dysfunction is also common, since the drug molecule is chemically related to thyroxine. Hypothyroidism seems to be more common, but hyperthyroidism can also occur. Since many patients experience an exaggerated response to the harmful effects of sunlight, avoidance of extensive sun exposure and the use of protective clothing should be used to help prevent this.

Long-term administration of amiodarone may occasionally result in a blue-gray discoloration of the skin. This effect seems to be more common in patients with fair skin. Patients also may experience visual impairment or other disturbances such as "halo lights" and blurred vision. Corneal deposits (microdeposits) occur in virtually all patients who receive amiodarone for at least 6 months.

Nitrates

- In **low doses**, nitrates increase venous dilation and subsequently reduce preload.
- In **medium doses**, nitrates increase arteriolar dilatation and subsequently decrease afterload and preload.
- In **high doses**, nitrates increase coronary artery dilatation and subsequently increase oxygen supply.

Side effects: Vasodilation can lead to orthostatic hypotension, reflex tachycardia, throbbing headache, and blushing. Nitrates are contraindicated if systolic blood pressure <90 mm Hg. You must have a window-free period of >8 hours with nitrate therapy to reduce the incidence of tachyphylaxis.

Antiarrhythmic Drugs

Table 5-15. Antiarrhythmic Drugs

Drug	Adverse Effects
Disopyramide	Anticholinergic effects; hypotension; heart failure; heart block; tachyarrhythmia
Lidocaine	CNS (drowsiness, agitation, seizures); heart block
Phenytoin	CNS (ataxia, nystagmus, drowsiness); hypotension and heart block with rapid IV injection
Procainamide	Lupus-like syndrome; GI; rash; hypotension; aggravation of arrhythmia; blood dyscrasias
Quinidine	Aggravation of arrhythmias ("quinidine syncope"); thrombocytopenia; fever, rash; cinchonism; GI symptoms; digoxin-quinidine interaction (elevation of digoxin levels)
β-adrenergic blocking agents	Heart block; hypotension; asthma; hypoglycemia; lethargy; impotence
Verapamil	CHF, asystole, constipation
Adenosine	Transient dyspnea, noncardiac chest pain, rarely hypotension
Mexiletine	Lidocaine-like drug; local anesthetic
Tocainide	Lidocaine-like drug
Amiodarone	Very long half-life (20–40 d); may increase digoxin level; may worsen existing cardiac conduction disturbances; may prolong Coumadin effect
Encainide	Negative inotropism; QRS and PR prolongation
Flecainide	Negative inotropism; QRS and PR prolongation
Propafenone	Negative inotropism; QRS and PR prolongation

Beta Blockers

- Decrease heart rate, blood pressure, and contractility, which decrease myocardial oxygen requirement
- Contraindicated in presence of severe asthma in about one-third of patients
- Nonselective beta blockers may mask hypoglycemic symptoms in insulin-dependent diabetics
- Shown to improve survival after an acute MI and in CHF

Adverse effects of beta blockade therapy are as follows:

- Fatigue, insomnia
- Mental depression
- Adverse effects on lipid panel
- Hallucinations
- Raynaud phenomenon
- Bronchoconstriction
- Mask signs and symptoms of insulin-induced hypoglycemia
- Sexual dysfunction

Table 5-16. Pharmacologic Properties of Select β-Blocking Agents

Generic Name (Trade Name)	Cardio-Selective
Metoprolol (Lopressor)	Yes
Atenolol (Tenormin)	Yes
Propranolol (Inderal)	No
Nadolol (Corgard)	No
Timolol (Blocadren)	No
Pindolol (Visken)	No
Acebutolol (Sectral)	Yes
Labetalol (Normodyne or Trandate)	No
Esmolol (IV)	Yes

Nebivolol is a unique beta blocker; it is a beta-1 specific blocker that increases nitric oxide and thus does not cause erectile dysfunction.

Calcium Channel Blockers

Calcium channel blockers work by producing decreases in preload and afterload. They may be harmful in the postinfarction period, especially if the patient has left ventricular failure. Their efficacy in angina is very limited—there is no mortality benefit.

Adverse effects of calcium channel blockers are as follows:

Cardiac

- CHF
- Reflex tachycardia
- Hypotension
- Lightheadedness
- AV block

Noncardiac

- Flushing
- Headache
- Weakness
- Constipation
- Nasal congestion
- Wheezing
- Peripheral edema
- Gingival hyperplasia

SHOCK SYNDROMES

Shock is a broad term that describes a state where oxygen delivery to the tissues is inadequate to meet the demands. Shock can be described as the imbalance between tissue oxygen supply and demand.

Four general types of shock syndromes are recognized: distributive, cardiogenic, hypovolemic, and obstructive. There are many etiologies within each class.

- **Distributive shock:** caused by pathologic peripheral blood vessel vasodilation
  - Examples are sepsis (especially gram-negative), anaphylaxis, neurogenic
  - Septic shock is the most common form of shock among patients admitted to the ICU (followed by cardiogenic and hypovolemic shock)
- **Cardiogenic shock:** related to impaired heart pump function
  - Typical causes include acute coronary syndromes, valve failure (especially acute) and dysrhythmias
- **Hypovolemic shock:** caused by decreased circulatory volume
  - Examples are hemorrhage (GI bleed) and fluid loss
- **Obstructive shock:** non-cardiac obstruction to blood flow
  - Examples are pulmonary embolus, tension pneumothorax, and cardiac tamponade

The diagnosis of shock is a clinical diagnosis.

Table 5-17. Physiologic Characteristics of Various Forms of Shock

Type of Shock	Heart Rate	Central Venous Pressure	Contractility	Systemic Vascular Resistance
Cardiogenic	↑	↑	↓↓	↑
Hypovolemic	↑	↓↓	±↑	↑
Distributive (sepsis)	↑	↓↓	±	↓
Obstructive	↑	±↑	±	↑ (tamponade, PE) ↓ (tension PTX)

In all of the forms above, cardiac output decreases; the only exceptions are the hyperdynamic state of septic shock and rarely traumatic shock, both of which may have elevated cardiac output.

Treatment should begin emergently since early therapy has been shown to improve outcomes.

- Always start with the ABCs and strongly consider intubation in most cases of shock for airway protection.
- Arterial oxygen saturation should be maximized.
- Circulatory support with IV fluids is paramount in most cases; use caution with rapid fluid administration to the patient with cardiogenic shock and pulmonary edema.
- Transfusion of blood products may be necessary in certain types of shock.
- If volume resuscitation does not improve hemodynamic status, consider epinephrine, dopamine, or vasopressin.

Furthermore, aggressive treatment of the underlying cause of the shock is warranted, e.g., sepsis syndromes should be treated with broad-spectrum antibiotics, while obstructive shock due to PE may need thrombolysis and anticoagulation.

Hematology 6

Learning Objectives

- ❑ List the types of anemia and describe their pathophysiology, diagnosis, and treatment
- ❑ Describe the presentation and diagnosis of hematologic neoplasias including acute leukemia, chronic leukemias, plasma cell disorders, and lymphomas
- ❑ Describe common platelet disorders
- ❑ List defects that can occur in the coagulation cascade and their associated disorders

ANEMIA

Definition. Anemia is a condition marked by the following:

- Hematocrit <41% in men or <36% in women, or
- Hemoglobin <13.5 gm/dL in men or <12 gm/dL in women

Etiology. Anemias are most easily classified according to their cell size.

- **Microcytic anemia** means a low mean corpuscular volume (MCV) <80. These are most commonly a result of iron deficiency, anemia of chronic disease, thalassemia, sideroblastosis, and lead poisoning. Anemia of chronic disease can be either microcytic or normocytic.
- **Macrocytic anemia** is characterized by an elevated MCV >100. This is most commonly from vitamin B12 or folic acid deficiency but can also result from the toxic effects of alcohol, liver disease, or chemotherapeutic agents such as methotrexate or medications such as zidovudine (AZT) or phenytoin.
- **Normocytic anemia** is characterized by a normal MCV. This can be from an early form of the conditions described above, as well as most forms of hemolysis and aplastic anemia.

Clinical Presentation. The predominant symptoms of anemia are based on the severity of the anemia rather than the specific etiology. Early symptoms include fatigue, tiredness, and poor exercise tolerance. As the anemia worsens, the patient develops dyspnea on exertion and lightheadedness. Eventually, confusion and altered mental status may develop as oxygen delivery to the brain decreases. Death from anemia is most often from decreased oxygen delivery to the heart, resulting in the development of myocardial ischemia.

The severity of symptoms is related to the underlying condition of the patient. A healthy young patient may have no symptoms at all with hematocrit 27–29%, whereas an older patient with heart disease may develop dyspnea or anginal symptoms with the same hematocrit.

Diagnosis. Once a diagnosis of anemia is determined based on a low hematocrit or hemoglobin, the first step is to determine the MCV. Iron studies, reticulocyte count, peripheral smear, red cell distribution width (RDW), Coombs test, vitamin B12, folate levels, and even occasionally a bone marrow biopsy may be necessary to determine a specific etiology. The tests ordered depend on the specifics of the case presented.

Treatment. Besides blood transfusion, treatment cannot be generalized. Packed RBCs are used to maintain a hematocrit >25–30%. This is based on the underlying condition of the patient. A healthy young patient can have transfusion withheld until the hematocrit is in the low 20%s. An older patient with coronary artery disease will need to be maintained when hematocrit >30%. The hematocrit should rise approximately 3 points for every unit of packed RBCs given. Whole blood is rarely, if ever, used.

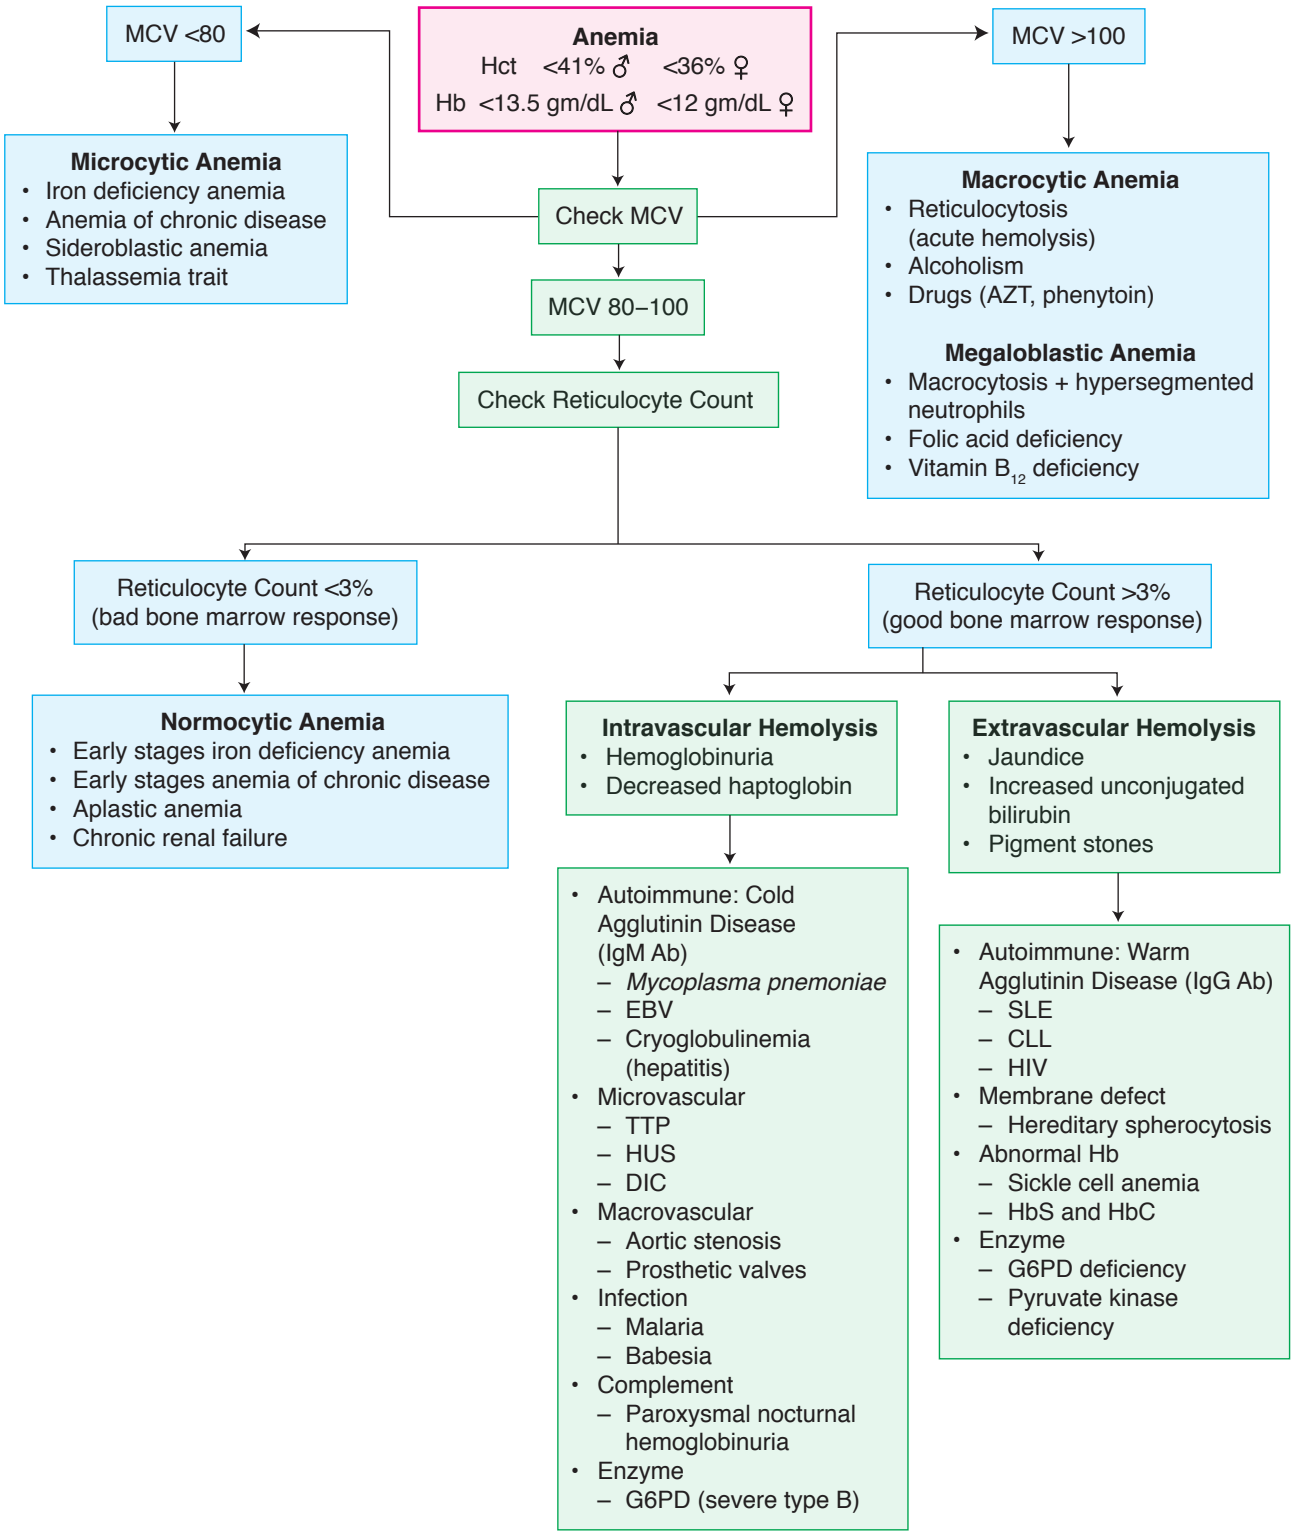

Figure 6-1. Evaluation of Patients with Anemia

MICROCYTIC ANEMIA

Iron Deficiency Anemia

Definition. An anemia with diminished red blood cell production and an MCV <80 characterized by hypochromic cells and low levels of stored iron.

Etiology. Iron deficiency anemia is almost always caused by blood loss. The most common type of blood loss is GI or menstrual. Iron absorption is tightly regulated. A man requires about 1 mg per day and a woman about 2–3 mg per day on average. It is difficult for the body to increase the level of iron absorption. If there is even a modest increase in blood loss—occult blood in the stool, a heavier menstrual flow, or an increased demand such as during pregnancy—the body is poorly equipped to increase its level of absorption to exceed 3–4 mg per day. Other etiologies are increased urinary loss of blood, malabsorption, hemolysis, and poor oral intake.

Clinical Presentation. Mild anemia may result in absent or very limited symptoms. As the hematocrit approaches 30%, symptoms of fatigue and poor exercise tolerance may develop. As the hematocrit lowers to 25%, tachycardia, palpitations, dyspnea on exertion, and pallor develop. Older patients and those with coronary artery disease may become dyspneic at higher levels of hematocrit. More severe anemia results in lightheadedness, confusion, syncope, and chest pain. A systolic ejection murmur ("flow" murmur) may develop in any patient with moderately severe anemia. These symptoms are not specific for iron deficiency anemia and may develop with any form of anemia provided it is sufficiently severe.

Symptoms specific to iron deficiency are rare and cannot be relied upon to determine the diagnosis. These include brittle nails, spoon shaped nails, glossitis, and pica. Iron deficiency anemia as a specific diagnosis is determined by laboratory findings, not symptoms.

Clinical Pearl

In early iron deficiency, serum iron may be normal. (Ferritin is low and TIBC is elevated.)

Diagnosis. A low serum ferritin <10 ng/mL is the most characteristic finding of iron deficiency anemia. Low ferritin has good specificity (>99%) but poor sensitivity (60%); the ferritin level may be falsely elevated because it is an acute phase reactant and may be elevated in other inflammatory states or with malignancy. MCV is low except in very early cases. The serum iron is low and the total iron binding capacity is high. The RDW is elevated. The most specific test, although rarely necessary, is a bone marrow biopsy looking for stainable iron stores. The reticulocyte count is low. Platelet levels rise.

Treatment. Oral therapy with ferrous sulfate tablets is the most common method of therapy. Oral therapy should be continued until Hb and Ht have normalized and an additional 2-3 months to "restore" iron stores. With replacement of iron, a brisk increase in reticulocytes will be seen 2 weeks into treatment. Parenteral iron is used in patients with malabsorption, kidney disease, or an intolerance to oral therapy. Blood transfusion is the most effective method of delivering iron but, of course, is not a standard method of correcting iron deficiency anemia except in cases with severe symptoms.

Anemia of Chronic Disease

Definition. A defect in the ability to make use of iron sequestered in stores within the reticuloendothelial system. It can be either microcytic or normocytic.

Etiology. Anemia can accompany virtually any chronic inflammatory, infectious, or neoplastic condition. Hepcidin, a regulator of iron metabolism, plays an important role in anemia of chronic disease. In states where hepcidin level is abnormally high (e.g., inflammation), serum iron falls due to iron trapping within macrophages and liver cells and decreased gut iron absorption. This typically leads to anemia caused by an inadequate amount of serum iron being available for developing red cells.

- Hepcidin inhibits iron transport by binding to the iron export channel ferroportin located on the surface of gut enterocytes and the plasma membrane of macrophages.
- By inhibiting ferroportin, it prevents iron from being exported and the iron is sequestered in the cells. It also prevents enterocytes from allowing iron into the hepatic portal system, thereby reducing dietary iron absorption.
- The iron release from macrophages is also reduced by ferroportin inhibition.
- In genetic diseases where hepcidin level is abnormally low, iron overload may occur (hemochromatosis) due to unwarranted ferroportin facilitated iron influx.

Clinical Presentation. The symptoms are based on the severity of the anemia as described above. The only other symptoms are based on the specifics of the underlying disease.

Diagnosis. The serum ferritin level is normal or elevated. The serum iron level and total iron binding capacity (TIBC) are both low. The reticulocyte count is low.

Treatment. Correct the underlying disease. Iron supplementation and erythropoietin will not help, except in renal disease and anemia caused by chemotherapy or radiation therapy.

Sideroblastic Anemia

Definition. A microcytic anemia caused by a disorder in the synthesis of hemoglobin characterized by trapped iron in the mitochondria of nucleated RBCs.

Etiology. There are both hereditary and acquired forms. The hereditary form is from either a defect in aminolevulinic acid synthase or an abnormality in vitamin B6 metabolism. Acquired forms are from drugs such as chloramphenicol, isoniazid, or alcohol. Lead poisoning can cause sideroblastic anemia as well. There is an association with myelodysplastic syndromes and refractory anemia. Sideroblastic anemia may progress to acute myelogenous leukemia in a small percentage of patients.

Clinical Presentation. The symptoms are related to the severity of the anemia as described above. There is no specific presenting finding that will be sufficiently suggestive of sideroblastic anemia to allow a diagnosis without significant laboratory evaluation.

Diagnosis. The serum ferritin level is elevated. Transferrin saturation is very high, and therefore the TIBC is very low. The serum iron level is high. The most specific test is a Prussian Blue stain of RBCs in the marrow that will reveal the ringed sideroblasts. Marrow reticuloendothelial iron is strikingly increased. Sideroblastic anemia is the only microcytic anemia in which serum iron is elevated.

Treatment. Remove the offending drug as appropriate. Some patients, especially those with INH-associated sideroblastic anemia, will respond to pyridoxine therapy 2-4 mg per day. Occasionally, sideroblastic anemia may be severe enough to warrant transfusion. In refractory cases, BMT may be considered.

Clinical Pearl

Both iron deficiency and anemia of chronic disease may have decreased serum iron.

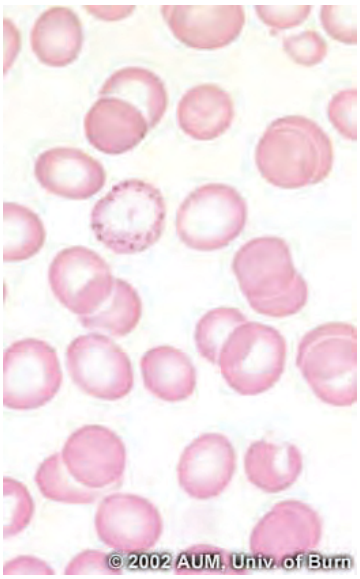

Figure 6-2. Basophilic Stippling, a Feature of Lead Poisoning and Other Diseases

Thalassemia

Definition. The hereditary underproduction of either the alpha or beta globin chains of the hemoglobin molecule resulting in a hypochromic, microcytic anemia.

Etiology. Gene deletion results in variable levels of disease. There are 4 genes coding for the alpha chain of hemoglobin. There can be deletions of 1, 2, 3, or all 4 genes. Beta thalassemia can be mutated in either one or two genes. Alpha thalassemia is more common in Asian populations. Beta thalassemia is more common in Mediterranean populations.

Clinical Presentation. The presentation is dependent on the number of abnormal genes.

- In alpha thalassemia, 1 gene deleted yields a normal patient. The CBC is normal, the hemoglobin level is normal, and the MCV is normal. Individuals with 2 genes deleted have a mild anemia with hematocrits ranging from 30–40% with a strikingly low MCV. Those with 3 genes deleted have more profound anemia with hematocrits 22–32% as well as the very low MCV. Four-gene-deleted alpha thalassemia patients die in utero secondary to gamma chain tetrads called hemoglobin Barts.
- In beta thalassemia trait there is a mild anemia with marked microcytosis (low MCV). Patients with beta thalassemia major are homozygous for mutations of both genes coding for the beta hemoglobin gene. These patients with beta thalassemia major, also known as Cooley anemia, become severely symptomatic starting at 6 months of age when the body would normally switch from fetal hemoglobin to adult hemoglobin. They are severely symptomatic with growth failure, hepatosplenomegaly, jaundice, and bony deformities secondary to extramedullary hematopoiesis. They are later symptomatic from hemochromatosis, cirrhosis, and CHF from chronic anemia and transfusion dependence.

Diagnosis. Clues to the diagnosis of thalassemia trait is a mild anemia with a profound microcytosis. Beta thalassemia major has the severe symptoms, large spleen, and bone abnormalities described above. Both forms of thalassemia are diagnosed by having a microcytic anemia with normal iron studies. Hemoglobin electrophoresis differentiates which type of thalassemia is present. In beta thalassemia, there is an increased level of hemoglobin F and hemoglobin A_2. In beta thalassemia major, the hemoglobin is as low as 3–4 g/dL. Those with alpha thalassemia will have normal amounts of hemoglobins F and A_2. Tetrads of beta chains are called hemoglobin H. Hemoglobin H is present in alpha thalassemia with 3 of 4 genes deleted. Target cells are present in all forms of thalassemia trait and thalassemia major. The RDW is normal in all forms because all of the cells are of the same size.

Treatment. Thalassemia traits of both the alpha and beta types do not require specific treatment. Beta thalassemia major patients require blood transfusions once or twice a month. The chronic transfusions lead to iron overload, which requires treatment with deferasirox. Oral deferasirox is the standard of care. This is easier to give than deferoxamine, which requires a subcutaneous pump. Splenectomy eliminates a major area of hemolysis and therefore helps reduce transfusion requirements. A small number of patients can be treated with a bone marrow transplantation.

Clinical Pearl

Thalassemia trait syndromes are asymptomatic.

Table 6-1. Iron Indices in Microcytic Anemia Syndromes

Fe Panel	Iron Deficiency Anemia	Anemia of Chronic Disease	Sideroblastic Anemia	Thalassemia Minor
Serum Iron	Decreased	Decreased	Increased	Normal
Serum Ferritin	Decreased or Normal (early)	Increased	Increased	Normal
Transferrin/ TIBC	Increased	Decreased	Decreased	Normal
% Saturation	Decreased	N/ Decreased	Increased	Normal

MACROCYTIC ANEMIA

A 72-year-old alcoholic man comes to the office with several weeks of memory loss and tingling in his feet. He has a hematocrit of 32% with an MCV of 110.

Vitamin B12 (Cyanocobalamine) Deficiency

Definition. Decreased absorption or intake of vitamin B12 resulting in hematologic and/or neurologic abnormalities.

Etiology. The most common cause of B12 deficiency is pernicious anemia, which is a disorder resulting in decreased intrinsic factor production due to autoimmune destruction of parietal cells. The incidence of pernicious anemia increases with age. Gastrectomy and atrophic gastritis can also decrease intrinsic factor production. Various forms of malabsorption such

as sprue, regional enteritis, and blind loop syndrome can block absorption of vitamin B12. Pancreatic insufficiency can result in the inability to absorb the vitamin. Rarely, tapeworm infection with *Diphyllobothrium latum* can decrease absorption. Decreased intake is unusual and requires several years to produce disease.

Clinical Presentation. Manifestations vary with the severity of the anemia. As such, you cannot specifically determine that a patient has B12 deficiency only from the symptoms of anemia. Neurologic manifestations may involve almost any level of the neurologic system. Patients may have peripheral neuropathy, position sense abnormality, vibratory, psychiatric, autonomic, motor, cranial nerve, bowel, bladder, and sexual dysfunction. Glossitis, diarrhea, and abdominal pain may occur. You may have either the hematologic or neurologic deficits individually or combined.

Diagnosis. Anemia with macrocytosis (increased MCV). A smaller number of patients may have the neurologic deficits alone. The WBCs have hypersegmented neutrophils with a mean lobe count >4. The red cells are characterized by macro-ovalocytes. Although macrocytosis can occur with hemolysis, liver disease, and myelodysplasia, these give *round* macrocytes. B12 and folate deficiency produce oval macrocytes. The hematologic pattern of vitamin B12 deficiency is indistinguishable from folate deficiency. The reticulocyte count is reduced, although the bone marrow is hypercellular. Pancytopenia may occur. An elevated LDH, bilirubin, and iron level may occur and are due to mild hemolysis of immature erythrocytes.

The most specific test is a low B12 level. Antibodies to intrinsic factor and parietal cells confirm the etiology as pernicious anemia. The Schilling test is rarely used to determine the etiology of vitamin B12 deficiency. It is not necessary if the patient has a low B12 level combined with the presence of antibodies to intrinsic factor. An elevated methylmalonic acid level occurs with B12 deficiency and is useful if the B12 level is equivocal.

Treatment. Replace the vitamin B12 lifelong. Options available for treating clinical vitamin B12 deficiency include **oral (daily)** and **parenteral (monthly intramuscular or subcutaneous)** preparations. Parenteral route is recommended for patients with neurologic manifestations of B12 deficiency. IV dosing is not recommended because that would result in most of the vitamin being lost in the urine.

Response of vitamin B12 deficiency anemia to treatment is usually rapid, with reticulocytosis occurring within 2–5 days and hematocrit normalizing within weeks. Treatment with cobalamin effectively halts progression of the deficiency process but **might not fully reverse more advanced neurologic effects**. If the underlying cause of the vitamin B12 deficiency is treatable (e.g., fish tapeworm infection or bacterial overgrowth), then treatment should include addressing the underlying etiology.

Patients who have vitamin B12 deficiency with associated megaloblastic anemia might experience severe **hypokalemia** and fluid overload early in treatment due to increased erythropoiesis, cellular uptake of potassium, and increased blood volume. Once treated for a vitamin B12 deficiency due to pernicious anemia or other irreversible problems with absorption, patients need to continue some form of cobalamin therapy **lifelong**.

Folic acid replacement can correct the hematologic abnormalities of B12 deficiency, but not the neurologic abnormalities.

Folic Acid Deficiency

Definition. Deficiency in folic acid levels leading to anemia.

Etiology. Folic acid deficiency is almost always due to some form of decreased dietary intake. Occasionally, increased requirements from pregnancy, skin loss in diseases like eczema, or increased loss from dialysis and certain anticonvulsants such as phenytoin may occur. Consumption of high amounts of alcohol may have a direct effect on the folate absorption, due to inhibition of the enzyme intestinal conjugase. Folate is presented in foods as polyglutamate, which is then converted into monoglutamates by intestinal conjugase.

Clinical Presentation. Entirely dependent on the severity of the anemia. As described above.

Diagnosis. The hematologic presentation of folic acid deficiency is identical to B12 deficiency. The diagnosis is based on a low red-blood-cell, folic-acid level.

Treatment. Replace folic acid, almost always orally.

HEMOLYTIC ANEMIA

Hemolytic anemias are caused by decreased red blood cell survival from increased destruction of the cells. The destruction may be either in the blood vessels (intravascular) or outside the vessels (extravascular), which generally means inside the spleen.

Etiology. Hemolytic anemias may either be chronic, as in sickle cell disease, paroxysmal nocturnal hemoglobinuria, and hereditary spherocytosis, or acute, such as in drug-induced hemolysis, autoimmune hemolysis, or glucose 6-phosphate dehydrogenase deficiency.

Table 6-2. Classification of Hemolytic Anemias

Hereditary Anemias	Acquired Anemias
Membrane: heriditary spherocytosis, hereditary elliptocytosis	**Immune** • **Autoimmune:** warm antibody type, cold antibody type • **Alloimmune:** hemolytic transfusion reactions, hemolytic disease of the newborn, allografts (especially stem cell transplantation) • **Drug-associated**
Metabolism: G6PD deficiency, pyruvate kinase deficiency	**Red Cell Fragmentation Syndromes**
Hemoglobin: genetic abnormalities (Hb S, Hb C, unstable)	**Infections**: malaria, clostridia
	Chemical and Physical Agents: drugs, industrial/domestic substances, burns
	Secondary: liver and renal disease
	Paroxysmal Nocturnal Hemoglobinuria

Clinical Presentation. The usual symptoms of anemia are present based on the severity of the disease, not necessarily the etiology. Fatigue and weakness occur with mild disease. Dyspnea and later confusion occur with more severe disease. The major difference between hemolytic anemia and the micro- and macrocytic anemias is that hemolysis is more often the etiology when the onset is sudden. This is, of course, provided that simple blood loss has been excluded. Hemolysis is often associated with jaundice and dark urine as well. Specific findings associated with each disease are described below. Fever, chills, chest pain, tachycardia, and backache may occur if the intravascular hemolysis is particularly rapid.

Diagnosis. Patients with hemolytic anemias generally have a normal MCV, but the MCV may be slightly elevated because reticulocytes are somewhat larger than older cells. The reticulocyte count is elevated. The LDH and indirect bilirubin are elevated. Bilirubin levels above 4 are unusual with hemolysis alone. The peripheral smear may aid in the specific diagnosis, and the haptoglobin may be low with intravascular hemolysis. Hemoglobin may be present in the urine when intravascular hemolysis is sudden and severe because free hemoglobin spills into the urine. There should not be bilirubin in the urine because indirect bilirubin is bound to albumin and should not filter through the glomerulus. Hemosiderin is a metabolic product of hemoglobin. Hemosiderin may be present in the urine if the hemolysis is severe and lasts for several days.

Treatment. Transfusion is needed as in all forms of anemia when the hematocrit becomes low. Hydration is, in general, useful to help prevent toxicity to the kidney tubule from the free hemoglobin. Specific therapy is discussed with each disease below. Patients with chronic hemolytic anemia need to be maintained on chronic folic acid therapy, as there is an increase in cell turnover.

Sickle Cell Disease

Definition. A hereditary form of chronic hemolysis ranging from asymptomatic to severe, overwhelming crisis. It is characterized by irreversibly sickled cells and recurrent painful crises.

Etiology. Sickle cell disease is an autosomal recessive hereditary disease. Hemoglobin S is due to a substitution of a valine for glutamic acid as the sixth amino acid of the beta globin chain. The heterozygous form (trait) is present in 8% of the African-American population, and the homozygous form (disease) is present in 1 in 400 African-Americans. All of those with the trait are asymptomatic.

- A sickle cell acute painful crisis can be precipitated by hypoxia, dehydration, acidosis, infection, and fever. However, the crisis may occur without the presence of these factors.
- Sickle cell crisis is usually not associated with an increase in hemolysis or drop in hematocrit. When increased hemolysis occurs, another etiology such as concomitant glucose 6 phosphate dehydrogenase deficiency (G6PD) or acute splenic sequestration in a child should be considered. A sudden drop in hematocrit may also be caused by Parvovirus B_{19} infection or folate deficiency. This drop in hematocrit is from acute aplasia (decrease in cell production), not hemolysis.

Clinical Presentation. Chronic manifestations include renal concentrating defects (isosthenuria), hematuria, ulcerations of the skin of the legs, bilirubin gallstones, aseptic necrosis of the femoral head, osteomyelitis, retinopathy, recurrent infections from *Pneumococcus* or *Haemophilus*, growth retardation, and splenomegaly followed in adulthood by autosplenectomy. The acute painful crisis consists of back, rib, chest, and leg pain. Occasionally some patients will have very severe and life-threatening manifestations of sickling. These include the acute chest

syndrome consisting of severe chest pain, fever, leukocytosis, hypoxia, and infiltrates on the chest x-ray. The acute chest syndrome is indistinguishable from pneumonia. Stroke and TIA may also occur. Priapism can occur from infarction of the prostatic plexus of veins. Blindness and even myocardial infarction and cardiomyopathy may also occur. Pregnant patients experience increased rates of spontaneous abortion and low birth weight.

Sickle trait gives normal hematologic picture with no anemia and a normal MCV. The only significant manifestation of trait is the renal concentrating defect presenting with isosthenuria and **microscopic hematuria**. Sickle trait also increases the frequency of UTI. Those with trait will rarely develop the acute pain crisis under conditions of profound hypoxia and acidosis.

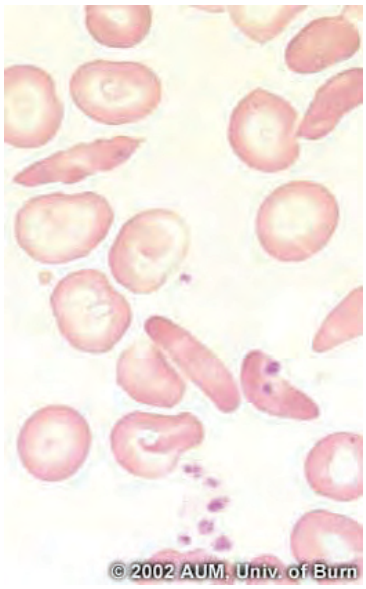

Figure 6-3. Sickle Cells Noted on a Peripheral Blood Smear

Diagnosis. Patients with sickle cell disease typically have a mild to moderate anemia with a normal MCV. The reticulocyte count should always be elevated in the 10–20% range unless they have folate deficiency or Parvovirus B_{19} aplastic crisis. LDH and bilirubin are elevated as in all types of hemolytic anemias. The hemoglobin electrophoresis is the most specific test. The peripheral smear shows sickled cells. The sickle prep (or Sickledex) is a quick screening test used to diagnose evidence of sickle cell trait and cannot distinguish between trait and homozygous disease. The urinalysis usually has blood present, although it is often microscopic. The white blood cell count is often elevated in the 10,000–20,000 range, although this can also indicate the presence of infection.

Treatment. An acute sickle cell pain crisis is treated with fluids, analgesics, and oxygen. Antibiotics are given with infection or even to patients with fever and leukocytosis even if a definite site of infection has not been documented. Ceftriaxone is the preferred agent because it covers *Pneumococcus* and *Haemophilus* influenza. Severe or life-threatening manifestations such as acute chest syndrome, CNS manifestations, priapism, and acute cardiac manifestations are managed with red blood cell transfusions if the hematocrit is low, and **exchange transfusion** if the hematocrit is high. Chronic management includes folic acid replacement

and vaccinations against *Pneumococcus* and influenza. **Hydroxyurea** is used to decrease the frequency of the vaso-occlusive pain crisis. Bone marrow transplantation can be curative in severe cases.

Autoimmune, Cold Agglutinin, and Drug-Induced Hemolytic Anemia

Definition. Various forms of acquired hemolytic anemias resulting from the production of IgG, IgM, or activation of complement C_3 against the red cell membrane. They are often sudden and idiopathic. The lysis can be either extravascular or intravascular but is far more often extravascular. This is based on the fact that the destruction of the cells most often occurs through macrophages in the spleen or by Kupfer cells in the liver.

Etiology. Autoimmune destruction is often idiopathic. Known causes of autoimmune destruction are from antibodies produced in relationship to various forms of leukemia, especially chronic lymphocytic leukemia, viral infections, lymphoma, collagen vascular diseases like lupus, or in relationship to drugs. The most common drugs are the penicillins, cephalosporins, sulfa drugs, quinidine, alphamethyldopa, procainamide, rifampin, and thiazides.

Ulcerative colitis can also lead to autoimmune hemolytic anemia. **Cold agglutinin disease** is an IgM antibody produced against the red cell in association with malignancies such as lymphoma or Waldenstrom macroglobulinemia and infections such as *Mycoplasma* or mononucleosis. Cold agglutinin destruction occurs predominantly in the liver. Liver-mediated destruction is not affected by steroids. Up to 50% of patients do not have an associated underlying disorder.

Clinical Presentation. Symptoms are generally related to the severity of the anemia, not the etiology. The onset may be very sudden resulting in fever, syncope, congestive failure, and hemoglobinuria. Mild splenomegaly is present when the disease has been occurring long enough for the time it takes for the spleen to enlarge. The drug history is often the clue with drug-induced varieties. Cold agglutinin disease results in cyanosis of the ears, nose, fingers, and toes. Weakness, pallor, jaundice, and dark urine may occur as it can in all forms of hemolysis of sufficient severity.

Diagnosis. Autoimmune hemolysis gives a normocytic anemia, reticulocytosis, increased LDH, absent or decreased haptoglobin, and increased indirect bilirubin, as can all forms of hemolysis. The Coombs test is the specific test that diagnoses autoimmune, cold agglutinin, and often even drug-induced hemolysis. Spherocytes are often present on the smear.

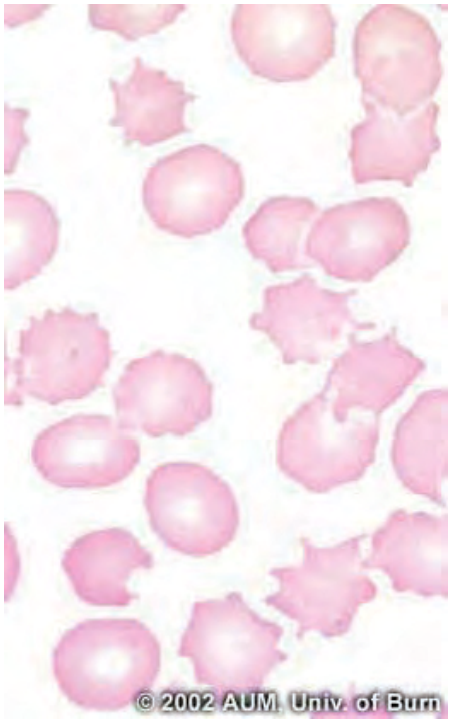

Figure 6-4. Acanthocytes, a Feature of Several Hematologic and Systemic Diseases

Treatment. Mild disease often occurs, which needs no treatment. In cases of drug-induced hemolysis, stop the offending drug. More severe autoimmune hemolysis is treated with steroids first. Splenectomy is done for those unresponsive to steroids. Cold agglutinin disease is primarily managed with avoiding the cold. Most cases of cold agglutinin disease are mild, but in those who have severe disease despite conservative measures, azathioprine, cyclosporine, or cyclophosphamide can be used. Rituximab is also useful. This is an anti-CD20 antibody. Steroids and splenectomy don't work well with cold agglutinin disease because the destruction occurs in the liver. You need to control the lymphocytes which control the production of IgM.

Hereditary Spherocytosis

Definition. A chronic mild hemolysis with spherocytes, jaundice, and splenomegaly from a defect in the red cell membrane.

Etiology. An autosomal dominant disorder where the loss of spectrin in the red cell membrane results in the formation of the red cell as a sphere, rather than a more flexible and durable biconcave disc. Hemolysis occurs because the spheres are not able to pass the narrow passages in the spleen.

Clinical Presentation. A chronic disorder with mild to moderate symptoms of anemia. Because the hemolysis occurs in the spleen, there is often splenomegaly and jaundice. Severe anemia occasionally occurs from folate deficiency or Parvovirus B_{19} infection such as in sickle cell disease. Bilirubin stones often occur, leading to cholelithiasis, often at a young age.

Diagnosis. A normal to slightly decreased MCV anemia with the elevated LDH; indirect bilirubin and reticulocyte count similar to any kind of hemolysis. Although spherocytes may be present with autoimmune hemolysis, hereditary spherocytosis has a negative Coombs test. The cells have increased sensitivity to lysis in hypotonic solutions known as an osmotic fragility test. The mean corpuscular hemoglobin concentration (MCHC) is elevated.

Treatment. Most patients require no treatment beyond folate replacement chronically. In those with more severe anemia, removal of the spleen will eliminate the site of the hemolysis. The symptoms and jaundice will resolve but the spherocytes will remain.

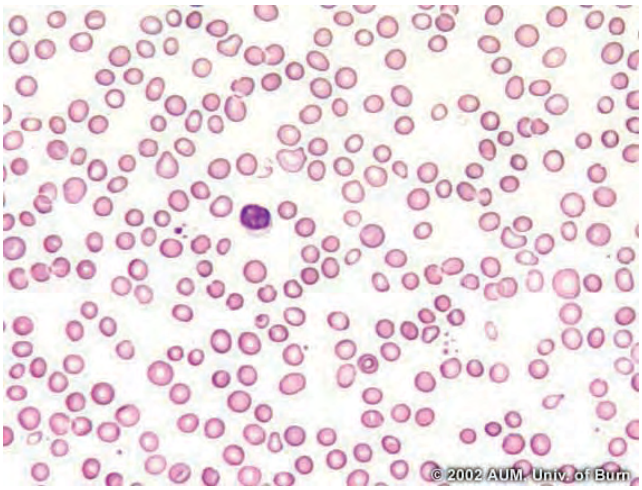

Figure 6-5. Features of Hereditary Spherocytosis Seen on Peripheral Blood Smear

Paroxysmal Nocturnal Hemoglobinuria (PNH)

Note

Decay accelerating factor (DAF) is also known as CD55 and CD59. DAF are the main proteins that protect RBCs from complement destruction.

Definition. A red cell membrane defect leading to intermittent dark urine and venous thrombosis and a chronic form of hemolysis.

Etiology. A red cell membrane defect in phosphatidyl inositol glycan A (PIG-A) allows increased binding of complement to the red cell leading to increased intravascular hemolysis. It is a clonal stem-cell disorder and therefore can develop into aplastic anemia and leukemia as well. The cells are more susceptible to lysis by complement in an acid environment. Everyone becomes a little acidotic at night because of a relative hypoventilation.

Clinical Presentation. In addition to symptoms of anemia, these patients characteristically present with dark urine from intravascular hemolysis. **Thrombosis** of major venous structures, particularly the hepatic vein (Budd-Chiari syndrome), is a common cause of death in these patients. The hemoglobinuria is most commonly in the first morning urine because the hemolysis occurs more often when patients develop a mild acidosis at night.

Diagnosis. Besides the usual lab findings of hemolysis, such as an increased LDH, bilirubin, and reticulocyte count, these patients have brisk intravascular hemolysis and therefore have a low haptoglobin and hemoglobin in the urine. Hemosiderinuria occurs when the capacity of renal tubular cells to absorb and metabolize the hemoglobin is overwhelmed, and the

sloughed off iron-laden cells are found in the urine. The gold standard test is flow cytometry for CD55 and CD59 on white and red cells. In PNH, levels are low or absent.

Treatment. Treatment for PNH depends on the severity of symptoms. Some patients with few or no symptoms require only folic acid and possible iron supplementation. Over time, the disease may progress and thus require more aggressive care.

- In the anemic patient with signs of hemolysis, prednisone is often given to slow the rate of red blood cell destruction.
- In the patient with acute thrombosis, thrombolytic therapy (streptokinase, urokinase, or tissue plasminogen activator) is often administered, followed by long-term anticoagulation drugs to help prevent further blood clots.
- Antiplatelet agents such as aspirin and ibuprofen may also help prevent blood clots. Unfortunately, some patients will continue to develop blot clots despite aggressive anti-coagulation agents.
- Avoid medications that increase the risk for thrombosis, such as oral birth control pills.

PNH is often associated with bone marrow failure. Occasionally patients will respond to antithymocyte globulin, but frequently they will continue to require red cell and/or platelet transfusions. Allogeneic bone marrow transplantation has been the mainstay of curative therapy for PNH. Recently, the drug eculizumab (brand name Soliris) was approved by the FDA to treat symptoms of the disease.

Glucose-6-Phosphate Dehydrogenase (G6PD) Deficiency

Definition. The hereditary deficiency of an enzyme for producing the reducing capacity necessary for neutralizing oxidant stress to the red cell resulting in acute hemolysis.

Etiology. Various forms of oxidant stress result in sudden hemolysis. The most common type of oxidant stress is actually from infections, not drugs. The most commonly implicated drugs are sulfa drugs, primiquine, dapsone, quinidine, and nitrofurantoin.

Clinical Presentation. Patients are normal until exposed to the stress. A sudden, severe, intravascular hemolysis can occur including jaundice, dark urine, weakness, and tachycardia. The history of recent drug ingestion is the main clue to the diagnosis.

Diagnosis. The usual findings of an intravascular hemolysis include high LDH, bilirubin, and reticulocyte count with a normal MCV, low haptoglobin, and hemoglobinuria. Heinz bodies are precipitated hemoglobin inclusions seen in red cells. Bite cells are seen on smear indicating the removal of the Heinz bodies. The definitive test is the G6PD level, which can be falsely normal immediately after an episode of hemolysis. Hence, the level is best tested about 1 week after the event.

Treatment. There is no specific therapy beyond hydration and transfusion if the hemolysis is severe. The main therapy is to avoid oxidant stress in the future.

APLASTIC ANEMIA

Definition. Aplastic anemia is failure of all 3 cell lines produced in the bone marrow, resulting in anemia, leukopenia, and thrombocytopenia (pancytopenia). The marrow is essentially empty with the absence of precursor cells.

Etiology. Many things can cause bone marrow failure, but the most common cause of true aplastic anemia is rarely precisely determined. Radiation, toxins such as benzene, drugs such as NSAIDs, choramphenicol, alcohol, and chemotherapeutic alkylating agents can all cause aplastic anemia. Infiltration of the marrow with infections such as tuberculosis or cancer such as lymphoma can cause pancytopenia, but this is not truly aplastic anemia. Aplastic anemia can also be caused by infections such as hepatitis, HIV, CMV, Epstein-Barr virus, or Parvovirus B19 in immunocompromised patients.

Clinical Presentation. Patients most commonly present with bleeding from the thrombocytopenia, but may present with a combination of the findings associated with deficiencies in all 3 cell lines. Fatigue from anemia and infections from neutropenia may also occur. The clinical presentation may give a clue to the presence of pancytopenia but is not sufficient to determine a true aplastic anemia by clinical manifestations alone. The absence of a classical association such as benzene, radiation, or chloramphenicol would most certainly not exclude a diagnosis of aplastic anemia. The most common single etiology is idiopathic.

Diagnosis. Pancytopenia on a CBC is the first test. A bone marrow biopsy confirms the diagnosis when alternative etiologies for a pancytopenia are not present. In other words, the marrow is empty of almost all precursor cells as well as evidence of primary or metastatic cancer, infection, or fibrosis. The marrow is hypoplastic and fat filled with no abnormal cells seen.

Treatment. Bone marrow transplantation should be carried out whenever the patient is young and healthy enough to withstand the procedure and there is a donor available. Allogeneic transplant can cure up to 80–90% of patients under 50. When a bone marrow transplantation is not possible, immunosuppressive agents should be tried. This is a combination of antithymocyte globulin, cyclosporine, and prednisone. These agents can lead to remission in 60–70% of patients. It is believed that T lymphocytes are primarily causal in the bone marrow failure, so drugs are used to decrease the T-cell response.

ACUTE LEUKEMIA

Definition. Acute leukemia is the rapid onset of bone marrow failure from the derangement of the pluripotent stem cell, causing the relentless destruction of the normal production of the entire bone marrow. The blood cells lose the ability to mature and function normally.

Etiology. Most cases of acute leukemia arise with no apparent cause, but there are several well known associations: radiation exposure, benzene, chemotherapeutic agents such as melphalan and etoposide, and some retroviruses. Genetic disorders such as Down syndrome and Klinefelter can result in an increased incidence of leukemia. Myelodysplasia and sideroblastic anemia can also develop into acute leukemia.

Clinical Presentation. The most common presentation results from the effects of the leukemic blast cells crowding out the normal marrow cells, resulting in symptoms of bone marrow failure (even if total WBC count is elevated or normal). Fatigue from anemia is the most common presenting complaint. Bleeding from thrombocytopenia occurs. Infection from the underproduction or abnormal function of WBCs also occurs.

Acute lymphocytic leukemia (ALL) is more common in children and acute myelogenous leukemia (AML) is more common in adults, but they are indistinguishable clinically. ALL is more often associated with infiltration of other organs, but AML can do it as well. Enlargement of the liver, spleen, and lymph nodes and bone pain are common at presentation. Disseminated intravascular coagulation (DIC) is associated with M3 promyelocytic leukemia. CNS involvement

resembling meningitis is present at the time of initial diagnosis in about 5% of patients. CNS involvement is most characteristic of M4 and M5 monocytic leukemia. Rarely, a syndrome of "leucostasis" can occur when the white cell count is extremely elevated. This results from sludging of the leukemic cell in the vasculature, resulting in headache, dyspnea, confusion, and brain hemorrhage.

Diagnosis. The CBC is the first clue to the diagnosis. Most commonly, WBC is elevated, along with thrombocytopenia and anemia. In about 10% of acute leukemias, depression of all 3 cell lines is evident (aleukemic leukemia). Many other disorders can present as pancytopenia similar to leukemia such as aplastic anemia, infections involving the marrow, metastatic cancer involving the marrow, vitamin B12 deficiency, SLE, hypersplenism, and myelofibrosis. None of these will have leukemic blasts circulating in the peripheral blood, however. A bone marrow biopsy showing >20% blasts confirms the diagnosis of acute leukemia. The presence of blasts tells you the patient has acute leukemia, but blast analysis cannot be relied upon to always tell which type is present. AML is characterized by the presence of Auer rods, myeloperoxidase, and esterase. ALL is characterized by the presence of the common ALL antigen (CALLA) and terminal deoxynucleotidyl transferase (TdT). Auer rods are most specific for M3. Ultimately, the diagnosis rests upon the use of monoclonal antibodies, which recognize specific types of leukemia as well as the expression of specific CD antigens on the surfaces of the cells. Nonspecific findings that are also present are hyperuricemia and an increased level of LDH.

Treatment. Chemotherapy is used initially in all patients to induce a remission. Inducing a remission means a removal of over 99.9% of the leukemic cells in the body and the elimination of peripheral blasts in circulation. This is followed by further rounds of chemotherapy to "consolidate" the leukemia further. After chemotherapy, adults with AML or ALL should be referred for **allogeneic** bone marrow transplantation. The initial chemotherapy for AML is cytosine arabinoside (AraC) and either daunorubicin or idarubicin. The initial chemotherapy for ALL is daunorubicin, vincristine, and prednisone. Promyelocytic leukemia is managed with the addition of the **vitamin A derivative all-trans-retinoic acid (ATRA)**. Leucostasis events are managed with leukapheresis in addition to the chemotherapy.

ALL patients must also undergo prophylaxis of the central nervous system to prevent relapse there. The best agent for this is intrathecal methotrexate.

CHRONIC LEUKEMIA

Chronic Myelogenous Leukemia (CML)

Definition. A chronic myeloproliferative disorder characterized by the massive overproduction of myeloid cells. These cells retain most of their function until later in the course of the disease.

Etiology. Although the Philadelphia chromosome is characteristic of the disease, the cause of the production of this chromosome is unknown. It is a clonal disorder of myelocytes. The Philadelphia chromosome is a translocation between chromosomes 9 and 22, resulting in a gene producing an enzyme with tyrosine kinase activity. Five percent of cases are Philadelphia chromosome negative.

Clinical Presentation. A markedly elevated white blood cell count can be found on routine blood count. The most common symptoms are fatigue, night sweats, and low-grade fever. Abdominal pain from massive enlargement of the spleen is common. Bone pain from infiltration with white cells can occur. Enlarged lymph nodes are rare. Infection and bleeding are

Note

CML can be confused with a leukemoid reaction. They are distinguishable based upon the leukocyte alkaline phosphatase score.

uncommon because these white cells retain the majority of their function. Rarely, a leukostasis reaction can occur from extremely elevated amounts of white cells being produced in the range of 200,000–500,000/mm^3. The white cells then clog up the vasculature, resulting in dyspnea, blurry vision, priapism, thrombosis, and stroke.

Diagnosis. The main feature of the disease is an elevated white blood cell count consisting predominantly of neutrophils with a left shift. Blasts are either absent or present in very small amounts (<5%). The leukocyte alkaline phosphatase score (LAP) is diminished. Basophilia is characteristic of CML and *all* myeloproliferative disorders such as polycythenia vera. Although the B12 level is often elevated, this would not be enough to establish the diagnosis. The Philadelphia chromosome is a far more specific test for CML and should be done in a patient with a markedly elevated white cell count. A low LAP score is not as important as the PCR for Bcr/Abl. The platelet count can also be markedly elevated.

Treatment. The best initial therapy for CML is imatinib, which is also known by the manufacturer's name, Gleevec®. Imatinib is a direct inhibitor of the tyrosine kinase produced by the Philadelphia chromosome. There is nearly a 90% hematologic response to imatinib, and as many as 60 to 70% of patients may lose the Philadelphia chromosome. The milder the disease, the greater the degree of hematologic response. Bone marrow transplantation is no longer the clear first choice as therapy for CML. This is because of the extraordinary response to imatinib, as well as the high mortality associated with the bone marrow transplantation itself. If imatinib fails, then the therapy is bone marrow transplantation.

Chronic Lymphocytic Leukemia (CLL)

Definition. Massive overproduction of mature, but still leukemic, lymphocytes usually from the monoclonal production of B lymphocytes.

Etiology. The etiology of CLL is unknown.

Clinical Presentation. CLL can often present as an asymptomatic elevation of white cells found on routine evaluation of patients or during investigations for other problems. Patients are exclusively older with 90% being age >50. When patients do have symptoms, they are often nonspecific—fatigue, lethargy, and uncomfortable enlargement of lymph nodes. Infiltration of other parts of the reticuloendothelial system such as the spleen, liver, and bone marrow also occurs. Infection and bleeding are unusual presentations of the disease. Staging for CLL is as follows:

Stage 0: lymphocytosis alone
Stage 1: lymphadenopathy
Stage 2: splenomegaly
Stage 3: anemia
Stage 4: thrombocytopenia

Staging is important because the survival of untreated stage 0 and stage 1 disease is 10–12 years even without treatment. The survival of stage 3 and stage 4 disease is 1–2 years. CLL can be associated with various autoimmune phenomena such as thrombocytopenia and autoimmune hemolytic anemia.

Diagnosis. CLL is strongly suspected when an older patient has a marked elevation in the white cell count with a marked lymphocytic predominance in the range of 80–98% lymphocytes. The marrow is often infiltrated with the leukemic lymphocytes. CD19 is an antigen

strongly associated with CLL. The cell count is usually elevated in the range of 30,000–50,000, but may go as high as 150,000. "Smudge cells" seen on a smear are characteristic of CLL.

Treatment. Early stage CLL with only an elevated white cell count or enlargement of lymph nodes is not treated. However, patients with symptomatic disease always need to be treated. Those with more advanced-stage disease should receive initial therapy with fludarabine. Fludarabine has greater efficacy than chlorambucil and should be considered the drug of choice. Autoimmune hemolysis and thrombocytopenia are treated with prednisone. Rituximab is used in those patients who express CD20, especially with autoimmune ITP or hemolytic anemias.

Hairy cell leukemia

Hairy cell leukemia (HCL), classified as a subtype of chronic lymphoid leukemia, makes up approximately 2% of all leukemias. HCL is characterized by an accumulation of abnormal B lymphocytes. The malignant B lymphocytes ("hairy cells") accumulate in the bone marrow, interfering with the production of normal cells commonly causing pancytopenia. Consequently, patients may develop infections, anemia and fatigue, or easy bleeding. Early satiety may occur from massive splenomegaly.

Diagnosis. HCL is commonly considered in the differential diagnosis after routine blood count shows unexpectedly low numbers of cell lines or after unexplained bruising or recurrent infections in an otherwise apparently healthy patient. Bone marrow biopsy is necessary for final diagnosis: the biopsy is used to confirm both the presence of HCL and the absence of any additional diseases. The diagnosis can be confirmed by viewing the cells with a special stain known as TRAP (tartrate resistant acid phosphatase). Pancytopenia in HCL is caused primarily by marrow failure and splenomegaly. Bone marrow failure is caused by the accumulation of hairy cells and reticulin fibrosis in the bone marrow, as well as by the unfavorable effects of dysregulated cytokine production.

Treatment. Purine analogs cladribine (2CDA) and pentostatin are the most common first-line therapies. For cladribine-resistant disease, consider monoclonal antibodies (rituximab most common) which destroy the malignant B cells. Alpha interferon is helpful in about 60% of patients, to stabilize the disease or produce a slow, minor improvement. More than 95% of new patients are treated well or at least adequately by cladribine or pentostatin. A majority of new patients can expect a disease-free remission time span of 10 years or even longer after taking one of these drugs just once.

Myelodysplastic Syndrome (MDS)

MDS is an idiopathic disorder that is considered "pre-leukemic," in that a number of people go on to develop acute myelogenous leukemia (AML). MDS is probably from a genetic defect. The most common defect is 5q deletion or "5q–." Patients are usually elderly and present with a pancytopenia, elevated MCV, fatigue, infections, and/or bleeding because of the low cell counts. There is a small number of blasts from 1–20% and, in fact, it is the percentage of blasts present that tells how "close" a person is to AML.

Most patients die of infection or bleeding before they develop AML. This is because the disorder is slowly progressive and older patients "wear out" so to speak from cytopenias, more often than not going into the "blast phase" that characterizes AML. By definition, you must exclude B12 and folate deficiency because the disorder is so similar.

CBC and bone marrow are indispensible. You may find a bi-lobed neutrophil called a Pelger-Huet cell which is characteristic. Genetic testing for the 5q– is essential.

Treatment is periodic transfusions and control of the infections as they arise. Disease-specific therapy consists of the TNF inhibitor lenalidomide or thalidomide. Azacitidine or decitabine is useful when the 5q- is present. Some patients who are young enough with a match can undergo bone marrow transplantation.

Polycythemia Vera

Definition. A disorder of red cell production. Red cells are produced in excessive amounts in the absence of hypoxia or increased erythropoietin levels.

Clinical Presentation. Patients present with:

- Markedly elevated hematocrit
- Splenomegaly
- Sometimes elevation of the platelet and white cell counts
- Thromobosis
- "Plethora" or redness and fullness of the face
- Pruritis (approximately 40% of patients), particularly after exposure to warm water such as in a shower or bath; possibly caused by abnormal histamine or prostaglandin production

Diagnosis. Diagnose with a high hematocrit in the absence of hypoxia, carbon monoxide poisoning, or elevated erythropoietin level. The most specific test is the Janus Kinase or JAK-2.

Treatment: Phlebotomy is the primary treatment; hydroxyurea may be used in addition to or as an alternative. Aspirin is used to reduce the risk of thrombotic events.

Essential Thrombocythemia

Essential thrombocythemia is a type of platelet cancer. Platelet count may be over a million. There is either thrombosis or bleeding. The most specific test is JAK-2. Treat with hydroxyurea and sometimes anagrelide.

PLASMA CELL DISORDERS

Multiple Myeloma

Definition. A clonal abnormality of plasma cells resulting in their overproduction replacing the bone marrow as well as the production of large quantities of functionless immunoglobulins. The disease is characterized by various systemic manifestations such as bone, kidney, and infectious complications.

Clinical Pearl

Multiple myeloma causes a low anion gap.

Etiology. The cause of multiple myeloma is unknown.

Clinical Presentation. Bone pain is the most common clinical manifestation. This is most commonly in the back and the ribs, secondary to pathologic fractures. Radiculopathy from the compression of spinal nerve roots is also common. Infection particularly with encapsulated

organisms such as *Pneumococcus* and *Haemophilus* is common. Renal failure and anemia are common. The symptoms of hypercalcemia such as polyuria, polydipsia, and altered mental status may occur. Weakness, fatigue, and pallor are common. Rarely, symptoms of a hyperviscosity syndrome such as blurry vision, confusion, and mucosal bleeding may occur.

Diagnosis. Although a normochromic, normocytic anemia is the most common laboratory finding, this is not specific for myeloma. A protein electrophoresis with a markedly elevated monoclonal immunoglobulin spike is present in almost all cases. This is most commonly IgG but may be IgA, IgD, or rarely a combination of two of these. In about 80% of individuals, routine x-ray will reveal the punched-out lytic lesion caused by the overproduction of osteoclast activating factor from the plasma cells and/or pathologic fractures at the time of diagnosis. Most commonly involved are the vertebrae, ribs, pelvic bones, and bones of the thigh and upper arm. If multiple myeloma is suspected with normal x-ray, consider MRI, CT, or PET. Serum B_2 microglobulin is elevated in 75% of patients. Hypercalcemia from the destruction of bone is common, as is an elevation in the BUN and creatinine from the damage to the kidney from the immunoglobulins, Bence-Jones protein, calcium, and hyperuricemia. A bone marrow biopsy with >10% plasma cells confirms a diagnosis of multiple myeloma. Bence-Jones protein is often not detected by a standard protein test on a urinalysis, which mainly is meant to detect albumin. A specific test for Bence-Jones protein involving acidification of the urine is required. Increased gamma globulin levels will increase the total protein and decrease the albumin level.

Treatment. Younger patients (age <70) should be treated with **autologous bone marrow transplantation** in an attempt to cure the disease. Older patients should receive a combination of melphalan and prednisone. Patients who are candidates for transplants should receive thalidomide (or lenalidomide) and dexamethasone. Patients who are not candidates for transplants should receive melphalan, prednisone, and thalidomide. Hypercalcemia is treated initially with hydration and loop diuretics and then with bisphosphonates such as pamidronate.

Bortezomib is a proteasome inhibitor useful for relapsed myeloma or in combination with the other medications. It can be combined with steroids, melphalan, or lenalidomide (thalidomide).

Monoclonal Gammopathy of Uncertain Significance (MGUS)

Definition. The overproduction of a particular immunoglobulin by plasma cells without the systemic manifestations of myeloma such as bone lesions, renal failure, anemia, and hypercalcemia.

Etiology. The cause of MGUS is unknown. MGUS is a very common abnormality present in 1% of all patients age >50 and in 3% of those age >70. Some patients with MGUS may progress to multiple myeloma.

Clinical Presentation. Patients with MGUS have no symptoms. It is found on routine blood testing for other reasons.

Diagnosis. An elevated monoclonal immunoglobulin spike of serum protein electrophoresis (SPEP) in amounts lower than found in myeloma. The creatinine, calcium, and hemoglobin levels are normal. An elevated total serum protein is the clue to the diagnosis. There are no lytic bone lesions, and the bone marrow has <5% plasma cells. The beta-2 microglobulin level will be normal in most patients.

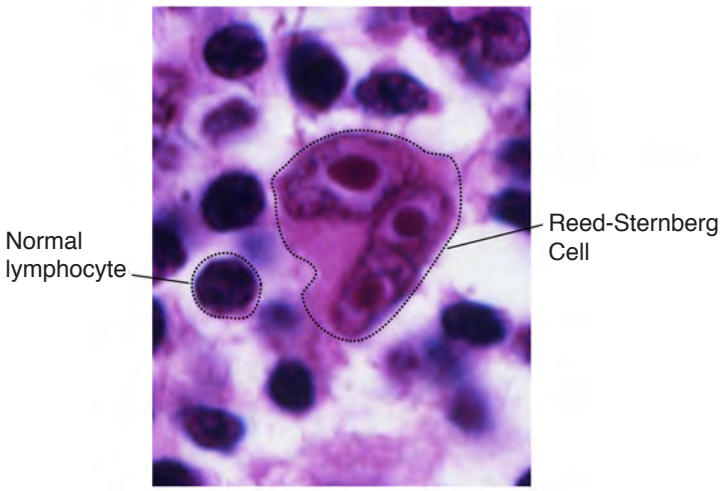
Treatment. Treatment is neither effective nor necessary.

LYMPHOMA

A 32-year-old woman comes to the office with a neck mass for the last several weeks. She also has fever, weight loss, and sweats.

Hodgkin Disease

Definition. A neoplastic transformation of lymphocytes particularly in the lymph node. It is characterized by the presence of Reed-Sternberg cells on histology which spreads in an orderly, centripetal fashion to contiguous areas of lymph nodes.



National Cancer Institute

Figure 6-6. Reed-Sternberg Cell

Etiology. Although there is a clear increase in Hodgkin disease among relatives of those with the disease, there are no clear environmental or infectious etiologies for the disorder.

Hodgkin disease has bimodal age distribution—one peak in the 20s and 60s.

Clinical Presentation. Enlarged, painless, rubbery, nonerythematous, nontender lymph nodes are the hallmark of the disease. Patients may also develop what are labeled "B" symptoms, which are drenching night sweats, 10% weight loss, and fevers. Although pruritus is common in the disease, it is not one of the "B" symptoms. Cervical, supraclavicular, and axillary lymphadenopathy are the most common initial signs of disease. Lymphadenopathy may develop anywhere in the body, however. Extralymphatic sites such as splenic involvement, skin, gastric, lung, CNS, or any other organ may possibly be involved. Extralymphatic involvement is more common with non-Hodgkin lymphoma.

Staging is as follows:

Stage 1: 1 lymphatic group or single extra lymphatic site

Stage 2: 2 lymphatic groups or extra lymphatic sites on same side of the diaphragm

Stage 3: Involvement of lymphatic groups on both sides of the diaphragm or involvement of any extralymphatic organ contiguous to the primary nodal site

Stage 4: Widespread disease with involvement of diffuse extralymphatic sites such as bone marrow or liver

The staging is the same for both Hodgkin as well as non-Hodgkin lymphoma. In Hodgkin lymphoma, staging is the single most important predictor of outcomes.

Diagnosis. An excisional lymph node biopsy is the essential first step in determining the diagnosis. After the initial diagnosis is determined by the biopsy, the most important step is to determine the extent of disease because the stage will determine the nature of the therapy, i.e., radiation versus chemotherapy. Chest x-ray or chest CT, abdominal CT, or MRI is used to determine if the disease is localized to the supraclavicular area. Lymphangiography and laparotomy are no longer routinely used for staging. CT scan is sensitive enough to detect any involved lymph nodes. A bone marrow biopsy is used to definitively determine if the disease is truly localized.

Size alone is insufficient to determine the content of some enlarged nodes. PET scan can also be used for that purpose.

Other labs tests that are often abnormal, but don't directly alter the stage of the disease, include a CBC looking for anemia as well as increased white cell or platelet count. Eosinophilia is common. An elevated LDH level indicates an adverse prognosis. The ESR is useful prognostically. Elevated liver function tests help determine the need for liver biopsy.

Treatment. Therapy is entirely based on the stage of the disease. Localized disease such as stage IA and IIA is managed predominantly with radiation. In the early stages (IA, IIA), adjunct chemotherapy may be used with radiation. All patients with evidence of "B" symptoms as well as stage III or stage IV disease are managed with chemotherapy. The most effective combination chemotherapeutic regimen for Hodgkin disease is ABVD (adriamycin [doxorubicin], bleomycin, vinblastine, and dacarbazine). ABVD is superior to MOPP (meclorethamine, oncovin [vincristine], prednisone, and procarbazine) because ABVD has fewer adverse effects such as permanent sterility, secondary cancer formation, leukemia, aplastic anemia, and peripheral neuropathy.

Hodgkin disease has several histologic subtypes. Lymphocyte-predominant has the best prognosis, and lymphocyte-depleted has the worst prognosis. The histologic subtype does not alter anything described above. The lab tests, staging, and treatments are the same.

Note

Adverse Prognostic Factors

- Large mediastinal lymphadenopathy
- Age >40
- "B" symptoms
- ↑ ESR

Non-Hodgkin Lymphoma (NHL)

Definition. The neoplastic transformation of both the B and T cell lineages of lymphatic cells. NHL causes the accumulation of neoplastic cells in both the lymph nodes as well as more often diffusely in extralymphatic organs and the bloodstream. The Reed-Sternberg cell is absent.

Etiology. There are a number of infectious and autoimmune disorders associated with the development of NHL. Their absence, however, by no means excludes the presence of NHL. Infections such as HIV, hepatitis C, Epstein-Barr, HTLV-I, and *Helicobacter pylori* predispose to the development of NHL. HIV and Epstein-Barr are both more often associated

with Burkitt lymphoma. HIV can also be associated with immunoblastic lymphoma. The main point of knowing this is that they are both high-grade lymphomas with an aggressive progression of disease.

Clinical Presentation. Enlarged, painless, rubbery, nonerythematous, nontender lymph nodes are the hallmark of the disease. Patients may also develop what are labeled "B" symptoms, which are drenching night sweats, 10% weight loss, and fevers. Although pruritus is common in the disease, it is not one of the "B" symptoms. In this sense, NHL is the same as Hodgkin disease. The difference is that Hodgkin disease is localized to cervical and supraclavicular nodes 80–90% of the time, whereas NHL is localized only 10–20% of the time. NHL is far more likely to involve extralymphatic sites as well as to have blood involvement similar to chronic lymphocytic leukemia. CNS involvement is also more common with NHL. HIV-positive patients often have CNS involvement.

The staging system for NHL is the same as that for Hodgkin disease as described above.

Diagnosis. The diagnosis of NHL rests initially on an excisional lymph node biopsy. After this, the most important step is to determine the stage of the disease to determine therapy. Although this is quite similar to that described above for Hodgkin disease, there are several significant differences because NHL is far more likely to be widespread at initial presentation. Lymphangiography is never necessary, and staging laparotomy is rarely needed. The bone marrow biopsy is more central as an initial staging tool. Because the presence of marrow involvement means the patient has Stage IV disease and therefore needs combination chemotherapy, further invasive testing such as the laparotomy is not necessary. As with Hodgkin disease anemia, leukopenia, eosinophilia, high LDH, and high ESR often accompany the disease. PET scanning is highly sensitive and specific for nodal and extranodal sites but not for bone marrow disease.

Treatment. As with Hodgkin disease, local disease such as stage IA and stage IIA are treated predominantly with radiation, and all those with "B" symptoms as well as stages III and IV receive combination chemotherapy. Given the frequency of more widespread disease with NHL, however, this means few NHL patients are treated with radiation alone. The initial chemotherapeutic regimen for NHL is still CHOP (cyclophosphamide, hydroxy-adriamycin, oncovin [vincristine], prednisone). More elaborate chemotherapeutic regimens for NHL, of which there are many, are beyond the scope of what is necessary to know for the Step 2 exam.

Note

Knowing each of the histologic subtypes of NHL is not necessary for the exam.

CNS lymphoma is often treated with radiation, possibly in addition to CHOP. Relapses of NHL can be controlled with autologous bone marrow transplantation. Some patients with NHL express CD20 antigen in greater amounts. When this occurs, monoclonal antibody rituximab should be used. Rituximab is an anti-CD20 antibody that has limited toxicity and adds survival benefit to the use of CHOP. Thus, R-CHOP would then become first-line therapy. Prior to using R-CHOP, always test completely for hepatitis B and C, as rituximab can cause fulminant liver injury in those with active hepatitis B or C disease.

Tumor lysis syndrome

Tumor lysis syndrome (TLS) is an oncologic emergency caused by massive tumor cell lysis, with the release of large amounts of potassium, phosphate, and uric acid into the systemic circulation. Uric acid excretion can result in the precipitation of uric acid in the renal tubules; it can also induce renal vasoconstriction, reduced renal blood flow, and inflammation, resulting in acute kidney injury. Hyperphosphatemia with calcium phosphate deposition in the renal tubules can also cause acute kidney injury.

TLS most often occurs after the initiation of cytotoxic therapy in patients with high-grade lymphoma (particularly Burkitt's and acute lymphoblastic leukemia), though it can occur spontaneously and with other tumor types having a high proliferative rate or large tumor burden.

Patients about to receive chemotherapy for a cancer with a high cell turnover rate--especially lymphomas and leukemias--should receive prophylactic oral or IV allopurinol plus adequate IV hydration to maintain high urine output (>2.5 L/day). Rasburicase maybe used as an alternative to allopurinol and is reserved for those at high-risk for developing TLS. Alkalization of the urine as a treatment of TLS is controversial.

PLATELET DISORDERS

Immune Thrombocytopenic Purpura (ITP)

Definition. Thrombocytopenia of unknown etiology.

Etiology. The idiopathic production of an antibody to the platelet, leading to removal of platelets from the peripheral circulation by phagocytosis by macrophages. The platelets are bound by the macrophage and brought to the spleen, leading to low platelet counts. ITP is often associated with lymphoma, CLL, HIV, and connective tissue diseases.

Clinical Presentation. Like all platelet disorders, the patient presents initially with signs of bleeding from superficial areas of the body such as the skin, nasal and oral mucosa, GI tract, urine, and vagina. The patient is generally young, more often female, and complains of epistaxis, bruising, hematuria, dysfunctional uterine bleeding, and sometimes GI bleeding. Petechiae, purpura, and ecchymoses are often found on exam. The patient is generally otherwise healthy. Splenomegaly should be absent.

Diagnosis. Thrombocytopenia is the major finding. A normal spleen on exam and on imaging studies such as an U/S is characteristic. Antiplatelet antibodies have a high sensitivity but poor specificity. The bone marrow should be filled with megakaryocytes indicating that there is a problem with platelet destruction and not platelet production. The bone marrow will also exclude other causes of thrombocytopenia such as primary or metastatic cancer, infiltration by infections such as tuberculosis or fungi, or decreased production problems such as drug, radiation, or chemotherapy effect on the bone marrow. The peripheral smear and creatinine should be normal, excluding other platelet destruction problems such as hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, and disseminated intravascular coagulation.

Treatment. Prednisone is the initial therapy in almost all patients. Splenectomy is used in patients in whom very low platelet counts <10,000–20,000/mm^3 continue to recur despite repeated courses of steroids. IVIG or RhoGAM™ may be used in patients with profoundly low platelet counts (<10,000 μL) or in patients at risk for life-threatening bleeding. Note that RhoGAM may only be used in Rh-positive patients. In those who recur after splenectomy, we use thrombopoietin agents romiplostim or eltrombopag. Rituximab has also been used.

Clinical Pearl

Platelet disorders can broadly be classified into 2 groups:

- Quantitative (low platelet count, eg, ITP)
- Qualitative (normal platelet count but abnormal platelet function, eg, Von Willebrand, Bernard Soulier)

Von Willebrand Disease (vWD)

A 22-year-old woman comes to the emergency department with epistaxis and heavy periods. She has a PT of 11 seconds (normal), a PTT of 40 seconds (prolonged), and 217,000/mm^3 platelets.

Definition. An increased predisposition to platelet-type bleeding from decreased amounts of von Willebrand factor.

Etiology. An autosomal dominant disorder resulting in a decreased amount of von Willebrand factor. This is the most common congenital disorder of hemostasis. vWD results in a decreased ability of platelets to **adhere** to the endothelial lining of blood vessels. This is different from platelets aggregating with each other, which is mediated by fibrinogen. In vWD, aggregation is normal, whereas adherence is abnormal. It is not necessary to know the difference between the different subtypes of vWD for the Step 2 exam.

Clinical Presentation. Patients with vWD manifest platelet-type bleeding such as that described above for ITP. This is mucosal and skin bleeding such as epistaxis, petechiae, bruising, and menstrual abnormalities. Both platelet problems as well as clotting factor abnormalities can result in GI and urinary tract bleeding. There is often a marked increase in bleeding after the use of aspirin.

Diagnosis. The platelet count and appearance are normal. The bleeding time is increased particularly after the use of aspirin. The level of von Willebrand factor, also known as factor VIII antigen, is low. The ristocetin platelet aggregation test, which examines the ability of platelets to bind to an artificial endothelial surface (ristocetin), is abnormal. The PTT may be elevated in some patients because of a concomitant decrease in levels of factor VIII coagulant portion.

Treatment. Desmopressin acetate (DDAVP) is used for mild bleeding or when the patient must undergo minor surgical procedures. It releases subendothelial stores of von Willebrand factor. Factor VIII replacement is used if desmopressin is not effective and the bleeding continues. Factor VIII replacement contains von Willebrand factor. This replaces the use of cryoprecipitate, which is now seldom necessary. Patients should not use aspirin. FFP is not useful.

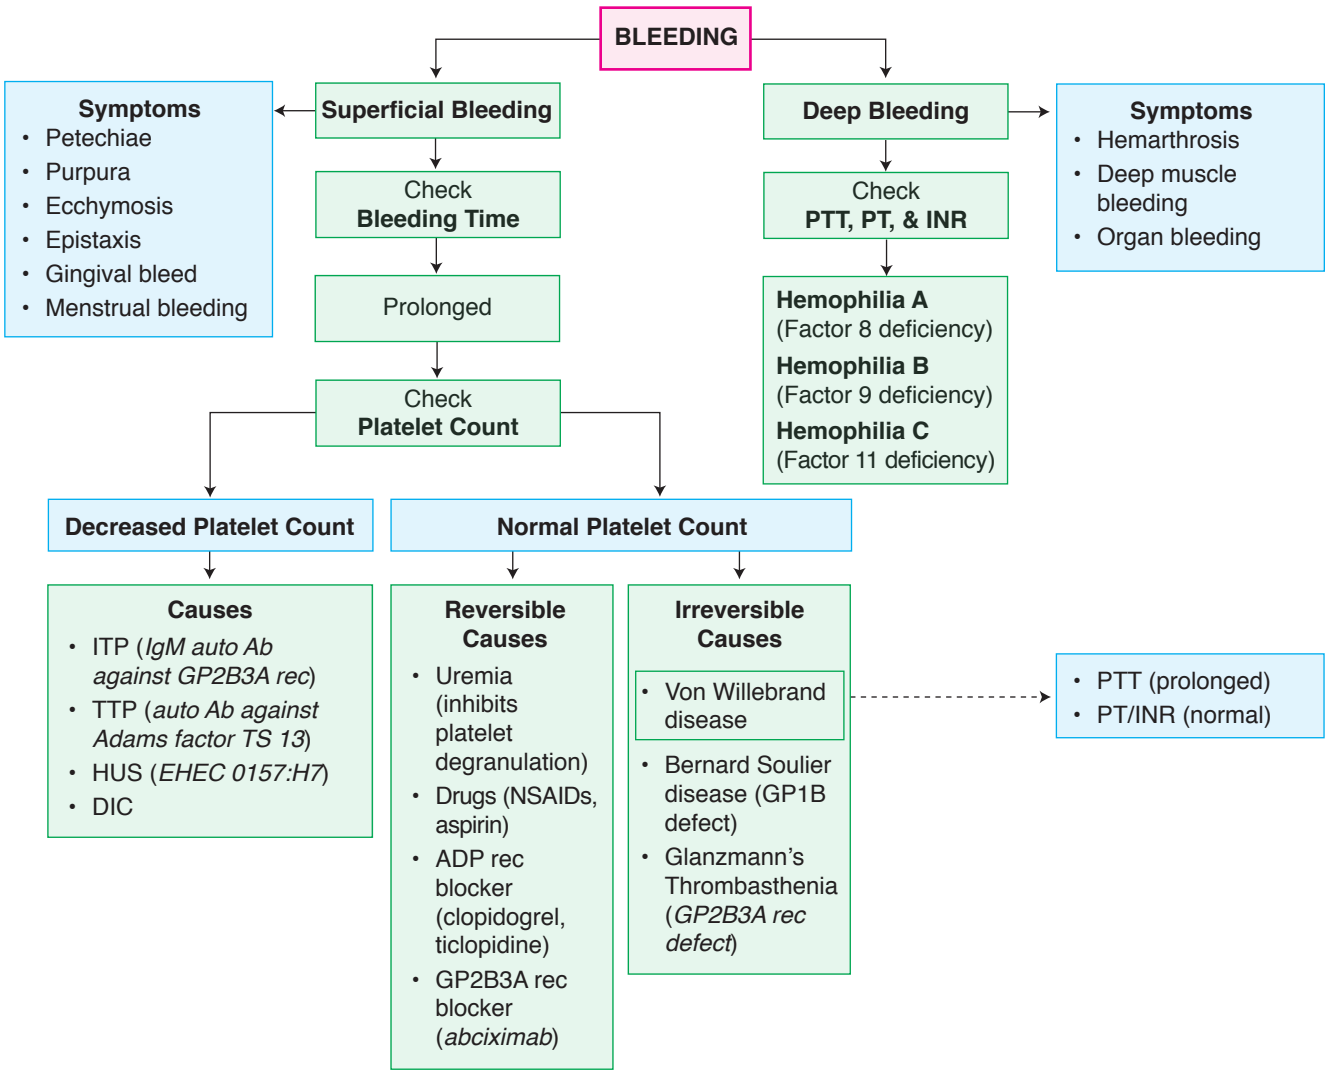


Figure 6-7. Evaluation of Patients with Bleeding

COAGULOPATHY

Hemophilia A and B

Definition. The deficiency of factor VIII in hemophilia A and factor IX in hemophilia B resulting in an increased risk of bleeding.

Etiology. Both hemophilia A and B are X-linked recessive disorders resulting in disease in males. Females are carriers of the disease. Females do not express the disease because they would have to be homozygous, which is a condition resulting in intrauterine death of the fetus. Hemophilia A is far more common than B.

Clinical Presentation. Mild deficiencies (25% or greater activity) result in either the absence of symptoms or with symptoms only during surgical procedures or with trauma. More severe deficiency (<5–10% activity) can result in spontaneous bleeding. Factor-type bleeding is generally deeper than that produced with platelet disorders. Examples of the type of bleeding found with factor deficiencies are hemarthrosis, hematoma, GI bleeding, or urinary bleeding. Bruising and central nervous system bleeding can also occur. Severe hemophilia is obvious in most patients by the age of two. The disorder becomes apparent often at the time of circumcision.

Diagnosis. A prolonged PTT with a normal PT is expected. A factor deficiency is strongly suspected when a 50:50 mixture of the patient's blood is created with a normal control and the PTT drops to normal. This is known as a "mixing study." If the PTT does not correct with mixing, then an antibody inhibitor of the factor is suspected. The mixing study will only tell you that a deficiency is present; it will not tell you which specific factor is deficient. Specific factor VIII or IX levels are necessary to determine a precise diagnosis. This is true of both hemophilia A and B.

Treatment. Mild hemophilia can be treated with desmopressin (DDAVP). Desmopressin can also be used prior to surgical procedures in mild hemophiliacs. Desmopressin works by releasing subendothelial stores of factor VIII. More severe deficiencies are treated with replacement of the specific factor. Desmopressin does not work for hemophilia B.

Table 6-3. Causes of Prolonged PT or PTT

	Prolonged PT	Prolonged PTT	Prolonged PT and PTT
Inherited causes	Factor VII deficiency	vWF and factors VIII, IX, XI, or XII deficiencies	Prothrombin, fibrinogen, factor V, factor X, or combined factor deficiencies
Acquired causes	• Vitamin K deficiency • Liver disease • Warfarin use • Factor VII inhibitor	• Heparin • Antiphospholipid antibody	• Vitamin K deficiency • Liver disease • Disseminated intravascular coagulation • Supratherapeutic heparin or warfarin • Combined heparin and warfarin use • Direct thrombin inhibitors • Inhibitor of prothrombin, fibrinogen, or factor V or X

PT, prothrombin time; PTT, partial thromboplastin time; vWF, von Willebrand factor.

Vitamin K Deficiency

Definition. The deficiency of vitamin K resulting in decreased production of factors II, VII, IX, and X.

Etiology. Vitamin K deficiency can be produced by dietary deficiency, malabsorption, and the use of antibiotics that kill the bacteria in the colon that produce vitamin K. The antibiotics most commonly associated are broad-spectrum drugs such as fluroquinolones, cephalosporins, and other penicillin derivatives.

Clinical Presentation. Bleeding may mimic that of hemophilia and may occur at any site. Look for oozing at venapuncture sites.

Diagnosis. Both the PT and PTT are elevated. The PT usually elevates first and more severely. A correction of the PT and PTT in response to giving vitamin K is the most common method of confirming the diagnosis.

Treatment. Severe bleeding is treated with infusions of fresh frozen plasma. Vitamin K is given at the same time to correct the underlying production defect.

Liver Disease

Definition. Coagulopathy from the decreased production of clotting factors by the liver.

Etiology. Any severe liver disease or cirrhosis leads to a decreased production of the majority of clotting factors that are generally all made in the liver, except for factor VIII and von Willebrand factor. Factor VII is first factor to be depleted.

Clinical Presentation. Bleeding may occur at any site, but the GI tract is the most common site.

Diagnosis. Patients have an elevation of both the PT and PTT, but the PT elevates first and is often more severely affected. The disorder is clinically indistinguishable from vitamin K deficiency except that there is no improvement when vitamin K is given. A clear history of liver disease is often present, suggesting the diagnosis. Low platelet counts are often present from the hypersplenism that accompanies the liver disease.

Treatment. Fresh frozen plasma is used acutely to correct severe bleeding such as melena. Long-term management is based on the nature of the liver disease.

Disseminated Intravascular Coagulation (DIC)

Definition. Consumptive coagulopathy from major underlying illness resulting in consumption of both platelet and clotting factor type and occasionally thrombosis. The bleeding is associated with a marked production of fibrin degradation products such as d-dimers.

Etiology. Although essentially an idiopathic disorder, there is almost always a major underlying disease in the case history. Look for evidence of sepsis most commonly. Almost any disorder that results is cellular destruction and the release of tissue factor can initiate the cascade of consumption of platelets as well as clotting factors. These problems include rhabdomyolysis, adenocarcinomas, heatstroke, hemolysis from transfusion reactions, burns, head trauma, obstetrical disasters such as abruptio placenta and amniotic fluid embolism, as well as trauma, pancreatitis, and snakebites. Promyelocytic leukemia (M3) is a classic association.

Gram-negative sepsis causes DIC by the releasing endotoxin. In acute promyelocytic leukemia (M3), the destruction of leukemic granulocyte precursors results in the release of large amounts of proteolytic enzymes from their storage granules, causing microvascular damage. Other malignancies may also cause DIC by augmenting the expression of various oncogenes that result in the release of tissue factor. DIC exists in acute and chronic forms.

- **Acute DIC** develops when sudden exposure of blood to procoagulants (tissue factor, tissue thromboplastin) generates intravascular coagulation. The compensatory hemostatic mechanisms are quickly overwhelmed, and, as a consequence, a severe consumptive coagulopathy leading to hemorrhage develops.
- In contrast, **chronic DIC** reflects a compensated state that develops when blood is continuously or intermittently exposed to small amounts of tissue factor. Compensatory mechanisms are not overwhelmed. Chronic DIC is more frequently observed in patients with solid tumors and in those with large aortic aneurysms.

Clinical Presentation. Bleeding from any site in the body is possible because of a decrease in both the platelet as well as clotting factor levels. Thrombosis is less common. Hemolysis is often present and may lead to acute renal failure, jaundice, and confusion.

Diagnosis. DIC is suspected when a patient has a serious underlying disorder as described above with bleeding and there is elevation in both the PT and PTT with a decrease in the platelet count. The fibrinogen level is often low because it has been consumed. D-dimers and fibrin-split products are present in increased amounts, suggesting the consumption of all available elements of the coagulation system. The peripheral blood smear often shows the schistocytes as fragmented cells consistent with intravascular hemolysis.

Treatment. Because most patients present with severe bleeding, fresh frozen plasma (FFP) and sometimes platelet transfusions are necessary to correct the bleeding. Heparin is controversial and is rarely used except in those patients presenting predominantly with thrombosis. Don't forget to correct the underlying disorder.

Thrombotic Thrombocytopenic Purpura/Hemolytic Uremic Syndrome

Thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) are two varieties of the same disease process with considerable overlap. There is no specific diagnostic test, so the diagnosis is based on the clinical triad (HUS) or pentad (TTP).

- Most cases of TTP are idiopathic and arise from inhibition of the enzyme ADAMTS13, which is responsible for cleaving large multimers of von Willebrand factor into smaller units. The increase in circulating multimers of vWF increase platelet adhesion to areas of endothelial injury, particularly the arteriole-capillary junctions.
- Some cases of TTP are associated with specific diseases (cancer, HIV) and drugs (ticlopidine, clopidogrel, cyclosporine, and interferon) and are referred to as secondary TTP. ADAMTS13 activity is generally not as depressed in secondary TTP.

HUS predominantly affects children. Most cases are caused by a shiga-like toxin produced by *E. coli* O157:H7 although *Campylobacter*, shigella and some viruses have also been implicated. It is one of the most common causes of acute renal failure in childhood and carries up to 10% mortality.

HUS consists of a triad of hemolytic anemia, uremia, and thrombocytopenia. TTP has the same 3 findings, and is also associated with fever and neurologic problems. You do not have to have all 5 findings simultaneously to be considered to have TTP. The anemia in both will be intravascular in nature and will have an abnormal blood smear showing schistocytes, helmet cells, and fragmented red cells. LDH and reticulocyte count will be elevated and haptoglobin decreased.

Treatment for TTP is plasmapheresis. Plasmapheresis is used to treat severe cases of HUS but is not established in the treatment of mild disease. Mild disease resolves spontaneously. Dipyridamole may help treat TTP by preventing platelet aggregation.

Do not give antibiotics to those with possible HUS; if antibiotics are given, organism may release more toxins as it dies and may worsen the disease.

Do not transfuse platelets. Even if the platelet count is low, administering platelets can actually worsen the CNS and renal abnormalities by giving more platelets as a substrate to precipitate. Small platelet plugs are actually the cause of the problem.

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT), a complication of heparin therapy, can occur with any form of heparin. It is more common with IV unfractionated heparin than with low molecular weight (LMW) heparin.

Type 1 HIT presents within first 2 days after exposure to heparin.

- Non-immune-mediated disorder that results from the direct effect of heparin on platelet activation
- This form of thrombocytopenia is benign, self-limited, and not associated with bleeding or increased risk of thrombosis

Type 2 HIT (**generally referenced as HIT**) occurs 4-10 days after exposure to heparin.

- Immune-mediated disorder
- Has life- and limb-threatening thrombotic complications (low platelet count causes embolism, paradoxically)

Suspect HIT when a patient who is receiving heparin has a decreased platelet count, particularly if the drop is >50% of the baseline count, even if the platelet count nadir remains >150,000. Clinically, HIT is not often marked by bleeding; the most common complication is venous thromboembolism (deep venous thrombosis, pulmonary embolism), and less often, arterial thrombosis (stroke, myocardial infarction). For that reason, the disorder is sometimes called **heparin-induced thrombocytopenia and thrombosis** (**HITT**). Thrombosis develops in approximately 20% of patients with HIT, with mortality as high as 30%.

Diagnosis of HIT is based on the combined clinical findings, thrombocytopenia characteristics, and lab studies of HIT antibodies (positive in ~85% of patients with type 2 HIT). Treatment begins with discontinuation of all heparin products (including heparin flushes of intravenous catheters), and later the administration of an alternative anticoagulant such as argatroban or lepirudin. Patients diagnosed with HIT should avoid all forms of heparin for life.

Warfarin

Warfarin (Coumadin) is the most widely prescribed anticoagulant for the prevention and treatment of thromboembolic disease. It was initially introduced as a pesticide against rodents, and long-acting forms of warfarin are still used for this purpose.

Warfarin anticoagulates by inhibiting an enzyme that recycles oxidized vitamin K to its reduced form. Warfarin does not antagonize the action of vitamin K, but rather antagonizes vitamin K recycling. Once vitamin K is reduced, the vitamin K dependent factors (factors 2,7,9,10) are eventually reduced (3-5 days).

Despite its efficacy, treatment with warfarin has several limitations.

- Many commonly used medications interact with warfarin, as do some foods—particularly green vegetables—since they typically contain large amounts of vitamin K.
- Warfarin activity has to be monitored by the PT and international normalized ratio (INR) to ensure an adequate yet safe dose (typically **INR 2–3** is considered adequate and safe anticoagulation). The pharmacologic action of warfarin may always be reversed by fresh vitamin K.

Table 6-4. Recommended Management of a Supratherapeutic INR

INR	Bleeding Present	Recommended Action
<Ther to 5.0	No	• Lower warfarin dose, **or** • Omit a dose and resume warfarin at a lower dose when INR is in therapeutic range, **or** • No dose reduction needed if INR is minimally prolonged
>5.0 to 9.0	No	• Omit the next 1–2 doses of warfarin, monitor INR more frequently, and resume treatment at a lower dose when INR is in therapeutic range, **or** • Omit a dose and administer 1–2.5 mg oral vitamin K*
>9.0	No	• Hold warfarin and administer 5–10 oral vitamin K. Monitor INR more frequently and administer more vitamin K as needed. Resume warfarin at a lower dose when INR is in therapeutic range.
>20	—	• Hold warfarin and administer 10 mg vitamin K by slow IV infusion; supplement with fresh frozen plasma, or recombinant human factor VIIa, depending on clinical urgency. Monitor and repeat as needed.
Any	Life-threatening	As per "INR >20" above

INR: International Normalized Ratio; Ther: therapeutic INR range for the patient in question.

*Preferred in patients at increased risk for bleeding (e.g., history of bleeding, stroke, anemia).

Infectious Diseases 7

Learning Objectives

- ❑ Provide an overview of common antibiotics and their uses
- ❑ Describe the unique conditions and considerations for infections which occur in the CNS, head, neck, lung, pericardium, endocardium, GI tract, urinary tract, bones, and joints
- ❑ Present the treatment of acute herpes viral hepatic infections
- ❑ Describe the presentation and management of Lyme disease and Rocky Mountain spotted fever
- ❑ Describe the epidemiology, presentation, and treatment of genital and sexually transmitted diseases
- ❑ Describe the epidemiology, presentation and management of AIDS and related opportunistic infections

INTRODUCTION TO ANTIBIOTICS

Antibiotics can be grouped either by the type of organism they are effective against or by the chemical class of the medication. The organisms that cause specific diseases do not change very much over time. For example, *Staphylococcus aureus* is still the most common cause of osteomyelitis, and *Escherichia coli* is still the most common cause of pyelonephritis. What does change over time is the antibiotic that is effective against each organism and the sensitivity pattern of each organism.

Gram-Positive Cocci

Semisynthetic penicillinase-resistant penicillins (oxacillin, cloxacillin, dicloxacillin, nafcillin)

Staphylococcal and streptococcal organisms are effectively treated by medications such as the semisynthetic penicillins, including oxacillin, nafcillin, dicloxacillin, and cloxacillin. These agents are exclusively effective against Gram-positive cocci, in particular staphylococci.

Methicillin belongs to this group of antibiotics as well, and was one of the original drugs developed in the class. Methicillin is not used clinically, however, because it may cause interstitial nephritis. Hence the term "methicillin-sensitive" or "methicillin-resistant *Staphylococcus aureus*"

Note

Do not use vancomycin if the organism is oxacillin-sensitive.

(MRSA) is somewhat of a misnomer because we don't actually use methicillin. When this term is used, think of the drugs oxacillin, cloxacillin, dicloxacillin, and nafcillin. When *Staphylococcus* is sensitive to the semisynthetic penicillins and if concurrent Gram-negative infection is not suspected, these are the ideal agents. They are more efficacious than vancomycin is when the organism is sensitive. These drugs are also sometimes referred to as "beta-lactamase–resistant penicillins" or "antistaphylococcal penicillins." The latter term is somewhat misleading because they are also effective against a number of streptococci such as *S. pneumoniae*, the Viridans Strep group, and groups A, B, C, and G Strep.

MRSA is treated primarily with vancomycin. Linezolid, telavancin, daptomycin, ceftaroline, and tigecycline are alternatives for MRSA.

Penicillin G, penicillin VK, ampicillin, and amoxicillin

These agents are effective against streptococci, such as *S. pyogenes*, viridans group streptococci, and *S. pneumonia*, but *not* against staphylococci. Ampicillin and amoxicillin are only effective against staph when ampicillin is combined with the beta-lactamase inhibitor sulbactam or when amoxicillin is combined with clavulanate. Ampicillin also has some activity against *E. coli*. Both are effective against enterococci and *Listeria*. All of the agents can be useful against Gram-negative bacteria, such as *Neisseria*.

Cephalosporins (first-generation agents: cefazolin, cefadroxil, cephalexin; second-generation agents: cefoxitin, cefotetan, cefuroxime, cefprozil, loracarbef)

The first- and second-generation cephalosporins will all cover the same range of organisms that the semisynthetic penicillins will cover. In addition to staphylococci and streptococci, first- and second-generation cephalosporins will also cover some Gram-negative organisms. First-generation agents will only reliably cover *Moraxella* and *E. coli*. Second-generation agents will cover everything a first-generation cephalosporin covers, as well as a few more Gram-negative bacilli such as *Providencia*, *Haemophilus*, *Klebsiella*, *Citrobacter*, *Morganella*, and *Proteus*. In general, your answer should correspond most specifically to the organism you are treating. For example, if you are treating a sensitive *Staph aureus* or *Strep*, you should answer with a specific Gram-positive drug. Your answer should not be an extremely broad-spectrum agent such as imipenem or meropenem, even though these drugs will treat the organism. Don't give an answer that gives more coverage than you need unless there is definite evidence to support the presence of other organisms. In the case of Gram-positive infection, you should generally answer the use of a first-generation agent.

Third-generation agents, particularly ceftazidime, are not reliable in their staphylococcal coverage. Although the fourth-generation cephalosporin cefepime will cover staph and strep, you should never answer this agent when you have an exclusively Gram-positive infection.

Allergic Cross-Reactivity with Penicillins. For persons with a genuine allergy to penicillin, there is only a <1% risk of cross-reaction with cephalosporins. When this reaction occurs it is seldom an anaphylactic reaction. When the allergic reaction is described as a rash, you can safely use a cephalosporin. When the reaction is more severe, such as anaphylaxis, you should not answer a cephalosporin. For minor infections, use a macrolide (clarithromycin or azithromycin) or one of the new fluoroquinolones (levofloxacin, gemifloxacin, or moxifloxacin). For serious infections in those with a life-threatening penicillin allergy, you should use vancomycin, linezolid, or daptomycin.

Macrolides (erythromycin, clarithromycin, azithromycin), fluoroquinolones (levofloxacin, gemifloxacin, moxifloxacin), and clindamycin

These agents are alternatives to penicillins and cephalosporins for Gram-positive infection. Macrolides should not be used for serious staph infections. The new quinolones are very good for streptococcal infections, particularly *Strep pneumoniae* in the absence of outright penicillin resistance. They are also sufficient against staph. Ciprofloxacin is a quinolone as well but it does not cover *Strep pneumoniae*.

Vancomycin, linezolid, tigecycline, ceftaroline, telavancin

These agents are alternatives for Gram-positive infections. They are your answer when there is either a life threatening penicillin allergy or there is MRSA. Linezolid is the only oral medication available against MRSA. Linezolid, daptomycin, and quinupristin/dalfopristin are also effective against vancomycin-resistant enterococci. Ceftaroline is used like a third-generation such as ceftriaxone combined with an MRSA agent such as vancomycin. Ceftaroline is the only cephalosporin to cover MRSA. These medications should not be used if the organism is sensitive to methicillin.

Note

Daptomycin, ceftaroline, and tigecycline are drugs also effective against MRSA.

Gram-Negative Bacilli

Penicillins (piperacillin, ticarcillin, mezlocillin)

These agents are fully active against the full range of Gram-negative bacilli, such as the Enterobacteriaceae as well as *Pseudomonas*. Enterobacteriaceae include *E. coli*, *Proteus*, *Enterobacter*, *Citrobacter*, *Morganella*, *Serratia*, and *Klebsiella*. They are only active against staph when they are combined with a beta-lactamase inhibitor such as piperacillin/tazobactam or ticarcillin/clavulanate. Ampicillin/Sulbactam and amoxicillin/clavulanate will also cover staph and Gram-negative bacilli, but not *Pseudomonas*. All penicillins will cover sensitive streptococci, but if the patient described has only a sensitive strep you should answer with a narrower agent, such as penicillin G or penicillin VK.

Cephalosporins (third-generation agents: ceftazidime, cefotaxime, ceftriaxone, cefotaxime; fourth-generation agent: cefepime)

Third- and fourth-generation agents are fully active against the full range of Gram-negative bacilli such as the Enterobacteriaceae. Only ceftazidime and cefepime will cover *Pseudomonas*. Cefepime also covers staph. Second-generation agents cover some of the Enterobacteriaceae, but not *Pseudomonas*. Although predominantly for use against Gram-negative organisms, ceftriaxone and cefotaxime are the best answers for penicillin-insensitive pneumococci-causing meningitis or pneumonia.

Note

Cephalosporins are safe in penicillin allergy if it is only a rash.

Quinolones (ciprofloxacin, levofloxacin,gemifloxacin, moxifloxacin, ofloxacin)

These agents all cover most of the Enterobacteriaceae, such as *E. coli*, *Proteus*, *Enterobacter*, *Haemophilius, Moraxella, Citrobacter*, *Morganella*, *Serratia*, and *Klebsiella*. Only ciprofloxacin will reliably cover *Pseudomonas*. The new fluoroquinolones (moxifloxacin, levofloxacin, and gemifloxacin) are also active against Gram-positive cocci, in particular *Strep pneumoniae*. They are amongst the first-line therapies for empiric treatment of pneumonia because they will also cover *Mycoplasma*, *Chlamydia*, and *Legionella*.

Clinical Pearl

Ceftriaxone does not have adequate pseudomonal coverage.

Aminoglycosides (gentamicin, tobramycin, amikacin) and monobactams (aztreonam)

These agents have essentially the same Gram-negative coverage as listed above for the other agents. Although aminoglycosides can be synergistic with a penicillin in the treatment of staph, they are essentially exclusively Gram-negative agents. Aztreonam is exclusively a Gram-negative agent, with no strep or staph coverage at all.

Carbapenems (imipenem, meropenem, ertapenem, doripenem)

Fully active against Enterobacteriaceae and *Pseudomonas*, they are similar in Gram-negative coverage to the aminoglycosides and third-generation cephalosporins. In addition, they have excellent staph and anaerobic coverage. Although effective in polymicrobial infections, they are best used in Gram-negative infections. Ertapenem will not cover *Pseudomonas*. All carbapenems are equally effective against anaerobes, as compared to metronidazole.

Anaerobes

The agent most active against anaerobes is metronidazole. Clindamycin is less active against intraabdominal anaerobes. Metronidazole has some advantages against the anaerobic Gram-negative bacteria in the bowel, such as *Bacteroides fragilis*. Metronidazole is also the first-line agent against *Clostridium difficile*. Clindamycin may have some advantages against the anaerobic streptococci found in the mouth. The other agents with excellent anaerobic coverage virtually equal to metronidazole are the carbapenems and the beta-lactam/beta-lactamase combination medications such as piperacillin/tazobactam, ticarcillin/clavulanate, ampicillin/sulbactam, or amoxicillin/clavulanate. The second-generation cephalosporins cefoxitin and cefotetan have fair activity against anaerobes, but they are not as good as the agents described above.

Skin MRSA

Note

Sensitive *Staph* should not be treated with TMP/SMZ, doxycycline, or clindamycin.

TMP/SMZ, clindamycin, doxycycline, and linezolid are oral agents useful for MRSA. Oral therapies such as these should only be used for minor MRSA infections. TMP/SMZ, clindamycin, and doxycycline cannot be used for MRSA bacteremia.

CENTRAL NERVOUS SYSTEM INFECTIONS

Meningitis

> A 45-year-old man is brought to the emergency department with 1–2 days of fever, headache, nausea, and vomiting. On physical examination he is found to have neck stiffness and photophobia.

Definition. An infection or inflammation of the meninges, which is the connective tissue covering the central nervous system (CNS).

Etiology. Most cases of meningitis arise sporadically, and the precise method of spread of the microorganism into the central nervous stem is not determined. Overall, most cases of meningitis are due to viruses. *Streptococcus pneumoniae* is the most common cause of bacterial meningitis for all patients beyond the neonatal period. In the past, *Haemophilus influenzae* was the most

common cause in children, but this has been markedly decreased by the use of the *Haemophilus* type B vaccine in children. *Neisseria meningitidis* is spread by respiratory droplets and is the most common cause of meningitis in adolescents. *Listeria monocytogenes* is more common in those with immune system defects, particularly of the cellular (T-cell) immune system and sometimes neutrophil defects. These defects include HIV, steroid use, leukemia, lymphoma, and various chemotherapeutic agents. Neonates and the elderly have decreased T-cell immune function; therefore, *Listeria* is more common in the very young and the very old.

Even with immune deficits, *Streptococcus pneumoniae* is still the *most* common etiology—it is just that *Listeria* is *more* common in these patients, as compared to fully immunocompetent patients. *Staphylococcus aureus* is more common in those who have had any form of neurosurgery because instrumentation and damage to the skin introduce the organism into the CNS. *Cryptococcus* is more common in those who are HIV positive and who have profound decreases in T-cell counts to levels <100 cells.

Rocky mountain spotted fever (RMSF) is common in those who have been exposed to ticks in the appropriate geographic area. The areas with the highest RMSF infection are in the mid-Atlantic areas, such as the Carolinas, Kentucky, Tennessee, etc. Lyme disease can also cause meningitis and is more common in the Northeast, such as Massachusetts, Connecticut, New York, and New Jersey. Tuberculosis and syphilis are also associated with meningitis. Viruses are the most common cause of aseptic meningitis, a syndrome in which patients present in a manner similar to bacterial meningitis, but CSF analysis mostly reveals a lymphocytic pleocytosis and bacterial cultures are negative. Viruses causing aseptic meningitis include entero viruses, arboviruses (St. Louis encephalitis virus, West Nile virus), HIV, herpes simplex, and lymphocytic choriomeningitis virus. In the past, most of these were not diagnosed, but with the availability of PCR-based testing, more cases of aseptic meningitis are being accurately classified. Group B *Streptococcus (Streptococcus agalactiae)* is the most common cause of meningitis in the neonatal period.

The spread of the organism into the CNS can be by sporadic (unknown) mechanisms or by means of contiguous local infection or by hematogenous spread. Local infections that can lead to meningitis include otitis media, sinusitis, mastoiditis, and dental infections. Hematogenous spread could possibly occur from any infection but is more common with endocarditis and pneumonia.

Clinical Presentation. Regardless of microbiologic etiology, all forms of meningitis present with fever, photophobia, headache, nuchal rigidity (neck stiffness, positive Kernig and Brudzinski signs), as well as nausea and vomiting. Altered mental status is possible as well and can make a patient seem like they have encephalitis. Any form of CNS infection can present with seizures. Focal neurologic deficits can also occur, the most common being visual field and cranial nerve deficits. The most common long-term neurologic deficit from bacterial meningitis is damage to the 8th cranial nerve.

Rash is associated with several different types of meningitis. A petechial rash is suggestive of *Neisseria*. A rash on the wrists and ankles with centripetal spread toward the body is suggestive of RMSF. Facial nerve palsy is suggestive of Lyme disease. The targetlike erythema migrans rash of Lyme disease is seldom present by the time the meningitis develops. Pulmonary symptoms or an abnormal chest x-ray suggest tuberculosis (TB).

Diagnosis. Lumbar puncture is essential for establishing the diagnosis. CT scan of the head is the best initial diagnostic test if the patient has papilledema, focal motor deficits, new onset seizures, or severe abnormalities in mental status, or is immunocompromised (HIV infection, immunosuppressive medications, post-transplantation, etc.). If none of the above is present, a lumbar puncture can be safely done without doing a CT scan of the head first, which can

significantly delay the diagnosis. If the lumbar puncture is delayed >20–30 minutes for any reason, then the best initial step is to give an empiric dose of antibiotics.

Clinical Pearl

In patients presenting with symptoms and signs of meningitis, treat empirically for bacterial meningitis while awaiting test results from the lumbar puncture.

The most accurate test for bacterial meningitis on the lumbar puncture is the culture of the CSF. The results are always delayed for several days, however, and are rarely, if ever, available at the time that the initial therapy must be instituted. Protein levels are elevated most commonly with bacterial meningitis, but they can be elevated in any type of meningitis. An elevated protein level and/or a decreased glucose level by themselves are relatively nonspecific findings. The opening pressure can be elevated with any cause of meningitis.

The Gram stain has a limited sensitivity and is positive in 50–70% of patients at most. When positive, however, the Gram stain has a high degree of specificity.

Initially, the most useful test is the cell count. Although elevated cell count by itself is nonspecific, the differential of the cells is useful. Only bacterial meningitis gives thousands of cells that are all neutrophils. A mild-to-moderate elevation in lymphocytes, with several dozen to several hundred cells, can occur with viral infection, *Rickettsia*, Lyme disease, tuberculosis, syphilis, or fungal (cryptococcal) etiology. A normal CSF cell count is <5 cells/mm^3, which should be predominantly lymphocytes.

Specific diagnosis of nonbacterial meningitis is based on the nature of the organism. Lyme disease and RMSF are best detected with a specific immunologic response and serology. *Cryptococcus neoformans* is detected initially with an India ink test and then later with an elevation in the serum and CSF cryptococcal antigen titer. Syphilis is confirmed by the presence of a positive VDRL or FTA on CSF. TB is rarely detected by AFB smear. Culture for TB has a much higher yield, particularly on several repeated LPs. PCR can also aid in the diagnosis of TB.

Treatment. Empiric therapy of bacterial meningitis in adults is best achieved with vancomycin (because of the increasing prevalence worldwide of pneumococci with decreasing sensitivity to penicillins) plus a third-generation cephalosporin, such as ceftriaxone. Ampicillin is added to those with immune defects to cover *Listeria* and for patients age >50 years or ≤ 1 month old. You will have to recognize the risks such as HIV, steroid use, pregnancy, or hematologic malignancies in the case description. *Listeria* is resistant to all forms of cephalosporins. Vancomycin is used if you know you have definite or suspected pneumococcal resistance to penicillin or if there is a chance of staphylococcal infection after neurosurgery. Lyme disease is best treated with ceftriaxone. *Cryptococcus* is treated initially with amphotericin. This is followed by fluconazole therapy in HIV-positive patients for life or until the patient is on HAART (highly active antiretroviral therapy) and is asymptomatic with a CD4 count >100/μL for at least 3–6 months. Neurosyphilis is treated with high-dose IV penicillin. TB meningitis is treated in the same fashion as you would use for pulmonary TB (though a longer duration of 9–12 months of therapy is given). Steroid use in adult meningitis is appropriate for TB meningitis and bacterial meningitis. There is no treatment currently proven useful for viral (or aseptic) meningitis.

Dexamethasone (corticosteroid) therapy for patients with bacterial meningitis decreases mortality and rates of deafness. The rationale for this is the inflammatory response elicited in the subarachnoid space due to bacterial cell wall lysis after antibiotics are administered; this inflammatory reaction can worsen morbidity and mortality due to bacterial meningitis. Accordingly, dexamethasone given 15–20 minutes before or concurrently with the administration of antibiotics resulted in improved outcomes (morbidity and mortality); the benefit is greatest for patients with pneumococcal meningitis. Dexamethasone should be continued for 4 days if bacterial meningitis is confirmed (a positive Gram stain of CSF fluid or >1000 WBCs within the CSF can be taken as confirmation of bacterial meningitis) and discontinued if the etiology is nonbacterial (viral, fungal, etc.).

Encephalitis

A young man is brought to the emergency department by his friends because of 1–2 days of confusion and strange behavior. He had been originally complaining of a headache and fever. On the day of admission, he became markedly worse and is now delirious. He is generally healthy. On physical examination, you find a lethargic, confused man with an elevated temperature. You are unable to determine if he has focal neurologic findings or to obtain an accurate neurologic exam because his confusion makes him unable to follow commands.

Definition. An infection of the brain. This includes both the meninges, as well as the brain parenchyma.

Etiology. Although any bacterial, protozoal, or rickettsial infection can cause encephalitis, the majority is caused by viruses. Although virtually any virus can cause encephalitis, the most common cause is herpes simplex, usually type I (HSV-1). Varicella-zoster virus, CMV, enteroviruses, Eastern and Western equine encephalitis, St. Louis encephalitis, and West Nile encephalitis can also occur but are much less common than HSV.

Clinical Presentation. Fever and a headache occur but these findings are relatively nonspecific. Altered mental status with fever and headache is the primary clue to the diagnosis. Any level of neurologic deficit may occur, ranging from slight confusion to lethargy or coma. Focal deficits of any kind can occur. Neck stiffness similar to that found in meningitis can occur, making it difficult to distinguish encephalitis from meningitis. Seizures may also occur.

Diagnosis. Although CT or MRI scan of the head should be performed, it cannot give a specific diagnosis. HSV has a predilection for involvement of the temporal lobes, which can sometimes be seen on CT. A lumbar puncture is the key to the diagnosis. Formerly, a brain biopsy was necessary, but PCR (polymerase chain reaction) amplification techniques have virtually eliminated that need. PCR for HSV has a 98% sensitivity and >95% specificity, making it at least equal to the biopsy.

Treatment. HSV encephalitis is best treated with IV acyclovir. Although famciclovir and valacyclovir have activity against HSV, they are not available intravenously. Ganciclovir or foscarnet are active against CMV. Acyclovir-resistant herpes is treated with foscarnet.

Clinical Pearl

Encephalitis usually presents with altered mental status, erratic behavior, etc (brain parenchyma involved).

Brain Abscess

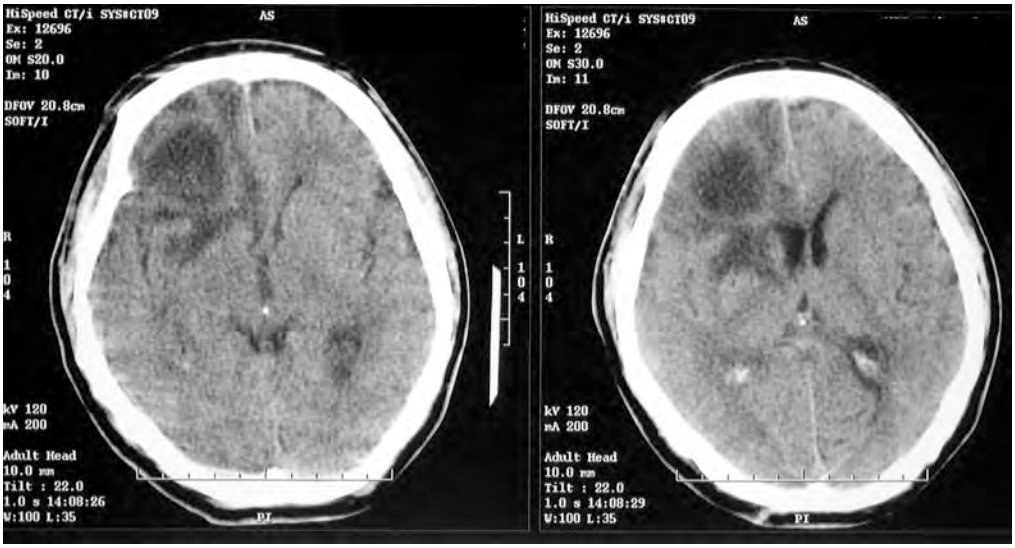
An HIV-negative man is brought to the hospital because of a seizure. When he becomes more alert, you find that he has aphasia and weakness of the right hand and leg. A CT scan of the head with contrast shows enhancement of the lesion with a "ring" around the lesion.

Definition. A collection of infected material within the brain parenchyma.

Etiology. Bacteria can spread into the brain from contiguous infections such as otitis media, sinusitis, mastoiditis, or dental infections. Organisms may also spread through the bloodstream from endocarditis or pneumonia and seed the brain. Toxoplasmosis can reactivate in those

with severe HIV disease when their CD4 counts are very low (<50–100/μL). Brain abscesses most commonly have *Streptococcus* in 60–70%, *Bacteroides* in 20–40%, Enterobacteriaceae in 25–35% and *Staphylococcus* in 10%, and are often polymicrobial. Because of the diversity of the organisms potentially involved, it is difficult to have a single standard therapy.

Clinical Presentation. Headache is the most common symptom. Fever can be present. Focal neurologic deficits are the initial complaint in about 60% of patients. Seizures may occur, as with any form of anatomic abnormality of the CNS. All CNS infections can cause seizures.



aic.cuhk.edu.hk/web8

Figure 7-1. CT Scan Demonstrating Large Cerebral Abscess

Diagnosis. The initial test is the CT scan. Contrast is used to help identify the lesion, although CNS malignancy enhances with contrast as well. MRI is even more accurate than is the CT scan. No radiologic test alone can give the precise etiology, however. In the case of bacterial brain abscess, examination of the abscess fluid (obtained by stereotactic aspiration or surgical excision of the abscess) for Gram stain and culture is essential. In HIV-positive patients, 90% of brain lesions will be either toxoplasmosis or lymphoma. This is the only circumstance where empiric therapy is sufficient to establish a specific diagnosis. If the lesion responds to 10–14 days of therapy with pyrimethamine and sulfadiazine, then the patient should simply continue to receive this therapy, as it accurately predicts cerebral toxoplasmosis.

Treatment. Almost always, successful treatment requires a combination of surgical and medical management. Stereotactic aspiration (preferred) and surgical excision of the abscess are the two methods used; the latter is rarely used nowadays because of significant complications.

With the exception of HIV-positive patients, who are best treated with pyrimethamine and sulfadiazine, therapy must be based on the specific etiology found. One example of a combination of therapy (but certainly not the only one) would be penicillin, metronidazole, and a third-generation cephalosporin, such as ceftazidime. Penicillin would cover the streptococci, metronidazole the anaerobes, and ceftazidime the Gram-negative bacilli.

HEAD AND NECK INFECTIONS

Otitis Media

Definition. An infection of the middle ear between the eustachian tube and the tympanic membrane.

Etiology. Viral upper respiratory infection can cause edema of the eustachian tube, which often leads to middle ear infection. The most common organisms are *Strep pneumoniae* (35–40%), *H. influenzae* (nontypeable; 25–30%), and *Moraxella catarrhalis* (15–20%). Viruses probably account for the rest of the cases. This is roughly the same breakdown of organism type and frequency that occurs in bronchitis and sinusitis.

Clinical Presentation. Patients complain of ear pain, fever, and decreased hearing. On physical examination you'll find a red, bulging tympanic membrane with loss of the light reflex. The most sensitive clinical finding is immobility of the membrane on insufflation of the ear with air. Perforation of the tympanic membrane with otorrhea occurs rarely.

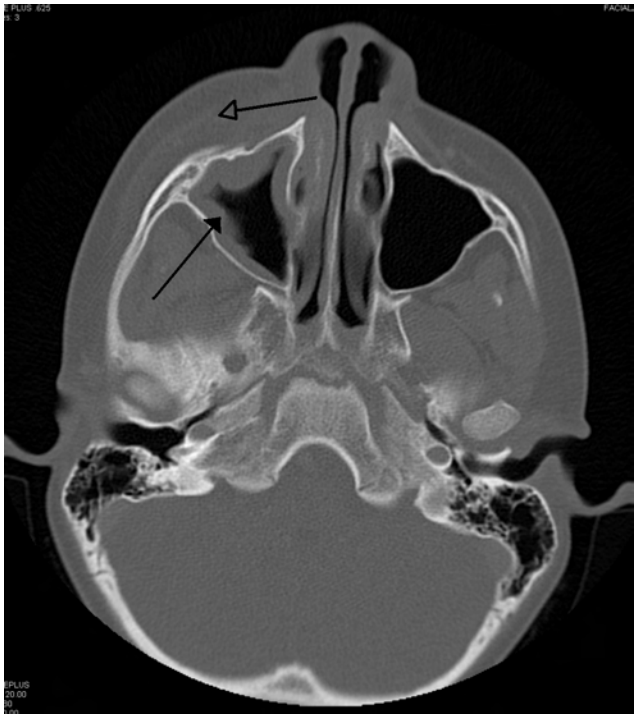
Diagnosis. Physical examination of the ear is the chief means of establishing the diagnosis. Radiologic tests are not useful. A specific bacteriologic diagnosis can be obtained with tympanocentesis for culture, but this is rarely performed.

Treatment. Oral therapy with amoxicillin is still the best initial therapy. Amoxicillin-clavulanate is used if there has been recent amoxicillin use or if the patient does not respond to amoxicillin. Other alternatives to amoxicillin-clavulanate are second-generation cephalosporins, such as cefuroxime, loracarbef, or cefprozil, or third-generation agents, such as cefdinir or cefixime. Patients with severe penicillin allergies should receive macrolides such as azithromycin or clarithromycin. New fluoroquinolones such as levofloxacin, moxifloxacin, or gatifloxacin are certainly microbiologically acceptable but are broader coverage than necessary and should not be used in children (concern for arthropathy). TMP/SMZ is sometimes used but is poorly active against *Streptococcus pneumoniae*.

Sinusitis

> A young woman comes to the office with several days of facial pain, a headache, cough, fever, and discolored nasal drainage. On physical examination, you find tenderness over the maxillary sinuses and decreased transillumination of the maxillary sinuses.

Definition. An infection of the sinuses. The most common site is the maxillary sinus, followed by ethmoid, frontal, and sphenoid sinuses.



Wikipedia, James Heilman, MD

Figure 7-2. Sinusitis

Etiology. Viruses are responsible for most of the cases. Bacterial organisms that cause sinusitis are the same ones causing otitis media.

Clinical Presentation. Patients complain of facial pain, headache, postnasal drainage, and purulent nasal drainage. Headache is common and is worse when the patient leans forward. Fever occurs in about half of the cases. Tooth pain also occurs because of the proximity of the sinuses to the teeth.

Diagnosis. Obvious cases such as that described above do not always need radiologic confirmation prior to treatment. Sinus x-rays are of little value, and routine imaging as a rule is not recommended. However, if imaging is required because of concern of complications or the diagnosis is uncertain, or if there is no response to treatment, a CT scan of the sinuses is the test of choice. CT scans provide greater detail. Occasionally, a sinus puncture is necessary to confirm a specific bacteriologic etiology, particularly when the patient does not respond to therapy or if there are frequent recurrences.

Treatment. Mild or acute uncomplicated sinusitis can be managed with decongestants, such as oral pseudoephedrine or oxymetazoline sprays. More severe pain with discolored nasal discharge is treated with antibiotics. The drugs used are in the same order and type as those listed above for otitis media because the microbiology is almost identical.

Most cases of viral rhinosinusitis resolve in 7–10 days with symptomatic management (antihistamines, NSAIDS, and decongestants). If symptoms persist beyond that point or get worse, antibiotics should be considered.

Pharyngitis

Etiology. Although the majority of pharyngeal infections are from viruses, the most important cause is from group A beta-hemolytic streptococci (*S. pyogenes*). This is because of the possibility of the organism progressing on to rheumatic fever or glomerulonephritis. *S. pyogenes* only accounts for 15–20% of cases of pharyngitis.

Clinical Presentation. Sore throat with cervical adenopathy and inflammation of the pharynx with an exudative covering is highly suggestive of *S. pyogenes*. Most viruses do not give an exudate, although the Epstein-Barr virus can. Mild *S. pyogenes* infections may not give an exudate, and this is one of the reasons diagnostic testing is useful. Hoarseness and cough are not suggestive of pharyngitis.

Wikipedia, James Heilman, MD

Figure 7-3. Strep Throat

Diagnosis. The rapid streptococcal antigen test is 80% sensitive but >95% specific. A positive test can be considered the equivalent of a positive culture, whereas a negative test should be confirmed with a culture.

Treatment. Penicillin remains the mainstay of therapy. Macrolides and oral, second-generation cephalosporins are alternatives in the penicillin-allergic patient.

Influenza

Definition/Etiology. A systemic viral illness from influenza A or B, usually occurring in an epidemic pattern and transmitted by droplet nuclei. Influenza can lead to damage to the respiratory epithelium, leading to sinusitis, otitis media, bronchitis, and pneumonia.

Clinical Presentation. Patients have a systemic illness characterized by fever, myalgias, headache, and fatigue. Upper respiratory symptoms tend to predominate. These include runny nose (coryza), nonproductive cough, sore throat, and conjunctival injection.

Diagnosis. Confirmation is best achieved initially with rapid antigen detection methods of swabs or washings of nasopharyngeal secretions. Viral culture is the most accurate test but is usually not available rapidly enough to make it useful in acute patient management.

Note

Flu vaccine is indicated annually for everyone age >6 months.

Treatment. Symptomatic therapy with acetaminophen and antitussives is useful. Specific antiviral medications for both influenza A and B are the neuraminidase inhibitors oseltamivir and zanamivir. They should be used within 48 hours of the onset of symptoms to limit the duration of symptoms. Amantadine and rimantadine should not be used in the empiric therapy of influenza. Influenza vaccine is recommended annually in the general public.

The most important candidates for vaccination are those with chronic lung and cardiac disease, pregnant women in any trimester, residents of chronic care facilities, health-care workers, immunosuppressed patients, and those with diabetes and renal dysfunction. Influenza vaccine is contraindicated in those who are highly allergic to eggs and which would result in anaphylaxis.

LUNG INFECTIONS

Bronchitis

A 63-year-old man comes to the office with a cough productive of yellowish sputum for the last several days. He has smoked 1 pack of cigarettes a day for the last 30 years. On physical examination, he has clear lungs and a temperature of 101°F. His chest x-ray is normal.

Definition/Etiology. Bronchitis is an infection of the lung, which is limited to the bronchial tree with limited involvement of the lung parenchyma. Acute exacerbations of chronic bronchitis (COPD) are often difficult to distinguish from a pneumonia until after a chest x-ray is performed.

Acute bronchitis is an acute inflammation of the tracheobronchial tube. The vast majority of cases are caused by viruses. *S. pneumoniae* and *H. influenzae* have not been implicated. A small percentage of nonviral cases are due to *M. pneumoniae*, *C. pneumoniae*, and *B. pertussis*. The most common organisms responsible for *chronic bronchitis* are similar to those causing sinusitis and otitis media, which are *Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae*, and *Moraxella*. Viruses account for a significant percentage but are often not confirmed. Cigarette smoking is the most common causative factor. Even a single cigarette a day is enough to paralyze the cilia, which clear the bronchial tree of mucus and inhaled impurities, for 24 hours.

Clinical Presentation. Patients present with a cough often accompanied by sputum production. A bacterial etiology is suggested by discolored sputum, but it is impossible to determine the specific bacterial etiology by sputum characteristics alone. Although the lung examination may reveal rales, patients most commonly have clear lungs. Signs of consolidation, such as increased fremitus, are absent. Low-grade fever may be present, but patients are most commonly afebrile.

Diagnosis. Signs of respiratory infection, such as cough and sputum, with a normal chest x-ray confirm the diagnosis.

Treatment. Mild acute cases often do not require therapy because they are often caused by viruses that resolve spontaneously. Acute exacerbations of chronic bronchitis can be treated

with amoxicillin, doxycycline, or TMP/SMZ, if there has not been recent antibiotic use. Repeated infection or patients not responding to amoxicillin should be treated with any of the following: amoxicillin/clavulanate, clarithromycin, azithromycin, oral second- or third-generation cephalosporins, or the new fluoroquinolones, gemifloxacin, levofloxacin, or moxifloxacin.

Lung Abscess

A 58-year-old alcoholic man was admitted last night for several weeks of cough, sputum, and fever. He has lost 15 pounds and is feeling weak. On initial examination he is febrile and appears thin. He has very poor dentition. The lung examination is normal. The patient also exhibits a foul odor on the oral examination.

Definition. Necrosis of the pulmonary parenchyma caused by microbial infection.

Etiology

Microbiology

- 90% have at least some anaerobes involved
- The most commonly implicated anaerobes are *Peptostreptococcus*, *Prevotella*, and *Fusobacterium* species, which are oral anaerobes found in the gingival crevices
- 45% only anaerobic, 45% mixed with aerobes, 10% aerobes only
- Aerobic bacteria, most frequently involved are *S. aureus, E. coli, Klebsiella,* and *Pseudomonas*

Pathogenesis

- 85–90% have a clear association with periodontal disease or some predisposition to aspiration (e.g., altered sensorium, seizures, dysphagia).
- Pulmonary infarction, cancer, and vasculitis (like Wegener granulomatosis) are 3 examples of noninfectious causes of lung cavities.

Presentation. Besides the usual symptoms of pulmonary infection, such as fever, cough, sputum production, and chest pain, the features associated with lung abscesses are putrid, foul-smelling sputum in 60–70%, and a more chronic course. Several weeks of symptoms with weight loss, anemia, and fatigue have usually been present prior to diagnosis. This is probably due to the delay of 1–2 weeks between the aspiration of oral contents and the development of necrosis and cavitation.

Diagnosis. Sputum for Gram stain and culture will *not* be able to show the causative anaerobic organism in a lung abscess. The chest x-ray in an abscess will often show a thick-walled cavitary lesion. A chest CT scan is useful to help define the exact extent of the cavity. The lower lobes are the most common sites of aspiration in the upright position, and the posterior segment of the right upper lobe is the most common site in the supine position. Aspiration of the abscess fluid is necessary for a specific bacteriologic diagnosis.

Treatment. In the absence of specific microbiologic diagnosis, clindamycin is good empiric coverage for the "above the diaphragm" anaerobes most often found. Penicillin is also acceptable.

In contrast to most abscesses where drainage is the rule, lung abscesses rarely require drainage in the antibiotic era. Most respond to antimicrobial therapy and drain spontaneously by communicating with larger bronchi. Therefore, the answer to the question, *what is the best initial therapy for a lung abscess*, is antibiotics such as clindamycin, not drainage.

Pneumonia

Definition. An infection of the lung parenchyma.

Etiology. It is not necessary to have a particular predisposing condition to have pneumonia. Pneumonia is the only cause of death from an infectious disease in the top ten causes of death in the United States. It is the sixth leading cause of death. Some conditions do predispose to having pneumonia more commonly. These include cigarette smoking, diabetes, alcoholism, malnutrition, obstruction of the bronchi from tumors, and immunosuppression in general. Neutropenia and steroid use predispose to *Aspergillus* infection.

The most common cause of community-acquired pneumonia in all groups is *S. pneumoniae* when an actual cause is identified (however, viruses are the most common cause in children <5 years of age). The subsequent causes may vary, but *Strep pneumoniae* is always number one. Hospital-acquired or ventilator-associated pneumonia shows a predominance of Gram-negative bacilli such as *E. coli*, the other Enterobacteriaceae, or *Pseudomonas*, as well as MRSA.

Table 7-1. Frequency of Infectious Agents Causing Pneumonia

"Typical"	40–60%
Strep pneumoniae	15–35%
Haemophilus	2–10%
Moraxella	<5%
"Atypical"	10–30%
Legionella	0–15%
Mycoplasma	10%
Chlamydia	5–10%
Viral	2–20%
Unknown	30–60%

Specific predispositions are as follows:

- *Haemophilus influenzae*—smokers, COPD
- *Mycoplasma*—young, otherwise healthy patients
- *Legionella*—epidemic infection in older smokers, particularly when located near infected water sources, such as air-conditioning systems
- *Pneumocystis jiroveci* (formerly *carinii*) pneumonia—HIV-positive persons with <200 CD4 cells not on prophylaxis
- *Coxiella burnetti* (Q-fever)—exposure to animals, particularly at the time they are giving birth

- *Klebsiella*—alcoholics
- *Staphylococcus aureus*—following viral syndromes or viral bronchitis, especially influenza
- *Coccidioidomycosis*—exposure to the deserts of the American Southwest, particularly Arizona
- *Chlamydia psittaci*—birds
- *Histoplasma capsulatum*—exposure to bat or bird droppings, spelunking (recreational cave exploration)
- *Bordetella pertussis*—cough with whoop and post-tussive vomiting
- *Francisella tularensis*—hunters, or exposure to rabbits
- *SARS, Avian influenza*—travel to Southeast Asia
- *Bacillus anthracis*, *Yersinia pestis*, and *Francisella tularensis*—bioterrorism

Clinical Presentation. Patients with pneumonia present with cough, fever, and often sputum production. Severe pneumonia of any cause may present with dyspnea. The quality and degree of sputum produced might provide useful clues to the microbiologic etiology of pneumonia at the initial presentation. Bacterial infections such as *Streptococcus pneumoniae*, *Haemophilus*, and *Klebsiella* have significant purulent sputum production because they are infections of the alveolar air space. The sputum in patients with *S. pneumoniae* has been classically described as rusty. This "rust" is simply hemoptysis. As the blood oxidizes, it becomes brownish-red; hence, the comparison to rust. Any form of persistent cough may be associated with hemoptysis, however, and hemoptysis by itself is nonspecific. *Klebsiella pneumoniae* has been associated with sputum described as being like currant jelly. This is simply hemoptysis with mucoid characteristics from a combination of the necrotizing nature of *Klebsiella* with the organism's thick mucopolysaccharide coating. Interstitial infections such as those caused by *Pneumocystis* pneumonia (PCP), viruses, *Mycoplasma*, and sometimes *Legionella* often give a nonproductive or "dry" cough.

Any cause of pneumonia may be associated with pleuritic chest pain. This is pain worsened by inspiration. Commonly, pleuritic pain is associated with lobar pneumonia, such as that caused by *Pneumococcus*. This is because of localized inflammation of the pleura by the infection. Lobar pneumonia is the type most commonly associated with signs of consolidation on examination.

On physical examination pneumonia presents with rales, rhonchi, or signs of lung consolidation, including dullness to percussion, bronchial breath sounds, increased vocal fremitus, and egophony (E to A changes).

The respiratory rate is essential in determining the severity of a pneumonia. The respiratory rate is often a close correlate of the level of oxygenation. Severe pneumonia leads to hypoxia, which leads to hyperventilation.

Organism-specific presentations are as follows:

- *Mycoplasma*—Dry cough and chest soreness. Dyspnea is rare. Bullous myringitis and anemia from hemolysis from cold agglutinin disease is occasionally present. Patients with *Mycoplasma pneumoniae* rarely need to be admitted to the hospital; therefore, any patient presented to you as an inpatient is less likely to have *Mycoplasma*.
- *Legionella*—CNS manifestations such as confusion, headache, and lethargy. GI manifestations include diarrhea and abdominal pain.
- PCP—Marked dyspnea, particularly on exertion, with chest soreness with cough in an HIV-positive person. Patients invariably have AIDS with a CD4 count of <200/μL.

Diagnosis. The most important initial test for any type of pneumonia is the chest x-ray. Besides being able to simply show the presence of disease, the chest x-ray gives the initial clue to determining the diagnosis. The most important initial clue to the diagnosis is whether the infiltrates are localized to a single lobe of the lung or whether they are bilateral and interstitial. *S. pneumoniae* (and other causes of "typical" pneumonia) usually appear as a lobar pneumonia with parapneumonic pleural effusion. Interstitial infiltrates are associated with PCP, viral, *Mycoplasma*, *Chlamydia*, *Coxiella*, and sometimes *Legionella* pneumoniae. Sputum should be obtained for both Gram stain as well as culture. Sputum culture is the most specific diagnostic test for lobar pneumonia, such as with *S. pneumoniae*, *Staphylococcus*, *Klebsiella*, and *Haemophilus*. The other organisms (viral, *Mycoplasma, Chlamydia, Coxiella*, etc.), the so-called "atypical" organisms, will not show up on a Gram stain or regular bacterial culture for various reasons. Occasionally, more invasive tests are necessary to confirm the diagnosis such as bronchoscopy, thoracentesis, pleural biopsy, or culture of pleural fluid. Ultimately, the most specific diagnostic test for pneumonia is with an open lung biopsy.

Organism-specific diagnostic methods are as follows:

- *Mycoplasma*—Specific serologic antibody titers. Cold agglutinins have both limited specificity and sensitivity.
- *Legionella*—Specialized culture media with charcoal yeast extract, urine antigen tests, direct fluorescent antibodies, and antibody titers.
- PCP—Bronchoalveolar lavage, increased LDH
- *Chlamydia pneumoniae*, *Coxiella*, *Coccidioidomycoses*, and *Chlamydia psittaci*—All of these are diagnosed with specific antibody titers.

Note

CURB-65 indicates need for hospitalization in pneumonia:

Confusion

Uremia

Respiratory distress

Blood pressure low

Age >65

Treatment. Treatment depends on whether the patient has a mild disease that can be treated as an outpatient or a more severe illness that must be treated with IV antibiotics as a hospitalized inpatient. The major determinants of severity are the degree of hypoxia, such as a Po_2 <60 mm Hg, oxygen saturation <94% on room air, or a respiratory rate >30/min; confusion or disorientation; uremia; and hypotension (systolic BP <90 mm Hg and diastolic BP <60 mm Hg). Other markers of severity are high fever, hypothermia, leukopenia (WBC <4,000/mm^3), rapid pulse (>125/min), hyponatremia, or dehydration as determined by an elevated BUN. Patients with serious underlying diseases such as cancer, liver disease, renal disease, or chronic lung disease often do better in hospital with IV medications.

The specific organism causing pneumonia is rarely, if ever, known at the time that the initial therapeutic decision must be made. Empiric therapy for pneumonia managed as an outpatient is with a macrolide, such as azithromycin or clarithromycin. This is because of the high frequency of *Mycoplasma* and *Chlamydia pneumoniae* as the cause of less severe community-acquired pneumonia (CAP). New fluoroquinolones (levofloxacin, moxifloxacin, or gemifloxacin) are alternatives. Although oral second- and third-generation cephalosporins and amoxicillin/clavulanate are often used, they do not cover the atypical pathogens well.

Hospitalized patients with CAP should receive either levofloxacin, moxifloxacin, or gatifloxacin *or* a second- or third-generation cephalosporin such as cefotaxime or ceftriaxone combined with a macrolide antibiotic such as azithromycin or clarithromycin (or doxycycline).

Table 7-2. Empiric Therapy of Community-Acquired Pneumonia

Outpatient (Nonhospitalized)	Inpatient (Hospitalized)
First choice: macrolides: Azithromycin, clarithromycin *Alternatives: new fluoroquinolones:* Levofloxacin, moxifloxacin, gemifloxacin	New fluoroquinolones (levofloxacin, moxifloxacin, or gemifloxacin) *or* Second- or third-generation cephalosporins (cefuroxime or ceftriaxone) combined with a macrolide or doxycycline *or* Beta-lactam/beta-lactamase combination drug (ampicillin/sulbactam; ticarcillin/clavulanate; piperacillin/tazobactam) combined with doxycycline or a macrolide

Treatment of Hospital-Acquired Pneumonia. Those patients who develop pneumonia after 5–7 days in the hospital are at increased risk of infection from drug-resistant, Gram-negative bacilli (*Pseudomonas*, *Klebsiella*, *E. coli*, etc.) or gram-positive bacilli such as methicillin-resistant *Staphylococcus aureus* (MRSA). Empiric therapy of hospital-acquired pneumonia is with third-generation cephalosporins with antipseudomonal activity (such as ceftazidime) or carbapenems (such as imipenem) or with beta-lactam/beta-lactamase inhibitor combinations (such as piperacillin/tazobactam) and coverage for MRSA with vancomycin or linezolid. Aminoglycosides (gentamicin, tobramycin, amikacin) are often added to empiric gram-negative coverage for synergy and to ensure that the patient might be getting at least one drug if the bacteria is multidrug resistant. Antibiotic therapy can then be adjusted when results of cultures (sputum, blood, bronchoalveolar lavage, and/or pleural) become available.

Treatment of specific organisms is as follows:

- *Haemophilus influenzae*—Second- or third-generation cephalosporins
- *Mycoplasma*—Macrolides, doxycycline, or a quinolone
- *Legionella*—Macrolides, doxycycline, or a quinolone
- *Pneumocystis* pneumonia—Trimethoprim/Sulfamethoxazole (TMP/SMZ). Steroids should be used if the infection is severe. Severe is defined as an arterial P_{O_2} <70 mm Hg or an A-a gradient of >35 mm Hg. If the patient is allergic to TMP/SMZ, IV pentamidine or atovaquone should be used. Dapsone or atovoquone can be used prophylactically.
- *Coxiella brunetti* (Q-fever)—Doxycycline (or erythromycin as an alternative)
- *Klebsiella*—Third-generation cephalosporins and the other drugs for Gram-negative bacilli
- *Staphylococcus aureus*—Semisynthetic penicillins (oxacillin, nafcillin, etc.) if methicillin sensitive. In the nosocomial setting, isolates are invariably methicillin-resistant, and vancomycin or linezolid is administered.
- *Coccidioidomycosis*—Primary pulmonary disease does not need to be treated. Treatment is only used for disseminated disease or in those with pulmonary disease who are immunosuppressed. Life-threatening disease is treated with amphotericin. Mild disease is treated with fluconazole or itraconazole.

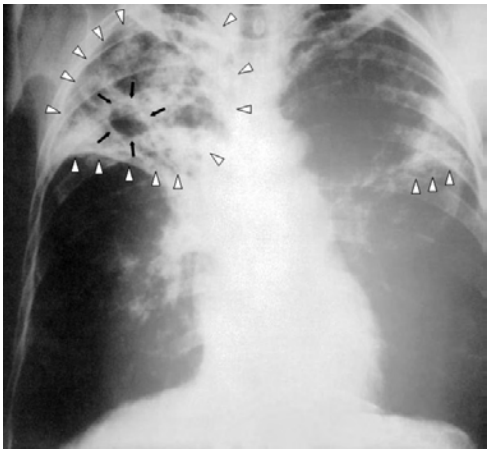
Pneumococcal vaccine

Those patients at increased risk for pneumonia should receive pneumococcal vaccine. Those who should receive the vaccine include all patients age >65, as well as those with any serious underlying lung, cardiac, liver, or renal disease. Immunocompromised patients, such as those on steroids, HIV-positive persons, splenectomized patients, diabetics, and those with leukemia or lymphoma, should be vaccinated at the earliest possible opportunity. The vaccine is 60–70% effective. Re-dosing in 5 years is only necessary for those with severe immunocompromise or in those who were originally vaccinated before the age of 65. In generally healthy persons vaccinated age >65, a single dose of vaccine is enough to confer lifelong immunity.

Tuberculosis

A 37-year-old resident of a maximum-security correctional facility has been having a cough, voluminous sputum production, and fever for the last few weeks. He has had a 10-pound weight loss and feels very weak.

Definition/Etiology. Tuberculosis is an infection with *Mycobacterium tuberculosis* (TB). Worldwide, TB is one of the top 3 causes of all deaths. Nearly a quarter of the entire world's population has been exposed and would be reactive to PPD testing. Up until the middle of this century, TB was the most common cause of death in the United States, but at present TB is at an all-time low in the United States with an incidence of <15,000 cases per year. More than half of all cases are in recent immigrants. TB is spread exclusively by person-to-person transmission by means of respiratory droplet infection. There is no animal reservoir of the disease. Bacillus Calmette-Guérin (BCG) vaccination is used in many parts of the world outside of the United States to try to prevent infection. It is, at best, 50% effective and is never indicated for routine use in the United States. Besides immigrants, TB predominantly occurs in persons with specific risks for exposure such as alcoholics, healthcare workers, prisoners, residents of homeless shelters and nursing homes, and in chronically debilitated patients whose weakened immune systems allow for more frequent re-activation of latent infection. Impairment of T-cell–mediated cellular immunity is the most significant defect associated with re-activation. This is why steroid use, organ transplantation, leukemia, lymphoma, and HIV are such important risk factors.



Centers for Disease Control and Prevention

Figure 7-4. Tuberculosis X-ray

Clinical Presentation. Patients present with cough, sputum, fever, and an abnormal lung examination. They may be impossible to distinguish clinically from those with pneumonia. Weight loss is common because of the chronicity of the infection. Even when untreated, tuberculosis usually takes up to 5 years to become fatal. Night sweats may occur. TB occurs outside of the lungs in 15–20% of cases. The presentation is dependent on the site involved. Any part of the body may be involved, although the lymph node, meningeal, GI, and genitourinary are the most frequent sites involved in extrapulmonary TB. Lymph node involvement (adenitis) is the most frequently involved extrapulmonary site.

Diagnosis. Chest x-ray is the best initial test, as it is with all forms of pulmonary infections. Apical involvement with infiltrates and sometimes cavitation is the most common finding. Adenopathy, effusion, and calcified nodules (Ghon complex) are associated findings. Sputum examination with specific staining for acid-fast bacilli (AFB) allows specific diagnosis. AFB stain has limited sensitivity, and you need 3 negative smears to reach >90% sensitivity. AFB-positive sputum staining is usually the trigger to start therapy for TB. Culture is the most specific test, but because it routinely takes 4–6 weeks to grow, the culture is often not available to guide initial therapy. The culture is also necessary in order to do sensitivity testing. Other diagnostic modalities sometimes necessary if the sputum AFB stain is unrevealing are thoracentesis (to examine the pleural fluid), gastric aspirate in children, biopsy or needle aspiration of the specific extrapulmonary organ involved, and lumbar puncture with meningitis. Pleural biopsy is the single most sensitive diagnostic test. A single pleural biopsy can have up to 75% sensitivity. TB will give caseating necrosis on biopsy of any tissue.

Do not use PPD testing to diagnose acute cases of TB. PPD is relatively insensitive and nonspecific particularly with acute illness.

Treatment. Initial therapy of TB before the results of sensitivity testing are known consists of 4-drug therapy with isoniazid (INH), rifampin (Rif), pyrazinamide (PZA), and ethambutol (ETB). All 4 drugs are continued for the first 2 months or until sensitivity testing is known. PZA and ETB are then discontinued, and therapy continues with INH and rifampin for another 4 months. This makes routine therapy last for a total of 6 months. The fourth drug, ETB, is given if the sensitivity is not known. The only forms of TB that definitely must be treated for longer than 6 months are TB meningitis (12 months), TB in pregnancy (9 months), and osteomyelitis. HIV-positive persons may be treated for 6–9 months, but there is no clear evidence that 9 months is necessary, i.e., even in HIV-positive persons, 6 months of therapy is effective. INH use should generally be combined with vitamin B_6 (pyridoxine) to prevent peripheral neuropathy that can be a side effect of INH.

Pregnant patients should not receive PZA or streptomycin. Steroid use with TB medications is only your answer for TB meningitis and TB pericarditis.

All of the TB medications can cause liver toxicity, except streptomycin. INH also causes peripheral neuropathy because of pyridoxine deficiency. Rifampin is associated with causing a benign change in the color of all bodily fluids to orange/red. This color is dangerous only because it could stain contact lenses and white underwear. Ethambutol is associated with optic neuritis, which can cause color blindness and other visual disturbances. PZA can cause a benign hyperuricemia. Don't treat the hyperuricemia unless there are symptoms of gout associated with it, which rarely occurs.

Diagnosis and Treatment of Latent TB Infection. The PPD test and interferon gamma release assay (IGRA) are used to screen asymptomatic populations at risk of TB to see if they have been exposed and are at increased risk of re-activating the disease. The AFB stain and culture of the affected tissues should be performed. PPD is considered positive based on the amount

Clinical Pearl

Newer tests may provide TB sensitivity testing in a few weeks, thus the period of using 4 drugs is significantly shortened.

of induration of the skin 48–72 h after the intradermal (not subcutaneous) injection of the PPD. Erythema is irrelevant. A positive PPD or IGRA roughly indicates a 10% lifetime risk of developing TB in HIV-negative persons. Most of the active cases will develop within the first 2 years after converting to a positive test. HIV-positive persons have a roughly 7–10% risk per year of developing active disease. Previous BCG vaccination does not alter these recommendations. The cutoffs are as follows:

≥5 mm:

- Close contacts of active TB cases
- HIV-positive persons
- Abnormal chest x-ray consistent with old, healed TB
- Steroid use or organ transplantation recipients

≥10 mm: High-risk groups, such as healthcare workers, prisoners, and nursing home residents; recent immigrants (within 5 years) from areas with a high prevalence; homeless patients; persons with immunocompromise other than those described above, such as those with leukemia, lymphoma, diabetics, dialysis patients, and injection drug users who are HIV-negative or whose HIV status is unknown; and children <4 years of age, or infants, children, and adolescents exposed to adults at high risk of TB.

≥15 mm: Low-risk populations, i.e., *not* the people described above, i.e., people who should never have been tested in the first place.

Two-Stage Testing: Those in whom there has not been a recent PPD test and now show some reactivity that is <10 mm should have a second test within 2 weeks. This is to make sure the first test was not a false negative. A reaction of >10 mm on the second test is simply a positive test, not a recent converter. You cannot make a PPD-negative person become positive with repeated testings.

All patients who test positive on the PPD test or IGRA should have a chest x-ray to see if they have early asymptomatic evidence of TB on their film. Those with abnormal chest x-rays should have 3 sputum AFB stains done to see if they have active disease. Positive AFB smears indicate the need for the start of 4 TB drugs as described above.

Patients with positive PPD tests or IGRA and no evidence of active disease should receive therapy with 9 months of INH and vitamin B_6. A normal chest x-ray or an abnormal x-ray and 3 negative AFB stains of sputum are sufficient to exclude active disease. Although 6 months of INH/B6 is an acceptable alternative, the recommendation is that *all* patients, including those who are HIV positive, should receive the same 9-month course of therapy. Previously, this was referred to as "prophylaxis." The proper designation is now "treatment of latent TB."

The IGRA is not altered at all with previous BCG vaccine. The IGRA has the same meaning and treatment as a positive PPD skin test. Previous BCG vaccination does not alter these recommendations in any way. Previous BCG will not make the IGRA positive.

GASTROINTESTINAL INFECTIONS

Infectious Diarrhea/Food Poisoning

A 27-year-old medical student leaves the Step 2 class at 12:30 to go to lunch. At 3 P.M. she starts having repeated episodes of diarrhea. The diarrhea contains blood and mucus. She is also febrile and has abdominal pain.

Definition. Most infectious diarrhea is caused by contaminated food and water, so the overlap between food poisoning and infectious diarrhea is considerable. There are several types of food poisoning, such as *Bacillus cereus* and *Staphylococcus aureus*, that present predominantly with vomiting, so the two terms are not entirely synonymous.

Etiology. A wide variety of agents can cause food poisoning.

- The most common agent causing food poisoning is *Campylobacter*.
- The most commonly associated agent with contaminated poultry and eggs is *Salmonella*.
- *E. coli* is still the most common cause of travelers' diarrhea; it produces a wide spectrum of disease depending on whether it makes toxin or is invasive.
  - *E. coli* 0157:H7 is associated with undercooked hamburger meat.
  - *Bacillus cereus* is associated with fried rice; the rice becomes contaminated with bacillus spores, and as it is prepared for serving it is warmed only at a moderate temperature not hot enough to kill the spore.
  - *Giardia lamblia* and cryptosporidiosis are acquired from contaminated water sources that have not been appropriately filtered, such as fresh water found on a camping trip.
    - Cryptosporidiosis is also associated with HIV, particularly when there is profound immunosuppression and CD4 count drops <50 cells.
- There are several types of *Vibrio* causing human disease.
  - *V. cholera* is very rare in the United States.
  - *V. parahaemolyticus* is associated with ingestion of contaminated shellfish such as clams, oysters, and mussels.
  - *V. vulnificus* is associated with ingestion of raw shellfish; it causes severe disease in those with underlying liver disease; it is also associated with iron overload and the development of bullous skin lesions.
- Viral infections such as rotavirus or Norwalk agents are most commonly associated with outbreaks in children.
- Clostridia associations are as follows:
  - *C. difficile* with previous antibiotic use
  - *C. botulinum* with ingestion of infected canned foods
  - *C. perfringens* with ingestion of meat contaminated with spores due to unrefrigeration

Although it is important to be familiar with these associations, remember that virtually any food can be contaminated by almost any organism. In reality, the most important thing is not what food you eat but whose dirty hands touched your food and what were they contaminated with.

Clinical Presentation. The most important feature of any person presenting with possible food poisoning is the presence or absence of blood in the stool. Blood is most commonly associated with invasive enteric pathogens, such as *Salmonella*, *Shigella*, *Yersinia*, invasive *E. coli*, and *Campylobacter*. The time between the development of the diarrhea from the ingestion of the food is not as important as the presence of blood. Incubation times are helpful only if you have a group outbreak and you can pinpoint a common source of contamination. In other words, the last thing you eat is not necessarily the thing that was contaminated. The invasive enteric pathogen may be causing infection in the absence of blood, however, and the absence of blood does not exclude them. *Campylobacter* is rarely associated with Guillain-Barré syndrome.

Ingestion of ciguatera toxin causes symptoms within 2–6 hours, which includes paresthesias, numbness, nausea, vomiting, and abdominal cramps. In severe cases symptoms can be neurologic (weakness, reversal of hot-cold sensations), and cardiovascular (hypotension). Neurologic symptoms can be severe, progressive, and debilitating. There is no specific therapy to reverse ciguatera poisoning. The most commonly implicated fish are barracuda, red snapper, and grouper.

E. coli 0157:H7 and *Shigella* are associated with hemolytic uremic syndrome (HUS).

Bacillus cereus and *Staphlococcus* predominantly present with vomiting within 1–6 hours of their ingestion because they contain a preformed toxin. They can give diarrhea later.

Giardia, *Cryptosporidium*, *Cyclospora*, and most other protozoans do not give bloody diarrhea. The major protozoan associated with blood in the stool is *Entamoeba histolytica*.

Viruses can give voluminous watery diarrhea but do not result in bloody diarrhea.

Scombroid is a type of poisoning that occurs after ingesting scombroid fish (tuna, mackerel, mahi mahi), which may contain a large amount of histamine. When ingested, scombroid can give symptoms within a few minutes: rash, diarrhea, vomiting, and wheezing, along with a burning sensation in the mouth, dizziness, and paresthesias.

Diagnosis. When there is no blood present in the stool, the best initial method of determining the etiology of the diarrhea is to test the stool for the presence of WBCs with methylene blue testing. WBCs will tell you that you have an invasive pathogen but will not distinguish the specific type. Culture is necessary to determine the specific type.

Giardia and *Cryptosporidia* are detected by direct examination of the stool for the parasites, as well as for their eggs. A special modified AFB stain is necessary to detect *Cryptosporidia*. Stool ELISA is also used for *Giardia*.

Treatment. Therapy is determined by the severity of disease. Mild infections with the invasive pathogens and viruses usually require only oral fluid and electrolyte replacement. More severe infections, such as those producing high fever, abdominal pain, tachycardia, and hypotension, require IV fluids and oral antibiotics. You rarely, if ever, have the luxury of a specific etiology identified when the initial therapeutic decision must be made. The best initial empiric antibiotic therapy of an invasive pathogen is with a fluoroquinolone such as ciprofloxacin.

Organism-specific therapy is as follows:

- *Campylobacter*—Erythromycin
- *Giardia*—Metronidazole
- *Cryptosporidium*—Control of underlying HIV disease with antiretrovirals, nitazoxanide
- Nitazoxanide is the first truly useful therapy for cryptosporidiosis.
- Scombroid—Antihistamines such as diphenhydramine

ACUTE VIRAL HEPATIC INFECTIONS

An 18-year-old woman comes to the emergency department because of several days of nausea, vomiting, and fever. She uses no medications. She reports unprotected sex. Her stool is light in color. On physical examination she is jaundiced.

Definition. Viral hepatitis is an infection of the liver caused by hepatitis A, B, C, D, or E.

- **Hepatitis A and E** are transmitted by contaminated food and water. They are orally ingested and have an asymptomatic incubation period of several weeks, with an average of 2–6 weeks. They cause symptomatic disease for several days to weeks, have no chronic form, and do not lead to either cirrhosis or hepatocellular carcinoma.
- **Hepatitis B, C, and D** are transmitted by the parenteral route. They can be acquired perinatally or through sexual contact, blood transfusion, needlestick, and needle sharing.
- **Hepatitis G** has been identified in a small number of patients through screening of the blood supply but has not yet been associated with clinical disease.
- **Hepatitis B and C** can lead to a chronic form, which can cause cirrhosis and hepatocellular carcinoma. Four million people in the United States are infected with hepatitis C. Hepatitis C is the most common disease leading to the need for liver transplantation in the United States.

All forms can occasionally present with fulminant hepatic necrosis and acute liver failure.

Clinical Presentation. The most common presentation of acute hepatitis of any cause is jaundice, dark urine, light-colored stool, fatigue, malaise, weight loss, and a tender liver. On physical examination the liver may be enlarged. You cannot distinguish the precise viral etiology of the hepatitis by initial presentation alone. In fact, drug-induced hepatitis, such as that from isoniazid or massive alcohol use, may present with the same symptoms. Hepatitis B and C can also give symptoms similar to serum sickness, such as joint pain, rash, vasculitis, and glomerulonephritis. They also lead to cryoglobulinemia. Hepatitis B has been associated with the development of polyarteritis nodosa (PAN). Hepatitis E has been associated with a more severe presentation in pregnant women.

Table 7-3. Comparative Features: Hepatitis A, B, C, E, and Delta

Feature	Hepatitis A	Hepatitis B	Hepatitis C	Delta	Hepatitis E
Incubation period (wk)	2–6 (avg. 4)	4–26 (avg. 13)	2–20	4–8	—
Transmission	Fecal-oral	Sexual > parenteral	Parenteral > sexual	Parenteral, sexual	Fecal-oral
Severity	Mild	Occasionally severe	Usually subclinical	Co-infection with B	Mild, except in pregnant women
Fulminant hepatitis	Rare	Very rare (1% of icteric patients	Extremely rare	Co-infection occasional	Rare
Symptoms	Fever, malaise, headache, anorexia, vomiting, dark urine, jaundice	As with A, but 10–20% with serum sickness-like (joint pain, rash)	Only 20% acutely symptomatic	As with A	As with A
Carrier state	None	Yes	Yes	Yes	None
Chronicity (%)	0	5–10	80	5	0
Associated with blood transfusion (%)	Very rare	5–10	Almost negligible 2% to routine screening	Occurs, but frequency unknown	Rare
Serology	Anti-HAV IgM fraction IgG fraction	HBsAg, HBsAb HBeAg Anti-HBs Anti-HBc Anti-HBe	Antibody to hepatitis C PCR-RNA	Anti-delta IgM fraction IgG fraction	Anti-Hep E IgM IgG
Postexposure prophylaxis	Immunoglobin Hep A vaccine	HBIg/Hep B vaccine	None effective	None	Unknown
Association with cirrhosis	No	Yes	Yes	Yes	No
Association with primary hepatocellular carcinoma	No	Yes	Yes	Yes	No

Diagnosis. All forms of viral and drug-induced hepatitis will produce elevated total and direct bilirubin levels.

- Viral hepatitis will produce both elevated ALT and AST, but ALT is usually greater than the AST.
- With drug- and alcohol-induced hepatitis, AST is usually more elevated than the ALT.
- Alkaline phosphatase and GGTP are less often elevated because these enzymes usually indicate damage to the bile canalicular system or obstruction of the biliary system.
- If there is very severe damage to the liver, prothrombin time and albumin levels will be abnormal.

Hepatitis A, C, D, and E are diagnosed as **acute** by the presence of the IgM antibody to each of these specific viruses. IgG antibody to hepatitis A, C, D, and E indicates old, resolved disease.

- Hepatitis C activity can be followed with PCR-RNA viral load level. However, do not use PCR to establish the initial diagnosis.
- Hepatitis B is diagnosed as acute with the presence of the hepatitis B surface antigen, which is the first viral marker to elevate. The hepatitis B e antigen and IgM core antibody also help establish acute infection.
  - The e antigen indicates high levels of viral replication and is a marker for greatly increased infectivity.
  - Resolution of the infection is definitively indicated by the loss of surface antigen activity and the development of hepatitis B surface antibody.
  - Hepatitis B core antibody of the IgG type and hepatitis e antibody also indicate that the acute infection is about to resolve and may be the only marker present in the period of 2-6 weeks between the loss of surface antigen activity and development of the surface antibody.

Treatment. There is no effective therapy for acute hepatitis B. Chronic hepatitis B can be treated with either interferon, entecavir, adefovir, or lamivudine.

With the approval of the newest hepatitis C drugs, the goal of HCV treatment is to cure the virus, which can be done with a combination of drugs. The specific medications used and the duration of treatment depend on a number of factors:

- HCV genotype
- Viral load
- Past treatment experience
- Degree of liver damage
- Ability to tolerate the prescribed treatment
- Whether patient is waiting for a liver transplant or is transplant recipient

There are a number of approved therapies to treat HCV, such as sofosbuvir/ledipasvir (Harvoni), simeprevir (Olysio), sofosbuvir (Sovaldi) and Viekira Pak (ombitasvir, paritaprevir and ritonavir tablets co-packaged with dasabuvir tablets that may be prescribed with or without ribavirin). Sofosbuvir and simeprivir may be prescribed together with or without ribavirin, or each may be separately combined with ribavirin and in some cases peginterferon as well.

Sofosbuvir/ledipasvir, the current preferred HCV treatment, is 2 drugs formulated in to one daily pill. For genotype 1 success rates of sofosbuvir/ledipasvir are around 94–99%, while treatment duration is 8–12 weeks. Both are direct-acting antivirals (DAAs) which means they

Note

Entecavir, adefovir, tenofovir, and telbivudine can be used in place of lamivudine for the treatment of hepatitis B.

directly interfere with hepatitis C virus replication. Sofosbuvir is a polymerase inhibitor while ledipasvir, an NS5A inhibitor. Patients who have never been treated for HCV—whether they have cirrhosis or not—take sofosbuvir/ledipasvir for 12 weeks. Treatment-naïve patients without cirrhosis whose pre-treatment viral load (HCV RNA) is <6 million IU/mL may be considered for **8 weeks of treatment**.

When hepatitis C treatment is working, the virus will become undetectable within 4-12 weeks and will remain that way throughout treatment. Patients are considered cured when they have achieved what is known as a sustained virologic response (SVR), or continuation of this undetectable status, 12-24 weeks after completing therapy.

After a needlestick from a hepatitis B surface-antigen–positive patient, the person stuck should receive hepatitis B immunoglobulin (HBIg) and hepatitis B vaccine. If the person stuck already has protective levels of surface antibody to hepatitis B present in the blood, then no further therapy is indicated. There is no effective postexposure prophylaxis to hepatitis C, and there is no vaccine. All healthcare workers, IV drug users, and others at risk should be vaccinated for hepatitis B. All newborn children are vaccinated against hepatitis B and A. Hepatitis A vaccine should be given to those traveling to countries that may have contaminated food and water, those with chronic liver disease, and those with high risk sexual behavior.

GENITAL AND SEXUALLY TRANSMITTED INFECTIONS

Urethritis

A 31-year-old man is in your clinic today with several days of urinary frequency, urgency, and burning.

Definition. Inflammation of the urethra.

Etiology

- Gonococcal urethritis caused by *Neisseria gonorrhoeae*
- Nongonococcal urethritis caused by either *Chlamydia trachomatis* (50%), *Ureaplasma urealyticum* (20%), *Mycoplasma hominis* (5%), *Trichomonas* (1%), herpes simplex

Clinical Findings. Purulent urethral discharge; dysuria, urgency, and frequency in urination.

Diagnosis. Smear can show the Gram-negative, coffee bean–shaped diplococci intracellularly. Serology (fluorescent antibodies) for chlamydia by swabbing the urethra, or by ligase chain reaction test of voided urine. Culture for gonorrhea is the most specific test for gonorrhea.

Treatment. Single-dose ceftriaxone intramuscularly and single-dose azithromycin orally is now the treatment of choice. An alternative regimen with doxycycline for 7 days can also be used. Gonorrhea can also be treated with single-dose cefixime. This is the same treatment as that for cervicitis. Ciprofloxacin should not be used as first-line therapy for gonorrhea.

Pelvic Inflammatory Disease

Definition. Infections involving the fallopian tubes, uterus, ovaries, or ligaments of the uterus.

Etiology. *N. gonorrhoeae*, *Chlamydia*, *Mycoplasma*, anaerobic bacteria, or Gram-negative bacteria. Intrauterine devices predispose to PID.

Clinical Findings. Lower abdominal and pelvic pain on palpation of the cervix, uterus, or adnexa; fever, leukocytosis, and discharge are common. Cervical motion tenderness is key. Discharge from the cervix may be present.

Diagnosis. Culture on Thayer-Martin for gonococcus and Gram stain of discharge, increased ESR. Laparoscopy is the only definitive test. If there is fluid in the retrouterine cul-de-sac, a culdocentesis will rarely be performed. A pregnancy test should be done. Ultrasonography of the pelvis may also be helpful to exclude other pathology, such as an ovarian cyst or tubo-ovarian abscess. Clinical presentation is the main method (CMT/adnexal tenderness).

Treatment. Doxycycline and cefoxitin (or cefotetan) for inpatient therapy. Outpatient therapy is with single-dose ceftriaxone intramuscularly and doxycycline orally for two weeks. The main reason to treat in hospital is a high WBC or high fever. Outpatient therapy can also be with 2 weeks of oral ofloxacin and metronidazole as a second-line agent.

Complications. Infertility and ectopic pregnancy.

Syphilis

A 43-year-old man comes to the clinic with several days of an ulcerated genital lesion. He also has some surrounding adenopathy.

Definition. A systemic contagious disease caused by a spirochete; characterized by periods of active manifestations and by periods of symptomless latency.

Etiology. *Treponema pallidum.*

Clinical Findings. Syphilis can be classified as being congenital or acquired.

Congenital

- **Early:** symptomatic; seen in infants up to age 2
- **Late:** symptomatic, Hutchinson teeth, scars of interstitial keratitis, bony abnormalities (saber shins)

Acquired

- Early infectious syphilis
  - Primary stage: Chancre that appears within the third week and disappears within 10–90 days; also, regional lymphadenopathy is painless, rubbery, discrete, and nontender to palpation. Primary chancres are usually found on the penis, anus, rectum in men, and vulva, cervix, and perineum in women (may be found in other places such as lips, tongue, etc.).
  - Secondary stage: Cutaneous rashes appear 6–12 weeks after infection, usually found symmetrically and more marked on the flexor and volar surfaces of the

body (pinkish or pale red in white persons; pigmented spots, copper-colored macules in blacks). Lymphadenopathy, papules that develop at mucocutaneous junctions and moist areas, are termed condylomata lata (extremely infectious), and alopecia can be seen.

- Latent stage: Asymptomatic; may persist for life, and one-third of patients develop late or tertiary syphilis.
- Late or tertiary syphilis: Most commonly neurologic

Centers for Disease Control and Prevention, M. Rein, VD

Figure 7-5. Syphilis, Primary Chancre

Note

Use the FTA to exclude neurosyphilis in CSF.

These patients are symptomatic but not contagious. Benign tertiary develops 3–20 years after the initial infection, and the typical lesion is the gumma (a chronic granulomatous reaction), found in any tissue or organ. It will heal spontaneously and leave a scar. Cardiovascular syphilis and neurosyphilis are the other manifestations of tertiary syphilis. The Argyll Robertson pupil (usually only with neurosyphilis) is a small irregular pupil that reacts normally to accommodation but not to light. Tabes dorsalis (locomotor ataxia) results in pain, ataxia, sensory changes, and loss of tendon reflexes. Neurosyphilis is rare and is essentially the only significant manifestation of tertiary syphilis likely to be seen. The FTA on CSF is far more sensitive for neurosyphilis than a VDRL.

Centers for Disease Control and Prevention

Figure 7-6. Syphilis, Secondary Palms

Diagnosis

- Screening tests are the VDRL and RPR; specific tests are the FTA-ABS, MHA-TP, and Darkfield exam of chancre.
- False–positives VDRL with EBV, collagen vascular disease, TB, subacute bacterial endocarditis

Treatment. Penicillin is the drug of choice for all stages of syphilis. A reaction called Jarisch-Herxheimer can occur in >50% of patients (general malaise, fever, headache, sweating rigors, and temporary exacerbations of the syphilitic lesions 6–12 hours after initial treatment).

- Primary, secondary, and latent syphilis are treated with 2.4 million units of intramuscular benzathine penicillin given once a week. Primary and secondary syphilis receive one week of therapy. Late latent syphilis is treated with 3 weeks of therapy and diagnosed when the VDRL or RPR titers are elevated >1:8 without symptoms.
- Tertiary syphilis is treated with penicillin 10–20 million units/day IV for 10 days.
- Penicillin-allergic patients receive doxycycline for primary and secondary syphilis, but must be desensitized in tertiary syphilis. Pregnant patients must also undergo desensitization.

Chancroid

Definition. An acute, localized, contagious disease characterized by painful genital ulcers and suppuration of the inguinal lymph nodes.

Centers for Disease Control and Prevention

Figure 7-7. Chancroid Lesion

Etiology. *Haemophilus ducreyi* (Gram-negative bacillus).

Clinical Findings. Small, soft, painful papules that become shallow ulcers with ragged edges. They vary in size and coalesce. Inguinal lymph nodes become very tender and enlarged.

Diagnosis. Made on clinical findings; usually Gram stain initially with culture to confirm; PCR testing is useful.

Treatment. Azithromycin single dose or ceftriaxone intramuscularly (single dose). Erythromycin for 7 days or cipro for 3 days are alternatives.

Lymphogranuloma Venereum

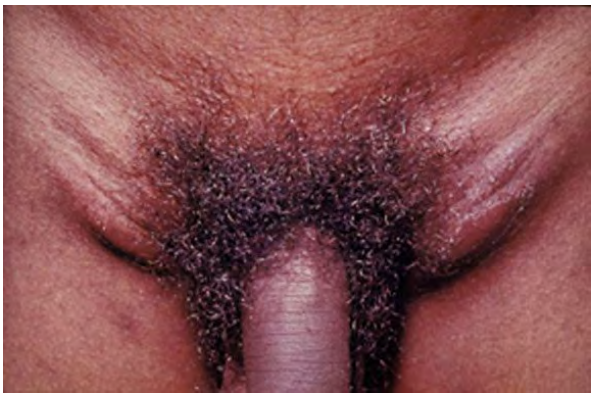
Definition. A contagious, sexually transmitted disease having a transitory primary lesion followed by suppurative lymphangitis.

Etiology. *Chlamydia trachomatis.*

Clinical Findings. A small, transient, nonindurated lesion that ulcerates and heals quickly; unilateral enlargement of inguinal lymph nodes (tender); multiple draining sinuses (buboes) develop (purulent or bloodstained); scar formation occurs, sinuses persist or recur; fever, malaise, joint pains, and headaches are common.

Diagnosis is made by clinical examination, history, and a high or rising titer of complement fixing antibodies. Isolate chlamydia from pus in buboes.

Treatment. Doxycycline (or erythromycin as an alternative).



Wikimedia, Herbert L. Fred, MD, and Hendrik A. van Dijk

Figure 7-8. Lymphogranuloma Venereum

Granuloma Inguinale

Definition. A chronic granulomatous condition, probably spread by sexual contact.

Etiology. Donovania granulomatis, *Calymmatobacterium granulomatis.*

Clinical Findings. A painless, red nodule that develops into an elevated granulomatous mass. In males, usually found on the penis, scrotum, groin, and thighs; in females on the vulva, vagina, and perineum. In homosexual males, the anus and buttocks are common areas. Healing is slow, and there is scar formation. Looks like condyloma lata or carcinoma.

Diagnosis

- Clinically and by performing a Giemsa or Wright stain (Donovan bodies) or smear of lesion
- Punch biopsy

Treatment. Doxycycline ceftriaxone or TMP/SMZ. Erythromycin as an alternative.

phil.cdc.gov

Figure 7-9. Lesions of Granuloma Inguinale Due to *Calymmatobacterium Granulomatis* Infection

Genital Herpes

Etiology. Herpes virus, Type II, although Type I can be seen in genital herpes.

Clinical Findings. Vesicles develop on the skin or mucous membranes; they become eroded and painful and present with circular ulcers with a red areola. Itching and soreness usually precede them. The ulcers are scarring; there can be inguinal lymphadenopathy. Lesions are commonly seen in the penis in males and on the labia, clitoris, perineum, vagina, and cervix in females.

Diagnosis. Tzanck test and culture.

Treatment. Oral acyclovir, famciclovir, or valacyclovir. Must explain to the patient the relapsing nature of the disease. Those with frequent recurrence should be given **chronic suppressive therapy**.

Clinical Pearl

Transmission of genital herpes commonly occurs during an asymptomatic phase, when a person who is shedding the virus inoculates virus onto a mucosal surface of the sexual partner.

Genital Warts

Definition. Also known as condylomata acuminata or venereal warts.

Etiology. Papilloma virus.

Clinical Findings. Genital warts commonly found on warm, moist surfaces in the genital areas. They appear as soft, moist, minute, pink, or red swellings that grow rapidly and become pedunculated. Their cauliflower appearance makes them unique in appearance.

Note

Refer to the discussion of mulluscom contagiosum in Dermatology chapter.

Diagnosis. Clinical appearance. Differentiation must be made between flat warts and condylomata lata of secondary syphilis.

Treatment

- Destruction (curettage, sclerotherapy, trichloroacetic acid)
- Cryotherapy
- Podophyllin
- Imiquimod (an immune stimulant)
- Laser removal

URINARY TRACT INFECTIONS

Cystitis

A 32-year-old woman is in your office because of dysuria. For the last several days, she has burning on urination with increased frequency and urgency to urinate.

Definition. Infection of the urinary bladder.

Epidemiology

- Very common; 6 million office visits per year in the United States
- Majority in women

Etiology

- Roughly the same as for pyelonephritis
- Any cause of urinary stasis or any foreign body predisposes
- Tumors/stones/strictures/prostatic hypertrophy/neurogenic bladder
- Sexual intercourse in women ("honeymoon cystitis")
- Catheters are a major cause, and the risk is directly related to the length of catheterization (3–5% per day).
- Microbiology: *E. coli* in >80%; second are other coliforms (Gram-negative bacilli) such as *Proteus*, *Klebsiella*, *Enterobacter*, etc.; enterococci occasionally, and *Staph. saprophyticus* in young women.

Presentation

- Dysuria, frequency, urgency, and suprapubic pain are common.
- Hematuria, low-grade fever; foul-smelling and cloudy urine are less common.
- On exam, suprapubic tenderness but no flank tenderness.

Diagnosis

- Best initial test is the urinalysis looking for WBCs, RBCs, protein, and bacteria; WBCs is the most important.
- Nitrites are indicative of Gram-negative infection.
- A count of <5 WBCs is normal.

- Urine culture with >100,000 colonies of bacteria per mL of urine confirmatory but not always necessary with characteristic symptoms and a positive urinalysis.

Treatment

- For uncomplicated cystitis, 3 days of trimethoprim/sulfamethoxazole, nitrofurantoin, or any quinolone is adequate.
- Seven days of therapy for cystitis in diabetes
- Quinolones should not be used in pregnancy.
- Fosfomycin is a single-dose oral therapy for cystitis only

Acute Bacterial Pyelonephritis

Definition. An acute patchy, most often unilateral, pyogenic infection of the kidney.

Etiology

- Infection usually occurs by ascension after entering the urethral meatus.
- Predisposing factors: obstruction due to strictures, tumors, calculi, prostatic hypertrophy, or neurogenic bladder, vesicoureteral reflux
- More common in women, in childhood, during pregnancy, or after urethral catheterization or instrumentation
- *E. coli* is the most common pathogen; others include: *Klebsiella*, *Proteus*, and *Enterococcus*. Patients who are immunosuppressed and subjected to indwelling catheters are more prone to *Candida.*

Pathology. Polymorphonuclear neutrophils, leukocytes (in interstitial tissue and lumina of tubules).

Clinical Findings. Chills, fever, flank pain, nausea, vomiting, costovertebral angle tenderness, increased frequency in urination, and dysuria.

Diagnosis. Dysuria, flank pain and confirmation with:

- Clean-catch urine for urinalysis, culture, and sensitivity
- >100,000 bacteria/mL of urine in the majority of cases.

Routine imaging is not required. However, if the patient does not improve in 48–72 hours or complications are suspected (obstruction, renal, or perinephric abscess), U/S or CT scan can be done.

Treatment. Antibiotics for 10–14 days (fluoroquinolone), or ampicillin and gentamicin, or a third-generation cephalosporin are all acceptable. Essentially, any of the antibiotics for Gram-negative bacilli are effective.

Most patients can be treated as outpatients, though pregnant women who appear very ill and those unable to tolerate oral medication due to nausea or vomiting should initially be hospitalized. Because of increasing resistance to TMP/SMZ, which has approached almost 20% in some parts of the United States, this agent is no longer recommended for empiric therapy until culture results and antibiotic sensitivity results are available.

Perinephric Abscess

Definition. A collection of infected material surrounding the kidney and generally contained within the surrounding Gerota fascia. Very uncommon.

Etiology. Although any factor predisposing to pyelonephritis is contributory, stones are the most important and are present in 20–60%. Other structural abnormalities, recent surgery, trauma, and diabetes are also important.

Pathophysiology

- Arises from contiguous pyelonephritis that has formed a renal abscess
- Rupture occurs through the cortex into the perinephric space
- Microbiology: *1*) The same coliforms as in cystitis and pyelonephritis; *2*) *E. coli* most common, then *Klebsiella*, *Proteus*; *3*) *Staph. aureus* sometimes accounts for hematogenous cases

Signs and Symptoms

- Often insidious; 2–3 weeks of symptoms prior to first physician visit
- Fever is the most common symptom
- Flank pain/palpable abdominal mass/abdominal pain
- Persistence of pyelonephritis-like symptoms despite treatment for pyelonephritis

Diagnosis. Urinalysis (normal 30%) and urine culture (normal 40%) are the best initial tests. Fever and pyuria with a negative urine culture or a polymicrobial urine culture are suggestive.

- Imaging is essential; U/S is the best initial scan but CT or MRI scan offers better imaging.
- Aspiration of the abscess is necessary for definitive bacteriologic diagnosis.

Treatment

- Antibiotics for Gram-negative rods
- Third-generation cephalosporins, antipseudomonal penicillin, or ticarcillin/clavulanate, often in combination with an aminoglycoside, for example
- Antibiotics alone are unlikely to be successful. Drainage (usually percutaneous) is necessary.

BONE AND JOINT INFECTIONS

Osteomyelitis

A 59-year-old man was admitted last night because of a painful leg for 2 weeks. Over the last 4 days, he developed an ulcer over the proximal portion of his tibia just below the knee. He has a history of peripheral vascular disease and diabetes. He is afebrile. He has a sinus tract in the center of the red, inflamed ulcer that is draining purulent material.

Definition. Infection of any portion of the bone including marrow, cortex, and periosteum.

Etiology. There are 3 types:

- **Acute hematogenous:** Occurs mostly in children in the long bones of the lower extremities and is secondary to a single organism 95% of the time. The most common organism is *Staphylococcus aureus.* The most commonly involved bones are the tibia and femur, and the location is usually metaphyseal due to the anatomy of the blood vessels and endothelial lining at the metaphysis. In adults, hematogenous osteomyelitis accounts for about 20% of all cases and the most common site is the vertebral bodies (lumbar vertebrae are most frequently involved). The infection can extend posteriorly to form an epidural abscess. A patient with this diagnosis would present with fever and back tenderness.
- **Secondary to contiguous infection:** Can occur in anyone with recent trauma to an area or placement of a prosthetic joint. Although this is secondary to a single organism most of the time, a higher percentage is polymicrobial in origin. *S. aureus* is the most common organism.
- **Vascular insufficiency:** Majority are age >50, with diabetes or peripheral vascular disease, resulting in repeated minor trauma, which is not noticed because of neuropathy and decreased sensation. It is most common in small bones of the lower extremities. The majority is polymicrobial, but the single most common organism is still *S. aureus.*

Presentation. Pain, erythema, swelling, and tenderness over the infected bone. With vascular insufficiency, there is often an obvious overlying or nearby ulceration or wound. Occasionally, a draining sinus tract is present.

Diagnosis. The earliest tests to detect osteomyelitis are the technetium bone scan and the MRI. Both have equal sensitivity for early pick-up, but the MRI can allow better differentiation between the overlying soft-tissue infection and bone. The MRI can be less readily available, however.

- **Plain x-ray:** Usually the initial test because it is more easily obtained, easily read, and inexpensive. Periosteal elevation is the first abnormality visible. The disadvantage is that 50–75% of bone calcification must be lost before the bone itself appears abnormal, which usually takes at least two weeks to develop.
- **Erythrocyte sedimentation rate (ESR):** Nonspecific. It is useful to follow during treatment. A normal value strongly points away from osteomyelitis.
- **Bone biopsy and culture:** This is the best diagnostic test but also the most invasive.
- **CT scan, indium, and gallium:** All 3 can be abnormal in osteomyelitis, but none are as specific or sensitive as the tests listed above.

Treatment. Acute hematogenous osteomyelitis in children can usually be treated with antibiotics alone; however, osteomyelitis in adults requires a combination of surgical (wound drainage and debridement, removal of infected hardware) and antibiotic therapy. Antibiotic therapy depends on the specific isolate obtained, which must be as precise as possible because empiric treatment for 6–12 weeks would be undesirable. A semisynthetic penicillin (oxacillin, nafcillin) or vancomycin (if MRSA is suspected) plus an aminoglycoside or a third-generation cephalosporin would be adequate until a specific diagnosis is obtained. Chronic osteomyelitis must be treated for as long as 12 weeks of antibiotic therapy, and in some cases, even longer periods of antibiotics may be required. The other MRSA drugs are daptomycin, linezolid, ceftaroline, and tigecycline.

Note

Injection drug use is a significant risk factor for vertebral osteomyelitis in adults.

Septic Arthritis

A 73-year-old woman was admitted to your service today with a swollen right knee for the last several days. The knee has an obvious effusion and decreased mobility. There is also redness and tenderness of the knee.

Definition. Infection of a joint due to virtually any agent. The most common etiology is bacterial; specifically, *Neisseria gonorrhoeae*, staphylococci or streptococci, but *Rickettsia*, viruses, spirochetes, etc., may also cause it. Generally, bacterial arthritis is divided into gonococcal and nongonococcal types.

Etiology

Pathogenesis. Sexual activity is the only significant risk factor for gonococcal septic arthritis. A total of 1–5% of people with gonorrhea will develop disseminated disease, and 25% will have a history of recent symptomatic gonorrhea. Nongonococcal bacterial arthritis is usually spread by the hematogenous route. Additional routes may include bites (animal or human), direct inoculation of bacteria into the joint through surgery or trauma, or spread of infection from surrounding structures such as bone. Even though both normal or damaged joints can get infected, any previous damage to a joint, such as from rheumatoid arthritis or osteoarthritis, previous surgery, prothesis placement, gout, sickle cell disease, or the presence of certain risk factors such as IV drug abuse, diabetes mellitus, or HIV infection can predispose a joint to infection. Any cause of bacteremia can seed the joint because the synovium does not have a basement membrane.

Microbiology. Nongonococcal:

- Gram-positive (>85); (*S. aureus* [60%], *Streptococcus* [15%], *Pneumococcus* [5%])
- Gram-negative (10–15%)
- Polymicrobial (5%)

Presentation

Nongonococcal. Monoarticular in >85%, with a swollen, tender, erythematous joint with a decreased range of motion. Knee is the most common. Skin manifestations are rare.

Gonococcal. Polyarticular in 50%; a tenosynovitis is much more common. Effusions are less common. Migratory polyarthralgia are common. Skin manifestations with petechiae or purpura are common.

Diagnosis

Nongonococcal. Culture of joint aspirate fluid is positive in 90–95% and Gram stain is positive in 40–70%. The cell count of the synovial fluid is high (>50,000) and is predominantly PMNs with a low glucose. Blood culture is positive in 50%.

Gonococcal. Much harder to culture. Only 50% of joint aspirates have positive synovial fluid culture; <10% of blood cultures are positive. Other sites such as cervix, pharynx, rectum, and urethra may also be positive. In the aggregate, culture of the other sites has a greater yield than culturing the joint itself.

Treatment. Bacterial arthritis is usually treated by a combination of joint aspiration and antimicrobial therapy.

Nongonococcal. In the absence of a specific organism seen on a stain or obtained from culture, good empiric coverage is nafcillin or oxacillin (or vancomycin) combined with an aminoglycoside or a third-generation cephalosporin. Combine an antistaphylococcal/antistreptococcal drug with a Gram-negative drug.

Gonococcal. Ceftriaxone is the drug of choice.

Gas Gangrene (Clostridial Myonecrosis)

Definition. The necrotizing destruction of muscle by gas-producing organisms, associated with signs of sepsis.

Epidemiology. Gas gangrene is uncommon; a large referral center may admit 10 cases per year; there are 1,000–3,000 cases per year in the United States, though incidence markedly increases during times of war.

Etiology. Gas gangrene is largely due (80%) to the spread of infection from wounds contaminated by *Clostridium perfringens* (the toxins produced by clostridia play a significant role in tissue damage). It is strongly associated with traumatic injury (50%), shrapnel in war, and motor vehicles in peacetime. The trauma may be as minor as an intramuscular injection; however, the wound must be deep, necrotic, and without exit to the surface. Postoperative (30%), nontraumatic (20%). Uterine gangrene was formerly a major complication of improper abortion.

Signs and symptoms. Symptoms usually begin <1–4 days of incubation after the wound and include pain, swelling, and edema at the site of the wound. Later hypotension, tachycardia, and fever can occur. Crepitation over the site and renal failure are late developments, usually prior to death.

Diagnosis. A Gram stain of the wound shows Gram-positive rods, but no white cells. A culture may be positive for *C. perfringens* as early as 1 day; however, this is not necessarily diagnostic because up to 30% of wounds can be colonized by *Clostridia*. Gas bubbles on x-ray are suggestive but may be caused by streptococci as well. Direct visualization (usually at surgery) of pale, dead muscle with a brownish, sweet-smelling discharge is ultimately diagnostic.

Treatment. High-dose penicillin (24 million/day) or clindamycin (if penicillin allergic) is necessary, but surgical debridement or amputation is the absolute center of treatment. Hyperbaric oxygen is of possible benefit, but this is still controversial.

CARDITIS

Infective Endocarditis

A 40-year-old man is brought to the hospital because of fever. He has a history of IV drug use. On physical examination, there is a systolic murmur at the lower left sternal border.

Definition. Colonization of heart valves with microbial organisms causing friable infected vegetations and valve injury. Bacterial endocarditis produces large vegetations and may affect any value in the heart, although left-sided lesions of the aortic and mitral valves are more common.

Epidemiology and etiology. There are several important invasive and other predisposing factors to bacterial endocarditis:

- Dental procedures that cause bleeding
- Oral and upper respiratory tract surgery
- Genitourinary surgery
- Prosthetic heart valves
- Catheters in the right heart
- Pressure-monitoring catheters
- IV drug use

Table 7-4. Relative Risk of Various Predisposing Conditions for Infective Endocarditis

High Risk	Intermediate Risk	Low/Negligible Risk
Prosthetic valves*	Mitral valve prolapse with regurgitation	Mitral prolapse without regurgitation
Aortic valve disease	Mitral stenosis	Atrial septal defect
Mitral regurgitation	Tricuspid valve disease	Luetic aortitis
Patent ductus arteriosus	Hypertrophic obstructive cardiomyopathy	Transvenous pacemakers
Arteriovenous fistula	Calcific aortic sclerosis Tetralogy of Fallot	Surgically corrected congenital lesions (no prosthesis) >6 mo after surgery
Coarctation of the aorta Indwelling right heart catheters (hyperalimentation)	Indwelling right heart and pulmonary artery catheters	Aortocoronary bypass surgery Cardiac pacemakers
Previous infective endocarditis	Nonvalvular intracardiac prosthesis	—
Marfan syndrome	—	—

*Indication for endocarditis prophylaxis.

Table 7-5. Microorganisms Responsible for Infective Endocarditis

Organism	Incidence, %
Native valves	
Streptococcus viridans	50–60
Enterococci	5–15
Other streptococci:	15–20
Staphylococcus aureus	20–30
Staphylococcus epidermidis	1–3
Gram-negative bacilli	<5
Fungi (*Candida, Aspergillus, Histoplasma*)	<3
Culture negative	<5
In narcotic addicts	
Staphylococcus aureus	60–95
Staphylococcus epidermidis	5–10
Streptococci	10–20
Enterococci	8–10
Gram-negative bacilli	4–8
Fungi	4–5
Diphtheroids	1–2
Prosthetic valves	Acutely: first 2 months after surgery
Staphylococcus epidermidis	40–50 acutely; 10–20 later
Streptococcus viridans	5–20 acutely; 40–60 later
Staphylococcus aureus	15–20 acutely; 20–30 later
Enterococci	5–10
Other streptococci	1–5
Culture negative	<5

Pathogenesis. Acute infective endocarditis is caused by bacteremia.

- *S. aureus* is the most common cause of *acute* endocarditis
- Seed previously *normal* valves, producing necrotizing, ulcerative, invasive infection
- Produces large, bulky vegetations (2 mm to 2 cm) on the atrial side
- IV drug use a major risk factor
- Rapid onset with fever and sometimes sepsis
- Splenomegaly
- Associated with invasion of myocardium (abscess cavities) and rapid valve destruction
- Embolic complications, particularly to the lungs with right-sided lesions

With subacute infective endocarditis, viridans group streptococci is the most common organism and is associated with low virulence.

- Seed previously *abnormal* valves
- Produce smaller vegetations composed of fibrin, platelets, debris, and bacteria
- *Risk factors: 1*) Ventricular septal defect with shunt, *2*) stenosis of any valve, *3*) prosthetic valves, *4*) indwelling catheters, *5*) bicuspid aortic valve, *6*) mitral valve prolapse, and *7*) Marfan syndrome
- *Clinical course: 1*) Slow onset with vague symptoms; *2*) malaise, low-grade fever, weight loss, flulike symptoms; *3*) destruction of valves is also present; and *4*) less fatal than acute, with 5-year survival 80–90% with treatment

Clinical manifestations

Table 7-6. Incidence of Clinical Findings in Infective Endocarditis

Symptoms, %	Signs, %
Chills, 41	Heart murmur or changing murmur, 80–90
Weakness, 38	Fever, 90
Dyspnea, 36	Embolic events, 50
Sweats, 24	Skin manifestations, 50
Anorexia, weight loss, 24	Splenomegaly, 28
Malaise, 24	Septic complications, 19
Cough, 24	Mycotic aneurysms, 18
Skin lesions, 21	Glomerulonephritis, 10
Stroke, 18	Digital clubbing, 12
Nausea, vomiting, 17	Retinal lesions, 5
Chest pain, 16	

Table 7-7. Peripheral Manifestations of Infective Endocarditis

Physical Findings (Frequency)	Pathogenesis	Most Common Organisms
Petechiae (20–30%): red, nonblanching lesions in crops on conjunctivae, buccal mucosa, palate, extremities	Vasculitis or emboli	*Streptococcus, Staphylococcus*
Splinter hemorrhages (15%): linear, red-brown streaks most suggestive of IE when proximal in nailbeds	Vasculitis or emboli	*Staphylococcus, Streptococcus*
Osler's nodes (5–10%): 2–5 mm painful nodules on pads of fingers or toes	Vasculitis	*Streptococcus*
Janeway lesions (10–15%): macular, red, or hemorrhagic, painless patches on palms or soles	Emboli	*Staphylococcus*
Roth's spots (<5%): oval, pale, retinal lesions surrounded by hemorrhage	Vasculitis	*Streptococcus*

Complications of infective endocarditis are as follows:

- CHF (most common cause of death)
- Septic embolization (related to infarctions and metastatic infections): brain ("mycotic" aneurysm); spleen (greater with subacute); kidneys; coronary arteries
- Glomerulonephritis with nephrotic syndrome or renal failure (immune complex)

Diagnosis. The major criteria for the diagnosis of endocarditis are a combination of positive blood cultures and an abnormal echocardiogram. The sensitivity of transthoracic echo is <60%, but its specificity is excellent. Transesophageal echo is >90% sensitive and >95% specific.

If 1 of the major criteria is absent, a combination of 1 major and 3 minor criteria will constitute a diagnosis. The minor criteria are:

- Fever
- Predisposing cardiac lesion
- IV drug use
- Vascular phenomena (arterial embolic, septic pulmonary infarcts, Janeway lesions), immunologic phenomena (such as Osler nodes, Roth spots, glomerulonephritis, or a positive rheumatoid factor)
- Microbiologic evidence (positive blood cultures not meeting major criteria or evidence of active infection with an organism consistent with infective endocarditis)

Treatment. Treatment decisions for infective endocarditis should be based on the identification of the specific organism found in blood culture and its specific antimicrobial sensitivities. Prior to the results of blood cultures, therapy can be started if the patient is very ill or there is very clear evidence of endocarditis such as fever, a clearly new or changing murmur, and embolic phenomena. Acceptable empiric therapy would be a combination of an antistaphylococcal drug such as nafcillin (or oxacillin), a streptococcal drug such as penicillin (or ampicillin), and gentamicin. You *must* alter therapy as soon as a specific microbiologic agent is known. Vancomycin and gentamicin are the standard empiric treatment of infective endocarditis.

Table 7-8. Therapy of Specific Microorganisms Causing Endocarditis

Organism	Medication	Duration
Strep. viridans	Penicillin	4 weeks
	Penicillin-allergic: ceftriaxone *or* vancomycin	4 weeks
	Penicillin or ceftriaxone + 2 weeks of gentamicin	4 weeks
***Staph. aureus*, native valve** (Methicillin-sensitive)	Nafcillin (+ 5 days of gentamicin)	4–6 weeks
	Penicillin-allergic: cefazolin *or* vancomycin + gentamicin for first 5 days	4–6 weeks
(Methicillin-resistant)	Vancomycin	4–6 weeks
Enterococcal	Penicillin (or ampicillin) *and* gentamicin (vancomycin if penicillin-allergic)	4–6 weeks
	Penicillin-allergic or resistant: vancomycin *and* gentamicin	4–6 weeks

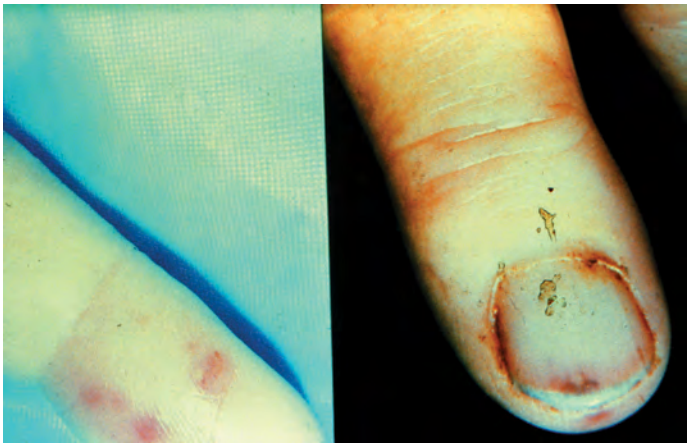
Criteria for Surgery in Infective Endocarditis

Major criteria

- CHF, progressive or unresponsive to "simple" measures
- Recurrent systemic emboli
- Persistent bacteremia despite adequate antibiotic therapy
- Fungal etiology
- Extravalvular infection (atrioventricular block, purulent pericarditis)
- Prosthetic valve dehiscence or obstruction
- Recurrence of infection despite adequate therapy

Minor criteria

- CHF, resolved with medical therapy
- Single systemic embolic event
- Large aortic or mitral vegetations on echocardiography
- Premature mitral valve closure in acute aortic insufficiency
- Prosthetic valve infection due to organisms other than highly penicillin-sensitive streptococci
- Tricuspid endocarditis due to Gram-negative bacilli
- Persistent fever without other identifiable cause
- New regurgitation in an aortic prosthesis



Gold Standard Multimedia Inc., 2007

phil.cdc.gov

Figure 7-11. Petechial Hemorrhage, an Embolic Phenomenon Due to Septicemia/Endocarditis

Prevention of bacterial endocarditis

The number of cardiac lesions which are an indication for endocarditis prophylaxis has markedly diminished over the years. AS, MS, AR, and MR **no longer** need prophylaxis, even for dental procedures. Prophylactics are indicated when there is both a serious underlying cardiac defect and a procedure causing bacteremia.

- **Dental procedures:** amoxicillin; for penicillin-allergic patients, use clindamycin, azithromycin, clarithromycin, or cephalexin
- **Urinary or GI procedures:** no longer require prophylaxis

Cardiac Conditions Which Do Require Prophylactic Therapy

- Prosthetic cardiac valves, including bioprosthetic and homograft valves
- Previous bacterial endocarditis, even in the absence of heart disease
- Most congenital cardiac malformations, especially cyanotic lesions (negligible risk with isolated ASD) if **not** repaired

Conditions Which Do Not Require Prophylactic Therapy

- Surgically corrected systemic pulmonary shunts and conduits
- Rheumatic and other acquired valvular dysfunction, even after valvular surgery
- Hypertrophic cardiomyopathy
- Mitral valve prolapse with valvular regurgitation
- Surgically repaired intracardiac defects

Dental or Surgical Procedures Which Predispose to Endocarditis

- Dental procedures known to induce gingival or mucosal bleeding, including professional cleaning
- Tonsillectomy and/or adenoidectomy

Procedures in Which Indication for Prophylaxis Is Unclear

- Surgical operations that involve intestinal or respiratory mucosa

Anatomic Defects or Conditions Which Require Prophylaxis

- Prosthetic valves
- Unrepaired cyanotic heart disease
- Previous endocarditis
- Transplant status

LYME DISEASE

A couple comes to your office after a recent camping trip. The woman has sustained a tick bite but did not develop any symptoms. The man has developed a red skin lesion that resolved and was followed by the onset of facial palsy. He does not recall having sustained a tick bite.

Definition/Etiology. Lyme disease is spread by the bite of the *Ixodes scapularis* (dammini) tick. On the basis of animal studies we know that the tick needs at least 24 hours of attachment to transmit the *Borrelia burgdorferi* organism. The tick is small, and the bite is often not remembered.

Clinical presentation. Symptoms begin 3–30 days after the bite of the tick. Eighty percent of patients develop the erythema migrans rash at the site of the bite. (An erythematous patch, which may enlarge in the first few days, may have partial central clearing, giving it a "bull's-eye" appearance, although this is not commonly seen.) Even without treatment, the rash resolves in several weeks. A flulike illness with fever, chills, and myalgias occurs in half of patients.

Neurologic symptoms develop several weeks later in 10–20% of patients. This is most commonly paralysis of the seventh cranial nerve (facial paralysis) and may be bilateral. Meningitis, encephalitis, headache, and memory disturbance may develop as well. Cardiac symptoms develop in <10% of patients and is most commonly AV heart block. Myocarditis, pericarditis, and various forms of arrhythmias may develop as well. Joint involvement may develop months to years later in up to 60% of patients, most commonly as a migratory polyarthritis, although a small percentage can have chronic monoarticular arthritis, most commonly affecting the knee.

Diagnosis. Definite diagnostic criteria for Lyme are the development of the erythema migrans rash combined with the presence of at least one late manifestation, as well as laboratory confirmation of the presence of the organism. Most patients are treated on the basis of the presence of the rash alone. Serologic testing is the most commonly used test. An ELISA test combined with a western blot is the standard method of establishing the diagnosis. The problem with the serologic test is that it often does not distinguish between current and previous infection. Also, in early disease when patients have the rash, testing is often negative because patients have not had sufficient time to mount an immune response. In such circumstances, treatment should be given based on strong clinical suspicion, and serologic testing should not be done. Serology will almost always be positive later in the course of the disease.

Treatment. Minor symptoms are treated with doxycycline or amoxicillin. The rash, facial palsy, and joint pain can be treated with oral doxycycline. More serious manifestations such as heart block, meningitis, myocarditis, or encephalitis are treated with IV ceftriaxone. In other words, all cardiac and serious neurologic manifestations should be treated with IV ceftriaxone.

Centers for Disease Control and Prevention,
James Gathany

Figure 7-12. Erythema-Migrans – Lyme Disease

ROCKY MOUNTAIN SPOTTED FEVER

Etiology. *R. rickettsii* is transmitted by the wood tick. Mid-Atlantic coast, upper South, and Midwest are the most common areas.

Clinical Findings

- More common in spring and summer
- Triad: abrupt onset of fever, headache, and rash (erythematous maculopapules). This disease starts at wrist and ankles and spreads centripetally (can involve palms and soles).
- Differential diagnosis with syphilis

Signs and Symptoms. Confusion, lethargy, dizziness, irritability, stiff neck, and GI symptoms. Rash starts before day 6.

Diagnosis. Specific serology: Biopsy of skin lesion

Treatment. Doxycycline

phil.cdc.gov

Figure 7-13. Rash of Rocky Mountain Spotted Fever on an Infant

ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS)

AIDS is caused by the human immunodeficiency virus (HIV). The primary mechanism of HIV is infection of a particular subset of T lymphocytes called CD4 cells, often just referred to as T cells. Over time, HIV decreases the number of CD4 cells. As a person's CD4 count drops, he becomes at increasing risk of developing opportunistic infections and certain malignancies.

The mode of HIV acquisition is different in different parts of the world. In the United States, the earlier part of the epidemic was fueled by men who had sex with men (MSM) and injection drug use. Nowadays, the most common risk factors are MSM and heterosexual intercourse. In women, the most common mode is heterosexual transmission. In most developing countries, including Africa, Asia, and Latin America, heterosexual transmission is the primary mode. There is often a 10-year lag between contracting HIV infection and developing the first symptoms. This is because CD4 cells drop at a rate of 50–100/μL/year without therapy. It would take 5–10 years to drop from a normal level of around 700/mm^3 to a CD4 count of 200/mm^3.

Opportunistic Infections in AIDS

Pneumocystis jirovecii (formerly carinii) (CD4 count <200/μL)

Principal Manifestations. pneumonia; dyspnea on exertion; dry cough; fever; chest pain; usually subacute onset and progression.

Principal Diagnostic Test. Bronchoscopy with bronchoalveolar lavage for direct identification of the organism. Chest x-ray reveals bilateral, interstitial infiltrates. Pneumothorax may be present and it is possible to have PCP pneumonia with a normal chest x-ray. Serum LDH is usually moderately elevated.

Treatment and Side Effects

- Trimethoprim-sulfamethoxazole (TMP-SMZ) is the first-line therapy for mild-severe disease and may cause a rash. Alternative therapy for mild-moderate disease is a combination of dapsone and trimethoprim or primaquine and clindamycin or atovaquone or trimetrexate (with leucovorin).
- Pentamidine—pancreatitis, hyperglycemia, hypoglycemia
- Steroids are used as adjunctive therapy for any patient with severe pneumonia. Severe is defined with a Pa_{O_2} of <70 mm Hg or an A-a gradient of >35 mm Hg.

Prophylaxis (in Order of Preference)

- TMP/SMZ orally—this is most effective.
- Dapsone
- Atovaquone
- Aerosolized pentamidine—fails the most
- Prophylaxis of PCP may be discontinued if antiretrovirals raise CD4 count >200/μL for >6 months.

Cytomegalovirus (CD4 <50/μL)

Principal Manifestations

- *Retinitis:* blurry vision, double vision, or *any* visual disturbance in a patient with a very low CD4 count
- *Colitis:* diarrhea (<20% of patients)
- *Esophagitis:* odynophagia, fever, retrosternal chest pain (endoscopy reveals multiple *shallow ulcers in the distal esophagus*)
- *Encephalitis:* altered mental status, cranial nerve deficits

Principal Diagnostic Tests

- Funduscopy for retinitis
- Colonoscopy with biopsy for diarrhea or upper GI endoscopy with biopsy of ulcers

Treatment and Side Effects

- Valganciclovir—an oral prodrug of ganciclovir, achieves levels in the serum comparable to IV ganciclovir. This drug can be used to treat CMV retinitis (along with intravitreal ganciclovir) and GI manifestations of CMV disease. IV ganciclovir is reserved for serious CNS infections and for patients that cannot tolerate oral medications. Foscarnet and cidofovir are used when ganciclovir resistance or failure occurs.
- Ganciclovir—neutropenia *or* foscarnet-renal toxicity
- Cidofovir—renal toxicity

Prophylaxis. Valganciclovir is used for maintenance therapy. Primary prophylaxis is not indicated.

Mycobacterium avium complex (CD4 <50/mL)

Principal Manifestations. A ubiquitous atypical mycobacteria found in the environment; mode of infection is inhalation or ingestion. Fevers, night sweats, bacteremia, wasting, anemia, diarrhea.

Principal Diagnostic Tests

- Blood culture
- Culture of bone marrow, liver, or other body tissue or fluid

Treatment. Clarithromycin *and* ethambutol ± rifabutin.

Prophylaxis

- Azithromycin orally once a week *or* clarithromycin twice a day
- Prophylaxis may be discontinued if antiretrovirals raise the CD4 count >100/μL for several months.

Toxoplasmosis (CD4 <100/μL)

Principal Manifestation. Brain mass lesion: headache, confusion, seizures, and focal neurologic deficits

Principal Diagnostic Tests

- CT or MRI scan of the head showing a "ring" (contrast) enhancing lesion with edema and mass effect. A trial of specific therapy is given for 2 weeks, and the scan is repeated. Shrinkage of the lesions is considered diagnostic.
- Brain biopsy is occasionally necessary if there is no shrinkage of the lesions with treatment for toxoplasmosis.

Treatment. Pyrimethamine and sulfadiazine. Clindamycin can be substituted for sulfadiazine in the sulfa-allergic patient. Leucovorin is given to prevent bone marrow suppression.

Prophylaxis

- TMP/SMZ
- Dapsone

Cryptococcosis (CD4 <100/μL)

Principal Manifestation. Meningitis; patients mostly present with fever, headache, and malaise.

Principal Diagnostic Tests

- Lumbar puncture with initial evaluation by India ink and then specific cryptococcal antigen testing. A lower CSF cell count implies worse disease.
- Serum cryptococcal antigen testing. A high antigen titer, high opening pressure, and low CSF cell count all imply a worse prognosis.

Treatment. Amphotericin intravenously for 10–14 days at least (with flucytosine), followed by fluconazole orally for maintenance and surpressive therapy.

Prophylaxis. Oral fluconazole is not recommended for general use as a prophylaxis. This is because the incidence of cryptococcal meningitis is too low to demonstrate a mortality benefit with its use.

Vaccinations

All HIV-positive persons should receive vaccinations for pneumococcus, influenza, and hepatitis B. If the CD4 level is >200, even varicella vaccine can be given.

Monitoring the Immune System

CD4 count monitoring and viral load testing can be compared to the staging of cancer in terms of assessing prognosis for the patient. They are indispensable for determining appropriate treatment.

CD4 cell count

The CD4 count is the most accurate method for determining what infections or other diseases the patient is at risk for. At the present time the CD4 count provides an assessment of the extent of immunologic damage at the time of diagnosis and is usually the most important factor when deciding the timing of therapy. It is also the strongest predictor of disease progression and survival. Without treatment, CD4 count drops 50–100 cells per year.

The following is an approximate breakdown of when the risk of certain diseases begins to increase.

CD4 Count	
700–1,500/μL:	Normal
200–500/μL:	Oral thrush, Kaposi sarcoma, tuberculosis, Zoster
100–200/μL:	*Pneumocystis carinii* pneumonia, disseminated histoplasmosis and coccidiomycosis
<100/μL:	Toxoplasmosis, *Cryptococcus*, cryptosporidiosis, disseminated herpes simplex
<50/μL:	Cytomegalovirus, *Mycobacterium avium* complex. Progressive, multifocal leukoencephalopathy (PML), CNS lymphoma

In addition to determining the risk of opportunistic infections, the other uses of the CD4 count are to determine:

- When to start prophylactic medications
- When to initiate antiretroviral medications (<500)
- Adequacy of response to antiretroviral medications (though the best test to monitor response to therapy is the HIV-RNA viral load)

Viral load monitoring

Tests now exist to give a numerical value to the quantity of HIV in the blood. Viral load can be compared to glucose level for patients with diabetes. Monitoring of viral load is the best method to monitor adequate response to therapy when the patient is on antiretroviral medications and the goal is undetectable viremia. High viral loads indicate a greater risk of complications of the disease and a worse prognosis. **A high viral load generally indicates that the level of CD4 cells is going to drop more rapidly.**

Other uses of viral load testing are to determine:

- When to initiate antiretroviral medications
- The adequacy of response to antiretroviral medications; usually with current assays, the goal is complete suppression of viremia with <50 to 70 copies of HIV-RNA/mL

Viral sensitivity/resistance monitoring

Viral sensitivity testing is done to determine which antiviral medications will be effective in an individual patient. Sensitivity testing should always be done if a patient is failing a combination of medications and a change in therapy is necessary. It should also be done in any pregnant woman who has not been fully suppressed on the initial combination of medications.

Antiretroviral Therapy

Currently available agents and their major adverse effects

Nucleoside Reverse Transcriptase Inhibitors

- Zidovudine (ZDV or AZT)—Leukopenia, anemia, GI
- Didanosine (DDI)—Pancreatitis, peripheral neuropathy
- Stavudine (D4T)—Peripheral neuropathy
- Lamivudine (3TC)—Nothing additional to placebo
- Emtricitabine—Structurally related to lamivudine; few side effects as for lamivudine
- Tenofovir is a nucleo*tide* analog as compared to the others that are nucleo*side* analogs.
- Abacavir—Most important side effect is a hypersensitivity reaction that usually occurs in the first 6 weeks of therapy. Patients may have a rash, fever, nausea/vomiting, muscle and joint aches, and shortness of breath. In these cases, the drug should be immediately stopped and never restarted because recurrence of hyperactivity symptoms can be rapid and life-threatening.
- Zalcitabine (DDC)—Pancreatitis, peripheral neuropathy, lactic acidosis

Protease Inhibitors. Hyperlipidemia, hyperglycemia, and elevated liver enzymes for all in the group; abnormal fat loss (lipoatrophy) from the face and extremities with redistribution of fat in the back of the neck and abdominal viscera can be seen.

- Nelfinavir—Gastrointestinal
- Indinavir—Nephrolithiasis (4%), hyperbilirubinemia (10%)
- Ritonavir—Severe GI disturbance
- Saquinavir—Gastrointestinal
- Amprenavir
- Lopinavir/Ritonavir combination—Diarrhea
- Atazanavir—Diarrhea, asymptomatic hyperbilirubinemia

Non-Nucleoside Reverse Transcriptase Inhibitors. These drugs are noncompetitive inhibitors of reverse transcriptase.

- Efavirenz—Neurologic; somnolence, confusion
- Nevirapine—Rash, hepatotoxicity
- Delavirdine—Rash
- Rilpivirine

Guidelines for starting therapy

Start therapy once HIV is diagnosed, regardless of CD4 count. Regarding what to start:

- Use 2 nucleosides combined with a protease inhibitor *or*
- Use 2 nucleosides combined with efavirenz
- Emtricitabine, tenofovir, and efavirenz are available as a single pill once a day.

A combination therapy (highly active antiretroviral therapy, HAART) should be used with medications having synergistic activity by acting at different sites of the virus replicative process; hence current guidelines recommend two NRTIs (usually tenofovir/emtricitabine or zidovudine/lamivudine) combined with either a NNRTI (efavirenz preferred) *or* a PI (atazanavir/ritonavir, fosamprenavir/ritonavir, or lopinavir/ritonavir).

Giving **"boosted protease inhibitors"** is the practice of giving most protease inhibitors in combination with a low dose of ritonavir (also a PI). Ritonavir given alone as a PI has modest efficacy and significant drug interactions, but when given in a low dose with other PIs, it decreases their metabolism and enables higher drugs levels of the "boosted" PI over a prolonged period of time. This increases chances of success and also decreases pill burden.

Any regimen that increases the CD4 count and drops the viral load to undetectable amounts or close to undetectable amounts is considered **adequate therapy**. When starting medication, a drop of at least 50% of viral load in the first month is expected to indicate adequate therapy.

Pregnant Patients

Without treatment, approximately 25–30% of children born to HIV-positive mothers will truly be HIV positive. All children at birth will carry the maternal antibody to the virus and will be positive by ELISA testing, but only 25–30% will remain truly infected.

- Pregnant women with serious disease (i.e., low CD4 or high viral load) should be treated fully for their HIV infection. That is, they should get triple antiretroviral therapy as you would in a nonpregnant person.
- C-section is only used routinely in those whose CD4 count and viral load are not controlled with medications (when viral load is >1000 copies/mL of HIV-RNA at the time of delivery).
- Treatment is indicated in *all* pregnant women. Zidovudine (AZT) should be used in combination with 2 other antiretroviral medications. Even when the CD4 is high and viral load is <1000, you should start therapy as soon as you know the patient is pregnant.
- The only known teratogen is efavirenz in animal studies.

Note

Efavirenz is the only antiretroviral medication that is contraindicated in pregnancy.

Breast Feeding

Breast feeding is associated with transmission of virus to the infant. If a pregnant woman is already on antiretrovirals, she should continue on them. She should start immediately regardless of gestational age. If the woman has high CD4 cells and does not need treatment for herself, combination therapy can end after delivery. The majority of women can deliver with a normal vaginal delivery. Avoid efavirenz in pregnancy.

Postexposure Prophylaxis (e.g., Needlestick Injury)

All persons with serious exposure to blood containing body fluids of HIV-positive patients should receive AZT, lamivudine, and nelfinavir or raltegravir or any other fully suppressive 3-drug combination for 4 weeks. Modify the regimen as needed to ensure compliance. The point is to use any fully suppressive combination for at least 4 weeks; we know zidovudine alone will decrease the risk of transmission by 80%. We don't know how much the combination will decrease transmission.

Tetanus

Etiology. A severe infectious complication of wounds caused by the toxin of *Clostridium tetani* (neurotoxin); takes 1–7 days to develop; spore forming, Gram-positive rod.

Clinical Findings. Tonic spasms of voluntary muscles; respiratory arrest; difficulty in swallowing (dysphagia); restlessness; irritability; stiff neck, arms, and legs; headache; lockjaw; flexion of the arms and extension of the lower extremities; and high mortality rate.

Diagnosis. Clinical.

Treatment. Prophylactic.

- Tetanus toxoid (Tdap) boosters every 10 years
- Immediate surgical care, débride wound
- Antitoxin, tetanus immunoglobulin
- Penicillin 10–14 days

Wound Management

Patient	Not Tetanus Prone	Tetanus Prone
	Linear, 1 cm deep cut, without devitalized tissue, without major contaminants, <6 hours old	Blunt/missile, burn, frostbite, 1 cm deep; devitalized tissue present + contaminants (e.g., dirt, saliva); any wound 6 hours old
Not completed primary or vaccination history unknown	Vaccine	Vaccine and TIG*
Completed primary series	Vaccine if >10 years since last booster	Vaccine if >5 years since last booster

*TIG = tetanus immunoglobulin (human)

Aspergillosis

Definition. A fungus that is widespread in the environment; primarily causes pulmonary disease in the immunocompromised.

Etiology

- 90% species known, with *A. fumigatus* the most common
- Ubiquitous in natural decaying organic matter, ceiling tile, and ventilation systems
- Spores can be isolated from air anywhere on earth

Signs and Symptoms

- Various degrees of respiratory tract invasion
- Rarely it can disseminate to any organ but starts in the lung
- Allergic bronchopulmonary-like asthma with cough/fever/wheezing
- Mycetoma—literally a "fungal ball": *1*) Sets up residence in a pre-existing cavity, with hemoptysis as chief complaint; and *2*) it is *not* invasive.

- Invasive pulmonary
- 90% have 2 of these 3 risks: *1*) neutropenia <500, *2*) steroid use, and *3*) cytotoxic drugs (e.g., azathioprine, cyclophosphamide).

Diagnosis. Depends on the type of disease being caused; however, all can have an abnormal chest x-ray and *Aspergillus* in sputum.

- Allergic bronchopulmonary elevation of markers of allergy/asthma, such as eosinophil/IgE levels
- Positive skin testing
- Mycetoma: abnormal sputum culture/serum precipitins/x-ray
- Invasive: Sputum culture not sufficient; biopsy to show invasion necessary. CT scan (or sometimes chest x-ray) will show a "halo" sign, a zone of low attenuation around a nodular lesion; this is often an early finding in invasive pulmonary aspergillosis.

Treatment. Depends on syndrome (really, they are separate diseases).

- Allergic: steroid taper and asthma medications, not antifungals
- Mycetoma: surgical removal
- Invasive: Voriconazole is superior to amphotericin; there are fewer failures seen with it (and caspofungin) as compared with amphotericin. Itraconazole for very mild disease or after initial treatment with amphotericin. Caspofungin is active against *Aspergillus* and may be superior to amphotericin. Caspofungin is an echinocandin. The other echinocandins are micafungin and anidulafungin. Echinocandins have virtually no toxicity.

Note

Voriconazole and caspofungin are used to treat aspergillosis and some other fungal infections.

Nephrology 8

Learning Objectives

- ❑ Outline the approach to investigating kidney problems, fluid and electrolyte disorders, and acid-base disturbances
- ❑ Describe the presentation, diagnosis, and management of acute renal failure, renal tubular acidosis, glomerulonephritis, nephrolithiasis, hereditary cystic disease, and end-stage renal disease
- ❑ List the indication and complications of dialysis and criteria to qualify for renal transplantation
- ❑ Describe the renal causes of hypertension and their management

ACUTE RENAL FAILURE

Acute renal failure (ARF), or better referred to as acute kidney injury (AKI), is defined as a rapid rise in blood urea nitrogen (BUN) or creatinine over a period of several hours to days. There is no precise duration to define it as acute. ARF may, in fact, develop over a period as short as several hours, such as in the case of rhabdomyolysis or contrast-induced renal failure. It can also happen several weeks later, such as from aminoglycoside toxicity or from post-streptococcal glomerulonephritis.

There are several terms for renal failure, which all roughly mean a rise in creatinine and a decrease in renal function or decrease in glomerular filtration rate.

- **Renal insufficiency** means renal failure, but generally not to the point of needing dialysis. **Azotemia** can be used interchangeably with the term renal insufficiency; literally, azotemia means the buildup of azole groups or nitrogen in the blood.
- **Uremia** describes a syndrome of very severe renal failure in which there is the need for dialysis to save life. Uremia, which literally means "urea in the blood," is more severe than azotemia.
- In uremia there is severe acidosis, mental status changes, hyperkalemia, and fluid overload, as well as anemia, hypocalcemia, and possible pericarditis. Patients also develop bleeding diathesis.
- Uremia can be used interchangeably with the phrase **end-stage renal disease**. Both mean such severe renal dysfunction as to be life threatening and both require dialysis.

- Uremia does **not** necessarily mean the same thing as **chronic renal failure**. Although most patients develop uremia only after years of renal insufficiency such as from diabetes or hypertension, it is possible to become uremic in as little as 1–2 weeks with a severe illness such as tumor lysis syndrome or rhabdomyolysis.
- ARF or AKI is also classified as prerenal, postrenal, or intrarenal to determine the site of the defect.
  - **Prerenal** azotemia means decreased perfusion of the kidney.
  - **Postrenal** azotemia means decreased drainage from the kidney or decreased forward flow of urine. In both prerenal and postrenal azotemia, the kidney is not intrinsically defective. If the kidney in prerenal or postrenal azotemia were taken out and transplanted into another person, it would function normally.
  - **Intrarenal** means there is a tubular or glomerular problem, and the kidney itself is defective.

Diagnostic Tests. The BUN becomes abnormally elevated in all forms of renal failure. It can also be falsely elevated even when renal function is normal, in response to an increased protein load in the diet or from GI bleeding. This is also from increased catabolism. The BUN is derived from protein waste products; blood in the gut acts like a big protein meal. This is also from increased catabolism.

The BUN improves after a session of dialysis. The BUN can be falsely low when there is liver disease, malnutrition, or SIADH. The BUN level corresponds to the degree of renal failure; the higher the BUN, the worse the kidney function is.

Creatinine is our main measure of renal function. Creatinine clearance is our closest approximation of glomerular filtration rate (GFR) without the use of more cumbersome testing such as the clearance of inulin. Inulin does not naturally exist in the human body. Creatinine is a metabolic product of skeletal muscle. Creatinine clearance slightly overestimates GFR because there is some tubular secretion of creatinine. Creatinine can be falsely low just because of a decrease in muscle mass. That is why the creatinine clearance is always adjusted for weight. More muscles mean more creatinine. A bodybuilding weight lifter with 100 kg of muscle will naturally have a higher creatinine than a wimpy librarian who weighs 50 kg. The higher creatinine in the bodybuilder does not necessarily mean worse renal function.

Creatinine needs some time to rise. Even if the patient becomes anuric, the creatinine will only rise at a rate of 0.5–1.0 point per day. This rise will be faster if the body muscle mass is greater. Hence, if the patient has a renal injury and the creatinine goes from 1 to 3 over a 2-day period, this is consistent with fully dead or nonfunctioning kidneys.

Prerenal Azotemia

Prerenal azotemia is a form of renal insufficiency caused by diminished perfusion of the kidney on any basis. The kidney itself is normal. If the kidney could receive adequate perfusion, the BUN and creatinine would normalize. The causes of prerenal azotemia include hypovolemia on any basis (dehydration, burns, poor oral intake, diuretic, vomiting, diarrhea, sweating, hemorrhage), hypotension on any basis (septic shock, cardiogenic shock, anaphylactic shock), and third spacing of fluids such as peritonitis, osmotic diuresis, or low aldosterone states such as Addison disease. Addison disease results in intravascular volume depletion. This leads to diminished tissue perfusion.

Decreased perfusion from a decrease in cardiac output also results in prerenal azotemia. Although there may be total body fluid overload with significant edema, all that matters in terms of renal function is how much fluid is still in the vascular space and how much can provide meaningful perfusion of the kidney. With severe CHF, constrictive pericarditis, or coarctation of the aorta, you may experience edema and fluid overload, but the kidney is receiving virtually no perfusion, hence the rising BUN and creatinine. This is the concept of effective arterial volume.

The first clue to the diagnosis of prerenal azotemia is a BUN:creatinine ratio of 20:1. There is also a low urine sodium and low fractional excretion of sodium (FeNa <1%). This is because the kidney perceives the body as being volume-depleted; hence, there will be a vigorous sodium and water reabsorption by the kidney. This results in a very high urine osmolality as well. This is because the kidney attempts to retain all the water it can in the kidney and therefore excretes very concentrated urine. Concentrated urine has a high specific gravity (>1.010) and a high urine osmolality (>500). These laboratory findings are irrespective of the etiology of the prerenal azotemia. In other words, the BUN:creatinine ratio rises to 20:1, urine sodium is low, and the urine osmolality is high no matter what the etiology of the decreased perfusion or hypotension.

Low albumin states also lead to decreased renal perfusion. Nephrotic syndrome and other malabsorptive states lead to a low albumin level. This leads to renal failure.

Renal artery stenosis

Renal artery stenosis results in a high BUN and creatinine with a high BUN:creatinine ratio. Although the systemic blood pressure may be markedly elevated, the result is still a form of prerenal azotemia. There is markedly diminished renal perfusion because of the obstruction in the renal artery. The systemic blood pressure does not matter. All that matters is how much is getting to the kidney. Hence, to the kidney, renal artery stenosis functions like hypotension. This effect is greatly exaggerated with the use of ACE inhibitors, which markedly diminish renal perfusion. This is because of the extremely high aldosterone state in renal artery stenosis.

Hepatorenal syndrome

Hepatorenal syndrome is renal failure based entirely on the presence of hepatic failure. The kidneys are normal. The etiology of the rise in BUN and creatinine is thought to be from an intense vasoconstriction of the afferent arteriole, resulting in decreased renal perfusion. Because the defect is at the afferent arteriole, the laboratory numbers are consistent with prerenal azotemia, i.e., a high BUN:creatinine ratio above 20:1. In addition, those with hepatorenal syndrome have a urine sodium that is low (<10) and a fractional excretion of sodium <1%. It is important to measure the urine sodium off of antibiotics. Intrinsic renal disease should be excluded to make a diagnosis. No improvement in renal failure after 1.5 L of colloid, like albumin, is diagnostic of hepatorenal syndrome.

The treatment of hepatorenal syndrome is to correct the underlying liver disease. Midodrine, an alpha agonist, and octreotide may be beneficial in hepatorenal syndrome. However, the best treatment is liver transplantation.

ACE inhibitor effect on the kidney

ACE inhibitor–induced renal failure is from vasodilation of the efferent arteriole. Angiotensin has a significant vasoconstrictive effect on the efferent arteriole; ACE inhibitors block this. This results in a decrease in GFR that is usually transient. However, in patients who are elderly, diabetic, hypertensive, or who have baseline renal disease such as from myeloma, an ACE inhibitor can result in quite a marked decrease in renal function. Hence, there can be a rise in BUN and creatinine after initiating ACE inhibitors if there is underlying renal insufficiency. Severe decline in renal function may be observed in patients with bilateral renal artery stenosis after initiation of ACE inhibitors.

Despite the ability of ACE inhibitors to potentially worsen renal function, the overall effect on the kidney is diminishing the rate of progression to uremia and renal failure. This beneficial effect is most likely secondary to the decrease in intraglomerular hypertension. ACE inhibitors and angiotensin receptor blockers decrease hypertension inside the glomerulus. ACE inhibitors decrease proteinuria by 35–45%. ACE inhibitors give a brief decrease in GFR in the short term with a long-term beneficial effect on decreasing proteinuria and the rate of progression of renal failure. This is particularly true in patients with diabetes.

Postrenal Azotemia

This is caused by any decrease in the outflow of urine. The precise etiology of the obstruction is not particularly relevant when it comes to the degree of renal failure. All that matters is that there is an obstruction bilaterally to the flow of urine out of the kidney. You cannot get renal failure by the obstruction of only a single kidney if a patient has both kidneys in place. In other words, a large stone in 1 ureter cannot cause renal failure because the creatinine does not rise if there is a loss of only 1 kidney. A small stone or clot in the bladder can obstruct both kidneys and this can cause postrenal azotemia. Other causes of postrenal azotemia are bladder cancer, prostate hypertrophy or cancer, bilateral ureteral disease such as retroperitoneal fibrosis, neurogenic bladder, or any other cause of bilateral obstructive disease. Strictures can cause this problem but only if they are bilateral in location. The complete obstruction of only 1 kidney does not cause renal failure because you only need one-third of 1 kidney in order to live. Creatinine will only begin to rise when you have lost at least 70–80% of renal function. Hence, you lose a greater percentage of renal function as you go from a creatinine of 1 to 2 than you do when going from a creatinine of 2 to 10. Patients usually have a preceding history of obstructive symptoms followed by sudden onset of oliguria or anuria. Neurologic causes such as multiple sclerosis, spinal cord lesions, and neuropathy may lead to poor function of the urinary bladder and obstruction.

Initially, the BUN and creatinine will elevate in a ratio of 20:1 as it does with prerenal azotemia. There will also be a low fractional excretion of sodium (FeNa) and low urine sodium. When the obstruction continues for such a long time that there is permanent damage to the kidney and the kidney tubule cells die, then the BUN:creatinine ratio will lower to closer to 10:1, such as that seen in acute tubular necrosis (ATN). Early diagnosis is, therefore, essential. Complete recovery is possible until 10 to 14 days of obstruction.

ATN is the most common cause of ARF (intrinsic) in hospitalized patients.

The diagnosis of postrenal azotemia is determined by finding a distended bladder on examination, bilateral hydronephrosis on renal sonogram or CT scan, or by finding large volumes of urine in the bladder after passing a Foley urinary catheter. After urinating (voiding), there should be no more than 50 mL of urine left in the bladder. If this post-void residual is markedly elevated, it implies an obstruction to the flow of urine out of the bladder.

The treatment of postrenal azotemia is based on relieving the cause of the obstruction.

Intrarenal: Tubulointerstitial Disease

Acute tubular necrosis

Acute tubular necrosis (ATN) is defined as acute renal failure on the basis of tubular damage as opposed to glomerular damage, or simply decreased perfusion of the kidney or drainage out of the kidney.

- About 85% of acute renal failure is secondary to intrinsic renal disease such as ATN.
- ATN is from either hypoperfusion of the kidney leading to such severe ischemia that there is cellular death or from a toxic injury to the kidney such as aminoglycoside toxicity or from amphotericin. This is from sepsis, or after cardiac or aortic surgeries.
- ATN often occurs from a combination of both toxic and ischemic injury. If tissue ischemia seems similar in concept to what was described above for prerenal azotemia, that is because there is overlap. It is like the difference between myocardial ischemia and a myocardial infarction.
  - If there is modest hypotension or hypovolemia, the BUN and creatinine will rise in a 20:1 ratio consistent with prerenal azotemia. Prerenal azotemia is essentially reversible.
  - If the ischemia becomes more severe, the tubular cells will necrose and slough off into the urine and become visible as granular, muddy brown, or pigmented casts.
- At the point of necrosis, the renal insufficiency can be permanent. In less severe disease and nonoliguric ATN, urinalysis may be relatively normal.

The hypotension causing tubular ischemia can be of any etiology. This can be either from surgery or medical problems. The degree and especially the duration of hypotension are extremely important. The longer the duration of hypotension/hypoperfusion, the greater the chance of ATN. The risk of ATN goes up even further when there is a toxic injury as well as hypotension. In other words, the likelihood of rhabdomyolysis causing renal failure is markedly increased when there is hypoperfusion of the kidney. The same can be said of cisplatin toxicity, tumor lysis syndrome, or injury from hemoglobin toxicity.

Three Phases (Not Seen in All Patients)

- **Prodromal**—This is the time between the acute injury and the onset of renal failure.
- **Oliguric** (<400 mL per 24 hours) or anuric (<100 mL per 24 hours)
- **Postoliguric**—This is a diuretic phase when all the water not previously excreted will now leave the body in a vigorous polyuria.

Diagnosis. The initial clue is a BUN:creatinine ratio close to 10:1. By itself, the BUN:creatinine ratio simply implies the damage is intrarenal, or inside the kidney itself, as opposed to abnormalities of perfusion (prerenal) or drainage (postrenal). Further clues to the diagnosis of ATN are a high urine sodium (>40), high fractional excretion of sodium (>1%), and low urine osmolality (<350). This is because tubular cells are responsible for forming either concentrated or dilute urine. If the tubular cells die from ischemia, then the kidney can neither concentrate nor dilute the urine. Dead cells don't work.

Table 8-1. Diagnosis: How to Confirm the Difference between Prerenal and ATN (Based on Lab Values)

	Prerenal	ATN
Urine osmolarity	>500	<350
Urine Na^+	<20	>40
$FeNa^+$	<1%	>1%
Urine sediment	Scant	Full (brownish pigmented granular casts, epithelial casts)

Note: In ATN, the urine cannot concentrate. In prerenal, you hold on to all free H_2O and Na^+.

Treatment of ATN. There is no specific therapy for ATN to reverse the renal failure. The underlying cause must be corrected. Hydration is often given to make sure there is no prerenal component. Diuretics such as furosemide or mannitol do not reverse the ATN. Hydration can prevent contrast-induced renal failure, but it does not reverse it once it occurs. Another form of ineffective therapy is dopamine at low dose to increase renal perfusion. This is a nice idea, but it does not work. ATN is a combined ischemic/toxic disease. It is like a sunburn for the kidney. Once it occurs, all you can do is support the patient and wait to see if the renal tubular cells can restore themselves. No medical therapy reverses ATN.

If the degree of renal failure is severe and life threatening, then dialysis is used.

Allergic interstitial nephritis

Allergic interstitial nephritis (AIN) accounts for 10–15% of intrinsic renal failure. It can be distinguished from other causes of renal failure by the presence of fever and rash on physical examination and many WBCs, occasionally eosinophils.

Note

Other Meds

- NSAIDS
- Allopurinol
- Proton pump inhibitor

The etiology of AIN is usually from an adverse effect to medications in 70% of cases. The medications most likely to be allergenic in general are the medications most likely to cause AIN. For example, skin rash from an allergic drug reaction can be from penicillins, cephalosporins, sulfa drugs, allopurinol, rifampin, and quinolones.

These are the same medications to cause AIN. In addition, many of these same drugs cause drug-induced hemolysis as well. In other words, 10% of the population is allergic to penicillins or sulfa drugs. This allergic reaction can take the form of a rash, Stevens-Johnson syndrome, hemolysis, or AIN. In the same way, calcium channel blockers rarely cause a rash. Calcium blockers also rarely cause nephritis or hemolysis. Most patients require several weeks of drug exposure before developing renal injury.

It is important to remember that any sulfa drug can cause allergic reactions. Besides antibiotics, other examples of sulfa drugs are diuretics such as thiazides, furosemide, or acetazolamide.

AIN is also caused by infections themselves, such as viruses, bacteria, and fungi. The most common infections to result in AIN are leptospirosis, legionella, CMV, rickettsia, and streptococci. The least common causes of AIN are several autoimmune disorders such as systemic lupus erythematosus (SLE), Sjögren syndrome, sarcoidosis, and cryoglobulins. Cryoglobulins can cause renal failure from membranous glomerulonephritis as well. Eight percent of cases are idiopathic.

Fever is present in 80% of those with AIN. It can be very difficult to determine if the fever is from the underlying illness or from the AIN. Rash is present in 25–50% of patients. Joint pain is common because AIN acts somewhat like serum sickness.

Laboratory abnormalities include eosinophilia, eosinophiluria, hematuria, proteinuria, and an increase in serum IgE levels. Although hematuria is present in 95% of patients, this finding is rather nonspecific. More people with AIN have eosinophils in the urine rather than in the blood. The level of proteinuria is mild and nearly always <2 grams per 24 hours. The best initial test for AIN is a urinalysis (UA) looking for white cells. Remember that the UA cannot distinguish eosinophils from other white cells. The most accurate test for urine eosinophils is a Hansel stain or Wright stain of the urine. Although the single most accurate test for AIN is a kidney biopsy, this is essentially not necessary if you have some of the other findings described above. NSAID-induced injury typically lacks fever, rash, and eosinophilia.

There is no specific therapy necessary for AIN in the majority of patients. AIN resolves spontaneously after stopping the offending agent. If renal failure persists or worsens after stopping the offending agent, you may use a short course of steroids.

Pigments (hemoglobin/myoglobin)

> A 25-year-old man is undergoing a physical examination to become a firefighter. He must carry a 200-pound bag up a flight of stairs followed by push-ups and a walk across a balance beam. He becomes very weak afterward and is brought to the emergency department with painful muscles and dark urine. What is the most important test to do first?

Etiology. Rhabdomyolysis is caused by sudden, severe crush injury; seizures; severe exertion; and sometimes by hypokalemia, hypophosphatemia, or medications such as statins. Massive hemoglobinuria severe enough to cause renal failure is generally only caused by an ABO incompatibility. Both of these disorders result in enough pigment release in the bloodstream to cause nephrotoxicity. The toxicity is because the pigment is directly toxic to the tubular cells as well as from precipitation of the pigment in the tubules. The degree of toxicity is related to the duration of contact of the tubular cells with the hemoglobin or myoglobin. This toxicity is compounded by dehydration. Hence, a person who has run a marathon has both myoglobin release as well as poor kidney perfusion. This is cumulative in the risk of renal failure.

Laboratory Testing. The most important test when there has been a severe crush injury or seizure and the rhabdomyolysis is potentially life threatening is an EKG or potassium level. This implies that you know how a patient with rhabdomyolysis will die. Acidosis and hyperkalemia can lead to an arrhythmia. If there are peaked T-waves on the EKG, you will give calcium chloride or calcium gluconate. The best initial test that is specific for rhabdomyolysis is a UA in which you find a dipstick that is positive for blood but in which no red cells are seen. This is because myoglobin can react with the reagent on the dipstick and come out as if there were red cells present. Hemoglobin will do the same thing. The dipstick of the UA cannot distinguish among hemoglobin, myoglobin, and RBCs. This is because myoglobin has heme in it.

Rhabdomyolysis is confirmed with a markedly elevated serum CPK level. Elevated serum CPK is a biochemical marker of skeletal muscle neurosis. In order for nephrotoxicity to occur, the level must be enormously elevated into the 10,000 to 100,000 range with a normal value generally <500 or less. You will also find metabolic acidosis with a decreased serum bicarbonate, hyperphosphatemia secondary to muscle breakdown, and hypocalcemia secondary to the deposition of calcium in muscles that have been damaged. Severe hyperuricemia may develop because of release of purines from damaged muscles.

Rhabdomyolysis is associated with a very rapidly rising creatinine level. This is because of both the renal failure and massive release of muscle products. Thus, the BUN:creatinine ratio may be low, below 10:1.

Treatment. If there are EKG abnormalities from the hyperkalemia the best initial therapy is calcium chloride or gluconate. In general, therapy consists of hydration and mannitol as a diuretic to decrease the duration of contact between the nephrotoxic hemoglobin or myoglobin and the kidney tubule. Alkalinizing the urine with bicarbonate may help prevent the precipitation of the pigment in the tubule.

Proteins

Bence-Jones proteins, such as in myeloma, also cause tubular damage. Myeloma is most prominently a cause of nephritic syndrome, however, not tubular damage.

> A man with myeloma is being evaluated for an elevated creatinine. His UA shows trace positive for protein, but the 24-hour urine shows 5 grams of protein. What is the etiology of this discrepancy?

Crystals

Oxalate. The most common cause of hyperoxaluria resulting in acute renal failure is from ethylene glycol overdose in a suicidal person who ingests antifreeze. Look for an intoxicated person with a metabolic acidosis with an elevated anion gap who is found to have renal insufficiency. The diagnosis is confirmed by finding oxalate crystals on a UA. Oxalate crystals are shaped like envelopes.

Acute ethylene glycol overdose is treated with fomepizole infusion to prevent the formation of the toxic metabolite of ethylene glycol, which is oxalic acid. Fomepizole is preferred. It is the oxalic acid that causes the renal failure. Dialysis must also be used to then remove the ethylene glycol. Sodium bicarbonate can be given to correct acidosis.

Chronic hyperoxaluria and kidney stones can be caused by Crohn's disease because of fat and calcium malabsorption.

Urate. Acute renal failure from uric acid toxicity occurs in the setting of tumor lysis syndrome. This is why patients with leukemia or lymphoma receive vigorous hydration and allopurinol prior to being given chemotherapy. Allopurinol reduces the production of uric acid by inhibiting conversion of xanthine to hypoxanthine to uric acid. Uric acid stones precipitate in an acidic urine, unlike oxalate crystals, which precipitate in alkaline urine. Allopurinol treatment with alkalinization of urine markedly reduces the risk of uric acid nephropathy. Chronically, gout causes renal impairment through a slower and milder version of the same mechanism. The diagnosis is by finding uric acid crystals in the urine.

Hypercalcemia

Calcium precipitates in the kidney tubule, forming stones. In addition, hypercalcemia can lead to distal RTA and nephrogenic diabetes insipidus. The most common cause of hypercalcemia is primary hyperparathyroidism. If there is no renal damage or decrease in GFR and there are no symptoms, then mild hyperparathyroidism is not treated surgically. If the hyperparathyroidism is associated with evidence of renal impairment, then surgical resection of the glands is performed.

Toxins

The most common toxins to be associated with renal insufficiency and ATN are NSAIDs, aminoglycosides, cephalosporins, contrast agents, amphotericin, chemotherapy such as cisplatin, radiation effect, heavy metals such as lead, mercury, or gold, and cyclosporine. The difference between the basis of allergic interstitial nephritis and direct toxins is that allergic nephritis occurs with the first dose and is associated with fever, rash, joint pain, and eosinophils in both blood and urine.

Direct acting toxins can take several days to weeks to result in enough cumulative toxicity to lead to renal failure and are not associated with eosinophils, fever, joint pains, or rash. There is no specific test to confirm a specific toxin as the etiology of the renal failure. You must exclude the other causes of renal failure and find the toxin in the history. There is no specific therapy to reverse the renal insufficiency of any of the direct acting toxins.

Aminoglycosides. Tobramycin is the least nephrotoxic compared with gentamicin and amikacin. Aminoglycoside toxicity generally takes 5–10 days of administration to result in toxicity. The likelihood of toxicity is associated with trough levels. Renal failure due to aminoglycosides is frequently non-oliguric (K+ levels not elevated). Hypokalemia and hypomagnesemia predispose the patient to aminoglycoside toxicity. The ability of antibiotics to kill bacteria is associated with the peak level, but the likelihood of toxicity is associated with the trough level. This is most likely because a low trough allows time for the renal tubular cells and neural cells of the inner ear to regenerate themselves. Aminoglycosides also exert a bactericidal effect after their level has become low because they enter the bacteria and continue to kill. This ability to exert an effect despite low or absent levels is called *postantibiotic effect*. Hence, aminoglycosides should be given once a day. Once-a-day dosing allows high bactericidal levels with the same efficacy and very low trough levels. The low trough levels reduce toxicity. Aminoglycoside-related nephrotoxicity is estimated to be between 10–20% of all drug-induced nephrotoxicity and is usually reversible.

Amphotericin B. This medication is associated with renal insufficiency as well as distal renal tubular acidosis. It is expected that after several days or weeks of amphotericin use, the patient will develop a high creatinine as well as a decreased magnesium, bicarbonate, and potassium level. These often revert to normal after the medication is stopped. This form of toxicity is from cumulative dosing.

Atheroembolic Disease. Look for a patient who undergoes a vascular catheter procedure such as angioplasty who develops renal failure several days later. Atheroemboli are also associated with eosinophilia, low complement levels, bluish discoloration of the fingers and toes, and livedo reticularis. Although the most accurate test is a skin biopsy to see cholesterol crystals in the skin, this is rarely done. There is no therapy for atheroemboli. High doses of statins have been tried.

Contrast Agents. Radiocontrast material for CT scanning can result in renal failure in as little as 12–24 hours after the use of the agent. This is one of the main ways to distinguish this form of renal failure from aminoglycoside or amphotericin toxicity, which need several days to weeks of cumulative exposure. The rise in creatinine peaks at 3–5 days after the injury. The BUN and creatinine may be up in a 20:1 ratio, such as in prerenal azotemia, because the hypertonicity of the agent provokes an intense vasospasm of the afferent arteriole. The worse the underlying renal parenchyma, the more likely the patient is to have renal failure secondary to contrast material. If you are elderly, diabetic, and hypertensive with myeloma, you are far more likely to experience contrast-induced renal insufficiency.

Other Toxins. Pentamidine is associated with renal failure in addition to its toxicity on the pancreas. Vancomycin, cyclosporine, and lithium can all cause renal failure in a dose-dependent fashion. Indinavir is a protease inhibitor that results in renal failure usually from the drug precipitating out in the kidney tubules. Indinavir stones need contrast to be identified on a spiral CT scan.

Analgesic nephropathy

NSAIDs are a frequent cause of renal failure. NSAIDS cause renal failure by several mechanisms:

- Interstitial nephritis
- Direct toxic effect on the tubules
- Papillary necrosis
- Inhibition of vasodilatory prostaglandins in the afferent arteriole
- Membranous glomerulonephritis

A person without underlying renal insufficiency should not experience a rise in creatinine from the use of NSAIDs. This only occurs in those with significant impairment such as the elderly or those with hypertension or diabetes. NSAIDs can also cause toxicity by a combination of these. More than half the patients have pyuria, which if persistently associated with sterile urine can be an important clue to diagnosis. There is no specific test to confirm that NSAIDs caused the renal failure. You see a rise in BUN and creatinine and a history of the use of NSAIDs. There is no specific therapy.

Papillary necrosis

Acute papillary necrosis occurs in patients with a history of sickle cell disease, diabetes, urinary obstruction, or chronic pyelonephritis. It can be brought on acutely by the ingestion of NSAIDs. The presentation is with the sudden onset of flank pain, hematuria, pyuria, and fever. This can be very similar in presentation to acute pyelonephritis. In a patient with the risks described above, symptoms for papillary necrosis will come on very suddenly. The findings of white and red cells on UA will not distinguish them. However, papillary necrosis will not grow any organisms on culture. The most accurate diagnostic test for papillary necrosis is a CT scan. The CT scan will show "bumpy" contours in the renal pelvis where the papillae have sloughed off. There is no specific therapy for papillary necrosis.

Prevention of contrast-induced renal failure

In those patients with significant underlying renal disease who have an unavoidable radiologic procedure requiring contrast, you must hydrate with 1–2 liters of normal saline over 12 hours before the procedure. Hydration has been shown to decrease the likelihood of contrast-induced renal failure. Bicarbonate and N-acetyl cysteine have also been shown to decrease the risk of renal failure. Ineffective preventive measures are diuretics such as furosemide or mannitol. If the question asks, "Which of the following is most likely to prevent the development of renal failure with contrast?" you should answer hydration.

GLOMERULONEPHRITIS

Glomerulonephritis (GN) is an inflammation of the glomerulus, often on the basis of an autoimmune event, circulating antibodies, or vasculitis. Diabetes and hypertension cause glomerular disease and are certainly the most common causes of nephrotic syndrome and end stage renal disease. Diabetes and hypertension, however, do not have the acute inflammatory stage of glomerulonephritis characterized by hematuria.

All forms of GN can be characterized by edema, hematuria, red cell casts, and hypertension. The red cells develop an abnormal shape as they squeeze through the abnormal glomerulus and are termed "dysmorphic." The edema of GN is found first in areas of low tissue tension, such as the periorbital area or the scrotum. When more severe, edema can be found anywhere. With the salt and water retention leading to edema, you also develop hypertension. GN is also characterized by modest amounts of protein in the urine with the daily total being <2 grams per 24 hours, although by definition nephrotic syndrome does not begin until there are >3.5 grams per 24 hours. The most important distinction between GN and nephrotic syndrome is the degree of proteinuria.

Glomerulonephritis is also characterized by low urine sodium with a fractional excretion of sodium of <1%.

Many, but not all, forms of GN have a characteristic blood test such as ANCA, basement membrane antibodies, ANA, or antistreptolysin. However, the single most important test to diagnose GN is the renal biopsy. Unlike in tubular diseases, the renal biopsy is extremely important in GN because it guides therapy. There are few treatments to reverse a form of ATN based on the specific etiology. In GN, however, there are cytotoxic medications such as cyclophosphamide to use, or other treatments such as mycophenolate for SLE nephritis or plasmapheresis for Goodpasture syndrome. Hence, before we commit a patient to long-term therapy with potentially harmful medications (cyclophosphamide causes hemorrhagic cystitis), we should obtain a precise diagnosis.

Table 8-2. Causes of Glomerulonephritis Disease Spectrum

Vascular Disease	Glomerular Disease
Wegener granulomatosis	Goodpasture syndrome
Churg-Strauss syndrome	Postinfectious glomerulonephritis
Henoch-Schönlein purpura	IgA nephropathy (Berger disease)
Polyarteritis nodosa	SLE
Thrombotic thrombocytopenic purpura (TTP)	Idiopathic rapidly progressive glomerulonephritis
Hemolytic uremic syndrome (HUS)	Alport syndrome
Cryoglobulinemia	Diabetes and hypertension (most common causes)
	Amyloid

Wegener Granulomatosis

Wegener granulomatosis (WG) is characterized by systemic vasculitis that most often involves the kidney, lung, and upper respiratory tract such as the sinuses or middle ear. In a patient with chronic upper and lower respiratory illness, not responding to antibiotics should evoke WG as a possibility. If there is renal disease as well, then WG is the most likely diagnosis. In addition, WG can have involvement of the skin (50%), joints, eyes (50%), and GI tract, as well as neuropathy.

Laboratory abnormalities are elevated ESR, anemia, and leukocytosis. Rheumatoid factor is positive in 50%. These findings are rather nonspecific and could be found in almost any vasculitis or chronic infectious or inflammatory condition. The best initial test that is specific for WG is the anti-proteinase-3 antibody, which is also known as cytoplasmic antineutrophil cytoplasmic antibody, or C-ANCA. The perinuclear pattern, or P-ANCA, is found in a much smaller number. The other name for P-ANCA is antimyeloperoxidase antibody. Complement levels are normal in WG.

The most accurate test for WG is a biopsy of the kidney, nasal septum, or lung looking for granulomas. Sinus biopsy, specifically the nasal septum, is less sensitive and has more false negative results. Treatment is with cyclophosphamide and steroids.

Churg-Strauss Syndrome

Churg-Strauss syndrome (CS) is a vasculitis similar to Wegener granulomatosis and is also characterized by chronic lung involvement, neuropathy, skin lesions, GI, cardiac, and renal involvement. All forms of vasculitis are characterized by fever, weight loss, and a generalized malaise. CS is characterized by a history of asthma, eosinophilia, and other atopic diseases. The characteristic diagnostic tests are the elevated eosinophil count and positive P-ANCA or antimyeloperoxidase. The most accurate test is a lung biopsy showing the granulomas and eosinophils. Treatment is with glucocorticoids and cyclophosphamide.

Goodpasture Syndrome

Goodpasture syndrome (GP) is an idiopathic disorder of renal and lung disease characterized by a unique antibasement membrane antibody. Unlike Wegener or Churg-Strauss, GP does not affect multiple organs or sites in the body besides the lung and the kidney. Hence, the absence of skin or eye findings is a clue to the diagnosis. One-third of patients have no lung involvement and they only present with hematuria and proteinuria. Lung involvement is characterized by hemoptysis, cough, and shortness of breath. There will be hemosiderin-laden macrophages. The macrophages are cells that phagocytose free hemoglobin in the lung where it is metabolized to hemosiderin. The best initial test to confirm the diagnosis is the level of antibasement membrane antibodies to type IV collagen. The single most accurate test is a lung or kidney biopsy. The biopsy shows linear deposits on immunofluorescence. Therapy is with plasmapheresis and steroids. Cyclophosphamide may also help.

Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is a systemic vasculitis of small- and medium-sized arteries that affects virtually every organ in the body with the exception of the lung. In PAN, renal involvement is common and manifests as hypertension, renal insufficiency, and hemorrhage due to microaneurysms. The most accurate diagnostic test is a biopsy, and treatment is with cyclophosphamide and steroids.

Like all vasculitides, PAN is associated with fever, weight loss, and malaise. Like WG and Churg-Strauss, there is involvement of the skin, eyes, muscles, GI tract, heart, kidneys, and neurologic system. Although the liver is involved, there is usually no clinically evident hepatic effect. Hepatitis B is associated with 10–30% of patients. This is especially true in injection drug users. Abdominal pain and joint pain may be prominent. The abdominal pain may mimic mesenteric ischemia, and the pain will occur with eating. In this case, an angiogram of the involved vessels in the GI tract may eliminate the need for a biopsy. The sural nerve is a frequent location for the biopsy. Anemia and an elevated sedimentation rate are present but are too nonspecific to be useful diagnostically. P-ANCA is only present in a minority of patients. Treatment of PAN is with steroids and cyclophosphamide.

IgA Nephropathy (Berger Disease)

Note

Most common glomerulopathy worldwide.

IgA nephropathy presents with mild hematuria that resolves spontaneously in 30% of patients. About 40–50% of patients progress to end stage renal disease. Like HSP, this is a disorder of the deposition of IgA, however, symptoms arise only from the kidney. Hypertension is frequent. This is most likely secondary to abnormally increased salt and water retention by the kidney. Look for an Asian patient under 35 years of age who has had a recent viral illness or pharyngitis who develops hematuria 1–2 days later. This is to distinguish it from poststreptococcal glomerulonephritis, in which the renal involvement occurs 1–2 weeks later or longer. Although this is an IgA deposition disease, blood IgA levels are elevated in only 50% of patients. Complement levels are normal. The diagnosis is based on finding IgA deposited in the kidney on biopsy.

The treatment of IgA nephropathy is difficult. There is no proven effective therapy. Anyone with proteinuria should receive ACE inhibitors or angiotensin receptor blockers (ARB). When the proteinuria is massive, steroids should be tried. The value of fish oil is marginal. You trade fishy breath for a minimal possibility of improvement that is not proven. The presence of proteinuria and hypertension imply a worse course.

Postinfectious Glomerulonephritis

In addition to group A beta hemolytic streptococci (*Streptococcus pyogenes*), numerous other infections can be associated with postinfectious glomerulonephritis. Virtually any infectious agent can cause it, including hepatitis B and C, CMV, and chronic staphylococcal infections such as endocarditis. In the pre-antibiotic era, glomerulonephritis was the most common cause of death in endocarditis. Poststreptococcal glomerulonephritis (PSGN) can occur with either throat or skin infection with *Streptococcus pyogenes*, although rheumatic fever only occurs with the strains that cause pharyngitis. PSGN occurs in about 10–15% of patients with pharyngitis infected with a nephritogenic strain.

The presentation is characterized by smoky, cola, or tea-colored urine. This abnormal urine color is from hematuria, red cell casts, and proteinuria. Periorbital edema and hypertension are common. The best initial test is the antistreptolysin (ASO) test and the antihyaluronic acid (AHT) test. Complement levels, particularly C3, are low. The most accurate test is the renal biopsy showing "humps" on electron microscopy. IgG and C3 will be deposited in the mesangium as subepithelial humps.

Treatment is largely supportive, with management of the fluid overload and hypertension with diuretics. The vast majority of cases resolve spontaneously. This is why a biopsy is rarely needed. Antibiotics should be given to eradicate the organism from the pharynx.

Cryoglobulinemia

Renal disease from cryoglobulinemia is associated with chronic hepatitis C or less commonly B. Besides the renal disease, cryoglobulinemia is associated with joint pain, neuropathy, and purpuric skin lesions. This is similar to other types of vasculitis. There is no GI involvement as there is with Henoch-Schönlein purpura. Cryoglobulinemia is associated with an elevated ESR and low levels of complement and is confirmed with a test for the cryoglobulins. A positive rheumatoid factor is a marker for the disease as well. The main treatment is to manage the underlying chronic hepatitis with interferon and ribavirin. For severe disease, pulse doses of steroids and occasionally plasmapheresis are also used.

Diabetes

The incidence of glomerular involvement in diabetes is directly proportional to the duration of the diabetes. The standard dipstick becomes positive for albumin at a level 150–300 mg per 24 hours of excretion. Microalbuminuria is a level of protein excretion that is abnormal but is <300 mg. If albumin is not present on dipstick all patients with diabetes should be screened for microalbuminuria annually. Annual screening with a serum creatinine level should also be performed. Treatment for albuminuria is with an ACE inhibitor or ARB. The blood pressure goal is also lower in diabetes, and <130/80 is optimal. Although a renal biopsy is the most accurate test for renal involvement in diabetes, it is not routinely performed unless there is the possibility of another disease causing the renal failure.

SLE

SLE is associated with an enormously wide variation in the degree of renal involvement. There may be asymptomatic proteinuria or hematuria, or there may be severe renal disease requiring dialysis. Double-stranded DNA levels go up and complement levels go down as a marker of severity in flare-ups of the disease. The most accurate test is a biopsy. Biopsy is essential with lupus nephritis in order to guide therapy.

Sclerosis: No therapy needed. This is simply scarring of the kidney.

Proliferative disease: Use steroids combined with mycophenolate. Mycophenolate is superior to cyclophosphamide.

Alport Syndrome

Alport syndrome is the combination of glomerular disease with congenital eye and ear abnormalities. There is sensorineural hearing loss.

Idiopathic Rapidly Progressive Glomerulonephritis

RPGN may occur with any of the glomerular diseases described above, in which case it simply refers to a time course of the disease. In addition, there is an idiopathic form associated with crescent formation in the kidney and the presence of ANCA negative. Diagnosis is with renal biopsy, and the treatment is with steroids and cyclophosphamide.

Amyloidosis

There are 2 common types of amyloidosis:

- **AL:** Plasma cell dyscrasia causing deposition of protein derived from immunoglobulin light chains. This may be associated with multiple myeloma.
- **AA:** Amyloid is produced as a proteinaceous material in association with multiple chronic infectious or inflammatory conditions, such as rheumatoid arthritis, inflammatory bowel disease, or myeloma. The amyloid protein builds up in the kidney, causing glomerulonephritis, and in the GI tract, nerves, and muscles. In the heart, amyloid is associated with restrictive cardiomyopathy, rhythm disorders, and heart block. A large tongue (macroglossia) is also characteristic. Neural involvement produces carpal tunnel syndrome. Malabsorption may occur from GI involvement.

The diagnosis of amyloidosis is established by biopsy of an involved organ such as the kidney. Other unique methods of diagnosis are aspirating the abdominal fat pad or taking a sample of the rectum. Congo red testing shows green birefringence. Amyloidosis treatment is very difficult and consists of controlling the underlying disease. Melphalan and prednisone can control protein production.

Nephrotic Syndrome

Nephrotic syndrome is defined as the presence of renal disease sufficient to produce a level of proteinuria >3.5 grams per 24 hours, hyperlipidemia, edema, and a low serum albumin level. Nephrotic syndrome refers to the severity of glomerular disease and does not, by itself, imply one specific etiology. The edema is from increased salt and water retention by the kidney, as well as low oncotic pressure in the serum. Hyperlipidemia is of unclear etiology but is most likely from the loss of the lipoprotein markers or signals on the surface of chylomicrons and LDL that lead to the clearance of these lipids from the bloodstream.

One-third of nephrotic syndrome is associated with systemic diseases such as diabetes, hypertension, or amyloidosis. In addition, patients with any of the diseases associated with glomerulonephritis described above may develop nephrotic syndrome if the severity of disease is bad enough to cause massive proteinuria and low serum albumin levels. Nephrotic syndrome is a descriptor of severity, not a specific etiology. When the glomerular basement membrane loses its negative charges, protein is spilled into the urine.

Nephrotic syndrome is associated with hyperlipiduria, which gives a droplet found on urinalysis that may form the shape of Maltese crosses.

Hypercoagulable states or thrombophilia develops from the urinary loss of natural anticoagulant proteins such as antithrombin, protein C, and protein S. Patients can develop spontaneous arterial or venous thrombosis. There is also iron, copper, and zinc deficiency from the urinary loss of their transport proteins such as transferrin and ceruloplasmin.

Diagnosis. The diagnosis of nephrotic syndrome is based on the presence of a high protein level in the urine, a low protein level in the blood, edema, and hyperlipidemia. The 24-hour urine shows >3.5 grams of protein; however, this test is cumbersome to perform. An easier test with equal accuracy is a single spot urine for albumin and creatinine. When you correct the albumin level in a single spot urine, the ratio that is found is equivalent to the 24-hour urine. In other words, if you find a protein:creatinine ratio of >3.5 on a single urine, this is equal to 3.5 grams of protein on a 24-hour urine. Remember that Bence-Jones protein is not found on the routine urine dipstick, which only detects albumin. You must do a urine immune electrophoresis to detect Bence-Jones protein.

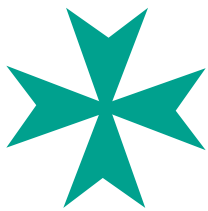

Figure 8-1. Maltese cross

The most accurate test to determine the specific etiology of nephrotic syndrome is a renal biopsy.

Treatment. Treatment of nephrotic syndrome is to control the underlying disease. In addition, steroids are used to treat all forms of idiopathic primary renal causes of nephrotic syndrome, such as membranous, nil lesion, membranoproliferative, mesangial, and focal-segmental disease. If steroids do not work, the next best step in therapy is to add cyclophosphamide or mycophenolate. Azathiaprine is sometimes useful. ACE inhibitors or ARBs are used for all patients with proteinuria, but they do not reverse the underlying disease.

All of the following syndromes are diagnosed as described above and treated with steroids and sometimes cyclophosphamide or mycophenolate.

Focal-Segmental Glomerulosclerosis (FSGS). Associated with the use of heroin as well as HIV. Limited response (only 20–40%) to steroids. May progress to end stage renal disease (ESRD) over 5–10 years. FSGS is the **most common cause of nephrotic syndrome** in adults.

Membranous. Associated with cancer such as lymphoma or breast cancer, and infections such as endocarditis or chronic hepatitis B or C. Other etiologies are lupus, penicillamine, gold salts, and NSAIDs.

Nil Lesion (Minimal Change Disease). Most common form in children, although it may account for 15% of adult disease. NSAIDs have also been associated with nil lesion disease. Light microscopy is normal and electron microscopy is needed to see fusion of foot processes. Nil lesion disease is treated with steroids. Hodgkin's lymphoma has an association with nil lesion disease.

Mesangial. Mostly idiopathic, steroid-resistant type of nephrotic syndrome. Immunofluorescent staining shows IgM deposits in an expanded mesangium.

Membranoproliferative. Associated with chronic hepatitis and low serum complement levels. Dipyridamole and aspirin are also useful therapeutically. Cryoglobulins are treated with interferon and ribavirin, which address the hepatitis.

DIAGNOSTIC TESTING IN RENAL DISEASE

Urinalysis

There is no recommendation for routine testing of the general population by urinalysis. Diabetics or those with systemic diseases such as hypertension are not the general population.

Proteinuria. The urine dipstick detects albumin but no other proteins, such as immunoglobulin light chains. This can be from either glomerular or tubular diseases, although glomerular diseases can give greater amounts. Microalbuminuria is defined as levels 30–300 mg per 24 hours. Mild amounts of proteinuria under 1 gram per day can be seen in up to 10% of the population and most often resolve spontaneously. Proteinuria can also occur from stressors such as fever, CHF, and severe exercise. Proteinuria is also caused by prolonged standing, which is known as orthostatic proteinuria. It is diagnosed by splitting the 24-hour urine sample. If you find no protein in the first 8 hours and then find it in the second part, it is orthostatic proteinuria, which is considered benign.

Hematuria. Red cells can be found in the urine from any cause of disease in the bladder or kidney. Etiologies are stones, cancer, bleeding disorders, trauma to urinary system, and treatment such as cyclophosphamide (which causes hemorrhagic cystitis or glomerular disease). Hematuria is also from infections such as cystitis or prostatitis. The red cells change shape in glomerular disease and can be dysmorphic.

Nitrites. Gram-negative bacteria reduce nitrate to nitrite, which is a marker of infection.

Bacteriuria. By itself, the isolated finding of bacteria in the urine is of very limited significance. The most important exception is in pregnant women, whom you should screen for bacteria and treat. About 30% of pregnant women with bacteriuria progress to pyelonephritis.

Table 8-3. Casts

Casts	Significance
Hyaline	Dehydration. These casts develop as an accumulation of the normal amount of tubular protein. They do not necessarily mean disease.
Red cell	Glomerulonephritis
Broad, waxy	Chronic renal failure
Granular	Also called "dirty" or "muddy." They are associated with acute tubular necrosis and represent accumulated epithelial cells.
White cell	Pyelonephritis, interstitial nephritis

END-STAGE RENAL DISEASE/DIALYSIS

The most common causes of end stage renal disease (ESRD) that require dialysis are diabetes and hypertension. Glomerulonephritis is the etiology of about 15%, with cystic disease and interstitial nephritis causing 4–5% each.

The indications for dialysis are life-threatening abnormalities that cannot be corrected another way, such as fluid overload refractory to diuretics, acidosis, pericarditis, encephalopathy, and other severe neuropathies including myoclonus, wrist or foot drop, and hyperkalemia. Another indication is persistent nausea, vomiting, and bleeding diathesis attributable to uremia.

Hemodialysis is used in 85% of patients and peritoneal dialysis in 15%. The most common complication of peritoneal dialysis is peritonitis.

Other complications of ESRD are as follows.

Anemia. This is from the loss of production of erythropoietin from the kidney. It is treated with replacement of erythropoietin. The anemia of ESRD is normochromic and normocytic.

Hypocalcemia/Hyperphosphatemia. This is from the loss of 1,25-dihydroxyvitamin D production. The hypocalcemia is treated with vitamin D replacement. Hyperphosphatemia is from the inability of the kidney to excrete phosphate. High phosphate levels contribute to low calcium levels by precipitating out in tissues in combination with the calcium. High phosphate levels are treated with phosphate binders, such as calcium carbonate or calcium acetate. Sevelamer and lanthanum are two phosphate binders that do not contain either aluminum

or calcium. They are used when the calcium level is abnormally high because of vitamin D replacement. Cinacalcet is a substance that simulates the effect of calcium on the parathyroid. Cinacalcet is used in severe, refractory cases. Cinacalcet will tell the parathyroid to shut off parathyroid hormone production and helps decrease phosphate in this way.

Aluminum-containing phosphate binders should not be used. Aluminum is associated both with CNS accumulation and dementia as well as bone abnormalities.

Osteodystrophy. This is also known as osteitis fibrosa cystica. Bone abnormalities occur because dead kidneys don't make 1,25 vitamin D. This leads to a low calcium level. The low calcium leads to secondary hyperparathyroidism, which removes calcium from the bones. In addition, bones buffer acidosis by removing calcium from bone. When you want to demineralize a piece of bone in a lab, you soak it in acid; this is what is happening in the body. Renal osteodystrophy is controlled with improving calcium and phosphorous levels and treating the secondary hyperparathyroidism.

Hypermagnesemia. Magnesium accumulates because of decreased renal excretion. Treatment is by restricting magnesium intake.

Hypertension and Accelerated Atherosclerosis. Renal disease results in a rapidly progressive coronary artery disease. The reason for this is not precisely clear, however, this is the most common cause of death for those on dialysis. This is why the goal of blood pressure management is lower at <130/80 for those with renal impairment.

Infection. ESRD patients are at increased risk of infection because neutrophils and other white cells do not work normally in a uremic environment. This is the second most common cause of death in dialysis patients. The most common organism is *Staphylococcus* because of the constant need to penetrate the skin to place someone on dialysis for 4–6 hours 3–4 times a week.

Bleeding. Although nephrotic syndrome gives thrombophilia because of the urinary loss of protein C, protein S, and antithrombin, the most common coagulation problem with ESRD is bleeding. This is because of uremia-induced platelet dysfunction. It gives an increased bleeding time. Uremia-induced bleeding is treated with desmopressin, which releases subendothelial stores of von Willebrand factor and factor VIII, which increase platelet aggregation and adherence. Rarely, estrogen or cryoprecipitate are used.

Dietary Treatment. Patients with severe renal disease should be on a diet restricted in potassium, sodium, protein, magnesium, and phosphate.

Other abnormalities associated with ESRD are pruritus, hyperuricemia, decreased libido from low testosterone levels, weakness, fatigue, and glucose intolerance. Although not life threatening, they do have a significant impact on function. The only way to improve them is with dialysis, although, by themselves, they are not indications for dialysis (the indications for dialysis are hyperkalemia, acidosis, fluid overload, encephalopathy, and pericarditis).

RENAL TRANSPLANTATION

The duration of survival is by far superior with transplantation when compared with maintenance on dialysis.

Table 8-4. Duration of Survival

Live related donor	95% at 1 year, 72% at 5 years
Cadaver donor	88% at 1 year, 58% at 5 years
Dialysis alone	30–40% at 5 years
Diabetics on dialysis	20% at 5 years

The average wait to obtain a kidney for transplantation is 2–4 years and becoming longer because of an insufficient donor supply.

Post-transplantation renal graft rejection is prevented by using cyclosporine, tacrolimus, and mycophenolate. These are all medications that inhibit T-cell function.

FLUID AND ELECTROLYTE DISORDERS

Hyponatremia

Hyponatremia is defined as a low serum sodium concentration with a level <135 mEq. This generally occurs from either increased free water retention or urinary sodium loss. About 85–90% of sodium is extracellular. Serum osmolality is largely a function of the serum sodium level.

$$\text{Serum osmolality} = (2 \times \text{sodium}) + \text{BUN}/2.8 + \text{glucose}/18$$

When the glucose and BUN are normal, this roughly comes out to be 2 × sodium + 10.

Presentation. The symptoms of hyponatremia are predominantly neurologic. They range from mild confusion and forgetfulness to disorientation and obtundation to seizure or coma, depending on the severity of the hyponatremia. The symptoms do not correspond to a specific level of sodium because the symptoms largely depend on how fast the level dropped. An acute 15–20 point drop in sodium level can result in a seizure or coma. If the level drops gradually, the patient can sustain an extremely low sodium level with no symptoms at all. Generally, there should be no symptoms at all unless the level drops below 125.

Treatment. Mild hyponatremia should resolve with fluid restriction. "Mild" refers to the absence of symptoms, not a specific level.

Moderate hyponatremia can be managed with normal saline administration combined with a loop diuretic such as furosemide. The saline gives sodium, and the loop diuretic causes a net free water loss.

Severe and chronic hyponatremia such as that resulting in seizure or coma should be managed with 3% hypertonic saline or the V2 receptor-antagonists conivaptan and tolvaptan. It would be unusual to see severe symptoms with a sodium level >120.

The rate of rise of the sodium level should be monitored so as not to cause central pontine myelinolysis. This is what occurs if the sodium level is corrected too rapidly. Generally, the rate of rise should not exceed 0.5–1 mEq per hour. This means no more than a 12-point rise in a 12–24-hour period. Hyponatremia can be corrected as rapidly as 2 mEq per hour if the patient is seizing and it is extremely urgent. Fludrocortisone is used for cerebral salt wasting disease.

Specific etiologies

Pseudohyponatremia. These are conditions in which the total body sodium level is truly normal and the sodium blood level is artificially low. Treatment is directed at etiology of the lab artifact, not specifically the sodium level.

- Hyperglycemia: The sodium level is decreased by 1.6 mEq/L for every 100 mg/dL increase in glucose above normal. The high glucose load causes a transcellular shift of water out of the cell into the vascular space unaccompanied by sodium. This drops the serum sodium level. Mannitol and sorbitol can do the same.
- Hyperlipidemia: In this case, there is a normal sodium level and this is simply a lab artifact.

Hypervolemic States (Increased ECF). These are all conditions in which there is a decrease in intravascular volume resulting in an increase in ADH secretion from the posterior pituitary. This is a form of appropriate increased ADH syndrome.

- CHF
- Nephrotic syndrome and low albumin states
- Cirrhosis
- Renal insufficiency: When renal failure becomes advanced, the impaired free water excretion will drop the sodium level.

Hypovolemic States (Decreased ECF). For most of these, the hyponatremia develops because of the loss of sodium through body fluids and replacement with free water. For example, sweating is a cause of hypernatremia because sweat is mostly free water and only has a little sodium. However, when you sweat and replace only with free water, the sodium level drops over time.

- GI loss: vomiting, diarrhea, gastric suction
- Skin loss: burns, sweating, cystic fibrosis
- Diuretics: you urinate out a little salt but replace with only free water
- Renal sodium loss: The kidney can lose the ability to reabsorb sodium in the proximal convoluted tubule as the kidney is damaged. Damaged tubules cannot reabsorb sodium.
- Adrenal insufficiency (Addison disease): Aldosterone reabsorbs sodium from the kidney. Without aldosterone, you lose sodium.
- ACE inhibitors: unclear etiology

Table 8-5. Causes of Hypovolemic Hyponatremia

Urine Na <20	Urine Na >20
Dehydration	Diuretics
Vomiting	ACE inhibitors
Diarrhea	Renal salt wasting
Sweating	Addison disease
	Cerebral sodium wasting

Euvolemic States. These patients are neither dehydrated nor volume overloaded. There is no edema, neither is there orthostasis or decreased skin turgor.

- Psychogenic polydipsia: patients must drink at least 15–20 liters a day of fluid to overwhelm the diluting capacity of the kidney
- Hypothyroidism: mechanism unknown
- Diuretics: can be both hypovolemic and euvolemic
- ACE inhibitors: probably through an increase in ADH
- Endurance exercise
- Syndrome of inappropriate secretion of ADH (SIADH)

SIADH

Etiology

- CNS diseases: infections, stroke, tumor, trauma, vasculitis, pain
- Pulmonary diseases: pneumonia, TB, PE, asthma
- Neoplastic disease: lung cancer, as well as cancer of the pancreas, duodenum, or thymus

Medications

- SSRIs
- Tricyclic antidepressants
- Haloperidol
- Cyclophosphamide
- Vincristine
- Carbamazepine
- Thiazide diuretics

The presentation of SIADH is similar to all forms of hyponatremia in terms of neurologic symptoms in proportion to the degree of hyponatremia. The diagnosis is based on finding an elevated urine osmolality and urine sodium level. This is inappropriate to find in a patient with hyponatremia. The range on urine osmolality is 50–1,200 mOsm/L. If urine osmolality is >100 in the presence of hyponatremia, the person most likely has SIADH. The single most accurate test is an elevated ADH level, though it is rarely done and is inferred from the urine osmolarity.

Treatment of SIADH is to restrict fluids for mild disease and give hypertonic saline for severe disease as was previously described. Normal saline with a loop diuretic is also useful to raise the sodium level. For chronic disease in which the underlying cause of the SIADH cannot be corrected, therapy with conivaptan, tolvaptan, or demeclocycline is used. These medications inhibit the effect of ADH on the kidney tubule and lead to water diuresis. Conivaptan and tolvaptan are V2 receptor-antagonists. Demeclocycline and lithium treat SIADH by inducing nephrogenic diabetes insipidus. Lithium, due to toxicity, is rarely used.

Hypernatremia

Etiology

- **Insensible losses:** extrarenal loss without intake of hypotonic fluids; increased skin loss (sweating, burns, fever, exercise) or respiratory infections
- **GI loss:** osmotic diarrhea (e.g., lactulose, malabsorption), some infectious diarrhea
- **Transcellular shift:** rhabdomyolysis or seizures causing muscles to avidly take up water and ↑Na
- **Renal**
  - Nephrogenic diabetes insipidus (NDI), secondary to renal disease, increased calcium, decreased potassium, lithium, demeclocycline, sickle cell disease, and others
  - Central DI (CDI)
  - Idiopathic, trauma, infectious, tumor, granulomatous, hypoxic brain damage or from neurosurgery. Idiopathic most common.
  - Osmotic diuresis: diabetic ketoacidosis (DKA), nonketotic hyperosmolar coma, mannitol, diuretics

Presentation

- Primarily neurologic
- Lethargy, weakness, irritability, seizures, and coma are present with severe hypernatremia of any cause. Diabetes insipidus gives a dilute diuresis of 3–20 L per day.

Diagnosis. Watching for a decrease in urine volume after administering ADH **distinguishes CDI from NDI**.

Treatment. Acute hypernatremia is treated with isotonic fluids intravenously. Correction of sodium should not be >1 mEq every 2 hours or 12 mEq per day. Complications of overly rapid correction include cerebral edema, permanent neurologic damage, or seizures. A rate of correction as fast as 1 mEq per hour is also acceptable if the patient is seizing.

CDI. Correct the underlying cause, if possible.

- Vasopressin (ADH). It can be given subcutaneously, intravenously, intramuscularly, or by nasal spray (all routes except oral).

NDI. Correct underlying cause, if possible.

- Diuretic or NSAIDs. NSAIDs work by inhibiting prostaglandins, which impair concentrating ability. NSAIDs will increase the action of ADH at the kidney.

Hypokalemia

Potassium levels are maintained by transcellular shift and rates of renal excretion. About 95% of potassium is intracellular.

Etiology

- GI losses. This can be from any form of GI loss, such as vomiting, diarrhea, or tube drainage.
- Increased entry into cells (transcellular shift) can be from alkalosis, increased levels of insulin, beta adrenergic activity, and the replacement of vitamin B12 in B12-deficient patients. Trauma patients have increased beta adrenergic activity, that may lead to hypokalemia.

- Urinary losses:
  - Diuretics
  - Increased aldosterone states, such as Conn syndrome, excessive licorice ingestion, Bartter syndrome, or Cushing disease. Aldosterone is the most important regulator of potassium levels in the body. Renal artery stenosis results in a high renin/aldosterone state.
  - Low magnesium levels. Magnesium decreases urinary loss of potassium. When you are deficient in magnesium, you start to spill potassium into the urine.

Presentation. The symptoms of hypokalemia predominantly affect muscles and the heart. Patients have weakness, paralysis when it is severe, arrhythmias that can be fatal, and even rhabdomyolysis. Potassium is necessary for ADH effect on the kidney, and hypokalemic patients present with nephrogenic diabetes insipidus.

Diagnostic testing. In emergency cases, the most important diagnostic test is the EKG. EKG abnormalities include T-wave flattening and U-waves. A U-wave is an extra wave after the T-wave that is indicative of Purkinje fiber repolarization.

Treatment. Correction of underlying cause when possible. Replete as follows:

- IV maximum 10–20 mEq/h; do not use dextrose containing fluids, as they increase insulin release and lower potassium.
- Oral: Gut regulates absorption; there is no maximum rate of oral potassium replacement.
- GI tract slows absorption; no dextrose-containing fluids; dextrose brings increased extracellular potassium entry into cells.
- Potential complication of too-rapid repletion is fatal arrhythmia.

Very large amounts of potassium may be necessary to raise the body potassium level by even 1 or 2 points. The total body requirement is to give 4–5 mEq per kg per point. It is important not to use IV fluids that contain dextrose. Dextrose will provide the shift of potassium into the cells and will further lower potassium levels.

Hyperkalemia

Etiology

- Increased intake (orally or by IV)—usually in presence of impaired excretion
- Movement from cells to extracellular fluid (ECF)
  - Pseudohyperkalemia—secondary hemolysis, mechanical trauma during venipuncture, platelet count >1,000,000 (106), WBC count >100,000 (105)
  - Acidosis—secondary cellular buffering (H+ moves into cells, K+ moves out)
  - For every 0.1-point decrease in the pH, the potassium level will increase by 0.7 points because of the transcellular shift
  - Insulin deficiency
  - Tissue breakdown—rhabdomyolysis, tumor lysis after seizures or severe exercise
  - Periodic paralysis—mild, brief episodes of muscle weakness with mild increase in K+; diagnosis with recurrent attacks and family history

- Decreased urinary excretion
  - Renal failure
  - Hypoaldosteronism: ACE inhibitors, type IV RTA, adrenal enzyme deficiency; heparin inhibits production of aldosterone
  - Primary adrenal insufficiency (Addison disease) or adrenalectomy
  - Potassium-sparing diuretics—amiloride, spironolactone
  - NSAIDs

Presentation

- Muscular weakness can begin usually with K^+ levels >6.5.
- Abnormal cardiac conduction is the most common cause of death, hypoventilation.

Diagnosis. EKG findings: peaked T waves, widened QRS, short QT, or prolonged PR

Treatment

- Calcium chloride—membrane stabilization (most emergent treatment in presence of EKG abnormalities). Effect is immediate and short lived.
- Sodium bicarbonate—alkalosis drives K^+ into cells. Do not give in same IV line as calcium. Forms $CaCO_3$ precipitates.
- Glucose and insulin—drives K^+ intracellular, takes 30–60 minutes to work
- Diuretics, beta agonists
- Cation exchange resin (Kayexalate®)—resin absorbs 1 mEq K^+ per g and releases 1 mEq Na^+. Given with sorbitol to prevent constipation. Kayexalate must be given with the above treatments because they only cause cellular redistribution of K^+ and do not remove it from the body. It can also be given as a retention enema for those who cannot take it orally.
- Dialysis

ACID/BASE DISTURBANCES

Alkalosis (High pH)

Metabolic

For every 1-point increase in the level of serum bicarbonate, there is a 0.7-point increase in the pCO_2. Volume contraction of dehydration results in an increased level of aldosterone, which leads to metabolic alkalosis. Increased levels of aldosterone in volume contraction lead to increased levels of hydrogen ion (H^+) excretion. Increased sodium delivery to the distal tubule leads to increased sodium reabsorption in a segment of the tubule that excretes H^+ and K^+.

H^+ Ion Loss

- Exogenous steroids
- GI loss (vomiting, nasogastric suction)
- Renal loss (Conn syndrome, Cushing, ACTH overproduction, licorice, Bartter syndrome)
- Decreased chloride intake
- Diuretics

HCO_3 Retention

- Bicarbonate administration
- Contraction alkalosis
- Milk-alkali syndrome

H^+ Movement into Cells

- Hypokalemia

Respiratory

Hyperventilation of Any Cause

- Anemia
- Pulmonary embolus
- Sarcoid
- Anxiety
- Pain

Progesterone, catecholamines, hypoxia, cirrhosis, pregnancy, and salicylates are all events or substances that increase the respiratory rate and minute ventilation and lead to respiratory alkalosis.

Anion gap = $(Na^+) - (HCO_3^- + Cl^-)$

(normal: 8–12)

Acidosis (Low pH)

Metabolic

Low Anion Gap

- Myeloma
- Low albumin level
- Lithium

The anion gap is a gauge of the unmeasured anions in the bloodstream. The majority of the unmeasured anions are usually albumin, which has a significant amount of negative charge. In addition to albumin, which is normal, the other anionic substances are lactate, ketoacids, and the metabolic end products of toxic alcohols.

Na^+ and cations = HCO_3^- and Cl^- and anions

Hence, if the sodium and cations remain the same and the anions go up, then HCO_3^- must go down. On the other hand, if the amount of cations goes up, this leads to an increase in the amount of HCO_3^- and Cl^-. This is why there is a decreased anion gap in myeloma. Myeloma proteins are cationic. This leads to an increase in the chloride and bicarbonate levels and therefore a decreased anion gap.

A low albumin level does the same thing. For every 1-point decrease in albumin, there is a 2-point decrease in the anion gap. If albumin, the main unmeasured anion, goes down, then the levels of chloride and bicarbonate increase to assure electrical neutrality.

Lithium, magnesium, and calcium are all divalent cations that decrease the sodium level. If the sodium level drops and everything else remains the same, there will be a decreased anion gap. If sodium is lower, but bicarbonate and chloride stay the same, then the anion gap must decrease.

Normal Anion Gap

- Diarrhea
- Renal tubular acidosis
- Ureterosigmoidostomy

Increased Anion Gap

LA MUD PIE (Mnemonic)

Lactate (sepsis, ischemia, etc.)

Aspirin

Methanol

Uremia

Diabetic ketoacidosis (DKA)—*Beta hydroxybutyric acid (BHB) and acetoacetate, which are formed from fatty acids, are an alternate fuel source because the cells cannot absorb glucose because there is a deficiency of insulin*

Paraldehyde, **P**ropylene glycol

Isopropyl alcohol, **I**NH

Ethylene glycol (antifreeze, low calcium)

Respiratory

Hypoventilation of any cause

- Chronic obstructive pulmonary disease (COPD)
- Pickwickian
- Obesity
- Suffocation
- Opiates
- Sleep apnea
- Kyphoscoliosis
- Myopathies
- Neuropathy
- Effusion
- Aspiration

RENAL TUBULAR ACIDOSIS

Distal (Type I)

Etiology

- Usually sporadic
- Also secondary to autoimmune disease (e.g., Sjögren syndrome, SLE)
- Drugs—amphotericin, lithium, analgesics, iphosphamide
- Nephrocalcinosis, sickle cell, chronic infection
- Familial
- Chronic hepatitis

Presentation

- Inability to develop a high H^+ concentration in urine. Urine pH is >5.3.
- Secondary hyperaldosteronism and hypokalemia
- Nephrocalcinosis and nephrolithiasis

Diagnosis. Acid load test; give ammonium chloride, which should lower urine pH secondary to increased H^+ formation. With type I RTA, the urine pH remains elevated. Serum bicarbonate = 10.

Patients with distal RTA develop hypokalemia because patients lose the ability to secrete hydrogen ions or H^+. Instead of excreting H^+, the kidney will excrete K^+.

Diarrhea: Metabolic acidosis with intact ability to excrete acid. The NH_4Cl level will be high in urine. The urinary anion gap will be negative.

RTA: Kidneys cannot excrete acid in the urine. The urine NH_4Cl level will be low. The urinary anion gap will be positive.

Basically, urine anion gap is a way of distinguishing whether a patient with a normal anion gap metabolic acidosis has diarrhea or distal RTA as the etiology.

Treatment. Oral bicarbonate is the treatment because bicarbonate reabsorption in the proximal tubule still works. Also, potassium replacement; potassium citrate will replace both bicarbonate as well as potassium in distal RTA. Further, citrate is an effective calcium stone antagonist.

Proximal (Type II)

Etiology. Fanconi syndrome, Wilson disease, amyloidosis, myeloma, acetazolamide, vitamin D deficiency, secondary hyperparathyroidism, chronic hypocalcemia, heavy metals, chronic hepatitis, autoimmune diseases such as SLE and Sjögren syndrome.

Presentation

- Inability to absorb bicarbonate. The initial urine pH is basic (until the body loses enough bicarbonate that it is within the range of absorption of the distal tubule), then the urine will become acidic (pH <5.4).
- Also with hypokalemia and a serum bicarbonate of 18–20, as well as proximal tubule leak of glucose, phosphate, urate, amino acids
- Patients with type II get bone lesions (osteomalacia and rickets), whereas type I get kidney stones. Both get hypokalemia.

Diagnosis. Patients are unable to absorb bicarbonate loading (sodium bicarb IV) and have a basic urine in the presence of acidemia. Normal individuals do not excrete bicarbonate in their urine until serum bicarbonate is >24.

Treatment. Give potassium; mild volume depletion will enhance proximal bicarbonate reabsorption (a type of contraction alkalosis). Thiazide diuretics and very large amounts of bicarbonates are used. Bicarbonate is generally ineffective and that is why they must be used in such high amounts. Bicarbonate administration increases renal potassium loss.

Hyporeninemic/Hypoaldosteronism (Type IV)

Etiology

- An aldosterone deficiency of any cause or adrenal insensitivity to angiotensin II, which normally stimulates aldosterone release
- Diabetes (50%)
- Addison disease
- Sickle cell disease
- Renal insufficiency

Presentation

- Usually asymptomatic hyperkalemia
- Mild to moderate renal insufficiency
- Hyperchloremic metabolic acidosis (nonanion gap)

Diagnosis. Presence of high urine sodium with oral salt restriction establishes the diagnosis.

Treatment. Administration of fludrocortisone. Fludrocortisone has a high degree of mineralocorticoid effect and is similar to administering aldosterone. Further, loop diuretics will lower potassium.

NEPHROLITHIASIS

Etiology. Occurs in 1–5% of the population.

- Composition of stones
- Calcium oxalate 70%
- Calcium phosphate 10%
- Mg/aluminum/phosphate (Struvite) 5–10%
- Uric acid 5%
- Cysteine 1%
- Indinavir

Hypercalciuria

- *Increased absorption*
  - Vitamin D intoxication
  - Increased vitamin D with sarcoid and other granulomatous disease
  - Familial
- *Idiopathic renal hypercalciuria*
- *Resorptive*
  - Hyperparathyroidism (10–30% of patients present with stones)
  - Multiple myeloma, metastatic disease to bone, hypercalcemia of malignancy

Hyperoxaluria

- Primary familial
- Enteric

With fat malabsorption, the fat binds to calcium, leaving oxalate to be reabsorbed in increased amounts.

Hypocitraturia

Citrate usually binds with calcium and prevents calcium absorption. Low citrate leads to an increase in calcium absorption. Causes of hypocitraturia include any acidotic condition.

Uric acid stones

They form in an acid environment and are associated with diseases like gout, hematologic malignancies, and Crohn's disease. Radiolucent on x-rays.

Cystinuria

Only associated with the genetic disorder.

Infection

Urinary infection with urease-producing organisms such as *Proteus*, *Staphylococcus*, *Pseudomonas*, and *Klebsiella* give a highly alkaline urine that produces struvite stones.

Presentation

- Constant flank pain (not colicky), hematuria, and pain radiating to groin
- Stones <5 mm should pass spontaneously

Diagnosis

- Plain x-ray (80% yield)—x-ray is rarely used
- U/S—high-yield test and most cost-effective
- Strain the urine
- Check serum and urine calcium
- IV pyelogram—always wrong
- Helical (spiral) CT scan—no contrast needed for stones; contrast is to identify masses, abscesses, and tumors; high-yield test

Treatment. Analgesia, hydration, and bed rest are the mainstays of treatment.

- Shockwave lithotripsy for stones <2 cm. Unfortunately, the fragments may cause obstruction themselves.
- Ureteroscopy
- Percutaneous removal (requires more anesthesia and hospital stay)
- Borderline-sized stones 5–7 mm can be expelled by using nifedipine and tamsulosin.

HEREDITARY CYSTIC DISEASE

Adult Polycystic Kidney Disease

Etiology

- Genetic—prevalence of 1:200 to 1:1,000
- Pathogenesis is uncertain

Presentation

- Flank pain, hematuria (micro and gross), infections, and calculi
- May also present as asymptomatic on screening of family members
- Extra-renal manifestations
  - Hepatic cysts (40–60%)
  - Colonic diverticula
  - Hypertension (50%)
  - Intracranial aneurysm (10–20%)—other vascular aneurysms may be seen
  - Mitral valve prolapse (25%)

Diagnosis. U/S and CT scan.

Treatment. Nonspecific; management of complications (UTI, calculi, and hypertension).

Simple Cysts

They are very common, and if they are smooth-walled with no debris in the cyst, they can be managed without any further treatment or need for diagnostic tests. Cysts with irregular walls or debris inside should be closely followed to exclude malignancy. Dialysis causes cysts.

HYPERTENSION

Essential Hypertension

Definition. The most recent guidelines recommend that hypertension be diagnosed when a person's systolic blood pressure is 140 mm Hg or diastolic blood pressure ≥90 mm Hg (or both) on repeated examination.

Systolic blood pressure is particularly important, and is the basis for diagnosis in most patients. These numbers apply to all adults age >18 years, although for patients age ≥80 a systolic blood

pressure up to 150 mm Hg is now regarded as acceptable. The goal for treatment of hypertension is to reduce blood pressure to levels below the numbers used for making the diagnosis.

Some recent guidelines have recommended diagnostic values of 130/80 mm Hg for patients with **diabetes or chronic kidney disease**. However, the clinical benefits of this lower target **have not been established**, so these patients should be treated to <140/90 mm Hg.

Patients with very severe hypertension, such as those with a blood pressure >160/100 mm Hg, should receive initial therapy with 2 medications, this is because patients with a blood pressure >160 mm Hg will not be successfully controlled with just one medication.

Table 8-6. Guidelines

Normal	BP 120/80 mm Hg
Hypertension	
Stage 1	Systolic 140–159 Diastolic 90–99
Stage 2	Systolic ≥160 Diastolic ≥100

Etiology/Epidemiology. An estimated 50 million Americans have high blood pressure. Essential hypertension accounts for >95% of all cases of hypertension. Despite multiple theories on the mechanism, there is **no clear understanding** of what causes essential hypertension. It is more common with increasing age and is found in half the population over age 60. It is more common in men than women until after menopause. It is more common in the black population at all ages, and the incidence of end organ damage is more common in blacks as well. Onset is usually between ages 25–55.

Presentation. The most common presentation of essential hypertension is an asymptomatic patient on whom the elevation of blood pressure is found during a routine examination or during evaluation for other medical problems.

When symptoms are associated with hypertension, it is more correct to think of them as:

- Acute symptoms associated with a hypertensive emergency, or
- Complications from end-organ damage

With **hypertensive emergency,** signs and symptoms of cardiac, neurologic, renal, and retinal involvement are the most common. These include evidence of stroke, subarachnoid hemorrhage, encephalopathy, myocardial ischemia, and abnormalities on fundoscopic examination. Requires substantial reduction of blood pressure within one hour to avoid serious morbidity or death. These can acutely and most commonly result in headache, dizziness, chest pain, dyspnea, blurred vision, and palpitations. Malignant HTN is defined as encephalopathy or nephropathy with accompanying papilledema as seen on funduscopic examination.

Long-Term Complications

- **Cardiac**—myocardial ischemia or infarction, CHF, left ventricular hypertrophy, aortic aneurysm, and dissection, on physical exam an S4 gallop, accentuated A2 heart sound, and prominent left ventricular impulse can be present
- **Cerebrovascular**—transient ischemic attack (TIA) or stroke

- **Renal proteinuria**—microscopic hematuria, and elevation of BUN/creatinine, which may lead to the necessity of dialysis
- **Retinopathy**—hemorrhages, exudates, arteriolar narrowing, and papilledema; they result in blurred vision, scotomata, and sometimes blindness

Secondary Hypertension. Less than 5% of patients have secondary hypertension. The presentation depends upon the individual cause. For example: renovascular disease gives an abdominal bruit; Cushing disease gives weight gain, moon-like facies, striae, and ecchymoses; pheochromocytoma gives episodic hypertension associated with headache, palpitations, and sweating; primary aldosteronism (Conn syndrome) gives muscular weakness and polyuria/polydipsia from hypokalemia. These are discussed more fully later in the notes.

Diagnosis. As much as 20–25% of mild office hypertension is artifactual in nature. These initial elevated readings merely represent a manifestation of anxiety on the part of the patient to the doctor and medical environment. This is known as "white coat hypertension." In this case, we are talking about patients who have no evidence of end-organ damage. When these patients are given time to adjust to the environment by being allowed to sit quietly before the reading is taken, their pressure will lower. When these patients are given an ambulatory pressure-monitoring device to measure their own pressure at home or work, many of them will normalize their pressure. In addition, with each subsequent visit to the physician's office, the patient's pressure will often lower toward its true value.

Hence, prior to labeling a patient with a mild elevation as truly hypertensive and initiating therapy, the following steps are necessary:

- Allow the patient to sit quietly for 5 minutes before the pressure is measured
- Never label a patient as hypertensive after only a single reading
- Repeat the reading 3–6 times over several months before confirming the diagnosis and initiating therapy

Laboratory Investigation. Most routine lab testing will generally be normal. Testing is usually kept within the bounds of those done during a routine medical evaluation. The purpose is to evaluate the extent of end-organ damage as well as to exclude some forms of secondary hypertension. The reasons listed are the most common ones, not the only ones.

Basic studies include:

- Urinalysis for protein, glucose, and RBCs
- Hematocrit
- Serum potassium to exclude hyperaldosteronism
- Serum creatinine and BUN
- Electrocardiogram to evaluate for left ventricular hypertrophy
- Glucose and plasma lipid analysis as an indicator of atherosclerotic risk

Treatment. Patients with confirmed mild and moderate hypertension should initially be treated with nonpharmacologic modifications in lifestyle. These include weight reduction in the obese, dietary sodium restriction, aerobic exercise, and avoiding excessive alcohol intake. Dietary modifications such as a low-fat diet with increased dietary fiber can also be effective. Relaxation methods have inconsistent effects. DASH eating plan: increase fruits, vegetables, low-fat dairy, and low-fat diet.

Patients with severe hypertension (diastolic >100 mm Hg) should generally be started immediately on drug therapy. Patients with a blood pressure of >160/100 mm Hg should be started on two medications as part of initial therapy. There is a linear correlation of increasing weight with increasing blood pressure. Obesity further increases cardiovascular risk by increasing LDL cholesterol, decreasing HDL, and decreasing glucose tolerance. There is generally a 0.5–1.0 mm Hg drop in systolic and diastolic blood pressure for every kilogram of weight lost.

Drug Treatment

- ***Who to treat?***

  Patients who continue to have a diastolic BP >90 mm Hg despite a 3- to 6-month trial of nonpharmacologic therapy should generally be started on antihypertensive drugs.

  The decrease in end-organ damage, such as myocardial infarction and stroke with drug treatment, is generally greater in those who have a higher baseline BP. In other words, someone who has a diastolic pressure >100 will show a much greater reduction in risk of stroke with drug therapy compared with someone whose diastolic pressure is only 90–95 mm Hg.

- ***What to use?***

  There are almost 50 different medications approved for the initial treatment of hypertension, not including combination medications. The major medications with their individual characteristics are listed at the end of this section.

- General principles:

  In the absence of a specific indication or contraindication, diuretics are still recommended as initial treatment. For stage III HTN, BP >160/100, a two-drug combination should be used—diuretic with an ACE/ARB/CCB or beta blocker.

  The mortality benefit of diuretics has been unsurpassed when compared with other medications. If diuretics do not control the blood pressure, then a second medication should be added. The second medication can be a beta-blocker, calcium-channel blocker, ACE inhibitor, or angiotensin-receptor blocker. Beta blockers should be avoided in those with a history of asthma, COPD, heart block, or depression.

  Every attempt should be made to individualize therapy based on the characteristics of each patient. To do this, you must be familiar with the characteristics of each class of drugs.

- ***What are the indications for specific hypertensive groups?***

  Diabetics: Should be treated with ACE inhibitors or ARBs, which prevent the development of nephropathy. The blood pressure goal in a diabetic is lower, at <130/80 mm Hg; this is also true in those with renal insufficiency, CHF, retinopathy, or stroke. Patients with microalbuminuria should receive an ACE inhibitor.

  Postmyocardial infarction (ischemic heart disease): Should be treated with beta blockers.

  Diminished left-ventricular systolic function (such as with CHF or postmyocardial infarction): Should receive ACE inhibitors and/or beta blockers.

  African-American patients are least effectively treated with ACE inhibitors.

  Pregnant patients are best treated with alpha-methyldopa, labetalol, hydralazine, or calcium-channel blockers. ACE inhibitors and angiotensin-receptor blockers are absolutely contraindicated in pregnant patients. Diuretics are relatively contraindicated.

Note

Malignant HTN

Encephalopathy or nephropathy with accompanying papilledema as seen on funduscopic examination.

Hypertensive Emergencies

Definition. The acute onset of severe hypertension in association with severe and rapidly worsening symptoms of end-organ damage. This usually happens with diastolic pressure >120–130 mm Hg. The terms "malignant" and "accelerated" hypertension are difficult to distinguish clinically, with "malignant" usually referring to the more severe syndrome.

Etiology/Epidemiology. The cause is unknown. Hypertensive emergencies occur in about 1% of hypertensive patients.

Presentation

Neurologic: Encephalopathy, headache, confusion, seizures, and subarachnoid or intracerebral hemorrhage.

Cardiac: Chest pain, myocardial infarction, palpitations, dyspnea, pulmonary edema, jugular venous distension, and gallops.

Nephropathy: Acutely progressive hematuria, proteinuria, and renal dysfunction.

Retinopathy: Papilledema, hemorrhages, and blurred vision.

Diagnosis. The laboratory evaluation is the same as with essential hypertension except that there is no concern of artifactual "white coat hypertension" given the clear symptoms. CT scan of the head may be necessary to exclude hemorrhage. EKG is more important as an initial test to exclude infarction.

Note

Resistant HTN

Failure to reach blood pressure control in those who are adherent to full doses of a 3-drug regimen, which includes a diuretic.

Treatment. IV therapy is indicated. Nitroprusside and labetalol are the two best agents. Nitroglycerin is preferable in those who have evidence of myocardial ischemia. Enalaprilat is an IV ACE inhibitor that is now being used as well. Other less commonly used agents include esmolol, diazoxide, and trimethaphan.

The most important point in management is not to lower the pressure too far (e.g., not <95–100 mm Hg diastolic) so as not to compromise myocardial or cerebral perfusion. The initial goal is to reduce BP by no more than 25% within the first 1 to 2 hours.

Secondary Hypertension

Definition. Hypertension in the presence of an identifiable underlying cause.

Etiology/Epidemiology. <5% of cases of hypertension are secondary to an identifiable underlying cause. Renal artery stenosis is the most common of these causes.

The following groups should be screened for secondary hypertension:

- Those who become hypertensive either very young or very old (age <25 or >55)
- Those with a key feature of history, physical examination, or laboratory abnormality consistent with a particular form as described below
- Patients who remain hypertensive despite increasing dosages and numbers of antihypertensive medications, i.e., those refractory to what should normally be effective therapy

Renal Artery Stenosis. This is due to atherosclerotic disease in elderly persons and fibromuscular dysplasia in young women.

Presentation: The key feature is an upper abdominal bruit radiating laterally, which is present in 50–70% of patients.

Diagnosis: The best initial screening test is the abdominal U/S. The captopril renogram is a test that measures the uptake of a radioisotope before and after the administration of captopril. A positive test is when there is decreased uptake of the isotope (i.e., decreased GFR) after giving the captopril. The captopril renogram is a noninvasive method of confirming the diagnosis of renal artery stenosis. The accuracy is diminished with renal insufficiency. The arteriogram is still the best method of confirming the diagnosis. Duplex Doppler ultrasonography and magnetic resonance angiography are also used to noninvasively detect stenosis. The accuracy of duplex U/S is operator-dependent.

Treatment: The best initial treatment is percutaneous transluminal angioplasty. If stenosis recurs, then the procedure should be repeated. If angioplasty fails, surgical resection is attempted. Medical therapy with ACE inhibitors should be reserved only for those in whom angioplasty or surgery either fails or is not possible. For unilateral disease it is not clear that angioplasty is superior to ACE inhibitors.

Primary Hyperaldosteronism (Conn Syndrome). This is most commonly due to a unilateral adenoma. Adenomas can also be bilateral. The rest of the cases are from bilateral hyperplasia. Cancer is rare as a cause of hyperaldosteronism.

Presentation: The key features are either:

- Hypertension in association with hypokalemia found on routine screening tests *or*
- Symptoms of hypokalemia such as muscular weakness and polyuria and/or polydipsia from a nephrogenic diabetes insipidus

Diagnosis: Elevated aldosterone levels in urine and blood.

Treatment: Surgical resection in those with an adenoma. Potassium-sparing diuretics such as spironolactone in those with hyperplasia.

Pheochromocytoma. Most often due to a benign tumor of the adrenal gland; 10% are bilateral, 10% are malignant, and 10% are extra-adrenal.

Presentation: The key feature is episodic hypertension in association with headaches, sweating, palpitations, and tachycardia. Pallor or flushing may also occur.

Diagnosis: The best initial tests are urinary vanillylmandelic acid (VMA), metanephines, and free urinary catecholamines. Plasma catecholamine evaluation is helpful as well. CT and MRI scanning is used to localize the site of the tumor.

Treatment: Alpha-adrenergic blockade followed by surgical removal.

Cushing Disease. Most often due to ACTH hypersecretion by a pituitary adenoma.

Presentation: The key feature is hypertension in association with characteristic cushingoid manifestations such as truncal obesity, buffalo hump, menstrual abnormalities, striae and impaired healing, etc.

Diagnosis: Dexamethasone suppression testing and 24-hour urine cortisol are the best initial tests.

Treatment: Surgical resection is best when possible.

Coarctation of the Aorta. The key feature is hypertension markedly greater in the upper extremities compared with the lower extremities.

Miscellaneous. Other causes of secondary hypertension are the use of oral contraceptives, acromegaly, congenital adrenal enzyme deficiencies, and virtually any cause of chronic renal disease such as glomerulonephritis, polycystic disease, diabetic nephropathy, or chronic pyelonephritis.

Antihypertensive Medications

Table 8-7. Antihypertensive Medications

Thiazides	Loop Diuretics	Potassium Sparing
Hydrochlorothiazide	Furosemide	Spironolactone
Chlorthalidone	Bumetanide	Amiloride
Metolazone	Torsemide	Triamterene
Indapamide		

Diuretics

Specific Indications. CHF, edematous states, African-American patients; least expensive.

Major Side Effects. Decreases in potassium and magnesium; increases in calcium, uric acid, glucose, LDL-cholesterol; gynecomastia.

Relative Contraindications. Diabetes, gout, hyperlipidemia.

Angiotensin converting enzyme (ACE) inhibitors

Benazepril	Enalaprilat (only IV form)	Moexipril
Captopril	Fosinopril	Quinapril
Enalapril	Lisinopril	Ramipril

Specific Indications

- Diabetics with hypertension to prevent neuropathy; the blood pressure goal in a diabetic patient is <130/80 mm Hg
- CHF as afterload reduction
- Postmyocardial infarction with left ventricular impairment

Major Side Effects. Cough, angioneurotic edema, neutropenia, hyperkalemia, taste disturbances, anaphylactoid reactions.

Relative Contraindications. Less effective in African-American patients.

Absolute Contraindications. Bilateral renal artery stenosis, pregnancy.

Calcium channel blockers

Amlodipine	Nicardipine
Diltiazem	Nifedipine
Felodipine	Verapamil
Isradipine	

Specific Indications. Angina pectoris, supraventricular arrhythmia, migraine, Raynaud phenomenon, esophageal spasm.

Major Side Effects. Peripheral edema, constipation, heart block, reflex tachycardia.

Relative Contraindications. Atrioventricular conduction defects, CHF from systolic dysfunction.

Angiotensin receptor antagonists

Losartan	Valsartan	Irbesartan
Candesartan	Telmisartan	

Specific Indications. Those intolerant to ACE inhibitors (especially because of cough).

Major Side Effects. Few. This is the newest class of antihypertensives.

Absolute Contraindications. Pregnancy.

The remainder of these medications should be considered second- or third-line agents.

Beta blockers

Acebutolol	Bisoprolol	Metoprolol	Pindolol
Atenolol	Labetalol (combined alpha/beta)	Nadolol	Propranolol
Betaxolol		Penbutolol	Timolol

Metoprolol and atenolol are the most commonly used.

Specific Indications

- Myocardial infarction or ischemic heart disease
- Supraventricular arrhythmias
- Migraine headaches, glaucoma, anxiety (resting tachycardia)
- Congestive failure from diastolic dysfunction

Major Side Effects. Bronchospasm, heart block, bradycardia, Raynaud phenomenon, depression, impotence, fatigue, decreased HDL, increased triglycerides, hyperglycemia.

Relative Contraindications. Asthma or COPD, atrioventricular conduction defects, CHF from systolic dysfunction, diabetes because of masking signs of hypoglycemia.

Central-acting sympatholytics

Clonidine	Guanabenz
Guanfacine	Methyldopa

Specific Indications. Clonidine can be useful in opiate detoxification.

Major Side Effects. Depression, fatigue, dry mouth, impotence, bradycardia, heart block, memory loss. Methyldopa gives hepatitis and Coombs-positive hemolytic anemia.

Relative Contraindications. Elderly or depressed patients.

Direct vasodilators

Hydralazine	Minoxidil

Specific Indications

- Hydralazine is used in eclampsia
- Minoxidil is used locally to treat baldness

Major Side Effects

- Minoxidil gives marked fluid retention, pericardial effusion, and hirsutism
- Hydralazine gives a lupus-like syndrome

Relative Contraindications. Angina pectoris.

Alpha-adrenergic blockers

Doxazosin	Prazosin	Terazosin

Specific Indications. Patients with lipid disorders (they reduce LDL and increase HDL), prostatic hypertrophy (to reduce obstructive symptoms).

Major Side Effects. Syncope after the first dose, dizziness, headache.

Relative Contraindications. None.

Practice Questions

1. What acid-base disorders are represented by the following sets of arterial blood tests?

	pH	P_{CO_2}, mm Hg	HCO_3^-, mEq/L
(A)	7.32	28	14
(B)	7.47	20	14
(C)	7.08	49	14
(D)	7.51	49	38

Answers:

(A) Metabolic acidosis (low pH, low HCO_3^- concentration, compensatory reduction in P_{CO_2}).

(B) Respiratory alkalosis (high pH, low P_{CO_2}, compensatory reduction in HCO_3^- concentration). Note that a low HCO_3^- concentration does not necessarily imply a primary metabolic acidosis.

(C) Combined respiratory and metabolic acidosis (low pH, high P_{CO_2}, low HCO_3^- concentration).

(D) Metabolic alkalosis (high pH, high HCO_3^- concentration, compensatory increase in P_{CO_2}).

2. Match the clinical histories with the appropriate arterial blood values.

	pH	P_{CO_2}, mm Hg	HCO_3^-, mEq/L
(A)	7.37	65	37
(B)	7.22	60	26
(C)	7.35	60	32

1. A 60-year-old man with chronic bronchitis develops persistent diarrhea
2. A markedly obese 24-year-old man
3. A 14-year-old girl with a severe acute asthmatic attack
4. A 56-year-old woman with chronic bronchitis is started on diuretic therapy for peripheral edema, resulting in a 3-kg weight loss

Answers:

It is easiest to answer this problem by first determining the acid-base disorders represented by the 3 sets of blood values.

(A) The low pH and high P_{CO_2} indicate respiratory acidosis. In chronic respiratory acidosis, a P_{CO_2} of 65 mm Hg (25 mm Hg greater than normal) should be associated with a plasma HCO_3^- concentration of approximately 33 mEq/L (3.5 mEq/L increase in the plasma HCO_3^- concentration for each 10 mm Hg elevation in the P_{CO_2}). Thus, the HCO_3^- concentration of 37 mEq/L represents a superimposed metabolic alkalosis.

(B) At a P_{CO_2} of 60 mm Hg, the HCO_3^- concentration should be roughly 26 mEq/L in acute respiratory acidosis (1 mEq/L increase per 10 mm Hg elevation in the P_{CO_2}) and 31 mEq/L in chronic respiratory acidosis. Therefore, these values may represent acute respiratory acidosis or metabolic acidosis (lower the HCO_3^- concentration from 31 to 26 mEq/L) superimposed on chronic respiratory acidosis.

(C) Chronic respiratory acidosis or metabolic acidosis (raising the HCO_3^- concentration from 26 to 32 mEq/L) superimposed on acute respiratory acidosis.

From the history:

1. Chronic bronchitis plus diarrhea suggests combined chronic respiratory acidosis and metabolic acidosis, or B.

2. Marked obesity suggests chronic hypercapnia, or C.

3. Severe acute asthma suggests acute respiratory acidosis, or B.

4. Chronic bronchitis plus diuretics suggests chronic hypercapnia with superimposed metabolic alkalosis, or A. The metabolic alkalosis in this case is on the basis of volume contraction from the use of the diuretic.

Pulmonology 9

Learning Objectives

- ❑ Interpret results of pulmonary function testing and chest radiography
- ❑ Diagnose disturbances of gas exchange
- ❑ Describe the presentation and management of obstructive lung disease, atelectasis, interstitial lung disease, and acute respiratory distress syndrome
- ❑ Outline the presentation, diagnosis, and management of sleep apnea
- ❑ List the types of lung cancer and their epidemiologic associations and prognosis
- ❑ Present risk factors, diagnosis, and treatment plan for pulmonary thromboembolism

DIAGNOSTIC TESTS

Pulmonary Function Tests

Pulmonary function tests (PFTs) are non-invasive tests used mainly to do the following:

- Categorize of different types of lung processes (restrictive versus obstructive)
- Assess disease severity (in overall prognosis and preoperative evaluation)
- Evaluate post-treatment lung function

Spirometry can be done in the office setting and allows the determination of most lung volumes and capacities, as well as expiratory flows and bronchodilator response. Complete PFTs are done in the pulmonary lab and allow the measurement of TLC, DLco, and methacholine challenge testing.

PFTs consist of different tests:

- **Static lung compartments** are measured by lung volumes, such as total lung capacity (TLC), residual volume (RV) and vital capacity (VC).
- **Airflow or air movement** is measured by the expiratory flow rate (ratio of forced expiratory volume in 1 second to forced vital capacity [FEV1/FVC] and forced expiratory flow 25–75% of expiration [FEF25–75, also called midmaximal flow rate MMFR]).
- **Alveolar membrane permeability** is measured by the diffusing capacity of a gas (DLco).
- The **methacholine challenge test** is an adjunct test used for evaluating bronchial hyperactivity in asthma patients who have normal PFTs.

Clinical Pearl

Perform PFTs in all patients before they undergo lung resection surgery.

Generally, **<80% of predicted in any lung volume or flow rate is considered abnormal**, while **>120% of predicted is consistent with air trapping.**

Table 9-1. Pulmonary Function Tests

PFT	Normal Range
TLC	80–120% predicted
RV	75–120%
FEV_1/FVC Ratio	80%
DLCO	75–120%
FEV_1	80–120%

Lung volumes

Ventilatory function is measured under static conditions for the determination of lung volumes (*see* Figure 9-1) and thus allows for the diagnosis of restrictive lung disease.

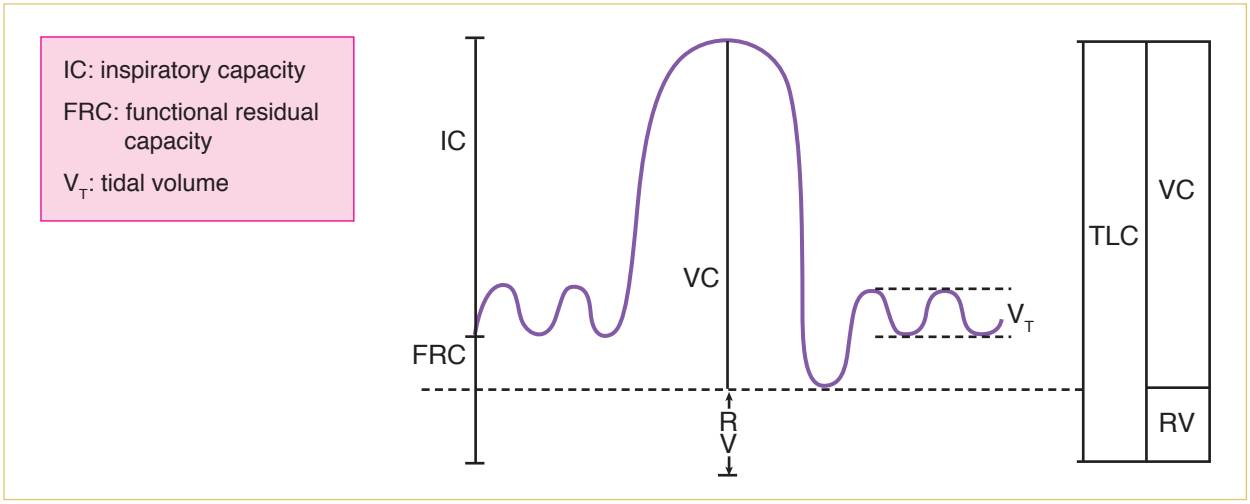

Figure 9-1. Determination of Lung Volumes

Table 9-2. Pulmonary Indices

Index	Description
Total lung capacity (TLC)	Volume of gas in the lungs after maximal inspiration
Residual volume (RV)	Volume of gas remaining in the lungs after forced maximal expiration (unused space)
Vital capacity (VC)	Volume of gas exhaled with maximal forced expiration TLC = RV + VC or VC = TLC – RV

Forced expiratory volumes (FEVs)

Forced expiratory volumes measure air movement in and out of the lungs (airflow measurement under dynamic conditions). FEVs can determine the degree of obstruction by comparing the forced volume expired at 1 second (FEV_1) to the forced vital capacity (FVC). In patients with no obstruction, the ratio is 0.80 (80% of predicted). It is decreased in patients with chronic obstructive disease (emphysema and chronic bronchitis) and asthma.

The FEVs are normal or elevated in patients who have restrictive disease because there is no problem with airflow. Also, asthmatic patients may have a normal FEV_1/FVC because they may have normal airflow (no bronchoconstriction) when asymptomatic.

Forced expiratory flow ($FEF_{25–75}$) is another measurement that can be done during the FEVs and is another way to express airflow. Generally consider the $FEF_{25–75}$ equivalent to the FEV_1/FVC, but the $FEF_{25–75}$ usually detects obstructive disease earlier.

FEVs can be determined during spirometry or full pulmonary function testing.

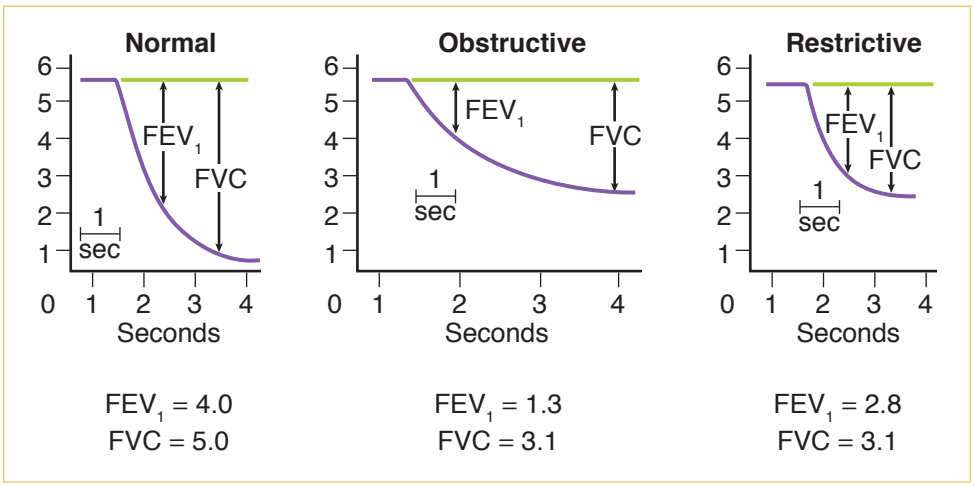

Figure 9-2. Forced Expiratory Volumes

Carbon monoxide diffusing capacity (DLco)

Lung diffusion testing is used to determine how well oxygen passes from the alveolar space of the lungs into the blood. Whereas spirometry measures the mechanical properties of the lungs, the lung diffusing capacity test (DLCO) measures the ability of the lungs to perform gas exchange. The single-breath DLCO test requires the patient to inhale DLCO gas consisting of helium, carbon monoxide, and room air. Generally, diffusing capacity is reduced when alveolar walls are destroyed and pulmonary capillaries are obliterated by emphysema, or when the alveolar-capillary membrane is thickened by edema, consolidation, or fibrosis (as in interstitial lung disease).

PFTs with an obstructive pattern and decreased DLCO should prompt the consideration of emphysema. PFTs with a restrictive pattern and decreased DLCO are likely to be some type of interstitial lung disease (intrapulmonary restriction) or mild left heart failure.

Increased DLCO may be seen in pulmonary hemorrhage, e.g., Goodpasture syndrome.

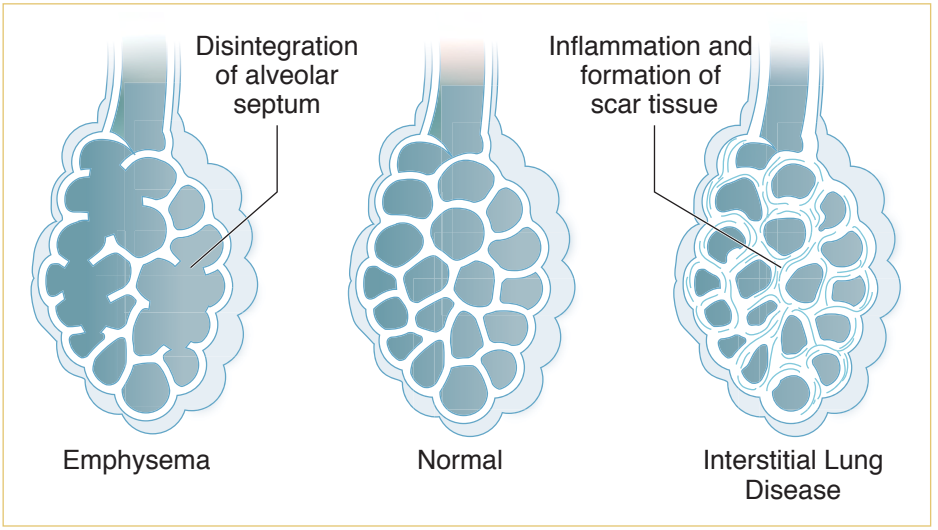

Figure 9-3. Alveolar Diffusing Capacity

Clinical Pearl

Patients with asthma may have normal PFTs. In these patients, methacholine challenge will provoke an asthmatic crisis and allow the diagnosis of asthma to be made by PFTs. Thus, perform methacholine challenge only for patients with normal PFTs and for whom you are considering a diagnosis of asthma.

Methacholine challenge test

Bronchoprovocation with methacholine is done to evaluate patients with cough or wheezing and who have a normal PFT, for possible asthma (bronchial reactivity).

During the test, the patient inhales an aerosol of methacholine. Results of PFTs (e.g., spirometry) performed before and after the inhalations are used to quantitate the response. A positive test is defined as a decrease from the baseline FEV_1 of 20% or more.

Bronchodilator reversibility

Nonreversible obstructive lung disease and reversible obstructive lung disease can be distinguished by giving the patient an inhalation of a beta-agonist (albuterol). Consider asthma as the likely diagnosis when PFTs show evidence of an obstructive pattern, but then reverse by more than 12% and 7,200 mL after using the bronchodilator.

Table 9-3. PFT Questions

PFT Indices	Patient 1	Patient 2
TLC	110%	55%
RV	120%	50%
VC	90%	50%
FEV_1/FVC	80%	90%
$FEF_{25–75}$ (MMFR)	50%	90%
DLCO	Patient 1a: 90% Patient 1b: 40%	Patient 2a: 90% Patient 2b: 40%
What is your diagnosis?		

Note

Diagnoses for Patients 1 and 2 are revealed at the end of this chapter.

Flow Volume Loops

Flow volume loop diagrams also express airflow in different lung diseases and give the relationship between flow rates compared with lung volumes. On the *y*-axis is flow rate and on the *x*-axis is volume. Lung volumes increase to the left on the abscissa. The shape of the loop can characterize the type and distribution of airway obstruction.

When comparing a normal flow volume loop with one of restrictive lung disease, the restrictive lung disease alters the size of the loop (a shift to the right of the *x*-axis), which is related to a reduction in lung volumes.

On the other hand, obstructive lung disease alters the shape of the loop by causing a reduction of airflow (alterations on the *y*-axis).

In the case of a fixed airway-obstruction (tracheal stenosis after prolonged intubation), the flow volume loop is flattened on the top and bottom.

With dynamic extrathoracic airway obstruction (vocal cord paralysis), the obstruction occurs mostly with inspiration while expiration is mostly normal. This effect causes the flow volume loop to be flattened only on bottom.

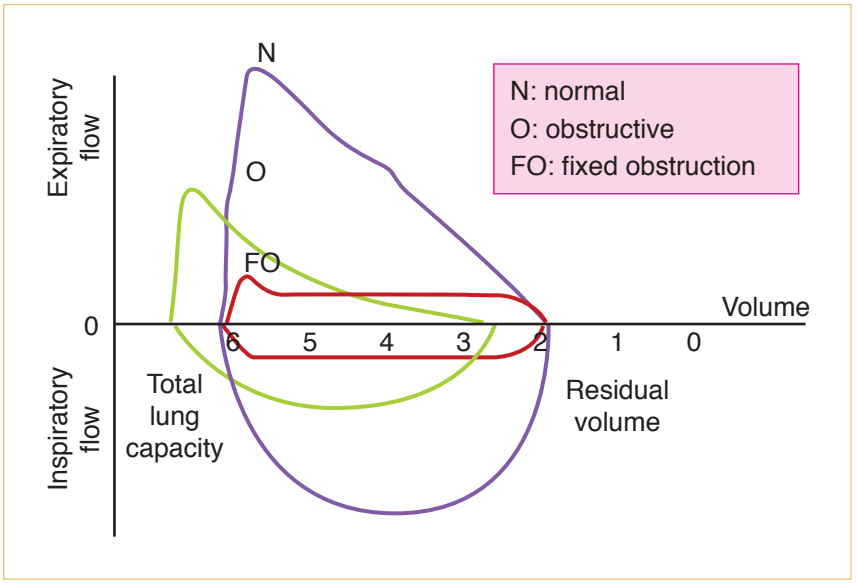

Figure 9-4. Flow Volume Loops

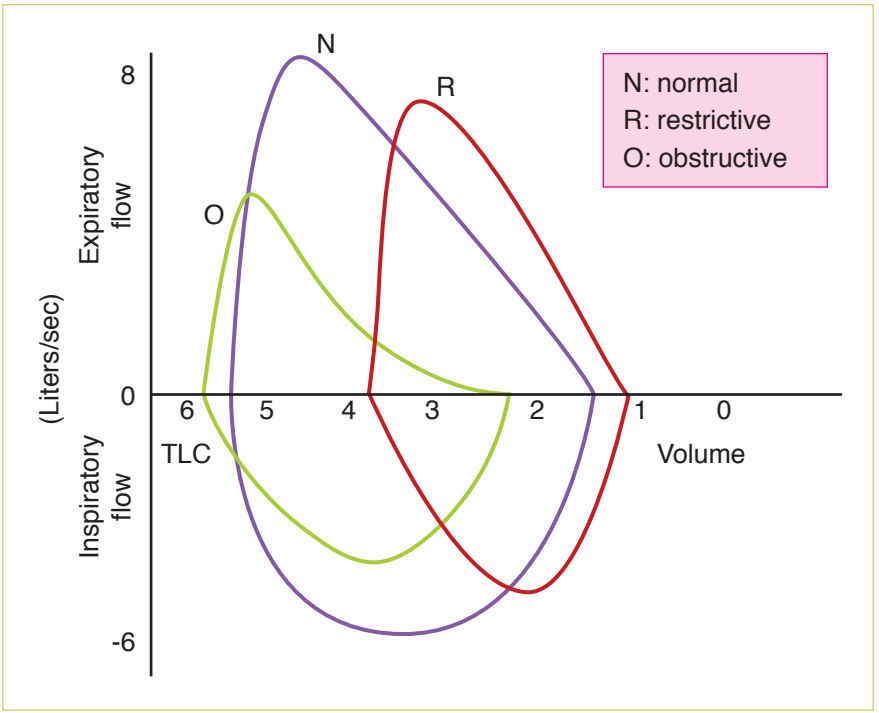

Figure 9-5. Flow Volume Loops

Clinical Pearl

FEO may occur in the setting of a tracheal tumor or foreign object aspiration or tracheal stenosis after prolonged intubation.

DISTURBANCES IN GAS EXCHANGE

The most important factor in gas exchange is **oxygen delivery** (Do_2) to the vital organs. Remember, Do_2 is not Pao_2 (Pao_2 is calculated in the arterial blood gases). We can calculate Do_2 from the following equation:

$$Do_2 = \text{Cardiac Output} \times (1.34 \times Hb \times HbSat) + 0.0031 \times Pao_2$$

where Do_2 represents oxygen delivery, HbSat is hemoglobin saturation, and Pao_2 represents partial pressure of oxygen in the blood (oxygen dissolved in plasma).

Don't memorize the above formula, just know the concept.

Notice that the amount of oxygen delivered to the tissues accounted for by the Pao_2 (oxygen dissolved in blood) is minimal. The two most important factors in the delivery of oxygen to the vital organs are the **cardiac output** and **hemoglobin**.

In a critically ill patient, it is most important (the next step) to keep the hemoglobin and cardiac output near normal. There will be minimal change in Do_2 if you increase the Pao_2 from 60 to 100 mm Hg by giving the patient 100% oxygen.

The **alveolar–arterial gradient** (PAo_2–Pao_2 gradient) is useful in the assessment of oxygenation and is calculated by the following formula:

$$PAo_2\text{–}Pao_2 \text{ gradient} = (150 - 1.25) \times Pco_2 - Pao_2$$

or

$$A - a = [150 - (1.25 \times PaCO_2) - PaO_2]$$

Know this formula and how to calculate the PAo_2–Pao_2 gradient.

The above formula is valid only in patients who are breathing room air. This gradient is 5–15 mm Hg in normal young patients. It increases with all causes of hypoxemia except hypoventilation and high altitude. The gradient also increases with age.

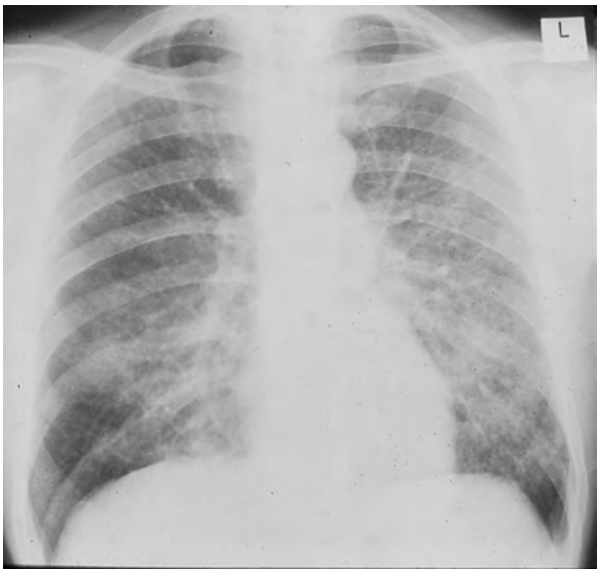
Clinical Problem. Can you think of any clinical condition in which the patient would have severe hypoxemia but a normal gradient? Hint: You will commonly see this in the emergency room.

Note

The answer to this clinical problem can be found at the end of this chapter.

CHEST RADIOGRAPHY

Chest radiography is often the initial diagnostic study performed to evaluate patients with respiratory symptoms. It may also be the initial evidence of pulmonary disease in a patient without symptoms, e.g., the pulmonary nodule found on an incidental x-ray.



Dr. Conrad Fischer

Figure 9-6. Bilateral Interstitial Infiltrates on Chest X-ray

Pulmonary Nodule

A 26-year-old man is found to have a 2.5-cm calcified nodule in the right middle lung on a routine chest x-ray before starting his residency. He has never smoked and otherwise feels well. The physical examination is unremarkable. What will you recommend for this patient?

The solitary pulmonary nodule that is found incidentally on an x-ray poses a specific problem for the clinician. Almost one-third of all solitary nodules are malignant.

Calcification of the nodule points toward a benign diagnosis, e.g., popcorn calcifications usually are caused by hamartomas, whereas bull's-eye calcifications are caused by granulomas.

Clinical Pearl

In all patients with a pulmonary nodule, first try to obtain an old chest x-ray.

The **first step** is to look for a **prior x-ray**. Finding the same pulmonary nodule on an x-ray done years ago may save you from doing any further workup. If no prior x-ray is available, then consider whether this patient is high or low risk for lung cancer.

- In **low-risk patients**, age <35 and nonsmokers with calcified nodules, follow the patient with chest x-ray or chest CT every 3 months for 2 years. Stop the follow-up if after 2 years there is no growth.
- **High-risk patients** age >50 with a smoking history and a nodule are likely to have bronchogenic cancer. The best diagnostic procedure is to biopsy (or possibly resect) the nodule. Bronchoscopy will **not** reach peripheral lesions and will mislabel 10% of central cancers by finding only nonspecific inflammatory changes. Bronchoscopy is performed blindly and the specimen obtained can be limited, hence the nonspecific findings (inflammation, etc.). If you suspect cancer in a patient and the bronchoscopy returns with a negative result, open lung biopsy and lung nodule resection must be

considered. For peripheral nodules, consider CT-guided biopsy, VATS, or open lung biopsy and nodule removal. PET-CT has not so far been well studied in the evaluation of high-risk patients with lung nodules.

Pleural Effusion

A 67-year-old man presents with complaints of dyspnea and pleuritic chest pain that has worsened over the past month. He has also noticed weight loss of 20 pounds and low-grade fever over this time period. On physical examination his respiratory rate is 24/min, and you find decreased air entry in the right lower lobe with dullness to percussion. Chest x-ray shows a pleural effusion involving about one-third of the lung field. A decubitus x-ray shows layering of the fluid.

Definition. The accumulation of fluid in the pleural cavity. It is either transudative or exudative.

Transudative effusion is caused by systemic factors: either increased hydrostatic pressure (e.g., CHF) or decreased oncotic pressure (e.g., nephrotic syndrome or cirrhosis). Because these diseases are systemic, they usually cause bilateral and equal effusion.

A transudative effusion needs no further evaluation. It resolves by adequate treatment of the primary disease.

Exudative effusion is caused by local processes: pneumonia, cancer, and tuberculosis.

An exudative effusion will cause unilateral effusions. This type of effusion needs further investigation.

How do we make the distinction between these two?

Thoracentesis should be performed for new and unexplained pleural effusion when sufficient fluid is present to allow a safe procedure. It is reasonable to observe pleural effusion when there is overt CHF (especially if bilateral), viral pleurisy, or recent thoracic or abdominal surgery. However, it is important not to assume that new effusions in a patient with a history of CHF are solely due to the CHF. Have a low threshold for performing diagnostic thoracentesis in any new or unexplained effusions.

Table 9-4. Causes of Pleural Effusion

Transudative	Exudative
Heart failure	Parapneumonic effusions (pneumonia)
Nephrotic syndrome	Malignancy (lung, breast, lymphoma)
Liver disease	Tuberculosis
Pulmonary embolism	Pulmonary embolism
Atelectasis	Collagen vascular disease (rheumatoid arthritis, systemic lupus erythematosus)
	Drug induced
	Pancreatitis

Get 2 tests from the thoracocentesis fluid—lactate dehydrogenase (LDH) and protein—and get 2 tests from the serum—LDH and protein. Do the ratios of effusion to serum for these measurements, and you have a diagnosis (Table 9-5).

Table 9-5. Light Criteria for Exudative Pleural Effusion

	Transudative	Exudative
LDH effusion	<200 IU/mL	>200 IU/mL
LDH effusion/serum ratio	<0.6	>0.6
Protein effusion/serum ratio	<0.5	>0.5

If at least one criterion is not met, then this is an exudative effusion; in that case, further evaluation has to be done.

One of the few conditions that can cause a transudate or exudate is pulmonary embolism (PE). The clinical significance of this is that if a patient has a transudative effusion but no apparent cause, consider PE.

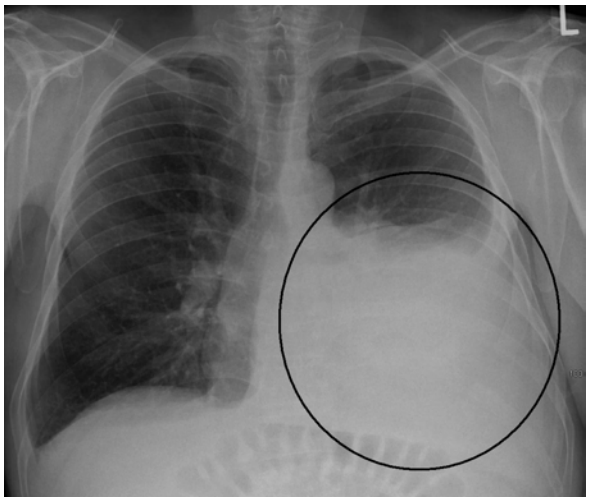
Parapneumonic effusion is caused by bacterial pneumonia. A thoracocentesis is mandatory also in this setting to rule out a complicated parapneumonic effusion (because of the possibility of progression to an empyema). An empyema (or complicated effusion) needs chest-tube drainage to resolve, while an uncomplicated parapneumonic effusion responds to antibiotics alone.

The most common causes of malignant pleural effusion are lung cancer, breast cancer, and lymphoma. When considering a malignant pleural effusion, make sure to send the thoracocentesis fluid for *cytologic examination.*

Hemorrhagic pleural effusion may be seen in mesothelioma, metastatic lung or breast cancer, pulmonary thromboembolism (with infarction), and trauma.

In patients with lymphocytic predominant exudative pleural effusions, consider tuberculosis. The pleural effusion is thought to be due to a hypersensitivity reaction to the tuberculosis mycobacterium and its antigens. The adenosine deaminase is elevated, and the polymerase chain reaction (PCR) for tuberculous DNA is positive. The acid-fast stain and culture for tuberculosis are positive in <30% of the cases. A pleural biopsy confirms the diagnosis and is the most sensitive and specific test for pleural tuberculosis.

Always perform thoracocentesis under the guidance of ultrasonography. If ultrasonography is not available, then perform a decubitus chest x-ray before the thoracocentesis. If the decubitus chest x-ray detects 1 cm or more of *free-flowing fluid*, the thoracocentesis can be performed with a minimal risk of complications. If the decubitus detects non-free fluid (loculated), it would be safer to perform an U/S-guided thoracocentesis.



Wikipedia, James Heilman, MD

Figure 9-7. Pleural Effusion

Evaluating patients with acute respiratory compromise and distress

Respiratory compromise may result from airway obstruction (asthma, COPD, foreign object), but it also accompanies parenchymal lung disease (bacterial or viral pneumonia, lung injury), heart failure, pulmonary embolism, neurogenic processes (respiratory depression from opiates), and neuromuscular disease (myasthenia gravis).

Respiratory distress is usually the presenting complaint or sign. Complaints of shortness of breath or signs of tachypnea or labored breathing are the most common. The patient may also develop neurologic symptoms: agitation, confusion, and a depressed level of consciousness. Stridor indicates upper airway obstruction.

The physician's first task is to ensure that the patient's airway is patent and that breathing is adequate. Supplemental oxygen should be provided immediately to ensure adequate oxygen saturation. The resources to perform endotracheal intubation and assisted ventilation should be made available.

The history should focus on the quickness of onset, as well as associated symptoms (cough, fever, etc.). Acute presentations accompanied by cough, fever, and sputum production suggest an infectious etiology. Sudden onset of dyspnea without systemic symptoms should raise the possibility of airway obstruction, cardiac disease, or thromboembolic disease. Chronic and progressive dyspnea (with or without recent exacerbation) is usually associated with a chronic pulmonary process, like interstitial lung disease or COPD.

The physical examination should focus on finding the cause, as well as assessing the degree of respiratory compromise. A respiratory rate >30/min in an adult suggests severe respiratory compromise. Wheezing on auscultation accompanies asthma and COPD. Localized wheezing usually suggests a foreign object or mass. Rales on examination may accompany pneumonia, interstitial lung disease, or heart failure. Consolidative changes may accompany pneumonia or atelectasis. Normal lung examination may be seen in thromboembolic disease, infections like *Pneumocystis carinii*, and disorders of the central respiratory drive.

An arterial blood-gas (ABG) measurement is the most important initial laboratory test in determining the presence and severity of respiratory compromise.

The **hallmark** of acute respiratory failure is a rise in P_{CO_2} accompanied by a drop in pH. The bicarbonate level will initially be normal, but will increase over 24–48 hours with the appropriate renal compensation. Hypercapnia may accompany hypoxemia or may be absent if ventilation is adequate. The presence of metabolic acidosis (lactic acidosis) in the presence of hypercapnia should prompt the consideration of mechanical ventilation.

In the setting of acute-on-chronic respiratory failure, the administration of supplemental oxygen is often associated with a rise in Pa_{CO_2}. Although attributed to a decreased respiratory drive, the pathophysiology of this is more complex. For the clinician, fear of a rising Pa_{CO_2} should **never** preclude the administration of enough supplemental oxygen to ensure adequate oxygen delivery. The target range of 88–92% oxygen saturation usually allows for adequate oxygen delivery while minimizing the potential increase in Pa_{CO_2}.

Other diagnostic tests

- **B-type natriuretic peptide (BNP)** appears useful as an adjunct to clinical assessment in determining the cause of acute dyspnea in patients presenting emergently. An elevated BNP is seen in almost all patients with left heart failure. It is important to remember that cor pulmonale and acute right ventricular failure (thromboembolism) may also cause a rise in the BNP. Thus, although the BNP is a very sensitive test for heart failure, it is not specific.
- The **chest x-ray** is particularly helpful in determining the cause of respiratory failure. A chest x-ray without parenchymal infiltrates accompanies respiratory failure due to thromboembolism, central respiratory depression, neuromuscular disease, and upper airway obstruction. Airway obstruction that accompanies asthma and COPD is usually associated with evidence of hyperinflation (large lung volumes and hyperlucency). The chest x-ray is diagnostic in cases of respiratory compromise caused by large pleural effusions or tension pneumothorax. Focal infiltrates suggest bacterial, viral, or fungal pneumonia; aspiration; or pulmonary hemorrhage. Unusual causes of localized infiltrates may be Churg-Strauss or Wegener granulomatosis. Heart failure and ARDS present with a diffuse edema pattern.

Treatment. New, persistent hypoxemia is generally an indication for admission to the hospital. The need for mechanical ventilation and close monitoring of a patient with respiratory compromise is an indication for admission to the ICU. Also, ICU admission should be considered for all patients with increasing oxygen demands, as well as those requiring continuous nursing.

The presence of respiratory acidosis and hypercapnia in a patient presenting with asthma exacerbation is an ominous sign and should prompt consideration for intubation and mechanical ventilation. Indications for intubation (with or without ventilation) also include upper-airway injury (burns, laryngeal edema, trauma) and airway compromise, often in the setting of neurologic depression with loss of protective reflexes, including gag and cough.

Acute respiratory failure presenting during hospitalization deserves a specific mention. The immobility which accompanies the hospitalized patient puts him at significant risk for pulmonary thromboembolic disease, so that should be considered in any patient who develops dyspnea, tachypnea, and/or hypoxemia. Inpatients are also at risk for developing aspiration, which may precipitate respiratory failure directly or through the development of pneumonia or acute respiratory distress syndrome (ARDS). The risk factors for aspiration include impaired consciousness and upper airway instrumentation (nasogastric tubes). Iatrogenic

causes must also be considered, especially respiratory depression from opiates causing respiratory arrest.

ARDS is a frequent cause of respiratory failure in patients suffering from other serious illnesses. ARDS represents a diffuse inflammatory response of the lung and develops within 24–72 hours of the onset of illness or injury. The clinical presentation is increasing respiratory distress with tachypnea and hypoxemia. The chest x-ray reveals diffuse pulmonary infiltrates, consistent with pulmonary edema (noncardiogenic pulmonary edema).

VENTILATION

Noninvasive Ventilation

Noninvasive ventilation (NIV) is a modality that supports breathing without the need for intubation. NIV avoids the adverse effects of invasive ventilation and has become an important mechanism of ventilator support both inside and outside the ICU.

Forms of NIV include bilevel positive airway pressure (BiPAP) and continuous positive airway pressure (CPAP).

- **Bi-level positive airway pressure** (BiPAP or BPAP) applies 2 different levels of PAP, i.e., it delivers positive pressure at alternating levels—higher for inspiration and lower for expiration— optimizing lung efficiency and at the same time diminishing the work of breathing. BPAP has been shown to be an effective management tool for COPD and acute (pneumonia, status asthmaticus, etc.) and chronic respiratory failure.
- **Continuous positive airway pressure** (CPAP) applies air pressure on a continuous basis, allowing the airways to continuously be open (splinted). It is typically used in the treatment of obstructive sleep apnea, preterm infants with underdeveloped lungs, CHF with pulmonary edema, near drowning, and other severe causes of respiratory distress. Portable CPAP machines used at home deliver a constant flow of pressure and are thus effective at preventing the airway from collapsing.

Note

BiPAP versus CPAP

Don't confuse BiPAP with CPAP, which applies a single level of positive airway pressure throughout the whole respiratory cycle and is used for clinical conditions such as obstructive sleep apnea.

Invasive Ventilation

Invasive ventilation, or mechanical ventilation, follows endotracheal intubation, and is used to improve oxygen exchange during acute hypoxemic or hypercapnic respiratory failure with respiratory acidosis. While hypoxemia and respiratory failure is one of the common reasons for endotracheal intubation, it is also introduced in order to protect the airways.

- **Positive end-expiratory pressure** (PEEP) is the alveolar pressure above atmospheric pressure that exists at the end of expiration.
- **Applied (extrinsic) PEEP** is one of the first ventilator settings chosen when mechanical ventilation is initiated, and it is set directly on the ventilator.
- A small amount of applied PEEP (4–5 cm H_2O) is used in most mechanically ventilated patients to mitigate end-expiratory alveolar collapse. A higher level (>5 cm H_2O) is sometimes used to improve hypoxemia or reduce ventilator-associated lung injury in patients with acute respiratory distress syndrome or another type of hypoxemic respiratory failure.
- Complications of PEEP include decrease in systemic venous return, pulmonary barotrauma, renal dysfunction, and electrolyte imbalance.

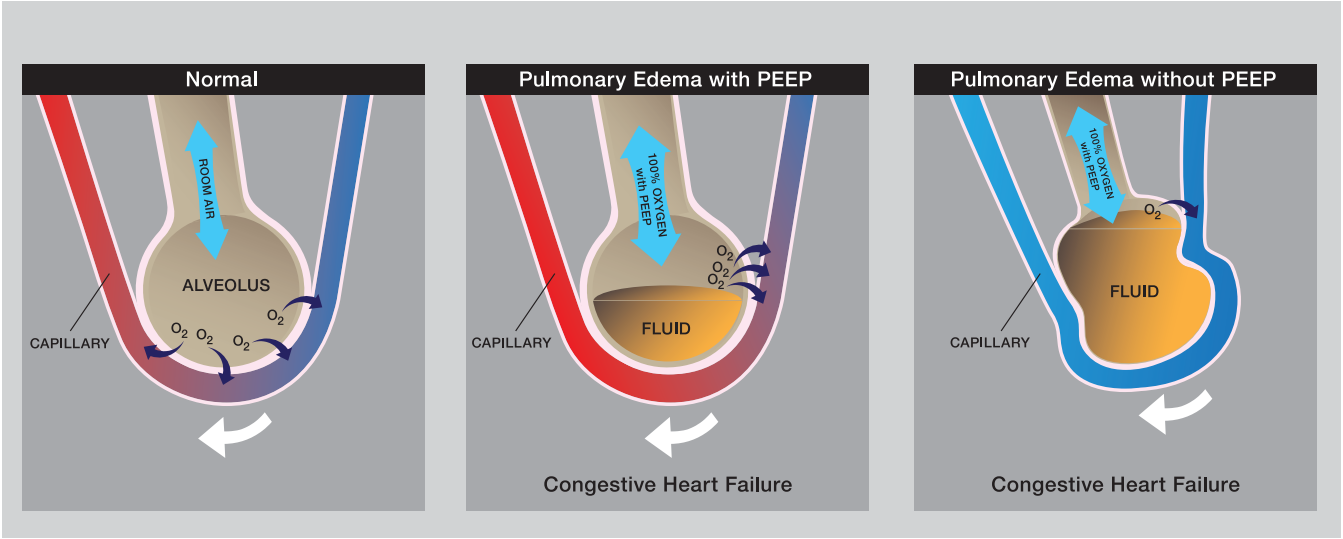


Figure 9-8. Effect of PEEP (Positive End-Expiratory Pressure)

Both PEEP and CPAP stent the alveoli open and thus recruit more of the lung's surface area for ventilation. But while PEEP imposes positive pressure only at the end of the exhalation, CPAP devices apply **continuous** positive airway pressure throughout the breathing cycle. Thus, no additional pressure above the level of CPAP is provided, and patients must initiate all of their breaths.

OBSTRUCTIVE DISEASES

Asthma

A 26-year-old woman with a history of asthma presents to the emergency room with 3 days of progressive wheezing and shortness of breath after an upper respiratory tract infection. She is taking inhaled albuterol and an over-the-counter medication for her cold symptoms. Her respiratory rate is 28/min and pulse 110/min; she is afebrile. Her right nasal turbinate is edematous and erythematous. There is evidence of wheezing throughout both lungs, but no crackles are noted. Supplemental oxygen by nasal cannula is administered. What should be the next appropriate treatment?

Definition. A disease characterized by inflammatory hyperreactivity of the respiratory tree to various stimuli, resulting in *reversible* airway obstruction. A combination of mucosal inflammation, bronchial musculature constriction, and an excessive secretion of viscous mucus-causing mucous plugs which produce bronchial obstruction. The bronchial hyperreactivity occurs in an episodic pattern with interspersed normal airway tone. Asthma can occur at any age but is usually seen in young persons, 50% of whom "outgrow" their asthma by adulthood.

Etiology

There are 2 types of asthma. Many patients have features of both types.

- **Intrinsic or idiosyncratic asthma** occurs in 50% of asthmatics who are nonatopic (nonallergic). A bronchial reaction occurs secondary to nonimmunologic stimuli, such as infection, irritating inhalant, cold air, exercise, and emotional upset. The asthma attacks are severe, and prognosis is less favorable.
- **Extrinsic (allergic, atopic) asthma** (20% of asthmatics) results from sensitization. Specific immunoglobulins (IgE class [type 1]) are produced, and total serum IgE concentration is elevated. There is a positive family history of allergic disease. Extrinsic asthma is precipitated by allergens. Other symptoms include allergic rhinitis, urticaria, and eczema. Prognosis is good.

Respiratory infections are the most common stimuli to cause asthma exacerbation; studies have documented that viruses (respiratory syncytial virus in young children, rhinoviruses in adults) are the major causes.

Pharmacologic stimuli are very important in some cases; the most common etiologic agents associated with asthma exacerbation are aspirin, coloring agents such as tartrazine, and β-adrenergic antagonists.

- The typical aspirin sensitivity (10% prevalence) nasal polyposis syndrome, affecting adults, starts with perennial vasomotor rhinitis; later, asthma occurs with minimal ingestion of aspirin.
- There is significant cross-reactivity between aspirin and other NSAIDs. Patients can be desensitized by daily administration of aspirin; cross-tolerance also develops to other NSAIDs.
- The mechanism by which aspirin and similar drugs cause asthma appears to be chronic over-excretion of leukotrienes, which activate the mast cells. This is the reason why leukotriene inhibitors are considered to be so effective.

Pathophysiology. There is a narrowing of large and small airways caused by hypertrophy and spasm of bronchial smooth muscle, edema and inflammation of the bronchial mucosa, and production of viscous mucus. The mediators released by the lung during an acute asthmatic attack are histamine, bradykinin, leukotrienes (LTs) C, D, and E, and prostaglandins (PGs) E_2, $F_{2\alpha}$, and D_2, which cause an intense inflammatory process leading to bronchoconstriction and vascular congestion. The cells thought to play an important role in the inflammatory response are the mast cells, lymphocytes, and eosinophils.

Signs and Symptoms. In a mild attack, slight tachypnea, tachycardia (increased respiratory rate), prolonged expirations, and mild, diffuse wheezing are seen. In a severe attack, use of accessory muscles of respiration, diminished breath sounds, loud wheezing, hyper-resonance (increased vocal fremitus), and intercostal retraction are noted.

Poor prognostic factors include fatigue, diaphoresis, pulsus paradoxus (>20 mm Hg), inaudible breath sounds, decreased wheezing, cyanosis, and bradycardia.

Variants of asthma include asthma presenting primarily with *nocturnal cough* and *exercise-induced asthma* (both presentations of asthma are commonly tested).

In the acute phase, **arterial blood gas (ABG)** abnormalities will be consistent with a decrease in arterial carbon dioxide tension ($PaCO_2$), increase in pH, and normal or low PaO_2. In severe asthma or status asthmaticus there will be a decreased PaO_2, increased $PaCO_2$, and decreased

Clinical Pearl

Samter's Triad

Samter's triad or aspirin-sensitive asthma:

- Asthma
- Nasal polyposis (causing recurrent sinus disease)
- Sensitivity to aspirin and NSAIDs

pH (bicarbonate level usually will not be elevated in an acute setting, but it becomes elevated in chronic obstructive pulmonary disease). A normal $Paco_2$ may indicate respiratory muscle fatigue in an acute asthmatic patient.

Chest x-ray findings are nonspecific in an asthmatic attack. The chest x-ray may be helpful in ruling out acute infection as the cause of an acute attack.

Diagnosis. PFTs show an obstructive pattern that typically reverses with bronchodilation (FEV_1 must show 12% and 200 mL reversibility at 5 and 20 min with the use of a β_2-adrenergic agonist). Sometimes the PFTs may be entirely normal because asthma is reversible and episodic; in this case a provocative challenge may be performed with methacholine or cold air, which typically shows a decrease in FEV_1/FVC or $FEF_{25–75}$ of 20%.

Treatment. β-adrenergic agonist inhalers like albuterol (salbutamol) and terbutaline are the mainstay of treatment in acute and chronic asthma. Inhaled (metered-dose inhalers [MDIs]) β-adrenergic agonists are the preferred route of administration because they allow maximal bronchodilation with minimal side effects. Their most common side effect is tremor. β-adrenergic agonists alone terminate approximately 70% of asthmatic attacks.

Salmeterol is a long-lasting (12 h) type of albuterol that is effective in nocturnal cough variant and exercise-induced asthma. Salmeterol has no benefit in acute episodes.

β-adrenergic agonists must be used with caution in patients who have coexisting cardiovascular disorders, hypothyroidism, diabetes mellitus, hypertension, and coronary insufficiency.

Other adrenergic stimulant drugs like the *catecholamines* (isoproterenol, epinephrine, and isoetharine) are given orally or intravenously and are *not* routinely used.

Aminophylline (ethylenediamine salt of theophylline) and *theophylline* are only modest bronchodilators. They are sometimes of benefit in chronic management, especially in patients with nocturnal cough. Their mechanism of action is by improving contractility of the diaphragm as well as other respiratory muscles. Generally, aminophylline and theophylline are *not* routinely used in asthma because they appear to add no benefit to optimal inhaled beta-agonist therapy.

Anticholinergic drugs (ipratropium bromide and tiotropium) have particular benefit in patients with heart disease, in whom the use of β-adrenergic agonists and theophylline may be dangerous. Their major disadvantages are that they take *significant time* to achieve maximal bronchodilation *(~90 min)* and they are only of medium potency.

Supplemental oxygen, by nasal cannula or mask, should be given immediately when a patient presents with acute asthma exacerbation. Always maintain an oxygen saturation above 90%.

The use of "routine" *antibiotic treatment* in asthma exacerbation has not been established. Two recent prospective trials have not showed a benefit. Antibiotic treatment should be considered in patients with symptoms (purulent sputum) and chest x-ray findings (infiltrates) consistent with bacterial pneumonia.

Treatment of asthma in the **outpatient setting (chronic management)** consists of looking for and removing environmental irritants and allergens. The goal is to remove or minimize contact with precipitating factors of asthma (such as pets).

Inhaled corticosteroids are the cornerstone of chronic asthma therapy in adults. They work by reducing airway inflammation. Inhaled corticosteroids have been shown in studies to reduce

asthma exacerbations and hospitalizations. Side effects of inhaled corticosteroids include oral candidiasis, glaucoma, cataracts, diabetes, muscle weakness, and osteoporosis. Appropriate technique in use of inhalers should be reviewed with the patient, as well as the use of spacers and/or mouth-rinsing to avoid oral candidiasis.

Systemic steroids are used only in acute exacerbations (for 10–14 days) and in the treatment of chronic severe asthma. Systemic corticosteroids should not be used before inhaled corticosteroids.

Inhaled **short-acting** beta 2 agonists such as albuterol are the mainstays of treatment of chronic asthma and are usually used in conjunction with inhaled corticosteroids. Use of short-acting beta-2 agonists for 3 days/week indicates poor control of symptoms, and treatment should be intensified.

Inhaled **long-acting** beta 2 agonists like salmeterol and formeterol have a sustained effect on bronchial smooth muscle relaxation. They are indicated for the treatment of moderate to severe persistent asthma (after initial therapy with short-acting beta 2 agonist plus inhaled corticosteroids) and especially when the patient has a significant nocturnal component. Long-acting beta-2 agonists should not be used during **acute exacerbation** of asthma; moreover, they should never be used **alone** and always in conjunction with inhaled corticosteroids. Studies have shown that when long-acting beta 2 agonists are used as a single agent, patients may have increased mortality.

Note

Neither short-acting nor long-acting beta 2 agonists address the inflammatory component of asthma.

The leukotriene modifiers are approved for severe asthma resistant to maximum doses of inhaled corticosteroids and as a last resort before using chronic systemic corticosteroids. Leukotriene modifiers inhibit 5-lipoxygenase, the enzyme involved in leukotriene production (LTC4, LTD4, LTE4), or competitive antagonist the principal moiety (LTD4). Zileuton is a typical leukotriene inhibitor that is available. The receptor antagonists are zafirlukast and montelukast.

MAST cell stabilizers (cromolyn and nedocromil) have been used in the treatment of chronic asthma. In terms of preventing asthma exacerbations and reducing inflammation in adults, they are not as effective as inhaled corticosteroids. They may be used also in exercise-induced asthma and allergic asthma. Cromolyn and Nedocromil are used extensively in the chronic treatment of pediatric asthma.

Theophylline is generally not preferred for the treatment of asthma. In chronic treatment of asthma, it is indicated only as a possible adjunct to inhaled corticosteroids for difficult-to-control asthma. In an acute exacerbation of asthma, a long-acting beta agonist plus inhaled corticosteroids has been shown to have better efficacy.

Clinical guidelines have classified asthma in 4 categories, based on frequency, severity of symptoms, and requirements for medication. This classification provides general guidelines for therapy.

- Mild intermittent
- Mild persistent
- Moderate
- Severe

Treatment of asthma in the **inpatient setting** (acute exacerbation) requires a different approach. Let's go back to the presented case. The patient is likely having an acute exacerbation of asthma.

- What are the treatments of choice?
- What are the bad prognostic indicators in this patient?
- Which of the following ABGs is considered ominous for this patient, as well as all asthmatic patients? 7.32/45/60 or 7.45/30/50

Note

The answers can be found at the end of this chapter.

Respiratory acidosis or 'normalization' of pH in patients with acute asthma exacerbation may be an indication for intubation.

Three days after hospitalization the patient is improving, and you decide to send her home. What is her drug regimen likely to be at this time?

She comes to you 3 months later for follow-up. She needs documentation of asthma for her work. What will you do now? What medications is she likely to be taking now?

For testing purposes, we will simplify the guidelines into the following classifications.

- **Mild Intermittent Asthma**
  - Symptoms of cough, wheeze, chest tightness, or difficulty breathing <2x/week
  - Flare-ups-brief, but intensity may vary
  - Nighttime symptoms <2x/month
  - No symptoms between flare-ups
  - Lung function test FEV1 that is ≥80 percent of normal values
  - Treatment: inhaled short-acting bronchodilators as needed
- **Mild Persistent Asthma**
  - Symptoms of cough, wheeze, chest tightness or difficulty breathing 3–6x/week
  - Flare-ups-may affect activity level
  - Nighttime symptoms 3–4x/month
  - Lung function test FEV1 that is ≥80 percent of normal values
  - Treatment: start with inhaled corticosteroid and SABA; if not enough improvement, add leukotriene inhibitor and possible LABA
- **Moderate Persistent Asthma**
  - Symptoms of cough, wheeze, chest tightness, or difficulty breathing daily
  - Flare-ups-may affect activity level
  - Nighttime symptoms ≥5x/month
  - Lung function test FEV1 that is >60 percent but <80 percent of normal values
  - Treatment: start with inhaled corticosteroid and SABA; leukotriene inhibitor and LABA will likely be needed to improve nighttime symptoms
- **Severe Persistent Asthma**
  - Symptoms of cough, wheeze, chest tightness or difficulty breathing continual
  - Nighttime symptoms frequently
  - Lung function test FEV1 that is ≤60 percent of normal values
  - Treatment: inhaled corticosteroid, SABA (as needed), leukotriene inhibitor, and LABA will likely be needed, as well as oral steroids (prednisone) at lowest possible dose
  - Do not stop leukotriene inhibitors and LABA once oral corticosteroids have been started

Allergic Bronchopulmonary Aspergillosis

Allergic bronchopulmonary aspergillosis (ABPA) is an allergic lung reaction to a fungus (most commonly *Aspergillus fumigatus*) seen in some patients with asthma or cystic fibrosis. Other fungi, including *Penicillium* and *Candida*, can cause an identical illness. In some people, the effects of the allergic reaction combine with the effects of the fungus to damage the airways and lungs further.

- The fungus does not actually invade the lung tissue and directly destroy it; rather, it colonizes the mucus in the airways of patients with asthma or cystic fibrosis (both of whom have increased amounts of mucus) and causes recurrent allergic inflammation in the lung.
- The alveoli become packed primarily with eosinophils.
- If the disease has caused extensive damage, bronchiectasis and scarring occur.

The first indications of allergic bronchopulmonary aspergillosis are usually progressive symptoms of asthma, such as wheezing and shortness of breath, and mild fever. The person usually does not feel well. Appetite may decrease. Brownish flecks or plugs may appear in coughed-up sputum. Repeated chest x-rays show areas that look like pneumonia, but they appear to persist or migrate to new areas of the lung (most often the upper parts). In people with long-standing disease, chest x-ray or CT may show bronchiectasis.

The fungus itself, along with excess eosinophils, may be seen when a sputum sample is examined under a microscope. Blood test reveal high levels of eosinophils and antibodies to *Aspergillus*. The level of immunoglobulin E in the blood is also elevated. Skin testing can determine if the person is allergic to *Aspergillus*, though it does not distinguish between allergic bronchopulmonary aspergillosis and a simple allergy to *Aspergillus*. Treatment is with corticosteroids.

Chronic Obstructive Pulmonary Disease (COPD)

> A 67-year-old woman with COPD is evaluated for dyspnea that occurred the prior day. She denies fever and chills but has noted productive cough. Her medications include ipratropium MDI. Her respiratory rate is 32/min and pulse 106/min; she is afebrile. She looks cachectic and is breathing fast. You note an increased anteroposterior diameter, distant heart sounds, and expiratory wheezing.

Definition. COPD includes patients with emphysema and chronic bronchitis. Emphysema and bronchitis must be identified as separate entities, but most patients with COPD have characteristics of both conditions. Patients with chronic bronchitis have productive cough for most days of a 3-month period for at least 2 consecutive years. In emphysema patients have abnormal permanent dilation of air spaces distal to the terminal bronchioles with destruction of air space walls.

Both of these processes are defined by *nonreversible obstruction* of the airways. This is the pathognomonic differentiating finding on PFTs when compared with asthma.

Cigarette smoking is a cause of COPD, with 10–15% of smokers developing COPD (80–90% of COPD patients are cigarette smokers). COPD symptoms usually begin after at least 20 pack-years of tobacco exposure. The number of pack-years of smoking correlates to the reduction of FEV_1. The fact that a small percentage (10–15%) of smokers develops COPD suggests that other factors may be involved in the pathogenesis. Air pollution, airway infections, and allergies can lead to bronchitis.

α_1-*antitrypsin deficiency* is a rare hereditary autosomal recessive disease that can cause emphysema and liver abnormalities.

Pathogenesis. After long-term exposure to cigarette smoke, inflammatory cells are recruited in the lung. These inflammatory cells in turn secrete proteinases, which may lead to air space destruction and permanent enlargement. Eventually, decreased elastic recoil (mainly in emphysema) and increased airway resistance (mainly with chronic bronchitis) occur.

Physical Examination. In emphysema, distant breath sounds will be heard on auscultation. In chronic bronchitis, there may be evidence of rhonchi and wheezes to auscultation. Signs and symptoms of right heart failure (cor pulmonale) and clubbing can also be seen on physical examination in COPD.

wikipedia.com

Figure 9-9. Clubbing of the Fingers Seen with Chronic Hypoxemia

In chronic bronchitis, increased pulmonary markings can be seen on chest x-ray; in emphysema, hyperinflation of bilateral lung fields with diaphragm flattening, small heart size, and increase in retrosternal space can be seen.

Cor pulmonale in COPD is associated with chronic pulmonary hypertension.

Note

The answer to this question can be found at the end of this chapter.

Diagnosis. PFTs are the diagnostic test of choice. On PFT, a reduction in FEV_1/FVC ratio and $FEF_{25–75}$ occurs. RV and TLC are usually increased in COPD. Emphysema will have a decreased DL_{CO}, whereas chronic bronchitis will generally have a normal DL_{CO}.

After a bronchodilator is given, you would expect the FEV_1/FVC to _____.

Complications. Hypoxemia with **nocturnal desaturation** is sometimes seen. Secondary **erythrocytosis** can result from chronically low P_{O_2}. Pulmonary hypertension is a complication that can lead to **cor pulmonale** and subsequent right heart failure. Chronic ventilatory failure and CO_2 retention are seen in chronic bronchitis early and at the end stages of emphysema.

Management of Stable Phase COPD. The goal in treatment is to treat airway inflammation and bronchospasm, reduce airway resistance and work of breathing, and improve gas exchange and ventilation-perfusion ($\dot{V}/Q$) mismatching.

Anticholinergic agents (ipratropium bromide [Atrovent®] and tiotropium) are the first-line drugs in COPD. These agents are given via MDI and control airway caliber and tone. Anticholinergic agents can be used synergistically with β_2-adrenergic agonists in patients with COPD.

β_2-**adrenergic agonists** (albuterol) are used after anticholinergic agents. The inhaled route is the preferred administration.

Beta agonists are not first-line agents in the management of COPD because many of the patients have underlying heart disease and the tachycardia commonly associated with these agents may precipitate heart failure.

Chronic **inhaled corticosteroids** are reserved for severe cases of COPD.

Theophylline, a xanthine derivative, may be added to the regimen if beta-2 agonists and anticholinergics are not effective in managing the symptoms of chronic obstructive lung disease. Remember that theophylline has significant toxicity. Symptoms include nausea and vomiting, palpitations, and tremulousness. Death can occur from theophylline toxicity from cardiac arrhythmias.

The list of drug interactions with theophylline is significant. Theophylline levels increase with fluoroquinolones, clarithromycin, H2-blockers (cimetidine, ranitidine), certain beta blockers and calcium channel blockers. Theophylline levels decrease (due to increased clearance) with rifampin, dilantin, phenobarbital, and smoking.

Despite the above treatments, the only interventions which have been shown to decrease mortality in patients with COPD are **home oxygen** and **smoking cessation**.

Home oxygen therapy is given to patients with hypoxemia (PaO_2 <55 mm Hg or saturation <88%), and the goal is to try to keep the O_2 saturation >90% as much as possible, especially at night when patients generally desaturate. Patients with cor pulmonale will benefit from home oxygen when PaO_2 <59 mm Hg. A special category is the patient who desaturates with exercise; she or he will benefit from intermittent oxygen.

All patients with COPD must have the pneumococcal vaccine (Pneumovax®) every 5 years and the influenza vaccine yearly. They should also receive the *H. influenzae* vaccine if they were not previously immunized.

Several trials have failed to find a beneficial effect for the regular chronic use of inhaled corticosteroids in patients with COPD.

Management and Treatment of COPD Exacerbation (Acute Setting Treatment). Acute exacerbation of COPD is considered acute worsening of the patient's respiratory symptoms (increased dyspnea, increased sputum volume, production of purulent sputum) that necessitates a change in medications.

The most common causes of COPD exacerbation are viral lung infections. Other precipitating causes that should be sought out are bacterial infections, heart failure, myocardial ischemia, pulmonary embolism, lung cancer, esophageal reflux disease, and medications (e.g., beta-blockers).

Initial Management

1. **Measure O_2 saturation** via pulse oximetry (on the spot) to determine oxygen saturation.
2. **ABG determination** is very useful to identify the level of hypercapnia and thus the severity of exacerbation.
3. **Chest x-ray** is expected in all patients with COPD exacerbation to identify pulmonary infiltrates consistent with pneumonia. It may also show evidence of pulmonary edema, indicating possible heart failure as the cause of the exacerbation.

4. Spirometry (and other PFT evaluation) is **not** helpful in COPD exacerbation because measurements (FEV_1, etc.) have not been shown to correlate well with the severity of the exacerbation.
5. In the acute setting, check levels in patients on chronic treatment with theophylline. Drugs like erythromycin, cimetidine, and ciprofloxacin may decrease theophylline clearance and cause **theophylline toxicity**.
6. Other tests as part of the initial evaluation of COPD exacerbation might include *CBC* (looking for elevated WBCs and polycythemia); *ECG* (looking for new arrhythmias, e.g., atrial fibrillation that may precipitate heart failure and exacerbate COPD).
7. Any significant changes of hypercapnia or hypoxemia from baseline should prompt consideration for *admission to the hospital.* Also, patients on home O_2 who have exacerbation, and those with severe symptoms, should be hospitalized.
8. Consider *intubation and mechanical ventilation* in patients with decreased levels of consciousness, cyanosis, or hemodynamic instability and in those with persistent hypoxemia despite adequate oxygen supplementation.

Specific Therapy

1. **Oxygen supplementation** should be titrated to ~90% saturation on the pulse oximeter. The first and foremost concern is to deliver adequate oxygenation. In COPD exacerbation, we should be concerned about CO_2 retention as a secondary issue.
2. **Inhaled bronchodilators** are the **most effective** medications to improve airway diameter (the drugs of choice). In acute COPD exacerbations, use both beta-agonists (albuterol) and anticholinergics (ipratropium) **simultaneously**. Trials have shown that administration of these drugs by a nebulizer or metered dose inhaler (MDI) with a spacer is equally efficacious. Patients with severe exacerbations are unable to hold their breath for more than a few seconds and are thus initially treated with nebulizers and then switched to the MDIs.
3. **Systemic corticosteroids** have now been shown in multiple trials to shorten the recovery time of lung function and decrease the length of stay in patients with COPD exacerbation. Corticosteroids may be given intravenously or orally because the **efficacy is similar** in both modes of administration. The equivalent of 60 mg prednisone appears to be the sufficient starting dose and is usually continued for 2 weeks. It makes sense clinically to start patients who have a severe exacerbation with IV methylprednisolone (it is difficult for these patients to take oral meds), then change to oral prednisone as they improve. Inhaled corticosteroids have *not* been shown to improve outcomes in patients with COPD exacerbation and cannot be substituted for systemic corticosteroids.
4. **Antibiotics** seem to be beneficial in COPD exacerbations despite "normal" chest radiograms. Patients with productive, purulent cough benefit the most because they are more likely to have an underlying bacterial infection. Antibiotics commonly used are second-generation macrolides (clarithromycin, azithromycin), extended-spectrum fluoroquinolones (levofloxacin, moxifloxacin), cephalosporins (second- and third-generation), and amoxicillin clavulanate.
5. There is no real benefit to using IV aminophylline. However, if the patient is using theophylline on a chronic basis (in outpatient setting), it should be continued during the exacerbation because abrupt discontinuation may worsen symptoms.
6. Always avoid opiates and sedatives because they may suppress the respiratory system.
7. Although specific chest physiotherapy (postural drainage, etc.) has not been shown to benefit patients with exacerbation, they should be encouraged to increase activities as tolerated to prevent deconditioning.

8. Counseling the patient on smoking cessation in the hospital setting is the single most important intervention.
9. Teaching the patient optimal use of MDIs has been shown to reduce readmission rates.

Prognosis. FEV_1 is the best predictor of survival (the higher the FEV_1, the better the survival and the less symptomatic the patients). The rate of FEV_1 decline may also predict survival because patients with a faster decline will have increased morbidity. Patients that have a FEV_1 ≤25% will usually complain of dyspnea at rest.

Tobacco cessation is the only means of slowing progression of COPD and the decrease in FEV_1.

It is very important that patients with COPD have vaccinations against *Pneumococcus* with a booster at 5 years and yearly for influenza. Some experts consider the *H. influenzae* vaccine mandatory.

Let's go back to our patient.

What are you likely to find on her PFTs? How will you treat this patient in the acute exacerbation? What are your treatment options after she goes home?

She asks you to inform her about "how bad her disease is." What will you do next to assess the severity of her disease?

Note

The answers to these questions can be found at the end of this chapter.

Bronchiectasis

A 17-year-old girl is admitted to the hospital with a right lower lobe pneumonia. She gives you a history of recurrent pneumonias, some of which have kept her in the hospital for weeks, and of chronic productive cough that occurs every day. Her parents inform you that she has had "loose stools" since childhood. On the examination she is thin and in distress. There are diminished breath sounds on the right lower lobe with rhonchi.

Definition and Etiology. Bronchiectasis is the permanent dilation of small- and medium-sized bronchi that results from destruction of bronchial elastic and muscular elements. Eventually the bronchi become fibrotic. Bronchiectasis can occur secondary to repeated pneumonic processes such as tuberculosis (TB), fungal infections, lung abscess, and pneumonia (focal bronchiectasis) or when the defense mechanisms of the lung are compromised as in cystic fibrosis and immotile cilia syndrome (diffuse bronchiectasis).

About 50% of patients with primary ciliary dyskinesia will have situs inversus and sinusitis—Kartagener syndrome.

Bronchiectasis should be suspected in any patient with chronic cough, hemoptysis, foul-smelling sputum production, and recurrent pulmonary infections, sinusitis, and immune deficiencies.

Signs and Symptoms. Patients will have persistent cough with purulent copious sputum production, wheezes, or crackles. There is a significant history of recurrent pneumonias that commonly involve gram-negative bacteria, especially *Pseudomonas* species.

Hypoxemia may occur causing secondary polycythemia.

Clinical Pearl

- 5–7% of patients with cystic fibrosis initially present in early adulthood.
- Consider cystic fibrosis in adult patients with chronic productive cough (symptoms of bronchiectasis), especially if they have history of recurrent sinusitis, nasal polyps, and weight loss. Most males are infertile.

Diagnosis. Early chest x-ray findings may be normal. Chest x-ray in advanced cases may show 1- to 2-cm cysts and crowding of the bronchi (tram-tracking). High-resolution CT scan of the chest is the best noninvasive test to detect bronchiectasis.

Treatment. Bronchodilators, chest physical therapy, and postural drainage are used to control and improve drainage of bronchial secretions**.** Patients should be treated with antibiotics such as trimethoprim sulfamethoxazole, amoxicillin, and amoxicillin/clavulanic acid (Augmentin®) when sputum production increases or they have mild symptoms. This is referred to as "rotating antibiotics" because a different antibiotic is chosen each time to diminish resistance of microorganisms. Chronic prophylaxis with antibiotics is not recommended.

If the patient exhibits significant symptoms or pneumonia, treat with IV antibiotics that cover gram-negative bacteria, e.g., quinolones, ceftazidime, or aminoglycosides. Consider **surgical therapy** for patients with localized bronchiectasis who have adequate pulmonary function or in massive hemoptysis.

All patients with bronchiectasis require yearly vaccination for influenza and vaccination for pneumoccocal infection with a single booster at 5 years.

Specific considerations for the treatment of CF include:

- Aggressive percussion and lung exercises
- Pancreatic enzymes
- Supplemental vitamins
- Recombinant human DNAse
- Inhaled hypertonic saline

Note

The answers to these questions can be found at the end of this chapter.

Complications include massive hemoptysis, amyloidosis, cor pulmonale, and visceral abscesses.

Let's go back to our patient.

How would you treat this patient?

What investigations will you consider based on her history?

INTERSTITIAL LUNG DISEASE

Interstitial lung disease (ILD) is a group of heterogeneous diseases and includes >100 disorders. ILD is characterized by chronic inflammation and fibrosis of the interstitium and lung parenchyma. The worst prognosis is with idiopathic pulmonary fibrosis and usual interstitial pneumonitis.

The interstitium of the lung (supporting structure) is the area in and around the small blood vessels and alveoli where the exchange of oxygen and carbon dioxide takes place. Inflammation and scarring of the interstitium (and eventually extension into the alveoli) will disrupt normal gas exchange. Although the progression of ILD may be variable from one disease to another, they have common clinical, radiographic, and spirometric findings.

All patients with ILD develop exertional dyspnea (the most common complaint that brings them to the physician) and nonproductive cough. The examination shows the typical coarse crackles, evidence of pulmonary hypertension (increased pulmonic sound, right heart failure),

and clubbing (not always). The chest x-ray is consistent with reticular or reticulonodular pattern ("ground-glass" appearance). PFTs show evidence of intrapulmonary restrictive pattern.

Causes include:

- Idiopathic pulmonary fibrosis
- Sarcoidosis
- Pneumoconiosis and occupational lung disease
- Connective tissue or autoimmune disease–related pulmonary fibrosis
- Hypersensitivity pneumonitis
- Eosinophilic granuloma (a.k.a. Langerhan cell histiocytosis)
- Chronic eosinophilic pneumonia
- Wegener granulomatosis
- Idiopathic pulmonary hemosiderosis
- Bronchiolitis obliterans
- Lymphangioleiomyomatosis

Diagnostic evaluation should include high-resolution CT scan and, eventually, biopsy via bronchoscopy or open lung biopsy.

Idiopathic Pulmonary Fibrosis (IPF)

> A 55-year-old man comes for evaluation of exercise intolerance over the past 6 months. He has no significant past medical history. He informs you that over the past week he cannot walk across the room without getting "short of breath." He takes no medications and has never smoked. The physical exam is significant for a respiratory rate of 24/min, jugular venous distention ~8 cm, coarse crackles on auscultation, clubbing, and trace pedal edema on both legs. The chest x-ray reveals diffuse reticular disease.

Definition. IPF is an inflammatory lung disease of unknown origin that causes lung fibrosis and restrictive lung disease. This disease characteristically involves only the lung and has no extrapulmonary manifestations except clubbing.

Prevalence. IPF occurs in patients in the fifth decade of life, with an equal distribution between men and women.

Clinical Manifestations. Progressive exercise intolerance and dyspnea are seen most commonly. There are coarse dry crackles on auscultation.

The chest x-ray reveals reticular or reticulonodular disease. High-resolution CT scan may show ground-glass appearance. As IPF progresses, there is evidence on imaging of extensive fibrosis with honeycomb pattern. A restrictive intrapulmonary process is evident on PFTs.

Bronchoalveolar lavage will show nonspecific findings, specifically increased macrophages.

A lung biopsy is done to exclude other causes that may have similar findings, e.g., vasculitis, infections, cancer.

Treatment.

Pharmacologic treatment includes pirfenidone, a new small-molecule compound that has antifibrotic effects. A recent trial showed that pirfenidone significantly reduced decline in lung function and IPF disease progression.

Drugs no longer used in the treatment of IPF include corticosteroids, anticoagulants, interferon, and bosentan.

Non-pharmocologic treatment includes lung transplantation and is suitable for those patients physically eligible to undergo a major transplant operation. In IPF patients, lung transplant has been shown to reduce the risk of death by 75% as compared with those who remain on the waiting list.

Sarcoidosis

A 27-year-old woman comes to your office with painful erythematous papules that occurred yesterday. She has no other complaints except joint swelling and pain that occurred 3 days ago. Physical examination discloses low-grade fever, symmetric swelling of the knees, PIP (proximal interphalangeal) and MCP (metacarpophalangeal) joints, and well demarcated, 3- to 4-cm papules over the anterior aspect of her legs. What is the next step in confirming the likely diagnosis?

Definition. Sarcoidosis is a systemic disease of unknown cause, characterized histologically by the presence of nonspecific noncaseating granulomas in the lung and other organs.

Prevalence. There is an increased incidence of sarcoidosis among blacks and patients age 20–40 years.

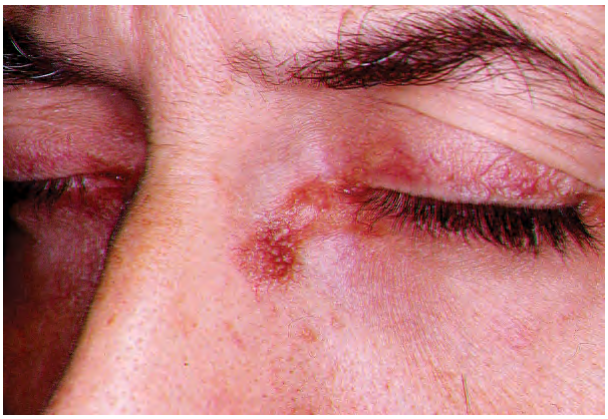
Clinical Manifestations. Sarcoidosis can involve almost any organ system, but pulmonary involvement is most common. Ocular, cutaneous, myocardial, rheumatologic, GI, and neurologic manifestations can also occur. The dermatologic manifestations occur in 25% of patients with sarcoidosis; they include lupus pernio, erythema nodosum, non-scarring alopecia, and papules.

Commonly, sarcoidosis is discovered in a completely asymptomatic patient, usually in the form of hilar adenopathy on a chest x-ray.

There are 2 distinct sarcoid syndromes with acute presentation:

- **Löfgren syndrome** includes erythema nodosum, arthritis, and hilar adenopathy.
- **Heerfordt-Waldenstrom syndrome** describes fever, parotid enlargement, uveitis, and facial palsy.

Lung involvement in sarcoidosis occurs in 90% of patients at some time in their course. Hilar and left paratracheal adenopathy is the most common presentation. Interstitial lung disease with or without hilar adenopathy can also be a presentation of sarcoidosis.



Dermatoweb.net

Figure 9-10. Lupus Pernio Sometimes Seen with Sarcoidosis

Chest X-Ray. Chest x-ray findings can show 4 stages of disease (the stages are not progressive), which include bilateral hilar adenopathy, hilar adenopathy with reticulonodular parenchyma, reticulonodular parenchyma alone, or honeycombing of bilateral lung fields with fibrosis.

Laboratory Findings. Hypercalcemia or hypercalciuria caused by increased circulation of vitamin D produced by macrophages.

Elevation in angiotensin-converting enzyme (ACE) can be seen in 60% of patients with sarcoidosis. ACE levels are **nonspecific** but can be used to follow the course of the disease.

Abnormalities in liver function tests are seen in 30% of patients with liver involvement, with 90% of patients being symptomatic.

Other findings on diagnosis of sarcoidosis include skin anergy, and PFTs may be normal or show a restrictive pattern. All patients with suspected sarcoidosis should have an ophthalmologic examination because uveitis and conjunctivitis are found in >25% of the cases.

Diagnosis. The definitive diagnosis of sarcoidosis rests on biopsy of suspected tissues, which show noncaseating granulomas.

Prognosis. Eighty percent of patients with lung involvement from sarcoidosis remain stable, or the sarcoidosis spontaneously resolves. Twenty percent of patients develop progressive disease with evidence of end-organ compromise.

Treatment. There is no evidence that any therapy alters the course of disease. Generally in the setting of organ impairment, a trial of steroids may be used, giving a high dose for 2 months followed by tapering the dose over 3 months. There are certain scenarios in which *steroids are mandatory:* uveitis, sarcoidosis involving the CNS, and heart, and in those who develop hypercalcemia.

Clinical Pearl

Don't use serum ACE levels to diagnose sarcoidosis.

Clinical Pearl

If a patient is asymptomatic and has bilateral hilar adenopathy on a routine chest x-ray, assume this is sarcoidosis and follow with imaging.

Pneumoconiosis

Definition. The pneumoconioses are occupational lung diseases in which inhalation of certain fibers initiates an inflammatory process that eventually leads to fibrosis of the lung.

Usually, pneumoconiosis appears 20–30 years after constant exposure to offending agents (metal mining of gold, silver, lead, copper) but can develop in <10 years when dust exposure is extremely high.

History is of primary importance in assessing possible occupational lung diseases.

Pathology. Alveolar macrophages engulf offending agents, causing inflammation and fibrosis of the lung parenchyma in pneumoconiosis. Respiratory insufficiency is the ultimate consequence of the pneumoconioses.

Diagnosis. Signs and symptoms include dyspnea, shortness of breath, cough, sputum production, cor pulmonale, and clubbing. PFTs show a restrictive pattern with a decreased DLCO. Hypoxemia is evident with an increased PAO_2-PaO_2 gradient. Chest x-ray findings include small irregular opacities, interstitial densities, ground glass appearance, and honeycombing.

Asbestosis

Definition. Asbestosis is an occupational lung disease caused by prolonged inhalation of asbestos dust. The result is lung parenchymal fibrosis which results in respiratory compromise.

Epidemiology. Asbestos fiber exposure may be seen in mining, milling, foundry work, shipyards, or the application of asbestos products to pipes, brake linings, insulation, and boilers.

History of exposure to asbestos is needed to consider the diagnosis.

Signs and Symptoms. These include exertional dyspnea and reduced exercise tolerance, cough and wheezing (especially among smokers), chest wall pain, and ultimately respiratory failure.

On chest x-ray, diffuse or local pleural thickening, pleural plaques, and calcifications at the level of the diaphragm are seen. Pleural effusions are commonly seen, and the interstitial lung process associated with asbestosis usually involves the lower lung fields.

The most common cancer associated with asbestosis is bronchogenic carcinoma (adenocarcinoma or squamous cell carcinoma).

Pleural or peritoneal mesotheliomas are also associated with asbestos exposure but are not as common as bronchogenic cancer.

Diagnosis. A lung biopsy is usually necessary for the diagnosis of asbestosis, in which the classic barbell-shaped asbestos fiber is found.

Treatment. No specific treatment is offered. It is important that patients with asbestos exposure stop smoking since the risk of lung cancer is 75 times higher than that of the normal population.

Silicosis

Definition. Silicosis is an occupational lung disease caused by inhalation of silica dust.

Epidemiology. Silicosis is seen in individuals who work in mining, quarrying, tunneling, glass and pottery making, and sandblasting.

Signs and Symptoms. Silicosis will cause similar symptoms to asbestosis (or any other pneumoconiosis) except the acute form of silicosis, which is caused by massive exposure that causes lung failure in months.

Pathology. Silica causes inflammatory reactions with pathologic lesions being the hyaline nodule.

Chest X-Ray. In silicosis there are nodules (1–10 mm) seen throughout the lungs that are most prominent in the upper lobes. A characteristic finding is eggshell calcifications (rare). In progressive massive fibrosis, densities are 10 mm or more and coalesce in large masses.

Diagnosis. Same as asbestosis.

Treatment. There is no effective therapy for silicosis. Death occurs usually because of progressive respiratory insufficiency.

There is an association of silicosis with pulmonary TB. Patients with silicosis should have yearly purified protein derivative (PPD) tuberculin testing; a patient with positive reactive PPD (>10 mm) should get isoniazid (INH) prophylaxis for 9 months.

Coal miner's lung/coal worker's pneumoconiosis (CWP)

Epidemiology. The risk of development and progression of CWP is related to the amount of coal dust exposure, higher rank (hardness) of coals, and increased silica content of inhaled dust. Simple CWP is seen in 12% of all miners.

Signs and Symptoms. CWP clinically presents as any other occupational lung disease.

Chest X-Ray. Small round densities are seen in the parenchyma, usually involving the upper half of the lungs. Complicated or progressive massive fibrosis is diagnosed by the presence of larger densities from 1 cm in diameter to the entire lobe.

Associated Immunologic Abnormalities. Increased levels of IgA, IgG, C3, antinuclear antibodies (ANA), and rheumatoid factor are abnormalities seen in CWP.

In *Caplan syndrome* there are rheumatoid nodules in the periphery of the lung in a patient with rheumatoid arthritis and coexisting pneumoconiosis (usually CWP).

PULMONARY THROMBOEMBOLISM

A 32-year-old woman is brought to the emergency department with an acute onset of shortness of breath and pleuritic chest pain that occurred while she was shopping. She has never been sick and takes no medications other than oral contraceptives. Her respiratory rate is 26/min and pulse 107/min. Auscultation is clear, and the rest of the examination is normal. ABG shows evidence of mild hypoxemia (7.52/70/25/93%). Chest x-ray is normal.

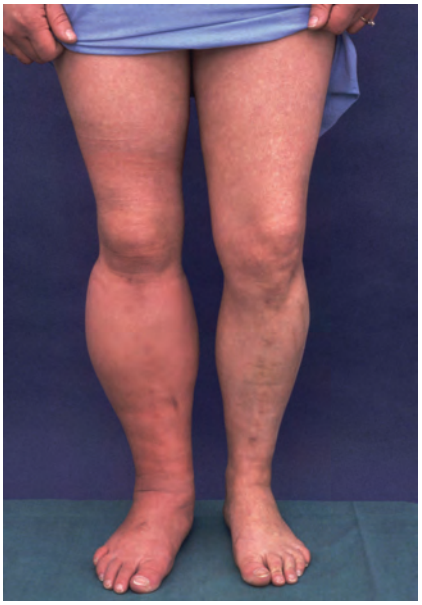
Overview. Thromboembolic disease is a common cause of morbidity and mortality in the hospital and outpatient setting and poses a diagnostic challenge even for seasoned clinicians.

Clinically significant pulmonary emboli, for the most part, arise from proximal (above-the-knee) deep vein thrombi (DVT). In turn, most proximal DVT are a consequence of propagation of distal (below-the-knee) DVT. Studies have shown that distal DVT, by themselves, do not pose a risk for the development of a pulmonary embolus. In one-third of the cases, they extend to the proximal veins and thus become a source of pulmonary emboli.

Pulmonary embolism can infrequently occur with upper extremity, subclavian, and internal jugular vein thrombosis. This type of thromboembolic disease occurs in patients when IV catheters are placed in the associated veins. Also, in the pregnant patient, thrombosis may occur initially in the pelvic veins rather than follow the usual course of starting in the distal and then extending to the proximal veins.

Pulmonary embolism and DVT are considered one disease.

- Be concerned about (and treat) proximal vein thrombosis because this may result in pulmonary embolism.
- In pregnant patients and those with IV catheters, look for the source of the thromboembolism in uncommon places (pelvic veins, upper extremity veins, etc.).



Biomedical Communications 2007—Custom Medical Stock Photo.

Figure 9-11. Unilateral Right Leg Swelling Due to Deep Venous Thrombosis

Clinical Pearl

In patients with patent foramen ovale, venous thromboembolism may result in embolization involving the systemic circulation. This frequently presents as CVA.

Natural Course. After a proximal DVT dislodges, it travels through the vena cava and into the right side of the heart. It usually breaks off into multiple thrombi as it goes into the pulmonary circulation, obstructing parts of the pulmonary artery. This results in increased alveolar dead space, vascular constriction, and increased resistance to blood flow. When ~50% of the lung vasculature is involved, significant pulmonary hypertension may occur. This is followed by an increase in right ventricular workload and may lead to right-sided heart failure. A massive pulmonary embolus occurs when >70% of one lung is involved.

About 10% of patients with pulmonary embolus will die within 1 hour of the event, most from a massive pulmonary embolus or significant comorbid conditions (e.g., preexisting CHF or COPD).

When to Consider Pulmonary Embolism and DVTs:

High-risk patients

- Recent surgery, especially orthopedic surgery (knee replacement surgery carries a 70% risk for DVT)
- Cancer history (prostate, pelvic, abdominal, and breast). *Note:* Studies following patients with unexplained DVT found that 15–20% of these patients developed cancer within the first 2 years after the diagnosis of a DVT.
- Immobile patients (especially those hospitalized); patients with significant heart failure; long travel
- Acquired thrombophilia, especially lupus anticoagulant, nephrotic syndrome (loss of antithrombin III in the urine), and oral contraceptives (the risk increases further if the patient is a current smoker)
- Inherited thrombophilia, of which the most common is *factor V Leiden mutation* (protein C resistance); others include protein C and S deficiency and antithrombin III deficiency
- Pregnancy, for which increased risk for thromboembolism will continue until 2 months after the delivery

Consistent symptoms and signs:

- Sudden onset of dyspnea (shortness of breath) and tachypnea
- Thigh or calf swelling with or without dyspnea
- Pleuritic chest pain
- Hemoptysis (occurs only with infarction, which is rare because of the dual circulation [bronchial and pulmonary] that supports lung parenchyma)
- On exam, always increased respiratory rate with tachycardia; increased pulmonic sound (P_2)

The **Wells' Criteria** risk stratifies patients for PE, and has been validated in both inpatient and emergency department settings. While there are other scoring systems for PE and DVT, the Wells criteria are the most widely used in the United States:

- Symptoms of DVT (3 points)
- No alternative illness that explains symptoms (3 points)
- Immobilization (≥3 days) or surgery in the previous 4 weeks (1.5 points)
- Prior history of DVT or PE (1.5 points)
- Presence of hemoptysis (1 point)
- Presence of malignancy (1 point)

Scoring is done as follows:

- **Score >6** = high probability of PE
- **Score ≥2** but <6 = mean moderate probability of PE
- **Score <2** = low probability of PE

Tests for the Diagnosis of Thromboembolic Disease

General tests are nonspecific, though they may provide important clues for the diagnosis. They are done routinely in the emergency department in the evaluation of patients with dyspnea.

Arterial blood gas (ABG) tests usually show evidence of hypoxemia with an elevated A-a gradient. In ~10% of patients with documented pulmonary thromboembolism, the A-a gradient may be normal and the hypoxemia mild.

Chest x-rays are very important in finding other causes that may account for the patient's symptoms. The most common chest x-ray finding associated with pulmonary thromboembolism is a "normal" chest x-ray. Other nonspecific findings include atelectasis and pleural effusion (transudative and exudative).

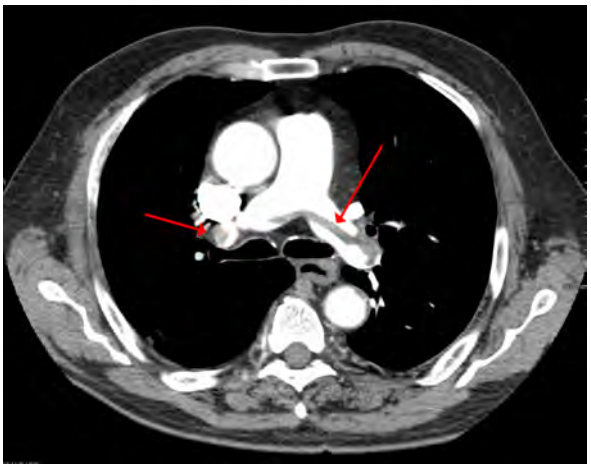
- Westermark sign is the lack of vascular markings that occur distal to the pulmonary embolus.
- Hampton hump is a wedge-shaped infiltrate (just above the diaphragm) and is due to pulmonary infarction

Clinical Pearl

Consider pulmonary embolus in all patients with dyspnea and **normal** chest radiography.

The ECG may show evidence of right heart strain (due to the development of acute pulmonary hypertension), which manifests as large S waves in lead I and deep Q waves in lead III with T-wave inversion in the same lead (mnemonic: S_1, Q_3, T_3). The most common finding on the ECG is sinus tachycardia. The ECG is also an important tool in excluding other causes with similar symptoms, specifically acute pericarditis and myocardial ischemia.

Specific tests are more specific for the evaluation of thromboembolic disease (do them when considering the diagnosis).



Wikipedia, James Heilman, MD

Figure 9-12. Pulmonary Embolism CT

- Pulmonary embolism:
  - CT pulmonary angiogram (CT-PA) is the most frequently performed initial test for the diagnosis of pulmonary embolism. It allows direct visualization of the pulmonary embolus, and it also allows for the diagnosis of alternative diseases involving the lung parenchyma (pneumonia, pneumothorax, etc.). The older generation of CT-PAs may miss pulmonary emboli that involve the smaller (peripheral) pulmonary arteries.

  - *Ventilation-perfusion ($\dot{V}/\dot{Q}$)* scan is a pair of nuclear scan tests that use inhaled and injected material to measure breathing (ventilation) and circulation (perfusion) in all areas of the lung. A pulmonary embolus will typically cause perfusion defects with normal ventilation. The $\dot{V}/\dot{Q}$ scan, depending on the number of defects, is classified as normal, low probability, intermediate probability, or high probability. Patients that have any preexisting lung disease (COPD) will have at least intermediate scans, which make this test less helpful. A *normal* $\dot{V}/\dot{Q}$ scan rules out pulmonary embolus.
  - *Pulmonary angiogram* is the gold standard procedure for the diagnosis of pulmonary embolus. Its risk of complication (e.g., pulmonary artery rupture) is <1%. With the new generation of CTs able to visualize the smallest peripheral vessels, the invasive pulmonary angiogram is becoming obsolete.
- DVT: compression on duplex U/S (US); venogram (rare); MRI
- Both pulmonary embolism and DVT:
  - *D-dimer* is the most sensitive test for thromboembolic disease. Elevated D-dimer indicates the presence of an abnormally high level of fibrin degradation products, possibly because of thrombus formation and breakdown. An elevated D-dimer may be due to a thromboembolism, but it may also be due to a recent surgery, infection, trauma, pregnancy, and DIC. Normal D-dimer tests mean that there is no thrombus formation or breakdown. For the above reasons, a D-dimer can only be used to *rule out* PE or DVT if the levels are normal. Trials have shown that the D-dimer is most useful when the test is done on patients considered to be low-risk and is recommended as an adjunct test (i.e., a negative D-dimer and a normal CT-PA scan rule out thromboembolism 98% of the time).
  - There are many types of D-dimer tests with different sensitivities. The ELISA assay is the best test overall, whereas the latex agglutination test is less sensitive.

General diagnostic concepts in patients suspected of pulmonary embolism:

- It makes sense to start with a CT-PA after a chest x-ray is completed.
- Normal CT scan and normal D-dimer test in low-risk patients excludes pulmonary embolism.
- Normal CT scan and normal Doppler U/S in low-risk patients excludes pulmonary embolism.
- Even if all tests are negative for pulmonary embolism but the patient is high risk, go for the angiogram.
- If a $\dot{V}/\dot{Q}$ scan is completely normal (not near normal or low probability), the chance of pulmonary embolism is almost 0%.
- Know how to use Doppler U/S in the evaluation of pulmonary embolism. For example, if a $\dot{V}/\dot{Q}$ scan is reported as low probability, still be concerned about pulmonary embolism. An angiogram is not preferred unless absolutely necessary because it is an invasive procedure. Therefore, do an U/S of both lower extremities to look for a DVT (remember that most pulmonary emboli are complications of DVTs arising in the proximal veins).
- All patients (especially high risk) should be on anticoagulation while completing diagnostic evaluations, so start heparin before sending that patient off to the radiology department for the CT or the $\dot{V}/\dot{Q}$ scan.

Clinical Pearl

- Order CT-PA as the primary test to diagnose pulmonary embolus.
- Use $\dot{V}/\dot{Q}$ scan in patients with iodine allergy, renal insufficiency, or morbid obesity.

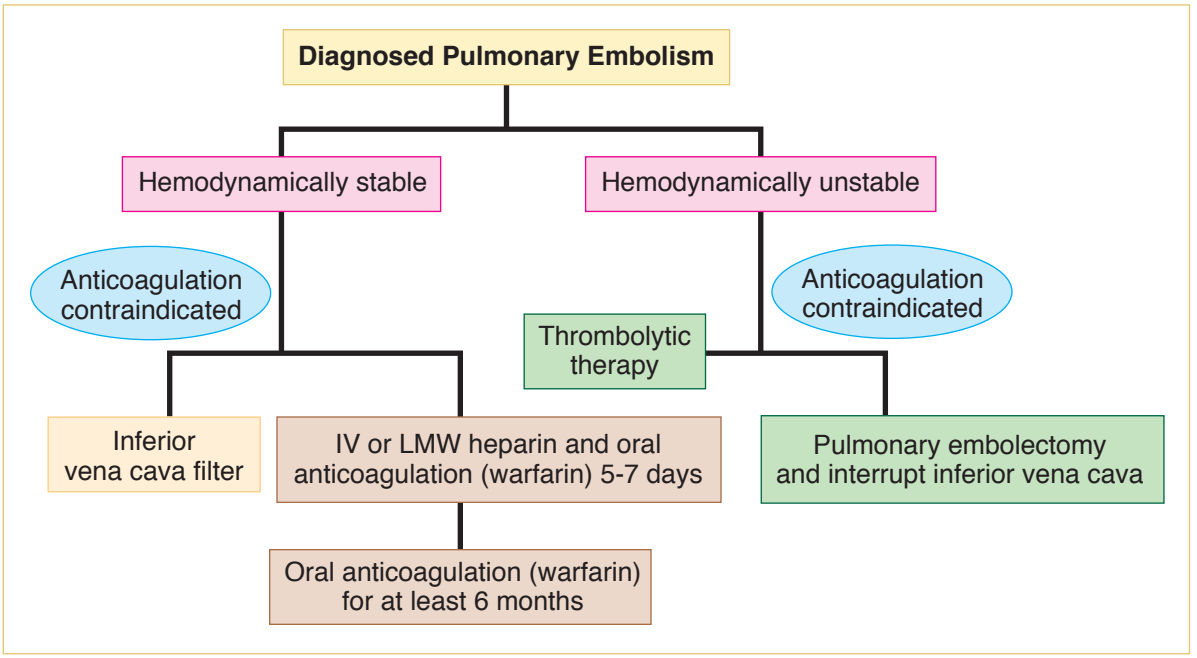


Figure 9-13. Management of Diagnosed Pulmonary Embolism

Treatment. Give oxygen and start heparin immediately before the diagnosis is confirmed and while the diagnostic workup is being completed. Once the diagnosis is confirmed:

- Heparin—LMWH or unfractionated for 5–7 days (or until INR is therapeutic)
- In most institutions, LMWH has supplanted the use of unfractionated heparin as the primary heparinoid in the treatment of PE and DVT.
- Warfarin (Coumadin®)—should be *started with heparin* and continued for 6 months for both pulmonary emboli and DVT.

LMWH or fractionated heparin inactivates factor Xa but has no effect on thrombin (no need to follow PTT). Dosing is based on patient's weight, and the effect is very predictable. The long half-life makes it ideal for a 1× or 2×/day dosing interval. Trials have shown that LMWH is as good as unfractionated heparin in the treatment of DVT and pulmonary emboli; also, LMWH is less likely to cause hemorrhage or heparin-induced thrombocytopenia (HIT).

HIT is a common complication of heparin treatment and occurs 5–7 days after starting treatment in about 5% of patients. Paradoxically, it is associated more with thrombotic events than bleeding diathesis. Always stop heparin when platelets decrease by a significant amount. Also, consider HIT in a patient with recurrent pulmonary embolism or DVT despite heparin treatment. HIT is treated with the new anticoagulants (argatroban, lepirudin).

Warfarin works by inhibiting the vitamin K–dependent factors (II, VII, IX, and X). Because factor VII has the shortest half-life of all the affected factors, prothrombin time (PT) is monitored to assess the warfarin anticoagulant effect. International normalized ratio (INR) is a way to report PT and is used to control for variability in PT between different laboratories. The warfarin dose should be titrated to an INR of 2–3 for effective anticoagulation.

Warfarin skin necrosis is a rare procoagulant effect that occurs in patients who have preexisting protein C deficiency and receive warfarin. Protein C is also a vitamin-dependent factor with a shorter half-life than factor VII. A "transient hypercoagulable state" occurs when warfarin is started in patients with subclinical protein C deficiency. This leads to diffuse thrombosis of the skin and other organs. By starting patients on heparin and warfarin at the same time, you minimize the risk for this complication.

Anticoagulation is contraindicated in patients with recent neurosurgery or eye surgery. Consider using an inferior vena cava filter (Greenfield filter) to prevent further embolism in these patients.

Warfarin is contraindicated in pregnant patients. LMWH for 6 months is the best alternative. The patient should have injections once or twice a day.

Thrombolytics (tPA, streptokinase) are not used routinely in pulmonary embolism and should be reserved for patients that become hemodynamically unstable (indicated by hypotension, right heart failure, etc.). In clinical practice, thrombolytics are sometimes also considered in patients with massive DVT to prevent the postphlebitic syndrome.

Although the available vitamin K antagonists are highly effective for the prevention and treatment of most thrombotic disease, significant patient variability in dose response, the narrow therapeutic index, and the numerous drug and dietary interactions associated with these agents have led clinicians to search for alternative agents. These new anti-thrombotic drugs have relatively discrete targets within the coagulation pathway. Two new classes of orally administered anticoagulants, inhibitors of factor X and thrombin inhibitors, have been approved for the management and prevention of venous thromboembolic disease. Rivaroxaban is a direct factor Xa inhibitor. Dabigatran is a direct thrombin inhibitor that has been approved for venous thromboembolism prophylaxis.

The postthrombotic syndrome (postphlebitic syndrome) is the most common complication of DVT, occurring in up to two-thirds of patients. It may result from some obstructions that remain in the vein or backflow of blood due to destruction of the valves or both. Signs and symptoms include pain, edema, hyperpigmentation, and skin ulceration. The use of compression stockings has been shown to prevent the postthrombotic syndrome.

Other Concepts in Treatment

- Noncomplicated proximal DVTs are usually treated for a total of 6 months.
- In patients with thrombophilias (hypercoagulable states), lifelong anticoagulation is considered with warfarin (usually reserved for at least two episodes of thrombosis).
- Do not check for protein C or protein S deficiency during acute thrombosis. Both warfarin (which the patient should be on) and acute clot formation *lower* protein C and S.
- In patients that develop recurrent thrombosis while on anticoagulants, consider HIT or cancer-related thrombosis (very resistant). Consider placing an inferior vena cava (IVC) filter or using some of the newer anticoagulant classes (e.g., hirudin derivatives). IVC filters are associated with clot formation around the filter site and may cause pulmonary thromboembolism.
- **Limited distal DVT** (below-the-knee DVT) are not themselves a cause of pulmonary embolism, unless they extend to the proximal veins. Management of distal DVT includes 2 options: monitor for possible extension to the proximal veins by using serial U/S or treat with anticoagulation for 3 months.

Fat embolism is a rare type of embolism that occurs 3 days after long bone fracture (most commonly seen with femur fracture). It may occur, although rarely, after CPR. The clinician should consider this entity with presence of acute dyspnea, petechiae (neck and axilla), and confusion. Treatment is supportive (no anticoagulation).

ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS)

A 32-year-old man is admitted to the intensive care unit with the presumed diagnosis of gram-negative sepsis. He is placed on double gram-negative antibiotic coverage and remains stable for 24 hours. The blood cultures grow pseudomonas sensitive to both ceftazidime and ciprofloxacin, which the patient has been started on. The patient seems to improve but suddenly during day 2 of hospitalization develops severe dyspnea. The examination reveals diffuse crackles; an ABG shows hypoxemia and hypercarbia. Diffuse alveolar densities are seen on chest x-ray (the admission chest x-ray was unremarkable).

ARDS is defined as an acute lung injury that is characterized by increased permeability of the alveolar-capillary membrane and pulmonary edema. It eventually leads to severe hypoxemia and decreased pulmonary compliance.

Etiology. Etiology of ARDS includes sepsis, trauma, disseminated intravascular coagulation, drug overdose, inhalation of toxins, Goodpasture syndrome, systemic lupus erythematosus, drowning, and the period after bypass surgery.

ARDS usually occurs within 5 days of the initiating event, and >50% will develop it within the first 24 hours. A major component of ARDS seems to be accumulation of inflammatory cells and their mediators.

Signs and Symptoms. Signs and symptoms of ARDS are dyspnea, increased respiratory rate, and diffuse rales and rhonchi on auscultation.

Chest x-ray findings include diffuse interstitial or alveolar infiltrates; whiteout of both lung fields may be seen. **ABGs** reveal decreased Pa_{O_2} and increased or normal Pa_{CO_2}. Swan-Ganz catheter findings will reveal normal cardiac output and normal capillary wedge pressure but increased pulmonary artery pressure.

Treatment. Treat underlying disorder. Mechanical support with increased positive end-expiratory pressure and permissive hypercapnea. Studies have shown that conservative fluid replacement decreased ICU and ventilatory time but mortality remained unchanged. Steroid use is controversial.

Prognosis. Mortality rates are approximately 50%.

Clinical Pearl

Chronic elevation of serum bicarbonate may be seen in patients with sleep apnea. This is a response to respiratory acidosis.

SLEEP APNEA

Sleep apnea is defined as the cessation of airflow (>10 s) that occurs at least 10–15x per hour during sleep. Oxygen saturation decreases during those apneic episodes, and pulmonary pressures increase.

Daytime somnolence is mandatory for the diagnosis of sleep apnea. Other manifestations include daytime headaches and fatigue. Systemic hypertension also occurs. When severe, sleep apnea will cause pulmonary hypertension and cor pulmonale.

The diagnosis of sleep apnea is based on evaluation of clinical symptoms (daytime sleepiness, fatigue, sleep diary findings, and the results of objective testing with polysomnography.

There are 2 main classes of sleep apnea:

- **Obstructive** sleep apnea (OSA) occurs because of floppy airways despite adequate ventilatory effort. Patients are usually obese and have abnormal airways. Treatment is weight loss and nasal continuous positive airway pressure (CPAP). When noninasive measures are not effective, surgical procedures (uvuloplasty) may be considered.
- **Central** sleep apnea (<5%) is caused by inadequate ventilatory drive. Treatment includes conservative measures (weight loss; avoidance of alcohol, sedatives, and sleep deprivation), acetazolamide, progesterone, and supplemental oxygen.

LUNG CANCER

Bronchogenic Carcinoma

A 65-year-old man is admitted because of headache and blurry vision the past few days. In the emergency room the physicians also notice that he has neck vein distension and darker coloration over his face and neck. He is confused. Chest x-ray reveals a right upper lobe lung mass, and blood tests indicate significant hypercalcemia.

Bronchogenic carcinoma is the leading cause of death because of malignancy in men and women. The overall 5-year survival rate for small cell cancer is 5% and non-small cell cancer is 8%.

Etiology. Ninety percent of cases of bronchogenic carcinoma are directly related to cigarette smoking in both men and women. The occasional nonsmoker who has lung cancer develops adenocarcinoma.

Smoking is the major cause of lung cancer. Active smokers have a 10× greater risk compared with nonsmokers. The risk is directly related to the number of pack-years (40-pack-year history increases risk 60–70×). Asbestos exposure increases the risk of bronchogenic carcinoma 75× that in the nonexposed normal patients.

All lung cancers are associated with smoking.

There is no available screening test for lung cancer at this time.

Pathology. The most common lung cancers are adenocarcinoma (~40% in some studies) and squamous cell carcinoma.

- **Adenocarcinoma.** Adenocarcinoma is a peripherally located lesion. This lesion metastasizes widely to essentially the same sites as small-cell carcinoma. Bronchioalveolar carcinoma is a subtype of adenocarcinoma; it is a low-grade carcinoma that can occur in single or multiple nodules. Asbestos exposure can be an underlying causative agent,

usually after a latent period of 30 years. Adenocarcinoma is usually associated with pleural effusions that have high hyaluronidase levels. Diagnosis often requires thoracotomy with pleural biopsy.

- **Squamous Cell Carcinoma.** Squamous cell carcinoma is a centrally located lesion. It is associated with cavitary lesions. Squamous cell carcinoma usually metastasizes by direct extension into the hilar node and mediastinum. These lesions are associated with hypercalcemia from the secretion of a parathyroid hormone–like substance.
- **Small-Cell Carcinoma.** Small-cell carcinomas are centrally located lesions. These tumors are rapidly growing with early distant metastasis to extrathoracic sites such as liver, adrenal glands, brain, and bone. Prognosis does not improve with early diagnosis. Small-cell carcinoma is associated with Eaton-Lambert syndrome, syndrome of inappropriate antidiuretic hormone, and other paraneoplastic syndromes. Small-cell carcinoma is also the most common cause of venocaval obstruction syndrome.
- **Large-Cell Carcinoma.** Large-cell carcinoma is a peripherally located lesion. This carcinoma can metastasize to distant locations late in the course of disease. Large-cell carcinoma in early stages is associated with cavitation.

Symptoms. The most common symptom at the time of diagnosis is cough (74%). Weight loss is seen in 68% of patients. Dyspnea is seen in 58% of patients. Other associated symptoms of bronchogenic carcinoma include hemoptysis, chest wall pain, and repeated pneumonic processes (caused by postobstructive pneumonia).

Hoarseness when seen indicates a nonresectable bronchogenic carcinoma.

Diagnosis. The diagnosis of bronchogenic carcinoma can be made by sputum cytology, with the highest yield in patients with squamous cell carcinoma (>80%) because it is intraluminal and centrally located. Bronchoscopy is best for centrally located lesions (yield of 90%) and is helpful in staging. For the 10% of centrally located lesions not detected by bronchoscopy, a needle aspiration biopsy should be performed if carcinoma is highly suspect. In other words, if there is a high degree of suspicion for carcinoma and the bronchoscopy results are nonspecific, a biopsy must be requested. Needle aspiration biopsy is also good for peripheral nodules with pleural fluid aspirate (positive in 40–50% of cases). Mediastinoscopy is useful in diagnosing and staging mediastinal tumors.

- **Workup of a chest x-ray with an effusion and a lung mass.** 90% of tumors with malignant effusions are unresectable. These tumors are usually adenocarcinomas. Atelectasis on chest x-ray suggests central airway obstruction. Next step in such a patient is to do thoracocentesis and cytologic evaluation of the pleural fluid.

Treatment. Symptoms that suggest an unresectable lesion include weight loss >10%, bone pain or other extrathoracic metastases, CNS symptoms (treated by radiation or chemotherapy), superior vena cava syndrome, hoarseness, mediastinal adenopathy on the contralateral side, split-lung test tidal volume <800 ml, tumor classification of M1 within 3 months, and tumor involving the trachea, esophagus, pericardium, or chest wall.

Resectable lesions of small-cell carcinoma are treated with chemotherapy; VP16 (etoposide and platinum) is the treatment of choice. Surgery is not indicated for these lesions. Non-small- cell lesions that are resectable are treated with chemotherapy and radiation therapy or CAP (cyclophosphamide, adriamycin, and platinum). Effusions can be sclerosed with tetracycline. Complications are treated with radiation therapy, which in most cases is palliative.

Prognosis. Prognosis is best after surgical resection of squamous-cell carcinoma (30–35%). Large-cell carcinoma and adenocarcinoma have a prognosis of 25%. Prognosis is poorest for small-cell carcinoma.

Recommendation for **lung cancer screening** are as follows (see also Preventive Medicine section):

- In cases where >30 pack-years of smoking, patients age 55-80 should receive lung cancer screening with **low dose CT** (non-contrast). The patient has to be a current smoker or has quit >15 years.
- In cases where patients age >80, quit >15 years, has other medical problems such as severe COPD which significantly limits life expectancy or ability to undergo surgery, **no screening** is recommended.

ATELECTASIS

A 62-year-old man is dyspneic 24 h after cholecystectomy. His respiratory rate is 22/min and pulse 112/min. He has a mild fever, and decreased breath sounds are noted in the left lower lobe. Complete blood count shows leukocytosis 27,000/mm^3.

Definition. A collapse of part or the entire lung. It is seen most commonly in the immediate postoperative period. It occurs secondary to poor inspiration or lack of coughing during this time. A mucous plug, tumor, or foreign body can also lead to atelectasis.

Signs and Symptoms. Acute symptoms include tachycardia, dyspnea, fever, and hypoxemia. In the chronic phase patients may be asymptomatic with only x-ray abnormalities. On x-ray, upper lobe atelectasis can appear as tracheal deviation to the affected side. This phenomenon occurs secondary to volume loss from atelectasis. Lower lobe atelectasis may cause an elevation of the corresponding part of the diaphragm. In massive atelectasis, a mediastinal shift to the involved side can be seen. The atelectatic lobe will appear to be densely consolidated and smaller than the normal lobe on x-ray.

Treatment. In the postoperative phase, it is important to induce deep breathing and stimulate coughing. Incentive spirometry and pulmonary toilet are effective. Bronchoscopy with subsequent removal of mucous plugs is highly effective for spontaneous atelectasis.

ANSWERS TO QUESTIONS THROUGHOUT CHAPTER

Pg. 307

Patient 1a—chronic bronchitis or asthma

Patient 1b—emphysema

Patient 2a—extrapulmonary restriction (e.g., kyphoscoliosis, morbid obesity)

Patient 2b—interstitial lung disease

Pg. 309

Clinical problem—overdose from opiates (any scenario in which the respiratory rate is decreased)

Pg. 319–320

What is the treatment of choice in this patient? bronchodilator: albuterol; systemic corticosteroids (usually start IV) and oxygen. Remember, long-acting bronchodilators are contraindicated in the acute setting.

What are bad prognostic indicators in this patient? cyanosis, silent lung, increase in CO_2

Which one of the ABGs below…? The first ABG with CO_2 of 45 is the worst.

Three days after hospitalization…What is her drug regimen...? oral prednisone taper, albuterol inhaler, steroid inhaler

What will you do now? What medications is she likely to be taking now? She should have a PFT to document asthma, and her basic asthma regimen should be inhaled steroids daily and albuterol inhaler as needed.

Pg. 322

After a bronchodilator is given, you would expect the FEV_1/FVC to remain the same or improve minimally.

Pg. 325

What are you likely to find…? decreased DLCO

How will you treat…? systemic steroids, antibiotics, and bronchodilators; O_2 as needed

What are your treatment options…? ipratropium inhaler, home O_2

She asks you to…what will you consider now? measure FEV_1

Pg. 326

How would you treat this patient? antipseudomonal antibiotics (ciprofloxacin, ceftazidime)

What investigations will you consider…? chloride test to diagnose cystic fibrosis

Emergency Medicine 10

Learning Objectives

- ❑ List the steps to follow in basic life support (cardiopulmonary resuscitation)
- ❑ Interpret ECG strips to diagnose cardiac dysrhythmias and present the appropriate emergency management
- ❑ Answer questions about principles of toxicology and initial management with specific management for poisoning or overdose with acetaminophen, various alcohols, carbon monoxide, caustics, corrosives, digoxin, heavy metals, salicylates, tricyclic antidepressants, anticholinergic agents, organophosphates, and drugs of abuse
- ❑ Describe direct and indirect complications and emergency management of acute/chronic alcohol use
- ❑ Describe the emergency management of head trauma, anaphylaxis, subarachnoid hemorrhage, burns, radiation injuries, electrical injuries, drowning, and venomous bites/stings

BASIC LIFE SUPPORT (CARDIOPULMONARY RESUSCITATION)

A 54-year-old man is at the opera when he suddenly jumps up and clutches his chest. He falls to his side into the lap of the woman sitting next to him.

Definition. The initial management algorithm of any patient who seems to have become unresponsive.

Etiology. A cardiac, neurologic, or toxicologic event leading to markedly diminished responsiveness or loss of pulse. Most causes of cardiac arrest are related to ventricular rhythm disturbance. The most common etiology of serious cardiac dysrhythmia is ischemia-related, particularly with coronary artery disease or another cardiac anatomic abnormality (especially cardiomyopathy).

Clinical Presentation. Any patient with diminished responsiveness that is usually sudden in onset.

Diagnosis. This is a clinically determined diagnosis at first. The initial step is, in fact, to assess the responsiveness of the patient to make sure that he is truly unresponsive and not just asleep. This is accomplished by calling to or gently shaking the patient. Be careful about shaking a patient who might have serious traumatic injury, particularly of the cervical spine.

Treatment. After determining that the patient is truly unresponsive, the next step is to call for help (dial 911). Although it is natural to reach down to check a pulse, this is not the action that the USMLE or the American Heart Association (AHA) wants you to build as a reflex. Without the EKG, defibrillator, and cardiac medications you need, there is very little that one or even two rescuers can do for a patient with a serious dysrhythmia beyond chest compressions and opening the airway.

If a patient has a serious dysrhythmia such as asystole or ventricular fibrillation, there is virtually no survival if the heart has not been restarted within 10 minutes. Chest compressions just perfuse vital organs; they will not convert the arrhythmia back to normal sinus.

AHA guidelines emphasize the following:

- High-quality CPR with uninterrupted chest compressions of adequate depth (5 cm, 2 in.) at a rate of 100/min
- Decreased intervals between stopping the chest compression and shock delivery

Avoid excessive ventilation because it can be detrimental. ABC, according to new guidelines, is now **CAB** (excluding newborns). Removing the 2 rescue breaths allows chest compressions to be delivered sooner. Earlier chest compressions and defibrillation are critical elements of CPR.

- Do look, listen, feel for breathing.
- Do check for pulse (for 10 seconds); if you establish that there is no pulse, start chest compressions (after calling 911).
- Do not give rescue breaths first, as that has been shown to delay vital chest compressions, which leads to an increase in mortality.
- Do not perform jaw thrust, which just delays chest compression.

After calling for help, position the patient on a firm, flat surface, and roll the patient so that he or she is face up. Check to see if there is a pulse by feeling for at least 5-10 seconds at the carotid artery. If there is no pulse, perform chest compressions at a rate of 100 per minute, "push hard and push fast." In adults, provide 30 compressions and then 2 ventilations, regardless of whether one or two rescuers is present. In children, perform 30 compressions and 2 ventilations if one rescuer is present, and give 15 compressions and 2 ventilations if two rescuers are present. Depth of chest compression is 2 in. or 5 cm.

Advanced Cardiac Life Support Algorithms

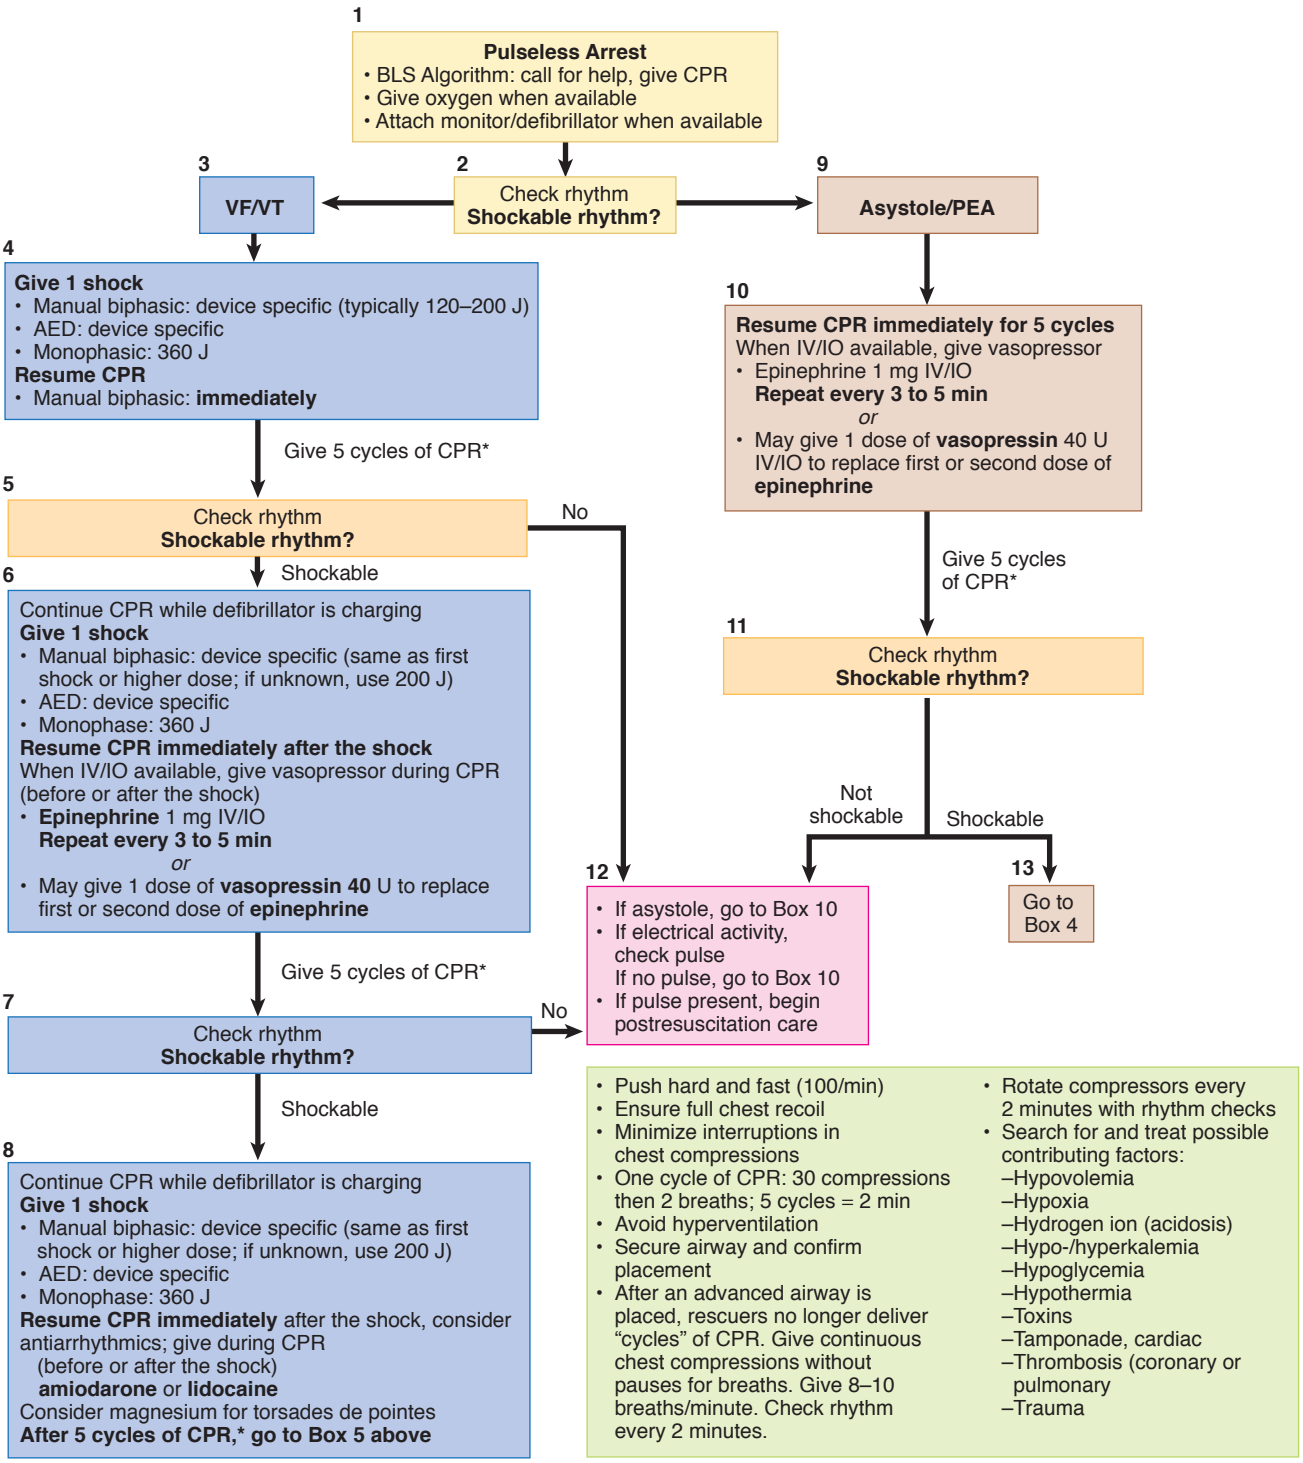

Figure 10-1. ACLS Pulseless Arrest Algorithm

CARDIAC DYSRHYTHMIAS

Management of Specific Cardiac Dysrhythmias

Asystole

A 54-year-old man is at the opera when he suddenly jumps up and clutches his chest. He falls to his side into the lap of the woman sitting next to him. After confirming that he is unresponsive, a nearby physician performs chest compressions and ventilations. An EKG is done and reveals no evidence of electrical activity.

Definition. The complete absence of electrical activity in the heart. This does not necessarily mean a completely flat line on an EKG because there may be slight variability on the rhythm strip.

Etiology. Ischemia and severe underlying cardiac disease most commonly underlie asystole. Other possible etiologies include metabolic derangements, drug overdose, trauma, and others.

Clinical Presentation. An unresponsive person with asystole on EKG; person has no pulse.

Diagnosis. Asystole should always be confirmed by observing the rhythm in more than one lead on the EKG.

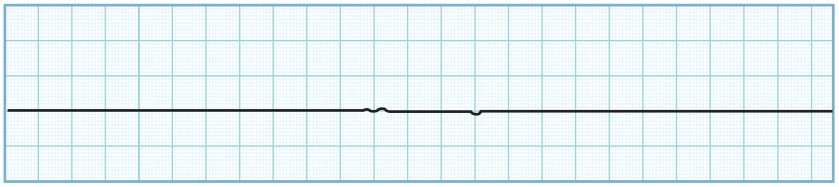

Figure 10-2. Asystole

Treatment. As you continue cardiopulmonary resuscitation (CPR), obtain IV access and prepare the patient for intubation.

1. Transcutaneous pacing should be considered and performed only for very slow bradycardia. Perform it as early as possible. Pacing is not for asystole.
2. Next, administer 1 mg epinephrine via IV push every 3–5 minutes. (**Atropine is no longer recommended for asystole.**)
3. If asystole persists, withhold resuscitative efforts in order to evaluate the presence of atypical clinical features or cease-effort protocol.

When you see asystole on the monitor, make sure of the following:

- There are no loose or disconnected leads
- The power to ECG machine and monitor is on
- There is not a low signal gain on the monitor

Note

For asystole and other arrhythmias in this chapter, remember the "Hs and Ts":

Hypoxia
Hyper/Hypokalemia
Hypothermia
Hypoglycemia
Hypovolemia
Trauma
Toxins (including overdose)
Tamponade
Tension pneumothorax
Thrombosis (coronary and pulmonary)

Note

Atropine is no longer indicated in asystole.

Note

Transcutaneous pacemaker is not useful for asystole.

Note: Bicarbonate is useful if the cause of asystole is attributed to a preexisting acidosis (except hypercarbic acidosis), tricyclic antidepressant overdose, aspirin overdose, hyperkalemia, or diabetic ketoacidosis.

Ventricular fibrillation

A 54-year-old man is at the opera when he suddenly jumps up and clutches his chest. He falls to his side into the lap of the woman sitting next to him. He is not breathing. After confirming that he is unresponsive, a nearby physician performs chest compressions and ventilations. An EKG is done and reveals ventricular fibrillation. He has no spontaneous respirations.

Definition. Significant electrical activity on EKG with no signs of an organized pattern.

Etiology. Ischemia, myocardial infarction, cardiomyopathy, and severe underlying cardiac disease most commonly underlie ventricular fibrillation. Remember the "Hs and Ts."

Clinical Presentation. A dead person with ventricular fibrillation on EKG.

Diagnosis. Entirely based on the EKG.

Treatment. The differences between defibrillation and cardioversion are very important.

- **Defibrillation** is a nonsynchronized delivery of shock at any phase of cardiac cycle. It is used in VF and pulseless VT. During defibrillation you depolarize all of the myocytes simultaneously, hoping that the SA node will start up normal sinus rhythm.
- **Cardioversion** means that the shock is synchronized with the QRS complex. When performing cardioversion, the defibrillator will not shock until the QRS complex appears. You will be able to see spikes over the QRS complexes on the monitor. If you shock on the T wave, when ventricular repolarization is taking place, you may induce VF.

Make sure that the SYN button is pushed when performing cardioversion. Use UNsynchronized shock (defibrillation) for VF or pulseless VT only.

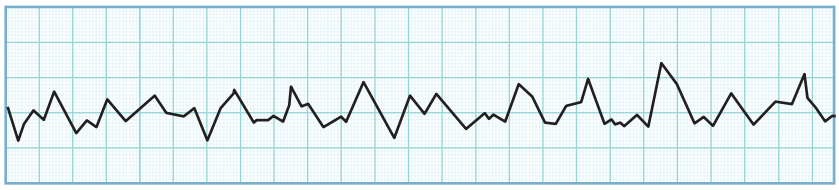

Figure 10-3. Ventricular Fibrillation

Post-Resuscitation Care. Most patients who survive resuscitation have anoxic brain injury. Hypothermia protocol reduces the risk of this type of severe neurologic injury. If a patient is not following commands or showing purposeful movements, the hypothermia protocol should be used. The goal of protocol is to reach core temperature 32–34° C (90–93° F) within 6 hours and maintain for 12–24 hours. Absolute contraindications for induced hypothermia are active bleeding and do-not-resuscitate order.

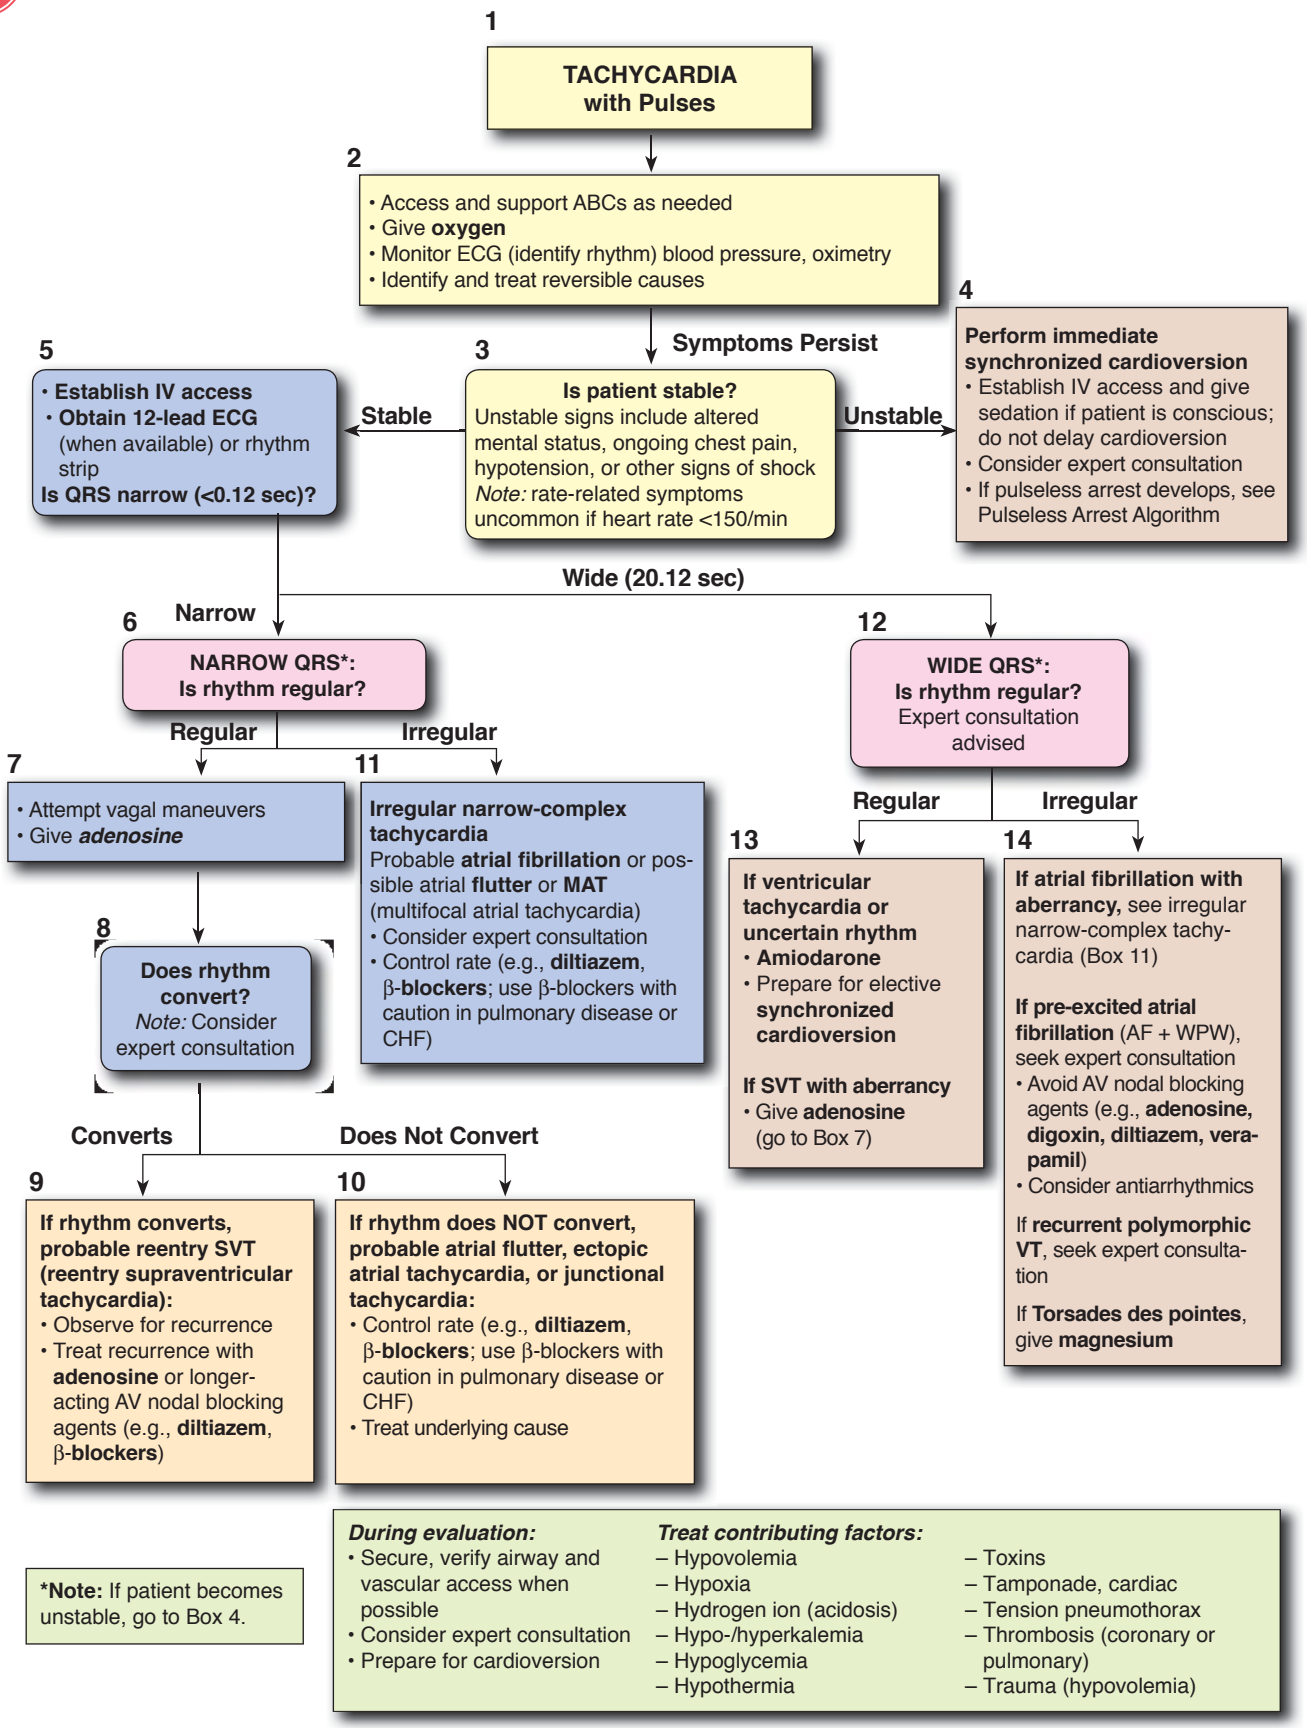

Figure 10-4. Algorithm for Tachycardia with Pulses

Ventricular tachycardia

A 54-year-old man is at the opera when he suddenly jumps up and clutches his chest. He falls to his side into the lap of the woman sitting next to him. He is awake but disoriented and confused. He is complaining of dyspnea and lightheadedness. His exam reveals jugulovenous distention and a blood pressure of 114/80. The EKG shows ventricular tachycardia at a rate of 180.

Definition. A wide complex tachycardia with an organized, uniform pattern on the EKG. There are no P-waves visible.

Etiology. Ischemia, myocardial infarction, and anatomic cardiac disease most commonly underlie VT. Other possible etiologies include quinidine, tricyclics, and phenothiazines. Long QT syndromes also cause VT. The dysrhythmia originates from an ectopic focus in the myocardium or from the AV node. When the impulse originates from around the AV node, this is from reentry. The electrical impulses must travel throughout the myocardium from myocyte to myocyte without the benefit of the more rapidly conducting normal pathways, such as the bundle branches or the His-Purkinje fibers.

The slowness of the conduction produces the slower and therefore wider complexes on the EKG. The rate most often varies 160–240/min. Torsade de pointes is a form of VT in which the morphology varies with an undulating amplitude, making it seem that it "twists around a point." Torsade may be associated with hypomagnesemia and preceded by long QT interval.

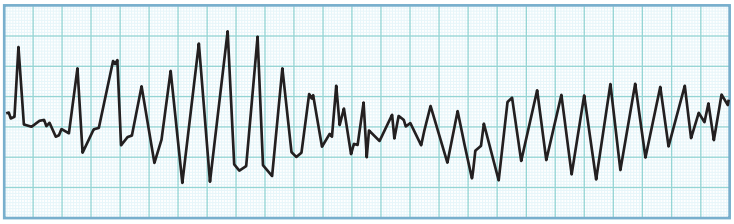

Figure 10-5. Torsade

Clinical Presentation. Symptoms are often related to duration of the dysrhythmia. Short bursts of a few seconds may produce no symptoms at all. VT lasting >30 seconds is referred to as sustained VT. Symptoms include lightheadedness, hypotension, CHF, syncope, and death.

Diagnosis. The EKG shows the VT. For those patients presenting with syncope suspected to be of cardiac origin and in whom an arrhythmia is not visible on the initial EKG, an electrophysiologic study can be done to try to elicit the VT.

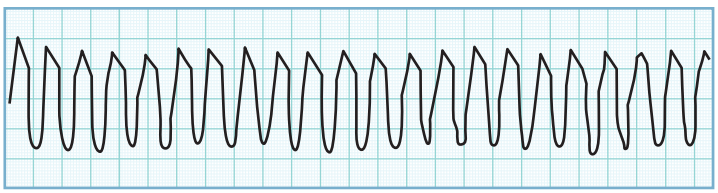

Figure 10-6. Ventricular Tachycardia

Note

Medications that prolong QT interval

TCAs
Antipsychotics
Erythromicin
Methadone
Fluoroquinolones
Amiodarone
Quinidine
Sotolol
Flecainide
Procainamide

Causes of prolonged QT and Torsade

Mg
K
Ca

Note

Amiodarone is superior to lidocaine for VF/VT.

Note

Management of VT without hemodynamic instability

1. Amiodarone
2. Lidocaine
3. Cardioversion

Note

For systolic dysfunction, the only antiarrhythmics that are safe are amiodarone, lidocaine, and dofetilide.

Treatment. For those with sustained VT and a pulse who are hemodynamically unstable, immediate synchronized cardioversion is required. Signs of hemodynamic instability requiring cardioversion include hypotension, chest pain, altered mental status, and CHF. A lower dose of electricity, starting at 100 J, can be used at first for monomorphic VT. The cardioversion should be synchronized. Conscious patients should be sedated with midazolam, fentanyl, or morphine before cardioversion.

VT in those patients without a pulse should be managed in the same way as ventricular fibrillation (unsynchronized shock). Stable VT (wide, monomorphic, regular) without serious hemodynamic compromise can be treated medically with adenosine initially and then with antiarrhythmics if no response. In stable patients with pulse, procainamide and sotalol are preferred drugs. If there is no response to procainamide, then amiodarone may be tried, followed by lidocaine and finally electrical cardioversion.

Magnesium may be useful in general but it is most useful for Torsade de pointes. If magnesium fails to treat Torsade, then isoproterenol or lidocaine can be attempted. Overdrive pacing can be used if pharmacologic treatment fails. Patients undergoing cardioversion should be sedated first with midazolam, fentanyl, or morphine. Long-term therapy is most effective with beta-blockers. VT that produces sudden death or VT that is sustained through initial drug therapy may require the placement of an implantable cardiac defibrillator (ICD). All patients with ejection fraction <35% should have ICD, due to increased risk of VT and VF.

Pulseless electrical activity

Definition. Hypotension to the point of losing one's pulse; there is still some type of electrical activity on the EKG that may even be normal or a simple tachycardia.

Etiology. More than the other dysrhythmias, knowing the etiology of pulseless electrical activity (PEA) is the key to the therapy because the specific therapies are so divergent. Essentially, the heart may still be beating, but there is no blood in the heart, and therefore there is no cardiac output. Examples of this type of PEA are severe hypovolemia, cardiac tamponade, tension pneumothorax, massive pulmonary embolism, and a massive myocardial infarction. Other types of PEA in which there may not be actual muscular contraction are hypoxia, hypothermia, potassium disorders, acidosis, and drug overdoses with tricyclics, digoxin, beta-blockers, or calcium-channel blockers.

Clinical Presentation. The patient appears to be dead with no pulse. Other symptoms are based on the specific nature of what led to the PEA, such as those described above.

Diagnosis. A pulseless patient who has significantly organized, and occasionally normal, activity on the EKG.

Treatment. The most important action is to maintain CPR while determining the specific origin of the PEA. General therapy includes CPR, IV access, intubation, and epinephrine. Do not shock PEA arrest. The most important therapy is repair of the cause (possibilities described above). Bicarbonate is useful if a known acidosis has caused the arrest; it can also be used in a prolonged resuscitation if severe lactic acidosis develops and causes the refractory state of arrest. Pericardiocentesis may be attempted if all else fails.

Atrial dysrhythmias

A 24-year-old medical student is brought to the emergency department because of palpitations. He has been studying vigorously for the USMLE Step 2 exam and has been up for the last 24 hours. He has had 5 cups of coffee, 4 beers, 3 stimulant tablets, 2 cheeseburgers, and 1 Viagra. An electrocardiogram reveals an atrial dysrhythmia.

Definition. A-fib, atrial flutter, and SVT are all characterized by either an ectopic focus in the atrium or re-entry at the AV node. All have normal conduction in the ventricular myocardium once the impulse successfully passes the AV node and travels down the normal ventricular conduction system. They all have a normal or narrow QRS complex and the absence of a normal P-wave.

Etiology. A-fib is most commonly caused by chronic hypertension, but it can be caused as well by valvular heart disease (most often mitral valve pathology), left ventricular hypertrophy, cardiomyopathy, atrial fibrosis, atrial dilation, CAD, and CHF. Another cause is toxicity causing overstimulation of the heart, i.e., hyperthyroidism, pheochromocytoma, caffeine, theophylline, alcohol, and cocaine. Drug toxicity (such as digoxin), pericarditis, pulmonary embolism, surgery, chest wall trauma, or ischemia can also cause atrial dysrhythmias.

SVT is caused by a re-entrant mechanism around or within the AV node.

Clinical Presentation. Symptoms vary on the basis of the duration of the disorder, the ventricular rate, and the underlying health of the heart. With a normal heart, only 10-20% of cardiac output is directly derived from the contribution of atrial systole. With a dilated or postinfarction heart, or with significant valvular disease, this contribution may rise to 30-40%, in which case more severe symptoms arise. Symptoms range from complete absence to palpitations to lightheadedness, hypotension, disorientation, CHF, and syncope. Rate-related symptoms are unlikely in those with heart rate <150 per minute in atrial dysrhythmias.

Narrow complex tachycardia is always atrial in origin (QRS <0.12). Wide complex tachycardia can be atrial or ventricular. For example, it is very difficult to distinguish A-fib in the presence of LBBB and VT. The key is that in A-fib with LBBB, the rate is irregular on EKG, whereas in VT it is regular. If in doubt, treat as VT.

Diagnosis. Initially, the diagnosis is based entirely on the EKG. Other patients may need a 24-72 hour Holter monitor to detect brief paroxysms of the dysrhythmia not seen on the initial brief EKG.

Figure 10-7. Normal Sinus Rhythm

Note

For the exam, you will need to know atrial fibrillation (A-fib), atrial flutter, and supraventricular tachycardia (SVT). They are discussed as a group because the initial management has considerable overlap.

Note

- Narrow complex tachycardia is *always* atrial in origin (QRS <0.12).
- Wide complex tachycardia can be atrial or ventricular in origin.

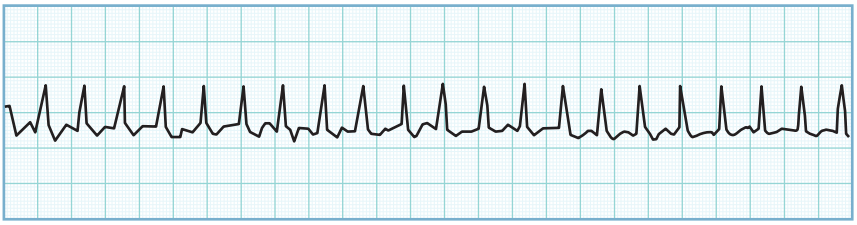

Figure 10-8. Atrial Tachycardia

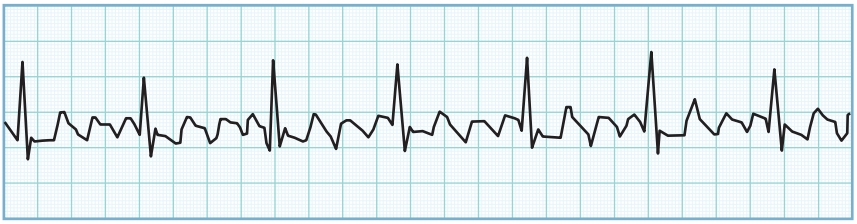

Figure 10-9. Atrial Flutter

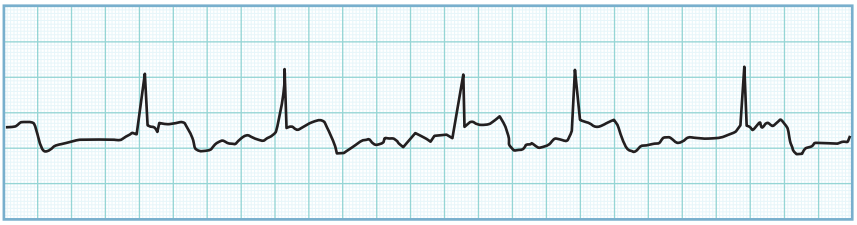

Figure 10-10. Atrial Fibrillation

Treatment. Initial therapy is based on whether there are signs or symptoms of severe hemodynamic compromise, such as hypotension, confusion, CHF, or chest pain. If these are present, then immediate synchronized cardioversion is performed. Palpitations and lightheadedness are not signs of hemodynamic compromise. If the patient is hemodynamically stable, then the first step is to control the ventricular rate. Vagal maneuvers such as carotid sinus massage, Valsalva, or ice water immersion are most effective in SVT. Do not do carotid sinus massage bilaterally. Avoid carotid massage in those with carotid bruits. If vagal maneuvers do not work, SVT is initially treated with several rapid IV infusions of adenosine. For atrial fibrillation, atrial flutter, and in SVT after the failure of adenosine, several therapies are available to slow the heart rate. These include calcium-channel blockers (such as diltiazem or verapamil), beta-blockers, or digoxin. Do not use verapamil in those with severe left ventricular dysfunction and low ejection fractions and beware of using beta-blockers in those with a history of reactive airway disease.

After the rate has been lowered to <110 beats/min, conversion of the rhythm to normal sinus does not need to be routinely done. Chronic rate control with anticoagulation with warfarin to an INR of 2–3 is superior to converting the patient into sinus rhythm. Returning the patient to a normal sinus rhythm is preferable because chronic atrial fibrillation can result in embolic stroke in 5-7% of patients per year.

Amiodarone, ibutilide, propafenone, and dofetilide can all convert a minority of patients to sinus rhythm. At the level of Step 2, you will not need to know much about the specific indications for each. You do, however, need to know that elective cardioversions should be preceded and followed by several weeks of anticoagulation with coumadin.

Rate Control vs. Rhythm Control. When patients present in A-fib with rapid ventricular response, hemodynamic stability must first be determined. If they are hemodynamically stable, they should be rate-controlled with AV nodal blocking agents. If they are unstable, immediate synchronized cardioversion is required. With long-term management, rate control and anticoagulation are preferred over rhythm control. **Rhythm control** should be considered in the following situations:

- Symptomatic patients on rate control (poor exercise tolerance)
- Younger patients with normal heart structure and function
- Patients that are unable to be rate controlled with AV nodal blocking agents

It is very difficult to keep patients with structural heart disease in normal sinus rhythm. Several studies have shown an increase in overall mortality with rhythm control. Catheter-directed ablation of the AV node or accessory pathway may also be used when pharmacological treatment fails to control rate.

The rate control goal is 60–80 bpm at rest and 90–115 bpm with moderate exercise. Medications that might be used for **rate control** are diltiazem, beta-blockers, verapamil, or digoxin. Most patients require combined therapy. B-blockers with digoxin have been shown to be the best combination. Digoxin should be used for rate control in patients with CHF first; amiodarone can be used as second-line therapy. B-blockers should be started with caution in CHF patients once they are euvolemic on exam.

Agents for chemical cardioversion in A-fib: amiodarone, dofetilide, flecainide, ibutilide, propafenone. In CHF patients, use amiodarone and dofetelide.

Agents for maintaining sinus rhythm: flecainide, propafenone, sotalol, dofetilide, and amiodarone. To maintain normal sinus rhythm in CHF patients, use only amiodarone or dofetilide. In patients with coronary artery disease, dofetilide and sotalol are superior to amiodarone.

The $CHADS_2$ score is used to determine if a patient with non-valvular A-fib needs anticoagulation.

$CHADS_2$ Score	Treatment
0	Give aspirin
1	Give aspirin or anticoagulation
≥2	Give anticoagulation

Dabigatran is an oral direct thrombin inhibitor that has been shown to reduce the incidence of ischemic stroke compared to warfarin, with similar rates of bleeding. Rivaroxaban is an oral factor Xa inhibitor. For anticoagulation, you can use coumadin, dabigatran, or rivaroxaban. Apixaban, another oral factor Xa inhibitor, may be used instead of coumadin for stroke prophalaxis in patients with atrial fibrillation and a high risk of stroke ($CHADS_2$ score of 2 or higher). All 3 drugs—dabigatran, rivaroxaban, and apixaban—lead to similar or lower rates

Note

A-fib Plus Flutter

- For patients with A-fib and flutter, give rate control treatment along with anticoagulation (aspirin, warfarin, etc).
- When warfarin is used, optimal INR therapeutic range should be 2.0–3.0.

Note

$CHADS_2$ RISKS

CHF

HTN

Age >75

Diabetes mellitus

Stroke (gives 2 points)

both of ischemic stroke and major bleeding compared to coumadin; there is no need for monitoring INR.

Important additional advantages of these newer agents include convenience (no requirement for routine testing of the international normalized ratio), a small reduction in the risk of intracranial hemorrhage, and less susceptibility to dietary and drug interactions.

Disadvantages include lack of an antidote and the potential that new side effects may be seen over time.

Note

Patients with A-fib and thyrotoxicosis always get anticoagulation until euthyroid and back in NSR.

For patients undergoing elective cardioversion, first determine if they have been in A-fib for >48 hours. If they have, there are 2 options:

- Transesophageal echo can be done to exclude a clot; then, cardioversion (electrical or chemical). Cardioversion should be followed by 6 weeks of coumadin.
- Coumadin can be administered for 3 weeks before electrical or chemical cardioversion. Cardioversion should be followed by another 6 weeks of coumadin.

It is very difficult to maintain patients with structural heart disease in NSR, and most convert back into atrial fibrillation. Atrial flutter is managed the same way as atrial fibrillation.

For patients in A-fib with Wolff-Parkinson-White syndrome, administration of drugs which slow AV node conduction (Ca-channel blockers, digoxin) is strongly contraindicated as they can induce VT. Procainamide, ibutilide, flecanide, or amiodarone can be used in such cases.

If none of the medications described above can successfully convert the patient to a normal sinus rhythm, then elective electrical cardioversion can be attempted. This too must be preceded and followed by several weeks of anticoagulation if the A-fib has been present for >48 hours. Transesophageal echo can be done to exclude a clot and allow the cardioversion without preconversion anticoagulation. Neither medical nor electrical cardioversion can permanently maintain the majority of patients on sinus rhythm. Most convert back into atrial fibrillation.

Bradycardia

A 48-year-old manager comes for advice about vaccinations and travel medicine before traveling to a far-off land. He feels well and has no symptoms. He takes no medications. On examination you find a blood pressure 118/76 mm Hg and pulse 40/min.

Definition. A slow heart with a rate <60 beats/min.

Etiology. Sinus bradycardia can be a normal phenomenon, particularly in trained athletes. Medications such as beta-blockers can also give a sinus bradycardia without serious sequelae. Symptomatic sinus bradycardia from sinus node disease can be from degeneration of the node or from ischemia. More serious types of bradycardia can be from Mobitz type II second-degree heart block and third-degree (complete) heart block. These can occur secondary to ischemic damage of the AV node. Other causes are myocarditis, infiltrative disease, such as amyloidosis or sarcoidosis, or neoplasms.

Clinical Presentation. This can range from the lifelong absence of symptoms to severe symptoms of hypotension and decreased cardiac output.

Diagnosis. EKG

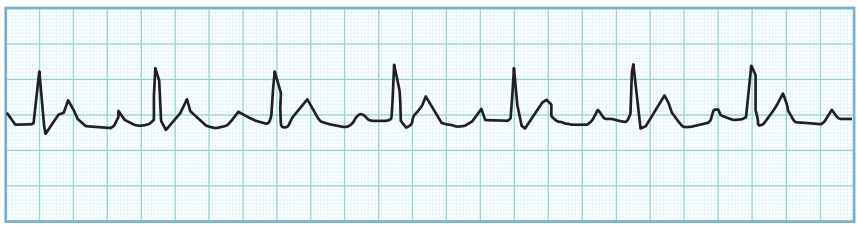

Figure 10-11. First-Degree Heart Block

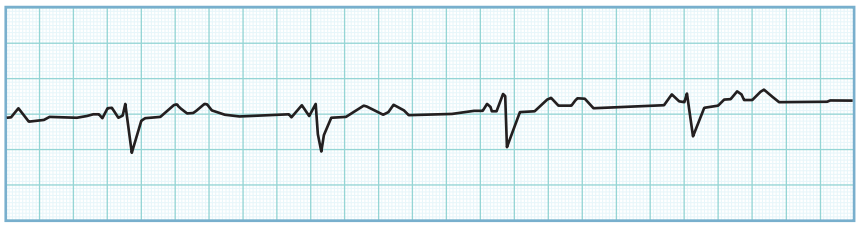

Figure 10-12. Second-Degree Heart Block

Figure 10-13. Complete Heart Block

Treatment. Asymptomatic sinus bradycardia, first-degree AV block, and Mobitz type I (Wenckebach) second-degree AV block often need no specific therapy. Any form of severe symptomatic bradycardia is treated initially with atropine and then a pacemaker, if there is no improvement in symptoms.

Mobitz type II second-degree block and third-degree block require the placement of a pacemaker, even in the absence of symptoms. Dopamine or epinephrine is used to improve blood pressure if there is still hypotension after the use of atropine.

For symptomatic sinus bradycardia, treatment is atropine. If atropine fails, then use transcutaneous pacing.

Note

Mobitz type I second-degree block is characterized by *progressive* P-R lengthening, whereas in Mobitz-type II, the P-R interval remains constant.

Note

Transcutaneous pacing is always preferred over transvenous pacing in the acute setting.

Note

If the patient is on a beta blocker, give glucagon.

If the patient is on a calcium channel blocker, give calcium.

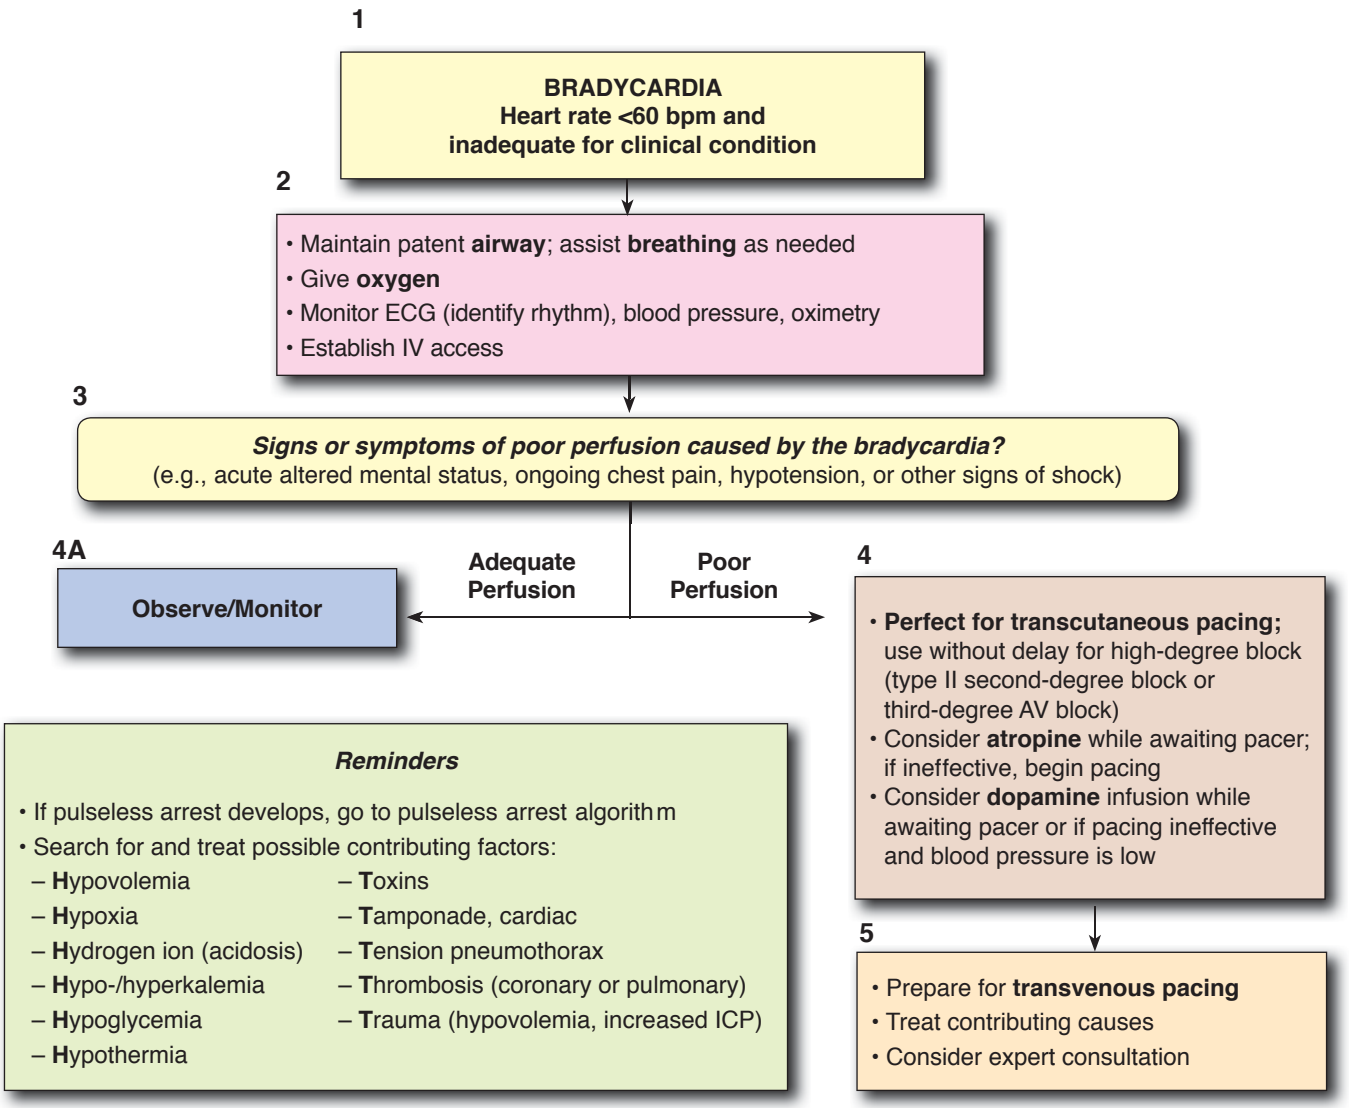

Figure 10-14. Algorithm for Bradycardia

TOXICOLOGY: GENERAL PRINCIPLES/INITIAL EVALUATION

A 25-year-old medical student goes home after class and finds no messages on the answering machine from his girlfriend. In a fit of despair he takes a full bottle of pills in an attempt to commit suicide. He takes the label off the bottle to prevent any attempt to reverse the poisoning through the identification of the specific agent. Immediately after doing this, his girlfriend calls, after which he runs to the nearest emergency department and states that he has changed his mind and wants to live after all. He walks into the emergency department 30 minutes after the ingestion. He won't tell you the specific name of what he took and wants to know what is the next best thing to do.

Management. The initial evaluation of a patient who has been poisoned involves attempting to find out the nature of the toxin ingested. At the same time, history and physical examination can give clues to the nature of the toxin. In this patient, the key issue is the short time between the ingestion and his arrival in the emergency department. He is awake.

Toxidromes

Associated physical findings in specific toxidromes

- Miosis: clonidine, barbiturates, opiates, cholinergics, pontine stroke
- Mydriasis: sympathomimetics, anticholinergics
- Dry skin: anticholinergics
- Wet skin: cholinergics, sympathomimetics
- Blisters: barbiturates, carbon monoxide poisoning

Management of Toxic Ingestions or Overdose

Gastric emptying is rarely, if ever, utilized. In ingestions of an unknown type, a urine or blood toxicology screen should be performed, but this should not delay the administration of antidotes, charcoal, or gastric emptying in the rare circumstances in which emptying is indicated.

- **Induced vomiting.** Ipecac can only be used within 1-2 hours after ingestion, so it has no use in the hospital setting. Very few people arrive within the first hour. In addition, ipecac can delay the use of oral antidotes such as charcoal or N-acetyl cysteine because of the vomiting it induces. Ipecac is more useful for ingestions in the home, in which the time period since ingestion is short and there are no other effective modalities immediately available. Ipecac decreases absorption by 60% at 5 minutes after ingestion, 32% at 30 minutes, and 30% at one hour. Ipecac is never recommended for use in children.
- **Lavage.** Gastric emptying with a large-bore (37-42 French) oropharyngeal hose (e.g., an Ewald tube) should only be used in those with an altered mental status and in whom ipecac is dangerous because of possible aspiration. Lavage should therefore be preceded by endotracheal intubation. Lavage is also only useful within the first hour after ingestion, and is therefore very rarely, if at all, useful any more. Both ipecac and lavage are contraindicated with the ingestion of caustic substances such as acids or alkalis. Lavage decreases absorption by 52% at 5 minutes, 26% at 30 minutes, and 16% at 60 minutes. The exact indications for lavage are not clear, however, the contraindications are very clear.

Note

- Ipecac is never used by physicians.
- Lavage has almost no utility.

Note

Charcoal does not bind to some substances **(PHAILS)**:

Pesticides

Heavy metals

Acid/alkali/alcohol

Iron

Lithium

Solvents

Note

Substances/drugs that may require hemodialysis for removal include **(I STUMBLE)**:

Isopropanol

Salicylates

Theophylline

Uremia

Methanol

Barbiturates

Lithium

Ethylene glycol

- **Charcoal.** After gastric emptying or if, as in most cases, the patient arrives >1-2 hours after the ingestion, the mainstay of therapy is activated charcoal administration. Repeated doses every 2-4 hours are recommended to both block further absorption of the substance and to accelerate the removal of already absorbed toxins from the body. Charcoal is safe for all patients.
- **Whole bowel irrigation.** For large-volume pill ingestions in which the pills can be seen on an x-ray, whole bowel irrigation can be effective. A gastric tube is placed and high-volume (1-2 liters per hour) GoLYTELY (polyethylene glycol) is administered until the bowel movements run clear.
- **Dialysis.** Dialysis is rarely necessary because the time delay to its initiation limits its efficacy. If it is necessary, hemodialysis is 20x more efficacious at removing drugs from the body than peritoneal dialysis. Dialysis is your answer when there are profoundly serious symptoms such as coma, hypotension, or apnea, especially when renal or hepatic failure limits the usual means of excreting substances from the body.
- **Cathartics.** Cathartics are useful when used with charcoal administration. Otherwise, they are almost never helpful. When you see cathartics in the answer, it is generally the wrong answer.
- **Forced diuresis.** Alkaline diuresis can help eliminate salicylates and phenobarbital. Otherwise, simply making patients urinate in high volumes does not help the patient. Except for salicylates and phenobarbital, forced diuresis is generally the wrong answer.
- **Naloxone/dextrose/thiamine.** These agents should be given first to any patient who presents with altered mental status or coma. They are particularly useful in any toxin ingestion that produces confusion. Naloxone has almost no adverse effects and works instantly. Because of its rapid response, naloxone is both therapeutic and diagnostic. Dextrose is also very effective at preventing permanent brain damage from hypoglycemia. It does not matter whether the dextrose or thiamine is given first.

Remember: Any toxin-related seizure should be treated with benzodiazepines as first-line therapy. When benzodiazepines are not effective, barbiturates should be used next. Phenytoin and fosphenytoin are not indicated or even effective for this type of seizure.

Toxicology Screening

Toxicology screen (tox screen) is a testing used to determine the approximate amount and type of legal and/or illegal drugs. It is used to screen for drug abuse, monitor a substance abuse problem, and evaluate drug intoxication for overdose.

- **The best initial test** in toxicology screen is the **urine immunoassay** (qualitative test). The drugs typically screened for include alcohol, cocaine, PCP, amphetamines, and cannabinoids.
- The **confirmatory test** is considered **gas chromatography/mass spectrometry**, which provides qualitative analysis and allows identification of the specific drug or its metabolites.

Tox screen must be done within a certain amount of time after the drug is taken, or while metabolites can still be detected in the body. Some examples of the time it takes for drugs to clear are listed below.

- **Alcohol:** 3–10 hrs
- **Amphetamines:** 24–48 hrs

- **Barbiturates:** up to 6 wks
- **Benzodiazepines:** up to 6 wks with heavy use
- **Cocaine:** 2–4 days; up to 10–22 days with high level use
- **Codeine:** 1–2 days
- **Heroin:** 1–2 days
- **Hydromorphone:** 1–2 days
- **Methadone:** 2–3 days
- **Morphine:** 1–2 days
- **Phencyclidine (PCP):** 1–8 days
- **Tetrahydrocannabinol (THC):** 6–11 wks with heavy use

ACETAMINOPHEN

A 38-year-old man comes to the emergency department 4 days after the ingestion of a full bottle (60 tablets) of acetaminophen (500 mg each). He complains of vomiting and right upper quadrant pain. He has an elevated bilirubin, AST, and prothrombin time.

Definition. Acetaminophen is one of the few toxins about which precise toxicity levels are known; the ingestion of approximately 140 mg per kg is usually sufficient to cause serious toxicity. In other words, in an average-sized, 70-kg person, about 7–10 grams is enough to produce toxicity, and fatalities can occur >12–15 grams. In those patients with liver disease or concomitant alcohol abuse and thus depleted glutathione stores, the hepatotoxic dose is less (4 grams/day).

Clinical Presentation. As with most large-dose pill ingestions, the initial symptoms are nausea and vomiting, caused mostly from a gastritis caused by irritation from the pills over the first 12-24 hours (Stage I). Between 24-72 hours (Stage II), there often follows an asymptomatic period as the acetaminophen is metabolized and part of the drug is converted to a toxic metabolite. Starting at 24-48 hours, subclinical elevation of the transaminases and bilirubin develops. This is followed at 48-72 hours after ingestion by clinically symptomatic signs of liver damage: more nausea, jaundice, abdominal pain, and signs of hepatic encephalopathy, renal failure, and death.

Diagnosis. A clear history of a large volume of acetaminophen ingestion is initially sufficient to establish a diagnosis that warrants therapy with N-acetyl cysteine (NAC). Starting at 4 hours after ingestion, when most of the drug has been absorbed, drug levels are reliable. A nomogram based on relating the drug level to the time of ingestion is necessary to determine who will develop toxicity. In other words, a level by itself is not enough to determine who will develop toxicity. A certain level at 5 or 6 hours may not be toxic; however, the same level at 10–12 hours after ingestion may lead to the development of liver failure.

Elevated AST is more common than elevated ALT. If a patient is known for alcohol abuse and presents with AST and ALT >500 U/L, the diagnosis is more likely to be acetaminophen toxicity than alcoholic hepatitis. NAC should be given in such cases. Elevated bilirubin and prothrombin time indicates severe toxicity and hepatic necrosis. Studies show that NAC administration within the first 8 hours of severe drug poisoning improves liver microcirculation and prevents the need for liver transplant.

Treatment. Gastric emptying should not be used because it will delay the administration of NAC as a specific antidote. Activated charcoal is given in repeated doses. NAC is preferably given within 8 hours of the ingestion, when it is most efficacious. When >24 hours have elapsed since ingestion, there is no specific therapy that can prevent or reverse the toxicity, but still give NAC always. NAC and charcoal are superior to any form of gastric emptying.

ALCOHOLS (METHANOL AND ETHYLENE GLYCOL)

At the opera, you go to see the Three Tenors, who exhibit confusion, ataxia, lethargy, drowsiness, and slurred speech; which is to say, you have really gone to see the Three *Drunken* Tenors. How would you distinguish between the tenors drunk on methanol or ethylene glycol from those drunk on simple ethanol?

Etiology. Methanol (wood alcohol) is found in paint thinner, sterno, photocopier fluid, solvents, and windshield washer solution. Ethylene glycol is most often found in automotive antifreeze. All of the alcohols are metabolized by alcohol dehydrogenase. Alcohol dehydrogenase metabolizes methanol to formaldehyde and formic acid. Ethylene glycol is metabolized partially to oxalic acid and oxalate, which leads to kidney damage.

Note

Ingestion of methanol, ethylene glycol, and isopropyl alcohol will all result in an osmolar gap.

Clinical Presentation. Ethanol, methanol, ethylene glycol, and isopropyl alcohol can all produce intoxication. Methanol is more characteristically associated with visual disturbances up to and including blindness from the production of formic acid. Ethylene glycol is distinguished by the development of renal failure and oxalate crystals and stones in the urine. Isopropyl alcohol ingestion can only be distinguished before a specific drug level is done by the history or by the development of acidosis in the absence of an elevated anion gap.

Diagnosis. Determining specific levels of each alcohol is the most specific test. Ethylene glycol is characterized by oxalate crystals in the urine, increasing BUN/creatinine, or by adding fluorescein to the urine and then observing for urine fluorescence with an ultraviolet Wood's lamp. Ingestion of methanol and ethylene glycol will be characterized by an increased serum osmolar gap and metabolic acidosis with an elevated anion gap. Isopropyl alcohol will produce an osmolar gap without an increased anion gap. Remember this difference when differentiating them. Ethylene glycol intoxication may also be characterized by hypocalcemia.

Note

Charcoal will not inhibit the absorption of alcohols.

Treatment. Ethylene glycol and methanol intoxication were previously treated with an ethanol infusion (to prevent the production of the toxic metabolites) followed by hemodialysis to remove the substance from the body. Fomepizole (alcohol dehydrogenase inhibitor) is the drug of choice. Fomepizole inhibits the production of toxic metabolites without leading to intoxication. Dialysis can be used in patients with severe anion gap metabolic acidosis or signs of end-organ damage (coma, seizures, renal failure).

CARBON MONOXIDE (CO)

You are the chief resident at a great metropolitan training program at the time of a fire at a large office building. A total of 2,500 people come to your emergency department at the same time to be treated for smoke inhalation. Among them is a 68-year-old man with a history of aortic stenosis who had to walk down 90 flights of stairs. What is the most important initial test for this man?

Source. Poisoning with CO occurs with exposure to various forms of burning materials, such as gasoline, wood, and natural gas, and with entrapment in fires and smoke inhalation. Low levels of CO poisoning are present in most tobacco smokers. CO itself is odorless and tasteless.

Metabolism. CO binds to hemoglobin 200 times more avidly than oxygen. Carboxyhemoglobin decreases release of oxygen to tissues and inhibits mitochondria. This results in tissue hypoxia and anaerobic metabolism similar to what would occur with anemia.

Clinical Presentation. Pulmonary symptoms include dyspnea, tachypnea, and shortness of breath. Cardiac symptoms include chest pain, arrhythmia, and hypotension.

Early neurologic symptoms include headache (most common), nausea, blurry vision, and dizziness, while late symptoms include confusion, seizures, impaired judgment, and syncope.

Laboratory. Carboxyhemoglobin levels can give an indication of the severity of the exposure.

<10%:	Levels up to 10% may occur in city dwellers who are smokers
20-30%:	Mild symptoms
30-50%:	Moderate to severe symptoms
>50-60%:	May be fatal

Influenza is the most common misdiagnosis because most people present during wintertime. When an entire family presents with "flu" symptoms without fever, think CO poisoning.

- Arterial blood gases or venous blood gases. Metabolic acidosis is present from the failure of carboxyhemoglobin to release oxygen to tissues. The pO_2 will be normal.
- CPK may be elevated.
- Routine pulse oximetry is not helpful. **Carbon monoxide pulse oximetry** provides a way to measure carboxyhemoglobin and is the initial diagnostic test for suspected CO poisoning.

Treatment

- Removal from source of exposure
- 100% oxygen administration
- Hyperbaric oxygen in severe cases
  - COHb levels >25%
  - Myocardial ischemia
  - EKG changes
  - CNS abnormalities other than headache or chest pain
  - Pregnant women when carboxyhemoglobin levels >15%

In room air, carbon monoxide has a half-life of 4-6 hours, which decreases to 40-80 minutes on 100% oxygen and to 15-30 minutes with hyperbaric oxygen.

Note

In the winter of Northern climates, space heaters are a common cause of carbon monoxide poisoning. Headache is the most common symptom. Nausea is also very common.

Note

CO poisoning initially presents just like hypoglycemia. When a fingerstick glucose is normal, this should raise your suspicions.

CAUSTICS/CORROSIVES (ACIDS AND ALKALI)

Definition. The oral ingestion, inhalation, or cutaneous or ocular contact with a wide variety of corrosive substances.

Etiology. The most common household acids are various toilet, drain, swimming pool, and metal cleaners. The most common alkali ingestions or exposures are from liquid and crystalline lye, dishwasher detergents, hair relaxers, and oven cleaners. The most common serious injury is from the oral ingestion of liquid drain cleaner.

Clinical Presentation. The most common symptoms from ingestion injury are oral pain, drooling, odynophagia, and abdominal pain. Esophageal injury with subsequent stricture formation may occur from either acid or alkali ingestion. Gastric perforation may occur. In most circumstances, alkali exposures are more serious than acid exposures. Alkaline substances are more destructive to tissues.

Diagnosis. The history of exposure with subsequent characteristic injury is sufficient to establish the diagnosis. Upper endoscopy is critical for determining the extent of the injury.

Treatment. The management of both acid and alkali caustic ingestions is essentially the same. Immediately wash out the mouth with large volumes of cold water. Irrigate ocular exposures with large volumes of either saline or water, followed by fluorescein staining to determine if there is significant corneal injury. **Do not induce emesis** with either acids or alkaline ingestion because it can worsen the injury. Simply give water. **Do not try to neutralize the acid** with a base or a base with an acid because a heat-producing reaction can occur, which would destroy more tissue. Charcoal is not useful, nor are steroids or prophylactic antibiotics.

DRUGS OF ABUSE

Opiates

Opiate toxicity is predominantly respiratory related, via depressant effects upon the respiratory centers in the brain stem. Death can occur through acute respiratory acidosis. In addition to their analgesic and euphoric effects, opiates also cause pupillary constriction, constipation, bradycardia, hypothermia, and hypotension. Opiates can be rapidly reversed by naloxone. Since opioids decrease gastric emptying by relaxation of smooth muscle, gastric lavage may be used in cases of overdose with oral agents.

Although withdrawal of opiates is uncomfortable, it is not fatal. It is usually treated with methadone or buprenorphine. Opiate withdrawal symptoms are the following.

- 3–4 hours: fear, anxiety, and drug craving
- 8–14 hours: insomnia, yawning, rhinorrhea, diaphoresis, mydriasis, anxiety
- 1–3 days: tremor, muscle spasms, vomiting, diarrhea, tachycardia, chills, piloerection

Cocaine

Pathophysiology. Cocaine blocks the reuptake of norepinephrine and other catecholamines at the synapse. This leads to a wide variety of euphoric and toxic effects. Amphetamines work in a similar way but are less likely to produce severe toxicity or death. Severe toxicity from cocaine is far more likely with smoked ("crack") or injected cocaine rather than snorted (inhaled).

Clinical Presentation. Toxic effects of cocaine are related to a very significant alpha-adrenergic stimulatory effect, resulting in very high blood pressure, hemorrhagic stroke, subarachnoid hemorrhage, myocardial infarction, arrhythmia, and seizures. These may lead to death. Metabolic acidosis, rhabdomyolysis, and hyperthermia may also occur with cocaine toxicity. Pulmonary edema is specific to smoked cocaine. Cocaine withdrawal results in depression from norepinephrine depletion. There is limited physiologic withdrawal from cocaine.

Treatment. Benzodiazepines such as diazepam are used to control acute agitation. Combined alpha/beta agents such as labetalol or alpha-blockers such as phentolamine are useful to control hypertension. Pure beta-blockers should be avoided because they lead to unopposed alpha stimulatory effects. There is no specific drug to reverse cocaine.

Benzodiazepines

Benzodiazepines (BZDs) produce somnolence, dysarthria, ataxia, and stupor. Very infrequently, BZDs lead to death from respiratory depression; most deaths are associated with ethanol or barbiturate ingestion.

Patients receiving prolonged parenteral administration of BZDs are at risk for propylene glycol poisoning (used in parenteral formulations of diazepam and lorazepam). Rarely, this may cause hypotension, cardiac dysrhythmias, lactic acidosis, seizures, or coma.

Treatment. Good supportive care and monitoring are the foundation of treatment. As with any overdose, the first step is to stabilize the patient's airway, breathing, and circulation.

- Flumazenil is a specific antidote for BZD poisoning, although its use in acute BZD overdose is controversial.
- In long-term BZD users, flumazenil may precipitate withdrawal and seizures.
- In BZD use for a medical condition, flumazenil may exacerbate the condition.

BZD withdrawal can be similar to the symptoms of alcohol withdrawal. Although rare, deaths have been reported from severe withdrawal. The recommendation for treatment of severe forms of withdrawal is the administrations of BZDs.

Barbiturates

This is a class of drugs with a large variety of long- and short-acting agents. Massive overdose can result in death from respiratory depression or CNS depression. Barbiturates can cause hypothermia, loss of deep tendon reflexes, and loss of corneal reflexes, and could result in a coma simulating brain death. Barbiturates may lead to absent EEG activity. Barbiturate withdrawal may result in seizures similar to alcohol or benzodiazepine withdrawal. Although there is no specific antidote for any of the barbiturates, you can increase the urinary excretion of phenobarbital by the use of bicarbonate. This is similar to the treatment for salicylate intoxication.

Hallucinogens

This includes a wide variety of agents such marijuana, LSD, mescaline, peyote, and psilocybin. Although they may cause delirium and bizarre behavior, the adverse effects are often limited to their anticholinergic effects, such as flushed skin, dry mouth, dilated pupils, and urinary retention. The only hallucinogen associated with a potentially fatal outcome is the artificially created, dissociative, anesthetic phencyclidine (PCP or "angel dust"), which may cause seizures. Treatment for severe hallucinogen intoxication is with benzodiazepines.

HEAVY METALS

Lead

Epidemiology/Source. Up to 12 million preschool children per year may be affected in the United States. Lead is ingested from paint, soil, dust, drinking water, and in the past from gasoline.

Metabolism. Lead can be absorbed from the GI tract, the skin, or by inhalation. GI absorption is increased by deficiencies of zinc, iron, and calcium.

Excretion is primarily through the urine (80–90%), with the remainder through the stool. Lead poisoning is primarily a chronic condition, not acute.

Clinical Presentation

- Adults: Abdominal pain, anemia, renal disease, and neurologic manifestations, such as headache and memory loss. Hypertension can occur as well.
- Children: Acute: abdominal pain, anemia, lethargy, seizures, and coma; chronic: irreversible neurologic damage, such as mental retardation and poor cognitive and behavioral function.

Laboratory. *Blood lead levels* are the key to diagnosis and <10 μg/dL is considered acceptable. "Lead lines" are densities seen at the metaphyseal plate of the long bones of children. They indicate long-term exposure. Anemia and azotemia occur.

Note

Think *lead* in patients with microcytic anemia and abdominal pain.

Treatment. Chelation with calcium EDTA, dimercaprol (BAL), penicillamine, or succimer (oral therapy). In acute lead poisoning, use GI decontamination with charcoal. Urine output should be maintained at a rate of 1–2 mL/kg/hr to aid in maximal excretion.

Management of lead toxicity/poisoning should be done according to blood lead levels:

- **Mild (5–44 mcg/dL):** no treatment needed; repeat level in 1 month
- **Moderate (45–69 mcg/dL):** 2,3 dimercaptosuccinic acid (DMSA)
- **Severe (≥70 mcg/dL):** DMSA + EDTA (calcium disodium edetrate)

LITHIUM

Lithium is a commonly used medication for the treatment of bipolar disorder and acute mania. Although effective, it has a narrow therapeutic window and is associated with toxicity. There are 2 main types:

- In **acute poisoning**, patients do not have a lithium burden
  - Symptoms are primarily GI: nausea, vomiting, cramping, and possible diarrhea
  - Progression can involve neuromuscular signs: tremulousness, dystonia, hyperreflexia, and ataxia
  - Most common electrocardiographic finding is T-wave flattening
- In **chronic poisoning**, patients often have a large body burden of lithium
  - Symptoms are primarily neurologic; mental status is often altered
  - Progression can lead to coma and seizures if the diagnosis is unrecognized
  - May be difficult to treat
  - Usually precipitated by introduction of new medication which may impair renal function or cause hypovolemic state

Three major drug classes have been identified as **potential precipitants of lithium toxicity**:

- Diuretics that promote renal sodium wasting
- ACE inhibitors that reduce glomerular filtration rate (GFR) and enhance the tubular reabsorption of lithium
- NSAIDs that reduce the GFR and interrupt renal prostaglandin synthesis

Systemic effects include renal toxicity (nephrogrenic diabetes insipidus is most severe manifestation). Lithium inhibits the action of antidiuretic hormone (ADH) on the distal renal tubule, impairing sodium and water absorption. Other manifestations of lithium toxicity on the kidney include renal tubular acidosis, chronic tubulointerstitial nephritis, and nephrotic syndrome.

The most common endocrine disorder secondary to chronic toxicity is hypothyroidism. Lithium is taken up by thyroid cells and blocks thyroid hormone release from thyroglobulin, which inhibits adenylate cyclase and prevents thyroid-stimulating hormone (TSH) from activating thyroid cells via the TSH receptor. Acute exposure to lithium can cause leukocytosis, whereas chronic exposure can produce aplastic anemia.

Elevated lithium levels in the blood confirm toxicity, although levels may not correlate with clinical symptoms. Serial levels may be warranted in cases of sustained-release tablets.

Treatment. Supportive therapy is the mainstay of treatment. Airway protection is crucial due to emesis and risk of aspiration. Seizures can be controlled with BZDs, phenobarbital, or propofol. Gastric lavage may be attempted if the patients presents within 1 hour of ingestion.

Lithium is a monovalent cation that does not bind to charcoal; therefore, activated charcoal has no role.

Fluid therapy is critical. The goal of saline administration is to restore GFR, normalize urine output, and enhance lithium clearance.

Lithium is readily dialyzed because of water solubility, low volume of distribution, and lack of protein binding. Thus, hemodialysis is indicated for patients who have renal failure (and unable to eliminate lithium) and patients who cannot tolerate hydration (e.g., those with CHF, liver disease, or severe toxicity meaning neurologic symptoms >4 m/Eq/L).

SALICYLATES

> An elderly woman with osteoarthritis comes to the emergency department with dyspnea, intractable nausea, vomiting, and tinnitus. She is fully alert and able to give a good history. Her only other problem is hypertension. She is on a wide variety of medications to reduce her pain. Her husband says she was in so much pain lately that she took half a bottle of extra pills 30 minutes ago.

Definition. Salicylate intoxication results from the ingestion of a large amount of aspirin and other salicylate-containing medications, resulting in a complex, systemic toxicity.

Clinical Presentation. The most common presentation is GI distress, such as nausea, vomiting, and gastritis. Salicylates are complex metabolic poisons. Tinnitus is one of the more specific complaints and is one of the best ways to identify the case, so as to answer the question:

"Which of the following is the most likely diagnosis?" Salicylates affect respiratory function in 2 ways: They directly stimulate the respiratory centers in the brainstem to cause a centrally mediated hyperventilation and hyperpnea; in addition, they are directly toxic to the lungs themselves and can cause a noncardiogenic pulmonary edema similar to ARDS. Hyperthermia is possible. CNS toxicity such as confusion, coma, seizures, and encephalopathy can also occur. This can cause death. Salicylates also interfere with Krebs cycle and lead to a metabolic acidosis through the reversion to anaerobic glycolysis as a method of energy production in the body. In other words, salicylates lead to significant lactic acid production with metabolic acidosis and an elevated anion gap. This ultimately results in a compensatory respiratory alkalosis.

Diagnosis. The most specific test is an *aspirin level*. Suggestive findings are an *elevated anion gap* with *metabolic acidosis*. However, a respiratory alkalosis may be the predominant defect, especially early on. Hence the blood gas can show a low pH, a high pH, or a normal pH. An elevated prothrombin time and hypoglycemia may also occur. The chest x-ray may be normal or occasionally show pulmonary edema.

Treatment. If the patient comes within the first hour after ingestion, gastric decontamination may be attempted. Charcoal is also useful, as it is in many types of ingestions. The mainstay of therapy, however, is by trying to *increase urinary excretion by alkalization of the urine* along with aggressive fluid resuscitation to maximize urinary output. When the urinary pH rises, this will charge the salicylate molecule, which is a weak acid. This will block the reabsorption of the substance at the kidney tubule. Dialysis is sometimes necessary.

Indications for dialysis:

- Renal failure
- CHF
- ARDS
- Persistent CNS symptoms (confusion/seizures)
- Hemodynamic instability
- Severe acid/base or electrolyte imbalance
- Hepatic failure with coagulopathy
- Salicylate level >100 mg/dL

DIGOXIN

Epidemiology. Toxicity occurs from a suicide attempt or accidentally during therapeutic use. Toxicity is more common with renal failure because 60% of digoxin is normally excreted renally, and it will accumulate. The most common precipitating cause of digitalis toxicity is the reduction of potassium stores, which occurs often in patients with heart failure due to diuretic therapy or secondary hyperaldosteronism. **Hypokalemia** predisposes to toxicity because potassium and digoxin bind to the same site on the sodium-potassium ATPase pump, leading to increased intracellular calcium, thus leading to increased cardiac contractility. Drugs that have been implicated in digoxin toxicity include amiodarone, beta blockers, diltiazem, cyclosporine, macrolide antibiotics, indomethacin, spironolactone, and furosemide.

Presentation. GI symptoms are most common: nausea, vomiting, diarrhea, and anorexia. Neurologic and visual symptoms include blurred vision, color vision abnormality, hallucinations, and confusion. Cardiac disturbance is predominantly secondary to arrhythmia.

Laboratory. EKG abnormalities are most common. Bradycardia, premature contractions, ventricular tachycardia, and any other type of arrhythmias may be seen. Paroxysmal atrial tachycardia is the most common arrhythmia. Hyperkalemia occurs acutely from inhibition of Na^+/K^+ ATPase by digoxin. A serum digoxin level should be ordered in patients you suspect of being toxic (history, etc.).

Treatment

- GI decontamination with repeated doses of *charcoal* is effective.
- Digoxin-specific antibodies (Digibind®) are useful for life-threatening toxicity, particularly with arrhythmias.
- Electrolyte abnormality correction: *Potassium correction* is most important.
- Antiarrhythmic medications, such as phenytoin and lidocaine, are used as necessary with ventricular arrhythmias.
- Pacemaker placement may be necessary for bradycardia or third-degree AV block refractory to atropine.

TRICYCLIC ANTIDEPRESSANTS

A 28-year-old man with a history of depression comes to the emergency department one hour after a suicide attempt with his tricyclic antidepressants and benzodiazepines. He is stuporous with a respiratory rate of 7/min. An EKG shows a wide QRS. What would you do next?

Etiology/Pathophysiology. Tricyclic antidepressants (TCAs) are characterized by a number of anticholinergic and sodium channel blocker side effects. This is the predominant cause of their cardiac and CNS toxicities.

Clinical Presentation. The most common adverse effects are *anticholinergic*-mediated findings of dry mouth, tachycardia, dilated pupils, and flushed skin. A quick onset with rapid deterioration is common. The most serious effects are cardiac dysrhythmia with *widening of the QRS complex*, resulting in ventricular tachycardia and first-degree conduction blocks. CNS effects include altered mental status, confusion, and seizure.

Diagnosis. Serum drug levels are the most specific test, but an EKG showing abnormalities is more important to determine who will have serious toxicity. The EKG may be normal or show any range of ventricular or atrial arrhythmias or conduction delays.

Treatment. TCA overdose has anticholinergic side effects, which include impaired peristalsis and delayed gastric emptying. Charcoal is the primary treatment in the acute setting. Any sign of cardiac toxicity should lead to the immediate use of bicarbonate. *Bicarbonate protects the heart from the TCAs*. Bicarbonate is not to increase urinary excretion (as opposed to the treatment of aspirin overdose). This case also shows why patients with benzodiazepine ingestions should generally not be treated with flumazenil. Flumazenil would reverse the effects of the benzodiazepines and therefore lead to a seizure.

ANTICHOLINERGIC POISONING

A 65-year-old man is brought to the emergency department by his wife with lethargy and confusion. She says that he has had a cold and has taken over-the-counter cold preparations for the last few days. On examination he is confused and does not recognize his wife. His temperature is 39.2° C (102.5° F), pulse 130/min and blood pressure 100/60 mm Hg. The skin is flushed, dry, and warm. The eyes are dilated.

Definition. Anticholingeric overdose may occur in any age group with high dose, but most commonly presents in the elderly. Anticholinergic drugs competitively inhibit binding of the neurotransmitter acetylcholine to muscarinic acetylcholine receptors, and are commonly called "antimuscarinic agents." Muscarinic receptors are found on peripheral postganglionic cholinergic nerves in smooth muscle (intestinal, bronchial, and cardiac), in secretory glands (salivary and sweat), on the ciliary body of the eye, and in the central nervous system (CNS). Anticholinergic agents do not antagonize the effects at nicotinic acetylcholine receptors, such as at the neuro-muscular junction.

The onset of anticholinergic toxicity varies depending on the particular toxin, but usually occurs within 1–2 hours of oral ingestion. Some drugs may take up to 12 hours to have an effect. Be aware with patients on psychotropic agents.

The following medications may cause anticholinergic effects:

- Diphenhydramine
- Scopolamine and hyoscyamine
- TCAs
- Cyclobenzaprine
- Benztropine
- Belladonna

Clinical Presentation. Patients will present with the following characteristics:

- "Red as a beet": flushed, red skin due to cutaneous vasodialation
- "Dry as a bone": dry skin (anhydrosis) due to inability to sweat
- "Hot as a hair" anhydrotic hyperthermia
- "Blind as a bat": mydriasis
- "Mad as a hatter": delirium, psychosis, hallucinations, and seizures
- "Full as a flask": urinary retention and absent bowel sounds
- Tachycardia

Treatment. ABCs, supportive care, EKG monitoring. Anticholinergic poisoning may also cause prolonged QRS and QT intervals. In that case, sodium bicarbonate can be used to stabilize the myocyte membrane and prevent ventricular tachycardia. If a patient develops seizures, treat with benzodiazepines, NOT with phenytoin or fosphenytoin.

ORGANOPHOSPHATES

Etiology. Inhibits cholinesterase and has muscarinic and nicotinic effects. Patients will be farmers or gardeners.

Nicotinic effects are weakness and decreased respiratory drive. Muscarinic effects are as follows, otherwise known as DUMBELSS syndrome:

- **D**efecation
- **U**rinary incontinence
- **M**uscle weakness, miosis
- **B**radycardia/bronchospasm
- **E**mesis
- **L**acrimation
- **S**alivation
- **S**eizure

Diagnosis. Check RBC cholinesterase levels. Do not delay treatment while waiting for results.

Treatment. First step is for physician to put on protective clothing, as organophosphates are absorbed by the skin. Then, have patient remove clothing immediately. Start atropine immediately to treat the bradycardia. Start pralidoxime (2-PAM), which restores cholinesterase activity and reverses both the nicotinic and muscarinic effects.

ALCOHOL

A 35-year-old man is brought to the emergency department by his wife after he had a seizure. He is agitated and combative. He is yelling and trying to hit the nurses, and tells you that he is in France. He is also yelling at his mother, who is not in the room. His wife tells you that he drinks a liter of whiskey a day, though he has not had any in the last few days because he didn't have the money. His pulse is 130/min, blood pressure 160/90 mm Hg, and respirations 24/min. He is diaphoretic and extremely irritable. His temperature is 38° C (100.4° F). The rest of the exam is unremarkable.

Presentation. Alcoholics may present with any one of the following:

Mild withdrawal:

Symptoms are tremors, tachycardia, and anxiety. Seizures may be seen 6–12 hours after the last drink.

Delirium tremens (DT):

- Manifests 48–72 hours after the last drink but can last up to 10 days
- Mental confusion
- Autonomic hyperactivity
- Visual hallucinations
- Severe agitation
- Diaphoresis

Note

The diagnosis of all alcohol withdrawal–related syndromes is made clinically, not by lab values.

Alcoholic hallucinosis:

- May be confused with DT
- Starts 12–24 hours after last drink but can last days to weeks
- Paranoid psychosis without tremors and confusion
- Normal vital signs (no hypertension or tachycardia)
- No agitation
- Normal appearance except for auditory (most common), visual, or tactile hallucinations

Wernicke encephalopathy:

- Confusion, ataxia, and ophthalmoplegia (nystagmus)

Korsakoff psychosis:

- Amnesia and confabulations

Treatment. Alcohol withdrawal has a very high mortality rate (5%).

Benzodiazepines can be life-saving (important to taper dose slowly). Diazepam and chlordiazepoxide are common, due to their long half-life. There is no role for anticonvulsants.

Antipsychotics such as haloperidol should be avoided because they can lower the seizure threshold and cause prolonged QT interval.

Hydrate with isotonic fluids and electrolyte replacement.

Symptom-triggered therapy is recommended. A work-up for alternative diagnosis is also very important.

- Use only lorazepam or oxazepam for cirrhosis
- CT head to look for intracranial bleed
- Lumbar puncture to rule out meningitis if there is a fever
- Chest x-ray: look for aspiration pneumonia
- High doses of thiamine IV for Wernicke and Korsakoff. Treatment for alchoholic hallucinosis is benzodiazipines and haldoperidol (there is no risk of siezures, so it can be used here)

HEAD TRAUMA

A 20-year-old man is playing football when he is struck in the head and loses consciousness for a few minutes. He awakens and has some motor weakness of his left arm, which seems to slowly worsen over the course of the next hour as he is brought to the emergency department.

Definition. Any degree of traumatic brain injury resulting in a range of injury from scalp laceration to headache to loss of consciousness or focal neurologic deficits. The term does not imply a specific mechanism of injury. The injury can result in concussion, contusion, epidural hematoma, subdural hematoma, or traumatic subarachnoid hemorrhage. Cerebral contusion can progress to intraparenchymal hemorrhage.

Clinical Presentation. The presentation is often only suggestive of the degree of injury. The specific injury can only be determined by the use of CT scanning. All forms of head trauma can result in headache, amnesia, and loss of consciousness. The degree of amnesia is loosely associated with the degree of head trauma. That is to say, the worse the trauma, the more memory one loses. Memory loss starts from the time of the episode of injury and stretches both forward (anterograde), in which one doesn't remember events since the time of the injury, as well as backward (retrograde), in which one forgets past events. Retrograde amnesia starts from the time of the injury and moves further back in time depending on the severity of the injury. The more severe the injury, the further back in time you forget. Retrograde amnesia is more common. Recovery of memory starts with recollection of the most distant progressing to the most recent memories.

Loss of consciousness, although possible in any form of head trauma, is not always present, even with relatively severe forms of brain injury. You can have very severe intracranial bleeding (such as a subdural hematoma) without a loss of consciousness. This is particularly true of chronic subdural hematoma.

Concussion is generally not associated with focal neurologic findings, such as motor or sensory deficits. The presence of focal findings, starting in order of highest frequency, is most commonly associated with epidural and subdural hematomas and contusion.

Diagnosis. CT scanning of the head is the mainstay of diagnosis of brain injury. Contrast enhancement is not necessary because blood does not enhance with contrast. Hemorrhage should be visible instantly if present at the time of the initial presentation. When evaluating head CT scans, subdural hematomas are crescent-shaped and epidural hematomas are lens-shaped. Follow-up scanning is also accomplished with CT scanning when necessary. Skull x-rays are always the wrong answer when presented as one of the diagnostic choices. Normal x-rays do not exclude hemorrhage, and abnormal x-rays do not confirm the presence of a hemorrhage. Cervical spine x-rays should be obtained in head trauma if there are focal findings consistent with a cervical radiculopathy or if spinal tenderness is present. Even without these findings, you should have a very low threshold for obtaining cervical spine x-rays.

Note

A concussion is diagnosed by a history of loss of consciousness plus a negative CT scan of the head.

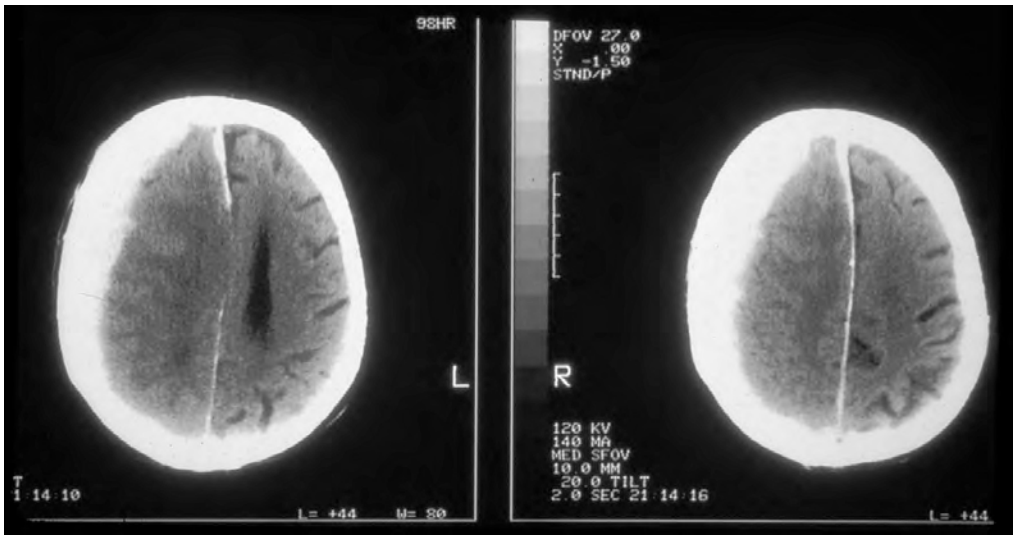
(petechial hemorrhage and/or edema, which may worsen over days)



Dr. Conrad Fischer

Figure 10-19. CT Scan Demonstrating Subdural Hematoma with a Midline Shift

Treatment. Severe intracranial hemorrhage should be managed by lowering the intracranial pressure. This is accomplished acutely with hyperventilation to PCO2 of 30–35, which will cause vasoconstriction of cerebral vessels, leading to a decrease in intracranial pressure. It should be used in moderation and for limited amount of time.

Osmotic diuretics such as mannitol and elevation of the head of the bed are also helpful to reduce intracranial pressure. This is in preparation for surgical evacuation. Steroids are not effective, and when an answer choice in head trauma is a steroid, it is always wrong. Select simpler measures such as elevation of the head of the bed to 30 degrees and maintenance of systolic blood pressure to 110–160 mm Hg. This slight degree of hypertension assures that the cerebral perfusion pressure is adequate.

Cerebral perfusion pressure is best when mean arterial pressure ≥60 mm Hg above the intracranial pressure. Stress ulcer prophylaxis with PPI is used after all severe head trauma and after intubation.

SUBARACHNOID HEMORRHAGE

A 52-year-old woman is at her job in the office when she develops the sudden onset of a severe headache, stiff neck, photophobia, and loss of consciousness. She awakens within the hour that she arrived in the hospital. She is noted to have a severe headache, nuchal rigidity, photophobia, and a temperature of 38.5 C (101.3 F).

Definition. A subarachnoid hemorrhage (SAH) is the sudden onset of bleeding into the subarachnoid space.

Etiology. Aneurysm formation is the most common etiology. The aneurysms can be saccular or fusiform and are most commonly around the circle of Willis. The most common sites are anterior communicating artery, middle cerebral artery, and posterior communicating artery. There is an association with polycystic kidney disease, Ehlers-Danlos syndrome, and some other connective tissue diseases. SAH most commonly occurs spontaneously. Head trauma is rare as a cause of SAH.

Clinical Presentation. Sudden onset of severe headache is the hallmark of SAH. The sudden rise in intracranial pressure results in loss of consciousness in as many as 50% of patients. Focal neurologic symptoms occur in >30%, the most common from compression of the oculomotor cranial nerve. Sometimes the pressure of the bleed can dissect into the surrounding tissues and cause other neurologic defects. Nuchal rigidity, photophobia, headache, and papilledema occur because of meningeal irritation. Fever can occur 3–4 days after the initial hemorrhage. This can simulate meningitis because an SAH is a form of chemical meningitis from irritation by the blood. Seizures are also an extremely common finding. One-year mortality can be up to 50%, with half of the people dying upon immediate occurrence of the bleed.

Figure 10-20. Subarachnoid Hemorrhage on CT Scan

Note

A spinal headache may occur after a lumbar puncture in some patients. This is treated with a blood patch.

Longer-term manifestations include the development of focal deficits, seizures, rebleeding, and hydrocephalus. Vasospasm after the bleed results in hypoperfusion to portions of the brain parenchyma and the development of stroke. Rebleeding occurs when the clot falls off of the original site of bleeding. Up to half of the people who rebleed will die. Hydrocephalus occurs when the blood cells clog up the arachnoid granulations through which CSF normally drains.

Clinical Pearl

Traumatic lumbar puncture may cause RBC in the CSF, but xanthochromia is absent.

Diagnosis. The initial test is the CT scan, which is more sensitive than MRI for the diagnosis of SAH. The CT scan of the head is without the use of contrast and has a sensitivity of 90–95% within the first 24 hours after the onset of the bleed. The diagnostic sensitivity of the CT scan actually diminishes with time as the red cells within the CSF hemolyze and are resorbed and converted into the yellowish coloring described on CSF examination as *xanthochromia*.

If the initial CT scan is normal and an SAH is still suspected, *a lumbar puncture is done*. The lumbar puncture is the most sensitive diagnostic test. The absence of red cells and xanthochromia on the lumbar puncture essentially excludes an SAH. Xanthochromia is due to lysis of RBCs and formation of bilirubin (straw-colored CSF). Xanthochromia needs 4–6 hours to develop. Angiography is used to determine the specific anatomic site of the vascular defect and the site of the bleeding. EKG abnormalities, such as inverted or enlarged T-waves, are often associated with the development of an SAH and are not a cause for alarm.

Treatment. Initially, management consists of maintaining systolic blood pressure at 110-160 mm Hg. Pressure higher than this can provoke more bleeding. Pressure lower than this can provoke cerebral ischemia through hypoperfusion, given the increased intracranial pressure. Seizure prophylaxis is not necessary in these patients.

Corticosteroids are used to prevent hydrocephalus. Nimodipine is a calcium-channel antagonist that can be used to lower the risk of spasm in the blood vessel and therefore, lower the risk of subsequent stroke. *Angiography* should be done to determine the anatomic site that will need catheter or surgical correction. It is important to perform this so that surgical correction (usually performed through embolization or clipping of the AVM) can occur before rebleeding develops. If hydrocephalus occurs, then shunting will be needed. Embolization is superior to surgical clipping.

BURNS

> A 32-year-old fireman is caught in a fire and is briefly trapped under a burning staircase. He is quickly extracted and brought to the emergency department. His respiratory rate is 14/min. He is fully alert and weighs 220 pounds. There is soot in his mouth and nose and on his face, and his sputum not carbonaceous. The nasal hairs are singed. He has no stridor or hoarseness, and the lungs are clear to auscultation. He has first-degree burns on his right leg and second- and third-degree burns on his right arm and chest.

Injuries due to burns can be divided into several types. The most common causes of death from fires are **smoke inhalation** and **carbon monoxide poisoning**. Thermal injury is most dangerous when it is respiratory related. Skin injury is labeled first degree when the skin is fully intact, even though it may be discolored. First-degree burns are not associated with blister formation and appear "sunburn-like." The skin may be red or gray, but capillary refill remains normal. **Second-degree** burns result in blister formation. **Third-degree** burns are deeper and destroy skin appendages such as sweat glands, hair follicles, and sometimes pain receptors. This leaves third-degree burns insensate. Pain perceived by third-degree-burn patients is from surrounding structures where pain receptors are intact.

Pathophysiology. Although not apparent at first, respiratory injury can be the most life-threatening injury. Soot in the mouth or nose, stridor, wheezing, altered mental status, burned nasal hairs, and burns involving closed spaces are all clues to impending pulmonary and laryngeal edema. Shock occurs not only from direct skin loss but also from the release of a host of mediators that result in **diffuse capillary leak** for the first 18-24 hours. Serious capillary leak occurs when the percentage of serious body surface area burn exceeds 20-25%.

Note

Rule of Nines

The Rule of Nines differs between adults and children. Refer to Pediatrics for more information on the treatment and calculation of burns in children.

Clinical Presentation. Altered mental status, dyspnea, headache, and chest pain are clues to severe carbon monoxide poisoning. Laryngeal edema can result in stridor, hoarseness, and dyspnea. Soot in the nose and mouth can imply impending airway compromise. Skin injury is estimated with the "Rule of Nines" to assess fluid resuscitation. The head and arms are 9% each. The chest, back, and legs are 18% each. Patchy burns can be estimated by using one hand's width as an estimate of 1% of body surface area burned. Circumferential burns are critical in the assessment because as they heal they tighten and cut off circulation, leading to limb compromise and the need for escharotomy.

Diagnosis. Besides the obvious burn, carboxyhemoglobin levels are essential in severe burns. Severe burns are defined as combined second- and third-degree burns >20% in adults or >10% in the very old or very young or third-degree burns >5% of body surface area (BSA). Chest x-ray and bronchoscopy help determine the exact extent of respiratory injury when it is uncertain. Bronchoscopy can reveal severe thermal injury to the lungs even when the initial chest film is normal. Foley catheter placement helps determine the adequacy of fluid resuscitation.

Treatment. If the patient has signs of severe respiratory injury, as described above, the first step is to intubate the patient before more severe laryngeal edema can occur and make the intubation difficult. If the carboxyhemoglobin level is significantly elevated (>5-10%), 100% oxygen should be administered. Fluid resuscitation over the first 24 hours is based on a formula of 4 ml per % BSA burned per kg. Use Ringer's lactate as the preferred fluid. Use second- and third- degree burns in your calculation. Give half the fluid in the first 8 hours, with one-quarter in the second 8 hours, and one-quarter in the final 8 hours. This is known as the Parkland formula. Afterward, when the diffuse capillary leak improves, give enough fluid to maintain a urine output >0.5-1 mL per kg per hour.

Stress ulcer prophylaxis with H_2 blockers or PPIs should be given. Topical treatment with silver sulfadiazine is used to prevent infection. Do not break blisters and do not use steroids. Escharotomy is useful in circumferential burns. Skin grafting is done on the basis of the size and severity of the injury. Patients with burn injuries are at increased risk for pseudomonal and staphylococcal infections; if there is concern for infection, give IV antibiotics that cover these organisms.

Heat Disorders

Heat disorders are divided into 2 main groups: exertional and nonexertional. **Exertional** disorders vary from mild heat cramps to more severe heat exhaustion to potentially lethal heat stroke. **Nonexertional** disorders are malignant hyperthermia and neuroleptic malignant syndrome.

- **Heat Cramps.** This is a mild disorder that can happen to any healthy person who develops fluid and electrolyte depletion. The patient develops painful muscular contractions lasting a few minutes with muscle tenderness present. The patient is able to sweat, and there are no neurologic abnormalities. The body temperature is normal. Treatment is rest, oral rehydration, and salt replacement.
- **Heat Exhaustion.** This is a more severe exertional heat disorder. The patient is weaker with more systemic symptoms. Body temperature may be slightly elevated. Mild neurologic symptoms such as headache, nausea, and anxiety may occur, but severe confusion is rare. Death is very unlikely, but the disorder can progress to heat stroke if not treated. The patient is still able to sweat and remove heat from the body. Treatment can be accomplished with oral fluid and electrolyte replacement, but with severe weakness, the patient may need IV hydration.

- **Heat Stroke.** This is a very severe and potentially life-threatening disorder. Most patients have lost the ability to remove heat from the body because of the impairment of the ability to sweat. Fifty percent of patients still retain some capacity to sweat, but in insufficient amounts to keep up with heat generation. Body temperature may become severely elevated (>41°C), resulting in confusion, disorientation, nausea, blurred vision, and seizures. Numerous laboratory abnormalities may occur such as hemoconcentration, rhabdomyolysis, and elevated BUN, creatinine, and white cell count. Anuria, DIC, and lactic acidosis may develop.
- Treatment of heat stroke is with IV fluid replacement and rapid cooling of the body (place in cool environment and spray with water, then fan to evaporate the fluid). Ice-water immersion can result in overcooling and hypothermia. Chlorpromazine and diazepam can be used to control shivering.
- **Malignant Hyperthermia.** This is a nonexertional heat disorder occurring as an idiosyncratic reaction to the use of anesthetic agents such as halothane or succinylcholine. Virtually any anesthetic may cause it. Rhabdomyolysis may develop. Treatment is with dantrolene.
- **Neuroleptic Malignant Syndrome.** This is an idiosyncratic reaction to a wide variety of phenothiazines or butyrophenones such as haloperidol. Muscular rigidity and rhabdomyolysis may occur as well. Treatment, besides stopping the drug, is with bromocriptine or dantrolene.

Hypothermia

Definition. A reduction of core body temperature below 35°C (normal 37°C). Core temperature is measured with a rectal probe or through the esophagus. Severe hypothermia is a core temperature below 30°C.

Etiology. Hypothermia often occurs in association with alcohol intoxication, particularly in the elderly.

Clinical Presentation. The most common symptoms of severe hypothermia are related to the central nervous system. Lethargy, confusion, and weakness may occur. Death is most commonly from **arrhythmia** (Osborne wave or J wave). This is from the effect of the cold on altering cardiac conduction. Other complications include metabolic acidosis, respiratory acidosis, kidney injury, and hyperkalemia.

Diagnosis. The EKG can show a wide variety of serious arrhythmias, including ventricular fibrillation or ventricular tachycardia. The most characteristic finding is an elevation of the J-point, known as Osborne waves. J-wave elevation may mimic ST-segment elevation.

Treatment. Most patients will respond well to common-sense treatment, such as a warm bed, bath, or heated blankets. Warmed IV fluids or warmed humidified oxygen can be used in very severe cases, although care must be taken because overly rapid rewarming can result in arrhythmias as well. When life-threatening arrhythmias occur, it is important to continue resuscitative efforts until the body temperature is **>35°C**. If the patient is cold but not shivering, active measures should be used:

Active external rewarming

- Only to truncal areas
- Warm blankets

Note

Hypothermia must be worked up for precipitant factors:

- Hypoglycemia (most common cause)
- Hypothyroidism
- Sepsis

- Heat lamps
- Hot-water bottles

Active internal rewarming

- Warm IVFs (45° C)
- Warm humidified oxygen (45° C)
- Warmed gastric lavage via NGT
- Warmed hemodialysis

Hypothermia is one of the few times in which a patient can be resuscitated from pulselessness beyond the usual 10 minutes of efforts.

RADIATION INJURIES

Ionizing radiation damages tissues primarily through destructive changes to DNA molecules. Ionizing radiation is lethal and can often cause cancer. Longer exposures give worse injury. **Nonionizing radiation** is less destructive to tissue and causes injury primarily as burns. Examples include infrared, ultraviolet, and microwave radiation.

Presentation. To give a sense of scale, mortality is almost zero with <2 Gy (or Sv) of exposure. This rises almost to 100% mortality with >10 Gy (or Sv). (10 Gy = 1,000 rad.)

Any cell can be damaged by ionizing radiation, but the more rapidly the cell divides, the more vulnerable it is to radiation. This is because more DNA damage can be done during the time of division.

Bone Marrow. As little as 2-3 Gy (200-300 rad) can depress the lymphocyte count. Neutrophils are the next most sensitive cell, and erythrocytes are the least sensitive. Long-term, leukemia is the earliest and most common cause of cancer from radiation exposure. Thrombocytopenia can result in death from bleeding. Overall, *infection* and *bleeding* from depressed bone marrow function are the most common causes of death in acute exposure.

Gonads. Two to 3 grays result in temporary aspermatogenesis. Four to 5 grays can make men permanently sterile. Testes are more sensitive than ovaries.

GI. Nausea and vomiting are the most common early symptoms of radiation exposure. This develops in 50% of cases with a 2 Gy (200 rad) exposure and in 100% of patients with >3 Gy exposure. In addition to nausea and vomiting, the rapidly reproducing intestinal lining ulcerates, leading to bleeding and infection later.

Other Sites. Other common sites of radiation injury are the skin, salivary glands, respiratory epithelium, and thyroid glands.

Treatment. The management of radiation injury is supportive only. There is no specific therapy to reverse radiation injury.

- Antiemetics. Given that nausea is such a common feature of radiation sickness, antiemetics are a mainstay of therapy.
- Blood products. Platelets and RBC transfusions are needed. WBC transfusions don't help.
- Colony-stimulating factors (G-CSF, GM-CSF). These will help restore marrow function.
- Antibiotics. Use as needed when infection develops.
- Bone marrow transplantations. These are occasionally useful.

DROWNING

Risk/Mechanism. Alcohol and drug use are strongly associated with an increased risk of death by drowning. Muscular exhaustion, head and spinal trauma, or acute myocardial infarction are also predispositions to drowning and near drowning. Ten to twenty percent of drowning victims may have suffered dry drowning in that there is no water aspirated into the lungs. Dry drowning is secondary to laryngospasm.

Drowning from aspiration of water can be divided into 2 types:

- Freshwater, which is hypotonic, alters pulmonary surfactant, resulting in unstable alveoli, which then collapse. **The hypotonic freshwater is absorbed into the body, resulting in acute hypervolemia, hemodilution, and intravascular hemolysis.** At autopsy, the lungs may contain little water.
- With seawater, **the hypertonic water draws water out of the body into the lung, causing systemic hypovolemia and hemoconcentration.** The lungs become even more heavy and fluid-filled because the surfactant is essentially washed out.

Presentation. Only the presentation of near drowning is important to discuss because drowned victims are dead. The presentation can vary from coma to agitation. Cyanosis, coughing, and signs of pulmonary edema, such as tachypnea, tachycardia, and blood-tinged sputum, are common. Rales and rhonchi can be found on the exam. Hypothermia is also common.

Laboratory Findings. Arterial blood gases show hypoxia and hypercarbia, as well as metabolic acidosis from anaerobic metabolism. Hyperkalemia may be present if there is significant hemolysis. Renal insufficiency on the basis of hypoxia is a rare finding.

Treatment. The first task is to remove the patient from the water and do ABCs (airway/breathing/circulation) of resuscitation.

- Endotracheal intubation as needed
- Supplemental oxygen
- Positive pressure mechanical ventilation as needed

After removal from water, establishment of adequate airway is the most important initial step. Continuous positive airway pressure (CPAP) is the most effective treatment and gives the best correction of hypoxia and acidosis. Even if the patient appears comfortable initially, continue observation for 24 hours because ARDS (acute respiratory distress syndrome) may develop as a late finding.

The following treatments **do not help and may be harmful**:

- **Abdominal thrusts.** These may lead to aspiration of gastric contents.
- **Prophylactic antibiotics.** Antibiotics are only indicated if pneumonia develops.
- **Steroids.** There are no benefits to administering steroids.

ANAPHYLAXIS

Definition. A syndrome of histaminergic release in which there are signs of severe injury such as urticaria, angioedema, hypotension, tachycardia, and respiratory compromise.

Etiology. As an idiosyncratic reaction, patients can potentially develop anaphylaxis from any food, medication, insect bite, or antigenic substance entering the body by oral or parenteral route. Although medications such as penicillin, phenytoin, contrast agents, and allopurinol are most often associated with anaphylaxis, patients can potentially be allergic to anything. Chocolate, peanuts, and strawberries are common, but patients can be allergic to any food.

Note

Near Drowning vs. Drowning

- **Near drowning** is survival after immersion, at least for some time. Morbidity is high and death may occur later. The exact definition is still the topic of much debate.
- **Drowning** is defined as death within 24 hours after submersion in water.

The same is true of insect stings. Although bees may be common, patients can conceivably be allergic to any insect's venom.

Clinical Presentation. Mild symptoms include a rash known as "hives." More severe symptoms include dyspnea, stridor, tachycardia, hypotension, and hemodynamic collapse.

Treatment. Mild allergies may respond to simply stopping the offending toxin and waiting. More severe symptoms require the use of an antihistamine, such as diphenhydramine. Severe symptoms of anaphylaxis with hemodynamic instability require epinephrine injections, IV fluids, antihistamines, and systemic corticosteroids.

VENOMOUS BITES AND STINGS

Cat and Dog Bites

Epidemiology. Dog bites are the most common bites in the United States.

Etiology/Presentation. Dog bites are usually ripping and tearing in nature, whereas, cat bites are usually in the form of a puncture wound. Infection is more likely in patients with a delay in treatment, extremes of age and extremity injuries. Infections are most often polymicrobial. Cat bites are highly associated with *Pasteurella multocida* and dog bites are associated with *Pasteurella, Eikenella*, hemolytic streptococci, *Staph aureus*, and *Capnocytophaga canimorsus.*

Treatment. This includes exploration, debridement, irrigation, and proper wound care. If prophylactic antibiotics are indicated, the drug of choice is amoxicillin and clavulanate (a combination of clindamycin plus ciprofloxacin or trimethoprim/sulfamethoxazole or doxycycline can be used with penicillin allergy). Moxifloxacin may be used alone, as it has good aerobic and anaerobic activity.

Indications for antibiotic prophylaxis:

- For any cat bite
- Any bite on hand, face, or genitals
- Immunocompromised patients
- Asplenic patients (high risk of overwhelming sepsis from *Capnocytophaga canimorsus*)

Most wounds should be left unsutured except for facial wounds for cosmetic reasons. Never suture the hand.

Note

All human and monkey bites should always receive prophylactic antibiotics.

Human Bites

Epidemiology. Human bites carry an infection rate of 15%, which is greater than cat and dog bites together.

Etiology. The most common organisms are anaerobic and aerobic bacteria, specifically, *Eikenella corrodens*. Hepatitis B and HIV can also be transmitted through bites but are much less common.

Treatment. Clean and irrigate wound well. No place for cultures on fresh bites. If the bite is <12 hours old, close loosely. Give counseling for tetanus, hepatitis B, and prophylaxis. Initiate 5 to 7 day course of prophylactic antibiotics.

Rabies

Epidemiology. Carried by raccoons, rats, wild dogs, woodchucks, skunks, foxes. Nearly 100% fatal once the disease has been contracted. Bats are the most common cause.

Etiology/Clinical Presentation. Incubation period up to 1 year. Prodrome of 2 to 10 days including fevers and paresthesias at the bite site. Neurologic changes include aphasia, paralysis, hypersalivation, and myoclonus.

Diagnosis. Viral cultures from saliva, CSF, or serum

Treatment. Ribavirin has been used in confirmed cases. Prophylaxis with human rabies immunoglobin (HR16), which gives immediate passive immunity, and human diploid cell vaccine (HDCV) should be given. The current guidelines for rabies vaccination are as follows:

- **Preventive vaccination (no exposure)** (usually 3 doses)
  - Those at high risk of exposure to rabies (veterinarians, animal handlers, rabies lab workers, etc.) should be offered the vaccine
  - Those whose activities bring them into frequent contact with rabies virus or potentially rabid animals (e.g., an international traveler who is likely to come into contact with animals in a region where rabies is common) should be offered the vaccine
- **Vaccination post-exposure**
  - Those who have been bitten by an animal or who may have been exposed to rabies should receive wound cleaning and started on vaccine
    - If had never been vaccinated against rabies: give 4 doses (1 dose right away and additional doses on days 3, 7, and 14); a rabies immune globulin should also be given at the first dose
    - If had been previously vaccinated against rabies, give 2 doses (1 dose right away and another on day 3); rabies immune globulin is not needed

Snakebites

Epidemiology. Although 50,000 snakebites are reported per year worldwide, only about 8,000 of those are poisonous. There are <5–10 deaths per year, with rattlesnakes accounting for almost all fatalities.

Mechanism. Snake venom contains numerous potentially dangerous substances, such as hemolysis toxin, cardiotoxin, neurotoxin, and proteolytic enzymes, in addition to others. Some of these substances can result in neuromuscular blockade.

Factors that affect the severity of the bite:

- Body size. The smaller the body, the worse the effects; hence, bites tend to be worse in children.
- Location of bite. Trunk and face bites are worse than extremity bites.
- Exercising after bite. Muscular activity helps spread the venom through the lymphatics.
- Depth of injury. No poisoning occurs in 20-50% of bites because they are too superficial.

Treatment. Transport the patient immediately to the nearest medical facility.

1. Immobilize the patient. This will help to decrease the spread of venom through the lymphatics, which increases with muscular contraction.
2. Apply compression bandage. This will also help to decrease lymph flow. It should not be so tight as to decrease venous flow.
3. Antivenin. Be cautious of anaphylactic reactions that may occur to the horse serum.
4. Supportive. Hypotension is managed with fluids. Ventilatory support may be necessary.

Ineffective therapy includes incision and suction of the bites. Tourniquets and ice immersion do not help and might be harmful.

Neurology 11

Learning Objectives

- ❑ Outline the presentation, diagnosis, and management of disease of the spinal cord including spinal cord compression, syringomyelia, subacute combined degeneration, anterior spinal artery occlusion, ALS, and Brown-Sequard syndrome
- ❑ Describe the epidemiology, classification, and treatment of seizures and epilepsy
- ❑ Describe the presentation, diagnosis, and management of movement disorders including benign essential tremor, restless leg syndrome, Huntington disease, and Parkinson disease
- ❑ Present the diagnosis and management of autoimmune neurological diseases, including Guillain-Barre syndrome, MS, and myasthenia gravis
- ❑ Provide a differential diagnosis and work-up of patients presenting with headache, vertigo, or dizziness
- ❑ List the criteria for prevention of cerebrovascular accident in patients with TIA, and outline the management of patients with acute cerebrovascular accident
- ❑ Describe the epidemiology of dementia and typical course and complications

SPINAL CORD COMPRESSION

A 63-year-old African-American man is brought to the emergency department complaining of back pain that started gradually 3 days ago. The patient describes the pain as "band-like" around the abdomen, without radiation. His past medical history is significant for prostate cancer, diagnosed 3 years earlier, and treated with radiation.

Definition. An acute syndrome of back pain associated with compression of the spinal cord. It is considered a neurologic emergency.

Etiology. Commonly caused by cancer (lymphoma; multiple myeloma; carcinomas of prostate, lung, breast, kidney, or colon), herniated disk, epidural abscess, hematoma, or trauma. Acute cases are caused by trauma.

Note

Spinal Cord Compression

Acute: trauma

Subacute: most common cause–neoplams

Chronic: herniation

Clinical Presentation. Patients commonly present with insidious onset of mild sensory disturbance, lower extremity weakness, and/or sphincter or sexual dysfunction. Pain is the earliest symptom in the majority of patients (96%). Pain may be intensified by actions that increase intrathoracic and thus cerebral spinal fluid pressure. The diagnosis of acute spinal cord compression has to be suspected on the basis of the history and neurologic exam. The importance of having a high index of suspicion for the diagnosis is essential to instituting appropriate therapy early in the course of the disease. A history of cancer, fever, and bowel or bladder incontinence/retention are all points in the clinical history that strongly suggest the possibility of acute spinal cord compression. On neurologic exam, a dermatomal sensory level with bilateral lower extremity weakness, increased lower extremity muscle tone, and upper motor neuron signs below the level of compression are all consistent with the diagnosis of acute cord compression. The thoracic cord is the most common site of compression (70%) because the spinal cord is narrowest at that point. Symptoms may progress quickly.

Diagnosis. Plain x-rays are abnormal in 84 to 94% of all cases. The diagnostic test of choice is an MRI of the spine. When MRI of the spine is contraindicated, CT myelogram is the diagnostic test of choice.

Treatment. High-dose dexamethasone should be started immediately once the diagnosis is suspected. After the specific etiology is delineated more clearly by MRI, specific therapy may be initiated. For radiosensitive tumors, such as lymphoma or multiple myeloma, radiation therapy should be started as soon as possible. Surgical decompression is the treatment of choice for a herniated disk, epidural abscess, or hematoma. The prognosis depends mainly on the functional status of the patient at the time of presentation. Up to 80% of patients who are initially able to ambulate retain that ability after treatment. Only 5% of patients without antigravity leg strength are able to ambulate after treatment.

SYRINGOMYELIA

Syringomyelia is defined as cavitation of the spinal cord. It occurs as either communicating (with the CSF pathways) or noncommunicating. Communicating syringomyelia is usually associated with the congenital Arnold Chiari malformation, whereas the noncommunicating syringomyelia is typically secondary to trauma or tumors of the spinal cord.

In the cervical vertebrae of both gray and white matter, there is typically sensory dissociation with impaired pain and temperature and intact sensation to light touch. The loss of pain and temperature occurs in a cape-like distribution across the neck and arms. There is sparing of tactile sensation, position, and vibratory sense. Reflexes are lost.

As the lesion enlarges, there may be lower motor neuron manifestations at the level of the lesion with upper motor neuron signs below the lesion. Cavitation most commonly occurs at the level of the cervical cord. MRI is the most accurate diagnostic test. Treatment is surgical, but often unsatisfactory.

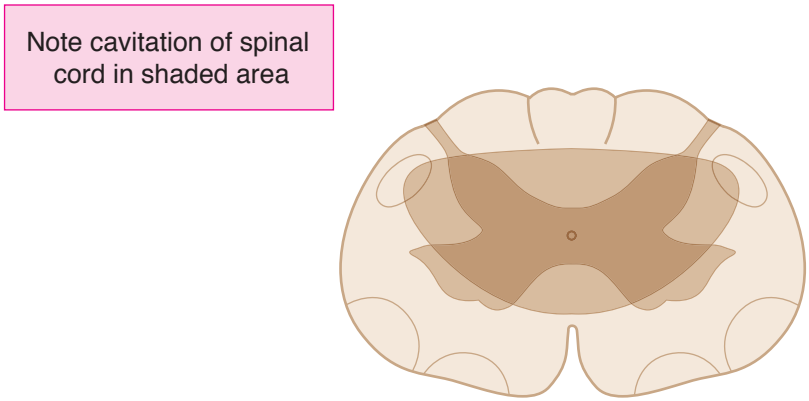


Figure 11-1. Syringomyelia

SUBACUTE COMBINED DEGENERATION

Subacute combined degeneration occurs with vitamin B12 deficiency. Patients will complain of distal paresthesias and weakness of the extremities followed by spastic paresis and ataxia. On exam there is a combined deficit of vibration and proprioception with pyramidal signs (plantar extension and hyperreflexia). Diagnosis is established by finding a low serum vitamin B12 and treatment is with vitamin B12 replacement.

ANTERIOR SPINAL ARTERY OCCLUSION

Anterior spinal artery occlusion presents with acute onset of flaccid paralysis that evolves into a spastic paresis over days to weeks. Additionally, there is loss of pain and temperature sensation with sparing of vibration and position sense as the posterior columns are supplied by the posterior spinal artery. Everything (motor, sensory, autonomic) is lost below the level of the infarction with the striking exception of retained vibration and position sense. Treatment is supportive.

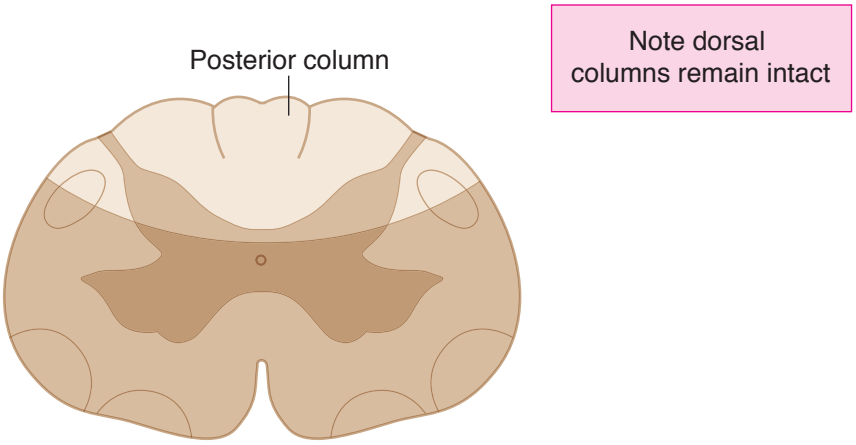

Figure 11-2. Anterior Spinal Artery Occlusion

BROWN-SÉQUARD SYNDROME

Hemisection of the cord results in a lesion of each of the 3 main neural systems: the principal upper motoneuron pathway of the corticospinal tract, one or both dorsal columns, and the spinothalamic tract. The hallmark of a lesion to these 3 long tracts is presentation with 2 ipsilateral signs and 1 contralateral sign.

- Lesion of the corticospinal tract results in an ipsilateral spastic paresis below the level of the injury.
- Lesion to the fasciculus gracilis or cuneatus results in an ipsilateral loss of joint position sense, tactile discrimination, and vibratory sensations below the lesion.
- Lesion of the spinothalamic tract results in a contralateral loss of pain and temperature sensation starting 1 or 2 segments below the level of the lesion.

At the level of the lesion, there will be an ipsilateral loss of all sensation, including touch modalities as well as pain and temperature, and an ipsilateral flaccid paralysis in muscles supplied by the injured spinal cord segments.

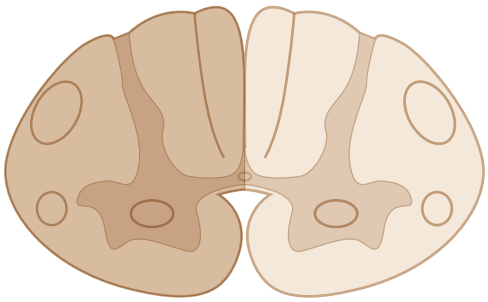

Figure 11-3. Hemisection: Brown-Séquard Syndrome

CEREBROVASCULAR ACCIDENT (CVA)

A 56-year-old woman is brought to the emergency department by her daughter complaining of sudden onset of right upper extremity weakness that began while she was watching television early this morning. The daughter became concerned when her mother was unable to talk in response to questions. Neurologic examination shows right upper extremity weakness with pronator drift and right facial nerve palsy. When questioned, the patient seems to understand what is being said but cannot clearly respond.

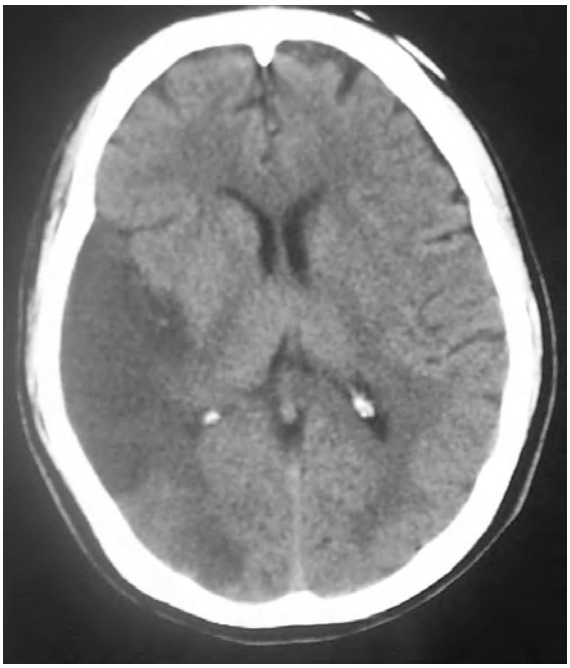
Definition. A sudden onset of a focal neurologic deficit.

Etiology. The principal mechanisms by which strokes occur are:

1. Large artery thrombosis
2. Small artery thrombosis (lacunar)
3. Embolic (cardiogenic or artery-to-artery)
4. Vascular dissection
5. Systemic hypertension
6. Bleeding

Clinical Presentation. Stroke should be considered in any patient who presents with acute onset of a focal neurologic deficit. The specific clinical syndrome is determined by the mechanism and vascular territory affected. The blood supply to the brain is divided into two major systems: the carotid (anterior) circulation, and the vertebrobasilar (posterior) circulation. The major blood vessels comprising the anterior circulation include the anterior cerebral artery (ACA) and middle cerebral artery (MCA).

Occlusion of the ACA presents with contralateral weakness and sensory loss in the leg more than in the upper extremity. Urinary incontinence, confusion, and behavioral disturbances are common. Lower extremity weakness exceeds upper extremity weakness.



aic.cuhk.edu.hk/web8

Figure 11-4. CT Scan Demonstrating a Right MCA Infarction

Occlusion of the MCA presents with contralateral hemiplegia, hemisensory loss, and homonymous hemianopia with eyes deviated toward the cortical lesion. Dominant hemisphere involvement results in aphasia. Nondominant hemisphere involvement results in preserved speech, comprehension with confusion, and apraxia with spatial and constructional deficits.

The posterior circulation provides blood supply to the cerebellum, brain stem, occipital lobe of the cortex, and pons. The major blood vessels that comprise the posterior circulation are the posterior cerebral artery (PCA), basilar artery (BA), and vertebral arteries.

Table 11-1. Posterior Circulation Syndromes

	Ipsilateral	Contralateral
Weber	CN III	Hemiplegia
Benedikt	CN III	Ataxia
Wallenberg	Facial sensory loss	Body sensory loss

Occlusion of the PCA presents with contralateral homonymous hemianopia, visual hallucinations, and agnosias. Occlusion of the penetrating branches of this vessel can result in CN III palsy with contralateral hemiplegia (Weber syndrome) or CN III palsy with contralateral ataxia or athetosis (Benedikt syndrome).

Specific syndromes associated with occlusion of basilar artery branches include the "locked-in syndrome" (paramedian branches), presenting as quadriparesis with intact vertical eye movements; and Wallenberg syndrome (posterior inferior cerebellar artery), which presents as ipsilateral facial sensory loss, contralateral body sensory loss, vertigo, ataxia, dysarthria, dysphagia, and Horner syndrome.

Occlusion of the major cerebellar arteries produces vertigo, vomiting, nystagmus, and ipsilateral limb ataxia.

Diagnosis. The initial test of choice will always be a noncontrast CT scan of the head. This test is done to distinguish between hemorrhagic and ischemic stroke. Noncontrast CT is the most sensitive test for detecting blood in the brain. CT scans are often negative for ischemia within the first 48 hours after symptom onset. Diffusion-weighted MRI is the most accurate test for detecting cerebral ischemia.

The diagnostic workup of patients with acute ischemic stroke involves searching for embolic sources (echocardiogram, carotid duplex, and 24-hour Holter monitor). Also consider a workup for inherited hypercoagulability. Subarachnoid hemorrhage is associated with EKG abnormalities such as ischemia or inverted T-waves, called cerebral T-waves. A "bubble study" is done on the echocardiogram to detect the presence of a patent foramen ovale or other cardiac defect.

Treatment. Tissue plasminogen activator is given if the patient presents within 3 hours of symptom onset. Contraindications to the use of tissue plasminogen activator include stroke or serious head trauma within 3 months, hemorrhage (GI or genitourinary) within 21 days, surgery within 14 days, history of intracranial hemorrhage, BP >185/110 mm Hg, current use of anticoagulants, platelets <100,000/mm^3, or coagulopathy (PT >15 seconds). Patients who receive tissue plasminogen activator in an appropriate manner have better neurologic function 3 months after CVA as compared with patients who did not receive tissue plasminogen activator.

There is no clear benefit to the use of heparin with stroke. This is because of the increased risk of bleeding. Any benefit is offset by adverse events associated with treatment. For every stroke prevented, one intracranial hemorrhage is caused. Therefore, treatment with heparin in acute ischemic stroke is always wrong.

Antiplatelet therapy is most useful in secondary prevention of ischemic stroke. Aspirin is considered first-line treatment for secondary prevention of ischemic stroke. Aspirin is started 24 hours after TPA. When patients have a known allergy to aspirin or continue to have recurrent cerebrovascular events on aspirin alone, dipyridamole may be added or the patient may be switched to clopidogrel to enhance antiplatelet therapy. Ticlopidine is no longer used because the rates of thrombotic thrombocytopenic purpura and leukopenia are unacceptably high. For those with a recurrent stroke while on aspirin, the single best answer is to add dipyridamole or switch to clopidogrel. *Do not combine* aspirin and clopidogrel for a stroke. Combination of anti-platelet agents is used on coronary disease but not cerebral disease.

Subarachnoid hemorrhage is treated with nimodipine to reduce the risk of ischemic stroke. Early surgical intervention to clip off the aneurysm or embolize the vessel with a catheter should be done in good operative candidates. "Early" means within several days. Don't wait for the unrepaired aneurysm to rebleed. Unruptured aneurysms found incidentally should be repaired if they exceed 10 mm in size.

Carotid endarterectomy is recommended when an occlusion exceeds 70% of the arterial lumen and the lesion is *symptomatic.* Endarterectomy may benefit those who are asymptomatic if there is >60% stenosis in men age <60. The benefit of endoarterectomy is less certain in women because they have a lower risk of stroke. The more severe the disease, the greater the benefit. Carotid stenting is an alternative to endarterectomy.

Endarterectomy is simply not clear in asymptomatic carotid stenosis. The Step 2 exam does not engage in unanswerable, controversial issues.

Carotid angioplasty and stenting are not as good as endarterectomy for symptomatic patients with >70% stenosis. Angioplasty and stenting should be considered only for those who cannot undergo surgical endarterectomy.

SEIZURES AND EPILEPSY

A 29-year-old man is brought to the emergency department by ambulance after being found convulsing in his bedroom. The patient's mother says that during the episode her son was unable to respond to her frantic cries, and she describes jerking movements that became more frequent and then stopped after approximately 1 minute. The mother says that he seemed tired and lethargic for at least 20 minutes after the episode. She then called the ambulance to bring her son to the hospital.

Definition. A seizure is a paroxysmal event due to abnormally discharging central nervous system (CNS) neurons. Epilepsy is defined as a condition of recurrent seizures due to a chronic underlying process.

Etiology. Seizures are caused by "VITAMINS":

Vascular (stroke, bleed, arteriovenous malformation)
Infection (meningitis, abscess, encephalitis)
Trauma (especially penetrating)
Autoimmune (CNS vasculitis)
Metabolic (hyponatremia, hypocalcemia, hypomagnesemia, hypoglycemia, hypoxia, drug overdose/withdrawal)
Idiopathic
Neoplasm
p**S**ychiatric

Clinical Presentation. A seizure is essentially a paroxysmal, involuntary event (associated with abnormal movement or change of consciousness or both). Characteristically, seizures are sudden in onset, with or without an aura. Patients often complain of disorientation, sleepiness, and aching muscles for minutes to hours after the event. Patients may also experience incontinence, tongue biting, and headache as a result of the seizure. It may be difficult at times to differentiate a seizure from syncope, and it is important to obtain a complete history from any individual who witnessed the event. Generally, patients with syncope will not complain of significant postictal symptoms. They will recover consciousness within several minutes of the event, and on physical exam will not have evidence of incontinence or tongue biting.

It is important to classify seizures according to their clinical features because this will determine what medications will be used for treatment. Seizures can be classified as **partial versus generalized** and **complex versus simple**.

Partial seizures occur within discrete portions of the brain. The patient will often complain of involuntary jerking of a finger or hand. When consciousness is maintained for the duration of the seizure, the seizure is termed a **simple partial seizure**. When there is a change in consciousness during the seizure, the seizure is termed a **complex partial seizure**. When a partial seizure progresses to a generalized seizure, it is called a partial seizure with secondary generalization. Typically, the seizure will begin focally and become generalized as the seizure activity involves both cerebral hemispheres.

Generalized seizures arise from both cerebral hemispheres spontaneously without any detectable focal onset. **Generalized tonic-clonic (grand mal)** seizures are characterized by tonic contraction of muscles throughout the body followed by intermittent relaxation of various muscle groups (clonic phase). **Absence seizures (petit mal)** are more common in children than adults; they are characterized by sudden, brief loss of consciousness without loss of postural tone. Characteristically, the EEG will show a generalized, symmetric 3-Hz spike-and-wave discharge pattern. Atonic seizures are characterized by sudden loss of postural tone lasting 1 to 2 seconds. Myoclonic seizures are characterized by sudden, brief muscle contraction.

Status epilepticus is defined as recurrent or continuous seizures (lasting at least 5–30 min).

Diagnosis. EEG is the test of choice for the diagnosis of epilepsy. The diagnosis of idiopathic seizures is made only after secondary precipitating factors have been ruled out. An abnormal EEG alone is not diagnostic of epilepsy. Approximately 2 to 18% of the population has an abnormal EEG. Always check serum electrolytes, glucose, toxicology, and arterial blood gas to rule out hypoxia as a cause of a patient's seizure. CT scan or MRI of the head is usually indicated to rule out a structural lesion as the cause of seizure. Think of any seizure as a symptom, much like shortness of breath or chest pain, which has an extensive differential diagnosis. The evaluation of any seizing patient is to rule out reversible causes of seizure.

Treatment. The treatment of seizures can be divided into the acute management of the acutely seizing patient (status epilepticus) and the chronic management of the epileptic patient.

The first step in the treatment of any acutely seizing patient is to secure the **a**irway, **b**reathing, and **c**irculation. Once an adequate airway is established, breathing is assured, and the patient is hemodynamically stable, the next step is to simultaneously evaluate and treat any precipitating causes of seizure. If a reversible cause is identified, treat aggressively. If the patient continues to seize, the following strategy is appropriate. The initial drug of choice is lorazepam or diazepam, both of which are benzodiazepines. These medications work by potentiating GABA receptor function. If the patient continues to seize, add phenytoin or fosphenytoin, which inhibits sodium-dependent action potentials. CNS side effects of phenytoin include diplopia, dizziness, and ataxia. Systemic side effects include gum hyperplasia, lymphadenopathy, hirsutism, and rash. If the patient continues to seize add phenobarbital. Side effects include sedation, ataxia, and rash. If, despite all of the above therapy, the patient continues to seize, add midazolam or propofol.

In patients with first-time seizure, anticonvulsant therapy should be started *only* if the patient has an abnormal neurologic exam, presented with status epilepticus, has a strong family history of seizure, or has an abnormal EEG. Otherwise, first-time seizures are generally not treated with long-term anticonvulsant therapy.

There is no superior drug in pregnancy. Valproic acid is clearly more dangerous in pregnancy.

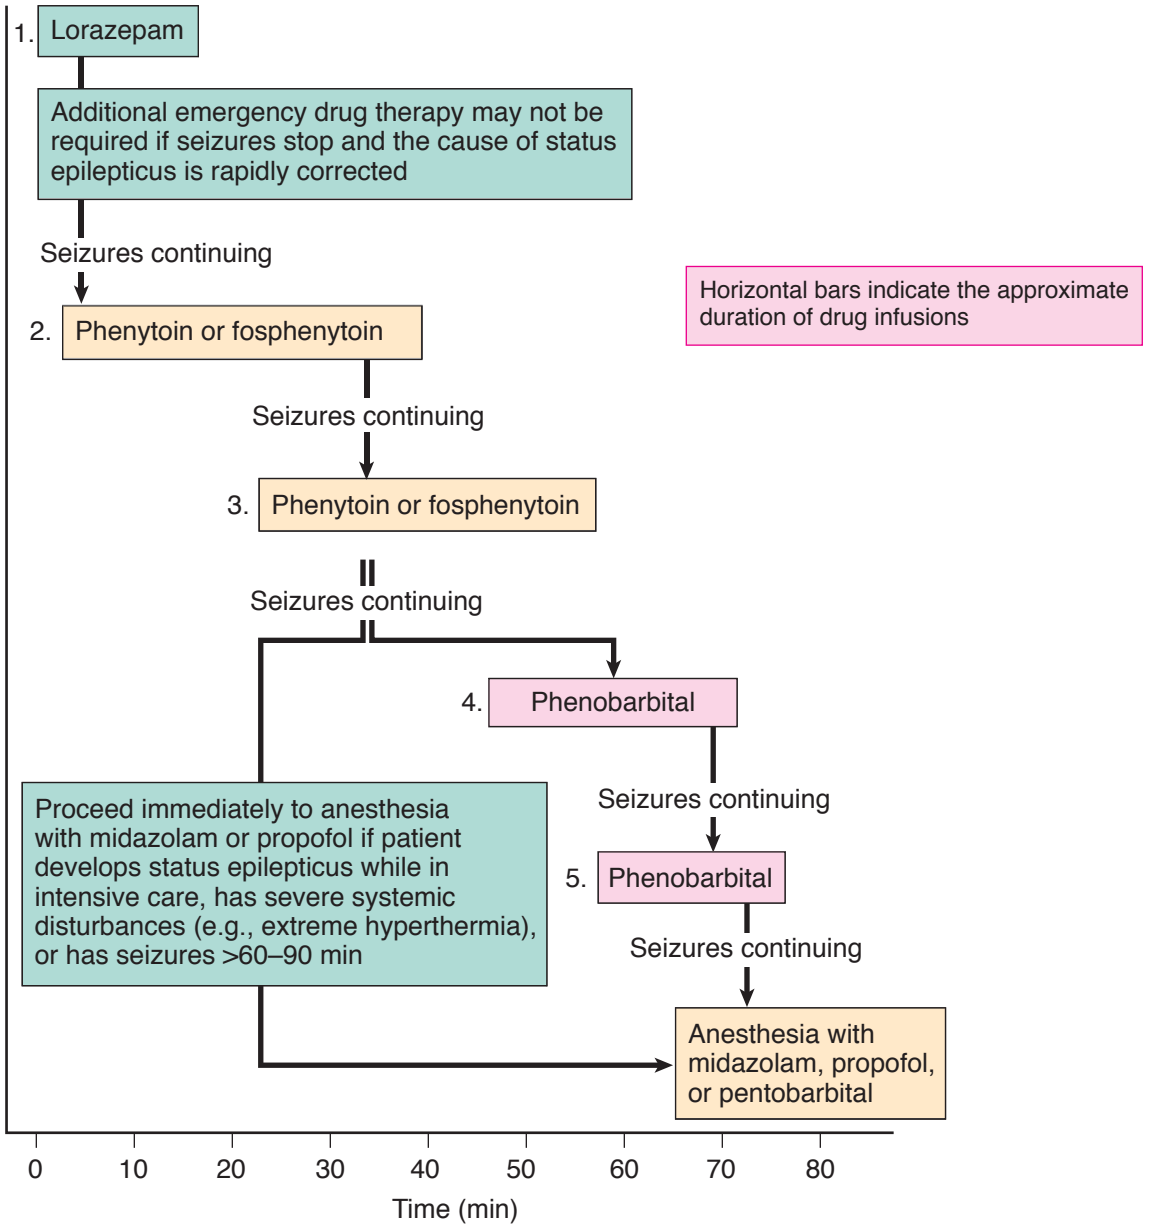


Figure 11-5. Development of Status Epilepticus

For primary generalized tonic-clonic seizures, valproic acid, phenytoin, lamotrigine, carbamazepine, or levetiracetam can be used. Lamotrigine works by decreasing glutamate release. Side effects include Stevens-Johnson syndrome. Absence seizures are treated with ethosuximide as first-line therapy. If ethosuximide is not an answer choice, valproic acid is an acceptable option. For myoclonic and atonic seizures, valproic acid is the treatment of choice. Overall, there is no single antiepileptic drug that's truly superior to the others—valproic acid, phenytoin, levetiracetam and carbamazepine are all nearly equal in efficacy.

Partial seizures, whether they are complex or simple, and whether or not they progress to secondary generalized seizures, are all treated the same. Carbamazepine and phenytoin are considered first-line therapy. Valproic acid and lamotrigine are considered acceptable alternatives, as is levetiracetam. It is very difficult to determine when to stop therapy. Therapy may be stopped if the patient has been free of seizures for 2–3 years. Sleep-deprivation EEG may be done first to determine if the patient is at low risk of a recurrence. A normal sleep-deprivation EEG means there is a lower likelihood of seizures.

VERTIGO AND DIZZINESS

> A 53-year-old woman is brought to the emergency department complaining of dizziness. She describes walking to her bathroom and experiencing a sudden feeling of nausea. She then vomited and fell to the floor. She was unable to get up but was able to call 911. The patient describes a feeling of the room "spinning" around her, even though she realizes she was not moving.

Definition. Vertigo is defined as a false sensation of movement, i.e., the sensation of movement in the absence of actual movement.

Etiology. Vertigo may be caused by Ménière disease, labyrinthitis, positional vertigo, traumatic vertigo, perilymphatic fistula, and cervical vertigo. Other causes include vascular disease of the brain stem, arteriovenous malformations, brain tumor, multiple sclerosis, drug overdose, and vertebrobasilar migraine.

Clinical Presentation. With the dizzy patient, the first step in the evaluation is to determine the nature of the patient's complaints. "Dizziness" is a nonspecific term that provides no meaningful information about what is occurring to the patient. Simply by taking a complete history, it is possible to determine whether the patient is experiencing vertigo or presyncope.

Patients who experience vertigo will describe a sensation of movement without actually moving. Commonly, patients will describe their environment spinning around them. Sensations of tilting, swaying, or falling forward or backward are all consistent with vertigo. Acutely, these episodes are commonly associated with nausea and vomiting.

Patients who complain of presyncope will describe their symptoms as "lightheadedness" or "feeling like I'm going to black out." Associated symptoms include generalized weakness, palpitations, and shortness of breath. It is essential to differentiate vertigo from presyncope because vertigo is usually a manifestation of neurologic disease, whereas presyncope is a cardinal manifestation of cardiovascular disease.

Once you are convinced by the history that the patient is indeed experiencing an episode of vertigo, the next diagnostic question you have to answer is whether the vertigo is secondary to peripheral or central vestibular disease. This distinction is important because the management will differ between peripheral and central vertigo.

Several points on history and physical examination will distinguish central from peripheral vertigo.

Table 11-2. Vertigo

	Central Vertigo	Peripheral Vertigo
Onset	Gradual	Usually sudden
Tinnitus, hearing loss	Absent	Present
Neighborhood signs (diplopia, cortical blindness, dysarthria, extremity weakness/numbness)	Present	Absent
Nystagmus	Pure, vertical, does not suppress with fixation, and multidirectional	Mixed, horizontal, suppresses with fixation, and unidirectional

Once you have determined that the patient has peripheral vertigo, there is a wide differential diagnosis that should be considered.

Ménière disease is characterized by tinnitus, hearing loss, and episodic vertigo. Each episode lasts 1 to 8 hours. The symptoms wax and wane as the endolymphatic pressure rises and falls. The two most common causes of Ménière disease are syphilis and head trauma.

Benign paroxysmal positional vertigo is a cause of peripheral vertigo that characteristically is exacerbated by head movement or change in head position. Typically, episodes will occur in clusters that persist for several days. There will be a latency of several seconds after head movement before the onset of vertigo. The vertigo usually lasts 10 to 60 seconds.

Labyrinthitis presents with sudden onset of severe vertigo that lasts for several days with hearing loss and tinnitus. The disease frequently follows an upper respiratory tract infection.

Perilymphatic fistula is a form of peripheral vertigo related temporally to head trauma (blunt trauma to the ear, e.g., a slap to the ear) or extreme barotrauma during air flight, scuba diving, or vigorous Valsalva maneuver. Explosions deafen people.

Central vertigo is caused by any cerebellar or brain-stem tumor, bleed, or ischemia. Drug toxicity or overdoses are important causes of central vertigo. Also, in the young patient with unexplained central vertigo, consider multiple sclerosis.

Treatment. Symptomatic treatment for peripheral vertigo includes meclizine or, in severe cases, diazepam.

Ménière disease is treated with a low-salt diet and diuretics. In patients who fail medical therapy, you can consider surgical decompression.

Benign paroxysmal positional vertigo is treated with positional maneuvers that attempt to move the otolith out of the circular canals (e.g., Dix Hallpike and Barany maneuvers).

Vertigo secondary to *labyrinthitis* is treated symptomatically with meclizine and diazepam when the symptoms are severe. Steroids help labyrinthitis.

DISORDERS ASSOCIATED WITH HEADACHE

Headache

A 32-year-old woman comes to the office complaining of a headache that started 2 days ago. She locates her headache at the right side of her head and describes it as throbbing in quality. The headache is worsened by walking up stairs or around the block. She experiences nausea but denies vomiting. She also states that loud noise and bright light exacerbate her pain.

Definition. Headache is defined as pain located in the head, neck, or jaw.

Etiology. There are many causes of headache that can be divided into primary or secondary headache syndromes. Primary headache syndromes include migraine, cluster, and tension headache. Secondary causes of headache include intracranial hemorrhage, brain tumor, meningitis, temporal arteritis, and glaucoma. Migrane affects 15% of the general population.

Clinical Presentation. The single most important question that has to be answered in any patient who presents complaining of a headache is whether there exists a serious underlying cause for the symptoms. By taking a thorough history and performing an adequate physical examination, it is possible to make this differentiation. An essential point in the history is to determine whether this is the first episode of headache that the patient has experienced. A history of recurrent symptoms makes the diagnosis of a primary headache disorder more likely. A history of a first-time headache, especially when severe and rapidly peaking, speaks strongly for serious underlying pathology.

Headache with fever and nuchal rigidity suggests meningitis as the underlying cause. Conversely, a headache that is described as "the worst headache of my life" and/or "thunderclap" at onset, and is accompanied by nuchal rigidity *without* fever, suggests an intracranial hemorrhage as the underlying cause. Patients with brain tumors will present complaining of headache that is described as a deep, dull, aching pain that disturbs sleep. The history of vomiting that precedes the onset of headache by a number of weeks, or a history of headache induced by coughing, lifting, or bending, is typical of posterior fossa brain tumors. Patients with temporal arteritis complain of a unilateral pounding headache associated with visual changes, described as dull and boring with superimposed lancinating pain. Patients will also complain of polymyalgia rheumatica, jaw claudication, fever, weight loss, and scalp tenderness (difficulty combing hair or lying on a pillow). The scalp tenderness is from pain over the temporal artery. Temporal arteritis is a disorder of the elderly, generally presenting in patients age >50. Temporal arteritis gives an elevated sedimentation rate and is diagnosed with biopsy of the temporal artery. Do not wait for the biopsy results to initiate therapy with steroids. Patients with glaucoma will usually give a history of eye pain preceding the onset of the headache.

Once serious underlying pathology is excluded by history and physical examination, primary headache syndromes should be considered. The main primary headache syndromes are migraine, cluster, and tension headache.

Note

Any patient who presents with headache and the following should be considered to have a secondary headache syndrome:

- "Worst headache of my life"
- Worsening symptoms over days to weeks
- Abnormal neurologic exam
- Fever
- Vomiting preceding the headache
- Headache induced by coughing, bending, lifting; or onset age >55

Migraine headaches are defined as a benign and recurrent syndrome of headache, nausea/vomiting, and other varying neurologic dysfunctions. Patients will describe the headache as pulsatile, throbbing, unilateral, and aggravated by minor movement. Other associated features include photophobia, phonophobia, and the time to maximal pain (4 to 72 hours). Migraine is a likely diagnosis when a typical trigger can be identified. Typical triggers include alcohol, certain foods (such as chocolate, various cheeses, monosodium glutamate), hunger, or irregular sleep patterns.

- Migraine without aura is a migraine without a preceding focal neurologic deficit.
- Migraine with aura (classic migraine) is a migraine accompanied by a preceding aura that consists of motor, sensory, or visual symptoms. Focal neurologic symptoms usually occur during the headache rather than as a prodrome. The pathognomonic aura for classic migraine is the scintillating scotoma. Only 20% of migraine headaches are accompanied by an aura. Visual auras are also described as stars, sparks, and flashes of light. Migraine equivalent is defined as focal neurologic symptoms without the classic complaints of headache, nausea, and vomiting.
- Complicated migraine is migraine with severe neurologic deficits which persist after the resolution of pain.
- Basilar migraine is migraine associated with symptoms consistent with brain-stem involvement (vertigo, diplopia, ataxia, or dysarthria).

Tension-type headaches are described as tight, band-like headaches that occur bilaterally. Patients may also describe their headache as "vise-like," and these headaches may be associated with tightness of the posterior neck muscles. Patients will describe their pain as one that builds slowly, and the pain may persist for several days with or without fluctuations. Movement will not generally exacerbate the headache.

Cluster headaches, common in men, begin without warning and are typically described as excruciating, unilateral, periorbital, and peaking in intensity within 5 minutes of onset. They are rarely described as pulsatile in nature. The attacks last from 30 minutes to 3 hours and occur 1–3× day for a 4-to-8-week period. Symptoms associated with cluster headaches include rhinorrhea, reddening of the eye, lacrimation, nasal stuffiness, nausea, and sensitivity to alcohol. Horner syndrome is sometimes found. Emotion and food rarely will trigger a cluster headache.

Diagnosis. Patients with severe, sudden onset of a first-time headache accompanied by strong evidence for an underlying cause on history or physical examination should have a CT scan of the head to rule out any secondary causes.

Treatment. Always begin with an attempt to identify probable triggers for the patient and to modify lifestyle by avoiding those triggers. Most patients will require pharmacotherapy as well.

Pharmacologic treatment for migraine headaches can be divided into management of an acute episode and prophylaxis. Initially, for a mild migraine—which is defined as headache in the absence of nausea or vomiting—NSAIDs may be used.

Acutely, abortive therapy consists of sumatriptan, which acts as a serotonin receptor agonist. Dihydroergotamine is the alternative to the triptans. Ergotamine can be used in combination with caffeine. The triptans are contraindicated in patients with known cardiovascular disease, uncontrolled hypertension, or pregnancy. In addition to sumatriptan, there is almotriptan, naratriptan, zolmitriptan, and eletriptan. These medications can be given orally, intranasally, or even subcutaneously, depending on the severity of the headache. Alternatively, ergotamine can be given for acute abortive therapy. Dopamine antagonists such as metoclopramide can be given acutely as oral formulations to aid in the absorption of other abortive

medications. When given parenterally, dopamine antagonists can provide relief acutely for migraine headaches.

Prophylactic treatment for migraine therapy should be initiated when patients have acute migraine headaches >3–4/month. The best prophylactic medication is a beta blocker. Propranolol, valproic acid, and topiramate are all considered first-line therapy for migraine prophylaxis. Verapamil and tricyclics can also be used. These medications take 2 to 6 weeks to have an effect and can be discontinued gradually over 6 months once clinical stabilization has occurred. Methysergide is not used because of the serious side effects associated with prolonged use (valvular and retroperitoneal fibrosis). SSRIs such as sertraline and fluoxetine can also be used for prophylaxis.

Table 11-3. Migraine Therapies

Abortive	Prophylactic
• NSAIDs, aspirin, acetaminophen • Triptans • Ergotamine derivatives	• Beta blockers • Calcium blockers • Tricyclics • SSRIs • Valproic acid • Topiramate

Opioid analgesics are not routinely recommended for the treatment of migraine headaches because of the possibility of developing addiction. They are used only in patients with severe, infrequent migraines that are unresponsive to other therapy. Other therapies for migraine headaches are acetaminophen and NSAIDs such as ibuprofen.

Treatment for tension headaches consists of relaxation. Patients should be encouraged to find activities that are relaxing for them. Initial pharmacotherapy consists of acetaminophen and NSAIDs. If the headache remains refractory to these medications, a muscle relaxant can be added to the regimen.

Cluster headaches are treated with a triptan or 100% oxygen. Prophylaxis of cluster headaches is best done with a calcium channel blocker. Prednisone and lithium are sometimes used.

Pseudotumor Cerebri

Definition. An idiopathic increase in intracranial pressure also known as benign intracranial hypertension.

Etiology. The disorder is 8 to 10 times more common in women. There is an association with obesity, chronic lung disease, Addison disease, oral contraceptives, tetracycline use, and vitamin A toxicity. Often there is no identified cause and the disorder resolves spontaneously after several months.

Clinical Presentation. Patients present with a headache, visual disturbances such as diplopia, and sixth cranial nerve (abducens) palsy. Clinical findings include diplopia, papilledema, and enlargement of the blind spot on visual field testing. The CT and MRI are normal, and evaluation of cerebrospinal fluid is normal beyond an increase in pressure.

Treatment. Treatment consists of weight loss, removing offending agents such as oral contraceptives, and the use of diuretics such as acetazolamide or furosemide. Steroids such as prednisone may help as well. In urgent cases, repeated lumbar punctures may help. If this is not effective and the disorder does not resolve, definitive treatment can be achieved with the placement of a surgical shunt between the ventricles and the peritoneum.

Trigeminal Neuralgia

Also known as tic douloureux, trigeminal neuralgia is an idiopathic pain syndrome resulting in sudden, severe, sharp pain starting near the side of the mouth and progressing to the ear, eye, or nostril. Attacks can be triggered by touch or movement such as talking or by eating. Trigeminal neuralgia can be so severe as to be nearly incapacitating. The pain lasts for a few seconds and disappears. Despite the pain, the sensory examination will be normal. Generally, trigeminal neuralgia is felt to be secondary to compression of the trigeminal nerve root by a blood vessel. Occasionally it can be a manifestation of multiple sclerosis or a posterior fossa tumor. With the exception of multiple sclerosis or the posterior fossa tumor, all imaging and neurologic testing will be normal.

Carbamazepine is the standard of care for treatment. In those not controlled with carbamazepine, phenytoin, baclofen, or gabapentin can be tried. In those not responding to any form of medical therapy, surgery or radio-frequency lesioning into the affected nerve may work.

GUILLAIN-BARRÉ SYNDROME (GBS)

> A 46-year-old man is brought to your office complaining of "rubbery legs." The patient states that his symptoms began 2 days ago and that approximately 3 weeks ago, he experienced several episodes of diarrhea, which resolved spontaneously. On neurologic examination, bilateral lower-extremity weakness and a loss of reflexes are noted.

Definition. An acute, often severe polyradiculopathy whose underlying pathophysiology is an autoimmune destruction of myelin.

Etiology. Evidence suggests that GBS is caused by a misdirection of the immune response, where the body's immune system attacks self-antigens mistaken for foreign antigens (molecular mimicry).

Clinical Presentation. Most patients will present with rapidly developing weakness that typically begins in the lower extremities and moves upward. On physical examination the patient is noted to lack reflexes in the muscle groups affected. The progression of the symptoms will develop over the course of hours to days. The legs are usually more affected than the arms and face. Fever, constitutional symptoms, or bladder dysfunction are rare and should raise the possibilities of alternate diagnoses.

In addition to the motor weakness, patients will typically complain of sensory disturbances that can take the form of pain or tingling dysesthesia. Sensory changes are due to loss of large sensory fibers, producing loss of reflexes and proprioception. Autonomic instability (profuse sweating, postural hypotension, labile blood pressure, cardiac dysrhythmias) occurs in severe GBS, requiring patient treatment in an intensive care unit.

Approximately 75% of patients who present with GBS will have a history of an infection 1 to 3 weeks preceding the onset of symptoms. The infection is typically in the respiratory or GI systems (*Campylobacter jejuni*), although GBS may be preceded by infections with human herpesvirus, cytomegalovirus, or the Epstein-Barr virus. The only association between immunizations and GBS occurred in 1976 with the introduction of the swine influenza vaccine. More recent formulations of influenza vaccine are associated with one case of GBS per million patients immunized. GBS occurs more frequently in patients with HIV, systemic lupus erythematous, and lymphoma.

Diagnosis. Diagnosis lies principally in recognizing the typical pattern of weakness with the absence of reflexes, fever, and constitutional symptoms. A lumbar puncture for protein and cell count is always the best initial test. The characteristic finding is an elevated protein without an associate rise in the cell count on CSF. These changes in the cerebral spinal fluid do not occur until 48 hours after the onset of symptoms. The most accurate test for the diagnosis is electromyography (EMG). EMG is used to detect evidence of demyelination of the peripheral nerves.

Treatment. Treatment should be initiated as quickly as possible because available therapy becomes ineffective approximately 2 weeks after the onset of symptoms.

IV immunoglobulin and plasmapheresis are equally effective treatments. There is no benefit to combination therapy. Glucocorticoids are not effective in the treatment of acute GBS. Also, it is extremely important to monitor the vital capacity in patients with GBS and initiate early respiratory support to prevent death from respiratory failure.

MYASTHENIA GRAVIS

> A 35-year-old woman comes to the clinic complaining of double vision that seems to worsen near the end of the day. She also complains of difficulty chewing meat and other hard foods. She notices that her symptoms improve following a good night's sleep. On neurologic examination, you note a snarling appearance when the patient is asked to smile, and a nasal tone is heard in her voice. You also note a weakness in the upper extremities when the patient is asked to clench her fist around your finger repeatedly.

Definition. Myasthenia gravis (MG) is a disease of the neuromuscular junction characterized by weakness and fatigability.

Etiology. In myasthenia gravis, an autoimmune process characterized by acetylcholine-receptor antibodies leads to a decreased number of active and functional acetylcholine receptors at the postsynaptic membrane.

Clinical Presentation. The major features in a patient's history that help to diagnose myasthenia gravis are muscle weakness and fatigability. Initially, patients will complain of diplopia, ptosis, and difficulty swallowing. Speech may have a "mushy" or nasal quality and facial weakness may manifest as a "snarling" appearance when smiling. As the disease progresses, weakness may become generalized, involving proximal muscles in an asymmetric pattern. Deep tendon reflexes are intact. Pupillary responses are normal. There are no sensory abnormalities. Very severe disease may affect the muscles of respiration.

Eaton-Lambert myasthenic syndrome is characterized by *increasing* muscle strength on repetitive contraction. This syndrome is seen in association with malignancy, especially small-cell carcinoma of the lung.

Botulism may cause a myasthenic-like illness, but the pupils are usually dilated and repetitive nerve stimulation (on EMG) shows an incremental increase in muscular fiber contraction (opposite of myasthenia gravis).

Diagnosis. The best initial test for the diagnosis of myasthenia gravis is the acetylcholine-receptor antibody test. In generalized myasthenia gravis, 80–90% of patients will have a positive test. In the presence of fatigable muscle weakness, a positive antibody test is specific and virtually diagnostic. Antibodies are present in only 70% of those with disease limited to the eyes.

The edrophonium (Tensilon) test is sensitive but not specific for the diagnosis. Additionally, patients may experience nausea, diarrhea, fasciculations, syncope (rare), or bradycardia during the test, which are cholinergic symptoms.

Imaging studies of the chest such as x-rays and CT scan should be performed to detect a thymoma. Thymoma is found in 10–15% of patients. Thymic hyperplasia is found in 65%.

The most accurate test for the diagnosis of myasthenia gravis is electromyography (EMG). The characteristic finding is a decremental decrease in muscle fiber contraction on repetitive nerve stimulation.

Treatment. Anticholinesterase (usually pyridostigmine or neostigmine) medications are useful for the symptomatic treatment of myasthenia gravis. Pyridostigmine is longer lasting. If treatment with anticholinesterase medications is unsuccessful in providing symptomatic relief, the physician should consider immunosuppressive therapy.

There are numerous medications used for immunosuppressive therapy. These interventions primarily differ in the onset of therapeutic benefit. They are used if thymectomy is not effective.

Glucocorticoids are effective in improving weakness but take 1 to 3 months for you to observe a clinical benefit. Steroids are the initial immunosuppressive of choice. If patients fail steroid therapy, azathioprine is the most widely used medication used in combination with steroids. The benefits of azathioprine therapy may take >3–6 months to peak. Cyclosporine and cyclophosphamide are alternatives to azothiaprine but are more toxic.

Plasmapheresis and IV immunoglobulin are immunosuppressive therapies noted for their ability to rapidly improve weakness in myasthenia gravis. They are therefore reserved for patients in acute myasthenic crisis. These therapies are used when respiratory involvement occurs or when patients go to the operating room.

Thymectomy is indicated in postpubertal patients and in those age <60 with generalized myasthenia gravis before initiation of immunosuppressive therapy. Thymectomy is performed in those not controlled with anticholinesterase medications to prevent the use of potentially toxic medication such as systemic steroids. Thymectomies are also performed when a thymoma is present to prevent the spread of malignant thymic disease.

Aminoglycoside antibiotics may exacerbate myasthenia gravis and should be avoided. In fact, many medications may worse myasthenia gravis.

Mycophenolate is a newer immunosuppressive drug with less adverse effects than steroids or cyclophosphamide.

AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS) is an idiopathic disorder of both upper and lower motor neurons. ALS has a unique presentation of muscle weakness combined with signs of upper motor neuron loss, cranial nerve palsies, respiratory involvement, and lower motor neuron destruction, while at the same time preserving bowel, bladder sensory, cognitive, and sexual function. The cranial nerve, or bulbar, palsies result in dysphagia, difficulty chewing, decreased gag reflex, dysarthria (difficulty in articulating words), and difficulty in handling saliva. Since there is often respiratory muscle involvement, recurrent aspiration pneumonia is the most common cause of death. A weak cough is also characteristic, and this only worsens the respiratory problem.

There is no pain from abnormal sensory neuropathy because this is entirely a motor neuron disease. On the other hand, the upper motor neuron involvement gives significant spasticity that can lead to pain. Mentation, bowel, bladder, and sexual function remain intact for the same reason. In other words, a fully mentally alert patient loses nearly all motor control while still being able to think and perceive. The patient becomes fully aware of being trapped in a body that does not function. Head ptosis occurs because the extensor muscles of the neck become too weak to keep the head up.

Upper motor neuron manifestations are weakness with spasticity and hyperreflexia. Lower motor neuron manifestations are weakness with muscle wasting, atrophy, and fasciculations; this includes tongue atrophy. The combination of upper and lower motor neuron weakness is the unique presentation of ALS. The most accurate confirmatory test is the electromyogram, which will show diffuse axonal disease. CPK levels are sometimes mildly elevated, and the cerebrospinal fluid and MRI scans are normal.

The only treatment that may slow down the progression of the disease is riluzole, which is thought to work by inhibiting glutamate release. Death typically results in 3–5 years. Spasticity is treated with baclofen and tizanidine.

Many of the exam questions regarding ALS will be ethical questions on issues of the withholding of care. Since ALS has no impact on cognitive function, the patient is felt to retain the capacity to make medical decisions. This means the patient has the right to refuse potentially lifesaving therapy such as antibiotics, nasogastric tube placement, tracheostomy, or the use of mechanical ventilation. The patient should not be allowed to commit suicide nor should the physician assist with the suicide. Withholding intubation or antibiotics is not considered assisting a suicide. Every adult patient with the capacity to understand the implications of their choice is allowed to refuse any therapy they do not want.

MULTIPLE SCLEROSIS

> A 32-year-old woman comes to the emergency department complaining of numbness and tingling in her right hand. Her symptoms began several days ago and have worsened over the last several hours. She states that 3 years ago she had an episode of "seeing double" that lasted 2 days and resolved on its own. Physical examination is significant for hyperreactive reflexes bilaterally in her lower extremities. Increased spasticity is also noted in her lower extremities.

Definition. An autoimmune inflammatory disease of the CNS white matter characterized by a relapsing or progressive course.

Etiology. The cause of multiple sclerosis (MS) is thought to be multifactorial. There is evidence that genetic susceptibility plays an important role. The disease occurs primarily in female populations of Northern European descent and of child-bearing age, respectively. This implies a role for some sort of environmental trigger (infectious, dietary, climatic). Pathologically, focal areas of demyelination are characteristic of the disease.

Clinical Presentation. Commonly, patients will present complaining of weakness, numbness, tingling, or unsteadiness of a limb. Urinary urgency or retention, blurry vision, and double vision are all common initial manifestations of the disease. Symptoms may persist for several weeks or may resolve spontaneously over a few days.

There are several forms of the disease that may change the course of management and are therefore important to recognize. Most patients will have a months-long to years-long disease-free period after their first exacerbation.

- **Relapsing remitting disease:** progression is characterized by relapses of active disease with incomplete recovery during the periods of remission
- **Secondary progressive disease:** progression becomes more aggressive so that a consistent worsening of function occurs
- **Primary progressive disease:** symptoms are progressive from the onset of disease with the early onset of disability (least common form)

It is important to understand when the diagnosis of multiple sclerosis should be suspected. Classically, the diagnosis is made clinically when a young patient (usually age <55) presents with a history of multiple neurologic complaints that cannot be explained by the presence of one CNS lesion. In other words, suspect the diagnosis when a patient presents with multiple neurologic deficits **separated by time and space (anatomy)**.

A number of triggers are known to exacerbate the disease. Infections or trauma may acutely worsen the disease. Pregnancy, especially the 2 to 3 months following birth, may also exacerbate symptoms. However, there are generally fewer attacks during the pregnancy. Uncomplicated MS typically has no adverse effects on the outcome of the pregnancy.

Diagnosis. To diagnose MS you have to rely on clinical criteria supplemented with radiologic and laboratory confirmations. The advent of MRI scanning of the brain has dramatically changed the methods by which multiple sclerosis is diagnosed.

MRI of the brain is the most accurate test to diagnose MS, reaching a sensitivity of 85 to 95% in symptomatic persons. Increased T2 and decreased T1 intensity represent the increased water content of demyelinated plaques in the cerebrum and spine. Enhancement of lesions with gadolinium indicates active MS lesions that may enhance for up to 2 to 6 weeks after an exacerbation. MS is an unusual disease in that the best initial test for the diagnosis is also the most sensitive one, namely MRI of the brain and spine.

Evoked response potentials detect slow or abnormal conduction in response to visual, auditory, or somatosensory stimuli. The limitation of this test for the diagnosis of MS is that many other neurologic diseases can give an abnormal result. The test is not specific for the diagnosis of MS. As a result, evoked potentials are rarely used to make the diagnosis.

Cerebrospinal fluid (CSF) analysis usually reveals a mild pleocytosis (usually <50 cells/μL) and a total protein that is mildly elevated. A protein level exceeding 100 mg/dL is unusual and should be considered as evidence against the diagnosis of MS. An elevated IgG index (oligoclonal bands) is found in 70 to 90% of patients with MS. The finding is nonspecific, and as a result, CSF for oligoclonal banding is recommended only when the MRI is nonconfirmatory but clinical suspicion for MS remains high.

Treatment. The treatment of multiple sclerosis can be divided into disease-modifying therapy, treatment of complications, and treatment for symptomatic relief during an acute exacerbation. The specific agents used depend on progression of the disease at the time of diagnosis.

In relapsing-remitting disease, there are 3 disease-modifying agents that have been shown to reduce the number of clinical exacerbations and the number of MRI lesions:

- Interferon-β1a
- Interferon-β1b
- Glatiramer acetate

More importantly, these medications seem to delay the onset of significant disability. Glatiramer is also known as copolymer I.

In secondary progressive disease, interferon-β1b and mitoxantrone have been shown to reduce the number of exacerbations, decrease MRI activity, and delay onset of disability. In patients who receive mitoxantrone, dose-related cardiotoxicity is a concern; mitoxantrone should be given only to patients with a normal ejection fraction. Mitoxantrone is not a first-line agent to prevent disease progression because of its cardiotoxicity. In patients with relapsing-remitting disease or secondary progressive disease who cannot tolerate treatment with IFN-β1b, IFN-β1a, or glatiramer acetate, you can consider treatment with methotrexate, mitoxantrone, cyclophosphamide, IV immunoglobulin, or azathioprine. ACTH is no longer used.

No approved disease-modifying therapy exists at this time for primary progressive disease.

Mitoxantrone, cyclophosphamide, and natalizumab are not used for a first episode of disease. Natalizumab is associated with progressive multifocal leukoencephalopathy (PML).

The length and intensity of an acute exacerbation is shortened by the administration of glucocorticoids. Typically, an acute exacerbation is treated with 3 days of intense IV steroids followed by a course of oral medication tapered over 4 weeks. In patients with severe disease who are unresponsive to steroid therapy, plasma exchange can be used as an alternative treatment.

For patients with spasticity, baclofen is the most effective medication. Tizanidine and diazepam are useful for nocturnal spasticity but are limited in their use for daytime symptoms because they cause intense somnolence. Pain secondary to trigeminal neuralgia and dysesthesias responds well to carbamazepine, gabapentin, phenytoin, pregabalin, or tricyclic antidepressants. Bladder hyperactivity is treated with oxybutynin, whereas urinary retention is treated with bethanechol. Fatigue may be treated with amantadine or fluoxetine. Erectile dysfunction can be treated with sildenafil acetate.

All disease-modifying therapies are relatively contraindicated in pregnancy. Interferon and glatiramer should both be stopped for a pregnancy.

Fingolimod is an oral disease-modifying medication that decreases rates of MRI progression. It prevents lymphocytes from proliferating outside of lymph nodes. Cardiac toxicity can be severe.

Dalfampridine is an oral disease-modifying medication that increases walking speed. It is a unique potassium channel blocker for which the precise mechanism of action (for improved walking speed) is not clearly known.

DEMENTIA

A 67-year-old woman is brought to the clinic complaining of forgetfulness. She states that recently she has been forgetting common phone numbers and the name of her mailman, whom she has known for 25 years. Her past medical history is significant for hypertension, coronary artery disease, and high cholesterol. Her physical examination is unremarkable.

Definition. Cognitive function is measured by various mental functions, including memory, concentration, language, praxis, visuospatial functioning, and executive functions. "Dementia" refers to loss of memory with impairment of any other cognitive function sufficient to interfere with social or occupational functioning.

Etiology. There are >100 identifiable causes of dementia in the elderly. Among the many **reversible causes** of dementia, you should consider hypothyroidism, vitamin B12 deficiency, hepatic or uremic encephalopathy, CNS vasculitis, syphilis, brain abscess, brain tumor (primary or metastatic), medications (especially anticholinergics), obstructive sleep apnea, central sleep apnea, trauma, subdural hematoma, normal pressure hydrocephalus (NPH), and depression. **Irreversible causes** of dementia include progressive multifocal leukoencephalopathy, Alzheimer disease, dementia with Lewy bodies, frontotemporal degeneration including Pick disease, vascular dementia including multi-infarct dementia and Binswanger disease, and Creutzfeldt-Jakob disease (CJD). Alzheimer disease accounts for 60 to 80% of all causes.

The prevalence of dementia is 1–5% between ages 65–69, rising to 45% by age 100. Only 5% of Alzheimer disease is inherited.

Clinical Presentation. The most common cause of dementia is Alzheimer disease. Typically, patients will present with problems in memory and visuospatial abilities that generally occur early in the course of the disease. Social graces can be retained despite significant loss of cognitive decline. Hallucinations and personality changes typically occur late in the course of the disease.

Mild cognitive impairment refers to memory loss without dysfunction of other cognitive domains. These patients have a higher risk of developing Alzheimer disease later in life but do not have Alzheimer disease. The rate of progression is 15–20% per year.

Alzheimer disease is, by definition, the loss of memory as well as other cognitive disturbances, such as aphasia, agnosia (the failure to identify entities despite intact sensory function), apraxia, or the loss of the ability to make plans and execute them. There is no single diagnostic test for Alzheimer disease.

Patients with frontotemporal dementias such as Pick disease will typically present with personality changes early in the course of their disease, with relative sparing of their visuospatial function. Social, interpersonal, and emotional abnormalities precede memory impairment. Frontotemporal dementia is often noted primarily by the family because the patient lacks insight into their condition. There is no proven therapy for this condition.

Dementia with Lewy bodies (DLB) can be confused with delirium and is characterized by fluctuating cognitive impairment.

Dementia secondary to Parkinson disease should be accompanied by clinical findings consistent with that disease. Recurrent visual hallucinations are also characteristic.

Dementia secondary to CJD is characterized by a shorter (weeks to months), more aggressive course than Alzheimer disease. Patients with CJD will present with dementia and myoclonus. Variant CJD is bovine spongiform encephalopathy (BSE). BSE is from the ingestion of prions from affected cattle. The diagnosis of CJD is by rapidly progressive dementia, myoclonus, ataxia, and the presence of 14-3-3 protein in the CSF. EEG may also help diagnose. These criteria can eliminate the need for brain biopsy.

Vascular dementia is divided into multi-infarct dementia, which typically has a stepwise progression associated with discrete cerebrovascular events, and Binswanger disease, involving the subcortical white matter, which presents with a slowly progressive course.

Normal pressure hydrocephalus will present with prominent gait abnormalities early in the course of the disease that usually precede the onset of cognitive impairment. There will also be associated urinary incontinence.

Diagnosis. All patients with cognitive impairment should be assessed with a Mini Mental Status Examination (MMSE) to identify the areas of cognitive impairment.

Initially, the workup should focus on ruling out reversible causes of the dementia. If a reversible cause is identified, it should be treated, with the hope that cognitive function can be recovered. Laboratory studies should include a complete blood count (CBC), electrolytes, calcium, creatinine, liver function studies, glucose, thyroid-stimulating hormone (TSH), vitamin B12, RPR, and HIV.

Brain imaging is most useful for patients who have a focal neurologic exam, seizures, gait abnormalities, and an acute or subacute onset of their symptoms. EEG and CSF evaluation are not necessary except for NPH-opening pressure. No CSF marker is proven beneficial with the exception of 14-3-3 protein in CJD.

Treatment. Treatment of dementia revolves around insuring that the family and the patient have the proper medical and emotional support to cope with the disease. Caregivers are at an increased risk for depression and anxiety. Their concerns and frustrations should be addressed at frequent intervals.

Raising the level of acetylcholine in CSF benefits patients with Alzheimer disease. Pharmacotherapy with donepezil has been shown to improve cognitive function in mild to moderate dementia. Other anticholinesterase inhibitors (rivastigmine, galantamine) appear to have similar efficacy.

Memantine is a disease-modifying drug used in advanced disease either alone or with a cholinesterase inhibitor. Memantine seems to be neuroprotective and reduces the rate of progression of disease.

HUNTINGTON DISEASE

A 34-year-old man comes to the clinic for an evaluation of strange spontaneous movements that have been occurring lately. Recently, while sitting at a family dinner, the patient experienced uncontrolled grimacing with grunting. His father died at the age of 41 from "dementia."

Definition. A genetic degenerative brain disorder.

Etiology. Huntington disease is caused by the presence of the HD gene located on chromosome 4p. The gene contains a CAG trinucleotide repeat expansion that codes for a protein called *huntingtin*. The HD mutation leads to abnormal cleavage of the huntingtin protein, interfering with nuclear mechanisms, and causing cell death. The disease is inherited in an autosomal dominant fashion. Successive generations tend to have the disease occuring at an earlier age. This is called *anticipation*.

Clinical Presentation. The clinical hallmarks of the disease include chorea and behavioral disturbance. Onset is usually in the fourth or fifth decade and can begin with either chorea or behavioral change. The personality changes consist of irritability, anger, paranoia, or signs of depression. Antisocial behavior may develop. The chorea may begin as fidgeting that progresses to sudden movements of the trunk or limbs. Gait is poorly coordinated and has a choreic quality. Memory is usually preserved until late in the disease but lack of judgment, disinhibition, and inattention are early manifestations. There is frequently an associated depression. Dementia becomes severe later in the disease.

Diagnosis. Diagnosis is made by genetically testing for the presence of the CAG trinucleotide DNA repeat expansion. There is a 50% chance of passing it on to children. CT scanning shows cerebral atrophy. Atrophy of the caudate nucleus is severe later.

Treatment. Tetrabenazine helps the movement disorder of Huntington disease but will not reverse or cure the underlying disease process. Death occurs 15–20 years after the diagnosis. Haloperidol or clozapine can be used to control behavioral changes.

PARKINSON DISEASE

A 56-year-old man is brought to the office by his wife for evaluation of a resting tremor that she noticed recently. She also states that her husband has been moving "very slowly" as of late. When questioned, the patient states that he feels fine and does not know why his wife is dragging him from doctor to doctor. His past medical history is significant for mild hypertension that has been treated with a thiazide diuretic.

Physical examination is significant for a resting tremor noted in his right hand. When walking, the patient is stooped forward, taking small steps. You note cogwheel rigidity in his right upper extremity with a positive Myerson sign.

Definition. Parkinson disease is defined as a neurologic syndrome resulting from the deficiency of the neurotransmitter dopamine as a consequence of degenerative, vascular, or inflammatory changes in the basal ganglia.

Etiology. There are numerous causes of Parkinsonism. Many drugs can cause Parkinsonism, including neuroleptic agents (haloperidol, chlorpromazine), antiemetics (metoclopramide), alpha-methyldopa, and reserpine. Poisoning from MPTP, carbon monoxide, cyanide, and manganese are also causes of Parkinsonism. Any structural lesion around the basal ganglia (trauma, tumor, abscess, infarct) can produce clinical Parkinson disease. Patients who have survived an episode of encephalitis can develop *postencephalitic Parkinsonism*.

Clinical Presentation. The cardinal manifestations of Parkinson disease are bradykinesia (manifested by slow movements, mask facies, reduction of automatic movements), cog-wheel rigidity, postural instability, and resting tremor. A useful mnemonic is to think of Mr. Parkinson as a fine **BRIT**ish gentleman.

Bradykinesia

Rigidity (cogwheel)

Instability (postural)

Tremor (resting)

There are a number of "Parkinson plus" syndromes, which are characterized by their relative lack of response to therapy with levodopa/carbidopa.

Parkinsonism + vertical gaze palsy = supranuclear palsy

Parkinsonism + prominent ataxia = olivopontocerebellar atrophy

Parkinsonism + prominent orthostatic hypotension = Shy-Drager syndrome (now called *multiple-system atrophy*)

Several other diseases can imitate Parkinsonism. Severe depression can cause a paucity of spontaneous movement that can mimic Parkinsonism. Essential tremor can be mistaken for the tremor of Parkinson disease, but the lack of other neurologic symptoms and a positive family history of tremor and its amelioration with alcohol distinguish the two entities. A normal pressure hydrocephalus can present with ataxia and gait disturbances, which can also be mistaken for Parkinson disease. The presence of dementia and urinary incontinence with dilated ventricles on a CT scan of the head can help identify this disorder. Huntington disease can present with akinesia and chorea. The positive family history and dementia usually suggest the correct diagnosis.

Diagnosis. The diagnosis of Parkinson disease is a clinical one. It is important to identify any secondary causes of a patient's Parkinsonism that are potentially reversible. There is no diagnostic test of choice that can identify patients with Parkinson disease.

Treatment. There are many medications available for the treatment of Parkinson disease. The underlying pathophysiology that causes Parkinson disease is the imbalance of dopaminergic (too little) and cholinergic (too much) tone on the basal ganglia. Thus, medical treatment revolves around increasing dopaminergic tone or decreasing cholinergic tone on the basal ganglia.

Not surprisingly, the medications available for the medical treatment of Parkinson disease directly stimulate dopamine receptors (carbidopa/levodopa, dopamine agonists), indirectly increase the amount of dopamine available (COMT inhibitors, selegiline, amantadine), or block acetylcholine stimulation of the basal ganglia (benztropine, trihexyphenidyl).

Direct-acting dopamine agonists such as pramipexole or ropinirole can be used alone as initial therapy or in combination with small doses of levodopa/carbidopa. Two other dopamine agonists are bromocriptine and cabergoline. All of them are less efficacious than levodopa. Dopamine agonists do, however, have less dyskinetic side effects. Bromocriptine and pergolide are ergot derivatives and can cause cardiac toxicity.

The first step when considering what medication to start with is evaluating the patient's functional status. Patients with an intact functional status are managed differently from patients with a compromised functional status.

Patients with intact functional status (less bradykinesia) are not generally given carbidopa/levodopa as initial therapy. Such patients are started on anticholinergic medication when they are age <60. This is particularly true for those in whom tremor is the predominant symptom. When age >60, the treatment of choice is amantadine. The reason why anticholinergics are relatively contraindicated in elderly patients is because the side effects (dry mouth, urinary retention, constipation, confusion/hallucinations) occur more frequently and severely. Anticholinergics such as benztropine and trihexyphenidyl are used mostly to relieve tremor and rigidity. Avoid with BPH and glaucoma.

For patients with compromised functional status (more significant bradykinesia), the best initial therapy is carbidopa/levodopa. Carbidopa inhibits extracerebral dopa-decarboxylase, allowing more of the levodopa to reach the central nervous system, where it is needed. Levodopa is the precursor to dopamine. Carbidopa protects the levodopa from breakdown in the periphery, ensuring its secure delivery to the central nervous system. There are several late complications to carbidopa/levodopa therapy: Dyskinesia (abnormal movements), akathisia (restlessness), and "on-off" phenomena are all disconcerting to the patient. All of these late side effects are termed "response fluctuations" and can be managed by using a sustained release form of carbidopa/levodopa, adding a dopamine agonist, selegiline, or a COMT inhibitor, or restricting the main protein meal to the night. COMT inhibitors are tolcapone and entacapone. They are always used in conjunction with levodopa to help reduce the dose or modify response fluctuations. COMT inhibitors have no effect alone; they decrease the metabolism of the levodopa. They are an adjunct to the use of levodopa to reduce adverse effects.

Selegiline was once thought to slow the progression of the disease. Selegiline can be used in those with a declining or fluctuating response to levodopa. Selegiline offers mild symptomatic benefit in early disease. Rasagiline is a newer version.

Surgery should only be considered for patients who cannot tolerate or respond adequately to medical therapy. The procedures usually performed are pallidotomy or thalamotomy. The placement of deep brain stimulators is also effective when placed in the globus pallidus or subthalamic nuclei. Surgical therapy is a last resort.

BENIGN ESSENTIAL TREMOR

This is an idiopathic disorder consisting of an isolated tremor of the hands, head, or both. The lower extremities tend to be spared. Essential tremor can be worsened by the use of caffeine or beta agonists. Examination reveals no other abnormalities. Although the level of disability tends to be limited, there can be interference with manual skills such as the ability to write. It is characteristic of this disorder that there is an improvement with the use of alcohol. The patient will describe shaky hands, which improve with 2–3 drinks.

There is no specific diagnostic test for this disorder. Treatment is propranolol. If propranolol is ineffective, alternate medications are primidone, alprazolam, and clozapine. If no medical therapy is effective, thalamotomy is indicated.

RESTLESS LEG SYNDROME

Restless leg syndrome (RLS) is an idiopathic condition resulting in a sensation of creeping and crawling dysesthesia within the legs, leading to involuntary movements during sleep. Often the condition is brought to attention because of multiple bruises sustained by the sleep partner. The condition can be familial and is exacerbated by sleep deprivation, caffeine, and pregnancy. There is also an association with uremia, iron deficiency, and peripheral neuropathy.

There is no specific diagnostic test for this disorder. Treatment is a dopamine agonist such as pramipexole or ropinirole, although some patients may need levodopa/carbidopa. Other therapies are narcotics and benzodiazepines.

Dermatology 12

Learning Objectives

- ❏ Describe the mechanism of bullous and blistering diseases and approaches to treatment
- ❏ List the common dermatologic parasitic diseases, treatments, and common side effects
- ❏ Outline the treatment of skin and ulcer infections, including decubitis (pressure) ulcers and acne
- ❏ Describe the presentation and management of scalp, hair, and scaling disorders (eczema), and papulosquamous dermatitis
- ❏ Provide an overview of toxin-mediated diseases, hypersensitivity, and toxin-mediated diseases
- ❏ Describe benign lesions, precancerous lesions, and malignant diseases of the skin and their treatment and prognosis

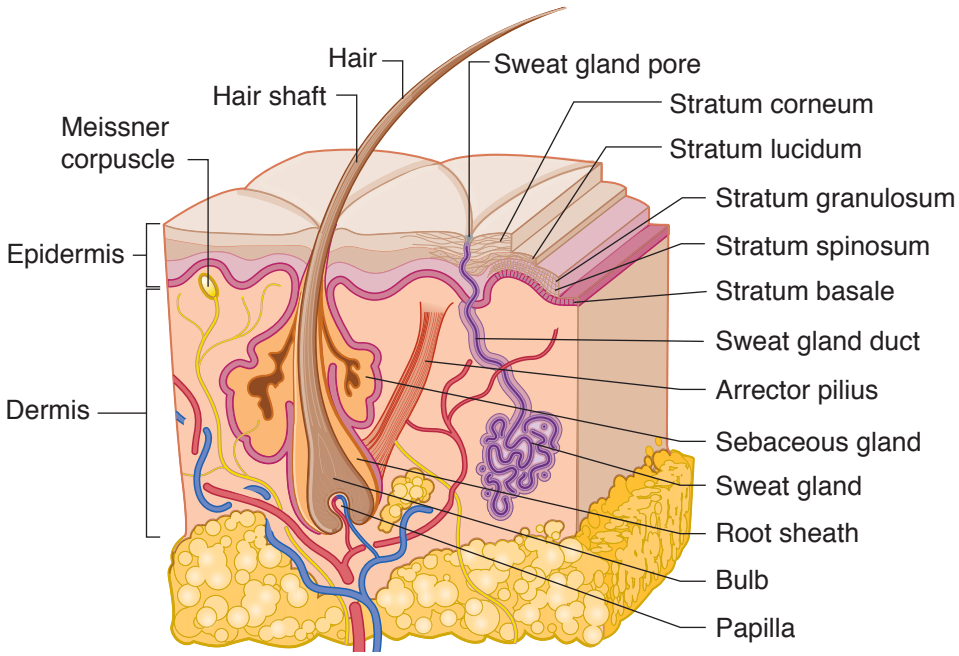

Figure 12-1. Skin

BULLOUS/BLISTERING DISEASES

Pemphigus Vulgaris

Pathogenesis. Pemphigus vulgaris is an **autoimmune** disease of unclear etiology in which the body essentially becomes allergic to its own skin. Antibodies are produced against antigens in the intercellular spaces of the epidermal cells. They attack the **"glue" that holds the epidermal cells together**. "Pemphix" is from the Greek word for bubble, which is what a bulla looks like before it is broken. Pemphigus vulgaris is most often idiopathic, but ACE inhibitors or penicillamine can occasionally cause it.

Clinical Presentation. Vulgaris occurs in patients age 30s and 40s, whereas bullous pemphigoid occurs in those age 70s and 80s. Pemphigus vulgaris is a much more serious and potentially life-threatening disease than pemphigoid. Vulgaris occurs prominently in the mouth and often starts there. The oral lesions are erosions, not bullae. The bullae are very thin and flaccid and break easily. This leads to the loss of large volumes of skin surface area, so it acts like a burn. This is because the bullae occur from destruction *within* the epidermis, making them thinner and more fragile. The presence of the **Nikolsky sign** (the easy removal of skin by just a little pressure from the examiner's finger, pulling the skin off like a sheet) is seen in pemphigus vulgaris, staphylococcal scalded skin syndrome, and toxic epidermal necrolysis.

The lesions of pemphigus vulgaris are **painful**, not pruritic.

Diagnosis. The most accurate diagnostic test is to **biopsy** the skin and to use immunofluorescent stains. These stains will detect intercellular deposits of *IgG and C3* in the epidermis.

Treatment. Treatment is with systemic glucocorticoids, such as prednisone. Topical steroids will not be sufficiently strong. Before the invention of steroids, pemphigus vulgaris was often fatal, with patients dying of sepsis and dehydration—just like a burn patient. For those in whom steroids are ineffective or not tolerated, you can use azathioprine, mycophenolate, or cyclophosphamide. Rituximab and *IVIG* are also effective.

Bullous Pemphigoid

Pathogenesis. Pemphigoid is 2× as common as pemphigus vulgaris and occurs in elderly persons age 70s and 80s. It can also be drug induced with sulfa drugs, including furosemide, penicillamine, and others.

Clinical Presentation. The defect occurs at the **dermo-epidermal junction**, so the layer of skin that separates off is much thicker. Because the fracture of the skin causing the blisters is deeper, the bullae are thicker walled and much less likely to rupture. Oral lesions are rare. Because the bullae are tense and intact, the skin is better protected. There is no dressing for skin as good as skin itself. Hence, there is much less fluid loss, and infection is much less likely as compared with pemphigus vulgaris. Mortality is much less likely in bullous pemphigoid.

Diagnosis. The most accurate diagnostic test is a biopsy with immunofluorescent antibodies at the dermo-epidermal junction (basement membrane).

Treatment. Systemic steroids, such as prednisone, are the standard means of treatment. Tetracycline or erythromycin combined with nicotinamide is the alternative to steroids. Use **topical** steroids only if **no oral lesions** are present.

Porphyria Cutanea Tarda

Pathogenesis. Porphyria cutanea tarda is a disorder of porphyrin metabolism. Deficiency of the enzyme uroporphyrinogen decarboxylase results in an abnormally high **accumulation of porphyrins**, which then leads to a photosensitivity reaction. The test question should give a history of HIV, alcoholism, liver disease, chronic hepatitis C, or a woman taking oral contraceptives. The liver disease may be from any cause but is most likely to involve chronic infectious hepatitis or hemochromatosis because porphyria cutanea tarda is associated with increased liver iron stores. Diabetes is found in 25% of patients.

Clinical Presentation. Fragile, **nonhealing blisters** are seen on the *sun-exposed* parts of the body, such as the backs of the hands and the face. This leads to hyperpigmentation of the skin in general and hypertrichosis of the face.

Diagnosis. The diagnostic test is a level of **urinary uroporphyrins**. Uroporphyrins are elevated 2–5× above the coproporphyrins in this disease.

Treatment. The best initial step in management is to **stop drinking** alcohol (although it is unlikely to be effective) and to **discontinue all estrogen use**. Combine treatment with barrier sun protection, such as clothing, because most sunscreens do not seem to block the wavelength of light causing the dermal reaction. The most effective therapy to use if this is insufficient is phlebotomy to remove iron. Deferoxamine is used to remove iron if phlebotomy is not possible. Also, the antimalarial drug chloroquine increases the excretion of porphyrins.

DRUG ERUPTIONS/HYPERSENSITIVITY

Urticaria

Pathogenesis. Acute urticaria is a hypersensitivity reaction most often mediated by **IgE and mast cell activation**, resulting in evanescent **wheals and hives**. It is a type of localized, cutaneous anaphylaxis, but without the hypotension and hemodynamic instability. The most common causes of acute urticaria are allergic reactions to medications, insect bites, and foods, and occasionally, the result of emotions. The most common medications are aspirin, NSAIDs, morphine, codeine, penicillins, phenytoin, and quinolones. ACE inhibitors are also associated with urticaria, as well as angioedema. The most common foods are peanuts, shellfish, tomatoes, and strawberries. Contact with latex in any form can also cause urticaria.

Clinical Presentation. Acute urticaria lasts <6 weeks in duration and two-thirds of cases are self-limited. Chronic urticaria lasts >6 weeks in duration and is associated with pressure on the skin, cold, or vibration. Pressure on the skin resulting in localized urticaria is also known as **dermatographism**. In acute cases, the onset of the wheals and hives is usually within 30 minutes and lasts for <24 hours. Itching is prominent. In patients with chronic urticaria lasting >6 weeks, you should investigate the etiology.

Treatment. Urticaria is treated with H_1 antihistamines. Severe, acute urticaria is treated with older medications, such as diphenhydramine (Benadryl™), hydroxyzine (Atarax™), or cyproheptadine. If it is life-threatening, use H_2 antihistamines when H_1 antihistamines fail and add systemic steroids. Chronic therapy is with newer, nonsedating antihistamines, such loratadine, desloratadine, fexofenadine, or cetirizine. Astemizole and terfenadine should never be used and are no longer marketed; they cause potentially fatal rhythm disturbances particularly when combined with other medications, such as macrolide antibiotics, because of their effect on the hepatic P450 system.

Note

For urticaria:

Answer "**terfenadine**" or "astemizole" only when the test question asks what will kill the patient or which is the most dangerous medication.

Answer "**desensitization**" when the trigger cannot be avoided, e.g., a beesting in a farmer. Beta-blocker medications must be stopped prior to desensitization because they inhibit epinephrine, which may be used if there is an anaphylactic reaction.

Wikipedia, James Heilman, MD

Figure 12-2. Urticaria

Morbilliform Rashes

Pathogenesis. A morbilliform rash is a milder version of a hypersensitivity reaction compared with urticaria. This is the "typical" type of drug reaction and is **lymphocyte mediated**.

Clinical Presentation. The rash resembles measles and is usually secondary to medications that the patient is allergic to, such as penicillin, sulfa drugs, allopurinol, or phenytoin. It is a generalized, maculopapular eruption that **blanches** with pressure. The reaction can appear a few days after the exposure and may begin even after the medication has been stopped.

Treatment. Antihistamines are effective, and steroids are rarely necessary.

Erythema Multiforme

Although erythema multiforme (EM) may be caused by the same types of medications that cause urticaria and morbilliform rashes (penicillins, phenytoin, NSAIDs, and sulfa drugs), the **most common cause** of EM is a **reaction to infection**. The majority of cases follow infection with herpes simplex or *Mycoplasma*.

Clinical Presentation. The most characteristic feature of EM is **target-like lesions** that occur especially on the **palms and soles**. These lesions can also be described as "iris-like." Bullae are not uniformly found. EM of this type usually does not involve mucous membranes.

Treatment is with antihistamines and by treating the underlying infection.

Wikipedia, James Heilman, MD

Figure 12-3. Erythema Multiforme

Stevens-Johnson Syndrome

Pathogenesis. Stevens-Johnson syndrome (SJS) is sometimes called **erythema multiforme major**. It is sometimes difficult to distinguish SJS from toxic epidermal necrolysis (TEN) and, in fact, the two diseases may be considered a spectrum of severity of the same disorder. All of these disorders may arise as a hypersensitivity response to the same set of medications, such as penicillins, sulfa drugs, NSAIDs, phenytoin, and phenobarbital.

Clinical Presentation. SJS usually involves <10 to 15% of the total body surface area, and the overall mortality rate is <5 to 10%. There is mucous-membrane involvement in 90% of cases, most often of the oral cavity and the conjunctivae, although there may be extensive involvement of the respiratory tract.

Treatment. These patients should be treated with early admission to a burn unit, withdrawal of the offending drug, and supportive care. Respiratory-tract involvement may be so severe as to require mechanical ventilation. Death occurs from a combination of infection, dehydration, and malnutrition.

There is no proven benefit for steroids. The best initial therapy for severe disease is IV immunoglobulins. Other therapies of unclear value are cyclophosphamide, cyclosporine, and thalidomide.

Toxic Epidermal Necrolysis

Pathogenesis. Toxic epidermal necrolysis (TEN) is the most serious version of a cutaneous hypersensitivity reaction. Mortality may be as high as 40 to 50%.

Clinical Presentation. Much more of the body surface area (BSA) is involved and may range from 30 to 100%. The Nikolsky sign is present, and the skin easily sloughs off. TEN has certain features similar to staphylococcal scalded skin syndrome; however, TEN is *drug induced* as opposed to being caused by a toxin coming from an organism.

Diagnosis. The diagnosis is usually clinical. The most accurate diagnostic test is a skin biopsy, which will reveal full thickness epidermal necrosis. A skin biopsy is usually not necessary.

Treatment. Sepsis is the most common cause of death, but *prophylactic* systemic antibiotics are *not* indicated. Systemic steroids are *not* effective and may, in fact, decrease survival.

Fixed Drug Reaction

Pathogenesis. This is a *localized* allergic drug reaction that recurs at precisely the *same anatomic site* on the skin with repeated drug exposure. It is not known why the reactions are anatomically localized and do not become generalized morbilliform rashes. The most commonly implicated drugs include aspirin, NSAIDs, tetracycline, and barbiturates.

Clinical Presentation. Fixed drug reactions are generally round, sharply demarcated lesions that leave a hyperpigmented spot at the site after they resolve.

Treatment. In addition to discontinuation of the offending drug, the reactions can be treated with topical steroids.

Clinical Pearl

Always do a chest x-ray on a patient with EN, to exclude sarcoidosis.

A biopsy of EN lesions will show nonspecific inflammation.

Erythema Nodosum

Pathogenesis. Erythema nodosum (EN) is a localized inflammatory condition of the skin or panniculitis. It is secondary to recent infections or inflammatory conditions. It is also associated with pregnancy. The most common causes of EN are recent streptococcal infections, coccidioidomycoses, histoplasmosis, sarcoidosis, inflammatory bowel disease, syphilis, TB, and hepatitis. Enteric infections such as *Yersinia* also cause the disorder.

Clinical Presentation. Erythema nodosum consists of multiple painful, red, raised nodules on the anterior surface of the lower extremities. They are extremely tender to palpation. They do not ulcerate, and they generally last about 6 weeks.

Diagnosis. ASLO titers can help determine who has recently had a streptococcal infection if there is no other etiology apparent from the history.

Treatment. Therapy consists of treating the underlying disease, as well as the use of analgesics and NSAIDs. Potassium iodide solution can be used in those who do not respond to symptomatic therapy. Erythema nodosum is usually a self-limiting condition.

INFECTIONS

Fungal Infections

Tinea pedis, cruris, corporis, versicolor, capitis, and onychomycosis

All of the superficial fungal infections of the body share a number of common characteristics leading to the same answer on the test for similar questions for each of these diseases. "Superficial fungal infections" refer to those infections limited to the skin, nails, and hair. Remember, though, that these answers would not be valid for more deep-seated, life-threatening infections, such as fungal endocarditis, meningitis, or abscesses.

Clinical Presentation and Diagnosis. All superficial fungal infections of the skin, hair, and nails are primarily diagnosed by their *visual appearance* and confirmed by a potassium hydroxide *(KOH) test* of the skin. The leading edge of the lesion on the skin or nails is scraped with a scalpel to remove some of the epithelial cells or some of the nail and hair. KOH has the ability to dissolve the epithelial cells and collagen of the nail, but does not have the ability to melt away the fungus. Hence, a KOH preparation gives an immediate diagnostic answer by revealing fungal hyphae. This is particularly characteristic in tinea versicolor, where the *Malassezia furfur (Pityrosporum orbiculare)* organism appears in a "spaghetti and meatballs" pattern.

The most accurate test is to culture the fungus. This is usually not clinically practical because molds that grow on the skin (dermatophytes) take up to 6 weeks to grow even on specialized fungal media. A specific species usually does not need to be isolated in most cases, unless it is an infection of the hair or nails. In the case of nail and hair infections, oral therapy is necessary, and it is important to be precise because there are fewer medications that can be used to effectively treat onychomycosis. Tinea tonsurans is the cause of >90% of cases of tinea capitis.

Treatment. For onychomycosis (nail infection) or hair infection (tinea capitis), the medications with the greatest efficacy are oral terbinafine or itraconazole. These medications are used for at least 6 weeks for fingernails and 12 weeks for toenails. Terbinafine is potentially hepatotoxic, and it is important to periodically check liver function tests. Griseofulvin must be used for 6 to 12 months in the treatment of fingernails and has much less antifungal efficacy than terbinafine. Griseofulvin is no longer recommended in the treatment of onychomycosis of the toenails. In the treatment of tinea capitis, griseofulvin is recommended for 6 to 8 weeks.

The other fungal infections of the skin that don't involve hair or nails may be treated with any of the following topical medications: ketoconazole, clotrimazole, econazole, terbinafine, miconazole, sertaconazole, sulconazole, tolnaftate, or naftifine. There is no clear difference in efficacy or adverse effects between them when used topically. Ketoconazole has more adverse effects when used systemically, such as hepatotoxicity and gynecomastia. This is why ketoconazole is not a good choice for onychomycosis. There is no topical form of fluconazole. Fluconazole is also less efficacious for dermatophytes of the nails when used systemically.

Antifungal medications generally should not be used in combination with topical steroids, unless a diagnosis has been confirmed. Steroids in a cream can relieve redness and itching and give the appearance of improvement even in impetigo and contact dermatitis.

Note

Drug of choice for oral antifungal treatment:

- Tinea capitis and onchomycosis
  - Terbinafine or itraconazole

Tinea versicolor

Definition. Skin infection characterized by multiple macules (usually asymptomatic), varying in color from white to brown.

Etiology. Pityrosporum orbiculare (Malassezia furfur).

Clinical Presentation. Tan, brown, or white scaling macular lesions that tend to coalesce; found on chest, neck, abdomen, or face. Lesions do not tan.

Diagnosis. Skin scrapings examined with 10% KOH under a microscope. The classic description is of "spaghetti and meatballs," which refers to the hyphae and spores that can be seen in the KOH prep.

Treatment. Topical selenium sulfide, clotrimazole, ketoconazole, or oral itraconazole. The need for local or systemic therapy is decided on the basis of the amount of surface area involved.

Clinical Correlate

Tinea versicolor has some additional features that are important in its management. It presents with lesions of different colors from tan to pink (hence the name *versi*color). The lesions often do not tan, and they present with pale areas in the middle of a normal tan. This can be distinguished from vitiligo by the fact that vitiligo has *no* pigmentation, whereas tinea versicolor presents with *altered* pigmentation. The organism may also be contagious. A KOH preparation and fungal culture are used in the same manner as for the other dermatophytes. The main therapeutic difference is the use of topical selenium sulfide every 2 to 3 weeks versus oral therapy with itraconazole or fluconazole. This is not because of antifungal resistance; it is because tinea versicolor is much more likely to involve large amounts of body surface area so it is difficult to cover this volume of skin with an ordinary topical cream or lotion.

Candidiasis

Definition. A yeast infection usually involving skin and mucous membranes, but it can also be systemic.

Etiology. *Candida albicans*. Usually spreads in patients with decreased host defenses. Patients with any of the following have an increased susceptibility: systemic antibacterial therapy, obesity, diabetes mellitus, corticosteroid or antimetabolite therapy, pregnancy, debilitating disease and blood dyscrasias, or HIV.

Clinical Presentation

- *Intertriginous infection:* Well-demarcated, erythematous, itchy, exudative patches, usually rimmed with small red-based pustules that occur in the groin, gluteal folds (diaper rash), axilla, umbilicus, and inframammary areas.
- Vulvovaginitis: White or yellowish discharge with inflammation of the vaginal wall and vulva. Common in pregnant women and patients with diabetes mellitus.
- Oral candidiasis (thrush): White patches of exudates on tongue or buccal mucosa
- Candidal paronychia: Painful red swelling around the nail

Diagnosis. Potassium hydroxide on slide to visualize fungal forms. Culture is definitive.

Treatment

- Topical nystatin, clotrimazole, miconazole, ciclopirox, econazole, or terconazole
- Systemic amphotericin in serious invasive infections. Fluconazole in less serious infections. *Candida paronychia* requires systemic therapy.

Bacterial Infections

Antistaphylococcal antibiotics

The most common bacterial organisms to cause skin infections of any kind are *Staphylococcus* and *Streptococcus*. Antibiotics used to treat *Staphylococcus* are dicloxacillin, cephalexin (Keflex™), or cefadroxil (Duricef™). Cefadroxil, cefazolin, or cephalexin are the preferred agents. If a patient is allergic to penicillin, but the reaction is only a rash, then cephalosporins can be safely used. There is far less than 5% cross-reaction between penicillins and cephalosporins. The IV

equivalents of oral dicloxacillin include oxacillin and nafcillin. The IV equivalent of cefadroxil is cefazolin.

If the penicillin reaction is anaphylaxis then cephalosporins cannot be used. The alternative antibiotics that will treat the skin are macrolides, such as erythromycin, azithromycin, clarithromycin, or the newer fluoroquinolones (levofloxacin or moxifloxacin). Ciprofloxacin will not adequately cover the skin. Vancomycin is only for IV use for skin infections, and oral vancomycin is not absorbed. Oral therapy for MRSA is with clindamycin, TMP/SMX, or doxycycline. The ultimate form of oral MRSA therapy is linezolid.

Impetigo

Definition. A superficial, pustular skin infection, seen mainly in children (ecthyma is an ulcerative form of impetigo), with oozing, crusting, and draining of the lesions. It is a superficial bacterial infection of the skin largely limited to the epidermis and not spreading below the dermal-epidermal junction.

Etiology. Group A beta-hemolytic *Streptococcus* and *S. aureus* (*bullous impetigo*).

Clinical Presentation. Because it is limited to the epidermis, the purulent material is easily able to express itself through the surface; therefore, the patient history will describe the infection with words such as "weeping," "oozing," "honey colored," or "draining." Impetigo occurs more often in warm, humid conditions, particularly when there is poverty and crowding of children. This is because it is both contagious and autoinoculable. More common on arms, legs, and face. May follow trauma to skin. Begins as maculopapules and rapidly progresses to vesicular pustular lesions or bullae. The crusts are described as having a golden or yellow appearance and if untreated can progress to lymphangitis, furunculosis, or cellulitis, and acute glomerulonephritis. Impetigo may cause glomerulonephritis, but it will not cause rheumatic fever.

Note

Group A *streptococci* and *S. aureus* are the most common causes of impetigo.

Treatment

- Oral first-generation cephalosporin or semisynthetic penicillin, e.g., oxacillin, cloxacillin, dicloxacillin (for severe or widespread cases)
- Topical mupirocin, bacitracin, or retapamulin for mild cases of impetigo
- Penicillin-allergic patients can be treated with macrolides such as clarithromycin or azithromycin.
- TMP/SMZ, clindamycin, or doxycycline for MRSA

Note

Retapamulin is a topical antibacterial more active against staph and strep than mupirocin or bacitracin are.

Erysipelas

Pathogenesis. Erysipelas is a bacterial infection of a deeper layer of the skin than impetigo. Erysipelas involves both the dermis and epidermis and is most commonly caused by group A *Streptococcus* (*pyogenes*).

Clinical Presentation. Because it involves lymphatic channels in the dermis, erysipelas is more likely to result in fever, chills, and bacteremia. It often involves the face, giving a bright red, angry, swollen appearance. Usually bilateral, shiny red, indurated edematous tender lesions on the face, arms, and legs. These lesions are often sharply demarcated from the surrounding normal skin. Differentiate from herpes, contact dermatitis, and angioneurotic edema.

Treatment. Semisynthetic penicillin or first-generation cephalosporin if you cannot distinguish it from cellulitis; penicillin (if *Streptococcus* is certain).

Cellulitis

Pathogenesis. Cellulitis is a bacterial infection of the dermis and subcutaneous tissues with *Staphylococcus* and *Streptococcus*.

Clinical Presentation. Cellulitis is characterized by redness, swelling, and warmth and tenderness of the skin. Because it is *below the dermal-epidermal junction*, there is no oozing, crusting, weeping, or draining.

Treatment. Cellulitis is treated with the antibiotics prescribed for erysipelas on the basis of the severity of the disease. If there is fever, hypotension, or signs of sepsis or if oral therapy has not been effective, then the patient should receive IV therapy. Oxacillin, nafcillin, or cefazolin is the best therapy. Treatment is generally empiric because injecting and aspirating sterile saline for a specific microbiologic diagnosis has only a 20% sensitivity. Oral therapy for MRSA is with clindamycin, TMP/SMX, or doxycycline.

Folliculitis, furuncles, and carbuncles

Pathogenesis. Folliculitis, furuncles, and carbuncles represent *3 degrees of severity* of staphylococcal infections occurring around a hair follicle. Occasionally, folliculitis can be the result of those who contract *Pseudomonas* in a whirlpool or from a hot tub.

Clinical Presentation. As folliculitis worsens from a simple superficial infection around a hair follicle, it becomes a small collection of infected material known as a furuncle. When several furuncles become confluent into a single lesion, the lesion becomes known as a carbuncle, which is essentially a localized skin abscess. Folliculitis is rarely tender, but furuncles and carbuncles are often extremely tender.

Treatment. Folliculitis mainly can be treated with warm compresses locally without the need for antibiotics. If antibiotics are required, mupirocin is the best choice. Furuncles and carbuncles require treatment with systemic antistaphylococcal antibiotics, and in the case of carbuncles, should be administered intravenously. Treatment with dicloxacillin, cephalexin, or cefadroxyl is acceptable. A large furuncle or carbuncle will also require surgical drainage.

Clinical Pearl

Necrotizing fasciitis is commonly associated with varicella infection, where the skin lesions are infected by *Streptococcus* or *Staph*.

Necrotizing fasciitis

Pathogenesis. Necrotizing fasciitis is an extremely severe, life-threatening infection of the skin. It starts as a cellulitis that dissects into the fascial planes of the skin. *Streptococcus* and *Clostridium* are the most common organisms because they are able to produce a toxin that further worsens the damage to the fascia. Diabetes increases the risk of developing fasciitis.

Clinical Presentation. The features that distinguish necrotizing fasciitis from simple cellulitis are a *very high fever*, a portal of entry into the skin, pain out of proportion to the superficial appearance, the presence of *bullae*, and *palpable crepitus*.

Note

If an exam question presents an obvious clinical case with crepitus, pain, high fever, and a portal of entry, you should answer "surgery" (not a test, such as an x-ray) as the best initial step.

Diagnosis. Laboratory evidence of necrotizing fasciitis is an elevated creatine phosphokinase and an x-ray, CT scan, or MRI that show *air in the tissue or necrosis*. All of these laboratory methods of establishing a diagnosis lack both sensitivity and specificity. Surgical debridement is the best way to confirm the diagnosis and is also the mainstay of therapy.

Treatment. Surgery is the mainstay of therapy. The best empiric antibiotics are the beta-lactam/beta-lactamase combination medications, such as ampicillin/sulbactam (Unasyn™), ticarcillin/clavulanate (Timentin™), or piperacillin/tazobactam (Zosyn™). If there is a definite diagnosis of group A *Streptococcus (pyogenes)*, then treat with clindamycin and penicillin. Without adequate therapy, necrotizing fasciitis has an 80% mortality rate.

Paronychia

Paronychia is an infection loculated under the skin surrounding a *nail*. It is generally treated with a small incision to allow drainage and with antistaphylococcal antibiotics. The antistaphylococcal antibiotics are dicloxacillin, cefadroxil, or cephalexin orally, or oxacillin, nafcillin, or cefazolin intravenously.

Viral Infections

Herpes simplex

Pathogenesis. Herpes simplex infections of the genitals are characterized by multiple, painful vesicles.

Clinical Presentation. The vesicles are usually obvious by examination, and antibiotic therapy should be initiated immediately without waiting for results of the tests.

Diagnosis. This is done with active lesions only. In the event that the diagnosis is not clear or the lesions have become confluent into an ulcer, the best initial test is a Tzanck smear. The Tzanck smear is somewhat nonspecific in that it will determine only that the infection is in the herpesvirus family. Tzanck smears detect *multinucleated giant cells* and are similar in technique to a Pap smear. A scraping of the lesion is immediately placed on a slide and sprayed with fixative. Tzanck smears have 75% sensitivity in diagnosing facial herpetic lesions, but only 40% sensitivity in diagnosing genital lesions.

The most accurate diagnostic test is a viral culture, which will grow in 24 to 48 hours. Serology is *not* a useful test for diagnosing herpes infections.

Treatment. Immediate therapy is with oral acyclovir, famciclovir, or valacyclovir. Topical acyclovir has extremely little efficacy; it will slightly improve resolution in primary lesions and will do absolutely nothing for recurrent herpes simplex lesions. Topical penciclovir has some use for oral herpetic lesions, but it must be applied every 2 hours. The treatment of acyclovir-resistant herpes is with foscarnet.

Centers for Disease Control and Prevention

Figure 12-4. Herpes Simplex Lip

Herpes zoster/varicella

Pathogenesis. Chickenpox is primarily a disease of children. Complications of varicella are pneumonia, hepatitis, and dissemination. Episodes of dermatomal herpes zoster, also known as shingles, occur more frequently in the elderly and in those with defects of the lymphocytic portion of the immune system (i.e., leukemia, lymphoma, HIV, or those on steroids).

Clinical Presentation. The vesicles are 2 to 3 mm in size at all stages of development and are on an erythematous base.

Diagnosis. Although the Tzanck prep and viral culture are the best initial and most accurate diagnostic tests, they are generally not necessary because little else will produce a band of vesicles in a dermatomal distribution besides herpes zoster.

Treatment. Chickenpox is generally not treated with antivirals. If the child is immunocompromised or the primary infection occurs in an adult, then acyclovir, valacyclovir, or famciclovir should be given.

Steroid use is still not clearly beneficial, although the best evidence for efficacy is in elderly patients with severe pain. The rapid administration of acyclovir still has the best efficacy for decreasing the risk of postherpetic neuralgia.

Other treatments for managing the pain are gabapentin, tricyclic antidepressants, and topical capsaicin. The most effective analgesic specific for postherpetic neuralgia is gabapentin. Nonimmune adults exposed to chickenpox should receive varicella zoster immunoglobulin within 96 hours of the exposure in order for it to be effective.

Molluscum contagiosum

Definition. Skin-colored, waxy, umbilicated papules.

Etiology. Poxvirus.

Clinical Presentation. Small papules that appear anywhere on the skin (genital and pubic area), usually by venereal contact, and are asymptomatic. The lesions have a central umbilication. They can be transmitted by skin-to-skin contact or sexually. Commonly seen in children; frequency is increased severalfold in patients infected with HIV.

Diagnosis

- Mainly on appearance; lab testing is rarely, if ever, necessary.
- Giemsa stain: large cells with inclusion bodies

Treatment. Freezing, curettage, electrocautery, or cantharidin.

PARASITIC INFECTIONS

Scabies

Pathogenesis. Scabies involves vesicular eruptions resulting from the females of the *Sarcoptes scabiei (hominis)* burrowing into the skin.

Definition. A parasitic skin infection characterized by superficial burrows, intense pruritus, and secondary infections.

Etiology. Itch mite, *Sarcoptes scabiei*. Transmitted by skin-to-skin contact.

Clinical Presentation. Scabies primarily involves the web spaces of the hands and feet. It also produces pruritic lesions around the penis, breasts, and axillary folds. Itching can be extreme. Because *Sarcoptes scabiei* is quite small, all that can be seen with the naked eye are the burrows and excoriations around small pruritic vesicles. Scabies often spares the head. Immunocompromised patients, such as those with HIV, are particularly vulnerable to an extremely exuberant form of scabies with severe crusting and malodorousness, known as Norwegian scabies.

Diagnosis. The diagnosis in all cases is confirmed by scraping out the organism after mineral oil is applied to a burrow; however, skin scrapings are usually not necessary and are not routinely done.

Treatment. Scabies can be successfully treated with permethrin. Lindane (Kwell) has equal efficacy, but also greater toxicity. Lindane should not be used in pregnant women. Ivermectin is a suitable alternative and is given as oral therapy if the disease is extensive. Treat Norwegian scabies with a combination of permethrin and ivermectin.

Pediculosis

Definition. Skin infestation by lice.

Etiology

- Head: *Pediculus humanus capitis*
- Body: *Pediculus humanus corporis*
- Pubic area: *Phthirus pubis* ("crab louse")

Clinical Findings. Itching, excoriations, erythematous macules and papules, and sometimes secondary bacterial infection.

Diagnosis. Direct examination of the pubic area, axillae, scalp, and other hair-bearing surfaces for the organism (louse or nits).

Treatment. Permethrin, lindane (Kwell).

TOXIN-MEDIATED DISEASES

Toxic Shock Syndrome

Pathogenesis. This disorder is a systemic reaction to a toxin produced from *Staphylococcus* attached to a foreign body. The majority of cases now are not from a menstrual source, such as a tampon or vaginal packing. Nasal packing, retained sutures, or any other form of surgical material retained in the body can promote the growth of the type of staphylococci that produces the toxin.

Clinical Presentation/Diagnosis. Because there is no single specific test, cases are matters of definition. The definition of a case of toxic shock syndrome is the presence of 3 or more or of the following findings: fever >102°F, a systolic blood pressure <90 mm Hg, a desquamative rash, vomiting, involvement of the mucous membranes of the eyes, mouth, or genitals, elevated bilirubin, or platelets <100,000. In addition, toxic shock is a systemic disease that also raises the creatinine, creatine phosphokinase (CPK), and liver function tests; lowers the platelet count; and can cause central nervous system dysfunction, such as confusion. Hypocalcemia is common, usually because of a diffuse capillary leak syndrome that drops the albumin level. Streptococcal toxic shock syndrome is essentially the same.

Treatment. In addition to removing the source of the infection, treatment is with vigorous fluid resuscitation, pressors (such as dopamine), and antibiotics. Empiric treatment is with clindamycin plus vancomycin until cultures return. In confirmed cases of methicillin sensitive strains, treatment should be with clindamycin plus an antistaphylococcal medication (oxacillin, nafacillin). In methicillin resistant strains (MRSA), either vancomycin or linezolid can be used.

Note

Differential Diagnosis

SSSS:

- From an infection
- Splits off only the superficial granular layer of skin

TEN:

- From drug toxicity
- Full-thickness split of skin

Staphylococcal Scalded Skin Syndrome

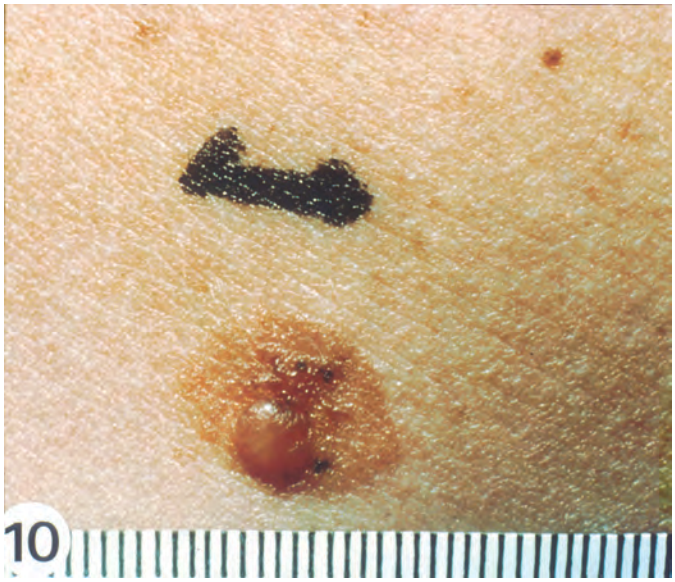
Pathogenesis. Staphylococcal scalded skin syndrome (SSSS) is transmitted through physical contact with surroundings. It most commonly occurs in infants and young children and in the immunocompromised.

Clinical Presentation. SSSS is mediated by a toxin from *Staphylococcus*. The major presentation is the loss of the superficial layers of the epidermis in sheets. Nikolsky sign is present. It is markedly different from toxic shock syndrome in that there is normal blood pressure and no involvement of the liver, kidney, bone marrow, or central nervous system.

Treatment. Patients should be managed in a burn unit and given oxacillin or other antistaphylococcal antibiotics. Vancomycin can be added because of the possibility of MRSA.

BENIGN AND PRECANCEROUS LESIONS

The predominant method of distinguishing between benign and malignant lesions is by the shape and color of the lesion. Benign lesions, such as the junctional or intradermal nevus, do not grow in size and have smooth, regular borders with a diameter usually <1 cm. In addition, they are homogenous in color, and this remains constant. Biopsy is the most accurate method of making a diagnosis, and benign lesions need to be removed only for cosmetic purposes.



visualsonline.cancer.gov

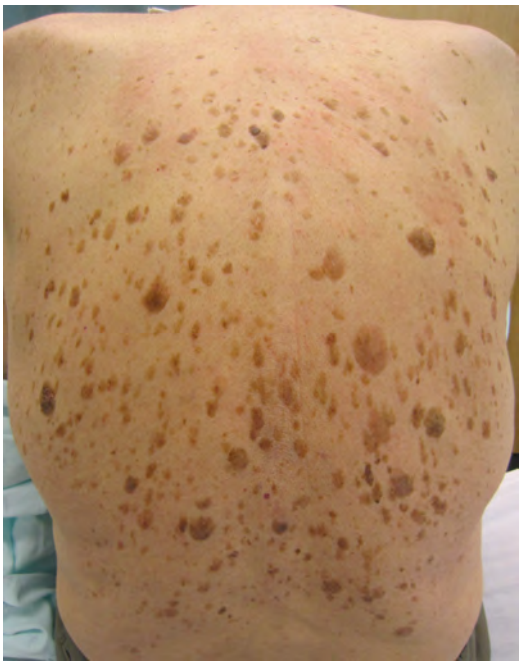
Figure 12-5. Dysplastic Nevus

Seborrheic Keratosis

Pathogenesis. This is a benign condition with hyperpigmented lesions occurring in the elderly. Seborrheic keratosis has no malignant potential and no relation to either actinic keratosis or seborrheic dermatitis.

Clinical Presentation. The lesions have a "stuck on" appearance and are most common on the face, shoulders, chest, and back.

Treatment. They are removed only for cosmetic purposes with liquid nitrogen or curettage.



Wikipedia, James Heilman, MD

Figure 12-6. Seborrheic Keratosis

Actinic Keratosis

Pathogenesis. Actinic keratosis presents with precancerous lesions occurring on sun-exposed areas of the body in older persons. The lesions occur more often in those with light skin color. They contain chromosomal abnormalities, and although only 1:1,000 lesions progresses to squamous cell cancer, an individual patient may have dozens of them. Hence, the rate of transformation to squamous cell cancer is 0.25% per patient.

Clinical Presentation. Although the lesions are usually asymptomatic, they can be tender to the touch and lighter in color.

Treatment. Therapy is universally with sunscreen to prevent progression and recurrence. In addition, the lesions should be removed with cryotherapy, topical 5 fluorouracil (5-FU), imiquimod, topical retinoic-acid derivatives, or even curettage.

MALIGNANT DISEASES

Melanoma

Pathogenesis. Superficial spreading melanoma is the most common type of malignancy, accounting for two-thirds of cases. The rate of occurrence of melanoma is rising faster than any other cancer in the United States.

Clinical Presentation. Malignant lesions grow in size, have irregular borders, are uneven in shape, and have inconsistent coloring. Lentigo maligna melanoma arises on sun-exposed body parts in the elderly. Acral-lentiginous melanoma arises on the palms, soles of feet, and nail beds.

Diagnosis. Biopsy diagnosis is best performed with a full-thickness sample because tumor thickness is by far the most important prognostic factor.

Table 12-1. Ten-Year Survival Rates for Melanoma

Lesion Size (mm)	Survival Rate
<0.76	96%
0.76–1.69	81%
1.7–3.6	57%
>3.6	31%

Treatment. Melanoma is removed by excision. Huge 5-cm margins are not routinely indicated. The size of the margin is determined by the thickness of the tumor. Melanoma in situ needs only a 0.5-cm margin, with a 1.0-cm margin for those lesions <1 mm in thickness. Lesions 1- to 2-mm depth get 2-cm margins, and those >2 mm in depth get 2- to 3-cm margins. There is no definitive chemotherapy for any form of skin cancer. Interferon seems to reduce recurrence rates.

National Cancer Institute

Figure 12-7. Melanoma

Squamous Cell Carcinoma

Pathogenesis. Develops on sun-exposed skin surfaces in elderly patients.

Clinical Presentation. It is particularly common on the lip, where the carcinogenic potential of tobacco is multiplicative. Ulceration of the lesion is common. Metastases are rare (3–7%).

Diagnosis. Biopsy.

Treatment. Surgical removal. Radiotherapy can be used for lesions that cannot be treated surgically.

Basal Cell Carcinoma

Pathogenesis. Sixty-five to eighty percent of all skin cancers are basal cell. (10–25% percent are squamous cell.)

Clinical Presentation. Shiny or "pearly" appearance. Rate of metastases is <0.1%.

Diagnosis. Confirmed by shave or punch biopsy.

Treatment. Surgical removal. Mohs microsurgery has the greatest cure rate. In this technique, instant frozen sections are done to determine when enough tissue has been removed to give a clean margin. 5-FU can be used in treatment of superficial lesions.

Wikimedia, John Hendrix

Figure 12-8. Basal Cell Carcinoma

Kaposi Sarcoma

Pathogenesis. Human herpes virus 8 is the causative organism.

Clinical Presentation. These are purplish lesions found on the skin, predominantly of patients with HIV and CD4 counts <100/mm^3.

Treatment. Antiretroviral therapy to raise the CD4 count. When that does not occur, the specific chemotherapy for Kaposi sarcoma is liposomal doxorubicin hydrochloride or vinblastine.

SCALING DISORDERS (ECZEMA)/PAPULOSQUAMOUS DERMATITIS

Psoriasis

Pathogenesis. The etiology of psoriasis is unknown.

Clinical Presentation. Silvery scales develop on the extensor surfaces. It can be local or enormously extensive. Nail pitting is a common accompaniment. The Koebner phenomenon is the development of lesions with epidermal injury.

Treatment. Salicylic acid is used to remove heaped-up collections of scaly material so that the other therapies can make contact. If the disease is relatively localized, topical steroids are used. Severe disease also needs coal tar or anthralin derivatives. To avoid the long-term use of steroids, which can cause skin atrophy, and to avoid coal tars, which are messy to use, substitute topical vitamin D and vitamin A derivatives. The vitamin D derivative most frequently used is calcipotriene. Tazarotene is a topical vitamin A derivative.

All patients should use emollients such as Eucerin™, Lubriderm™, or mineral oil. When >30% of the body surface area is involved, it is difficult to routinely use topical therapy to control disease. Ultraviolet light in that case is the most rapid way to control extensive disease. The most severe, widespread, and progressive forms of the disease can be controlled with methotrexate; however, it has the highest toxicity and may cause liver fibrosis.

The newest therapy is immunomodulatory biologic agents, such as alefacept, efalizumab, etanercept, and infliximab. These are monoclonal antibodies that target defects in the immune system, such as tumor necrosis factor.

Wikipedia, James Heilman, MD

Figure 12-9. Psoriasis

Atopic Dermatitis

Pathogenesis. Atopic dermatitis is an extraordinarily pruritic disorder characterized by high IgE levels.

Clinical Presentation. Red, itchy plaques appear on the flexor surfaces. In children, lesions are common on the cheeks and scalp. Adults present with lichenification.

Treatment. Preventive therapy is achieved by keeping the skin moist with emollients, avoiding hot water and drying soaps, and using only cotton clothes because these patients are extremely sensitive to drying. Active disease is managed with topical steroids, antihistamines, coal tars, and phototherapy. Antistaphylococcal antibiotics are used if there is impetiginization of the skin. Topical immunosuppressants, such as tacrolimus and pimecrolimus, can be used to decrease dependence on steroid use. Every effort must be made to avoid scratching. The topical tricyclic doxepin can be used to help stop pruritus.

Seborrheic Dermatitis

Pathogenesis. An oversecretion of sebaceous material and a hypersensitivity reaction to a superficial fungal organism, *Pityrosporum ovale*, underlie seborrheic dermatitis.

Clinical Presentation. These patients present with "dandruff," which may also occur on the face. Scaly, greasy, flaky skin is found on a red base on the scalp, eyebrows, and in the nasolabial fold.

Treatment. Therapy consists of low-potency topical steroids, such as hydrocortisone, or topical antifungals in the form of shampoos, such as ketoconazole or sulfide. Zinc pyrithione is also used as a shampoo.

Stasis Dermatitis

Pathogenesis. Stasis dermatitis is a hyperpigmentation built up from hemosiderin in the tissue. It occurs over a long period, from venous incompetence of the lower extremities leading to the microscopic extravasation of blood in the dermis.

Treatment. There is no way to reverse this problem. Prevention of progression is with elevation of the legs and lower-extremity support hose.

Contact Dermatitis

Pathogenesis. Contact dermatitis is a hypersensitivity reaction to soaps, detergents, latex, sunscreens, or neomycin over the area of contact. Jewelry is a frequent cause, as is contact with the metal nickel from belt buckles and wristwatches.

Clinical Presentation. It can occur as linear, streaked vesicles, particularly when it is from poison ivy.

Diagnosis. A definitive diagnosis can be determined with patch testing.

Treatment. Identify the causative agent and treat with antihistamines and topical steroids.

phil.cdc.gov

Figure 12-10. Contact Dermatitis Due to Poison Ivy

Pityriasis Rosea

Pathogenesis. Pityriasis rosea is a pruritic eruption that begins with a "herald patch" 70 to 80% of the time. It is mild, self-limited, and usually resolves in 8 weeks without scarring.

Clinical Presentation. It is erythematous, salmon colored, and looks like secondary syphilis, except that it spares the palms and soles and has a herald patch. The lesions on the back appear in a pattern like a Christmas tree (if the observer is especially imaginative).

Diagnosis. The VDRL/RPR is negative. This is a clinical diagnosis.

Treatment. Very itchy lesions may be treated with topical steroids.

DECUBITUS (PRESSURE) ULCERS

Pathogenesis. Decubitus ulcers are chronic sores that occur in the pressure areas of the body, where bone is closer to the skin. It is often associated with patients who are immobilized or bedridden.

Clinical Presentation. Stage I lesions consist of nonblanchable redness. Stage II lesions result in destruction of the superficial epidermis or partial destruction of the dermis. Stage III lesions have destroyed the full thickness of the skin, but not the fascia, and stage IV lesions show destruction all the way to the bone.

Diagnosis. Never culture a swab of the superficial ulcer or drainage from the ulcer. It will be impossible to determine whether it is a genuine infection or simply colonization. A definitive microbiologic diagnosis is often obtained only in the operating room after debridement.

Treatment. The major theme of management is to relieve pressure. If the lesions are definitely infected, then antibiotics are useful.

HAIR

Alopecia Areata

Pathogenesis. This is an autoimmune disease in which antibodies attack the hair follicles and destroy hair production.

Treatment. The majority will resolve spontaneously over time. Immediate therapy is with localized steroid injection into the area of hair loss.

Telogen Effluvium

Pathogenesis. This is the loss of hair in response to an overwhelming physiologic stress, such as cancer or malnutrition.

Treatment. The management is to correct the underlying stress or disease.

ACNE

Pathogenesis. The contributing organism is *Propionibacterium acnes*. Pustules and cysts occur, which rupture and release free fatty acids, which in turn causes further irritation. Acne is more common in girls, but boys have more severe disease.

Clinical Presentation. There are both closed comedones, which are white, and open comedones, which are black. The discharge, although purulent, is odorless.

Treatment. Mild disease is treated with topical antibiotics, such as clindamycin, erythromycin, or sulfacetamide. In addition, the bacteriostatic agent benzoyl peroxide is used. Topical retinoids are applied if the attempts to control the load of bacteria locally are ineffective.

Moderate disease treatment combines benzoyl peroxide with the retinoids tazarotene, tretinoin, and adapalene. Severe cystic acne is treated with oral antibiotics, such as minocycline, tetracycline, clindamycin, and oral isotretinoin. Oral retinoic-acid derivatives are a strong teratogen.

Radiology/Imaging 13

Learning Objectives

- List the indications and common abnormal findings for chest X-ray, abdominal X-ray, PET scan, bone scan
- Answer questions about different approaches to visualizing the CNS

This concise section should help you understand when to order each of the different types of tests in radiology. A description of what is found on each type of test is provided. For example, What does a sonogram show, and what doesn't it show? When does one use a CT scan or an MRI? When is contrast the best answer in a test question?

CHEST X-RAY

The most basic radiologic examination is a chest x-ray. Standard x-rays are based on the degree of density of tissue and how much x-ray energy each type of tissue will absorb. The closer a bone structure is in density, the greater the energy it will absorb. Therefore, because bones block the most amount of x-ray energy, they will come out white on the film. Conversely, air absorbs or blocks the least amount of energy and thus will appear darkest.

Chest x-rays are *not* routine screening tests. There is no routine screening of the general population for cancer or tuberculosis. You can do a chest x-ray if the PPD skin test is positive, but this is not the same thing as just doing a general screening.

Most x-rays are posterior-anterior (PA) films. The x-ray plate is placed in front of the chest, and the patient is leaning forward against the plate. The x-ray beam is directed from posterior to anterior. The patient must be able to stand for a PA film to be performed.

Anterior-posterior (AP) films are less accurate but must be done in patients who are too ill or unstable to stand up. All patients with central venous lines or chest tubes, or unstable patients, such as those in the intensive care unit, undergo AP films. The single greatest difference on AP films is that the heart size is artificially enlarged on them because the heart is more anterior in the chest and will therefore cast a wider shadow. On a normal PA film, the heart should be <50% of the total transthoracic diameter. This is increased to >50% on an AP film. (This phenomenon is no different than holding your hand in a light shined against a wall. The farther your hand is away from the wall, the larger your hand's shadow will appear.)

Technical Aspects of Normal Film Quality

When examining a chest x-ray, first assess the film for its technical quality. If the patient's body is abnormally rotated, then the film will be less accurate. You can determine this by seeing if the trachea and the spinous apophysis are midway between the clavicles.

Chest x-rays should be performed when the patient is holding in a full inhalation. There should be at least 10 ribs visible, counting from top to bottom.

An underexposed film will have the structures appearing too white. An overexposed film will have the blood vessels appearing too dark, preventing one from accurately assessing the blood vessels.

Note that on a PA film, the right hemidiaphragm is typically higher than is the left hemidiaphragm. This is because the liver is underneath the right hemidiaphragm, pushing it up.

Expiratory Films

Expiratory films are used when one is looking for a pneumothorax. The lungs will appear smaller because less air will remain in the lungs on expiration. Because a pneumothorax is air outside the lungs in the pleural space, this air will appear relatively larger. The volume of air in the pleural space does not decrease on exhalation.

Lateral Chest X-ray

Lateral chest x-rays will determine whether a structure in the chest is more anterior or posterior. For example, they can determine whether a mass that is visible in the center of the mediastinum on a PA film is posterior, making it more likely to be a neurally derived tumor attached to the spinal cord or an anterior mass. Anterior mediastinal masses are from the thymus, thyroid, lymph nodes, or a teratoma.

Note

The right hemidiaphragm will appear higher on a lateral x-ray and a PA film because the liver pushes it upward.

Lateral x-rays also have a greater sensitivity for the detection of small pleural effusions. On a PA film, you need at least 100 to 200 mL of fluid present to even begin to see an effusion. Each hemithorax can contain 3 liters of fluid if it is filled to capacity. A lateral chest x-ray can detect as little as 50 mL. These figures represent the amount of fluid needed to barely begin seeing "blunting," or obliteration, of the costophrenic angle.

On a lateral x-ray, the right hemidiaphragm is the one crossing the heart shadow.

Decubitus Films

Decubitus films help detect the presence of a pleural effusion. These are taken with the patient lying on his or her side and are employed when blunting or obscuration of the costophrenic angle is seen on a PA or lateral x-ray. Effusions will move and form a layer on the side of the chest wall. Infiltrates from alveolar disease do not move with gravity. You cannot determine if an effusion is infected just from its appearance on an x-ray.

APPEARANCES OF COMMON DISORDERS ON CHEST X-RAY

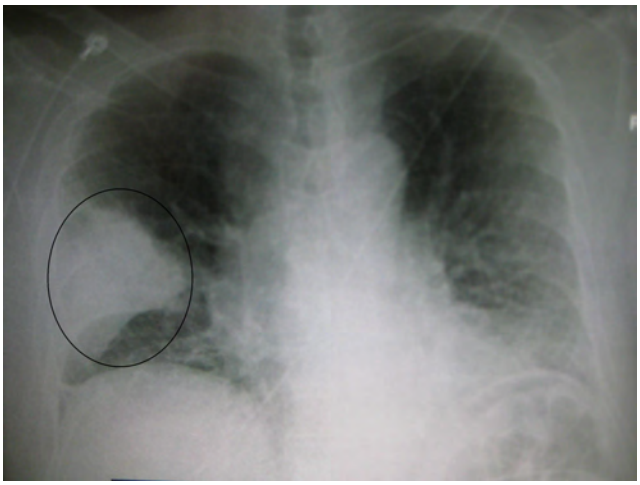
COPD/Emphysema

The most common appearance of COPD on a chest x-ray is related to hyperinflation of the lung. This leads to a darkening of the lung fields because more air is present. This trapped air also flattens the diaphragm and gives the impression of an elongated or tubular-shaped heart because it has been stretched down. There is an increased anterior/posterior diameter, or "barrel chest." Further, bullae are large, air-filled cavities that can give thin, white lines on a chest x-ray as the walls of the cavities press up against each other.

Pneumonia

Lobar pneumonia causes a whitening of each individual lobe of the lung because of the greater density of the lung. The "silhouette" sign is present, which is when the border between the affected lobe and the surrounding denser structure is obscured. (The density of the lung increases because of alveolar infiltration to the point where it takes on the density of the nearby heart or diaphragm; hence, one can no longer tell where the lung ends and the denser structure nearby begins). Lower lobe pneumonia gives a silhouette over each half of the diaphragm. Right middle-lobe pneumonia obscures the right heart border and will not pass the minor or horizontal fissure seen on a PA chest x-ray. Upper-lobe infiltration will not pass the major fissure, and this is more easily seen on a lateral x-ray. You cannot determine a specific microbiologic etiology from the x-ray alone.

Diseases of the lung outside the airspace but in the interstitial membrane give a fine, lacy appearance visible in most, if not all, of the lobes. Examples of disorders that give interstitial infiltrates are *Pneumocystis* pneumonia, *Mycoplasma*, viruses, chlamydia, and sometimes *Legionella*. Noninfectious etiologies of an interstitial infiltrate are pulmonary fibrosis secondary to silicosis, asbestosis, mercury poisoning, berylliosis, byssinosis (from cotton), or simply idiopathic pulmonary fibrosis. As the long-standing disorders become worse and more chronic, a greater degree of fibrosis occurs. This leads to greater thickening of the membrane. The terms that are used for this more chronic, thicker appearance are *reticular-nodular* and, later, *honeycombing*.



Wikipedia, James Heilman, MD

Figure 13-1. Pneumonia

Note

Interstitial Syndromes of the Lung include:

Sarcoidosis
Histiocytosis X
IPF (interstitial pulmonary fibrosis)
Tumor
Failure
Asbestosis
Collagen disorders
Environmental
Dust
Drugs

Congestive Heart Failure

The majority of pulmonary vascular flow is normally at the base of the lungs because of gravity. When there is fluid overload, the blood vessels toward the apices become fuller. This is known as pulmonary vascular congestion, or "cephalization" of flow. The term *cephalization* is used because more flow is moving toward the head. The other findings associated with CHF are cardiomegaly, effusions, and Kerley B lines.

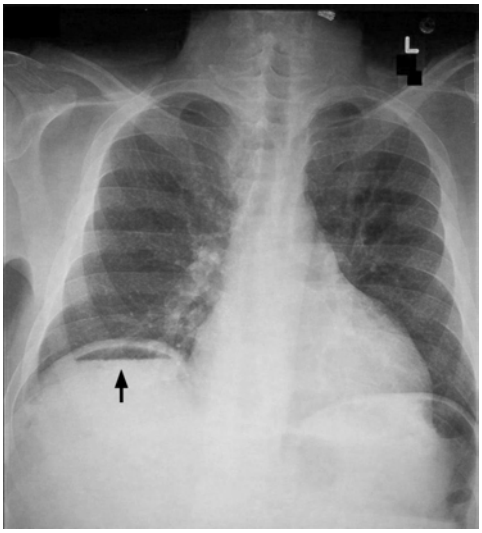
Kerley B lines are the least important. They are small, horizontal lines at the bases that represent fluid in the interlobular septa. Each lung has several lobes. When fluid builds up outside the lobes, this is known as a pleural effusion. When fluid builds up within each lobe, in between the lobules, this is known as a Kerley B line. This type of subtle radiologic finding is less important in the evaluation of congestive heart failure since the advent of the widespread use of echocardiography.

Position of Lines and Tubes

Chest x-rays are routinely used to determine the appropriate position of central venous lines and both endotracheal and chest tubes. The proper position of the tip of an endotracheal tube is 1 to 2 cm above the carina. It is important to keep some space above the carina so that when the head moves forward, the tube does not push into the carina, which is extremely uncomfortable and will provoke coughing. The tip of central venous lines is at the junction of the superior vena cava and the right atrium, at the point where the right mainstem bronchus is seen. The tip of the line should not be fully inside the atrium because this can irritate the heart and may provoke an arrhythmia.

Air under the Diaphragm

When there is perforation of an abdominal hollow organ, such as the duodenum, air is released and is visible under the diaphragm. The proper film to detect this is a chest x-ray taken in the upright position. This will allow the air to collect under the diaphragm, which should be easily visible. Abdominal x-rays do not always visualize the top of the diaphragm because of differences in body size. Chest x-rays always visualize the top of the diaphragm.



Wikimedia, Clinical Cases

Figure 13-2. Pneumoperitoneum

Imaging Tools for Lung Parenchyma

High resolution CT scan provides greater detail than a chest x-ray or CT scan because of 1 mm cut. This has a sensitivity of 95% and a specificity of close to 100% for lung parenchymal disease. High resolution CT scan is indicated in the following conditions:

- Symptomatic patients with a normal chest x-ray
- Detecting metastatic lesions, solitary nodules, bullae, bronchiectasis, and diffuse parenchymal disease (i.e., idiopathic lung diseases)
- To determine the type of lung biopsy required and site of biopsy

ABDOMINAL X-RAYS

Compared with chest x-rays, standard abdominal films without barium contrast provide far less information. Abdominal x-rays are beneficial only in the detection of an abdominal obstruction, such as an ileus or a volvulus; they do *not* reliably detect mass lesions, polyps, cancer, ascites, or inflammatory bowel disease. Mass lesions in all abdominal organs are best detected with CT scan or MRI of the abdomen. Polyps are best detected by colonoscopy. Ascites are visualized by sonography (U/S) or CT scanning. Inflammatory bowel disease, diverticulosis, and cancer are best detected by either endoscopy or barium studies of the bowel. Although 80 to 90% of kidney stones (nephrolithiasis) can be seen on abdominal films, they are also best detected by sonography or CT scanning. Only 10 to 15% of gallstones can be detected on an abdominal film because most of them do not calcify. Pancreatic calcifications can be detected in 30 to 50% of patients with chronic pancreatitis.

Sonography (U/S)

Sonography is used for evaluation of abdominal and pelvic pathology. Sonograms should be employed first for evaluation of the biliary tract because of their accuracy in evaluating dilation and obstruction of the ducts. The majority of cholelithiasis should be detected with sonography because cholesterol gallstones should be easily visible by sonography. The majority of nephrolithiasis is visible by sonography, although there is less accuracy in detecting stones in the ureters because they become retroperitoneal structures.

Sonography is useful in the evaluation of masses in the liver, spleen, pancreas, and pelvis, as well as for evaluating the presence of ascites. Despite this accuracy, CT scanning tends to have a greater sensitivity and specificity for the abdomen and pelvis. Sonography is particularly valuable in the evaluation of pregnant patients because it avoids radiation exposure to the fetus. Although less accurate, sonography is also practical in patients who have an absolute contraindication to the use of IV contrast. A total of 1:10,000 patients have a life-threatening reaction to the use of iodinated contrast agents.

There is very little utility of sonography in the evaluation of thoracic structures because the ribs block the sound waves. Also, sonography in the evaluation of intracranial structures, such as the brain, is not recommended because the skull blocks the sound waves.

Endoscopic U/S involves introducing a sonographic device into the abdomen at the end of an endoscope. Endoscopic U/S is extremely accurate in evaluating pancreatic pathology that is not easily visualized on CT scanning, such as a gastrinoma. Pancreatic lesions can also be effectively evaluated in this way.

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is an endoscopically introduced contrast procedure designed to visualize the biliary tract and pancreatic structures. ERCP is for therapy. The endoscope is introduced into the small bowel, and a catheter is placed through the sphincter of Oddi. Contrast is injected through the catheter. This allows extremely accurate visualization of the pancreatic ductal and biliary systems. ERCP is excellent for detecting strictures, stones, and neoplastic causes of obstruction. The other advantages of ERCP are the ability to perform therapy with the removal of these stones, to dilate strictures, and to perform biopsies. The scope does not routinely go up the sphincter of Oddi because it is too large to pass. MRCP is an MRI alternative to ERCP. It is less invasive than ERCP but does not allow an intervention.

The most common complication of ERCP is acute pancreatitis (around 10% in some series). Most of the time the pancreatitis is mild.

Note

MRCP: diagnosis

ERCP: treatment

Barium Studies

Barium studies of the large bowel are never as accurate for colonic pathology as is endoscopy. In addition, you cannot biopsy with barium studies or perform therapeutic procedures, such as cautery or epinephrine injection for bleeding. The upper GI series is never as accurate as is upper endoscopy for the same reasons.

However, barium studies of the esophagus are a good test to start with for the evaluation of esophageal pathology. Barium esophagram is particularly good for the detection of strictures, rings, and webs, or Zenker diverticulum. Barium is not as accurate as an upper endoscopy for the detection of esophageal cancer because a biopsy is required. (Endoscopy is far superior for the detection and therapy of esophageal varices as well.) Barium is not as accurate as manometry for the confirmation of the diagnoses of achalasia or muscular disorders, such as diffuse esophageal spasm and nutcracker esophagus.

Clinical Pearl

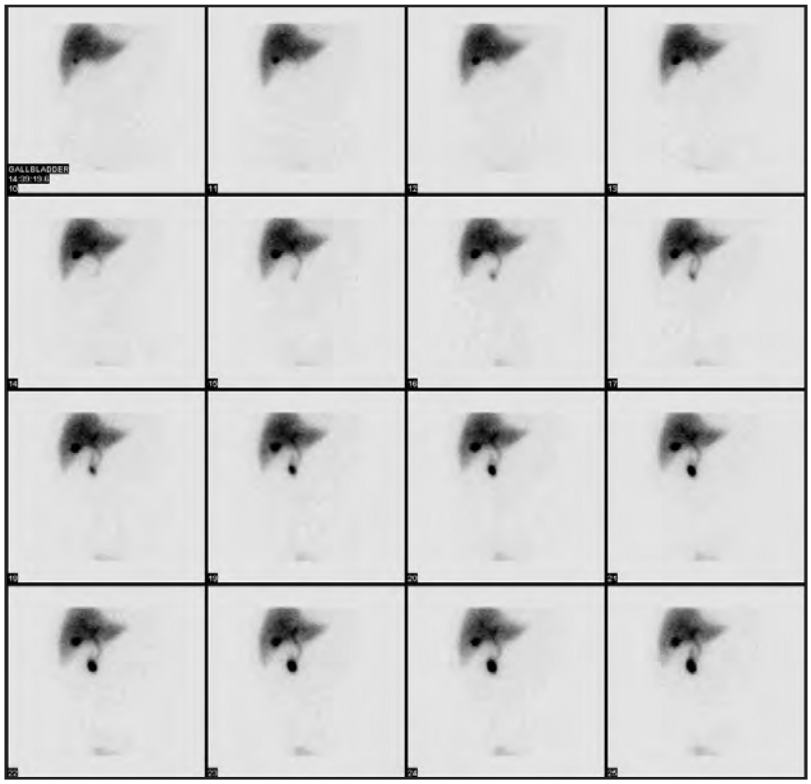
Capsule endoscopy is not a screening test to detect colon cancer. Perform capsule endoscopy to evaluate obscure small bowel GI bleeding.

Capsule Endoscopy

The ileum and jejunum are the hardest parts of the bowel to visualize by radiologic studies or endoscopy. In the past, a "push enteroscopy" was performed by introducing an extremely long, thin scope into the small bowel. Capsule endoscopy is a new technology that allows direct visualization of the small bowel by swallowing a camera that electronically relays thousands of photographic images from the small bowel to a receiver outside the body. The drawback of this procedure is that it is not possible to perform therapeutic interventions in this way. If a patient has GI bleeding that is serious and both upper and lower endoscopy do not reveal the source, then answer "capsule endoscopy" on the exam.

HIDA Scanning

This is a nuclear medicine scan useful only in the detection of acute cholecystitis. HIDA scanning is most useful in patients in whom the diagnosis of cholecystitis is not clear. An abnormal or positive test is the lack of visualization of the gallbladder. This is because the neck of the gallbladder or cystic duct becomes too edematous to allow the passage of the nuclear material. A normal scan will visualize the gallbladder. An abnormal scan will not visualize or fill the gallbladder.



Wikimedia, Myo Han

Figure 13-3. HIDA Scan

Virtual Colonoscopy

This procedure uses CT scan or MRI to provide a computer-simulated bidimensional or tridimensional image of the air-filled, distended colon.

PET SCANNING

Positron emission tomography (PET) scans are useful in the detection of cancer. They are particularly useful in determining whether lesions that are visible on a CT scan of the chest are malignant or benign. Cancer is typically associated with the increased uptake of fluorodeoxyglucose. PET scanning is used after chemotherapy to assess for the presence of residual cancer in some patients and can also be used to determine whether a patient is an operative candidate to remove a primary cancer. If the PET scan does not reveal malignancy, then the resection of certain primary cancers, such as lung cancer, is more likely to be successful.

Remember that slow-growing cancers (e.g., broncheoalveolar) may have a negative PET scan. Be careful when evaluating pulmonary nodules with PET scanning.

Clinical Pearl

Always check the patient's glucose before doing a PET scan. If the glucose is elevated, the PET scan can be falsely negative.

CENTRAL NERVOUS SYSTEM VISUALIZATION

In general, the most accurate test for evaluating the central nervous system is magnetic resonance imaging (MRI). The MRI is superior for the detection of stroke, cancer, multiple sclerosis, and infections and in the evaluation of the posterior fossa, such as the cerebellum and brainstem.

The CT scan does not visualize the brainstem well. For example, a stroke is visible on an MRI in >90% of cases within the first 24 hours after its onset, whereas the CT scan needs 3 to 4 days before >90% are visible. This is because the MRI is based on the water content of tissues rather than on the calcium content or simple density of tissue. Within a few hours after the onset of a stroke, the cells begin to swell and increase their water content. This is immediately visible on an MRI, whereas for a CT scan to detect an abnormality, the cells must die to decrease the density of visible cells.

The single exception in which a CT scan is superior to an MRI is in the detection of blood. As soon as bleeding occurs, it is visible on a CT scan. Therefore, the two cases in which a CT scan is a better study are to evaluate head trauma and to exclude hemorrhagic stroke. When a patient arrives within 3 hours of the onset of the symptoms of a stroke, a CT scan is first performed to exclude hemorrhage. This is to see if a patient is eligible for the use of thrombolytic therapy within these first 3 hours.

A CT scan is also used first for the detection of subarachnoid hemorrhage. On the first day after the stroke's onset, the CT scan has 95% sensitivity. The sensitivity diminishes by about 5% per day as the blood is hemolyzed and removed.

Contrast on a scan of the head is indicated primarily for the detection of cancers and infection. When an abscess or neoplastic process is present, there is some disruption of the blood-brain barrier, causing some extravasation of the contrast, which is visible as a contrast, or "ring"-enhancing lesion around the mass.

BONE IMAGING

An x-ray is certainly the first study to implement when evaluating trauma and fracture. Unfortunately, the bone scan has much less specificity and does not reliably distinguish between bone infection and infection of the overlying soft tissue. The MRI is both 90 to 95% sensitive and 90 to 95% specific.

Osteomyelitis

When there is the suspicion of osteomyelitis, then an x-ray is done first. Although plain x-rays lack sensitivity for the first 1 to 2 weeks, the specificity for osteomyelitis is excellent. More than 50% of the calcium content of bone must be lost for osteomyelitis to be visible. The earliest finding of osteomyelitis on an x-ray is elevation of the periosteum. If the film returns normal and there is still suspicion of osteomyelitis, then the best test is an MRI. The MRI and technetium nuclear bone scan have the same sensitivity (90–95%); however, the MRI's specificity is far greater (90–95%). Both studies should become abnormal within 2 days of the onset of osteomyelitis. Therefore, a negative bone scan is very useful if it is normal; it means that there is no osteomyelitis. If it is abnormal, you may still need to perform an MRI.

Learning Objectives

- ❑ Describe the presentation and treatment of glaucoma, cataracts, keratitis, uveitis, periorbital cellulitis, retinal diseases, and conjunctival diseases

RETINAL DISEASES

Diabetic Retinopathy

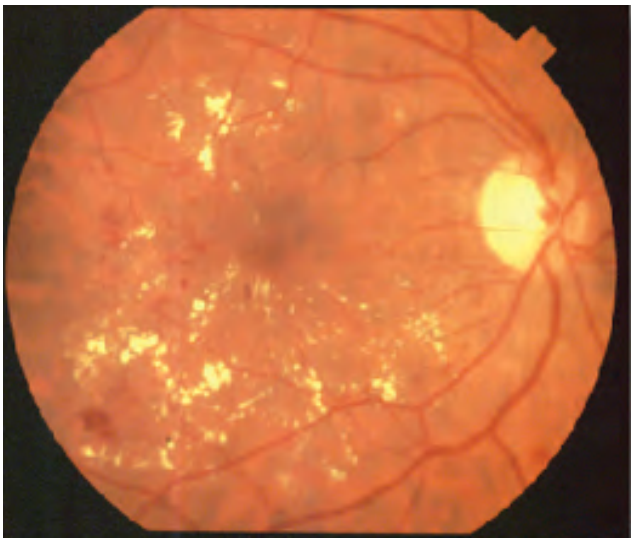
Pathogenesis. The etiology of diabetic retinopathy is based on damage to the endothelial lining of the small blood vessels of the eye. This is identical in pathogenesis to the damage that diabetes causes to all blood vessels in the body, such as in the heart, kidney, brain, and peripheral nervous system. The endothelial lining of the retinal vessels becomes damaged, leading to progressive occlusion on a microscopic level. The occlusion leads to obstruction and increased pressure.

The earliest form of this adverse effect on the retina is called **nonproliferative** (or **background**) retinopathy. Nonproliferative retinopathy is characterized by dilation of veins, microaneurysms, retinal edema, and retinal hemorrhages. Hemorrhages into the retina are not as damaging as intravitreal hemorrhages because they do not obstruct sight.

Proliferative retinopathy is a more advanced form of the disease and is markedly more serious, meaning it progresses more rapidly to blindness. As the microvascular damage to the vessels worsens, these vessels secrete increased amounts of an angiogenesis factor. The vessels are not providing sufficient nutrition to the retina. The vessels themselves exert an increased effort to have more of them produced in an effort to deliver more nutrition and oxygen to the retina. Unfortunately, this "neovascularization," or new blood vessel formation, leads to the optic nerve getting covered with abnormal new vessel formation. In addition, hemorrhages protrude into the vitreous chamber. Vitreal hemorrhages are much more serious than microaneurysms or intraretinal hemorrhages because they are much more sight threatening.

The whole point of therapy for diabetic retinopathy is to first prevent the patient from ever progressing to the proliferative phase and, second, to slow down the disease's progress with laser photocoagulation, if it occurs.

Clinical Presentation. The clinical presentation of diabetic retinopathy is highly variable. There may be very advanced disease occurring with no symptoms. Vision may decrease slowly or rapidly. Vitreal hemorrhages may develop suddenly, and patients will complain of "floaters" in their vision.



Retina-Vitreous Surgeons of Central New York

Figure 14-1. Features of Diabetic Retinopathy

Diagnosis. Screening for the presence of retinopathy should be performed on an annual basis by an ophthalmologist. This is how candidates for fluorescein angiography and laser photocoagulation are found. Fluorescein helps identify which vessels should undergo laser photocoagulation. The laser selectively destroys focal areas of the retina and diminishes the production of the angiogenesis factor, which causes the proliferative retinopathy.

Treatment of both stages of diabetic retinopathy involves the attempt to have tight control of glucose, blood pressure, and lipid levels. Proliferative retinopathy additionally involves immediate treatment with laser photocoagulation. Aspirin, clopidogrel, and other platelet-inhibiting medications have shown no benefit. The more tightly the glucose is controlled within the normal range, the slower the progression of the retinopathy. Blood pressure should be controlled to a level of <130/80 mm Hg.

Diabetes is considered by the National Cholesterol Education Program (NCEP) to be the equivalent to coronary artery disease in terms of its effect on cardiac mortality and on LDL targets. Even if there is no evidence of coronary artery disease, the target LDL in a diabetic patient is <100 mg/dL. If the patient is diabetic *and* has evidence of coronary disease, then the target LDL can be as low as <70 mg/dL. Glucose control is the most effective of these methods of retarding progression of the disease.

Retinal Detachment

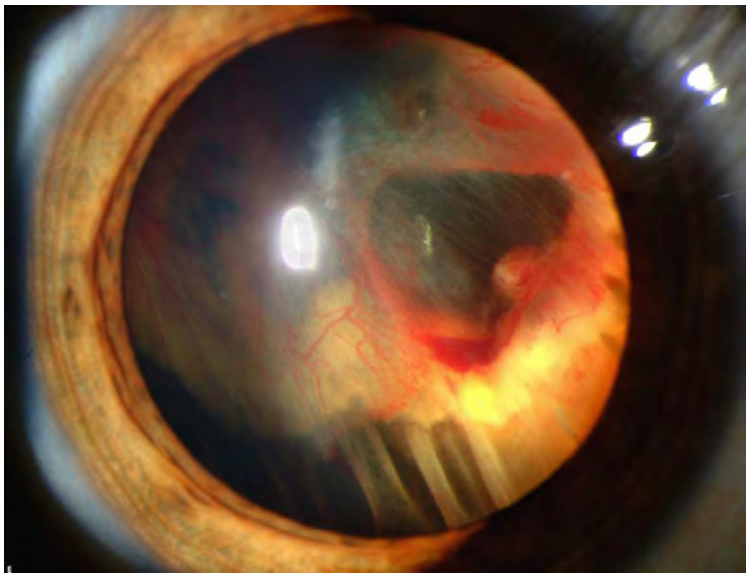
A 71-year-old woman presents to the physician with blurry vision in her left eye since that morning. She says it was as if "a curtain came down." She has had floaters in the periphery of her left eye over the past few weeks but has had no pain or erythema. She has a history of stage I hypertension but is otherwise healthy.

Pathogenesis. Retinal detachment is usually spontaneous, but it may result from trauma. The term *rhegmatogenous*, which is used to describe the detachment, is from the Greek word for "tear." The two most common predisposing factors are myopia and surgical extraction of cataracts. Traction on the retina can also occur from proliferative retinopathy from diabetes, retinal vein occlusion, and age-related macular degeneration.

Clinical Presentation. The most common presentation is blurry vision developing in one eye without pain or redness. The patient may complain of seeing "floaters," as well as flashes at the periphery of vision. Sometimes it is described as a "curtain coming down," as the retina falls off the sclera behind it.

Diagnosis is made by ophthalmologic examination.

Treatment. Various methods of trying to reattach the retina are employed. Patients should lean their heads back to promote the chance that the retina will fall back into place. The retina can be mechanically reattached to the sclera surgically, by laser photocoagulation, cryotherapy, or by the injection of expansile gas into the vitreal cavity. The gas will press the retina back into place. A "buckle," or belt, can be placed around the sclera to push the sclera forward so that it can come into contact with the retina. If all of these methods fail to reattach the retina, then the vitreous can be removed and the retina can be surgically attached to the sclera. The majority (80%) of uncomplicated rhegmatogenous retinal detachments can be cured with one operation, with 15% needing a second operation.



National Eye Institute/National Institutes of Health

Figure 14-2. Retinal Detachment

Age-Related Macular Degeneration

Pathogenesis. Age-related macular degeneration (ARMD) is the most common cause of legal blindness in older persons in the Western world. The etiology is unknown. ARMD is characterized by the formation of deposits of extracellular material collecting into yellowish deposits

seen on ophthalmoscopy. These deposits are known as "drusen." They are small, granular, subretinal deposits that are age related.

Clinical Presentation. There are 2 types of ARMD. The first is a *dry,* or atrophic, form characterized by slowly progressive visual loss in the elderly. Diagnosis is confirmed by finding clearly visible drusen on dilated eye exam.

The second type of ARMD is the *wet,* or exudative, form of the disease, characterized by the abnormal growth of vessels from the choroidal circulation into the subretinal space. These vessels leak, leading to collections of subretinal fluid and a localized, exudative retinal detachment.

Dry-type ARMD leads to visual loss of a slow, gradual nature. Wet type can present with the rapid distortion of vision over weeks to months. Fluorescein angiography will help confirm the diagnosis of exudative ARMD.

Treatment. There is no clear evidence that any therapy will stop the progression of dry-type ARMD. There is some evidence that zinc, antioxidant vitamins such as vitamins C and E, and beta-carotene may retard the progression of the disease. Wet-type ARMD is treated with VEGF inhibitors ranibizumab and bevacizumab.

Central Retinal Artery Occlusion

Pathogenesis. The etiology of the disorder can be from carotid artery embolic disease, temporal arteritis, cardiac thrombi or myxoma, or any of the usual causes of thrombophilia, such as factor V Leiden mutation.

Clinical Presentation. There is a sudden, painless, unilateral loss of vision. There is no redness of the eye. Ophthalmoscopy reveals a pale retina, with overall diminished perfusion and a "cherry-red" spot at the fovea. There is also "box-car" segmentation of the blood in the veins.

Diagnosis. These patients should undergo evaluation with carotid artery imaging, echocardiography, and evaluation for thrombophilia.

Treatment. Central retinal artery occlusion is managed in much the same way as for a stroke (cardiovascular accident [CVA]) or a transient ischemia attack (TIA). It includes laying the patient flat and supplying oxygen and ocular massage in an attempt to unobstruct the vessel. Other potential therapies are acetazolamide and thrombolytics. Anterior chamber paracentesis has been used to try to decompress the pressure in the eye and dislodge the embolus.

Central Retinal Vein Occlusion

Pathogenesis. Patients with retinal vein occlusion are at particularly high risk for developing glaucoma. These patients should be monitored for the possible use of laser photocoagulation. Younger patients should be investigated for inherited causes of thrombophilia, such as factor V mutation, protein C deficiency, and antiphospholipid syndromes.

Clinical Presentation. These patients have a clinical presentation similar to those with retinal artery occlusion. There is the sudden loss of vision without pain, redness, or abnormality in pupillary dilation. Ocular examination by funduscopy reveals disk swelling, venous dilation, tortuosity, and retinal hemorrhages.

Diagnosis. Retinal hemorrhages are the main way of distinguishing venous obstruction from arterial obstruction. You can't have a hemorrhage in the retina if you don't have blood getting into the eye.

Treatment. There is no specific therapy for retinal vein obstruction.

GLAUCOMA

Pathogenesis. The precise etiology of the majority of glaucoma is not clearly known. Acute angle-closure glaucoma can be precipitated by the use of anticholinergic medications, such as ipratropium bromide or tricyclic antidepressants; however, the majority of people with narrow angles in their anterior chambers never develop glaucoma.

In those with open-angle glaucoma, the precise etiology of the decrease in the outward flow of aqueous fluid has never been elucidated. Hence, the precise cause of the increase in intraocular pressure is not known.

Open-Angle Glaucoma

This disorder accounts for >90% of cases of glaucoma. Patients are asymptomatic for a long time, and this is the reason why it is important to screen older patients.

Diagnosis. The first clue to the diagnosis is a cup-to-disk ratio of >0.3, which should be confirmed by repeated measurements of an elevation in intraocular pressure as determined by tonometry.

Treatment of glaucoma is based on decreasing the production of aqueous humor while increasing its drainage. Medications that decrease the production of aqueous humor are beta-blockers (timolol, betaxolol, levobunolol), alpha-adrenergic agonists (apraclonidine, brimonidine), and carbonic anhydrase inhibitors (dorzolamide and brinzolamide).

Medications that increase the outflow of the humor are prostaglandin analogs, such as topical latanoprost, travoprost, and bimatoprost. The prostaglandin analogs can lead to a change in the color of the eyes and a darkening of the eyelid. Pilocarpine is a miotic agent that constricts the pupil to allow greater outflow of the aqueous humor.

Surgery is performed if maximal medical therapy is ineffective in controlling intraocular pressure. Laser trabeculoplasty or surgical trabeculectomy are the most commonly performed procedures.

Closed-Angle Glaucoma

Pathogenesis. This disorder is often an ophthalmologic emergency precipitated by the use of medications that have anticholinergic properties.

Clinical Presentation. It presents with an eye that is red, painful, hard to palpation, and associated with a fixed midpoint pupil. The cornea has a hazy cloudiness, and there is marked diminishment of visual acuity.

Treatment of acute angle-closure glaucoma is an ophthalmologic emergency. IV acetazolamide, urea, and osmotic diuretics, such as mannitol or glycerol, are used acutely. Pilocarpine can be used to open the canal of Schlemm, and beta-blockers are used to decrease humor production. If these medical therapies are ineffective, laser trabeculoplasty can be performed.

CATARACTS

Pathogenesis. Cataracts are opacifications of the lens. They are slowly progressive, with a blurring of vision occurring over months to years. Glare from the headlights of cars is particularly a problem when driving at night. Color perception is reduced in general. The etiology of cataracts is unknown, although there is an association with cigarette smoking.

Clinical Presentations. Mature cataracts can be easily seen on physical examination. Earlier-stage disease is seen with a slit lamp.

Treatment. There is no medical therapy for cataracts. Surgical removal with the placement of an intraocular lens is the standard of care.

CONJUNCTIVAL DISEASES

Conjunctivitis

Pathogenesis. Conjunctivitis can occur from any infectious agent, including bacteria, viruses, and fungi.

Clinical Presentation. Bacterial conjunctivitis is more often unilateral and presents with a marked purulent discharge from the eye. This is most symptomatic in the morning, when the patient's eye has developed a significant crust overnight, sometimes making it hard to open the eye. There is less itching compared with viral conjunctivitis. Although the eye can be red, there is a normally reactive pupil, as well as normal ocular pressure and no impairment of visual acuity.

Viral conjunctivitis is more often bilateral in nature, with much more severe ocular itching and enlarged preauricular adenopathy. The eyes are also red, but again, the pupil reacts normally and there is no photophobia.

Treatment of bacterial conjunctivitis is with topical antibiotics, such as erythromycin ointment, sulfacetamide drops, or topical fluoroquinolones. There is no specific microbiologic treatment for viral conjunctivitis. It is treated symptomatically with topical antihistamine/decongestants.

Subconjunctival Hemorrhage

Subconjunctival hemorrhage is more dangerous in its appearance than in its actual damage to vision or even the eye itself. The most common cause is trauma, particularly in the presence of thrombocytopenia. The collection of the hematoma stops at the limbus, which is the anatomic connection between the conjunctiva and the cornea. Because this prevents the blood from covering the cornea, there is no impairment of vision. There is no intraocular or intravitreal damage and hence no impairment of vision. No specific therapy for subconjunctival hemorrhage is necessary.

KERATITIS

Pathogenesis. Keratitis refers to any infection or inflammation of the cornea. Usually, keratitis happens as a result of trauma to the cornea with the inoculation of bacterial or fungal elements into the cornea.

Herpes Simplex Keratitis

Clinical Presentation. Herpes simplex keratitis is characterized by severe pain in the eye and a sensation that something is caught under the eyelid.

Diagnosis. The diagnosis is based on finding a characteristic dendritic pattern over the cornea on fluorescein staining of the eye with examination under a blue light.

Treatment. Therapy for herpes simplex keratitis is with oral acyclovir, famciclovir, or valacyclovir and topical trifluridin 1% solution or idoxuridine. It is most important for the general physician to *never* use oral or topical steroids in an attempt to relieve inflammation. This can markedly worsen the growth of the virus and essentially acts as fertilizer for the virus.

PERIORBITAL CELLULITIS

Pathogenesis. Cellulitis is caused by *Staphylococcus aureus* or *Streptococcus* invading the dermis and subcutaneous tissues surrounding the eye.

Treatment. Antistaphylococcal penicillins, such as oxacillin or nafcillin, should be administered. If there is an allergic reaction to penicillins, such as a rash, then first-generation cephalosporins can be used (i.e., cefazolin).

UVEITIS

Pathogenesis. The uveal tract refers to the iris, ciliary body, and choroid. When these structures are inflamed, the condition is called uveitis. The etiology of uveitis is from a large number of systemic inflammatory conditions, such as psoriasis, sarcoidosis, syphilis, Reiter syndrome, or inflammatory bowel disease.

Clinical Presentation. Uveitis leads to a painful, red eye with marked photophobia. One of the clues to the diagnosis is that pain occurs even when shining a light in the unaffected eye. This is because of the consensual light reflex in which the affected pupil will constrict even when light is shined in the normal eye.

Diagnosis. A specific diagnosis is made by slit lamp examination. Inflammation of the iris, ciliary body, and choroid is visible. Inflammatory cells may accumulate on the inside of the cornea after they precipitate out of the aqueous humor, rather like an accumulating snowfall. These focal collections are called keratic precipitates.

Treatment. The basic management, despite the varied underlying conditions, is to treat with topical or, sometimes, systemic steroids.

Reproductive Basics 1

Learning Objectives

- ❏ Describe the basic physiology of spermatogenesis, ovulation, pregnancy, and lactation
- ❏ List the stages of fetal development and risks related to premature birth
- ❏ Answer questions about the terminology and epidemiology of perinatal statistics and genetic disorders detectable at birth

PHYSIOLOGY OF REPRODUCTION

Human Chorionic Gonadotropin (hCG)

Source—It is produced by the placental syncytiotrophoblast, first appearing in maternal blood 10 days after fertilization, peaking at 9–10 weeks, and then gradually falling to a plateau level at 20–22 weeks.

Structure—By chemical structure it is a glycoprotein with two subunits. The α-subunit is similar to luteinizing hormone (LH), follicle-stimulating hormone (FSH), and thyrotropin (TSH). The β-subunit is specific for pregnancy.

Purposes

- **Maintain corpus luteum production** of progesterone until the placenta can take over maintenance of the pregnancy.
- **Regulate steroid biosynthesis** in the placenta and fetal adrenal gland as well.
- **Stimulate testosterone production** in the fetal male testes.

If levels are excessive—**twin pregnancy**, **hydatidiform mole**, choriocarcinoma, embryonal carcinoma.

If levels are inadequate—**ectopic pregnancy**, **threatened abortion**, missed abortion.

Human Placental Lactogen

Structure—Chemically it is similar to anterior pituitary growth hormone and prolactin.

Pregnancy change—Its level parallels placental growth, rising throughout pregnancy.

OB Triad

Human Chrorionic Gonadotropin (hCG)

- Produced by syncytiotrophoblast
- Similar to LH, FSH, & TSH
- Maintains corpus luteum

OB Triad

Human Placental Lactogen (hPL)

- Produced by syncytiotrophoblast
- Similar to HGH, prolactin
- Decreases insulin sensitivity

Effect—It **antagonizes** the cellular action of insulin, decreasing insulin utilization, thereby contributing to the predisposition of pregnancy to glucose intolerance and diabetes.

If levels are low—threatened abortion, intrauterine growth restriction (IUGR).

Progesterone

Structure—This is a steroid hormone produced after ovulation by the luteal cells of the corpus luteum to induce endometrial secretory changes favorable for blastocyst implantation.

Source—It is initially produced exclusively by the corpus luteum up to 6–7 menstrual weeks. Between 7 and 9 weeks, both the corpus luteum and the placenta produce progesterone. After 9 weeks the corpus luteum declines, and progesterone production is exclusively by the placenta.

Purposes

- **In early pregnancy** it induces endometrial secretory changes favorable for blastocyst implantation.
- **In later pregnancy** its function is to induce immune tolerance for the pregnancy and prevent myometrial contractions.

OB Triad

Progesterone

- Produced by corpus luteum
- Prepares endometrium for implantation
- Decreased myometrial contractility

Estrogen

These are steroid hormones, which occur in 3 forms, each of unique significance during a woman's life.

Estradiol is the predominant moiety **during** the nonpregnant **reproductive years**. It is converted from androgens (produced from cholesterol in the follicular theca cells), which diffuse into the follicular granulosa cells containing the aromatase enzyme that completes the transformation into estradiol.

Estriol is the main estrogen **during pregnancy**. Dehydroepiandrosterone-sulfate (DHEAS) from the fetal adrenal gland is the precursor for 90% of estriol converted by sulfatase enzyme in the placenta.

Estrone is the main form **during menopause**. Postmenopausally, adrenal androstenedione is converted in peripheral adipose tissue to estrone.

Table 1-1. Estrogens Throughout a Woman's Life

Estra*di*ol	Nonpregnant reproductive years	**Follicle** Granulosa
Est*ri*ol	Pregnancy	**Placenta** from fetal adrenal DHEAS
Estr*one*	After menopause	**Adipose** from adrenal steroids

PHYSIOLOGIC CHANGES IN PREGNANCY

Skin

Striae gravidarum—"Stretch marks" that develop in genetically predisposed women on the abdomen and buttocks.

Spider angiomata and **palmer erythema**—From increased skin vascularity.

Chadwick sign—Bluish or purplish discoloration of the vagina and cervix as a result of increased vascularity.

Linea nigra—Increased pigmentation of the lower abdominal midline from the pubis to the umbilicus.

Chloasma—Blotchy pigmentation of the nose and face.

Cardiovascular

Arterial blood pressure—Systolic and diastolic values both decline early in the first trimester, reaching a nadir by 24–28 weeks, then they gradually rise toward term but never return quite to prepregnancy baseline. Diastolic falls more than systolic, as much as 15 mm Hg. **Arterial blood pressure is never normally elevated in pregnancy**.

Venous blood pressure—Central venous pressure (CVP) is **unchanged with pregnancy**, but femoral venous pressure (FVP) increases two- to threefold by 30 weeks' gestation.

Plasma volume—Plasma volume increases up to 50% with a significant increase by the first trimester. Maximum increase is by 30 weeks. This increase is even greater with multiple fetuses.

Systemic vascular resistance (SVR)—SVR equals blood pressure (BP) divided by cardiac output (CO). Because BP decreases and CO increases, SVR **declines** by 30%, reaching its nadir by 20 weeks. This enhances uteroplacental perfusion.

Cardiac output (CO)—CO **increases** up to 50% with the major increase by 20 weeks. CO is the product of heart rate (HR) and stroke volume (SV), and both increase in pregnancy. HR increases by 20 beats/min by the third trimester. SV increases by 30% by the end of the first trimester. **CO is dependent on maternal position.** CO is the lowest in the supine position because of inferior vena cava compression resulting in decreased cardiac return. CO is the highest in the left lateral position. CO increases progressively through the three stages of labor.

Murmurs—A systolic ejection murmur along the left sternal border is normal in pregnancy owing to increased CO passing through the aortic and pulmonary valves. **Diastolic murmurs are never normal in pregnancy** and must be investigated.

Table 1-2. Cardiovascular Changes

Arterial blood pressure	Systolic	↓
	Diastolic	↓↓
Venous pressure	Central	Unchanged
	Femoral	↑
Peripheral vascular resistance		↓

Hematologic

Red blood cells (RBC)—RBC mass **increases** by 30% in pregnancy; thus, oxygen-carrying capacity increases. However, because plasma volume increases by 50%, the calculated hemoglobin and hematocrit values decrease by 15%. The nadir of the hemoglobin value is at 28–30 weeks' gestation. **This is a physiologic dilutional effect, not a manifestation of anemia.**

White blood cells (WBC)—WBC count **increases** progressively during pregnancy with a mean value of up to 16,000/mm^3 in the third trimester.

Erythrocyte sedimentation rate (ESR)—ESR **increases** in pregnancy because of the increase in gamma globulins.

Platelet count—Platelet count normal reference range is **unchanged** in pregnancy.

Coagulation factors—Factors V, VII, VIII, IX, XII, and von Willebrand Factor **increase** progressively in pregnancy, leading to a hypercoagulable state.

Gastrointestinal

Stomach—Gastric motility **decreases** and emptying time **increases** from the progesterone effect on smooth muscle. This increase in stomach residual volume, along with upward displacement of intraabdominal contents by the gravid uterus, predisposes to aspiration pneumonia with general anesthesia at delivery.

Large bowel—Colonic motility **decreases** and transit time **increases** from the progesterone effect on smooth muscle. This predisposes to increased colonic fluid absorption resulting in constipation.

Pulmonary

Tidal volume (Vt)—Vt is volume of air that moves in and out of the lungs at rest. Vt **increases** with pregnancy to 40%. It is the only lung volume that does not decrease with pregnancy.

Minute ventilation ($\dot{V}e$)—$\dot{V}e$ **increases** up to 40% with the major increase by 20 weeks. $\dot{V}e$ is the product of respiratory rate (RR) and Vt. RR remains unchanged with Vt increasing steadily throughout the pregnancy into the third trimester.

Residual volume (RV)—RV is the volume of air trapped in the lungs after deepest expiration. RV decreases up to 20% by the third trimester. To a great extent this is because of the upward displacement of intraabdominal contents against the diaphragm by the gravid uterus.

Blood gases—The rise in Vt produces a **respiratory alkalosis** with a decrease in Pco_2 from 40–30 mm Hg and an increase in pH from 7.40 to 7.45. An increased renal loss of bicarbonate helps compensate, resulting in an alkalotic urine.

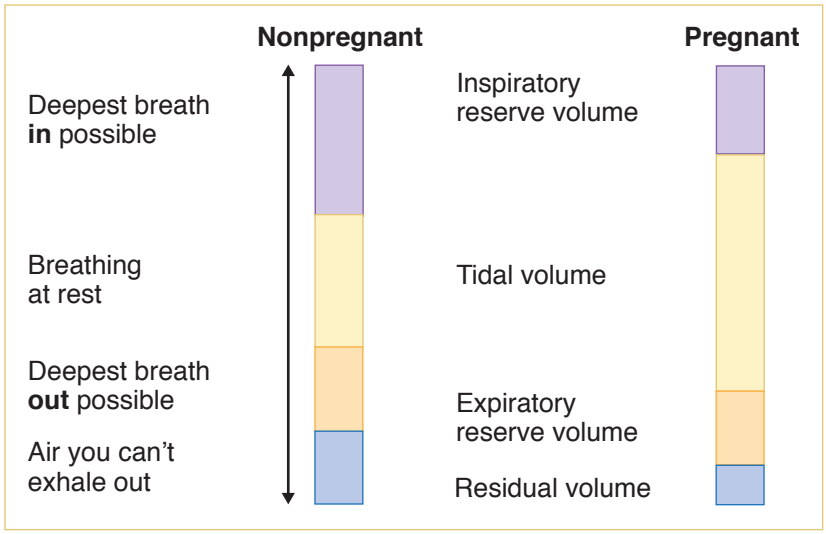

Figure I-1-1. Changes in Pulmonary System

Renal

Kidneys—The kidneys **increase** in size because of the increase in renal blood flow. This hypertrophy doesn't reverse until 3 months postpartum.

Ureters—Ureteral diameter **increases** owing to the progesterone effect on smooth muscle. The right side dilates more than the left in 90% of patients.

Glomerular filtration rate (GFR)—GFR, renal plasma flow, and creatinine clearance all **increase** by 50% as early as the end of the first trimester. This results in a 25% decrease in serum blood urea nitrogen (BUN), creatinine, and uric acid.

Glucosuria—Urine glucose normally **increases**. Glucose is freely filtered and actively reabsorbed. However, the tubal reabsorption threshold falls from 195 to 155 mg/dL.

Proteinuria—Urine protein remains **unchanged**.

Endocrine

Pituitary—Pituitary size **increases** by 100% by term from increasing vascularity. This makes it susceptible to ischemic injury (Sheehan syndrome) from postpartum hypotension.

Adrenals—Adrenal gland size is unchanged, but production of cortisol **increases** two- to threefold.

Thyroid—Thyroid size **increases** 15% from increased vascularity. Thyroid binding globulin (TBG) increases, resulting in **increased** total T_3 and T_4, although free T_3 and free T_4 remain **unchanged**.

Fetal Circulation

Three **in utero shunts** exist within the fetus. The **ductus venosus** carries blood from the umbilical vein to the inferior vena cava. The **foramen ovale** carries blood from the right to the left atrium, and the **ductus arteriosus** shunts blood from the pulmonary artery to the descending aorta.

Ductus venosus	Umbilical vein → inferior vena cava
Foramen ovale	Right atrium → left atrium
Ductus arteriosus	Pulmonary artery → descending aorta

OB Triad

Fetal Circulation Shunts

- Ductus venosus (UA → IVC)
- Foramen ovale (RA → LA)
- Ductus arteriosus (PA → DA)

PHYSIOLOGY OF LACTATION

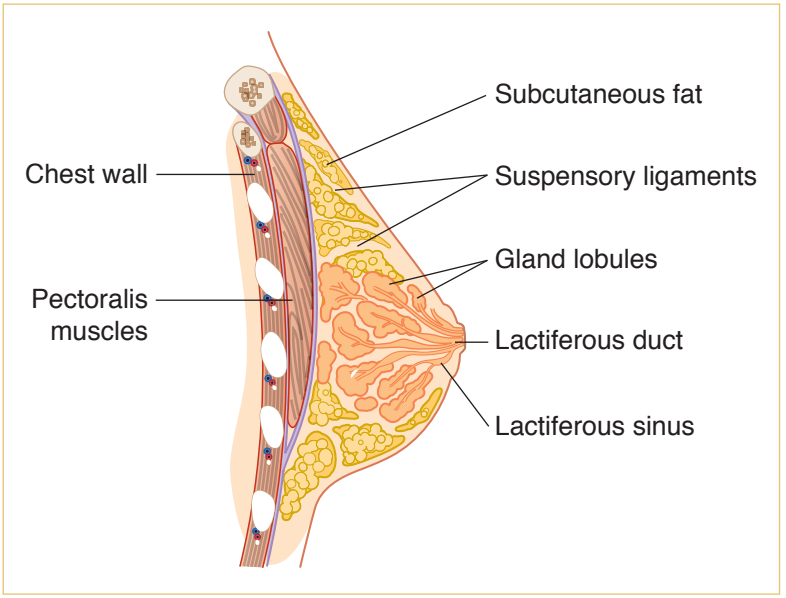

Figure I-1-2. Sagittal View of Breast

Embryology

Breasts begin developing in the embryo about 7 to 8 weeks after conception, consisting only of a thickening or ridge of tissue.

- From weeks 12 to 16, tiny groupings of cells begin to branch out, laying the foundation for future **ducts** and milk-producing **glands**. Other tissues develop into **muscle** cells that will form the nipple (the protruding point of the breast) and areola (the darkened tissue surrounding the nipple).
- In the later stages of pregnancy, maternal hormones cause breast cells to organize into branching, tubelike structures, thus forming the milk ducts. In the final 8 weeks, lobules (milk-producing glands) mature and actually begin to secrete a liquid substance called colostrum.

- In both female and male newborns, swellings underneath the nipples and areolae can easily be felt and a clear liquid discharge (colostrum) can be seen.

Puberty

From infancy to just before puberty, there is no difference between female and male breasts.

- With the beginning of female puberty, however, the release of estrogen—at first alone, and then in combination with progesterone when the ovaries functionally mature—causes the breasts to undergo dramatic changes which culminate in the fully mature form.
- This process, on average, takes 3 to 4 years and is usually complete by age 16.

Anatomy

The breast is made of lobes of glandular tissue with associated ducts for transfer of milk to the exterior and supportive fibrous and fatty tissue. On average, there are 15 to 20 lobes in each breast, arranged roughly in a wheel-spoke pattern emanating from the nipple area. The distribution of the lobes, however, is not even.

- There is a preponderance of glandular tissue in the upper outer portion of the breast. This is responsible for the tenderness in this region that many women experience prior to their menstrual cycle.
- About 80–85% of normal breast tissue is fat during the reproductive years. The 15 to 20 lobes are further divided into lobules containing alveoli (small saclike features) of secretory cells with smaller ducts that conduct milk to larger ducts and finally to a reservoir that lies just under the nipple. In the nonpregnant, nonlactating breast, the alveoli are small.
- During pregnancy, the alveoli enlarge; and during lactation, the cells secrete milk substances (proteins and lipids). With the release of oxytocin, the muscular cells surrounding the alveoli contract to express the milk during lactation.
- Ligaments called **Cooper's ligaments**, which keep the breasts in their characteristic shape and position, support breast tissue. In the elderly or during pregnancy, these ligaments become loose or stretched, respectively, and the breasts sag.
- The lymphatic system drains excess fluid from the tissues of the breast into the axillary nodes. Lymph nodes along the pathway of drainage screen for foreign bodies such as bacteria or viruses.

Hormones

Reproductive hormones are important in the development of the breast in puberty and in lactation.

- **Estrogen**, released from the ovarian follicle, promotes the growth ducts.
- **Progesterone**, released from the corpus luteum, stimulates the development of milk-producing alveolar cells.
- **Prolactin**, released from the anterior pituitary gland, stimulates milk production.
- **Oxytocin**, released from the posterior pituitary in response to suckling, causes milk ejection from the lactating breast.

Table 1-3. Effect of Hormones on Breast

Estrogen	Ducts, nipples, fat
Progesterone	Lobules, alveoli
Prolactin	Milk production
Oxytocin	Milk ejection

Lactation

The breasts become fully developed under the influence of **estrogen**, **progesterone**, and **prolactin** during pregnancy. **Prolactin** causes the production of milk, and **oxytocin** release (via the suckling reflex) causes the contraction of smooth-muscle cells in the ducts to eject the milk from the nipple.

- The first secretion of the mammary gland after delivery is colostrum. It contains more protein and less fat than subsequent milk, and contains IgA antibodies that impart some **passive immunity** to the infant. Most of the time it takes 1 to 3 days after delivery for milk production to reach appreciable levels.
- The expulsion of the placenta at delivery initiates milk production and causes the drop in circulating estrogens and progesterone. **Estrogen** antagonizes the positive effect of prolactin on milk production.
- The physical stimulation of suckling causes the release of oxytocin and stimulates prolactin secretion, causing more milk production.

EMBRYOLOGY AND FETOLOGY

Embryonic and Fetal Development

Postconception Week 1

OB Triad

Post-Conception Week 1

- **Starts** at conception
- **Ends** with implantation
- **Yields** morula → blastula

The most significant event of week 1 is the **implantation of the blastocyst** on the endometrium. Week 1 begins with fertilization of the egg and ends with implantation of the blastocyst onto the endometrial surface. Fertilization usually occurs in the distal part of the oviduct. The egg is capable of being fertilized for 12–24 hours. The sperm is capable of fertilizing for 24–48 hours.

Week 1 can be divided into 2 phases:

- The **intratubal** phase extends through the first half of the first week. It begins at conception (day 0) and ends with the entry of the morula into the uterine cavity (day 3). The conceptus is traveling down the oviduct as it passes through the 2-cell, 4-cell, and 8-cell stages.
- The **intrauterine** phase begins with entry of the morula into the uterus (day 3) and ends with implantation of the blastocyst onto the endometrial surface (day 6). During this time the morula differentiates into a hollow ball of cells. The outer layer will become the trophoblast or placenta, and the inner cell mass will become the embryo.

Postconception Week 2

The most significant event of week 2 is the development of the **bilaminar germ disk with epiblast and hypoblast layers**. These layers will eventually give rise to the 3 primordial germ layers.

Another significant event is the invasion of the maternal sinusoids by syncytiotrophoblast. Because β-human chorionic gonadotropin (β-hCG) is produced in the syncytiotrophoblast, this now allows β-hCG to enter the maternal blood stream. **β-hCG pregnancy test now can be positive for the first time.**

OB Triad

Post-Conception Week 2

- **Starts** with implantation
- **Ends** with 2-layer embryo
- **Yields** bi-laminar germ disk

Postconception Week 3

The most significant event of week 3 is the migration of cells through the primitive streak between the epiblast and hypoblast to form the **trilaminar germ disk with ectoderm, mesoderm, and endoderm layers**. These layers will give rise to the major organs and organ systems.

OB Triad

Post-Conception Week 3

- **Starts** with 2-layer embryo
- **Ends** with 3-layer embryo
- **Yields** tri-laminar germ disk

Postconception Weeks 4–8

During this time the major organs and organ systems are being formed. This is the period of major teratogenic risk.

- **Ectoderm**—central and peripheral nervous systems; sensory organs of seeing and hearing; integument layers (skin, hair, and nails).
- **Mesoderm**—muscles, cartilage, cardiovascular system, urogenital system.
- **Endoderm**—lining of the gastrointestinal and respiratory tracts.

OB Triad

Post-Conception Week 4-8

- 3 germ layers differentiating
- Greatest risk of malformations
- Folic acid prevents NTD

Paramesonephric (Müllerian) Duct

This duct is present in all early embryos and is the primordium of the female internal reproductive system. **No hormonal stimulation is required.**

- In males the Y chromosome induces gonadal secretion of müllerian inhibitory factor (MIF), which causes the müllerian duct to involute.
- In females, without MIF, development continues to form the fallopian tubes, corpus of the uterus, cervix, and proximal vagina.

Female External Genitalia

No hormonal stimulation is needed for differentiation of the external genitalia into labia majora, labia minora, clitoris, and distal vagina.

Mesonephric (Wolffian) Duct

This duct is also present in all early embryos and is the primordium of the male internal reproductive system. **Testosterone stimulation is required** for development to continue to form the vas deferens, seminal vesicles, epididymis, and efferent ducts. This is present in males from testicular sources. In females, without androgen stimulation, the Wolffian duct undergoes regression. If a genetic male has an absence of androgen receptors, the Wolffian duct will also undergo regression.

Male External Genitalia

Dihydrotestosterone (DHT) stimulation is needed for differentiation of the external genitalia into a penis and scrotum. If a genetic male has an absence of androgen receptors, external genitalia will differentiate in a female direction.

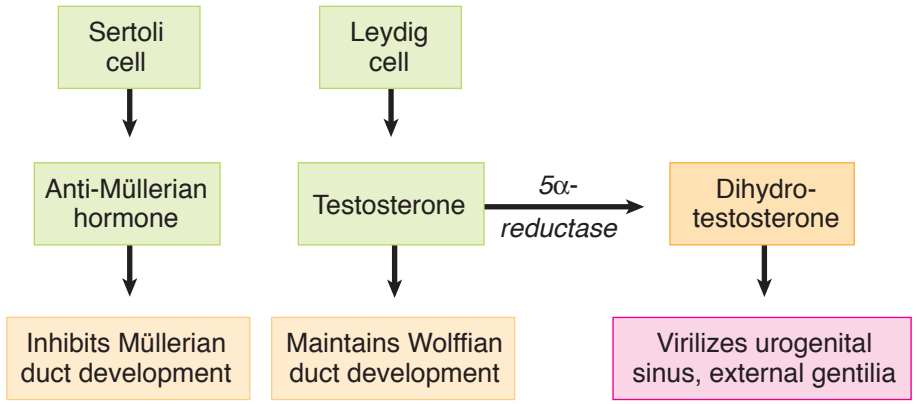

Figure 1-3. Testicular Function

Hormones Needed for Genital Development		
♀	External?	None
	Internal?	
♂	External?	Androgen
	Internal?	

Table 1-4. Embryology

Primordia	Female	Male	Major Determinant Factors
Gonadal Germ cells Coelomic epithelium Mesenchyme Mesonephros	 Oogonia Granulosa cells Theca cells Rete ovarii	 Spermatogonia Sertoli cells Leydig cells Rete testis	 Sex chromosomes
Ductal Paramesonephric (Müllerian) Mesonephric (Wolffian) Mesonephric tubules	 Fallopian tubes Uterus Part of vagina Gartner's duct Epoophoron Paraoophron	 Testis hydatid Vas deferens Seminal vesicles Epididymis Efferent ducts	 Absence of Y chromosome Testosterone Müllerian-inhibiting factor
External Genitalia Urogenital sinus Genital tubercle Urogenital folds Genital folds	 Vaginal contribution Skene's glands Bartholin's glands Clitoris Labia minora Labia majora	 Prostate Bulbourethral glands Prostatic utricle Penis Corpora spongiosa Scrotum	 Presence or absense of testosterone, dihydrotestosterone, and 5-alpha reductase enzyme

Teratology

A 36-year-old woman underwent a barium enema for rectal bleeding on February 1 with estimated radiation dose of 4 rad. Her last menstrual period (LMP) was January 1 and she has 35-day cycles. She was not using any contraception. A urine pregnancy test was positive on March 15. She inquires about the risk to her fetus of teratogenic injury.

Definition. A teratogen is any agent that disturbs normal fetal development and affects subsequent function. The nature of the agent as well as its timing and duration after conception are critical. There are critical periods of susceptibility with each teratogenic agent and with each organ system.

Stages of Teratogenesis

- **From conception to end of second week**—The embryo will either survive intact or die because the 3 germ layers have not yet been formed.
- **Postconception weeks 3–8**—This is the period of greatest teratogenic risk from formation of the 3 germ layers to completion of organogenesis.
- **After week 9 of postconception**—During this time teratogenicity is low, but adverse effects may include diminished organ hypertrophy and hyperplasia.

Types of Agents Resulting in Teratogenesis or Adverse Outcomes

Infectious: Agents in this category include bacteria (e.g., chlamydia and gonorrhea cause neonatal eye and ear infections), viral (e.g., rubella, cytomegalovirus, herpes virus), spirochetes (e.g., syphilis), or protozoa (e.g., toxoplasmosis).

Ionizing radiation: No single diagnostic procedure results in radiation exposure to a degree that would threaten the developing pre-embryo, embryo, or fetus. No increase is seen in fetal anomalies or pregnancy losses with exposure of <5 rads. The greatest risk of exposure is between 8 and
15 weeks' gestation with the risk a nonthreshold, linear function at doses of at least 20 rads.

Chemotherapy: Risk is predominantly a first-trimester phenomenon. Second- and third-trimester fetuses are remarkably resistant to chemotherapeutic agents.

Environmental: Tobacco is associated with intrauterine growth restriction (IUGR) and preterm delivery, but no specific syndrome. Alcohol is associated with fetal alcohol syndrome: midfacial hypoplasia, microcephaly, mental retardation, and IUGR.

Recreational drugs: Cocaine is associated with placental abruption, preterm delivery, intraventricular hemorrhage, and IUGR. Marijuana is associated with preterm delivery but not with any syndrome.

Medications: These agents account for 1–2% of congenital malformations. The ability of a drug to cross the placenta to the fetus depends on molecular weight, ionic charge, lipid solubility, and protein binding. Drugs are listed by the FDA as category A, B, C, D, and X.

FDA Categories of Drugs

- **Category A—Controlled studies show no risk.** Adequate studies show no risk to the fetus in any pregnancy trimester. This includes acetaminophen, thyroxine, folic acid, and magnesium sulfate.
- **Category B—No evidence of risk in animals but human studies have not been done.** This includes penicillins, cephalosporins, methyldopa, insulin, Pepcid, Reglan, Tagamet, Vistaril, Paxil, Prozac, Benadryl, and Dramamine.
- **Category C—Risk cannot be ruled out.** Risk is present in animals but controlled studies are lacking in humans. This includes codeine, Decadron, methadone, Bactrim, Cipro, AZT, β-blockers, Prilosec, heparin, Protamine, Thorazine, Alupent, Robitussin, and Sudafed.
- **Category D—Positive evidence of risk.** Studies demonstrate fetal risk, but potential benefits of the drug may outweigh the risk. This includes aspirin, Valium, tetracycline, Dilantin, Depakote, and Lithium.
- **Category X—Contraindicated in pregnancy.** Studies demonstrate fetal risk, which outweighs any possible benefit. This includes Accutane (isotretinoin), Danocrine, Pravachol, Coumadin, and Cafergot.

Specific Syndromes

Alcohol. Fetal alcohol syndrome—IUGR, **midfacial hypoplasia**, developmental delay, short palpebral fissures, **long philtrum**, multiple joint anomalies, cardiac defects.

Diethylstilbestrol. DES syndrome—**T-shaped uterus**, **vaginal adenosis** (with predisposition to **vaginal clear cell carcinoma**), cervical hood, incompetent cervix, preterm delivery.

Dilantin. Fetal hydantoin syndrome—IUGR, **craniofacial dysmorphism** (epicanthal folds, depressed nasal bridge, oral clefts), **mental retardation**, **microcephaly**, nail hypoplasia, heart defects.

Isotretinoin (Accutane). Congenital deafness, **microtia**, CNS defects, congenital heart defects.

Lithium. Ebstein's anomaly (right heart defect).

Streptomycin. VIII nerve damage, hearing loss.

Tetracycline. After fourth month, deciduous teeth discoloration.

Thalidomide. Phocomelia, **limb reduction defects**, ear/nasal anomalies, cardiac defects, pyloric or duodenal stenosis.

Trimethadione. Facial dysmorphism (short upturned nose, slanted eyebrows), cardiac defects, IUGR, mental retardation.

Valproic acid (Depakote). Neural tube defects (spina bifida), cleft lip, renal defects.

Warfarin (Coumadin). Chondrodysplasia (stippled epiphysis), microcephaly, mental retardation, optic atrophy.

PERINATAL STATISTICS AND TERMINOLOGY

Table 1-5. Terminology for Perinatal Statistics

Terminology	Definition
Gravidity	Total number of pregnancies irrespective of the pregnancy duration
Nulligravida	Woman who is not currently pregnant and has never been pregnant
Primigravida	Woman who is pregnant currently for the first time
Multigravida	Woman who is pregnant currently for more than the first time
Parity	Total number of pregnancies achieving ≥20 weeks' gestation
Nullipara	Woman who has never carried a pregnancy achieving ≥20 weeks' gestation
Primipara	Woman who has carried one pregnancy achieving ≥20 weeks' gestation
Multipara	Woman who has carried more than one pregnancy to ≥20 weeks' gestation
Parturient	Woman who is in labor
Puerpera	Woman who has just given birth

Table 1-6. Terminology for Perinatal Losses

Terminology	Definition
Abortion	Pregnancy loss prior to 20 menstrual weeks
Antepartum death	Fetal death between 20 menstrual weeks and onset of labor
Intrapartum death	Fetal death from onset of labor to birth
Fetal death	Fetal death between 20 menstrual weeks and birth
Perinatal death	Fetal/neonatal death from 20 menstrual weeks to 28 days after birth
Neonatal death	Newborn death between birth and the first 28 days of life
Infant death	Infant death between birth and first year of life
Maternal death	A woman who died during pregnancy or within 90 days of birth

Table 1-7. Terminology for Mortality Rates

Terminology	Definition
Birth rate	Number of live births per 1,000 total population
Fertility rate	Number of live births per 1,000 women ages 15–45 years
Fetal mortality rate	Number of fetal deaths per 1,000 total births
Neonatal mortality rate	Number of neonatal deaths per 1,000 live births
Perinatal mortality rate	Number of fetal + neonatal deaths per 1,000 total births
Infant mortality rate	Number of infant deaths per 1,000 live births
Maternal mortality ratio	Number of maternal deaths per 100,000 live births

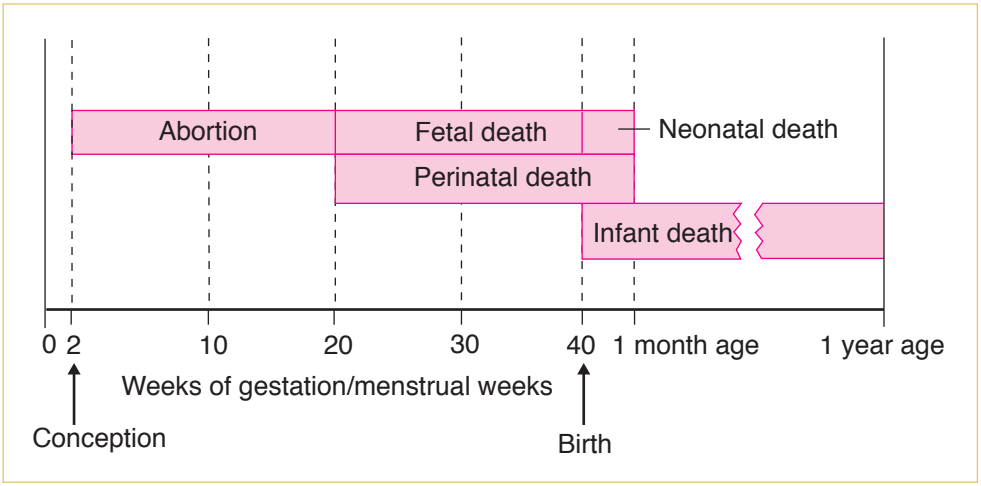

Figure I-1-4. Perinatal Mortality Terminology

GENETIC DISORDERS

Human Genetics and Indications for Genetic Counseling

A 37-year-old G5 P0 Ab4 comes for prenatal care at 7 weeks' gestation. She has experienced 4 previous spontaneous first-trimester abortions. She is concerned about the likelihood of her next pregnancy being successful.

- **Advanced maternal age:** women ≥35 years of age at increased risk of fetal nondisjunction trisomies (e.g., trisomies 21 and 18)
- **Incidence of chromosomal abnormalities by maternal age:**

Age	Down Syndrome	Total Risk
20	1 in 1,670	1:525
25	1 in 1,250	1:475
30	1 in 885	1:385
35	1 in 365	1:180
40	1 in 110	1:63
45	1 in 32	1:18
49	1 in 12	1:7

- **Multiple fetal losses**
- **Previous child:** neonatal death, mental retardation, aneuploidy, known genetic disorder
- **Pregnancy or fetal losses:** stillborn with birth defect, multiple pregnancy or fetal losses
- **Family history:** genetic diseases, birth defects, mental retardation
- **Abnormal prenatal tests:** triple marker screen, sonogram
- **Parental aneuploidy**

Chromosomal Aberration

Aneuploidy

This refers to **numeric chromosome abnormalities** in which cells do not contain 2 complete sets of 23 chromosomes. This usually occurs because of **nondisjunction**. The **most common** aneuploidy is **trisomy**, the presence of an extra chromosome. Most autosomal trisomies result in spontaneous abortions. The **most common** trisomy in first-trimester losses is trisomy 16. The **most common** trisomy at term is trisomy 21.

Polyploidy

This refers to numeric chromosome abnormalities in which cells contain complete **sets of extra chromosomes**. The most common polyploidy is **triploidy** with 69 chromosomes, followed by **tetraploidy** with 92 chromosomes. An example of triploidy is **incomplete molar** pregnancies, which occurs from fertilization of an egg by two sperm.

Structural alterations

This refers to conditions in which chromosomal material is deleted, gained, or rearranged. It can involve single or multiple chromosomes. An example of a chromosomal deletion is del (5p) or cri du chat syndrome, which is a deletion of the short arm of chromosome 5.

Mosaicism

This refers to the presence of ≥2 cytogenetically distinct cell lines in the same individual. Mosaicism can involve the placenta, the fetus, or both. Gonadal mosaicism can result in premature ovarian failure and predispose the gonad to malignancy.

Common aneuploidies are as follows:

Trisomy	Extra single	47,XX+21
Monosomy	Missing single	45,X
Polyploidy	Extra set	69,XXY

Translocations

Reciprocal

This involves any two or more nonhomologous chromosomes, and occurs when there is a **breakage and reunion** of portions of the involved chromosomes to yield new products. Carriers of **balanced reciprocal translocations** have 46 chromosomes, with both derivative chromosomes present. The offspring may also have 46 chromosomes but have only one of the derivative chromosomes present.

Robertsonian

This always involves the **acrocentric chromosomes**, and is caused by centric fusion after loss of the satellite region of the short arms of the original acrosomic chromosome. The karyotype of a balanced Robertsonian translocation will appear to have only 45 chromosomes; however, the full complement of genetic material is present, and there are no clinical effects. The offspring may have 46 chromosomes but have double the genetic material of a particular chromosome.

Genetics of Pregnancy Loss

Miscarriage

At least 50% of first-trimester abortuses have abnormal chromosomes. The 2 **most common** aneuploidies in miscarriages are trisomy 16 and monosomy X. Fifty percent of these abnormalities are autosomal trisomies, with trisomy 16 being the most common.

Turner Syndrome (45,X)

Also known as **gonadal dysgenesis** or **monosomy X**, Turner syndrome is seen in 1 in 2,000 births. In most cases it is the result of loss of the paternal X chromosome. Ninety-eight percent of these conceptions abort spontaneously. Obstetric ultrasound shows the characteristic nuchal skin-fold thickening and cystic hygroma. Those fetuses that survive to term have absence of secondary sexual development, short stature, streak gonads, primary amenorrhea, primary infertility, broad chest, and neck webbing. Urinary tract anomalies, bicuspid aortic valve, and aortic coarctation are commonly seen. Intelligence is usually normal. Mosaic patterns can occur with ovarian follicles present.

OB Triad

Turner Syndrome

- Primary amenorrhea
- Web neck
- Streak gonads

Klinefelter Syndrome (47,XXY)

Klinefelter syndrome is seen in 1 in 1,000 births. Diagnosis is seldom made before puberty. Physical findings include tall stature, testicular atrophy, azoospermia, gynecomastia, and truncal obesity. Learning disorders, autoimmune diseases, and low IQ are common.

OB Triad

Klinefelter Syndrome

- Testicular atrophy
- Gynecomastia
- Azoospermia

Down Syndrome

Trisomy 21 is seen in 1 in 800 births and accounts for 50% of all cytogenetic diseases at term. IUGR and polyhydramnios are common. T21 incidence increases with advancing maternal age. The syndrome is characterized by mental retardation, short stature, muscular hypotonia, brachycephaly, and short neck. The typical facial appearance is oblique orbital fissures, flat nasal bridge, small ears, nystagmus, and protruding tongue. Congenital heart disease (endocardial cushion defects) is more common along with duodenal atresia.

OB Triad

Down Syndrome

- Short stature
- Mental retardation
- Endocardial cushion cardiac defects

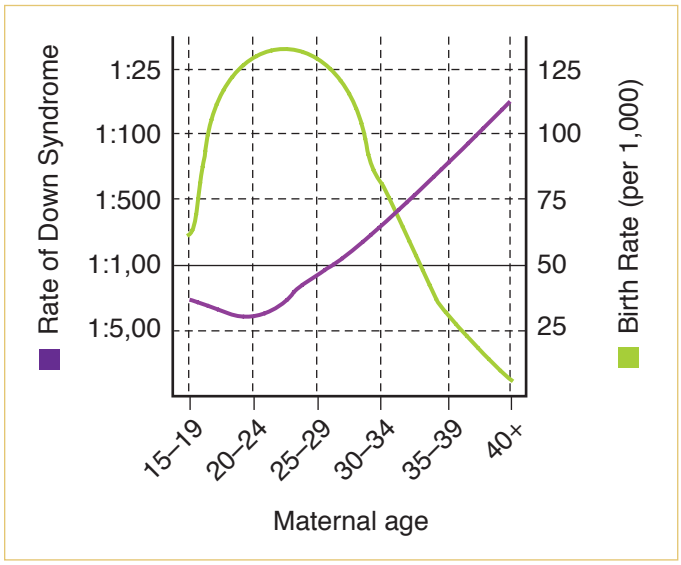

Figure I-1-5. Birth Rate and Rate of Down Syndrome versus Maternal Age

Edward syndrome

Trisomy 18 is seen in 1 in 5,000 births and is more frequent with advancing maternal age. IUGR is common. It is associated with profound mental retardation. Unique findings are rocker-bottom feet and clenched fists. Eighty percent of cases occur in females. Survival to 1 year of age is <10%. Mean survival is 14 days.

Patau syndrome

Trisomy 13 is also seen more frequently with advancing maternal age. It is associated with profound mental retardation. Associated findings include IUGR, cyclopia, proboscis, holoprosencephaly, and severe cleft lip with palate. Survival to 1 year of age is rare, with mean survival 2 days.

Table 1-8. Genetic Syndromes

Name	Karyotype	Stature IQ		Unique finding
Klinefelter	47,XXY	TALL	↓ IQ	Microgenitals, infertility
Turner	45,X	SHORT	Normal IQ	Web neck, coarctation aorta
Down	T21	SHORT	Functional MR ↓ Severe MR ↓ Profound mental retardation	Duodenal atresia, AV canal defect
Edward	T18	SHORT	Functional MR ↓ Severe MR ↓ Profound mental retardation	Abnormal feet, fist
Patau	T13	SHORT	Functional MR ↓ Severe MR ↓ Profound mental retardation	Holoprosencephaly Cyclops

Mendelian Genetics

A 23-year-old black primigravida is seen at 12 weeks' gestation. She has been diagnosed with sickle cell trait (AS). Her husband and father of the baby is also AS. She inquires as to the risk of her baby having sickle cell disease (SS).

Prevalence. About 1% of liveborn infants have a congenital Mendelian disorder. **15%** of all birth defects are attributable to Mendelian disorders. Of these, **70%** are autosomal dominant. The remainder are autosomal recessive or X-linked.

Autosomal dominant genetics

Transmission occurs equally to males and females, and serial generations are affected. **Gross anatomic abnormalities are the most common findings.** Age of onset is usually delayed, with variability in clinical expression. Each affected individual has an affected parent (unless this is a new mutation). Affected individuals will transmit the disease to 50% of their offspring. Unaffected individuals will bear unaffected children (if penetrance is complete). **There are no carrier states.**

OB Triad

Autosomal Recessive

- Transmitted by both sexes
- Often skips generations
- Male and female carriers

Autosomal dominant examples:

Polydactyly	Marfan syndrome	Polycystic kidneys
Huntington chorea	Myotonic dystrophy	Neurofibromatosis
Achondroplasia		Osteogenesis imperfecta

Autosomal recessive

Transmission occurs equally to males and females, but the disease often skips generations. Enzyme deficiencies are most common findings. Age of onset is usually earlier with consistency in clinical expression. If both parents are heterozygous for the gene, 25% of offspring are affected, 50% are carriers, and 25% are normal. If one parent is homozygous and one is heterozygous, 50% of offspring will be affected, and 50% will be carriers. If both parents are homozygous, 100% of children will be affected. **Carrier states are common.**

Autosomal recessive examples:

Deafness	Albinism	Phenylketonuria (PKU)
Cystic fibrosis (CF)	Sickle cell anemia	Congenital adrenal hyperplasia (CAH)
Thalassemia	Tay-Sachs (TS) disease	Wilson disease

X-linked recessive

These conditions are functionally dominant in men, but may be dominant or recessive in women. There is no male-to-male transmission (because the father gives only his Y chromosome to his son), but transmission is 100% male to female. The usual transmission is from heterozygous females to male offspring in an autosomally dominant pattern. The disease is expressed in all males who carry the gene. Family history reveals the disorder is only found in male relatives, and commonly in maternal uncles.

X-linked recessive examples:

Hemophilia A	Diabetes insipidus	G-6-PD deficiency
Color blindness	Hydrocephalus	Duchenne muscular dystrophy
Complete androgen insensitivity		

OB Triad

X-Linked Recessive

- No male–male transmission
- Expressed only in males
- Female carriers

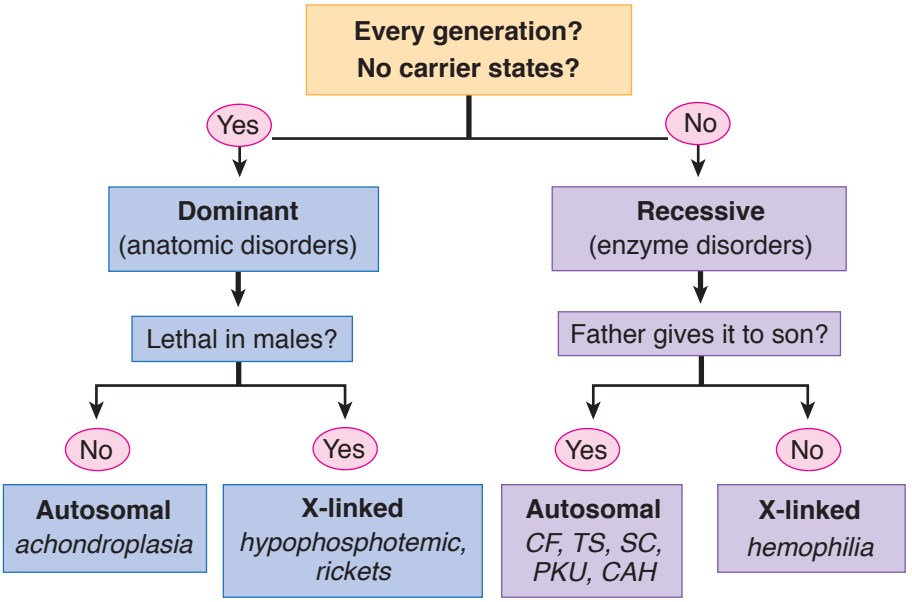

Figure I-1-6. Mendelian Genetics

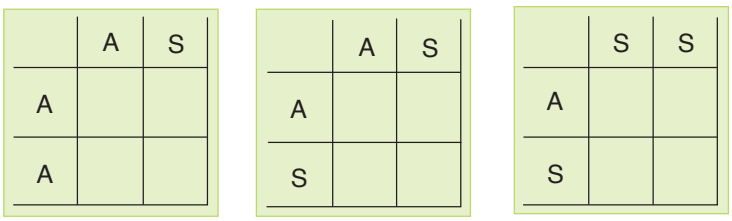
X-linked dominant

These conditions may show up as two types of disorders: (1) manifested in female heterozygotes as well as carrier males (hemizygotes). Example is hypophosphatemic rickets. (2) manifested in female heterozygotes but lethal in males. The increased spontaneous abortion rate represents male fetuses. Examples are incontinentia pigmenti, focal dermal hypoplasia, and orofaciodigital syndrome.



Calculations of Autosomal Recessive Risk

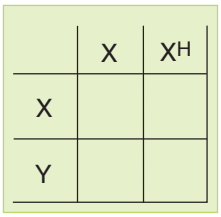


Figure I-1-7. Calculations of X-linked Risk (Hemophilia)

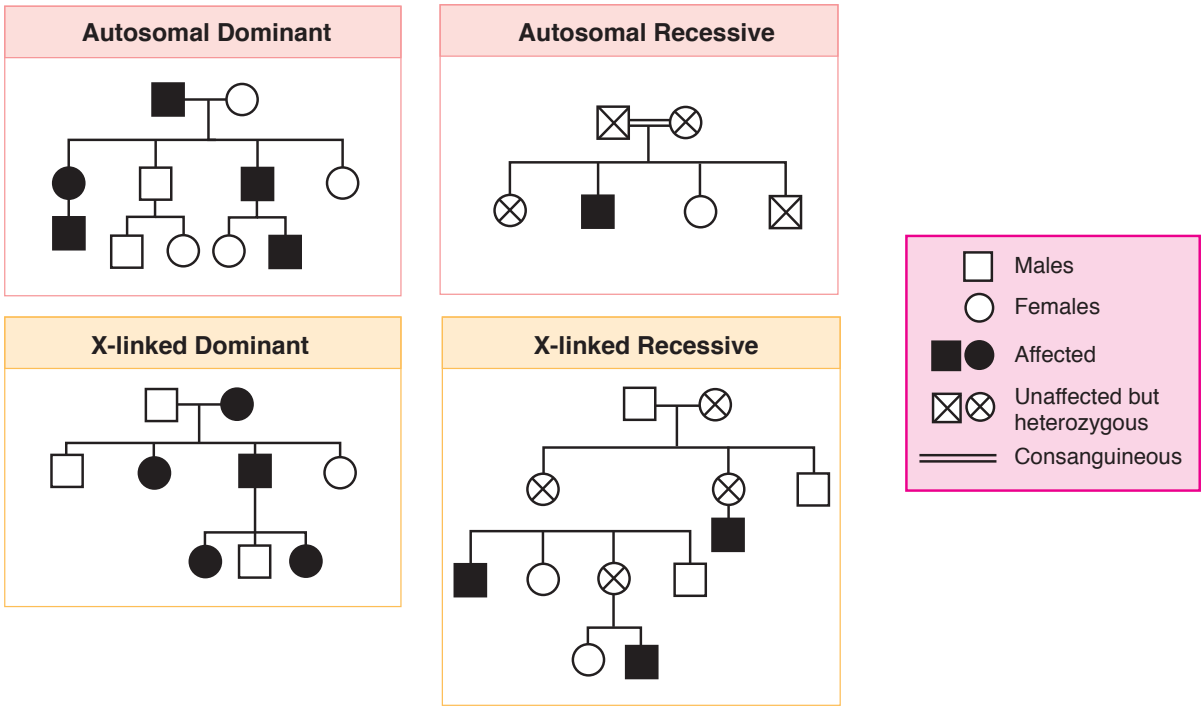

Figure 1-8. Familial Transmission Patterns of Inheritance

Multifactorial Inheritance

A 32-year-old woman with corrected tetralogy of Fallot is pregnant at 18 weeks' gestation with a male fetus. She inquires as to the chance that her son has congenital heart disease.

Prevalence. The majority of birth defects (70%) are multifactorial or polygenic in origin, which means there is an interaction of multiple genes with environmental factors. Characteristic Mendelian patterns are not found, but there is an increased frequency of the disorder or phenotype in families. **The overall recurrence rate is 2–3%.**

- As the number of genes for a multifactorial trait increases, the liability for the disease increases.
- The more severe the malformation, the higher the risk for recurrence.
- Examples of multifactorial inheritance include neural tube defects, congenital heart disease, cleft lip and palate, and pyloric stenosis.

Neural tube defects (NTD)

The incidence of NTD is 1–2 per 1,000 births. These anomalies result from failure of neural tube closure by **day 22–28 postconception**. The spectrum ranges from anencephaly to very slight vertebral defects. Anencephaly and spina bifida occur with equal frequency.

Polyhydramnios is frequently seen. **Preconception folic acid supplementation** may decrease incidence of NTD. Women with high risk for NTD should take **4 mg** of folic acid. All women should take **0.4 mg** of folic acid.

Congenital heart disease (CHD)

The incidence of CHD is 1% of births. The majority of isolated CHD are multifactorial **with an overall recurrence risk of 2%**. However, the specific recurrence risk depends on the defect and the family history details. It is important to distinguish isolated defects from those that are part of a syndrome with a higher recurrence risk. Preconception folate reduces the risk of congenital CHD, as well as NTD.

Cleft lip and palate

The incidence is 1 per 1,000 births. The risk of cleft lip in a second child of unaffected parents is 4%. If two children are affected, the risk of the third child being affected is 10%.

Pyloric stenosis

This condition is more common in males. The risk of the condition in the offspring of an affected parent is much greater if that parent is female.

Failed Pregnancy 2

Learning Objectives

- ❏ Describe the detection and risks of ectopic pregnancy
- ❏ List the approaches to induced abortion at different stages of fetal development
- ❏ Describe the epidemiology and management of early pregnancy bleeding and fetal demise

INDUCED ABORTION

Nearly half of all pregnancies among American women are unintended, and 4 in 10 of these are terminated by abortion. A quarter of all pregnancies (excluding miscarriages) end in abortion.

- Early first-trimester abortions pose virtually no long-term risk of infertility, ectopic pregnancy, spontaneous abortion (miscarriage), or congenital malformation (birth defect), and little or no risk of preterm or low birth-weight deliveries. <0.3% of abortion patients experience a complication that requires hospitalization.
- Numerous epidemiologic studies have shown no association between abortion and breast cancer or any other type of cancer.
- The risk of maternal death associated with abortion increases with advancing gestational age. The maternal mortality associated with childbirth is about 12 times as high as that associated with early first-trimester abortion.

First-Trimester Methods

Vacuum curettage—dilation and curettage (D&C)

- This is the **most common** abortion procedure in the United States (90%), and is performed before 13 weeks' gestation.
- Prophylactic antibiotics are given to reduce the infection rate, and conscious sedation and paracervical block local anesthetic are administered for pain relief.
- The cervical canal is dilated with tapered metal cervical dilators or hygroscopic/osmotic dilators such as **laminaria**.
- Complications are rare but include endometritis, treated with outpatient antibiotics; and retained products of conception (POC), treated by repeat curettage.
- Maternal mortality ratio: **1 per 100,000** women.

Medical abortion

- Mifepristone has been marketed over the past decade as an alternative to surgical abortion.
- Medical induction of abortion can be induced using oral mifepristone (Mifeprex; a **progesterone antagonist**) and oral misoprostol (Cytotec; prostaglandin E1). Use is limited to the first 63 days of amenorrhea.
- Approximately 85% of patients will abort within 3 days. The earlier the gestational age, the higher the success rate. About 2% of patients abort incompletely and require vacuum curettage.
- Rare cases of ***Clostridium sordellii*** sepsis have been reported.

Second-Trimester Methods

The more advanced the gestation, the higher the rate of complications.

Dilation and evacuation (D&E)

- This is the most common second-trimester abortion procedure.
- Cervical dilation is performed by inserting osmotic laminaria dilators 24 hours prior to the procedure. The cervical dilation in millimeters equals the number of weeks of gestation (e.g., at 18 weeks, the cervix should be dilated 18 mm).
- Early second-trimester abortions (13–14 weeks) can be performed by vacuum aspiration. After 14 weeks, the fetus is morcellated and removed in pieces. Ultrasound guidance can ensure complete evacuation of pregnancy tissues. A D&E is difficult to perform after 20 weeks due to toughness of fetal tissues.
- An **intact D&E** involves more advanced pregnancies, with 2 or more days of laminaria treatment to obtain wide cervical dilation allowing assisted breech delivery of the fetus under ultrasound guidance and decompression of the calvaria, with the fetus otherwise delivered intact. In lay terminology, this has been called a "partial birth" abortion. An intact D&E can be performed up to 24 weeks.
- Pain relief is achieved through local, intravenous, or spinal anesthesia.
- Immediate complications may include uterine perforation, retained tissue, hemorrhage, infection, and, rarely, disseminated intravascular coagulation.
- Delayed complications may include cervical trauma with resulting cervical insufficiency.
- Maternal mortality ratio: **4 per 100,000** women.

Labor induction methods

Stimulation of **uterine contractions** to dilate the cervix can be achieved with any of the following: **prostaglandins** (intra-amniotic $PGF_{2\alpha}$), vaginal PGE_2 (dinoprostone [Cervidil®]), IM 15-methyl $PGF_{2\alpha}$ (carboprost tromethamine [Hemabate®]), PGE_1 (misoprostol [Cytotec®]). Interval from induction to delivery may be up to 24 hours.

Delivery of a live fetus may occur with use of prostaglandin (PG) analogs; feticidal agents used include intracardiac injection of KCl or digoxin.

Immediate complications include retained placenta (the most common problem with all PG abortions), hemorrhage, and infection. **Delayed complications** include cervical trauma with resulting cervical insufficiency.

Maternal mortality ratio: **8 per 100,000** women.

Table 2-1. Methods of Induced Abortion

Trimester	Method	Procedure	Maternity-Mortality Ratio
First Trimester	Surgical	Suction dilation & curettage (D&C)	1
	Medical	Mifepristone (progesterone antagonist)	1
Second Trimester	Surgical	Dilation & evacuation (D&E)	4
	PGE_1	Induction of labor contractions	8
Any Trimester	Major surgery	Hysterotomy, hysterectomy	25

EARLY PREGNANCY BLEEDING

A 40-year-old woman (G3 P1 Ab1) at 9 weeks' gestation comes to the office complaining of vaginal bleeding. A urine pregnancy test was positive 3 weeks ago. She initially experienced breast tenderness; however, it has now disappeared. She denies passage of any tissue vaginally.

Definition. Bleeding that occurs before 12 weeks' gestation. The most common cause of early pregnancy loss is fetal in origin.

Etiology

- **Cytogenetic etiology.** The majority of early pregnancy losses are caused by gross chromosomal abnormalities of the embryo or fetus.
- **Mendelian etiology.** Other losses may be caused by autosomal or X-linked dominant or recessive diseases.
- **Antiphospholipid syndrome.** An uncommon cause of early pregnancy loss. Some women with SLE produce antibodies against their own vascular system and fetoplacental tissues. Treatment is subcutaneous heparin.

Clinical Presentation: **Speculum examination** is essential to rule out vaginal or cervical lesions that are causing bleeding.

- **RhoGAM** should be administered to all Rh-negative gravidas who undergo dilatation and curettage (D&C).
- Molar and ectopic pregnancy should be ruled out in all patients with early pregnancy bleeding.

Clinical Entities

The following diagnoses represent findings along a continuum from the beginnings of losing the pregnancy to complete expulsion of the products of conception (POC).

Note

For more discussion about antiphospholipid syndrome, refer to the thrombophilias section in chapter 10.

Missed abortion

Sonogram finding of a nonviable pregnancy without vaginal bleeding, uterine cramping, or cervical dilation. **Management:** Scheduled suction D&C, conservative management awaiting a spontaneous completed abortion, or induce contractions with misoprostol (Cytotec®) (PGE 1).

Threatened abortion

Sonogram finding of a viable pregnancy with vaginal bleeding but no cervical dilation. Half of these pregnancies will continue to term successfully. **Management:** Often the cause is implantation bleeding. Observation. No intervention is generally indicated or effective.

Inevitable abortion

Vaginal bleeding and uterine cramping leading to cervical dilation, but no POC has yet been passed. **Management:** Emergency suction D&C if bleeding is heavy to prevent further blood loss and anemia. Otherwise conservative management awaiting a spontaneous completed abortion or induce contractions with misoprostol (Cytotec®) PGE 1.

Incomplete abortion

Vaginal bleeding and uterine cramping leading to cervical dilation, with some, but not all, POC having been passed. **Management:** Emergency suction D&C if bleeding is heavy to prevent further blood loss and anemia. Otherwise conservative management awaiting a spontaneous completed abortion or induce contractions with misoprostol (Cytotec(R)) PGE1.

Completed abortion

Vaginal bleeding and uterine cramping have led to all POC being passed. This is confirmed by a sonogram showing no intrauterine contents or debris. **Management:** Conservative if an intrauterine pregnancy had been previously confirmed. Otherwise, serial β-human chorionic gonadotropin (β-hCG) titers should be obtained weekly until negative to ensure an ectopic pregnancy has not been missed.

FETAL DEMISE

A 28-year-old multigravida at 33 weeks' gestation comes to the office stating she has not felt her baby move for 24 hours. A previous 18-week sonogram showed a single fetus with grossly normal anatomy. You are unable to find fetal heart tones by auscultation with a Doppler stethoscope.

Definition. From a medical viewpoint, the term applies to any death after the embryo period (**≥10 menstrual weeks**). From a perinatal statistics viewpoint, the term applies to in utero death of a fetus after 20 weeks' gestation before birth. **Antenatal demise** occurs before labor. **Intrapartum demise** is the term if death occurs after the onset of labor.

Significance

- Disseminated intravascular coagulation (DIC) is the most serious consequence with prolonged fetal demise (>2 weeks) resulting from release of tissue thromboplastin from deteriorating fetal organs.
- Grief resolution may be prolonged if psychosocial issues are not appropriately addressed.

Risk Factors. Fetal demise is most commonly idiopathic. When a cause is identified, risk factors include antiphospholipid syndrome, overt maternal diabetes, maternal trauma, severe maternal isoimmunization, fetal aneuploidy, and fetal infection.

Presentation

- Before 20 weeks' gestation, the most common finding is uterine **fundus less than dates**.
- After 20 weeks' gestation, the most common symptom is maternal report of **absence of fetal movements**.

Diagnosis. Ultrasound demonstration of lack of fetal cardiac activity.

Management

- **DIC present.** DIC is usually not seen until 4 weeks after demise. Coagulopathy should be ruled out with appropriate laboratory testing: platelet count, d-dimer, fibrinogen, prothrombin time, partial thromboplastin time. If DIC is identified, immediate delivery is necessary with selective blood product transfusion as clinically indicated.
- **No DIC present.** Delivery may best be deferred for a number of days to allow for an appropriate grief response to begin. Or if the patient wishes conservative management, follow weekly serial DIC laboratory tests. Ninety percent of patients start spontaneous labor after 2 weeks.
- **Mode of delivery.** A dilatation and evacuation (D&E) procedure may be appropriate in pregnancies of <23 weeks' gestation if no fetal autopsy is indicated. Induction of labor with vaginal prostaglandin is appropriate in pregnancies of ≥23 weeks or if a fetal autopsy is indicated. Cesarean delivery is almost never appropriate for dead fetus.
- **Psychosocial issues.** Acceptance of the reality of the loss may be enhanced by allowing the patient and her family to see the fetus, hold the fetus, name the fetus, and have a burial. Encouraging expression of feelings and tears may speed grief resolution.
- **Identify cause.** Workup may include cervical and placental cultures for suspected infection, **autopsy** for suspected lethal anatomic syndrome, **karyotype** for suspected aneuploidy, **total body x-ray** for suspected osteochondrodysplasia, maternal blood for **Kleihauer-Betke** (peripheral smear for suspected fetomaternal bleed). Amniocentesis can yield living fetal amniocyte cells although the fetus is demised. Up to 10% of the karyotypes show aneuploidy.

ECTOPIC PREGNANCY

A 28-year-old patient visits the emergency department complaining of unilateral left-sided abdominal pain and vaginal spotting of 3 days' duration. Her last menstrual period was 8 weeks ago, and before this episode she had menses every 28 days. Her only previous pregnancy was an uncomplicated term spontaneous vaginal delivery. She had used intrauterine contraception for 3 years in the past. On pelvic examination the uterus is slightly enlarged and there is left adnexal tenderness but no palpable mass. A quantitative serum β-hCG value is 2,600 mIU.

GYN Triad

Ectopic Pregnancy

- **Secondary** amenorrhea
- **Unilateral** abdominal/pelvic pain
- Vaginal bleeding

Definition. This is a pregnancy in which implantation has occurred outside of the uterine cavity. The most common location of ectopic pregnancies is an oviduct. The **most common** location within the oviduct is the distal ampulla.

Differential Diagnosis. With a positive pregnancy test, the differential diagnosis consists of a threatened abortion, incomplete abortion, ectopic pregnancy, and hydatidiform mole. In a reproductive age woman with abnormal vaginal bleeding, the possibility of pregnancy or complication of pregnancy should always be considered.

Risk Factors. The **most common** predisposing cause is previous pelvic inflammatory disease (PID). Ectopic pregnancy risk is increased from any obstruction of normal zygote migration to the uterine cavity from tubal scarring or adhesions from any origin: infectious (PID, IUD), postsurgical (tubal ligation, tubal surgery), or congenital (diethylstilbestrol [DES] exposure). One percent of pregnancies are ectopic pregnancies, and if the patient has had one ectopic pregnancy, the incidence becomes 15%.

Table 2-2. Risk Factors for Ectopic Pregnancy

Scarring or Adhesions Obstructing Normal Zygote Migration	
Infectious	Pelvic inflammatory disease
Postsurgical	Tuboplasty/ligation
Congenital	Diethylstilbestrol
Idiopathic	No risk factors

Clinical Findings

- **Symptoms.** The **classic triad** with an unruptured ectopic pregnancy is amenorrhea, vaginal bleeding, and unilateral pelvic-abdominal pain. With a ruptured ectopic pregnancy, the symptoms will vary with the extent of intraperitoneal bleeding and irritation. Pain usually occurs after 6–8 menstrual weeks.
- **Signs.** The classic findings with an unruptured ectopic pregnancy are unilateral adnexal and cervical motion tenderness. Uterine enlargement and fever are usually absent. With a ruptured ectopic pregnancy, the findings reflect peritoneal irritation and the degree of hypovolemia. Hypotension and tachycardia indicate significant blood loss. This results in abdominal guarding and rigidity.
- **Investigative findings.** A β-hCG test will be positive. Sonography may or may not reveal an adnexal mass, but most significantly no intrauterine pregnancy (IUP) will be seen.

Diagnosis. The diagnosis of an unruptured ectopic pregnancy rests on the results of a quantitative serum β-hCG titer combined with the results of a vaginal sonogram. It is based on the assumption that when a normal intrauterine pregnancy has progressed to where it can be seen on vaginal sonogram at 5 weeks' gestation, the serum β-hCG titer will exceed 1,500 mIU. With the lower resolution of abdominal sonography, an IUP will not consistently be seen until 6 weeks' gestation. The β-hCG discriminatory threshold for an abdominal ultrasound to detect an intrauterine gestation is 6,500 mIU compared with 1,500 mIU for vaginal ultrasound.

Specific criteria. Failure to see a normal intrauterine gestational sac when the serum β-hCG titer is >1,500 mIU is presumptive diagnosis of an ectopic pregnancy.

Diagnosis of unruptured ectopic pregnancy is presumed when:

β-hCG titer >1,500 mIU
No intrauterine pregnancy is seen with vaginal sonogram

Management

- **Ruptured ectopic.** The diagnosis of ruptured ectopic pregnancy is presumed with a history of amenorrhea, vaginal bleeding, and abdominal pain in the presence of a hemodynamically unstable patient. Immediate surgical intervention to stop the bleeding is vital, usually by laparotomy.
- **Intrauterine pregnancy.** If the sonogram reveals an IUP, management will be based on the findings. If the diagnosis is hydatidiform mole, the patient should be treated with a suction curettage and followed up on a weekly basis with β-hCG.
- **Possible ectopic.** If the sonogram does not reveal an IUP, but the quantitative β-hCG is <1,500 mIU, it is impossible to differentiate a normal IUP from an ectopic pregnancy. Because β-hCG levels in a normal IUP double every 58 hours, the appropriate management will be to repeat the quantitative β-hCG and vaginal sonogram every 2–3 days until the β-hCG level exceeds 1,500 mIU. With that information an ectopic pregnancy can be distinguished from an IUP.
- **Unruptured ectopic.** Management can be medical with methotrexate or surgical with laparoscopy. Medical treatment is preferable because of the lower cost, with otherwise similar outcomes.
  - **Methotrexate.** This **folate antagonist** attacks rapidly proliferating tissues including trophoblastic villi. Criteria for methotrexate include pregnancy mass <3.5 cm diameter, absence of fetal heart motion, β-hCG level <6,000 mIU, and no history of folic supplementation. Single dose 1 mg/kg is 90% successful. Patients with an ectopic pregnancy should be advised of the somewhat increased incidence of recurrent ectopic pregnancies. Follow-up with **serial β-hCG levels** is crucial to ensure pregnancy resolution. Rh-negative women should be administered **RhoGAM**.
  - **Laparoscopy.** If criteria for methotrexate are not met, surgical evaluation is performed through a laparoscopy or through a laparotomy incision. The preferred procedure for an unruptured ampullary tubal pregnancy is a **salpingostomy**, in which the trophoblastic villi are dissected free preserving the oviduct. Isthmic tubal pregnancies are managed with a **segmental resection**, in which the tubal segment containing the pregnancy is resected.

– **Salpingectomy** is reserved for the patient with a ruptured ectopic pregnancy or those with no desire for further fertility. After a salpingostomy β-hCG titers should be obtained on a weekly basis to make sure that there is resolution of the pregnancy. Rh-negative women should be administered **RhoGAM**.

Follow-Up. Patients who are treated with methotrexate or salpingostomy should be followed up with β-hCG titers to assure there has been complete destruction of the ectopic trophoblastic villi.

Obstetric Procedures 3

Learning Objectives

- ❏ Describe routine and high risk prenatal diagnostic testing
- ❏ Describe the appropriate use of obstetrical monitoring procedures including U/S, chorionic villus sampling, amniocentesis, percutaneous umbilical blood sampling, and fetoscopy

OBSTETRIC ULTRASOUND

This imaging modality uses low-energy, high-frequency sound waves.

MODALITIES

- **Transvaginal sonogram:** used in first trimester, producing high-resolution images that are not influenced by maternal BMI. Dating accuracy of first trimester sonogram is +/- 5–7 days.
- **Transabdominal sonogram:** used any time during the pregnancy, but image quality may be limited by maternal obesity. No adverse fetal effects have been noted during decades of research studies. Dating accuracy of early second trimester sonogram is +/- 7-10 days.
- **Doppler** ultrasound studies: used to assess umbilical artery (UA) and middle cerebral artery (MCA) blood flow. This modality assesses fetal well-being in **IUGR** pregnancies as well as fetal anemia in alloimmunized pregnancies.

Indications for obstetrical ultrasound include:

- Pregnancy location & viability, gestational age dating
- Multiple gestation (zygosity, chorionicity, amnionicity)
- Amniotic fluid volume (oligohydramnios, polyhydramnios)
- Fetal growth (IUGR, macrosomia)
- Fetal anomalies, fetal well-being
- Pregnancy bleeding, fetal anemia

Note

Accuracy of Sonogram Dating

Crown-Rump Length (CRL)

+/- 5 days	<9 weeks
+/- 7 days	9-14 weeks

BPD, HC, AC, FL

+/- 7 days	14-16 weeks
+/- 10 days	16-22 weeks
+/- 14 days	22-28 weeks
+/- 21 days	28+ weeks

Genetic sonogram, ideally performed at 18-20 weeks, looks for anatomic markers of fetal aneuploidy which includes:

- **Generic:** any structural abnormalities
- **Specific:** nuchal skin fold thickness (strongest predictor), short long bones, pyelectasis, echogenic intracardiac focus, hyperechoic bowel.

Nuchal translucency (NT) measurement is a screening test, performed between 10-14 weeks, measuring the fetal fluid collection behind the neck.

- A thickened NT increases the likelihood of aneuploidy and cardiac disease.
- It is combined with two maternal blood tests (free β-hCG & PAPP-A) in first-trimester screening to increase the sensitivity and specificity for aneuploidy screening.

CHORIONIC VILLUS SAMPLING (CVS)

CVS is a diagnostic outpatient office procedure performed under ultrasound guidance without anesthesia. Procedure-related pregnancy loss rate is 0.7%.

- The catheter is placed directly into the placental tissue without entering the amniotic cavity. Chorionic villi, which are placental precursors, are aspirated from a pregnant uterus between 10 and 12 weeks' gestation.
- The tissue is sent to the laboratory for karyotyping. The chromosomes of the villi are almost always identical to those of the embryo.
- The procedure can be performed either **transcervically** or **transabdominally**. Since the fetus and chorionic villi are both derived from a common origin (the zygote), their karyotype is identical more than 99% of the time.

AMNIOCENTESIS

Amniocentesis is a diagnostic, outpatient office procedure performed **after 15 weeks** under ultrasound guidance without anesthesia. Pregnancy loss rate is 0.5%

- A needle is placed into a pocket of amniotic fluid under direct ultrasound guidance, aspirating amniotic fluid containing desquamated living fetal cells (**amniocytes**).
- Fetal karyotyping is performed on amniocytes. NTD (neural tube defect) screening is performed on amniotic fluid with biochemical analysis (**AFP and acetylcholinesterase**).

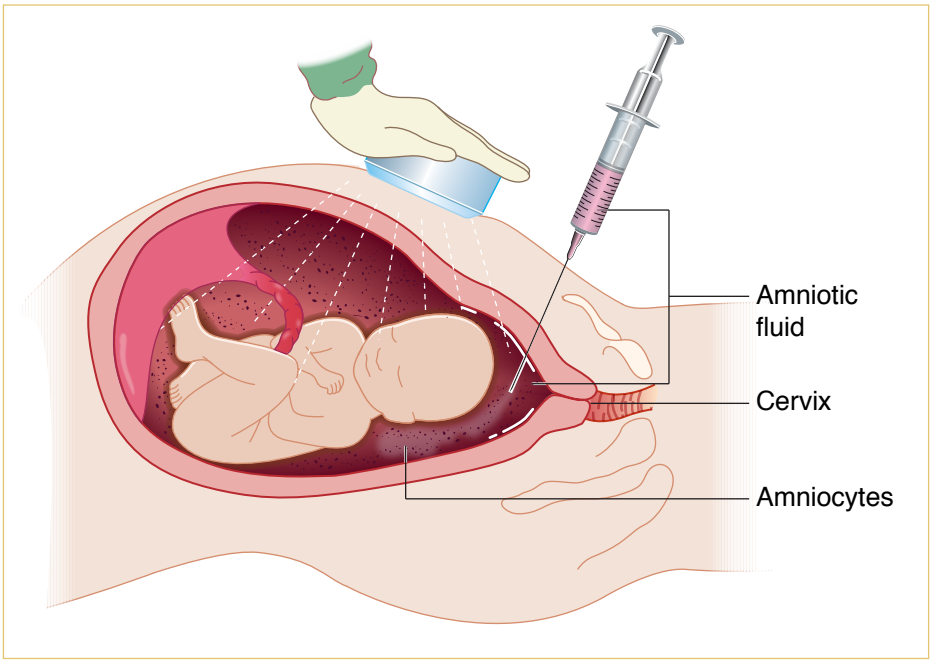

Figure I-3-1. Amniocentesis

PERCUTANEOUS UMBILICAL BLOOD SAMPLE (PUBS)

This transabdominal procedure, performed under ultrasound guidance, aspirates fetal blood from the umbilical vein after 20 weeks' gestation.

- The procedure can be **diagnostic** (e.g., blood gases, karyotype, IgG and IgM antibodies) as well as **therapeutic** (e.g., intrauterine transfusion with fetal anemia).
- Procedure-related pregnancy loss rate is **1–2%**.

FETOSCOPY

A fetoscopy is a **transabdominal** procedure performed with a fiberoptic scope in the operating room **after 20 weeks** under regional or general anesthesia.

- Indications for fetoscopy include **intrauterine surgery** or **fetal skin biopsy**.
- Laser is used for coagulating placental vessels in twin–twin transfusion syndrome (TTTS). Skin biopsy may be performed for suspected fetal ichthyosis.
- **Risks** are bleeding, infection, membrane rupture, fetal loss.
- The pregnancy loss rate is **2–5%.**

PRENATAL DIAGNOSTIC TESTING

Table 3-1. Prenatal Diagnostic Testing

CVS	10-12 wks	0.7% pregnancy loss rate
		Placental precursor
First Trimester	10-14 wks	0% pregnancy loss rate
		Nuchal T, PAPP-A
Amniocentesis	≥15 wks	0.5% pregnancy loss rate
		Amniocytes; amniotic fluid AFP
Expanded X-AFP	15-20 wks	0% pregnancy loss rate
		MS-AFP, β-hCG, estriol, inhibin
Sonogram	18-20 wks	0% pregnancy loss rate
		Non-invasive anatomy scan
Fetoscopy	18-20 wks	3-5% pregnancy loss rate
		Laser in TTTS, fetal biopsy
PUBS	≥20 wks	1-2% pregnancy loss rate
		Umbilical vein blood

Prenatal Management of the Normal Pregnancy

4

Learning Objectives

- ❏ Describe methods for diagnosing pregnancy, establishing gestational age, and identifying risk factors
- ❏ List normal pregnancy events and complaints
- ❏ Differentiate between safe and unsafe immunizations in pregnancy

DIAGNOSIS OF PREGNANCY

Presumptive signs of pregnancy include amenorrhea, breast tenderness, nausea and vomiting, increased skin pigmentation, and skin striae.

Probable signs of pregnancy include **enlargement of the uterus**, maternal sensation of uterine contractions or fetal movement, Hegar sign (softening of the junction between the corpus and cervix), and positive urine or **serum β-human chorionic gonadotropin** (**β-hCG**) testing.

Positive signs of pregnancy include hearing **fetal heart tones, sonographic visualization of a fetus**, perception of fetal movements by an external examiner, and x-ray showing a fetal skeleton.

Table 4-1. Signs of Pregnancy

Presumptive	Unrelated to uterus or fetus	Amenorrhea
Probable	Related to uterus or mother's feelings	↑ uterine size β-hCG
Definitive	Related to the fetus	Sonogram of fetus Heard FHT

ESTABLISHING GESTATIONAL AGE

Conception Dating

Normal pregnancy duration postconception is 266 days or 38 weeks. However, most women can't identify conception date accurately.

Menstrual Dating

Because the last menstrual period (LMP) is more easily identified than conception, pregnancy duration in most cases is determined to be 280 days or 40 weeks from the LMP. We assume a 28-day menstrual cycle in which ovulation occurs on day 14 after the beginning of the LMP. Yet only 10% of women have a 28-day cycle. A normal cycle length can vary from 21 to 35 days.

Naegele's Rule

Assuming 28-day cycles, a due date can be estimated as the LMP minus 3 months + 7 days.

Table 4-2. Pregnancy Dating

Duration of pregnancy using:	Conceptional dating	266 days or 38 weeks
Duration of pregnancy using:	Menstrual dating	280 days or 40 weeks
Assumed cycle length		28 days
Calculate due date	Naegele's rule	LMP–3 months + 7 days

Definition of abbreviations: LMP, last menstrual period.

Basal Body Temperature (BBT)

The rise in BBT is assumed to be caused by the thermogenic effect of progesterone produced by the corpus luteum that formed after ovulation. The accuracy of BBT is ±1 week.

Menstrual History

Menstrual dating assumes ovulation occurred on day 14 after the first day of the LMP. However, normal menstrual cycles can vary from 21 to 35 days, making ovulation possible on day 7 to day 21. Because most women's cycles are more or less than 28 days, adjustment of the due date may be necessary. Accuracy of menstrual dating is variable depending on the patient's memory and record keeping. The accuracy of menstrual history is ±1 week.

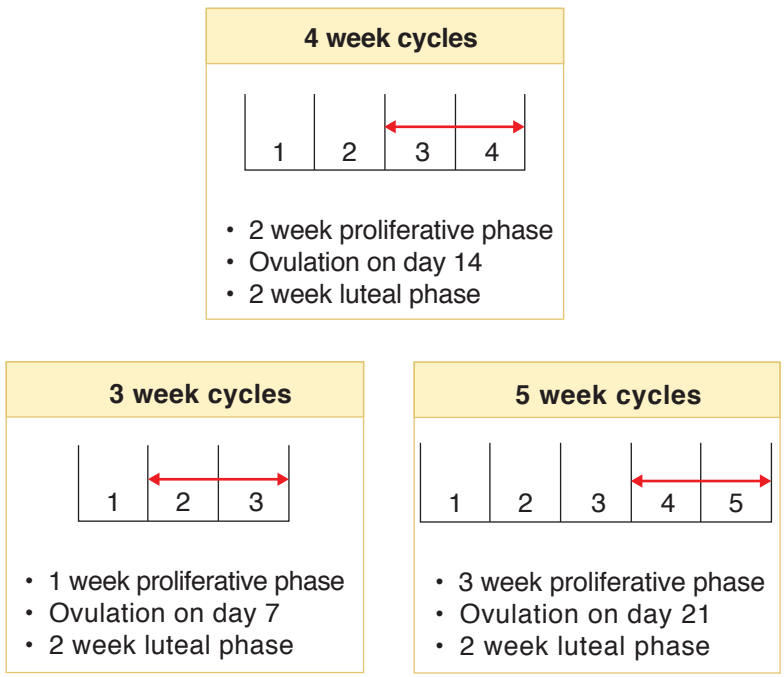

Figure I-4-1. Variations in Menstrual Cycle

OB Triad

Precise Day of Ovulation

- 21-day cycle: day 7
- 28-day cycle: day 14
- 35-day cycle: day 21

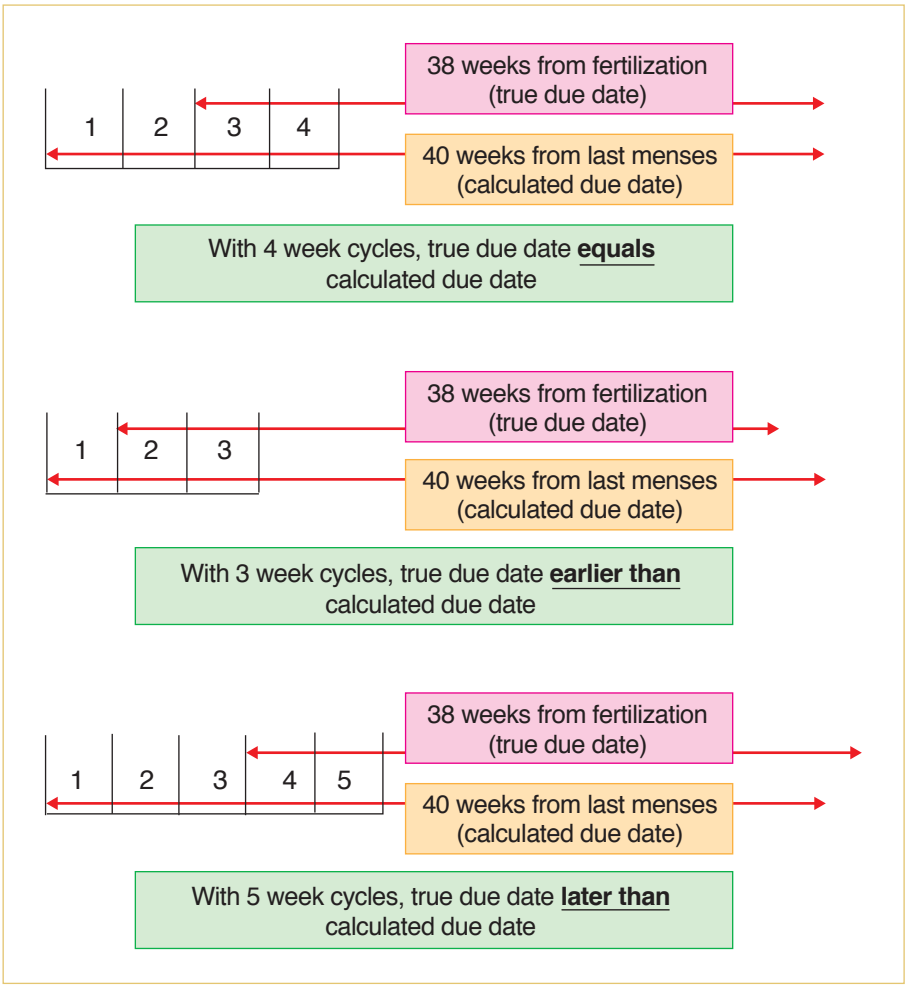

Figure I-4-2. Effect of Cycle Length on Calculated Due Date

IDENTIFICATION OF RISK FACTORS

Obstetrical history—number of pregnancies, pregnancy duration, complications, mode of delivery, perinatal outcome

Medical and surgical history—diabetes mellitus, hypertension, cardiac, thyroid, seizure disorder, anemia

Social history—educational level, marital status, social support, abusive relationships

Family history—inherited diseases, mental retardation, birth defects, perinatal deaths

Sexual history—age of first intercourse, current partners, lifetime sexual partners, previous sexual abuse

Lifestyle—alcohol, tobacco, recreational drugs, poor nutrition, eating disorders

Teratogenic exposure—x-radiation, toxins, chemicals, prescription medications

NORMAL PREGNANCY EVENTS

First Trimester

Assuming a 40 menstrual week pregnancy, the first trimester is assumed to extend from conception through to 13 weeks.

- Normal symptoms seen in the majority of pregnancies include nausea, vomiting, fatigue, breast tenderness, and frequent urination.
- **Spotting and bleeding** occur in 20% of pregnancies, 50% of which will continue successfully.
- Average weight gain is 5–8 pounds.
- Complications—spontaneous abortion.

Second Trimester

Assuming a 40 menstrual week pregnancy, the second trimester is assumed to extend from 13 to 26 weeks.

- Normal symptoms are an improved feeling of general well-being.
- Round ligament pain is common.
- **Braxton-Hicks** contractions are painless, low-intensity, long-duration contractions that can be palpated as early as 14 weeks.
- **Quickening** (maternal awareness of fetal movement) is detected at 18–20 weeks by primigravidas and 16–20 weeks by multigravidas.
- Average weight gain is 1 pound per week after 20 weeks.
- Complications include incompetent cervix (painless cervical dilation leading to delivery of a nonviable fetus); premature membrane rupture, and premature labor.

Third Trimester

Assuming a 40 menstrual week pregnancy, the third trimester is assumed to extend from 26 to 40 weeks.

- Normal symptoms include decreased libido, lower back and leg pain, urinary frequency, and Braxton-Hicks contractions.
- **Lightening** describes descent of the fetal head into the pelvis resulting in easier maternal breathing, pelvic pressure.
- **Bloody show** describes vaginal passage of bloody endocervical mucus, the result of cervical dilation before labor.
- Average weight gain is 1 pound per week after 20 weeks.
- Complications include premature membrane rupture, premature labor, preeclampsia, urinary tract infection, anemia, and gestational diabetes.

NORMAL PREGNANCY COMPLAINTS

- **Backache** is very common, especially in the latter part of pregnancy because of the change in center of gravity with the enlarging uterus. Muscles and ligaments are now used that otherwise would not be. **Management** is encouragement of correct posture.

- **Bleeding gums** is caused by the increase of blood flow to the gums with pregnancy. If it is associated with clinical swelling, it is known as epulis. **Management** is conservative.
- **Breast enlargement.** Each breast increases in size by 400 grams and may result in an increase of one to two cup sizes. **Management** is a support bra.
- **Carpal tunnel.** As many as 50% of pregnant women will experience numbness, tingling, burning, or pain in at least two of the three digits supplied by the median nerve. **Management** is fitting with a wrist splint (most cases will spontaneously resolve after delivery).
- **Complexion changes**. Some women develop brownish or yellowish patches called chloasma, or the "mask of pregnancy," on their faces. Others may develop a linea nigra on the lower abdominal midline, as well as hyperpigmentation of the nipples and external genitalia. **Management** is conservative.
- **Dizziness.** BP normally decreases in pregnancy, which may lead to postural hypotension. **Management** is avoiding rapid postural changes, such as standing up quickly.
- **Fatigue** is very common in pregnancy, probably because of rapid hormonal changes. **Management** is adequate resting and the avoidance of excessive activity.
- **Fluid retention.** Increased circulating steroid levels and decreased serum albumin results in edema in over half of pregnant women. Edema is not a criterion for preeclampsia. **Management** is elevating legs and using support hose.
- **Hair and nails.** Hair shedding decreases in pregnancy. **Telogen effluvium** is the excessive shedding of hair occurring 1–5 months after pregnancy. Telogen effluvium occurs in 40–50% of women. Nails may become more brittle. **Management** is conservative.
- **Headaches.** Muscle contraction and migraine headaches are more common in pregnancy probably because of increased estrogen levels. **Management** is physical therapy (e.g., ice packs, massage) with medication only as a last resort.
- **Leg cramps.** Lower extremity muscle cramps are frequent in pregnancy. **Management** is hydration, stretching exercises, and calcium supplementation.
- **Morning sickness.** Nausea and vomiting are common in early pregnancy and are probably mediated by elevated hCG levels. **Management** is eating small meals emphasizing crackers and carbohydrates.
- **Nosebleeds.** Vasodilation and increased vascular supply results in more frequent nosebleeds. **Management** is saline drops and the avoidance of nasal sprays.
- **Stretch marks.** Genetic predisposition and pregnancy can result in striae gravidarum. Women with stretch marks have increased risk of delivery lacerations. **Management** is conservative.
- **Stress incontinence.** Pressure on the bladder with an enlarging uterus frequently results in an involuntary loss of urine. **Management** is strengthening the pelvic diaphragm with Kegel exercises.
- **Varicose veins.** Increased blood volume, the relaxing effect of progesterone on smooth muscle, and an increased lower-extremity venous pressure often result in lower-extremity varicosities. **Management** is discouraging prolonged standing and sitting.

Table 4-3. Pregnancy Danger Signs

Complaint	Possible Diagnosis
Vaginal bleeding	Early (spontaneous abortion) Later (abruption, previa)
Vaginal fluid leakage	Rupture of membrane (ROM) Urinary incontinence
Epigastric pain	Severe preeclampsia
Uterine cramping	Preterm labor Preterm contractions
↓ fetal movement	Fetal compromise
Persistent vomiting	Hyperemesis (early) Hepatitis Pyelonephritis
Headache, visual changes	Severe preeclampsia
Pain with urination	Cystitis Pyelonephritis
Chills and fever	Pyelonephritis Chorioamnionitis

SAFE AND UNSAFE IMMUNIZATIONS

Safe

Safe immunizations include antigens from killed or inactivated organisms:

- Influenza (all pregnant women in flu season)
- Hepatitis B (pre- and postexposure)
- Hepatitis A (pre- and postexposure)
- Pneumococcus (only high-risk women)
- Meningococcus (in unusual outbreaks)
- Typhoid (not routinely recommended)

Unsafe

Unsafe immunizations include antigens from live attenuated organisms:

- Measles
- Mumps
- Polio
- Rubella
- Yellow fever
- Varicella

Prenatal Laboratory Testing 5

Learning Objectives

- ❏ Use knowledge of first trimester laboratory tests
- ❏ Use knowledge of second trimester laboratory tests
- ❏ Explain information related to third-trimester laboratory tests

FIRST TRIMESTER LABORATORY TESTS

A 21-year-old primigravida G1 PO presents for her first prenatal visit at 11 weeks' gestation, which is confirmed by obstetric sonogram. She has no risk factors. What laboratory tests should be ordered on her?

Complete Blood Count

Hemoglobin and hematocrit

Normal pregnancy hemoglobin reference range is 10–12 g/dL. Although nonpregnant female hemoglobin reference range is 12–14 g/dL, normal values in pregnancy will reflect the dilutional effect of greater plasma volume increase than red blood cell (RBC) mass.

Mean corpuscular volume (MCV)

Because hemoglobin and hematocrit reflect pregnancy dilution, MCV may be the most reliable predictor of true anemia. A low hemoglobin and low MCV (<80 μm^3) most commonly suggests iron deficiency, but may also be caused by thalassemia. A low hemoglobin and high MCV (>100) suggests folate deficiency or, rarely, vitamin B12 deficiency.

Platelet count

A low platelet count (<150,000/mm^3) is most likely indicative of gestational (pregnancy-induced) thrombocytopenia. Preeclampsia with severe features and idiopathic thrombocytopenic purpura (ITP) are uncommon causes of low platelets. Disseminated intravascular coagulation is rare.

Leukocyte count

White blood cell count in pregnancy is normally up to 16,000/mm^3. Leukopenia suggests immune suppression or leukemia.

Rubella IgG Antibody

Immunity

The presence of rubella antibodies rules out a primary infection during the pregnancy. Antibodies derived from a natural, wild infection lead to lifelong immunity. Antibodies from a live-attenuated virus are not as durable.

Susceptibility

An absence of antibodies leaves the woman at risk for a primary rubella infection in pregnancy that can have devastating fetal effects, particularly in the first trimester. Rubella immunization is contraindicated in pregnancy because it is made from a live virus but is recommended after delivery.

Hepatitis B Virus (HBV)

Surface antibody

HBV surface antibodies are expected from a successful vaccination.

Surface antigen

The presence of HBV surface antigen represents either a previous or current infection. HBV surface antigen indicates **high risk for vertical transmission** of HBV from the mother to the fetus or neonate. This is the only specific hepatitis test obtained routinely on the prenatal laboratory panel.

E antigen

The presence of HBV E antigen signifies a highly infectious state.

Type, Rh, and Antibody Screening

Direct Coombs test

The patient's blood type and Rh is determined with the **direct Coombs test**. If the patient is Rh negative, she is at risk for anti-D isoimmunization.

Indirect Coombs test or atypical antibody test (AAT)

The presence of atypical RBC antibodies is determined with the indirect Coombs test. Isoimmunization is identified if atypical antibodies are present. Follow-up testing is necessary to identify whether the fetus is at risk.

STD Screening

Cervical cultures

Screening cultures for **chlamydia** and **gonorrhea** will identify whether the fetus is at risk from delivery through an infected birth canal.

Syphilis

Nonspecific screening tests (**veneral disease research laboratory** [VDRL] or **rapid plasma reagin** [RPR]) are performed on all pregnant women. Positive screening tests must be followed up with treponema-specific tests (microhemagglutination assay for antibodies to *T. pallidum* [**MHA-TP**] or **fluorescent treponema antibody absorption** [FTA]). **Treatment** of syphilis in pregnancy requires penicillin to ensure adequate fetal treatment.

Hepatitis B

Maternal hepatitis-B surface antigen (HBsAg) screening assesses if the mother could have active hepatitis, as well as if she could transmit HBV to her newborn at the time of delivery.

Table 5-1. Initial Prenatal Labs STDs

Chlamydia/Gonorrhea (GC)	Screening	DNA probes
Hepatitis B virus	Screening	HBsAg
Syphilis	Screening	VDRL/RPR
	Definitive	MHA/FTA
HIV	Screening	ELISA
	Definitive	Western Blot

Definition of abbreviations: FTA, fluorescent treponema antibody absorption; HBsAg, hepatitis B surface antigen; ELISA, enzyme-linked, immunosorbant assay; MHA, microhemagglutination assay; RPR, rapid plasma reagin.

Urine Screening

Urinalysis

Assessment of proteinuria, ketones, glucose, leukocytes, and bacteria is important to screen for **underlying renal disease**, diabetes, and infection.

Culture

Screening for **asymptomatic bacteriuria** (ASB) is essential. Eight percent of pregnant women have ASB. Left untreated, 30% of ASB progresses to pyelonephritis, which is associated with septic shock, pulmonary edema, and adult respiratory distress syndrome.

Tuberculosis (TB) Screening

PPD or Tine test

This screening skin test determines **previous exposure to TB**. A positive test is induration, not erythema. If the screening test is negative, no further follow-up is necessary. TB screening is not done routinely and performed only on high-risk populations.

Chest x-ray

A chest x-ray is performed to rule out active disease only if the screening skin test is positive. If the chest x-ray is negative, isoniazid (INH) (and vitamin B_6) is given for 9 months. If the chest x-ray is positive, induced sputum is cultured and triple medications begun until cultures define the organisms involved. Antituberculosis drugs are not contraindicated in pregnancy.

HIV Screening

Screening

HIV screening is recommended for all pregnant women as part of the initial lab testing. The CDC recommends **Informed Refusal** (or "**Opt Out**," where a patient is tested unless she refuses), rather than **Informed Consent** (or "**Opt In,**" where a patient must specifically consent). Retesting should take place in the third trimester in areas of high HIV prevalence or an at-risk patient. Rapid HIV testing in labor is recommended if the patient's HIV status is not known.

ELISA test

This **screening test** assesses presence of detectable HIV antibodies. A 3-month lag exists between HIV infection and a positive ELISA test. All babies born to HIV-positive women will be HIV antibody positive from passive maternal antibodies.

Western blot test

This **definitive test** identifies the presence of HIV core and envelope antigens. Triple antiviral therapy is recommended for all HIV-positive women starting at 14 weeks and continuing through delivery. With cesarean delivery and triple antiviral therapy, transmission rates are as low as 1%.

Cervical Pap Smear

Cervical cytologic screening can identify if the mother has cervical dysplasia or malignancy.

SECOND TRIMESTER LABORATORY TESTS

A 23-year-old woman (G3 P1 Ab1) is seen at 16 weeks' gestation. Her previous pregnancy resulted in an anencephalic fetus that did not survive. She took 4 mg of folate preconception before this pregnancy but wants to know whether this fetus is affected.

Maternal Serum α-Fetoprotein (MS-AFP)

AFP

This is the **major serum glycoprotein** of the embryo. The concentration peaks at 12 weeks in the fetus and amniotic fluid (AF), then rises until 30 weeks in the maternal serum. Fetal structural defects (open neural tube defect [NTD] and ventral wall defects) result in increased spillage into the amniotic fluid and maternal serum. Other causes include twin pregnancy, placental bleeding, fetal renal disease, and sacrococcygeal teratoma.

Table 5-2. Alpha-Fetoprotein

Major Serum Glycoprotein of the Embryo		
Normal AFP changes	Fetal serum	Peaks at **12** weeks
	Amniotic fluid	Peaks at **12** weeks
	Maternal serum	Peaks at **30** weeks

MS-AFP

MS-AFP is reported in multiples of the median (MoM) and is always performed as part of multiple marker screenings. Maternal serum testing is performed within a gestational window of **15–20 weeks**. Because reference ranges are specific to gestational age, accurate pregnancy dating is imperative.

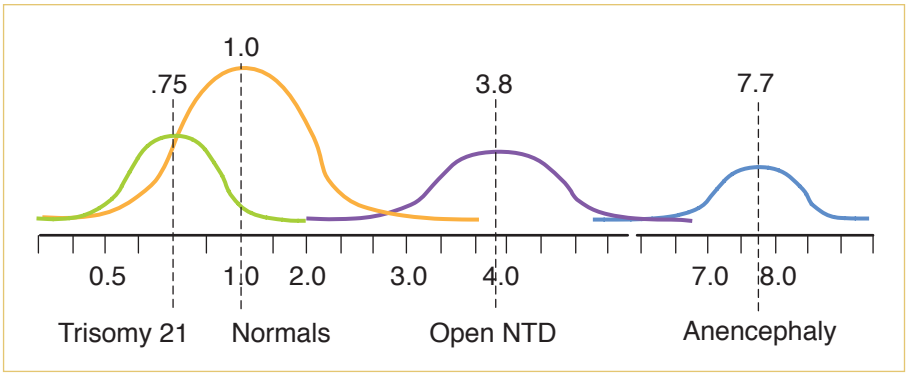

Figure I-5-1. Midpoints of MSAFP

Elevated MS-AFP

A positive high value is >2.5 MoM. The next step in management is to obtain an obstetric ultrasound to confirm gestational dating. The most common cause of an elevated MS-AFP is **dating error**.

- If the true gestational age is more advanced than the assumed gestational age, it would explain the positive high value. In cases of dating error, repeat the MS-AFP if the pregnancy is still within the 15- to 20-week window. A normal MS-AFP will be reassuring.

- If the dates are correct and no explanation is seen on sonogram, perform amniocentesis for AF-AFP determination and acetylcholinesterase activity. Elevated levels of **AF acetylcholinesterase** activity are specific to open NTD.
- With unexplained elevated MS-AFP but normal AF-AFP, the pregnancy is statistically at risk for intrauterine growth restriction (IUGR), stillbirth, and preeclampsia.

Low MS-AFP

A positive low value is **<0.85 MoM**. The sensitivity of MS-AFP alone for trisomy 21 is only 20%. The next step in management is to obtain an obstetric ultrasound to confirm gestational dating. The most common cause of a low MS-AFP is **dating error**.

- If the true gestational age is less than the assumed gestational age, it would explain the positive low value. In cases of dating error, repeat the MS-AFP if the pregnancy is still within the window. A normal MS-AFP will be reassuring.
- If the dates are correct and no explanation is seen on sonogram, perform amniocentesis for **karyotype**.

This is an elective prenatal test, not a routine one.

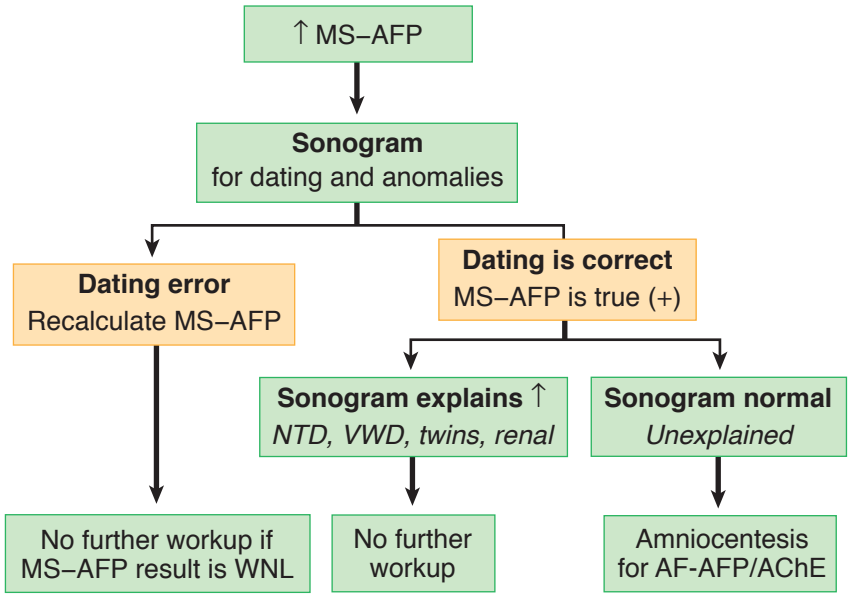

Figure I-5-2. Midtrimester Labs

Quadruple Marker Screen

Trisomy screening

The sensitivity for trisomy 21 detection can be increased to 80% by performing maternal serum screen for not only **MS-AFP**, but also **hCG**, **estriol**, and **inhibin-A**. The window for testing is also **15–20 weeks**. Because reference values are gestational age specific, accurate dating is important.

Trisomy 21

With Down syndrome, levels for MS-AFP and estriol are decreased, but **hCG and inhibin-A are, increased**. Perform an amniocentesis for **karyotype**.

Trisomy 18

With Edward syndrome, levels for **all 4 markers** (MS-AFP, estriol, inhibin-A, and hCG) **are decreased**. Perform an amniocentesis for **karyotype**.

THIRD-TRIMESTER LABORATORY TESTS

A 33-year-old woman (G4 P3) is at 25 weeks' gestation. Her height is 63 inches and weight 250 pounds. She has gained 30 pounds thus far this pregnancy. With her last pregnancy she gained 60 pounds, was diagnosed with gestational diabetes, and delivered a 4,300-g female neonate by cesarean section. She wants to know whether she has diabetes with this pregnancy.

Diabetic Testing

1-h 50-g oral glucose tolerance test (OGTT)

This **screening** test is administered to all pregnant women between 24 and 28 weeks' gestation. No fasting state is needed. A 50-g glucose load is given, and serum glucose is measured 1 h later. A **normal value** is <140 mg/dL. Fifteen percent of pregnant women will have an abnormal screening test, which is ≥140 mg/dL. **Management** is a 3-h 100-g OGTT.

3-h 100-g OGTT

This is the **definitive** test for glucose intolerance in pregnancy. Fifteen percent of women with an abnormal screening test will be found to have gestational diabetes mellitus. After an overnight fast, a fasting blood sugar (FBS) is drawn. An FBS >125 mg/dL indicates overt diabetes mellitus, and no further testing is performed. If the FBS is <126 mg/dL, administer a 100-g glucose load, followed by glucose levels at 1, 2, and 3 h. Normal values are FBS <95 mg/dL, 1 h <180 mg/dL, 2 h <155 mg/dL, and 3 h <140 mg/dL. Gestational diabetes is diagnosed if ≥2 values are abnormal. Impaired glucose intolerance is diagnosed if only 1 value is abnormal.

Complete Blood Count

Anemia

A complete blood count (CBC) should be performed between 24 and 28 weeks' gestation in all women. With the increasing diversion of iron to the fetus in the second and third trimester, iron deficiency, which was not present early in pregnancy, may develop. This is particularly so in the woman who is not taking iron supplementation. A hemoglobin <10 g/dL is considered anemia. The most common cause is **iron deficiency**, which occurs only after bone marrow iron stores are completely depleted.

Platelet count

Reassessment of pregnancy-induced thrombocytopenia can be also be done with the CBC.

Atypical Antibody Screen

Before giving prophylactic RhoGAM to an Rh-negative woman, an indirect Coombs test is performed at 28 weeks. This is obtained to ensure she has not become isoimmunized since her previous negative AAT earlier in pregnancy. Two-tenths of a percent of Rh-negative women will become isoimmunized from spontaneous feto-maternal bleeding before 28 weeks. If it is discovered that the patient already has anti-D antibodies, administration of RhoGAM is futile.

Late Pregnancy Bleeding 6

Learning Objectives

- ❏ Differentiate between placenta disorders and late pregnancy bleeding, including abruptio placenta, placenta previa, vasa previa, placenta accreta, placenta increta, and placenta precreta
- ❏ Describe the risk factors for and prognosis of uterine rupture

DIFFERENTIAL DIAGNOSIS OF LATE PREGNANCY BLEEDING

Definition. Vaginal bleeding occurring after 20 weeks' gestation. Prevalence is <5%, but when it does occur, prematurity and perinatal mortality quadruple.

Etiology

- **Cervical** causes include erosion, polyps, and, rarely, carcinoma.
- **Vaginal** causes include varicosities and lacerations.
- **Placental** causes include abruptio placenta, placenta previa, and vasa previa.

Initial Evaluation. What are patient's vital signs? Are fetal heart tones present? What is fetal status? What is the nature and duration of the bleeding? Is there pain or contractions? What is the location of placental implantation?

Initial Investigation. Complete blood count, disseminated intravascular coagulation (DIC) workup (platelets, prothrombin time, partial thromboplastin time, fibrinogen, **D-dimer**), type and cross-match, and sonogram for placental location. **Never perform a digital or speculum examination until ultrasound study rules out placenta previa.**

Initial Management. Start an IV line with a large-bore needle; if maternal vital signs are unstable, run isotonic fluids without dextrose wide open and place a urinary catheter to monitor urine output. If fetal jeopardy is present or gestational age is ±36 weeks, the goal is delivery.

OB Triad

Abruptio Placenta

- Late trimester **painful** bleeding
- Normal placental implantation
- Disseminated intravascular coagulopathy (DIC)

ABRUPTIO PLACENTA

A 32-year-old multigravida at 31 weeks' gestation is admitted to the birthing unit after a motor-vehicle accident. She complains of sudden onset of moderate vaginal bleeding for the past hour. She has intense, constant uterine pain and frequent contractions. Fetal heart tones are regular at 145 beats/min. On inspection her perineum is grossly bloody.

Etiology/Pathophysiology

- A normally implanted placenta (not in the lower uterine segment) separates from the uterine wall before delivery of the fetus. Separation can be partial or complete.
- Most commonly bleeding is **overt and external**. In this situation blood dissects between placental membranes exiting out the vagina.
- Less commonly, if bleeding remains **concealed or internal**, the retroplacental hematoma remains within the uterus, resulting in an increase in fundal height over time.

Diagnosis. This is based on the presence of painful late-trimester vaginal bleeding with a normal fundal or lateral uterine wall **placental implantation** not over the lower uterine segment.

Clinical Presentation. Abruptio placenta is the most common cause of late-trimester bleeding, occurring in 1% of pregnancies at term. It is the most common cause of painful late-trimester bleeding.

Classification

- With **mild abruption**, vaginal bleeding is minimal with no fetal monitor abnormality. Localized uterine pain and tenderness is noted, with incomplete relaxation between contractions.
- With **moderate abruption**, symptoms of uterine pain and moderate vaginal bleeding can be gradual or abrupt in onset. From 25 to 50% of placental surface is separated. Fetal monitoring may show tachycardia, decreased variability, or mild late decelerations.
- With **severe abruption**, symptoms are usually abrupt with a continuous knifelike uterine pain. Greater than 50% of placental separation occurs. Fetal monitor shows severe late decelerations, bradycardia, or even fetal death. Severe disseminated intravascular coagulation (DIC) may occur.
- Ultrasound visualization of a retroplacental hematoma may be seen.

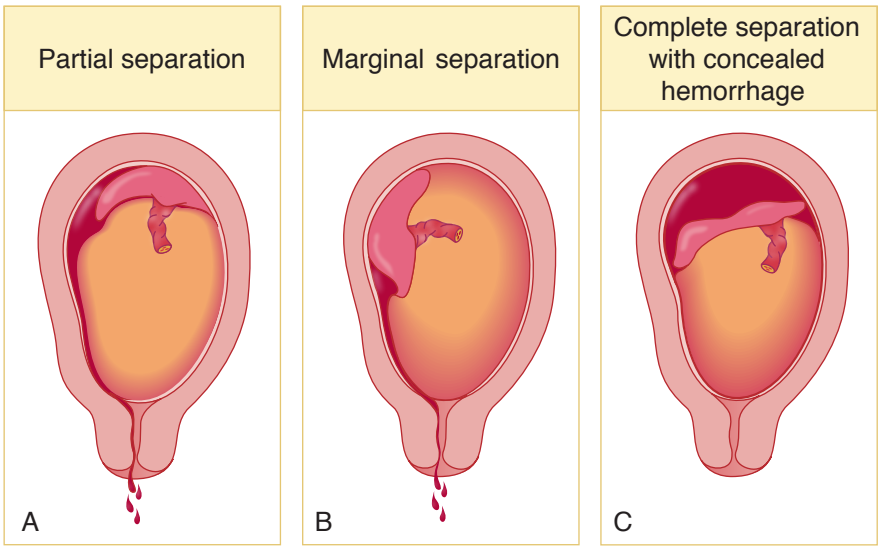

Figure I-6-1. Abruptio Placenta

Risk Factors. Abruptio placenta is seen more commonly with **previous abruption**, **hypertension**, and **maternal blunt trauma**. Other risk factors are smoking, maternal cocaine abuse and premature membrane rupture.

Management. Management is variable:

- **Emergency cesarean delivery**—This is performed if maternal or fetal jeopardy is present as soon as the mother is stabilized.
- **Vaginal delivery**—This is performed if bleeding is heavy but controlled or pregnancy is >36 weeks. Perform amniotomy and induce labor. Place external monitors to assess fetal heart rate pattern and contractions. Avoid cesarean delivery if the fetus is dead.
- **Conservative in-hospital observation**—This is performed if mother and fetus are stable and remote from term, bleeding is minimal or decreasing, and contractions are subsiding. Confirm normal placental implantation with sonogram and replace blood loss with crystalloid and blood products as needed.

Complications. Severe abruption can result in hemorrhagic shock with **acute tubular necrosis** from profound hypotension, and **DIC** from release of tissue thromboplastin into the general circulation from the disrupted placenta. **Couvelaire uterus** refers to blood extravasating between the myometrial fibers, appearing like bruises on the serosal surface.

PLACENTA PREVIA

A 34-year-old multigravida at 31 weeks' gestation comes to the birthing unit stating she woke up in the middle of the night in a pool of blood. She denies pain or uterine contractions. Examination of the uterus shows the fetus to be in transverse lie. Fetal heart tones are regular at 145 beats/min. On inspection her perineum is grossly bloody.

OB Triad

Placenta Previa

- Late trimester bleeding
- Lower segment placental implantation
- No pain

Etiology/Pathophysiology

- Placenta previa is present when the placenta is implanted in the **lower uterine segment**. This is common early in the pregnancy, but is most often not associated with bleeding.
- Usually the lower implanted placenta atrophies and the upper placenta hypertrophies, resulting in **migration of the placenta**. At term placenta previa is found in only 0.5% of pregnancies.
- Symptomatic placenta previa occurs when painless vaginal bleeding develops through avulsion of the anchoring villi of an **abnormally implanted** placenta as lower uterine segment stretching occurs in the latter part of pregnancy.

Diagnosis. This is based on the presence of **painless** late-trimester vaginal bleeding with an obstetric ultrasound showing placental implantation over the **lower uterine segment**.

Classification

- **Total, complete, or central previa** is found when the placenta completely covers the internal cervical os. This is the most dangerous location because of its potential for hemorrhage.
- **Partial previa** exists when the placenta partially covers the internal os.
- **Marginal or low-lying previa** exists when the placental edge is near but not over the internal os.

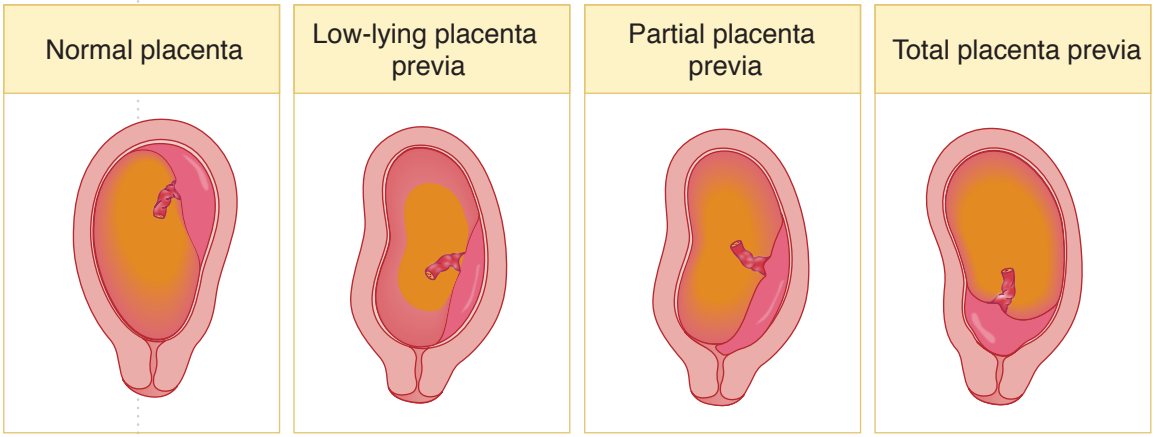

Figure I-6-2. Placenta Previa

Clinical Presentation. The classic picture is **painless** late-pregnancy bleeding, which can occur during rest or activity, suddenly and without warning. It may be preceded by trauma, coitus, or pelvic examination. The uterus is nontender and nonirritable.

Risk Factors. Placenta previa is seen more commonly with **previous placenta previa** and **multiple gestation**. Other risk factors are multiparity and advanced maternal age.

Management. Management is variable:

- **Emergency cesarean delivery**—This is performed if maternal or fetal jeopardy is present after stabilization of the mother.
- **Conservative in-hospital observation**—Conservative management of bed rest is performed in preterm gestations if mother and fetus are stable and remote from term. The initial bleed is rarely severe. Confirm abnormal placental implantation with sonogram and replace blood loss with crystalloid and blood products as needed.
- **Vaginal delivery**—This may be attempted if the lower placental edge is >2 cm from the internal cervical os.
- **Scheduled cesarean delivery**—This is performed if the mother has been stable after fetal lung maturity has been confirmed by amniocentesis, usually at 36 weeks' gestation.

Complications. If placenta previa occurs over a previous uterine scar, the villi may invade into the deeper layers of the decidua basalis and myometrium. This can result in intractable bleeding requiring **cesarean hysterectomy**. Profound hypotension can cause anterior pituitary necrosis (**Sheehan syndrome**) or **acute tubular necrosis**.

PLACENTA ACCRETA/INCRETA/PERCRETA

- Placental villi normally invade only the superficial layers of the endometrial decidua basalis. When the villi invade too deeply into the wall of the uterus, the condition is known as placenta accreta, placenta increta, or placenta percreta, depending the depth of the invasion. Approximately 1 in 2,500 pregnancies experience placenta accreta, increta, or percreta.
- **Placenta accreta** occurs when the villi invade the deeper layers of the endometrial deciduus basalis but do not penetrate the myometrium. Placenta accreta is the most common, accounting for approximately 80% of all cases.
- **Placenta increta** occurs when the villi invade the myometrium but do not reach the uterine serosal surface or the bladder. It accounts for approximately 15% of all cases.
- **Placenta percreta** occurs when the villi invade all the way to the uterine serosa or into the bladder. Placenta percreta is the least common of the 3 conditions, accounting for approximately 5% of all cases.

OB Triad

Abnormal Placental Invasion

- **Accreta:** deeper layers decidua basalis
- **Increta:** myometrium not complete
- **Percreta:** uterine serosa or bladder

VASA PREVIA

A 21-year-old primigravida at 38 weeks' gestation is admitted to the birthing unit at 6-cm dilation with contractions occurring every 3 min. Amniotomy (artificial rupture of membranes) is performed, resulting in sudden onset of bright red vaginal bleeding. The electronic fetal monitor tracing, which had showed a baseline fetal heart rate (FHR) of 135 beats/min with accelerations, now shows a bradycardia at 70 beats/min. The mother's vital signs are stable with normal blood pressure and pulse.

OB Triad

Vasa Previa

- Amniotomy–AROM
- Painless vaginal bleeding
- Fetal bradycardia

Etiology/Pathophysiology. Vasa previa is present when fetal vessels traverse the fetal membranes over the internal cervical os. These vessels may be from either a velamentous insertion of the umbilical cord or may be joining an accessory (succenturiate) placental lobe to the main disk of the placenta. If these fetal vessels rupture the bleeding is from the fetoplacental circulation, and fetal exsanguination will rapidly occur, leading to fetal death.

Diagnosis. This is rarely confirmed before delivery but may be suspected when antenatal sonogram with color-flow Doppler reveals a vessel crossing the membranes over the internal cervical os. The diagnosis is usually confirmed after delivery on examination of the placenta and fetal membranes.

Clinical Presentation. The **classic triad** is rupture of membranes and **painless** vaginal bleeding, followed by fetal bradycardia.

Risk Factors. Vasa previa is seen more commonly with **velamentous insertion** of the umbilical cord, **accessory placental lobes**, and multiple gestation.

Management. Immediate cesarean delivery of the fetus is essential or the fetus will die from hypovolemia.

UTERINE RUPTURE

A 27-year-old G2 P1 woman comes to the maternity unit for evaluation for regular uterine contractions at 34 weeks' gestation. Her previous delivery was an emergency cesarean section at 32 weeks because of hemorrhage from placenta previa. A classical uterine incision was used because of lower uterine segment varicosities. Pelvic exam shows the cervix to be closed and long. As she is being evaluated, she experiences sudden abdominal pain, profuse vaginal bleeding, and fetal bradycardia. Uterine contractions cannot be detected. The fetal head, which was at –1 station, now is floating.

OB Triad

Uterine Rupture

- Late trimester painful bleeding
- Previous uterine incision
- High perinatal mortality

Definition. Uterine rupture is **complete separation** of the wall of the pregnant uterus with or without expulsion of the fetus that endangers the life of the mother or the fetus, or both. The rupture may be **incomplete** (not including the peritoneum) or **complete** (including the visceral peritoneum).

Clinical Presentation. The most common findings are vaginal bleeding, loss of electronic fetal heart rate signal, abdominal pain, and loss of station of fetal head. Rupture may occur both before labor as well as during labor.

Diagnosis. Confirmation of the diagnosis is made by **surgical exploration** of the uterus and identifying the tear.

Risk Factors. The most common risk factors are previous **classic uterine incision, myomectomy**, and excessive oxytocin stimulation. Other risk factors are grand multiparity and marked uterine distention.

Significance. A vertical fundal uterine scar is 20 times more likely to rupture than a low segment incision. Maternal and perinatal mortality is also much higher with the vertical incision rupture.

Management. Treatment is surgical. **Immediate delivery** of the fetus is imperative. Uterine repair is indicated in a stable young woman to conserve fertility. Hysterectomy is performed in the unstable patient or one who does not desire further childbearing.

Perinatal Infections 7

Learning Objectives

- ❑ Describe the route of transmission and common complications of perinatal infections including group B beta-hemolytic streptococci, toxoplasmosis, varicella zoster, rubella, cytomegalovirus, HSV, HIV, syphilis, and hepatitis B

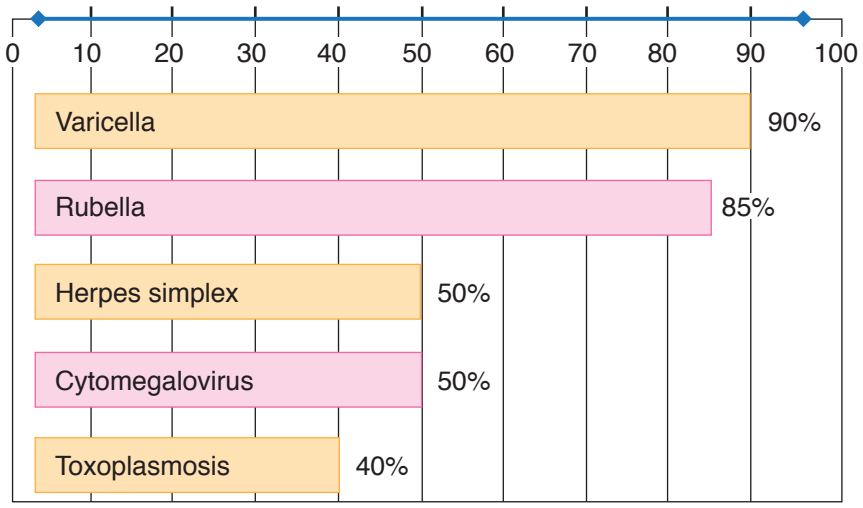

Figure I-7-1. Prevalence of IgG Seropositivity in Pregnant Women

GROUP B β-HEMOLYTIC STREPTOCOCCI (GBS)

A 20-year-old woman G2 P1 is admitted to the birthing unit at 35 weeks' gestation in active labor at 6-cm dilation. Her prenatal course was unremarkable with the exception of a positive first-trimester urine culture for GBS. Her first baby was hospitalized for 10 days after delivery for GBS pneumonia.

OB Triad

GBS Neonatal Sepsis

- Newborn sepsis
- Within hours of birth
- Bilateral diffuse pneumonia

Pathophysiology. GBS is a bacterium commonly found in normal GI tract flora. Thirty percent of women have asymptomatic **vaginal colonization** with GBS, with the majority having intermittent or transient carrier status. Most neonates delivered to colonized mothers will be culture positive.

Significance. One in 500 neonates will develop serious clinical infections or sepsis.

- **Early onset** infection is the most common finding, occurring within a few hours to days of birth, and is characterized by fulminant **pneumonia and sepsis**. This is usually vertical transmission from mother to neonate with a 30% mortality rate at or before 33 weeks but less than 5% at term.
- **Late-onset** infection is less common, occurring after the first week of life, and is characterized by meningitis. This is usually hospital acquired, with a 5% mortality rate.

Prevention. The purpose is to decrease early-onset infection only. Intrapartum antibiotic prophylaxis of neonatal GBS sepsis is given with IV penicillin G. If the patient is penicillin allergic, use clindamycin or vancomycin. Candidates for antibiotic prophylaxis are selected as follows:

- **No screening**—All women with a positive GBS urine culture or a previous baby with GBS sepsis will receive intrapartum prophylaxis. Prophylaxis of other women is based on either of the following two protocols, each of which will prevent 70% of neonatal sepsis.
- **Screening by vaginal culture**—Third-trimester vaginal and rectal cultures are obtained at 35–37 weeks gestational age, and intrapartum prophylaxis is administered only to those with positive GBS cultures. Antepartum treatment is not given.
- **Screening by intrapartum risk factors**—No vaginal cultures are obtained. Intrapartum prophylaxis is given on the basis of risk factors being present: preterm gestation (<37 weeks), membranes ruptured >18 h, or maternal fever (≥100.4°F) (38°C).

TOXOPLASMOSIS

A 26-year-old primigravida was admitted to the birthing unit at 39 weeks' gestation in active labor at 6-cm dilation. During her second trimester she experienced a mononucleosis-like syndrome. Uterine fundal growth lagged behind that expected on the basis of a first-trimester sonogram. Serial sonograms showed symmetrical intrauterine growth retardation (IUGR). She delivered a 2,250-g male neonate who was diagnosed with microcephaly, intracranial calcifications, and chorioretinitis.

OB Triad

Congenital *Toxoplasma*

- Chorioretinitis
- Intracranial calcifications
- Symmetrical IUGR

Note

Remember to distinguish between *intracranial* calcifications with *Toxoplasma* and *periventricular* calcifications with CMV.

Pathophysiology. Toxoplasmosis is caused by a **parasite** (*Toxoplasma gondii*) transmitted most commonly in the United States from exposure to infected **cat feces**. Infections can also occur from drinking raw goat milk or eating raw or undercooked infected meat.

- **Vertical transmission** from mother to fetus or neonate can only occur during the parasitemia of a primary infection because the result is residual lifelong immunity.
- Up to 40% of pregnant women are toxoplasmosis IgG seropositive.
- First-trimester infection risk is **low** (15%), but infections are **most serious**, even lethal.
- Third-trimester infection risk is **high** (50%), but infections are **mostly asymptomatic**.

Significance

- **Fetal infection**—Manifestations may include symmetric IUGR, nonimmune fetal hydrops, microcephaly, and **intracranial calcifications**.
- **Neonatal findings**—Manifestations may include **chorioretinitis**, seizures, hepatosplenomegaly, and thrombocytopenia.

Prevention. Avoid infected cat feces, raw goat milk, and undercooked meat.

Treatment. Pyrimethamine and sulfadiazine are used to treat a known infection. Spiramycin is used to prevent vertical transmission from the mother to the fetus.

VARICELLA (VZV)

A 29-year-old woman (G2 P1) is at 34 weeks' gestation. She complains of uterine contractions every 5 min. During the last few days she has developed diffuse pruritic vesicles on her neck that appear to be also developing on her chest and breasts. She has a fever and complains of malaise.

OB Triad

Congenital Varicella

- "Zig-zag" skin lesions
- Microphthalmia
- Extremity hypoplasia

Pathophysiology. Varicella zoster is a DNA virus that is the causative agent of chicken pox and herpes zoster. It is spread by **respiratory droplets**, but is less contagious than rubeola or rubella. More than 90% of women are immune by adulthood.

Significance

- **Fetal infection**—Transplacental infection rate is as low as 2% with 25% mortality.
- **Neonatal findings**—Congenital varicella syndrome is characterized by "zigzag" skin lesions, mulberry skin spots, optic atrophy, cataracts, chorioretinitis, extremity hypoplasia, and motor and sensory defects. The greatest neonatal risk is if maternal rash appears between 5 days antepartum and 2 days postpartum. No passive IgG antibodies are present.
- **Maternal infection**—10% of patients with varicella will develop **varicella pneumonia**, which has a high maternal morbidity and mortality. Communicability begins 1–2 days before vesicles appear and lasts until all vesicles are crusted over. Pruritic vesicles begin on the head and neck, progressing to the trunk. The infection can trigger labor.

Prevention. Administer **VZIG** (varicella zoster immune globulin) to a susceptible gravida within 96 h of exposure. Live-attenuated varicella virus (Varivax III) can be administered to nonpregnant or postpartum to varicella IgG-antibody–negative women.

Treatment. Administer IV antiviral treatment with **acyclovir** for varicella pneumonia, encephalitis, or the immunocompromised.

RUBELLA

An 18-year-old primigravida is at 30 weeks' gestation and is employed in a childcare center. One of the children had a rash that was diagnosed as rubella. The patient's rubella IgG titer is negative. She is concerned about the possibility of her fetus getting infected with rubella.

OB Triad

Congenital Rubella

- Congenital deafness
- Congenital cataracts
- Congenital heart disease

Pathophysiology. Rubella is a highly contagious RNA virus that is spread by **respiratory droplets**. Up to 85% of pregnant women are rubella IgG seropositive.

- **Vertical transmission** from mother to fetus or neonate can only occur during the viremia of a primary infection because the result is residual lifelong immunity.

Significance

- **Fetal infection**—Transplacental infection rate is >90% in the first 10 weeks of pregnancy, but 5% in the third trimester. Manifestations may include symmetric IUGR, microcephaly, or ventriculoseptal defect (VSD).
- **Neonatal infection**—Congenital rubella syndrome is characterized by **congenital deafness** (**most common** sequelae), **congenital heart disease**, **cataracts**, mental retardation, hepatosplenomegaly, thrombocytopenia, and "blueberry muffin" rash.
- **Maternal infection**—Rubella infection during pregnancy is generally a mild, low-morbidity condition.

Prevention. All pregnant women should undergo rubella IgG antibody screening. Rubella-susceptible women should avoid known rubella cases, then receive active immunization after delivery. Because rubella vaccine is made using a live attenuated virus, pregnancy should be avoided for 1 month after immunization.

Treatment. No specific treatment. Rubella has been eradicated from the United States; no cases have been reported here since 2004.

CYTOMEGALOVIRUS (CMV)

A 31-year-old neonatal intensive care unit nurse has just undergone an uncomplicated term spontaneous vaginal delivery of a 2,300-g female neonate with a diffuse petechial rash. At 12 weeks' gestation she experienced a flulike syndrome with right upper quadrant pain. Obstetric sonograms showed fetal growth was only at the fifth percentile.

OB Triad

Cytomegalovirus (CMV)

- Most common congenital viral syndrome
- Most common cause of deafness in children
- Neonatal thrombocytopenia and petechiae

Pathophysiology. CMV is a DNA herpes virus that is spread by infected body secretions. Up to 50% of pregnant women are CMV IgG seropositive.

Vertical transmission from mother to fetus or neonate occurs mainly during the viremia of a primary infection. However, because the result of primary infection is predisposition to a residual lifelong latency, fetal infection can occur with reactivation.

Significance

- **Fetal infection**—Transplacental infection rate is 50% with maternal primary infections regardless of the pregnancy trimester, but <1% with recurrent infections. Manifestations may include nonimmune hydrops, symmetric IUGR, microcephaly, and cerebral calcifications in a periventricular distribution.
- **Neonatal infection**—From 1 to 2% of newborns have evidence of in utero exposure to CMV. Congenital CMV syndrome is the **most common** congenital viral syndrome in the United States. CMV is the **most common** cause of sensorineural deafness in children. Only 10% of infected infants have clinical disease, which includes **petechiae**, mulberry skin spots, meningoencephalitis, periventricular calcifications, hepatosplenomegaly, thrombocytopenia, and jaundice.

- **Maternal infection**—CMV infection during pregnancy is generally a mild, low-morbidity condition appearing as a mononucleosis-like syndrome with hepatitis.

Prevention. Follow universal precautions with all body fluids. Avoid transfusion with CMV-positive blood.

Treatment. Antiviral therapy with ganciclovir.

HERPES SIMPLEX VIRUS (HSV)

A 21-year-old multipara was admitted to the birthing unit at 39 weeks' gestation in active labor at 6-cm dilation. The bag of water is intact. She has a history of genital herpes preceeding the pregnancy. Her last outbreak was 8 weeks ago. She now complains of pain and pruritis. On examination she had localized, painful, ulcerative lesions on her right vaginal wall.

Pathophysiology. HSV is a DNA herpes virus that is spread by intimate **mucocutaneous contact**. Up to 50% of pregnant women are HSV IgG seropositive.

- Most genital herpes results from HSV II, but can also occur with HSV I.
- Transplacental transmission from mother to fetus can occur with viremia during the primary infection but is rare. HSV infection predisposes to a residual lifelong latency with periodic recurrent attacks. The most common route of fetal infection is contact with **maternal genital lesions** during a recurrent HSV episode.

Diagnosis. The definitive diagnosis is a positive HSV culture from fluid obtained from a ruptured vesicle or debrided ulcer, but there is a 20% false-negative rate. PCR is 2–4x more sensitive and is best to detect viral shedding.

Significance

- **Fetal infection**—The transplacental infection rate is 50% with maternal primary infections. Manifestations may include spontaneous abortions, symmetric IUGR, microcephaly, and cerebral calcifications.
- **Neonatal infection**—With passage through an HSV-infected birth canal, the neonatal attack rate is 50% with a primary infection, but <5% with a recurrent infection. Neonatal mortality rate is 50%. Those who survive have severe sequelae: meningoencephalitis, mental retardation, pneumonia, hepatosplenomegaly, jaundice, and petechiae.
- **Maternal infection** (2 types):
  - **Primary herpes** results from a viremia and has systemic manifestations: fever, malaise, adenopathy, and diffuse genital lesions (vagina, cervix, vulva, and urethra). Transplacental fetal infection is possible. However, in 2/3 of cases, the infection is mild or subclinical.
  - **Recurrent herpes** results from migration of the virus from the dorsal root ganglion but is localized and less severe with no systemic manifestations. Fetal infection results only from passing through a birth canal with lesions present.

Prevention. A cesarean section should be performed in the presence of genital HSV lesions at the time of labor. If membranes have been ruptured >8–12 h, the virus may already have infected the fetus and cesarean delivery would be of no value.

Treatment. Acyclovir.

HUMAN IMMUNODEFICIENCY VIRUS (HIV)

A 22-year-old multigravida is a former IV drug user. She was diagnosed as HIV positive 12 months ago during her previous pregnancy. She underwent vaginal delivery of an infant who is also HIV positive. She is now pregnant again at 15 weeks' gestation.

Pathophysiology. HIV is an RNA retrovirus that is spread by infected body secretions. Sharing contaminated needles, having sexual intercourse with an infected partner, and perinatal transmission are the most common ways of transmission.

The infected patient develops acquired immunodeficiency syndrome (**AIDS**). The clinical course from HIV to AIDS is a gradual but relentless immunosuppression during a period of years, resulting in death caused by overwhelming infection from opportunistic diseases.

Significance

- **Fetal infection**—Transplacental infection occurs, but the major route of vertical transmission is contact with infected genital secretions at the time of vaginal delivery. Without maternal azidothymidine (AZT) prophylaxis, the vertical transmission rate is 30%, but with AZT the infection rate is lowered to 10% with vaginal delivery. With elective cesarean section without labor and before membrane rupture, the perinatal infection rate may be <5%. The greatest benefit to the fetus of cesarean delivery is probably in women with low CD4 counts and high RNA viral loads, making infection through a vaginal delivery much more likely.
- **Neonatal infection**—At birth neonates of HIV-positive women will have positive HIV tests from transplacental passive IgG passage. HIV-infected breast milk can potentially transmit the disease to the newborn. Progression from HIV to AIDS in infants is more rapid than in adults.
- **Maternal infection**—Pregnancy in an HIV-positive woman does not enhance progression to AIDS.

Prevention

- **Antiviral prophylaxis**—The U.S. Public Health Service recommends that HIV-infected pregnant women be offered combination treatment with HIV-fighting drugs to help protect their health and prevent passing the infection on to their babies. Infected pregnant women should take triple-drug therapy including the drug zidovudine (ZDV) as part of their drug regimen, starting at 14 weeks and continuing throughout pregnancy, intrapartum, and after delivery.
- **Mode of delivery**—Vaginal delivery should be planned at 39 weeks. The guidelines for vaginal delivery are 1) to avoid amniotomy as long as possible, 2) do not use scalp electrodes in labor, 3) avoid forceps or vacuum extractor operative delivery, and 4) use gentle neonatal resuscitation. Cesarean section is offered at 38 weeks without amniocentesis if viral load is ≥ 1,000 copies/mL.

- **Breast feeding**—This is probably best avoided in HIV-positive women.
- **Universal precautions**—Pay careful attention to handling of all body fluids.

Treatment. All HIV-positive pregnant women should be on combination triple anti-viral HAART therapy. This includes 2 nucelotide reverse transcriptase inhibitors (NRTIs) with either an NNRTI or a protease inhibitor. An example would be zidovudine, lamivudine, or ritonavir.

SYPHILIS

A 34-year-old multigravida presents for prenatal care in the second trimester. She admits to a past history of substance abuse but states she has been clean for 6 months. With her second pregnancy she experienced a preterm delivery at 34 weeks' gestation of a male neonate who died within the first day of life. She states that at delivery the baby was swollen with skin lesions and that the placenta was very large. She was treated with antibiotics but she does not remember the name or other details. On a routine prenatal panel with this current pregnancy she is found to have a positive VDRL (Venereal Disease Research Laboratory) test.

Pathophysiology. Syphilis is caused by *Treponema pallidum*, a motile anaerobic spirochete that cannot be cultured. Syphilis does not result in either a state of immunity or latency. The infection can be eradicated by appropriate treatment, but reinfection can occur over and over again. It is spread as a sexually transmitted disease by intimate contact between moist mucous membranes or congenitally through the placenta to a fetus from an infected mother.

Significance

- **Fetal infection—**Transplacental infection is common with vertical transmission rates of 60% in primary and secondary syphilis. The rate of fetal infection with latent or tertiary syphilis is lower. Without treatment, manifestations of early congenital syphilis include nonimmune hydrops, macerated skin, anemia, thrombocytopenia, and hepatosplenomegaly. Fetal death rates are high, with perinatal mortality rates approaching 50%. The placenta is typically large and edematous.
- **Neonatal infection**—Late congenital syphilis is diagnosed after age 2 years and includes "Hutchinson" teeth, "mulberry" molars, "saber" shins, "saddle" nose, and 8th nerve deafness.
- **Maternal infection** (4 types):
  - **Primary syphilis** is the first stage after infection. Papules become painless ulcers with rolled edges (chancres) which appear 2–3 weeks after contact at the site of infection, most commonly the vulva, vagina, or cervix. Darkfield microscopy of lesion exudate is positive for the spirochete, but the nonspecific serologic tests VDRL or rapid plasma reagin [**RPR**] test) are not yet positive. Without treatment the chancre spontaneously disappears.
  - **Secondary syphilis** is characterized by systemic spirochetemia. Two to three months after contact, fever, malaise, general adenopathy, and a maculopapular skin rash ("money spots") are seen. Broad exophytic excrescences (**condyloma lata**) appear on the vulva. These physical findings also spontaneously disappear without treatment. Darkfield microscopy of condyloma exudate is positive for treponema. The VDRL or RPR test will be positive, but a diagnosis of syphilis must be confirmed with a

treponema-specific test, such as the fluorescent titer antibody absorption (FTA-ABS) or microhemagglutination assay for antibodies to *T. pallidum* (MHA-TP). The treponema-specific tests do not correlate with disease activity and remain positive in spite of treatment.

- **Latent syphilis** is characterized by absence of symptoms or physical findings. One third of cases proceed to tertiary disease. The nonspecific and treponema-specific tests remain positive.
- **Tertiary syphilis** is a symptomatic stage with symptoms dependent on which organ system is affected by the classic necrotic, ulcerative nodules (**gummas**). Lesion location may include the cardiovascular system (aortitis, saccular aneurysms), CNS (meningitis, tabes dorsalis, dementia, ataxia), or bone (osteitis). Not only are the blood tests positive, but also the cerebrospinal fluid will be positive with CNS involvement.

Table 7-1. Syphilis in Pregnancy

Characteristic	Primary	Secondary
Classic lesion	Chancre	Condyloma lata ("money spots")
Extent of disease	Localized	Systemic
Lab tests (VDRL, Darkfield, FTA-ABS)	VDRL (–) Darkfield (+) FTA-ABS (+)	VDRL (+) Darkfield (+) FTA-ABS (+)
Fetal infection rate	60%	60%
Treatment of choice	Penicillin	Penicillin

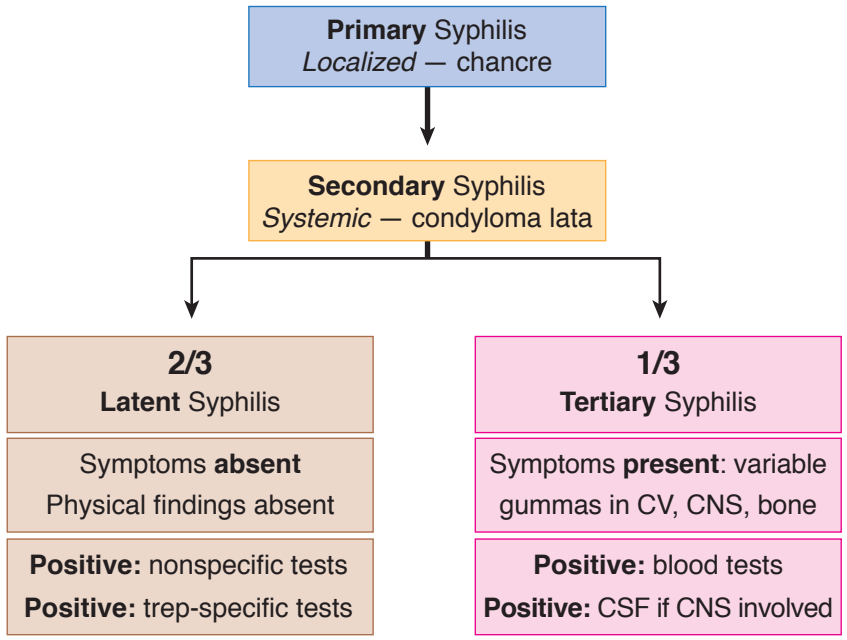

Figure I-7-2. Maternal Syphilis

Prevention

- Vaginal delivery is appropriate with cesarean section only for obstetric indications.
- Follow the principles of avoiding multiple sexual partners, and promote use of barrier contraceptives.

Management. Benzathine penicillin 2.4 million units IM × 1 is given in pregnancy to ensure adequate antibiotic levels in the fetus. Other antibiotics do not cross the placenta well. Even if the gravida is penicillin-allergic, she should still be given a full penicillin dose using an oral desensitization regimen under controlled conditions.

Follow serology titers at 1, 3, 6, 12, and 24 months. Titers should be decreased fourfold by 6 months, and should be negative in 12-24 months.

The Jarisch-Herxheimer reaction is associated with treatment and occurs in half of pregnant women. It starts in 1-2 hours, peaks in 8 hours, and resolves in 24-48 hours. It is associated with acute fever, headache, myalgias, hypotension, and uterine contractions. Management is supportive care.

HEPATITIS B (HBV)

A 29-year-old multigravida was found on routine prenatal laboratory testing to be positive for hepatitis B surface antigen. She is an intensive care unit nurse. She received 2 units of packed red blood cells 2 years ago after experiencing postpartum hemorrhage with her last pregnancy.

Pathophysiology. Hepatitis B is a DNA virus that is spread by infected body secretions. Sharing contaminated needles, having sexual intercourse with an infected partner, and perinatal transmission are the most common ways of transmission. Vertical transmission accounts for 40% of all chronic HBV infections. Most HBV infections are asymptomatic.

Significance

- **Fetal infection—**Transplacental infection is rare, occurring mostly in the third trimester. The main route of fetal or neonatal infection arises from exposure to or ingestion of infected genital secretions at the time of vaginal delivery. There is no perinatal transmission risk if the mother is positive for HBV surface antibodies but negative for HBV surface antigen.
- **Neonatal infection—**Neonatal HBV develops in only 10% of mothers positive for HBsAg but in 80% of those positive for both HBsAg and HBeAg. Of those neonates who get infected, 80% will develop chronic hepatitis, compared with only 10% of infected adults.
- **Maternal infection** (3 types):
  - **Asymptomatic HBV.** The majority of all infected patients fall into this category with no impact on maternal health. Hepatitis B surface antigen (HBsAg) is the screening test used for identifying existing infection and is obtained on all pregnant women. A positive HBsAg test is followed up with a complete hepatitis panel and liver enzymes assessing for active or chronic hepatitis.
  - **Acute hepatitis.** Acute and chronic HBV infections can result in right upper quadrant pain and lethargy varying according to the severity of the infection. Laboratory studies show elevated bilirubin and high liver enzymes. The majority of patients with acute hepatitis will recover normal liver function.

– **Chronic hepatitis.** Cirrhosis and hepatocellular carcinoma are the most serious consequences of chronic hepatitis.

Prevention

- Vaginal delivery is indicated with cesarean section only for obstetric indications.
- Avoid scalp electrodes in labor as well as scalp needles in the nursery. Neonates of HBsAg-positive mothers should receive passive immunization with hepatitis B immunoglobulin (HBIg) and active immunization with hepatitis B vaccine. Breast feeding is acceptable after the neonate has received the active immunization and HBIG.
- HBsAg-negative mothers at high risk for hepatitis B should receive HBIg passive immunization. Active immunization is safe in pregnancy because the agent is a killed virus.

Management. There is no specific therapy for acute hepatitis. Chronic HBV can be treated with interferon or lamivudine.

	Lifelong	Treatment/Delivery	
Group β beta streptococcus	Colonization	Penicillin G	**Vaginal Delivery**
Toxoplasmosis	Immunity	Pyrimethamine Sulfadiazine	
Rubella		None	
Cytomegalovirus	Latency	Ganciclovir	**Cesarean Section** if active HSV or few HIV
Varicella/HSV		Acyclovir	
HIV		Triple Rx antivirals	

	Findings	Findings
Toxoplasmosis*+	Intracranial calcifications	Chorioretinitis
Varicella+	Zig zag lesions	Small eyes
Rubella*+	Deafness	Congenital heart disease
Cytomegalovirus*+	Petechiae	↑ liver, spleen
Syphilis+	Hydrops	Macerated skin
HSV, HIV, HBVΔ	None	

*Associated with IUGR
+Transplacental vertical transmission
ΔVaginal delivery vertical transmission

Obstetric Complications 8

Learning Objectives

- ❏ Describe the management of cervical insufficiency and multiple gestation
- ❏ Answer questions about alloimmunization
- ❏ List the management steps for preterm labor, premature rupture of membranes, and post-term pregnancy

CERVICAL INSUFFICIENCY

A 32-year-old primigravida at 18 weeks' gestation comes to the maternity unit complaining of pelvic pressure and increasing vaginal mucus discharge. She denies any uterine contractions. On pelvic examination the fetal membranes are seen bulging into the vagina, and no cervix can be palpated. Fetal feet can be felt through the membranes. Two years ago she underwent a cervical conization for cervical intraepithelial neoplasia.

The terms "cervical insufficiency" and "cervical incompetency" have been used to describe the inability of the uterine cervix to retain a pregnancy to viability in the absence of contractions or labor. A diagnosis was made in the past on the basis of a history of painless cervical dilation after the first trimester with expulsion of a previable living fetus.

Recent studies using ultrasound to examine cervical length suggest that cervical function is not an all-or-none phenomenon, but may be a continuous variable with a range of degrees of competency that may be expressed differently in subsequent pregnancies.

Etiology. Causes may include trauma from rapid forceful cervical dilation associated with second trimester abortion procedures, cervical laceration from rapid delivery, injury from deep cervical conization, or congenital weakness from diethylstilbestrol (DES) exposure.

Diagnosis

- Studies show the benefit of elective cervical cerclage with a history of 1 or more unexplained second-trimester pregnancy losses. The benefit of cervical cerclage placement is unclear in the following situations: sonographic findings of a short cervix or funneling, history of cervical surgery, DES exposure.
- Serial transvaginal ultrasound evaluations of the cervix after 16–20 weeks may be helpful.

OB Triad

Cervical Insufficiency

- Pregnant 18–22 weeks
- Painless cervical dilation
- Delivery of previable fetus

Management

- Elective cerclage placement at 13–14 weeks' gestation is appropriate after sonographic demonstration for fetal normality.
- Emergency or urgent cerclage may be considered with sonographic evidence of cervical insufficiency after ruling out labor and chorioamnionitis.
- Cerclage should be considered if cervical length is <25 mm by vaginal sonography prior to 24 weeks and prior preterm birth at <34 weeks gestation.
- McDonald cerclage places a removable suture in the cervix. The benefit is that vaginal delivery can be allowed to take place, avoiding a cesarean.
- Cerclage removal should take place at 36–37 weeks, after fetal lung maturity has taken place but before the usual onset of spontaneous labor that could result in avulsion of the suture.
- Shirodkar cerclage utilizes a submucosal placement of the suture that is buried beneath the mucosa and left in place. Cesarean delivery is performed at term.

MULTIPLE GESTATION

A 21-year-old primigravida at 15 weeks' gestation is seen for a routine prenatal visit. At her last visit 4 weeks ago, her uterus was appropriate for size and dates. Today, her uterine fundus is palpable at the umbilicus.

Definition. This is a pregnancy in which more than one fetus is present. The fetuses may arise from one or more zygotes and are usually separate, but may rarely be conjoined.

Risk Factors

- **Dizygotic twins** are most common. **Identifiable risk factors** include by race, geography, family history, or ovulation induction. Risk of twinning is up to 10% with clomiphene citrate and up to 30% with human menopausal gonadotropin.
- **Monozygotic twins** have **no identifiable risk factors**.

Diagnosis. Obstetric sonogram demonstration of more than one intrauterine fetus.

Complications for all twin pregnancies include nutritional anemias (iron and folate), preeclampsia, preterm labor (50%), malpresentation (50%), cesarean delivery (50%), and postpartum hemorrhage.

OB Triad

Di–Di Di or Mono–Di–Di Twins

- Twin pregnancy
- Gender same or unknown
- Two placentas seen

Mono–Mono–Di Twins

- Twin pregnancy
- Gender always same
- *One* placenta but *two* sacs

Mono–Mono–Mono Twins

- Twin pregnancy
- Gender always same
- *One* placenta and *one* sac

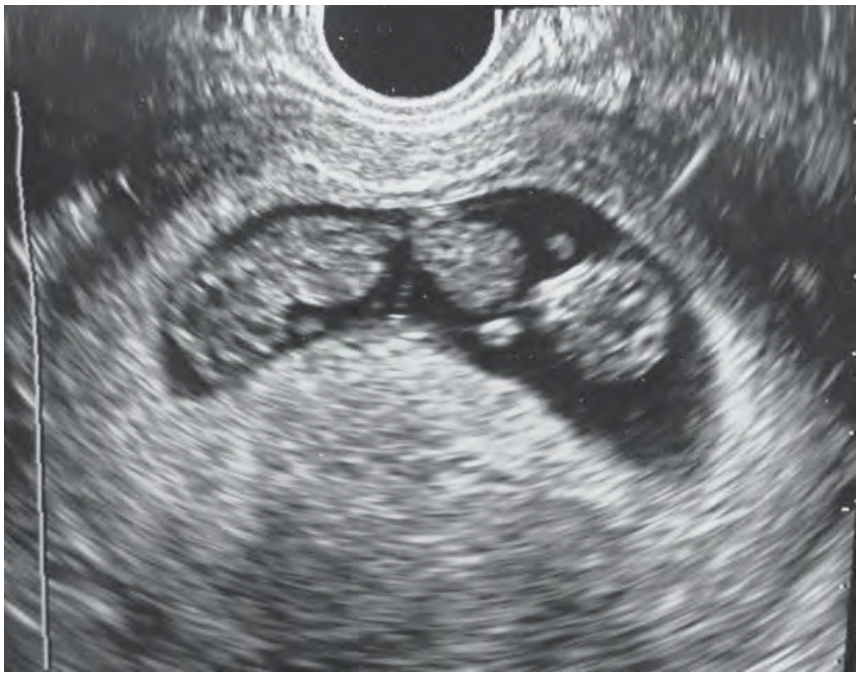
Table 8-1. Complications of Twin Pregnancies

ANTEpartum	Anemia ↑ 3x (iron & folate)
	Preeclampsia ↑ 3x
	Gestational diabetes ↑ 2x
	Thromboembolism ↑ 4x
INTRApartum	Preterm labor (50%)
	Malpresentation (50%)
	Cesarean delivery (50%)
POSTpartum	Hemorrhage ↑ 5x

Dizygotic twins arise from multiple ovulation with 2 zygotes. They are always dichorionic, diamnionic.

Monozygotic twins arise from one zygote. Chorionicity and amnionicity vary according to the duration of time from fertilization to cleavage.

- **Up to 72 hours** (separation up to the morula stage), the twins are **dichorionic, diamnionic**. There are 2 placentas and 2 sacs. This is the **lowest** risk of all monozygotic twins.
- **Between 4 and 8 days** (separation at the blastocyst stage), the twins are monochorionic, diamnionic. There is 1 placenta and 2 sacs. A specific additional complication is **twin–twin transfusion**, which develops in 15% of mono-di twins. The twins share a single placenta but do so unequally. The donor twin gets less blood supply, resulting in growth restriction, **oligohydramnios**, and anemia. However, neonatal outcome is usually better. The **recipient twin** gets more blood supply, resulting in excessive growth, **polyhydramnios**, and polycythemia. Intrauterine fetal surgery is indicated to laser the vascular connections on the placental surface between the 2 fetuses. Neonatal course is often complicated.



Medical Education Division of the Brookside Associates, brooksidepress.org

Figure I-8-1. Monochorionic, Diamniotic Twin Gestation

- **Between 9 and 12 days** (splitting of the embryonic disk), the twins are **monochorionic, monoamnionic.** There is only 1 placenta and 1 sac. Specific additional risks are twin–twin transfusion but particularly **umbilical cord entanglement** which can result in fetal death. This is the highest risk of all monozygotic twins.
- **After 12 days**, conjoined twins result. Most often this condition is **lethal**.

Table 8-2. Postconception Days to Identical Twin Cleavage

Dichorionic–diamnionic	0–3 days Morula
Monochorionic–diamnionic	4–8 days Blastocyst
Monochorionic–monoamnionic	9–12 days Embryonic disk
Conjoined	>12 days Embryo

Clinical Findings. Hyperemesis gravidarum is more common from high levels of β-hCG. Uterus is larger than dates. Maternal serum α-**fetoprotein** is excessively higher than with one fetus.

Management

- **Antepartum:** Give mother iron and folate supplementation to prevent anemia, monitor BP to detect preeclampsia, educate mother regarding preterm labor symptoms and signs, and perform serial ultrasound examinations looking for twin–twin transfusion (amniotic fluid discordance).
- **Intrapartum:** Route of delivery is based on presentation in labor—vaginal delivery if both are cephalic presentation (50%); cesarean delivery if first twin in noncephalic presentation; route of delivery is controversial if first twin is cephalic and second twin is noncephalic.
- **Postpartum:** Watch for postpartum hemorrhage from uterine atony owing to an overdistended uterus.

ALLOIMMUNIZATION

A 32-year-old woman, G2 P1, was seen for her first prenatal visit at 12 weeks' gestation. Her prenatal laboratory panel reveals a blood type of O negative. Her atypical antibody screen (indirect Coombs test) is positive. She has been married to the same husband for 10 years and states he is the father of both her pregnancies. She did not receive RhoGAM during her last pregnancy.

Definition. A pregnant woman has developed **antibodies to foreign red blood cells** (RBCs), most commonly against those of her current or previous fetus(es), but also caused by transfusion of mismatched blood.

Pathophysiology

- The most common RBC antigens are of the Rh system (C, c, D, E, e), with the **most common being big D**.
- Antibodies to RBC antigens are detected by **indirect Coombs test** (atypical antibody test [ATT]). The concentration of antibodies is reported in dilutional titers with the lowest level being 1:1, and titers increasing by doubling (e.g., 1:1, 1:2, 1:4, 1:8, 1:16, 1:32…1:1,024, etc.).
- **Hemolytic disease of the newborn** (HDN) is a continuum ranging from hyperbilirubinemia to erythroblastosis fetalis. HDN is caused by maternal antibodies crossing into the fetal circulation and targeting antigen-positive fetal RBCs, resulting in hemolysis. When severe, this can result in anemia, fetal hydrops, and even death.

Risk Factors. Alloimmunization most commonly occurs when **fetal RBCs enter** the mother's circulation transplacentally at delivery. It can also occur if a woman is transfused with mismatched RBCs. Other pregnancy-related risk factors are amniocentesis, ectopic pregnancy, D&C, abruptio placenta, and placenta previa.

Protective Factors. ABO incompatibility decreases the risk of maternal alloimmunization from foreign RBCs. Naturally occurring anti-A and anti-B antibodies rapidly lyse foreign RBCs before maternal lymphocytes are stimulated to produce active antibodies.

Requirements (all must be present).

- Mother must be antigen negative.
- Fetus must be antigen positive, which means the father of the pregnancy must also be antigen positive.
- Adequate fetal RBCs must cross over into the maternal circulation to stimulate her lymphocytes to produce antibodies to the fetal RBC antigens.
- Antibodies must be associated with HDN.
- A significant titer of maternal antibodies must be present to cross over into the fetal circulation and lead to fetal RBC hemolysis.

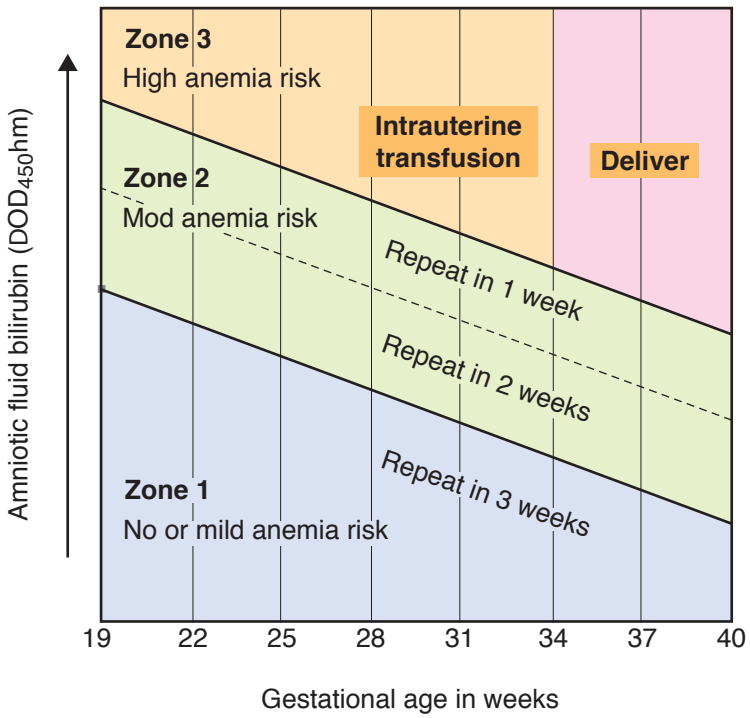


Figure I-8-2. Liley Graph

Management.

Determine whether there is any fetal risk.

- **Fetal risk is present only** if (1) atypical antibodies are detected in the mother's circulation, (2) antibodies are associated with HDN, (3) antibodies are present at a significant titer (>1:8), and (4) the father of the baby (FOB) is RBC antigen positive. Fetal blood type may be determined by amniocentesis or percutaneous umbilical blood sampling (PUBS). If the fetus is RBC antigen negative, there is no fetal risk.
- **No fetal risk is present** if (1) the AAT is negative, (2) antibodies are present but are NOT associated with HDN, (3) antibody titer is ≤1:8, or (4) the FOB is RBC antigen negative.
- **If the atypical antibody titer** is ≤1:8, management is conservative. Repeat the titer monthly as long as it remains ≤1:8.

Assess the degree of fetal if the fetus is RBC antigen positive or if fetal blood typing is impossible. This can be done by serial amniocentesis, PUBS, or ultrasound Doppler.

- **Amniotic fluid bilirubin** indirectly indicates fetal hemolysis because bilirubin accumulates as a byproduct of RBC lysis. The bilirubin is plotted on a **Liley graph**.
- **PUBS** directly measures fetal hematocrit and degree of anemia.
- **Ultrasound Doppler**—measurement of peak flow velocity of blood through the fetal middle cerebral artery (MCA). As fetal anemia worsens, the peak systolic velocity rises.

  Doppler MCA ultrasound is the **procedure of choice since it is non-invasive and has a high correlation with fetal anemia.**

Intervene if there is severe anemia. This is diagnosed when amniotic fluid bilirubin is in Liley zone III or PUBS shows fetal hematocrit to be ≤25% or MCA flow is elevated.

- Intrauterine intravascular transfusion is performed if gestational age is <34 weeks.
- Delivery is performed if gestational age is ≥34 weeks.

Prevention. RhoGAM is pooled anti-D IgG passive antibodies that are given IM to a pregnant woman when there is significant risk of fetal RBCs passing into her circulation. The passive IgG antibodies attach to the foreign RBC antigens, causing lysis to occur before the maternal lymphocytes become stimulated.

RhoGAM is routinely given to Rh(D)-negative mothers at 28 weeks, and within 72 h of chorionic villus sampling (CVS), amniocentesis, or D&C. It is also given within 72 h of delivery of an Rh(D)-positive infant. 300 mcg of RhoGAM will neutralize 15 ml of fetal RBCs or 30 mL of fetal whole blood.

Rosette test is a qualitative screening test for detecting significant feto-maternal hemorrhage (≥10 mL).

Kleihauer-Betke test quantitates the volume of fetal RBCs in the maternal circulation by differential staining of fetal and maternal RBCs on a peripheral smear. This can assess whether more than one vial of RhoGAM needs to be given when large volumes of fetal–maternal bleed may occur (e.g., abruptio placenta).

OB Triad

Preterm Contractions

- Pregnancy 20–36 weeks
- ≥3 contractions in 30 min
- Dilated <2 cm and no change

OB Triad

Magnesium Toxicity

- Preterm labor tocolysis
- Respiratory depression
- Muscle weakness

PRETERM LABOR

A 24-year-old woman, G2 P1, at 28 weeks' gestation by dates comes to the birthing unit complaining of regular uterine contractions every 7–10 min. She is a smoker with chronic hypertension. She has had no prenatal care. On examination her fundal height is 35 cm. Her previous pregnancy ended with spontaneous vaginal delivery at 30 weeks' gestation.

Preterm delivery is the most common cause of perinatal morbidity and mortality. Overall, 12% of pregnancies deliver prematurely. Many patients will have preterm contractions but not be in preterm labor. Three criteria need to be met:

- **Gestational age**—pregnancy duration ≥20 weeks, but <37 weeks
- **Uterine contractions**—at least 3 contractions in 30 min
- **Cervical change**—serial examinations show a change in dilation or effacement, or a single examination shows cervical dilation of ≥2 cm

OB Triad

Preterm Labor

- Pregnancy 20–36 weeks
- ≥3 contractions in 30 min
- Dilated ≥2 cm or changing

Preterm Delivery Categories:

- Extreme preterm: <28 weeks
- Very preterm: <32 weeks
- Moderate preterm: 32–34 weeks
- Late preterm: 34–36 6/7 weeks

Risk Factors:

- **Most common**: prior preterm birth (PTB), short transvaginal (TV) cervical length (<25 mm), PROM, multiple gestation, uterine anomaly
- Others: low maternal pre-pregnancy weight, smoking, substance abuse, and short inter-pregnancy interval (<18 months)

All gravidas should be screened:

- **History:** previous PTB
- **Sonographic cervical length:** prior to 24 weeks

Interventions to prevent preterm delivery:

- **Singleton** pregnancy:
  - Weekly IM 17-hydroxy progesterone caproate (17-0H-P) if cervical length ≥25 mm with prior spontaneous PTB
  - Weekly IM 17 -OH-P plus cervical cerclage placement if cervical length <25 mm before 24 weeks with prior PTB
  - Daily vaginal progesterone if cervical length <20 mm before 24 weeks but no prior PTB
- **Twin pregnancy:** no interventions shown to have any benefit

Symptoms. Lower abdominal pain or pressure, lower back pain, increased vaginal discharge, or bloody show. Particularly in primigravidas, the symptoms may be present for a number of hours to days but are not recognized as contractions by the patient.

Fetal Fibronectin (fFN):

fFN is a protein matrix produced by fetal cells that acts as a biological glue binding the trophoblast to the maternal decidua. It "leaks" into the vagina if PTB is likely and can be measured with a rapid test using a vaginal swab.

- Prerequisites for testing: gestation **22-35 weeks**, cervical dilation <3 cm, and membranes intact.
- Interpretation: main value of the test is a negative, since the chance of PTB in the next 2 weeks is <1%. With a positive result, the likelihood of PTB is 50%.

Intravenous Magnesium Sulfate for Fetal Neuroprotection:

Matemal IV $MgSo_4$ may reduce the severity and risk of cerebral palsy in surviving very preterm neonates.

- Start infusion if PTB is anticipated **<32 weeks** gestation regardless of the anticipated route of delivery.
- It takes 4 hours of infusion to achieve steady state of Mg in the fetus.

Antenatal Corticosteroid Therapy:

- A single course of corticosteroids is recommended for pregnant women with gestational age **23–34 weeks** of gestation who are at risk of preterm delivery within 7 days.
- A complete course is two IM 12-mg doses of betamethasone given 24 hours apart OR four IM 6-mg doses of dexamethasone given 12 hours apart.
- Neonates whose mothers receive antenatal corticosteroids have significantly lower severity, frequency, or both of respiratory distress syndrome, intracranial hemorrhage, necrotizing enterocolitis and death.

Tocolytic Contraindications. These are conditions under which stopping labor is either dangerous for mother and baby or futile (makes no difference in outcome). Examples include the following:

- **Obstetric conditions**—severe abruptio placenta, ruptured membranes, chorioamnionitis.
- **Fetal conditions**—lethal anomaly (anencephaly, renal agenesis), fetal demise or jeopardy (repetitive late decelerations).
- **Maternal conditions**—eclampsia, severe preeclampsia, advanced cervical dilation.

Tocolytic Agents. Parenteral agents may prolong pregnancy but for no more than 72 h. This does provide a window of time for (1) administration of **maternal IM betamethasone** to enhance fetal pulmonary surfactant and (2) **transportation of mother and fetus in utero** to a facility with neonatal intensive care. Oral tocolytic agents are no more effective than placebo.

- **Magnesium sulfate** is a competitive inhibitor of calcium. Clinical monitoring is based on decreasing but maintaining detectable deep tendon reflexes.
  - Side effects include muscle weakness, respiratory depression, and pulmonary edema. Magnesium overdose is treated with IV calcium gluconate.
  - Contraindications include renal insufficiency and myasthenia gravis.
- **β-Adrenergic agonists include terbutaline.** Tocolytic effect depends on the β_2-adrenergic receptor myometrial activity.
  - Cardiovascular side effects (hypertension, tachycardia) are from β_1 receptor cardiovascular activity. Other side effects are hyperglycemia, hypokalemia, and pulmonary edema.
  - Contraindications include cardiac disease, diabetes mellitus, uncontrolled hyperthyroidism.
- **Calcium-channel blockers** decrease intracellular calcium (e.g., nifedipine).
  - Side effects include tachycardia, hypotension, and myocardial depression.
  - Contraindications include hypotension.
- **Prostaglandin synthetase inhibitors** decrease smooth muscle contractility by decreasing prostaglandin production (e.g., indomethacin).
  - Side effects include oligohydramnios, in utero ductus arteriosus closure, and neonatal necrotizing enterocolitis.
  - Contraindications include gestational age >**32 weeks**.

OB Triad

Beta Agonists

- Preterm labor tocolysis
- Hypokalemia
- Hyperglycemia

OB Triad

Calcium Channel Blocker

- Preterm labor tocolysis
- Hypotension
- Myocardial depression

OB Triad

Indomethacin

- Preterm labor tocolysis
- Oligohydramnios
- PDA closure in utero

Management:

- Confirm labor using the 3 criteria listed earlier.
- Rule out contraindications to tocolysis using criteria listed above.
- Initiate IV hydration with isotonic fluids.
- Start IV $MgSo_4$ for fetal neuroprotection (if <32 weeks) at least 4 hours before anticipated birth.
- Start tocolytic therapy with terbutaline, nifedipine or indomethacin (if <32 weeks) for no longer than 48 hours to allow for antenatal steroid effect.
- Obtain cervical and urine cultures before giving IV penicillin G (or erythromycin) for group B b Streptococcus sepsis prophylaxis.
- Administer maternal IM betamethasone to stimulate fetal type II pneumocyte surfactant production if gestational age is <34 weeks.

Prevention. Weekly intramuscular injections of 17α-OH progesterone caproate starting at 20 weeks' gestation has been shown to decrease preterm deliveries in women with a history of previous idiopathic preterm deliveries.

PREMATURE RUPTURE OF MEMBRANES (PROM)

OB Triad

Ruptured Membranes

- Posterior fornix **pooling**
- Fluid is Nitrazine (phenaphthazine) (+)
- Glass slide drying: fern (+)

A 22-year-old primigravida at 33 weeks' gestation comes to the birthing unit stating that 2 h ago she had a gush of fluid from her vagina. She denies vaginal bleeding or uterine contractions. Her perineum appears moist to gross inspection. On examination her temperature is 102°F.

Definition. Rupture of the fetal membranes before the onset of labor, whether at term or preterm.

Risk Factors. Ascending infection from the lower genital tract is the most common risk factor for PROM. Other risk factors are local membrane defects and cigarette smoking.

Clinical Presentation. Typical history is a sudden gush of copious vaginal fluid. On external examination, clear fluid is flowing out of the vagina. Oligohydramnios is seen on ultrasound examination.

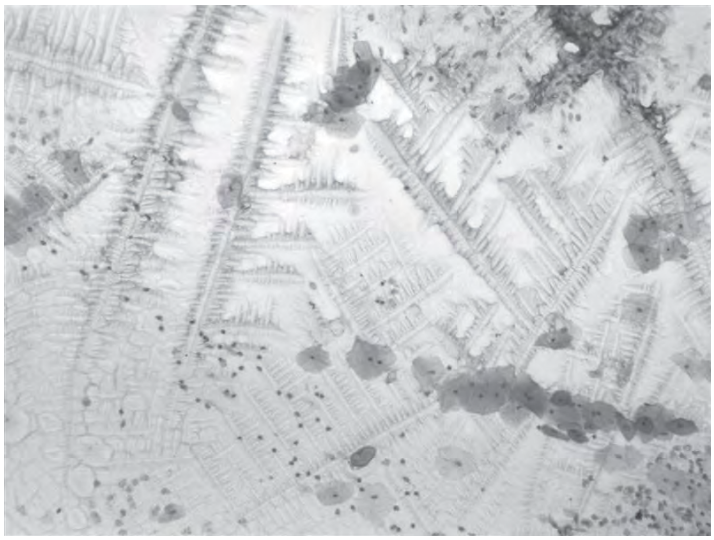
Diagnosis.

PROM is diagnosed by **sterile speculum examination** meeting the following criteria:

- **Pooling positive**—clear, watery amniotic fluid is seen in the posterior vaginal fornix
- **Nitrazine positive**—the fluid turns pH-sensitive paper blue
- **Fern positive**—the fluid displays a ferning pattern when allowed to air dry on a microscope glass slide

Chorioamnionitis is diagnosed **clinically** with all the following criteria needed:

- Maternal fever and uterine tenderness in the presence of confirmed PROM in the absence of a URI or UTI



With permission, Australian Society of Cytology Inc., cytology-asc.com

Figure I-8-3. Ferning Pattern of Amniotic Fluid

Management

- If **uterine contractions** occur, tocolysis is contraindicated.
- If **chorioamnionitis** is present, obtain cervical cultures, start broad-spectrum therapeutic IV antibiotics, and initiate prompt delivery.
- If **no infection** is present, management will be based on gestational age as follows:
  - **Before viability** (<23 weeks), outcome is dismal. Either induce labor or manage patient with bed rest at home. Risk of fetal pulmonary hypoplasia is high.
  - **With preterm viability** (23 0/7–33 6/7 weeks), conservative management. Hospitalize the patient at bed rest, administer IM betamethasone to enhance fetal lung maturity if <34 weeks, obtain cervical cultures, and start a 7-day course of prophylactic ampicillin and erythromycin.
  - **At term** (≥34 weeks), initiate prompt delivery. If vaginal delivery is expected, use oxytocin or prostaglandins as indicated. Otherwise, perform cesarean delivery.

Table 8-3. Hazards Associated with PROM

If Fetus Remains In Utero	If Preterm Delivery Occurs
Neonatal conditions • Infection and sepsis • Deformations • Umbilical cord compression • Pulmonary hypoplasia	**Neonatal conditions** • Respiratory distress syndrome (most common) • Patent ductus arteriosus • Intraventricular hemorrhage • Necrotizing enterocolitis • Retinopathy of prematurity • Bronchopulmonary dysplasia • Cerebral palsy
Maternal conditions • Chorioamnionitis, sepsis • Deep venous thrombosis (DVT) • Psychosocial separation	

OB Triad

Chorioamnionitis

- Ruptured membranes
- Maternal fever
- No UTI or URI

POSTTERM PREGNANCY

A 21-year-old primigravida at 42 weeks' gestation by dates comes to the outpatient prenatal clinic. She has been seen for prenatal care since 12 weeks' gestation, confirmed by an early sonogram. She states that fetal movements have been decreasing. Fundal height measurement is 42 cm. Her cervix is long, closed, posterior, and firm. Nonstress test is reactive, but amniotic fluid index is 4 cm.

Definition

- **Academic.** The most precise definition is a pregnancy that continues for ≥40 weeks or ≥280 days postconception. This includes 6% of all pregnancies.
- **Practical.** Because most of the time the date of conception is not known, a practical definition is a pregnancy that continues ≥42 weeks or ≥294 days after the first day of the last menstrual period.
- **Statistics.** Generally, 50% of patients deliver by 40 weeks, 75% by 41 weeks, and 90% by 42 weeks. These statistics assume ovulation occurred on day 14 of a 28-day menstrual cycle. These figures probably overstate the actual number because up to half of these patients had cycles longer than 28 days.

Etiology. The most common cause of true postdates cases are idiopathic (no known cause). It does occur more commonly in young primigravidas and rarely with placental sulfatase deficiency. Pregnancies with anencephalic fetuses are the longest pregnancies reported.

Significance. Perinatal mortality is increased two- to threefold. This is a direct result of changes on placental function over time.

- **Macrosomia syndrome.** In most patients, **placental function continues** providing nutritional substrates and gas exchange to the fetus, resulting in a healthy but large fetus. **Cesarean rate is increased** owing to prolonged or arrested labor. Shoulder dystocia is more common with risks of fetal hypoxemia and brachial plexus injury.
- **Dysmaturity syndrome.** In a minority of patients, **placental function declines** as infarction and aging lead to placental scarring and loss of subcutaneous tissue. This reduction of metabolic and respiratory support to the fetus can lead to the asphyxia that is responsible for the increased perinatal morbidity and mortality. **Cesarean rate is increased** owing to nonreassuring fetal heart rate patterns. Oligohydramnios results in umbilical cord compression. Hypoxia results in acidosis and in utero meconium passage.

Management. Management is based on 2 factors.

- **Confidence in dates.** Identify how much confidence can be placed on the gestational age being truly >42 weeks.
- **Favorableness of the cervix.** Assess the likelihood of successful induction of labor by assessing cervical dilation, effacement, position, consistency, and station. The Bishop score is a numerical expression of how favorable the cervix is and the likelihood of successful labia induction.
  - Favorable cervix is dilated, effaced, soft, and anterior to mid position. Bishop score is ≥8.
  - Unfavorable cervix is closed, not effaced, long, firm, and posterior. Bishop score is ≤5.

Bishop Scoring Method

Parameter\Score	0	1	2	3
Position	Posterior	Intermediate	Anterior	-
Consistency	Firm	Intermediate	Soft	-
Effacement	0–30%	31–50%	51–80%	>80%
Dilation	0 cm	1–2 cm	3-4 cm	>5 cm
Fetal station	-3	-2	-1, 0	+1,+2

Patients can be classified into 3 groups.

- **Dates sure, favorable cervix.** Management is aggressive. There is no benefit to the fetus or mother in continuing the pregnancy. Induce labor with IV oxytocin and artificial rupture of membranes.
- **Dates sure, unfavorable cervix.** Management is controversial. Management could be aggressive, with cervical ripening initiated with vaginal or cervical prostaglandin E_2 followed by IV oxytocin. Or management could be conservative with twice weekly NSTs and AFIs awaiting spontaneous labor.
- **Dates unsure.** Management is conservative. Perform twice weekly NSTs and AFIs to ensure fetal well-being and await spontaneous labor. If fetal jeopardy is identified, delivery should be expedited.

Table 8-4. Placental Function in Post-term Pregnancy

Maintained	Deteriorates
Macrosomia (80%)	Dysmaturity (20%)
Difficult labor and delivery	Placental insufficiency
↑ C section (forceps, vacuum extractor, shoulder dystocia, birth trauma)	↑ C section (acidosis, meconium aspiration, oxygen deprivation)

Management of Meconium. Previous recommendations to prevent meconium aspiration syndrome (MAS) included:

- **In labor**, amnioinfusion (with saline infused through an intrauterine catheter) to dilute meconium and provide a fluid cushion to prevent umbilical cord compression.
- **After the head is delivered**, suction the fetal nose and pharynx to remove any upper airway meconium.
- **After the body is delivered**, visualize the vocal cords with a laryngoscope to remove meconium below the vocal cords.

Newer recommendations (American Heart Association, American Academy of Pediatrics):

- **Amnioinfusion** may be helpful to prevent umbilical cord compression; okay to perform it.
- **Suctioning of fetal nose and pharynx** makes no difference in preventing MAS; do not routinely perform.
- **Laryngoscopic visualization** of vocal cords is only indicated if the neonate is depressed; perform selectively.

Hypertensive Complications 9

Learning Objectives

- ❏ Differentiate between gestational hypertension, preeclampsia, eclampsia, and chronic hypertension with or without superimposed preeclampsia
- ❏ Describe the diagnosis, management, and complications of hypertensive syndromes in pregnancy
- ❏ Answer questions about HELLP syndrome

HYPERTENSION IN PREGNANCY

Systolic and diastolic BP both decline early in the first trimester, reaching a nadir by 24–28 weeks; then they gradually rise toward term but never return quite to prepregnancy baseline. Diastolic falls more than systolic, as much as 15 mm Hg. **Arterial BP is never normally elevated in pregnancy.**

Note

Refer to Physiologic Changes in Pregnancy in chapter 1 for a review of normal BP during pregnancy.

GESTATIONAL HYPERTENSION

A 19-year-old primigravida is seen in the outpatient prenatal clinic for routine visit. She is at 32 weeks' gestation, confirmed by first trimester sonogram. She has no complaints. She denies headache, epigastric pain, or visual disturbances. She has gained 2 pounds since her last visit 2 weeks ago. On examination her blood pressure is 155/95 mm Hg, which is persistent on repeat check 10 minutes later. She has only trace pedal edema. A spot urine dipstick is negative.

Definition. Gestational hypertension is diagnosed with **sustained** elevation of BP ≥ 140/90 mm Hg after 20 weeks of pregnancy **without** proteinuria. BP returns to normal baseline postpartum.

Symptoms. No symptoms of preeclampsia are seen, e.g., headache, epigastric pain, visual disturbances. Physical findings are unremarkable for pregnancy.

Laboratory Abnormalities. Laboratory tests are unremarkable for pregnancy. Proteinuria is absent.

Diagnostic Tests. The key finding is sustained elevation of BP >140/90 mm Hg without proteinuria.

OB Triad

Gestational Hypertension

- Pregnancy >20 wk
- Sustained HTN
- No proteinuria

Management. Conservative outpatient management is appropriate. Close observation is prudent since 30% of patients will develop preeclampsia. Appropriate laboratory testing should be performed to rule out preeclampsia, e.g., urine protein, hemoconcentration assessment. Deliver by 40 weeks.

Differential Diagnosis. Preeclampsia should always be ruled out.

PREECLAMPSIA

OB Triad

Preeclampsia

- Pregnancy >20 wk
- Sustained HTN (>140/90 mm Hg)
- Proteinuria (≥300 mg/24 h)

A 21-year-old primigravida without severe features is seen in the outpatient prenatal clinic for routine visit. She is at 32 weeks' gestation, confirmed by first trimester sonogram. She denies headache, epigastric pain, or visual disturbances. She has gained 10 pounds since her last visit 2 weeks ago. On examination her BP is 155/95, and remains unchanged on repeat check in 15 min. She has 2+ pedal edema, and her fingers appear swollen. A spot urine dipstick shows 2+ protein.

Definition. Preeclampsia is **sustained BP** elevation in pregnancy **after 20 weeks'** gestation in the absence of preexisting hypertension.

Diagnostic Criteria. There are no pathognomic tests. The diagnostic dyad includes the following:

- **Sustained BP elevation** of ≥140/90 mm Hg.
- **Proteinuria** of ≥300 mg on a 24-h urine collection or protein/creatinine ratio of ≥0.3.

Risk Factors. Preeclampsia is found 8 times more frequently in **primiparas**. Other risk factors are multiple gestation, hydatidiform mole, diabetes mellitus, age extremes, chronic hypertension, and chronic renal disease.

Etiology/Pathophysiology. Pathophysiology involves **diffuse vasospasm** caused by (1) loss of the normal pregnancy-related refractoriness to vasoactive substances such as angiotensin; and (2) relative or absolute changes in the following **prostaglandin** substances: increases in the vasoconstrictor thromboxane along with decreases in the potent vasodilator **prostacyclin**. This vasospasm contributes to intravascular volume constriction and decreased perfusion of most organs including uteroplacental unit, kidneys, liver, brain, and heart. Decreased renal blood flow leads to decreased clearance of body metabolic wastes. Capillary injury leads to loss of intravascular volume into the interstitial space and subsequent edema.

Presenting Symptoms and Physical Examination. With preeclampsia without severe features the symptoms and physical findings, if present, are generally related to excess weight gain and fluid retention. Presence of new onset of persistent headache, epigastric pain, or visual disturbances would move the diagnosis from preeclampsia without severe features to preeclampsia with severe features.

Laboratory Abnormalities. Evidence of **hemoconcentration** is shown by elevation of hemoglobin, hematocrit, blood urea nitrogen (BUN), serum creatinine, and serum uric acid. **Proteinuria** is present (described under diagnostic criteria). Evidence of disseminated intravascular coagulation (**DIC**) or liver enzyme elevation would move the diagnosis from preeclampsia without severe features to preeclampsia with severe features.

Management. The only definitive cure is delivery and removal of all fetal-placental tissue. However, delivery may be deferred in preeclampsia without severe features to minimize neonatal complications of prematurity. Management is based on gestational age.

- **Conservative management.** Before 37 weeks' gestation as long as mother and fetus are stable, mild preeclampsia is managed in the hospital or as outpatient, watching for possible progression to severe preeclampsia. No antihypertensive agents or $MgSO_4$ are used.
- **Delivery.** At ≥37 weeks' gestation, delivery is indicated with dilute IV oxytocin induction of labor and continuous infusion of IV $MgSO_4$ to prevent eclamptic seizures.

Complications. Progression from preeclampsia without severe features to preeclampsia with severe features may occur.

Differential Diagnosis. Chronic hypertension should always be ruled out.

PREECLAMPSIA WITH SEVERE FEATURES

A 21-year-old primigravida is seen in the outpatient prenatal clinic for a routine visit. She is at 32 weeks' gestation, confirmed by first trimester sonogram. For the past 24 h she had experienced severe, unremitting occipital headache, and mid-epigastric pain not relieved by acetaminophen, and she has also seen light flashes and spots in her vision. She has gained 10 pounds since her last visit 2 weeks ago. On examination her BP is 165/115. She has 2+ pedal edema, and her fingers appear swollen. Fundal height is 29 cm. Fetal heart tones are regular at 145 beats/min. A spot urine dipstick shows 4+ protein.

Diagnostic Tests. The diagnosis is made on the basis of the finding of at least mild elevation of BP and mild proteinuria plus any one of the following:

- **Sustained BP** elevation of ≥160/110.
- **Evidence of maternal jeopardy.** This may include symptoms (headache, epigastric pain, visual changes), thrombocytopenia (platelet count <100,000/mL), doubling of liver transaminases, pulmonary edema, serum creatinine >1.1 mg/dL, or doubling of serum creatinine.
- **Edema** may or may not be seen.

Risk Factors. These are the same as preeclampsia with the addition of diseases with small vessel disease such as systemic lupus and longstanding overt diabetes.

Etiology/Pathophysiology. Pathophysiology is the same as preeclampsia but involves **severe diffuse vasospasm** and **more intense capillary injury** to where the ischemia demonstrates itself in overt, usually multiorgan system injury.

Presenting Symptoms. Presence of new onset of persistent headache, epigastric pain, or visual disturbances is characteristic of preeclampsia with severe features.

Laboratory Abnormalities. Evidence of **hemoconcentration** will be more severe. Proteinuria is described under diagnostic tests. Evidence of DIC and hepatocellular injury is characteristic of severe preeclampsia.

Note

Preeclampsia with severe features has many presentations.

Note

Quantification of proteinuria (e.g., ≥5 g on a 24-h urine collection) is no longer used as a finding indicating a severe feature of preeclampsia. Proteinuria may even be absent, yet the diagnosis still can be made if there is new onset of hypertension with evidence of maternal jeopardy.

OB Triad

Preeclampsia with Severe Features

- Pregnancy >20 wk
- Sustained HTN (>140/90 mm Hg)
- Headache or epigastric pain or visual changes

- Pregnancy >20 wk
- Sustained HTN (>140/90 mm Hg)
- DIC or ↑ liver enzymes or pulmonary edema

Management. Aggressive prompt delivery is indicated for preeclampsia with severe features at any gestational age with evidence of maternal jeopardy or fetal jeopardy. Main goals are seizure prevention and BP control.

- **Administer IV $MgSO_4$** to prevent convulsions. Give a 5-g loading dose, then continue maintenance infusion of 2 g/h. Continue IV $MgS0_4$ for 24 hours after delivery.
- **Lower BP** to diastolic values 90–100 mm Hg with IV hydralazine and/or labetalol. More aggressive BP control may jeopardize uteroplacental fetal perfusion.
- **Attempt vaginal delivery** with IV oxytocin infusion if mother and fetus are stable.
- Cesarean section is only for obstetric indications.

Conservative inpatient management may rarely be attempted in absence of maternal and fetal jeopardy with gestational age 26–34 weeks if BP can be brought <160/110 mm Hg. This should take place in an intensive care, tertiary-care setting. Continuous IV $MgSO_4$ should be administered, and maternal betamethasone should be given to enhance fetal lung maturity.

Complications. Progression from preeclampsia with severe features to eclampsia may occur.

Note

Because IUGR is managed similarly with and without preeclampsia, it has been removed as a finding indicating a severe feature of preeclampsia.

ECLAMPSIA

A 21-year-old primigravida is brought to the emergency department after suffering from a generalized tonic-clonic seizure at 32 weeks' gestation. The seizure was preceded by a severe headache. She lost control of her bowels and bladder. She has gained 10 pounds since her last prenatal visit 2 weeks ago. On examination she is unresponsive and in a postictal state. Her BP is 185/115, and a spot urine dipstick shows 4+ protein.

Definition. Eclampsia is the presence of **unexplained generalized seizures** in a hypertensive, proteinuric pregnant woman in the last half of pregnancy.

Risk Factors. These are the same as in preeclampsia. A primary seizure disorder does not predispose to eclampsia.

Etiology/Pathophysiology. Pathophysiology is **severe diffuse cerebral vasospasm** resulting in cerebral perfusion deficits and cerebral edema.

Presenting Symptoms. In addition to those of mild and severe preeclampsia, the most significant finding is **unexplained tonic-clonic seizures**.

Laboratory Abnormalities. These are the same as found with mild and severe preeclampsia.

Diagnosis. The diagnosis is made clinically with unexplained generalized seizures occurring in a hypertensive, proteinuric pregnant woman in the last half of pregnancy.

Management. The first step is to protect the mother's airway and tongue.

- **Administer $MgSO_4$** with an IV bolus of 5 g to stop seizures, continuing maintenance infusion rate of 2 g/h. Continue IV $MgS0_4$ for 24 hours after delivery.
- **Aggressive prompt delivery** is indicated for eclampsia at any gestational age after stabilization of the mother and the fetus. Attempt vaginal delivery with IV oxytocin infusion if mother and fetus are stable.
- **Lower diastolic BP** between 90 and 100 mm Hg with IV hydralazine and/or labetalol.

Complications. Intracerebral hemorrhage can occur with even death resulting.

Table 9-1. Preeclampsia–Eclampsia Spectrum

	Preeclampsia without Severe Features	Preeclampsia with Severe Features	Eclampsia
Symptoms	None	Headache or epigastric pain or visual changes	Unexplained convulsions
Sustained ↑ blood pressure	>140/90 mm Hg <160/110 mm Hg	At least >140/90 (if other findings) or >160/110 mm Hg	At least >140/90 mm Hg
Laboratory tests	Hemoconcentration >300 mg proteinuria in 24 hrs No DIC, normal liver function tests	Hemoconcentration, or DIC, or ↑ liver function tests	Hemoconcentration At least 1-2 + proteinuria
Other findings	None	Pulmonary edema	May or may not be present
Management	<36 wk: observe in hospital, no $MgSO_4$, or blood pressure meds ≥36 wks: prompt delivery	$MgSO_4$: prevent or treat convulsions Lower diastolic, BP to 90–100 mm Hg Prompt delivery: not necessarily Cesarean section	

CHRONIC HYPERTENSION WITH OR WITHOUT SUPERIMPOSED PREECLAMPSIA

A 35-year-old multigravida is seen in the outpatient prenatal clinic for her first prenatal visit. She is at 12 weeks' gestation with a BP of 155/95. Chronic hypertension was diagnosed 5 years ago for which she has been treated with oral nifedipine. A spot urine dipstick protein is 2+. A recent 24-h urine collection showed 1.2 g of protein and a creatinine clearance of 85 ml/min. Serum creatinine is 1.2 mg/dl. She has no complaints of headache or visual changes.

Risk Factors. Most chronic hypertension (HTN) is **idiopathic** without specific antecedents. Risk factors are obesity, advanced maternal age, positive family history, renal disease, diabetes, and systemic lupus erythematosus.

Etiology/Pathophysiology. Pathophysiology is **vasospasm** causing **decreased end-organ perfusion**, resulting in injury and damage. The acute problems arise from excessive systolic pressures, whereas the long-term problems arise from excessive diastolic pressures.

OB Triad

Chronic HTN

- Pregnancy <20 wk or prepregnancy
- Sustained HTN (>140/90 mm Hg)
- +/– proteinuria

Diagnosis. The diagnosis of chronic HTN is made when BP ≥140/90 mm Hg with onset before the pregnancy or before 20 weeks' gestation.

Pregnancy Prognosis with Chronic HTN:

- **Good.** Favorable maternal and neonatal outcome is found when BP 140/90–179/109 mm Hg and no evidence of end-organ damage.
- **Poor.** Pregnancy complications are more common in patients with severe HTN with the following end-organ damage: cardiac, renal, and retinal.
  - **Renal disease.** Pregnancy loss rates increase significantly if serum creatinine value are >1.4 mg/dL.
  - **Retinopathy.** Longstanding HTN is associated with retinal vascular changes including hemorrhages, exudates, and narrowing.
  - **Left ventricular hypertrophy.** This is seen mostly in women with prolonged BP values >180/110 mm Hg.
- **Worst.** Tenfold higher fetal loss rate if uncontrolled HTN (before conception or early in pregnancy) and chronic HTN with superimposed preeclampsia.

OB Triad

Chronic HTN with Superimposed Preeclampsia

- Chronic HTN
- Worsening BP
- Worsening proteinuria

Chronic HTN with Superimposed Preeclampsia:

- This complication occurs in 25% of patients with chronic HTN. Risk factors include renal insufficiency, HTN for previous 4+ years, and HTN in a previous pregnancy.
- Adverse pregnancy outcomes for both mother and baby are markedly increased. Abruptio placenta incidence is markedly increased.
- The diagnosis is made on the basis of established chronic HTN along with any of the following: documented **rising BP values**; demonstrated **worsening proteinuria**; or evidence of **maternal jeopardy** (headache, epigastric pain, visual changes, thrombocytopenia [platelet count <100,000/mL], elevated liver enzymes, pulmonary edema, oliguria [<750 mL/24 h], or cyanosis). Edema may or may not be seen.

Laboratory Abnormalities. Chronic HTN patients have a spectrum of etiologies and disease severity. Those with mild HTN and no end-organ involvement have normal laboratory tests, whereas those with renal disease may have evidence of decreased renal function including proteinuria, lowered creatinine clearance, and elevated BUN, creatinine, and uric acid.

Antihypertensive Drug Therapy Issues

- **Discontinue medications.** This may be done in patients with mild-to-moderate HTN caused by the normal decrease in BP that occurs in pregnancy. Pharmacologic treatment in patients with diastolic BP <90 mm Hg or systolic BP <140 mm Hg does not improve either maternal or fetal outcome.
- **Maintain medications.** This may be necessary in patients with severe HTN. The drug of choice is methyl-dopa because of extensive experience and documented fetal safety. Labetalol and atenolol are acceptable alternatives. However, β-blocking agents are associated with intrauterine growth retardation (IUGR).
- **"Never use" medications.** Angiotensin-converting enzyme inhibitors are contraindicated in pregnancy, as they have been associated with fetal hypocalvaria, renal failure, oligohydramnios, and death. **Diuretics** should not be initiated during pregnancy owing to possible adverse fetal effects of associated plasma volume reduction.
- **BP target range.** Reduction of BP to normal levels in pregnancy may jeopardize uteroplacental blood flow. Maintain diastolic values between **90 and 100 mm Hg**.

Management

Conservative outpatient management is appropriate with uncomplicated mild-to-moderate chronic HTN.

- **Stop drug therapy.** Attempt discontinuation of antihypertensive agents. Follow guideline outlined.
- **Serial sonograms** and antenatal testing is appropriate after 30 weeks' gestation to monitor for increased risk of IUGR.
- **Serial BP and urine protein** assessment is indicated for early identification of superimposed preeclampsia.
- **Induce labor at 39 weeks** if the cervix is favorable.

Aggressive prompt delivery is indicated for chronic HTN with superimposed preeclampsia at any gestational age.

- Administer IV **$MgSO_4$** to prevent convulsions. Continue IV $MgS0_4$ for 24 hours after delivery.
- **Keep diastolic BP** between 90 and 100 mm Hg with IV hydralazine and/or labetalol.
- Attempt **vaginal delivery** with IV oxytocin infusion if mother and fetus are stable.

Complications. Progression from chronic HTN to superimposed preeclampsia, which can lead to maternal and fetal death.

HELLP SYNDROME

A 32-year-old multigravida is at 32 weeks' gestation. At a routine prenatal visit her BP was noted to be 160/105. Previous BP readings were normal. Preeclampsia workup was begun and revealed the following: elevated total bilirubin, lactate dehydrogenase, alanine aminotransferase, and aspartate aminotransferase, as well as platelet count of 85,000. She has no complaints of headache or visual changes.

Definition. HELLP syndrome occurs in 5–10% of preeclamptic patients and is characterized by hemolysis (**H**), elevated liver enzymes (**EL**), and low platelets (**LP**).

Risk Factors. HELLP syndrome occurs twice as often in multigravidas as primigravidas.

Differential Diagnosis. It can be confused with thrombotic thrombocytopenic purpura and hemolytic uremic syndrome. HTN, although frequently seen, is not always present.

Management. Prompt delivery at any gestational age is appropriate. Use of maternal **corticosteroids** may enhance postpartum normalization of liver enzymes and platelet count.

Complications. Conditions that are associated with HELLP syndrome include DIC, abruptio placenta, fetal demise, ascites, and hepatic rupture.

OB Triad

HELLP Syndrome

- Hemolysis
- ↑ liver enzymes
- ↓ platelets

Medical Complications in Pregnancy 10

Learning Objectives

- ❏ Describe the risks and special management of co-occurring medical conditions in pregnancy, including seizure disorders, DM, anemia, thyroid disease, cardiac disease, and liver disease
- ❏ Manage common infections occurring in pregnancy including urinary tract infections, pyelonephritis, cystitis, bacteriuria, and asymptomatic bacteriuria
- ❏ Give an overview of diagnosis and management of thrombophilias and antiphospholipid syndrome

CARDIAC DISEASE

A 30-year-old multigravida with a childhood history of rheumatic fever has echocardiography-diagnosed mitral stenosis. She is now at 20 weeks' gestation and has no symptoms at rest but has mild shortness of breath and dyspnea with activity. On examination she has a diastolic murmur.

Definition. General types of heart disease:

- **Coronary heart disease.** This condition is rarely found in women of childbearing age. Adverse consequences of hypoxic heart disease include miscarriage, fetal death, preterm delivery, and increased perinatal morbidity and mortality.
- **Rheumatic heart disease.** The most common **acquired lesion** in pregnancy is rheumatic heart disease. The most common rheumatic heart disease is mitral stenosis. With severe stenosis (mitral valve area <2 cm^2), the main problem is **inadequate diastolic flow** from the left atrium to the left ventricle. Obstruction to left ventricular filling may lead to left atrial enlargement, pulmonary congestion, atrial fibrillation, and subacute bacterial endocarditis (SBE) with valvular vegetations causing thromboemboli. Tachycardia and increased plasma volume, which are normal changes of pregnancy, will only exacerbate these problems. Balloon valvuloplasty may need to be performed as a last resort.
- **Congenital heart disease.** The **most common congenital** lesions are atrial (ASDs) and ventricular septal defects (VSDs). The **most common cyanotic** congenital heart disease in pregnancy is tetralogy of Fallot. ASDs and VSDs are tolerated well with pregnancy, as are any regurgitation lesions.

Maternal Mortality Risk

- **Low maternal mortality** (<1% risk of death): ASD, VSD, patent ductus arteriosus (PDA), minimal mitral stenosis, porcine heart valve, and corrected tetralogy of Fallot.
- **Intermediate maternal mortality** (5–15% risk of death): mitral stenosis with atrial fibrillation, artificial heart valve, uncorrected tetralogy of Fallot, and Marfan syndrome with normal aortic root diameter.
- **High maternal mortality** (25–50% risk of death): pulmonary hypertension, Eisenmenger's syndrome, Marfan syndrome with aortic root >40 mm diameter, and peripartum cardiomyopathy.

Unique High-Risk Conditions

Eisenmenger syndrome

This condition is characterized by pulmonary hypertension and a bidirectional intra-cardiac shunt. The normal decrease in systemic vascular resistance (SVR) in pregnancy places the patient at risk for having the pulmonary vascular resistance (PVR) exceed the SVR. When this develops, the path of least resistance for blood from the right heart is to bypass the pulmonary circulation across the shunt. This results in the left heart pumping unoxygenated blood into the systemic circulation, resulting in a 50% mortality risk. Management is by avoiding hypotension.

Marfan syndrome

This is an autosomal dominant connective tissue disorder. In pregnancy, if the aortic root diameter is >40 mm, the risk of aortic dissection is high, placing the patient at a 50% mortality risk.

OB Triad

Peripartum Cardiomyopathy

- Late pregnancy or postpartum
- Multiparity
- Biventricular cardiac failure

Peripartum cardiomyopathy

In this condition, the patient has no underlying heart disease, but develops idiopathic biventricular cardiac decompensation between the last few weeks of pregnancy and the first few months postpartum. Risk factors include advanced maternal age, multiparity, hypertension, and multiple pregnancy. Mortality rate is 75% if reversal does not occur within 6 months. Management is supportive, intensive care unit (ICU) care.

Classification of Heart Disease in Pregnancy

Following are the **New York Heart Association** (NYHA) functional classifications of heart disease in pregnancy:

- Class I—no signs or symptoms of cardiac decompensation with physical activity
- Class II—no symptoms at rest, but minor limitations with activity
- Class III—no symptoms at rest, but marked limitations with activity
- Class IV—symptoms present at rest, increasing with any physical activity

Signs of Heart Disease

- Any diastolic or continuous heart murmur
- Any systolic murmur associated with a thrill
- Any severe arrhythmias
- Unequivocal cardiac enlargement

General Principles in Pregnancy Management of Rheumatic Mitral Heart Disease

- Minimize tachycardia.
- Minimize excessive intravascular volume.

Specific Management

- **Antepartum.** Left lateral rest, 2 g sodium diet, digitalis as indicated, diuretics as indicated, avoid strenuous activity, avoid anemia, fetal echocardiogram (if patient has congenital heart disease).
- **Intrapartum.** Aim for vaginal delivery, left lateral rest, monitor intravascular volume, administer oxygen, reassurance, sedation, SBE prophylaxis, epidural, no pushing, elective forceps to shorten the second stage of labor, possible arterial line and pulmonary artery catheter (if Class III or IV status).
- **Postpartum.** Watch closely for postpartum intravascular overload caused by sudden emptying of uterine venous sinuses after placental delivery.

Table 10-1. Heart Disease in Pregnancy

Diagnosis	Problems	Management
Rheumatic mitral stenosis	↓ diastolic filling time	↓ HR; ↓ IV vol
ASD, VSD	Regurgitation	Conservative
Tetralogy of Fallot corrected	No problem	Conservative
Eisenmenger syndrome	1 Pulmonary HTN 2 Intracardiac shunt	Avoid hypotension
Marfan syndrome	Dilated aortic root External diameter ≥4 cm	Surgical reconstruction
Peripartum cardiomyopathy	Biventricular cardiac failure	Supportive care

THYROID DISEASE

A 23-year-old primigravida is at 30 weeks' gestation. She has lost 4 pounds during the past 2 months. She states her heart "feels like it is racing," and her resting pulse is 135 beats/min. There is a noticeable tremor when she holds her arms out straight. Her eyes appear prominent and protruding. She is complaining of frequent uterine contractions.

Normal Thyroid Physiology. Increased thyroid blood flow leads to thyromegaly. Increased glomerular filtration rate (GFR) in pregnancy enhances iodine excretion, lowering plasma iodine concentrations. Estrogen causes an increase in liver-produced thyroid binding globulin (TBG), thus increasing total T3 and T4. However, **free T3 and T4 remain unchanged**. Fetal thyroid function begins as early as 12 weeks with minimal transfer of T3 or T4 across the placenta.

Hyperthyroidism

OB Triad

Graves Disease

- ↓ TSH level
- ↑ free T_4 level
- TSHR-Ab

Underlying etiology may be Graves disease, toxic nodular goiter (Plummer disease), hydatidiform mole, or toxic diffuse goiter.

- **If uncontrolled**, it is associated with increased spontaneous abortions, prematurity, intrauterine growth retardation (IUGR), and perinatal morbidity and mortality.
- **If controlled**, pregnancy outcome is not altered. Clinical features include elevated resting pulse, thyromegaly, exopthalmus, inadequate weight gain or even weight loss, and markedly elevated total and free T_4.
- **Thyroid storm** is a life-threatening hypermetabolic state presenting with pyrexia, tachycardia, and severe dehydration. **Management** is propylthiouracil (PTU), β-blocking agents, steroids, and iodine.

Graves disease

This is the most common kind of hyperthyroidism in pregnancy.

Pathophysiology. It is mediated by autoimmune production of thyrotropin-receptor antibodies (TSHR-Ab) that drives thyroid hormone production independent of thyrotropin (TSH). TSHR-Ab can cross the placenta, potentially causing fetal hyperthyroidism.

Diagnosis. The diagnosis is confirmed by elevated free T_4 and TSHR-Ab, as well as low TSH in the presence of clinical features described above.

Management

- **Antithyroid medications** are the first line of therapy in pregnancy, but can cross the placenta leading to fetal hypothyroidism. PTU and methimazole are thioamides that block thyroid hormone synthesis. Methimazole is an FDA pregnancy category D so should not be used in the first trimester, though it is acceptable in the second and third. PTU has a risk of liver failure (rare) so it should be used only in the first trimester.
- **Subtotal thyroidectomy** is primarily indicated when antithyroid medical therapy fails and is ideally performed in the second trimester.
- **Thyroid ablation** with radioactive iodine (I^{131}) is **contraindicated** because it can cross the placenta, destroying the fetal thyroid.

Hypothyroidism

This condition is most commonly a primary thyroid defect and often results in **anovulation and infertility**. If uncontrolled it is associated with spontaneous abortion; however, if pregnancy continues, the infant is healthy. If controlled with appropriate thyroid replacement, normal fertility and pregnancy outcomes are noted.

Diagnosis. Demonstration of an elevated TSH.

Management. Increase supplemental thyroid hormone by 30% in pregnancy.

OB Triad

Hypothyroidism

- ↑ TSH level
- ↓ free T_4 level
- Anovulation

Table 10-2. Thyroid Disorders in Pregnancy

	Hyperthyroid	Hypothyroid
Most common cause	Graves disease	Hashimoto's thyroiditis
Diagnostic criteria	↓ TSH, ↑ free T4 TSHR-antibody	↑ TSH, ↓ free T4
Complication if untreated	Thyroid storm, IUGR	Anovulation, spontaneous abortion
Outcome if properly treated	Normal pregnancy	Normal pregnancy
Treatment medications	1st trimester: PTU 2nd+3rd trimester: methimazole	Synthroid (↑ dose 30% above prepregnancy)

SEIZURE DISORDERS

A 25-year-old primigravida is 19 weeks' gestation. She has a 10-year history of generalized seizures poorly controlled requiring hydantoin and valproic acid. A triple marker screen result showed an elevated maternal serum alpha feto protein.

Significance. Prevalence of seizure disorders is 0.5% in women of childbearing age.

Classification:

- **Partial seizures** do not involve both hemispheres. They can be either **simple**, with no loss of consciousness, or **complex**, in which consciousness may be impaired.
- **Generalized seizures** involve both hemispheres. They can be either **absence** type, with duration <20 s (formerly called "petit mal"), or **tonic-clonic**, with duration lasting up to several minutes (formerly called "grand mal").

Effect of pregnancy on seizure disorder

- **Seizures unchanged.** Up to 25% of these women will experience deterioration of seizure control during pregnancy, with 75% seeing no change. The more severe the disorder, the more likely it will worsen.
- **Anticonvulsant metabolism increased.** Seizure medication clearance may be enhanced by higher hepatic microsomal activity, resulting in lower blood levels.

Effect of seizure disorder on pregnancy

Pregnancy complications are minimal with appropriate prenatal care and compliance with anticonvulsant medications.

Effect of anticonvulsants on fetus and infant

Congenital malformation rate is increased from 3% to >10%. In addition, cerebral palsy, seizure disorders, and mental retardation are increased in offspring of epileptic women. Maternal phenytoin use is associated with neonatal deficiency of vitamin K-dependent clotting factors: II, VII, IX, and X.

Management. Ensure extra **folic acid supplementation** before conception and during embryogenesis to minimize neural tube defects.

- **Anomaly screening.** Offer triple-marker screen and second trimester sonography to identify neural tube defects (NTDs) or other anomalies.
- **Drug monotherapy.** Use a single drug if possible, at the lowest possible dose, to ensure freedom from seizures.
- **Medication levels.** Monitor anticonvulsant levels each trimester and adjust dose as needed. Prevent seizures to minimize maternal and fetal hypoxia.

DIABETES

A 32-year-old Hispanic multigravida is at 29 weeks' gestation. Her 1-h 50-g glucose screen came back at 175 mg/dL. She is 60 inches tall and weighs 200 pounds. Her pregnancy weight gain has been 30 pounds thus far. Her previous babies weighed 3,800 and 4,200 g.

Definition. A pregnant woman is unable to maintain fasting (FBS) or postchallenge glucose values in the normal pregnant range before or after a standard 100-g glucose challenge.

Risk factors. Obesity, age >30 years, and **positive family history** are the most common risk factors for gestational diabetes. Other risk factors are fetal macrosomia, unexplained stillbirth or neonatal death, polyhydramnios, and previous traumatic delivery.

Classification by pathophysiology. Prevalence of glucose intolerance in pregnancy is 2–3%.

- Gestational diabetes mellitus (**GDM**) is the most common type with onset during pregnancy, usually diagnosed in the last half. Pathophysiology involves the diabetogenic effect of human placental lactogen (**hPL**), placental insulinase, cortisol, and progesterone. Thirty-five percent of women with GDM will develop overt diabetes within 5 to 10 years after delivery.
- **Type 1 DM** is juvenile onset, ketosis prone, insulin-dependent diabetes caused by pancreatic islet cell deficiency.
- **Type 2 DM** is adult onset, ketosis resistant, non–insulin-dependent diabetes caused by insulin resistance.

Table 10-3. Classification of Diabetes Mellitus by Pathophysiology

Gestational	Pregnancy onset	Insulin resistance
Type 1	Juvenile onset	Ketosis prone
Type 2	Adult onset	Insulin resistance

Table 10-4. White Classification of Diabetes in Pregnancy

Class A1	GDM with normal FBS not requiring insulin
Class A2	GDM with elevated FBS requiring insulin
Class B	Overt DM onset after age 20 years and duration <10 years
Class C	Overt DM onset age 10–19 years or duration 10–19 years
Class D	Overt DM onset before age 10 years or duration ≥20 years
Class E	Overt DM with calcified pelvic vessels
Class F	Overt DM with nephropathy
Class R	Overt DM with proliferative retinopathy

Screening. Screening is performed on **all pregnant women** 24–28 weeks' gestation when the anti-insulin effect of hPL is maximal. On patients with **risk factors** it is performed on the first prenatal visit then repeated at 24–28 weeks if initially negative.

- The screening test is a 1-h 50-g oral glucose challenge test (OGTT) with normal values being <140 mg/dL. This does not need to be in a fasting state.
- If screening value ≥140 mg/dL, then proceed to a definitive 3-h 100-g OGTT. If screening value ≥200 mg/dL, and an FBS is ≥95 mg/dl, GDM is diagnosed and no further OGTT testing is needed.

Diagnosis. The 3-h OGTT is performed on **all patients with an abnormal screening test**. Definitive diagnosis is based on an abnormal 3-h 100-g OGTT performed after an overnight fast. Four glucose values are obtained.

- Normal pregnant values are FBS <95 mg/dL, 1 h <180 mg/dL, 2 h <155 mg/dL, 3 h <140 mg/dL. **Impaired glucose tolerance** is diagnosed if only one value is abnormal. **GDM** is diagnosed if ≥2 values are abnormal.
- If the FBS is ≥125, overt diabetes is diagnosed and the 100-g glucose load should not be given.

Antepartum General Management

The most significant factor in management of diabetic pregnancies is achieving maternal euglycemia.

- **American Diabetes Association diet.** Educate patient regarding spreading calories evenly throughout the day, encourage complex carbohydrates. Eighty percent of patients with GDM can maintain glucose control with diet therapy.

- **Home blood glucose monitoring.** Patient checks her own blood glucose values at least four times a day with target values of FBS <90 mg/dL and 1 h after meal of <140 mg/dL.
- **Insulin therapy.** Start subcutaneous insulin with type 1 and type 2 DM and with GDM if home glucose values are consistently above the target range. Initial dose is based on pregnancy trimester.

  Total daily insulin units = actual body weight in kilograms × 0.8 (first trimester), 1.0 (second trimester), or 1.2 (third trimester)

  Insulin is divided with two thirds of total daily dose in morning (split into 2/3 NPH and 1/3 regular) and one third of total daily dose in evening (split into 1/2 NPH and 1/2 regular). Insulin is a large molecule and **does not cross the placenta**. Insulin requirements will normally increase through the course of the pregnancy. 15% of patients with GDM will require insulin.
- **Oral hypoglycemic agents.** These were contraindicated in the past because of concern that they would cross the placenta and cause fetal or neonatal hypoglycemia. **Glyburide** appears to cross the placenta minimally, if at all, and is being used for patients with GDM who cannot be controlled by diet alone.

Table 10-5. Gestational Diabetes

Questions	Criteria/Problems	Diag/Mgmt
1-hr 50g OGTT Screening test	<140 mg/dL	GDM ruled out
3-hr 100g OGTT Definitive diagnosis	≥2 values ↑	GDM diagnosed
Home glucose monitoring	Mean glucose values FBS >90; 1 hr pp >140	Start insulin or glyburide
Fetal demise risk factors	1: needs insulin or glyburide 2: HTN 3: previous demise	Starting 32 wk NST & AFI 2/wk
L&D problems	Arrest stage 1 or 2 Shoulder dystocia	CS if estimated fetal weight >4500 g
Post partum management	Prevent postpartum hemorrhage	FBS ≥126 mg/dL 2 hr 75 gm OGTT

Antepartum Overt Diabetes Management

- **Hemoglobin A_{1C}.** Obtain a level on the first visit to ascertain degree of glycemic control during the previous 60–120 days. Repeat levels each trimester.
- **Renal status.** Obtain an early pregnancy baseline 24-h urine collection for total protein and creatinine clearance.
- **Retinal status.** Obtain an early pregnancy ophthalmologic funduscopic evaluation for proliferative retinopathy.
- **Home blood glucose monitoring.** Patient checks her own blood glucose values at least 4 times a day with target values of FBS 60–90 mg/dL and 1 h after a meal of <140 mg/dL.

Preconception Anomaly Prevention

- **Anomaly risk.** Women with overt diabetes are at increased risk of fetal anomalies. This risk can be minimized by lifestyle modification.
- **Euglycemia.** Maintaining glucose values at normal levels reduces anomaly risk close to that of nondiabetes; start 3 months prior to discontinuing contraception.
- **Folate supplementation.** Folic acid, 4 mg a day, should be started 3 months prior to conception to prevent both fetal neural tube defects, as well as congenital heart defects.

Antepartum Fetal Assessment

- **Anomaly screening**. Anomalies are mediated through hyperglycemia and are highest with poor glycemic control during embryogenesis. **Anomalies are not increased in GDM** because hyperglycemia is not present in the first half of pregnancy. Most common fetal anomalies with overt DM are **NTD and congenital heart disease**. An uncommon anomaly, but one highly specific for overt DM, is **caudal regression syndrome**. Obtain a **quadruple-marker screen** at 16–18 weeks to assess for NTD as well as a targeted ultrasound at 18–20 weeks to look for structural anomalies. If the glycosylated hemoglobin is elevated, order a fetal echocardiogram at 22–24 weeks to assess for congenital heart disease.
- **Fetal growth.** Monthly sonograms will assess fetal macrosomia (most commonly seen) or IUGR (seen with longstanding DM and vascular disease).
- **Fetal surveillance.** Start weekly NSTs and amniotic fluid index (AFIs) at **32 weeks** if taking insulin, macrosomia, previous stillbirth, or hypertension. Start NSTs and AFIs at **26 weeks** if small vessel disease is present or there is poor glycemic control. Biophysical profiles can be performed at the time of monthly sonograms.

Intrapartum Management

- **Timing of delivery.** Fetal maturity is often delayed in fetuses of diabetic mothers, yet prolonging the pregnancy may increase the risk of stillbirth; delivery planning is a result of balancing these factors. The target delivery gestational age is 40 weeks, but may be necessary earlier in the presence of fetal jeopardy and poor maternal glycemic control. An amniotic fluid lecithin to sphingomyelin **(L/S) ratio of 2.5** in the presence of **phosphatidyl glycerol** assures fetal lung maturity.
- **Mode of delivery.** The cesarean section rate in diabetic pregnancies approaches 50% because of fetal macrosomia, arrest of labor, and concern regarding shoulder dystocia.
- **Glycemic control.** Maintain maternal blood glucose levels between 80 and 100 mg/dL using 5% dextrose in water and an insulin drip.

Postpartum Management

- **Postpartum hemorrhage.** Watch for uterine atony related to an overdistended uterus.
- **Hypoglycemia.** Turn off any insulin infusion because insulin resistance decreases with rapidly falling levels of hPL after delivery of the placenta. Maintain blood glucose levels with a sliding scale.

Neonatal Problems

- **Hypoglycemia** caused by persistent hyperinsulinemia from excessive prenatal transplacental glucose.
- **Hypocalcemia** caused by failure to increase parathyroid hormone synthesis after birth.
- **Polycythemia** caused by elevated erythropoietin from relative intrauterine hypoxia.
- **Hyperbilirubinemia** caused by liver immaturity and breakdown of excessive neonatal red blood cells (RBCs).
- **Respiratory distress syndrome** caused by delayed pulmonary surfactant production.

ANEMIA

An 18-year-old woman G3 P2 had prenatal laboratory tests drawn when she was seen for her first prenatal visit at 18 weeks' gestation. The complete blood count showed the following: hemoglobin 9.5 g/dL, hematocrit 28%, MCV 75, and RDW 17.0. Her first child was delivered 2 years ago, with her second child born 1 year ago.

Definition. A hemoglobin concentration of <10 g/dL during pregnancy or the puerperium. This is less than the 12 g/dL, which is the lower limits of normal in the nonpregnant woman.

OB Triad

Iron Deficiency Anemia

- Hemoglobin <10 g
- MCV <80 μm^3
- RDW >15%

Iron Deficiency Anemia

This is a nutritional anemia resulting in decreased heme production. It is the **most common** anemia in women because of **menstrual and pregnancy** needs.

Diagnosis. RBCs are microcytic and hypochromic. Hemoglobin <10 g/dL, MCV <80, RDW >15.

Pathophysiology. Falling hemoglobin values do not occur until complete depletion of iron stores in the liver, spleen, and bone marrow, which is followed by a decrease in serum iron with increase in total iron binding capacity (TIBC).

Pregnancy Requirements. A pregnant woman needs 800 mg of elemental iron, of which 500 mg goes to expand the RBC mass and 300 mg goes to the fetal-placental unit.

Risk Factors. Chronic bleeding, poor nutrition, and frequent pregnancies.

Symptoms. Findings may vary from none to general malaise, palpitations, and ankle edema.

Fetal Effects. Increased IUGR and Preterm birth.

Treatment. $FeSO_4$ 325 mg po tid.

Prevention. Elemental iron 30 mg per day.

Folate Deficiency Anemia

This is a nutritional anemia resulting in decreased hemoglobin production.

Diagnosis. RBCs are macrocytic. Hemoglobin ≤10 g/dL, MCV >100, RDW >15. RBC folate levels are low. Peripheral smear may show hypersegmented neutrophils.

Pathophysiology. Folate stores in the body are usually enough for 90 days. Falling hemoglobin values do not occur until complete depletion of folate stores.

Risk Factors. Chronic hemolytic anemias (e.g., sickle cell disease), anticonvulsant use (phenytoin, phenobarbital), and frequent pregnancies.

Symptoms. Findings may vary from none to general malaise, palpitations, and ankle edema.

Fetal Effects. Increased IUGR ,Preterm birth and NTD.

Treatment. Folate 1 mg po daily.

Prevention. Folate 0.4 mg po daily for all women; 4 mg po daily for those at high risk for NTDs.

Sickle Cell Anemia

This is an inherited autosomal recessive disease resulting in normal production of abnormal globin chains.

Screening Test. These are peripheral blood tests used to detect the presence or absence of hemoglobin S. They do not differentiate between disease and trait.

Diagnostic Test. A hemoglobin electrophoresis will differentiate between SA trait (<40% hemoglobin S) or SS disease (>40% hemoglobin S).

Risk Factors. African and Mediterranean descent is the only significant risk factor for sickle cell anemia.

Effects on Pregnancy.

- **With SA,** the patient may have increased urinary tract infections (UTIs) but pregnancy outcome is not changed.
- **With SS**, the pregnancy may be complicated by increased spontaneous abortions, IUGR, fetal deaths, and preterm delivery.

Treatment. Avoid hypoxia, take folate supplements, and monitor fetal growth and well-being.

OB Triad

Folate Deficiency Anemia

- Hemoglobin <10 g
- MCV >100 μm^3
- RDW >15%

LIVER DISEASE

Intrahepatic Cholestasis of Pregnancy

A 31-year-old primigravida woman with a history of infertility underwent ovulation induction. She is now at 20 weeks' gestation with dizygotic twins of different genders. She is of Swedish descent and complains of intense skin-itching. She has not experienced these symptoms previously. Her sister experienced similar complaints when she was pregnant, and delivered her baby prematurely. No identifiable rash is noted on physical examination. She states that her urine appears dark-colored.

Pathophysiology. Intrahepatic cholestasis is stimulated by estrogen in genetically predisposed women in the second half of pregnancy. Risk is increased with twins.

Bile acids are incompletely cleared by the liver and accumulate in the plasma. The overall prevalence is 0.5% in North America and Europe. There is a high recurrence rate with subsequent pregnancies.

Findings. The most significant symptom is intractable pruritus on the palms and soles of the feet, worse at night, without specific skin findings.

- Laboratory tests show a mild elevation of bilirubin but diagnostic findings are serum bile acids increased 10- to 100-fold.

Outcome. No adverse effect on maternal outcome, but preterm births and stillbirths are increased

Management

- Oral antihistamines can be helpful in mild cases.
- Cholestyramine has been used to decrease enterohepatic circulation.
- Ursodeoxycholic acid is the treatment of choice. Antenatal fetal testing should be initiated at 34 weeks. Symptoms disappear after delivery.
- Induce labor at 38 weeks gestation.

Acute Fatty Liver

A 29 year-old primagravida is at 33 weeks' gestation. She is brought to the maternity unit by her husband who states she is becoming mentally confused. He reports she started experiencing nausea and vomiting 3 days ago which are becoming worse, associated with lack of appetite. Fundal height is 30 cm. Fetal heart rate is 145/min with non-reactive non-stress test. Her BP is 150/95 mm Hg. Random blood glucose is 52 mg/dL. Platelet count is 75,000. PTT is prolonged at 64.7 seconds. Creatinine is 2.1 mg/dL. Uric acid is 11.9 mg/dL, lactic dihydrogenase 1063 U/I, ALT 220 U/I, AST 350 U/I, total bilirubin 8.4 mg/dL. Serum ammonia is elevated. Urine protein dipstick is 3+.

Description. This is a rare life-threatening complication of pregnancy that usually occurs in the third trimester. Prevalence is 1 in 15,000. Maternal mortality rate is 20%. It is thought to be caused by a disordered metabolism of fatty acids by mitochondria in the fetus, caused by deficiency in the long-chain 3-hydroxyacyl-coenzyme A dehydrogenase (LCHAD) enzyme.

Findings. Symptom onset is gradual, with nonspecific flulike symptoms including nausea, vomiting, anorexia, and epigastric pain.

- Jaundice and fever may occur in as many as 70% of patients.
- Hypertension, proteinuria, and edema can mimic preeclampsia.
- This may progress to involvement of additional systems, including acute renal failure, pancreatitis, hepatic encephalopathy, and coma. Laboratory findings may include: moderate elevation of liver enzymes (e.g., ALT, AST, GGT), hyperbilirubinemia, DIC.
- **Hypoglycemia** and **increased serum ammonia** are unique laboratory abnormalities.

Management. Intensive care unit stabilization with acute IV hydration and monitoring is essential.

- Prompt delivery is indicated.
- Resolution follows delivery if mother survives.

URINARY TRACT INFECTION, PYELONEPHRITIS, AND BACTERIURIA

A 23-year-old primigravida at 31 weeks' gestation comes to the birthing unit with complaints of flank pain, nausea, vomiting, and shaking chills for the past 12 h. She has been diagnosed with sickle cell trait. On examination her temperature is 103°F, pulse 125 beats/min, and respirations 30 breaths/min. Her skin is grossly diaphoretic and she has exquisite right costovertebral angle tenderness. Electronic fetal monitoring shows baseline heart rate 170/min with reactivity. Uterine contractions are noted every 10 min.

Definition. UTI may involve either the **lower tract** (including the bladder or urethra) or the **upper tract** (including the kidney). The most common organisms are **gram-negative enteric bacteria** with *Escherichia coli* the most frequent.

Risk Factors. Pregnancy is a risk factor. Others include mechanical urinary obstructions and systemic diseases (such as sickle cell trait/disease, diabetes mellitus, and gout).

Asymptomatic Bacteriuria

This is the **most common** UTI in pregnancy.

Clinical Findings. No symptoms or signs are present.

Significance. If not treated, 30% of cases will develop acute pyelonephritis.

Diagnosis. Made with a positive urine culture showing >100K colony-forming units (CFU) of a single organism.

Treatment. Single-agent, outpatient oral antibiotics.

OB Triad

Asymptomatic Bacteriuria

- No urgency, frequency, or burning
- No fever
- Urine culture (+)

OB Triad

Acute Cystitis

- Urgency, frequency, and burning
- No fever
- Urine culture (+)

Acute Cystitis

This is a UTI localized to the bladder without systemic findings.

Clinical Findings. Urgency, frequency, and burning are common.

Significance. If not treated, 30% of cases will develop acute pyelonephritis.

Diagnosis. Made with a positive urine culture showing >100 K CFU of a single organism.

Treatment. Single-agent, outpatient oral antibiotics.

OB Triad

Acute Pyelonephritis

- Urgency, frequency, and burning
- Fever and costovertebral angle tenderness (CVAT)
- Urine culture (+)

Acute Pyelonephritis

This is a UTI involving the upper urinary tract with systemic findings. This is one of the **most common** serious medical complications of pregnancy.

Symptoms. Include shaking chills, anorexia, nausea, vomiting, and flank pain.

Signs. Include high fever, tachycardia, and costovertebral angle tenderness (R>L).

Significance. Preterm labor and delivery can occur. Severe cases are complicated by sepsis, anemia, and pulmonary dysfunction, sometimes requiring ICU care, including intubation.

Diagnosis. Confirmed with a positive urine culture showing >100 K CFU of a single organism.

Treatment. Hospital admission, generous IV hydration, parenteral antibiotics e.g., ceftriaxone, and tocolysis as needed.

THROMBOPHILIAS

A 26-year-old G4 P1 Ab2 woman comes in for her first prenatal visit at 8 weeks' gestation by dates. Her first pregnancy was a spontaneous first-trimester loss, for which she underwent a D&C. In her second pregnancy she developed right lower extremity deep venous thrombosis at 29 weeks, which was followed by an unexplained fetal demise at 30 weeks. Labor was induced with PGE2. The fetus was normal in appearance, without congenital anomalies. Autopsy on the fetus was unremarkable. Her last pregnancy was also a spontaneous first-trimester loss. Her sister has a history of recurrent deep venous thrombosis.

Description. The thrombophilias are a group of disorders that promote blood clotting, because of either an excess of clotting factors or a deficiency of anticlotting proteins that limit clot formation. Prevalence is as high as 20% of the population, but most individuals are asymptomatic. Some will develop deep vein thrombosis or venous thromboembolism (VTE) that can become life-threatening. Risk factors include immobilization, surgery, or pregnancy.

Pregnant women with a thrombophilia are also at higher risk than other pregnant women of developing a VTE. Pulmonary embolus is the leading cause of maternal death in the United States. More than half of pregnant women who develop a pulmonary embolus or other VTE have an underlying thrombophilia.

Diagnosis. Indications for testing are history of VTE or first-degree relative with high-risk thrombophilia or VTE age <50 years.

- **Inherited thrombophilias to test for**: Factor V Leiden (FVL) mutation, prothrombin gene mutation (PGM) G2021 OA, protein C deficiency (PCD), protein S deficiency (PSD), antithrombin deficiency (ATD)
  - **High risk** thrombophilias include homozygous FVL or PGM; compound heterozygote FVL & PTM; and all ATD
  - **Low risk** thrombophilias include heterozygous FVL or PGM; and all PCD & PSD
- **Acquired thrombophilias to test for:** Antiphospholipid Syndrome (APS).

  One or more of the following 3 antiphospholipid antibodies must be positive on ≥2 occasions at least 12 weeks apart.
  - Lupus anticoagulant
  - Anticardiolipin antibody (lgG & IgM)
  - Anti-β_2-glycoprotein 1 (lgG & IgM)

Treatment. Anticoagulation options:

- **Unfractionated heparin** (UFH) can be used antepartum & postpartum
  - Advantages: inexpensive, can be reversed with protamine sulfate,
  - Disadvantages: cannot use orally, short half-life, needs monitoring with aPTT levels, heparin-induced osteopenia, heparin-induced thrombocytopenia (HIT)
- **Low molecular weight heparin** (LMWH) can be used antepartum & postpartum
  - Advantages: longer half-life, less need for monitoring with antifactor Xa levels
  - Disadvantages: cannot use orally, higher cost, can not be reversed
- **Warfarin/coumadin** can be used only postpartum
  - Advantages: oral administration, long half-life, inexpensive, OK for breast feeding
  - Disadvantages: crosses placenta, needs monitoring with INR,

For anticoagulation medications, use the following guidelines:

Antepartum: Use LMWH from first trimester to 36 weeks; then at 36 weeks transition to UFH until delivery

- **None or prophylactic dose**
  - Low-risk thrombophilia without VTE episode
- **Prophylactic or intermediate-dose**
  - Low-risk thrombophilia with single VTE episode
  - High-risk thrombophilia without VTE episode
- **Therapeutic dose**
  - High-risk thrombophilia with single VTE episode
  - Any thrombophilia with VTE in current pregnancy

Intrapartum

- Discontinue UFH during immediate peripartum interval to decrease risk of hemorrhage and permit regional anesthesia
- Protamine sulfate can be used to reverse UFH effect

Postpartum

- VTE risk increased 20-fold in the first week postpartum.
- All patients at risk should be receive postpartum anticoagulation even if they did not receive it antepartum.
- Resume anticoagulation 6 hours after vaginal delivery and 12 hours after cesarean section.
- Coumadin is safe for breastfeeding moms

ANTIPHOSPHOLIPID SYNDROME (APS)

Definition: This is an autoimmune disorder defined by both the presence of characteristic clinical features and circulating antiphospholipid antibodies. Diagnosis requires that at least one clinical and one laboratory criterion are met.

Clinical Criteria for Diagnosis / Indications for Laboratory testing

- **Vascular thrombosis:** 1 or more clinical thrombotic episodes (arterial, venous, or small vessel)
- **Pregnancy morbidity (unexplained):** fetal demise: 1 or more at ≥10 weeks; consecutive miscarriages: 3 or more at <10 weeks

Laboratory criteria: 1 or more of the following 3 anti-phospholipid antibodies must be positive on ≥2 occasions at least 12 weeks apart.

- Lupus anticoagulant
- Anticardiolipin antibody (lgG & IgM)
- Anti-132-glycoprotein I (lgG & IgM)

Management:

Antepartum anticoagulation management:

- APS without a thrombotic event: no heparin or only prophylactic heparin
- APS with a thrombotic event: prophylactic heparin

General management for all women with APS:

- Antepartum: sono assessment of fetal growth monthly; modified Biophysical Profile weekly starting at 32 weeks
- Intrapartum: stop anticoagulation
- Postpartum: resume or start anticoagulation in 6 hours (after vaginal delivery) or 12 hours (after cesarean section); continue anticoagulation for 6 weeks using either heparin or coumadin (safe for breastfeeding moms); avoid estrogen-containing contraceptives

THROMBOEMBOLISM

The mediating factor is frequently endothelial injury from traumatic delivery or cesarean section. In the postpartum period, the risk is increased fivefold. Vascular stasis is the strongest predisposing factor with decreased pelvic and lower extremity blood flow. Enhanced blood coagulability in pregnancy is due to increased factors II, VII, VIII, IX, and X. Risk is even more elevated if the patient has coagulation protein deficiencies: antithrombin III, protein C, protein S, and plasminogen.

Superficial Thrombophlebitis

Superficial thrombophlebitis does not predispose to thromboembolism but may mimic more severe disease.

- **Findings:** Symptoms include localized pain and sensitivity. Signs include erythema, tenderness, and swelling. Diagnosis is one of exclusion after ruling out DVT.
- **Management**: Treatment is conservative: bed rest, local heat, NSAIDs.

Deep Venous Thrombosis (DVT)

DVT **does** predispose to thromboembolic disease. The site of thrombosis is typically in the lower half of the body. Half of cases occur in the pelvic veins and half occur in the lower extremities.

- **Findings:** Symptoms may include pain and increased skin sensitivity, but there may be no complaints. Signs may include calf pain on foot dorsiflexion (Homan sign), although these findings are not highly sensitive or specific. Diagnosis is by duplex Doppler.
- **Management:** Treatment is full anticoagulation with IV heparin to increase PTT by 1.5 to 2.5 times the control value. Subcutaneous heparin is used once therapeutic levels are achieved. No warfarin is used antepartum because of teratogenicity concerns with the fetus. Thrombophilia workup should be performed.

Pulmonary Embolus (PE)

PE is a potentially fatal result of DVT in which emboli travel through the venous system to the lungs. The source of the emboli is most commonly in the lower extremities or pelvis.

- **Findings:** Symptoms include chest pain and dyspnea (80%) but no single symptom(s) predominate because thrombi location varies. Physical and imaging findings include:
  - Tachypnea (90%)
  - **Chest x-ray** often normal
  - **ABG** showing low pO_2 (but often in the normal range)
  - **EKG** that may show tachycardia
  - Right axis deviation (but usually is normal)
- **Diagnosis** depends on the pulmonary imaging modalities used. Spiral CT scan of the chest is the best initial test for suspected PE. **Pulmonary angiography** is the most definitive diagnostic method; most common indication is a negative spiral CT scan in a high-risk and symptomatic patient.
- **Management**: Treatment is full anticoagulation (IV, SQ) heparin to increase PTT by 1.5 to 2.5 times the control value. No warfarin is used antepartum due to teratogenic concerns. Thrombophilia workup should be performed.

Disproportionate Fetal Growth 11

Learning Objectives

- ❏ Demonstrate understanding of intrauterine growth restriction
- ❏ Answer questions about macrosomia

INTRAUTERINE GROWTH RESTRICTION (IUGR)

Common Definition. Fetus with estimated fetal weight (EFW) <5–10th percentile for gestational age. This assumes the fetus is not growing to its genetic potential.

Birth Weight. Another definition is <2,500 grams (5 lb, 8 oz). Clearly, neonatal morbidity and mortality are affected by lowering birth weight. However, **70% of these fetuses are constitutionally small.**

Dating. Accurate early pregnancy dating is essential for making the diagnosis. An early sonogram (<20 weeks) is most accurate if conception date is unknown. **Don't change gestational age based on a late sonogram.**

Fetal Causes. Examples include aneuploidy (e.g., T21, T18, T13); infection (e.g., TORCH), structural anomalies (e.g., congenital heart disease, neural tube defects, ventral wall defects). These causes typically lead to **symmetric** IUGR.

Placental Causes. Examples include infarction, abruption, twin-twin transfusion syndrome (TTTS), velamentous cord insertion. These causes typically lead to **asymmetric** IUGR.

Maternal Causes. Examples include hypertension (e.g., chronic, preeclampsia), small vessel disease (e.g., SLE, long-standing type 1 diabetes), malnutrition, tobacco, alcohol, street drugs. These causes typically lead to **asymmetric** IUGR.

Symmetric IUGR

- All ultrasound parameters (HC, BPD, AC, FL) are smaller than expected.
- Etiology is **decreased growth potential**, i.e., aneuploidy, early intrauterine infection, gross anatomic anomaly.
- Workup should include detailed sonogram, karyotype, and screen for fetal infections.
- **Antepartum tests are usually normal.**

OB Triad

Symmetric IUGR

- Head and abdomen both small
- Etiology: fetal (aneuploidy, infection, anomaly)
- Decreased growth potential

OB Triad

Asymmetric IUGR

- Head normal; abdomen small
- Etiology: maternal-fetal (inadequate nutritional substrates)
- Decreased placental perfusion

Asymmetric IUGR

- Ultrasound parameters show **head sparing**, but **abdomen is small**.
- Etiology is **decreased placental perfusion** due to chronic maternal diseases (hypertension, diabetes, SLE, cardiovascular disease) or abnormal placentation (abruption and infarction).
- Amniotic fluid index is often decreased, especially if uteroplacental insufficiency is severe.
- **Monitoring** is with serial sonograms, non-stress test, amniotic fluid index, biophysical profile, and umbilical artery Dopplers.

MACROSOMIA

Definition. Fetus with estimated fetal weight (EFW) >90–95th percentile for gestational age. Birth weight ≥4,000–4,500 grams (8 lb, 13 oz to 9 lb, 15 oz).

Sonogram EFW. Accuracy in estimating birth weight is poor. Errors in prediction of EFW at term are ±400 grams.

Risk Factors. Gestational diabetes mellitus, overt diabetes, prolonged gestation, increase in BMI (obesity), increase in pregnancy weight gain, multiparity, male fetus.

Maternal Hazards. Operative vaginal delivery, perineal lacerations, postpartum hemorrhage (uterine atony), emergency cesarean section, pelvic floor injury.

Fetal Hazards. Shoulder dystocia, birth injury, asphyxia.

Neonatal Hazards. Neonatal intensive care admission, hypoglycemia, Erb palsy.

Prevention. No accurate ways of predicting or prevention are currently available.

Management. Consider elective cesarean (if EFW >4,500 g in diabetic mother or >5,000 g in nondiabetic mother) or early induction, but this may result in increased cesarean delivery rate due to failure of induction.

Antepartum Fetal Testing 12

Learning Objectives

- ❏ Describe the appropriate use antepartum fetal testing including nonstress test, amniotic fluid index, biophysical profile, contraction stress test, and umbilical artery Doppler

OVERVIEW

A 37-year-old multipara with systemic lupus erythematosus is at 31 weeks' gestation. She has chronic hypertension that is being controlled with methyldopa. She comes to the office stating her fetus is not moving as much as it used to.

Antenatal fetal tests are highly accurate in confirming fetal well-being but are poor predictors of fetal jeopardy. The most common reasons for fetal testing are decreased fetal movements, diabetes, post dates, chronic hypertension, and IUGR.

NONSTRESS TEST (NST)

This test assesses the frequency of fetal movements using an external fetal heart rate (FHR) monitoring device to detect the presence or absence of accelerations. These are abrupt increases in FHR above the baseline lasting <2 min and are unrelated to contractions. The criteria vary by gestational age:

- <32 weeks, the increase should be ≥10 beats/min lasting ≥10 s
- >32 weeks, the increase should be ≥15 beats/min lasting ≥15 s

They are mediated by the **sympathetic** nervous system and always occur in response to **fetal movements**. **Interpretation: accelerations are always reassuring**.

- **Reactive NST** requires the presence of 2 accelerations in a 20-min window of time meeting the above criteria. This is reassuring and highly predictive for fetal well-being. Fetal death rate is only 3 per 1,000 in the next week. **Management** is weekly NST.
- **Nonreactive NST** is diagnosed when any criteria for reactivity are not met: either the number of accelerations in 20 min or the amplitude or duration of the acceleration. Eighty percent of nonreactive NSTs are false positives (meaning the fetus is not hypoxemic). Nonhypoxemic causes include fetal sleep, prematurity, drug effects, and CNS anomalies. **Management** is fetal vibroacoustic stimulation to see whether this results in reactivity. If the NST is persistently nonreactive, perform a biophysical profile.

Table 12-1. Nonstress Test (NST)

Reactive NST	**Criteria:** ≥2 accelerations in 20 min: ↑ FHR ≥15 beats/min and lasting ≥15 seconds
	Assessment: reassuring of fetal well-being
	Follow-up: repeat weekly/biweekly
Nonreactive NST	**Criteria:** no FHR accelerations or did not meet criteria
	Assessment: sleeping, immature, or sedated fetus; acidotic, compromised fetus?
	Follow-up: VAS
	If still NR: do CST or BPP

Definition of abbreviations: BPP, biophysical profile; CST, contraction stress test; FHR, fetal heart rate; VAS, vibroacoustic stimulation.

AMNIOTIC FLUID INDEX

The 4-quadrant amniotic fluid index test assesses in centimeters the deepest single vertical amniotic fluid pocket in each of the 4 quadrants of the uterus. The sum of the pockets is known as the amniotic fluid index, or AFI. Interpretation is as follows:

<5 cm—oligohydramnios

5–8 cm—borderline

9–25 cm—normal

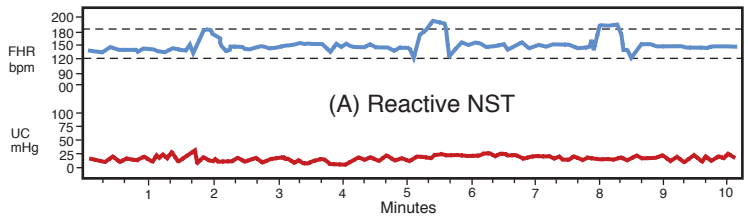
>25 cm—polyhydramnios

BIOPHYSICAL PROFILE (BPP)

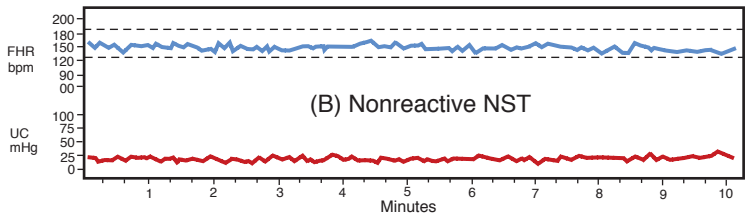
A complete BPP measures **5 components of fetal well-being:** NST, amniotic fluid volume, fetal gross body movements, fetal extremity tone, and fetal breathing movements. The last 4 components are assessed using obstetric ultrasound. Scores given for each component are 0 or 2, with maximum possible score of 10 and minimum score of 0.

- **Score of 8 or 10**—highly **reassuring** of fetal well-being. Management is to repeat the test weekly or as indicated. Fetal death rate is only 1 per 1,000 in the next week.
- **Score of 4 or 6—worrisome**. Management is delivery if the fetus is ≥36 weeks or repeat the biophysical profile in 12–24 h if <36 weeks. An alternative is to perform a CST.
- **Score of 0 or 2**—highly predictive of fetal **hypoxia** with low probability of false positive. Management is prompt delivery regardless of gestational age.

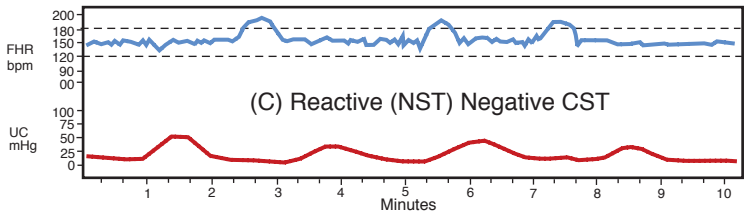
A **modified BPP** includes only the NST and amniotic fluid volume. Its predictive value is almost as high as a complete BPP.



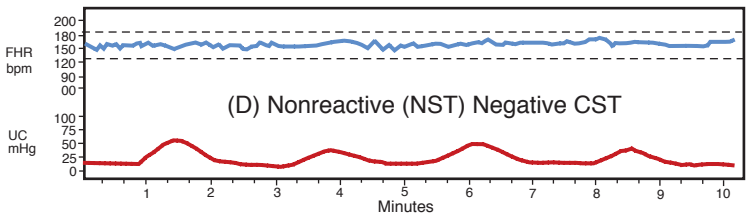
(A) Normal baseline range, and no UCs are present. Thus, only the NST component can be assessed. Because 3 accelerations are present, the assessment is reactive NST. **This is a reassuring tracing.**



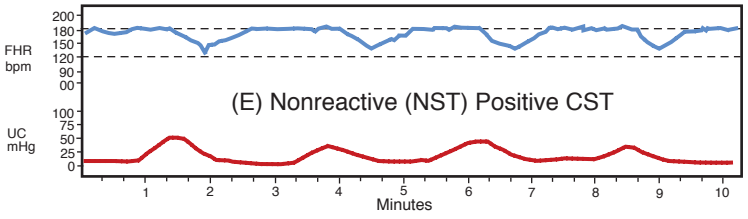
(B) Normal baseline range and no UCs are present. Thus, only the NST component can be assessed. Because no accelerations are present, the assessment is nonreactive NST. Because **this is not a reassuring tracing**, the next step should be a vibroacoustic fetal stimulation.



(C) Normal baseline range and 4 UCs are present in 10 minutes. Thus, both the NST and CST components can be assessed. Because 3 accelerations are present, and no late decelerations are present, the assessment is reactive NST, negative CST. This is a reassuring tracing.



(D) Normal baseline range and 4 UCs are present in 10 minutes. Thus, both the NST and CST components can be assessed. Even though no accelerations can be seen, no late decelerations are present. The assessment is nonreactive NST, negative CST. **This suggests fetal sleep, sedation, or central nervous system (CNS) abnormality.**



(E) Elevated baseline range and 4 UCs are present in 10 minutes. Thus, both the NST and CST components can be assessed. No accelerations can be seen, but repetitive late decelerations are present. The assessment is nonreactive NST, positive CST. **This is highly suggestive of fetal compromise.**

Figure I-12-1. Antepartum Electronic Fetal Monitor (EFM) Tracings

All EFM tracings should be evaluated for the nonstress test (NST) and the contraction stress test (CST). If a technically adequate fetal heart rate (FHR) tracing is present, the NST component can be assessed as reactive or nonreactive. If 3 or more uterine contractions (UCs) are present in 10 minutes, the CST components can be assessed as negative or positive.

CONTRACTION STRESS TEST (CST)

This test assesses the ability of the fetus to tolerate transitory decreases in intervillous blood flow that occur with uterine contractions. It uses both external FHR and contraction monitoring devices and is based on the presence or absence of **late decelerations**. These are **gradual** decreases in FHR below the baseline with onset to nadir of ≥30 s. The deceleration onset and end is **delayed** in relation to contractions. If 3 contractions in 10 min are not spontaneously present, they may be induced with either IV oxytocin infusion or nipple stimulation. This test is **rarely performed** because of the cost and personnel time required. The most common indication is a **BPP of 4 or 6**.

- **Negative CST** requires absence of any late decelerations with contractions. This is reassuring and highly reassuring for fetal well-being. Management is to repeat the CST weekly. Fetal death rate is only 1 per 1,000 in the next week.
- **Positive CST** is worrisome. This requires the presence of late decelerations associated with at least 50% of contractions. Fifty percent of positive CSTs are false positive (meaning the fetus is not hypoxemic). They are associated with good FHR variability. The 50% of true positives are associated with poor or absent variability. Management is prompt delivery.
- **Contraindications**—CST should not be performed whenever contractions would be hazardous to the mother or fetus. Examples include previous classical uterine incision, previous myomectomy, placenta previa, incompetent cervix, preterm membrane rupture, and preterm labor.

Table 12-2. Contraction Stress Test (CST)

Negative CST	No **late decelerations** are seen in the presence of 3 uterine contractions in 10 min
	Assessment: reassuring of fetal well-being
	Follow-up: repeat CST weekly as needed
Positive CST	Repetitive **late decelerations** are seen in the presence of 3 uterine contractions in 10 min
	Assessment: worrisome, especially if nonreactive non-stress test
	Follow-up: prompt delivery

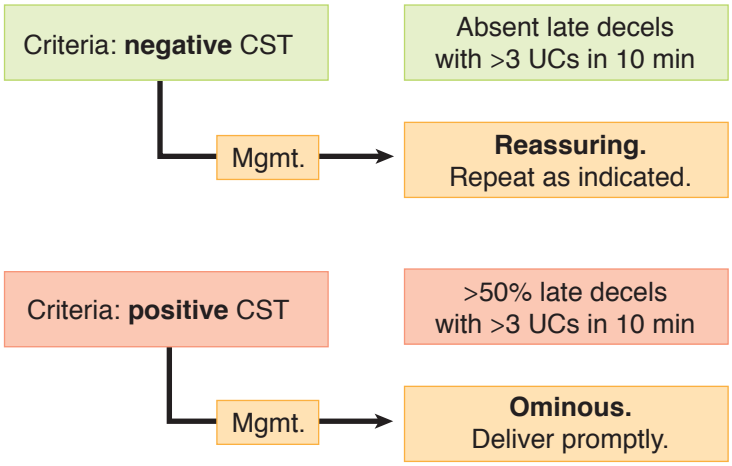


Figure I-12-2. Contraction Stress Test

UMBILICAL ARTERY DOPPLER

This test measures the ratio of systolic and diastolic blood flow in the umbilical artery. The umbilical circulation normally has low resistance, so significant diastolic blood flow is expected. The systolic/diastolic (S/D) ratio normally decreases throughout pregnancy.

This test is predictive of poor perinatal outcome only in IUGR fetuses. Nonreassuring findings, which may indicate need for delivery, are absent diastolic flow and reversed diastolic flow.

Fetal Orientation in Utero 13

Learning Objectives

- List the possible fetal orientations in utero and their relation to potential complications of delivery

ANATOMY OF THE BONY PELVIS

The **pelvis** is constructed of **4 bones**: ileum superior-laterally, ischium inferior-laterally, pubis anteriorly, and the sacrum and coccyx posteriorly. It is held together by the following **4 joints**: **bilateral sacroiliac joints**, the **symphysis pubis**, and the **sacrococcygeal joint**. The sacrum has 5 vertebrae joined together. The anterior superior edge of the first sacral vertebra is called the **sacral promontory**.

Landmarks. The pelvis is divided by the **linea terminalis** into the false pelvis above and the true pelvis below. The **false pelvis** is bordered by lumbar vertebrae posteriorly, by the iliac fossa laterally, and by the abdominal wall anteriorly. The **true pelvis** is a bony canal formed by posterior sacrum and coccyx, lateral ischial, and anterior pubis.

Types of Pelvic Shapes

Gynecoid shape is the classic female pelvis and is found in 50% of women. The inlet is a round oval with largest diameter transverse. It has straight side walls, well-curved sacrum, and spacious subpubic arch with a 90° angle. **Assessment:** This pelvis is **spacious** for the fetal head to pass through.

Android shape is the typical male pelvis and is found in 30% of women. The inlet is triangular with convergent side walls, shallow sacral curve, and narrow subpubic arch. **Assessment:** This pelvis is **restricted** at all levels. Arrest of descent in labor is common.

Anthropoid shape resembles that of anthropoid apes and is found in 20% of women. The inlet is larger anterior-posteriorly with side walls that converge. Subpubic arch is narrow. **Assessment:** The fetal head **engages anterior-posteriorly**, often in occiput posterior position, making **delivery difficult**.

Platypelloid shape is like a flattened gynecoid pelvis. The inlet is an elongated transverse oval. It has straight side walls with deep sacral curve and wide subpubic arch. **Assessment:** The fetal head **engages transversely and delivers occiput transverse position**.

ORIENTATION IN UTERO

Lie

Orientation of the long axis of the fetus to the long axis of the uterus. The **most common lie is longitudinal**. 99% of fetuses at term.

- **Longitudinal:** fetus and mother are in same vertical axis
- **Transverse:** fetus at right angle to mother
- **Oblique:** fetus at 45° angle to mother

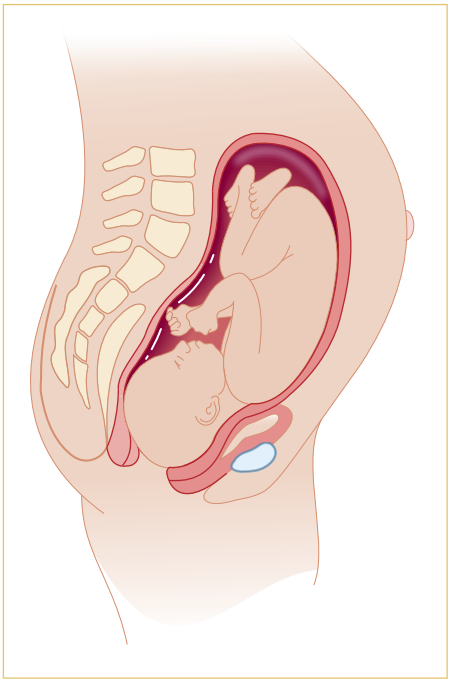

Figure I-13-1. Longitudinal Fetal Lie

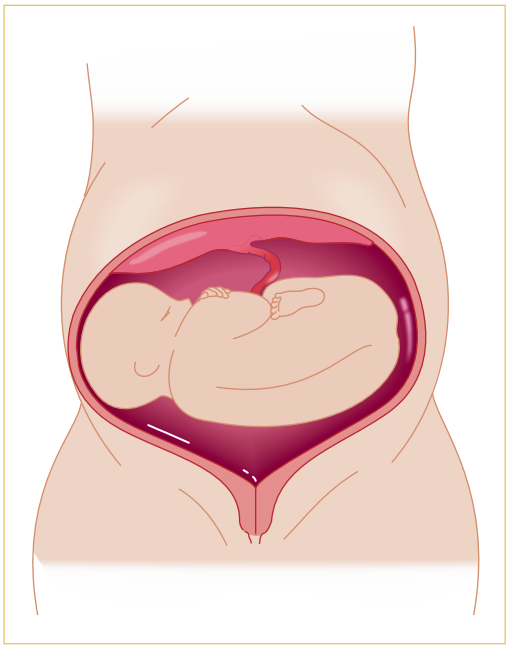

Figure I-13-2. Transverse Fetal Lie

Presentation

Portion of the fetus overlying the pelvic inlet. The **most common presentation is cephalic**. This is 96% of fetuses at term.

- **Cephalic:** head presents first
- **Breech:** feet or buttocks present first. The major risk of vaginal breech delivery is entrapment of the after-coming head.
  - **Frank** breech means thighs are flexed and legs extended. This is the only kind of breech that potentially could be safely delivered vaginally.
  - **Complete** breech means thighs and legs flexed.
  - **Footling** breech means thighs and legs extended.
- **Compound:** more than one anatomic part is presenting (e.g., head and upper extremity)
- **Shoulder:** presents first

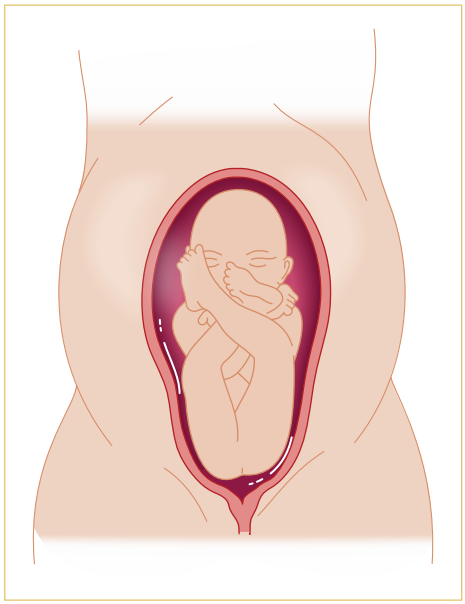

Figure I-13-3. Frank Breech

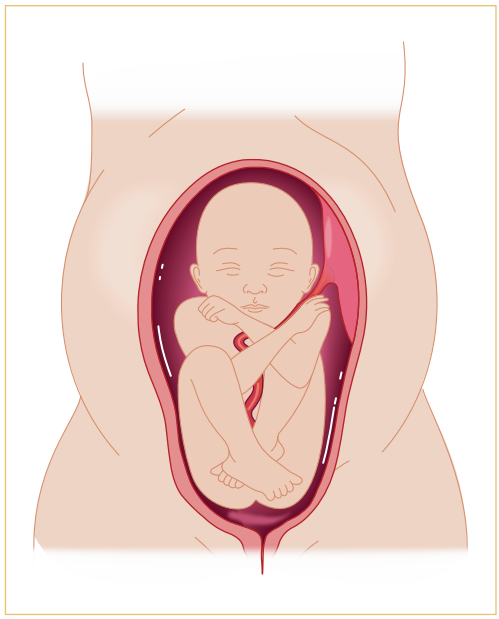

Figure I-13-4. Complete Breech

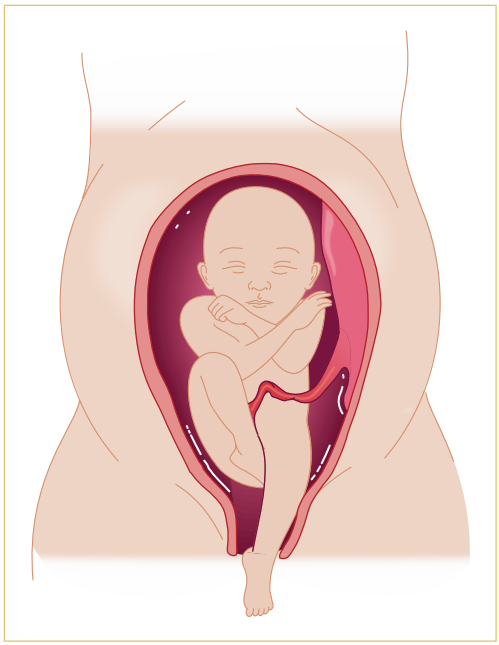

Figure I-13-5. Footling Breech

OB Triad

Breech Presentations

- Frank: thighs flexed, legs extended
- Complete: thighs and legs flexed
- Footling: thighs and knees extended

Position

Relationship of a definite presenting fetal part to the maternal bony pelvis. It is expressed in terms stating whether the orientation part is anterior or posterior, left or right. The **most common position at delivery is occiput anterior**.

- **Occiput:** with a flexed head (cephalic presentation)
- **Sacrum:** with a breech presentation
- **Mentum (chin):** with an extended head (face presentation)

Attitude

Degree of extension-flexion of the fetal head with cephalic presentation. The **most common attitude is vertex**.

- **Vertex:** head is maximally flexed
- **Military:** head is partially flexed
- **Brow:** head is partially extended
- **Face:** head is maximally extended

Station

Degree of descent of the presenting part through the birth canal; expressed in centimeters above or below the maternal ischial spine.

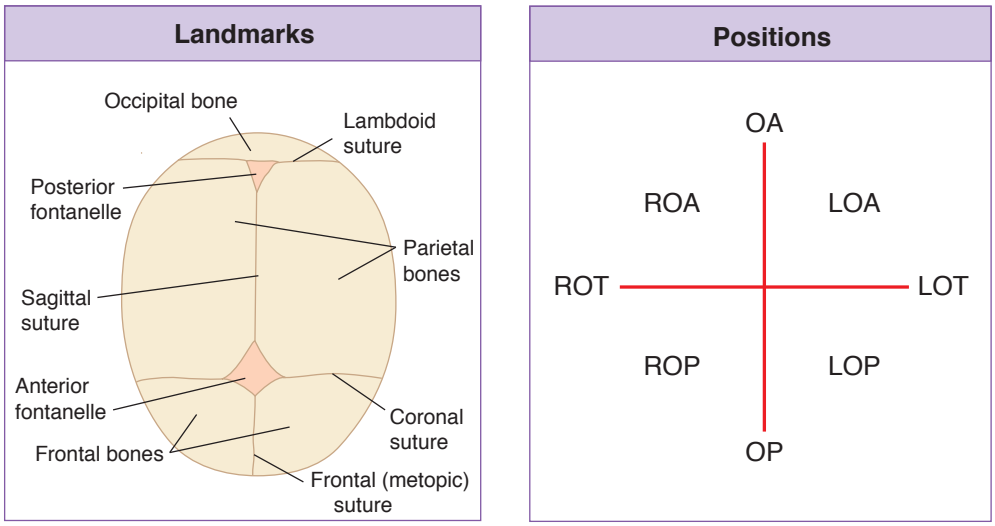

Figure I-13-6. Landmarks and Positions

Synclitism

The condition of parallelism between the plane of the pelvis and that of the fetal head.

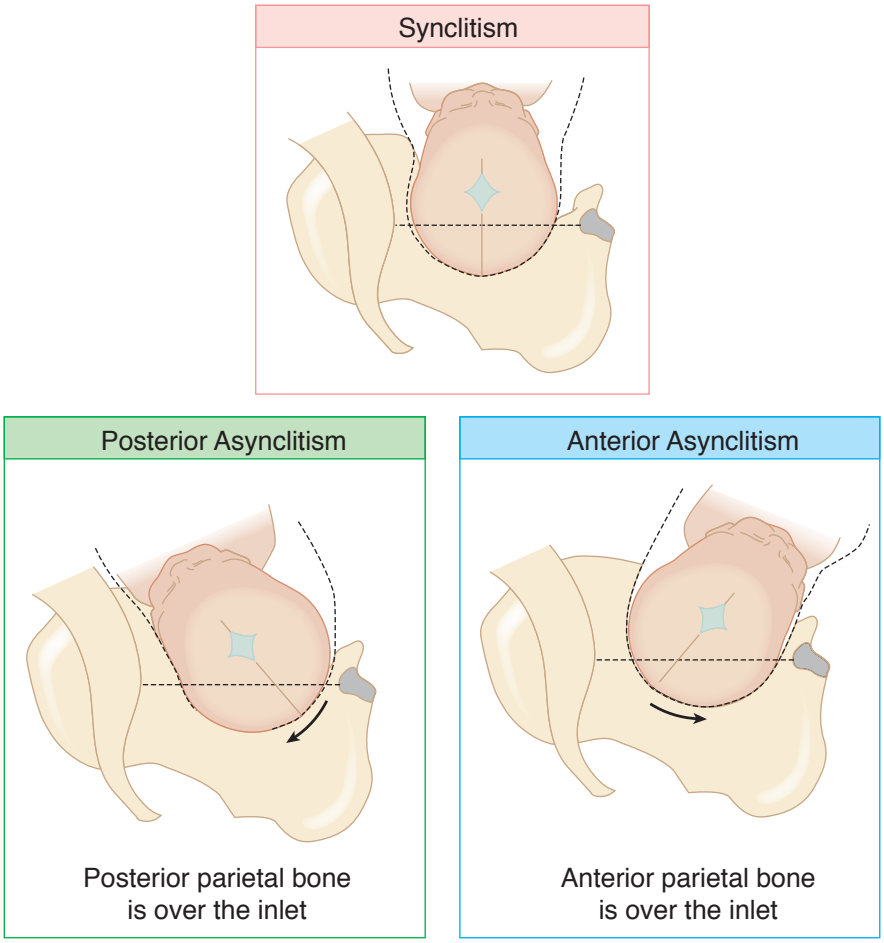

Figure I-13-7. Synclitism

Normal and Abnormal Labor 14

Learning Objectives

- ❏ List the normal stages of labor and abnormalities that can occur in the process
- ❏ Describe the risks and management of obstetric complications during labor

OVERVIEW OF LABOR

Labor is a process whereby over time regular uterine contractions bring about progressive effacement and dilation of the cervix, resulting in delivery of the fetus and expulsion of the placenta. Contractions will occur at least every 5 min lasting 30 s.

Physiology. Increasing frequency of contractions is associated with the formation of **gap junctions** between uterine myometrial cells. These events are correlated with increasing levels of **oxytocin** and **prostaglandins** along with multiplication of specific **receptors**.

Uterine Changes. The contractile **upper uterine segment**, containing mostly smooth muscle fibers, becomes thicker as labor progresses, exerting forces that expel the fetus down the birth canal. The **lower uterine segment**, containing mostly collagen fibers, passively thins out with contractions of the upper segment.

Cervical Effacement. Cervical softening and thinning occur as increasing levels of oxytocin and prostaglandins lead to breakage of **disulfide linkages** of collagen fibers, resulting in increasing water content. Effacement is often expressed in percentages with the uneffaced (0%) cervix assumed to be 2 cm long and 2 cm wide. Progressive shortening and thinning lead to full effacement (100%) in which the cervix has no length and is paper-thin.

Cervical Dilation. This occurs as the passive lower uterine segment is thinned and pulled up by the contractile upper segment. In early labor (latent phase), the rate of dilation is slow, but at 6 cm of dilation, the rate accelerates to a maximum rate in the active phase of labor. Complete dilation is expressed as 10 cm.

Cardinal Movements of Labor. The first 3 steps occur simultaneously.

- **Engagement:** movement of the presenting part below the plane of the pelvic inlet.
- **Descent:** movement of the presenting part down through the curve of the birth canal.
- **Flexion:** placement of the fetal chin on the thorax.

simultaneous

The next 4 steps occur in order.

- **Internal rotation:** rotation of the position of the fetal head in the mid pelvis from transverse to anterior-posterior.
- **Extension:** movement of the fetal chin away from the thorax.

- **External rotation:** rotation of the fetal head outside the mother as the head passes through the pelvic outlet.
- **Expulsion:** delivery of the fetal shoulders and body.

STAGES OF LABOR

Labor refers to the complex process through which uterine contractions bring about progressive dilation/opening and effacement/thinning of the cervix leading to descent of the fetus through the birth canal ending with expulsion of the neonate from the mother's body.

The classic studies in defining normal labor (Friedman, 1954) were conducted on 500 women at a single U.S. hospital in the 1950s. These studies established norms for various parts of labor that have been used by obstetricians for decades. Friedman's labor curves have dominated the obstetrical literature for 60 years. "Normal" labor was characterized as:

- Transition from latent to active labor occurring at 3-4 cm dilation
- Progress in active phase of labor was ≥1.2 cm/hr for nulliparas; ≥1.5 cm/hr for multiparas
- Length of second stage of labor was ≤3 hr for nulliparas; ≤1 hr for multiparas

Note

These Notes use current evidence-based management based on the Zhang labor data.

Over the past half-century, however, there have been marked increases in the average pregnant women's body-mass-index (BMI), along with modifications in obstetrical and anesthesia practices resulting in alterations in the typical progress of labor. These changes suggest the criteria for normal labor progress needs to be revised.

More recent studies (**Zhang et al, 2010**) are based on over 60,000 women in labor at 19 U.S. medical centers producing contemporary labor curves and norms that differ significantly from the older Friedman data.

Stage 1 begins with onset of regular uterine contractions and ends with complete cervical dilation at 10 cm. The precise identification when regular contractions began is often difficult. The first stage of labor is divided into a **latent** and an **active** phase.

Latent phase begins with onset of regular contractions and ends with the acceleration of cervical dilation. Its **purpose** is to soften and efface the cervix preparing it for rapid dilation. Minimal descent of the fetus through the birth canal occurs in this phase. The main abnormality is prolonged latent phase**. Latent phase rate of dilation is slower than previous studies showed and is similar in both multiparas and nulliparas.**

- Both nulliparas and multiparas may take more than 6 hours to dilate from 4 to 5 cm; and more than 3 hours to dilate from 5 to 6 cm.
- The upper limit of latent phase **duration** may be up to 20 h in a primipara and up to 14 h in a multipara.

Active phase begins with cervical dilation acceleration, usually by 6 cm of dilation, ending with complete cervical dilation. Its **purpose** is rapid cervical dilation. The **cardinal movements of labor occur** in the active phase with beginning descent of the fetus in the latter part. The main abnormality is Arrest of Active Phase. **The active phase dilation rate is more rapid in multiparas than nulliparas**.

- In a nullipara the average **rate of dilation** is 2 cm/h (abnormal would be <0.7 cm/hr)
- In a multiipara the average **rate of dilation** is 3 cm/h (abnormal would be <1.0 cm/hr)

Stage 2 begins with complete cervical dilation and ends with delivery of the fetus. Its **purpose** is descent of the fetus through the birth canal. Whereas in Stage 1 uterine contractions are the only force that acts on cervical dilation, in Stage 2 maternal pushing efforts are vitally important to augment the uterine contractions to bring about descent of the fetal presenting part. The **duration of stage 2** may be up to 3 h in a primipara and 2 h in a multipara. The main abnormality is prolonged second stage or arrest of descent.

Stage 3 begins with delivery of the fetus and ends with expulsion of the placenta. The mechanism of placental separation from the uterine wall is dependent on myometrial contractions shearing off the anchoring villi. This is usually augmented with IV oxytocin infusion. **Signs of the third stage** include gush of blood vaginally, change of the uterus from long to globular, "lengthening" of the umbilical cord. **Duration** may be up to 30 min in all women. The main abnormality is prolonged third stage.

Stage 4 is not an official stage of labor, but is a critical 2-h period of close observation of the parturient immediately after delivery. Vital signs and vaginal bleeding are monitored to recognize and promptly treat preeclampsia and postpartum hemorrhage.

Table 14-1. Stages of Labor

Labor Stage	Definition	Function	Duration
Stage 1—Latent phase Effacement	Begins: onset of regular uterine contractions Ends: acceleration of cervical dilation	**Prepares cervix for dilation**	<20 hours in primipara <14 hours in multipara
Stage 1—Active phase Dilation	Begins: acceleration of cervical dilation Ends: 10 cm (complete)	**Rapid cervical dilation**	≥0.7 cm/hours primipara ≥1.0 cm/hours multipara
Stage 2 Descent	Begins: 10 cm (complete) Ends: delivery of baby	**Descent of the fetus**	<3 hours in primipara <2 hours in multipara Add 1 hour if epidural
Stage 3 Expulsion	Begins: delivery of baby Ends: delivery of placenta	**Delivery of placenta**	<30 minutes

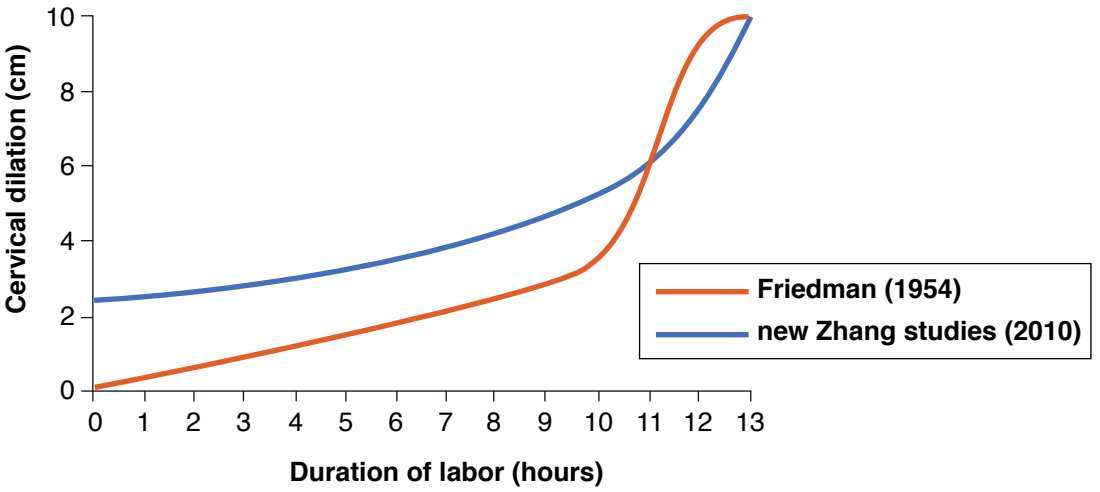

Figure I-14-1. Old versus New Labor Curves

CONDUCT OF NORMAL SPONTANEOUS LABOR

A 20-year-old primigravida comes to the maternity unit at 39 weeks' gestation complaining of regular uterine contractions every 3 min for the past 6 h. The contractions are becoming more frequent. She denies any vaginal fluid leakage. Vital signs are blood pressure is 125/75 mm Hg, pulse 80 beats/min, respirations 17 breaths/min. On pelvic examination the fetus is cephalic presentation at −1 station. Her cervix is 5 cm dilated, 90% effaced, and soft and anterior in position. On the electronic fetal monitor (EFM) the fetal heart rate baseline is 135 beats/min with moderate variability, frequent accelerations, and no decelerations. How will you manage this patient?

Preadmission

The parturient is not admitted to the maternity unit until cervical dilation is at least 3 cm, unless premature membrane rupture has occurred. Fetal presentation is confirmed to be cephalic.

Admission

On admission intravenous access is established, and oral clear liquid may be ingested. The patient is allowed whatever position is comfortable; however, the lateral recumbent position is encouraged as it optimizes uteroplacental blood flow.

First Stage

The fetal heart rate is assessed, usually with continuous electronic monitoring. Cervical dilation and fetal head descent are followed through appropriately spaced vaginal examinations. Amniotomy is performed in the active phase when the fetal head is well applied to the cervix. Obstetric analgesia is administered at patient request.

Second and Third Stages

Maternal pushing efforts augment uterine contractions in the second stage of labor. An episiotomy is not routine, but is performed as indicated. After delivery of the fetus, the placenta is allowed to spontaneously separate, after which IV oxytocin is administered to prevent uterine atony and bleeding.

Recovery Period

For the first 2 hours postpartum, the parturient is observed closely for excessive bleeding and development of preeclampsia.

ABNORMAL LABOR

Prolonged Latent Phase

> A 29-year-old multigravida at 40 weeks' gestation is being observed in the maternity unit. She states she has been having regular uterine contractions for 24 h but cervical dilation remains at 1–2 cm. Her vital signs are stable. EFM tracing is reassuring regarding fetal status.

Diagnosis. Prolonged latent phase requires that, in the face of regular uterine contractions, the cervical dilation is <6 cm for a duration of >20 h in a primipara or >14 h in a multipara.

Cause. Latent-phase abnormalities are most commonly caused by injudicious analgesia. Other causes are contractions, which are hypotonic (inadequate frequency, duration, or intensity) or hypertonic (high intensity but inadequate duration or frequency).

Management. This involves (a) therapeutic rest with narcotics or sedatives, (b) oxytocin administration or (c) amniotomy. Cesarean delivery is never appropriate management for prolonged latent phase.

OB Triad

Prolonged Latent Phase

- Pregnant with regular uterine contractions
- Cervix dilated 2 cm
- No cervical change in 14 h

Arrested Active Phase

> A 22-year-old primigravida at 39 weeks' gestation has progressed in labor to 8 cm of cervical dilation but has not changed for 3 h. Her vital signs are stable. EFM tracing is reassuring regarding fetal status.

Diagnosis. Arrested active phase is diagnosed if membranes are ruptured and cervical dilation has not changed for (a) ≥4 h with adequate uterine contractions or (b) ≥6 h of IV oxytocin administration with inadequate uterine contractions.

OB Triad

Active Phase Arrest

- Pregnant with regular uterine contractions
- Cervix dilated 8 cm
- No cervical change in 4 h

Causes. Active-phase abnormalities may be caused by either abnormalities of the **passenger** (excessive fetal size or abnormal fetal orientation in the uterus), abnormalities of the **pelvis** (bony pelvis size), or abnormalities of **powers** (dysfunctional or inadequate uterine contractions).

Management. This is directed at assessment of uterine contraction quality. Contractions should occur every 2–3 min, last 45–60 s with 50 mm Hg intensity. If contractions are hypotonic, IV oxytocin is administered. If contractions are hypertonic, give morphine sedation. If contractions are adequate, proceed to emergency cesarean section.

Prolonged Second Stage

A 20-year-old primigravida at 41 weeks' gestation has progressed in labor to 10 cm of cervical dilation and has been pushing for the past 3 hrs. The fetus is cephalic presentation, right occiput transverse position. The fetal head has not descended below +2 station. Her vital signs are stable. EFM tracing is reassuring regarding fetal status.

Diagnosis.

- **Nulliparous** women: After complete dilation, no progress in either **descent or rotation** of the fetus after ≥3 h without epidural anesthesia and ≥4 h with epidural anesthesia.
- **Multiparous** women: After complete dilation, no progress in either **descent or rotation** of the fetus after ≥2 h without epidural anesthesia and ≥3 h with epidural anesthesia.

Management. This involves assessment of uterine contractions and maternal pushing efforts. IV oxytocin can strengthen the contractions. Enhanced coaching to optimize maternal pushing should be utilized as needed. If they are both adequate, assess whether the fetal head is engaged. If the head is not engaged, proceed to emergency cesarean. If the head is engaged, consider a trial of either obstetric forceps or a vacuum extractor delivery.

Prolonged Third Stage

A 20-year-old primigravida at 39 weeks' gestation underwent a spontaneous vaginal delivery 40 min ago of a healthy 3,500-g daughter. However, the placenta has still not delivered. Her vital signs are stable.

Diagnosis. Failure to deliver the placenta within 30 minutes.

Cause. May be inadequate uterine contractions. If the placenta does not separate, in spite of IV oxytocin stimulation of myometrium contractions, think of abnormal placental implantation (e.g., placenta **accreta**, placenta **increta,** and placenta **percreta**).

Management. May require manual placental removal or rarely even hysterectomy.

OB Triad

Second-Stage Arrest

- Pregnant with regular uterine contractions
- 10 cm dilation at +1 station
- No descent change in 3 h

OBSTETRIC COMPLICATIONS DURING LABOR

Prolapsed Umbilical Cord

A 34-year-old multigravida with a known uterine septum comes to the maternity unit at 34 weeks' gestation complaining of regular uterine contractions. She underwent a previous cesarean at 37 weeks' gestation for breech presentation. Pelvic examination determines that the fetus is a footling breech. Her cervix is 6 cm dilated with bulging membranes. During the examination, the patient's bag of waters suddenly ruptures, and a loop of umbilical cord protrudes through the cervix between the fetal extremities.

OB Triad

Prolapsed Umbilical Cord

- Pregnant with regular uterine contractions
- Amniotomy at –2 station
- Severe variable decelerations

Umbilical cord prolapse is an obstetric emergency because if the cord gets compressed, fetal oxygenation will be jeopardized, with potential fetal death.

Prolapse can be **occult** (the cord has not come through the cervix but is being compressed between the fetal head and the uterine wall), partial (the cord is between the head and the dilated cervical os but has not protruded into the vagina), or **complete** (the cord has protruded into the vagina).

Risk Factors. Rupture of membranes with the presenting fetal part not applied firmly to the cervix, malpresentation.

Management. Do not hold the cord or try to push it back into the uterus. Place the patient in knee-chest position, elevate the presenting part, avoid palpating the cord, and perform immediate cesarean delivery.

Shoulder Dystocia

A 20-year-old primigravida at 39 weeks' gestation was pushing in the second stage of labor for 90 min and has just delivered the fetal head. However, in spite of vigorous pushing efforts by the mother, and moderate traction on the fetal head, you are unable to deliver the anterior shoulder. Since delivery of the fetal head, 30 s has passed. The fetal heart rate is now 70 beats/min.

OB Triad

Shoulder Dystocia

- Second stage of labor
- Head has delivered
- No further delivery of body

Diagnosis. This diagnosis is made when delivery of the fetal shoulders is delayed after delivery of the head. It is usually associated with fetal shoulders in the anterior-posterior plane, with the anterior shoulder impacted behind the pubic symphysis. It occurs in 1% of deliveries and may result in permanent neonatal neurologic damage in 2% of cases.

Risk Factors. Include **maternal diabetes**, obesity, and postdates pregnancy, which are associated with fetal macrosomia. Even though incidence increases with birth weight, half of shoulder dystocias occur in fetuses <4,000 grams.

Management. Includes suprapubic pressure, maternal thigh flexion (McRobert's maneuver), internal rotation of the fetal shoulders to the oblique plane (Wood's "corkscrew" maneuver), manual delivery of the posterior arm, and Zavanelli maneuver (cephalic replacement).

Obstetric Lacerations

Perineal lacerations are classified by the extent of tissue disruption between the vaginal introitus and the anus.

- **First degree:** involve only the vaginal mucosa. Suture repair is often not needed.
- **Second degree:** involve the vagina and the muscles of the perineal body but do not involve the anal sphincter. Suturing is necessary.
- **Third degree:** involve the vagina, the perineal body, and the anal sphincter but not the rectal mucosa. Suturing is necessary to avoid anal incontinence.
- **Fourth degree:** involve all the way from the vagina through to the rectal mucosa. Complications of faulty repair or healing include rectovaginal fistula.

Episiotomy

This is a surgical incision made in the perineum to enlarge the vaginal opening and assist in childbirth. It is one of the most common female surgical procedures. American trained physicians tend to prefer a midline episiotomy whereas British trained physicians tend to perform mediolateral episiotomies. It is not practiced routinely in the United States today because the arguments made in its favor **have not been shown** to have scientific support.

- **False arguments:** less perineal pain; more rapid return of sexual activity; less urinary incontinence; less pelvic prolapse.
- **Disadvantages:** more perineal pain than with lacerations; longer return to sexual activity; more extensions into the anal sphincter and rectum.
- **Possible indications:** shoulder dystocia, non-reassuring fetal monitor tracing, forceps or vacuum extractor vaginal delivery, vaginal breech delivery, narrow birth canal.

Obstetric Anesthesia 15

Learning Objectives

- ❏ Differentiate the physiology of anesthesia as applied to a pregnant versus a non-pregnant woman
- ❏ Describe possible anesthetic complications and management strategies

PHYSIOLOGY

Pain relief from uterine contractions and cervical dilation in **stage 1 of labor** involves thoracic nerve roots, T10 to T12. Pain relief from perineal distention in **stage 2 of labor** involves sacral nerve roots, S2 to S4.

- Pregnancy predisposes to hypoxia because of decreased functional residual capacity.
- Placental transfer of medications exposes the fetus to lipid-soluble anionic substances.
- Antacids should be given prophylactically because of delayed gastric emptying time in pregnancy.
- Uterus should be laterally displaced to avoid inferior vena cava compression in the supine position.

ANESTHETIC OPTIONS DURING LABOR

Intravenous Agents

This includes narcotics and sedatives, which are frequently given in the active phase of labor. **Advantages** include ease of administration and inexpensive cost. **Disadvantages** include neonatal depression if given close to delivery. The neonate may need administration of **naloxone** to reverse the effect.

Paracervical Block

This is a mode of conduction anesthesia that involves bilateral transvaginal local anesthetic injection to block **Frankenhauser's ganglion** lateral to the cervix. It is administered in the active phase of labor. **Disadvantages** include temporary high levels of local anesthetic in the uterus which may lead to **transitory fetal bradycardia**, which is managed conservatively.

OB Triad

Paracervical Block Effect

- Term pregnancy in active labor
- Local anesthetic injection into cervix
- Immediate fetal bradycardia

Pudendal Block

This is a mode of conduction anesthesia that involves bilateral transvaginal local anesthetic injection to block the pudendal nerve as it passes by the ischial spines. It is administered in stage 2 of labor to provide perineal anesthesia.

OB Triad

Epidural Block Side Effect

- Pregnancy in active labor
- Conduction anesthesia given
- ½ body numb; ½ body pain

Epidural Block

This is a mode of conduction anesthesia that involves injection of local anesthetic into the epidural space to block the lumbosacral nerve roots during both stages 1 and 2 of labor. **Advantages** include use for either vaginal delivery or cesarean section. **Disadvantages** include patchy block from nonuniform spread of the local anesthetic around the nerve roots. **Complications** include hypotension from peripheral vascular dilation owing to sympathetic blockade and spinal headache from inadvertent dural puncture, as well as CNS bleeding or infection (rare). Hypotension is treated with IV fluids and IV ephedrine. Spinal headache is treated with IV hydration, caffeine, or blood patch.

OB Triad

High Spinal (Intrathecal)

- Pregnancy in active labor
- Conduction anesthesia given
- Patient stops breathing

Spinal Block

This is a mode of conduction anesthesia that involves injection of local anesthetic into the subarachnoid space to block the lumbosacral nerve roots. It is used as a saddle block for stage 2 of labor and for cesarean delivery. **Advantages** are complete predictable anesthesia. **Complications** include hypotension from peripheral vascular dilation because of sympathetic blockade (common) and spinal headache (rare), as well as CNS bleeding or infection (rare).

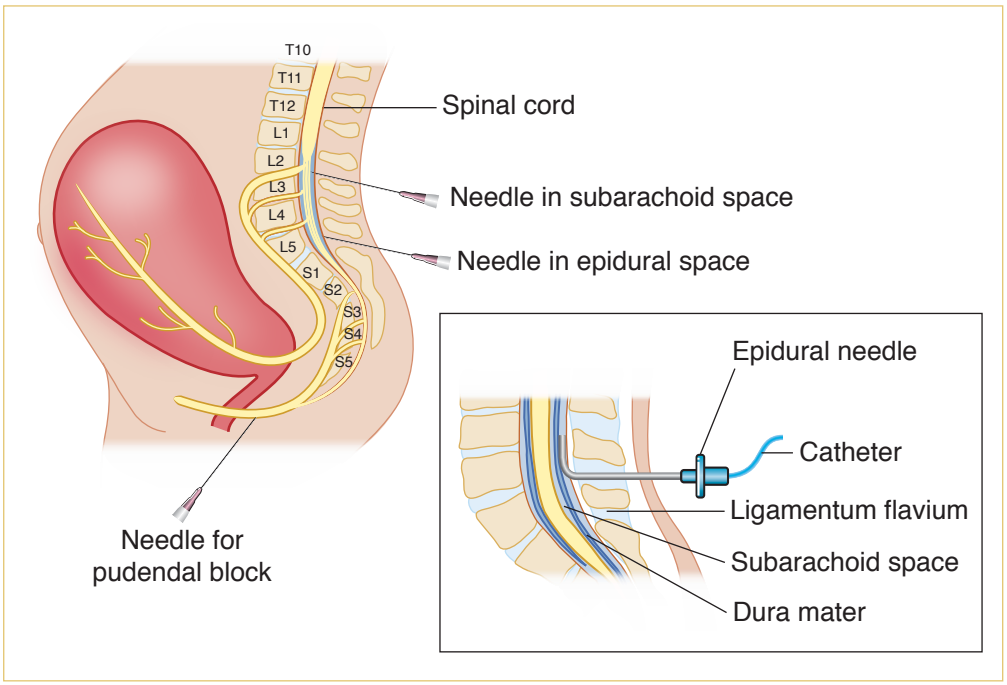

Figure I-15-1. Anesthetic Options During Labor

General Anesthesia

This is seldom used for vaginal delivery and rarely for cesarean section. **Indications** include need for rapid emergency delivery, maternal medical conditions in which conduction anesthesia is unsafe (e.g., blood dyscrasia, thrombocytopenia). **Complications** include aspiration pneumonia, atelectasis, and uterine atony (associated with inhalation agents, e.g., halothane, enflurane).

Intrapartum Fetal Monitoring 16

Learning Objectives

- ❏ Describe the appropriate use of intrapartum fetal monitoring including FHR monitoring, fetal pH assessment, and category III fetal monitoring tracings
- ❏ Describe intrauterine resuscitation

FETAL HEART RATE (FHR) MONITORING

Normal FHR findings are highly reassuring of fetal well-being. Abnormal FHR findings are poor predictors of fetal compromise. Wide usage of electronic FHR monitoring has not lowered the rate of cerebral palsy (CP) because the antecedents of CP appear not to be intrapartum events but rather antenatal events. The false-positive rate for electronic FHR monitoring for predicting CP is >99%.

Modalities of Labor Monitoring

Both of the following modalities are equivalent in predicting fetal outcome.

- **Intermittent auscultation** of FHR is performed with a fetoscope using auditory FHR counting averaged for 10–15 s.
- **Electronic monitoring** measures the milliseconds between consecutive cardiac cycles giving an instantaneous FHR continuously.

External Devices

These are placed on the uterine fundus and are the **most common device** used. **Advantages** are utilization before significant cervical dilation and membrane rupture. **Disadvantages** are poor quality tracing with maternal obesity and maternal discomfort from the device belts.

- **Fetal.** A continuous ultrasound transducer picks up fetal cardiac motion but also can register maternal great vessel pulsations.
- **Contractions.** A tocographic transducer device senses the change in uterine wall muscle tone. It can measure the beginning and ending of contractions but cannot assess contraction intensity.

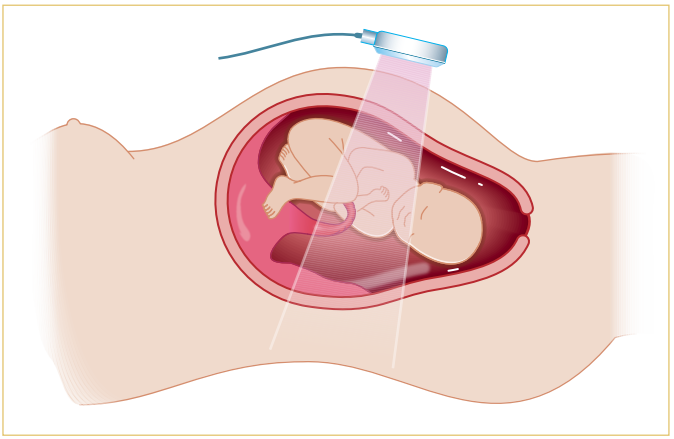

Figure I-16-1. Electronic Fetal Heart Rate Monitor

Internal Devices

These are placed through the dilated cervix. **Advantages** include optimum signal quality, which is unaffected by maternal obesity. **Disadvantages** include limitation to labor when cervical dilation and membrane rupture have occurred.

- **Fetal.** A direct scalp electrode precisely senses each QRS complex of the fetal cardiac cycle. Complications can include fetal scalp trauma and infection.
- **Contractions.** An intrauterine pressure catheter (IUPC), placed into the uterine cavity, precisely registers intrauterine hydrostatic changes with each contraction.

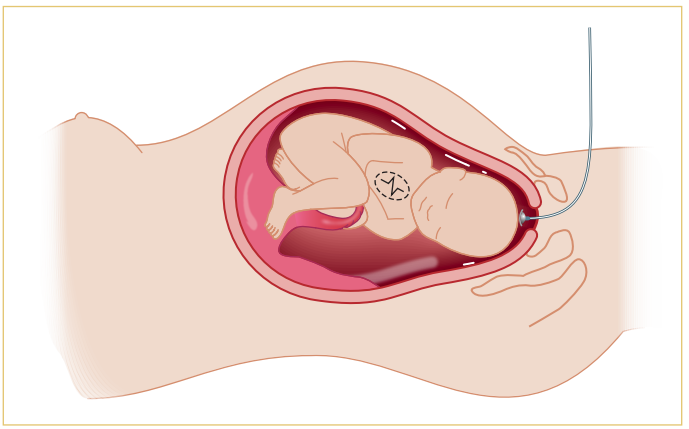

Figure I-16-2. Internal Fetal Heart Rate Monitoring

INTRAPARTUM FETAL HEART RATE MONITORING

Electronic Fetal Monitoring (EFM) Definitions

Baseline Fetal Heart Rate (FHR): The mean FHR rounded to increments of 5 beats/min during a 10-minute segment. Normal FHR baseline: 110–160 beats/minute

Tachycardia: FHR baseline is >160 beats/min

- Non-hypoxic explanations include:
  - **Maternal:** medications (β-adrenergic agonists [terbutaline], atropine, scopolamine), fever, thyrotoxicosis
  - **Fetal:** repetitive accelerations (from fetal movements), fetal tachyarrythmias, prematurity

Bradycardia: FHR baseline is <110 beats/min

- Non-hypoxic explanations include:
  - **Maternal medications:** β-adrenergic blockers, local anesthetics
  - **Fetal arrhythmia:** congenital heart block (associated with maternal lupus)

Baseline variability: Fluctuations in the baseline FHR that are irregular in amplitude and frequency. It is a reflection of the autonomic interplay between the sympathetic and parasympathetic nervous system.

- **Absent** amplitude range undetectable
- **Minimal** amplitude range detectable but ≤5 beats/min
- **Moderate** (normal): amplitude range 6-25 beats/min
- **Marked:** amplitude range >25 beats/min

Acceleration: A visually apparent **abrupt** increase (onset to peak in <30 seconds) in the FHR. These are mediated by the sympathetic nervous system in response to fetal movements or **scalp stimulation**.

- **At ≥32 weeks gestation,** an acceleration has a peak of >15 beats/min above baseline, with a duration of >15 seconds but < 2 min from onset to return.
- **At <32 weeks gestation**, an acceleration has a peak of ≥10 beats/min above baseline, with a duration of ≥10 sec but <2 min from onset to return.

Early deceleration: A visually apparent usually symmetrical **gradual** decrease and return of the FHR associated with a uterine contraction. These are mediated by parasympathetic stimulation and occur in response to **head compression**.

- A gradual FHR decrease is defined as from the onset to the FHR nadir of ≥30 seconds.
- The decrease in FHR is calculated from the onset to the nadir of the deceleration.
- The nadir of the deceleration occurs at the same time as the peak of the contraction.

Late deceleration: A visually apparent usually symmetrical **gradual** decrease and return of the FHR associated with a uterine contraction. These are mediated by either vagal stimulation or myocardial depression and occur in response to **placental insufficiency**.

- A gradual FHR decrease is defined as from the onset to the FHR nadir of ≥30 seconds.
- The decrease in FHR is calculated from the onset to the nadir of the deceleration.
- The deceleration is delayed in timing, with the nadir of the deceleration occurring after the peak of the contraction.

OB Triad

Early Decelerations

- Gradual drop of FHR
- Gradual return of FHR
- Mirror image of contraction

OB Triad

Late Decelerations

- Gradual drop of FHR
- Gradual return of FHR
- Delayed in relation to contractions

OB Triad

Variable Decelerations

- Abrupt drop of FHR
- Sudden return of FHR
- Variable in relation to contractions

Variable deceleration: A visually apparent **abrupt** decrease in FHR. These are mediated by **umbilical cord compression.**

- An abrupt FHR decrease is defined as from the onset of the deceleration to the beginning of the FHR nadir of <30 seconds.
- The decrease in FHR is calculated from the onset to the nadir of the deceleration.
- The decrease in FHR is ≥15 beats per minute, lasting ≥15 seconds, and<2 minutes in duration.

Sinusoidal pattern:

- A visually apparent, smooth, sine wave-like undulating pattern in FHR baseline with a cycle frequency of 3–5/min which persists for ≥20 min.

FHR Categories

A 3-tiered system for the categorization of FHR patterns is recommended. It is important to recognize that FHR tracing patterns provide information only on the current acid–base status of the fetus.

- Categorization of the FHR tracing evaluates the fetus at that point in time; tracing patterns can and will change.
- FHR tracing may move back and forth between the categories depending on the clinical situation and management strategies used.

Category I: FHR tracings are normal

Criteria include all of the following:

- **Baseline rate:** 110-160 beats/min
- **Baseline FHR variability:** moderate
- **Late or variable decelerations:** absent
- **Early decelerations:** present or absent
- **Accelerations:** present or absent

Interpretation: strongly predictive of normal fetal acid-base status at time of observation

Action: monitoring in a routine manner, with no specific action required

Category II: FHR tracings are indeterminate

These include all FHR tracings not categorized as category I or III, and may represent an appreciable fraction of those encountered in clinical care.

Interpretation: not predictive of abnormal fetal acid-base status

Action: evaluation and continued surveillance and reevaluation, taking into account the entire associated clinical circumstances

Category III: FHR tracings are abnormal

Criteria include absent baseline FHR variability and any of the following:

- Recurrent late decelerations
- Recurrent variable decelerations

- Bradycardia
- Sinusoidal pattern

Interpretation: associated with abnormal fetal acid-base status at time of observation; requires prompt evaluation

Action: expeditious intrauterine resuscitation to resolve the abnormal FHR pattern; if tracing does not resolve with these measures, prompt delivery should take place.

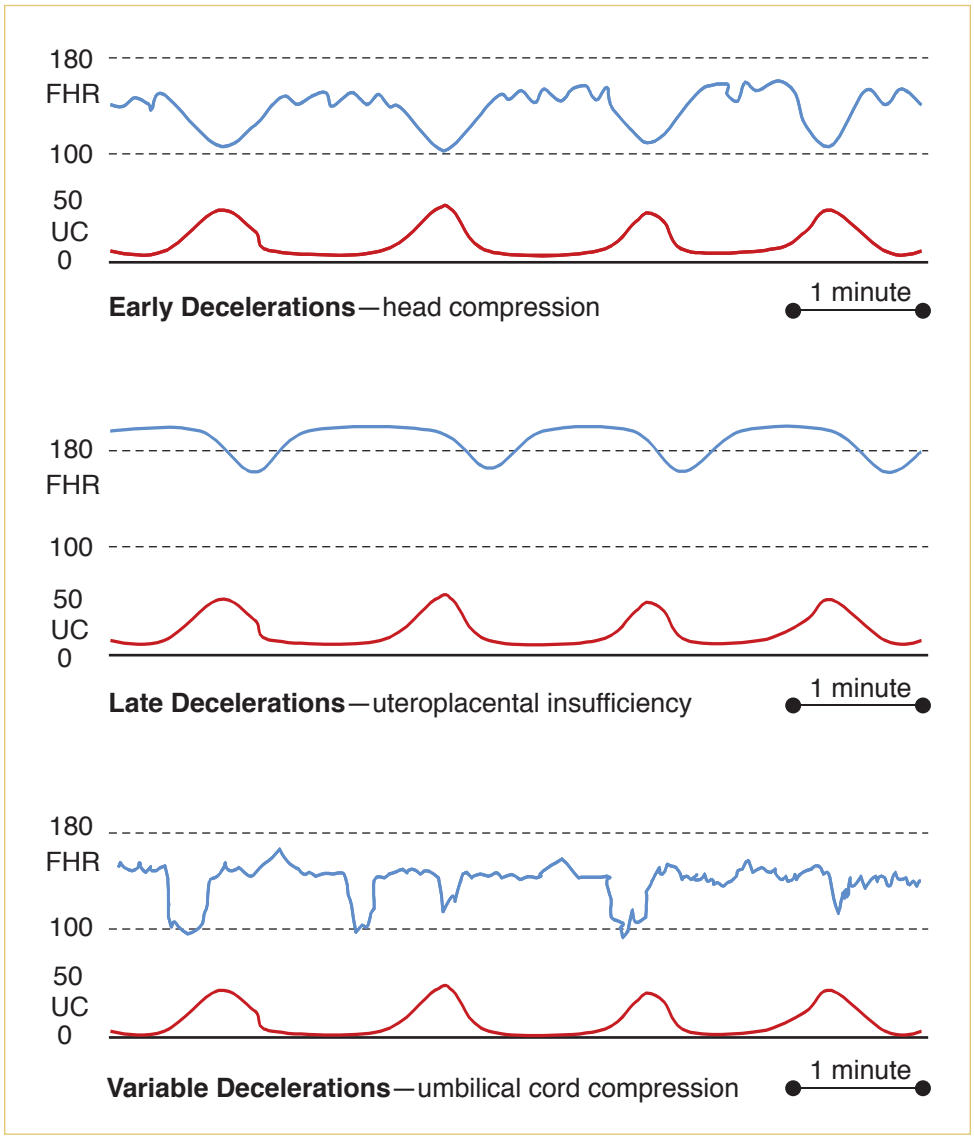

Figure I-16-3. Electronic Fetal Monitor Decelerations

INTRAUTERINE RESUSCITATION

Decrease uterine contractions: Turn off any IV oxytocin infusion or administer terbutaline 0.25 mg subcutaneously to enhance intervillous placental blood flow.

Augment IV fluid volume: Infuse the parturient with a 500 mL bolus of intravenous normal saline rapidly to enhance uteroplacental infusion.

Administer high-flow oxygen: Give the parturient 8–10 L of oxygen by facemask to increase delivery of maternal oxygen to the placenta.

Amniofusion is useful for eliminating or reducing the severity of variable decelerations.

Change position: Removing the parturient from the supine position decreases inferior vena cava compression and enhances cardiac return, thus cardiac output to the placenta. Turning the parturient from one lateral position to the other may relieve any umbilical cord compression that may be present.

Vaginal examination: Perform a digital vaginal examination to rule out possible prolapsed umbilical cord.

Scalp stimulation: Perform a digital scalp stimulation observing for accelerations, which would be reassuring of fetal condition.

FETAL pH ASSESSMENT

Intrapartum—fetal scalp blood pH may be used in labor if the EFM strip is equivocal. Prerequisites include cervical dilation, ruptured membranes, and adequate descent of the fetal head. Contraindications are suspected fetal blood dyscrasia. A small, shallow fetal scalp incision is made resulting in capillary bleeding. The blood is collected in a heparinized capillary tube and sent to the laboratory for blood gas analysis. Normal fetal pH is $\geq$7.20. This procedure is seldom performed today.

Postpartum—umbilical artery blood pH is used to confirm fetal status at delivery. It involves obtaining both umbilical cord venous and arterial samples. Arterial Pco_2 and base deficit values are higher than venous, but pH and Po_2 are lower. Normal fetal pH is $\geq$7.20.

APPROACH TO CATEGORY III FETAL MONITORING TRACINGS

> A 20-year-old primigravida at 39 weeks' gestation is in active labor at 7 cm of cervical dilation. The EFM strip shows a baseline heart rate of 175 beats/min, and variability is absent, but repetitive late decelerations are seen after each contraction. No accelerations are noted.

Recognize that most abnormal tracings are not caused by fetal hypoxia. Ask whether the tracing has biologic plausibility.

- **Examine the EFM strip carefully** looking for baseline heart rate, degree of variability, and presence of periodic changes (accelerations, decelerations).
- **Confirm abnormal findings** using criteria discussed above (category II or III).
- **Identify nonhypoxic causes** present that could explain the abnormal findings.

- **Initiate the intrauterine resuscitation measures** described previously (Intrauterine Resuscitation) to enhance placental perfusion and fetal oxygenation.
- **Observe for normalization** of the EFM tracing.
- Prepare for delivery promptly if resuscitation measures do not normalize EFM tracing.

Specific Interventions If Immediate Delivery Is Indicated

- In stage 1 of labor, the only option is emergency cesarean section.
- In stage 2 of labor, an operative vaginal delivery (e.g., vacuum extractor assisted or obstetrical forceps) may be appropriate, or an emergency cesarean section must be performed.

Operative Obstetrics 17

Learning Objectives

- ❑ Describe the risks and indications for the use of obstetric forceps, vacuum extractor, emergency cesarean section, and elective cesarean section

Operative obstetrics refers to any method used to deliver the fetus other than uterine contractions and maternal pushing efforts. It may include vaginal or cesarean routes.

OBSTETRIC FORCEPS

Definition. These are metal instruments used to provide traction, rotation, or both to the fetal head.

- **Simpson:** used for traction only.
- **Kielland:** used for head rotation and traction.
- **Piper:** used for the after-coming head of a vaginal breech baby.
- **Barton:** used to deliver the head in occiput transverse position with a platypelloid pelvis.

Figure I-17-1. Obstetric Forceps

Classification

- **Outlet:** fetal head is on the pelvic floor. Most forceps use is in this category.
- **Low:** fetal head is below +2 station, but has not reached the pelvic floor.
- **Mid:** fetal head is below 0 station, but has not reached +2 station. This is seldom used today.
- **High:** fetal head is unengaged, above 0 station. This is never appropriate in modern obstetrics because of the risk to both mother and fetus.

Indications

- **Prolonged second stage.** This may be because of dysfunctional labor or suboptimal fetal head orientation. This is the most common indication for forceps.
- **Category III EFM strip.** The fetal heart rate monitor pattern suggests the fetus is not tolerating labor.
- **Avoid maternal pushing.** These include a variety of conditions in which pushing efforts may be hazardous to the parturient, e.g., cardiac, pulmonary, or neurologic disorders.
- **Breech presentation.** Shorten the time to deliver the head of a vaginal breech fetus.

Prerequisites

- Clinically adequate pelvic dimensions
- Experienced operator
- Full cervical dilation
- Engaged fetal head
- Orientation of fetal head is certain.

Complications

- **Maternal:** lacerations to the vagina, cervix, perineum, and uterus.
- **Fetal-neonatal:** soft-tissue compression or cranial injury caused by incorrectly placed forceps blades.

VACUUM EXTRACTOR

Definition. These are cuplike instruments that are held against the fetal head with suction. Traction is thus applied to the fetal scalp, which along with maternal pushing efforts, results in descent of the head leading to vaginal delivery. The cups may be metal or plastic, rigid or soft.

Advantages Over Forceps

- **Fetal head orientation.** Precise knowledge of fetal head position and attitude is not essential.
- **Space required.** The vacuum extractor does not occupy space adjacent to the fetal head.
- **Perineal trauma.** Third- and fourth-degree lacerations are fewer.
- **Head rotation.** Fetal head rotation occurs spontaneously at the station best suited to fetal head configuration and maternal pelvis.

Disadvantages Over Forceps

- **Cup pop-offs.** Excessive traction can lead to sudden decompression as the cup suction is released.
- **Scalp trauma.** Scalp skin injury and lacerations are common.
- **Subgaleal hemorrhage and intracranial bleeding** are rare.
- **Neonatal jaundice** arises from scalp bleeding.

Indications Are Similar to Those of Forceps

- **Prolonged second stage.** This may be because of dysfunctional labor or suboptimal fetal head orientation.
- **Nonreassuring EFM strip.** The FHR monitor pattern suggests the fetus is not tolerating labor.
- **Avoid maternal pushing.** These include a variety of conditions in which pushing efforts may be hazardous to the parturient, e.g., cardiac, pulmonary, or neurologic disorders.

Prerequisites

- Clinically adequate pelvic dimension
- Experienced operator
- Full cervical dilation
- Engaged fetal head
- Gestational age is ≥34 weeks

Complications

- **Maternal:** vaginal lacerations from entrapment of vaginal mucosa between the suction cup and fetal head.
- **Neonatal:** neonatal **cephalohematoma** and scalp lacerations are common; life-threatening complications of **subgaleal hematoma** or **intracranial hemorrhage**, although uncommon, are associated with vacuum duration >10 min.

CESAREAN SECTION

Definition. This describes a procedure in which the fetus is delivered through incisions in the maternal anterior abdominal and uterine walls. The overall U.S. cesarean section rate in 2011 was approximately 33%, which includes both primary and repeat procedures.

Risks. Maternal mortality and morbidity is higher than with vaginal delivery, especially with emergency cesareans performed in labor. Maternal mortality is largely anesthetic related with overall mortality ratio of 25 per 100,000.

- **Hemorrhage:** Blood loss is twice that of a vaginal delivery with mean of 1,000 mL.
- **Infection:** Sites of infection include endometrium, abdominal wall wound, pelvis, urinary tract, or lungs. Prophylactic antibiotics can decrease infectious morbidity.
- **Visceral injury:** Surrounding structures can be injured (e.g., bowel, bladder, and ureters).
- **Thrombosis:** Deep venous thrombosis is increased in the pelvic and lower extremity veins.

Uterine Incisions

- **Low segment transverse.** This incision is made in the noncontractile portion of the uterus and is the one most commonly used. The bladder must be dissected off the lower uterine segment. It has a low chance of uterine rupture in subsequent labor (0.5%).
  - **Advantages** are trial of labor in a subsequent pregnancy is safe; the risk of bleeding and adhesions is less.
  - **Disadvantages** are the fetus(es) must be in longitudinal lie; the lower segment must be developed.

OB Triad

Low Transverse Uterine Incision

- Low risk of rupture (0.5% in labor)
- Less blood loss and adhesions
- Safe for subsequent labor trial

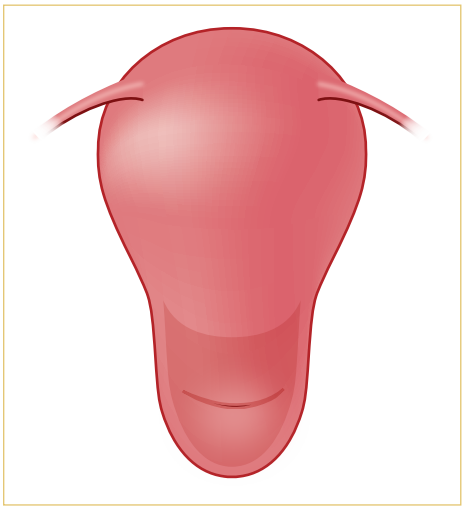

Figure I-17-2. Low Segment Transverse Incision

- **Classical.** This incision is made in the contractile fundus of the uterus and is less commonly performed. Technically it is easy to perform, and no bladder dissection is needed. Risk of uterine rupture both before labor as well as in subsequent labor is significant (5%). Repeat cesarean should be scheduled before labor onset.
  - **Advantages** are any fetus(es) regardless of intrauterine orientation can be delivered; lower segment varicosities or myomas can be bypassed.
  - **Disadvantages** are trial of labor in a subsequent pregnancy is unsafe; the risk of bleeding and adhesions is higher.

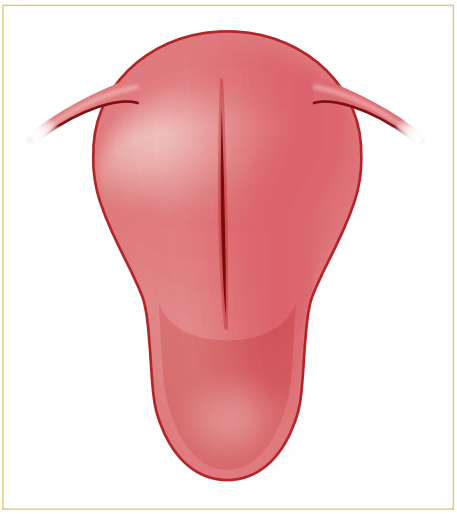

Figure I-17-3. Classical Uterine Incision

Indications for Primary Cesarean Section

- **Cephalopelvic disproportion (CPD).** This is the **most common** indication for cesarean delivery. This term literally means the pelvis is too small for the fetal head. In actual practice, it most commonly indicates failure of the adequate progress in labor, which may be related to dysfunctional labor or suboptimal fetal head orientation.
- **Fetal malpresentation.** This refers most commonly to breech presentation, but also means any fetal orientation other than cephalic.
- **Category III EFM strip.** The FHR monitor pattern suggests the fetus may not be tolerating labor, but commonly this is a false-positive finding.

Vaginal Birth After Cesarean (VBAC)

- Successful vaginal delivery rate is up to 80% in carefully selected patients.
- Criteria for trial of labor include patient consent, nonrepetitive cesarean indication (e.g., breech, placenta previa), previous low segment transverse uterine incision, clinically adequate pelvis.

External Cephalic Version. This procedure consists of externally manipulating the gravid abdomen without anesthesia to turn the fetus from transverse lie or breech presentation. The optimum time for version is 37 weeks' gestation, and success rates are 60–70%. Potential hazards are umbilical cord compression or placental abruption requiring emergency cesarean section.

ELECTIVE CESAREAN

The U.S. National Institutes of Health (NIH) held a consensus conference in March 2006 to determine the scientific basis for maternal and fetal risks and benefits to cesarean delivery on maternal request (CDMR). After 2 days of presentations by experts in the field and input from the audience, the consensus was that "the available information comparing the risks and benefits of CDMR versus planned vaginal birth do not provide the basis for a recommendation in either direction."

OB Triad

Classical Uterine Incision

- High risk of rupture (5% in labor)
- More blood loss and adhesions
- Risky for subsequent labor trial

Recommendations from the independent panel of experts include:

- Individual counseling for each woman regarding risks and benefits
- Women who are considering having >2 children should be aware that a cesarean section causes uterine scarring; these women should avoid a primary cesarean section.
- Women should not have a cesarean section prior to 39 weeks' gestation.

Postpartum Issues 18

Learning Objectives

- ❏ Describe the causes and management of postpartum hemorrhage and fever
- ❏ List the sequence of physiologic changes expected after delivery
- ❏ Provide and overview of the special considerations for immunizations and contraception postpartum

POSTPARTUM PHYSIOLOGIC ISSUES

Reproductive Tract Changes

Lochia. These are superficial layers of the endometrial decidua that are shed through the vagina during the first 3 postpartum weeks. For the first few days the color is red (**lochia rubra**), changing during the next week to pinkish (**lochia serosa**), ending with a whitish color (**lochia alba**) by the end of the second week.

Cramping. The myometrial contractions after delivery constrict the uterine venous sinuses, thus preventing hemorrhage. These lower midline cramps may be painful and are managed with mild analgesics.

Perineal Pain. Discomfort from an episiotomy or perineal lacerations can be minimized in the first 24 hours with ice packs to decrease the inflammatory response edema. A heat lamp or sitz bath is more helpful after the first day to help mobilize tissue fluids.

Urinary Tract Changes

Hypotonic Bladder. Intrapartum bladder trauma can result in increased postvoid residual volumes. If the residuals exceed 250 mL, the detrusor muscle can be stimulated to contract with bethanechol (Urecholine). Occasionally an indwelling Foley catheter may need to be placed for a few days.

Dysuria. Pain with urination may be seen from urethral irritation from frequent intrapartum catheterizations. **Conservative management** may be all that is necessary. A urinary analgesic may be required occasionally.

Gastrointestinal Tract Changes

Constipation. Decreased GI tract motility, because of perineal pain and fluid mobilization, can lead to constipation. Management is oral hydration and stool softeners.

Hemorrhoids. Prolonged second-stage pushing efforts can exaggerate preexisting hemorrhoids. **Management** is oral hydration and stool softeners.

Psychosocial Problems

Bonding. Impaired maternal–infant bonding is seen in the first few days postdelivery. Lack of interest or emotions for the newborn are noted. Risk is increased if contact with the baby is limited because of neonatal intensive care, as well as poor social support. **Management** is psychosocial evaluation and support.

Blues. Postpartum blues are very common within the first few weeks of delivery. Mood swings and tearfulness occur. Normal physical activity continues and care of self and baby is seen. **Management** is conservative with social support.

Depression. Postpartum depression is common but is frequently delayed up to a month after delivery. Feelings of despair and hopelessness occur. The patient often does not get out of bed with care of self and baby neglected. **Management** includes psychotherapy and antidepressants.

Psychosis. Postpartum psychosis is rare, developing within the first few weeks after delivery. Loss of reality and hallucinations occur. Behavior may be bizarre. **Management** requires hospitalization, antipsychotic medication, and psychotherapy.

OB Triad

Impaired Maternal–Infant Bonding

- Postpartum Day 1
- SVD: 1,900-g 31-week male in NICU
- Mom shows no interest in baby

OB Triad

Postpartum Blues

- Postpartum Day 2
- S/P SVD of term normal baby
- Mom cares for baby: tears

OB Triad

Postpartum Depression

- Postpartum Day 21
- S/P SVD of term normal baby
- Mom does not get out of bed, does not care for self or baby

OB Triad

Postpartum Psychosis

- Postpartum Day 21
- S/P SVD of term normal baby
- Mom exhibits bizarre behavior, hallucinations

POSTPARTUM CONTRACEPTION AND IMMUNIZATIONS

Contraception Planning

Breast feeding. Lactation is associated with temporary anovulation, so contraceptive use may be deferred for 3 months. A definitive method should be used after that time.

Diaphragm. Fitting for a vaginal diaphragm should be performed after involution of pregnancy changes, usually at the 6-week postpartum visit.

Intrauterine Device (IUD). Higher IUD retention rates, and decreased expulsions, are seen if IUD placement takes place at 6 weeks postpartum.

Combination Modalities. Combined estrogen-progestin formulations (e.g., pills, patch, vaginal ring) should not be used in breast-feeding women because of the estrogen effect of diminishing milk production. In nonlactating women, they should be started after 3 weeks postpartum to allow reversal of the hypercoagulable state of pregnancy and thus decrease the risk of deep venous thrombosis.

Progestin-only Contraception. Progestin steroids (e.g., mini-pill, Depo-Provera, Nexplanon) do not diminish milk production so can safely be used during lactation. They can be begun immediately after delivery.

Postpartum Immunizations

RhoGAM. If the mother is Rh(D) negative, and her baby is Rh(D) positive, she should be administered 300 μg of RhoGAM IM within 72 hours of delivery.

Rubella. If the mother is rubella IgG antibody negative, she should be administered active immunization with the live-attenuated rubella virus. She should avoid pregnancy for 1 month to avoid potential fetal infection.

POSTPARTUM HEMORRHAGE

Definition: vaginal delivery blood loss ≥500 mL **or** cesarean section blood loss ≥1,000 mL

Uterine Atony (80%)

This is the most common cause of excessive postpartum bleeding.

Risk Factors. Rapid or protracted labor (**most common**), chorioamnionitis, medications (e.g., $MgSO_4$, β-adrenergic agonists, halothane), and overdistended uterus.

Clinical Findings. A soft uterus (feels like dough) palpable above the umbilicus.

Management. Uterine massage and uterotonic agents (e.g., oxytocin, methylergonovine, or carboprost).

Lacerations (15%)

Risk Factors. Uncontrolled vaginal delivery (**most common**), difficult delivery, and operative vaginal delivery.

Clinical Findings. Identifiable lacerations (cervix, vagina, perineum) in the presence of a contracted uterus.

Management. Surgical repair.

Retained Placenta (5%)

Risk Factors. Accessory placental lobe (**most common**) and abnormal trophoblastic uterine invasion (e.g., cervix, vagina, perineum).

Clinical Findings. Missing placental cotyledons in the presence of a contracted uterus.

Management. Manual removal or uterine curettage under ultrasound guidance.

Disseminated Intravascular Coagulation (rare)

Risk Factors. Abruptio placenta (**most common**), severe preeclampsia, amniotic fluid embolism, and prolonged retention of a dead fetus.

Clinical Findings. Generalized oozing or bleeding from IV sites or lacerations in the presence of a contracted uterus.

Management. Removal of pregnancy tissues from the uterus, intensive care unit (ICU) support, and selective blood-product replacement.

Uterine Inversion (rare)

Risk Factors. Myometrial weakness (most common) and previous uterine inversion.

Clinical Findings. Beefy-appearing bleeding mass in the vagina and failure to palpate the uterus abdominally.

Management. Uterine replacement by elevating the vaginal fornices and lifting the uterus back into its normal anatomic position, followed by IV oxytocin.

Postpartum Hemorrhage

Clinical	Diagnosis	Management
Uterus not palpable	Inversion (rare)	Elevate vaginal fornices, IV oxytocin
Uterus like dough	Atony (80%)	Uterine massage, oxytocin, ergot, PG F2α
Tears vagina, cervix	Lacerations (15%)	Suture & repair
Placenta incomplete	Retain placenta (5%)	Manual removal or uterine curettage
Diffuse oozing	DIC (rare)	Remove POC, ICU care, blood products prn
Persistent bleeding	Unexplained (rare)	Ligate vessels or hysterectomy

Unexplained

If despite careful searching, no correctible cause of continuing hemorrhage is found, it may be necessary to perform a laparotomy and bilaterally surgically ligate the uterine or internal iliac arteries. Hysterectomy would be a last resort.

POSTPARTUM FEVER

Definition: Fever ≥100.4° F (38° C) on ≥2 occasions ≥6 hours apart, excluding first 24 hours post-partum

PP Day 0: Atelectasis

Risk Factors. General anesthesia with incisional pain (**most common**) and cigarette smoking.

Clinical Findings. Mild fever with mild rales on auscultation. Patient is unable to take deep breaths.

Management. Pulmonary exercises (e.g., deep breaths, incentive spirometry) and ambulation. Chest x-rays are unnecessary.

PP Day 1–2: Urinary Tract Infection

Risk Factors. Multiple intrapartum catheterizations and vaginal examinations due to prolonged labor.

Clinical Findings. High fever, costovertebral flank tenderness, positive urinalysis (e.g., WBC, bacteria) and urine culture.

Management. Single-agent intravenous antibiotics.

PP Day 2–3: Endometritis

Most common cause of postpartum fever.

Risk Factors. Emergency cesarean section after prolonged membrane rupture and prolonged labor.

Clinical Findings. Moderate-to-high fever with exquisite uterine tenderness. Peritoneal signs should be absent and peristalsis should be present.

Management. Multiple-agent intravenous antibiotics (e.g., gentamycin and clindamycin) to cover polymicrobial genital tract flora.

PP Day 4–5: Wound Infection

Risk Factors. Emergency cesarean section after prolonged membrane rupture and prolonged labor.

Clinical Findings. Persistent spiking fever despite antibiotics, along with wound erythema, fluctuance, or drainage.

Management. Intravenous antibiotics for cellulitis. Wound drainage with twice-daily, wet-to-dry wound packing used for an abscess, anticipating closure by secondary intention.

PP Day 5–6: Septic Thrombophlebitis

Risk Factors. Emergency cesarean section after prolonged membrane rupture and prolonged labor.

Clinical Findings. Persistent wide fever swings despite broad-spectrum antibiotics with normal pelvic and physical examination.

Management. Intravenous heparin for 7–10 days, keeping PTT values at 1.5 to 2.0 times baseline.

PP Day 7–21: Infectious Mastitis

Risk Factors. Lactational nipple trauma leading to nipple cracking and allowing Staphylococcus aureus bacteria to enter breast ducts and lobes.

Clinical Findings. Fever of variable degree with localized, unilateral breast tenderness, erythema, and edema.

Management. Oral cloxacillin. Breast feeding can be continued. Ultrasound imaging is needed to rule out an abscess if lactational mastitis does not respond to antibiotics.

Postpartum Fever

Physical Exam	Diagnosis	Management
Lung "crackles" PP Day 0	Atelectasis	Ambulation, pulmonary exercises
Flank pain, dysuria PP Day 1-2	Pyelonephritis	Single IV antibiotic
Tender uterus PP Day 2-3	Endometritis	IV gentamicin and clindamycin
Wound purulence PP Day 5-6	Wound infection	Wet-to-dry packs
Pelvic mass PP Day 5-6	Pelvic abscess	Percutaneous drainage
"Picket fence" fever PP Day 5-6	Septic thrombophlebitis	Full heparinization

SECTION II

Gynecology

Basic Principles of Gynecology 1

Learning Objectives

- ❏ Provide an overview of female reproductive anatomy
- ❏ List the Tanner stages of developed including expect changes and age of onset
- ❏ Describe the most common gynecologic procedures

FEMALE REPRODUCTIVE ANATOMY

Uterus

The embryologic origin of the uterus is from fusion of the two Müllerian ducts. **Major structures** include the corpus, cornu, isthmus and cervix. **Internal layers** of the uterus include the serosa, myometrium, and endometrium. **The ligaments** attached to the uterus include the broad ligament, round ligaments, cardinal ligaments, and uterosacral ligaments. **Anatomical positions** of the uterus include anteverted, retroverted, mid-position. Normal uterine position tips slightly anterior in the pelvis.

Oviducts

The oviducts extend from the uterus to the ovaries. **Segments** of the oviducts are the interstitium, isthmus, ampulla, and infundibulum. The oviducts function in facilitating sperm migration from the uterus to the ampulla and the transportation of the zygote toward the uterus. They are **attached** medially to the uterine corpus, laterally to the pelvic side wall, and inferiorly to the broad ligament.They receive dual **blood supply** from the ascending uterine artery and ovarian artery.

Ovaries

Functions of the ovaries include containment of oocytes within the ovarian follicles and **production of** reproductive and sexual hormones. The ovaries are **attached by the** ovarian ligament to the uterine fundus, by the suspensory ligaments to the pelvic side wall, and by the mesovarium to the broad ligament. **Lymphatic drainage** of the ovaries is through the pelvic and para-aortic lymph nodes.

Vagina

The vagina is a tubular structure, 8–9 cm in length that extends from the introitus to the cervix. The vagina traverses the urogenital diaphragm through the genital hiatus of the levator ani. It functions as the female copulatory organ, an outflow tract for menstrual flow, and birth canal in parturition.

TANNER STAGES OF DEVELOPMENT

The Tanner stages occur in a **predictable** sequence in the normal physical development of children, adolescents, and adults. The stages define physical measurements of development based on **external** primary and secondary sex characteristics, such as the size of breasts, genitalia, and development of pubic hair.

Pubic Hair

- **Tanner I:** none (prepubertal state)
- **Tanner II:** small amount of long, downy hair with slight pigmentation on the labia majora
- **Tanner III:** hair becomes more coarse and curly and begins to extend laterally
- **Tanner IV:** adult-like hair quality, extending across pubis but sparing medial thighs
- **Tanner V:** hair extends to medial surface of the thighs

Breasts

- **Tanner I:** no glandular tissue; areola follows the skin contours of the chest (prepubertal)
- **Tanner II:** breast bud forms with small area of surrounding glandular tissue; areola begins to widen
- **Tanner III:** breast begins to become more elevated and extends beyond the borders of the areola, which continues to widen but remains in contour with surrounding breast
- **Tanner IV:** increased breast size and elevation; areola and papilla form a secondary mound projecting from the contour of the surrounding breast
- **Tanner V:** breast reaches final adult size; areola returns to contour of the surrounding breast, with a projecting central papilla

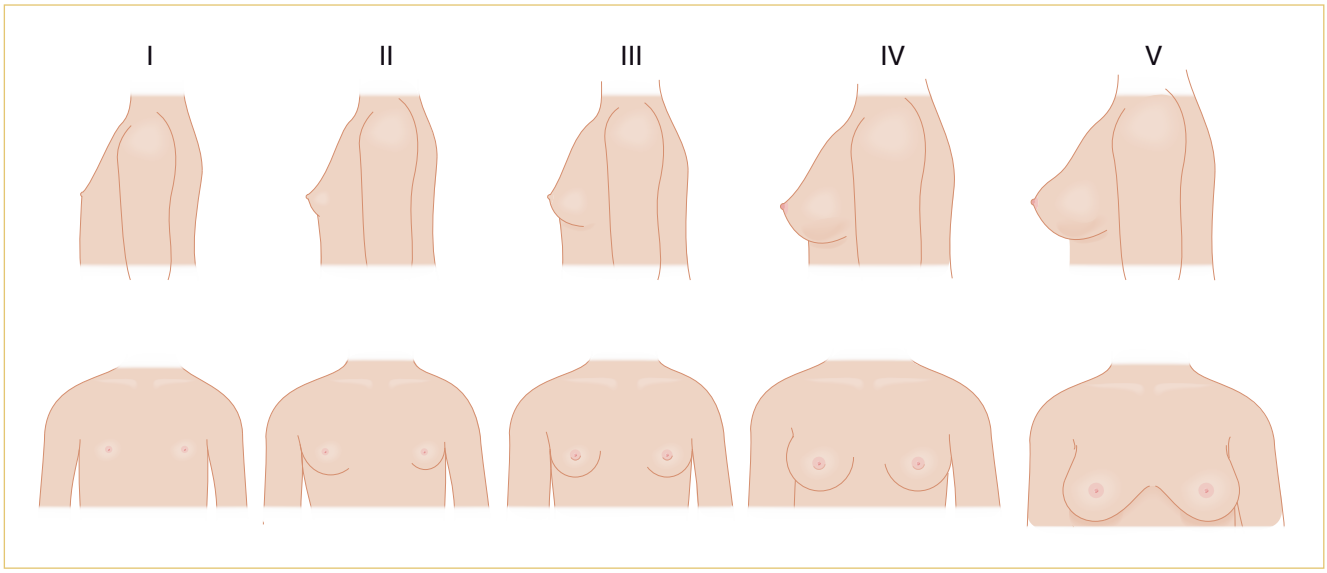

Figure II-1-1. Tanner Stages of the Maturing Female

GYNECOLOGIC PROCEDURES

Gynecologic Ultrasound

This imaging modality uses low-energy, high-frequency sound waves.

- **Transvaginal** transducers are utilized for lower pelvic masses, producing high-resolution images that are not influenced by the thickness of the maternal abdominal wall.
- **Transabdominal** transducers provide images throughout the entire pelvis as well as abdomen.
- Ultrasound works best when adjacent tissues have differing echodensities, particularly fluid/tissue interfaces.

Cervical Pap Smear

This is an outpatient office procedure. It is a screening, not diagnostic, test for premalignant cervical changes; it allows for early intervention, thus preventing cervical cancer.

The diagnostic test for cervical dysplasia or cancer requires a histologic assessment made on a tissue biopsy specimen.

Specimens required. Pap smear should include cytologic specimens from 2 areas: stratified squamous epithelium of transformation zone (TZ) of the ectocervix and columnar epithelium of the endocervical canal (EGG).

- **Ectocervix specimen.** Screening for squamous cell carcinoma, the most common cancer of the cervix (80%), involves scraping the TZ. The TZ is the area of the ectocervix between the old or "original" squamocolumnar junction (SCJ) and the new SCJ.

  - At puberty the vaginal pH falls, causing the "native" columnar epithelium to be transformed by metaplasia into normal-appearing "metaplastic" stratified squamous epithelium.
  - The TZ is the location where 95% of cervical dysplasia and cancer develop.
- **Endocervix specimen.** Screening for adenocarcinoma, the second most common cancer of the cervix (15%), involves scraping the endocervical canal with cytobrush.

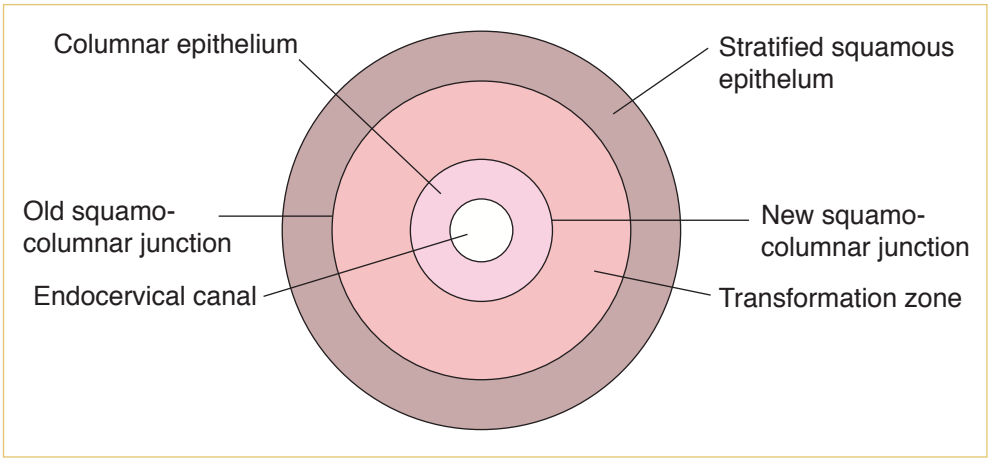

Figure II-1-2. Development of T-Zone

Specimen collection methods. Studies show that while the "liquid-based" methods, compared with the "traditional" method, reduces the percentage of unsatisfactory specimens, the 2 methods are equivalent in performance for detection of cervical dysplasia.

- **Traditional Pap smear**
  - Samples are obtained using a wooden **spatula** on the ectocervix and a **cyto-brush** for the endocervical canal rotating in one direction 360°. The cells from each area are then smeared evenly onto a glass slide, which is then fixed in formalin, then stained and examined under a microscope by a cytologist.
  - Potential problems include insufficient smearing of all abnormal cells onto the glass slide, air-drying artifacts if fixing is delayed, and clumping of cells, making cytology assessment difficult.
- **Liquid-based Pap smear**
  - Specimens can be collected using **cervical broom**. Long central bristles are placed into the endocervix and short outer bristles over the ectocervix. The broom is rotated 5 times in the same direction, collecting and sampling both endocervical cells and transformation zone. The cervical broom is placed in the preservative solution and rotated 10 times vigorously to release collected material into the solution.
  - Advantages include less chance of abnormal cells being discarded with the collecting instrument, less likelihood of air-drying artifacts, and cells spread more evenly on glass slide surface.

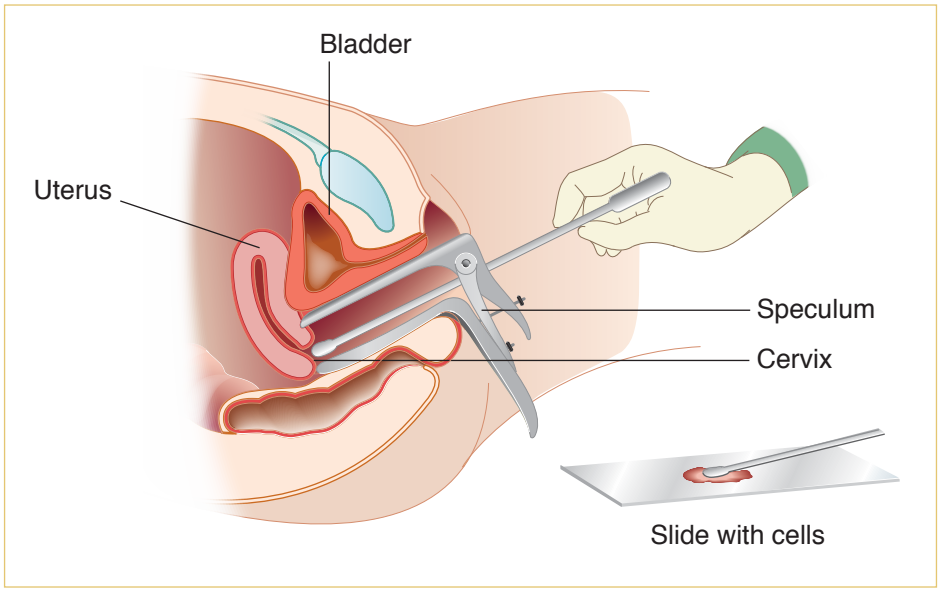

Figure II-1-3. Taking a Sample of Cells during Pap Smear

Colposcopy

Colposcopy is an outpatient office procedure. It uses a binocular, short focal-length instrument with a built-in light source to look at the cervix through a speculum. The purpose is to (1) visually identify where the abnormal Pap smear cells originated, and (2) biopsy that area to send for histologic diagnosis.

- The ectocervix is visually examined to localize areas of abnormal epithelium. Dilute acetic acid should be applied to the cervix to aid in the detection of dysplasia. Areas of abnormal-appearing tissue that are biopsied include **punctation**, **mosaicism**, **white epithelium**, and **abnormal vessels**. The specimens are sent to pathology for definitive diagnosis.

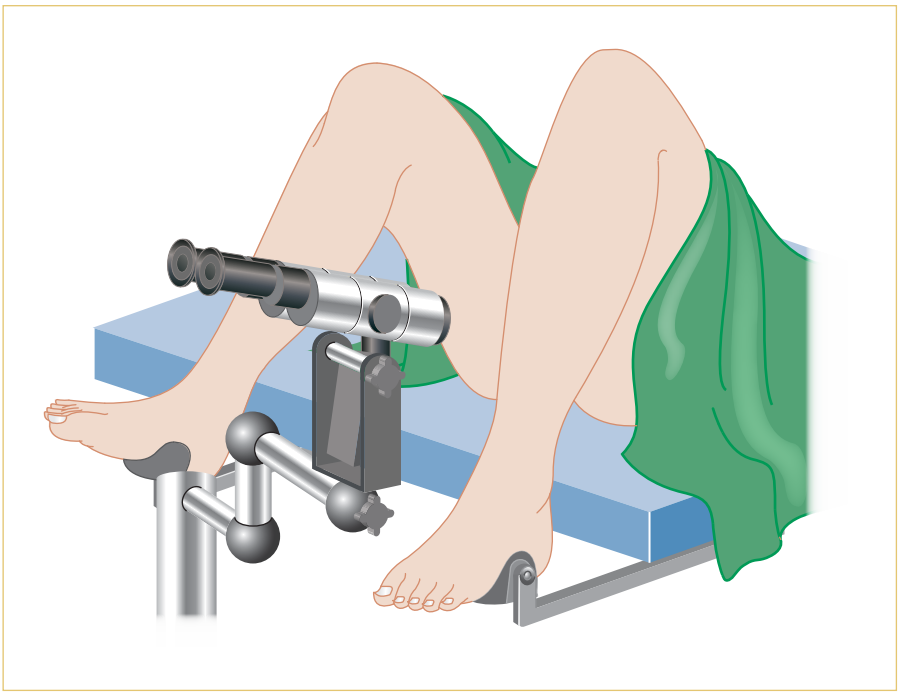

Figure II-1-4. Colposcopy

Cold Knife Cone Biopsy

Cold knife cone biopsy is a minor outpatient surgical procedure performed in the operating room under either local or general anesthesia. It is a diagnostic test that examines the histology of cervical lesions.

- A cone-shaped tissue specimen is obtained with a scalpel by performing a circumferential incision of the cervix with a diameter that is wider at the cervical os and narrower toward the endocervical canal. This tissue is sent to pathology for histologic diagnosis.
- **Wide-shallow cone** is performed if the Pap smear shows changes more severe than the colposcopically directed biopsy.
- **Narrow-deep cone** is performed if a lesion extends from the exocervix into the endocervical canal.
- Long-term risks include cervical **stenosis**, cervical **insufficiency**, and preterm birth.

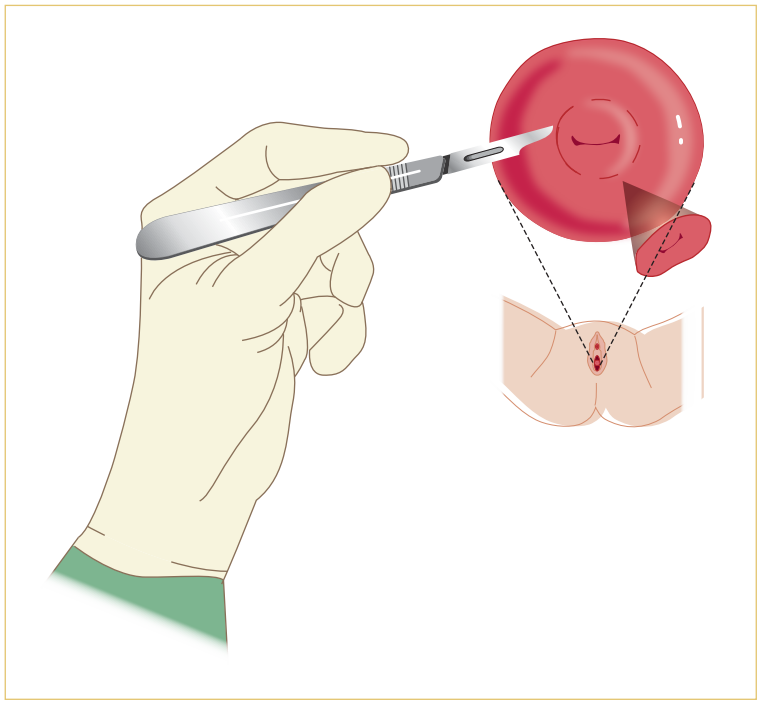

Figure II-1-5. Cold Knife Cone Biopsy

Loop Electrosurgical Excision Procedure (LEEP)

LEEP is a minor outpatient surgical procedure performed under local anesthesia. It is a diagnostic test that examines the histology of cervical lesions. Advantages are low cost, high success rate, and ease of use.

- This technique is used for diagnosing and treating cervical dysplasia. An electric current is passed through a thin wire loop to remove abnormal cervical tissues. The heated loop seals off blood vessels as it cuts.
- The tissue is sent to pathology. Followup Pap smears are performed every 6 months for 2 years to ensure that the dysplastic changes do not return.
- Long-term risks of LEEP include cervical stenosis and cervical insufficiency.

Cryotherapy

Cryotherapy is a minor outpatient procedure performed without anesthesia. It destroys dysplastic cervical tissue identified by colposcopy and cervical biopsy.

- A cryo probe is placed over the abnormal cervical epithelium. The probe temperature is lowered to –50°C with liquid nitrogen. This causes the metal cryo probe to freeze and destroy superficial abnormal cervical tissue. The freezing lasts for 3 minutes; the cervix is then allowed to thaw, and the freezing is repeated for another 3 minutes.

- A watery discharge will occur over the next few weeks as the destroyed tissue sloughs off. Followup Pap smears are performed every 6 months for 2 years to ensure that the dysplastic changes do not return.
- Long-term risks of cryotherapy include cervical **stenosis**.

Hysterectomy

Hysterectomy, removal of the uterus, is a major inpatient surgical procedure performed under either regional or general anesthesia. It is used for both diagnosis and therapy.

- Depending on the indications and pelvic exam, the procedure can be performed either vaginally, abdominally, laparoscopically, or robot-assisted.
- **Subtotal** or supracervical hysterectomy removes only the corpus of the uterus, leaving the cervix in place.
- **Total** hysterectomy, the most common procedure, removes both the corpus and cervix of the uterus. Total hysterectomy is also known as **simple** hysterectomy.
- **Radical hysterectomy**, performed for early-stage cervical carcinoma, involves removal of the uterus, cervix, and surrounding tissues, including cardinal ligaments, uterosacral ligaments, and the upper vagina.

Hysteroscopy

Hysteroscopy is a minor outpatient surgical procedure performed in the operating room under either local-intravenous or general anesthesia for diagnosis and possibly for therapy.

- A fiberoptic scope is placed through a previously dilated cervix to directly visualize the endometrial cavity. A clear fluid is infused through side ports of the scope to distend the uterine cavity, allowing visualization.
- Other side ports of the hysteroscope can be used in placing instruments to biopsy lesions or to resect submucous leiomyomas, polyps, or uterine septa.

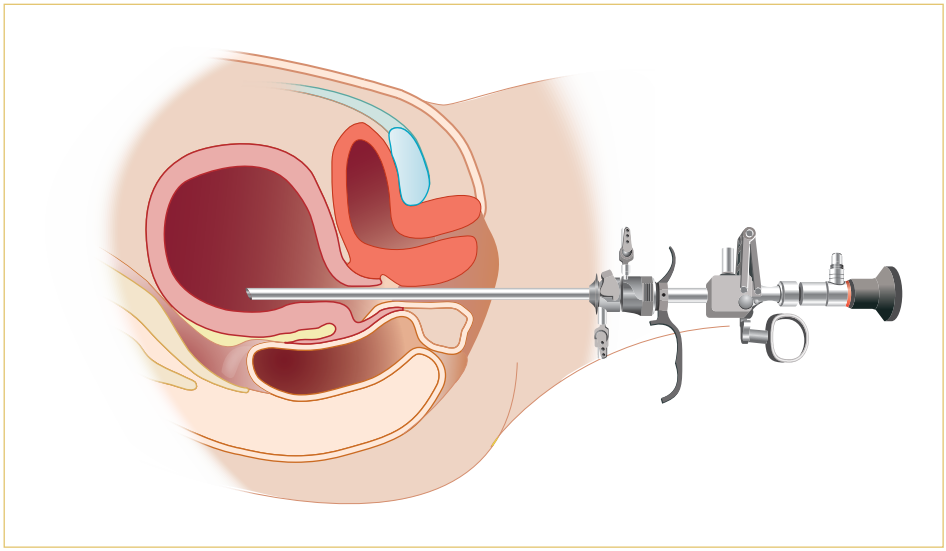

Figure II-1-6. Hysteroscopy

Laparoscopy

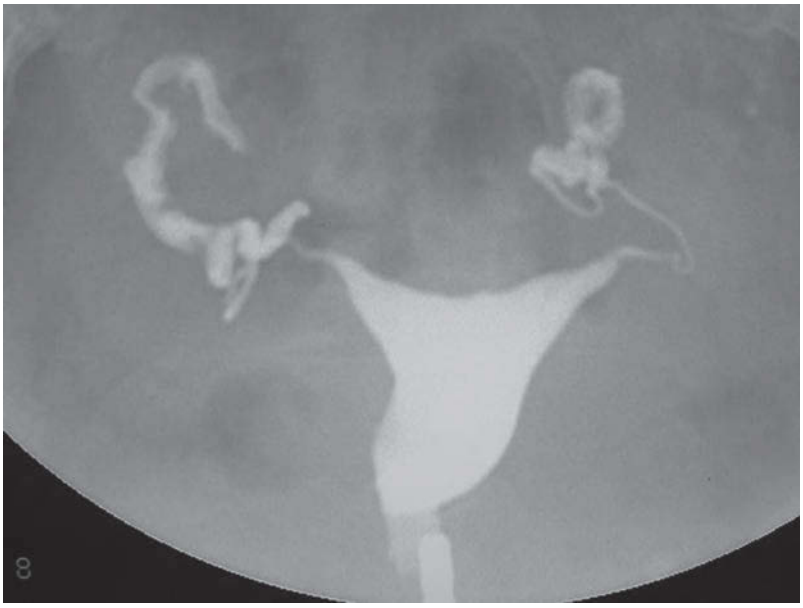
Laparoscopy is a minor outpatient surgical procedure performed in the operating room under general anesthesia for diagnosis and possibly for therapy.

- The pelvic-abdominal cavity is insufflated with pressured carbon dioxide to distend the abdomen and lift the abdominal wall away from the viscera. Through a port that is placed through the umbilicus, a fiberoptic scope is then inserted to visually examine the pelvis and abdomen.
- Common gynecologic indications for laparoscopy include diagnosing and treating causes of chronic pelvic pain (e.g., endometriosis or adhesions), resecting advanced ectopic pregnancies, and diagnosing and lysing tubal adhesions in infertility cases.

Hysterosalpingogram (HSG)

HSG is a diagnostic outpatient radiologic imaging procedure performed without anesthesia. A cannula is placed in the endocervical canal and radio-opaque fluid is injected, allowing assessment of uterine malformations (e.g., uterine septum, bicornuate uterus) and Asherman's syndrome.

Tubal pathology can also be assessed by observing internal tubal anatomy and seeing whether the dye spills into the pelvic cavity.



With permission, Medical Education Division of Brookside Associates, brooksidepress.org

Figure II-1-7. Normal HSG

Dilation and Curettage (D&C)

D&C is a minor outpatient surgical procedure performed under anesthesia in an operating room under either local-intravenous or general anesthesia. It is a diagnostic test that examines the histology of endometrial lesions.

D&C is performed similarly to an endometrial biopsy. However, the cervix frequently requires dilation with cervical dilators prior to introduction of the curette. The curette is used to scrape the endometrium, obtaining larger amounts of endometrial tissue that are then sent to pathology.

Endometrial Biopsy

Endometrial biopsy is an outpatient office procedure. It is a diagnostic test that examines the histology of endometrial lesions.

The direction of the cervical canal and endometrial cavity is identified by placing a uterine sound through the endocervical canal. A hollow suction cannula is then placed into the uterine cavity and suction is applied. As the cannula is rotated, endometrial tissue is aspirated into it. When the cannula is removed, the retrieved tissue is placed in formalin and sent to pathology.

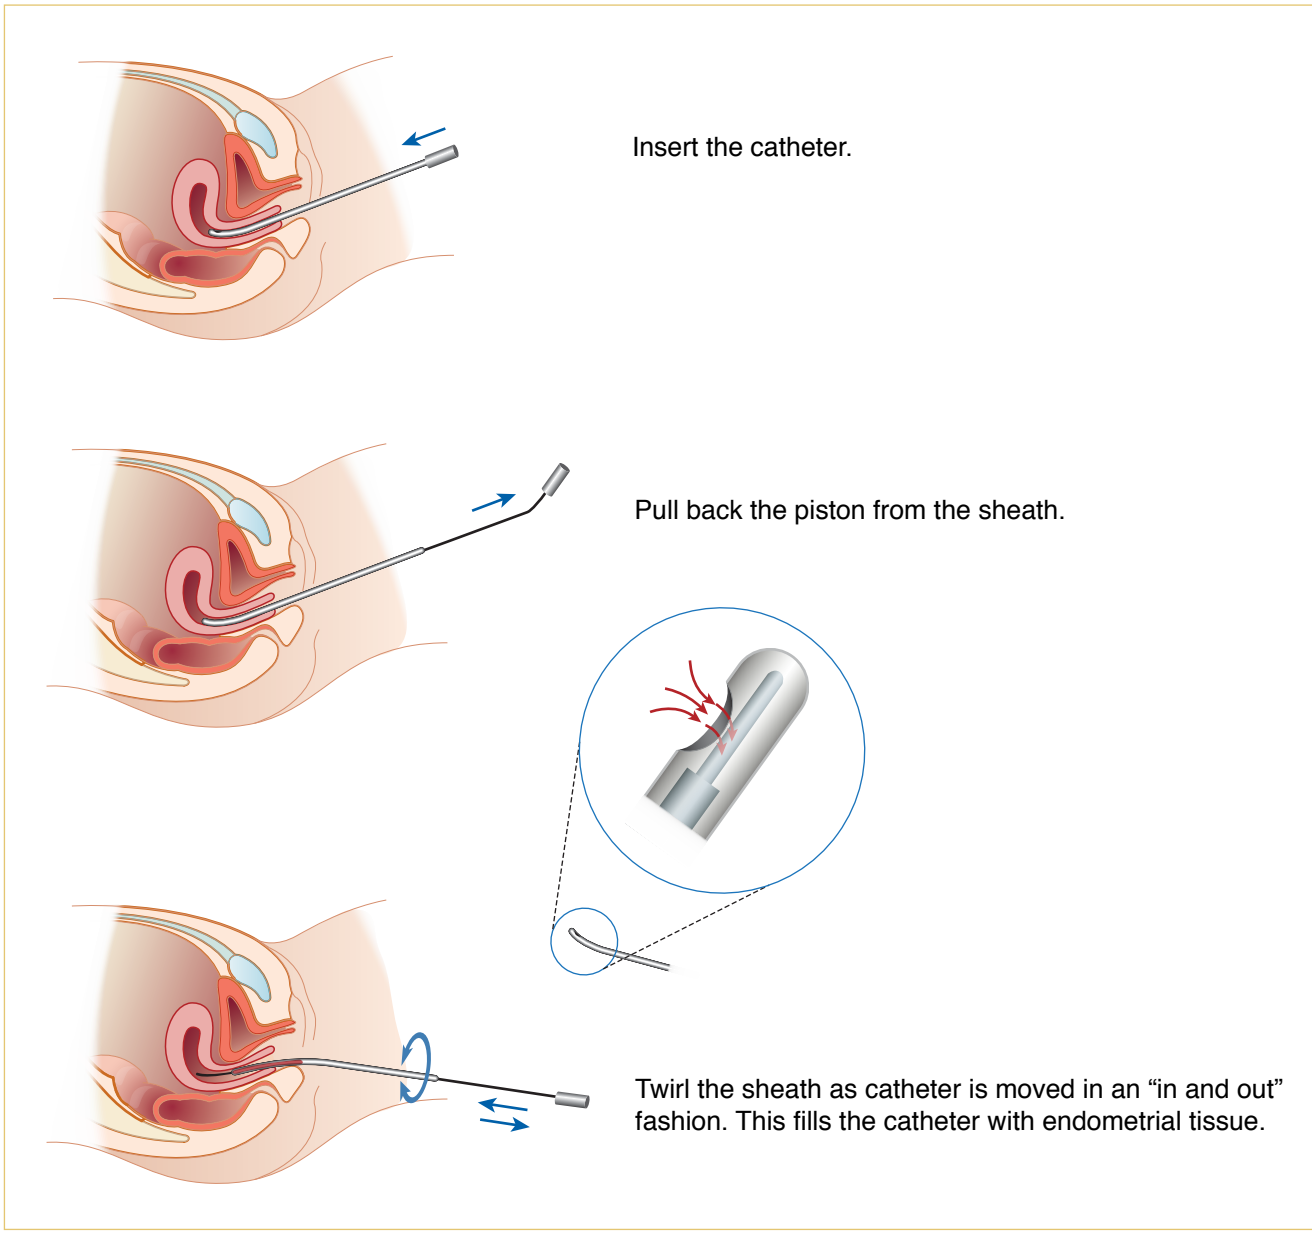


Figure II-1-8. Endometrial Biopsy

Vulvar Biopsy

This is a minor outpatient office procedure performed under local anesthesia. It is a diagnostic test that examines the histology of vulvar lesions.

- It can be performed using either a punch biopsy or a scalpel.

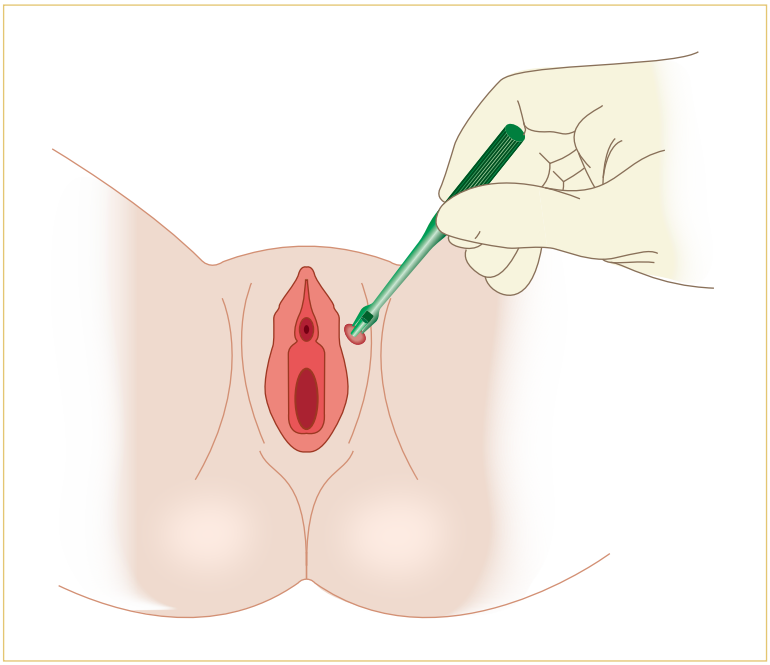

Figure II-1-9. Vulvar Biopsy

Mammography

Mammography is an outpatient office radiologic procedure.

- It may be a screening test for breast cancer when performed on asymptomatic women. These screenings typically use two views of each breast: **craniocaudal** and **lateral**. The patient is encouraged to lean in toward the device to image as much of the breast tissue as possible.
- Recommended **age to start mammograms** varies among medical organizations, ranging from age 40–50. The conflicting recommendations result from differing views of "harm versus benefit" studies.
  - **Starting screening at age 40** gives potentially earlier cancer diagnosis (benefit) but at the cost of higher false-positives with unnecessary follow-up testing and anxiety (harms). False-negatives occur more in younger women and those with denser breasts.
  - **Starting screening at age 50** gives fewer false negatives (benefit) but at a cost of potentially later diagnosis (harm).
  - The best strategy is for doctors to assess individual patient risk and engage in **shared decision-making** with the patient.
- If mammography is performed because of a breast complaint (e.g., breast mass, nipple discharge, abnormal screening mammogram), many images are taken, some under higher magnification to better visualize the target area.
- **Risks:** ionizing radiation exposure 0.7 mSv, which is about the same as the average person receives from background radiation in 3 months (1 Rad = 10 mSv).

Pelvic Relaxation 2

Learning Objectives

- ❏ Demonstrate the relation between uterine/vaginal prolapse and urinary incontinence
- ❏ Describe other expected complications

UTERINE AND VAGINAL PROLAPSE

A 62-year-old woman complains of low back pain and perineal pressure for 18 months. She had been recommended by another physician to wear a pessary, which she is reluctant to do. On pelvic examination a second-degree uterine prolapse with a cystocele and a rectocele is observed.

Anatomy. The pelvic floor is made up of the diaphragm and perineal membrane.

- **Pelvic diaphragm.** The pelvic diaphragm consists of the levator ani and coccygeus muscles. The levator ani consists of 3 muscles: puborectalis, pubococcygeus, and ileococcygeus.
- **Perineal membrane.** This is a triangular sheet of dense fibromuscular tissue that spans the anterior half of the pelvic outlet. The vagina and the urethra pass through the perineal membrane (urogenital diaphragm).
- **Uterine support.** The main structures that support the uterus are the cardinal ligaments, the uterosacral ligaments, and the endopelvic fascia.

Etiology. The etiology of pelvic relaxation is **most commonly** related to childbirth. The mechanical trauma of childbirth stresses and tears the supporting ligaments of the pelvic retroperitoneum in the pelvis whose main function is to support the pelvic viscera.

Classification. The components of pelvic relaxation include uterine prolapse, cystocele, rectocele, and enterocele. Lesser forms of pelvic relaxation include vaginal or vault prolapse.

- **Uterine prolapse.** The severity of prolapse is indicated by increase in grade from I to IV.
  - Grade I: Cervix descends half way to the introitus.
  - Grade II: Cervix descends to the introitus.
  - Grade III: Cervix extends outside the introitus.
  - Grade IV or procidentia: The entire uterus, as well as the anterior and posterior vaginal walls, extends outside the introitus.

GYN Triad

Cystocele

- Postmenopausal woman
- Anterior vaginal wall protrusion
- Urinary incontinence

- **Cystocele.** Herniation or bulging of the anterior vaginal wall and overlying bladder base into the vaginal lumen
- **Rectocele.** Herniation or bulging of the posterior vaginal wall and underlying rectum into the vaginal lumen
- **Enterocele.** Herniation of the pouch of Douglas containing small bowel into the vaginal lumen

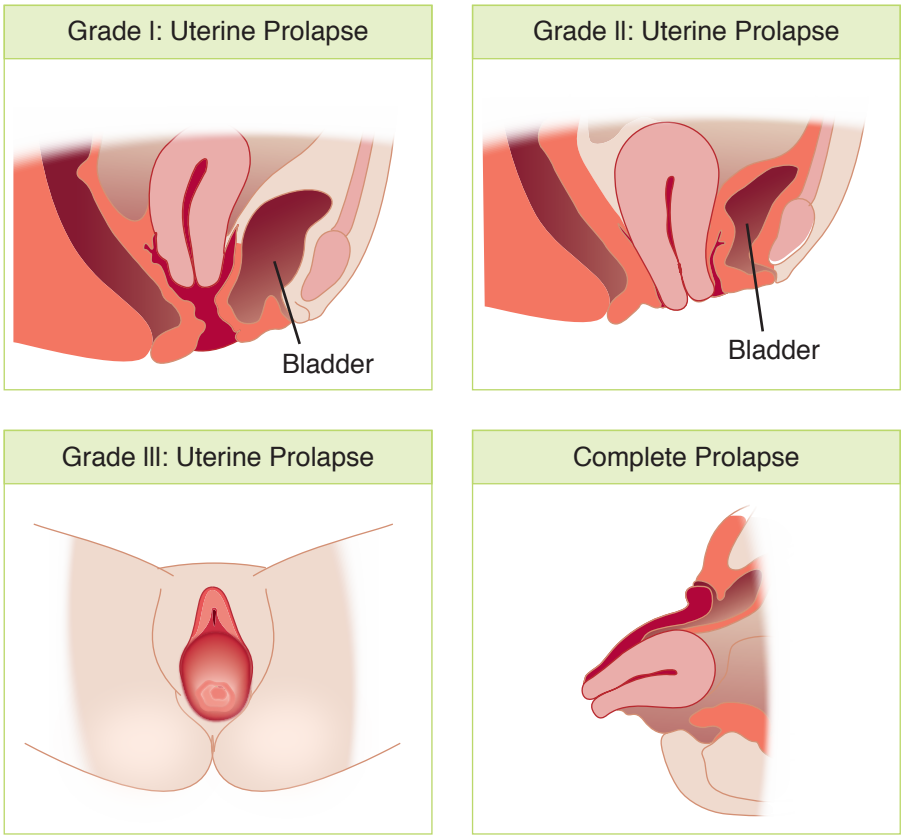

Figure II-2-1. Uterine Prolapse

GYN Triad

Rectocele

- Postmenopausal woman
- Posterior vaginal wall protrusion
- Digitally assisted removal of stool

Table II-2-1. Vaginal Prolapse

Anterior	Cystocele
Posterior	Rectocele
Pouch of Douglas	Enterocele

Diagnosis. The diagnosis of pelvic relaxation is mainly made through observation at the time of **pelvic examination**. The prolapsed vagina, rectum, and uterus are easily visualized particularly as the patient increases intraabdominal pressure by straining.

Management. The management of pelvic relaxation includes non-surgical and surgical treatment.

- **Non-surgical.** Used when there is a minor degree of relaxation. **Kegel** exercises involve voluntary contractions of the pubococcygeus muscle. **Estrogen** replacement may be useful in postmenopausal women. **Pessaries** are objects inserted into the vagina that elevate the pelvic structures into their more normal anatomic relationships.
- **Surgical.** Used when more conservative management has failed. The **vaginal hysterectomy** repairs the uterine prolapse, the anterior vaginal repair repairs the cystocele, and the posterior vaginal repair repairs the rectocele. The **anterior and posterior colporrhaphy** uses the endopelvic fascia that supports the bladder and the rectum, and a plication of this fascia restores normal anatomy to the bladder and to the rectum.

Follow-Up. Strenuous activity should be limited for about 3 months postoperatively to avoid recurrence of the relaxation.

URINARY INCONTINENCE

A 58-year-old woman complains of urinary leakage after exertion. She loses urine while coughing, sneezing, and playing golf. She underwent menopause 5 years ago and is not on estrogen therapy. On examination there is evidence of urethral detachment with a positive Q-tip test.

Definition. Urinary incontinence is the inability to hold urine, producing involuntary urinary leakage.

Physiology of Continence. Continence and micturition involve a balance between urethral closure and detrusor muscle activity. Urethral pressure normally exceeds bladder pressure, resulting in urine remaining in the bladder. The proximal urethra and bladder are normally both within the pelvis. Intraabdominal pressure increases (from coughing and sneezing) are transmitted to both urethra and bladder equally, leaving the pressure differential unchanged, resulting in continence. Normal voiding is the result of changes in both of these pressure factors: urethral pressure falls and bladder pressure rises. Spontaneous bladder muscle (detrusor) contractions are normally easily suppressed voluntarily.

Pharmacology of Incontinence

- **α-adrenergic receptors.** These are found primarily in the urethra and when stimulated cause contraction of urethral smooth muscle, preventing micturition. Drugs: ephedrine, imipramine (Tofranil), and estrogens. α-adrenergic blockers or antagonists relax the urethra, enhancing micturition. Drugs: phenoxybenzamine (Dibenzyline).
- **β-adrenergic receptors.** These are found primarily in the detrusor muscle and when stimulated cause relaxation of the bladder wall, preventing micturition. Drugs: flavoxate (Urispas) and progestins.
- **Cholinergic receptors.** These are found primarily in the detrusor muscle and when stimulated cause contraction of the bladder wall, enhancing micturition. Drugs: bethanecol (Urecholine) and neostigmine (Prostigmine). Anticholinergic medications block the receptors, inhibiting micturition. Drugs: oxybutynin (Ditropan) and propantheline (Pro-Banthine).

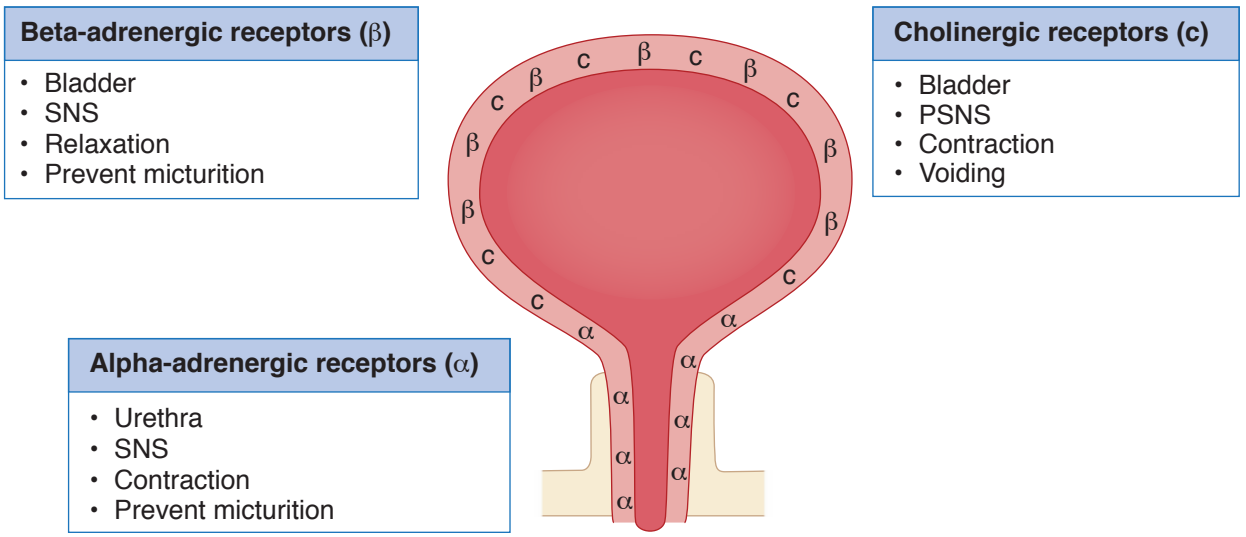

Figure II-2-2. Continence and Micturition

Cystometric studies. Basic office cystometry begins with the patient emptying her bladder as much as possible. A urinary catheter is first used to empty the bladder and then left in place to infuse saline by gravity, with a syringe into the bladder retrograde assessing the following:

- **Residual volume.** How much is left in the bladder? Normal is <50 mL.
- **Sensation-of-fullness volume.** How much infusion (in mL) until the patient senses fluid in her bladder? Normal is 200–225 mL.
- **Urge-to-void volume.** How much infusion (in mL) until the patient feels the need to empty her bladder? Normal is 400–500 mL.

Involuntary bladder contractions. By watching the saline level in the syringe rise or fall, involuntary detrusor contractions can be detected. The absence of contractions is normal.

Table II-2-2. Cystometric Volume Measurements

Post-void residual	<50 mL
Sensation of fullness	200–225 mL
Urge to void	400–500 mL

Classification of Incontinence

Most of the following types of incontinence result when bladder pressure rises in isolation of increases in urethral pressure.

Sensory Irritative Incontinence

- **Etiology.** Involuntary rises in bladder pressure occur owing to detrusor contractions stimulated by irritation from any of the following bladder conditions: infection, stone, tumor, or a foreign body.

- **History.** Loss of urine occurs with urgency, frequency, and dysuria. This can take place day or night.
- **Examination.** Suprapubic tenderness may be elicited, but otherwise the pelvic examination is unremarkable.
- **Investigative studies.** A urinalysis will show the following abnormalities: bacteria and white blood cells (suggest an infection) or red blood cells (suggest a stone, foreign body, or tumor). A urine culture is positive if an infection is present. Cystometric studies (which are usually unnecessary) would reveal normal residual volume with involuntary detrusor contractions present.
- **Management.** Infections are treated with antibiotics. Cytoscopy is used to diagnose and remove stones, foreign bodies, and tumors.

Genuine Stress Incontinence. This is the **most common** incontinence in **young women**.

- **Etiology.** Rises in bladder pressure because of intraabdominal pressure increases (e.g., coughing and sneezing) are not transmitted to the proximal urethra because it is no longer a pelvic structure owing to loss of support from pelvic relaxation.
- **History.** Loss of urine occurs in small spurts simultaneously with coughing or sneezing. **It does not take place when the patient is sleeping.**
- **Examination.** Pelvic examination may reveal a cystocele. Neurologic examination is normal. The Q-tip test is positive when a lubricated cotton-tip applicator is placed in the urethra and the patient increases intraabdominal pressure, the Q-tip will rotate >30 degrees.
- **Investigative studies.** Urinalysis and culture are normal. Cystometric studies are normal with no involuntary detrusor contractions seen.
- **Management.** Medical therapy includes Kegel exercises and estrogen replacement in postmenopausal women. Surgical therapy aims to elevate the urethral sphincter so that it is again an intraabdominal location (urethropexy). This is done by attachment of the sphincter to the symphysis pubis, using the Burch procedure as well as the Marshall-Marchetti-Kranz (MMK) procedure. The success rate of both of these procedures is 85–90%. A minimally invasive surgical procedure is the tension-free vaginal tape procedure in which a mesh tape is placed transcutaneously around and under the mid urethra. It does not elevate the urethra but forms a resistant platform against intraabdominal pressure.

GYN Triad

Stress Incontinence

- Involuntary loss of urine
- With coughing and sneezing
- No urine lost at night

Motor Urge (Hypertonic) Incontinence. This is the **most common** incontinence in **older women**.

- **Etiology.** Involuntary rises in bladder pressure occur from idiopathic detrusor contractions that cannot be voluntarily suppressed.
- **History.** Loss of urine occurs in large amounts often without warning. This can take place both day and night. The most common symptom is urgency.
- **Examination.** Pelvic examination shows normal anatomy. Neurologic examination is normal.
- **Investigative studies.** Urinalysis and culture are normal. Cystometric studies show normal residual volume, but involuntary detrusor contractions are present even with small volumes of urine in the bladder.
- **Management.** Anticholinergic medications (e.g., oxybutynin [Ditropan]); nonsteroidal antiinflammatory drugs (NSAIDs) to inhibit detrusor contractions; tricyclic antidepressants; calcium-channel blockers.

GYN Triad

Hypertonic Bladder

- Involuntary loss of urine
- Cannot suppress urge to void
- Urine loss day and night

GYN Triad

Hypotonic bladder

- Involuntary loss of urine
- Detrusor muscle not contracted
- Urine loss day and night

Overflow (Hypotonic) Incontinence

- **Etiology.** Rises in bladder pressure occur gradually from an overdistended, hypotonic bladder. When the bladder pressure exceeds the urethral pressure, involuntary urine loss occurs but only until the bladder pressure equals urethral pressure. The **bladder never empties**. Then the process begins all over. This may be caused by denervated bladder (e.g., diabetic neuropathy, multiple sclerosis) or systemic medications (e.g., ganglionic blockers, anticholinergics).
- **History.** Loss of urine occurs intermittently in small amounts. This can take place **both day and night**. The patient may complain of pelvic fullness.
- **Examination.** Pelvic examination may show normal anatomy; however, the neurologic examination will show decreased pudendal nerve sensation.
- **Investigative studies.** Urinalysis and culture are usually normal, but may show an infection. Cystometric studies show **markedly increased residual volume**, but involuntary detrusor contractions do not occur.
- **Management.** Intermittent self-catheterization may be necessary. Discontinue the offending systemic medications. Cholinergic medications to stimulate bladder contractions and α-adrenergic blocker to relax the bladder neck.

GYN Triad

Bypass Incontinence

- Involuntary loss of urine
- History: radical pelvic surgery or radiation
- Urine loss day and night continuously

Fistula

- **Etiology.** The normal urethral-bladder mechanism is intact, but is bypassed by urine leaking out through a fistula from the urinary tract.
- **History.** The patient usually has a history of radical pelvic surgery or pelvic radiation therapy. Loss of urine **occurs continually** in small amounts. This can take place **both day and night**.
- **Examination.** Pelvic examination may show normal anatomy and normal neurologic findings.
- **Investigative studies.** Urinalysis and culture are normal. An intravenous pyelogram (IVP) will demonstrate dye leakage from a urinary tract fistula. With a urinary tract-vaginal fistula, intravenous indigo carmine dye will leak onto a vaginal tampon.
- **Management.** Surgical repair of the fistula.

Table II-2-3. Inhibit/Promote Voiding

Inhibit Voiding	Promote Voiding
Bladder relaxants	**Bladder contraction**
Antispasmodics Oxybutynin (Ditropan) Flavoxate (Urispas)	**Cholinergics** Bethanechol (Urecholine) Neostigmine (Prostigmin)
Anticholinergics Pro-Banthine	
Tricyclics Imipramine (Tofranil)	
Vesical neck contraction	**Vesical neck relaxants**
Alpha adrenergics Ephedrine Imipramine	**Alpha antagonists** Methyldopa Phenothiazines
Estrogen stimulates alpha receptors	
Progesterone stimulates beta receptors	

Disorders of the Vagina and Vulva

3

Learning Objectives

- ❏ Describe the common causes, diagnosis, and treatment of vaginal discharge
- ❏ List the most common vulvar diseases

VAGINAL DISCHARGE

A 25-year-old woman complains of a whitish vaginal discharge. The patient states that this is the first time that she has this complaint, and it is associated with vaginal and vulvar pruritus. There is no significant medical history, and she is not on oral contraception.

Diagnostic Tests

- **Visual inspection.** The vulva and vagina should be examined for evidence of an inflammatory response as well as the gross characteristics of the vaginal discharge seen on speculum examination.
- **Vaginal pH.** Normal vaginal pH is an acidic <4.5. Identification of the pH is easily performed using pH-dependent Nitrazine paper. Normal vaginal discharge leaves the paper yellow, whereas an elevated pH turns the paper dark.
- **Microscopic examination.** Two drops of the vaginal discharge are placed on a glass slide with a drop of normal saline placed on one, and a drop of KOH placed on the other. The 2 sites are covered with cover slips and examined under the microscope for WBC, pseudohyphae, trichomonads, and clue cells.

Bacterial Vaginosis

Background. This is the **most common** (50%) cause of vaginal complaints in the United States. It is not a true infection but rather an alteration in concentrations of normal vaginal bacteria. The normal predominant lactobacilli are replaced by massive increases in concentrations of anaerobic species and facultative aerobes. It is frequently seen postmenopausally because of low levels of estrogen. It is not sexually transmitted, but it is associated with sexual activity.

Symptoms. The **most common** patient complaint is a fishy odor. Itching and burning are not present.

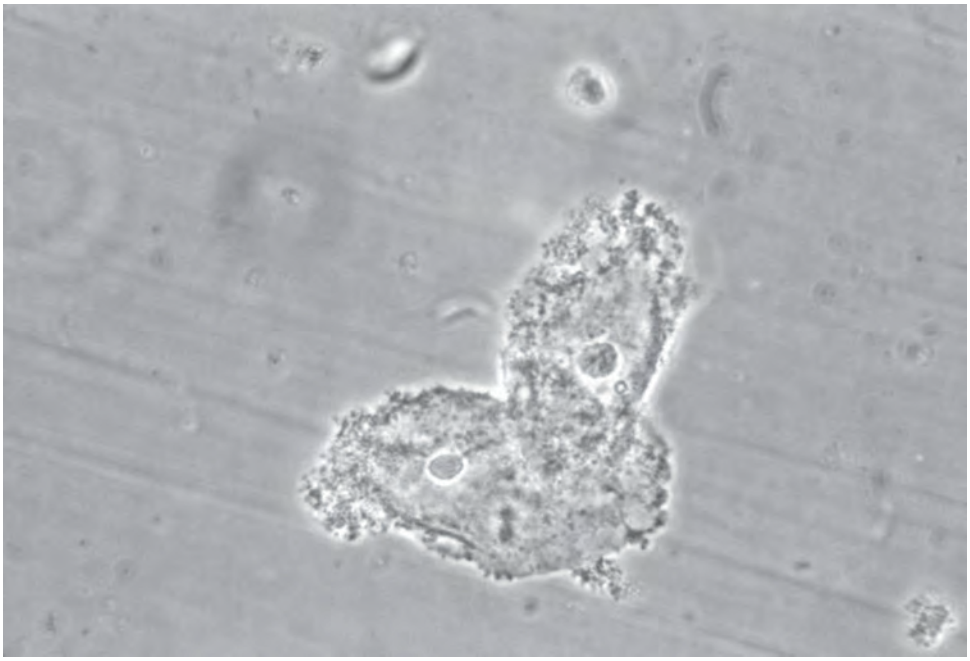
GYN Triad

Bacterial Vaginosis

- Vaginal discharge pH >4.5
- Fishy odor
- "Clue" cells

Speculum Examination. The vaginal discharge is typically thin, grayish-white. No vaginal inflammation is noted. The vaginal pH is elevated above 4.5. A positive **"whiff"** test is elicited when KOH is placed on the discharge, releasing a fishy odor.

Wet Mount. Microscopic examination reveals **"clue cells"** on a saline preparation. These are normal vaginal epithelial cells with the normally sharp cell borders obscured by increased numbers of anaerobic bacteria. WBCs are rarely seen.



phil.cdc.gov

Figure II-3-1. Clue Cells on Wet Mount

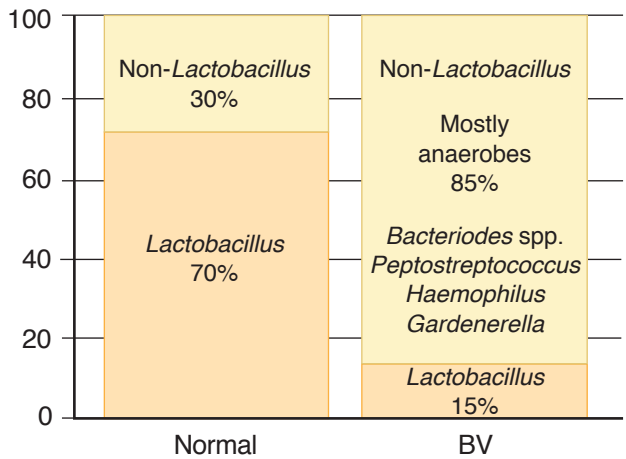


Figure II-3-2. Change in Vaginal Flora with Bacterial Vaginosis (BV)

Management. The treatment of choice is metronidazole or clindamycin administered either orally or vaginally. Metronidazole is safe to use during pregnancy, including the first trimester.

Trichomonas Vaginitis

Background. This is the **most common** cause of vaginal complaints worldwide and is the second most common sexually transmitted disease (**STD**) in the United States. It is caused by a flagellated pear-shaped protozoan that can reside asymptomatically in male seminal fluid.

Symptoms. The **most common** patient complaint is vaginal discharge associated with itching, burning, and pain with intercourse.

Speculum Examination. Vaginal discharge is typically frothy and green. The vaginal epithelium is frequently edematous and inflamed. The erythematous cervix may demonstrate the characteristic **"strawberry"** appearance. Vaginal pH is elevated >4.5.

Wet Mount. Microscopic examination reveals actively motile "trichomonads" on a saline preparation. WBCs are seen.

Management. The treatment of choice is oral metronidazole for both the patient and her sexual partner. Vaginal metronidazole gel has a 50% failure rate. Metronidazole is safe to use during pregnancy, including the first trimester.

GYN Triad

Trichomonas Vagin*itis*

- Vaginal discharge >4.5
- Itching and burning
- "Strawberry" cervix

Candida (Yeast) Vaginitis

Background. This is the second most common vaginal complaint in the United States. The **most common** organism is *Candida albicans*. It is not transmitted sexually.

Risk Factors. These include diabetes mellitus, systemic antibiotics, pregnancy, obesity, and decreased immunity.

Symptoms. The **most common** patient complaint is itching, burning, and pain with intercourse. *Candida* vaginitis is seen in non-sexually active patients as well.

Speculum Examination. Vaginal discharge is typically curdy and white. The vaginal epithelium is frequently edematous and inflamed. Vaginal pH is normal <4.5.

Wet Mount. Microscopic examination reveals **pseudohyphae** on a KOH prep. WBCs are frequently seen.

Management. The treatment of choice is either a single oral dose of fluconazole or vaginal "azole" creams. An asymptomatic sexual partner does not need to be treated.

GYN Triad

Yeast Vagin*itis*

- Vaginal discharge pH <4.5
- Itching and burning
- Pseudohyphae

Physiologic Discharge

Background. This condition is the result of the thin, watery cervical mucus discharge seen with estrogen dominance. It is a normal phenomenon and becomes a complaint with prolonged anovulation, particularly in patients with wide eversion of columnar epithelium.

Risk factors. These include chronic anovulatory conditions such as polycystic ovarian (PCOS) syndrome.

Symptoms. The **most common** patient complaint is increased watery vaginal discharge. There is no burning or itching.

Speculum Exam. The columnar epithelium of the endocervical canal extends over a wide area of the ectocervix, producing abundant mucus discharge. Vaginal discharge is typically thin and watery. The vaginal epithelium is normal appearing with no inflammation. Vaginal pH is normal (<4.5).

Wet Mount. Microscopic examination reveals an absence of WBCs, "clue cells," trichomonads, or pseudohyphae.

Management. The treatment of choice is steroid contraception with progestins, which will convert the thin, watery, estrogen-dominant cervical discharge to a thick, sticky progestin-dominant mucus.

VULVAR DISEASES

Vulvar Lesion with Pruritus/Neoplasia

A 70-year-old woman complains of vulvar itching for a year. She has been treated with multiple steroid medications with no relief. On pelvic examination there is a well-defined, 1-cm white lesion of the left labia minora. There are no other lesions in the vulva noted; however, there is a clinical enlargement of a left inguinal node.

Clinical Presentation. The **most common** symptom of both benign as well as malignant lesions is vulvar itching resulting in scratching.

Differential Diagnosis. This includes sexually transmitted diseases, benign vulvar dermatosis, or cancers.

Premalignant vulvar dermatosis

These are benign lesions with **malignant predisposition**. The most common symptom is vulvar itching, but most lesions are asymptomatic.

- **Squamous hyperplasia.** These lesions appear as whitish focal or diffuse areas that are firm and cartilaginous on palpation. Histologically, they show thickened keratin and epithelial proliferation. **Management** is fluorinated corticosteroid cream.
- **Lichen sclerosus.** This appears as bluish-white papula that can coalesce into white plaques. On palpation they feel thin and parchment-like. Histologically, they show epithelial thinning. **Management** is Clobetasol cream.
- **Squamous dysplasia.** These lesions appear as white, red, or pigmented, often multifocal in location. Histologically, they show cellular atypia restricted to the epithelium without breaking through the basement membrane. The appearance is almost identical to cervical dysplasia. **Management** is surgical excision.
- **CIS.** The appearance is indistinguishable from vulvar dysplasia. Histologically, the cellular atypia is full thickness but does not penetrate the basement membrane. **Management** is laser vaporization and vulvar wide local excision.

Note

Vulvar dystrophies must also be considered in patients presenting with vulvar itching.

Malignant vulvar lesions

Epidemiology. Vulvar carcinoma is an **uncommon** gynecologic malignancy, with a mean age at diagnosis of 65 years. It is the fourth most common gynecologic malignancy. Risk factors include older age, cigarette smoking, HIV, premalignant vulvar dermatosis.

- **Squamous cell** (90%). The **most common** type of invasive vulvar cancer is squamous cell carcinoma, which has been associated with HPV. Pathogenesis is chronic inflammation (for older women) and HPV infection (for younger women). The **most common** stage at diagnosis is Stage 1.
- **Melanoma** (5%). The **second most common** histologic type of vulvar cancer is melanoma of the vulva, and the most important prognostic factor for this type of tumor is the depth of invasion. Any dark or black lesion in the vulva should be biopsied and considered for melanoma.
- **Paget disease.** An uncommon histologic lesion is Paget disease of the vulva. Paget disease is characteristically a **red lesion**, which is **most common** in postmenopausal white women. Any patient with a red vulvar lesion must be considered for the possibility of Paget disease. Most of the time Paget disease is an intraepithelial process; however, in approximately 18–20% of cases invasion of the basement membrane has been identified. Patients with Paget disease of the vulva have a higher association of other cancers mainly from the GI tract, the genitourinary system, and breast.

Diagnosis. Biopsy. All vulvar lesions of uncertain etiology should be biopsied. Patients with vulvar pruritus should be considered for the possibility of preinvasive or invasive vulvar carcinomas if there is a vulvar lesion. A biopsy of this patient's lesion reveals invasive squamous cell carcinoma of the vulva.

Pattern of spread. It starts with local growth and extension that embolizes to inguinal lymph nodes and finally, hematogenous spread to distant sites.

Staging. Staging is **surgical**.

Stage 0:	CIS (basement membrane is intact)
Stage I:	Tumor confined to the vulva with size ≤2 cm; nodes not palpable
IA.	Invasion ≤1 mm deep
IB.	Invasion >1 mm deep
Stage II:	Tumor confined to the vulva with size >2 cm; nodes not palpable
Stage III:	Tumor any size with spread to lower urethra, vagina, or anus; unilateral nodes
Stage IV:	Widespread metastases
IVA.	Involves upper urethra, bladder or rectum, pelvic bone, bilateral nodes
IVB.	Distant metastasis

Management

- **Wide local excision only:** used only for stage IA; risk of metastasis is negligible so no lymphadenectomy is needed
- **Modified radical vulvectomy:** involves radical local excision
  - Ipsilateral inguinal dissection is used only if stage is IB & unifocal lesion >1 cm from midline AND no palpable nodes
  - Bilateral inguinal dissection is used if at least stage IB or a centrally located lesion OR palpable inguinal nodes or positive ipsilateral nodes

- **Radical vulvectomy:** involves removal of labia minora & majora, clitoris, perineum, perineal body, mons pubis; seldom performed due to high morbidity
- **Pelvic exenteration**. In addition to radical vulvectomy, it involves removal of cervix, vagina and ovaries in addition to lower colon, rectum and bladder (with creation of appropriate stomas); seldom indicated or performed due to high morbidity.
- **Radiation therapy:** used for patients who cannot undergo surgery

Table II-3-1. Management of Vulvar Carcinoma

Radical vulvectomy	Removes entire vulva (subcutaneous and fatty tissue, labia minora and majora, perineal skin, clitoris)	Sexual dysfunction
Modified radical vulvectomy	Wide local excision (for **unilateral** labial lesions that do not cross the midline)	Less sexual morbidity
Lymphadenectomy	Inguinal node dissection (**bilateral** if midline lesions >1 mm invasion; **unilateral** selectively)	Lower-extremity edema

Benign Vulvar Lesions

- ***Mulluscom contagiosum.*** A common benign, viral skin infection. Most commonly seen in children, sexually active adults, and immunodeficient patients. The molluscipox virus causes spontaneously regressing, umbilicated tumors of the skin rather than poxlike vesicular lesions. Mulluscom contagiosum is transmitted primarily through direct skin contact with an infected individual. **Management** includes observation, curettage, and cryotherapy.
- **Condylomata acuminata.** These are benign cauliflowerlike vulvar lesions due to HPV types 6 & 11. They have no malignant predisposition. Condylomata are discussed in detail in chapter 7. **Management** is to treat clinical lesions only.
- **Bartholin cyst.** Obstruction of the Bartholins gland duct may occur due to infection mostly due to *E. coli* and anaerobic *Bacteroides* species, and seldom due to gonococcus. After immune defenses overcome the infection the duct remains obstructed resulting in cystic dilation of the gland. Aspiration of the cyst yields sterile fluid. **Management** is conservative unless pressure symptoms due to size. Bartholin cyst is discussed in chapter 7.

Disorders of the Cervix and Uterus

4

Learning Objectives

- ❏ Explain the use of vaccination to prevent cervical dysplasia
- ❏ List the common findings and their significance when diagnosing cervical lesions
- ❏ Give an overview of the epidemiology and management of cervical neoplasia
- ❏ Describe Müllerian anomalies
- ❏ Give a differential diagnosis for enlarged uterus and describe the treatment and prognosis of endometrial neoplasia

CERVICAL LESIONS

Cervical Polyps

Description. Cervical polyps are fingerlike growths that start on the surface of the cervix or endocervical canal. These small, fragile growths hang from a stalk and push through the cervical opening.

- The cause of cervical polyps is not completely understood. They may be associated with chronic inflammation, an abnormal response to increased levels of estrogen, or thrombosed cervical blood vessels.
- Cervical polyps are relatively common, especially in older multiparous women. Only a single polyp is present in most cases, but sometimes two or three are found.

Findings

- The history is usually positive for vaginal bleeding, often after intercourse. This bleeding occurs between normal menstrual periods.
- Speculum examination reveals smooth, red or purple, fingerlike projections from the cervical canal.
- A cervical biopsy typically reveals mildly atypical cells and signs of infection.

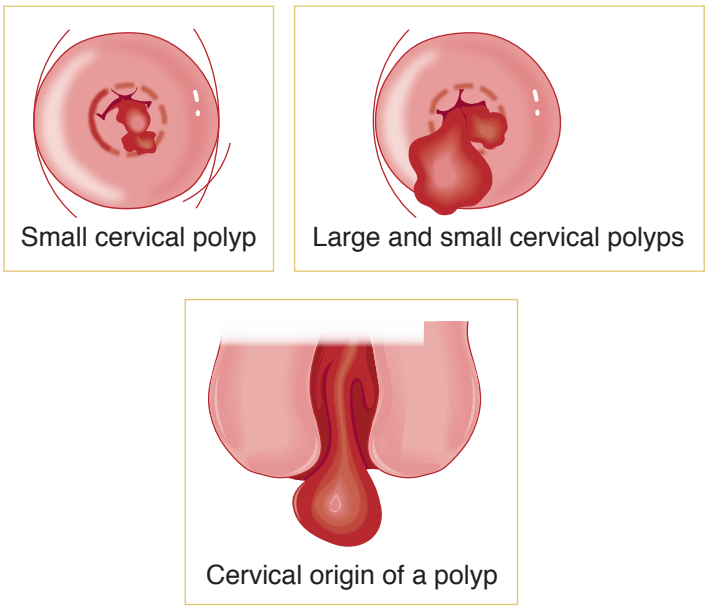

Figure II-4-1. Cervical Polyps

Management

- Polyps can be removed by gentle twisting or by tying a surgical string around the base and cutting it off. Removal of the polyp's base is done by electrocautery or with a laser.
- Because many polyps are infected, an antibiotic may be given after the removal even if there are no or few signs of infection. Although most cervical polyps are benign, the removed tissue should be sent to pathology. Regrowth of polyps is uncommon.

Nabothian Cysts

A nabothian cyst is a mucus-filled cyst on the surface of the uterine cervix. The cervical canal is lined by glandular cells that normally secrete mucus. These endocervical glands can become covered by squamous epithelium through metaplasia.

This is a benign condition. Rarely, cysts may become so numerous or enlarged that the cervix becomes clinically enlarged.

- These nests of glandular cells (nabothian glands) on the cervix may become filled with secretions. As secretions accumulate, a smooth, rounded lump may form just under the surface of the cervix and become large enough to be seen or felt upon examination.
- Each cyst appears as a small, white, pimple-like elevation. The cysts can occur singly or in groups, and they are not a threat to health. The cysts are more common in women of reproductive age, especially women who have already had children. There are no observable symptoms.

Findings. Pelvic examination reveals a small, smooth, rounded lump (or collection of lumps) on the surface of the cervix. Rarely, a colposcopic exam is necessary to distinguish nabothian cysts from other types of cervical lesions.

Management. No treatment is necessary. However, nabothian cysts do not clear spontaneously. They can be easily cured through electrocautery or cryotherapy. Both procedures can be done in the doctor's office.

Cervicitis

Symptoms. Often, there are no symptoms, except vaginal discharge.

Examination. The **most common** finding is mucopurulent cervical discharge and a friable cervix. This diagnostic finding is confirmed by endocervical bleeding easily induced by passage of a cotton swab through the cervical os. No pelvic tenderness is noted. Patient is afebrile.

Investigative Findings. Routine cervical cultures are positive for chlamydia or gonorrhea. WBC and ESR are normal.

Management. Oral azithromycin in a single dose or oral doxycycline BID for 7 days.

CERVICAL NEOPLASIA

Abnormal Pap Smear

A 24-year-old woman is referred because of a Pap smear showing HSIL (high-grade squamous intraepithelial lesion). The patient, states that her Pap smear 3 years ago was negative. She has been on combination steroid vaginal ring contraception for the past 4 years. Her cervix appears unremarkable on gross visual inspection.

Presentation. Premalignant lesions of the cervix are usually **asymptomatic**. The progression from premalignant to invasive cancer has been reported to be approximately 8–10 years. Most lesions will spontaneously regress; others remain static, with only a minority progressing to cancer.

Etiology. The **most common** etiology of cervical cancer is the human papilloma virus (HPV). Over 75 subtypes of HPV have been identified. HPV **16, 18, 31, 33,** and **35** are the **most common** HPV types associated with premalignant and cancerous lesions of the cervix. HPV **6** and **11** are the **most common** HPV types associated with benign condyloma acuminata.

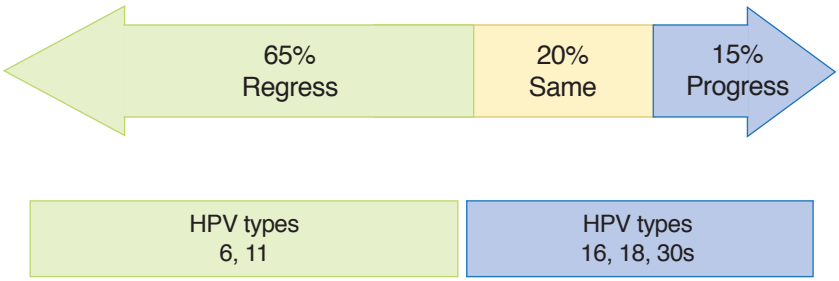

Figure II-4-2. Natural History of Cervical Dysplasia: Response to HPV types

Risk Factors. These include early age of intercourse, multiple sexual partners, cigarette smoking, and immunosuppression. The mediating factor for all these conditions is probably HPV.

Screening and Performing a Pap Smear

The best screening test for premalignant lesions is **cytology**. Cytologic screening uses the **Pap test**. The **most common** site for cervical dysplasia is the transformation zone (T-zone).

- **How is it performed?** Two specimens are obtained with the Pap smear: an ectocervical sample performed by scraping the T-zone with a spatula, and an endocervical sample obtained with a cytobrush in the nonpregnant woman or a cotton-tip applicator in a pregnant woman.
- **What cytologic screening methods can be used?**
  - With the **conventional method**, the specimens are smeared onto a glass slide, which is placed in fixative and then microscopically examined.
  - With the **thin-layer, liquid-based cytology**, the specimens are rinsed into a preserving solution and are then deposited on a slide as a thin layer of processed cells.
  - Both methods are equivalent for cancer screening but the liquid-based method has the advantage of doing reflex HPV-DNA typing.

Pap smear should be started at the following ages:

- **Age <21**: no Pap test or screening for HPV, regardless of sexual activity
- **Age 21***:* Start Pap test with cytology alone without HPV testing; the recommendation is the same whether HPV vaccinated or not

The frequency of recommended Pap smear is as follows:

- **Age 21–29**: repeat Pap every 3 years with cytology alone; do not perform HPV testing in this age group
- **Age 30–65**: repeat Pap every 3 years with cytology but no HPV testing **OR** repeat Pap every 5 years if both cytology and HPV testing (the recommended option in this age group)

Pap smears should be discontinued:

- **After age 65** if negative cytology and/or HPV tests for past 10 years **AND** no history of CIN 2, CIN 3 or cervical carcinoma
- **Any age** if total hysterectomy **AND** no history of cervical neoplasia

Pap Smear Classification

The **Bethesda system** is the current classification used in the United States.

- **Negative** for intraepithelial lesion or malignancy; comments may report trichomoniasis, candida, BV, HSV, or atrophy
- **Abnormal squamous cells** (99% of abnormal Pap smears)
  - **ASC-US (atypical squamous cells of undetermined significance):** changes suggestive of but not adequate to label LSIL
  - **LSIL (low-grade squamous intraepithelial lesion):** biopsy is expected to show histologic findings of HPV, mild dysplasia, or CIN 1
  - **ASC-H (atypical squamous cells can't rule out HSIL):** changes suggestive of but not adequate to label HSIL
  - **HSIL (high-grade squamous intraepithelial lesion):** biopsy is expected to show histologic findings of moderate–severe dysplasia, CIN 2, CIN 3, or CIS
  - **Squamous cell carcinoma**: biopsy is expected to show histologic findings of invasive cancer
- **Abnormal endocervical cells** (1% of abnormal Pap smears)
  - **AGC-NOS (atypical glandular cells, not otherwise specified)**
  - **AGC-neoplastic (atypical glandular cells, can't rule out neoplasia):** changes suggestive of but not adequate to call AIS or cancer
  - **AIS (adenocarcinoma in situ)**
  - **Adenocarcinoma**

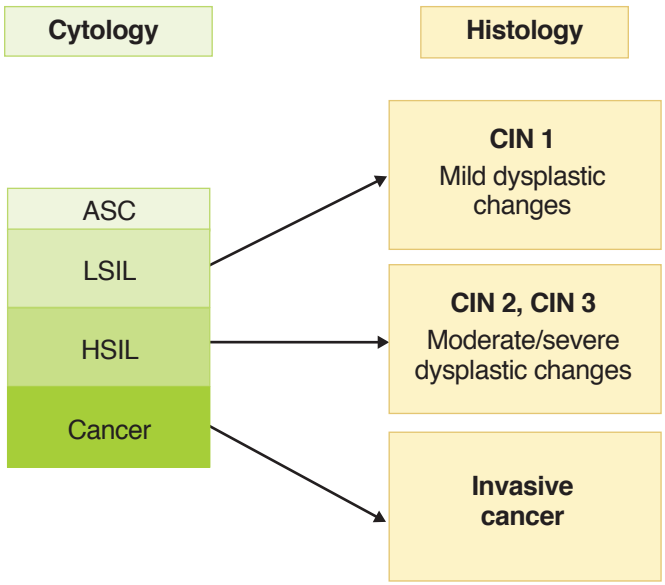

Figure II-4-4. Classification of Cervical Dysplasias

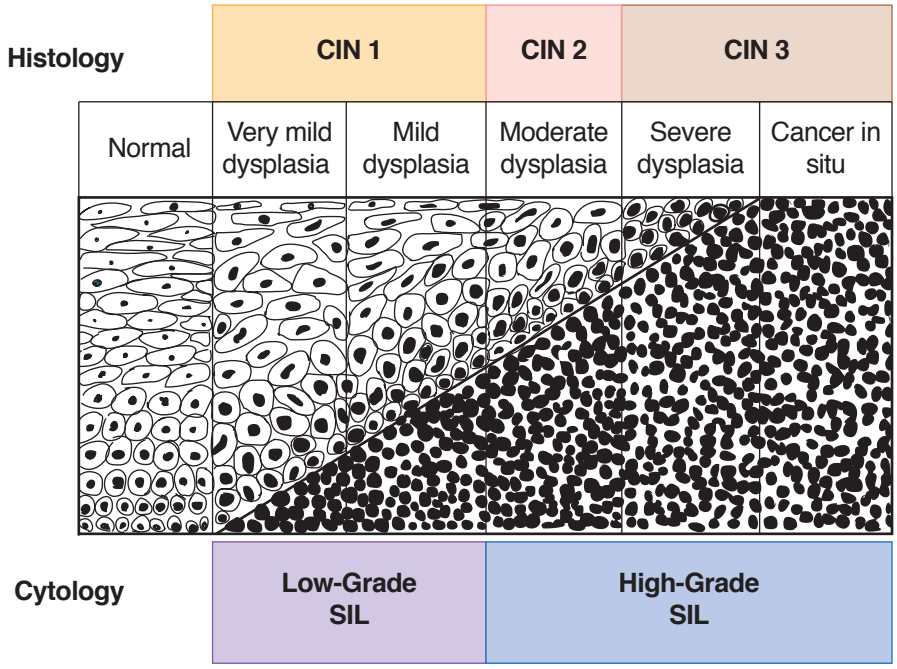

Figure II-4-5. Histologic Appearance of Cervical Dysplasia with Progressive Severity

Diagnostic Approach to Abnormal Pap Smears

- **Accelerated repeat Pap.** This is an option for findings of ASC-US in patients of any age, and the preferred option with either ASC-US or LSIL in patients ages 21-24. Repeat the Pap in 12 months.
  - If repeat cytology is negative, repeat Pap in another 12 months.
  - If repeat cytology is anything other than negative, proceed to colposcopy and biopsies.
- **HPV DNA testing.** This is the preferred option for findings of ASC-US in patients age ≥25.It is acceptable but not preferred in patients ages 21-24.
  - If liquid-based cytology was used on the initial Pap, one can use this specimen for DNA testing.
  - If conventional methods were used, repeat a second Pap. Perform colposcopy only if high-risk HPV DNA is identified.
- **Colposcopy.** This is indicated for evaluation of LSIL in patients age ≥25, and all patients with ASC-H and HSIL. Colposcopy is a magnification of the cervix (10–12x); it is aided by acetic acid, which makes the vascular patterns more visible.
  - **Satisfactory or adequate** colposcopy is diagnosed if the entire T-zone is visualized and no lesions disappear into the endocervical canal.
  - **Unsatisfactory or inadequate** colposcopy is diagnosed if the entire T-zone cannot be fully visualized.
- **Endocervical curettage (ECC).** All nonpregnant patients undergoing colposcopy which shows metaplastic epithelium entering the endocervical canal will undergo an ECC to rule out endocervical lesions.

- **Ectocervical biopsy.** Lesions identified on the ectocervix by colposcopy (e.g., mosaicism, punctation, white lesions, abnormal vessels) are biopsied and sent for histology.
- **Compare Pap smear and biopsy.** When the biopsy histology is complete, it is compared with the level of Pap smear abnormality to ensure the level of severity is comparable.
- **Cone biopsy.** If the Pap smear is worse than the histology (suggesting the site of abnormal Pap smear cells was not biopsied), then a cone biopsy is performed. Other indications for conization of the cervix include abnormal ECC histology, a lesion seen entering the endocervical canal, and a biopsy showing microinvasive carcinoma of the cervix. Deep cone biopsies can result in an **incompetent cervix**. Another risk of cone biopsy is **cervical stenosis**.

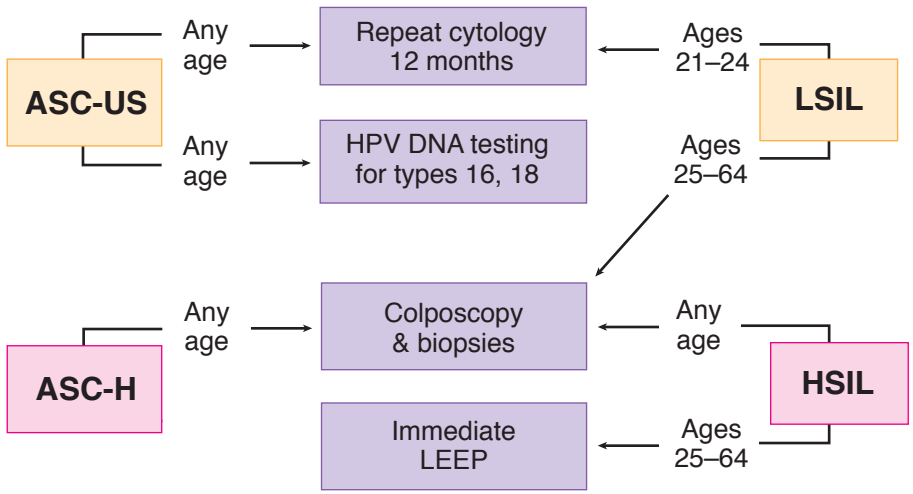

Figure II-4-7. Diagnostic Options for Abnormal Pap Smear (2013)

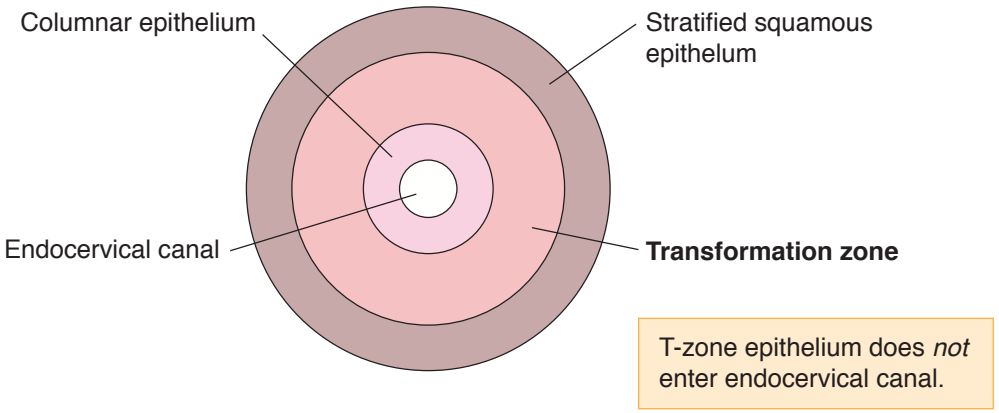

Figure II-4-8. Cervical Dysplasia: Satisfactory Colposcopy

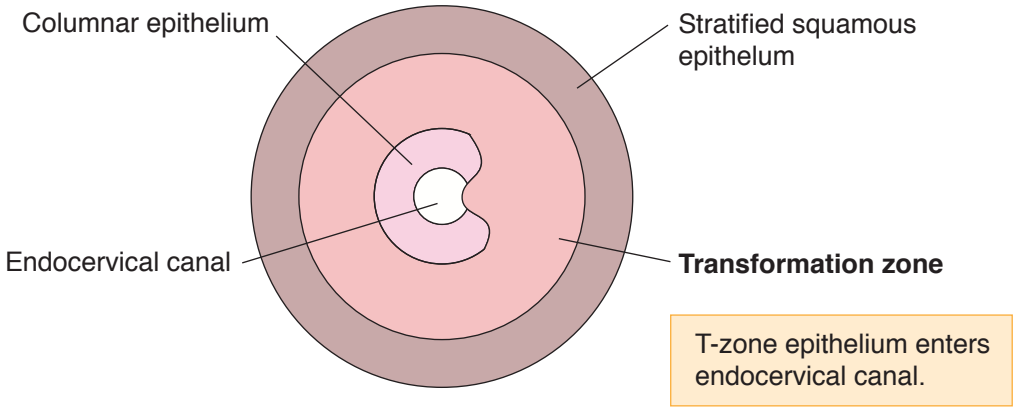

Figure II-4-9. Cervical Dysplasia: Unsatisfactory Colposcopy

Management According to Histology

- Observation and follow-up without treatment is appropriate for CIN 1 and includes any of the following: repeat Pap in 6 and 12 months; colposcopy and repeat Pap in 12 months; or HPV DNA testing in 12 months.
- Ablative modalities can be used for CIN 1, 2, and 3. These include cryotherapy (freezing), laser vaporization, and electrofulguration.
- Excisional procedures can be used for CIN 1, 2, and 3. These include LEEP (loop electrosurgical excision procedure) or cold-knife conization.
- Hysterectomy is only acceptable with biopsy-confirmed, recurrent CIN 2 or 3.

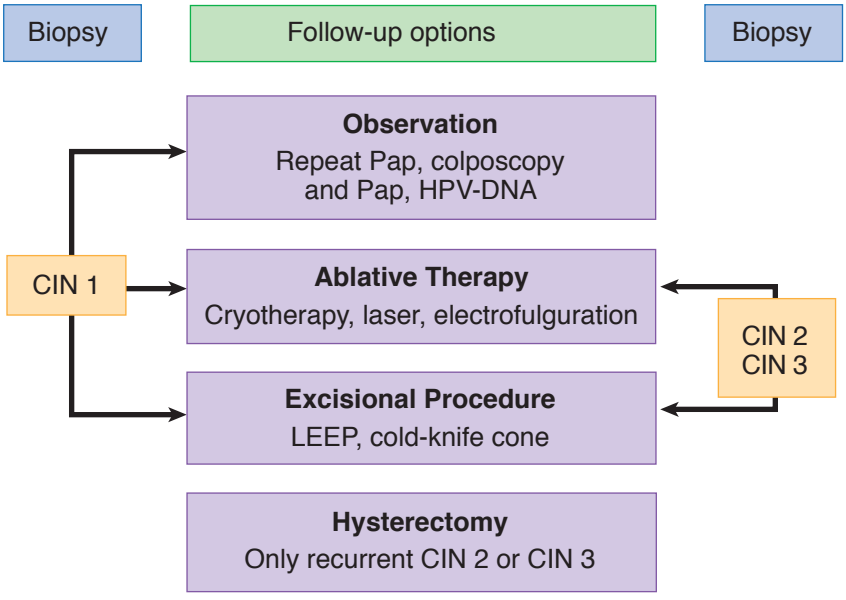

Figure II-4-10. Cervical Dysplasia: Management According to Histology

Follow-Up. Patients treated with either ablative or excisional procedures require follow-up repeat Pap smears, colposcopy and Pap smear, or HPV DNA testing every 4 to 6 months for 2 years.

Invasive Cervical Cancer

A 43-year-old woman complains of intermenstrual postcoital bleeding for the past 6 months between regular menstrual cycles that occur every 28 days. On pelvic examination a 3-cm exophytic mass is seen from the anterior lip of the cervix. The rest of the pelvic examination, including a rectovaginal examination, is normal.

Definition. Cervical neoplasia that has penetrated through the basement membrane.

Presentation. Patients with invasive cervical cancer can present with postcoital vaginal bleeding. Other symptoms of cervical cancer include irregular vaginal bleeding and, in advanced stage, lower extremity pain and edema.

Epidemiology. Cervical carcinoma is the **third most common** gynecologic malignancy with a mean age at diagnosis of **45 years**.

Diagnostic Tests/Findings

- **Cervical biopsy.** The initial diagnostic test should be a cervical biopsy, in which the most common diagnosis is squamous cell carcinoma.
- **Metastatic workup.** Once a tissue diagnosis of invasive carcinoma is made, a metastatic workup should be done that includes pelvic examination, chest x-ray, intravenous pyelogram, cystoscopy, and sigmoidoscopy.
- **Imaging studies.** Invasive cervical cancer is the only gynecologic cancer that is staged clinically; an abdominal pelvic CT scan or MRI cannot be used for clinical staging.

Staging. Staging is **clinical** based on pelvic examination and may include an intravenous pyelogram (IVP).

Stage 0: Carcinoma in-situ (CIS). The basement membrane is intact.

Stage I: Spread **limited** to the cervix. This is the **most common** stage at diagnosis.
- Ia1. Invasion is ≤3 mm deep (minimally invasive)
- Ia2. Invasion is >3 but ≤5 mm deep (microinvasion)
- IB. Invasion is >5 mm deep (frank invasion)

Stage II: Spread **adjacent** to the cervix
- IIa. Involves upper two thirds of vagina
- IIb. Invasion of the parametria

Stage III: Spread **further** from the cervix
- IIIA. Involves lower one third of vagina
- IIIB. Extends to pelvic side wall or hydronephrosis

Stage IV: Spread **furthest** from the cervix
- IVA. Involves bladder or rectum or beyond true pelvis
- IVB. Distant metastasis

Management. Patients treated surgically are evaluated for risk factors for metastatic disease and tumor recurrence. These include metastatic disease to the lymph nodes, tumor size >4 cm, poorly differentiated lesions, or positive margins. Patients with these findings are offered adjuvant therapy (radiation therapy and chemotherapy).

- **Specific by stage:**

  Stage Ia1: Total simple hysterectomy, either vaginal or abdominal

  Stage Ia2: Modified radical hysterectomy

  Stage IB or IIA: Either radical hysterectomy with pelvic and paraaortic lymphadenectomy (if premenopausal) and peritoneal washings or pelvic radiation (if postmenopausal). In patients who can tolerate surgery, a radical hysterectomy is preferred; however, studies have demonstrated equal cure rates with radiation or surgical treatment.

  Stage IIB, III, or IV: Radiation therapy and chemotherapy for all ages.

Table II-4-1. Stage I—Most Common (Spread Limited to Cervix)

Ia1	• ≤3 mm • Minimal invasion	Total simple hysterectomy
Ia2	• >3 mm but ≤5 mm • Microinvasion	Modified radical hysterectomy
IB	• >5 mm • Frank invasion	Radical hysterectomy

Follow-Up. All patients with invasive cervical cancer should be followed up with Pap smear every 3 months for 2 years after treatment, and then every 6 months for the subsequent 3 years.

- Patients who have a **local recurrence** can be treated with radiation therapy; if they had received radiation previously, they might be considered candidates for a pelvic exenteration.
- Patients with **distant metastases** should be considered for chemotherapy treatment. The most active chemotherapeutic agent for cervical cancer is cisplatinum.

Cervical Neoplasia in Pregnancy

A 25-year-old woman with intrauterine pregnancy at 14 weeks by dates is referred because of a Pap smear showing as HSIL (high-grade squamous intraepithelial lesion). On pelvic examination there is a gravid uterus consistent with 14 weeks size, and the cervix is grossly normal to visual inspection.

Diagnostic Tests/Findings

- **Effect of pregnancy.** Pregnancy per se does not predispose to abnormal cytology and does not accelerate precancerous lesion progression into invasive carcinoma.

- **Colposcopy and biopsy.** A patient who is pregnant with an abnormal Pap smear should be evaluated in the same fashion as when in a nonpregnant state. An abnormal Pap smear is followed with colposcopy with the aid of acetic acid for better visualization of the cervix. Any abnormal lesions of the ectocervix are biopsied.
- **Perform an ECC?** Owing to increased cervical vascularity, ECC is not performed during pregnancy.

Management

- **CIN.** Patients with intraepithelial neoplasia or dysplasia should be followed with Pap smear and colposcopy every 3 months during the pregnancy. At 6–8 weeks postpartum the patient should be reevaluated with repeat colposcopy and Pap smear. Any persistent lesions can be definitively treated postpartum.
- **Microinvasion.** Patients with microinvasive cervical cancer on biopsy during pregnancy should be evaluated with cone biopsy to ensure no frank invasion. If the cone biopsy specimen shows microinvasive carcinoma during pregnancy, these patients can also be followed conservatively, delivered vaginally, reevaluated, and treated 2 months postpartum.
- **Invasive cancer.** If the punch biopsy of the cervix reveals frankly invasive carcinoma, then treatment is based on the gestational age.
  - In general, if a diagnosis of invasive carcinoma is made **before 24 weeks** of pregnancy, the patient should receive definitive treatment (e.g., radical hysterectomy or radiation therapy).
  - If the diagnosis is made **after 24 weeks** of pregnancy, then conservative management up to about 32–33 weeks can be done to allow for fetal maturity to be achieved, at which time cesarean delivery is performed and definite treatment begun.

Prevention of Cervical Dysplasia by Vaccination

The quadrivalent HPV recombinant vaccine (**Gardasil**) is recommended for all females 8–26 years of age, with a target age of 11–12.

- The vaccine uses noninfectious particles to protect against the 4 HPV types (6, 11, 16, 18) that cause 70% of cervical cancer and 90% of genital warts.
- Three doses are given: initial, then 2 months later, then 6 months later, for an approximate cost of $300.

Recommendations

- Administer to all females age 9–26, with a target age of 11–12. Efficacy is highest before the patient's immune system has been presented with HPV.
- Testing for HPV is not recommended before vaccination. No easy method of identifying all HPV types is currently available.
- Continue regular Pap smears according to current guidelines because the vaccine does not prevent against all HPV types that can cause genital warts or cervical cancer.
- Sexually active women can receive the vaccine. Women with previous abnormal cervical cytology or genital warts also can receive the vaccine, but it may be less effective. It can be given to patients with previous CIN, but benefits may be limited.
- The vaccine is not recommended for pregnant, lactating, or immunosuppressed women.

MÜLLERIAN ANOMALIES

Uterine anomalies have been divided into 7 types by the American Fertility Society (1988). This classification is based on the developmental problem responsible for the irregular shape. Uterine anomalies may result from 3 mechanisms:

Stage 1: failure of one or both of the 2 müllerian ducts to form

Stage 2: failure of the 2 ducts to fuse completely

Stage 3: failure of the 2 fused mullerian ducts to dissolve the septum that results from fusion

Failure to Form

Hypoplasia/Agenesis

- A woman may lack a vagina, a cervix (the bottom one-third of the uterus that opens into the vagina), the fallopian tubes, or the entire vagina and body of the uterus (except for the fundus). This occurs from a developmental problem with a section of both of the müllerian ducts.
- These anomalies are commonly associated with urinary tract anomalies because the structures that give rise to the urinary tract lie close to the müllerian ducts and are affected by the same injurious insult.

Unicornuate Uterus

- When one of the müllerian ducts fails to form, a single-horn (banana-shaped) uterus develops from the healthy müllerian duct. This single-horn uterus may stand alone. However, in 65% of women with a unicornuate uterus, the remaining müllerian duct may form an incomplete (rudimentary) horn.
- There may be no cavity in this rudimentary horn, or it may have a small space within it, but there is no opening that communicates with the unicornuate uterus and vagina.
- In the latter case, a girl may have monthly pain during adolescence because there is no outlet for the menses from this rudimentary horn. This pain would lead to identification of this problem. In some cases, the rudimentary horn contains a cavity that is continuous with the healthy single-horn uterus, but is much smaller than the cavity within the healthy uterus.
- There is a risk that a pregnancy will implant in this rudimentary horn, but because of space limitations, 90% of such pregnancies rupture.

Failure to Fuse

Didelphys Uterus

- A double uterus results from the complete failure of the 2 Müllerian ducts to fuse together (stage 1 of development). So each duct develops into a separate uterus, each of which is narrower than a normal uterus and has only a single horn.
- These 2 uteri may each have a cervix or they may share a cervix. In 67% of cases, a didelphys uterus is associated with 2 vaginas separated by a thin wall. Preterm delivery is common if pregnancy occurs in these patients.

Bicornuate Uterus

- This is the most common congenital uterine anomaly (45%). It results from failure of fusion between the müllerian ducts at the "top." This failure may be "complete," which results in 2 separate single-horn uterine bodies sharing one cervix.
- Alternatively, in a "partial" bicornuate uterus, fusion between the müllerian ducts had occurred at the "bottom" but not the "top." Thus, there is a single uterine cavity at the bottom with a single cervix, but it branches into 2 distinct horns at the top. Because the ducts never fused at the top, these 2 horns are separate structures when seen from the outside of the uterus.
- Preterm delivery and malpresentation are common with pregnancy.

Failure to Dissolve Septum

Septate Uterus

- A septate uterus results from a problem in stage 2 or 3 of uterine development. The two müllerian ducts fused normally; however, there was a failure in degeneration of the median septum.
- If this failure was "complete," a median septum persists in the entire uterus, separating the uterine cavity into two single-horned uteri that share one cervix.
- If this failure was "partial," resorption of the lower part of the median septum occurred in stage 2 but the top of the septum failed to dissolve in stage 3. Thus, there is a single cervix and uterine cavity at the bottom, but at the top that cavity divides into two distinct horns.
- Because this uterine anomaly occurs later in uterine development, after complete duct fusion, the external shape of the uterus is a normal-appearing single unit. This is distinct from the bicornuate uterus, which can be seen branching into two distinct horns when viewed from the outside.
- Preterm delivery and malpresentation are common with pregnancy.

Arcuate Uterus

This type of uterus is essentially normal in shape with a small midline indentation in the uterine fundus, which results from failure to dissolve the median septum completely.

- It is given a distinct classification because it does not seem to have any negative effects on pregnancy in regard to preterm labor or malpresentation.

DES Uterus

The daughters of mothers exposed to diethylstilbestrol (DES) during pregnancy are predisposed to uterine abnormalities and clear cell carcinoma of the vagina.

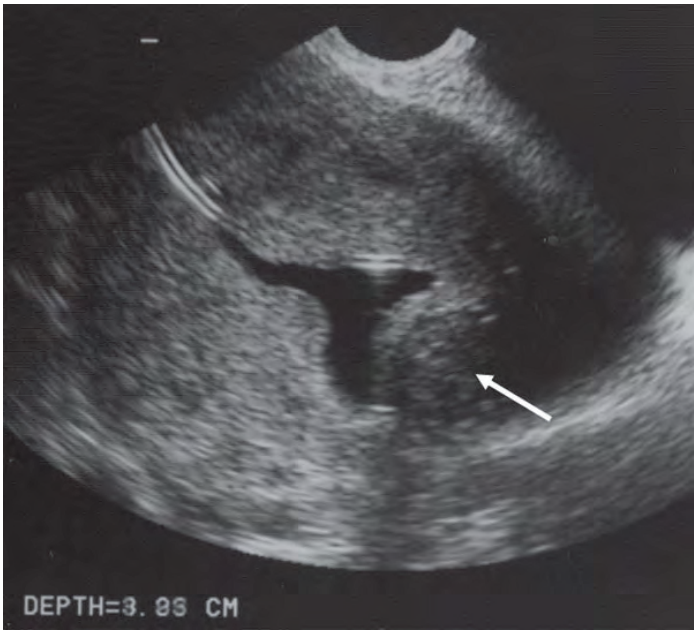
- Two-thirds have abnormalities, including a small, incompletely formed uterus ("hypoplastic") and/or a T-shaped cavity; and 50% have cervical defects, for example, an incompletely formed cervix that predisposes to cervical insufficiency. The mechanism by which DES disrupts normal uterine development is not known.

ENLARGED UTERUS

Leiomyoma Uteri

Location. It is a benign smooth muscle growth of the myometrium. It is the **most common** benign uterine tumor. It is 5 times more common in black women than white women. It can develop in a number of anatomic locations.

- **Intramural.** The **most common** location of a leiomyoma is within the wall of the uterus. When small it is usually asymptomatic and cannot be felt on examination unless it enlarges to where the normal uterine external contour is altered.
- **Submucosal.** These myomas are located beneath the endometrium and can distort the uterine cavity. The distorted overlying endometrium may not respond appropriately to the normal hormonal fluctuations, resulting in unpredictable, often intermenstrual, bleeding. Abnormal vaginal bleeding is the **most common** symptom of a submucosal myoma and can result in anemia. Menorrhagia is defined as heavy menses and metrorrhagia is defined as irregular bleeding in between menses. Menometrorrhagia consists of both heavy menses and bleeding in between the menses.
- **Subserosal.** These are located beneath the uterine serosa. As they grow they distort the external contour of the uterus causing the firm, nontender asymmetry. Depending on their location they can put pressure on the bladder, rectum or ureters. If they are pedunculated, attached to the uterus by a stalk, they can become parasitic fibroids. They break away from the uterus and receive their blood supply from another abdominal organ (such as the omentum or the mesentery of the intestine).



With permission Lyndon M. Hill, M.D., Magee Women's Hospital, iame.com

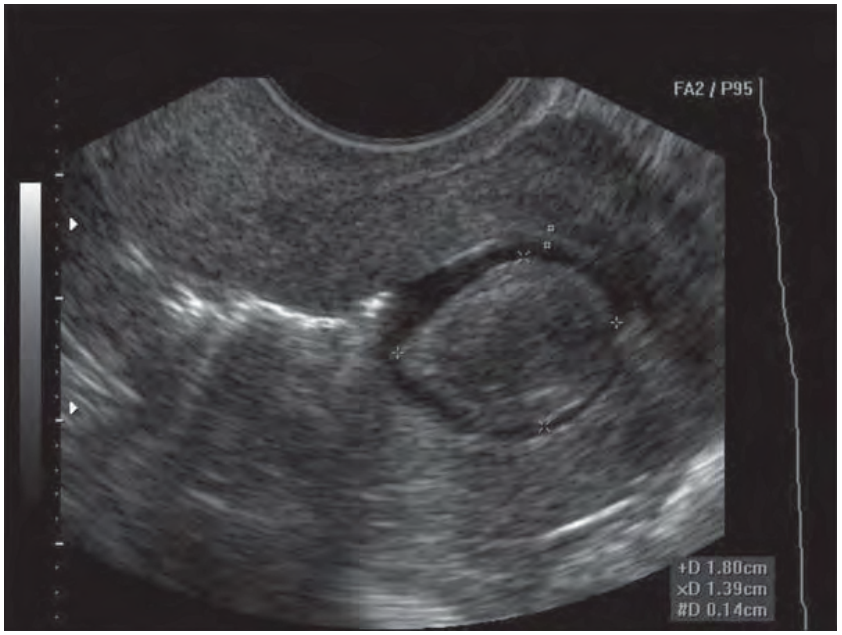
Figure II-4-11. Submucosal Leiomyoma

Natural History. Changes in size are dependent on the reproductive life stage of the woman.

- **Slow growth.** Most leiomyomas are small, grow slowly, and cause no symptoms. Only when massive in size do they cause pelvic pressure symptoms.
- **Rapid growth.** Estrogen receptors are increased in leiomyomas resulting in rapid enlargement during times of high estrogen levels, such as pregnancy.
- **Degeneration.** During times of rapid growth, myomas may outgrow their blood supply, resulting in ischemic degeneration of a fibroid. Common degenerations that are seen include hyaline, calcific, and red degeneration. The latter, also known as carneous degeneration, can cause such extreme, acute pain that the patient requires hospitalization and narcotics. This is **most common** during pregnancy.
- **Shrinkage.** When estrogen levels fall, with estrogen receptors no longer stimulated, leiomyomas will typically decrease in size. This predictably occurs after menopause but can also occur when estrogen levels are medically reduced through gonadotropin releasing hormone (GnRH) agonist suppression of follicle-stimulating hormone (FSH).

Diagnosis

- **Pelvic examination.** In most cases the diagnosis is made clinically by identifying an enlarged, asymmetric, nontender uterus in the absence of pregnancy. The size of the fibroid is compared with the size of a pregnant uterus. A pregnant uterus that reaches the umbilicus is approximately 20 weeks in gestation; if the pregnant uterus reaches the symphysis pubis, it is approximately 12 weeks in gestation.
- **Sonography.** Traditional abdominal or vaginal ultrasound can image large intramural or subserosal myomas. Saline infusion sonography is helpful for identifying submucosal myomas by instilling 5–10 mL of saline into the uterine cavity before visualizing the uterine cavity with an endovaginal sonogram probe.



With permission Lyndon M. Hill, M.D., Magee Women's Hospital, iame.com

Figure II-4-12. Saline Ultrasonography Demonstrating an Intracavitary Leiomyoma

- **Hysteroscopy.** Submucosal myomas may be identified by visualizing them directly with hysteroscopy.
- **Histology.** The only definitive diagnosis is by surgical confirmation of excised tissue.

Management

- **Observation.** Most leiomyomas can be managed conservatively and followed expectantly with regular pelvic examinations.
- **Presurgical shrinkage.** After 3–6 months of GnRH analog therapy, with resultant hypoestrogenic state, a 60–70% reduction in size of the fibroids can be expected. However, once the leuprolide (Lupron) is terminated, there will be a regrowth of the fibroid within 6 months. Thus, GnRH analogs cannot be used for definitive cure, but they can be used in the adjuvant setting with surgical therapy. If a myomectomy is done, a decrease in size will be associated with a decrease in blood loss, and if a hysterectomy is planned, then perhaps a vaginal instead of an abdominal hysterectomy can be performed.
- **Myomectomy.** This is a surgical procedure performed if the patient desires to maintain fertility. The uterus is incised and the myoma removed through either a laparoscopic or laparotomy approach. If the myomectomy incision entered the endometrial cavity, delivery of any subsequent pregnancy should be by cesarean section because of increased risk of scar rupture in labor.
- **Embolization.** This is an invasive radiology procedure in which a catheter is placed into the vessels supplying the myoma. Microspheres are injected, causing ischemia and necrosis of the myoma.
- **Hysterectomy.** If the patient has completed her childbearing, definitive therapy is an abdominal or vaginal hysterectomy.

Table II-4-2. Management of Leiomyomas

Management	Clinical effect/Method of Treatment
Observation	Most Serial pelvic exams
Presurgical shrinkage	↓ size by 70% GnRH analog 3–6 months; regrowth after stopping
Myomectomy	Preserves fertility Laparotomy, laparoscopy
Embolization	Preserves uterus Invasive radiology
Hysterectomy	Fertility completed Total abdominal hysterectomy, total vaginal hysterectomy

Adenomyosis

A 42-year-old woman complains of increasing pain with her menstrual periods for the past 8 months. She also states her periods are getting heavier, leaving her tired and weak. She underwent a postpartum tubal ligation after her last child 10 years ago. She has been treated for chronic hypertension for the past 3 years. On pelvic examination her uterus is 12-week size, globular, soft, and tender. Rectovaginal examination is unremarkable.

Definition. Ectopic endometrial glands and stroma are located within the myometrium of the uterine wall. The **most common** presentation is diffuse involvement of the myometrium. The lesion is known as an **adenomyoma** if the involvement is focal, surrounded by a pseudocapsule.

Diagnosis. In most cases the diagnosis is made clinically by identifying an enlarged, symmetric, tender uterus in the absence of pregnancy. The only definitive diagnosis is by histologic confirmation of the surgically excised tissue.

Table II-4-3. Differential Diagnosis for Enlarged Non-pregnant Uterus

Leiomyoma	Adenomyosis
Asymmetric	Symmetric
Firm	Soft
Nontender	Tender

Symptoms. The majority of women are asymptomatic. The most common symptoms are secondary dysmenorrhea and menorrhagia.

Examination. The uterus is globular and diffusely up to 2–3 times the normal size. Tenderness is most common immediately before and during menses.

Imaging. Ultrasound study or MRI imaging shows a diffusely enlarged uterus with cystic areas found within the myometrial wall.

Management. Medical treatment includes the levonorgestrel (LNG) intrauterine system (IUS), which may decrease heavy menstrual bleeding. Surgery, in the form of hysterectomy, is the definitive treatment.

ENDOMETRIAL NEOPLASIA

Postmenopausal Bleeding

A 65-year-old patient complains of vaginal bleeding for 3 months. Her last menstrual period was at age 52. She has not taken any hormone replacement. She was diagnosed with type 2 diabetes 20 years ago and was treated with oral hypoglycemic agents. She has chronic hypertension, for which she is treated with oral antihypertensives. Her height is 62 inches and weight 200 lb. Physical examination is normal with a normal-sized uterus and no vulvar, vaginal, or cervical lesions.

Definition. A patient is considered to be in menopause after 3 continuous months of cessation of menses and elevated gonadotropins. Menopause usually occurs at approximately 52 years of age. Postmenopausal bleeding is any bleeding that occurs after menopause.

Epidemiology. Endometrial carcinoma is the **most common** gynecologic malignancy, occurring in 1% of women. The mean age at diagnosis is 61 years.

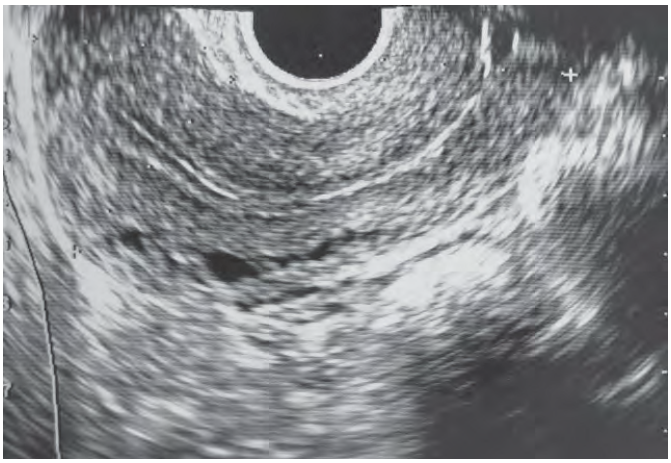
Differential Diagnosis. The differential diagnosis of postmenopausal bleeding includes endometrial carcinoma, vaginal or endometrial atrophy, and postmenopausal hormonal replacement therapy. Although the **most common** cause of postmenopausal bleeding is vaginal or endometrial atrophy, the most important diagnosis to rule out is endometrial carcinoma.

Pathophysiology. The mediating factor for most endometrial carcinomas appears to be unopposed estrogen. This results from excessive hyperstimulation of the endometrium without the stabilizing effect of progesterone.

Risk Factors. These include **obesity**, **hypertension**, and **diabetes mellitus**. Other risk factors include nulliparity, late menopause, and chronic anovulation conditions, such as PCO disease.

Diagnostic Tests: Either endometrial biopsy or transvaginal U/S can be used as an initial test for evaluating the endometrium.

- **Endometrial sampling.** This office procedure has historically been the initial diagnostic test for postmenopausal bleeding, due its high sensitivity, low complication rate, and low cost. It is ideal for global lesions but not very sensitive for diagnosing localized structural lesions such as polyps or submucus leiomyomas.
- **Transvaginal sonogram.** This is an acceptable alternative initial test for non-persistent minimal bleeding in women who are not on hormone replacement. A thin, homogenous endometrial stripe <5 mm can reasonably exclude endometrial carcinoma. A thicker endometrial stripe warrants further assessment with an endometrial sampling.
- **Hysteroscopy.** This procedure allows direct visualization of the endocervical canal and endometrial cavity. Endocervical or endometrial polyps, or submucus leiomyomas, can be removed at the time of the hysteroscopy.



With permission, Brookside Associates, brooksidepress.org

Figure II-4-13. Ultrasonography Demonstrating Normal Endometrial Stripe (<5 mm)

Staging

Staging is done after an evaluation of the pathology report. Staging is surgical.

Stage I:	Spread **limited** to the uterus (**most common** stage at diagnosis)
IA.	Limited to the endometrium or invasion less than half of myometrium
IB.	Invasion more than half of myometrium
Stage II:	Extension to the cervix but not outside the uterus
Stage III:	Spread **adjacent** to the uterus
IIIA.	Invades serosa or adnexa or positive cytology
IIIB.	Invasion of vagina
IIIC.	Invasion of pelvic or para-aortic nodes
Stage IV:	Spread **further** from the uterus
IVA.	Involves bladder or rectum
IVB.	Distant metastasis

Management. If the endometrial histology sampling reveals atrophy and no evidence of cancer, it can be assumed the patient is bleeding from atrophy and can be treated with hormone replacement therapy. With hormone replacement therapy, estrogen and progesterone should be given to the patient. If estrogen is given alone, the risk of endometrial cancer increases.

If the endometrial sampling reveals adenocarcinoma, the patient should be treated surgically.

- **Surgical therapy.** The mainstay of treatment of endometrial carcinoma is a total abdominal hysterectomy (TAH) and bilateral salpingo-oophorectomy (BSO), pelvic and para-aortic lymphadenectomy, and peritoneal washings.
- **Radiation therapy.** An evaluation of the postoperative pathology report will classify patients into poor or good prognosis. Patients with poor prognosis should be considered for radiation therapy. Poor prognostic factors include metastasis to lymph nodes, >50% myometrial invasion, positive surgical margins, or poorly differentiated histology.
- **Chemotherapy.** Medical treatment is used for metastatic disease and involves **progestins** and cytotoxic agents.

Table II-4-4. Endometrial Carcinoma Management

TAH-BSO: Basic Treatment for All Stages		
Stage I	TAH BSO Lymph node dissection	—
Stage II		Radiation
Stage III		Radiation, chemotherapy
Stage IV		

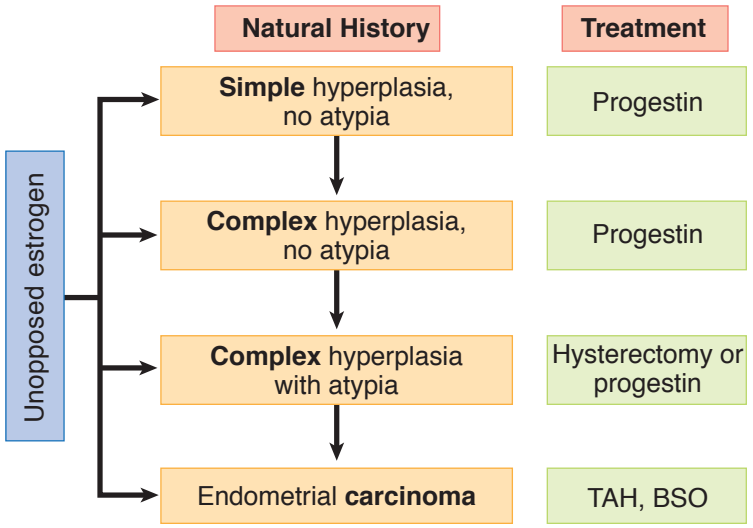


Figure II-4-14. Management of Endometrial Hyperplasia

Prevention

Postmenopausal patients taking estrogen replacement therapy must be also treated with progestins to prevent unopposed estrogen stimulation, which may lead to endometrial cancer.

Reproductive age women who have chronic anovulation, such as PCO syndrome, should also be treated with progestins to avoid endometrial hyperplasia from unopposed estrogen.

Disorders of the Ovaries and Oviducts

5

Learning Objectives

- ❏ Differentiate between physiologic enlargement of the adnexa and abnormal enlargement or painful adnexal mass
- ❏ List the causes of pelvic mass found prepubertal, premenopausal, and postmenopausal

PHYSIOLOGIC ENLARGEMENT

Functional Cysts

A 22-year-old woman comes for annual examination and requests oral contraceptives pills. On pelvic examination, a 6-cm mobile, smooth, soft, left adnexal mass is palpable. An endovaginal pelvic ultrasound shows a 6-cm, round, fluid-filled, simple ovarian cyst without septations or calcifications. She has no other significant personal or family history.

GYN Triad

Functional Ovarian Cyst

- Pelvic mass in reproductive years
- β-hCG (–)
- Sonogram: fluid-filled ovarian simple cyst

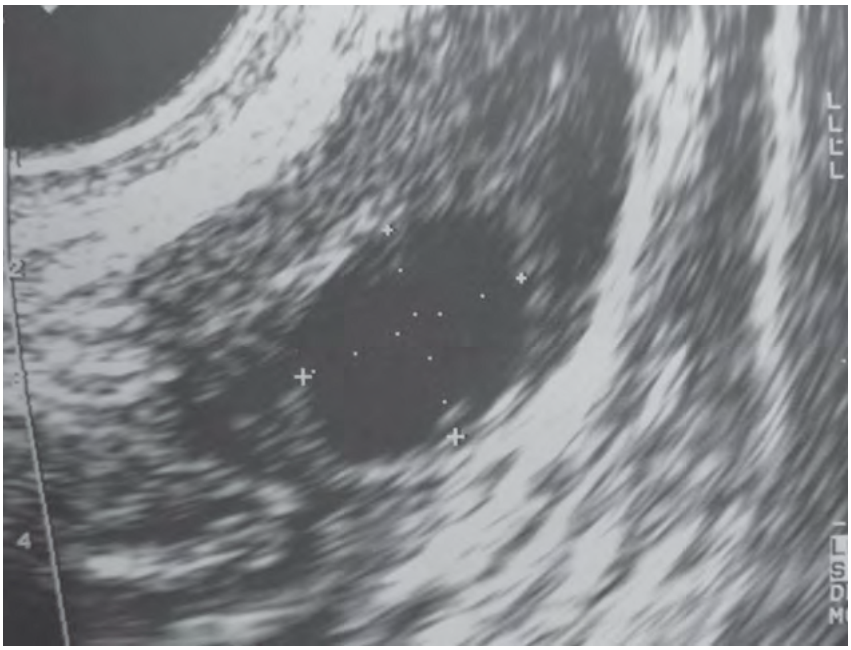
Definition. The **most common** cause of a simple cystic mass in the reproductive age years is a physiologic cyst (luteal or follicular cyst). During the reproductive years the ovaries are functionally active, producing a dominant follicle in the first half of the cycle and a corpus luteum after ovulation in the second half of the menstrual cycle. Either of these structures, the follicle or the corpus luteum, can become fluid-filled and enlarged, producing a functional cyst.

Differential Diagnosis

- **Pregnancy.** The **most common** cause of a pelvic mass in the reproductive years is pregnancy.
- **Complex mass.** The **most common** complex adnexal mass in young women is a dermoid cyst or benign cystic teratoma. Other diagnoses include endometrioma, tubo-ovarian abscess, and ovarian cancer.

Diagnosis

- **Qualitative b-human chorionic gonadotropin (β-hCG) test.** If negative, this will rule out pregnancy.
- **Sonogram.** A complex mass on ultrasound appearance is incompatible with a functional cyst.



With permission, Brookside Associates, brooksidepress.org

Figure II-5-1. Ultrasonographic Appearance of a Functional Cyst

Management. Most functional cysts can be managed expectantly, but surgery is indicated if certain characteristics are present.

- **Observation.** If the sonogram shows a simple cyst it is probably benign but careful follow-up is needed. Follow-up examination should be in 6–8 weeks, at which time the functional cyst should have spontaneously resolved. During this period of observation the patient should be alerted to the possibility of acute onset of pain, which may be indicative of torsion of the adnexal cyst. Oral contraceptive medication can be used to help prevent further functional cysts from forming.
- **Laparoscopy.** Even if the cyst is simple in appearance, surgical evaluation should be performed if the cyst is >7 cm or if patient had been on prior steroid contraception. Physiologic cysts do not usually get larger than 7 cm in diameter. Functional cysts should not form if the patient has been on oral contraception for at least 2 months because gonadotropins should have been suppressed.

Polycystic Ovarian Syndrome

The ovaries are bilaterally enlarged with multiple peripheral cysts (20-100 in each ovary). This is due to high circulating androgens and high circulating insulin levels causing arrest of follicular development in various stages. This along with stromal hyperplasia and a thickened ovarian capsule results in enlarged ovaries bilaterally. PCOS is associated with **valproic acid** use. Management is conservative regarding ovaries. For further discussion of PCOS pathophysiology and treatment, refer to chapter 12, Hormonal Disorders.

Ovarian Hyperthecosis

Definition. Ovarian hyperthecosis refers to the presence of nests of luteinized theca cells in the ovarian stroma that may be steroidogenically active. These nests, or islands, of luteinized theca cells are scattered throughout the stroma of the ovary, rather than being confined to areas around cystic follicles, as in polycystic ovary syndrome (PCOS). The result is greater production of androgens.

- Why hyperthecosis occurs is not known.
- The ovarian secretion of large amounts of androgen in women with hyperthecosis means that peripheral estrogen production is increased. As a result, the risks of endometrial hyperplasia and endometrial carcinoma are increased, especially in postmenopausal women.

Findings. The clinical features of hyperthecosis are similar to PCOS, and most patients are obese. However, women with ovarian hyperthecosis have more severe hirsutism, with shaving being common. Virilization is frequent, with clitoral enlargement, temporal balding, deepening of the voice, and a male habitus.

- Most patients have amenorrhea, and the remainder have irregular and anovulatory cycles. Most patients will have severe insulin resistance with high risk of type 2 diabetes mellitus and cardiovascular disease.
- Unlike PCOS, which occurs only during the reproductive years, hyperthecosis of the ovaries can occur in postmenopausal women. Severe hirsutism and virilization in postmenopausal women are more often due to ovarian hyperthecosis than to virilizing ovarian tumors.

Management. Treatment is similar to that for hirsutism, using oral contraceptive pills both to suppress androgen production (by reducing LH stimulation of the theca cells) and to decrease free androgens (by stimulating sex hormone binding globulin).

Luteoma of Pregnancy

Luteoma of pregnancy is a rare, **non-neoplastic tumor-like mass** of the ovary that emerges during pregnancy and **regresses spontaneously** after delivery. It is usually **asymptomatic** and is found **incidentally** during a cesarean section or postpartum tubal ligation. It can be **hormonally active** and produce **androgens** resulting in maternal and fetal hirsutism and virilization.

Theca Lutein Cysts

These are benign neoplasms stimulated by **high levels of FSH and β-hCG**. They are **associated with twins** and **molar** pregnancies but they are only rarely associated with a normal singleton pregnancy. The **natural course** of these tumors is postpartum **spontaneous regression and require only conservative managment**.

PREPUBERTAL PELVIC MASS

An 8-year-old girl is evaluated in the emergency department for sudden onset of severe lower abdominal pain. A general surgery consult was obtained, and appendicitis is ruled out. Pelvic ultrasound reveals a 7-cm solid and irregular right adnexal mass. Pelvic examination is consistent with a 7-cm right adnexal mass, and there is lower abdominal tenderness but no rebound present.

Etiology. An adnexal mass in the prepubertal age group is abnormal. During the prepubertal and the postmenopausal years, functional ovarian cysts are not possible because ovarian follicles are not functioning. Therefore any ovarian enlargement is suspicious for neoplasm.

Differential Diagnosis. If sonography shows a complex adnexal mass in a girl or teenager, the possibility of **germ cell** tumors of the ovary has to be considered. The following serum **tumor markers** should be obtained: lactate dehydrogenase (LDH) for dysgerminoma, β-hCG for choriocarcinoma, and α-fetoprotein for endodermal sinus tumor.

Presentation. Sudden onset of acute abdominal pain is a typical presentation of germ cell tumors of the ovary. These tumors characteristically grow rapidly and give early symptomatology as opposed to the epithelial cancers of the ovary that are diagnosed in advanced stages. Germ cell tumors of the ovary are **most common** in young women and present in early stage disease.

Diagnosis. Surgical exploration. In a prepubertal patient who is symptomatic and has ultrasound evidence of an adnexal mass, a surgical evaluation is recommended.

- **Simple mass.** If the ultrasound shows the consistency of the mass to be simple (no septations or solid components), this mass can be evaluated through a laparoscopic approach.
- **Complex mass.** If the mass has septations or solid components, a laparoscopy or laparotomy should be performed, depending on the experience of the surgeon.

Table II-5-1. Prepubertal Pelvic Mass

Surgical diagnosis	Simple cyst	Laparoscopy
	Complex mass	Laparotomy
Management	Benign	Cystectomy Annual followup
	Malignant	Unilateral S&O Staging, chemotherapy
Prognosis	95% survival with chemotherapy	

Definition of abbreviations: S&O, Salpingo-oophorectomy.

Management

- **Benign histology.** A cystectomy should be performed instead of a salpingo-oophorectomy. Because of the patient's age the surgical goal should be toward conservation of both ovaries. If the frozen section pathology analysis is benign, no further surgery is needed. **Follow-up** is on an annual basis.

- **Germ cell tumor.** A unilateral salpingo-oophorectomy and surgical staging (peritoneal and diaphragmatic biopsies, peritoneal cytology, pelvic and para-aortic lymphadenectomy, and omentectomy) should be done. All patients with germ cell tumors require postoperative chemotherapy. The most active regimen used is vinblastine, bleomycin, and cisplatin. Follow-up after conservative surgery is every 3 months with pelvic examination and tumor marker measurements.

Prognosis. The current survival is >95% in patients with germ cell tumors managed with conservative management and chemotherapy. Before the chemotherapy age the majority of these patients succumbed to their disease.

PREMENOPAUSAL PELVIC MASS

Complex Mass

A 28-year-old woman is in the emergency department complaining of lower abdominal discomfort the last 5 days. She has no history of steroid contraceptive use. A year ago, her pelvic exam and Pap smear were negative. Pelvic exam today shows a 7-cm, mobile, painless right adnexal mass. An endovaginal sonogram in the emergency department confirms a 7-cm, mobile, irregular complex mass with prominent calcifications.

GYN Triad

Dysgerminoma

- **Solid** pelvic mass in reproductive years
- β-hCG (–)
- ↑ LDH level

Definition. The **most common** complex adnexal mass in young women is a dermoid cyst or benign cystic teratoma (discussed below). Other diagnoses include endometrioma, tubo-ovarian abscess, and ovarian cancer.

Differential Diagnosis

- Pregnancy
- Functional cysts

Diagnosis.

- **Qualitative β-human chorionic gonadotropin (β-hCG)** test to rule out pregnancy.
- The appearance of a complex mass on ultrasound will rule out a functional cyst.

Management. Patients in the reproductive age group with a complex adnexal mass should be treated surgically. The surgery can be done by a laparoscopy or a laparotomy according to the experience of the surgeon.

- **Cystectomy.** At the time of surgery an ovarian cystectomy should be attempted to preserve ovarian function in the reproductive age. Careful evaluation of the opposite adnexa should be performed, as dermoid cysts can occur bilaterally in 10–15% of cases.
- **Oophorectomy.** If an ovarian cystectomy cannot be done because of the size of the dermoid cyst, then an oophorectomy is performed, but conservative management should always be attempted before an oophorectomy is done.

GYN Triad

Benign Cystic Teratoma

- Pelvic mass: reproductive years
- β-hCG (–)
- Sonogram: complex mass, calcifications

Benign cystic teratoma

Dermoid cysts are benign tumors. They can contain cellular tissue from all 3 germ layers. The most common histology seen is ectodermal skin appendages (hair, sebaceous glands), and therefore the name "dermoid." Gastrointestinal histology can be identified, and carcinoid syndrome has been described originating from a dermoid cyst. Thyroid tissue can also be identified, and if it comprises more than 50% of the dermoid, then the condition of struma ovarii is identified. Rarely, a malignancy can originate from a dermoid cyst, in which case the most common histology would be squamous cell carcinoma, which can metastasize.

PAINFUL ADNEXAL MASS

A 31-year-old woman is taken to the emergency department complaining of severe sudden lower abdominal pain for approximately 3 h. She was at work when she suddenly developed lower abdominal discomfort and pain, which got progressively worse. On examination the abdomen is tender, although no rebound tenderness is present, and there is a suggestion of an adnexal mass in the cul-de-sac area. Ultrasound shows an 8-cm left adnexal mass with a suggestion of torsion of the ovary.

GYN Triad

Ovarian Torsion

- Abrupt **unilateral** pelvic pain
- β-hCG (–)
- Sonogram: >7 cm adnexal mass

Diagnosis. Sudden onset of severe lower abdominal pain in the presence of an adnexal mass is presumptive evidence of ovarian torsion.

Management. The management of the torsion should be to untwist the ovary and observe the ovary for a few minutes in the operating room to assure revitalization. This can be performed with laparoscopy or laparotomy.

- **Cystectomy.** If revitalization occurs, an ovarian cystectomy can be performed with preservation of the ovary.
- **Oophorectomy.** If the ovary is necrotic, a unilateral salpingo-oophorectomy is performed.

Follow-Up. Patients should have routine examination 4 weeks after the operation and then should be seen on a yearly basis. The pathology report should be checked carefully to make sure that it is benign, and if this is the case, then they go to routine follow-up.

POSTMENOPAUSAL PELVIC MASS

A 70-year-old woman comes for annual examination. She complains of lower abdominal discomfort; however, there is no weight loss or abdominal distention. On pelvic examination a nontender, 6-cm, solid, irregular, fixed, left adnexal mass is found. Her last examination was 1 year ago, which was normal.

Definition. A pelvic mass identified after menopause. Ovaries in the postmenopausal age group should be atrophic; anytime they are enlarged, the suspicion of **ovarian cancer** arises.

Diagnostic Tests

- **GI tract lesions.** Abdominal pelvic CT scan or a pelvic ultrasound, and GI studies (barium enema) to rule out any intestinal pathology such as diverticular disease
- **Urinary tract lesions.** IVP to identify any impingement of the urinary tract

Screening Test. There is no current screening test for ovarian cancer. Pelvic ultrasound is excellent for finding pelvic masses, but is not specific for identifying which are benign and which are malignant. Only 3% of patients undergoing laparotomy for sonographically detected pelvic masses actually have ovarian cancer.

Epidemiology. Ovarian carcinoma is the **second most common** gynecologic malignancy, with a mean age at diagnosis of 69 years. One percent of women die of ovarian cancer. It is the **most common** gynecologic cancer leading to death.

Risk Factors. These include **BRCA1 gene**, positive family history, high number of lifetime ovulations, infertility, and use of perineal talc powder.

Protective Factors. These are conditions that decrease the total number of lifetime ovulations: oral contraceptive pills, chronic anovulation, breast-feeding, and short reproductive life.

Classification of Ovarian Cancer

- **Epithelial tumors—80%.** The **most common** type of histologic ovarian carcinoma is epithelial cancer, which predominantly occurs in postmenopausal women. These include serous, mucinous, Brenner, endometrioid, and clear cell tumors. The **most common** malignant epithelial cell type is **serous**.
- **Germ cell tumors—15%.** Another histologic type of ovarian cancer is the germ cell tumor, which predominantly occurs in teenagers. Examples are dysgerminoma, endodermal sinus tumors, teratomas, and choriocarcinoma. The **most common** malignant germ cell type is **dysgerminoma**. It is uniquely x-ray sensitive.
- **Stromal tumors—5%.** The third type of ovarian tumor is the stromal tumor, which is functionally active. These include granulosa-theca cell tumors, which secrete estrogen and can cause bleeding from endometrial hyperplasia and Sertoli-Leydig cell tumors, which secrete testosterone and can produce masculinization syndromes. Patients with stromal tumors usually present with early stage disease and are treated either with removal of the involved adnexa (for patients who desire further fertility) or a TAH and BSO (if their family has been completed). They metastasize infrequently, and then they require chemotherapy (vincristine, actinomycin, and Cytoxan).
- **Metastatic tumor.** These are cancers from a primary site other than the ovary. The **most common** sources are the endometrium, GI tract, and breast. **Krukenberg tumors** are mucin-producing tumors from the stomach or breast metastatic to the ovary.

GYN Triad

Serous Carcinoma

- Postmenopausal woman
- Pelvic mass
- ↑ CEA or CA-125 level

GYN Triad

Choriocarcinoma

- Postmenopausal woman
- Pelvic mass
- ↑ hCG level

GYN Triad

Sertoli-Leydig Tumor

- Postmenopausal pelvic mass
- Masculinization
- ↑ testosterone level

GYN Triad

Endometrial Carcinoma Metastatic to Ovaries

- Postmenopausal woman with **bilateral** pelvic masses
- Postmenopausal bleeding
- Enlarged uterus

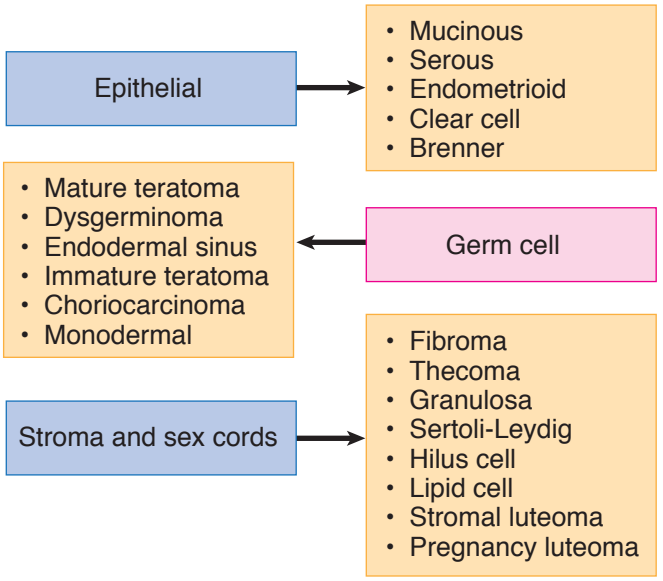


Figure II-5-2. Overview of Ovarian Oncology

Table II-5-2. Classic Histology Types of Ovarian Cancer

Type	Percentage	Age Group
Epithelial	80%	Older
Germ cell	15%	Young
Stromal	5%	All

Tumor Markers

- **CA-125** (cancer antigen 125) and **CEA** (carcinoembryonic antigen) should also be drawn for the possibility of ovarian epithelial cancer.
- **LDH, hCG**, and **α-fetoprotein** should be drawn for the possibility of germ cell tumors.
- **Estrogen** and **testosterone** should be drawn for the possibility of stromal tumors.

Staging. Staging is surgical.

Stage I: Spread limited to the **ovaries**
- IA. Limited to one ovary, capsule intact, negative cytology
- IB. Limited to both ovaries, capsules intact, negative cytology
- IC. One or both ovaries but ruptured capsule, positive cytology

Stage II: Extension to the **pelvis**
- IIA. Extension to uterus or tubes
- IIB. Extension to other pelvic structures
- IIC. Extension to pelvis with positive cytology

Stage III: **Peritoneal** metastases or positive nodes. This is the **most common** stage at diagnosis.

- IIIA. Microscopic peritoneal metastases
- IIIB. Macroscopic peritoneal metastases ≤2 cm
- IIIC. Macroscopic peritoneal metastases >2 cm

Stage IV: **Distant** metastases

- IVA. Involves bladder or rectum
- IVB. Distant metastasis

Management. A surgical exploration should follow preoperative studies and medical evaluation. If abdominal or pelvic CT scan shows no evidence of ascites or spread to the abdominal cavity, and if the surgeon is an experienced laparoscopist, then the evaluation could be performed laparoscopically. At the time of surgery, a unilateral salpingo-oophorectomy (USO) is done and sent for frozen section.

Benign Histology. If the patient is not a good surgical candidate or the patient desires to maintain her uterus and contralateral ovary, a USO is sufficient treatment. If the USO by frozen section is benign and the patient is a good surgical candidate, then a TAH and BSO may be performed even though it is benign disease because the uterus and ovaries are not unusual sites of pathology in a woman.

Malignant Histology. In this case, a debulking procedure (cytoreduction) should be performed. This procedure consists of a TAH and BSO, omentectomy, and bowel resection, if necessary. Postoperative chemotherapy (carboplatin and Taxol) should be administered.

Follow-Up. If the final pathology report of the enlarged adnexa was benign, the patient can be followed up in the office on a yearly basis for regular examination. If the pathology report was carcinoma, then she would be followed up every 3 months for the first 2 years and then every 6 months for the next 2 years with follow-up of the CA-125 tumor marker.

Borderline Cancers. Another entity of ovarian cancer is the borderline tumors also known as tumors of low malignant potential. These are characterized by no invasion of the basement membrane and can also be treated conservatively.

- **Conservative surgery.** A patient who desires further fertility with a unilateral borderline cancer of the ovary can be treated with a USO with preservation of the uterus and the opposite adnexa.
- **Aggressive surgery.** If the patient has completed her family then the most acceptable treatment would be a TAH and BSO.
- **Chemotherapy.** Patients with borderline cancer of the ovary do not require chemotherapy unless they have metastasis, and this is a rare occurrence.

Adnexal Mass With Ascites

A 65-year-old woman is referred for evaluation of abdominal distention and ascites and an adnexal mass. The patient has noted abdominal distention for the past 6 months, and on pelvic examination there is a 7-cm irregular and solid mass in the cul-de-sac, which is palpable by rectovaginal examination.

GYN Triad

Ovarian Carcinoma with Peritoneal Metastasis

- Postmenopausal bilateral pelvic masses
- Weight gain, anorexia
- Abdominal "shifting dullness"

Definition. Ascites is an abdominal accumulation of fluid in the peritoneal cavity, which usually causes abdominal distention.

Differential Diagnosis. The etiology of ascites can be multifactorial and includes heart, kidney, and liver disease and ovarian cancer. In a female patient with ascites, ovarian carcinoma must always be considered. Although the etiology of ovarian carcinoma is not known, ovulation inhibition, as occurs with OCPs or pregnancy, does decrease the risk of epithelial ovarian cancer. **Meigs syndrome** is the triad of ascites, pleural effusion, and benign ovarian fibroma.

Laboratory Abnormalities/Diagnostic Criteria. In a patient with an adnexal mass and ascites, an abdominal pelvic CT scan should be ordered for evaluation of the upper abdomen. The **most common** method of ovarian carcinoma spread is by peritoneal dissemination (exfoliation) and is commonly seen metastatic to the omentum and to the GI tract. The cause of death of patients with advanced ovarian carcinoma is bowel obstruction.

Management Steps

- **Surgical staging.** After an abdominal pelvic CT scan confirms the presence of ascites and the adnexal mass, an exploratory laparotomy and surgical staging should be performed. A salpingo-oophorectomy of the enlarged ovary should be done and sent for frozen section evaluation.
- **Debulking surgery.** If ovarian carcinoma is confirmed, then a debulking (cytoreductive) surgical procedure should be performed. This procedure usually includes a TAH, BSO, omentectomy, and, frequently, bowel resection.
- **Chemotherapy.** Postoperatively patients should be treated with 6 courses of a standard chemotherapy regimen, which includes Taxol and carboplatin. Patients are followed with the tumor marker CA-125.

Gestational Trophoblastic Neoplasia 6

Learning Objectives

- ❑ Explain origin of gestational trophoblastic neoplasia

GESTATIONAL TROPHOBLASTIC NEOPLASIA (GTN)

A 24-year-old Filipino nurse is 14 weeks pregnant by dates. She complains of vaginal bleeding as well as severe nausea and vomiting. Her uterus extends to her umbilicus but no fetal heart tones can be heard. Her blood pressure is 150/95. A dipstick urine shows 2+ proteinuria.

GYN Triad

Molar Pregnancy

- Pregnancy <20 weeks
- HTN and proteinuria
- No fetal heart tones (FHT)

Definition. GTN, or **molar pregnancy**, is an abnormal proliferation of placental tissue involving both the cytotrophoblast and/or syncytiotrophoblast. It can be benign or malignant. Malignant GTN can be characterized as either localized or metastatic as well as classified into either **Good Prognosis** or **Poor Prognosis**.

Classification

- **Benign GTN** is the classic hydatidiform mole (H-mole). Incidence is 1:1200 in the US, but 1:120 in the Far East.
  - **Complete mole** is the most common benign GTN. It results from fertilization of an empty egg with a single X sperm resulting in paternally derived (androgenetic) **normal 46,XX** karyotype. No fetus, umbilical cord or amniotic fluid is seen. The uterus is filled with grape-like vesicles composed of edematous avascular villi. Progression to malignancy is 20%.
  - **Incomplete mole** is the less common benign GTN. It results from fertilization of a normal egg with two sperm resulting in **triploid 69,XXY** karyotype. A fetus, umbilical cord and amniotic fluid is seen which results ultimately in fetal demise. Progression to malignancy is 10%.
- **Malignant GTN** is the gestational trophoblastic tumor (**GTT**) which can develop in 3 categories.
  - **Non-metastatic disease** is localized only to the uterus.
  - **Good Prognosis metastatic disease** has distant metastasis with the most common location being the pelvis or lung. Cure rate is >95%.
  - **Poor Prognosis metastatic disease** has distant metastasis with the most common location being the brain or the liver. Other poor prognosis factors are serum β-hCG levels >40,000, >4 months from the antecedent pregnancy, and following a term pregnancy. Cure rate is 65%.

GYN Triad

Molar Pregnancy

- Pregnancy <20 weeks
- HTN and proteinuria
- Vaginal passage of vesicles

Table II-6-1. Benign Gestational Trophoblastic Neoplasia—H Mole

Complete	Incomplete
Empty egg	Normal egg
Paternal X's only	Maternal and paternal X's
46,XX (**di**ploidy)	69,XXY (**tri**ploidy)
Fetus absent	Fetus nonviable
20% → malignancy	10% → malignancy
No chemotherapy; serial β-hCG titers until (–); follow-up 1 year on oral contraceptive pill	

Table II-6-2. Malignant Gestational Trophoblastic Neoplasia

Nonmetastatic	Good Prognosis	Poor Prognosis
Uterus only	Pelvis or lung	Brain or liver
100% cure	>95% cure	65% cure
Single-agent chemotherapy		Multiple agent chemotherapy
1 year follow-up on oral contraceptive pill after β-hCG (–)		5 year follow-up on oral contraceptive pill

Risk Factors. Increased prevalence **geographically** is most common in **Taiwan** and the **Philippines**. Other risk factors are maternal age extremes (<20 years old, >35 years old) and folate deficiency.

Clinical Findings

- **The most common** symptom is bleeding prior to 16 weeks' gestation and passage of vesicles from the vagina. Other symptoms of a molar pregnancy include hypertension, hyperthyroidism, and hyperemesis gravidarum, and no fetal heart tones appreciated.
- The **most common** sign is fundus larger than dates, absence of fetal heart tones, bilateral cystic enlargements of the ovary known as **theca-lutein cysts**.
- The **most common site of distant metastasis** is the **lungs**.

Diagnosis. "**Snowstorm**" ultrasound. The diagnosis is confirmed with sonogram showing homogenous intrauterine echoes without a gestational sac or fetal parts.

Management

- Baseline quantitative β-hCG titer
- Chest X-ray to rule out lung metastasis
- Suction D&C to evacuate the uterine contents

Place the patient on effective contraception (oral contraceptive pills) for the duration of the follow-up period to ensure no confusion between rising β-hCG titers from recurrent disease and normal pregnancy.

Table II-6-3. Gestational Trophoblastic Neoplasia—Basic Approach

β-hCG titer	Baseline for future comparison
Chest x-ray	Lung metastasis is ruled out
Suction D&C	Empty uterus contents
Oral contraceptive pills for 1 year	Prevent confusion: recurrent disease and normal pregnancy

- Treatment is then based on histology and location of metastasis.
  - **Benign GTN:** Weekly serial β-hCG titers until negative for 3 weeks, then monthly titers until negative for 12 months. **Follow-up is for 1 year.** If serial β-hCG titers plateau or rise and normal intrauterine pregnancy is ruled out by vaginal sonogram, the patients are diagnosed with persistent gestational trophoblastic disease. They should undergo a metastatic workup (CT scans of the brain, the thorax, the abdomen and the pelvis) and be managed as below.
  - **Non-metastatic or Good Prognosis metastatic disease: Single agent** (**methotrexate** or actinomycin D) until weekly β-hCG titers become negative for 3 weeks, then monthly titers until negative for 12 months. **Follow-up is for 1 year.**
  - **Poor Prognosis metastatic disease: Multiple agent** chemotherapy (which includes methotrexate, actinomycin-D and cytoxan) until weekly β-hCG titers become negative for 3 weeks, then monthly titers for 2 years, then every 3 months for another 3 years. F**ollow-up is for 5 years.**

Table II-6-4. Gynecologic Malignancy

Clinical staging	Cervical cancer
Surgical staging	Endometrial, ovarian, vulvar, and trophoblastic cancer

Sexually Transmitted Diseases 7

Learning Objectives

- ❏ Give an overview of the organisms involved in STDs
- ❏ Differentiate between STDs with and without ulcers
- ❏ Explain the role of azithromycin in treating STDs
- ❏ Describe what is known about the sexual transmission of hepatitis B and HIV

SPECTRUM OF ORGANISMS

Bacterial. These include chancroid, lymphogranuloma venereum, granuloma inguinale, chlamydia, gonorrhea, syphilis.

Viral. These include condyloma acuminatum, herpes simplex, hepatitis B virus, and human immunodeficiency virus.

Protozoan. This includes trichomoniasis.

STDs WITH ULCERS

Herpes Simplex Virus (HSV)

Refer to Obstetrics, Chapter 7, Perinatal Infections.

Syphilis

Refer to Obstetrics, Chapter 7, Perinatal Infections.

Chancroid

Chancroid is caused by *Haemophilus ducreyi*, a Gram-negative bacterium. It is uncommon in the United States. It is a cofactor for HIV transmission.

Symptoms. This is one of the two STDs that presents with a **painful** ulcer. A pustule, usually on the vulva, becomes a painful ulcer within 72 hours, with a typically "ragged edge."

Diagnosis. A positive culture confirms the diagnosis, although a diagnosis is often made clinically after excluding syphilis and genital herpes.

Management. CDC-recommended treatment includes a single oral dose of azithromycin, a single IM dose of ceftriaxone, or oral erythromycin base for 7 days.

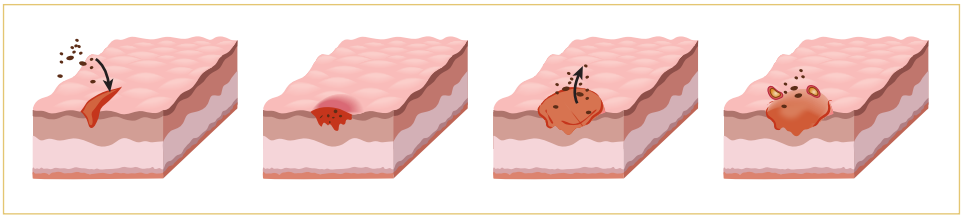

Figure II-7-1. Pathophysiology of Chancroids

Lymphogranuloma Venereum (LGV)

LGV is caused by the L serotype of *Chlamydia trachomatis*. It is uncommon in the United States.

Symptoms. The initial lesion is a **painless** ulcer.

Examination. A painless vesiculopustular eruption, usually on the vulva, spontaneously heals. This is replaced within a few weeks by perirectal adenopathy that can lead to abscesses and fistula formation. The classic clinical lesion is a double genitocrural fold, the "groove sign."

Diagnosis. A positive culture of pus aspirated from a lymph node confirms the diagnosis.

Management. CDC-recommended treatment includes oral doxycycline or erythromycin for 3 weeks.

Granuloma Inguinale (Donovanosis)

This disease is caused by *Calymmatobacterium granulomatis*, a Gram-negative intracellular bacterium. It is uncommon in the United States.

Symptoms. The initial lesion is a **painless** ulcer.

Examination. A vulvar nodule breaks down, forming a painless, beefy red, highly vascular ulcer with fresh granulation tissue without regional lymphadenopathy. Lymphatic obstruction can result in marked vulvar enlargement. Chronic scarring can lead to lymphatic obstruction.

Diagnosis. Culture of the organism is difficult but microscopic examination of an ulcer smear will reveal Donovan bodies.

Management. CDC-recommended treatment includes oral doxycycline or azithromycin for 3 weeks.

AZITHROMYCIN

Table II-7-1. Comparison of STDs

With Ulcers	No Ulcers	Painful Ulcers
Chancroid Granuloma inguinale Genital herpes LGV Syphilis	Chlamydia HPV Gonorrhea Hepatitis B HIV	Chancroid Genital herpes

Table II-7-2. Comparison of STDs with Ulcers

Chancroid (painful)	Ragged, soft edge inflamed
LGV	Groove sign
Granuloma inguinale	Beefy red; Donovan bodies
Syphilis	Rolled, hard edge
Herpes (painful)	Smooth edge inflamed

STDs WITHOUT ULCERS

Condyloma Acuminatum

Background. This disease is caused by the **human papilloma virus** (HPV). It is the **most common** overall STD in women, as well as the most common viral STD. Transmission can occur with subclinical lesions. HPV subtypes 16 and 18 are associated with cervical and vulvar carcinoma whereas condyloma is associated with HPV types 6 and 11. Predisposing factors include immunosuppression, diabetes, and pregnancy.

Symptoms. HPV is subclinical in most infected women. Symptoms of pain, odor, or bleeding occur only when lesions become large or infected.

Examination. Clinical lesions are found in only 30% of infected women. The characteristic appearance of a condyloma is a pedunculated, soft papule that progresses into a cauliflower-like mass. The most common site of lesions is the cervix.

Diagnosis. The lesions have an appearance so characteristic that biopsy is seldom necessary.

Management: is topical or local. Systemic therapy is not available.

- **Patient-applied topical treatment:** podofilox [Condylox] solution or gel (antimitotic drug); imiquimod [Aldara] cream (topically active immune-enhancer); or sinecatechins ointment (green-tea extract)
- **Provider-administered local treatment:** cryotherapy (liquid nitrogen or cryoprobe); podophyllin resin (not used in pregnancy); trichoroacetic acid [TCA] or biochloroacetic acid [BCA] (caustic agents); or surgical removal

Trichomonas Vaginitis

Refer to Gynecology, Chapter 3, Disorders of the Vagina and Vulva.

Chlamydia

Background. This disease is caused by *Chlamydia trachomatis*, an obligatory intracellular bacterium. It is the **most common** bacterial STD in women, occurring up to 5 times more frequently than gonorrhea. The long-term sequelae arise from pelvic adhesions, causing chronic pain and infertility. When the active infection ascends to the upper genital tract and becomes symptomatic, it is known as acute pelvic inflammatory disease (**acute PID**). Transmission from an infected gravida to her newborn may take place at delivery, causing conjunctivitis and otitis media.

Symptoms. Most chlamydial cervical infections, and even salpingo-oophoritis, are asymptomatic.

Examination. The classic cervical finding is mucopurulent cervical discharge. Urethral and cervical motion tenderness may or may not be noted.

Diagnosis. Nucleic acid amplification tests (NAAT) of either cervical discharge or urine is used.

Management. The CDC-recommended treatment includes a single oral dose of azithromycin or oral doxycycline for 7 days. Patients should avoid coitus for 7 days after therapy. A test-of-cure (repeat testing 3–4 weeks after completing therapy) is recommended for pregnant women.

Gonorrhea

Background. This disease is caused by *Neisseria gonorrhoeae*, a Gram-negative diplococcus. The long-term sequelae arise from pelvic adhesions, causing chronic pain and infertility. When the active infection becomes symptomatic, it is known as acute pelvic inflammatory disease (**acute PID**). Systemic infection can occur.

Symptoms. Lower genital tract infection may lead only to vulvovaginal discharge, itching, and burning with dysuria or rectal discomfort. Upper genital tract infection leads to bilateral abdominal-pelvic pain. Disseminated gonorrhea is characterized by dermatitis, polyarthralgia, and tenosynovitis.

Examination. Vulvovaginitis is seen on inspection. Mucopurulent cervical discharge is seen on speculum exam. Cervical motion tenderness is common with bimanual pelvic exam. A Bartholin abscess may be found if the gland duct becomes obstructed due to an acute infection. Petechial skin lesions, septic arthritis, and rarely, endocarditis or meningitis, may demonstrate with disseminated gonorrhea.

Diagnosis. Same as for chlamydia, above.

Management. Dual therapy for gonococcus and chlamydia is recommended by the CDC because of the frequency of coinfection. The CDC-treatment recommendations include a single dose of IM ceftriaxone plus a single oral dose of azithromycin. A Bartholin abscess needs to undergo incision and drainage with a Word catheter.

Bartholin Abscess/Cyst

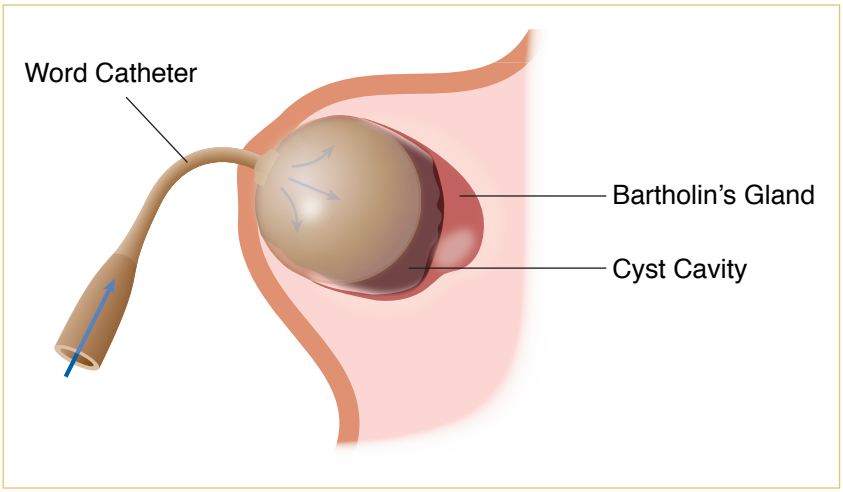

Figure II-7-2. Use of Word Catheter

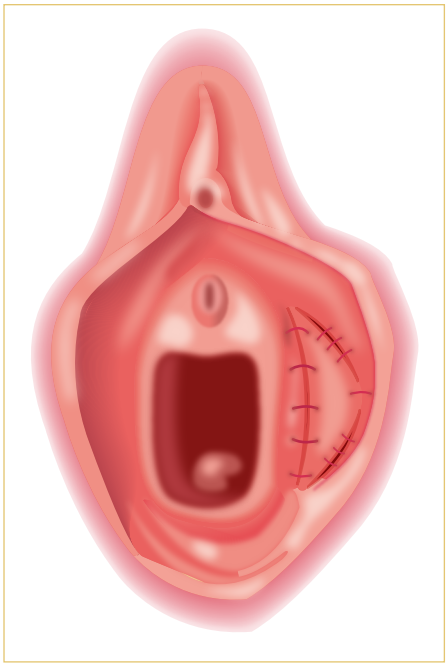

Figure II-7-3. Marsupialization

HEPATITIS B (HBV)

Refer to Obstetrics, Chapter 7, Perinatal Infections.

HUMAN IMMUNODEFICIENCY VIRUS (HIV)

Refer to Obstetrics, Chapter 7, Perinatal Infections.

Pelvic Pain 8

Learning Objectives

- ❏ Differentiate primary and secondary dysmenorrhea
- ❏ Provide an overview of the diagnosis and treatment of pelvic inflammatory disease

PELVIC INFLAMMATORY DISEASE (PID)

A 19-year-old nulligravida presents to the emergency department with bilateral lower abdominal pelvic pain. The onset was 24 hours ago after she had just finished her menstrual period. She is sexually active but using no contraception. Speculum examination reveals mucopurulent cervical discharge. Bimanual pelvic examination shows bilateral adnexal tenderness and cervical motion tenderness. She is afebrile. Qualitative urinary β-hCG test is negative. Complete blood cell count shows WBC 14,000. ESR is elevated.

Definition. PID is a nonspecific term for a **spectrum** of upper genital tract conditions ranging from acute bacterial infection to massive adhesions from old inflammatory scarring.

The **most common** initial organisms are **chlamydia** and **gonorrhea**. With persistent infection, secondary bacterial invaders include anaerobes and gram-negative organisms.

Pathophysiology

- **Cervicitis.** The initial infection starts with invasion of endocervical glands with chlamydia and gonorrhea. A mucopurulent cervical discharge or friable cervix may be noted. Cervical cultures will be positive, but symptoms are usually absent.
- **Acute salpingo-oophoritis.** Usually after a menstrual period with breakdown of the cervical mucus barrier, the pathogenic organisms ascend through the uterus, causing an endometritis, and then the bacteria enter the oviduct where acute salpingo-oophoritis develops.
- **Chronic PID.** If the salpingo-oophoritis is not appropriately treated, the body's immune defenses will often overcome the infection but at the expense of persistent adhesions and scarring.
- **Tubo-ovarian abscess (TOA).** If the body's immune defenses cannot overcome the infection, the process worsens, producing an inflammatory mass involving the oviducts, ovaries, uterus, bowel, and omentum.

Risk Factors. The **most common** risk factor is female sexual activity in adolescence, with multiple partners. PID is increased in the month after insertion of an IUD, but this is probably exacerbation of preexisting subclinical infection.

Cervicitis

Symptoms. Often there are no symptoms except vaginal discharge.

Examination. The **most common** finding is mucopurulent cervical discharge or a friable cervix. No pelvic tenderness is noted. The patient is afebrile.

Investigative Findings. This can be either a laboratory diagnosis or a clinical diagnosis. See Diagnosis section for chlamydia. WBC and ESR are normal.

Management. Single dose orally of cefixime and azithromycin.

Acute salpingo-oophoritis

GYN Triad

Acute Salpingo-Oophoritis

- **Bilateral** abdominal/pelvic pain
- Mucopurulent cervical discharge
- Cervical motion tenderness

Symptoms. Bilateral lower abdominal-pelvic pain may be variable ranging from minimal to severe. Onset may be gradual to sudden, often after menses. Nausea and vomiting may be found if abdominal involvement is present.

Examination. Mucopurulent cervical discharge, cervical-motion tenderness, and bilateral adnexal tenderness are present. Fever, tachycardia, abdominal tenderness, peritoneal signs, and guarding may be found depending on the extent of infection progression.

Investigative Findings. WBC and ESR are both elevated. Pelvic sonography is usually unremarkable. Laparoscopy will show erythematous, edematous, purulent oviducts. Cervical cultures will come back positive for chlamydia or gonorrhea.

Differential Diagnosis. Adnexal torsion, ectopic pregnancy, endometriosis, appendicitis, diverticulitis, Crohn disease, and ulcerative colitis.

Diagnosis. This is a made on **clinical grounds** using the following:

- **Minimal criteria:**
  - Sexually active young woman
  - Pelvic or lower abdominal pain
  - Tenderness: cervical motion or uterine or adnexal
- **Supportive criteria (but not necessary for diagnosis):**
  - Oral temperature >101°F (>38.3°C)
  - Abnormal cervical or vaginal mucopurulent discharge
  - Presence of abundant WBC on vaginal fluid saline microscopy
  - Elevated erythrocyte sedimentation rate
  - Positive lab findings of cervical *N. gonorrhoeae* or *C. trachomatis*
  - Most specific criteria for diagnosis:
  - Endometrial biopsy showing endometritis
  - Vaginal sono or MRI imaging showing abnormal adnexae
  - Laparoscopic abnormalities consistent with PID

Management is often based on a presumptive diagnosis. Empiric broad spectrum coverage need to include *N. gonorrhoeae* or *C. trachomatis* as well as anaerobes (e.g., *B. fragilis*).

- **Outpatient treatment** is equivalent to inpatient in mild to moderate cases.
  - **Criteria**: absence of inpatient criteria
  - **Antibiotics**: Ceftriaxone IM x 1 plus doxycycline po bid for 14 days with/without metronidazole po bid for 14 days
- **Inpatient treatment** is essential with severe cases
  - **Criteria:** Appendicitis cannot be ruled out; failed outpatient therapy; unable to tolerate oral medications; severe illness, high fever, nausea/vomiting; tubo-ovarian abscess or pregnancy
  - **Antibiotics:** (1) Cefotetan IV 12 h plus doxycycline po or IV q 12 h or (2) clindamycin plus gentamicin IV q 8 h

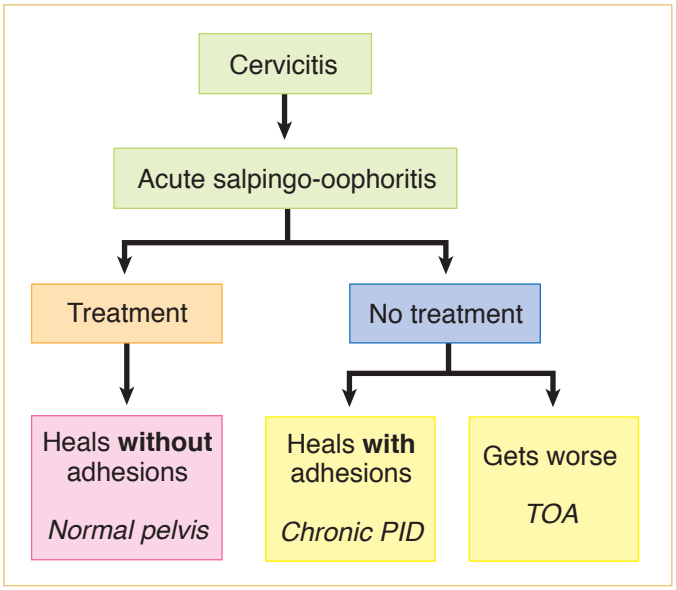

Figure II-8-1. Pelvic Inflammatory Disease

Tubo-ovarian abscess (TOA)

TOA is the accumulation of pus in the adnexae forming an inflammatory mass involving the oviducts, ovaries, uterus, or omentum.

Symptoms. The patient looks septic. Lower abdominal-pelvic pain is severe. Often the patient has severe back pain, rectal pain, and pain with bowel movements. Nausea and vomiting are present.

Examination. The patient appears gravely sick. She has high fever with tachycardia. She may be in septic shock with hypotension. Abdominal examination shows peritoneal signs, guarding, and rigidity. Pelvic examination may show such severe pain that a rectal examination must be performed. Bilateral adnexal masses may be palpated.

Investigative Findings. Cervical cultures are positive for chlamydia or gonorrhea. Blood cultures may be positive for gram-negative bacteria and anaerobic organisms such as *Bacteroides fragilis*. Culdocentesis may yield pus. WBC and ESR are markedly elevated. Sonography or CT scan will show bilateral complex pelvic masses.

Differential Diagnosis. Septic abortion, diverticular or appendiceal abscess, and adnexal torsion.

Management. Inpatient IV clindamycin and gentamicin should result in fever defervescence within 72 hours. If the patient does not respond or there is rupture of the abscess exposing free pus into the peritoneal cavity, significant mortality can occur. Exploratory laparotomy with possible TAH and BSO or percutaneous drainage through a colpotomy incision may be required.

GYN Triad

Chronic Salpingo-Oophoritis

- **Bilateral** abdominal/pelvic pain
- No cervical discharge
- Cervical motion tenderness

Chronic PID

Symptoms. Chronic bilateral lower abdominal-pelvic pain is present, varying from minimal to severe. Other symptoms may include history of infertility, dyspareunia, ectopic pregnancy, and abnormal vaginal bleeding. Nausea and vomiting are absent.

Examination. Bilateral adnexal tenderness and cervical-motion tenderness is present, but mucopurulent cervical discharge is absent. Fever and tachycardia are absent.

Investigative Findings. Cervical cultures are negative. WBC and ESR are normal. Sonography may show bilateral cystic pelvic masses consistent with hydrosalpinges.

Diagnosis. This is based on laparoscopic visualization of pelvic adhesions.

Management. Outpatient mild analgesics are used for pain. Lysis of tubal adhesions may be helpful for infertility. Severe unremitting pelvic pain may require a pelvic clean-out (TAH, BSO). If the ovaries are removed, estrogen replacement therapy is indicated.

PRIMARY DYSMENORRHEA

A 15-year-old girl comes to the outpatient office complaining of severe menstrual-period pain that started 6 months ago. Onset of menarche was age 13. The pain can be so severe that she is unable to attend school or carry on normal activities. She describes it as cramping in nature, and it is associated with nausea, vomiting, and diarrhea. When her menses are completed, the pain is gone. She is not sexually active. General exam is normal for age. Pelvic exam is unremarkable.

Definition. Primary dysmenorrhea refers to recurrent, crampy lower abdominal pain, along with nausea, vomiting, and diarrhea, that occurs during menstruation in the absence of pelvic pathology.

It is the **most common** gynecologic complaint among adolescent females. (Secondary dysmenorrhea refers to painful menstruation in the presence of pelvic pathology. It is more common among women in the fourth and fifth decades of life.)

Findings

- Onset of pain generally does not occur until ovulatory menstrual cycles are established. Maturation of the hypothalamic-pituitary-gonadal axis leading to ovulation occurs in half of teenagers within 2 years postmenarche, and the majority of the remainder by 5 years postmenarche.
- The symptoms typically begin several hours prior to the onset of menstruation and continue for 1 to 3 days.
- The severity of the disorder can be categorized by a grading system based on the degree of menstrual pain, presence of systemic symptoms, and impact on daily activities.

Pathogenesis

- Symptoms appear to be caused by excess production of endometrial **prostaglandin** $F_{2\alpha}$ resulting from the spiral arteriolar constriction and necrosis that follow progesterone withdrawal as the corpus luteum involutes. The prostaglandins cause dysrhythmic uterine contractions, hypercontractility, and increased uterine muscle tone, leading to **uterine ischemia**.
- The effect of the prostaglandins on the gastrointestinal smooth muscle also can account for nausea, vomiting, and diarrhea via stimulation of the gastrointestinal tract.

Management. Suppression of prostaglandins is the objective of treatment. Nonsteroidal anti-inflammatory drugs (**NSAIDs**, i.e., prostaglandin synthetase inhibitors) are the first choice in treatment.

- Continuous combination estrogen-progesterone steroid agents (e.g., oral contraceptives) are the second choice for suppressing prostaglandin release.

GYN Triad

Endometriosis

- Chronic pelvic pain
- Painful intercourse
- Painful bowel movements

SECONDARY DYSMENORRHEA

Endometriosis

A 34-year-old woman complains of painful periods, painful sex, painful bowel movements, and infertility for 2 years. She had used combination oral contraceptive pills from age 25 to 30. Pelvic examination reveals a tender, 5-cm cul-de-sac mass, along with tenderness and nodularity of the uterosacral ligaments.

Definition. Endometriosis is a benign condition in which endometrial glands and stroma are seen outside the uterus. This is not a premalignant condition.

Pathophysiology. Although the etiology of endometriosis is not known, the most accepted theory of explanation is that of Sampson, which is **retrograde menstruation**.

- The **most common** site of endometriosis is the ovary, and because this is functioning endometrium, it bleeds on a monthly basis and can create adnexal enlargements known as endometriomas, also known as a **chocolate cyst**.
- The **second most common** site of endometriosis is the **cul-de-sac**, and in this area the endometriotic nodules grow on the uterosacral ligaments, giving the characteristic **uterosacral ligament nodularity** and tenderness appreciated by rectovaginal examination. Menstruation into the cul-de-sac creates fibrosis and adhesions of bowel to the pelvic organs and a rigid cul-de-sac, which accounts for **dyspareunia**.

Clinical Findings

- **Symptoms.** Pelvic-abdominal pain is not necessarily related to the extent of disease. Painful intercourse (**dyspareunia**) is often experienced along with painful bowel movements (dyschezia). Infertility of endometriosis is not necessarily related to the extent of disease.
- **Examination.** Pelvic tenderness is common. A fixed, retroverted uterus is often caused by cul-de-sac adhesions. Uterosacral ligament nodularity is characteristic. Enlarged adnexa may be found if an endometrioma is present.
- **Investigative findings.** WBC and erythrocyte sedimentation rate (ESR) are normal. CA-125 may be elevated. Sonogram will show an endometrioma if present.

Diagnosis. The diagnosis of endometriosis is made by laparoscopy. There is a suspicion of the disease based on history and physical examination; however, laparoscopic identification of endometriotic nodules or endometriomas is the definitive way of making the diagnosis.

Medical therapy of endometriosis seeks to prevent shedding of the ectopic endometrial tissue, thus decreasing adhesion formation and pain.

- **Pregnancy** can be helpful to endometriosis because during pregnancy there is no menstruation and also the dominant hormone throughout pregnancy is progesterone, which causes atrophic changes in the endometrium. However, infertility may make this impossible.
- **Pseudopregnancy** achieves this goal through preventing progesterone withdrawal bleeding. Continuous oral medroxyprogesterone acetate (MPA [Provera]), subcutaneous medroxyprogesterone acetate (SQ-DMPA [Depo Provera]), or combination oral contraceptive pills (OCPs) can mimic the atrophic changes of pregnancy.
- **Pseudomenopause** achieves this goal by making the ectopic endometrium atrophic. The treatment is based on inhibition of the hypothalamic–pituitary–ovarian axis to decrease the estrogen stimulation of the ectopic endometrium. Several medications can be used to achieve inhibition of the axis.
  - Testosterone derivative (danazol or Danocrine)
  - Gonadotropin-releasing hormone (GnRH) analog (leuprolide or Lupron)

The best inhibition of the hypothalamic–pituitary–ovarian axis is achieved by GnRH analogs. GnRH stimulates the pituitary in a pulsatile fashion, and GnRH analogs stimulate by continuous stimulation, which produces a condition known as down-regulation of the pituitary.

Although regression of the endometriotic nodules can be achieved, the patient can become symptomatic with menopausal complaints. Patients on Lupron therapy for >3–6 months can complain of menopausal symptoms, such as hot flashes, sweats, vaginal dryness, and personality changes. Lupron medication is continued for 3–6 months' duration, and then a more acceptable medication for the inhibition of the axis can be used, such as birth control pill medication. An alternative to Lupron is DMPA (Depo Provera), which also suppresses FSH and LH but does not result in vasomotor symptoms.

Surgical management may be conservative or aggressive.

- **Conservative.** If preservation of fertility is desired, the procedures can be performed in many cases through laparoscopic approach. Lysis of paratubal adhesions may allow adherent fimbria to function and achieve pregnancy. Ovarian cystectomies as well as oophorectomies can be treatment for endometriomas. Laser vaporization of visible lesions is also performed laparoscopically.

- **Aggressive.** If fertility is not desired, particularly if severe pain is present because of diffuse adhesions, definitive surgical therapy may be carried out through a total abdominal hysterectomy (TAH) and bilateral salpingo-oophorectomy (BSO). Estrogen replacement therapy is then necessary.

Follow-Up. Endometriosis is not a malignant condition but is associated with higher risk of ovarian carcinoma; mechanism unclear.

Adenomyosis

Refer to Chapter 4, Disorders of the Cervix and Uterus.

Ectopic Pregnancy

Refer to Obstetrics, Chapter 2, Failed Pregnancy.

Fertility Control 9

Learning Objectives

- List the advantages and disadvantages of different forms of contraception including barrier-spermicidal methods, steroid contraception, intrauterine contraception, coitus interruptus, natural family planning, lactation, vaginal douche, and sterilization

OVERVIEW OF FERTILITY CONTROL

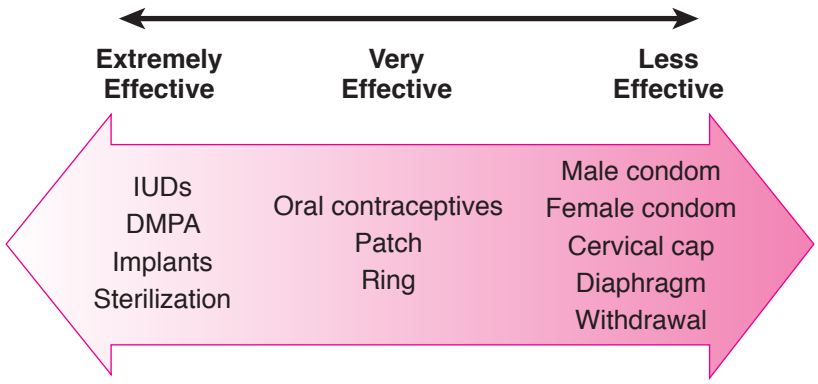

Figure II-9-1. Contraception

BARRIER-SPERMICIDAL METHODS

A 16-year-old adolescent comes to the family planning clinic requesting contraception. She has heard about the diaphragm and wonders if it would be appropriate for her.

Mechanisms of Action. These are locally active devices preventing entry of sperm in through the cervix, thus preventing pregnancy.

Advantages. Barrier methods become increasingly effective with advancing age and the associated natural decline in fertility. They do protect against some STDs. They do not have systemic side effects.

Disadvantages. Failure rate approaches 20%. They are coitally dependent, requiring a decision for each use, thus decreasing spontaneity. Barrier methods have no impact on excessive menstrual flow or excessively painful menses.

Specific Types

- **Condoms.** These are penile sheaths that must be placed on the erect penis. No individual fitting is required. They are the **most common** barrier contraceptive method used.
- **Vaginal diaphragm.** This is a dome-shaped device placed in the anterior and posterior vaginal fornices holding spermicidal jelly against the cervix. It can be placed an hour before intercourse. Individual fitting is required. If too large a size is used, it can result in urinary retention.
- **Spermicides.** The active ingredient is nonoxynol-9, a surface-active agent that disrupts cell membranes, thus the possible side effect of genital membrane irritation. These can take the form of jellies or foams placed into the vagina.

STEROID CONTRACEPTION

A 44-year-old woman, gravida 4 para 4, presents with questions about oral steroid contraception. She uses a diaphragm but is worried about contraceptive failure. She also expresses concern that her menses have become slightly heavier and more painful. She does not smoke and has no other medical problems.

Mechanisms of Action. These include inhibition of the midcycle luteinizing hormone (LH) surge, thus preventing ovulation; alteration of cervical mucus making it thick and viscid, thus retarding sperm penetration; and alteration of endometrium inhibiting blastocyst implantation.

Table II-9-1. Mechanism of Action of Steroid Contraception

Pituitary	↓ LH surge
Ovary	↓ ovulation
Endometrium	Atrophy
Cervix	Hostile mucus

Estrogen-Mediated Metabolic Effects. These include fluid retention from decreased sodium excretion; accelerated development of cholelithiasis; increase in hepatic protein production (e.g., coagulation factors, carrier proteins, angiotensinogen); healthy lipid profile changes (increase in high-density lipoproteins [HDL]; decrease in low-density lipoproteins [LDL]); and increased venous and arterial thrombosis.

Progestin-Mediated Metabolic Effects. These include mood changes and depression from decreased serotonin levels; androgenic effects (e.g., weight gain, acne); and unhealthy lipid profile changes (decreased HDL, increased LDL).

Absolute Contraindications. These include pregnancy; acute liver disease; history of vascular disease (e.g., thromboembolism, deep venous thrombosis [DVT], cerebrovascular accident [CVA], systemic lupus erythematosus [SLE]); hormonally dependent cancer (e.g., breast); smoker ≥35; uncontrolled hypertension; migraines with aura; diabetes mellitus with vascular disease; and known thrombophilia.

Relative Contraindications. These include migraine headaches, depression, diabetes mellitus, chronic hypertension, and hyperlipidemia.

Noncontraceptive Benefits. These include decreased ovarian and endometrial cancer; decreased dysmenorrhea and dysfunctional uterine bleeding; and decreased PID and ectopic pregnancy.

Table II-9-2. Noncontraceptive Benefits of Steroid Contraception

Mostly Progestin Component
↓ dysmenorrhea
↓ dysfunctional uterine bleeding
↓ pelvic inflammatory disease
↓ ectopic pregnancy

Combination Modalities

Combination OCPs. These contain both an estrogen and a progestin. They are administered most commonly in one of two ways: daily with 21 days on and 7 days off or daily 24 days on and 4 days off. When "off" the hormones, withdrawal bleeding will occur. Of all steroid contraceptives, they are the only one to have regular, predictable menses. Failure rate is 2% with ideal use. A newer combination is with daily hormones for 12 weeks followed by 1 week of placebo.

Oral Contraceptives. A unique combination of OCP (YAZ) reduces severe PMDD symptoms by 50%. It contains ethynyl estradiol and a new progestin, drospirenone. The dosing is 24 days of active pills then 4 days of placebo, rather than the traditional 21 days, followed by 7 days of placebo.

Combination Vaginal Ring. Marketed under the trade name of NuvaRing, this device, inserted into the vagina, contains both an estrogen and a progestin. It is removed after 3 weeks for 1 week to allow for a withdrawal bleed. A major advantage is relatively stable and constant blood levels of hormones. Failure rate is similar to combination OCPs.

Transdermal Skin Patch. Marketed under the trade name of Ortho Evra, this patch contains both an estrogen and a progestin. A patch is replaced every week for 3 weeks then removed for 1 week to allow for a withdrawal bleed. Levels of steroids are 60% higher than combination OCPs.

Progestin-Only Modalities

Progestin-Only OCPs. They contain only progestins and are sometimes called the "minipill." They need to be taken daily and continuously. A frequent side effect is break-through bleeding. Failure rate is 3% with ideal use.

Progestin-Only Injectable. Marketed under the trade name of Depo-Provera, this is an IM injection of depo-medroxyprogesterone acetate (DMPA). The slow release allows administration only every 3 months. A frequent side effect is break-through bleeding. Other side effects are prolonged time for fertility return and decreased bone mineral density. Failure rate is <1%.

Progestin-Only Subcutaneous Implant. Marketed under the trade name of Nexplanon, this uses etonogestrel as the active ingredient. The core contains a small amount of barium, making it visible on x-ray. The continuous release continues for 3 years. A frequent side effect is break-through bleeding. Failure rate is <1%.

"Morning-After" Pill. Marketed under the trade name of "Plan B," it uses levonorgestrel tablets. This postcoital contraception is administered as one tablet, immediately followed by one additional tablet in 12 h. Failure rate is 1%.

General. A recent evaluation of women's views regarding contraceptive health benefits demonstrated that most women are unaware of the protective effects of OCPs against endometrial and ovarian cancer, PID, ectopic pregnancy, benign breast disease, anemia, and dysmenorrhea.

Risks and Benefits. In nonsmoking women age >40, currently available OCPs are extremely safe. Low-dose contraceptive pills do not significantly increase the risk of cancer, heart disease, or thromboembolic events in women with no associated risk factors (hypertension, diabetes, or smoking). The combination estrogen/progestin pill tends to reduce menstrual flow and dysmenorrhea, and it regulates the menses, all of which would be excellent benefits for the patient.

INTRAUTERINE CONTRACEPTION

A 30-year-old woman with Crohn disease who periodically requires steroid therapy seeks advice regarding long-term contraception. She has had 3 pregnancies. A subserosal, fundal fibroid was noted at the time of her previous cesarean section delivery. She states that she is in a mutually monogamous relationship. She was treated for a chlamydia infection 2 months ago but does not like the idea of hormonal contraception and is asking about the risks associated with an IUS.

Intrauterine contraception is a long-acting reversible contraceptive method that involves placement of a small t-shaped object inside the uterus. Failure rate is <1%. Continuation rates at 1 year are almost 80%.

Mechanisms of Action. These include inhibition of sperm transport; increased tubal motility causing failure of implantation of immature zygote; inhibition of implantation secondary to endometrial inflammation; phagocytic destruction of sperm and blastocyst; and alteration of cervical mucus (only progesterone IUSs).

Table II-9-3. Mechanism of Action of Intrauterine System (IUS)

1. ↓ sperm transport
2. ↑ tubal motility
3. ↓ implantation
4. Sperm and blastocyst destroyed
5. Cervical mucus altered (LNG)

Definition of abbreviations: LNG, levonorgestrel.

Absolute Contraindications include a confirmed or suspected pregnancy; known or suspected pelvic malignancy; undiagnosed vaginal bleeding; and known or suspected salpingitis. **Relative Contraindications** include abnormal uterine size or shape; medical condition (e.g., corticosteroid therapy, valvular heart disease, or any instance of immune suppression increasing the risk of infection); nulligravidity; abnormal Pap smears; and history of ectopic pregnancy.

Side Effects. Menstrual bleeding and menstrual pain may be increased with the copper IUS, but not with the progesterone IUSs.

Potential Complications. The popularity of the IUS has varied greatly during the past 2 decades. Despite its excellence as a method of contraception, it has yet to recover from the negative publicity generated by the Dalkon Shield in the late 1970s. The LNG-containing IUS is effective for 5 years, the copper T-380A is effective for 10 years, making it potentially the least expensive contraceptive available.

- **Chlamydia.** This patient's recent chlamydia infection is a significant risk factor for IUS use. Most of the increased risk of infection actually attributable to IUS use is within 20 days after infection; consequently, any vaginal infection should be treated and resolved before insertion of the IUS to prevent introduction of organisms into the upper genital tract. Medical conditions that increase the risk of infection, such as HIV infection and immunosuppressive therapy, are also relative contraindications to IUS use. This patient's periodic need for steroid treatment for Crohn disease is a risk factor.
- **Leiomyomas.** Uterine fibroids could also be a relative contraindication because they alter the shape of the endometrial cavity or cause heavy bleeding. The subserosal fundal fibroids should not interfere with IUS placement.
- **Expulsion** is higher in young, low parity women.
- **Ectopic pregnancy.** The IUS does not increase ectopic pregnancies. However, with pregnancy from failed IUS, the likelihood of it being ectopic is higher because primarily, intrauterine pregnancies are prevented.
- **Septic abortion** occurs in 50% of patients with concurrent pregnancy.
- **Uterine perforation**, although rare, occurs more likely at time of insertion.
- **PID** may occur within the first 2 months after placement if pathogenic organisms are present in the reproductive tract.

IUS Options

- **"Mirena."** A levonorgestrel-impregnated (LNG) IUS that releases the hormone gradually over 5 years. Bleeding and cramping may be decreased. Failure rate is <1%.
- **Skyla**. A smaller (LNG) IUS similar to Mirena but effective for only 3 years. Failure rate is <1%.
- **Copper T-380A IUS.** Marketed under the trade name "Paraguard," this copper-banded IUS releases copper gradually over 10 years. Bleeding and cramping may be increased. Failure rate is <1%.

NATURAL FAMILY PLANNING—PERIODIC ABSTINENCE

This method is based on avoiding sexual intercourse around the time of predicted ovulation. It assumes the egg is fertilizable for 12 to 24 hours and sperm is capable of fertilizing the egg for 24 to 48 hours. Requires high degree of discipline from both sexual partners.

Methods used. Prediction or identification of ovulation may inferred from: menstrual records, basal body temperature charting (temperature rise from thermogenic effect of progesterone), change in cervical mucus from thin and watery to thick and sticky (reflects the change from estrogen dominance preovulation to progesterone dominance postovulation).

Advantages. Inexpensive. Readily available. No steroid hormonal side-effects. May be preferred for religious reasons.

Disadvantages. Inaccurate prediction of ovulation. High failure rate because of human frailities and the passions of the moment.

COITUS INTERRUPTUS

In this practice, also known as **withdrawal** or pull-out method, the man withdraws his penis from the woman's vagina prior to orgasm and ejaculation. It is one of the oldest contraceptive methods described.

Advantages: Readily available. Inexpensive. Free of systemic side effects.

Disadvantages: High failure rates. No protection against STDs. High degree of discipline required. Semen can enter vagina and cervical mucus prior to ejaculation.

VAGINAL DOUCHE

With vaginal douche, plain water, vinegar and other products are used immediately after orgasm to theoretically flush semen out of the vagina. It has a long history of use in the United States.

Advantages: None.

Disadvantages: High failure rates. No protection against STDs. Sperm can enter the cervical mucus within 90 seconds of ejaculation.

LACTATION

With lactation, elevated prolactin levels with exclusive breastfeeding inhibit pulsatile secretion of GnRH from the hypothalamus. Effectiveness is dependent on the frequency (at least every 4-6 hours day & night) and intensity (infant suckling rather than pumping) of milk removal.

Advantages: Enhanced maternal and infant health, bonding, and nutrition. Readily available. Inexpensive. Needs no supplies. Free of systemic side effects. Acceptable to all religious groups.

Disadvantages: High failure rate if not exclusively breastfeeding. Reliable for only up to 6 months. No protection against STDs.

STERILIZATION

> A 38-year-old multipara has completed her childbearing and is requesting sterilization. All 3 of her children were delivered vaginally. She has no medical problems and is in good health. General and pelvic examination is unremarkable.

Mechanisms of Action. These are surgical procedures usually involving ligation of either the female oviduct or male vas deferens. After the procedure is performed, there is nothing to forget and nothing to remember. They are to be considered permanent and irreversible.

Tubal Ligation. Destruction or removal of a segment of the oviduct is performed in an operating room through a transabdominal approach usually using a laparoscopy or minilaparotomy. Failure rate is 1 in 200. This is the **most common** modality of pregnancy prevention in the United States. If the procedure fails and pregnancy results, an ectopic pregnancy should be ruled out.

Vasectomy. Destruction or removal of a segment of vas deferens is performed as an outpatient procedure using local anesthesia. Failure rate is 1 in 500. A successful procedure can be confirmed by absence of sperm on a semen specimen obtained 12 ejaculations after the surgery. Sperm antibodies can be found in 50% of vasectomized patients.

Human Sexuality 10

Learning Objectives

- ❏ Take a sexual history
- ❏ Outline the human sexual response cycle
- ❏ List common sexual dysfunctions and their possible causes and treatments
- ❏ Explain the responsibilities of a health professional when examining a sexual assault victim

HUMAN SEXUAL RESPONSE CYCLE

A 31-year-old woman, mother of 4 children, comes to the office stating she has little interest in sexual intercourse with her husband for the past year. She says sex is painful, but she is able to experience orgasm occasionally. She has had no other sexual partners than her husband. These problems are affecting her marriage. She had a tubal sterilization procedure performed after her last delivery 2 years ago. Medications include thyroid replacement and fluoxetine.

Linear Model

Desire. In both women and men the desire for sexual activity is also known as libido. Desire is maintained by a balance between **dopamine** stimulation and **serotonin** inhibition. The threshold of response is determined by androgens, especially **testosterone**. This is true for women as well as men.

Excitement. This phase is also known as **arousal**. It is mediated by **parasympathetic** connections to the pelvic organs and results in vascular **engorgement**. Arousal in women is generally slower, responds more to **touch** and **psychic stimuli**, and is manifested by vaginal lubrication. Arousal in men is generally faster, responds more to **visual** stimuli, and is manifested by penile **erection**.

Plateau. This phase entails progression and intensification of the excitement phase. The length of this phase is variable. The neural pathway and physiologic mechanism is the same as excitement.

Orgasm. This phase is mediated by **sympathetic** connections resulting in reflex tonic-clonic **muscle contractions** of the pelvic floor followed by contractions of the uterus. Women have more individual orgasmic **variability** than men. A unique characteristic of women is the potential for consecutive **multiple orgasms**.

Resolution. This phase is marked by a return to basal physiologic state with reversal of vasocongestion and muscle tension. Resolution tends to be faster for men and slower for women.

Refractory Phase. This is a unique characteristic of men and is the period of inability to be aroused before another orgasm. It frequently varies directly with the age of the man.

Circular Relational Model

Linear biologic model (limitations)

Masters and Johnson's **linear,** 4-stage **biologic** model of sexual response for both men and women assumes that men and women have similar sexual responses. Many women, however, do not move progressively and sequentially through the phases as described. Women may not even experience all of the phases—for example, they may move from sexual arousal to orgasm and satisfaction without experiencing sexual desire, or they can experience desire, arousal, and satisfaction but not orgasm.

- The biologic model may be limited because it does not take into account nonbiologic experiences such as pleasure and satisfaction. It also does not place sexuality into the context of the relationship.
- Much of female sexual desire is actually a reaction to a partner's sexual interest rather than a spontaneous stirring of the woman's own libido. Women have many reasons for engaging in sexual activity other than sexual hunger or drive, as the traditional model suggests.

Circular relationship model (advantages)

The **circular,** variable-stage **relationship** model of female sexual response acknowledges how emotional intimacy, sexual stimuli, and relationship satisfaction affect the female sexual response.

- Female sexual functioning proceeds in a more complex and circuitous manner than does male sexual functioning. Also, female functioning is dramatically and significantly affected by numerous psychosocial issues.
- Many women start from a point of sexual neutrality—where a woman is receptive to being sexual but does not initiate sexual activity—and the desire for intimacy prompts her to seek ways to become sexually aroused via conversation, music, reading or viewing erotic materials, or direct stimulation. Once she is aroused, sexual desire emerges and motivates.
- The goal of sexual activity for women is not necessarily orgasm but rather personal satisfaction, which may be orgasm and/or feelings of intimacy and connection.

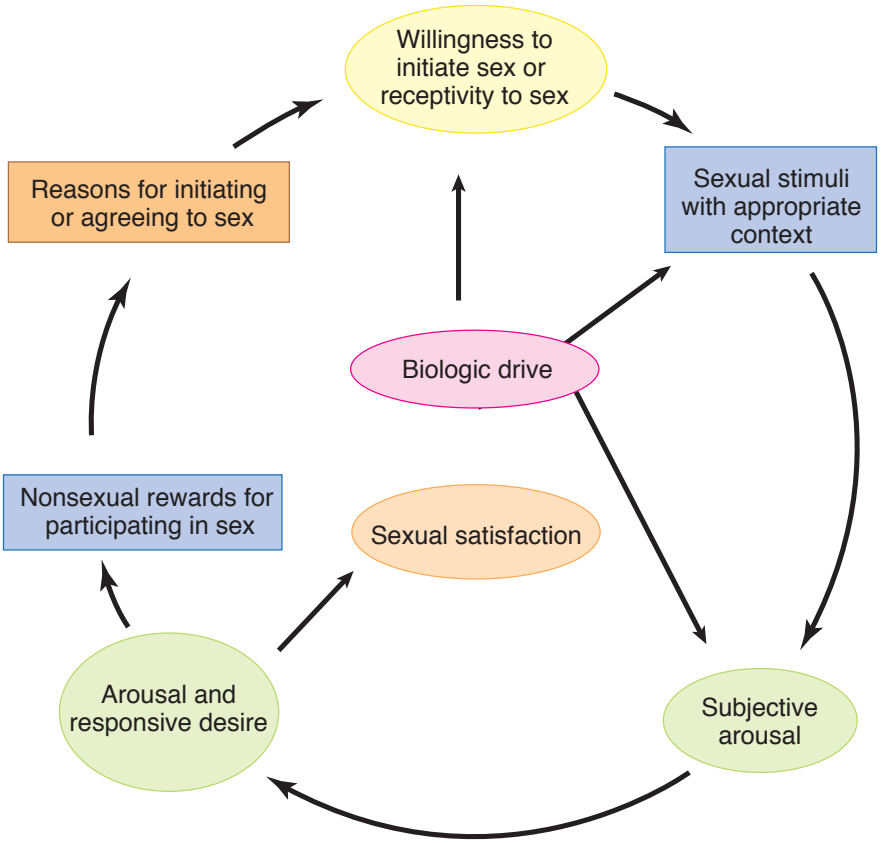

Figure II-10-1. Female Sexual Response Cycle

SEXUAL HISTORY-TAKING

The following questions should be asked of all new patients in developing a medical data base and problem list.

- **Sexual activity.** Start out with the following initial question: Is the patient currently sexually active? If not now, has she been in past?
- **Current history.** If she is currently sexually active, ask the following: Is the relationship with men or women or both? Is the relationship satisfying? Does she have any difficulty lubricating? Does she have pain with intercourse?
- **Previous history.** What was her age at first intercourse? What is the number of lifetime and current sexual partners? Does she have a history of sexual abuse or rape?

SEXUAL DYSFUNCTION

Each phase of the sexual response cycle can be dysfunctional.

- **Desire disorders.** Decreased sexual desire is the most common female sexual complaint. It may be organic (e.g., low androgens), medication related (e.g., selective serotonin reuptake inhibitors [SSRIs]), or psychological (e.g., poor partner relationship). **Treatment** can be difficult if it is relational in etiology.

- **Excitement disorders.** This usually results in difficulty in vaginal lubrication. The most common cause is estrogen deficiency. **Treatment** is highly successful.
- **Anorgasmia.** This can be primary or secondary. Inadequate clitoral stimulation is the most common cause. **Treatment** is highly successful using initially self-stimulation then partner education.
- **Dyspareunia.** Since pain with intercourse may arise from both psychological or physical causes, a thorough history and physical examination is essential. **Treatment** is directed at the specific cause found.
- **Vaginismus.** This occurs with painful reflex spasm of the paravaginal thigh adductor muscles. It is the only sexual dysfunction that can be diagnosed on physical examination. **Treatment** is highly successful using vaginal dilators.

SEXUAL ASSAULT

A 21-year-old university student presents to the emergency department stating she was walking home after an evening class when she was assaulted by a male stranger and was raped. She is not crying or upset, but rather looks almost without emotions. She is accompanied by her female roommate.

Definition. Rape is defined as sexual activity without the individual's consent occurring under coercion.

Management

- **Stabilization.** The first step is to determine the patient's vital signs and take whatever is needed to stabilize them. An informed consent needs to be obtained.
- **History-taking.** Record the events that happened in the patient's own words. Also obtain a reproductive, obstetric, sexual, and contraceptive history.
- **Examination.** A thorough general and pelvic examination should be performed with photographic or drawing documentation of any injuries or trauma.
- **Specimens.** A rape kit should be used to obtain biologic specimens (e.g., vaginal, oral, or anal specimens) for DNA or other evidence for use in potential legal proceedings. These must be appropriately labeled and documented, including signatures of receiving authorities. Also obtain baseline laboratory tests: VDRL, HIV screen, pregnancy test, urine drug screen, and blood alcohol level.
- **Prophylaxis.** Antibiotic therapy should be administered prophylactically for gonorrhea (ceftriaxone 125 mg IM × 1), chlamydia (azithromycin 1 g PO × 1), and trichomoniasis (metronidazole 2 g PO × 1). Antiviral HIV prophylaxis should be administered within 24 hours after exposure, but no medication should be given after 36 hours. Active and passive immunization for hepatitis B is appropriate.
- **Pregnancy prevention.** Administer 2 tablets of high progestin OCPs immediately, repeating two tablets in 12 h. A newly released formulation of levonogesterol tablets (Plan B) are now available specifically for postcoital pregnancy prevention.

Menstrual Abnormalities 11

Learning Objectives

- ❏ Describe the menstrual cycle
- ❏ Give a differential diagnosis and management of disorders of the menstrual cycle, including premenarchal menstrual bleeding, abnormal vaginal bleeding, primary/secondary amenorrhea

MENSTRUAL PHYSIOLOGY

The menstrual cycle is the cyclic pattern of activity of hypothalamus, pituitary, ovary, and uterus that produces a rhythm of bleeding every month for 30 years or more during the active reproductive phase of a woman's life.

Menarche is the first flow that signifies potential reproductivity. Menopause is the termination of the menstrual flow, which signifies diminished ovarian function.

Menstrual cycle occurs with the maturation of the hypothalamic–pituitary–ovarian axis. The hormones produced include gonadotropin-releasing hormone (GnRH) from the hypothalamus, which stimulates follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary, which stimulate estrogen and progesterone from the ovarian follicle.

Layers of the Endometrium

Functionalis Zone. This is the superficial layer that undergoes cyclic changes during the menstrual cycle and is sloughed off during menstruation. It contains the spiral arterioles that undergo spasm with progesterone withdrawal.

Basalis Zone. This is the deeper layer that remains relatively unchanged during the menstrual cycle and contains stem cells that function to renew the functionalis. It contains the basal arteries.

Phases of the Endometrium

Menstrual Phase. This is defined as the first 4 days of the menstrual cycle with the first day of menses taken as day 1. It is characterized by disintegration of the endometrial glands and stroma, leukocyte infiltration, and red blood cell (RBC) extravasation. Sloughing of the functionalis and compression of the basalis occurs.

Proliferative Phase. This follows the menstrual phase and is characterized by endometrial growth secondary to estrogen stimulation, including division of stem cells that migrate through the stroma to form new epithelial lining of the endometrium and new endometrial glands. The length of the spiral arteries also increases. **An estrogen-dominant endometrium is unstable** and, in the **presence of prolonged anovulation**, will **undergo hyperplasia with irregular shedding over time**.

Secretory Phase. This follows the proliferative phase and is characterized by glandular secretion of glycogen and mucus stimulated by progesterone from the corpus luteum. Endometrial stroma becomes edematous, and spiral arteries become convoluted. **A progesterone-dominant endometrium is stable** and will **not undergo irregular shedding**. Regression of the corpus luteum occurs by day 23 if there is no pregnancy, causing decreased levels of progesterone and estradiol and endometrial involution. Constriction of the spiral arteries occurs 1 day before menstruation, causing endometrial ischemia and release of prostaglandins, followed by leukocyte infiltration and RBC extravasation. The resulting necrosis leads to painful cramps and menstruation. When a pregnancy occurs, the serum β-human chorionic gonadotropin (β-hCG) becomes positive at day 22–23 of the cycle. The β-hCG becomes positive when the zygote implants into the endometrium, usually 7–8 days after ovulation. Therefore, the serum β-hCG becomes positive before the missed period.

Menstrual Cycle Hormones

FSH stimulates the growth of granulosa cells and induces the **aromatase** enzyme that converts androgens to estrogens. It raises the concentration of its own receptors on the granulosa cells. It stimulates the secretion of inhibin from the granulosa cells and is suppressed by inhibin.

LH stimulates the production of androgens by the theca cells, which then get converted to estrogens in the granulosa cells by the aromatase enzyme (2-cell theory). It raises the concentration of its own receptors in FSH-primed granulosa cells. The LH surge, which is dependent on a rapid rise in estrogen levels, stimulates synthesis of prostaglandins to enhance follicle rupture and ovulation. The LH surge also promotes luteinization of the granulosa cells in the dominant follicle, resulting in progesterone production as early as the 10th day of the cycle.

Estrogen is produced in the granulosa cells in response to even low FSH concentrations, and stimulates proliferative changes in the endometrium. It has a negative feedback to FSH at the hypothalamic–pituitary level, but has a positive feedback to increase GnRH receptor concentrations. At low estrogen levels there is negative inhibitory feedback for LH release, but as the level of estradiol increase is sustained for 50 hours, there is a transition to a positive stimulatory feedback, leading to the LH surge.

Androgens include androstenedione and testosterone. They are precursors of estrogen and are produced in the theca cells. In lower concentrations they stimulate aromatase enzyme activity, whereas at high levels they inhibit it. Androgens inhibit FSH induction of LH receptors.

Progesterone is produced by the corpus luteum and stimulates secretory changes in the endometrium in preparation for blastocyst implantation.

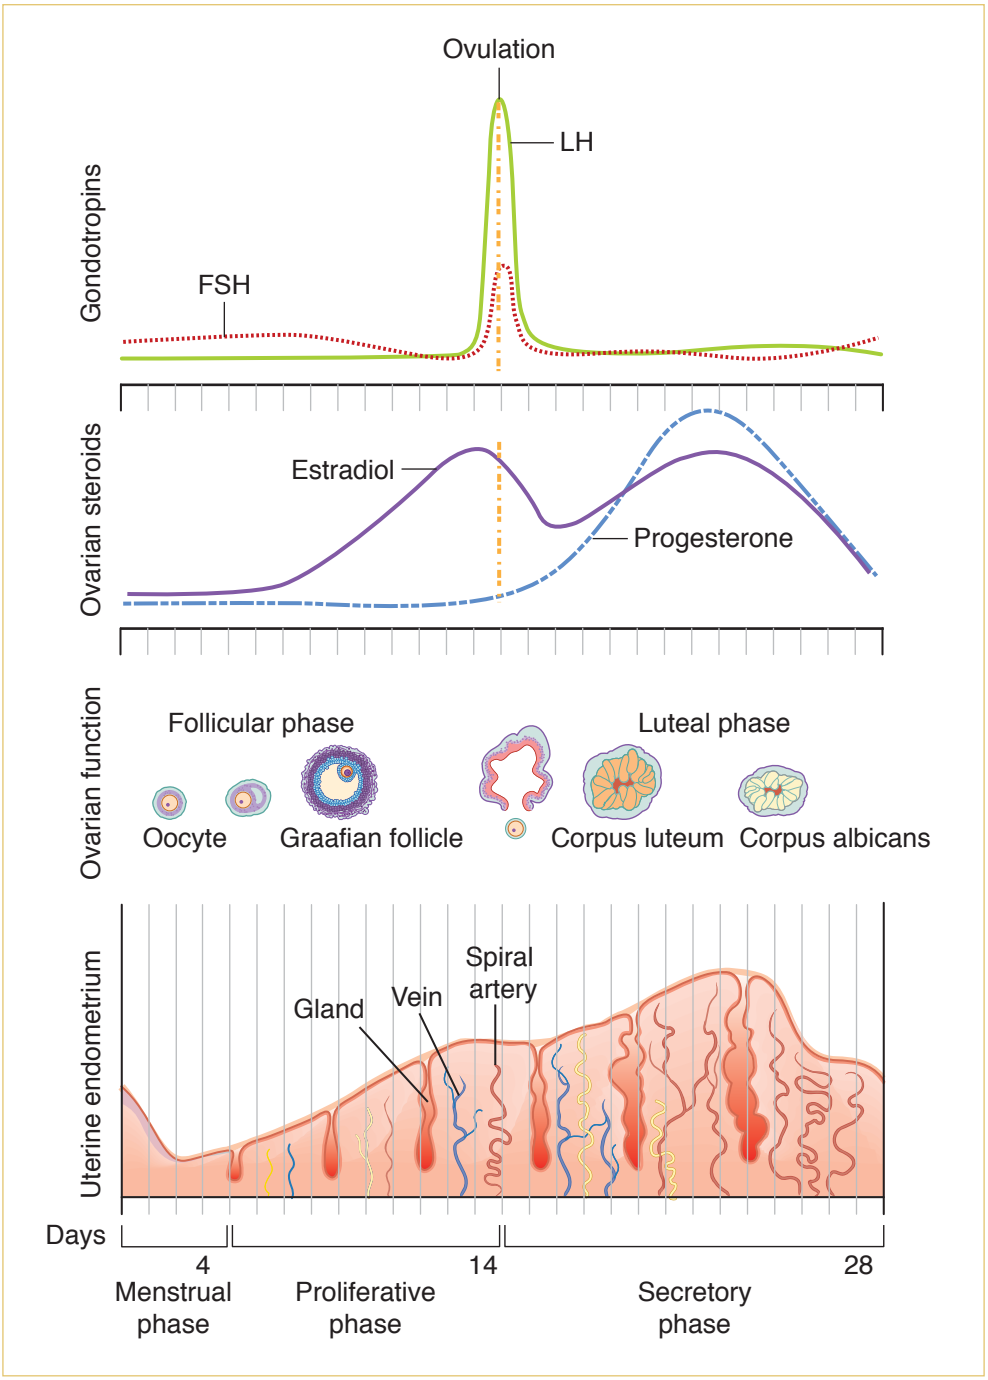

Figure II-11-1. Menstrual Cycle: Pituitary, Ovarian, and Endometrial Correlations

PREMENARCHAL VAGINAL BLEEDING

An 8-year-old girl is brought by her mother to the gynecologist's office because of vaginal bleeding for 2 weeks. The girl states that she has not taken any medication and gives no history suggestive of sexual abuse. She does not complain of headache or visual disturbance and has been doing well in school. On physical examination she is normal for her age without pubertal changes, and pelvic examination under sedation reveals a vaginal foreign body.

Definition. Premenarchal bleeding is bleeding that occurs before menarche. The average age at menarche is 12 years old.

Differential Diagnosis and Etiology. Possible causes include ingestion of estrogen medication, a foreign body that irritates the vaginal lining, a cancer of the vagina or of the cervix (sarcoma botryoides), a tumor of the pituitary or adrenal gland, an ovarian tumor, sexual abuse, or idiopathic precocious puberty. The most common cause of premenarchal bleeding is a foreign body.

Diagnosis and Management

- **Pelvic examination.** The patient who complains of premenarchal bleeding should have a pelvic examination under sedation. In this examination, evidence of a foreign body, sexual abuse, or tumor are looked for. Sarcoma botryoides typically looks like grapes arising from the vaginal lining or from the cervix.
- **Imaging study.** CT scan or MRI scan of the pituitary, abdomen, and pelvis should be done. The scans are looking for evidence of a pituitary, ovarian, or adrenal tumor, which may cause early estrogen production.

ABNORMAL VAGINAL BLEEDING

A 31-year-old woman complains of 6 months of menometrorrhagia. The patient states that she started having menstruation at age 13 and that she has had regular menses until the past 6 months. The pelvic examination including a Pap smear is normal. She has no other significant personal or family history.

Pregnancy

In a patient who has abnormal bleeding during the reproductive age group, pregnancy or a complication must first be considered.

Mechanism. Complications of early pregnancy that are associated with bleeding include incomplete abortion, threatened abortion, ectopic pregnancy, and hydatidiform mole.

Diagnosis. Urine or serum β-hCG test is required to confirm pregnancy. If pregnancy is identified vaginal ultrasound will help sort out which pregnancy complication is operative.

Management. Treatment will vary with the individual diagnosis identified.

Anatomic Lesion

If the pregnancy test is negative, then an anatomic cause of vaginal bleeding should be considered. The classic history is that of unpredictable bleeding (without cramping) occurring between normal, predictable menstrual periods (with cramping).

Mechanism. A variety of lower and upper reproductive tract factors can cause bleeding:

- Vaginal lesions: lacerations, varicosities or tumors
- Cervical lesions: polyps, cervicitis or tumors
- Endometrial lesions: submucous leiomyomas, polyps, hyperplasia or cancer
- Myometrial lesions: adenomyosis

Diagnosis. A number of tests can be used to for anatomic diagnosis.

- Lower genital tract: pelvic and speculum exam
- Upper genital tract: saline sonogram , endometrial biopsy, hysteroscopy

Management. Treatment will vary according to the individual diagnosis identified.

GYN Triad

Endometrial Polyp or Submucosal Leiomyoma

- Predictable vaginal bleeding with intermenstrual bleeding
- 33-year-old woman
- Normal height and weight

Inherited Coagulopathy

Up to 15% of patients with abnormal vaginal bleeding, especially in the adolescent age group, have coagulopathies. Review of systems may be positive for other bleeding symptoms including epistaxis, gingival bleeding and ecchyoses. Von Willebrand disease is the most common hereditary coagulation abnormality. The 3 types can vary in severity.

Mechanism. Coagulopathies can be due to vessel wall disorders, platelet disorders, coagulation disorders and fibrinolytic disorders. Von Willebrand disease arises from a deficiency of von Willebrand factor (vWF), a protein required for platelet adhesion.

Diagnosis. Positive family history and review of systems are helpful for screening. Initial laboratory tests include CBC with platelet count, PT and PTT. The best screening test for Von Willebrand disease is a vWF antigen.

Management. Consultation with hematology specialists is recommended in managing patients with inherited coagulopathies.

Dysfunctional Uterine Bleeding (DUB)

If the pregnancy test is negative, there are no anatomic causes for bleeding and coagulopathy is ruled out, then the diagnosis of hormonal imbalance should be considered. The classic history is that of bleeding that is unpredictable in amount, duration and frequency without cramping occurring.

Mechanism. The most common cause of DUB is anovulation. Anovulation results in unopposed estrogen. With unopposed estrogen, there is continuous stimulation of the endometrium with no secretory phase.

An estrogen dominant endometrium is structurally unstable as it increasingly thickens. With inadequate structural support, it eventually undergoes random, disorderly, and unpredictable breakdown resulting in estrogen breakthrough bleeding.

Diagnosis. Anovulatory cycles can usually be diagnosed from a history of irregular, unpredictable bleeding. Bleeding is usually without cramping since there is no PG release to cause myometrial contractions. Cervical mucus will be clear, thin and watery reflecting the estrogen dominant environment. Basal-body temperature (BBT) chart will not show a midcycle temperature rise due to the absence of the thermogenic effect of progesterone. Endometrial biopsy will show a proliferative endometrium.

GYN Triad

Abnormal Uterine Bleeding

PALM-COEIN Classification (FIGO 2011)

Visualizable by inspection or imaging:

P: Polyps (AUB-P)

A: Adenomyosis (AUB-A)

L: Leiomyoma (AUB-L)

M: Malignancy (AUB-M)

Needs further workup:

C: Coagulopathy (AUB-C)

O: Ovulatory disorders (AUB-O)

E: Endometrial (AUB-E)

I: Iatrogenic (AU B-1)

N: Not yet classified (AUB-N)

Progesterone trial involves administering progestin to stabilize the endometrium, stop the bleeding and prevent random breakdown. When the progestin is stopped, spiral arteriolar spasm results in PG release, necrosis, and an orderly shedding of the endometrium. A positive progesterone trial confirms a clinical diagnosis of anovulation. A negative progesterone trial rules out anovulation.

Correctable causes of anovulation. Anovulation can be secondary to other medical conditions. It is important to identify and correct a reversible cause of anovulation if present.

- Hypothyroidism is a common cause of anovulation, diagnosed by a high TSH and treated with thyroid replacement.
- Hyperprolactinemia, diagnosed by a serum prolactin test. An elevated prolactin inhibits GnRH by increasing dopamine. Treatment depends on the cause of the elevated prolactin.

Progestin management. Treatment involves replacing the hormone which is lacking (progesterone or progestin). These methods help regulate the menstrual flow and prevent endometrial hyperplasia, but do not reestablish normal ovulation.

- Cyclic MPA. Medroxyprogesterone acetate can be administered for the last 7 to 10 days of each cycle.
- Oral contraceptive pills (OCs). Estrogen-progestin oral contraceptives are often used for convenience. The important ingredient however, is the progestin not the estrogen.
- Progestin intrauterine system (LNG-IUS). The levonorgestrel lUS (Mirena or Skyla) delivers the progestin directly to the endometrium. This treatment can significantly decreasing menstrual blood loss.

Other managements. If progestin management is not successful in controlling blood loss, the following generic methods have been successful:

- **NSAIDs** can decrease dysmenorrheal, improve clotting and reduce menstrual blood loss. They are administered for only 5 days of the cycle and can be used and can be combined with OCs.
- **Tranexamic acid** (Lysteda) works by inhibiting fibrinolysis by plasmin. It is contraindicated with history of DVT, PE or CVA, and not recommended with E+P steroids.
- **Endometrial ablation** procedure destroys the endometrium by heat, cold or microwaves. It leads to a iatrogenic Asherman syndrome and minimal or no menstrual blood loss. Fertility will be affected.
- **Hysterectomy** (removal of the uterus) is a last resort and performed only after all other therapies have been unsuccessful.

PRIMARY AMENORRHEA

A 16-year-old girl presents with her mother, complaining she has never had a menstrual period. All of her friends have menstruated, and the mother is concerned about her daughter's lack of menstruation. On examination she seems to be well-nourished, with adult breast development and pubic hair present. Pelvic examination reveals a rudimentary vagina. No uterus is palpable on rectal examination.

Definition. Amenorrhea means absence of menstrual bleeding. Primary means that menstrual bleeding has never occurred.

Diagnosis. Primary amenorrhea is diagnosed with absence of menses at age 14 **without** secondary sexual development or age 16 **with** secondary sexual development.

Etiology. The origins of primary amenorrhea can be multiple. The two main categories of etiology are anatomic (e.g., vaginal agenesis/septum, imperforate hymen, or Müllerian agenesis) or hormonal (e.g., complete androgen insensitivity, gonadal dysgenesis [Turner syndrome], or hypothalamic-pituitary insufficiency).

Clinical Approach—Preliminary Evaluation

- **Are breasts present or absent?** A physical examination will evaluate secondary sexual characteristics (breast development, axillary and pubic hair, growth). **Breasts are an endogenous assay of estrogen.** Presence of breasts indicates adequate estrogen production. Absence of breasts indicates inadequate estrogen exposure.
- **Is a uterus present or absent?** An ultrasound of the pelvis should be performed to assess presence of a normal uterus.

GYN Triad

Imperforate Hymen

- Primary amenorrhea
- (+) breasts and uterus
- Normal height and weight

Table II-11-1. Müllerian Agenesis versus Androgen Insensitivity

Breasts Present/Uterus Absent	Müllerian Agenesis (46,XX)	Androgen Insensitivity (46,XY)
Uterus absent?	Idiopathic	MIF
Estrogen from?	Ovaries	Testes
Pubic hair?	Present	Absent
Testosterone level?	Female	Male
Treatment	No hormones Create vagina IVF—surrogate	Estrogen Create vagina Remove testes

Definition of abbreviations: MIF, Müllerian inhibitory factor.

Table II-11-2. Gonadal Dysgenesis versus HP Axis Failure

Breasts Absent/Uterus Present	Gonadal Dysgenesis (45,X)	HP Axis Failure (46,XX)
FSH	↑	↓
Why no estrogen?	No ovarian follicles	Follicles not stimulated
Ovaries?	"Streak"	Normal
Treatment pregnancy	E + P Egg donor	E + P Induce ovulation (HMG)
Diagnostic test?	—	CNS imaging

Definition of abbreviations: E + P, estrogen and progestin; HMG, human menopausal gonadotropin.

GYN Triad

Müllerian Agenesis
- Primary amenorrhea
- (+) breasts but (–) uterus
- (+) pubic and axillary hair

GYN Triad

Androgen Insensitivity

GYN Triad

Hypothalamic–Pituitary Failure
- Primary amenorrhea
- (–) breasts but (+) uterus
- ↓ FSH levels

GYN Triad

Kallmann Syndrome
- Primary amenorrhea
- (–) breasts but (+) uterus
- Anosmia

Clinical Approach Based on Findings Regarding Breasts and Uterus

- **Breasts present, uterus present.** Differential diagnosis includes an imperforate hymen, vaginal septum, anorexia nervosa, excessive exercise, and possible pregnancy before first menses.
  - History and physical examination will identify the majority of specific diagnoses.
  - Otherwise the workup should proceed as if for secondary amenorrhea.
- **Breasts present, uterus absent.** Differential diagnosis is Müllerian agenesis (Rokitansky-Kuster-Hauser syndrome) and complete androgen insensitivity (testicular feminization). Testosterone levels and karyotype help make the diagnosis.
  - **Müllerian agenesis.** These are genetically normal females (46,XX) with idiopathic absence of the Müllerian duct derivatives: fallopian tubes, uterus, cervix, and upper vagina; the lower vagina originates from the urogenital sinus.
    - Patients develop secondary sexual characteristics because ovarian function is intact; Müllerian ducts do not give rise to the ovaries.
    - Normal pubic and axillary hair is present. Testosterone levels are normal female.
    - **Management:** surgical elongation of the vagina for satisfactory sexual intercourse
  - **Androgen insensitivity.** In these genetically male (46,XY) individuals with complete lack of androgen receptor function, their bodies do not respond to the high levels of androgens present.
    - Without androgen stimulation, internal Wolffian duct structures atrophy. With testicular Müllerian inhibitory factor present, the Müllerian duct derivatives involute.
    - Without body recognition of dihydrotestosterone, external genitalia differentiate in a female direction. Patients function psychologically and physically as females and are brought up as girls. At puberty, when primary amenorrhea is noted, the diagnosis is made.
    - Female secondary sexual characteristics are present because the testes do secrete estrogens without competition from androgens. No pubic or axillary hair is noted. Testosterone levels are normal male.
    - **Management:** testes removal at age 20 because the higher temperatures associated with the intraabdominal position of the testes may lead to testicular cancer. Estrogen replacement is then needed.
- **Breasts absent, uterus present.** Differential diagnosis is gonadal dysgenesis (Turner syndrome) and hypothalamic–pituitary failure. FSH level and karyotype help make the diagnosis.
  - **Gonadal dysgenesis.** Turner syndrome (45,X) is caused by the lack of one X chromosome, essential for the presence of normal ovarian follicles. Instead of developing ovaries, patients develop streak gonads. FSH is elevated because of lack of estrogen feedback to the hypothalamus and pituitary. No secondary sexual characteristics are noted.
    - **Management:** Estrogen and progesterone replacement for development of the secondary sexual characteristics
  - **Hypothalamic–pituitary failure.** In the patient without secondary sexual characteristic but uterus present by ultrasound, another possibility is the hypothalamic causes of amenorrhea (stress, anxiety, anorexia nervosa, excessive exercise). FSH will be low. Kallman syndrome is the inability of the hypothalamus to produce GnRH and also anosmia. The defect is in the area of the brain that produces GnRH, but it's also close to the olfactory center. CNS imaging will rule out a brain tumor.

– **Management:** These patients should be treated with estrogen and progesterone replacement for development of the secondary sexual characteristics.

SECONDARY AMENORRHEA

A 32-year-old woman states that her last menstrual period was 1 year ago. She started menses at age 12, and was irregular for the first couple of years, but since age 14 or 15 she had menstruated every 28–29 days. She has not been pregnant and is concerned about the amenorrhea. She has not been sexually active and has not used contraception. She has no other significant personal or family history. Physical examination, including a pelvic exam, is normal.

Definition. Amenorrhea means absence of menstrual bleeding. Secondary means that previously menstrual bleeding had occurred.

Diagnosis. Secondary amenorrhea is diagnosed with absence of menses for 3 months if previously regular menses or 6 months if previously irregular menses.

Pathophysiology. There are multiple etiologies for secondary amenorrhea, which can be classified by alterations in FSH and LH levels. They include hypogonadotropic (suggesting hypothalamic or pituitary dysfunction), hypergonadotropic (suggesting ovarian follicular failure), and eugonadotropic (suggesting pregnancy, anovulation, or uterine or outflow tract pathology).

Specific etiology.

- **Pregnancy**. The first step is a β-hCG to diagnose pregnancy. This is the most common cause of secondary amenorrhea.
- **Anovulation**. If no corpus luteum is present to produce progesterone, there can be no progesterone-withdrawal bleeding. Therefore, **anovulation** is associated with unopposed estrogen stimulation of the endometrium. Initially the anovulatory patient will demonstrate amenorrhea, but as endometrial hyperplasia develops, irregular, unpredictable bleeding will occur. The causes of anovulation are multiple, including PCOS, hypothyroidism, pituitary adenoma, elevated prolactin, and medications (e.g., antidepressants).
- **Estrogen Deficiency.** Without adequate estrogen priming the endometrium will be atrophic with no proliferative changes taking place. The causes of hypoestrogenic states are multiple, including absence of functional ovarian follicles or hypothalamic–pituitary insufficiency.
- **Outflow Tract Obstruction.** Even with adequate estrogen stimulation and progesterone withdrawal, menstrual flow will not occur if the endometrial cavity is obliterated or stenosis of the lower reproductive tract is present.

Management

Pregnancy Test. The first step in management of secondary amenorrhea is to obtain a qualitative β-hCG test to rule out pregnancy.

Thyrotropin (TSH) Level. If the β-hCG test is negative, hypothyroidism should be ruled out (TSH level). The elevated thyrotropin-releasing hormone (TRH) in primary hypothyroidism can lead to an elevated prolactin. If hypothyroidism is found, treatment is thyroid replacement with rapid restoration of menstruation.

GYN Triad

Anovulatory Bleeding (Physiologic)

- Irregular, unpredictable vaginal bleeding
- 13-year-old adolescent
- Normal height and weight

GYN Triad

Anovulatory Bleeding (Chronic)

- Irregular, unpredictable vaginal bleeding
- 33-year-old woman
- Obese, hypertensive

Prolactin Level

- **Medications.** An elevated prolactin level may be secondary to antipsychotic medications or antidepressants, which have an anti-dopamine side effect (it is known that the hypothalamic prolactin-inhibiting factor is dopamine).
- **Tumor.** A pituitary tumor should be ruled out with CT scan or MRI of the brain. If a pituitary tumor is found and is <1 cm in its greatest dimension, treat medically with bromocriptine (Parlodel), a dopamine agonist. If >1 cm, treat surgically.
- **Idiopathic.** If the cause of elevated prolactin is idiopathic, treatment is medical with bromocriptine.

Progesterone Challenge Test (PCT). If the β-hCG is negative, and TSH and prolactin levels are normal, administer either a single IM dose of progesterone or 7 days of oral medroxyprogesterone acetate (MPA).

- **Positive PCT.** Any degree of withdrawal bleeding is **diagnostic of anovulation**. Cyclic MPA is required to prevent endometrial hyperplasia. Clomiphene ovulation induction will be required if pregnancy is desired.
- **Negative PCT.** Absence of withdrawal bleeding is caused by either inadequate estrogen priming of the endometrium or outflow tract obstruction.

Estrogen–Progesterone Challenge Test (EPCT). If the PCT is negative, administer 21 days of oral estrogen followed by 7 days of MPA.

- **Positive EPCT.** Any degree of withdrawal bleeding is diagnostic of inadequate estrogen. An FSH level will help identify the etiology.
  - **Elevated FSH suggests ovarian failure.** If this occurs age <25, the cause could be Y chromosome mosaicism associated with malignancy, so order a karyotype. **Savage syndrome** or resistant ovary syndrome is a condition in which follicles are seen in the ovary by sonogram, though they do not respond to gonadotropins.
  - **Low FSH suggests hypothalamic–pituitary insufficiency.** Order a CNS imaging study to rule out a brain tumor. Whatever the result, women with a positive EPCT will need estrogen-replacement therapy to prevent osteoporosis and estrogen-deficiency morbidity. Cyclic progestins are also required to prevent endometrial hyperplasia.
- **Negative EPCT.** Absence of withdrawal bleeding is diagnostic of either an outflow tract obstruction or endometrial scarring (e.g., **Asherman syndrome**). A hysterosalpingogram (HSG) will identify where the lesion is. Asherman is the result of extensive uterine curettage and infection-produced adhesions. It is treated by hysteroscopic adhesion lysis followed by estrogen stimulation of the endometrium. An inflatable stent is then placed into the uterine cavity to prevent re-adhesion of the uterine walls.

Hormonal Disorders 12

Learning Objectives

- ❏ Describe the causes of premenstrual disorders including precocious puberty
- ❏ Describe normal menopause and approaches to treating symptoms
- ❏ Outline the causes of hirsutism
- ❏ Provide epidemiology, diagnosis, and management information about polycystic ovarian syndrome
- ❏ List the steps for diagnosing infertility and treatment options available

PRECOCIOUS PUBERTY

A 6-year-old girl is brought to the office by her mother who has noticed breast budding and pubic hair development on her daughter. She has also experienced menstrual bleeding. Her childhood history is unremarkable until 3 months ago when these changes began.

Diagnosis. Criteria for diagnosis include development of female secondary sexual characteristics and accelerated growth before age 8 in girls and age 9 in boys. Precocious puberty is more common in girls than boys.

Normal Pubertal Landmarks. Complete puberty is characterized by the occurrence of all pubertal changes.

- The **most common** initial change is thelarche (breast development at age 9–10).
- This is followed by **adrenarche** (pubic and axillary hair at age 10–11).
- Maximal growth rate occurs age 11 and 12.
- Finally, the last change is **menarche** (onset of menses at age 12–13).

Table II-12-1. Precocious Puberty

Diagnosis	Female secondary sexual characteristics Accelerated growth <8 years of age in girls	
Normal pubertal landmarks	Thelarche Breast development	9–10 years
	Adrenarche Pubic and axillary hair	10–11 years
	Maximal growth Growth spurt	11–12 years
	Menarche Onset of first menses	12–13 years

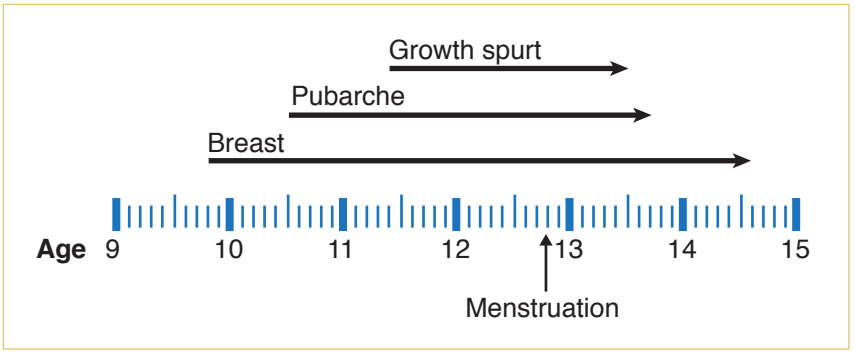

Figure II-12-1. Overview of Puberty

GYN Triad

Idiopathic or Constitutional

- Precocious complete isosexual puberty

- Normal head MRI

GYN Triad

CNS Lesions

- Precocious complete isosexual puberty
- 4-year-old girl
- Abnormal head MRI

Classification of precocious puberty

Incomplete Isosexual Precocious Puberty. This involves only one change—either thelarche, adrenarche, or menarche. This condition is the result of either transient hormone elevation or unusual end-organ sensitivity. Management is conservative.

Complete Isosexual Precocious Puberty. All changes of puberty are seen including breast development, growth spurt, and menstrual bleeding. The primary concern is premature closure of the distal epiphyses of the long bones, resulting in short stature. Fertility and sexual response are not impaired.

- **Gonadotropin-dependent.** This occurs because of increased secretion of estrogens that are dependent on premature release of gonadotropins from the hypothalamus and pituitary.
  - **Idiopathic.** The **most common** explanation is constitutional without a pathologic process present, accounting for 80% of precocious puberty. The age of the patient is usually 6 or 7 years. The diagnosis is usually one of exclusion after CNS imaging is shown to be normal. **Management** is GnRH agonist suppression (leuprolide or Lupron) of gonadotropins until appropriate maturity or height has been reached.
  - **CNS pathology.** This is a rare cause of precocious puberty. A CNS pathologic process stimulates hypothalamic release of GnRH, which leads to FSH release and ovarian follicle stimulation of estrogen production. This may include hydrocephalus,

von Recklinghausen disease, meningitis, sarcoid, and encephalitis. CNS imaging is abnormal. The age of the patient is usually <6 years. **Management** is directed at the specific pathologic process.

- **Gonadotropin-independent.** This occurs when estrogen production is independent of gonadotropin secretion from the hypothalamus and pituitary.
  - **McCune-Albright syndrome.** Also known as polyostotic fibrous dysplasia, this disorder is characterized by autonomous stimulation of aromatase enzyme production of estrogen by the ovaries. The syndrome includes multiple cystic bone lesions and **café au lait** skin spots. This accounts for 5% of precocious puberty. **Management** is administration of an aromatase enzyme inhibitor.
  - **Granulosa cell tumor.** A rare cause of precocious puberty is a gonadal-stromal cell ovarian tumor that autonomously produces estrogen. A **pelvic mass** will be identified on examination or pelvic imaging. **Management** is surgical removal of the tumor.

Follow-Up. Patients with idiopathic precocious puberty should be maintained with inhibition of the hypothalamic–pituitary–ovarian axis until the chronologic age catches up with the bone age.

PREMENSTRUAL DISORDERS

Premenstrual Syndrome (PMS)

A 36-year-old patient complains of depression, anxiety, irritability, and breast tenderness, which occur on a monthly basis. On further questioning, the symptoms most commonly occur 2 weeks before her menstruation and disappears with menses.

Definition. PMS includes a wide range of physical and emotional difficulties, as well as the more severe affective changes included in premenstrual dysphoric disorder (PDD).

Diagnosis. The basis for diagnosis is a **symptom diary** the patient keeps throughout 3 menstrual cycles. The specific symptoms are less important than their temporal relationship to the menstrual cycle. All the following must be present about the, symptoms:

- Must be recurrent in at least 3 consecutive cycles
- Must be absent in the preovulatory phase of the menstrual cycle
- Must be present in the 2 postovulatory weeks
- Must interfere with normal functioning
- Must resolve with onset of menses

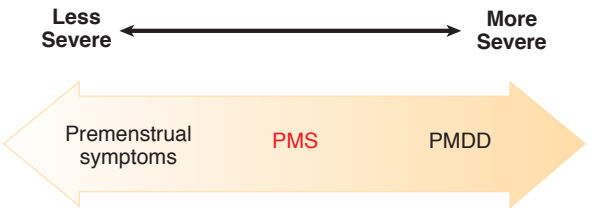

Figure II-12-2. Premenstrual Syndrome Diagnosis by Symptoms

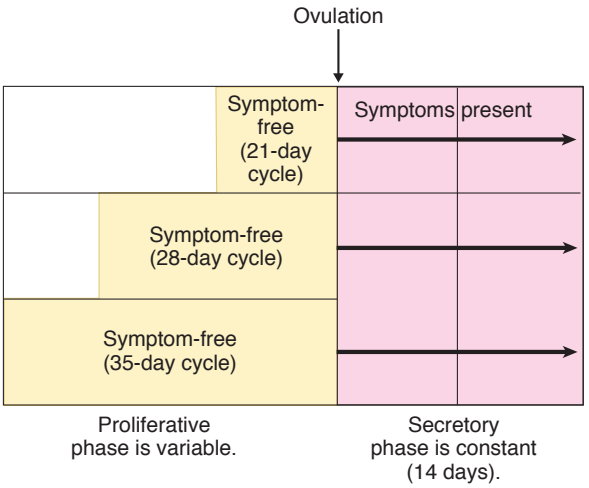

Figure II-12-3. Premenstrual Syndrome Diagnosis by Timing

- **Symptoms.** The symptoms may be of varied descriptions, including fluid retention (bloating, edema, breast tenderness), autonomic changes (insomnia, fatigue, heart pounding), emotional symptoms (crying, anxiety, depression, mood swings), or musculoskeletal complaints (headache, muscle aches, joint aches).

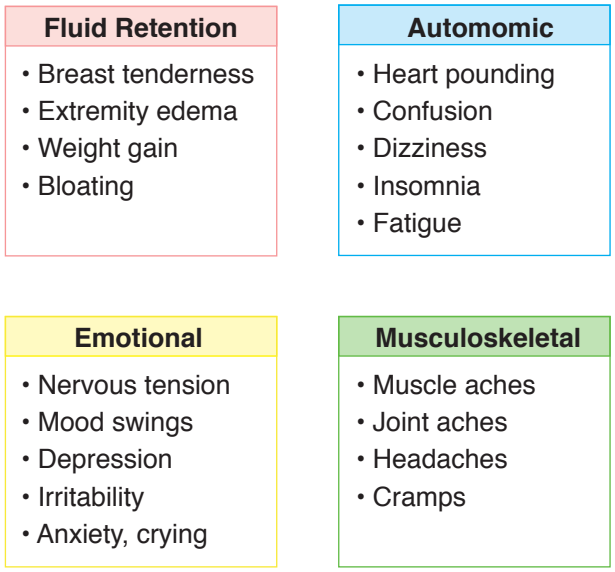

Figure II-12-4. PMS Symptoms

Management of PMS and PMDD

Proven treatments include the following:

- **Selective serotonin reuptake inhibitors (SSRIs).** Fluoxetine hydrochloride (Prozac); natural progesterone vaginal suppositories; MPA (Depo-Provera), spironolactone, and vitamin B_6 (pyridoxine). All of these options have been proposed for the treatment of PMS, but only fluoxetine, alprazolam (Xanax), and GnRH agonists have been shown in controlled, double-blind trials to be superior to placebo for the more severe symptoms of PDD. Recently reported double-blind trials of fluoxetine have shown reductions of 40–75% in troublesome behavioral and emotional symptoms. Similar outcomes have been reported for buspirone hydrochloride (BuSpar) and meclofenamate sodium in descriptive studies. SSRIs are the **treatment of choice** for emotional symptoms of PMS.
- **Yaz (drospirenone/ethinyl estradiol)**, with the unique progestin, drospirinon (DRSP), has been approved by the FDA for the treatment of PMS. Yaz is a low-dose, monophasic combination oral contraceptive with 24 hormone days with only a 4 day hormone-free interval. Studies show that the symptoms of PMS are decreased with a shorter hormone-free time period. DRSP is an analogue of spironolactone which differs from other OCP progestins by exhibiting both antimineralocorticoid and antiandrogenic effects.

Unproven treatments include the following:

- **Progesterone therapy** has a long history in the treatment of PMS, but neither natural progesterone (vaginal suppositories) nor progestin therapy has been shown to be any more effective than placebo. Because of both a lack of efficacy and the possibility of inducing menstrual irregularities, these agents should not be used.
- **Diuretics.** Because of the common complaint of "bloating" voiced by many patients with PMS, diuretics such as spironolactone have been advocated. Spironolactone has been studied in double-blind, randomized trials, and the results have been mixed. Although spironolactone may relieve some symptoms for some patients, the lack of consistent response across the studies in the literature suggests that other therapy is more effective.
- **Pyridoxine.** Vitamin B_6 in doses of 50-200 mg/d has been suggested as a treatment for PMS. A number of randomized, blinded studies have been performed, but no conclusive findings have emerged. Because of the lack of demonstrated efficacy and the possibility of permanent sensory neuropathy associated with high-dose vitamin B_6 consumptions, the use of vitamin B_6 should be discouraged.

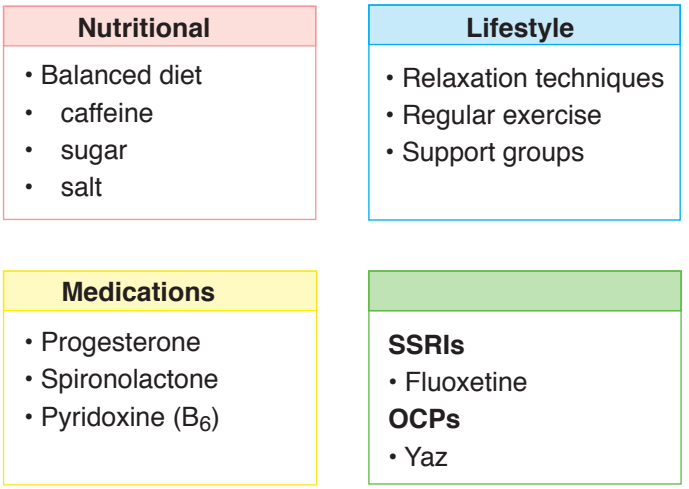

Figure II-12-5. PMS Treatment

HIRSUTISM

A 28-year-old woman complains of increased hair growth on the face and on the chest. She states that this has been going on for the past 10 years; however, she is more conscious of it at the present time. Her menses are irregular and unpredictable. Even though she has been married for 8 years and never used contraception, she has never been pregnant. On pelvic examination the ovaries bilaterally are slightly enlarged, but there are no other abnormalities noted.

Definition. Hirsutism is excessive male-pattern hair growth in a woman on the upper lip, chin, chest, abdomen, back, and proximal extremities. **Virilization** is excessive male-pattern hair growth in a woman **plus other masculinizing signs** such as clitorimegaly, baldness, lowering of voice, increasing muscle mass, and loss of female body contours.

Pathophysiology. Hirsutism involves the conversion of **vellus hair** (fine, nonpigmented hair) to **terminal hair** (coarse, dark hair) within the hair follicle. This conversion is under the influence of androgens. In women, androgens are generally produced in only 3 body locations: the ovaries, the adrenal glands, and within the hair follicle. The workup of hirsutism will seek to identify which of these body locations is producing the androgens that are responsible for the excess terminal hair.

Clinical Approach

- **History.** Is there a positive family history? What was the age of onset? Was onset gradual or abrupt? Have menstrual periods been irregular or regular? Is medication history positive for androgenic steroids?
- **Examination.** What is body-mass index? Location of excess hair? Evidence of virilization (frontal balding, loss of female body contour, clitorimegaly)? Presence of adnexal masses?

Laboratory Tests. The primary purpose of these tests is to identify elevated free androgens.

- **Dehydroepiandrosterone sulfate (DHEAS)** is produced only in the adrenal glands. A markedly elevated DHEAS is consistent with an adrenal tumor.
- **17-OH progesterone** is a precursor in the biosynthesis pathway of cortisol. It is elevated in late-onset congenital adrenal hyperplasia (CAH), with 21-hydroxylase deficiency. It is converted peripherally into androgens.
- **Testosterone** is produced by both the ovary and the adrenal glands. A mildly elevated level is suggestive of PCO syndrome. A markedly elevated level is consistent with an ovarian tumor.

Clinical entities

Adrenal Tumor

- **History.** Typically the onset has been **rapid** without positive family history.
- **Examination.** Physical examination will show evidence of **virilization**. Pelvic examination is unremarkable.
- **Laboratory tests.** DHEAS level is markedly elevated.
- **Imaging.** CT or MRI scan will show an abdominal-flank mass.
- **Management.** Treatment involves surgical removal of tumor.

GYN Triad

Adrenal Tumor

- Abrupt-onset virilization
- Abdominal/flank mass
- ↑↑ DHEAS levels

Ovarian Tumor

- **History.** Typically the onset has been **rapid** without positive family history.
- **Examination.** Physical examination will show evidence of **virilization**. An adnexal mass will be palpated on pelvic examination.
- **Laboratory tests.** Testosterone level is markedly elevated.
- **Imaging.** Pelvic ultrasound will show an adnexal mass.
- **Management.** Surgical removal of the mass, usually either a Sertoli-Leydig cell tumor or hilus cell tumor.

GYN Triad

Ovarian Tumor (Sertoli-Leydig)

- Abrupt-onset virilization
- Pelvic mass
- ↑↑ testosterone levels

Congenital Adrenal Hyperplasia (21-Hydroxylase Deficiency)

- **History.** Typically the onset has been **gradual** in the second or early third decade of life and is associated with menstrual irregularities and anovulation. Precocious puberty with short stature is common. Family history may be positive. Late-onset CAH is one of the most common autosomal recessive genetic disorders.
- **Examination.** Physical examination will show evidence of **hirsutism** without virilization. Pelvic examination is unremarkable.
- **Laboratory tests.** Serum 17-OH progesterone level is markedly elevated.
- **Management.** Treatment is medical with continuous corticosteroid replacement, which will arrest the signs of androgenicity and restore ovulatory cycles.

GYN Triad

Congenital Adrenal Hyperplasia 21-OH Deficiency

- Gradual-onset hirsutism
- Normal exam
- ↑ 17-OH progesterone

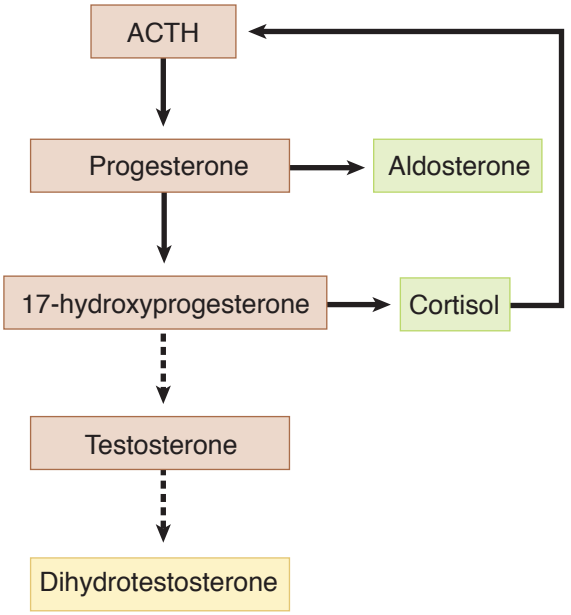

Figure II-12-6. Normal Adrenal Function

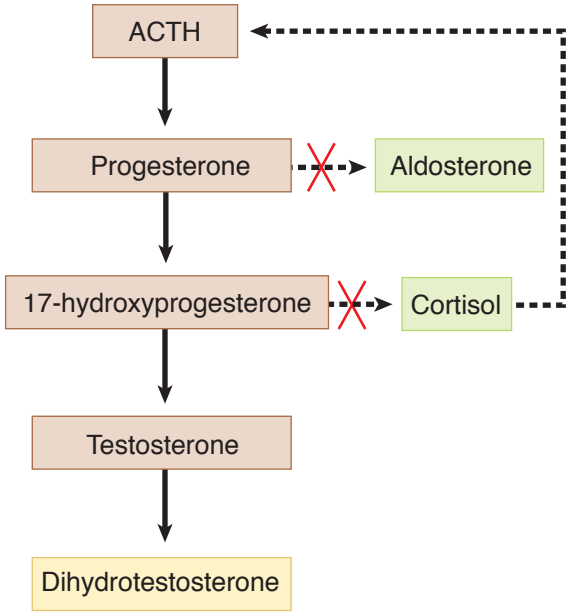

Figure II-12-7. Adrenal Hyperplasia

Polycystic Ovarian Syndrome (PCOS)

- **History.** Typically the onset has been **gradual**, frequently with a positive family history. In addition, the history is positive for irregular bleeding and infertility.
- **Examination.** Physical examination usually reveals **hirsutism** often with obesity and increased acne. Bilaterally enlarged, smooth, mobile ovaries will be palpated on pelvic examination. **Acanthosis nigricans** may be seen.
- **Laboratory tests.** Testosterone level is mildly elevated. LH to FSH ratio is elevated (3:1). Sex hormone binding globulin (SHBG) is decreased.
- **Imaging.** Pelvic ultrasound will show bilaterally enlarged ovaries with multiple subcapsular small follicles and increased stromal echogenicity.
- **Management.** The treatment of choice is combination OCPs. They will lower free testosterone levels in 2 ways. First, OCPs will lower testosterone production by suppressing LH stimulation of the ovarian follicle theca cells. Second, OCPs will also increase SHBG, thus decreasing free testosterone level. Metformin can decrease insulin resistance and lower testosterone levels.

Idiopathic

- **History.** Typically the onset has been **gradual**, frequently with a positive family history. Menses and fertility are normal. This is the **most common** cause of androgen excess in women.
- **Examination.** Physical examination reveals **hirsutism** without virilization. Pelvic examination is normal.
- **Laboratory tests.** Normal levels of testosterone, DHEAS, and 17-OH progesterone are identified.

GYN Triad

Idiopathic (Hair Follicle)
↑ 5-α Reductase Activity

- Gradual-onset hirsutism
- Normal exam
- Normal DHEAS, testosterone, 17-OH progesterone

- **Management.** The treatment of choice is **spironolactone**, a potassium-sparing diuretic. Its mechanism of action as an antiandrogen is twofold. First, it is an androgen-receptor blocker. It also suppresses hair follicle 5-α reductase enzyme conversion of androstenedione and testosterone to the more potent dihydrotestosterone. **Eflornithine** (**Vaniqa**) is the first topical drug for the treatment of unwanted facial and chin hair. It blocks ornithine decarboxylase (ODC), which slows the growth and differentiation of the cells within the hair follicles.

POLYCYSTIC OVARIAN SYNDROME

A 32-year-old woman visits the gynecologist's office complaining of vaginal bleeding, facial hair growth, and obesity. She states that she has noted the facial hair growth for many years and the irregular bleeding has been progressively getting worse during the past 6 months. She has no other significant personal or family history, and on pelvic examination she has slightly enlarged bilateral ovaries. A rectovaginal examination is confirmatory.

Definition. Polycystic ovarian syndrome (PCOS), historically called Stein-Leventhal syndrome, is a condition of chronic anovulation with resultant infertility. The patient presents typically with irregular vaginal bleeding. Other symptoms include obesity and hirsutism.

Pathophysiology

- **Chronic anovulation.** Instead of showing the characteristic hormone fluctuation of the normal menstrual cycle, PCOS gonadotropins and sex steroids are in a steady state, resulting in anovulation and **infertility**. Without ovulation, there is no corpus luteum to produce progesterone. Without progesterone there is unopposed estrogen. Endometrium, which is chronically stimulated by estrogen, without progesterone ripening and cyclic shedding, becomes hyperplastic with **irregular bleeding**. With time **endometrial hyperplasia** can result, which could progress to endometrial cancer.
- **Increased testosterone.** Increased LH levels cause increased ovarian follicular theca cell production of androgens. The increased levels of androstenedione and testosterone suppress hepatic production of SHBG by 50%. The combined effect of increased total testosterone and decreased SHBG leads to mildly elevated levels of free testosterone. This results in **hirsutism**. PCOS is one of the **most common** causes of hirsutism in women.
- **Ovarian enlargement.** On ultrasound the ovaries demonstrate the presence of the necklacelike pattern of multiple peripheral cysts (20–100 cystic follicles in each ovary). The increased androgens prevent normal follicular development, inducing premature follicle atresia. These multiple follicles, in various stages of development and atresia, along with stromal hyperplasia and a thickened ovarian capsule, result in ovaries that are bilaterally enlarged.

Table II-12-3. "HA-IR-AN" Syndrome (Polycystic Ovarian Syndrome)

HA	**H**yper**A**ndrogenism
IR	**I**nsulin **R**esistance
AN	**A**canthosis **N**igricans

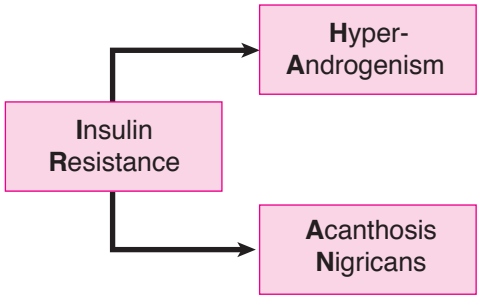

Figure II-12-8. Polycystic Ovarian Syndrome

Diagnosis. Diagnosis is based on the Rotterdam criteria, which requires 2 of the following 3 findings:

1. Oligomenorrhea or menstrual dysfunction
2. Hyperandrogenism, clinically or biochemically
3. Polycystic ovaries on TV sonogram (≥12 peripheral cysts)

Management. Treatment is directed toward the primary problem and the patient's desires.

- **Irregular bleeding.** OCPs will normalize her bleeding. The progestin component will prevent endometrial hyperplasia.
- **Hirsutism.** Excess male-pattern hair growth can be suppressed 2 ways. OCPs will lower testosterone production by suppressing LH stimulation of the ovarian follicle theca cells. OCPs will also increase SHBG, thus decreasing free testosterone levels. Spironolactone suppresses hair follicle 5-α reductase enzyme conversion of androstenedione and testosterone to the more potent dihydrotestosterone.
- **Infertility.** If she desires pregnancy, ovulation induction can be achieved through clomiphene citrate (Clomid) or human menopausal gonadotropin (HMG; Pergonal). Metformin, a hypoglycemic agent that increases insulin sensitivity, can enhance the likelihood of ovulation both with and without clomiphene.

INFERTILITY

A 30-year-old woman comes to the gynecologist's office complaining of infertility for 1 year. She and her husband have been trying to achieve pregnancy for >1 year and have been unsuccessful. There is no previous history of pelvic inflammatory disease and she used oral contraception medication for 6 years. The pelvic examination is normal, and a Pap smear is done.

Definition. Infertility is defined as inability to achieve pregnancy after 12 months of unprotected and frequent intercourse. Both male and female factors have to be evaluated in the patient with infertility. Fifteen percent of American couples suffer infertility.

Fecundability. This is the likelihood of conception occurring with one cycle of appropriately timed midcycle intercourse. With the female partner age of 20 years, the fecundity rate is 20%. By age 35 years, the rate drops to 10%.

Initial Noninvasive Tests

Semen analysis

- **Normal values.** Expected findings are volume >2 ml; pH 7.2–7.8; sperm density >20 million/ml; sperm motility >50%; and sperm morphology >50% normal. If values are abnormal, repeat the semen analysis in 4–6 weeks because semen quality varies with time.
- **Timing.** The first step in the infertility evaluation is a semen analysis, which should be obtained after 2–3 days of abstinence and examined within 2 h.
- **Minimally abnormal.** If sperm density is mild to moderately lower than normal, intrauterine insemination may be used. Washed sperm are directly injected into the uterine cavity. Idiopathic oligozoospermia is the most common male infertility factor.
- **Severely abnormal.** If semen analysis shows severe abnormalities, intracytoplasmic sperm injection may be used in conjunction with in vitro fertilization and embryo transfer.
- **No viable sperm.** With azoospermia or failed ICSI, artificial insemination by donor (AID) may be used.

Anovulation

Of all causes of infertility, treatment of anovulation results in the greatest success.

- **History.** Typically history is irregular, unpredictable menstrual bleeding, most often associated with minimal or no uterine cramping.
- **Objective data.** A basal body temperature (BBT) chart will not show the typical midcycle temperature elevation. A serum progesterone level will be low. An endometrial biopsy shows proliferative histology.
- **Correctible causes.** Hypothyroidism or hyperprolactinemia
- **Ovulation induction.** The agent of choice is **clomiphene** citrate administered orally for 5 days beginning on day 5 of the menstrual cycle. The biochemical structure of clomiphene is very similar to estrogen, and clomiphene fits into the estrogen receptors at the level of the pituitary. The pituitary does not interpret clomiphene as estrogen and perceives a low estrogen state, thus producing high levels of gonadotropins. **HMG** is administered parenterally and is used to induce ovulation if clomiphene fails. Careful monitoring of ovarian size is important because ovarian hyperstimulation is the **most common** major side effect of ovulation induction. When a patient is given clomiphene, her own pituitary is being stimulated to secrete her own gonadotropins, whereas when a patient is administered HMG, the patient is being stimulated by exogenous gonadotropins.

Follow-Up Invasive Tests

Hysterosalpinogram and Laparoscopy

Tubal Disease. Assessment of fallopian tube abnormalities is the next step if the semen analysis is normal and ovulation is confirmed.

- **Hysterosalpingogram (HSG).** In this imaging procedure, a catheter is placed inside the uterine cavity, and contrast material is injected. The contrast material should be seen on x-ray images spilling bilaterally into the peritoneal cavity. It should be scheduled during

the week after the end of menses after prophylactic antibiotics to prevent causing a recurrent acute salpingitis. No further testing is performed if the HSG shows normal anatomy. If abnormal findings are seen, the extent and site of the pathology is noted and laparoscopy considered.

- **Chlamydia antibody.** A negative IgG Antibody test for chlamydia virtually rules out infection induced tubal adhesions.
- **Laparoscopy.** If potentially correctible tubal disease is suggested by the HSG, the next step in management is to visualize the oviducts and attempt reconstruction if possible (tuboplasty). If tubal damage is so severe surgical therapy is futile, then IVF should be planned.

Unexplained Infertility

Definition. This diagnosis is reserved for couples in which the semen analysis is normal, ovulation is confirmed, and patent oviducts are noted.

Outcome. Approximately 60% of patients with unexplained infertility will achieve a spontaneous pregnancy within the next 3 years.

Management. Treatment consists of controlled ovarian hyperstimulation (*COH*) with clomiphene, and appropriately timed preovulatory intrauterine insemination (*IUI*). The fecundity rates for 6 months are comparable with IVF with a significantly lower cost and risk.

In Vitro Fertilization. With IVF, eggs are aspirated from the ovarian follicles using a transvaginal approach with the aid of an ultrasound. They are fertilized with sperm in the laboratory, resulting in the formation of embryos. Multiple embryos are transferred into the uterine cavity with a cumulative pregnancy rate of 55% after 4 IVF cycles.

Ovarian Reserve Testing (ORT)

This assessment is mostly reserved for the infertile woman aged 35 or over.

Definition. ORT refers to assessment of the capacity of the ovary to provide eggs that are capable of fertilization.

- It is a function of (1) number of follicles available for recruitment, and (2) the health and quality of the eggs in the ovaries.
- The most significant factor affection ORT is a woman's chronological age with a major decrease around age 35.

Measures of ovarian reserve. These tests help predict whether a woman will respond to ovarian stimulation or whether it would be best to proceed directly to in-vitro fertilization (IVF).

- **Day 3 FSH** is the most commonly used test for ORT. FSH levels are expected to be low due to the feedback of estrogen from the stimulated follicles. An increase in FSH level occurs if there is follicle depletion.
- **Anti-Mullerian hormone (AMH).** This glycoprotein is produced exclusively by small antral ovarian follicles and is therefore a direct measure of the follicular pool. As the number of ovarian follicles declines with age, AMH concentrations will decline.
- **Antral follicle count (AFC)** is the total number of follicles measuring 2-10 mm in diameter that are observed during an early follicular phase transvaginal sonogram. The number of AF correlates with the size of the remaining follicle pool retrieved by ovarian stimulation. AFC typically declines with age.

MENOPAUSE

A 53-year-old woman visits the gynecologist's office complaining of hot flashes, vaginal dryness, and irritability. She states that her symptoms started 1 year ago and have progressively been getting worse. Her last gynecologic examination was 2 years ago, at which time her mammogram was normal.

Definition. Menopause is a retrospective diagnosis and is defined as 12 months of amenorrhea. This is associated with the elevation of gonadotropins (FSH and LH). The mean age of 51 years is genetically determined and unaffected by pregnancies or use of steroid contraception. Smokers experience menopause up to 2 years earlier.

- **Premature menopause** occurs age 30–40 and is mostly idiopathic, but can also occur after radiation therapy or surgical oophorectomy.
- **Premature ovarian failure** occurs age <30 and may be associated with autoimmune disease or Y chromosome mosaicism.

Diagnosis. The laboratory diagnosis of menopause is made through serial identification of elevated gonadotropins.

Etiology. The etiology of menopausal symptoms is lack of estrogen.

Clinical Findings. The lack of estrogen is responsible for the majority of menopausal symptoms and signs.

- **Amenorrhea.** The **most common** symptom is secondary amenorrhea. Menses typically become anovulatory and decrease during a period of 3–5 years known as perimenopause.
- **Hot flashes.** Unpredictable profuse sweating and sensation of heat is experienced by 75% of menopausal women. This is probably mediated through the hypothalamic thermoregulatory center. Obese women are less likely to undergo hot flashes owing to peripheral conversion of androgens to estrone in their peripheral adipose tissues.
- **Reproductive tract.** Low estrogen leads to decreased vaginal lubrication, increased vaginal pH, and increased vaginal infections.
- **Urinary tract.** Low estrogen leads to increased urgency, frequency, nocturia, and urge incontinence.
- **Psychic.** Low estrogen leads to mood alteration, emotional lability, sleep disorders, and depression.
- **Cardiovascular disease.** This is the **most common** cause of mortality (50%) in postmenopausal women, with prevalence rising rapidly after menopause.
- **Osteoporosis.** This a disorder of decreased bone density leading to pathologic fractures when density falls below the fracture threshold.

GYN Triad

Premature Ovarian Failure r/o Y Chromosome Mosaic

- Hot flashes, sweats
- Age 25 years
- ↑ FSH level

Osteoporosis

Anatomy. The most common bone type of osteoporosis is trabecular bone. The **most common** anatomic site is in the vertebral bodies, leading to crush fractures, kyphosis, and decreased height. Hip and wrist fractures are the next most frequent sites.

Diagnosis. The **most common** method of assessing bone density is with a **DEXA** scan (dual-energy x-ray absorptiometry). The **most common** method of assessing calcium loss is 24-h urine hydroxyproline or NTX (N-telopeptide, a bone breakdown product).

Risk factors. The **most common** risk factor is positive family history in a thin, white female. Other risk factors are steroid use, low calcium intake, sedentary lifestyle, smoking, and alcohol.

Prevention. Maximum bone density is found in the mid-20s. Maintenance of bone density is assisted by both lifestyle and medications.

Table II-12-4. Osteoporosis

Lifestyle	Ca^{2+} and vitamin D intake
	Weight-bearing exercise
	Stop cigarettes and alcohol
Medical	Historic gold standard for comparing therapies: estrogen replacement
	Inhibit osteoclastics: bisphosphonates (alendronate, risedronate)
	Increase bone density: SERMs (raloxifene)

Definition of abbreviations: SERMS, selective estrogen receptor modulators.

- **Lifestyle.** Calcium and vitamin D intake, weight-bearing exercise, and elimination of cigarettes and alcohol.
- **Medications.** Bisphosphates (e.g., alendronate, risedronate) inhibit osteoclastic activity. Selective estrogen receptor modulators (SERMs; e.g., raloxifene) increase bone density. Bisphosphonates and SERMs are the first choices for osteoporosis treatment. Calcitonin and fluoride have also been used. While estrogen is a highly effective therapy, it should not be primarily used to treat osteoporosis because of concerns detailed in the next paragraph.

Hormone Replacement Therapy

Benefits and risks

- Estrogen therapy continues to be the most effective and FDA-approved method for relief of menopausal vasomotor symptoms (hot flashes), as well as genitourinary atrophy and dyspareunia.
- The Women's Health Initiative (WHI) study of the National Institutes of Health (NIH) studied 27,000 postmenopausal women with a mean age of 63 years. These included women with a uterus on hormone therapy (HT), both estrogen and progestin, and hysterectomized women on estrogen therapy (ET) only.

Table II-12-5. Critique of Women's Health Initiative Study

Excludes patients with vasomotor symptoms Primary indication for hormone replacement
Mean patient age was 63 years Missed the 10-year "window of opportunity"
Same dose of hormone for all ages Older women don't need as a high dose as do younger women
Patients were not all healthy Hypertension (40%), ↑ cholesterol (15%), diabetes mellitus (7%), myocardial infarction (3%)

- **Benefits:** Both HT and ET groups in WHI had decreased osteoporotic fractures and lower rates of colorectal cancer.
- **Risks:** Both HT and ET groups in WHI were found to have small increases in deep vein thrombosis (DVT). The HT group also had increased heart attacks and breast cancer, but these were not increased in the ET group.

Table II-12-6. WHI–Benefit and Risk (Mean Age of 63 Years)

	Estrogen and Progestin	Estrogen Only
Vaginal dryness	Benefit	Benefit
Hot flashes	Benefit	Benefit
Vasomotor symptoms	Benefit	Benefit
Osteoporosis	Benefit	Benefit
Breast cancer	Risk	No change
Heart disease	Risk	No change
Stroke	Risk	Risk

Contraindications. Personal history of an estrogen-sensitive cancer (breast or endometrium), active liver disease, active thrombosis, or unexplained vaginal bleeding

Modalities. Estrogen can be administered by oral, transdermal, vaginal, or parenteral routes. All routes will yield the benefits described. Women without a uterus can be given continuous estrogen. All women with a uterus should also be given progestin therapy to prevent endometrial hyperplasia. The **most common** current regimen is oral estrogen and progestin given continuously.

Recommendations. The **Global Consensus Statement on Menopausal Hormonal Therapy (MHT)** by the International Menopause Society (2013) says the following:

Proven Benefits of MHT and Only Indications For Use

- **Vasomotor symptoms.** MHT is the most effective treatment for vasomotor symptoms associated with menopause at any age, but benefits are more likely to outweigh risks for symptomatic women age <60 or within 10 years after menopause.

GYN Triad

Limitations of WHI

- Women with prominent vasomotor symptoms, the most common reason for initiating HT, were excluded from the study.
- The mean age of 63 was 10 years past the age that most women begin HT, thus missing the "window of opportunity" immediately after menopause.
- The same hormone dose was used in both older and younger women.

- **Vaginal dryness.** Local low-dose estrogen therapy is preferred for women whose symptoms are limited to vaginal dryness or associated discomfort with intercourse.
- **Premature menopause.** In women with premature ovarian insufficiency, systemic MHT is recommended at least until the average age of the natural menopause.

Benefits of MHT but Not Indications For Use

- **Osteoporosis.** MHT is effective and appropriate for the prevention of osteoporosis-related fractures in at-risk women age <60 or within 10 years after menopause.
- **Coronary heart disease.** Findings depend on the kind of MHT used.
  - **Estrogen-alone** (ET) may decrease coronary heart disease and all-cause mortality in women age <60 and within 10 years of menopause.
  - **Estrogen plus progestogen** (HT) in this age group shows a similar trend for decreased mortality but no significant increase or decrease in coronary heart disease has been found.

Risks of MHT

- **The risk of venous thromboembolism (VTE) and ischemic stroke** increases with oral MHT but the absolute risk is rare age <60. Observational studies point to a lower risk with transdermaltherapy.
- **The risk of breast cancer** in women age >50 associated with MHT is a complex one. The increased risk of breast cancer is primarily associated with the addition of a progestogen to estrogen therapy (HT) and related to the duration of use. The risk of breast cancer attributable to HT is small and decreases after treatment is stopped. Current safety data do not support the use of MHT in breast cancer survivors.

Administration of Menopausal Hormone Therapy (MHT)

- **Uterus present or absent.** Estrogen as a single systemic agent (ET) is appropriate in women after hysterectomy but additional progestogen (HT) is required in the presence of a uterus.
- **Individualized management.** The option of MHT is an individual decision in terms of quality of life and health priorities as well as personal risk factors such as age, time since menopause and risk of venous thromboembolism, stroke, ischemic heart disease and breast cancer.
- **Dose and duration.** Dose and duration of MHT should be consistent with treatment goals and safety issues, and thus should be individualized.
- **Bioidentical hormones.** The use of custom-compounded bioidentical hormone therapy is not recommended.

Estrogen alternatives

SERMs. In patients with contraindications to estrogen-replacement therapy, SERMs can be used. These are medications with estrogen agonist effects in some tissues, and estrogen antagonist effects on others. Although protective against the heart as well as bone, these medications do not have much effect on hot flashes and sweats.

- **Tamoxifen** (Nolvadex) is an SERM with endometrial and bone agonist effects, but breast antagonist effects.
- **Raloxifene** (Evista) has bone agonist effects, but endometrial antagonist effects.

The Female Breast 13

Learning Objectives

- ❏ Describe normal breast development
- ❏ Differentiate between benign breast disorders and breast cancer, in terms of diagnosis and treatment

NORMAL BREAST DEVELOPMENT

Embryology

Breasts begin developing in the embryo about 7 to 8 weeks after conception, consisting only of a thickening or ridge of tissue.

- From weeks 12 to 16, tiny groupings of cells begin to branch out, laying the foundation for future **ducts** and milk-producing **glands**. Other tissues develop into muscle cells that will form the nipple (the protruding point of the breast) and areola (the darkened tissue surrounding the nipple).
- In the later stages of pregnancy, maternal hormones cause fetal breast cells to organize into branching, tube-like structures, thus forming the milk ducts. In the final 8 weeks, lobules (milk-producing glands) mature and actually begin to secrete a liquid substance called colostrum.
- In both female and male newborns, swellings underneath the nipples and areolae can easily be felt, and a clear liquid discharge (colostrum) can be seen.

Puberty

From infancy to just before puberty, there is no difference between female and male breasts.

- With the beginning of female puberty, however, the release of estrogen—at first alone, and then in combination with progesterone when the ovaries are functionally mature—causes the breasts to undergo dramatic changes that culminate in the fully mature form.
- This process, on average, takes 3 to 4 years and is usually complete by age 16.

Anatomy

Note

Refer to Chapter 1, for a discussion of Tanner Stages.

The breast is made of lobes of glandular tissue with associated ducts for transfer of milk to the exterior and supportive fibrous and fatty tissue. On average, there are 15 to 20 lobes in each breast, arranged roughly in a wheel-spoke pattern emanating from the nipple area. The distribution of the lobes, however, is not even.

- There is a preponderance of glandular tissue in the upper outer portion of the breast. This is responsible for the tenderness in this region that many women experience prior to their menstrual cycle.
- About 80–85% of normal breast tissue is fat during the reproductive years. The 15 to 20 lobes are further divided into lobules containing alveoli (small sac-like features) of secretory cells with smaller ducts that conduct milk to larger ducts and finally to a reservoir that lies just under the nipple. In the nonpregnant, nonlactating breast, the alveoli are small.
- During pregnancy, the alveoli enlarge. During lactation, the cells secrete milk substances (proteins and lipids). With the release of oxytocin, the muscular cells surrounding the alveoli contract to express the milk during lactation.
- Ligaments called **Cooper's ligaments**, which keep the breasts in their characteristic shape and position, support breast tissue. In the elderly or during pregnancy, these ligaments become loose or stretched, respectively, and the breasts sag.
- The lymphatic system drains excess fluid from the tissues of the breast into the axillary nodes. Lymph nodes along the pathway of drainage screen for foreign bodies such as bacteria or viruses.

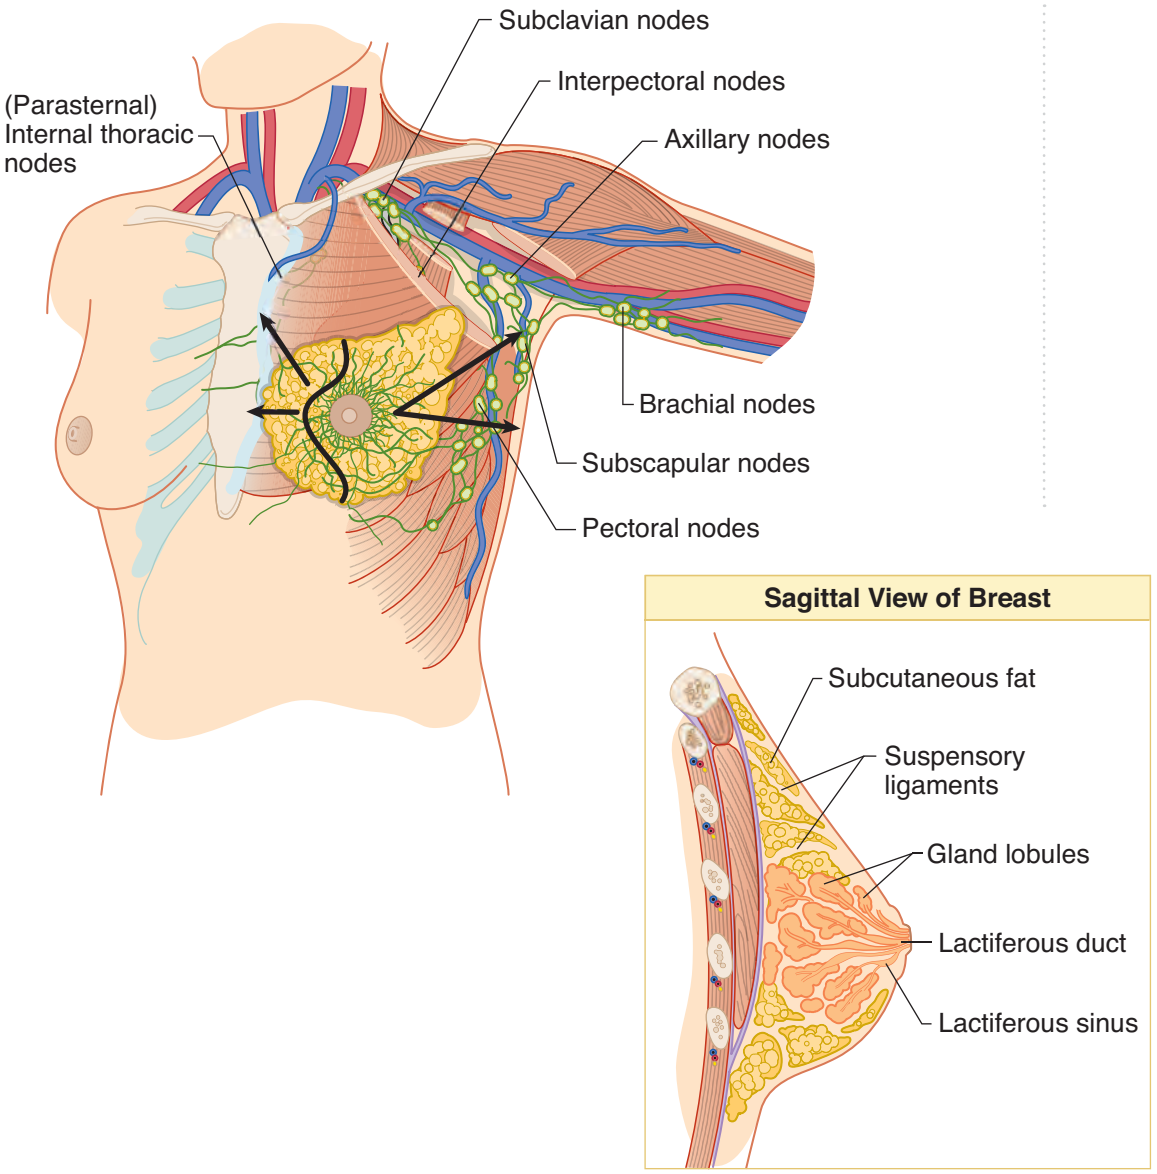

Figure II-13-1. Breast

Hormones

Reproductive hormones are important in the development of the breast in puberty and in lactation.

- **Estrogen**, released from the ovarian follicle, promotes the growth ducts.
- **Progesterone**, released from the corpus luteum, stimulates the development of milk-producing alveolar cells.
- **Prolactin**, released from the anterior pituitary gland, stimulates milk production.
- **Oxytocin**, released from the posterior pituitary in response to suckling, causes milk ejection from the lactating breast.

Lactation

- The breasts become fully developed under the influence of **estrogen**, **progesterone**, and **prolactin** during pregnancy. **Prolactin** causes the production of milk, and **oxytocin** release (via the suckling reflex) causes the contraction of smooth-muscle cells in the ducts to eject the milk from the nipple.
- The first secretion of the mammary gland after delivery is colostrum. It contains more protein and less fat than subsequent milk, and contains IgA antibodies that impart some **passive immunity** to the infant. Most of the time it takes 1 to 3 days after delivery for milk production to reach appreciable levels.
- The expulsion of the placenta at delivery initiates milk production and causes the drop in circulating estrogens and progesterone. **Estrogen** antagonizes the positive effect of prolactin on milk production.
- The physical stimulation of suckling causes the release of oxytocin and stimulates prolactin secretion, causing more milk production.

BENIGN BREAST DISORDERS

Note

Mammograms are discussed in detail in Gynecology, chapter 1.

Cystic Breast Mass

A 40-year-old menstruating woman had a 2-cm cystic breast mass confirmed by breast ultrasonography.

Diagnosis. Cyst aspiration and fine-needle aspiration are important components in the preliminary diagnosis of breast disorders. Fine-needle aspiration of a palpable macrocyst, the appropriate procedure for this patient, can be performed in an office setting. Interpretation of fine-needle aspiration requires the availability of a trained cytopathologist.

Management. Preaspiration mammography should be obtained. If the cyst disappears and the cytology is benign, no further workup is required.

Fibrocystic Breast Changes

A 30-year-old woman experiences bilateral breast enlargement and tenderness, which fluctuates with her menstrual cycle. On physical examination the breast feels lumpy, and the patient indicates a sensitive area with a discrete 1.5-cm nodule, which she says is consistently painful. A fine-needle aspiration is performed, and clear fluid is withdrawn. Clinically the cysts resolved.

Diagnosis. Cyclic premenstrual mastalgia is often associated with fibrocystic changes of the breast; a condition that is no longer considered a disease but a heterogeneous group of disorders. Breast discomfort may be accompanied by a palpable mass. Fine-needle aspiration can easily distinguish whether a mass is solid or cystic. The procedure requires no special skill other than stabilizing the mass so that needle aspiration can be done with precision. The goal of cyst aspiration is complete drainage of the cyst with collapse of the cyst wall.

Management

- **Mass disappears.** If the cyst fluid is clear, it may be discarded. If the cyst fluid is grossly bloody, it should be sent for cytologic examination to rule out the possibility of intracystic carcinoma. After aspiration, the affected area must be palpated to determine whether there is a residual mass. If there is no residual mass, the patient may be reexamined in 4–6 weeks for the reaccumulation of fluid. If fluid reaccumulates, it may be aspirated again.
- **Mass persists.** A mass that persists requires further workup. A persistent accumulation is managed by mammography and excision. Because changes such as hematoma related to aspiration may affect mammographic appearances, it is recommended that mammography not be performed until 2 weeks after aspiration. Definitive evaluation of a persistent mass requires excisional biopsy.
- **Conservative.** Ultrasonography is useful in distinguishing cysts from solid masses. If ultrasonography has been performed before aspiration and had shown a cyst with distinct smooth contours, an alternative management plan would be conservative follow-up with serial ultrasound scans. If the cyst disappears on aspiration and the fluid is clear, no further workup is required.

Breast Fibroadenoma

A 25-year-old woman visits the gynecologist for routine annual examination. During the examination she has a palpable, rubbery breast mass, which has been present and stable for the past 2 years. The pathology report of fine-needle aspiration was consistent with fibroadenoma.

Diagnosis. Fibroadenomas are the **most common** breast tumors found in adolescence and young women. In approximately 15% of patients they occur as multiple lesions. Clinically, fibroadenomas are discrete, smoothly contoured, rubbery, nontender, freely moveable masses. The most distinctive gross feature of fibroadenomas that allows them to be distinguished from other breast lumps is their mobility. Fibroadenomas arise from the epithelium and stroma of the terminal duct lobular unit, most frequently in the upper outer quadrant of the breast. An association of fibroadenomas with the development of breast cancer has not been well established. Any associated increases in breast cancer risk depends on the presence of proliferative changes in the fibroadenoma itself or in the surrounding breast, and on a family history of breast carcinoma.

Although cysts and fibroadenomas may be indistinguishable on palpation, ultrasound examination easily distinguishes cystic from solid lesions. On fine-needle aspiration, cysts typically collapse, whereas samples from a fibroadenoma present a characteristic combination of epithelial and stromal elements.

Management

- **Conservative.** Some clinicians advocate conservative management of fibroadenomas, especially in young women, because they can be diagnosed by ultrasonography and core-needle biopsy or fine-needle aspiration with a high degree of confidence, and in some cases they will resolve. A survey of patient preferences, however, has revealed that many women choose excisional biopsy even when they are assured that the lesion is benign by fine-needle aspiration.

- **Excision.** Typically, the lesion is "shelled out" with a surrounding thin rim of breast tissue to avoid the necessity of reexcision in the rare instances when the tumor proves to be a **phyllodes tumor**. This is a mixed epithelial and stromal tumor that has benign, borderline, and malignant variants. The biology of the phyllodes tumor is determined by its stromal elements; in its fully malignant form, it behaves as a sarcoma.

Mammography Microcalcifications

A 45-year-old woman visits her gynecologist after having her yearly mammogram done. The mammogram reveals a "cluster" of microcalcifications.

Diagnosis. A geographic cluster of microcalcifications is nonpalpable. Although most of these lesions are benign, approximately 15–20% represent early cancer. An occult lesion requires stereotactic needle localization and biopsy under mammographic guidance. The coordinates of the lesion are calculated by the computer according to the basic principles of stereotaxis. The radiologist selects the length of the biopsy needle, and a core biopsy is obtained. The procedure is performed in an outpatient setting.

Management. Treatment is based on the established histologic diagnosis.

Persistent Breast Mass

A 35-year-old woman has a persistent breast mass after a fine-needle aspiration has been performed. The breast mass is confirmed by ultrasonography.

Diagnosis. With the combination of physical examination, fine-needle aspiration or core biopsy, and mammography, open biopsies are being performed less frequently. Excisional biopsy has the advantage of a complete evaluation of the size and histologic characteristics of the tumor before definitive therapy is selected. An excisional biopsy is usually recommended in the following circumstances:

- Cellular bloody cyst fluid on aspiration
- Failure of a suspicious mass to disappear completely upon fluid aspiration
- Bloody nipple discharge, with or without a palpable mass
- Skin edema and erythema suggestive of inflammatory breast carcinoma, and a needle core biopsy cannot be performed

In the past, recurrent or persistent simple breast cysts were routinely excised. Because of improvement in ultrasonographic technology, these cysts may now be followed conservatively. This patient, who has had a fine-needle aspiration before, is a candidate for an excisional biopsy.

Management. Treatment is based on the established histologic diagnosis.

Bloody Nipple Discharge

A 60-year-old woman comes to the gynecologist's office complaining of a left breast bloody nipple discharge.

Diagnosis. A bloody nipple discharge usually results from an intraductal papilloma. The treatment is total excision of the duct and papilloma through a circumareolar incision. Modern ductography does not reliably exclude intraductal pathology and is not a substitute for surgery in patients with pathologic discharge. Its utility is in identifying multiple lesions or lesions in the periphery of the breast.

Management. Treatment is based on the established histologic diagnosis.

BREAST CANCER

Breast Cancer Prognosis

A 65-year-old woman visits the gynecologist with a solid 2-cm mass in the upper outer quadrant of the left breast. A biopsy of the lesion is done, which is consistent with "infiltrating ductal breast cancer."

Epidemiology. Breast cancer continues to be the **most common** cancer diagnosed in women of western industrialized countries. An estimated 182,000 new cases of invasive breast cancer were expected to occur among women in the United States during 2000. After increasing by approximately 4% per year in the l980s, breast cancer incidence rates in women have leveled off in the l990s to approximately 110 cases per 100,000 women.

Management. The preferred treatment for most patients with stage I or II breast cancer is considered to be breast-conserving therapy with a wide excision, axillary lymph node dissection or sentinel lymph node biopsy, and radiotherapy. Lymphatic mapping and sentinel lymph node biopsy are new procedures that offer the ability to avoid axillary lymph node dissection and its associated morbidity in patients with small primary tumors who are at low risk of axillary node involvement, while still offering nodal staging information.

Prognostic Factors. Some of the key decisions in the current management of primary breast cancer involve the need for prognostication. Prognostic factors serve to identity those patients who might benefit from adjuvant therapy.

- **Lymph node status.** This is important in determining cancer staging and treatment options. Axillary lymph node status is the most important factor in the prognosis of patients with breast cancer. As the number of positive axillary lymph nodes increases, survival rate decreases and relapse rate increases. An adequate dissection usually contains at least 10 lymph nodes; however, because these tumors in 25–30% of patients with negative nodes eventually recur, other biologic prognostic factors also are needed.
- **Tumor size.** This correlates with the number of histologically involved lymph nodes; however, it is also an independent prognostic factor, particularly in node-negative women. The use of size of the tumor, as the most significant prognostic factor, is problematic because 15% of patients with small tumors have positive nodal involvement.

- **Receptor status.** It is standard practice to determine both estrogen and progesterone receptor status at the time of diagnosis for definitive surgical therapy. Although hormone receptor status correlates with the prognosis, it does so to a lesser degree than nodal status. Hormone receptor determination is, however, of critical importance as a predictive factor. A predictive factor is any measurement associated with response or lack of response of a particular therapy.

  - Estrogen receptor status has clearly shown to be a predictive factor for hormone therapy, either in the adjuvant therapy or the metastatic disease setting. HER-2 (also known as HER-2.neu and c-erbB-2) is an epidermal growth factor receptor on the surface of a cell that transmits growth signals to the cell nucleus.
  - Approximately 25–30% of breast cancers overexpress HER-2, and overexpression of the receptor is associated with poor prognosis. This may be more of a reflection of the biologic correlates of HER-2 overexpression, e.g., rapid tumor cell proliferation, larger tumor size, and loss of hormone receptors, than an independent prognostic indicator.

- **DNA ploidy status.** DNA ploidy status of tumors is determined by flow cytometry. It measures the average DNA per cell. Tumors can be classified as diploid with normal DNA content or aneuploid. Disease-free survival rates are significantly worse in patients with aneuploid tumors than in those with diploid tumors; however, it is unclear whether ploidy has an independent prognostic value.

Infiltrating Ductal Carcinoma

This is the **most common** breast malignancy accounting for 80% of breast cancers. Most are unilateral and start as atypical ductal hyperplasia which may progress to ductal carcinoma in situ (DCIS) which then may break through the basement membrane and progress to invasive ductal carcinoma. Over time the tumor will become a stony hard mass as it increases in size and undergoes a fibrotic response.

Infiltrating Lobular Carcinoma

This is the **second most common** breast malignancy accounting for 10% of breast cancers. Most are unilateral and start as lobular carcinoma in situ (LCIS) which then may break through the basement membrane and progress to invasive lobular carcinoma. The prognosis is better with lobular than with ductal carcinoma.

Inflammatory Breast Cancer

This is an uncommon breast malignancy. Usually, there is no single lump or tumor. It is characterized by rapid growth with early metastasis. As the lymphatics get blocked, the breast becomes erythematous, swollen and warm to examination. The edematous skin of the breast appears pitted, like the skin of an orange, giving the classic **peau d'orange** appearance.

Paget Disease of the Breast/Nipple

This is an uncommon breast malignancy with a generally better prognosis than infiltrating ductal carcinoma. The lesion is pruritic and appears red and scaly often located in the nipple spreading to the areola. The skin appearance can mimic dermatosis like eczema or psoriasis. The nipple may become inverted and discharge may occur. It is almost always associated with DCIS or infiltrating ductal carcinoma.

Breast Cancer Risk Factors

BRCA 1 or 2 gene mutation	RR 15
Ductal or Lobular CIS	RR 15
Atypical hyperplasia	RR 4
Breast irradiation age < 20	RR 3
Positive family history	RR 3

Sentinel Node Biopsy

A sentinel node (SLN) is the first lymph node(s) to which cancer cells are likely to spread from the primary tumor. Cancer cells may appear in the sentinel node before spreading to other lymph nodes. A dye is injected near the tumor to allow flow to the SLN. A biopsy of the dye-stained node is performed to help determine the extent or stage of cancer. Because SLN biopsy involves the removal of fewer lymph nodes than standard lymph node removal procedures, the potential for side effects is lower.

Node-Positive Early Breast Cancer

> A healthy 55-year-old woman had a lumpectomy (negative margins) and axillary node dissection for a 2.5-cm tumor in the upper outer quadrant of the left breast, with three positive lymph nodes. The tumor was positive for both estrogen and progesterone receptors. She comes to the gynecologist's office wanting an opinion about further therapy.

Management. Breast-conserving therapy with a wide excision (lumpectomy), axillary dissection (or sentinel node biopsy), and radiation therapy is considered the preferred treatment for most patients with stage I or II breast cancer.

In patients at moderate or high risk of developing systemic metastasis, it is preferable to give adjuvant therapy, beginning with chemotherapy followed with radiation therapy. This patient has a high risk of recurrence because of the presence of lymph node metastasis, and it would be inappropriate to withhold further therapy.

Another high risk factor that this patient has is that the tumor is larger than 1 cm. Recommended adjuvant treatment for patients with node-positive breast cancer is explained in the table below.

A large number of prospective randomized trials, as well as recent overviews and meta-analysis of adjuvant systemic therapy, have determined that both chemotherapy and tamoxifen therapy reduce the odds of recurrence in breast cancer patients. A few randomized clinical trials and the overview of meta-analysis of randomized clinical trials have suggested that the combination of chemotherapy and tamoxifen is superior to chemotherapy alone or tamoxifen alone in postmenopausal patients with node-positive breast cancer. Women with estrogen receptor-negative breast cancer appear to have no improvement in recurrence or survival from tamoxifen use.

It has been established that combination chemotherapy is superior to single-agent therapy, and that 4 to 6 cycles of combination therapy are as effective as >6 cycles of treatment.

Table II-13-1. Recommended Adjuvant Treatment for Node-Positive Breast Cancer

Patient Group	Treatment
Premenopausal, ER- or PR-positive	Chemotherapy + tamoxifen, Ovarian ablation (or GnRH analog) ± tamoxifen, Chemotherapy ± ovarian ablation (or GnRH analog) ± tamoxifen
Premenopausal, ER- and PR-negative	Chemotherapy
Postmenopausal, ER- or PR-positive	Tamoxifen + chemotherapy
Postmenopausal, ER- and PR-negative	Chemotherapy
Elderly	Tamoxifen, If no ER and PR expression: chemotherapy

Abbreviations: ER, estrogen receptor; PR, progesterone receptor; GnRH, gonadotropin-releasing hormone.

The Newborn 1

Learning Objectives

- ❑ Calculate an Apgar score
- ❑ Use knowledge of birth injuries to predict symptomology
- ❑ Demonstrate understanding of newborn screening, fetal growth/maturity, and neonatal infections

APGAR SCORE

A newborn infant at birth is noted to have acrocyanosis, heart rate 140/min, and grimaces to stimulation. She is active and has a lusty cry. What is her Apgar score?

Table 1-1. Apgar Scoring System

Evaluation	0 Points	1 Point	2 Points
Heart rate	0	<100/min	>100/min
Respiration	None	Irregular, shallow, gasps	Crying
Color	Blue	Pale, blue extremities	Pink
Tone	None	Weak, passive	Active
Reflex irritability	None	Facial grimace	Active withdrawal

Apgar scores are routinely assessed at 1 and 5 minutes, and every 5 minutes thereafter as long as resuscitation is continuing.

- The **1-minute score** gives an idea of what was going on during labor and delivery.
- The **5-minute score** gives an idea of response to therapy (resuscitation).

In general, the Apgar score is *not* predictive of outcome; however, infants with score 0–3 at ≥5 minutes compared to infants with score 7–10 have a worse neurologic outcome.

Newborn Care

- Vitamin K IM
- Prophylactic eye erythromycin
- Umbilical cord care
- Hearing test
- Newborn screening tests

BIRTH INJURIES

On physical exam, a 12-h-old newborn is noted to have nontender swelling of the head that does not cross the suture line. What is the most likely diagnosis?

Table 1-2. Common Injuries During Deliveries

Injury	Specifics	Outcome
Skull fractures	In utero from pressure against bones or forceps; **linear:** most common	• Linear: no symptoms and no treatment needed • **Depressed:** elevate to prevent cortical injury
Brachial palsy	**Erb-Duchenne:** C5–C6; cannot abduct shoulder; externally rotate and supinate forearm; **Klumpke:** C7–C8 ± T1; paralyzed hand ± Horner syndrome	Most with full recovery (months); depends on whether nerve was injured or lacerated; Rx: proper positioning and partial immobilization; massage and range of motion exercises; if no recovery in 3–6 mo, then neuroplasty
Clavicular fracture	Especially with shoulder dystocia in vertex position and arm extension in breech	Palpable callus within a week; Rx: with immobilization of arm and shoulder
Facial nerve palsy	Entire side of face with forehead; forceps delivery or in utero pressure over facial nerve	Improvement over weeks (as long as fibers were not torn); need eye care; neuroplasty if no improvement (torn fibers)
Caput succedaneum	Diffuse edematous swelling of soft tissues of scalp; **crosses suture lines**	Disappears in first few days; may lead to molding for weeks
Cephalohematoma	Subperiosteal hemorrhage: **does not cross suture lines**	May have underlying linear fracture; resolve in 2 wk to 3 mo; may calcify; jaundice

PHYSICAL EXAMINATION—NORMAL AND ABNORMAL FINDINGS

A newborn infant has a blue-gray pigmented lesion on the sacral area. It is clearly demarcated and does not fade into the surrounding skin. What is the most likely diagnosis?

A newborn has a flat, salmon-colored lesion on the glabella, which becomes darker red when he cries. What is the best course of management?

Table 1-3. Physical Examination—Common Findings (*see* remaining chapter for other specific findings)

Finding/Diagnosis	Description/Comments
SKIN	
Cutis marmorata	Lacy, reticulated vascular pattern over most of body when baby is cooled; improves over first month; abnormal if persists
Salmon patch (nevus simplex)	Pale, pink vascular macules; found in nuchal area, glabella, eyelids; usually disappears
Mongolian spots	Blue to slate-gray macules; seen on presacral, back, posterior thighs; > in nonwhite infants; arrested melanocytes; usually fade over first few years; *differential*: child abuse
Erythema toxicum, neonatorum	Firm, yellow-white papules/pustules with erythematous base; peaks on second day of life; contain eosinophils; benign
Hemangioma	**Superficial**: bright red, protuberant, sharply demarcated; most often appear in first 2 months; most on face, scalp, back, anterior chest; rapid expansion, then stationary, then involution (most by 5–9 years of age); **deeper**: bluish hue, firm, cystic, less likely to regress; Rx: (steroids, pulsed laser) only if large and interfering with function
HEAD	
Preauricular tags/pits	Look for hearing loss and genitourinary anomalies.
Coloboma of iris	Cleft at "six o'clock" position; most with other eye abnormalities; CHARGE association
Aniridia	Hypoplasia of iris; defect may go through to retina; association with Wilms tumor
EXTREMITIES	
Polydactyly	>5 number of fingers or toes. No treatment needed if good blood supply.

NEWBORN SCREENING

A 1-month-old fair-haired, fair-skinned baby presents with projectile vomiting of 4 days' duration. Physical exam reveals a baby with eczema and a musty odor. Which screening test would most likely be abnormal?

Every newborn is screened before discharge or day 4 of life. It is more reliable if done after 48 hours of oral feedings (substrates for metabolic diseases).

The total diseases screened are determined by the individual state. Some examples:

- Phenylketonuria
- Tyrosinemia
- 21-hydroxylase deficiency
- Galactosemia
- Hb SS
- Hb C
- Hypothyroidism
- Cystic fibrosis

Table 1-4. Comparison of Two Newborn Screening Diseases*

	Phenylketonuria (PKU)	Classic Galactosemia
Defect	Phenylalanine hydroxylase; accumulation of PHE in body fluids and CNS	Gal-1-P uridylyltransferase deficiency; accumulation of gal-1-P with injury to **kidney, liver, and brain**
Presentation	**Mental retardation,** vomiting, growth retardation, purposeless movements, athetosis, seizures	**Jaundice (often direct),** hepatomegaly, vomiting, **hypoglycemia**, **cataracts**, seizures, poor feeding, poor weight gain, **mental retardation**
Associations	**Fair hair, fair skin, blue eyes**, tooth abnormalities, microcephaly	**Predisposition to *E. coli* sepsis**; developmental delay, speech disorders, learning disabilities
Other comments	**Normal at birth**; gradual MR over first few months	**May begin prenatally—transplacental galactose from mother**
Treatment	Low PHE diet for life	No lactose—reverses growth failure, kidney and liver abnormalities and cataracts, **but not neurodevelopmental problems**

Definition of abbreviations: CNS, central nervous system; G-1-P, galactose-1-phosphate; MR, mental retardation; PHE, phenylalanine.
*Items in **bold** have a greater likelihood of appearing on the exam.

FETAL GROWTH AND MATURITY

Table 1-5. Intrauterine Growth Restriction (IUGR)

Type	Reason	Main Etiologies	Complications
Symmetric	Early, in utero insult that affects growth of most organs	Genetic syndromes, chromosomal abnormalities, congenital infections, teratogens, toxins	Etiology dependent; delivery of oxygen and nutrients to vital organs usually normal
Asymmetric (head sparing)	Relatively late onset after fetal organ development; abnormal delivery of nutritional substances and oxygen to the fetus	Uteroplacental insufficiency secondary to maternal diseases (malnutrition, cardiac, renal, anemia) and/or placental dysfunction (hypertension, autoimmune disease, abruption)	Neurologic (asphyxia) if significant decreased delivery of oxygen to brain

Gestational Age and Size at Birth

Preterm	Large for Gestational Age (LGA)—Fetal Macrosomia	Post-term
• Premature—liveborn infants delivered prior to 37 weeks as measured from the first day of the last menstrual period • Low birth weight—birthweight <2,500 grams. This may be due to prematurity, IUGR, or both	• Birth weight >4,500 grams at term • Predisposing factors: obesity, diabetes • Higher incidence of birth injuries and congenital anomalies	• Infants born after 42 weeks' gestation from last menstrual period • **When delivery is delayed ≥3 weeks past term, significant increase in mortality.** • Characteristics – Increased birth weight – Absence of lanugo – Decreased/absent vernix – Desquamating, pale, loose skin – Abundant hair, long nails – If placental insufficiency, may be meconium staining

SPECIFIC DISORDERS

Endocrine Disorders

Infants of diabetic mothers

You are called to see a 9.5-pound newborn infant who is jittery. Physical exam reveals a large plethoric infant who is tremulous. A murmur is heard. Blood sugar is low.

- Maternal hyperglycemia (types I and II DM) → fetal hyperinsulinemia
- Insulin is the major fetal growth hormone → increase in size of all organs except the brain
- Major metabolic effect is at birth with sudden placental separation → **hypoglycemia**
- Infants may be **large for gestational age and plethoric** (ruddy).
- Other **metabolic findings: hypoglycemia and hypomagnesemia** (felt to be a result of delayed action of parathyroid hormone)
- **Common findings**
  - **Birth trauma** (macrosomia)
  - **Tachypnea** (transient tachypnea, respiratory distress syndrome, cardiac failure, hypoglycemia)
  - **Cardiomegaly—asymmetric septal hypertrophy** (insulin effect, reversible)
  - **Polycythemia (and hyperviscosity)** → hyperbilirubinemia → jaundice
  - **Renal vein thrombosis** (flank mass, hematuria, and thrombocytopenia) from polycythemia
  - **Increased incidence of congenital anomalies**
    - **Cardiac**—especially VSD, ASD, transposition
    - **Small left colon syndrome** (transient delay in development of left side of colon; presents with abdominal distention)
    - **Caudal regression syndrome:** spectrum of structural neurologic defects of the caudal region of spinal cord which may result in neurologic impairment (hypo, aplasia of pelvis & LE)
- Prognosis—Infants of diabetic mothers are more predisposed to diabetes and LGA infants are at increased risk of childhood obesity.
- Treatment
  - Monitor carefully and advocate good glucose control during pregnancy. Follow glucose carefully in infant after delivery.
  - Early, frequent feeds: oral, NG if episodes of hypoglycemia continue
  - Intravenous dextrose infusion if above does not result in euglycemia

Respiratory Disorders

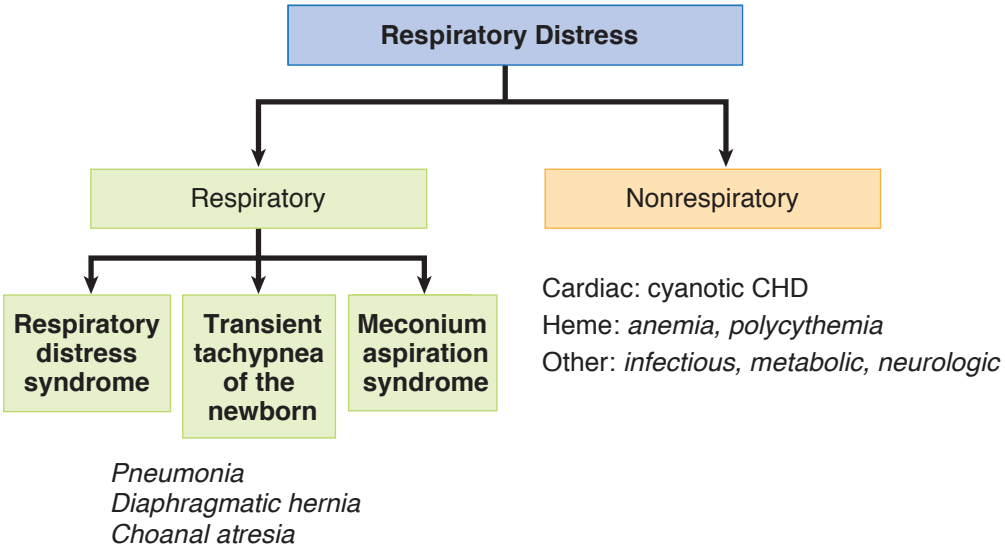

Figure 1-1. Respiratory Distress

Respiratory distress syndrome (RDS)

Shortly after birth, a 33-week gestation infant develops tachypnea, nasal flaring, and grunting and requires intubation. Chest radiograph shows a hazy, ground-glass appearance of the lungs.

- Deficiency of **mature surfactant** (surfactant matures biochemically over gestation; therefore, the incidence of surfactant deficiency diminishes toward term.)
- Inability to maintain alveolar volume at end expiration → decreased FRC (functional residual capacity) and atelectasis
- Primary initial pulmonary hallmark is **hypoxemia.** Then, **hypercarbia and respiratory acidosis ensue.**
- Diagnosis
  - **Best initial diagnostic test—chest radiograph**
    - Findings: **ground-glass appearance, atelectasis, air bronchograms**
  - **Most accurate diagnostic test—L/S ratio** (part of complete lung profile; lecithin-to-sphingomyelin ratio)
    - Done on amniotic fluid prior to birth
  - **Best initial treatment—oxygen**
  - **Most effective treatment—intubation and exogenous surfactant administration**
  - **Primary prevention**
    - Avoid prematurity (tocolytics)
    - **Antenatal betamethasone**

Transient tachypnea of the newborn (TTN)

- Slow absorption of fetal lung fluid → decreased pulmonary compliance and tidal volume with increased dead space
- Tachypnea after birth
- Generally minimal oxygen requirement
- **Common in term infant delivered by Cesarean section or rapid second stage of labor**
- **Chest x-ray (best test)**—air-trapping, fluid in fissures, perihilar streaking
- Rapid improvement generally within hours to a few days

Meconium aspiration

- Meconium passed as a result of hypoxia and fetal distress; may be aspirated in utero or with the first postnatal breath → airway obstruction and pneumonitis → failure and pulmonary hypertension
- **Chest x-ray (best test)—patchy infiltrates, increased AP diameter, flattening of diaphragm**
- Other complications—air leak (pneumothorax, pneumomediastinum)
- **Prevention—endotracheal intubation and airway suction of depressed infants with thick meconium**
- Treatment—positive pressure ventilation and other complex NICU therapies

Diaphragmatic hernia

- Failure of the diaphragm to close → abdominal contents enter into chest, causing **pulmonary hypoplasia.**
- Born with respiratory distress and **scaphoid abdomen**
- **Bowel sounds may be heard in chest**
- Diagnosis—prenatal ultrasound; **postnatal x-ray (best test) reveals bowel in chest**
- Best initial treatment—immediate intubation in delivery room for known or suspected CDH, followed by surgical correction when stable (usually days)

Gastrointestinal and Hepatobiliary Disorders

See also GI chapter on this topic.

Umbilical hernia

- Failure of the umbilical ring closure, weakness of abdominal muscles
- Most are small and resolve in 1-2 years without any treatment
- Surgery if getting larger after 1-2 years, symptoms (strangulation, incarceration), and/or persistent after age 4

Omphalocele

- Failure of intestines to return to abdominal cavity with gut through umbilicus
- Covered in a sac (protection)
- Associated with other major malformations and possible genetic disorders (trisomy)
- Large defects need a staged reduction (use of a surgical Silo), otherwise respiratory failure and ischemia

Gastroschisis

- Defect in abdominal wall lateral to umbilicus (vascular accident)
- Any part of the GI tract may protrude
- Not covered by a sac
- Major problem with the intestines: atresia, stenosis, ischemia, short gut
- Surgery based on condition of gut; if no ischemia, large lesions need a staged reduction as with omphalocele

Necrotizing enterocolitis (NEC)

- Transmural intestinal necrosis
- Greatest risk factor is prematurity; rare in term infants
- Symptoms usually related to **introduction of feeds**: bloody stools, apnea, lethargy, and abdominal distention once perforation has occurred
- **Pneumatosis intestinalis** on plain abdominal film is pathognomonic (air in bowel wall)
- Treatment: cessation of feeds, gut decompression, systemic antibiotics, and supportive care; surgical resection of necrotic bowel may be necessary

Imperforate Anus

- Failure to pass stool after birth
- No anal opening visible
- Treatment is surgical correction.
- May be part of VACTERL association.

Jaundice

A 2-day-old infant is noticed to be jaundiced. He is nursing and stooling well. Indirect bilirubin is 11.2 mg/dL; direct is 0.4 mg/dL. Physical exam is unremarkable except for visible jaundice.

- Pathophysiology
  - Increased production of bilirubin from breakdown of fetal red blood cells plus immaturity of hepatic conjugation of bilirubin and elimination in first week of life

– Rapidly increasing unconjugated (indirect reacting) bilirubin can cross the blood-brain barrier and lead to **kernicterus (unconjugated bilirubin in the basal ganglia and brain stem nuclei)** hypotonia, seizures, opisthotonos, delayed motor skills, choreoathetosis, and **sensorineural hearing loss** are features of kernicterus.

Note

Work up for pathologic hyperbilirubinemia when:

- It appears on the first day of life
- Bilirubin rises >5 mg/dL/day
- Bilirubin >13 mg/dL in term infant
- Direct bilirubin >2 mg/dL at any time

Table 1-6. Physiologic Jaundice Versus Pathologic Jaundice

Physiologic Jaundice	Pathologic Jaundice
Appears on second to third day of life (term)	May appear in first 24 hours of life
Disappears by fifth day of life (term)—7th	Variable
Peaks at second to third day of life	Variable
Peak bilirubin <13 mg/dL (term)	Unlimited
Rate of bilirubin rise <5 mg/dL/d	Usually >5 mg/dL/d

The **causes of hyperbilirubinemia** with respect to **bilirubin metabolism** are as follows:

- RBC metabolism
  - Increased number of RBCs
    - Normal newborn (normal Hct is 42–65)
      i. Physiologic jaundice
    - Polycythemia (Hct >65)
      i. **Increased RBC production:** Chronic hypoxia, IUGR, post-mature; IODM, Beckwith-Wiedemann syndrome (insulin effect); maternal Graves' disease (transplacental antibodies); trisomies (? mechanism)
      ii. **Extra RBCs entering the circulation:** delayed cord clamping, twin-twin transfusion, maternal-fetal transfusion
      iii. Treatment: partial exchange transfusion with normal saline (dilutional)
  - Increased hemolysis
    - **Immune-mediated** (labs: high unconjugated bilirubin, may be anemia, increased reticulocyte count, **positive direct Coombs test**)
      i. Rh negative mother/Rh positive baby: classic hemolytic disease of the newborn (erythroblastosis fetalis)
      ii. ABO incompatibility (almost all are type O mother and either type A or B baby): most common reason for hemolysis in the newborn
      iii. Minor blood group incompatibility (Kell is very antigenic; Kell negative mother), uncommon
    - **Non-immune mediated:** same as above but Coombs is negative; need to see blood smear
      i. Smear shows **characteristic-looking RBCs**: membrane defect (most are either spherocytosis or elliptocytosis)

ii. Smear shows **normal-looking RBCs**: enzyme defect (most are G6PD deficiency then pyruvate kinase deficiency)

iii. Extravascular: excessive bruising, cephalohematoma

- Bilirubin is then bound to albumin and carried in the blood; bilirubin may be uncoupled from albumin in the blood stream to yield free bilirubin, e.g. neonatal sepsis, certain drugs (ceftriaxone), hypoxia, acidosis.
- Bilirubin is transported to the hepatocytes: within the hepatocytes is the conversion of unconjugated (laboratory indirect-acting) fat-soluble bilirubin to conjugated (glucuronide) water-soluble bilirubin (laboratory direct-acting) by the action of **hepatic glucuronyl transferase (GT)**.
  - Decreased enzymatic activity of GT
    - Normal newborn first week of life
    - Primary liver disease of systemic disease affecting the liver (sepsis, TORCH, metabolic diseases)
    - No GT activity: Crigler-Najjar syndrome (type I)
- Transport through the intrahepatic biliary system to the porta hepatis for excretion into the duodenum; abnormalities of transport and excretion cause a conjugated (direct) hyperbilirubinemia (**>2 mg/dL direct-acting bilirubin in the blood in the newborn**).
  - **Biliary atresia** (progressive obliterative cholangiopathy): obstruction at birth due to fibrosis and atresia of the extrahepatic ducts (and so no gall bladder); then variable severity and speed of inflammation and fibrosis of the intrahepatic system which ultimately leads to cirrhosis
    - Most present in first 2 weeks of life with jaundice (conjugated hyperbilirubinemia), poor feeding, vomiting, lethargy, hepatosplenomegaly, **persistent acholic stools and dark urine**
    - **Best initial test:** U/S (triangular fibrotic cord at porta hepatis; no evidence of normal ductal anatomy; no gallbladder
    - **Most accurate test** (next step): percutaneous liver biopsy (is pathognomonic for this process)
    - **Best initial treatment** (palliative): hepatic portojejunostomy (Kasai procedure)
    - **Best long-term management:** liver transplant
  - Liver disease (primary or secondary to systemic disease): cholestasis (sepsis, perinatal infections, metabolic disease, neonatal hepatitis, severe hypothyroidism and others
- Intestinal transport and excretion: most bilirubin is eliminated in the stool with final products synthesized with help of colonic bacteria; some bilirubin is eliminated in the urine, some is reprocessed in the liver due to enterohepatic circulation (along with bile acids); **intestinal beta-glucuronidase** hydrolyzes glucuronide-bilirubin bonds to yield some unconjugated bilirubin, which is absorbed into the portal circulation and transported back to the liver to be acted upon by hepatic glucuronyl transferase
  - **Increased enterohepatic circulation**
    - Intestinal obstruction
    - Decreased colonic bacteria (first week of life, prolonged antibiotics, severe diarrhea)

Breast feeding jaundice vs. breast milk jaundice (see text box)

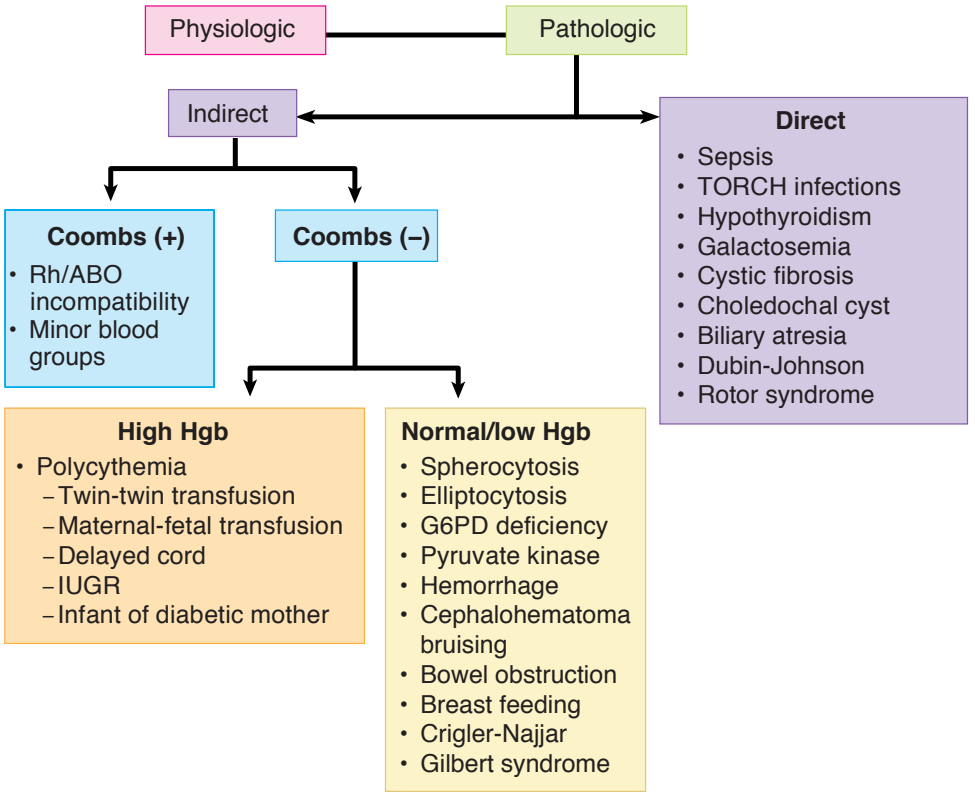

Figure 1-2. Jaundice Workup

Breast-Feeding Jaundice versus Breast-Milk Jaundice

Breast-feeding jaundice means a baby is not nursing well and so not getting many calories. This is common in first-time breast-feeding mothers. The infant may become dehydrated; however, it is lack of calories that causes the jaundice. Treatment is to obtain a lactation consultation and rehydrate the baby. The jaundice occurs in the first days of life.

Breast-milk jaundice occurs due to a glucoronidase present in some breast milk. Infants become jaundiced in week 2 of life. Treatment is phototherapy if needed. Although the bilirubin may rise again, it will not rise to the previous level. The baby may then be safely breast fed. The jaundice will be gone by 2–3 months.

- Treatment of hyperbilirubinemia
  - Phototherapy
    - Complications: loose stools, erythematous macular rash, overheating leading to dehydration, and **bronze baby syndrome (occurs with direct hyperbilirubinemia; dark, grayish-brown discoloration of the skin** [photo-induced change in porphyrins, which are present in cholestatic jaundice])
  - Double volume exchange transfusion—if bilirubin continues to rise despite intensive phototherapy and/or kernicterus is a concern

Table 1-7. Hyperbilirubinemia and Jaundice

Etiology	Reason for increased bilirubin	Hyperbilirubinemia	Hgb, Hct/ Reticulocytes	Other labs	Treatment
Excessive bruising/ cephalohematoma	RBCs → Hgb → Bilirubin	**In**direct	• Normal to slightly low Hgb/Hct • Normal to slight increase in reticulocytes		Phototherapy
Immune hemolysis • Rh • **ABO** • **Minor blood groups**	Anti-Rh, anti-A, anti-B, anti-minor blood group Abs	**In**direct	• Low Hgb/Hct (anemia) • Increased reticulocytes	• Rh negative mother and Rh positive baby • Type O mother and type A or B baby • Direct Coombs positive • Decreased RBCs	Phototherapy + possible exchange transfusion
Polycythemia	High Hct, Hgb → high bilirubin	**In**direct	High (Hct >65)/ normal	Increased RBCs	Phototherapy + partial exchange transfusion
Non-immune hemolysis	Abnormal RBC → splenic removal	**In**direct	Low (anemia)/ increased	• If no membrane defect →, G6PD, PK activity • Characteristic RBCs if membrane defect • Decreased RBCs	Phototherapy + transfusion
Displacement of bound bilirubin from albumin	Free bilirubin in circulation	**In**direct	Normal		Treat underlying problem
Familial nonhemolytic hyperbilirubinemia (Crigler-Najjar syndrome)	Absence of glucuronyl transferase (type I) vs. small amount of inducible GT (type II)	Indirect	Normal	GT activity	Phototherapy + exchange transfusion
Extrahepatic obstruction—biliary atresia	Bilirubin cannot leave the biliary system	Direct	Normal	Ultrasound, liver biopsy	Portojejunostomy, then later liver transplant
Cholestasis (TORCH, sepsis, metabolic, endocrine)	Abnormal hepatic function → decrease bilirubin excretion	Direct	Normal	With H and P, other select labs suggestive of underlying etiology	Treat underlying problem
Bowel obstruction	Increased enterohepatic recirculation	**In**direct	Normal		Relieve obstruction + phototherapy
Breast feeding jaundice	Increased enterohepatic recirculation	**In**direct	Normal		Phototherapy + hydration + teach breast feeding
Breast milk jaundice	Increased enterohepatic,, recirculation	**In**direct	Normal		Phototherapy + continued breast feeding

INFECTIONS

Neonatal Sepsis

A 3-week-old infant presents with irritability, poor feeding, temperature of 38.9°C (102°F), and grunting. Physical examination reveals a bulging fontanel, delayed capillary refill, and grunting.

- Signs and symptoms are very nonspecific.
- Risk factors
  - Prematurity
  - Chorioamnionitis
  - Intrapartum fever
  - Prolonged rupture of membranes
- **Most common organisms: group B *Streptococcus*, *E. coli*, and *Listeria monocytogenes*.**
- **Diagnosis**—sepsis workup: CBC, differential and platelets, blood culture, urine analysis and culture, chest radiograph (Lumbar puncture not routinely performed unless there is a likelihood of meningitis, e.g., irritability, lethargy, hypothermia, etc.)
- **Treatment**
  - **If no evidence of meningitis: ampicillin and aminoglycoside until 48–72-hour cultures are negative**
  - **If meningitis or diagnosis is possible: ampicillin and third-generation cephalosporin (*not* ceftriaxone)**

Note

Toxoplasmosis
Other (syphilis, varicella, HIV, and parvovirus B19)
Rubella
Cytomegalovirus (CMV)
Herpes

Transplacental Intrauterine Infections (TORCH)

TORCH infections are typically acquired in first or second trimester. Most infants have IUGR.

Toxoplasmosis

Toxoplasmosis is a maternal infection worldwide, due primarily to ingestion of undercooked or raw meat containing tissue cysts. Ingestion of water or food with oocytes that have been excreted by infected cats (fecal contamination) is the most common form of transmission in the United States. Advise pregnant women not to change/clean cat litter while pregnant.

- Findings
  - Jaundice, hepatosplenomegaly
  - Thrombocytopenia, anemia
  - Microcephaly
  - **Chorioretinitis**
  - **Hydrocephalus**
  - **Intracranial calcifications**
  - Seizures

- Outcomes
  - Psychomotor retardation
  - Seizure disorder
  - **Visual impairments**
- **Treatment—maternal treatment during pregnancy reduces the likelihood of transmission significantly (spiramycin)**
  - Infants are treated with pyrimethamine, sulfadiazide, and leucovorin.

phil.cdc.gov

Figure 1-3. Congenital Cataract Secondary to Maternal Rubella Infection

Congenital rubella

- Classic findings when maternal infection occurs in first 8 weeks' gestation.
- Findings
  - **Blueberry muffin spots** (extramedullary hematopoiesis), thrombocytopenia
  - Cardiac—**PDA, peripheral pulmonary artery stenosis**
  - Eye—**cataracts**
  - **Congenital hearing loss**
  - Thrombocytopenia
  - Hepatosplenomegaly
- Outcomes
  - Hearing loss
  - Persistent growth retardation
  - Microcephaly
  - Mental and motor retardation

Cytomegalovirus (CMV)

- Primary infection (higher risk of severe disease) or reactivation of CMV
- Findings
  - Hepatosplenomegaly, jaundice
  - **Periventricular calcifications**
  - **Intrauterine growth retardation**

  - Chorioretinitis
  - **Microcephaly**
  - Thrombocytopenia, hemolytic anemia
- Outcomes
  - **Sensorineural hearing loss**
  - Neuromuscular abnormalities
  - **Mental retardation**

Herpes simplex

- Keratojunctivitis, skin (5–14 days), CNS (3–4 weeks), disseminated (5–7 days)
- Best diagnosis: PCR, any body fluid
- Best treatment: IV acyclovir ASAP
- Outcomes
  - Microcephaly, spasticity
  - Deafness
  - Blindness
  - Seizure disorder
  - Psychomotor retardation
  - Death
- **Prevention is elective Cesarean section when active disease or visible lesions are identified; however, this is not 100% effective.**
- **Treatment—acyclovir**

Congenital syphilis

- Transplacental transmission usually during second half of gestation
- **At-risk infants must undergo serologic testing at the time of delivery.**
- Findings
  - Early (birth–2 yrs): snuffles, maculopapular rash (including palms of soles, desquamates), jaundice, periostitis, osteochondritis, chorioretinitis, congenital nephrosis
  - Late (>2 years of age): Hutchinson teeth, Clutton joints, saber shins, saddle nose, osteochondritis, rhagades (thickening and fissures of corners of mouth)
- **Diagnosis—*Treponema* in scrapings (most accurate test) from any lesion or fluid, serologic tests**
  - Infant with positive VDRL plus pathognomonic signs; if not, perform serial determinations—increasing titer in infection
  - **Most helpful specific test is IgM-FTA-ABS** (immunoglobin fluorescent treponemal antibody absorption); but it is not always positive immediately.
- **Treatment—penicillin**

Varicella

- Neonatal
  - Seen when delivery occurs <1 week before/after maternal infection
  - Treat with VZIG (varicella zoster immune globulin), if mother develops varicella 5 days before to 2 days after delivery.

- Congenital
  - Associated with limb malformations and deformations, cutaneous scars, microcephaly, chorioretinitis, cataracts, and cortical atrophy
  - Associated with infection during 1st or 2nd trimester

Many of the findings of the **TORCH infections** are very similar, so note the most likely presentations:

- Toxoplasmosis: hydrocephalus with **generalized calcifications** and chorioretinitis
- Rubella: the classic findings of **cataracts, deafness, and heart defects**
- CMV: microcephaly with **periventricular calcifications**; petechiae with thrombocytopenia
- Herpes: skin vesicles, keratoconjunctivitis, acute meningoencephalitis
- Syphilis: osteochondritis and periostitis; skin rash involving palms and soles and is desquamating; **snuffles** (mucopurulent rhinitis)

SUBSTANCE ABUSE AND NEONATAL WITHDRAWAL

A 2-day-old infant is noticed to have coarse jitters and is very irritable with a high-pitched cry. A low-grade fever is reported, as well as diarrhea. Maternal history is positive for heroin use.

Table 1-8. Neonatal Features of Maternal Major Illicit Drug Use

Opiates	Cocaine
High incidence low birth weight, most with intrauterine growth restriction	No classic withdrawal symptoms
Increased rate of stillborns	Preterm labor, abruption, asphyxia
No increase in congenital abnormalities	Intrauterine growth restriction
Early withdrawal symptoms, within 48 hours	Impaired auditory processing, developmental delay, learning disabilities
Tremors and hyperirritability	High degree of polysubstance abuse
Diarrhea, apnea, poor feeding, high-pitched cry, weak suck, weight loss, tachypnea, hyperacusis, seizures, others	Central nervous system ischemic and hemorrhagic lesions
Increased risk of sudden infant death syndrome	Vasoconstriction → other malformations

- Diagnostic tests: a good history and the clinical presentation usually are sufficient to make the diagnosis. Meconium toxicology can detect opioid and cocaine exposure after the first trimester. Urine drug screening provides maternal drug use data for only a few days prior to delivery. Cord blood sample has become the best test for diagnosis.
- Treatment: narcotics, sedatives, and hypnotics, as well as swaddling and reducing noxious stimulation
- Complications: infants of addicted mothers are at higher risk for low birth weight, IUGR, congenital anomalies (alcohol, cocaine), and sudden infant death syndrome, as well as of mother's complications, such as sexually transmitted diseases, toxemia, breech, abruption, and intraventricular hemorrhage (cocaine).

Genetics/Dysmorphology 2

Learning Objectives

- ❑ Demonstrate understanding of chromosome abnormalities
- ❑ Solve problems concerning early overgrowth with associated defects, defects with facial features as the major defect, osteochondrodysplasias, and disorders of connective tissue
- ❑ Explain information related to unusual brain and/or neuromuscular findings with associated defects

ABNORMALITIES OF CHROMOSOMES

Trisomy 21 (Down Syndrome)

Down syndrome is the **most common** pattern of human malformation.

- Genetics
  - 94% full trisomy 21(nondisjunction); risk of recurrence 1–2% and then increases with **advancing maternal age**
  - 4–6% with translocation; most are new mutations but must obtain parental karyotypes for possible balanced translocation carrier
- Findings
  - **Upward slanting palpebral fissures; speckling of iris (Brushfield spots); inner epicanthal folds**
  - Small stature, mouth open with tongue protrusion**;** mild microcephaly, short neck, flat occiput, short metacarpals and phalanges; **single palmar crease**
  - **Hypotonia**
  - **Hearing loss (sensorineural, conductive, and mixed)**
  - Primary gonadal deficiency
  - **Cardiac anomaly—ECD > VSD > PDA, ASD; also MVP**
  - Gastrointestinal anomalies: **duodenal atresia, Hirschprung**
  - **Atlanto-axial instability**
  - **Hypothyroidism**
  - **Acute lymphocytic leukemia** (but acute myeloblastic leukemia if in first 3 years of life)
  - **Mental retardation, variable**

Cardiac Abbreviations

ASD: atrial septal defect

ECD: endocardial cushion defect

MVP: mitral valve prolapse

PDA: patent ductus arteriosus

TOF: tetralogy of Fallot

VSD: ventricular septal defect

- Natural history
  - Major cause for early mortality is congenital heart disease
  - Muscle tone improves with age
  - Rate of development slows with age
  - Early onset of Alzheimer disease

Trisomy 18 (Edwards Syndrome)

Edwards syndrome is the **second most common** pattern of human malformation.

- Genetics—older maternal age; nondisjunction
- Findings
  - Growth deficiency
  - **Mental retardation**
  - **Low-set, malformed ears; microcephaly, micrognathia; prominent occiput**
  - **Clenched hand—index over third; fifth over fourth**
  - **Short sternum**
  - **VSD, ASD, PDA, cyanotic lesions**,
  - **Rocker-bottom feet, hammer toe**
  - **Omphalocele**
- Natural history
  - Many spontaneous abortions
  - Feeble from birth
  - Most do not survive first year

Trisomy 13 (Patau Syndrome)

Patau syndrome is a defect of midface, eye, and forebrain development → single defect in first 3 weeks' development of prechordal mesoderm. It involves older maternal age.

- Findings
  - **Holoprosencephaly and other CNS defects**
  - **Severe mental retardation**
  - **Microcephaly; microphthalmia**
  - **Severe cleft lip, palate, or both**
  - **Scalp defects in parietal-occipital area** (cutis aplasia)
  - **Postaxial polydactyly**
  - VSD, PDA, ASD, cyanotic lesions
  - Single umbilical artery

Aniridia–Wilms Tumor Association (WAGR Syndrome)

- Genetics
  - 1/70 with aniridia also has Wilms
  - WAGR syndrome: deletion of 11p13; **W**ilms + **A**niridia + **G**U anomalies + M**R**
  - Highest risk of Wilms' (compared to independent aniridia or GU defect)

Klinefelter Syndrome (XXY)

- Genetics; most common findings manifested at puberty
- Findings
  - **Decreased IQ** (average IQ 85–90)
  - **Behavioral/psychiatric problems**
  - **Long limbs** (decreased upper:lower segment ratio)
  - Slim (weight/height ratio low)
  - **Hypogonadism and hypogenitalism** (testosterone replacement at age 11–12 years) = hypergonadotrophic hypogonadism (increased FSH and LH, and decreased testosterone)
  - Infertilty in almost all
  - Gynecomastia

Turner Syndrome (XO)

- Genetics
  - Generally sporadic; no older maternal age seen
  - Paternal chromosome more likely to be missing
  - Many mosiac patterns (including Y-chromatin)
- Findings
  - Small-stature female
  - Gonadal dysgenesis–streak ovaries in XO
  - Average IQ 90
  - **Congenital lymphedema, residual puffiness over dorsum of fingers and toes**
  - **Broad chest, wide-spaced nipples**
  - **Low posterior hairline; webbed posterior neck**
  - **Cubitus valgus (elbow) and other joint problems**
  - **Horseshoe kidney, and other renal defects**
  - Cardiac:
    - **Bicuspid aortic valve** (number 1 cardiac anomaly)
    - **Coarctation**
    - Aortic stenosis, mitral valve prolapse
    - Hypertension common, even without cardiac or renal disease
  - Primary hypothyroidism, mostly autoimmune, and other autoimmune diseases (celiac disease)
- Natural history
  - Decreased height velocity with delayed bone age
  - **Estrogen treatment indicated**
  - **May increase height by 3–4 cm with growth hormone (GH)**

Note

Gonadal dysgenesis is not evident in childhood, so chromosomes are warranted in any short-stature female whose phenotype is compatible with Turner syndrome.

Also consider in any adolescent with absent breast development by age 13, pubertal arrest, or primary/secondary amenorrhea with increased FSH.

Fragile X Syndrome

- Genetics
  - Fragile site on long arm of X in affected males and some carrier females—Molecular diagnosis—variable number of repeat CGG (preferred diagnosis = DNA-based molecular analysis)
  - X-linked dominant—males (most common cause of inherited mental retardation); girls have lower number of trinucleotide sequences → NL phenotype but may have lower IQ
- Findings
  - **Mild to profound mental retardation; learning problems**
  - **Large ears, dysmorphic facial features, large jaw, long face**
  - **Large testes—mostly in puberty (macroorchidism)(fertile)**
- Natural history—normal lifespan

EARLY OVERGROWTH WITH ASSOCIATED DEFECTS

Beckwith-Wiedemann Syndrome

- Genetics
  - Usually sporadic
  - IGF-2 disrupted at 11p15.5 (imprinted segment)
- Findings
  - **Macrosomia**
  - **Macroglossia—may need partial glossectomy**
  - **Pancreatic beta cell hyperplasia—excess islets → hypoglycemia;** hypoglycemia may be refractory; glucose control most important initial management
  - Umbilical abnormalities, diastasis recti, **omphalocele**
  - **Hemihypertrophy** → increased risk of abdominal tumors (Wilms)
- **Management—obtain ultrasounds and serum AFP every 6 months through 6 years of age to look for Wilms tumor and hepatoblastoma**

UNUSUAL BRAIN AND/OR NEUROMUSCULAR FINDINGS WITH ASSOCIATED DEFECTS

Prader-Willi Syndrome

- Genetics
  - Most with deletion at 15q11-q13–imprinted segment
  - **Paternal** chromosome responsible
  - The **same deletion** causes both Prader-Willi and Angelman syndromes. This may be due to the **normal process of imprinting**, which is **epigenetic** (change in the chromatin and not the gene sequence) silencing (due to hypermethylation) of certain genes in either the male or female germ cells. The alleles in the opposite

germ line are expressed and therefore in the zygote this results in **monoallelic gene expression** so that for any imprinted segment there is a **functional haploid state**. It is established in the germ line and maintained in all somatic cells.

- If the deletion occurs in the **male germ cell**, then the inheritance is from the only expressed genes, which are maternal. This is Prader-Willi syndrome.
- If the deletion occurs in the **female germ cell**, then the inheritance is from the only expressed genes, which are paternal. This is Angelman syndrome.

– Negligible recurrence risk

- Findings
  - First year, difficulty feeding with poor growth; then, increased feeding and weight gain plus slow height attainment (short stature)
  - **Obesity—onset from 6 months to 6 years**
  - **Mild to severe mental retardation**
  - **Food-related behavioral problems (binge eating)**
  - **Small hands and feet, puffy; small genitalia**
  - **Hypothalamic—pituitary dysfunction (growth, thyroid, adrenal) hypogonadotrophic-hypogonadism**
- Natural history—decreased life expectancy relative to morbid obesity

Angelman Syndrome (Happy Puppet Syndrome)

- Genetics—also deletion of 15q11q13, but **maternally derived** (imprinted segment)
- Findings
  - **Severe MR**
  - **Paroxysms of inappropriate laughter**
  - **Absent speech or <6 words (100%); most can communicate with sign language**
  - **Ataxia and jerky arm movements resembling a puppet's movements (100%)**
  - Seizures—most at age 4 years, may stop by age 10

FACIAL FEATURES AS THE MAJOR DEFECT

Robin Sequence (Pierre Robin)

- Mandibular hypoplasia in utero → posteriorly placed tongue → posterior palatal, shelves → cleft palate and other palatal abnormalities
- Isolated finding or associated with some syndromes/malformations—fetal alcohol syndrome, Edwards Syndrome
- Findings
  - **Micrognathia**
  - **Retroglossia → possible airway obstruction**
  - **Cleft soft palate and other abnormalities**
- Jaw growth over first years of life if it results from a deformation; if part of a malformation syndrome, then it is a fixed finding

OSTEOCHONDRODYSPLASIAS

Achondroplasia/Hypochondroplasia

- Genetics
  - Autosomal dominant
  - Most common short-limb dwarfism
  - 90% from new gene mutation
  - Older paternal age
  - Mutations in gene for fibroblast growth factor receptor 3 at 4p16.3 (*FGFR3*)
- Findings
  - **Short stature (increased upper-to-lower segment ratio; short-limbed dwarfism)**
  - **Proximal femur shortening**
  - **Megalocephaly, small foramen magnum (may have hydrocephalus), small cranial base, prominent forehead**
  - **Lumbar lordosis**
- Natural history
  - Normal intelligence
  - Spinal cord compression is rare (cervicomedullary junction); usually occurs in first year of life
  - Tendency of late childhood obesity
  - Small eustachian tube—otitis media and hearing loss
  - Early cervical compression, respiratory problems, obstructive and central apnea, later cardiovascular disease

CONNECTIVE TISSUE DISORDERS

Marfan Syndrome

- Genetics
  - Autosomal dominant with wide variability
  - Mutation in fibrillin gene (*FBN1*)—15q21.1
- Findings
  - Early rapid growth of the appendicular skeleton and anterior ribs
  - Major findings are skeletal, cardiovascular, and ocular
  - **Tall stature with long, slim limbs and little fat**
  - Arm span > height
  - **Arachnodactyly**
  - Decreased U:L segment ratio (as with XXY)
  - **Joint laxity with kyphoscoliosis**
  - Pectus excavatum or carinatum
  - **Lens subluxation (upward; defect in suspensory ligament)**; secondary glaucoma, myopia, retinal detachment

  - **Ascending aortic dilatation with or without dissecting aneurysm** (uncommon in children and adolescents unless case is severe) with secondary aortic regurgitation. Mitral valve disease (MVP and regurgitation) is the most common in children.
- Natural history
  - Prevent scoliosis
  - Vascular complications chief cause of death
  - Evaluate heart and aorta

Ehlers-Danlos Syndrome

- Genetics
  - Type I most common (now 6 types)
  - Autosomal dominant with wide variability
- Findings
  - **Droopy ears**
  - **Hyperextensible skin, fragile, easy bruisability, poor wound healing**
  - **Joint hyperlaxity; tendency toward hip, shoulder, knee, and clavicular dislocation**
  - MVP, tricuspid valve prolapse, **aortic root dilatation;** dissecting aneurysm, ASD
  - **Blue sclera**, myopia, glaucoma, **ectopia lentis**, retinal detachment
  - Intracranial aneurysm

ENVIRONMENTAL AGENTS

Fetal Alcohol Syndrome (FAS)

- Alcohol—most common teratogen to which fetus can be exposed
- Findings—variable
  - **Pre- (symmetric IUGR) and postnatal growth deficiency (short stature)**
  - **Mental retardation, microcephaly**
  - Fine motor dysfunction
  - Irritability in infancy, **hyperactivity in childhood**
  - **Behavioral abnormalities**
  - **Mid-face dysmorphism (abnormal frontal lobe development)**, short palpebral fissures, maxillary hypoplasia, short nose, smooth philtrum, thin and smooth upper lip
  - **Joint abnormalities**—abnormal position and/or function
  - **Cardiac anomalies: VSD > ASD**, tetralogy of Fallot

Note

Etiology of FAS

Severity of maternal alcohol use and extent and severity of pattern is most predictive of ultimate prognosis.

Fetal Hydantoin Syndrome

- **Similar features with prenatal exposure to carbamazepine, valproate, primidone, and phenobarbital**
- **No dose-response relationship has been demonstrated**
- Growth deficiency

- Borderline to mild mental retardation
- Dysmorphic facial features; short neck; abnormal palmar crease
- Rib abnormalities
- **Hirsutism**
- **Cupid's-bow lips**

Fetal Valproate Syndrome

- **Midface hypoplasia;** cleft lip
- **Cardiac defects**
- Long, thin fingers and toes; convex nails
- **Meningomyelocele**

Note

All females who are to be treated with isotretinoin must:

- Take pregnancy test
- Use definitive method of birth control (e.g., OCPs)
- Use one back-up method of birth control (e.g., condoms)
- Receive counseling regarding teratogenicity

Retinoic Acid Embryopathy (from Isotretinoin)

- Mild facial asymmetry; **bilateral microtia/anotia (ear); facial nerve paralysis ipsilateral to ear;** narrow, sloping forehead; abnormal mottling of teeth
- **Conotruncal malformations**
- **CNS malformations**
- **Decreased intelligence**
- Thymic and parathyroid abnormalities
- **No problems if stopped before 15th postmenstrual day**
- Pregnancy test required prior to treatment with isotretinoin

MISCELLANEOUS SEQUENCES

Potter Sequence

Note

An U/S is necessary for the parents and siblings of patients with oligohydramnios secondary to agenesis and/or dysgenesis of both kidneys. This is because 9% of first-degree relatives have asymptomatic malformations.

- Etiology
  - **Renal agenesis/dysgenesis** or other type of urinary tract defect must occur prior to 31 days' gestation → **oligohydramnios** (also from chronic leakage)
  - Leads to **fetal compression (mid-face, ears)**
  - Lack of alveolar sac development → **pulmonary hypoplasia**
- Findings
  - **Pulmonary hypoplasia**
  - **Potter facies**—hypertelorism, epicanthal folds, low-set flattened ears, micrognathia, compressed flat nose
  - Breech presentation
  - Abnormal positioning of hands and feet; deformations, limb anomalies
  - **Death from respiratory insufficiency (hypoplasia)**

MISCELLANEOUS ASSOCIATIONS

VACTERL Association

- Nonrandom association of
  - V = Vertebral defects
  - A = Anal atresia (imperforate anus)
  - C = Cardiac defects (VSD and others)
  - T = TE fistula
  - E = Esophageal atresia
  - R = Renal defects
  - L = Limb defects (radial)

CHARGE Association

- Nonrandom association of
  - C = Coloboma (from isolated iris to anophthalmos; retinal most common)
  - H = Heart defects (TOF, PDA, and others)
  - A = Atresia choanae
  - R = Retardation of growth and/or development
  - G = Genital hypoplasia (in males)
  - E = Ear anomalies and/or deafness

Growth and Nutrition 3

Learning Objectives

- ❑ Demonstrate steps in evaluation of growth
- ❑ Solve problems related to breast feeding, feeding of solids, and other feeding issues
- ❑ Answer questions related to growth disorders

CHILDHOOD GROWTH

Basic Principles of Growth

- A newborn typically loses **up to 10% of birth weight (BW) in the first week of life** due to elimination of large amount of extravascular fluid. **Should regain or surpass BW by 2 weeks.**
- A neonate should gain about 30 grams (1 oz) per day in the first month of life, which slows to about 20 grams/day at 3–4 months.
- **An infant typically doubles BW by 6 months and triples by 1 year.**
- Growth rate slows further between 6 and 12 months and then appetite begins to decline through 18 months of age.
- Then height and weight increase at a steady rate, but head-circumference rate of growth decreases somewhat (2–5 years).
- Between age 6 and 12 years: **3–6 growth spurts** each year for 8-week periods each; slower brain growth; **myelination complete by age 7**
- Between age 10 and 20 years: acceleration in early adolescence. Boys' highest growth stops at age 18. **Their average peak is 13.5 years (2–3 years later than girls, and continues 2–3 years after girls have stopped).** Girls' **average peak is 11.5 years and it stops at age 16.**

Assessment of Growth

- Child is genetically programmed to stay on 1–2 growth curves after age 2 years.
- Height percentile at age 2 years correlates with final adult height percentile.
- Low-birth-weight and very-low-birth-weight infants may continue to show **catch-up growth through early school age.**
- **Weight/height <5th percentile is the single best growth curve indicator for acute malnutrition.** In nutritional insufficiency, weight decreases before length, and weight/height

is low. For causes of decreased linear growth, length decreases first or at the same time as weight (e.g., GH deficiency).

- **BMI is accepted as best clinical indicator for measure of under- and overweight.**
- For bone age-reference standards, use **radiographs of left hand and wrist. Skeletal maturity is linked more to sexual maturity than chronologic age.**

Growth Patterns

The **growth chart is the best tool to determine patterns of growth.** There are separate growth charts for boys and girls. The **charts measure weight for age, height for age, head circumference for age, weight for height, and body mass index (BMI).**

- Each chart has multiple curves (either 5–95% or 3–97%).

Evaluation of Growth

Definitions

- **Growth velocity (GV)**—yearly increments of growth; should follow a growth curve

$$\text{slope} = \frac{\text{change in height}}{\text{change in age}}$$

- **Chronologic age (CA)**—actual age
- **Bone age (BA)**—x-ray of left hand and wrist (non-dominant hand)

Table 3-1. Growth Velocity

	Normal	Abnormal
Bone age = Chronological age,	Ideal Genetic (familial) **short stature**	• Genetic • Chromosomal
Bone age < Chronological age	Constitutional delay	• Chronic systemic disease • Endocrine related
Bone age ≥ Chronological age	Obesity (tall) Familial **tall stature**	• Precocious puberty • Congenital adrenal hyperplasia • Hyperthyroidism

DISORDERS OF GROWTH

Height

Short stature

A father is worried that his 13-year-old son is short. The child has been very healthy. He is below the fifth percentile for height and has been all his life. Physical exam is normal. Father is 6 foot 3; mother is 5 foot 10. Father was a "late bloomer."

Note

Suspect *Turner syndrome* in females with pathologic short stature.

Suspect *craniopharyngioma* if short stature and vision problems.

- Constitutional growth delay—child is short prior to onset of delayed adolescent growth spurt; parents are of normal height; normal final adult height is reached; growth spurt and puberty are delayed; bone age delayed compared to chronological age.
- Familial short stature—patient is parallel to growth curve; strong family history of short stature; chronologic age equals bone age.
- Pathologic short stature—patient may start out in normal range but then starts crossing growth percentiles. Differential diagnosis: craniopharyngioma, hypothyroidism, hypopituitarism, nutritional problems, and other chronic illnesses.

Tall stature

- Usually a normal variant (familial tall stature)
- Other causes—exogenous obesity, endocrine causes (growth hormone excess [gigantism, acromegaly], androgen excess [tall as children, short as adults)
- Syndromes—homocystinuria, Sotos, Klinefelter

Weight

Organic failure to thrive

A baby weighs 16 pounds at 1 year of age. Birth weight was 8 pounds. Parents state that the baby feeds well. Physical exam reveals a baby with little subcutaneous fat, long dirty fingernails, impetigo, and a flat occiput.

- Malnutrition
  - Malabsorption (infection, celiac disease, cystic fibrosis, disaccharide deficiency, protein-losing enteropathy)
  - Allergies
  - Immunodeficiency
  - Chronic disease
- Initial diagnostic tests (when organic causes are suspected)—**document caloric intake,** CBC, urinalysis, liver function tests, serum protein, **sweat chloride**, stool for ova and parasites

Courtesy of Tom D. Thacher, M.D.

Figure 3-1. Kwashiorkor
Note generalized edema secondary to low serum albumin.

Non-organic failure to thrive

A 4-month-old infant presents to the emergency department because of upper respiratory symptoms. The patient is <5 percentile in weight and length. He is 3.5 kg. Birth weight was 4.2 kg. The mother states that the patient takes 16 oz of infant formula per day with cereal added.

- Child (usually infant) not fed adequate calories
  - Emotional or maternal deprivation concurrent with nutritional deprivation
  - Leads to neglect of infant; psychosocial deprivation most common reason in all age groups
  - Other factors: retarded or emotionally disturbed parents; poverty
- Clinical findings
  - Thin extremities, narrow face, prominent ribs, wasted buttocks
  - Neglect of hygiene
  - A flat occiput and hair loss may indicate excessive back-lying
  - Delays in social and speech development
  - Avoidance of eye contact, expressionless, no cuddling response
  - Feeding aversions
- Diagnosis—Feed under supervision (may need hospitalization) for 1 week.
  - Should gain >2 oz/24 hours over the week
  - May have a ravenous appetite
  - Careful observations of mother; may need videotape
  - Delay extensive lab evaluations until after dietary management has been attempted for 1 week and has failed.

- Management
  - **All cases caused by underfeeding from maternal neglect must be reported to CPS**
  - **Infants discharged to natural home require intensive and long-term intervention**
  - Feed, as above; usually require greater calories for catch-up growth. May need NG feedings or even gastrostomy tube in severe cases

Obesity

- Risk factors—predisposition, parental obesity, family/patient inactivity, feeding baby as response to any crying, and rarely associated in syndromes (Prader-Willi; Down)
- Presentation—tall stature in some, abdominal striae, associated obesity of extremities; increased adipose tissue in mammary tissue in boys, large pubic fat pad, early puberty
- Diagnostic tests
  - BMI >95% for age and sex is diagnostic of obesity
  - 85 to 95% = overweight
- Complications—Obese infants and children are at increased risk of becoming obese adults (the risk is greater with advanced age of onset); cardiovascular (hypertension, increased cholesterol), hyperinsulinism, slipped capital femoral epithesis, sleep apnea, type 2 diabetes, acanthosis nigrans.
- Treatment—exercise and balanced diet; **no medications**

FEEDING

- **Normal newborn has sufficient stores of iron to meet requirements for 4–6 months,** but iron stores and absorption are variable. **Breast milk has less iron than most formulas, but has higher bioavailability.**
- **Formula is supplemented with vitamin D; breast fed must be supplemental from birth (400 IU/d).**
- **Vitamin K routinely is given IM (intramuscularly) at birth**, so supplementation is not needed.
- Breast milk and formula are 90% H20, so no additional H2O needed

BREAST FEEDING

A nursing mother asks if her 3-month-old baby requires any vitamin supplementation.

- Most infants can breast feed immediately after birth and all can feed by 4–6 months. The feeding schedule should be by self-regulation; most establish by 1 month.
- Advantages
  - Psychological/emotional—maternal-infant bonding
  - Premixed; right temperature and concentration
  - Immunity—**protective effects** against enteric and other pathogens; **less diarrhea, intestinal bleeding, spitting up, early unexplained infant crying, atopic dermatitis, allergy, and chronic illnesses** later in life; passive transfer of T-cell immunity
  - Decreased allergies compared to formula fed
  - Maternal—weight loss and faster return to preconceptional uterine size

Note

Mothers with HBV infection are free to breast feed their infants **after** the neonate has received the appropriate recommended vaccinations against HBV.

- Contraindications
  - HIV
  - CMV, HSV (if lesions on breast)
  - HBV (*see* note)
  - Acute maternal disease if infant does not have disease (tuberculosis, sepsis)
  - Breast cancer
  - Substance abuse
  - Drugs: **(absolute contraindications)** antineoplastics, radiopharmaceuticals, ergot alkaloids, iodide/mercurials, atropine, lithium, chloramphenicol, cyclosporin, nicotine, alcohol; **(relative contraindications)** neuroleptics, sedatives, tranquilizers, metronidazole, tetracycline, sulfonamides, steroids
  - Breast feeding is *not* contraindicated in mastitis.

Table 3-2. Comparison of Breast Milk to Cow Milk

Component	Human Milk	Cow Milk
Water/solids	Same	Same
Calories	20 cal/oz	20 cal/oz
Protein	1–1.5% (whey dominant)	3.3% (casein dominant)
Carbohydrate	6.5–7% lactose	4.5% lactose
Fat	high in low chain fatty acids	high in medium chain fatty acids
Minerals	Iron better absorbed	Low iron and copper
Vitamins	Diet dependent, low in K	Low in C, D
Digestibility	Faster emptying	Same after 45 days
Renal solute load	**Low** (aids in renal function)	Higher

Formula Feeding

- **Infant formulas.** Formula feeding is used to **substitute** or **supplement** breast milk. Most commercial formulas are cow-milk–based with modifications to approximate breast milk. They contain **20 calories/ounce**. Specialty formulas (soy, lactose-free, premature, elemental) are modified to meet specific needs.
- Formula versus cow milk—**Fe-deficiency anemia with early introduction (<1 yr) of cow's milk**
- Advanced feeding—Stepwise addition of foods (one new food every 3–4 days)

Note

Do not give cow milk to infants age <1.

SOLIDS

- Iron-fortified cereal only at 4-6 months
- Step-wise introduction of strained foods (vegetables and fruits), then dairy, meats (6-9 months; stage I and II)
- Table foods at 9-12 months
  - Foods better saved for year 2:
    - Egg whites
    - Nuts
    - Wheat products
    - Chocolate
    - Citrus
    - Fish
  - No honey in first year of life—infant botulism

Development 4

Learning Objectives

- ❑ Explain information related to primitive reflexes and developmental milestones

OVERVIEW

- Five main skill areas
  - Visual-motor
  - Language
  - Motor
  - Social
  - Adaptive
- Assessment based on acquisition of milestones occurring sequentially and at a specific rate
  - Each skill area has a spectrum of normal and abnormal.
  - Abnormal development in one area increases likelihood of abnormality in another—**so need to do a careful assessment of all skills**
  - Developmental diagnosis—functional description/classification; does *not* specify an etiology
- Developmental delay—performance significantly below average, i.e., developmental quotient (developmental age/chronologic age × 100) of <75
  - May be in one or more areas
  - Two assessments over time are more predictive than a single assessment
- Major developmental disorders
  - Mental retardation—**IQ <70–75 *plus* related limitation in at least 2 adaptive skills**, e.g., self-care, home living, work, communication
  - Communication disorders (deficits of comprehension, interpretation, production, or use of language)
  - Learning disabilities, one or more of (defined by federal government; based on standardized tests): reading, listening, speaking, writing, math
  - Cerebral palsy
  - Attention deficit/hyperactivity disorder
  - Autism spectrum disorders

Medical Evaluation

- Thorough history and physical
- Developmental testing—age-appropriate motor, visual, cognitive, language, behavioral and learning
- Denver II Developmental Assessment
  - Tool for screening the apparently normal child between ages 0–6
  - Suggested at every well-child care visit
  - Allows generalist to identify possible delay → need further evaluation for definitive diagnosis
  - Screens in gross motor, fine motor, language, personal-social
  - **For infants born <38 weeks' gestation, correct age for prematurity up to age 2 years**
  - Failure is at least 2 delays

PRIMITIVE REFLEXES AND DEVELOPMENTAL MILESTONES

An infant can sit up with its back straight, has started crawling, has a pincer grasp, and plays peek-a-boo. What age is most appropriate for this baby?

- Appear and disappear in sequence during specific periods of development
- **Absence or persistence beyond a given time frame signifies CNS dysfunction**

Included here are the major milestones indicative of specific ages. Exam questions typically describe an infant's/child's skills and ask for the corresponding age.

Table 4-1. Newborn Reflexes

Reflex	Description	Appears	Disappears	CNS Origin
Moro	Extend head → extension, flexion of arms, legs	Birth	4–6 mo	Brain stem vestibular nuclei
Grasp	Finger in palm → hand, elbow, shoulder flexion	Birth	4–6 mo	Brain stem vestibular nuclei
Rooting	Cheek stimulus → turns mouth to that side	Birth	4–6 mo	Brain stem trigeminal system
Trunk incurvation	Withdrawal from stroking along ventral surface	Birth	6–9 mo	Spinal cord
Placing	Steps up when dorsum of foot stimulated	Birth	4–6 mo	Cerebral cortex
Asymmetric tonic neck (ATNR)	Fencing posture when supine	Birth to 1 month	4–6 mo	Brain stem vestibular nuclei
Parachute	Simulate fall → extends arms	6–8 mo	Never	Brain stem vestibular

Table 4-2. Developmental Milestones

	Gross Motor	Visual Motor	Language	Social Adaptive
Birth	• Symmetric movements in supine • Head flat in prone	• Visually fixes on an object	• Alerts to sound	• Regards face
2 months	• Head in midline while held sitting • Raises head in prone • Begins to lift chest	• Follows past midline	• Smiles in response to touch and voice	• Recognizes parent
4 months	• Holds head steadily • Supports on forearms in prone • Rolls from prone to supine	• Reaches with both arms together • Hands to midline	• Laughs • Orients to voice • Coos	• Likes to look around
6 months	• Sits with support (tripod) • Feet in mouth in supine	• Unilateral reach • Raking grasp • Transfers object	• Babbles	• Recognizes that someone is a stranger
7 months	• Rolls from supine to prone • May crawl • Starts to sit without support			
9 months	• Crawls well • Pulls to stand • Starting to cruise	• Immature pincer grasp • Holds bottle • Throws object (not overhand)	• "Mama," "dada," indiscriminately • Understands "no" • Understands gestures	• Plays gesture games • Explores environment (crawling and cruising)
12 months	• May walk alone (must by 18 months)	• Mature pincer grasp • Crayon marks • Object permanence (from 10 months)	• 1-2 words other than "mama" and "dada" (used appropriately) • Follows 1-step command with gesture	• Imitates actions • Comes when called • Cooperates with dressing
15 months	• Creeps up stairs • Walks backward	• Scribbles and builds towers of 2 blocks in imitation	• 4-6 words • Follows 1-step command without gesture	• Uses cup and spoon (variable until 18 months)
18 months	• Runs • Throws objects overhand while standing	• Scribbles spontaneously • Builds tower of 3 blocks	• 15-25 words • Knows 5 body parts	• Imitates parents in tasks • Plays in company of other children

(*Continued*)

Table 4-2. Developmental Milestones (*Cont'd*)

	Gross Motor	Visual Motor	Language	Social Adaptive
24 months	• Walks up, and down stairs one foot at a time	• Imitates stroke (up or down) with pencil • Builds tower of 7 blocks • Removes clothing	• 50 words • 2-word sentences • Follows 2-step commands • Uses pronouns inappropriately	• Parallel play
3 years	• Alternates feet going up the stairs • Pedals tricycle	• Copies a circle • Undresses completely • Dresses partially • Unbuttons • Dries hands	• ≥250 words • 3-word sentences • Plurals • All pronouns	• Group play • Shares • Takes turns • Knows full name, age and gender
4 years	• Alternates feet going downstairs • Hops and skips	• Copies a square • Buttons clothing • Dresses completely • Catches ball	• Knows colors • Recites songs from memory • Asks questions	• Plays cooperatively • Tells "tall tales"
5 years	• Skips alternating feet • Jumps over lower obstacles	• Copies triangle • Ties shoes • Spreads with knife	• Prints first name • Asks what a word means • Answers all "wh-" questions • Tells a story • Plays pretend • Knows alphabet	• Plays cooperative games • Abides by rules • Likes to help in household tasks

Possible Abnormalities

You must take into account the number of weeks of prematurity to assess development appropriately, i.e., per the preterm age, NOT chronological. For instance, a 6-month-old baby born at 32 weeks (i.e., 2 months preterm) must be assessed at 6 – 2 = 4 months CORRECTED AGE. Do this until chronological age 2 years, then consider delays to be true.

- If there appears to be a language delay, first consider conductive hearing loss. While all babies receive hearing testing within the first month of life, that is for congenital sensorineural hearing loss. Over the first year of life, conductive hearing loss may occur from repeated ear infections.
- If there is a lack of development or regression of language skills with impaired social interaction, restricted activities and interests and stereotypic behaviors, consider autistic spectrum disorder. Onset of abnormal findings must occur age <3 years.
  - After a complete H and P with neurologic exam and development testing, the first step is to perform an autism screening questionnaire. If you feel the diagnosis is likely, the next step is to refer to a specialist in this area.
- Delay is defined as ≥1 **skills significantly below average**, i.e., developmental quotient (developmental age/chronological age x 100) is <75. When you find this, you must first look for a possible reason, and the child will need developmental therapy in ≥1 areas.

Behavioral/Psychological Disorders 5

Learning Objectives

- ❑ Solve problems concerning eating disorders, elimination disorders, and sleep disorders

EATING DISORDERS

Pica

- Repeated or chronic ingestion of non-nutritive substances, e.g., paint, dirt
- After year 2, needs investigation
- Predisposing factors
  - **Mental retardation and lack of parental nurturing**
  - Also with family disorganization, poor supervision, and psychologic neglect
- More common with autism, brain-behavior disorders, and **low socioeconomic status**
- Increased risk for **lead poisoning, iron deficiency, and parasitic infections**

ELIMINATION DISORDERS

Enuresis

A 7-year-old boy has problems with bedwetting. The mother says that during the day he has no problems but is usually wet 6 of 7 mornings. He does not report dysuria or frequency, and has not had increased thirst. The mother also says that he is a deep sleeper.

- Definition—voluntary or involuntary repeated discharge of urine after a developmental age when bladder control should be present (most by age of **5 years**); there are 2 types
- **Primary:**
  - **No significant dry period**; most common and usually **nocturnal** (nocturnal enuresis)
  - Hyposecretion of ADH and/or receptor dysfunction

  - Relationship of sleep architecture, diminished arousability during sleep, and abnormal bladder function; anatomic malformations
  - Management—thorough history and physical, (should begin with behavioral treatment; not definitive, varying success rates):
    - Enlist cooperation of child—chart dryness, reward system
    - Child should void before going to sleep
    - Alarm to wake once 2–3 hours after falling asleep; may use alarm that goes off when child wets a special sheet (bell and pad alarm)
    - No punishment or humiliation
    - Psychotherapy for traumatized children or when behavioral therapy has failed
    - Pharmacotherapy for failed behavioral therapy in nocturnal enuresis—oral desmopressin (DDAVP)
- **Secondary**:
  - **After a period of dryness ≥6 months**
  - Causes—psychological, urinary tract infection, constipation, diabetes
  - More common in girls
  - Evaulation—urinalysis
  - Management—treat underlying disorder
- **Children with both diurnal and nocturnal enuresis:**
  - Especially with voiding difficulties, more likely to have abnormalities of the urinary tract
  - Ultrasonography or flow studies are indicated in these cases.

Encopresis

- Definition—passage of feces into inappropriate places after a chronologic age of 4 years, or equivalent developmental level
- May be primary or secondary
- Causes—psychological (toilet phobia), early toilet training, agressive management of constipation, painful defecation, fissures
- Types
  - Retentive encopresis most common:
    - 2/3 of cases
    - **Hard stool on rectal examination is sufficient to document, but a negative exam requires a plain abdominal x-ray**
    - Presence of fecal retention is evidence of chronic constipation, and thus treatment will require **active constipation management**
    - May have abnormal anal sphincter function
- Associations
  - Primary encopresis—especially in boys, associated with global developmental delays and enuresis
  - Secondary encopresis—high levels of psychosocial stressors and conduct disorder

- Management
  - **First—clear impacted fecal material and short-term use of mineral oil or laxatives. No long-term laxative use**
  - Concomitant behavioral management
  - Regular postprandial toilet-sitting
  - High-fiber diet
  - Familial support for behavior modification
  - Group or individual psychotherapy

SLEEP DISORDERS

Parasomnias

- Definition—**episodic** nocturnal behaviors that often involve cognitive disorientation and autonomic and skeletal muscle disturbance
- Associated with relative CNS immaturity
- More common in children than adults; abates with age

Table 5-1. Parasomnias

Sleepwalking and Sleep Terrors (Partial Arousal)	Nightmares
• First third of night	• Last third of night
• During slow-wave sleep	• REM sleep
• **No daytime sleepiness or recall**	• **Daytime sleepiness** (if prolonged waking) and **vivid recall**
• High arousal threshold (agitated if • awakened)	• **Low arousal threshold** (easily awakened)
• **Common family history**	• No family history
• Displaced from bed	• May be displaced from bed
• Sleepwalking relatively common; night terrors rare	• Very common
• Treatment: parental education, **reassurance**, avoid exacerbating factors, i.e., sleep deprivation, **safety precautions**	• No required treatment unless persistent/frequent, in which case possible abuse or anxiety disorder should be investigated.

Immunizations 6

Learning Objectives

- ❑ Define active immunization
- ❑ Describe different routes of immunization for specific routine vaccines

A 6-month-old patient is being seen for routine care. The baby is doing well, and physical examination, growth, and development are normal. The mother states that after the last set of immunizations the baby had a temperature of 39.4°C (103°F) and cried for 2 hours but was consolable. What is your advice to this mother before administering the next set of immunizations?

ACTIVE IMMUNIZATIONS

Table 6-1. Classification of Vaccines

Live Attenuated		
	• Viral	MMR, varicella, yellow fever, nasal influenza, smallpox, oral rotavirus
	• Bacterial	BCG, oral typhoid
Inactivated		
Whole	• Virus	Polio, rabies, hepatitis A
Fractional	• Protein-based	Subunit: hepatitis B, parenteral influenza, acellular pertussis
	• Polysaccharide based	Toxoid: diphtheria, tetanus Pure: pneumococcal, Hib, meningococcal Conjugate: Hib, pneumococcal, meningococcal

Vaccine Rules

- For stimulation of an adequate and persisting antibody response, 2 or more doses are usually required.
- Interchangeability of vaccine products—in general, most vaccines from different manufacturers may be interchangeable.

- Simultaneous administration—most can be safely and effectively given simultaneously.
- Lapsed immunizations—**a lapse in schedule does not require reinstitution of the entire series**.
- Unknown or uncertain immunization status
  - **When in doubt, the child should be considered to be disease-susceptible, and appropriate immunizations should be initiated without delay.**
  - **To be counted, the vaccine(s) must be documented on a formal immunization record, regardless of country.**
- Dose—No reduced dose or divided dose should be administered, **including to babies born prematurely or at low birth weight (exception: first dose hepatitis B)**.
- Active immunization of people who recently received gamma globulin
  - **Live virus vaccine may have diminished immunogenicity when given shortly before or during the several months after receipt of immunoglobulin (Ig) so live vaccine is delayed (3–11 months).**

Institute of Medicine Immunization Safety Review Committee findings

- Available evidence **does not support the hypothesis that the MMR causes autism, associated disorders, or inflammatory bowel disease**. (Lancet report of Wakefield has been found to be fraudulent)
- Based on epidemiologic evidence, there is **no causal relationship between multiple immunizations and increased risk of immune dysfunction and type 1 diabetes**.
- There is no causal relationship between hepatitis B vaccine administration and demyelinating neurologic disorders.
- There is no causal relationship between meningococcal vaccination and Guillain-Barré.
- Preservative thimerosal (Hg-containing) not causative of any problems (has now been removed)

Misconceptions

The following are *not* contraindications to immunizations:

- A reaction to a previous DTaP of temperature <105°F, redness, soreness, and swelling
- A mild, acute illness in an otherwise well child
- Concurrent antimicrobial therapy
- Prematurity—immunize at the chronological age
- A family history of seizures
- A family history of sudden infant death syndrome

Accepted Precautions and Contraindications

- Minor illness, with or without a fever, **does not contraindicate immunization**.
- **Fever, per se, is not a contraindication.**
  - **Guidelines for administration are based on the physician's assessment of illness and on specific vaccines the child is scheduled to receive.**

  - If fever or other problems suggest moderate or serious illness, the child should not be immunized until recovered.
- **Documented egg allergy is *not* a contraindication to the MMR.** MMR is derived from chick embryo fibroblast tissue cultures but *does not* contain significant amounts of egg cross-reacting proteins.
- **Influenza vaccine (and yellow fever) *does* contain egg protein** and on *rare* occasions may induce a significant immediate hypersensitivity reaction.

ACTIVE IMMUNIZATION AFTER DISEASE EXPOSURE

Measles

Table 6-2. Measles

Age	Management (post-exposure)
0–6 months	Immune serum globulin if mother is not immune
Pregnant or immunocompromised	Immune serum globulin
All others	Vaccine within 72 hours of exposure for susceptible individuals

Varicella

- Give vaccine **to susceptible immunocompetent contacts age >12 months as soon as possible and VZIG to all immunocompromised and susceptible pregnant women.** No vaccine or VZIG for healthy infants age 0-12 months.
- **VZIG also for** susceptible pregnant women, **newborn whose mother had the onset of chicken pox within 5 days before delivery to 48 hours after delivery,** and certain hospitalized premature infants

Hepatitis

- Hepatitis B: after exposure in nonimmune patient, give hepatitis B Ig plus vaccine; repeat vaccine at 1 and 6 months.
- Hepatitis A: if patient is not vaccinated, give 1 dose of vaccine as soon as possible but within 2 weeks of exposure

Mumps and Rubella

- Not protected by postexposure administration of live vaccine
- Recommended for exposed adults who were born in the United States in or since 1957 and who have not previously had or been immunized against either; except pregnancy

SPECIFIC VACCINES (ROUTINE VACCINATION)

Hepatitis B

- First dose should be given soon after birth, before hospital discharge, with a total of **3 doses by age 18 months** if mother is HBsAg negative.
- **The infant born to a hepititis B surface antigen (HBsAg)-positive mother should receive the first dose of hepatitis B virus (HBV) plus hepatitis B Ig at 2 different sites within 12 hours of birth;** all 3 doses should be given by age 6 months (treat same as exposure).
- All children and adolescents who have not been immunized should begin the series during any visit to the physician.

DTaP

- All DTaP vaccines for United States currently contain acellular **pertussis**.
- The rates of local reactions, fever, and other common systemic reactions are **substantially lower with acellular pertussis vaccines than with whole-cell vaccine (but may still occur).** Use DT if there has been a serious reaction and also for any catch-up after age 7 (i.e., no full dose pertussis after age 7).
- Total of 5 doses is recommended before school entry, with the final given at **preschool age, 4–6 years.**
- Pertussis booster (Tdap) vaccine **is now recommended during adolescence, regardless of immunization status; is also recommended even if one has already had pertussis disease.**
- Tdap (childhood tetanus) is given at **age 11–12**, and then Td (adult tetanus) every 10 years.

Tetanus

Table 6-3. Tetanus Prophylaxis in Wound Management

History of Doses of Tetanus Toxoid	Clean, Minor Wounds		All Others*	
	Td	TIG	Td	TIG
<3 or unknown	Yes	No	Yes	Yes
≥3	No, unless >10 years from last dose	No	No, unless >5 years from last dose	No

Definition of abbreviations: TIG, tetanus immune globulin; Td, tetanus and diptheria vaccine.

*All other wounds = increased risk of tetanus: dirt, saliva, feces, avulsions, frostbite, puncture, crush, burns, and missiles.

IPV

- Inactivated is now the **only poliovirus vaccine available in the United States**.
- Four doses of IPV, with the last at **preschool age, 4–6 years**
- Any child up to 18 years of age should receive all doses, if behind.
- Any child who has received OPV from another country should complete schedule in United States with IPV.

HiB Conjugated Vaccine

- ***Does not* cover nontypeable *Haemophilus***
- Depending on the vaccine brand, the recommended primary series consists of 3 or 4 doses.
- After the primary series, an additional booster dose is recommended at 12–15 months of age, regardless of which regimen was used for the primary series.
- If immunization is not initiated (i.e., child is behind) **until age 15–59 months**, then there is catch-up (1 dose), but **not given after age 5 years in normal children**
- Invasive disease does not confirm immunity; patients still require vaccines if age appropriate, i.e., age <5 years.

Pneumococcal Vaccines

- Pneumococcal conjugate vaccine (PCV13),
  - Purified polysaccharides of 13 serotypes conjugated to diphtheria protein
  - Routine administration as a **4-dose series for all children age 15 months and younger**
  - If no dose given yet between age 15–59 months, then there are catch-up doses
- 23-valent pneumococcal polysaccharide vaccine (PS23)—**given as additional protection to the PCV13 in some high-risk children (e.g., functional/anatomic asplenia) age >2 years**

Varicella

- Recommended at **age 12 months or older for healthy people who have not had varicella illness, with second dose at age 4–6 years**
- **Catch-up dosing:** both doses should be given for proper immunity
- May still have breakthrough varicella; milder than unimmunized, rarely spreads
- Has been associated with the development of herpes zoster after immunization (rare)
- Most people age >18 years, even without a reliable history of varicella infection, will still be immune.

MMR

- Live attenuated vaccine: issues as above for varicella
- First dose given at **age 12–15 months**
- Second dose given at **preschool age, 4–6 years**
- Catch-up with 2 doses

Hepatitis A Vaccine

- Recommended for all children age >1 year **(12–23 months)**
- **Two doses, 6 months apart**
- Also recommended routinely for chronic liver disease patients, homosexual and bisexual men, users of illegal drugs, patients with clotting-factor disorders, and those at risk of occupational exposure
- Can give with other vaccines

Meningococcal Conjugate Vaccine (MCV4)

- Administer MCV4 to
  - All children at **the age 11–12 visit and booster at age 16**
  - **All college freshmen living in dormitories, if not vaccinated**
  - There is now a vaccine for **serotype B** to be used for high risk patients and during outbreaks (status post concurrent type B outbreaks at Princeton and UC Santa Barbara)

Note

MPSV4 is the older, pure polysaccaride vaccine, while MCV4 is the newer, conjugated vaccine.

Influenza Vaccine

- Inactivated influenza vaccine (typical flu shot)
  - Administered intramuscularly
  - Caution in egg allergy (it has been found that most patients with no documented severe allergy to eggs can safely receive the vaccine; **appropriate cautions should be taken** and they should be watched in the medical setting for at least 30 minutes thereafter)
  - Given annually during flu season for children greater than 6 months of age (A strains, B strains, and H_1N_1)
- Live influenza vaccine
  - Administered intranasally
  - Contraindicated in the immunocompromised
  - Given *only to healthy people 2–49 years of age* who are not pregnant and do not have certain health conditions

Rotavirus Vaccine

- Oral live attenuated vaccine
- Given at ages 2, 4, 6 months
- Essentially no catch-up if behind (no dose after age 8 months)
- Safe, highly effective (no intussusception; M and M from disease reduced significantly)

Human Papilloma Virus Vaccine (HPV)

- Quadrivalent vaccine (6, 11, 16, 18) or bivalent vaccine (16, 18) to girls at the age 11-12 visit (through age 26) for cervical cancer prevention
- Quadrivalent vaccine (6, 11, 16, 18) to boys age 11–12; for genital warts caused by HPV 6,11.
- Can give in both males and females as early as age 9.
- 3 doses
  - Now 9-valent in both girls (9-26) and boys (9-15): 6,11 (genital warts), 16, 18, 31, 33, 45, 52, 58 (cervical cancer prevention)
  - Precancerous lesions (all 9) including anal intraepithelial neoplasia
  - Anal cancer (16,18,31,33,45,52,58)
- Doses 2 and 3: give at 2 months and then 6 months after first

For more details and specific footnotes, go to cdc.gov/ vaccines.

Recommended immunization schedule for persons aged 0 through 18 years – United States, 2016.

(FOR THOSE WHO FALL BEHIND OR START LATE, SEE THE CATCH-UP SCHEDULE).

These recommendations must be read with the footnotes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars in Figure 1. To determine minimum intervals between doses, see the catch-up schedule. School entry and adolescent vaccine age groups are shaded.

Vaccine	Birth	1 mo	2 mos	4 mos	6 mos	9 mos	12 mos	15 mos	18 mos	19–23 mos	2-3 yrs	4-6 yrs	7-10 yrs	11-12 yrs	13–15 yrs	16–18 yrs
Hepatitis B[1] (HepB)	1st dose	2nd dose			3rd dose											
Rotavirus[2] (RV) RV1 (2-dose series); RV5 (3-dose series)			1st dose	2nd dose	See footnote 2											
Diphtheria, tetanus, & acellular pertussis[3] (DTaP: <7 yrs)			1st dose	2nd dose	3rd dose			4th dose				5th dose				
Haemophilus influenzae type b[4] (Hib)			1st dose	2nd dose	See footnote 4		3rd or 4th dose, See footnote 4									
Pneumococcal conjugate[5] (PCV13)			1st dose	2nd dose	3rd dose		4th dose									
Inactivated poliovirus[6] (IPV: <18 yrs)			1st dose	2nd dose	3rd dose							4th dose				
Influenza[7] (IIV; LAIV)					Annual vaccination (IIV only) 1 or 2 doses						Annual vaccination (LAIV or IIV) 1 or 2 doses		Annual vaccination (LAIV or IIV) 1 dose only			
Measles, mumps, rubella[8] (MMR)					See footnote 8		1st dose					2nd dose				
Varicella[9] (VAR)							1st dose					2nd dose				
Hepatitis A[10] (HepA)							2-dose series, See footnote 10									
Meningococcal[11] (Hib-MenCY ≥ 6 weeks; MenACWY-D ≥9 mos; MenACWY-CRM ≥ 2 mos)			See footnote 11											1st dose		Booster
Tetanus, diphtheria, & acellular pertussis[12] (Tdap: ≥7 yrs)														(Tdap)		
Human papillomavirus[13] (2vHPV: females only; 4vHPV, 9vHPV: males and females)														(3-dose series)		
Meningococcal B[11]														See footnote 11		
Pneumococcal polysaccharide[5] (PPSV23)											See footnote 5					

Range of recommended ages for all children

Range of recommended ages for catch-up immunization

Range of recommended ages for certain high-risk groups

Range of recommended ages for non-high-risk groups that may receive vaccine, subject to individual clinical decision making

No recommendation

This schedule includes recommendations in effect as of January 1, 2016. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant Advisory Committee on Immunization Practices (ACIP) statement for detailed recommendations, available online at http://www.cdc.gov/vaccines/hcp/acip-recs/index.html. Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS) online (http://www.vaers.hhs.gov) or by telephone (800-822-7967). Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for vaccination, is available from CDC online (http://www.cdc.gov/vaccines/recs/vac-admin/contraindications.htm) or by telephone (800-CDC-INFO [800-232-4636]).

This schedule is approved by the Advisory Committee on Immunization Practices (http//www.cdc.gov/vaccines/acip), the American Academy of Pediatrics (http://www.aap.org), the American Academy of Family Physicians (http://www.aafp.org), and the American College of Obstetricians and Gynecologists (http://www.acog.org).

NOTE: The above recommendations must be read along with the footnotes of this schedule.

Child Abuse and Neglect 7

Learning Objectives

- ❑ Define physical, sexual, and psychological abuse
- ❑ Describe the epidemiology of child abuse

INTRODUCTION

Table 7-1. Scope of Child Abuse and Neglect

Physical		Psychological	
Abuse	**Neglect**	**Abuse**	**Neglect**
Fractures Bruises Burns	Food Clothing Schooling Medical care Safety	Terrorizing Putting down Comparing Insulting	Love Support Stimulation Recognition

- Definitions
  - **Child maltreatment**—abusive actions or acts of commission and lack of action, or acts of omission that result in morbidity or death
  - **Physical abuse**—intentional injuries to a child by a caregiver that result in bruises, burns, fractures, lacerations, punctures, or organ damage; also may be accompanied by short- or long-term emotional consequences
  - **Psychological maltreatment**—intentional verbal or behavioral acts or omissions that result in adverse emotional consequences—spurning, exploiting/corrupting, withholding emotional responsiveness, isolating, terrorizing
  - **Sexual abuse**—any act intended for sexual gratification of an adult
  - **Factitious disorder**—intentionally giving poisons or toxins, or any other deceptive action to simulate a disorder
- Consequences
  - Failure-to-thrive (FTT)—nutritional neglect is most common cause of underweight infants (>50% of all cases of FTT)
  - Developmental delay
  - Learning disabilities

Note

Physicians and other care providers to children are required by law in all 50 states to report suspected abuse and neglect.

- Affords lawsuit protection to those who report in good faith
- Allows for all clinical and lab evaluation and documentation without parents' permission
- Failure to report may result in penalties
- Failure to report may result in malpractice claims for damages

- Physical disabilities
- Death

Epidemiology

- Higher likelihood of abuse with:
  - Caregivers have history of abuse or violence
  - Young parental age
  - Closely spaced pregnancies
  - Lower socioeconomic status
  - On military bases
  - Spousal abuse
  - Substance abuse
  - Single parent (mother)
  - Mentally retarded child
  - High stress level
  - Preterm, low-birth-weight infants

Note

- Certainty is **not** required to file report to Child Protective Services (CPS).
- However, one must determine whether parents have an understanding of disease processes and intellectual, emotional, economic, and physical resources to provide for child.

PHYSICAL ABUSE

A 2-year-old boy presents to the emergency department with a skull fracture that the mother states the child acquired after falling from a sofa onto a carpeted floor. During the physical examination the child is alert. He is noted to have old bruising on the buttocks and back, as well as a cigarette burn on his palm. The mother states that the child "falls a lot" and is always touching things he should not.

Diagnosis

- When to suspect
  - Injury is unexplained or implausible
  - Injury is incompatible with the history given or with child's level of development
  - There are no reports of death or serious brain injury from witnessed falls <10 feet.

Clinical Findings

Note

Battered child syndrome is suggested by bruises, scars, internal organ damage, and fractures in various stages of healing.

Bruises

- Most common
- Accidental—thin, leading surfaces overlying bone edges (e.g., shins)
- Nonaccidental—buttocks, genitals, back, back of hands, thoraco-abdominal
- Shape of injury suggests object used—suspect with bilateral, symmetric, or geometric injuries
- Staging–**bruises in various stages are not compatible with a single event**
- Consider cultural issues, e.g., coining, cupping

Fractures

- Wrenching or pulling an extremity → corner **chip** or **bucket handle fracture** of metaphysis
- Inflicted fracture of bone shaft → more likely are **spiral fractures** from twisting rather than transverse from impact
- **A spiral fracture of the femur before child can walk independently has usually been inflicted by someone else.**
- Accidental impact rarely causes rib fractures or retinal hemorrhages in children.
- Highly specific for abuse
  - Rib fractures in infants
  - Fractures of different stages of healing
  - Bilateral fractures
  - Complex skull fracture

Burns

- Cigarette burns → circular, punched-out lesions of uniform size
- Immersion burns (most common in infants)
  - Glove-stocking pattern of extremity
  - Dipping into bathtub water:
    - Demarcation is uniform and distinct
    - Flexion creases spared
    - No splash burns
    - Hands and feet spared
    - **Incompatible with falling into tub or turning on hot water while in tub**

Intentional head trauma

- Most common cause of death
- **Consider when injured infant presents with coma, convulsions, apnea, increased ICP**
- A subdural hemorrhage in which there are no scalp marks or skull fracture is possibly from a hand blow.
- Retinal hemorrhages
- Shaking—acceleration-deceleration; may have no external marks; 85% associated with retinal hemorrhage

Note

Differential Diagnosis

With osteogenesis imperfecta or severe osteomalacia, there is an increased incidence of pathologic fractures, **but** they are rarely of the metaphysis.

Note

Always obtain a CT scan for intracranial bleeding and an eye exam for retinal hemorrhages.

Intra-abdominal injuries

- Impacts
- Recurrent vomiting, abdominal distension, absent bowel sounds, localized tenderness, shock
- If struck with fist → row of 3–4 teardrop-shaped, 1-cm bruises in a slight curve
- May rupture liver or spleen
- Laceration of small intestine at sites of ligamental support
- Intramural hematoma → temporary obstruction
- Free air

Laboratory Studies

- **Skeletal survey when you suspect abuse in child age <2 years; in child >2 years, appropriate film area of injury, complete survey not usually required**
- If infant is severely injured **despite** absence of CNS findings
  - Head CT scan
  - ± MRI
  - Ophthalmologic examination
- If abdominal trauma
  - Urine and stool for blood
  - Liver and pancreatic enzymes
  - Abdominal CT scan
- For any bleeding, bruises: PT, PTT, platelets, bleeding time, INR

Management. The first step is always to institute **prompt medical, surgical, or psychological treatment.**

- Consider separating child from caregiver in exam area.
- Report any child **suspected** of being abused or neglected to CPS; caseworker confers with M.D.
- Law enforcement agency performs forensics, interviews suspects, and if criminal act has taken place, informs prosecutor (state by state)
- Initial action includes a phone report, then, in most states,, a written report is required within 48 hours
- **Hospitalization is required if**
  - **Medical condition requires it**
  - **Diagnosis is unclear**
  - **There is no alternative safe place**
  - **Parents refuse hospitalization/treatment; M.D. must get emergency court order**
- M.D. should explain to parents
  - Why an inflicted injury is suspected
  - That M.D. is legally obligated to report
  - That referral is made to protect the child
  - That family will be provided with services
  - That a CPS worker and law enforcement officer will be involved
- Court ultimately decides guilt and disposition

Prognosis. The earlier the age of abuse, the greater the risk of mortality.

SEXUAL ABUSE

A 3-year-old girl presents with green vaginal discharge. Microscopic examination of the discharge revealed gram-negative intracellular diplococci.

- Epidemiology
  - Least common offender is a stranger
  - Most common reported abuse is that of daughters by fathers and stepfathers
  - **Most common overall is brother-sister incest**
  - Violence is not common but increases with age and size of victim
  - More likely to occur as a single incident with a stranger
- Clinical findings—sexual abuse should be **considered as a possible cause** if presenting with
  - Vaginal, penile, or rectal pain, discharge, bruising, erythema, or bleeding
  - Chronic dysuria, enuresis, constipation, or encopresis
  - **Any STDs in prepubertal child**
- Diagnosis
  - Test for pregnancy
  - Test for STDs
  - Test for syphilis, HIV, gonorrhea, hepatitis B
- Management:
  - Police and CPS notification
  - Psychiatric support
  - Foster care placement
  - Antibiotics, pregnancy (postmenarche in midcycle within 72 hours)

Note

Condyloma appearing after age 3 and *Trichomonas vaginalis* are probable diagnoses.

HSV-1 and nonvenereal warts may be autoinoculated.

Respiratory Disease 8

Learning Objectives

- ❑ Demonstrate understanding of upper airway obstruction from foreign bodies, congenital anomalies, and acute inflammatory upper airway obstruction
- ❑ Answer questions about inflammatory and infectious disorders of the small airways
- ❑ Describe the epidemiology and treatment of cystic fibrosis
- ❑ Recognize risk factors and presentation of sudden infant death syndrome

ACUTE INFLAMMATORY UPPER AIRWAY OBSTRUCTION

Croup

A 12-month-old child is brought to your office because of a barky cough. The mother states that over the past 3 days the child has developed a runny nose, fever, and cough. The symptoms are getting worse, and the child seems to have difficulty breathing. He sounds like a seal when he coughs.

- Infective agents—parainfluenza types 1, 2, 3
- Age 3 months–5 years; most common in winter; recurrences decrease with increasing growth of airway
- Inflammation of subglottis
- Signs and symptoms/examination—upper respiratory infection 1–3 days, then **barking cough, hoarseness, inspiratory stridor**; worse at night, gradual resolution over 1 week
- Complications—hypoxia only when obstruction is complete
- Diagnosis—**clinical, x-ray not needed** (**steeple sign if an x-ray is performed**)
- Treatment is basically supportive, but for more severe cases:
  - Nebulized epinephrine, followed by
  - Corticosteroids

Epiglottitis

Note

Epiglottitis is a medical emergency that requires anethesia for immediate intubation/emergent cricothyroidotomy.

A 2-year-old child presents to the emergency center with her parents because of high fever and difficulty swallowing. The parents state that the child had been in her usual state of health but awoke with fever of 40ºC (104°F), a hoarse voice, and difficulty swallowing. On physical examination, the patient is sitting in a tripod position. She is drooling, has inspiratory stridor, nasal flaring, and retractions of the suprasternal notch and supraclavicular and intercostal spaces.

- Infective agents
  - *Haemophilus influenzae* type B (HiB) no longer number one (vaccine success)
  - Now combination of *Streptococcus pyogenes, Streptococcus pneumoniae, Staphylococcus aureus, Mycoplasma*
  - Risk factor—adult or unimmunized child
- Inflammation of epiglottis and supraglottis
- Signs and symptoms/examination—dramatic acute onset
  - High fever, sore throat, dyspnea, and rapidly progressing obstruction
  - **Toxic-appearing**, difficulty swallowing, drooling, **sniffing-position**
  - **Stridor is a late finding (near-complete obstruction)**
- Complications—complete airway obstruction and death
- Diagnosis
  - **Clinical first** (do nothing to upset child), controlled visualization (laryngoscopy) of **cherry-red, swollen epiglottis**; **x-ray not needed (thumb sign if x-ray is performed)** followed by immediate intubation
- Treatment
  - **Establish patent airway** (intubate)
  - Antibiotics to cover staphylococci, HiB, and resistant strep (antistaphylococcal plus third-generation cephalosporin)

Table 8-1. Croup, and, Epiglottitis

Feature	Croup	Epiglottitis
Etiology	• Parainfluenza 1,2,3	• *S. aureus* • *S. pneumonia, S. pyogenes* • *H. influenza* type B
Age	• Preschool	• Toddler-young school age
Timing	• Cool months	• Year round
Diagnosis Key Words	• Barking cough • Inspiratory stridor • If the patient gets worse: Inspiratory stridor ↓ Expiratory stridor (biphasic stridor) ↓ Stridor at rest	• Acute onset • Extremely sore throat • Cannot swallow • High fever • Sniffing position • Drooling • Inspiratory stridor later
Best Initial Test	• Clinical Dx • CXR not needed-but shows steeple sign	• Laryngoscopy
Most Accurate Test	• PCR for virus • Not needed clinically	• C and S from tracheal aspirate
Best Initial Treatment	• None or nebulized epinephrine if severe	• Airway (intubation)
Definitive Treatment (If Needed)	• Parenteral steroid – Most common-single dose IM Dexamethasone → – Observation	• Airway (tracheostomy if needed) + broad-spectrum antibiotics • Then per sensitivities

CONGENITAL ANOMALIES OF THE LARYNX

Laryngomalacia

- Most common laryngeal airway anomaly and is the **most frequent cause of stridor in infants and children**.
- Collapse of supraglottic structures inward during inspiration stridor; less in prone position
- Starts in first 2 weeks of life, and symptoms increase up to 6 months of life; typically exacerbated by any exertion
- Diagnosis—Clinical suspicion is confirmed with **laryngoscopy**, bronchoscopy (for associated anomalies).
- Treatment—with most, supportive care; if significant, surgery (supraglottoplasty may prevent tracheostomy)

Congenital Subglottic Stenosis

- Second most common cause of stridor
- Common presentation—recurrent/persistent croup, i.e., stridor (no difference supine vs. prone position)
- Diagnosis—airway x-rays; confirm with laryngoscopy
- Treatment—surgery (cricoid split or reconstruction), may avoid tracheostomy

Vocal Cord Paralysis

- Third most common cause of stridor
- Often associated with meningomyelocele, Chiari malformation, hydrocephalus
- May be acquired after surgery from congenital heart defects or tracheoesophageal fistula (TEF) repair
- Bilateral—airway obstruction, high-pitched inspiratory stridor
- Unilateral—aspiration, cough, choking, weak cry and breathing
- Diagnosis—**flexible bronchoscopy**
- Treatment—usually resolves in 6–12 months; may require temporary tracheostomy

AIRWAY FOREIGN BODY

A toddler presents to the emergency center after choking on some coins. The child's mother believes that the child swallowed a quarter. On physical examination, the patient is noted to be drooling and in moderate respiratory distress. There are decreased breath sounds on the right with intercostal retractions.

Note

Larynx is the most common site of foreign body aspiration in children age <1 year.

In children age >1 year, think trachea or right mainstem bronchus.

- Most seen in children age 3–4 years
- Most common foreign body is peanuts
- Highly suggested if symptoms are *acute* choking, coughing, wheezing; often a witnessed event
- Clinical—depends on location
  - Sudden onset of respiratory distress
  - Cough, hoarseness, shortness of breath
  - Wheezing ((asymmetric) and decreased breath sounds (asymmetric))
- Complications—obstruction, erosion, infection (fever, cough, pneumonia, hemoptysis, atelectasis)
- Diagnosis—Chest x-ray reveals airtrapping (ball-valve mechanism). **Bronchoscopy** for definite diagnosis.
- Therapy—removal by **rigid bronchoscopy**

INFLAMMATORY DISORDERS OF THE SMALL AIRWAYS

Bronchiolitis

A 6-month-old infant presents to the physician with a 3-day history of upper respiratory tract infection, wheezy cough, and dyspnea. On physical examination, the patient has a temperature of 39°C (102°F), respirations of 60 breaths/min, nasal flaring, and accessory muscle usage. The patient appears to be air hungry, and the oxygen saturation is 92%.

- Infective agents—**respiratory syncytial virus** (**RSV**) (50%), parainfluenza, adenovirus, *Mycoplasma*, other viruses
- Typical age—almost all children infected by age <2 years, most severe at age 1–2 months in winter months.
- Inflammation of the small airways (inflammatory obstruction: edema, mucus, and cellular debris) → (bilateral) obstruction → air-trapping and overinflation
- Clinical presentation
  - Signs and symptoms:
    - Mild URI (often from household contact), decreased appetite and fever, irritability, paroxysmal wheezy cough, dyspnea, and tachypnea
    - **Apnea** may be more prominent early in young infants.
  - Examination:
    - Wheezing, increased work of breathing, fine crackles, prolonged expiratory phase
    - Lasts average of 12 days (worse in first 2–3 days)
- Complications—bacterial superinfection, respiratory insufficiency and failure (worse in infants with small airways and decreased lung function)
- Diagnosis
  - Clinical
  - Chest x-ray (not routine)—hyperinflation with patchy atelectasis (may look like early pneumonia)
  - Immunofluorescence of nasopharyngeal swab (not routine); PCR
- Treatment
  - Supportive care; hospitalize if respiratory distress; may give trial of hypertonic saline nebulization
  - **No steroids**
  - Ribavirin not routinely used; may prevent need for mechanical ventilation in severe cases
- Prevention—monoclonal antibody to RSV F protein (preferred: palivizumab) in **high-risk patients only**

PNEUMONIA

A 3-year-old child presents to the physician with a temperature of 40°C (104°F), tachypnea, and a wet cough. The patient's sibling has similar symptoms. The child attends daycare but has no history of travel or pet exposure. The child has a decreased appetite but is able to take fluids and has good urine output. Immunizations are up to date.

- Definition—inflammation of the lung parenchyma
- Epidemiology
  - **Viruses are predominant cause in infants and children age <5 years**
    - Major pathogen—**RSV**
    - Others—parainfluenza, influenza, adenovirus
    - More in fall and winter
  - **Nonviral causes** more common in **children >5 years**
    - Most—***M. pneumoniae* and *C. pneumoniae*** (genus has been changed to *Chlamydophila*; but remains *Chlamydia* for trachomatis)
    - *S. pneumoniae* most common with focal infiltrate in children of all ages
    - Others in normal children—*S. pyogenes* and *S. aureus* (no longer HiB)

Table 8-2. Clinical Findings in Viral Versus Bacterial Pneumonia

	Viral	Bacterial
Temperature	↑	↑↑↑
Upper respiratory infection	++	—
Toxicity	+	+++
Rales	Scattered	Localized
WBC	Normal to ↓	↑↑↑
Chest x-ray	Streaking, patchy	Lobar
Diagnosis	Nasopharyngeal washings	Blood culture, transtracheal aspirate (rarely done)

- Clinical findings
  - Viral:
    - Usually several days of URI symptoms; low-grade fever
    - Most consistent manifestation is tachypnea
    - If severe—cyanosis, respiratory fatigue
    - Examination—scattered crackles and wheezing
    - **Difficult to localize source in young children with hyper-resonant chests; difficult to clinically distinguish viral versus nonviral**

  - Bacterial pneumonia:
    - **Sudden shaking chills with high fever, acute onset**
    - Significant cough and chest pain
    - Tachypnea; productive cough
    - Splinting on affected side—minimize pleuritic pain
    - Examination—diminished breath sounds, localized crackles, rhonchi early; with increasing consolidation**, markedly diminished breath sounds and dullness to percussion**
  - *Chlamydia trachomatis* pneumonia:
    - No fever or wheezing (serves to distinguish from RSV)
    - **1–3 months of age**, with insidious onset
    - May or may not have conjunctivitis at birth
    - Mild interstitial chest x-ray findings
    - **Staccato cough**
    - **Peripheral eosinophilia**
  - *Chlamydophila pneumoniae* and *mycoplasma pneumoniae*
    - Cannot clinically distinguish
    - Atypical, insidious pneumonia; constitutional symptoms
    - **Bronchopneumonia**; gradual onset of constitutional symptoms with persistence of cough and hoarseness; coryza is unusual (usually viral)
    - Cough worsens with dyspnea over 2 weeks, then gradual improvement over next 2 weeks; becomes more productive; **rales** are most consistent finding (basilar)
- Diagnosis
  - Chest x-ray confirms diagnosis:
    - Viral—**hyperinflation with bilateral interstitial infiltrates and peribronchial cuffing**
    - Pneumococcal—**confluent lobar consolidation**
    - *Mycoplasma*—unilateral or bilateral lower-lobe interstitial pneumonia; **looks worse than presentation**
    - *Chlamydia*—interstitial pneumonia or lobar; as with *Mycoplasma*, chest x-ray often looks worse than presentation
  - White blood cells:
    - Viral—usually <20,000/mm^3 with lymphocyte predominance
    - Bacterial—usually 15,000–40,000/mm^3 with mostly granulocytes
    - *Chlamydia*—**eosinophilia**
  - Definitive diagnosis:
    - Viral—isolation of virus or detection of antigens in respiratory tract secretions; (usually requires 5–10 days); rapid reagents available for RSV, parainfluenza, influenza, and adenovirus
    - Bacterial—isolation of organism from blood (positive in only 10–30% of children with *S. pneumoniae*), pleural fluid, or lung; **sputum cultures are of no value in children.** For mycoplasma get IgM titers.

- Treatment
  - Based on presumptive cause and clinical appearance
  - Hospitalized—parenteral cefuroxime (if *S. aureus* suspected, add vancomycin or clindamycin)
  - **If suspect viral (outpatient, mild)—may withhold treatment *if* mild and no respiratory distress. Up to 30% may have coexisting bacterial pathogens**; deterioration should signal possible secondary bacterial infection and should start empiric treatment.
  - ***Chlamydophila* or *Mycoplasma*—erythromycin** or other macrolide

Table 8-3. Pneumonia

Feature	Bacterial	Viral	*C. trachomatis*	*M. pneumoniae or C. pneumonia*
Etiology	• *S. pneumoniae* • *HIB* • *S. aureus*	• *RSV* • *Parainfluenza* • *Influenza* • *Adenovirus*	*C. Trachomatis*	• *M. Pneumoniae* • *C. Pneumonia*
Age	• Any age • Most common reason for lobar is *S. pneumoniae*	Most common form <5 years	Age 1–3 months	Most common form age >5 years
Timing	More in cold months	Cold months	All year	All year; more in winter
Diagnosis Key Words	• Acute • Severe • Productive cough • Dyspnea • High fever • Chest pain • Rhonchi • Rales • Decreased breath sounds • May have empyema	• Insidious • Often worsening URI • Lower temperature • Wheeze • Cough • Mild dyspnea	• May have had conjunctivitis as newborn • Afebrile • No wheeze • Staccato cough	• Insidious • URI symptoms with persistence of cough worsening over 2 weeks • Rales most consistent finding (lower lobe uni- or bilateral)
Best Initial Test	• CXR = lobar consolidation	• CXR = bronchopneumonia, interstitial • Hyperinflation with increased peribronchial markings	• CXR = mild interstitial	• CXR most unilateral lower lobe interstitial • Classically looks worse than symptoms
Most Accurate Test	• Sputum C and S (cannot rely on in child) • Blood culture • Pleural fluid culture	Respiratory secretions for viral or antigen isolation (would not do routinely)	Sputum PCR (but not needed = classic clinical diagnosis)	PCR of NP or throat swab (but not usually needed)
Best Initial Treatment and Definitive Treatment	• Admit for IV cefuroxime • Then change if needed based on C and S	• No treatment of viral pneumonia • If uncertain, give oral amoxicillin	Oral macrolide	Oral macrolide

CYSTIC FIBROSIS (CF)

A 3-year-old white child presents with rectal prolapse. She is noted to be in the less than 5th percentile for weight and height. The parents also note that she has a foul-smelling bulky stool each day that "floats." They also state that the child has developed a repetitive cough over the last few months.

- Most common life-limiting recessive trait among whites
- Major cause of severe chronic lung disease and most common cause of exocrine pancreatic deficiency in children
- Primary pathogenic feature is dysfunction of epithelialized surfaces; obstruction and infection of airways; maldigestion
- Genetics
  - **Autosomal recessive**; CF gene most prevalent among **northern and central Europeans**
  - All of the gene mutations occur at a single locus on long arm of **chromosome 7.**
  - Codes for CF transmembrane regulator (**CFTR**—ion channel and regulatory functions)
    - Expressed mostly on epithelial cells of airways, gastrointestinal tract, sweat glands, genitourinary (GU) system
    - Not all children with CF can be identified by DNA testing; may need to sequence CFTR gene
- Pathogenesis and pathology
  - Membranes of CF epithelial cells **unable to secrete Cl^-** in response to cyclic adenosine monophosphate–mediated signals:
    - **Failure to clear mucous secretions**; paucity of water in mucous secretions
    - Increased salt content of sweat and other serous secretions
    - Manifestations:
      - Bronchiolar obliteration, bronchiectasis (end-stage; severe destructive disease)
      - Opacified paranasal sinuses
      - Large nasal polyps
      - Pancreatic dysfunction; fat and fat-soluble vitamin malabsorption
      - Intestinal glands distended with mucous secretions; focal biliary cirrhosis
      - Endocervitis
      - Body and tail of epididymis, vas deferens, seminal vesicles obliterated or atretic in males
- Clinical presentation
  - Intestinal tract—usually first presentation:
    - 10% of newborns with **meconium ileus**
      - X-ray shows dilated loops, air–fluid levels, "ground-glass" (bubbly appearance) material in lower central abdomen
      - Gastrografin enema → reflux into ileum may clear; if not, then surgery
    - Most with malabsorption from pancreatic exocrine insufficiency → **frequent, bulky, greasy stools and failure-to-thrive.**

- **Fat-soluble vitamin deficiency—ADEK**
- Hepatobiliary—icterus, ascites, hepatomegaly, cholelithiasis, varices
- Pancreas—increased incidence of diabetes mellitus, **acute pancreatitis**
- **Rectal prolapse**—most in infants with steatorrhea, malnutrition, and cough

– Respiratory tract:
- **Rate of progression of lung disease is chief determinant of mortality and morbidity**—early in life—nontypable *H. influenzae* and *S. aureus*, then colonization with *P. aeruginosa*, then later colonization with ***Burkholderia cepacia***: associated with rapid deterioration and death (end-stage)
- **Cough, purulent mucus**—early in first year, extensive bronchiolitis, then pulmonary function test (PFT) abnormalities, dyspnea; finally, cor pulmonale, respiratory failure, and death; high risk for pneumothorax
- Examination:
  - Increased A-P diameter
  - **Hyper-resonance**, rales, **expiratory wheezing**
  - **Clubbing**, cyanosis (late)
  - Sinuses almost always opacified

– Genitourinary tract:
- Delayed sexual development
- Almost all males with **azoospermia**
- Increased incidence of hernia, hydrocele, undescended testes
- Females: **secondary amenorrhea**, cervicitis, **decreased fertility**

– Sweat glands:
- Excessive loss of salt → salt depletion, especially with hot weather or gastroenteritis (serum–hypochloremic alkalosis)
- **Salty taste of skin**

• Diagnosis

– *See* Table 8-4.

Table 8-4. Diagnosing CF

Any of the Following	*Plus* Any of the Following
• Typical clinical features • History of a sibling with CF • Positive newborn screen	• Two increased sweat chlorides on 2 separate days • Identification of 2 CF mutations (homozygous) • Increased nasal potential difference

– Sweat test (**best test**):
- Difficult in first weeks of life
- Confirm positive results
- Diagnosis: >60 mEq/L

– If sweat test is equivocal:
- Increased potential difference across nasal epithelium
- Pancreatic function—72-hour fecal fat collection, stool for trypsin, pancreozymin-secretin stimulation, serum immunoreactive trypsinogen (↑ in neonates)

  - X-rays:
    - Hyperinflation of chest
    - Nodular densities, patchy atelectasis, confluent infiltrates, hilar nodes
    - With progression—flattening of diaphragm, sternal bowing, narrow cardiac shadow; cysts, extensive bronchiectasis
  - Pulmonary function tests:
    - By 5 years—**obstructive** pulmonary disease
    - Then **restrictive (fibrosis)**
  - Microbiologic—finding in sputum of ***S. aureus*** first, followed by ***P. aeruginosa*** (mucoid forms) is **virtually diagnostic** (also *B. cepacia*, but is usually late finding)
  - Genetic:
    - Antenatal diagnosis by mutational analysis in family previously identified by birth of child with CF
    - Test spouse of carrier with standard panel of probes
    - **Newborn screen—**determination of immunoreactive trypsinogen in blood spots and then **confirmation with sweat or DNA testing; does *not* improve pulmonary and therefore long-term outcome**
- Treatment
  - Clear airway secretions and control infections:
    - **Aerosol treatment; albuterol/saline**
    - Daily dose of **human recombinant DNAse (mucolytic)**
    - Chest physical therapy with postural drainage: 1–4 times per day
  - Antibiotics:
    - For acute infections (change in baseline condition)
    - Most frequent is *P. aeruginosa* (also non-typable *H. influenzae*, *S. aureus*, *B. cepacia*)
    - Must base choice on culture and sensitivity
    - Aerosolized antibiotics—**tobramycin**
  - Hospitalization:
    - Progressive despite intensive home measures
    - Typical 14-day treatment
    - Two-drug regimens to cover pseudomonas, e.g., **piperacillin plus tobramycin or ceftazidime**
  - Nutritional: **pancreatic enzyme replacement with meals/snacks; vitamin supplementation (ADEK)**
  - **Adequate fluid replacement when exercising or hot weather**

SUDDEN INFANT DEATH SYNDROME (SIDS)

A 2-month-old term infant born with no complications via spontaneous vaginal delivery is brought to the emergency center via ambulance with CPR in progress. According to the mother, the patient was in his usual state of good health until 4 A.M. when she found him cyanotic and not breathing. At midnight the infant was fed 4 ounces of formula without any difficulty and then placed to sleep in a crib. At 4 A.M. the mother returned and found the child unresponsive. She immediately called emergency medical services and began CPR. The child was pronounced dead on arrival to the emergency department.

- **Definition**—sudden death of an infant, unexplained by history or by thorough postmortem examination including autopsy, investigation of death scene, and review of medical history; recently, new nomenclature is **Sudden Unexplained Infant Death Syndrome** (SUIDS)
- Before 1992, incidence was constant at 1.4 in 1,000; then with **Back to Sleep** campaign, down to 0.45 in 1,000
- Differential diagnosis
  - Explained at autopsy: infections; congenital anomaly; unintentional injury; traumatic child abuse; other natural causes
  - Not explained: SIDS; **intentional suffocation**
- Pathology: no findings are pathognomonic and none are diagnostic (markers for preexisting, chronic, low-grade asphyxia): **petechial hemorrhages**; pulmonary edema
- Environmental risk factors
  - Nonmodifiable:
    - Low socioeconomic status
    - African American and Native American
    - **Highest at 2–4 months** of age; most by 6 months
    - Highest in winter, midnight to 9 A.M.
    - Males > females
  - Modifiable:
    - Shorter interpregnancy interval
    - Less prenatal care
    - Low birth weight, preterm, intrauterine growth retardation
    - **Maternal smoking**
    - **Postnatal smoking**
- **Sleep environment**
  - **Higher incidence related to prone sleeping**
  - **Supine position now better than side-lying**
  - No increased problems in supine, i.e., aspiration
  - Higher incidence with **soft bedding/surfaces**
  - Higher incidence with **overheating**
  - Pacifier shown to consistently decrease risk

- Other risk factors
  - Episode of an apparent life-threatening event (ALTE); recently, new nomenclature for ALTE is **Brief Resolved Unexplained Episode** (BRUE)
  - Subsequent sibling of SIDS victim
  - Prematurity—inverse with gestational age and birth weight
- **Home monitors do not decrease risk.**
- Reducing risk
  - **Supine while asleep**
  - Use crib that meets federal safety standards
  - No soft surfaces (sofas, waterbeds, etc.)
  - No soft materials in sleep environment
  - No bed-sharing
  - Avoid overheating and overbundling
  - Use prone position only while infant is awake and observed
  - No recommendation for home monitoring for this purpose
  - Expand national Back to Sleep campaign (up to 25% of infants still sleep prone).

Allergy and Asthma 9

Learning Objectives

- ❑ Apply knowledge of allergies and asthma to diagnose and describe treatment options

ALLERGIES

Allergic Rhinitis

- Generally established by age 6 years
- Increased risk—early introduction of formula (versus breast milk) or solids, mother smoking before child is 1 year old, heavy exposure to indoor allergens
- Most perennial or mixed; increased symptoms with greater exposure
- **Diagnosis suggested by typical symptoms in absence of URI or structural abnormality (nasal congestion/pruritus, worse at night with snoring, mouth-breathing; watery, itchy eyes; postnasal drip with cough; possible wheezing; headache)**
- Specific behaviors
  - Allergic salute (rhinorrhea and nasal pruritus) → nasal crease
  - Vigorous grinding of eyes with thumb and side of fist
- History of symptoms
  - Timing and duration (seasonal versus perennial)
  - Exposures/settings in which symptoms occur
  - Family history of allergic disease (atopy, asthma)
  - Food allergies more common (nuts, seafood) in young children (then skin, gastrointestinal, and, less often, respiratory)
- Physical examination
  - **Allergic shiners** (venous stasis)—blue-gray-purple beneath lower eyelids; often with **Dennie lines**—prominent symmetric skin folds
  - Conjunctival injection, **chemosis** (edema), stringy discharge, "cobblestoning" of tarsal conjunctiva
  - **Transverse nasal crease (from allergic salute)**
  - **Pale nasal mucosa**, thin and clear secretions, **turbinate hypertrophy**, polyps
  - Postnasal drip (posterior pharynx)
  - Otitis media with effusion is common

- Differential diagnosis
  - **Nonallergic inflammatory rhinitis (no IgE antibodies)**
  - **Vasomotor rhinitis (from physical stimuli)**
  - **Nasal polyps (think of CF)**
  - **Septal deviation**
  - **Overuse of topical vasoconstrictors**
  - Rare: neoplasms; vasculitides; granulomatous disorders (Wegener)
- Laboratory evaluation (no initial routine labs; clinical DX)
  - In vitro:
    - Peripheral eosinophilia
    - Eosinophils in nasal and bronchial secretions; **more sensitive than blood eosinophils**
    - Increased serum IgE
    - IgE-specific allergen in blood draw (**advantages** are safety and the results will be uninfluenced by skin disease/medications, while major **disadvantages** are its expense and less sensitivity); best use is for extensive dermatitis and for medications that interfere with mast cell degranulation, have high risk for anaphylaxis, or cannot cooperate with skin tests
  - In vivo—**skin test (best):**
    - Use appropriate allergens for geographic area plus indoor allergens.
    - May not be positive before two seasons
- Treatment—environmental control plus removal of allergen is **most effective method**
  - Avoidance of biggest triggers—house dust mite, cat, cockroach
  - Dehumidifiers, HEPA-filtered vacuuming, carpet removal, pillow and mattress encasement
  - Remove pets
  - No smoking
  - No wood-burning stoves/fireplaces
- Pharmacologic control
  - **Antihistamines (first-line therapy)**:
    - First generation—diphenhydramine, chlorpheniramine, brompheniramine; cross blood-brain barrier—sedating
    - **Second generation (cetirizine, fexofenadine, loratadine)**—nonsedating (**now preferred drugs**); easier dosing
    - **Oral antihistamines are more effective than cromolyn but significantly less than intranasal steroids; efficacy ↑ when combined with an intranasal steroid**
  - Intranasal corticosteroids—**most effective medication, but not first-line**:
    - Effective for all symptoms
    - Add to antihistamine if symptoms are more severe
  - Leukotriene-receptor antagonists
  - Chromones—cromolyn and nedocromil sodium:
    - Least effective
    - Very safe with prolonged use
    - Best for preventing an unavoidable allergen

Note

Differential Diagnosis of Eosinophilia

- Neoplasms
- Asthma/Allergy
- Addison disease
- Collagen Vascular Disorders
- Parasites

  - Decongestants—(alpha-adrenergic → vasoconstriction)—topical forms (oxymetazoline, phenylephrine) significant **rebound** when discontinued.
  - Epinephrine—alpha and beta adrenergic effects; **drug of choice for anaphylaxis**
  - Immunotherapy:
    - Administer gradual increase in dose of allergen mixture → decreases or eliminates person's adverse response on subsequent natural exposure
    - **Major indication**—duration and severity of symptoms are disabling in spite of routine treatment (for at least two consecutive seasons). This, however, is the **treatment of choice for insect venom allergy**.
    - **Should not** be used for (lack of proof): atopic dermatitis, **food allergy,** latex allergy, urticaria, children age <3 years (too many systemic symptoms)
    - Need several years of treatment; expensive
- Complications of allergic rhinitis
  - Chronic sinusitis
  - Asthma
  - Eustachian tube obstruction → middle ear effusion
  - Tonsil/adenoid hypertrophy
  - Emotional/psychological problems

Insect Venom Allergy

- Etiology/pathophysiology—systemic allergic responses are IgE-mediated and are almost always due to stings from the order Hymenoptera (yellow jackets most notorious—aggressive, ground-dwelling, linger near food)
- Clinical presentation
  - Local—limited swelling/pain <1 day
  - Large local area—develop over hours to days; extensive swelling
  - Systemic—urticaria/angioedema, pruritus, **anaphylaxis**
  - Toxic—fever, malaise, emesis, nausea
  - Delayed/late response—serum sickness, nephrotic syndrome, vasculitis, neuritis, encephalitis
- Diagnosis—for biting/stinging insects, **must pursue skin testing**
- Treatment
  - Local—cold compresses, topical antipruritic, oral analgesic, systemic antihistamine; **remove stingers by scraping**
  - **If anaphylaxis—epinephrine pen**, ID bracelet, avoid attractants (e.g., perfumes)
  - **Indication for venom immune therapy—severe reaction with + skin tests (highly effective in decreasing risk)**

Food Reactions

- Clinical presentation
  - Most infants and young children **outgrow milk and egg allergy** (half in first 3 years); majority with nut or seafood allergies retain for life:
    - **Most food allergies are—egg, milk, peanuts, nuts, fish, soy, wheat, but any food may cause a food allergy.**

    - **Food allergic reactions are most common cause of anaphylaxis seen in emergency rooms**
  - With food allergies, there is an **IgE and/or a cell-mediated response.**
  - Manifestations:
    - Skin—**urticaria/angioedema** and flushing, **atopic dermatitis;** 1/3 of children with atopic dermatitis have food allergies, but most common is acute urticaria/angioedema
    - Gastrointestinal—oral pruritus, nausea, **vomiting, diarrhea, abdominal pain,** eosinophilic gastroenteritis (**often first symptoms to affect infants**): predominantly a **cell-mediated response, so standard allergy tests are of little value; food protein–induced enterocolitis/proctocolitis presents with bloody stool/diarrhea** (**most cow milk or soy protein allergies**)
    - Respiratory—nasal congestion, rhinorrhea, sneezing, laryngeal edema, dyspnea, **wheezing, asthma**
    - Cardiovascular—dysrhythmias, **hypotension**
- Diagnosis
  - Must establish the food and amount eaten, timing, and nature of reaction
  - Skin tests, IgE-specific allergens are useful for IgE sensitization.
    - A negative skin test excludes an IgE-mediated form, but because of cell-mediated responses, may need a **food elimination and challenge test** in a controlled environment (**best test**)
- Treatment
  - **Only validated treatment is elimination**
  - **Epinephrine pens** for possible anaphylaxis

Urticaria and Angioedema

Causes:

- Acute, IgE-mediated (duration ≤6 weeks)
  - Activation of mast cells in skin
  - Systemically absorbed allergen: food, drugs, stinging venoms; with allergy, penetrates skin → hives (urticaria)
- Non IgE-mediated, but stimulation of mast cells
  - **Radiocontrast agents**
  - Viral agents (especially EBV, hepatitis B)
  - Opiates, NSAIDs
- Physical urticarias; environmental factors—temperature, pressure, stroking, vibration, light
- Hereditary angioedema
  - Autosomal dominant
  - C1 esterase-inhibitor deficiency
  - Recurrent episodes of nonpitting edema
- Diagnosis mainly clinical; skin tests, IgE-specific allergens (blood)
- Treatment
  - Most respond to avoidance of trigger and oral antihistamine
  - Severe—epinephrine, short-burst corticosteroids

  - If H_1 antagonist alone does not work, **H_1** plus **H_2** antagonists are effective; consider steroids
  - For chronic refractory angioedema/urticaria → IVIg or plasmapheresis

Anaphylaxis

- Sudden release of active mediators with cutaneous, respiratory, cardiovascular, gastrointestinal symptoms
- Most common reasons
  - In hospital—**latex, antibiotics**, IVIg (intravenous immunoglobulin), radiocontrast agents
  - Out of hospital—food (**most common is peanuts**), insect sting, oral medications, idiopathic
- Presentation—reactions from ingested allergens are delayed (minutes to 2 hours); with injected allergen, reaction is immediate (more gastrointestinal symptoms)
- Treatment
  - What the patient should do immediately:
    - **Injectable epinephrine**
    - Oral liquid diphenhydramine
    - Transport to ER
  - Medical:
    - **Oxygen and airway management**
    - Epinephrine IM (IV for severe hypotension); intravenous fluid expansion; H_1 antagonist; corticosteroids; nebulized, short-acting beta-2 agonist (with respiratory symptoms); H_2 antagonist (if oral allergen)

Atopic Dermatitis (Eczema)

- Epidemiology/pathophysiology
  - Interaction among genetic, environmental, and immunologic factors; familial with strong maternal influence
  - Majority develop allergic rhinitis and/or asthma
  - Most have increased eosinophils and IgE
- Clinical presentation
  - **Half start by age 1 year**; most by age 1 and 5 years; chronic or relapsing
  - Intense cutaneous reactivity and **pruritus**; worse at night; scratching induces lesions; becomes excoriated
  - Exacerbations with foods, inhalants, bacterial infection, decreased humidity, excessive sweating, irritants
  - Patterns for skin reactions:
    - Acute: **erythematous papules, intensely pruritic, serous exudate and excoriation**
    - Subacute—erythematous, excoriated, **scaling papules**
    - Chronic—**lichenification** (thickening, darkening)

Courtesy of Tom D. Thacher, M.D.

Figure 9-1. Subacute and Chronic Atopic Dermatitis Most Commonly Affects the Flexural Surfaces of Joints

  - Distribution pattern:
    - Infancy: **face, scalp, extensor** surfaces of extremities
    - Older, long-standing disease: **flexural** aspects
    - Often have remission with age, but skin left prone to itching and inflammation when exposed to irritants
- Treatment
  - Identify and eliminate causative factors
  - **Cutaneous hydration**
    - **Dry skin, especially in winter (xerosis)**
    - Lukewarm soaking baths followed by application of occlusive emollient (hydrophilic ointments)
  - **Topical corticosteroids**
    - **Seven classes—the higher potency classes are not to be used on face or intertriginous areas and only for short periods**
    - **Goal—emollients and low-potency steroids for maintenance**
  - Topical immunomodulators; **tacrolimus** (calcineurin inhibitor):
    - Inhibits activation of key cells
    - Ointment safe and effective
    - **Safe on face**
    - Can use as young as age **2 years**

  - Tar preparations
  - Phototherapy—UV light
  - Systemic: antihistamines (sedating at night; for pruritus); glucocorticoids; cyclosporine (refractory to all other treatment); interferon (if all else fails)
  - Treat with antibiotics for bacterial superinfection
- Complications
  - Secondary bacterial infection, especially *S. aureus*; increased incidence of *T. rubrum, M. furfur*
  - Recurrent viral skin infections—**Kaposi varicelliform eruption (eczema herpeticum) most common**
  - Warts/molluscum contagiosum

Contact Dermatitis

- Irritant
  - Nonspecific injury to skin
  - Results from prolonged or repetitive contact with various substances (e.g., diaper rash)
- Allergic
  - **Delayed hypersensitivity reaction (type IV)**; provoked by antigen applied to skin surface
  - Intense itching; chronically can mimic atopic dermatitis
  - Distribution provides clue to diagnosis
  - Causes—jewelry (especially nickel), shoes, clothing, and plants (poison ivy)
- Diagnosis—clinical
- Treatment—supportive; eliminate contact with allergen; cool compresses

ASTHMA

A 6-year-old boy presents to his physician with end-expiratory wheezing scattered throughout the lung fields. He is noted to have nasal flaring, tachypnea, and intercostal retractions. These symptoms are triggered by changes in the weather. He has a family history of asthma and atopic dermatitis. He has never been intubated or admitted to the pediatric ICU. His last hospitalization for asthma was 6 months ago. He takes medication for asthma only when he starts to wheeze.

- Etiology/pathophysiology
  - Chronic inflammation of airways with episodic at least partially reversible airflow obstruction
    - Genetic and environmental factors: concomitant allergies (perennial in most), induced by common viral agents, tobacco smoke; cold, dry air; strong odors
    - Most with onset age <6 years; most resolve by late childhood
    - Two main patterns:
      - Early childhood triggered primarily by common **viral infections**
      - Chronic asthma associated with **allergies** (often into adulthood; atopic)

- **Some risk factors for persistent asthma:** perennial allergies; atopic dermatitis, allergic rhinitis, food allergy; severe lower respiratory tract infections; wheezing other than with URIs (exercise, emotions); environmental tobacco smoke exposure; low birth weight

- Clinical presentation
  - **Diffuse wheezing, expiratory then inspiratory**
  - **Prolonged expiratory phase**
  - Decreased breath sounds
  - Rales/rhonchi → excess mucus and inflammatory exudate
  - Increased work of breathing
  - Exercise intolerance
- Diagnosis
  - **In children, neither lab tests nor provocation challenge tests are required for diagnosis; they may support the clinical diagnosis or may be used to follow the patient clinically.**
  - Lung function:
    - **Gold standard = spirometry during forced expiration**. $FEV_1/FVC < 0.8$ = airflow obstruction (the forced expiratory volume in 1 second adjusted to the full expiratory lung volume, i.e., the forced vital capacity) in children age ≥ 5 yrs
    - Bronchodilator response to inhaled beta-agonist—improvement in FEV_1 to >12%
    - Exercise challenge—worsening in FEV_1 of at least 15%
    - **Home tool—peak expiratory home monitoring (PEF);** A.M. and P.M. PEF for several weeks for practice and to establish personal best and to correlate to symptoms; based on personal best, divide PEFs into zones: green (80–100%), yellow (50–80%), red (<50%)
  - Radiology (no routine use):
    - **Hyperinflation—flattening of the diaphragms**
    - **Peribronchial thickening**
    - Use to identify other problems that may mimic asthma (e.g., aspiration with severe gastroesophageal reflux) and for complications during severe exacerbations (atelectasis, pneumonia, air leak)
- Treatment—based on asthma severity classification
  - Intermittent: symptoms ≤2 days/week and ≤2 nights/mo
    - No need for daily controller
  - Persistent (mild → moderate → severe) symptoms > intermittent
    - Need daily controller

Table 9-1. Severity Classification and Treatment (simplified from National Asthma Education and Prevention Program)

Class	Daytime Symptoms	Nighttime Symptoms	Treatment
Intermittent	≤2×/week	≤2×/month	Short-acting β, agonist PRN
Mild persistent	>2×/week	>2×/month	Inhaled steroids β agonist for, breakthrough
Moderate persistent	Daily	>1×/week	Inhaled steroids Long-acting β, agonist Short-acting β for, breakthrough Leukotrine-receptor antagonists
Severe persistent	Continual;, limited activities; frequent exacerbations	Frequent	High-dose inhaled steroid Long-acting β agonist Short-acting β agonist Systemic steroids Leukotrine-receptor antagonists

Note

With all asthma categories, a step-up, step-down dosing is typically used (high at first, then down to minimum necessary to prevent symptoms).

- Asthma medications
  - **Quick-relief medications**
    - Short-acting beta-2 agonists: **albuterol, levalbuterol** (nebulized only), terbutaline, metaproterenol (rapid onset, may last 4–6 hrs; **drug of choice for rescue and preventing exercise-induced asthma but inadequate control if need >1 canister/month**
    - Anticholinergics (much less potent than beta agonists): **ipratropium bromide**; mostly for added treatment of acute severe asthma in ED and hospital
    - Short-course systemic glucocorticoids: outpatient for moderate to severe flare-up, and prednisone 3–7 days; inpatient recommended with IV methylprednisolone IV

Note

Older children can use a metered dose inhaler (MDI); younger children often need to do so with a spacer and face mask. Infants may need to have nebulized medications.

- Management of asthma exacerbations
  - Emergency department:
    - Monitor, **oxygen** as needed
    - Inhaled **albuterol** q 20 minutes for one hour—add **ipratropium** if no good response for second dose
    - **Corticosteroids PO or IV**
    - Can go home if sustained improvement with normal physical findings and **SaO_2 >92% after 4 hours in room air**; PEF ≥70% of personal best
    - Home on q 3–4 hour **MDI + 3–7-day oral steroid**
  - Hospital—**for moderate–severe flare-ups without improvement within 1–2 hours of initial acute treatment with PEF <70% of personal best or SaO_2 <92% on room air**:
    - **Oxygen**
    - Nebulized **albuterol** (very frequently or continuous)
    - Add **ipratropium** q 6 hours

Note

Adjunct Treatment to Prevent Intubation and Ventilation

- IV beta agonist
- IV theophylline
- Heliox (70:30 $He:O_2$); decreased airway resistance and clinical response in 20 min
- IV $MgSO_4$– smooth-muscle relaxant; monitor BP every 10–15 min (risk of hypotension)

- **Intravenous corticosteroids**
- May need intravenous fluids
- Mechanical ventilation (rare)

Table 9-2. Bronchiolitis vs. Asthma

Feature	Bronchiolitis	Asthma
Etiology	Most RSV	Reversible bronchoconstriction with chronic inflammation
Age	Infants (especially <1 year)	Most start age <5 years
Timing	• Winter	• All year • Most with URI in winter
Diagnosis Key Words	• URI from another household contact • Getting worse • Fever • Tachypnea • Bilateral expiratory wheezing ± respiratory distress • Apnea	• Repeated episodes of expiratory wheezing • Chronic non-productive cough • Chest tightness • Respiratory distress • May have other atopic disease + family history • May occur primarily with URIs • Cannot make diagnosis of asthma for first-time wheezing in infant with fever (diagnosis is bronchiolitis)
Best Initial Test	• Clinical Dx • CXR only if severe and therefore possibility of secondary bacterial pneumonia	Worsening of FEV1/FVC with exercise and improvement with beta-agonist
Most Accurate Test	• NP rapid test or PCR for organism • ABG only for severe to evaluate possible need for ventilation	• Repeated episodes that improve with beta-agonist
Treatment	• Oxygen, if needed • Supportive Rx • May try nebulized hypertonic saline • Ribavirin in severe or worsening cases MAY prevent the need for intubation and ventilation	• Oxygen • Short-acting beta-agonist • Add oral steroid for acute attack • May need chronic maintenance Rx

Immune-Mediated Disease 10

Learning Objectives

- ❏ Explain information related to evaluation of suspected immune deficiency
- ❏ Categorize specific defects of immune deficiency

EVALUATION OF SUSPECTED IMMUNE DEFICIENCY

Table 10-1. Suspecting Immunodeficiency by Major Defect

	B-Cell	T-Cell	Complement	Neutrophil
Common organism	**Recurrent bacterial:** streptococci, staphylococci, *Haemophilus, Campylobacter*; ***Viral:*** *enteroviruses;* *Uncommon: giardia, cryptosporidia*	**Opportunistic organisms:** CMV, EBV, varicella, *Candida*, Pneumocystis jiroveci, mycobacteriwa	*Pneumococci, Neisseria*	**Bacteria:** Staphylococci, *Pseudomonas, Serratia, Klebsiella, Salmonella;* **Fungi:** *Candida, Aspergillus*
Age onset	5-7 months of age or later childhood to adult	Usually 2-6 months of age	Any age	Early onset
Infections	Most are **recurrent sinopulmonary infections and recurrent enteroviral meningitis**	**Mucocutaneous candidiasis;** pulmonary and GI infections	**Meningitis,** arthritis, septicemia, recurrent sinopulmonary infections	**Skin abscesses**, impetigo, cellulitis, **suppurative adenitis**, gingivitis, **oral ulcers**, osteomyelitis, internal organ abscesses
Other findings	**Autoimmunity, lymphoreticular malignancy**	**Chronic diarrhea and failure-to-thrive**; postvaccination dissemination - varicella, BCG; hypocalcemia in infancy; **graft-versus-host** from transplacental maternal engraftment or nonirradiated blood	Autoimmune disorders, vasculitis, glomerulonephritis, **angioedema**	**Prolonged attachment of umbilical cord**, poor wound healing, decreased signs of infection
Best initial test	**Screen with IgA**→if low, measure IgG and IgM (**quantitative immunoglobulins**)	Lymphocyte count (low)	Screen is total hemolytic complement (CH_{50})—will be depressed if any component is consumed	Neutrophil count
Other tests	Low antibody titers to specific antigens—isohemmaglutinins, vaccines	**Best cost-effective test for T-cell function – *Candida* skin test**	Identify mode of inheritance—all are autosomal except for properdin deficiency (X-linked)	Neutrophil respiratory burst after phorbol ester stimulation; most reliable now uses **rhodamine fluorescence (replaced the NBT test)**
Specific tests	Enumerate B-cells with **flow cytometry** (monoclonal antibodies to B-cell-specific CD antigens): B cell absent or present and number	Flow cytometry using monoclonal antibodies recognizing T-cell CD antigens (phytahemmaglutinin, concanavalin A, pokeweed mitogen)	Can easily measure C3 and C4 (hereditary angioedema); others require a research lab	Can identify leukocyte adhesion deficiencies with flow cytometric assays of lymphocytes and neutrophils (CD18, CD11, CD15)

Note: For each, the **most accurate test** is **molecular genetic diagnosis**.

SPECIFIC DEFECTS

Defects of Antibody Production

X-linked (Bruton) agammaglobulinemia

X-linked (Bruton) agammaglobulinemia (XLA) is a profound **defect in B-cell development** which leads to an absence of circulating B cells and thus leads to severe hypogammaglobulinemia **with small-to-absent tonsils and no palpable lymph nodes.**

- **Genetics:** >500 known mutations of the Btk gene (Bruton tyrosine kinase), which is necessary for pre-B-cell expansion and maturation; long arm of **X-chromosome**
- **Clinical findings: boys with pyogenic sinopulmonary infections**
- **Diagnosis:** clinical presentation + **lymphoid hypoplasia on exam; all immunoglobulins severely depressed**; flow cytometry shows absence of circulating B-cells; gene sequencing for specific mutation
- **Treatment:** appropriate use of antibiotics + **regular monthly IVIG**

NOTE: The only 2 B-cell defects for which stem cell transplantation is recommended are CD40 ligand defect (extremely rare; one of the known mutations on the X-chromosome for hyper IGM syndrome) and X-linked lymphoproliferative disease.

Common variable immunodeficiency

Common Variable Immunodeficiency (CVID) is hypogammaglobulinemia with phenotypically normal B-cells; **blood B-lymphocytes do not differentiate into IG-producing cells**

- **Genetics:** majority have no identified molecular diagnosis, so are sporadic; may have a common genetic basis with selective IgA deficiency (occurs in families together and some later with IgA may develop CVID)
- **Clinical findings:** boy or girl (**equal sex distribution**) with **later onset infections**, less severe; clinically similar to XLA, but rare echovirus meningoencephalitis
- **Diagnosis:** clinical presentation + serum IG and antibody deficiencies as profound or less than in XLA; **normal sized lymphoid tissue; later autoimmune disease and malignancy** (**lymphoma**)
- **Treatment:** need to be **screened for anti-IgA antibodies** (as in selective IgA deficiency)→ if present, therapy consists of the one IG preparation available that contains no IgA.

Selective IgA deficiency

Selective IgA deficiency is the **most common immunodeficiency**. It is caused by the absence or near absence of serum and secretory IgA with phenotypically normal B-cells

- **Genetics:** basic defect is unknown; boys and girls and **familial pattern** suggests autosomal dominant with variable expression; **also seen in families with CVID** (as above); both may be triggered by environmental factors
- **Clinical findings:** same bacteria as others with most infections in **respiratory, GI and urogenital** tracts; giardiasis is common

- **Diagnosis: very low-to-absent serum IgA with other IGs normal**; as with CVID, incidence of autoantibodies, autoimmune disease and malignancy increased; **serum antibodies to IgA can cause severe anaphylactic reactions if any blood product with IgA is administered (NOT a transfusion reaction)**
- **Treatment: IVIG is not indicated** (95–99% is IgG) because if usual IVIG (containing IgA) product is given, patients are at risk for severe reaction. Additionally, because it is specifically an IgA deficiency, the IVIG product with the IgA removed cannot be used. Treat the infections (generally milder).

Defects of Cellular Immunity (T-cell defects)

DiGeorge syndrome (thymic hypoplasia)

DiGeorge syndrome is thymic and parathyroid hypoplasia to aplasia from **dysmorphogenesis of the 3rd and 4th pharyngeal pouches**. Other structures are also involved: great vessel anomalies (right-sided aortic arch, interrupted aortic arch), esophageal atresia, bifid uvula, congenital heart disease (conotruncal malformations, septal defects), facial dysmorphism (short philtrum, thin upper lip, hypertelorism, mandibular hypoplasia, low-set, often notched ears), and cleft palate.

- **Genetics: microdeletions of 22q11.2** (DiGeorge syndrome chromosomal region, DGCR); 22q deletions also seen in velocardiolfacial syndrome and conotruncal anomaly face syndrome (**CATCH 22 syndromes:** Cardiac, Abnormal facies, Thymic hypoplasia, Cleft palate, Hypocalcemia); partial DiGeorge is more common, with variable thymic and parathyroid hypoplasia. About 1/3 with complete DiGeorge have the **CHARGE association**. Must confirm diagnosis for complete form by molecular genetics (fatal without definitive treatment).
- **Clinical findings:** from almost no infections with normal growth to **severe opportunistic infections and graft-versus-host disease**. **In most, initial presentation is neonatal hypocalcemic seizures.**
- **Diagnosis:** most with only moderately low absolute lymphocyte counts with variably decreased CD3 T-lymphocytes per the degree of thymic hypoplasia and variable response to mitogen stimulation. **Must get a T-cell count on all infants born with primary hypoparathyroidism, CHARGE, truncus arteriosus and interrupted aortic arch**
- **Treatment:** complete form correctable with either culture unrelated thymic tissue transplants or bone marrow or peripheral blood transplantation from HLA-identical sibling

Note

The rest of the isolated T-cell defects are extremely rare, known only to immunologists. They are not seen on the exam.

Combined Antibody and Cellular Immunodeficiencies

Severe combined immunodeficiency

Severe Combined Immunodeficiency (SCID) is the absence of all **adaptive immune function**, and in some, **natural killer cells** due to diverse mutations. It is the most severe immunodeficiency known.

- **Genetics:** mutations of any one of 13 genes encoding the components of immune system critical for lymphoid cell development; result in very small thymuses which

fail to descend from the neck and a lack of normal components + splenic depletion of lymphocytes and absent (or very undeveloped) remaining lymphatic tissue. X-linked SCID is the most common form in the United States.

- **Clinical findings: first 1-3 months of life with recurrent/persistent diarrhea and opportunistic infections that may lead to death; also at risk for graft-versus-host disease from maternal immunocompetent T-cells that crossed the placenta in utero**
  - **If patient continues to live without treatment, typical B-cell related infections will develop**
- **Diagnosis:** all patients have lymphopenia from birth, low-to-absent T-cells and absence of lymphocyte proliferative response to mitogens low-to-absent serum IGs and no antibodies after immunizations. The X-linked form has a low percentage of T and NK cells; autosomal recessive form more common in Europe (mutated forms in 12 genes). ADA deficiency affects primarily T-cell function (most severe lymphopenia from birth; second most common form; deletions of chromosome 20).
- **Treatment: stem cell transplantation** (HLA-identical or T-cell depleted half-matched parental); without it, most patients will die in first year but if diagnosed in first 3-4 months and treated, 94% will survive. The ADA form and X-linked have been treated with somatic gene therapy.

Combined immunodeficiency

Combined immunodeficiency is the **presence of low but not absent T-cell function and low but not absent antibodies;** patients survive longer but have failure-to-thrive and still die relatively early in life which are:

Wiskott-Aldrich syndrome

Wiskott-Aldrich Syndrome is an impaired humoral immune response and highly variable concentrations of the IGs with moderately reduced T-cells and variable mitogen responses.

- **Genetics: X-linked recessive** (Xp11.22-11.23); encodes a cytoplasmic protein restricted in expression to hematopoietic cell lines (WASP = Wiskott-Aldrich Syndrome Protein)
- **Clinical findings:** (1) thrombocytopenia presenting in neonatal period or early infancy most commonly with prolonged circumcision bleeding or bloody diarrhea, (2) atopic dermatitis, and (3) recurrent infections in first year of life (early encapsulated bacteria causing otitis, pneumonia, meningitis and sepsis, then later opportunistic infections)
- **Diagnosis:** clinical and molecular genetics; most common IG pattern is low IgM, high IgA and IgE and normal to slightly low IgG and variably reduced T-cells.
- **Treatment:** rare survival beyond adolescence (bleeding, infections and EBV-associated malignancies and autoimmune complications) without a **bone marrow transplant**

Ataxia-telangiectasia

Ataxia-telangiectasia is a moderately depressed response to T and B-cell mitogens, moderately reduced CD3 and CD4 T-cells with normal or increased percentages of CD8, T-helper cell and intrinsic B-cell defects, and hypoplastic thymus.

- **Genetics:** AT mutation (ATM) at 11.22-23
- **Clinical findings:** (1) ataxia evident with onset of walking and progresses until age 10-12 years when confined to a wheelchair (2) oculocutaneous telangiectasias develop at 3-6 years of age and (3) recurrent sinopulmonary infections most with common viruses and occasional fatal varicella; lymphoreticular malignancies and adenocarcinomas develop later; unaffected relatives also have increased incidence of malignancies
- **Treatment:** supportive care

Disorders of Phagocytic Function

Leukocyte adhesion deficiency

Leukocyte adhesion deficiency is a rare disorder of leukocyte function causing recurrent bacterial and fungal infections and **decreased inflammatory responses in the presence of neutrophilia (increased counts)**.

- **Genetics:** autosomal recessive with 3 types; affects neutrophil adhesion; mutation of 21q22.3 (results in decreased expression of β_2-integrin to the endothelial surface, exiting of neutrophils from the circulation and adhesion to microorganisms (which promotes phagocytosis and activation of NAPH oxidase)
- **Clinical findings:** infant with recurrent, **low-grade bacterial infections of the skin, large chronic oral ulcers with polymicrobes and severe gingivitis; respiratory tract and genital mucosa; delayed separation of the umbilical cord with omphalitis; typical signs of inflammation may be absent and there is no pus formation; most common organisms are *S. aureus,* gram-negatives and *Candida and Aspergillus***
- **Diagnosis: paucity of neutrophils in affected tissue but circulating neutrophil count is significantly elevated**; assessment of neutrophil and monocyte adherence, aggregation, chemotaxis and phagocytosis are all abnormal diagnosis confirmed with flow cytometry showing low CD15 on neutrophils
- **Treatment:** early allogenic stem-cell transplantation for severe forms otherwise supportive care

Chronic granulomatous disease

Chronic granulomatous disease (CGD) is when neutrophils and monocytes phagocytize but cannot kill **catalase-positive microorganisms as a result of a defect in production of oxidative metabolites.**

- **Genetics/pathogenesis:** one **X-lined** and 3 autosomal recessive genes; most are **males** with X-linked inheritance; neutrophils do not produce **hydrogen peroxide, which usually acts as a substrate for myeloperoxidase** needed to oxidize halide to hypochlorous acid and chloramines that kill microbes; if organism is **catalase**

positive, the organism's hydrogen peroxide is metabolized and the organism survives, **while catalase-negative organisms survive**

- **Clinical findings:** variable age on onset and severity; **recurrent abscesses** (skin, lymph nodes, liver), pneumonia, osteomyelitis; most common pathogens are ***S aureus*** and then *S marcesens, B cepacia**, Aspergillus and C. albicans**, Nocardia and Salmonella;* granuloma formation (due to abnormal accumulation of ingested material) and inflammatory processes are the hallmark (pyloric outlet obstruction, bladder or ureteral obstruction, rectal fistulae or granulomatous colitis
- **Diagnosis**: flow cytometry using **dihydrorhodamine 123 (DHR) to measure oxidant production through increased fluorescence when oxidized by hydrogen peroxide (has taken the place of the NBT);** identifying specific genetic subgroup is useful for genetic counseling and prenatal diagnosis
- **Treatment:** only cure is stem cell transplant; otherwise supportive care including interferon to reduce serious infections

OTHER IMMUNE DEFICIENCIES

Chediak-Higashi Syndrome

- Autosomal recessive
- Abnormal secretory/storage granules lead to large and irregular seen in neutrophils
- Oculocutaneous albinism from birth, prolonged bleeding time, peripheral neuropathy, recurrent infections
- Bone marrow transplant or death from infection or lymphoproliferative-like disorder

Complement Deficiencies (rare)

- Total hemolytic complement screens for most disease of the system; it depends on all 11 components of the classical system; alternative pathway activity (D and B factors) and properdin can be diagnosed with a different assay (AP_{50})
- All components are autosomal recessive or co-dominant, except for properdin deficiency which is X-linked recessive
- Decrease in both C3 and C4 suggests activation of the alternative pathway; this is most useful in distinguishing nephritis secondary to immune complex deposition from that due to nephritic factor
- Defect in complement function: recurrent angioedema, autoimmune disease, chronic nephritis, HUS, recurrent pyogenic infections, disseminated meningococcal or gonococcal infections or a second episode of bacteremia at any age; high incidence of pneumococcal and meningococcal infections
- The only significant one (in terms of numbers of people) is ineffective synthesis of active C1 inhibitor which produces hereditary angioedema.

Graft-Versus-Host Disease (GVHD)

- Major cause of morbidity and mortality after allogenic stem cell transplantation
- Caused by engraftment of immunocompetent donor lymphocytes in an immunocompromised host that shows histocompatibility differences with the donor lead to donor T-cell activation against recipient major or minor MHC antigens
- Acute GVHD: 2-5 weeks post-transplant; erythematous maculopapular rash, persistent anorexia, vomiting and/or diarrhea and abnormal liver enzymes and LFTs; primary prevention is with post-transplant immunosuppressive drugs and corticosteroids
- Chronic GVHD: develops or persists >3 months after transplant; major cause of non-relapse morbidity and mortality in long-term transplant survivors
  - Disorder of immune regulation: autoantibody production, increased collagen deposition and fibrosis and signs and symptoms of autoimmune disease

Disorders of the Eye 11

Learning Objectives

- ❏ Answer questions about congenital and acquired abnormalities of the eye structures
- ❏ Recognize and describe treatment approaches to periorbital versus orbital cellulitis

ABNORMALITIES OF THE EYE STRUCTURES

Pupils and iris

- **Coloboma of iris**
  - Often autosomal dominant
  - Defect of lid, iris, lens, retina, or choroid
  - Always inferior—**keyhole appearance of iris; in lid, manifests as cleft**
  - **Possible CHARGE association**
- **Leucokoria—white reflex**
  - **Retinoblastoma**
  - **Cataract**
  - Retinopathy of prematurity
  - Retinal detachment
  - Larval granulomatosis

Lens

- Cataracts—lens opacities; the most important congenital etiologies:
  - Prematurity (many disappear in a few weeks)
  - Inherited—most autosomal dominant
  - Congenital infection—TORCH (especially **rubella**); also, measles, polio, influenza, varicella, vaccinia
  - **Galactosemia**
  - Chromosomal (trisomies, deletions and duplications, XO)
  - Drugs, toxins, and trauma (**steroids**, contusions, penetrations)
- Ectopia lentis—instability or displacement of lens; edge of displaced lens may be visible in pupillary aperture
  - Differential:
    - **Trauma—most common**
    - Uveitis, congenital glaucoma, cataract, aniridia, tumor

- Systemic causes: **Marfan syndrome** (most with superior and temporal; bilateral), **homocystinuria** (inferior and nasal), **Ehlers-Danlos**

Ocular muscles

- **Strabismus**
  - Definition—Misalignment of the eyes from abnormal innervation of muscles
  - Diagnosis—**Hirschberg corneal light reflex**—most rapid and easily performed; **light reflex should be symmetric and slightly nasal to center of each pupil**
  - Patch the good eye to eliminate amblyopia, then eye muscle surgery
- Pseudostrabismus
  - Epicanthal folds and broad nasal bridge
  - Caused by unique facial characteristics of infant
  - Transient pseudostrabismus; common up to age 4 months

Conjunctiva

A 12-hour-old newborn is noted to have bilateral conjunctival injection, tearing, and some swelling of the left eyelid. Physical examination is otherwise normal.

- **Ophthalmia neonatorum**
  - Redness, chemosis, edema of eyelids, purulent discharge
  - Causes:
    - Chemical conjunctivitis **most common in first 24 hours of life**
    - From silver nitrate and erythromycin
    - *N. gonorrhea*—**2–5-day incubation**; may be delayed >5 days due to suppression from prophylactic eye treatment; mild inflammatory and serosanguineous discharge, then thick and purulent; complications are corneal **ulceration**, perforation, iridocyclitis
    - *C. trachomatis*—**5–14-day incubation; most common;** mild inflammation to severe swelling with purulent discharge; mainly **tarsal conjunctivae**; cornea rarely affected
  - **Diagnosis—Gram stain, culture, PCR (polymerase chain reaction) for chlamydia**
  - Treatment:
    - ***N. gonorrhea*: ceftriaxone × 1 dose IM + saline irrigation until clear**
    - **Chlamydia: erythromycin PO × 2 weeks + saline irrigation until clear (may prevent subsequent pneumonia)**
- **The red eye**
  - Bacterial conjunctivitis
    - General conjunctival hyperemia, edema, **mucopurulent exudate** (crusting of lids together), and eye discomfort
    - Unilateral or bilateral
    - *S. pneumonia, H. influenza* (non-typable), *S. aureus*, other strep
    - Treatment—warm compresses and **topical antibiotics**

Note

Chemical: first day

Gonorrhea: first week

Chlamydia: second week (most common)

Note

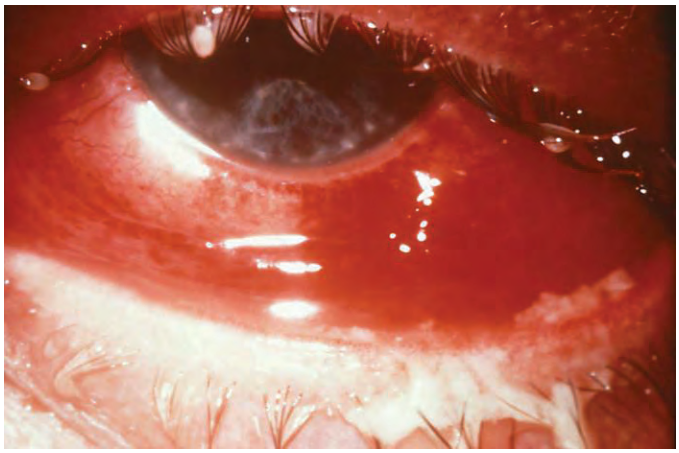
Congenital **nasolacrimal duct obstruction** (dacryostenosis)

- Failure of canalization of duct as it enters the nose
- Excessive tears, **mucoid material** that is produced in the lacrimal sac, erythema
- Treatment—**nasolacrimal massage** 2–3×/day and warm water cleansing
- **Most resolve <1 year of age**

Note

Topical erythromycin *does not* prevent chlamydia conjunctivitis.

- Viral conjunctivitis
  - **Watery discharge, bilateral, usually with URI**
  - Adenovirus, enterovirus
  - Epidemic keratoconjunctivitis = adenovirus type 8
  - Good hand-washing



phil.cdc.gov.

Figure 11-1. Purulent, Bacterial Conjunctivitis Secondary to Gonococcal Infection of the Eye

- Allergic
- Chemical
  - Household **cleaning substances**, sprays, smoke, smog
  - Extensive tissue damage, loss of sight
- Keratitis—**corneal** involvement
  - **H. simplex, adenovirus**, *S. pneumoniae, S. aureus*, pseudomonas, chemicals
- Foreign bodies → corneal abrasion (pain, photophobia)
- Anterior uveitis = iridocyclitis (from ciliary body to iris)
- Periorbital versus orbital cellulitis (*see below*)
- Dacryocystitis (*S. aureus, H. influenza, S. pneumoniae*), dacroadenitis (*S. aureus*, streptococci, CMV [cytomegalovirus], measles, EBV [Epstein-Barr virus], trauma)
- Treatment—underlying cause and topical steroids

Retina and vitreous

- Retinopathy of prematurity (ROP)
  - **Prematurity, hyperoxia, and general illness**
  - From mild to severe progressive **vasoproliferative scarring** and blinding retinal detachment
  - Treatment—**cryosurgery or laser photocoagulation**

- Retinoblastoma
  - **Most common primary malignant intraocular tumor**
    - Recessive-suppressive gene—13q14 → family members need to be screened
  - Average age of diagnosis = 15 months for bilateral and 25 months for unilateral
    - **Rarely discovered at birth**
  - Initial sign in most = **leucokoria**
    - Appears as **white mass**
    - Second most common—**strabismus**
  - Diagnosis—**CT scan** to confirm; **no biopsy** (spreads easily)
  - Need to **consider enucleation—**radiation, chemotherapy, laser therapy, cryotherapy
  - Prognosis poor if extends into orbit or optic nerve

EYE INJURIES

Corneal abrasions

- Symptoms—**pain, tearing**, photophobia, decreased vision
- Diagnosis—first anesthetize eye, then **fluorescein and blue-filtered light (Wood's lamp)**
- Treatment—**pain relief and topical antibiotics**

Foreign body

- Topical anesthetic and irrigation to remove
- If embedded, send to ophthalmologist

PERIORBITAL VERSUS ORBITAL CELLULITIS

Periorbital cellulitis

- Inflammation of **lids and periorbital tissue** without signs of true orbital involvement; insidious onset; low-grade fever; no toxicity
- Causes—**trauma, infected wound**, abscess of lid, **sinusitis, bacteremia** (***H. influenza* nontypable,** *S. pneumoniae, S. aureus*)
- May be first sign of sinusitis that may progress to orbital cellulitis
  - Physical exam: inflammation with intact eye movements; normal vision; no proptosis
- Diagnosis—clinical (blood culture unlikely to be positive)
- Treatment—**oral or IV (depending on severity) antibiotics (cover for *S. aureus* and gram positive resistant strains)**

Orbital cellulitis

A 7-year-old boy presents with swelling around the eye 2 days after suffering an insect bite to the eyelid. There is edema, erythema, and proptosis of the eye. Marked limitation of eye movements are noted. He has a low-grade fever.

- Infection of orbital tissue including subperiosteal and retrobulbar abscesses
- Physical examination
  - Ophthalmoplegia **(eyeball does not move)**
  - Chemosis
  - Inflammation
  - Proptosis
- Toxicity, fever, leukocytosis, acute onset
- Causes: **paranasal sinusitis, direct infection from wound, bacteremia**
- Organisms **nontypable *H. influenza, S. aureus*, beta hemolytic strep, *S. pneumoniae***, anaerobes
- Diagnosis—CT scan with contrast of orbits and surrounding area **(best initial test)**
- Treatment—**Intravenous antibiotics (again, cover for *S. aureus*) and may require sinus and/or orbital drainage** (will give you culture and sensitivities) if no improvement

Disorders of the Ear, Nose, and Throat

12

Learning Objectives

- ❑ Describe diagnosis and treatment of disorders of the ears, nose, and throat in childhood

EARS

External Ear

Otitis externa (swimmer's ear)

- Normal flora of external canal includes ***Pseudomonas aeruginosa*** **(most common cause)**, ***S. aureus*** **(second most common cause)**, coagulase-negative *Staphylococcus*, diphtheroids, *Micrococcus* spp., and viridans streptococci
- Causes—excessive wetness, dryness, skin pathology, or trauma
- Symptoms—**significant pain** (especially with **manipulation of outer ear**), conductive hearing loss
- Findings—edema, erythema, and **thick otorrhea,** preauricular nodes
- Malignant external otitis is invasive to temporal bone and skull base—with facial paralysis, vertigo, other cranial nerve abnormalities
  - **Requires immediate culture, intravenous antibiotics, and imaging (CT scan) → may need surgery**
- Treatment—**topical otic preparations ± corticosteroids**
- Prevention—**ear plugs, thorough drying of canal, and 2% acetic acid after getting wet**

Middle Ear

Otitis media (OM)

A 4-year-old child is seen in the office with a 3-day history of fever and cold symptoms, and now complains of right ear pain. Physical examination is remarkable for a bulging tympanic membrane with loss of light reflex and landmarks.

- Acute, suppurative otitis media; accompanied by a variable degree of hearing loss (20–30 dB)

- Etiology
  - Bacterial in up to 75%
    - ***S. pneumoniae*** (40%)
    - **Nontypeable *H. influenzae*** (25–30%)
    - ***Moraxella catarrhalis*** (10–15%)
  - Other 5%—Group A strep, *S. aureus*, gram negatives (neonates and hospitalized very young infants), respiratory viruses (rhinovirus, RSV most often)

Some Correlated Factors of Otitis Media

- Age: most in first 2 years
- Sex: boys > girls
- Race: more in Native Americans, Inuit
- SES: more with poverty
- Genetic: heritable component
- Breast milk versus formula: protective effect of breast milk
- Tobacco smoke: positive correlation
- Exposure to other children: positive correlation
- Season: cold weather
- Congenital anomalies: more with palatal clefts, other craniofacial anomalies, and Down syndrome

- Pathogenesis
  - Interruption of normal eustachian tube function (ventilation) by obstruction → inflammatory response → middle ear effusion → infection; most with URI
  - Shorter and more horizontal orientation of tube in infants and young children allows for reflux from pharynx (and in certain ethnic groups and syndromes)
- Clinical findings—highly variable
  - Symptoms—ear pain, fever, purulent otorrhea (ruptured tympanic membrane), irritability, or no symptoms
  - Pneumatic otoscopy—fullness/bulging or extreme retraction, intense erythema (otherwise erythema may be from crying, fever, sneezing; erythema alone is insufficient unless intense), some degree of opacity (underlying effusion)
  - Mobility is the most sensitive and specific factor to determine presence of a middle ear effusion (pneumatic otoscopy)
- Diagnosis—must have:
  - Acute onset
  - Tympanic membrane inflammation
  - Middle ear effusion
- Treatment—It is advisable to use routine antimicrobial treatment especially for age <2 years or those systemically ill, with severe infection, or with a history of recurrent acute otitis media.

- Pain relief is essential: acetaminophen, NSAIDs (except acetylsalicylic acid because of risk of Reye syndrome)
- **First-line drug of choice = amoxicillin (high dose)**
- **Alternate first-line drug or history of penicillin allergy = azithromycin**
- In some patients age >2 years who do not have high fevers or severe pain, the physician may just observe and reevaluate in 2-3 days. If no improvement or if any worsening, antibiotics should then be started.
- Duration—10 days; shorter if mild, older child
- Follow up—within days for young infants, continued pain or severe; otherwise 2 weeks (sustained improvement seen in TM)
- **Second-line drugs—if continued pain after 2–3 days**
  - **Amoxicillin — clavulinic acid** (effective against β-lactamase producing strains)
  - Cefuroxime axetil (unpalatable, low acceptance)
  - **IM ceftriaxone (may need repeat 1–2×; for severe infection if oral not possible), if patient is not taking/tolerating oral medications**
  - Also maybe cefdinir (very palatable, shorter duration)
  - If **clinical response to good second-line drug is unsatisfactory**, perform myringotomy or tympanoscentesis

Otitis media with effusion (OME)

- Generally after repeated infections with insufficient time for effusion to resolve
- **Fullness is absent or slight or TM retracted; no or very little erythema**
- Treatment
  - Monthly evaluation
  - Assess hearing if effusion >3 months; most resolve without problems
  - **Recent studies suggest that in otherwise healthy children an effusion up to 9 months in both ears during first 3 years of life poses no developmental risks at 3–4 years of life.**
  - **Routine antibiotic prophylaxis is *not* recommended.**
  - **Tympanostomy tubes**
    - **Suggested for children with bilateral OME and impaired hearing for >3 months; prolonged unilateral or bilateral OME with symptoms (school or behavioral problems, vestibular, ear discomfort); or prolonged OME in cases of risk for developmental difficulties (Down syndrome, craniofacial disorders, developmental disorders).**
    - Likelihood that middle ear ventilation will be sustained for at least as long as tubes remain in (average 12 months)
- Complications
  - Acute mastoiditis—**displacement of pinna** inferiorly and anteriorly and inflammation of posterior auricular area; pain on percussion of mastoid process
    - Diagnosis—When suspected or diagnosed clinically, perform CT scan of temporal bone.
    - Treatment—**myringotomy and IV antibiotics** (*S. pneumoniae*, nontypable *H. influenzae, P. aeroginosa*); if bone destruction, intravenous antibiotics and mastoidectomy

Note

Abnormal Exam Findings

Purulent otorrhea–sign of otitis externa, otitis media with perforation and/or drainage from middle ear through tympanostomy tube

Bulging TM–increased middle ear pressure with pus or effusion in middle ear

TM retraction–negative middle ear pressure (more rapid diffusion of air from middle ear cavity than its replacement via the eustachian tube)

Other findings for an effusion–bubbles, air-fluid level seen behind TM

- **Acquired cholesteatoma** = cyst-like growth within middle ear or temporal bone; lined by keratinized, stratified squamous epithelium
  - Most with long-standing chronic otitis media
  - **Progressively expands**—bony resorption and intracranially; life-threatening
  - **Discrete, white opacity of eardrum** through a defect in TM or persistent malodorous ear discharge
  - **CT scan** to define presence and extent
  - Treatment—**tympanomastoid surgery**

NOSE AND THROAT

Nose

Choanal atresia

A newborn is noted to be cyanotic in the wellborn nursery. On stimulation, he cries and becomes pink again. The nurse has difficulty passing a catheter through the nose.

- Unilateral or bilateral bony (most) or membranous septum between nose and pharynx
  - Half have other anomalies (**CHARGE** association)
  - Unilateral—asymptomatic for long time until first URI, then persistent nasal discharge with obstruction
  - Bilateral—**typical pattern of cyanosis while trying to breathe through nose, then becoming pink with crying**; if can breathe through mouth, will have problems while feeding
- Diagnosis
  - Inability to pass catheter 3–4 cm into nasopharynx
  - Fiberoptic rhinoscopy
  - Best way to delineate anatomy is CT scan
- Treatment
  - Establish oral airway, possible intubation
  - Transnasal repair with stent(s)

Foreign body

- Any small object
- Clinical—unilateral **purulent, malodorous bloody discharge**
- Diagnosis—may be seen with nasal speculum or otoscope; lateral skull film if radiopaque (may have been pushed back, embedded in granulation tissue)
- Treatment—if cannot easily remove with needle-nose forceps, refer to ENT

Epistaxis

An 8-year-old child has repeated episodes of nosebleeds. Past history, family history, and physical examination are unremarkable.

- Common in childhood; decreases with puberty
- Most common area—**anterior septum** (Kiesselbach plexus), prone to exposure
- Etiology
  - **Digital trauma** (nose picking; most common)
  - **Dry air (especially winter)**
  - **Allergy**
  - **Inflammation (especially with URI)**
  - **Nasal steroid sprays**
  - Severe GERD in young infants
  - Congenital vascular anomalies
  - Clotting disorders, hypertension
- Treatment—most stop spontaneously
  - Compress nares, upright, head forward; cold compress
  - If this does not work, then **local oxymetazolone or phenylephrine**
  - If this does not work, then **anterior nasal packing**; if it appears to be coming posteriorly, need **posterior nasal packing**
  - If bleeding site identified, **cautery**
  - Use humidifier, saline drops, petrolatum for prevention

Polyps

- Benign pedunculated tumors from chronically inflamed nasal mucosa
  - Usually from ethmoid sinus external to middle meatus
- **Most common cause is cystic fibrosis—suspect in any child <12 years old with polyp; EVEN in absence of other typical symptoms**
- May also be associated with the Samter triad (polyps, aspirin sensitivity, asthma)
- Presents with **obstruction** → hyponasal speech and mouth breathing; may have profuse mucopurulent rhinorrea
- Examination—generally glistening, gray, grape-like masses
- Treatment—**intranasal steroids/systemic steroids may provide some shrinkage (helpful in CF);** remove surgically if complete obstruction, uncontrolled rhinorrhea, or nose deformity.

Sinusitis

- Acute—viral versus bacterial
- Most with URI—most viral, self-limited; up to 2% complicated by bacterial sinusitis
- Sinus development
  - Ethmoid and maxillary present at birth, but only **ethmoid is pneumatized**

  - Sphenoid present by 5 years
  - Frontal begins at 7–8 years and not completely developed until adolescence
- Etiology—***S. pneumonia*, nontypeable *H. influenzae, M. catarrhalis; S. aureus* in chronic cases**
  - May occur at **any age**
  - Predisposed with URI, allergy, cigarette smoke exposure
  - Chronic—immune deficiency, CF, ciliary dysfunction, abnormality of phagocytic function, GERD, cleft palate, nasal polyps, nasal foreign body
- Pathophysiology—fluid in sinuses during most URIs from nose blowing. Inflammation and edema may block sinus drainage and impair clearance of bacteria.
- Clinical features
  - **Nonspecific complaints—nasal congestion, discharge, fever, cough**
  - Less commonly—bad breath, decreased sense of smell, periorbital edema headache, face pain
  - Sinus tenderness only in adolescents and adults; exam mostly shows mild erythema and swelling of nasal mucosa and discharge
- Diagnosis—**entirely historical and clinical presentation (evidence-based)**
  - **Persistent URI symptoms without improvement for at least 10 days**
  - **Severe respiratory symptoms with purulent discharge and temperature at least 38.9°C (102°F) for at least 3 consecutive days**
    - Only accurate method to distinguish viral versus bacterial is sinus aspirate and culture, but this is NOT done routinely
    - Sinus films/CT scans—show mucosal thickening, opacification, air-fluid levels, but does not distinguish viral versus bacterial
- Treatment
  - Initial—amoxicillin (adequate for majority)
  - Alternative—cefuroxime axetil, cefpodoxime, azithromycin
  - Treat 7 days past improvement
  - If still does not work—to ENT (maxillary sinus aspirate)

Note

The same organisms that are responsible for AOM are also implicated in sinusitis.

Throat

Acute pharyngitis

An 8-year-old girl complains of acute sore throat of 2 day's duration, accompanied by fever and mild abdominal pain. Physical examination reveals enlarged, erythematous tonsils with exudate and enlarged, slightly tender cervical lymph nodes.

- Viruses versus group A beta-hemolytic strep (GABHS)
- Viral—typical winter and spring; close contact
- GABHS—**uncommon <2–3 years of age**; increased incidence in childhood, then decreases in adolescence; **all year long** (but most in cold months)

- Clinical presentation
  - Strep pharyngitis
    - **Rapid onset**
    - **Severe sore throat and fever**
    - **Headache and gastrointestinal symptoms frequently**
    - **Exam—red pharynx, tonsilar enlargement with yellow, blood-tinged exudate, petechiae on palate and posterior pharynx, strawberry tongue, red swollen uvula, increased and tender anterior cervical nodes**
  - Scarlet fever—from GABHS that produce one of three streptococcal pyogenic exotoxins (SPE A, B, C); **exposure to each confers a specific immunity to that toxin, and so one can have scarlet fever up to three times**
    - Findings of pharyngitis plus **circumoral pallor**
    - **Red, finely papular erythematous rash diffusely that feels like sandpaper**
    - Pastia's lines in intertriginous areas
  - Viral—more gradual; with typical URI symptoms; erythematous pharynx, no pus
    - Pharyngoconjunctival fever (adenovirus)
    - **Coxsackie**:
      - Herpangina—small 1–2 mm vesicles and ulcers on posterior pharynx
      - Acute lymphonodular pharyngitis—small 3–6 mm yellowish-white nodules on posterior pharynx with lymphadenopathy
      - **Hand-foot-mouth disease—inflamed oropharynx with scattered vesicles on tongue, buccal mucosa, gingiva, lips, and posterior pharynx → ulcerate; also on hands and feet and buttocks; tend to be painful**
- Diagnosis of strep
  - First—**rapid strep test; if positive, do not need throat culture**
    - **But must confirm a negative rapid test with cultures if clinical suspicion is high**
- Treatment—early treatment only hastens recovery by 12–24 hours **but prevents acute rheumatic fever if treated within 9 days of illness**
  - **Penicillin**
  - **Allergy—erythromycin**
- Complications
  - Retropharyngeal and lateral pharyngeal abscess—deep nodes in neck; infection from extension of localized infection of oropharynx
    - Clinical—nonspecific—fever, irritability, decreased oral intake, **neck stiffness, torticollis, refusal to move neck, muffled voice**
    - **Examination—bulging of posterior or lateral pharyngeal wall**
    - Soft tissue neck film with head extended may show increase width
    - Definitive diagnosis—incision and drainage, **C and S—most polymicrobial (GABHS, anaerobes, *S. aureus*)**
    - **Treatment**
      - Intravenous antibiotics ± surgical drainage
      - **Third-generation cephalosporin plus ampicillin/sulbactam or clindamycin**
      - **Surgical drainage needed if respiratory distress or failure to improve**

Note

Causes of Cervical Lymphadenitis

- Infections
  - Viral/baceterial pharyngitis
  - Cat scratch disease
  - Tb/atypical mycobacteria
  - Mumps
  - Thyroglossal duct cyst
  - Branchial cleft cyst
- Cystic hygroma
- Tumors (rare)

- Peritonsillar abscess—bacterial invasion through capsule of tonsil
  - Typical presentation—adolescent with recurrent history of acute pharyngotonsillitis
  - Sore throat, fever, dysphagia, trismus
  - Examination—**asymmetric tonsillar bulge with displacement of uvula away from the affected side is diagnostic**
  - GABHS + mixed oropharyngeal anaerobes
  - Treatment
    - Antibiotics and **needle aspiration**
    - **Incision and drainage**
    - **Tonsillectomy if recurrence or complications (rupture with aspiration)**

Indications for tonsillectomy, and adenoidectomy

- Tonsillectomy
  - Rate of strep pharyngitis: ≥**7 documented** infections within past year or 5/year for 2 years or 3/year for 3 years
  - Unilateral enlarged tonsil (neoplasm most likely but rare)
- Adenoidectomy
  - Chronic nasal/sinus infection failing medical treatment
  - Recurrent/chronic OM in children with tympanostomy tubes and persistent otorrhea
  - Nasal obstruction with chronic mouth-breathing and loud snoring
- Tonsillectomy and adenoidectomy
  - ≥ 7 infections
  - Upper airway obstruction secondary to hypertrophy resulting in sleep-disordered breathing and complications

Cardiology 13

Learning Objectives

- ❑ Demonstrate understanding of the pediatric cardiac evaluation
- ❑ Categorize disorders in which left-to-right shunt, right-to-left shunt, or hypertension occurs
- ❑ Recognize stenotic, regurgitant, and mixed disorders
- ❑ Cardiac evaluation and congenital heart lesions

CARDIAC EVALUATION AND CONGENITAL HEART LESIONS

Children do not present with the typical features of congestive heart failure as seen in adults. Age is very important when assessing the child.

- Infants:
  - Feeding difficulties
  - Easily fatigued
  - Sweating while feeding
  - Rapid respirations
- Older children:
  - Shortness of breath
  - Dyspnea on exertion
- Physical examination
  - Need to refer to normal heart and respiratory rates for ages to determine tachycardia and tachypnea.
  - Height and weight should be assessed to determine proper growth.
  - Always get upper and lower extremity blood pressures and pulses.
  - Hepatosplenomegaly suggests right-sided heart failure.
  - Rales on auscultation may indicate pulmonary edema and left-sided heart failure.
  - Cyanosis and clubbing result from hypoxia.

Note

Orthopnea and nocturnal dyspnea are **rare** findings in children.

Table 13-1. Heart Murmur Gradation

Grade	Quality
1	Soft, difficult to hear
2	Easily heard
3	Louder but no thrill
4	Associated with thrill
5	Thrill; audible with edge of stethoscope
6	Thrill; audible with stethoscope just off chest

- Diagnostic tests—chest radiograph
  - Evaluate heart size, lung fields, ribs for notching, position of great vessels
  - Electrocardiogram
  - **Echocardiography—definitive diagnosis**
  - Other—MRI, cardiac catheterization, angiography, exercise testing
- Embryology—knowledge of cardiac embryology is helpful for understanding congenital cardiac lesions, their presentations, symptoms, and treatment.

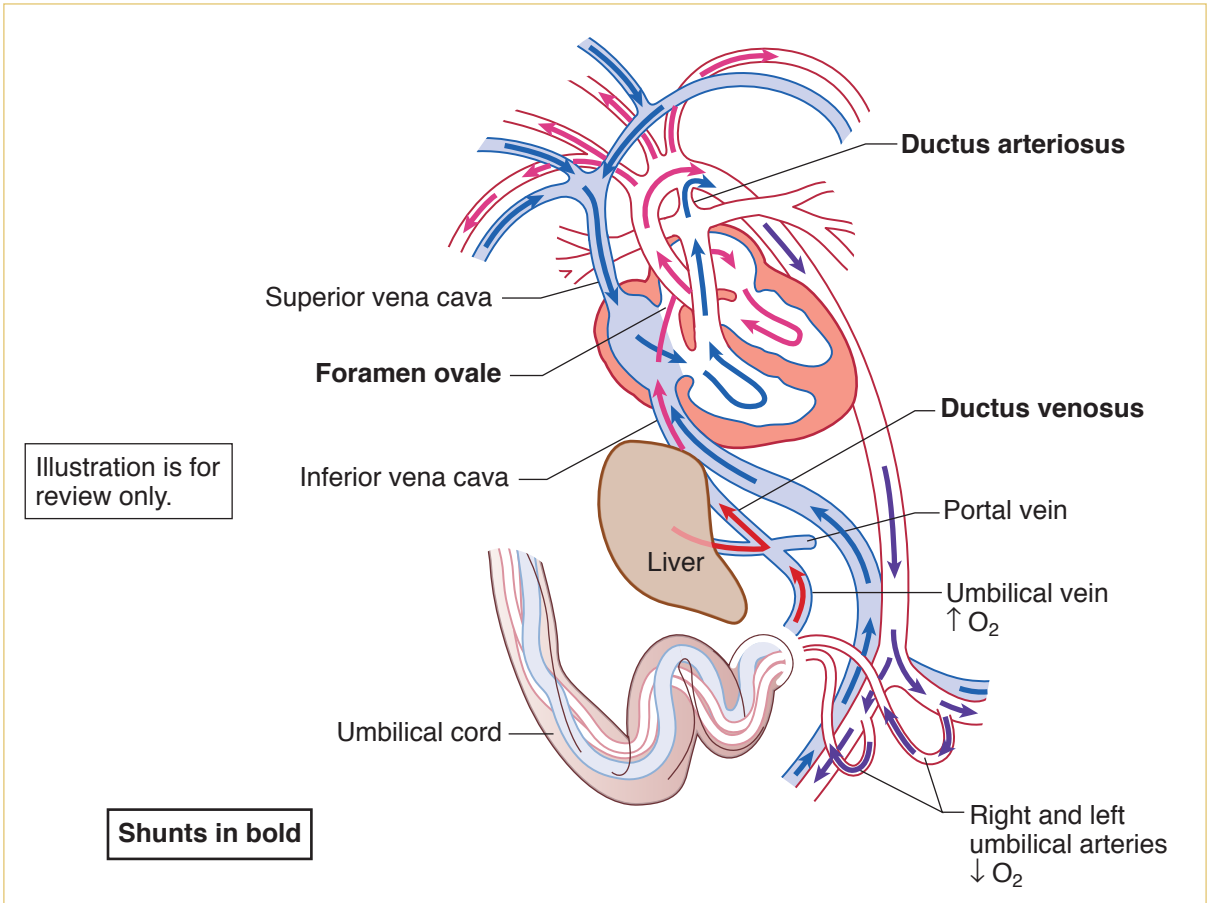


Figure 13-1. Fetal Circulation

PEDIATRIC HEART SOUNDS AND INNOCENT MURMURS

Heart Sounds

First heart sound (S1)

- Closure of mitral and tricuspid valves (MV, TV)
- High pitch, but lower pitch and greater intensity compared to S1
- Usually no discernible splitting of S1 but in completely normal child, a split S1 represents asynchronous closure of the 2 valves (20–30 msec difference); however, what sounds like a split S1 but is not represents pathology:
  - Split S1 best heard at apex or right upper sternal border may be a click (opening of stenotic valve) may be heard in aortic stenosis
  - Apical mid systolic click of mitral valve prolapse
  - At upper left sternal border, a click may be heard from pulmonic valve stenosis; compared to aortic stenosis, this changes with respiration (with inspiration, venous return is increased, thus causing the abnormal pulmonary valve to float superiorly after which the click softens or disappears)
  - Tricuspid valve abnormalities (e.g., Ebstein anomaly) may cause billowing of the leaflets and result in multiple clicks
- S1 may be inaudible at the lower left sternal border mostly due to sounds that obscure the closure of the MV and TV, e.g., in VSD, PDA, mitral or tricuspid regurgitation and severe right ventricular outflow tract obstruction. Therefore, if the **first heart sound is not heard at the lower left sternal border, there is most likely a congenital heart defect, and there will be other clinical and auscultatory findings.**

Second heart sound (S2)

- Closure of pulmonary and aortic valves (PV, AV), which close simultaneously on exhalation and a single heart sound is best heard with diaphragm at the upper left sternal border
  - **Wider splitting of S2 on inspiration is related not only to increased venous return but also to pressures in the aorta and pulmonary artery (PA) (it is significantly higher in the Ao than in the PA, so Ao valve closes first)**
- **Wider than normal splitting will occur with any lesion that allows more blood to traverse the PV compared to normal**
  - Increased splitting of S2 may be fixed with respect to respiration if there is increased volume and hence pressure in the right atrium (e.g., ASD); otherwise, it will continue to vary with respiration; may also hear fixed splitting with a right bundle branch block
- **Loud single S2**: heard with PA hypertension (increased pressure closing the PV causes early closure of the anterior semilunar valve resulting in a loud single S2)
  - In D-transposition, the AV is anterior and to the right of the PV, which overwhelms the sound from the PV, so one hears a loud single S2; in truncus arteriosus, there is only 1 valve so there is a single S2

Third heart sound (S3)

- Hear **early in diastole**; creates a gallop rhythm with S1 + S2; very low frequency and is best heard with bell of the stethoscope at cardiac apex; asking patient to lie on left side may increase intensity of S3
- **On occasion may be heard normally in children with no pathology:** in older people, it represents the presence of CHF and is caused by sudden deceleration of blood flow into LV from the LA

Fourth heart sound (S4)

- Occurs in **late diastole, just prior to S1 (presystolic) and is produced by a decrease in compliance (increased stiffness) of the LV**
- Low frequency (lower than S3) and best heard with bell of the stethoscope pressed lightly against the skin; never hear with atrial fibrillation because the contraction of the atria is ineffective
- Summation gallop rhythm (S3 + S4) may be found with improving CHF, myocarditis, or a cardiomyopathy

Innocent Murmurs

Peripheral pulmonic stenosis

- **Normal finding age 6 weeks to 1 year**
- Generated by blood flowing into the lungs due to (1) pulmonary arteries, which have limited blood flow in utero and are therefore small with significantly increased blood flow after birth (turbulence from RV blood flowing through these arteries), and (2) increasing cardiac output associated with declining [Hgb] over the first weeks of life (physiologic anemia)
- Normal infant with normal S1, then grade 1-2 systolic ejection murmur at the upper sternal border and radiating bilaterally into the axillae; then, normal splitting of S2

Still's murmur

- Commonly heard first at **age 3–5 years**
- Represents turbulence or vibrations in either ventricle; child is healthy and asymptomatic
- Precordial activity is normal, as are S1 and S2; the murmur is typically low-pitched (bell of stethoscope), musical-quality and often radiates throughout the precordium.
- Murmur is **loudest while supine (greater blood flow) and decreases sitting or standing—opposite to the finding of HOCM.** Also increases with fever or exercise (hyperdynamic states).

Venous hum

- Only diastolic murmur that is **not** pathological; **represents blood flow returning from the head and flowing from SVC into the RA**
- Described as "whooshing" sound (like holding a seashell to your ear at the ocean); is a **continuous murmur**
  - Best heard in sitting position with head in the neutral position
  - **Murmur becomes softer or disappears while in supine, with slight pressure to the right side of the neck or turning head to opposite side**

Aortic outflow murmur

- Heard **in adolescents and young adults** (especially athletes, due to lower resting heart rate and therefore larger stroke volume
- Best heard in upper right sternal border; represents blood flow in RV outflow tract (**without a click, as there is in aortic stenosis**)
- Precordial activity is normal, S1 and S2 are normal, the murmur is grade 1-2 ejection
  - Going from **supine to sitting or standing decreases the murmur** (again, opposite to HOCM)

Congenital Heart Disease

In most cases, diagnosis usually made by age 1 month. Murmurs may not be heard in early life because of increased pulmonary vascular resistance (from fetal to neonatal transition physiology).

- Etiology
  - Most are unknown
  - Associated with teratogens, such as alcohol and rubella
  - Genetic predisposition—trisomies; Marfan, Noonan, DiGeorge syndromes
- Classification

Table 13-2. Congenital Heart Disease

	Shunting			
Regurgitant	**Stenotic**	**Right → Left**	**Left → Right**	**Mixing**
MVP	Aortic stenosis	Tetralogy of Fallot	Patent ductus	Truncus
PI, AI	Pulmonic stenosis	Ebstein anomaly	Ventricular septal defect	TAPVR
MI, TI	Coarctation	Tricuspid atresia	Atrial septal defect, endocardiac cushion defect	HLH, Transposition

Definition of abbreviations: TAPVR *total anomalous pulmonary venous return*; HLH hypoplastic left heart; MVP mitral valve prolapse; PI pulmonic insufficiency; AI aortic insufficiency; MI myocardial infarction; TI tricuspid insufficiency

LEFT TO RIGHT SHUNTS

Ventricular Septal Defect (VSD)

A 3-month-old child presents with poor feeding, poor weight gain, and tachypnea. Physical examination reveals a harsh, pansystolic 3/6 murmur at the left lower sternal border, and hepatomegaly.

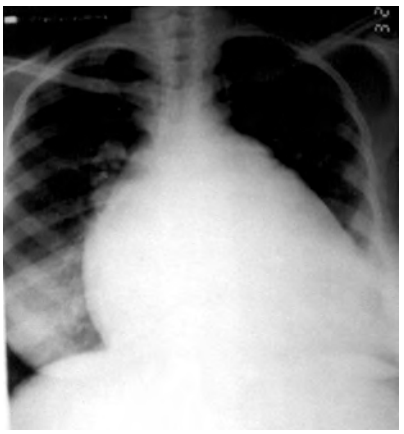
- **Most common** congenital heart lesion
- Most are **membranous**
- Shunt determined by **ratio of PVR to SVR**
  - **As PVR falls in first few weeks of life, shunt increases**
  - When PVR>SVR, **Eisenmenger** syndrome (must **not be allowed** to happen)

Note

Eisenmenger Syndrome

- Transformation of any untreated left-to-right shunt into a bidirectional or right-to-left shunt
- Characterized by cyanosis
- Results from high pulmonary blood flow, causing medial hypertrophy of pulmonary vessels and increased pulmonary vascular resistance

- Clinical findings
  - Asymptomatic if small defect with normal pulmonary artery pressure (most); large defect—**dyspnea, feeding difficulties, poor growth, sweating, pulmonary infection, heart failure**
  - Harsh holosystolic **murmur** over lower left sternal border ± thrill; S_2 widely split
  - With hemodynamically significant lesions, also a low-pitched diastolic rumble across the mitral valve heard best at the apex
- Diagnosis—chest-ray (large heart, pulmonary edema), ECG (LVH), echocardiogram is definitive
- Treatment
  - Small **muscular VSD more likely to close in first 1–2 years than membranous**
  - Less common for moderate to large to close → medical treatment for heart failure (**control failure and prevent pulmonary vascular disease**)
  - **Surgery in first year**; indications:
    - Failure to thrive or unable to be corrected medically
    - Infants at 6–12 months with large defects and pulmonary artery hypertension
    - More than 24 months of age with Qp:Qs >2:1 (shunt fraction)



Courtesy of Tom D. Thacher, M.D.

Figure 13-2. Cardiomegaly Due to Ventricular Septal Defect

- Complications
  - Large defects lead to heart failure, failure to thrive
  - Endocarditis
  - Pulmonary hypertension

Atrial Septal Defect (ASD)

- Ostium secundum defect **most common** (in region of fossa ovalis)
- Clinical
  - **Few symptoms early in life** because of structure of low-flow, left-to-right shunt
  - In older children, often with large defects; varying degrees of exercise intolerance
  - With hemodynamically significant lesions, also a low-pitched diastolic rumble across the tricuspid valve heard best at the lower sternum

- Physical examination
  - **Wide fixed splitting of S_2**
  - Systolic ejection murmur along left mid to upper sternal border (from increased pulmonary flow)
- Diagnosis
  - Chest x-ray—varying heart enlargement (right ventricular and right atrial); increased pulmonary vessel markings, edema
  - ECG—**right-axis deviation and RVH**
  - Echocardiogram definitive
- Treatment
  - Most in term infants close spontaneously; **symptoms often do not appear until third decade**
  - **Surgery or transcatheter device closure for all symptomatic patients or 2:1 shunt**
- Complications
  - Dysrhythmia
  - Low-flow lesion; does not require endocarditis prophylaxis

Endocardial Cushion Defect

- Pathophysiology
  - When both ASDs and VSDs occur, which are contiguous, and the atrioventricular valves are abnormal
  - Left-to-right shunt at both atrial and ventricular levels; some right-to-left shunting with desaturation (**mild, intermittent cyanosis**)
  - Atrioventricular valve insufficiency → increase volume load on one or both ventricles; **early heart failure, infections, minimal cyanosis, hepatomegaly, and failure to thrive**
- Physical examination
  - Heart failure early in infancy (hepatomegaly, failure to thrive)
  - Eisenmenger physiology occurs earlier
  - Moderate-to-severe increase in heart size with hyperdynamic precordium (**precordial bulge and lift**)
  - **Widely fixed split S_2** (like an isolated ASD)
  - **Pulmonary systolic ejection murmur, low-pitched diastolic rumble at left sternal border and apex;** may also have mitral insufficiency (apical harsh holosystolic murmur radiating to left axilla)
- Diagnostic tests
  - Chest x-ray—significant cardiomegaly, increased pulmonary artery and pulmonary blood flow and edema
  - ECG—signs of biventricular hypertrophy, right atrial enlargement, superior QRS axis
  - Echocardiogram (gold standard)
- Treatment—surgery more difficult with heart failure and pulmonary hypertension (increased pulmonary artery pressure by 6–12 months of age); **must be performed in infancy**
- Complications
  - Without surgery—death from heart failure
  - With surgery—arrhythmias, congenital heart block

Note

Patients with trisomy 21 are at a higher risk for endocardial cushion defects.

Patent Ductus Arteriosus (PDA)

- Results when the ductus arteriosus fails to close; this leads to blood flow from the aorta to the pulmonary artery
- Risk factors
  - **More common in girls** by 2:1
  - Associated with **maternal rubella infection**
  - Common in **premature infants** (developmental, not heart disease)
- Presentation
  - If small—possibly no symptoms
  - If large—heart failure, a wide pulse pressure, bounding arterial pulses, characteristic sound of "machinery," decreased blood pressure (primarily diastolic)
- Diagnostic tests
  - Chest x-ray—increased pulmonary artery with increased pulmonary markings and edema; moderate-to-large heart size
  - ECG—left ventricular hypertrophy
  - Echocardiogram—increased left atrium to aortic root; ductal flow, especially in diastole
- Treatment
  - May close spontaneously
  - Indomethacin (preterm infants)
  - Surgical closure
- Complications
  - Congestive heart failure
  - Infective endocarditis

Note

If a PDA persists beyond the first week of life, it is unlikely to close spontaneously.

STENOTIC LESIONS

Pulmonic Stenosis

- Pathophysiology
  - Deformed cusps → opens incompletely during systole; obstruction to right ventricular outflow → increased systemic pressure and wall stress → **right ventricular hypertrophy (depends on severity of pulmonary stenosis)**
  - **Arterial saturation normal unless ASD or VSD is present with R → L shunt**
  - Neonate with severe pulmonary stenosis = critical pulmonary stenosis = R → L shunt via foramen ovale
- Physical examination
  - Heart failure only in severe cases, most in first month of life
  - Mild cases—normal life, usually no progression
  - **Moderate to severe**—increasing gradient with growth: **signs of right ventricular failure** (hepatomegaly, peripheral edema, exercise intolerance)
  - **Pulmonary ejection click** after S_1 in left upper sternal border and normal S_2 (in mild); relatively **short, low-to-medium–pitched SEM** over pulmonic area radiating to both lung fields

Note

Pulmonic stenosis as a result of valve dysplasia is the common defect in **Noonan syndrome** (12a24.1; autosomal dominant; boys and girls with Turner phenotype).

Pulmonic stenosis (either valve or branched artery) is common in **Alagille syndrome** (arteriohepatic dysplasia).

- Diagnosis
  - ECG—**right ventricular hypertrophy in moderate to severe**; tall, spiked P-waves; right atrial enlargement (RAE)
  - Chest x-ray—**poststenotic dilatation of pulmonary artery;** normal-to-increased heart size (right ventricle) and **decreasing pulmonary vascularity**
  - Echocardiogram (gold standard)
- Complications
  - Heart failure
  - Endocarditis (lower risk)
  - Secondary subvalvular muscular and fibrous hypertrophy
- Treatment
  - Moderate to severe—**balloon valvuloplasty** initially; may need surgery
  - Neonate with **critical pulmonary stenosis—emergent surgery**

Aortic Stenosis

- Most are **bicuspid aortic valve**—usually asymptomatic in children
- Supravalvular stenosis (least common form)—sporadic, familial, or with Williams syndrome (mental retardation, elfin facies, heart disease, idiopathic hypercalcemia; deletion of elastin gene 7q11.23)
- Clinical presentation—**symptoms depend on severity of obstruction**
  - If severe early in infancy = **critical aortic stenosis** = left ventricular failure and decreased cardiac output
  - **If significant decrease in cardiac output—intensity of murmur at right upper sternal border may be minimal**
  - Mild to moderate—usually asymptomatic with normal growth and development
    - Often discovered with murmur on routine physical examination
    - Rare—older children present with syncope, fatigue, angina, dizziness
  - **With increasing severity—decreased pulses, increased heart size, left ventricular apical thrust**
  - **Early systolic ejection click at apex of left sternal border (does not vary with respiration)**
    - Severe—no click and decreased S1 (decreased left ventricular compliance), decreased S_2 (aortic component), and maybe an S_4
    - **SEM upper-right second intercostal space; the louder (harsher) and longer the murmur, the greater the degree of obstruction; radiates to neck and left midsternal border; positive thrill in suprasternal notch**
- Diagnosis
  - ECG—**left ventricular hypertrophy** and strain
  - Chest x-ray—**prominent ascending aorta**; may have valve calcification (older children and adults); if severe → increased heart size (left ventricular hypertrophy)
  - **Echocardiogram (gold standard)**
- Treatment
  - Balloon valvuloplasty
  - Surgery on valves
  - Valve replacement

Note

Coarctation of the aorta has a high association with Turner syndrome (70% with bicuspid aortic valve).

Note

Coarctation should be suspected in an asymptomatic child with hypertension.

Coarctation of the Aorta

- Definition—narrowing at any point from transverse arch to iliac bifurcation; 90% just below origin of left subclavian artery at origin of ductus arteriosus (juxtaductal coarctation)

Adult versus childhood

- **Discrete juxtaductal coarctation (adult type)**
  - Ascending aortic blood flows normally through narrowed segment to reach descending aorta, but there is left ventricular hypertrophy and hypertension
  - If mild, not recognized until later in childhood
  - Increased blood pressure in vessels proximal to coarctation and decreased blood pressure and pulses below constriction
    - Femoral and other lower pulses weak or absent; bounding in arms and carotids; also **delay in femoral pulse** compared to radial (femoral normally occurs slightly before radial)
    - Normally, leg systolic pressure is 10–20 mm Hg higher than in arms; in coarctation, leg systolic pressure is decreased (>5%)
    - If pressure is greater in right arm than left arm, suggests coarctation involving left subclavian artery
    - Short systolic murmur along left sternal border at third-to-fourth intercostal space → left scapula and neck
  - Hypertension due not only to mechanical but also to neurohormonal reasons
  - Over time, patient develops an extensive collateral circulation (systolic or continuous murmurs over left and right sides of chest with thrills), **rib notching** (dilated intercostal arteries)
- **Tubular hypoplasia (preductal, infantile type)**
  - Severe narrowing starting at one of the head or neck vessels and extending to the ductus
  - Right ventricular blood flows across the PDA to supply the descending aorta so the perfusion of the lower part of the body is dependent upon right ventricular output
  - Seen as differential cyanosis—**upper body is pink**, **lower is cyanotic**; prominent heart failure as ductus closes (if completely atretic = interrupted aortic arch)
  - Presents with lower body hypoperfusion, acidosis, and severe heart failure with ductal closure; large heart, systolic murmur along left sternal border
- Diagnostic tests
  - Chest x-ray—depends on age and effects of hypertension and collaterals
    - Severe (infantile)—increased heart size and pulmonary congestion
    - Adult—findings usually occur after first decade:
      - Increased size of subclavian artery—prominent shadow in left superior mediastinum
      - **Notching of inferior border of ribs** from passive erosion of increased collaterals in late childhood
      - Poststenotic dilatation of ascending aorta

- Diagnosis
  - ECG—left ventricular hypertrophy in older children; in neonates, biventricular hypertrophy
  - Echocardiogram (gold standard)
- Treatment
  - Neonate—PGE_1 infusion to maintain patent, ductus, which establishes adequate lower extremity blood flow; **surgery** after stabilization
  - **Surgery soon after diagnosis of any significant coarctation**
  - Adult—treat heart failure and hypertension, then follow with surgery
- Complications
  - Associated cerebrovascular disease
  - Systemic hypertension
  - Endocarditis
  - Aortic aneurysms

CYANOTIC LESIONS (RIGHT TO LEFT SHUNTS)

Cyanotic Lesions Associated with Decreased Pulmonary Blood Flow

Tetralogy of Fallot (TOF)

A 6-month-old infant is prone to episodes of restlessness, cyanosis, and gasping respirations. Symptoms resolve when he is placed in the knee-chest position. Physical examination reveals an underweight infant, with a harsh long systolic ejection murmur and a single second heart sound.

- Components
  - Pulmonary stenosis and infundibular stenosis (obstruction to right ventricular outflow)
  - VSD
  - Overriding aorta (overrides the VSD)
  - Right ventricular hypertrophy
- **Most common cyanotic lesion**
- Pulmonary stenosis plus hypertrophy of subpulmonic muscle (crista supraventricularis) → varying degrees of right ventricular outflow obstruction
  - Blood shunted right-to-left across the VSD with varying degrees of arterial desaturation and cyanosis
  - **If mild, patient may not be visibly cyanotic (pink tetralogy of Fallot)**
    - With growth and further hypertrophy of infundibulum, cyanosis may be seen later in first year of life
  - With severe obstruction, cyanosis in the immediate neonatal period (ductal dependent)

Note

Common Cyanotic Heart Disease (5 Ts)

Tetralogy of Fallot

Transposition of great vessels

Truncus arteriosis

Total anomalous pulmonary venous return

Tricuspid atresia

  - If not corrected, older children are blue, have marked clubbing, and have **dyspnea on exertion (child will squat to increase systemic vascular resistance and to decrease right-to-left shunt)**
  - Paroxysmal hypercyanotic attacks (tet spells)
    - Acute onset of hyperpnea and restlessness → increased cyanosis → gasping → syncope (increased infundibular obstruction with further right-to-left shunting
    - Treatment—place in lateral knee-chest position, give oxygen, inject subcutaneous morphine, give beta-blockers
- Physical examination—substernal right ventricular impulse, systolic thrill along third-to-fourth intercostal space on left sternal border, loud and harsh systolic ejection murmur (upper sternal border), may be preceded by a click; **either a single S_2** or soft pulmonic component
- Diagnosis
  - Chest x-ray—hypertrophied right ventricle causes the apex to be uplifted above the diaphragm → **boot-shaped heart** plus dark lung fields (decreased pulmonary blood flow)
  - ECG—right axis deviation plus right ventricular hypertrophy
  - Echocardiogram (gold standard)
- Pre-correction complications—cerebral thromboses, brain abscess, bacterial endocarditis, heart failure, but not common because of early correction
- Treatment
  - Depends on degree of obstruction
    - PGE_1 infusion—prevent ductal closure; given if cyanotic at birth
    - Augment pulmonary blood flow with **palliative systemic to pulmonary shunt** (modified Blalock-Taussig shunt)
    - Corrective surgery (electively at age 4–12 months)—remove obstructive muscle, valvulotomy, and patching of VSD

Tricuspid atresia

- Pathophysiology—**no outlet from the right atrium to the right ventricle;** entire venous (systemic) return enters the left atrium from a foramen ovale or ASD **(there must be an atrial communication)**; left ventricular blood to right ventricle (atretic) via a VSD and is augmented by PDA; **therefore, pulmonary blood flow depends on presence (and size) of VSD**
- Clinical presentation
  - Will present at birth with **severe cyanosis**
  - **Increased left ventricular impulse** (contrast to most others with right ventricular impulse), holosystolic murmurs along left sternal border (most have a VSD; though right ventricle is small, it is still a conduit for pulmonary blood flow)
- Diagnosis
  - Chest x-ray—**pulmonary undercirculation**
  - ECG—**left axis deviation plus left ventricular hypertrophy** (distinguishes from most other congenital heart disease)
  - Echocardiogram (gold standard)

Note

The combination of severe cyanosis in the newborn *plus* a chest x-ray showing decreased pulmonary blood flow *plus* an ECG with left axis deviation and left ventricular hypertrophy is most likely to be **tricuspid atresia**.

- Treatment
  - **PGE_1 until aortopulmonary shunt can be performed**
  - May need an **atrial balloon septostomy (to make larger ASD)**
  - Later, staged surgical correction

Ebstein anomaly

- Development associated with periconceptional maternal **lithium** use in some cases
- **Downward displacement of abnormal tricuspid valve into right ventricle;** the right ventricle gets divided into two parts: an atrialized portion, which is thin-walled, and smaller normal ventricular myocardium
- **Right atrium is huge; tricuspid valve regurgitant**
- **Right ventricular output is decreased** because
  - Poorly functioning, small right ventricle
  - Tricuspid regurgitation
  - Variable right ventricular outflow obstruction—abnormal anterior tricuspid valve leaflet. **Therefore, increased right atrial volume shunts blood through foramen ovale or ASD → cyanosis**
- Clinical presentation
  - Severity and presentation depend upon degree of displacement of valve and degree of right ventricular outflow obstruction
    - **May not present until adolescence or adulthood**
    - **If severe in newborn → marked cyanosis, huge heart**
  - **Holosystolic murmur** of tricuspid insufficiency over most of anterior left chest **(most characteristic finding)**
- Diagnosis
  - Chest x-ray—heart size varies from normal to **massive (increased right atrium)**; if severe, **decreased pulmonary blood flow**
  - ECG—tall and broad P waves, right bundle branch block
- Treatment
  - PGE_1
  - Systemic-to-pulmonary shunt
  - Then staged surgery

Note

Patients with Ebstein anomaly may have Wolff-Parkinson-White syndrome (delta wave and short PR interval) and present with episodes of supraventricular tachycardia.

Cyanotic Lesions Associated with Increased Pulmonary Blood Flow

Transposition of the great arteries (TGA)

- Pathophysiology
  - Aorta arises from the right ventricle, and the pulmonary artery from the left ventricle; d = dextroposition of the aorta anterior and the right of the pulmonary artery (normal is posterior and to the right of the pulmonary artery)
  - Series circuit changed to **2 parallel circuits; need foramen ovale and PDA** for some mixture of desaturated and oxygenated blood; better mixing in half of patients with a VSD

Note

Transposition of the Great Arteries

- Most common cyanotic lesion presenting in the immediate newborn period
- More common in infant of diabetic mother

- Clinical presentation
  - **With intact septum (simple TGA)**—as PDA starts to close, severe cyanosis and tachypnea ensue
  - **S_2 usually single and loud;** murmurs absent, or a soft systolic ejection murmur at midleft sternal border
  - If VSD is present, there is a harsh murmur at the lower left sternal border. If large, then holosystolic murmur, significant mixing of blood lessens cyanosis, but presents as heart failure
- Diagnosis
  - Chest x-ray:
    - Mild cardiomegaly, narrow mediastinum, and normal-to-increased pulmonary blood flow
    - **"Egg on a string" appearance**—narrow heart base *plus* absence of main segment of the pulmonary artery
  - ECG—**normal** neonatal right-sided dominance
  - Echocardiogram (gold standard)
- Treatment
  - PGE_1 (keeps PDA patent)
  - Balloon atrial septostomy
  - Arterial switch surgery in first 2 weeks

Note

Truncus arteriosis is one of the major conotruncal lesions associated with the **CATCH-22** syndrome, i.e., DiGeorge. Also seen are transposition of the great arteries and aortic arch abnormalities.

Truncus Arteriosus

- Pathophysiology
  - **Single arterial trunk arises from the heart and supplies all circulations.**
  - **Truncus overlies a ventral septal defect (always present) and receives blood from both ventricles (total mixing).**
  - Both ventricles are at systemic pressure.
- Clinical presentation
  - With dropping pulmonary vascular resistance in first week of life, **pulmonary blood flow is greatly increased and results in heart failure.**
  - Large volume of pulmonary blood flow with total mixing, **so minimal cyanosis**
  - If uncorrected, **Eisenmenger** physiology
  - **Single truncal valve**, which may be incompetent (high-pitched, early diastolic decrescendo at mid-left sternal border)
  - Initially, **SEM with loud thrill, single S_2, and minimal cyanosis**
  - With decreasing pulmonary vascular resistance (PVR) → **torrential pulmonary blood flow with heart failure;** runoff from truncus to pulmonary circulation → **wide pulse pressure with bounding pulses and hyperdynamic precordium**
  - Apical mid-diastolic rumble (increased flow across mitral valve)
- Diagnosis
  - Chest x-ray—**heart enlargement with increased pulmonary blood flow**
  - ECG—**biventricular hypertrophy**
  - Echocardiogram (gold standard)

- Treatment
  - **Treat heart failure**
  - Then surgery in first few weeks of life

MIXED LESIONS

Total Anomalous Pulmonary Venous Return (TAPVR)

- Pathophysiology
  - Complete anomalous drainage of the pulmonary veins into the systemic venous circulation; total mixing of **systemic venous and pulmonary venous blood** within the heart produces cyanosis
  - Right atrial blood → right ventricle and pulmonary artery *or* to left atrium via foramen ovale or ASD
  - **Enlarged right atrium, right ventricle, and pulmonary artery; and small left atrium; and left ventricle normal or small**
- **Clinical manifestations** depend on **presence or absence** of obstruction.
  - **Obstruction (of pulmonary veins, usually infracardiac):**
    - **Severe pulmonary venous congestion and pulmonary hypertension with decreasing cardiac output and shock**
    - Cyanosis and severe tachypnea; may not respond to ventilation and PGE_1 → **need emergent diagnosis and surgery for survival**
    - Heart failure early with mild-to-moderate obstruction and a large left-to-right shunt; pulmonary hypertension and mild cyanosis
  - **No obstruction—total mixing with a large left-to-right shunt; mild cyanosis; less likely to be severely symptomatic early**
- Diagnosis
  - Chest x-ray—large supracardiac shadow with an enlarged cardiac shadow forms a **"snowman" appearance**; pulmonary vascularity is increased
  - ECG—**RVH and tall, spiked P waves (RAE)**
  - Echocardiogram (gold standard)
- Treatment
  - **PGE_1**
  - **Surgical correction**

Note

TAPVR always has an atrial connection.

Hypoplastic Left Heart Syndrome

- Pathophysiology
  - **Atresia of mitral or aortic valves, left ventricle, and ascending aorta (or any combination)**
  - **Right ventricle maintains both pulmonary and systemic circulation.**
  - **Pulmonary venous blood passes through foramen ovale or ASD from left atrium → right atrium and mixes with systemic blood to produce total mixing**
  - Usually, the ventricular septum is intact and all of the right ventricular blood enters the pulmonary artery.

  - **Ductus arteriosus supplies the descending aorta, ascending aorta and coronary arteries from retrograde flow.**
  - Systemic circulation cannot be maintained, and if there is a **moderate-to-large ASD → pulmonary overcirculation**
- Clinical presentation
  - **Cyanosis may not be evident with ductus open,** but then **gray-blue** skin color (combination of hypoperfusion and cyanosis as ductus closes)
  - **Signs of heart failure, weak or absent pulses, and shock**
  - Enlarged heart with **right parasternal lift;** nondescript systolic murmur
- Diagnosis
  - Chest x-ray—**heart enlargement with increased pulmonary blood flow**
  - **ECG—right ventricular hypertrophy and right arial enlargement with decreased left-sided forces**
  - Echocardiogram (gold standard)
- Treatment
  - **May do nothing** if malformations or genotype not compatible with life
  - The best treatment today is the **three-stage Norwood procedure.** (better results currently than cardiac transplantation)
- Other—many have a significant **abnormality of central nervous system (CNS)** and/or kidneys: **need careful genetic, neurologic examination and screening tests on any child being considered for surgery**

REGURGITANT LESIONS

Mitral Valve Prolapse

Note

Mitral valve prolapse is a common finding in those with Marfan and Ehlers-Danlos syndrome.

- Abnormal cusps—billowing of one or both leaflets into left atrium toward end of systole (congenital defect)
- Usually not recognizable until adolescence or adulthood; girls > boys
  - May present with chest pain or palpitations
  - Arrhythmias, especially uni- or multifocal premature ventricular contractions
- **Apical late systolic murmur**, preceded by a **click**—in abrupt standing or Valsalva, click may appear earlier in systole and murmur may be more prominent
- Diagnosis
  - ECG—usually normal
  - Chest x-ray—normal
  - Echocardiogram (gold standard)
- No therapy, not progressive; adults (more in men) at risk for cardiovascular complications if have thickened leaflets

OTHER CARDIAC PATHOLOGY

Infective Endocarditis

A 6-year-old boy has had high intermittent fevers for 3 weeks, accompanied by chills. He has a past history of bicuspid aortic valves and recently had dental work.

- Etiology/epidemiology
  - Most are *Streptococcus viridans* (alpha hemolytic) and *Staphylococcus aureus*
  - Organism associations
    - *S. viridans*—after dental procedures
    - Group D streptococci—large bowel or genitourinary manipulation
    - *Pseudomonas aeruginosa* and *Serratia marcescens*—intravenous drug users
    - Fungi—after open heart surgery
    - Coagulase-negative *Staphylococcus*—indwelling intravenous catheters
  - Highest risk with prosthetic valve and uncorrected cyanotic heart lesions
  - Most cases occur after **surgical or dental procedures** (high risk with poor dental hygiene) are performed.
- Clinical presentation
  - **Prolonged intermittent fever, weight loss,** fatigue, myalgia, arthralgia, headache, nausea, vomiting
  - **New or changing heart murmur**
  - Splenomegaly, petechiae, embolic stroke, CNS abscess, CNS hemorrhage, mycotic aneurysm (all more with *Staphylococcus*)
  - Skin findings—rare; late findings (uncommon in treated patients); represent vasculitis from circulating Ag-Ab complexes; if present, are highly suggestive
    - **Osler nodes**—tender, pea-sized, intradermal nodules on pads of fingers and toes
    - **Janeway lesions**—painless, small erythematous or hemorrhagic lesions on palms and soles
    - **Splinter hemorrhage**—linear lesions beneath nail beds
    - **Roth spots**—retinal exudates
- Diagnosis
  - Duke criteria (2 major or 1 major + 3 minor or 5 minor)

Note

Staphylococcal endocarditis is more common in those without underlying heart disease. *Strep viridians* is more common in patients *with* underlying heart disease or after dental procedures.

Table 13-3. Duke Criteria

Major Criteria	Minor Criteria
• **Positive blood culture** (two separate for usual pathogens; at least two for less common) • Evidence on **echocardiogram** (intracardiac or valve lesion, prosthetic regurgitant flow, abscess, partial dehiscence of prosthetic valve, new valvular regurgitant flow)	• Predisposing conditions • Fever • Emboli or vascular signs • Immune complex disease (glomerulonephritis, arthritis, positive rheumatoid factor, Osler node, Roth spots [retinal hemorrhages with white centers]) • Single positive blood culture • Echocardiographic signs not meeting criteria

- Complications
  - **Most common—heart failure from aortic or mitral lesions**
  - Others—systemic or pulmonary emboli, myocardial abscess, myocarditis, valve obstruction, heart block, meningitis, osteomyelitis, arthritis, renal abscess, immune complex–mediated glomerulonephritis
- Treatment
  - Organism specific for 4–6 weeks (*S. viridans*, Enterococci, *S. aureus,* MRSA, *S. epidermidis*, HACEK)
  - Heart failure—digitalis, diuretic, salt restriction
  - Surgery—severe aortic or mitral involvement with intractable failure, failure of blood culture to clear, abscess, recurrent emboli, increasing size of vegetations with worsening regurgitation
  - Prophylaxis (AHA, 2007) for:
  - Artifical valves
    - Previous history of infective endocarditis
    - Unrepaired or incompletely repaired cyanotic disease, including those with palliative shunts and conduits
    - A completely repaired defect with prosthetic material or device for first 6 months
    - Any residual defect at site of any repair
    - Cardiac transplant which develops a problem in a valve
    - Given ONLY for dental procedures with manipulation of gingival tissue or periapical area or perforation of oral mucosa; incision or biopsy of respiratory tract mucosa and surgery on infected skin or musculoskeletal structures
    - Drug of choice is amoxicillin

Note

HACEK

- **H**emophilus spp.
- **A**ctinobacillus
- **A**ctinomycetemcomitans
- **C**ardiobacterium hominus
- **E**ikenella corrodens
- **K**ingella kingae

These are slow-growing gram negative organisms that are part of normal flora.

Acute Rheumatic Fever

A 6-year-old girl complains of severe joint pain in her elbows and wrists. She has had fever for the past 4 days. Past history reveals a sore throat 1 month ago. Physical examination is remarkable for swollen, painful joints and a heart murmur. Laboratory tests show an elevated erythrocyte sedimentation rate and high antistreptolysin (ASO) titers.

- Etiology/epidemiology
  - Related to group A *Streptococcus* infection within several weeks
  - Antibiotics that eliminate *Streptococcus* from pharynx prevent initial episode of acute rheumatic fever
  - Remains **most common form of acquired heart disease worldwide** (but Kawasaki in United States and Japan)
  - Initial attacks and recurrences with peak incidence *Streptococcus* pharyngitis: age 5–15
  - Immune-mediated—antigens shared between certain strep components and mammalian tissues (heart, brain, joint)
- Clinical presentation and diagnosis—Jones criteria. Absolute requirement: evidence of recent *Streptococcus* infection (microbiological or serology); then two major or one major and two minor criteria

Table 13-4. Jones Criteria

Major Criteria	Minor Criteria
Carditis	Fever
Polyarthritis (migratory)	Arthralgia
Erythema marginatum	Elevated acute phase reactants (ESR, CRP)
Chorea	Prolonged PR interval on ECG
Subcutaneous nodules	*Plus* evidence of preceding streptococci infection

- Treatment
  - Bed rest and monitor closely
  - **Oral penicillin** or erythromycin (if allergic) for 10 days will eradicate group A strep; then need long-term prophylaxis
  - Anti-inflammatory
    - **Hold if arthritis is only typical manifestation (may interfere with characteristic migratory progression)**
    - Aspirin in patients with arthritis/carditis *without* CHF
    - If carditis with CHF, **prednisone** for 2–3 weeks, then taper; start aspirin for 6 weeks
  - Digoxin, salt restriction, diuretics as needed
  - **If chorea is only isolated finding, do not need aspirin; drug of choice is phenobarbital** (then haloperidol or chlorpromazine)

Note

If arthritis is present, arthralgia cannot be used as a minor criterion.

The presence of Sydenham's Chorea alone is sufficient for diagnosis.

- Complications
  - Most have no residual heart disease.
  - **Valvular disease most important complication (mitral, aortic, tricuspid)**
- Prevention
  - **Continuous antibiotic prophylaxis**
    - If carditis—continue into adulthood, perhaps for life; without carditis—lower risk; can discontinue after patient is in their twenties and at least 5 years since last episode
    - Treatment of choice—**single intramuscular benzathine penicillin G** every 4 weeks
    - If compliant—penicillin V PO BID or sulfadiazine PO QD; if allergic to both: erythromycin PO BID

Hypertrophic Obstructive Cardiomyopathy (HOCM)

- Pathophysiology
  - **Obstructive left-sided congenital heart disease**
- Decreased compliance, so increased resistance and **decreased left ventricular filling,** mitral insufficiency
- Clinical presentation—weakness, fatigue, dyspnea on exertion, **palpitations, angina, dizziness, syncope; risk of sudden death**
- Cardiovascular examination—**left ventricular lift, no systolic ejection click (differentiates from aortic stenosis),** SEM at left sternal edge and apex (increased after exercise, during Valsalva, and standing)
- Diagnosis
  - ECG—left ventricular hypertrophy ± ST depression and T-wave inversion; may have intracardiac conduction defect
  - Chest x-ray—mild cardiomegaly (prominent LV)
  - Echocardiogram—left ventricular hypertrophy, mostly septal; Doppler—left ventricular outflow gradient usually mid-to-late systole (maximal muscular outflow obstruction)
- Treatment
  - **No competitive sports or strenuous exercise (sudden death)**
  - **Digoxin and aggressive diuresis are contraindicated** (and infusions of other inotropes)
  - **Beta blockers (propranolol) and calcium channel blockers (verapamil)**

Note

Suspect hypertrophic cardiopathy in an athlete with sudden death.

HYPERTENSION

A 5-year-old girl is noted to have blood pressure above the 95th percentile on routine physical examination. The rest of the examination is unremarkable. Her blood pressure remains elevated on repeat measurement over the next few weeks. Past history is remarkable for a treated urinary tract infection 1 year ago. Complete blood cell count is normal; urinalysis is normal. Blood urea nitrogen is 24 mg/dL and creatinine is 1.8 mg/dL.

Note

When a child presents with hypertension, think of renal causes.

- Routine blood pressure check beginning at 3 years of age
  - If increased blood pressure, check all 4 extremities (coarctation)
  - Normal—blood pressure in legs should be 10–20 mm Hg higher than in arms
- Blood pressure increases with age—need standard nomograms
  - If mild hypertension, repeat twice over next 6 weeks
  - If consistently >95% for age, need further evaluation
- Etiology—essential (primary) or secondary
  - Secondary—**most common in infants and younger children**
    - Newborn—umbilical artery catheters → renal artery thrombosis
    - Early childhood—renal disease, coarctation, endocrine, medications
    - Adolescent—essential hypertension
  - **Renal and renovascular hypertension—majority of causes may be due to urinary tract infection** (secondary to an obstructive lesion), acute glomerulonephritis, Henoch-Schönlein purpura with nephritis, hemolytic uremic syndrome, acute tubular necrosis, renal trauma, leukemic infiltrates, mass lesions, renal artery stenosis
  - Essential hypertension—more common in adults and adolescents
    - Positive family history
    - Multifactorial—obesity, genetic, and physiologic changes
- Diagnosis
  - CBC, blood chemistries, UA, ECG, echo, renal ultrasound, angiogram (less common)
- Treatment
  - If obese—weight control, aerobic exercise, no-added-salt diet, monitor blood pressure
  - Pharmacologic treatment (secondary hypertension and selective primary)—similar use of drugs as in adults

Gastrointestinal Disease 14

Learning Objectives

- ❑ Demonstrate understanding of disorders of the oral cavity
- ❑ Diagnose and describe treatments for children who present with gastroenteritis, vomiting, hematochezia, or constipation

ORAL CAVITY

Cleft Lip and Palate

- Most are **multifactorial** inheritance; also **autosomal dominant in families (most with isolated cleft palate)**
- Clefts are highest among Asians, lowest among African descent
- **Increase in other malformations with isolated cleft palate**
- **Most important early issue is feeding (special nipple needed)**
- Complications—increased risk of otitis media, hearing loss, speech problems
- Treatment—surgical correction
  - Lip at 3 months of age
  - Palate at <1 year

GASTROENTERITIS

Acute Diarrhea

A 13-month-old child has had a 3-day history of green watery stools. She has also been vomiting for 1 day. Physical examination reveals a febrile, irritable baby with dry mucous membranes and sunken eyes.

- Etiology (*see* Table 14-1)

Note

Common Causes of Bloody Diarrhea

- Campylobacter
- Amoeba (E. histolytica)
- Shigella
- *E. Coli*
- Salmonella

Table 14-1. Causes of Diarrhea (Acute and Chronic)

	Infant	Child	Adolescent
Acute	• Gastroenteritis • Systemic infection • Antibiotic	• Gastroenteritis/Food poisoning • Systemic infection	• Gastroenteritis/ food poisoning • Systemic infection
Chronic	• Postinfectious lactase deficiency • Milk/soy intolerance • Chronic diarrhea of infancy • Celiac disease • Cystic fibrosis	• Postinfectious lactase deficiency • Irritable bowel syndrome • Celiac disease • Lactose intolerance • *Giardiasis* • Inflammatory bowel disease	• Irritable bowel syndrome • Inflammatory bowel disease • Lactose intolerance • *Giardiasis* • Laxative abuse

- Common organisms (*see* Table 14-2)

Table 14-2. Common Causes of Acute Diarrhea

Bacterial (Inflammatory)	Viral	Parasitic
Campylobacter	**Norovirus**	***Giardia lamblia* (most common)**
Enteroinvasive *E. coli*	Rotavirus	*E. histolytica*
Salmonella	Enteric adenovirus	*Strongyloides*
Shigella	Astrovirus	*Balantidium coli*
Yersinia	Calicivirus	*Cryptosporidium parvum*
Clostridium difficile		*Trichuris trichiura*
E. coli 0157:H7		

Note

Antidiarrheal compounds should never be used in children.

- Major transmission is **fecal/oral** or by **ingestion of contaminated food or water**
- Clinical presentation
  - Diarrhea, vomiting, abdominal cramps, nausea, fever (suggests inflammation and dehydration)
  - Can present from an **extraintestinal infection**, e.g., urinary tract infection, pneumonia, hepatitis
- Management
  - **Assess hydration and provide fluid and electrolyte replacement**
  - Prevent spread
  - In some cases, determine etiology and provide specific therapy (some are not treated)
  - Think about **daycare** attendance, recent **travel,** use of **antibiotics,** exposures, intake of **seafood, unwashed vegetables, unpasteurized milk, contaminated water, uncooked meats to isolate differential diagnosis of organisms**
- Labs
  - Most cost-effective, noninvasive testing is **stool examination**

- Mucus, blood, leukocytes → colitis (invasive or cytotoxic organism)
- Stool cultures—with blood, leukocytes, suspected hemolytic uremic syndrome, immunosuppressed, in outbreaks
- *Clostridium difficile* toxin—if recent history of antibiotics
- Ova and parasites
- Enzyme immunoassays for viruses or PCR (rarely need to be diagnosed)

Chronic Diarrhea

Table 14-3. Organism-Specific Associations and Therapy

Organism	Association	Therapy
Rotavirus	Watery diarrhea, vomiting, ± fever	Supportive
Enteropathogenic *E. coli*	Nurseries, daycare	Supportive care in severe cases, neomycin or colistin
Enterotoxigenic *E. coli*	Traveler's diarrhea	Supportive care trimetho prim-sulfamethoxazole in severe cases
Enterhemorrhagic *E. coli*	Hemorrhagic colitis, HUS	**No antimicrobial therapy** in suspected cases due to ↑ risk of HUS; supportive care only
Salmonella	Infected animals and contaminated eggs, milk, poultry	Treatment indicated *only* for patients who are ≤3 months of age, toxic, has disseminated disease, or *S. typhi*
Shigella	Person-to-person spread, contaminated food	Trimethoprim/sulfamethoxazole
Campylobacter	Person-to-person spread, contaminated food	Self-limiting; erythromycin speeds recovery and reduces carrier state; recommended for severe disease
Yersinia enterocolitica	Pets, contaminated food, arthritis, rash	No antibiotic therapy; aminoglycosides plus a third-generation cephalosporin for infants ≤3 months of age or with culture-proven septicemia
Clostridium difficile	History of antibiotic use	Metronidazole or vancomycin and discontinuation of other antibiotics
Staphylococcus aureus	Food poisoning (onset within 12 h of ingestion)	Supportive care, antibiotics rarely indicated
Entamoeba histolytica	Acute blood diarrhea	Metronidazole
Giardia	Anorexia, nausea, abdominal distension, watery diarrhea, weight loss Cysts ingested from infected individual or from contaminated food or water	Metronidazole, furazolidone
Cryptosporidium	Mild diarrhea in immunocompromised infants; severe diarrhea in AIDS patients	Raising CD4 count to normal is best treatment. No proven therapy (antimicrobial); strong supportive care; may try rifabutin

Definition of abbreviations: HUS, hemolytic uremia syndrome

Chronic Diarrhea and Malabsorption

- Patterns
  - From birth
  - After introduction of a new food
- Clinical presentation
  - Chronic nonspecific diarrhea of infancy:
    - **Weight, height, and nutritional status is normal, and no fat in stool**
    - Excessive intake of fruit juice, carbonated fluids, low fat intake usually present in history
  - Diarrhea with carbohydrates—CHO malabsorption
  - Weight loss and stool with high fat—think malabsorption
- Workup of chronic diarrhea (simple, noninvasive testing to be done first)
  - History and physical, nutritional assessment; **stool** for pH, reducing substances, fat, blood, leukocytes, culture, *C. difficile* toxin, ova, and parasites
  - Blood studies—complete blood count and differential, ESR, electrolytes, glucose, BUN, and creatinine
  - **Sweat test, 72-hour fecal fat,** breath hydrogen tests
- Initial evaluation
  - Fat:
    - **Most useful screening test is stool for fat (Sudan red stain)**
    - **Confirm with 72-hour stool for fecal fat (gold standard for steatorrhea)**
    - **Steatorrhea is most prominent with pancreatic insufficiency; all require a sweat chloride**
    - Serum trypsinogen is also a good screen (reflects residual pancreatic function)
  - CHO malabsorption—screen with **reducing substances in stool (Clinitest)**
    - **Breath hydrogen test**—after a known CHO load, the collected breath hydrogen is analyzed and malabsorption of the specific CHO is identified
  - Protein loss—cannot be evaluated directly (large proportion of bacterial protein and dietary protein almost completely absorbed before terminal ileum; amino acids and peptides are reabsorbed)
    - Screen—**spot stool α_1-antitrypsin level**
- More common differential diagnosis of malabsorption
  - **Giardiasis—only common primary infection causing chronic malabsorption; duodenal aspirate/biopsy/immunoassay *(Giardia)***
  - HIV or congenital T- or B-cell defects
  - Small-bowel disease—**gluten enteropathy**, abetalipoproteinemia, lymphangiectasia
  - Pancreatic insufficiency—fat malabsorption (**cystic fibrosis is most common congenital disorder associated with malabsorption**)
  - Most common anomaly causing incomplete bowel obstruction with malabsorption is **malrotation**
  - **Short bowel**—congenital or postnatal loss of >50% of small bowel with or without a portion of the large intestine (presence of ileocecal valve is better)
  - **Celiac disease**—associated with exposure to **gluten** (rye, wheat, barley, derivatives)

Note

Schwachman-Diamond Syndrome
- Pancreatic insufficiency
- Neutropenia
- Malabsorption

Intestinal lymphangiectasia
- Lymph fluid leaks into bowel lumen
- Steatorrhea
- Protein-losing enteropathy

Disaccaridase Deficiency
- Osmotic diarrhea
- Acidic stools

Abetalipoproteinemia
- Severe fat malabsorption form birth
- Acanthocytes
- Very low to absent plasma cholesterol, triglycerides, etc.

  - Patients mostly age 6 months to 2 years
  - **Permanent intolerance**
  - Genetic predisposition (HLA DQ2)
  - Clinical presentation
  - Diarrhea
  - Failure to thrive
  - Growth retardation
  - Vomiting
  - Anorexia, not interested in feeding
  - Ataxia
- Evaluation
  - Blood for anti-tissue transglutaminase (IgA) and serum IgA (false if IgA deficiency) (best initial test)
  - Definitive test—small intestine biopsy
- Treatment—**lifelong, strict gluten-free diet**

VOMITING

Esophageal Atresia (EA) and Tracheoesophageal Fistula (TEF)

- Three basic types:
  - Isolated EA
  - Isolated (H-type) TEF
  - EA and distal TEF
- Most common anatomy is **upper esophagus ends in blind pouch and TEF connected to distal esophagus**
- **H-type—presents chronically** and diagnosed later in life with chronic respiratory problems
- Half with associated anomalies—**VACTERL** association
- Clinical presentation in neonate (EA or EA + TEF)
  - **Frothing, bubbling, cough, cyanosis, and respiratory distress**
  - **With feedings → immediate regurgitation and aspiration**
- Clinical presentation with just TEF—feeding problems and recurrent aspiration
- Diagnosis
  - **Inability to pass nasogastric/orogastric tube**
  - Esophageal atresia: x-ray shows coiled nasogastric tube in blind pouch with no distal gas (gasless abdomen)
  - **Isolated** TEF: **esophagram with contrast media** (or bronchoscopy or endoscopy with methylene blue)
  - Esophageal atresia and distal fistula: coiled nasogastric tube in blind pouch the large amount of air in stomach and intestines
- Treatment—surgical ligation of TEF and resection with end-to-end anastomosis of esophageal atresia

Note

VACTERL Association

Nonrandom association of birth defects:

Vertebral anomalies

Anal atresia

Cardiac defect

Tracheo**E**sophageal fistula

Renal anamolies

Limb abnormalities

Gastroesophageal Reflux Disease (GERD)

A 4-month-old is admitted with episodes of apnea occurring 20–30 min after feeds. The mother states the baby has been spitting up since birth. She is at the fifth percentile for weight.

- Etiology—insufficient lower esophageal sphincter tone early in life
- Symptoms during first few months of life; **resolves by 12–24 months of age;** in older children—chronic (more like adults); only half resolve completely
- Clinical presentation
  - **Postprandial regurgitation**
  - Signs of **esophagitis**—arching, **irritability,** feeding aversion, failure to thrive
  - **Obstructive apnea,** stridor, **lower airway disease (cough, wheezing)**
- Diagnosis
  - Most by history and physical
  - **Barium esophagram and upper gastrointestinal studies**
  - **Esophageal pH monitoring (best test)**—quantitative and sensitive documentation of acid reflux (normal pH in lower esophagus is <4 only 5–8% of time)
  - **Endoscopy—erosive esophagitis** and complications
  - Radionucleotide scintigraphy (Tc)—to document aspiration
  - Laryngotracheobronchoscopy—for extraesophageal GERD
- Management
  - **Conservative** with lifestyle management: normalize **feeding technique, appropriate volume, thicken feeds, positioning**
  - Pharmacologic:
    - **H_2-receptor antagonist** (ranitidine, cimetidine, famotidine)—**first-line** with overall best safety profile
    - **Proton pump inhibitor** (omeprazole, lansoprazole, pantoprazole)—most potent for severe reflux and esophagitis
  - Surgery—**fundoplication** for refractory esophagitis, strictures, chronic pulmonary disease, continued obstructive apnea

Note

Prokinetic agents (metaclopramide, bethanechol or erythromycin) have no efficacy in the treatment of GERD in children.

Pyloric Stenosis

A 4-week-old boy has nonbilious projectile vomiting. Physical examination is remarkable for a small mass palpated in the abdomen.

- Epidemiology—more common in whites of Northern European ancestry, **firstborn males**
- Clinical presentation
  - **Nonbilious, projectile vomiting**
  - **Still hungry and desire to feed more**
  - Usually age **≥3 weeks (1 week to 5 months)**

Note

Pyloric stenosis is high yield for the exam.

  - Mild-to-moderate dehydration, **hypochloremic, hypokalemic metabolic alkalosis**
  - Palpation of a firm, movable, 2-cm, **olive-shaped,** hard mass in midepigastrium; left to right peristaltic wave
- Diagnosis—best test is **ultrasound** (a target-like appearance in cross-section)
- Treatment
  - Rehydrate, correct electrolytes (NaCl, KCl)
  - **Pyloromyotomy**

Duodenal Atresia

A newborn presents with bilious vomiting with every feed. Abdominal film reveals a double bubble.

- Epidemiology
  - Half are born premature
  - **Down syndrome**
  - With other anomalies—malrotation, esophageal atresia, congenital heart defects, anorectal malformation, renal anomalies
- Clinical presentation
  - **Bilious vomiting *without* abdominal distention on first day of life** (obstruction just distal to ampulla)
  - **Polyhydramnios** prenatally
  - Many with **jaundice** (increased enterohepatic circulation)
- Diagnosis
  - X-ray shows classic **double bubble with *no* distal bowel gas.**
  - X-ray spine for anomalies; ultrasound for other anomalies
- Treatment
  - **Nasogastric decompression**
  - Intravenous fluids
  - **Surgery**—duodenoduodenostomy

Note

Jejunal or Ileal Atresia

Most present on the first day of life.

There is bile-stained emesis with abdominal distention. (With duodenal atresia, there is no abdominal distention.)

Plain films show air-fluid levels.

Contrast studies of the upper and lower intestine can delineate level of obstruction.

Ultrasound may also differentiate intestinal atresia from meconium ileus from malrotation.

Table 14-4. Congenital Bowel Obstruction

Lesion	Etiology	DDX	Clinical Background/ Presentation	Diagnosis	Management Algorithm/ Definitive Treatment
Duodenal Atresia	Failed recanalization of bowel lumen 4^{th}–7^{th} week gestation	• Duodenal stenosis • Annular pancreas • Duplication cysts • Ladd bands from malrotation	• Polyhydramnios • 50% premature • Other organ system anomalies • Half with chromosomal anomalies, especially trisomy 21 **Presentation** • First day • Bilious vomiting w/o abdominal distention • Jaundice	• **Prenatal sonogram** • **Postnatal plain X-ray:** double-bubble with NO distal bowel gas • **CXR, spine films** • **Echocardiogram** • **Renal ultrasound** for other most common anomalies	• NG/OG decompression • NPO + IV fluids + electrolyte balance • Broad-spectrum antibiotics **Definitive Treatment:** **Surgery when stable—** duodenoduodenostomy
Jejunal and Ileal Atresias	Intrauterine vascular accident → segmental infarction and resorption of fetal intestine	• Meconium ileus/ plug • Malrotation ± volvulus • Hirschprung disease	• Possible role with antenatal cigarette and/or cocaine use • Very little familial inheritance (aut. rec.) • Little extraintestinal anomalies **Presentation** • Polyhydramnios • Abdominal distention at birth or with first feeds + vomiting, may be bilious • Few with delayed or no passage of meconium • Jaundice	• Less likely to be detected in utero • **Plain X-ray:** multiple air-fluid levels proximal to obstruction in upright or lateral decubitus • **Ultrasound:** differentiate with meconium ileus and identify malrotation • **Contrast studies** to localize	• NG/OG • IV fluid and electrolyte balance prior to surgery • Antibiotics **Definitive Treatment:** **Surgery—**resect dilated proximal bowel then end-to-end anastamosis

(*Continued*)

Table 14-4. Congenital Bowel Obstruction (*Continued*)

Lesion	Etiology	DDX	Clinical Background/ Presentation	Diagnosis	Management Algorithm/ Definitive Treatment
Meconium Ileus	Abnormal viscous secretions → distal 20-30 cm of ileum collapsed and proximal bowel dilated and filled with thick meconium impacted in ileum	• Meconium plug • Atresias • Hirschprung disease • Malrotation ± volvulus	• 80-90% will be diagnosed with CF • May perforate in utero → meconium peritonitis (calcifications) **Presentation:** • Vomiting becomes persistent with prominent abdominal distention • No passage of meconium • May present as bowel perforation and peritonitis • Palpation of "doughy" or cordlike masses	• **Plain films:** dilated loops of bowel proximal to obstruction that vary with width and not evenly filled with gas • Presence of bubbly or granular appearance in RLQ (meconium with gas bubbles) • No air-fluid levels as secretions are too viscid to layer • **Ultrasound** to verify if questionable • **Water-soluble enema** (Gastrografin or Hypaque) will localize • **Test for CF**	• NPO • NG/OG decompression • IV fluid and electrolyte balance • Antibiotics **Definitive Treatment:** **First:** hypertonic water-soluble contrast enema to attempt wash-out **If fails**—laparotomy
Meconium Plugs	Decreased water content for many possible reasons leads to lower colonic or anorectal meconium plug	• Meconium ileus • Hirschprung disease	• Majority not associated with CF, unless in small bowel • Infants with polycythemia, dehydration and small left colon as may be seen with IODM • Maternal opiate use or treatment with MgSO4 **Presentation:** Failure of meconium passage and abdominal distention	• **Plain films:** low obstruction with proximal bowel dilatation and multiple air-fluid levels	• NG/OG + NPO • IV fluid and electrolyte balance • Antibiotics **Definitive Treatment:** • Evacuation with glycerin suppository if very low or saline enema or hypertonic water-soluble contrast if higher • Observe for possible Hirschprung disease • Consider sweat test if contrast shows small bowel plug.

(*Continued*)

Table 14-4. Congenital Bowel Obstruction (*Continued*)

Lesion	Etiology	DDX	Clinical Background/ Presentation	Diagnosis	Management Algorithm/ Definitive Treatment
Malrotation	• As developing bowel rotates in and out of abdominal cavity (weeks 5-12), superior mesenteric artery acts as the axis • With nonrotation, 1st and 2nd part of duodenum are in normal position, but because of inadequate mesenteric attachment to posterior wall, rest of small bowel occupies RLQ and colon the left • Failure of cecum to move to the RLQ → failure to form broad-based adhesions to posterior wall → superior mesenteric artery is tethered by a narrow stalk (causes volvulus) and Ladd bands can extend from cecum to RUQ and obstruct at duodenum.	• Intestinal atresias • Meconium ileus • Hirschprung disease	• Other anomalies of abdominal wall – Diaphragmatic hernia – Gastroschisis – Omphalocele – Heterotaxy syndrome (CHD, malrotation, asplenia/ polysplenia) **Presentation:** • 1st year of life with > 50% in first month with symptoms due to intermittent volvulus and/ or Ladd band obstruction -acute and chronic obstruction (recurrent pain and vomiting) • Can present in first week with bilious emesis and acute obstruction • May have, malabsorption due to bacterial overgrowth • Any age with acute obstruction due to volvulus	• **Plain film:** may show double-bubble with evidence of small amount of distal gas (prior to the volvulus) or a gasless abdomen • **Ultrasound:** inversion of superior mesenteric artery and vein • **Upper GI:** malposition of ligament of Treitz and small bowel obstruction with corkscrew appearance or duodenal obstruction with "bird's beak" appearance	• **If volvulus:** emergency surgery after IV and fluids • Otherwise NPO, NG/ OG • Correct fluid and electrolyte imbalance. **Definitive Treatment:** • **Surgery:** any patient of any age with any significant rotational abnormality • **Volvulus:** acute surgical emergency

(*Continued*)

Table 14-4. Congenital Bowel Obstruction (*Continued*)

Lesion	Etiology	DDX	Clinical Background/ Presentation	Diagnosis	Management Algorithm/ Definitive Treatment
Hirschprung Disease	• Developmental disorder of the enteric nervous system such that there are absence of ganglion cells in the submucosal and myenteric plexus • Arrest of neuroblast migration from proximal to distal bowel → inadequate relaxation and hypertonicity	• Long segment disease vs., intestinal atresia • Meconium plug • Meconium ileus	• Most common cause of intestinal obstruction in neonate • Usual short segment is male preponderance but equalizes with long segment disease • Increased familial incidence with long segment but must (short segment) are sporadic • May be associated with cardiovascular and urological defects and with Down syndrome • 80% are short (rectosigmoid) • 10-15% long (more than that) • 5% total bowel aganglionosis **Presentation:** • Most diagnosed in neonates • Suspect with any delayed meconium passage in full-term infant (99% within first 48 hours) or no passage with progressive abdominal distension and vomiting • Later with chronic constipation and empty rectum on digital exam with subsequent explosive release of small stool and gas • Main concern is meconium enterocolitis	• **Plain film:** distended loops of bowel • **Contrast enema** may not show classic line of demarcation form small aganglionic bowel to proximal dilatation (better >1 month of age) but 24 hr films usually show retained contrast and suggests the diagnosis • **Barium enema** also useful prior to surgery to define extent of aganglionic segment • **Gold standard confirmation is the suction rectal biopsy**	• NG/OG • NPO • Fluid and electrolyte management • Evaluate for other defects **Definitive Treatment:** Laparoscopic single-stage endorectal pull-through is procedure of choice.

Note

A delay in treating volvulus can result in short bowel syndrome.

Malrotation and Volvulus

- Etiology
  - **Incomplete rotation of intestine during fetal development**
  - Superior mesenteric artery acts as axis for rotation
  - **Ladd bands may extend from cecum to right upper quadrant (RUQ) to produce duodenal obstruction**
- Clinical presentation
  - Most present in first year of life with acute or chronic incomplete obstruction
  - **Bilious emesis, recurrent abdominal pain with vomiting**
  - **An acute small-bowel obstruction in a patient without previous bowel surgery is suspicious for volvulus (acute surgical abdomen)**
- Diagnosis
  - Plain film is nonspecific—may show double bubble if there is duodenal obstruction
  - Barium enema shows malposition of cecum (mobile cecum is not situated in the right lower quadrant); upper gastrointestinal will show malposition of ligament of Treitz
  - **Ultrasound will show inversion of superior mesenteric artery and vein (superior mesenteric vein to the left of the artery is suggestive) and duodenal obstruction with thickened bowel loops to the right of the spine; advantage is no need for contrast; start with this study**
- Treatment—surgery

Note

Meckel diverticulum: "Disease of 2s"

- 2 years of age
- 2% of population
- 2 types of tissue
- 2 inches in size
- 2 ft from ileocecal valve

HEMATOCHEZIA

Meckel Diverticulum

A 2-year-old boy presents with a 1-week history of painless rectal bleeding. Physical examination is unremarkable. The abdomen is soft and nontender. Rectal examination is unremarkable.

- Etiology
  - Remnant of embryonic yolk sac (omphalomesenteric or vitelline duct), **lining similar to stomach**
  - **Most frequent congenital gastrointestinal anomaly**
- Clinical presentation
  - Acid-secreting mucosa causes **intermittent painless rectal bleeding**
  - May get anemia, but blood loss is self-limited
  - May have partial or complete bowel obstruction (lead point for an intussusception) or develop diverticulitis and look like acute appendicitis (much less common presentation)
- Diagnosis—**Meckel radionuclide scan** (Tc-99m pertechnetate)
- Treatment—**surgical excision**

Intussusception

A 15-month-old child is seen for cramping, colicky abdominal pain of 12 h duration. He has had two episodes of vomiting and a fever. Physical examination is remarkable for a lethargic child; abdomen is tender to palpation. Leukocytosis is present. During examination, the patient passes a bloody stool with mucus.

- Etiology
  - **Telescoping** of bowel; most **ileal-colic**
  - Most present at age 3 months to 6 years (80% <2 years)
  - Commonly **following adenovirus or rotavirus** infection, upper respiratory infection, otitis media
  - Associated with HSP (Henoch-Schönlein purpura)
  - Can also occur with a **leading point**—Meckel diverticulum, polyp, neurofibroma, hemangioma, malignancy
- Pathophysiology—bowel drags mesentery with it and produces arterial and venous obstruction and mucosal necrosis → classic **"black currant jelly" stool**
- Clinical presentation
  - **Sudden onset of severe paroxysmal colicky abdominal pain; straining, legs flexed**
  - **Progressive weakness**
  - **Lethargy, shock with fever**
  - Vomiting in most (early on, it is bile-stained)
  - Decreased stooling
  - Blood in most patients in first 12 hours, but may be delayed or not at all
- Physical examination—slightly tender, **sausage-shaped mass on right in cephalocaudal axis**
- Diagnosis
  - Ultrasound to first screen for the diagnosis (non-invasive and cost-effective; "doughnut appearance") and look for free-air (if intussusception has caused perforation)
  - Air enema is the next study of choice as it is far safer than the previously-used barium enema (0.1 vs. 2.5% risk of perforation); air enema may be therapeutic and prevent the need for immediate surgery
- Treatment
  - If prolonged, shock, peritoneal irritation, or perforation → surgery
  - **Radiographic reduction under fluoroscopy**—most will reduce if done within 48 hours of presentation (goes down to half after that time)
  - If surgical—**if manual operative reduction is not possible or bowel is not viable, then resection and end-to-end anastomosis**

Note

Other causes of GI bleed

- Anal fissure (most common cause of lower GI bleed in infancy)
- Accidental swallowing of maternal blood (do Apt test)
- Peptic ulcer disease

CONSTIPATION

Functional Constipation

A 6-year-old boy complains of hard bowel movements every fifth day. Physical examination reveals normal weight and height. Abdomen is soft, and hard stool is palpable on rectal examination.

- Delay or difficulty in stooling for at least 2 weeks; typically after age 2 years
- Passage of painful bowel movements with **voluntary withholding** to avoid pain
- May have blood in stool
- Physical examination—**large volume of stool palpated in suprapubic area; rectal exam shows vault filled with stool**
- Treatment
  - Patient education (**bowel training program**)
  - **Relief of impaction**—enema, then stool softeners (mineral oil, lactulose, polyethylene glycol; no prolonged use of stimulants)
  - Behavioral modification
  - Deal with any psychosocial issues

Hirschsprung Disease

- Etiology—absence of a ganglion cells in bowel wall beginning at internal anal sphincter and extending variably proximally
- **Most common reason for bowel obstruction in neonates**
- Clinical presentation
  - Symptoms usually present at birth
  - **Suspect in any full-term infant with a delay in passage of meconium (>24 hours)**
  - May have subsequent history of chronic constipation (if short aganglionic segment)
- Diagnosis
  - Rectal manometry
  - Rectal suction biopsy is definitive
  - Presence of **transition zone** on barium enema (not necessary to perform)
- Treatment—**surgery** (most with temporary colostomy) and wait 6–12 months for definitive correction (most achieve continence)
- Complications—enterocolitis

Table 14-5. Functional Constipation Versus Hirschsprung Disease

	Functional Constipation	Hirschsprung Disease
Onset constipation	After 2 years of age	At birth
Failure to thrive	Uncommon	Possible
Enterocolitis	No	Possible
Abdominal distention	Usually not	Yes
Poor weight gain	Usually not	Common
Anal tone	Normal	Normal
Rectal	Stool in ampulla	No stool
Anorectal manometry	Distention of rectum → relaxation of internal sphincter	No sphincter relaxation
Barium enema	Large amount of stool; no transition zone	Transition zone with delayed evacuation

Renal and Urologic Disorders 15

Learning Objectives

- ❑ Recognize and describe treatment for urinary tract infection, vesicoureteral reflux, obstructive uropathy, and polycystic kidney disease
- ❑ Diagnose and describe treatments for disorders presenting with hematuria or proteinuria

URINARY TRACT INFECTION (UTI)

A 12-day-old infant presents with fever of 39°C (102°F), vomiting, and diarrhea. On physical examination, the infant appears to be ill and mildly dehydrated.

- Epidemiology—UTI more common in boys than in girls until after second year
- Etiology—colonic bacteria (mostly *E. coli,* then *Klebsiella* and *Proteus;* some *S. saprophyticus*)
- Types
  - *Cystitis*—dysuria, urgency, frequency, suprapubic pain, incontinence, **no fever** (unless very young)
  - *Pyelonephritis*—**abdominal or flank pain, fever, malaise, nausea, vomiting, diarrhea; nonspecific in newborns and infants**
  - *Asymptomatic bacteriuria*—positive urine culture without signs or symptoms; can become symptomatic if untreated; almost exclusive to girls
- Risk factors
  - Females:
    - Wiping
    - Sexual activity
    - Pregnancy
  - Males—uncircumcised
  - Both:
    - **Vesicoureteral reflux**
    - Toilet-training
    - Constipation
    - **Anatomic abnormalities**

- Diagnosis—**urine culture (gold standard)—and UA findings**
  - Need a proper sample—**if toilet-trained, midstream collection; otherwise, suprapubic tap or catheterization**
  - Positive if >50,000 colonies/mL (single pathogen) plus pyuria
- Treatment
  - Lower-urinary tract infection (cystitis) with amoxicillin, **trimethoprim-sulfamethoxazole, or nitrofurantoin** (if no fever)
  - **Pyelonephritis** start with oral antibiotics, unless patient requires hospitalization and IV fluids
- Follow up
  - **Do urine culture** 1 week after stopping antibiotics to confirm sterility; periodic reassessment for next 1–2 years
  - **Obtain ultrasound** for anatomy, suspected abscess, hydronephrosis, recurrent UTI
  - **Obtain voiding cystourethrogram** (VCUG) in recurrent UTIs or UTIs with complications or abnormal ultrasound findings

VESICOURETERAL REFLUX (VUR)

A 2-year-old girl presents with urinary tract infection. She has had multiple urinary tract infections since birth but has never had any follow-up studies to evaluate these infections. Physical examination is remarkable for an ill-appearing child who has a temperature of 40°C (104°F) and is vomiting.

- Definition—abnormal backflow of urine from bladder to kidney
- Etiology
  - Occurs when the submucosal tunnel between the mucosa and detrusor muscle is short or absent.
  - **Predisposition to pyelonephritis → scarring → reflux nephropathy (hypertension, proteinuria, renal insufficiency to end-stage renal disease [ESRD], impaired kidney growth)**
- Grading
  - *Grade I:* into nondilated ureter (common for anyone)
  - *Grade II:* upper collecting system without dilatation
  - *Grade III:* into dilated collecting system with calyceal blunting
  - *Grade IV:* grossly dilated ureter and ballooning of calyces
  - *Grade V:* massive; significant dilatation and tortuosity of ureter; intrarenal reflux with blunting of renal pedicles
- Diagnosis
  - **VCUG for diagnosis and grading**
  - **Renal scan for renal size, scarring and function; if scarring, follow creatinine**
- Natural history
  - Increased scarring with grade 5 (less so with bilateral 4)
  - Majority < grade 5 resolve regardless of age at diagnosis or whether it is unilateral or bilateral
  - With growth, tendency to resolve (lower > higher grades); resolve by age 6–7 years

- Treatment
  - Medical—based on reflux resolving over time; most problems can be taken care of **nonsurgically**
  - Careful ongoing monitoring for and aggressive treatment of all UTIs
  - Surgery if medical therapy fails, if grade 5 reflux, or if any worsening on VCUG or renal scan

OBSTRUCTIVE UROPATHY

- Definition—obstruction of urinary outflow tract
- Clinical presentation
  - **Hydronephrosis**
  - Upper abdominal or flank pain
  - Pyelonephritis, UTI (recurrent)
  - Weak, decreased urinary stream
  - Failure to thrive, diarrhea (or other nonspecific symptoms)
- Diagnosis
  - **Palpable abdominal mass in newborn; most common cause is hydronephrosis,,** due to ureteropelvic junction obstruction or **multicystic kidney disease** (less so–infantile polycystic disease)
  - **Most can be diagnosed prenatally with ultrasound.**
  - **Obtain VCUG in all cases of congenital hydronephrosis and in any with ureteral dilatation to rule out posterior urethral valves**
- Common etiologies
  - **Ureteropelvic junction obstruction—most common** (unilateral or bilateral hydronephrosis)
  - Ectopic ureter—drains outside bladder; causes continual incontinence and UTIs
  - Ureterocele—cystic dilatation with obstruction from a pinpoint ureteral orifice; mostly in girls
  - **Posterior urethral valves:**
    - **Most common cause of severe obstructive uropathy; mostly in boys**
    - **Can lead to end-stage renal disease**
    - **Present with mild hydronephrosis to severe renal dysplasia; suspect in a male with a palpable, distended bladder and weak urinary stream**
- Diagnosis—voiding cystourethrogram (VCUG)
- Treatment
  - Decompress bladder with catheter
  - Antibiotics (intravenously)
  - Transurethral ablation or vesicostomy
- Complications
  - If lesion is severe, may present with pulmonary hypoplasia (Potter sequence)
  - Prognosis dependent on lesion severity and recovery of renal function

DISEASES PRESENTING PRIMARILY WITH HEMATURIA

Acute Poststreptococcal Glomerulonephritis

A 10-year-old boy presents with Coca-Cola–colored urine and edema of his lower extremities. On physical examination, the patient has a blood pressure of 185/100 mm Hg. He does not appear to be in any distress. His lungs are clear to auscultation, and his heart has a regular rate and rhythm without any murmurs, gallops, or rubs. His past medical history is remarkable for a sore throat that was presumed viral by his physician 2 weeks before.

- Etiology
  - **Follows infection with nephrogenic strains of group A beta-hemolytic streptococci of the throat (mostly in cold weather) or skin (in warm weather)**
  - Diffuse mesangial cell proliferation with an increase in mesangial matrix; **lumpy-bumpy deposits of immunoglobulin (Ig) and complement** on glomerular basement membrane and in mesangium
  - Mediated by immune mechanisms but complement activation is mostly through the alternate pathway
- Clinical presentation
  - Most 5–12 years old (corresponds with typical age for strep throat)
  - **1–2 weeks after strep pharyngitis or 3–6 weeks after skin infection (impetigo)**
  - Ranges from asymptomatic microscopic hematuria to acute renal failure
  - **Edema, hypertension, hematuria (classic triad)**
  - Constitutional symptoms—malaise, lethargy, fever, abdominal or flank pain
- Diagnosis
  - Urinalysis—RBCs, **RBC casts**, protein 1–2 +, polymorphonuclear cells
  - Mild normochromic anemia (hemodilution and low-grade hemolysis)
  - **Low C3** (returns to normal in 6–8 weeks)
  - **Need positive throat culture or increasing antibody titer to streptococcal antigens; best single test is the anti-DNase antigen**
  - Consider biopsy only in presence of acute renal failure, nephrotic syndrome, absence of streptococcal or normal complement; or if present >2 months after onset
- Complications
  - Hypertension
  - Acute renal failure
  - Congestive heart failure
  - Electrolyte abnormalities
  - Acidosis
  - Seizures
  - Uremia
- Treatment (in-patient, if severe)
  - Antibiotics for 10 days (penicillin)
  - Sodium restriction, diuresis

Note

For diagnosis of prior Strep infection, use streptozyme (slide agglutination), which detects antibodies to streptolysin O, DNase B, hyaluronidase, streptokinase, and nicotinamide-adenine dinucleotidase.

  - Fluid and electrolyte management
  - Control hypertension (calcium channel blocker, vasodilator, or angiotensin-converting enzyme inhibitor)
  - Complete recovery in >95%

Other Glomerulonephritides

IgA Nephropathy (Berger disease)

- **Most common chronic glomerular disease worldwide**
- Clinical presentation
  - Most commonly presents with gross hematuria **in association with upper respiratory infection** or gastrointestinal infection
  - Then mild proteinuria, mild to moderate hypertension
  - **Normal C3**
- Most important primary treatment is blood pressure control.

Alport Syndrome

The school nurse refers a 7-year-old boy because he failed his hearing test at school. The men in this patient's family have a history of renal problems, and a few of his maternal uncles are deaf. A urinalysis is obtained from the patient, which shows microscopic hematuria.

- Hereditary nephritis (X-linked dominant); renal biopsy shows **foam cells**
- Asymptomatic hematuria and intermittent gross hematuria **1–2 days after upper respiratory infection**
- **Hearing deficits (bilateral sensorineural, never congenital)** females have subclinical hearing loss
- **Ocular abnormalities (pathognomonic is extrusion of central part of lens into anterior chamber**

Henoch-Schönlein Purpura

- Small vessel vasculitis with good prognosis
- Present with purpurie rash, joint pain, abdominal pain
- Most resolve spontaneously; antiinflammatory medications, steroids
- See also rheumatic and vasculitic disorders chapter on this topic

Hemolytic Uremic Syndrome (HUS)

A 3-year-old child presents to the emergency center with history of bloody diarrhea and decreased urination. The mother states that the child's symptoms began 5 days ago after the family ate at a fast-food restaurant. At that time the patient developed fever, vomiting, abdominal pain, and diarrhea. On physical examination, the patient appears ill. He is pale and lethargic.

- **Most common cause of acute renal failure in young children**
- **Microangiopathic hemolytic anemia, thrombocytopenia, and uremia**
- Most from *E. coli* O157:H7 (shiga toxin–producing)
  - Most from undercooked meat or unpasteurized milk; spinach
  - Also from **Shigella, Salmonella, Campylobacter**, viruses, drugs, idiopathic
- Pathophysiology
  - Subendothelial and mesangial deposits of granular, amorphous material—vascular occlusion, glomerular sclerosis, cortical necrosis
  - Capillary and arteriolar endothelial injury → **localized clotting**
  - **Mechanical damage to RBCs as they pass through vessels**
  - **Intrarenal platelet adhesion and damage** (abnormal RBCs and platelets then removed by liver and spleen)
  - Prothrombotic state
- Clinical presentation
  - Most common <4 years old
  - Bloody **diarrhea**
  - **5–10 days after infection, sudden pallor, irritability, weakness, oliguria occur; mild renal insufficiency to acute renal failure (ARF)**
  - Labs—hemoglobin 5–9 mg/dL, **helmet cells, burr cells, fragmented cells,** moderate reticulocytosis, white blood cells up to 30,000/mm^3, Coombs negative, **platelets usually 20,000–100,000/mm^3,** low-grade microscopic hematuria and proteinuria
- Many complications, including seizures, infarcts, colitis, intussusception, perforation,, heart disease, death
- Treatment
  - Meticulous attention to fluids and electrolytes
  - Treat hypertension
  - Aggressive nutrition (total parenteral nutrition [TPN])
  - Early peritoneal dialysis
  - **No antibiotics if *E. coli* O157:H7 is suspected—treatment increases risk of developing HUS**
  - Plasmapheresis or fresh frozen plasma—may be beneficial in HUS **not** associated with diarrhea or with severe central nervous system involvement
- Prognosis—more than 90% survive acute stage; small number develop ESRD (end-stage renal disease)

POLYCYSTIC KIDNEY DISEASE

Autosomal-Recessive Type (Infantile)

- Both kidneys **greatly enlarged** with many cysts through cortex and medulla
- **Microcysts** → development of **progressive interstitial fibrosis and tubular atrophy** → **renal failure**
- Also **liver disease**—bile duct proliferation and ectasia with hepatic fibrosis

- Clinical presentation
  - Bilateral flank masses in neonate or early infancy
  - May **present with Potter sequence**
  - Hypertension, oliguria, acute renal failure
  - About half have liver disease in newborn period
- Diagnosis
  - **Bilateral flank masses in infant with pulmonary hypoplasia (if severe)**
  - Oliguria and hypertension in newborn with absence of renal disease in parents
  - Ultrasound–prenatal and postnatal (numerous small cysts throughout)
- Treatment and prognosis
  - Symptomatic
  - Now more than 80% with 10-year survival
  - End-stage renal failure in more than half
  - **Need dialysis and transplant**

Autosomal-Dominant Type (Adults)

- **Most common hereditary human kidney disease**
- Both kidneys enlarged with cortical and medullary cysts
- Most present in **fourth to fifth decade,** but may present in children and neonates
- Renal ultrasound shows bilateral **macrocysts**
- Also **systemic cysts**—liver, pancreas, spleen, ovaries; **intracranial (Berry) aneurysm** (rarely reported in children)
- Diagnosis—**presence of enlarged kidneys with bilateral macrocysts with affected first-degree relative**
- Treatment—**control of blood pressure** (disease progression correlates with degree of hypertension); presentation in older children with favorable prognosis

DISEASES PRESENTING WITH PROTEINURIA

Nephrotic Syndrome

A 3-year-old child presents to the physician with a chief complaint of puffy eyes. On physical examination, there is no erythema or evidence of trauma, insect bite, cellulitis conjunctival injection, or discharge.

- **Steroid-sensitive minimal change disease is the most common nephrotic syndrome seen in children.**
- Features
  - **Proteinuria (>40 mg/m^2/hour)**
  - **Hypoalbuminemia (<2.5 g/dL)**
  - **Edema**
  - **Hyperlipidemia (reactive to loss of protein)**

Minimal Change Disease

- Clinical presentation
  - **Most common between 2 and 6 years of age**
  - May follow minor infections
  - **Edema**—localized initially around eyes and lower extremities; anasarca with serosal fluid collections less common
  - Common—diarrhea, abdominal pain, anorexia
  - Uncommon—hypertension, gross hematuria
- Diagnosis
  - Urinalysis shows proteinuria (3–4 +)
  - Some with **microscopic hematuria**
  - 24-hour urine protein—**40 mg/m^2/hour in children but now preferred initial test is a spot urine for protein/creatinine ratio >2**
  - **Serum creatinine usually normal** but may be increased slightly
  - **Serum albumin <2.5 g/dL**
  - **Elevated serum cholesterol and triglycerides**
  - **C3 and C4 normal**
- Treatment
  - Mild—outpatient management; **if severe—hospitalize**
  - Start **prednisone** for 4–6 weeks, then taper 2–3 months without initial biopsy
  - **Consider biopsy with hematuria, hypertension, heart failure, or if no response after 8 weeks of prednisone (steroid resistant)**
  - Sodium restriction
  - If severe—fluid restriction, plus intravenous 25% albumin infusion, followed by diuretic to mobilize and eliminate interstitial fluid
  - Re-treat relapses (may become steroid-dependent or resistant); may use alternate agents (cyclophosphamide, cyclosporine, high-dose pulsed methylprednisolone); renal biopsy with evidence of steroid dependency
- Complications
  - **Infection is the major complication**; make sure immunized against *Pneumococcus* and *Varicella* and check PPD
  - **Most frequent is spontaneous bacterial peritonitis (*S. pneumoniae* most common)**
  - Increased risk of thromboembolism (increased prothrombotic factors and decreased fibrinolytic factors) but really with aggressive diuresis
- Prognosis
  - Majority of children have **repeated relapses; decrease in number with age**
  - Those with steroid resistance and who have focal segmental glomerulosclerosis have much poorer prognosis (progressive renal insufficiency).

MALE GENITOURINARY DISORDERS

Undescended Testes

- **Most common disorder of sexual differentiation in boys (more in preterm)**
- Testes should be descended by **4 months** of age or will remain undescended
- Usually in inguinal canal, but some are ectopic
- Prognosis
  - Treated: bilateral (50–65% remain fertile), unilateral (85% remain fertile)
  - Untreated or delay in treatment: increased risk for **malignancy** (**seminoma** most common)
- **Surgery (orchiopexy) at 9–15 months**

Testicular Torsion

- **Most common cause of testicular pain age >12 years**
- Clinical presentation—**acute pain and swelling; tenderness to palpitation**
- Testicle in transverse lie and retracted, no crematic reflex
- Diagnosis—Doppler color flow ultrasound (only to determine direction of torsion and to guide manual detorsion, if urologist decides this is warranted; also to confirm successful detorsion in a completely asymptomatic patient)
- Treatment—**emergent surgery** (scrotal orchiopexy); if within 6 hours and <360-degree rotation, >90% of testes survive

Torsion of Appendix Testes

- **Most common cause of testicular pain age 2–11 years**
- Clinical presentation
  - **Gradual onset**
  - 3–5 mm, tender, inflamed mass at **upper pole of testis**
  - Naturally resolves in 3–10 days (bed rest, analgesia)
- Diagnosis
  - Clinical—**blue dot** seen through scrotal skin
  - Ultrasound if concerned with testicular torsion
  - Scrotal exploration if diagnosis still uncertain

Epididymitis

- **Ascending, retrograde urethral infection → acute scrotal pain and swelling (rare before puberty)**
- **Main cause of acute painful scrotal swelling in a young, sexually active male**
- Urinalysis shows **pyuria** (can be *N. gonorrhoeae* [GC] or *Chlamydia*, but organisms mostly undetermined)
- Treatment—**bedrest and antibiotics**

Note

Differentiate **undescended testes** from **retractile testes** (brisk cremasteric reflect age >1 [can manipulate into scrotum]).

Testicular Tumors

- 65% are malignant
- Palpable, hand mass that **does not** tranilluminate
- Usually **painless**
- Diagnosis
  - Ultrasound
  - Serum AFP, beta-HCG
- Treatment—radical orchiectomy

Endocrine Disorders 16

Learning Objectives

- ❑ Recognize and describe treatments for thyroid, parathyroid, and adrenal disorders
- ❑ Describe the epidemiology and treatment of childhood diabetes mellitus

PITUITARY DISORDERS

Hypopituitarism

- **Deficiency of growth hormone ± other hormones; also delay in pubertal development is common; results in postnatal growth impairment corrected by growth hormone**
- Isolated growth-hormone deficiency or multiple pituitary deficiencies
  - Congenital—autosomal dominant, recessive, or X-linked recessive
  - Acquired—any lesion that damages the hypothalamus, pituitary stalk, or anterior pituitary (**most common is craniopharyngioma**)
- Clinical presentation
  - **Congenital** hypopituitarism:
    - **Normal size and weight at birth; then severe growth failure in first year**
    - Infants—**present with neonatal emergencies**, e.g., apnea, hypoglycemic seizures, hypothyroidism, hypoadrenalism in first weeks or boys with microphallus and small testes ± cryptorchidism
    - Also have a variety of dysmorphic features; appearance
  - **Acquired** hypopituitarism:
    - Findings appear gradually and progress: growth failure; pubertal failure, amenorrhea; symptoms of both decreased thyroid and adrenal function; possible DI
    - If there is an **expanding tumor**: headache, vomiting; visual changes, decreased school performance; papilledema, cranial nerve palsies
- Laboratory evaluation
  - Screen for **low serum insulin-like growth factor (IGF)-1 and IGF-binding protein-3 (IGF-BP3)**
  - Definitive test—**growth-hormone stimulation test**
  - **Examine other pituitary function:**
    - Thyroid-stimulating hormone (TSH), T_4
    - Adrenocorticotropic hormone (ACTH), cortisol, dehydroepiandrosterone (DHEA) sulfate, gonadotropins, and gonadal steroids

Note

If there is a normal response to hypothalamic-releasing hormones, the pathology is located within the hypothalamus.

- Other studies
  - X-ray most helpful with **destructive lesions** (enlargement of sella, erosions)
  - Calcification
  - **Bone age—skeletal maturation markedly delayed (BA 75% of CA)**
  - **MRI is indicated in all patients with hypopituitarism.** (superior to CT scan)
- Differential diagnoses (the major ones)
  - **Systemic conditions** (Weight is often proportionally much less than height.)
  - **Constitutional delay** (delayed BA, delayed adolescent growth spurt, and pubertal development)
  - Familial **short stature** (BA = CA, short parents)
  - **Primary hypothyroidism**
  - **Emotional deprivation** (psychosocial dwarfism)
- Treatment
  - Classic growth-hormone deficiency—**recombinant growth hormone**
  - Need periodic thyroid evaluation—develop reversible hypothyroidism
- Indications—**growth hormone currently approved in United States for**
  - Documented growth-hormone deficiency
  - Turner syndrome
  - End-stage renal disease before transplant
  - Prader-Willi syndrome
  - Intrauterine growth retardation (IUGR) without catch-up growth by 2 years of age
  - Idiopathic pathologic short stature

Hyperpituitarism

Note

If the history suggests anything other than familial tall stature or obesity, or if there are positive physical findings, then the patient needs laboratory evaluation.

- Primary—**rare;** most are hormone-secreting **adenomas**
- Majority are deficiencies of target organs and because of negative feedback, there are increases in hypothalamus and pituitary hormones
- Laboratory evaluation
  - Screen—**IGF-1 and IGF-BP3 for growth hormone excess;** confirm with a glucose suppression test
  - **Need MRI of pituitary**
  - **Chromosomes especially in tall males** (decreased upper- to lower-body segment ratio suggests XXY; mental retardation suggests fragile X)
  - **Thyroid tests**
- Management
  - Treatment only if prediction of adult height (based on BA) >3 SD above the mean or if there is evidence of severe psychosocial impairment
  - Trial of sex steroids (accelerates puberty and epiphyseal fusion)

Prolactinoma

- Most common pituitary disorder of adolescents; more common in girls
- Headache, visual disturbances (with large tumors), galactorrhea, amenorrhea ± findings of hypopituitarism (again with large tumors)
- Diagnosis: increased serum prolactin level then best test, MRI
- Treatment: bromocriptine (still the only dopamine-agonist approved for children)

Physiologic Gynecomastia

- Breast tissue in the male: common (estrogen: androgen imbalance)
- Distinguish from pseudogynecomastia: adipose tissue in an overweight male
- May occur in newborns (estrogen effect) or adolescents (most common)
- Symmetric or asymmetric; may be tender
- Usually up to age 2 years
- If significant with psychological impairment, consider danzol (anti-estrogen) or surgery (rare)

Precocious Puberty

- Definition
  - Girls—sexual development age <8 years
  - Boys—sexual development age <9 years
- Most common etiologies
  - Sporadic and familial in girls
  - Hamartomas in boys
- Clinical presentation—advanced height, weight, and bone age; early epiphyseal closure and early/fast advancement of Tanner stages
- Evaluation
  - Screen—significant increase in leuteinizing hormone
  - Definitive—GnRH stimulation test; give intravenous GnRH analog for a brisk, leuteinizing hormone response
  - If positive, then order MRI
- Treatment—stop sexual advancement and maintain open epiphyses (stops BA advancement) with leuprolide

Incomplete Precocious Puberty

- Premature thelarche
  - Usually isolated, transient (from birth due to maternal estrogens)
  - May be first sign of true precocious puberty
- Premature adrenarche—early adrenal androgen production (variation of normal)—axillary, inguinal, and genital hair. It is familial.
- Premature menarche—very rare (other causes of bleeding much more common)

THYROID DISORDERS

Hypothyroidism

A 2-month-old patient appears to be having inadequate weight gain. His mother states he is constipated. On examination, he has decreased muscle tone, a large fontanel, a large tongue, and an umbilical hernia.

- *Congenital* hypothyroidism—**most are primary** (i.e., from thyroid gland)
  - Sporadic or familial; **with or without a goiter**
    - Most common is **thyroid dysgenesis** (hypoplasia, aplasia, ectopia); **no goiter**
    - Defect in **thyroid hormone synthesis—goitrous**; autosomal recessive
    - **Transplacental passage of maternal thyrotropin** (transient)
    - Exposure to maternal antithyroid drugs
    - Radioiodine exposure/fetal exposure to excessive iodine (topical iodine antiseptics) (now rare in U.S.)
    - Iodine deficiency or endemic goiter
    - Central hypopituitarism
  - Clinical presentation is known as "cretinism."
    - **Prolonged jaundice**
    - **Large tongue**
    - **Umbilical hernia**
    - **Edema**
    - **Mental retardation; developmental delay**
    - **Anterior and posterior fontanels wide**
    - **Mouth open**
    - **Hypotonia**
  - Other findings—weight and length normal at birth, feeding difficulties, apnea, sluggish, decreased appetite, increased sleep, constipation, decreased temperature, skin cold and mottled, peripheral anemia; apathetic appearance
  - Laboratory evaluation:
    - **Low serum T_4 or free T_4; increased TSH**
  - Treatment—**sodium thyroxine**
- *Acquired* hypothyroidism
  - **Hashimoto**; thryroiditis is most common cause; may be part of **autoimmune polyglandular syndrome**
  - Typically presents in **adolescence**
  - Other causes—iatrogenic (medications, irradiation, surgery, radioiodine); systemic disease (cystinosis, histiocytic infiltration)
- Clinical presentation
  - Many more girls than boys
  - **First sign usually deceleration of growth**

Note

Autoimmune Polyglandular Disease

Type I
- Hypoparathyroidism
- Addison disease
- Mucocutaneous candidiasis
- Small number with autoimmune thyroiditis

Type II *(Schmidt syndrome)*
- Addison disease, *plus*:
- Insulin-dependent DM
- With or without thyroiditis

  - Then myxedema, constipation, cold intolerance, decreased energy, increased sleep, delayed osseous maturation, delayed puberty, headache, visual problems
  - **Diffusely increased, firm, nontender thyroid;** but may be atrophic so can be non-goitrous
  - Laboratory and treatment—same as congenital

Hyperthyroidism

A 12-year-old girl has a 6-month history of hyperactivity and declining school performance. Appetite is increased, but she shows no weight gain. Physical examination reveals a slight tremor of the fingers, mild exophthalmos, and a neck mass.

- Almost all cases are **Graves disease**
- **Peak at age 11–15 years;** girls > boys
- **Most with family history** of some form of autoimmune thyroid disease
- Findings
  - **Infiltration of thyroid and retro-orbital tissue** with lymphocytes and plasma cells → exopthalmos
  - **Lymphadenopathy and splenomegaly**
  - Thymic hyperplasia
- In whites, association with HLA-B8 and **DR3** is also seen with other DR3-related disorders (Addison disease, diabetes mellitus, myasthenia gravis, celiac disease).
- Clinical
  - Most signs and symptoms appear **gradually**
  - Earliest **usually emotional lability and motor hyperactivity**
  - **Decreased school performance**, tremor, increased appetite with weight loss, skin flushed with increased sweating, muscle weakness, **tachycardia, palpitations, arrhythmias, hypertension**
  - **Goiter, exophthalmos**
  - **Thyroid storm**—acute onset of hyperthermia, severe tachycardia, restlessness → rapid progression to delirium, coma, and death
- Laboratory evaluation
  - **Increased T_4, T_3, free T_4**
  - **Decreased TSH**
  - Measurable TRS-AB (and may have thyroid peroxidase antibodies)
- Treatment
  - **Propylthiouracil (PTU) or methimazole**
  - **Beta blockers** for acute symptoms (thyroid storm)
  - If medical treatment not adequate, radioablation or surgery; then treat as hypothyroid (daily thyroxine replacement)

Note

Thyroid cancer in children is uncommon, but you should know about medullary carcinoma (parafollicular cells), seen in 2 of the multiple endocrine neoplasias (MEN):

- **MEN IIA:** hyperplasia or cancer of thyroid ***plus*** adrenal medullary hyperplasia or pheochromocytoma ***plus*** parathyroid hyperplasia
- **MEN IIB (mucosal neuroma syndrome):** multiple neuromas ***plus*** medullary thyroid cancer ***plus*** pheochromocytoma

PARATHYROID DISORDERS

Hypoparathyroidism

- Parathyroid hormone (PTH) deficiency
- Etiologies
  - Aplasia/hypoplasia—most with **DiGeorge** or velocardiofacial syndrome
  - X-linked recessive—**defect in embryogenesis**
  - Autosomal dominant—mutation in calcium-sensing receptor
  - Postsurgical (thyroid)
  - Autoimmune—**polyglandular disease**
  - Idiopathic (cannot find other cause)
- Clinical presentation
  - Early—muscle pain/cramps, numbness, tingling
  - **Laryngeal and carpopedal spasm**
  - **Seizures (hypocalcemic seizures in newborn; think DiGeorge)**
- Laboratory evaluation
  - **Decreased serum calcium** (5–7 mg/dL)
  - **Increased serum phosphorus** (7–12 mg/dL)
  - Normal or low alkaline phosphatase
  - Low 1,25 $[OH]_2D_3$ (calcitriol)
  - Normal magnesium
  - **Low parathyroid hormone** (immunometric assay)
  - EKG: **prolongation of QT**
- Treatment
  - Emergency for neonatal tetany → intravenous 10% calcium gluconate and then 1,25$[OH]_2D_3$ (calcitriol); this normalizes the calcium
  - Chronic treatment with calcitriol or vitamin D_2 (less expensive) *plus* adequate calcium intake (daily elemental calcium)
  - Decrease foods high in phosphorus (milk, eggs, cheese)

Vitamin D Deficiency

- Most common cause of rickets
- Poor intake, inadequate cutaneous synthesis
- Low serum phosphate, normal to low serum calcium lead to increased PTH and increased alkaline phosphatase
- Increased 25-hydroxy vitamin D
- Fractures, rachitic rosary, craniotabe bone deformities
- Treatment: initial vitamin D replacement and calcium, then adequate dietary calcium and phosphate

Table 16-1. Lab Diagnosis of Parathyroid Disease

	PTH	Calcium	Phosphate	Alkaline Phosphatase
Primary Hypo	Decreased	Low	High	Normal
Pseudo Hypo	Increased	Low	High	NL or SL increased
Primary Hyper	Increased	High	Low	Increased
Secondary Hyper	Increased	NL to SL decreased	Low	Huge increase

ADRENAL DISORDERS

TheFetus.net.

Figure 16-1. Ambiguous Genitalia Seen in Congenital Adrenal Hyperplasia

Congenital Adrenal Hyperplasia (CAH)

A 1-month-old infant is seen with vomiting and severe dehydration. Physical examination reveals ambiguous genitalia; laboratory tests show hyponatremia.

- **21-Hydroxylase deficiency (most common)**
  - Autosomal-recessive enzyme deficiency
  - Decreased production of cortisol → **increased ACTH → adrenal hyperplasia**
  - **Salt losing** (not in all cases; some may have normal mineralocorticoid synthesis)
  - Precursor steroids (17-OH progesterone) accumulate
  - **Shunting to androgen** synthesis → masculinizes external genitalia in females
  - Findings (with salt losing):
    - Progressive weight loss (through 2 weeks of age), anorexia, vomiting, dehydration
    - Weakness, hypotension

Note

Other 3 Main Defects in CAH

- **3-beta-hydroxysteroid deficiency:** salt-wasting, male and female pseudohermaphrodites, precocious pubarche; increased 17-OH pregnenolone and DHEA
- **11-beta-hydroxylase deficiency:** female pseudohermaphroditism, postnatal virilization, hypertension; increased compound S, DOC, serum androgens, and hypokalemia
- **17-alpha hydroxyl/17,20 lyase deficiency:** male pseudohermaphroditism, sexual infantilism, hypertension; increased DOC, 18-OH DOC, 18-OH corticosterone, and 17-alpha-hydroxylated steroids; hypokalemia

  - Hypoglycemia, **hyponatremia**, hyperkalemia
  - **Affected females—masculinized external genitalia (internal organs normal)**
  - Males normal at birth; postnatal virilization
- Laboratory evaluation
  - **Increased 17-OH progesterone**
  - Low serum sodium and glucose, high potassium, acidosis
  - Low cortisol, increased androstenedione and testosterone
  - Increased plasma renin and **decreased aldosterone**
  - **Definitive test**—measure 17-OH progesterone before and after an intravenous bolus of ACTH
- Treatment
  - **Hydrocortisone**
  - **Fludrocortisone** if salt losing
  - **Increased doses of both hydrocortisone and fludrocortisone in times of stress**
  - Corrective surgery for females

Cushing Syndrome

- Exogenesis—most common reason is **prolonged exogenous glucocorticoid administration.**
- Endogenous
  - In infants—**adrenocortical tumor (malignant)**
  - Excess ACTH from **pituitary adenoma** results in **Cushing disease** (age >7 years)
- Clinical findings
  - **Moon facies**
  - **Truncal obesity**
  - **Impaired growth**
  - **Striae**
  - **Delayed puberty and amenorrhea**
  - **Hyperglycemia**
  - Hypertension common
  - Masculinization
  - **Osteoporosis with pathologic fractures**
- Laboratory evaluation
  - **Dexamethasone-suppression test (single best test)**
  - **Determine cause—CT scan (gets most adrenal tumors) and MRI (may not see if microadenoma)**
- Treatment—remove tumor; if no response, remove adrenals; other tumor-specific protocols

DIABETES MELLITUS

Type 1

An 8-year-old boy is seen in the emergency department with vomiting and abdominal pain of 2 days' duration. His mother states he has been drinking a lot of fluids for the past month, and reports weight loss during that time. Physical examination reveals a low-grade fever, and a moderately dehydrated boy who appears acutely ill. He is somnolent but asks for water. Respirations are rapid and deep. Laboratory tests reveal a metabolic acidosis and hyperglycemia.

- Etiology—T-cell–mediated autoimmune destruction of islet cell cytoplasm, insulin autoantibodies (IAA)
- Pathophysiology—low insulin **catabolic state**
  - Hyperglycemia → osmotic diuresis; when renal threshold for glucose reabsorption is reached (180 mg/dL) → glycosuria
  - Loss of fluid, electrolytes, calories, and dehydration
  - Accelerated lipolysis and impaired lipid synthesis → increased free fatty acids → ketone bodies → metabolic acidosis and Kussmaul respiration → decreased consciousness
- Clinical presentation
  - **Polyuria**
  - **Polydipsia**
  - **Polyphagia**
  - **Weight loss**
  - **Most initially present with diabetic ketoacidosis**
- Diagnostic criteria
  - Impaired glucose tolerance test
    - Fasting blood sugar 110–126 mg/dL or 2-hour glucose during OGTT<200 mg/dL but ≥125 mg/dL
  - Diabetes
    - Symptoms + random glucose ≥200 mg/dL or
    - Fasting blood sugar ≥126 mg/dL or
    - 2 hour OGTT glucose ≥200 mg/dL
  - **Diabetic ketoacidosis—hyperglycemia, ketonuria, increased anion gap, decreased HCO_3 (or total CO_2), decreased pH, increased serum osmolality**
- Treatment
  - Insulin administration, dosed primarily with meals
  - Testing before meals and at night
  - Diet modification
  - Close patient follow up

- Diabetic ketoacidosis:
  - **Insulin must be started at beginning of treatment.**
  - **Rehydration** also lowers glucose.
  - Monitor blood sugar, electrolytes; avoid rapid changes
  - Sodium falsely low
- Exercise
  - All forms of exercise or competitive sports should be encouraged.
  - Regular exercise improves glucose control.
  - May need additional CHO exchange

Type 2

- **Most common cause of insulin resistance is childhood obesity.**
- Symptoms more insidious
  - Usually excessive weight gain
  - Fatigue
  - Incidental glycosuria (polydipsia and polyuria uncommon)
- Risk factors
  - Age 10-19 years
  - Overweight to obese (BMI for age and sex >85%)
  - Non-Caucasian
  - History of type 2 DM in 1st- or 2nd-degree relatives
  - Having features of the metabolic syndrome
- Features of the Metabolic Syndrome
  - Glucose intolerance leads to L hyperglycemia
  - Insulin resistance
  - Obesity
  - Dyslipidemia
  - Hypertension
  - Acanthosis nigricans
- Screening and Treatment
  - **Who:** All who meet the BMI criteria + 2 risk factors
  - **How to screen:** fasting blood glucose every 2 years beginning at age 10 years or onset of puberty if above criteria are met
  - **Diagnosis:** same criteria (glucose levels) as adults
  - **Treatment:** first and most important is nutritional education and improved exercise level, but most will eventually need an oral hypoglycemic

Maturity-Onset Diabetes of Youth (MODY)

- Primary autosomal dominant defect in insulin secretion (6 types based on gene mutation)
- Diagnosis: 3 generations of DM with autosomal; dominant transmission and diagnosis of onset age <25 years
- Best test: molecular genetics for mutation (facilitates management and prognosis)

Orthopedic Disorders 17

Learning Objectives

- ❑ Recognize and describe treatments for childhood disorders of the hip, knee, foot, spine, and upper limbs
- ❑ Diagnose and describe treatments for osteomyelitis, septic arthritis, osteogenesis imperfecta, and bone tumors

DISORDERS OF THE HIP

Developmental Dysplasia of the Hip (DDH)

- General ligamental laxity
  - Family history
  - Significantly more females
  - Firstborn
  - Breech
  - Oligohydramnios
  - Multiple gestation
- Physical examination
  - **Barlow is most important examination**; will dislocate an unstable hip; is easily felt (clunk not a click)
  - **Ortolani**—reduces a recently dislocated hip (most at 1–2 months of age), but after 2 months, usually not possible because of soft-tissue contractions
- All infants with positive exams should **immediately be referred to an orthopedic surgeon** (per standard of practice of the AAP); no radiographic confirmation is needed
- If equivocal, can repeat exam in 2 weeks and if equivocal then **a dynamic U/S** of the hips is the best test (age <4 months) or hip x-ray (age >4 months)
- Treatment
  - Pavilk harness for 1–2 months
  - Surgery, casting
- Complications—acetabular dysplasia, leg length discrepancy

Legg-Calvé-Perthes Disease

A 5-year-old boy has developed progressive limping. At first painless, it now hurts to run and walk. The pain is in the anterior thigh. The pain is relieved by rest. Parents recall no trauma.

- **Idiopathic avascular necrosis** of the **capital femoral epiphysis** in immature, growing child
- More in males; 20% bilateral; sometimes after trauma
- Presentation—mild intermittent pain in anterior thigh with **painless limp** with restriction of motion
- Diagnosis—anterior/posterior and frog leg lateral x-ray shows compression, collapse, and deformity of femoral head
- Treatment
  - Containment (femoral head within acetabulum) with orthoses or casting
  - Bedrest
  - Abduction stretching exercises
  - If significant femoral deformity persists, surgical correction

Figure 17-1. MRI Demonstrating Legg-Calve-Perthes Disease

Slipped Capital Femoral Epiphysis (SCFE)

- Most common adolescent hip disorder
- Either **obese** with delayed skeletal maturation, or **thin** with a **recent growth spurt**
- Can occur with an underlying endocrine disorder
- Clinical presentation
  - Pre-slip stable; exam normal; mild limp external rotation
  - Unstable slip; sudden-onset extreme pain; cannot stand or walk; 20% complain of knee pain with decreased hip rotation on examination

- Complications—osteonecrosis (avascular necrosis) and chondrolysis (degeneration of cartilage)
- Diagnosis—AP and frog-leg lateral x-ray, earliest finding: widening of physis without slippage (preslip); as slippage occurs, femoral neck rotates anteriorly while head remains in acetabulum
- Treatment—open or closed reduction (pinning)

Figure 17-2. X-ray of the Hips Demonstrating Slipped Capitol Femoral Epiphysis

Transient Synovitis

- Viral; most 7–14 days after a nonspecific upper respiratory infection; most at 3–8 years of age
- Clinical presentation
  - Acute mild pain with **limp** and mild restriction of movement
  - Pain in groin, anterior thigh, and knee
- Diagnosis
  - Small effusion (±)
  - Slight increase in ESR
  - **Normal x-rays**
  - No to low-grade fever; non-toxic-appearing
- Treatment—bedrest and no weight-bearing until resolved (usually <1 week), then 1–2 weeks of limited activities

INTOEING

Metatarsus Adductus

- Most common in firstborn (deformation)
- Forefoot adducted from flexible to rigid
- Treatment—primarily nonsurgical; serial plaster casts before 8 months of age; orthoses, corrective shoes; if still significant in a child age >4 years, may need surgery

Talipes Equinovarus (Clubfoot)

A newborn is noted to have a foot that is stiff and slightly smaller than the other one. The affected foot is medially rotated and very stiff, with medial rotation of the heel.

Note

In **talipes equinovarus**, the patient's heel can't go flat on the exam surface (as opposed to metatarsus adductus, in which the heel can).

- Congenital, positional deformation, or associated with neuromuscular disease
- Hindfoot equinus, hindfoot and midfoot varus, forefoot adduction (at talonavicular joint)
- Treatment
  - Complete correction should be achieved by 3 months (serial casting, splints, orthoses, corrective shoes); if not, then surgery

Internal Tibial Torsion

- **Most common cause of intoeing <2 years of age** (also because of in utero positioning); often with metatarsus adductus
- Measure prone thigh/foot angles
- No treatment needed—resolves with normal growth and development; takes 6–12 months (is physiologic)

Internal Femoral Torsion (Femoral Anteversion)

- Most common cause of intoeing ≥2 years of age; entire leg rotated inwardly at hip during gait
- Most are secondary to abnormal sitting habits (W-sitting).
- Treatment—observation; takes 1–3 years to resolve; surgery only if significant at >10 years of age

DISORDERS OF THE KNEE

Osgood-Schlatter Disease

- Traction apophysitis of tibial tubercle (**overuse injury**)
- Look for **active adolescent** (running, jumping)
- Swelling, tenderness, increased **prominence of tubercle**
- Treatment—**rest**, restriction of activities, knee immobilization, isometric exercises
- Complete resolution requires 12–24 months

DISORDERS OF THE SPINE

Scoliosis

A 12-year-old girl is seen for routine physical examination. She voices no complaints. Examination is remarkable for asymmetry of the posterior chest wall on bending forward. One shoulder appears higher than the other when she stands up.

- **Most are idiopathic**; rarely, hemivertebra
- Others are congenital, with neuromuscular disorders, compensatory, or with intraspinal abnormalities.
- Slightly more females than males; more likely to progress in females
- Adolescent (**>11 years**) more common
- **Adams test bending forward at hips** —almost all with >**20-degree** curvature are identified in school screening programs (but many false positives)
- Diagnosis—x-ray is standard: posterior/anterior and lateral of entire spine gives greatest angle of curvature
- Treatment—trial brace for immature patients with curves 30–45 degrees and surgery for those >45 degrees (permanent internal fixation rods)

DISORDERS OF THE UPPER LIMB

Nursemaid Elbow

- When longitudinal traction causes radial head subluxation
- **History of sudden traction or pulling on arm**
- Physical exam reveals a child who refuses to bend his/her arm at the elbow
- Treatment—rotate hand and forearm to the supinated position with pressure of the radial head → reduction

OSTEOMYELITIS AND SEPTIC ARTHRITIS

- Etiology
  - **Osteomyelitis:**
    - *S. aureus* most common overall, in all
    - *Pseudomonas*—puncture wound
    - More *Salmonella* in sickle cell (*S. aureus* still most common)
  - **Septic arthritis:**
    - Almost all *S. aureus*
    - Most in young children; hematogenous; LE > UE and other parts of body
- Presentation
  - Pain with movement in infants
  - Older—fever, pain, edema, erythema, warmth, limp, or refusal to walk (acute, toxic, high fever)

Note

X-rays for patients with **osteomyelitis** are initially normal. Changes are not seen until 10–14 days.

- Diagnosis
  - Blood culture, CBC, ESR
  - Radiographic studies:
    - **Initial plain film** if diagnosis not obvious to exclude other causes—trauma, foreign body, tumor; trabecular long bones do not show changes for 7–14 days (septic arthritis shows widening of joint capsule and soft-tissue edema)
    - **Ultrasound for septic arthritis**—joint effusion, guide localization of drainage
    - **Best test is MRI for osteo**; very sensitive and specific
    - Bone scan—can be valuable to augment MRI, especially if multiple foci are suspected or vertebrate
  - Definitive—aspirate for culture and sensitivity
    - Osteomyelitis → bone biopsy for culture and sensitivity
    - Septic arthritis → ultrasound guided arthrocentesis for culture and sensitivity
- Treatment
  - Intravenous antibiotics—always cover for *Staphylococcus* initially (treatment for osteo much longer)

OSTEOGENESIS IMPERFECTA

- Susceptibility to fracture of long bones or vertebral compression from mild trauma
- **Most common genetic cause of osteoporosis;** all types caused by structural or quantitative defects in type I collagen
- **Autosomal dominant**
- **Clinical triad is fragile bones, blue sclera, and early deafness** (and short stature)
- Four types, from perinatally **lethal** to mild, nonlethal
- Diagnosis
  - May see fractures on prenatal ultrasound as early as 6 weeks
  - Rule out child abuse due to fracture and injury history.
  - Confirmed by collagen biochemical studies using fibroblasts cultured from a skin-punch biopsy
- Treatment—no cure; physical rehabilitation; fracture management and correction of deformities

Courtesy of Tom D. Thacher, M.D.

Figure 17-3. Blue Sclera in Osteogenesis Imperfecta

Courtesy of Tom D. Thacher, M.D.

Figure 17-4. Skeletal Malformation Due to Osteogenesis Imperfecta

BONE TUMORS

Table 17.1. Comparison of Osteogenic Sarcoma, Ewing Sarcoma, and Osteoid Ostcoma

	Osteogenic Sarcoma	Ewing Sarcoma	Osteoid Osteoma
Presentation	Second decade	Second decade	Second decade
M:F	Slightly greater in males	Slightly greater in males	3x greater in males
Predisposition	Retinoblastoma, radiation	None	Male gender
X-ray	Sclerotic destruction: **"sunburst"**	Lytic with laminar periosteal elevation: **"onion skin"**	Small round **central lucency** with sclerotic margin
Malignant	Yes	Yes	No
Metastases	Lungs, bone	Lungs, bone	N/A
Treatment	Chemotherapy, ablative surgery	Radiation and/or surgery	NSAIDs Surgery recommended when associated pain
Prognosis	70% cure without metastasis at diagnosis	60% cure without metastasis at diagnosis	Over time it may resolve spontaneously
Outcome if metastasis	≤20%	20–30%	N/A

Rheumatic and Vasculitic Disorders 18

Learning Objectives

- ❑ Diagnose and describe management of juvenile idiopathic arthritis, systemic lupus erythematosus, Kawasaki disease, and Henoch-Schonlein Purpura

JUVENILE IDIOPATHIC ARTHRITIS (JIA)

A 7-year-old girl complains of pain and swelling of the left wrist and right knee off and on for the past 3 months. She has been previously healthy. The pain is worse in the morning and improves throughout the day. Physical examination is remarkable for swelling and effusion of the right knee, with decreased range of motion.

- Definition—idiopathic synovitis of peripheral joints associated with soft-tissue swelling and joint effusion
- Pathophysiology
  - Vascular endothelial hyperplasia and progressive erosion of articular cartilage and contiguous bone
  - Immunogenetic susceptibility and an external trigger
  - **DR8** and **DR5**
- Clinical presentation
  - **Morning stiffness**; easy fatigability
  - Joint pain later in the day, joint swelling, joints warm with decreased motion, and pain on motion, **but no redness**
- Criteria for diagnosis: the diagnosis of JRA is a clinical one, and one of exclusion. There are many diseases that mimic it and there are no pathognomonic diagnostic labs. The clinical exclusion of other diseases is essential, as lab studies may be normal.
  - Age of onset: <16 years
  - Arthritis in one or more joints
  - Duration: ≥6 weeks
  - Onset type by disease presentation in first 6 months

Note

A positive rheumatoid factor in JIA is indicative of a poor prognostic outcome.

  - Exclusion of other forms of arthritis, other connective tissue diseases and vasculitides, **Lyme disease**, psoriatic arthritis, inflammatory bowel disease, **lymphoproliferative disease**
- Prognosis for severe and persistent disease
  - Young age at onset
  - RF+
  - Rheumatoid nodules
  - Persistence of anti-cyclic citrullinated peptide (CCP) antibodies (like RF, a marker for more severe disease)
  - Large number of affected joints
  - Involvement of hip, hands and wrists
  - Systemic onset JRA is the most difficult to control in terms of both articular inflammation and systemic manifestations (poorer with polyarthritis, fever >3 months and increased inflammatory markers for >6 months)
- Category of disease:
  - **Pauciarticular (oligoarthritis)**
    - **Pattern**: 1-4 joints affected in first 6 months; primarily knees (++) and ankles (+), less so the fingers; never presents with hip involvement
    - **Peak age** <6 years
    - **F:M** = 4:1
    - **% of all**: 50-60%
    - **Extra-articular**: 30% with anterior uveitis
    - **Labs**: ANA+ in 60%; other tests normal; may have mildly increased ESR, CRP
    - **Treatment**: NSAIDs + intraarticular steroids as needed; methotrexate occasionally needed
  - **Polyarticular, RF negative**
    - **Pattern**: 5 joints in first 6 months; both UE and LE small and large joints; may have C-spine and TMJ involvement
    - **Peak age**: 6-7 years
    - **F:M**: 3:1
    - **% of all**: 30%
    - **Extra-articular**: 10% with anterior uveitis
    - **Labs**: ANA+ in 40%; RF negative; ESR increased (may be significantly), but CRP increased slightly or normal; mild anemia
    - **Treatment**: NSAIDs + methotrexate; if not responsive, anti-TNF or other biologicals (as FDA-approved for children)
  - **Polyarticular RF positive**
    - **Pattern**: ≥5 joints as above but will be aggressive symmetric polyarthritis
    - **Peak age**: 9-12 years
    - **F:M**: 9:1
    - **% of all**: <10%
    - **Extra-articular**: rheumatoid nodules in 10% (more aggressive)

- Labs: RF positive; ESR greatly, CRP increased top normal; mild anemia; if anti-CCP antibodies are positive, then significantly worse disease
- **Treatment**: long-term remission unlikely; early aggressive treatment is warranted

– **Systemic Onset**
- **Pattern**: arthritis may affect any number of joints, but course is usually polyarticular, destructive and ultimately affecting hips, C-spine and TMJ
- **Peak age**: 2-4 years
- **F:M:** 1:1
- **% of all**: <10%
- **Extra-articular**: For initial diagnosis, in addition to arthritis in ≥1 joint, must have with or be preceded by **fever** ≥2 weeks documented to be quotidian (daily, rises to 39° then back to 37°) for at least 3 days of the ≥2-week period plus ≥1 of the following:
  - **Evanescent** (nonfixed, migratory; lasts about 1 hour) erythematous, salmon-colored rash (linear or circular), most over the trunk and proximal extremities
  - Generalized lymph node involvement
  - Hepatomegaly, splenomegaly or both
  - Serositis (pleuritis, pericarditis, peritonitis)
- **Labs**: anemia, increased WBCs, increased ESR, CRP, increased platelets
- **Treatment**: less responsive to standard treatment with methotrexate and anti-TNF agents; consider IL-1 receptor antagonists in resistant cases.
- May have cervical spine involvement

• Labs
– No best test
– Increased acute-phase reactants; increased anemia of chronic disease
– Increased **antinuclear antibodies (ANA) in 40–85%**, mostly with poly- and pauciarticular disease
– **Positive rheumatoid factor (RF+)**—typically with onset of disease in an older child with polyarticular disease and development of rheumatoid nodules

• Treatment
– Most with pauciarticular disease respond to **nonsteroidal antiinflammatory drugs (NSAIDs)** alone
– Additional treatment—**methotrexate (safest and most efficacious of second-line agents)**; azathioprine or cyclophosphamide and biologicals
– Corticosteroids (few indications):
- Overwhelming inflammation
- Systemic illness
- Bridge treatment

– Ophthalmology follow up; physical therapy (PT)/occupational therapy

Table 18-1. JRA Prognosis

Category	Serology	Major Problems	Outcome
Polyarticular disease	RF+	Older girls; hand and wrist; erosions, nodules, unremitting	Poor
	ANA+	Younger girls	Good
	Seronegative	—	Variable
Pauciarticular disease	ANA+	Younger girls; chronic iridocyclitis	Excellent, (except eyes)
	RF+	Polyarthritis, erosions, unremitting	Poor
	HLA B27	Older males	Good
	Seronegative	—	Good
Systemic	—	Pauciarticular	Good
	—	Polyarticular	Poor

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)

A 10-year-old girl presents with fever, fatigue, and joint pains. Physical examination is remarkable for a rash on the cheeks, swelling of the right knee, and pericardial friction rub. Initial laboratory tests reveal anemia and an elevated blood urea nitrogen and creatinine.

Note

A pregnant woman with SLE will transfer IgG autoantibodies (usually anti-Ro) across the placenta at 12 to 16 weeks. This can cause a variety of manifestations, the most important being **congenital heart block**. All are temporary, except for the heart block, which may require permanent pacing.

- Etiology
  - Autoantibodies, especially against nucleic acids including DNA and other nuclear antigens and ribosomes; blood cells and many tissue-specific antigens; immune complex deposition
    - Immune complex deposition in the dermal/epidermal junction is **specific for SLE** (called the lupus band test)
    - **Diffuse proliferative glomerulonephritis** significantly increases risk for severe renal morbidity (pathology varies from minimal mesangial changes to advanced sclerosing nephritis)
- Epidemiology
  - **90% female**
  - Compared with adults, children have **more severe disease and more widespread organ involvement**
  - Highest rate among African-Americans, Hispanics, Asians, Native-Americans and Pacific Islanders
  - Rare age <5 years and only up to 20% present age <16 years, so **usual presentation is mid-to-late adolescence**

- Clinical presentation
  - Most common is a **female with fever, fatigue, rash, hematological abnormalities (anemia of chronic disease or hemolytic; thrombocytopenia, leukopenia) and arthralgia/arthritis**
  - Renal disease is often asymptomatic, so need careful monitoring of UA and BP; presents as either flares with quiescent periods or a more smoldering disease (hypertension, glomerulonephritis, nephrosis, acute renal failure)
  - Neuropsychiatric complications can occur with or without active disease
  - Less common: lymphadenopathy, HSM/hepatitis, abdominal pain, diarrhea, melena
- Lab studies
  - **Nonspecific:** elevated ESR, CRP, platelets, anemia, elevated WBC or leukopenia/lymphopenia; decreased CH_{50}, C3, C4 (typically decreased in active disease and increases with treatment)
  - **+ANA**: present in 95-99% of SLE patients but has poor specificity; does not reflect disease activity; first screening test
  - **+anti-DS-DNA**: more specific (but not 100%) and may correlate with disease activity, especially nephritis
  - **+anti-Smith antibody (anti-Sm):** 100% specific but no disease activity correlation
  - **Antiribonucleoprotein antibodies**: increased with Raynaud's phenomenon (blanching of fingers) and pulmonary hypertension; high titer may be diagnostic of mixed CT disorder; antiribosomal-P-antibody is a marker for lupus cerebritis
  - **Anti-Ro antibody (anti-SSA):** IgG maternal antibodies crossing the placenta and produce transient neonatal lupus; may suggest Sjögren syndrome
  - **Anti-La (anti-SSB):** also increased risk of neonatal lupus; may be associated with cutaneous and pulmonary manifestations of SLE or isolated discoid lupus; also seen in Sjögren syndrome
  - **Antiphospholipid antibodies** (APL; including anticardiolipin): when a clotting event occurs in the presence of APL antibodies, the antiphospholipid syndrome is suspected:
    - Increased risk of arterial and venous thrombosis
    - Livedo reticularis
    - Raynaud's phenomenon produces cyanosis and then erythema; caused by cold stress or emotional stress; initial arterial vasoconstriction creates hypoperfusion then venous stasis, followed by reflex vasodilation
    - Positive lupus anticoagulant: may give a false-positive serological test for syphilis; also seen in patients with neurological complications
    - Recurrent fetal loss
  - Coombs positive: hemolytic anemia
  - Antiplatelet antibodies: thrombocytopenia
  - Antithyroid antibodies: autoimmune thyroiditis
  - Antihistone antibodies: may be found with **drug-induced lupus**; may act as a trigger in those prone to lupus or cause a reversible syndrome hepatitis is common (otherwise rare in children with lupus); more common drugs: minocycline, tetracycline, sulfasalazine, penicillin, nitrofurantoin, IH, many antihypertensives, anticonvulsants, procainamide, lithium, glyburide, statins, PTU, penicillamine, chlorpromazine, some biologicals

Note

Diagnosis of SLE—"M.D. Soap 'n Hair"

- **M**alar rash
- **D**iscoid rash
- **S**erositis
- **O**ral ulcers
- **A**NA-positive
- **P**hotosensitivity
- **N**eurologic disorders
- **H**ematologic disorders
- **A**rthritis
- **I**mmune disorders (**LE [lupus erythematosus] prep test**, anti-DNA, Smith)
- **R**enal disorders

- General principles of treatment
  - Sunscreen and direct sun avoidance
  - Hydroxychloroquine for all, if tolerated
  - NSAIDs for joints
  - Corticosteroids for more severe disease, especially renal
  - Steroid-sparing immunosuppressives for severe disease (proliferative GN, continued vasculitis, pulmonary hemorrhage, severe persistent CNS disease)
  - LMW heparin is drug of choice for thrombosis, APL, lupus anticoagulant

NEONATAL LUPUS

- Passive transfer of IgG across placenta; most is maternal **anti-Ro and anti-La**
- Mostly presents at age 6 weeks with annular or macular rash affecting the face, especially periorbital area, trunk and scalp after exposure to any UV light; generally lasts 3-4 months
- At risk for future pregnancies; baby is at some risk for future autoantibody disease
- May manifest with any SLE finding, but all resolve unless there is **congenital heart block (can be detected in utero at 16 weeks); is permanent; if it is third degree, pacing is usually required.**

KAWASAKI DISEASE

An 18-month-old has had fever for 10 days. He now has conjunctival injection, a very red tongue and cracked lips, edema of the hands, and a truncal rash.

Note

The most serious sequelae of Kawasaki disease are cardiac-related.

- **Etiology**
  - Many factors point to an infective cause but no specific organism has been found
  - Genetic susceptibility: highest in **Asians** irrespective of location and in children and sibs of those with KD
  - KD-associated antigen in cytoplasmic inclusion bodies of ciliated bronchial epithelial cells, consistent with viral protein aggregates; suggests respiratory portal of entry
  - Seems to require an environmental trigger

Note

Any child suspected of having Kawasaki disease should have an echocardiogram.

- **Epidemiology**
  - Asians and Pacific Islanders at highest risk
  - 80% present at age **<5 years** (median is 2.5 years) but may occur in adolescence
  - Poor outcome predictors with respect to coronary artery disease: very young age, male, neutrophilia, decreased platelets, increased liver enzymes, decreased albumin, hyponatremia, increased CRP, prolonged fever
- **Pathology**
  - **Medium size vasculitis, especially coronary arteries**
  - Loss of structural integrity weakens the vessel wall and results in ectasia or saccular or fusiform aneurysms; thrombi may decrease flow with time and can become progressively fibrotic, leading to stenosis

- **Diagnosis**

  Absolute requirement: fever ≥5 days (≥101° F), unremitting and unresponsive; would last 1–2 weeks without treatment **plus any 4 of the following**:

  – **Eyes:** bilateral bulbar conjunctivitis, non-exudative
  – **Oral:** diffuse oral and pharyngeal erythema, strawberry tongue, cracked lips
  – **Extremities:** edema and erythema of palms and soles, hands and feet acutely; subacute (may have periungual desquamation of fingers and toes and may progress to entire hand)
  – **Rash:** polymorphic exanthema (maculopapular, erythema multiforme or scarlatiniform with accentuation in the groin); perineal desquamation common ion acute phase
  – **Cervical lymphadenopathy:** usually unilateral and >1.5 cm, nonsuppurative

Associated symptoms: GI (vomiting, diarrhea, pain); respiratory (interstitial infiltrates, effusions); significant irritability (likely secondary to aseptic meningitis); liver (mild hepatitis, hydrops of gallbladder); GU (sterile pyuria, urethritis, meatitis); joints (arthralgias/arthritis—small or large joints and may persist for several weeks)

- **Cardiac findings**
  – **Coronary aneurysms**: up to 25% without treatment in week 2-3; approximately 2–4% with early diagnosis and treatment; giant aneurysms (>8 mm) pose greatest threat for rupture, thrombosis, stenosis and MI; best detected by 2D echocardiogram
  – **Myocarditis**: in most in the acute phase; tachycardia out of proportion to the fever and decreased LV systolic function; occasional cardiogenic shock; pericarditis with small effusions. About 25% with mitral regurgitation, mild and improves over time; best detected by 2D echocardiogram plus EKG
  – Other arteries may have aneurysms (local pulsating mass)
- **Clinical phases**
  – **Acute febrile:** 1-2 weeks (or longer without treatment), diagnostic and associated findings and lab abnormalities; WBC increased (granulocytes), normocytic / normochromic anemia, normal platelets in first 1-2 weeks; ESR and CRP must be increased (usually significantly for the ESR); sterile pyuria, mild increase in liver enzymes and bilirubin; mild CNS pleocytosis. **Most important tests at admission** are **platelet count, ESR, EKG, and baseline 2D-echocardiogram.**
  – **Subacute:** next 2 weeks; acute symptoms resolving or resolved; extremity desquamation, significant increase in platelet count beyond upper limits of normal (rapid increase in weeks 2-3, often greater and a million); coronary aneurysm, if present, this is the time of highest risk of sudden death. **Follow platelets, ESR and obtain 2nd echocardiogram**.
  – **Convalescent:** next 2-4 weeks; when all clinical signs of disease have disappeared and continues until ESR normalizes; **follow platelet, ESR and if no evidence of aneurysm, obtain 3rd echocardiogram;** repeat echo and lipids at 1 year. If abnormalities were seen with previous echo, more frequent studies are needed, and cardiology follow-up and echocardiograms are tailored to their individual status.
- **Treatment**
  – **Acute:** (at admission): **(a)** IVIG over 10-12 hours (mechanism unknown but results in rapid defervescence and resolution of clinical symptoms in 85-90%);

Note

Kawasaki disease is one of the few instances in pediatrics for which you would use aspirin. (It is usually avoided because of the risk of developing Reye syndrome.)

the IVIG gives the large drop in incidence of aneurysms. If continued fever after 36 hours, then increased risk of aneurysm; give 2nd infusion. (**b**) oral high dose aspirin (anti-inflammatory dosing) until afebrile 48 hours

- If winter, give heat-killed **influenza vaccine** if not yet received (**Reye syndrome**); cannot give varicella vaccine acutely (live, attenuated vaccine and concurrent IVIG would decrease its effectiveness, so must delay any MMR and varicella vaccine until 11 months post-IVIG.

– **Subacute (convalescent)**: change ASA to low dose (minimum dose for antithrombotic effects as a single daily dose until ESR has normalized at 6-8 weeks and then discontinue if echocardiogram is normal; if abnormalities, continue indefinitely

- **Complications and prognosis**
  - Small solitary aneurysms: continue ASA indefinitely; giant or numerous aneurysms need individualized therapy, including thrombolytic
  - Long-term follow-up with aneurysms: periodic echo and stress test and perhaps angiography; if giant, catheter intervention and percutaneous transluminal coronary artery ablation, direct atherectomy and stent placement (and even bypass surgery)
  - Overall- 50% of aneurysms regress over 1-2 years but continue to have vessel wall anomalies; giant aneurysms are unlikely to resolve
  - Vast majority have normal health
  - Acute KD recurs in 1-3%
  - Fatality rate <1%; all should maintain a heart-healthy diet with adequate exercise, no tobacco and should have intermittent lipid checks.

HENOCH-SCHÖNLEIN PURPURA (HSP)

A 5-year-old boy is seen with maculopapular lesions on the legs and buttocks. He complains of abdominal pain. He has recently recovered from a viral upper respiratory infection. Complete blood cell count, coagulation studies, and electrolytes are normal. Microscopic hematuria is present on urine analysis.

- **Most common vasculitis among children in United States**; leukocytoclastic vasculitis (vascular damage from nuclear debris of infiltrating neutrophils) + **IgA deposition** in small vessels (arterioles and venules) of **skin, joints, GI tract and kidney**.
- Worldwide distribution, all ethnic groups; slightly greater in males; almost all age 3-10 years; occurs mostly in fall, winter and spring, many after an URI
- Infectious trigger is suspected, mediated by IgA and IgA-immune complexes
- Genetic component suggested by occasional family clusters
- Skin biopsy shows vasculitis of dermal capillaries and postcapillary venules with infiltrates of neutrophils and monocytes; in all tissues, immunofluorescence shows IgA deposition in walls of small vessels and smaller amounts of C3, fibrin and IgM
- Clinical presentation:
  - Nonspecific constitutional findings
  - Rash: **palpable purpura**, start as pink macules and then become petechial and then purpuric or ecchymotic; usually symmetric and in gravity-dependent areas (legs

and back of arms) and pressure points (buttocks); lesions evolve in crops over 3-10 days and may recur up to 4 months. Usually there is some amount of subcutaneous edema

- **Arthralgia/arthritis**: oligoarticular, self-limited and in lower extremities; resolves in about 2 weeks, but may recur
- **GI: in up to 80%:** pain, vomiting, diarrhea, ileus, melena, **intussusception**, mesenteric ischemia or perforation (purpura in GI tract)
- **Renal: up to 50%:** hematuria, proteinuria, hypertension, nephritis, nephrosis, acute or chronic renal failure
- Neurological: due to hypertension or CNS vasculitis, possible intracranial hemorrhage, seizures, headaches and behavioral changes
- Less common: orchitis, carditis, inflammatory eye disease, testicular torsion and pulmonary hemorrhage

- American College of Rheumatology diagnosis: need **2 of the following**:
  (a) palpable purpura
  (b) age of onset <10 years
  (c) bowel angina = postprandial pain, bloody diarrhea
  (d) biopsy showing intramural granulocytes in small arterioles and venules
- **Labs (none are diagnostic)**: increased WBCs, platelets, mild anemia, increased ESR, CRP; stool + for occult blood; increased serum IgA. Must assess and follow BP, UA, serum Cr; GI ultrasound: ball wall edema, rarely intussusception; skin and renal biopsies would be diagnostic but are rarely performed (only for severe or questionable cases)
- Treatment: supportive and **corticosteroids, but only with significant GI involvement or life-threatening complications (but steroids do not alter course alter overall prognosis nor prevent renal disease** (c) for chronic renal disease – azathioprine, cyclophosphamide, mycophenolate mofetil.
- Outcome: Most significant **acute complications** affecting morbidity and mortality = serious GI involvement; renal complications are **major long-term** and can develop up to 6 months after initial diagnosis, but rarely if initial UA and BP are normal. Monitor all patients x 6months with BP and UA. Overall prognosis is excellent; most have an acute, self-limited disease; about 30% have >1 recurrence, especially in 4-6 months, but with each relapse symptoms are less. If more severe at presentation, higher risk for relapses. 1-2% with chronic renal disease and 8% ESRD.

Hematology 19

Learning Objectives

- ❑ Categorize anemias into those caused by inadequate production, those caused by acquired production, and congenital anemias
- ❑ Describe the pathophysiology, diagnosis, and treatment of megaloblastic and hemolytic anemias
- ❑ Recognize and describe management of thalassemias and hemoglobin disorders
- ❑ Demonstrate understanding of coagulation disorders

ANEMIAS OF INADEQUATE PRODUCTION

Physiologic Anemia of Infancy

- Intrauterine hypoxia stimulates erythropoietin → ↑ RBCs (Hb, Hct)
- High F_iO_2 at birth downregulates erythropoietin
- **Progressive drop in Hb over first 2–3 months** until tissue oxygen needs are greater than delivery (typically 8–12 weeks in term infants, to Hb of 9–11 g/dL)
- **Exaggerated in preterm** infants and earlier; nadir at 3–6 weeks to Hb of 7–9 g/dL
- In term infants—no problems, **no treatment;** preterm infants usually need transfusions depending on degree of illness and gestational age

Iron-Deficiency Anemia

An 18-month-old child of Mediterranean origin presents to the physician for routine well-child care. The mother states that the child is a "picky" eater and prefers milk to solids. In fact, the mother states that the patient, who still drinks from a bottle, consumes 64 ounces of cow milk per day. The child appears pale. Hemoglobin is 6.5 g/dL and hemotocrit 20%. Mean corpuscular volume is 65 fL.

- Contributing factors/pathophysiology
  - Higher bioavailability of iron in breast milk versus cow milk or formula
  - **Introducing iron-rich foods is effective in prevention.**

  - Infants with decreased dietary iron typically are **anemic at 9–24 months** of age.
    - Caused by consumption of large amounts of **cow milk** and foods not enriched with iron
    - Also creates abnormalities in mucosa of gastrointestinal tract → **leakage of blood,** further decrease in absorption
  - **Adolescents** also susceptible → high requirements during growth spurt, dietary deficiencies, menstruation
- Clinical appearances—**pallor most common;** also irritability, lethargy, pagophagia, tachycardia, systolic murmurs; long-term with neurodevelopmental effects
- Laboratory findings
  - First decrease in bone marrow hemosiderin (iron tissue stores)
  - Then decrease in serum ferritin
  - Decrease in serum iron and transferrin saturation → increased total iron-binding capacity (TIBC)
  - Increased free erythrocyte protoporhyrin (FEP)
  - Microcytosis, hypochromia, poikilocytosis
  - Decreased MCV, mean corpuscular hemoglobin (MCH), increase RDW, nucleated RBCs, low reticulocytes
  - Bone marrow—no stainable iron
- Treatment
  - **Oral ferrous salts**
  - Limit milk, increase dietary iron
  - Within 72–96 hours—peripheral reticulocytosis and increase in Hb over 4–30 days
  - Continue iron for 8 weeks after blood values normalize; repletion of iron in 1–3 months after start of treatment

Lead Poisoning

- Blood lead level (BLL) **up to 5 μg/dL** is acceptable.
- Increased risks
  - Preschool age
  - Low socioeconomic status
  - **Older housing (before 1960)**
  - Urban dwellers
  - African American
  - Recent immigration from countries that use leaded gas and paint
- Clinical presentation
  - **Behavioral changes** (most common: hyperactivity in younger, aggression in older)
  - **Cognitive/developmental dysfunction**, especially long-term (also impaired growth)
  - **Gastrointestinal**—anorexia, pain, vomiting, **constipation** (starting at 20 μg/dL)
  - Central nervous system—**related to increased cerebral edema, intracranial pressure (ICP** [headache, change in mentation, lethargy, seizure, coma → death])
  - Gingival lead lines

- Diagnosis
  - Screening—targeted blood lead testing at **12 and 24 months** in high-risk
  - Confirmatory **venous sample—gold standard blood lead level**
  - Indirect assessments—**x-rays of long bones (dense lead lines);** radiopaque flecks in intestinal tract (recent ingestion)
  - Microcytic, hypochromic anemia
  - Increased FEP
  - Basophilic stippling of RBC
- **Treatment—chelation** ***(see*** **Table 19-1)**

Table 19-1. Treatment for Lead Poisoning

Lead Level (µg/dL)	Management
5–14	Evaluate source, provide education, repeat blood lead level in 3 months
15–19	Same *plus* health department referral, repeat BLL in 2 months
20–44	Same *plus* repeat blood lead level in 1 month
45–70	Same *plus* chelation: single drug, preferably dimercaptosuccinic acid (succimer, oral)
≥70	Immediate hospitalization *plus* 2-drug IV treatment: – ethylenediaminetetraacetic acid plus dimercaprol

CONGENITAL ANEMIAS

Congenital Pure Red-Cell Anemia (Blackfan-Diamond)

A 2-week-old on routine physical examination is noted to have pallor. The birth history was uncomplicated. The patient has been doing well according to the mother.

- **Increased RBC programmed cell death → profound anemia by 2–6 months**
- **Congenital anomalies**
  - **Short stature**
  - Craniofacial deformities
  - Defects of upper extremities; **triphalangeal thumbs**
- Labs
  - Macrocytosis
  - Increased HbF
  - **Increased RBC adenosine deaminase (ADA)**

  - **Very low reticulocyte count**
  - Increased serum iron
  - **Marrow with significant decrease in RBC precursors**
- Treatment
  - **Corticosteroids**
  - **Transfusions and deferoxamine**
  - Splenectomy; mean survival 40 years without stem cell transplant
- Definitive—**stem cell transplant** from related histocompatible donor

Congenital Pancytopenia

Note

Blackfan-Diamond

Triphalangeal thumbs

Pure RBC deficiency

Fanconi

Absent/hypoplastic thumbs

All cell lines depressed

A 2-year-old presents to the physician with aplastic anemia. The patient has microcephaly, microphthalmia, and absent radii and thumbs.

- Most common is **Fanconi anemia**—spontaneous chromosomal breaks
- Age of onset from infancy to adult
- Physical abnormalities
  - Hyperpigmentation and café-au-lait spots
  - **Absent or hypoplastic thumbs**
  - **Short stature**
  - Many other organ defects
- Labs
  - Decreased RBCs, WBCs, and platelets
  - Increased HbF
  - **Bone-marrow hypoplasia**
- Diagnosis—bone-marrow aspiration and cytogenetic studies for chromosome breaks
- Complications—increased risk of **leukemia (AML) and other cancers**, organ complications, and bone-marrow failure consequences (infection, bleeding, severe anemia)
- Treatment
  - **Corticosteroids and androgens**
  - **Bone marrow transplant definitive**

ACQUIRED ANEMIAS

Transient Erythroblastopenia of Childhood (TEC)

- **Transient hypoplastic anemia between 6 months–3 years**
  - Transient **immune suppression** of erythropoiesis
  - Often after nonspecific viral infection (not parvovirus B19)
- Labs—decreased reticulocytes and bone-marrow precursors, normal MCV and HbF

- Recovery generally **within 1–2 months**
- Medication not helpful; may need one transfusion if symptomatic

Anemia of Chronic Disease and Renal Disease

- Mild decrease in RBC lifespan and relative failure of bone marrow to respond adequately
- Little or no increase in erythropoietin
- Labs
  - Hb typically 6–9 g/dL, **most normochromic and normocytic (but may be mildly microcytic and hypochromic)**
  - Reticulocytes normal or slightly decreased for degree of anemia
  - Iron low without increase in TIBC
  - Ferritin may be normal or slightly increased.
  - Marrow with normal cells and normal to decreased RBC precursors
- Treatment—control underlying problem, may need erythropoietin; rarely need transfusions

MEGALOBLASTIC ANEMIAS

Background

- RBCs at every stage are larger than normal; there is an asynchrony between nuclear and cytoplasmic maturation.
- **Ineffective erythropoiesis**
- Almost all are **folate or vitamin B_{12} deficiency** from malnutrition; uncommon in United States in children; more likely to be seen in adult medicine.
- Macrocytosis; nucleated RBCs; **large, hypersegmented neutrophils**; low serum folate; iron and vitamin B_{12} normal to decreased; marked increase in lactate dehydrogenase; hypercellular bone marrow with megaloblastic changes

Folic Acid Deficiency

- Sources of folic acid—green vegetables, fruits, animal organs
- Peaks at 4–7 months of age—irritability, failure to thrive, chronic diarrhea
- Cause—inadequate intake (pregnancy, **goat milk feeding,** growth in infancy, chronic hemolysis), decreased absorption or congenital defects of folate metabolism
- Differentiating feature—low serum folate
- Treatment—daily folate; transfuse only if severe and symptomatic

Note

Hypersegmented neutrophils have >5 lobes in a peripheral smear.

Vitamin B_{12} (Cobalamin) Deficiency

- Only animal sources; produced by microorganisms (humans cannot synthesize)
- Sufficient stores in older children and adults for 3–5 years; but in **infants born to mothers with deficiency, will see signs in first 4–5 months**
- Inadequate production (extreme restriction [**vegans**]), lack of intrinsic factor (congenital pernicious anemia [rare], autosomal recessive; also juvenile pernicious anemia [rare] or gastric surgery), impaired absorption (terminal ileum disease/removal)

Note

If autoimmune pernicious anemia is suspected, remember the Schilling test and antiparietal cell antibodies.

- Clinical—weakness, fatigue, failure to thrive, irritability, pallor, **glossitis**, diarrhea, vomiting, jaundice, many **neurologic symptoms**
- Labs—normal serum folate and decreased vitamin B_{12}
- Treatment—parenteral B_{12}

Table 19-2. Comparison of Folic Acid Versus Vitamin B_{12} Deficiencies

	Folic Acid Deficiency	Vitamin B_{12} (Cobalamin) Deficiency
Food sources	Green vegetables, fruits, animals	Only from animals, produced by microorganisms
Presentation	Peaks at 4–7 months	Older children and adults with sufficient stores for 3–5 years Infants born to mothers: first signs 4–6 months
Causes	Goat milk feeding Chronic hemolysis Decreased absorption Congenital defects of folate metabolism	Inadequate production (vegans) Congenital or juvenile pernicious anemia (autosomal recessive, rare) Gastric surgery Terminal ileum disease
Findings	Low serum folate with normal to increased iron and vitamin B_{12}	Normal serum folate and decreased vitamin B_{12}
Treatment	Daily folate	Parenteral vitamin B_{12}

HEMOLYTIC ANEMIAS

Hereditary Spherocytosis and Elliptocytosis

- Most **autosomal dominant**
- Abnormal shape of RBC due to **spectrin deficiency → decreased deformability → early removal of cells by spleen**
- Clinical presentation
  - **Anemia and hyperbilirubinemia in newborn**
  - **Hypersplenism, biliary gallstones**
  - Susceptible to aplastic crisis (parvovirus B19)
- Labs
  - Increased reticulocytes
  - Increased bilirubin
  - Hb 6–10 mg/dL
  - Normal MCV; **increased mean cell Hb concentration (MCHC)**
  - **Smear—spherocytes or elliptocytes diagnostic**

- Diagnosis
  - Blood smear, family history, increased spleen size
  - Confirmation—**osmotic fragility test**
- Treatment—transfusions, splenectomy (after 5–6 years), folate

Enzyme Defects

Pyruvate kinase (glycolytic enzyme)

- Wide range of presentation
  - Some degree of pallor, jaundice, and splenomegaly
  - Increased reticulocytes, mild macrocytosis, polychromatophilia
- Diagnosis—**pyruvate kinase (PK) assay** (decreased activity)
- Treatment—exchange transfusion for significant jaundice in neonate; transfusions (rarely needed), splenectomy

Glucose-6-phosphate dehydrogenase (G6PD)

A 2-year-old boy presents to the physician's office for an ear check. Three weeks earlier, the child had an ear infection that was treated with trimethaprim-sulfamethoxazole. On physical examination the patient is noted to be extremely pale. Hemoglobin and hematocrit are 7.0 g/dL and 22%, respectively.

- Two syndromes
  - **Episodic hemolytic anemia** (most common)
  - Chronic nonspherocytic hemolytic anemia
- **X-linked;** a number of abnormal alleles
- Episodic common among **Mediterranean, Middle Eastern, African, and Asian** ethnic groups; wide range of expression varies among ethnic groups
- Within 24–48 hours after ingestion of an **oxidant (acetylsalicylic acid, sulfa drugs, antimalarials, fava beans) or infection and severe illness** → rapid drop in Hb, hemoglobinuria and jaundice (if severe)
- Acute drop in Hb, saturated haptoglobin → free Hb and hemoglobinuria, **Heinz bodies**, increased reticulocytes
- Diagnosis—**direct measurement of G6PD activity**
- Treatment—prevention (avoid oxidants); supportive for anemia

HEMOGLOBIN DISORDERS

Sickle Cell Anemia (Homozygous Sickle Cell or S-Beta Thalassemia)

A 6-month-old, African-American infant presents to the pediatrician with painful swollen hands and swollen feet.

- Occurs in endemic malarial areas
- Single base pair change (thymine for adenine) at the sixth codon of the beta gene (valine instead of glutamic acid)
- Clinical presentation
  - Newborn usually without symptoms; development of hemolytic anemia over **first 2–4 months (replacement of HbF)**; as early as age 6 months; some children have **functional asplenia; by age 5, all have functional asplenia**
  - First presentation usually **hand-foot syndrome (acute distal dactylitis)**—symmetric, painful swelling of hands and feet (ischemic necrosis of small bones)
  - **Acute painful crises:**
    - Younger—mostly **extremities**
    - With increasing age—**head, chest, back, abdomen**
    - Precipitated by **illness, fever, hypoxia, acidosis**, or without any factors (older)
  - More extensive **vaso-occlusive crises** → ischemic damage
    - Skin ulcers
    - Retinopathy
    - Avascular necrosis of hip and shoulder
    - Infarction of bone and marrow (increased risk of ***Salmonella* osteomyelitis)**
    - **Splenic autoinfarction**
    - Pulmonary—**acute chest syndrome** (along with sepsis, are most common causes of mortality)
    - **Stroke** (peak at 6–9 years of age)
    - **Priapism**, especially in adolescence
  - **Acute splenic sequestration** (peak age 6 mos to 3 yrs); can lead to rapid death
  - Altered splenic function → increased susceptibility to infection, especially with **encapsulated bacteria *(S. pneumococcus, H. influenzae, N. meningitidis)***
  - **Aplastic crisis**—after infection **with parvovirus B19**; absence of reticulocytes during acute anemia
  - Cholelithiasis—symptomatic gallstones
  - Kidneys—decreased renal function **(proteinuria first sign); UTIs, papillary necrosis**
  - Labs
    - Increased reticulocytes
    - Mild to moderate anemia
    - Normal MCV
    - If severe anemia: smear for **target cells,** poikilocytes, hypochromasia, **sickle RBCs,** nucleated RBCs, **Howell-Jolly bodies** (lack of splenic function); bone marrow **markedly hyperplastic**
  - Diagnosis
    - Confirm diagnosis with **Hb electrophoresis (best test)**
    - **Newborn screen**; use Hb electrophoresis
    - **Prenatal diagnosis** for parents with trait
- Treatment—Prevent complications:
    - Immunize (pneumococcal regular *plus* **23-valent**, meningococcal)
    - Start **penicillin prophylaxis** at 2 months until age 5

Note

Patients without a functioning spleen are predisposed to infection with encapsulated organisms. Pneumococcal vaccines 13 (PCV13) and 23 (PPSV23) are necessary.

- Educate family (assessing illness, palpating spleen, etc.)
- Folate supplementation

– Aggressive antibiotic treatment of infections
– Pain control
– **Transfusions** as needed
– Monitor for risk of stroke with **transcranial Doppler**
– **Hydroxyurea**
– **Bone-marrow transplant in selected patients age <16 years**

THALASSEMIAS

Figure 19-1. X-ray of Skull Demonstrating "Hair on End" Appearance of Thallasemia

Alpha Thalassemia

- **Alpha thalassemia trait**: deletion of 2 genes
  – Common in African Americans and those of Mediterranean descent
  – Mild hypochromic, microcytic anemia (normal RDW) without clinical problems;
  – Often diagnosed as iron deficiency anemia; need molecular analysis for diagnosis
- **HgB H disease**: deletion of 3 genes; Hgb Barts >25% in newborn period and easily diagnosed with electrophoresis
  – At least one parent has alpha-thalassemia trait; later beta-tetramers develop (Hgb H—interact with RBC membrane to produce Heinz bodies) and can be identified electrophoretically; microcytosis and hypochromia with mild to moderate anemia; target cells present, mild splenomegaly, jaundice and cholelithiasis
  – Typically do not require transfusions or splenectomy; common in Southeast Asians

- **Alpha-thalassemia major**: deletion of 4 genes; severe fetal anemia resulting in hydrops fetalis
  - Newborn has predominantly Hgb Barts with small amounts of other fetal Hgb; immediate exchange transfusions are required for any possibility of survival; transfusion-dependent with only chance of cure (bone marrow transplant)

Beta Thalassemia Major (Cooley Anemia)

A 9-year-old has a greenish-brown complexion, maxillary hyperplasia, splenomegaly, and gallstones. Her Hb level is 5.0 g/dL and MCV is 65 mL.

- **Excess alpha globin chains → alpha tetramers** form; **increase in HbF** (no problem with gamma-chain production)
- Presents in second month of life with progressive **anemia, hypersplenism, and cardiac decompensation** (Hb <4 mg/dL)
- **Expanded medullary space** with increased expansion of **face and skull (hair-on-end)**; extramedullary hematopoiesis, **hepatosplenomegaly**
- Labs
  - Infants born **with HbF only** (seen on **Hgb electrophoresis**)
  - **Severe anemia**, low reticulocytes, increased nucleated RBCs, hyperbilirubinemia microcytosis
  - **No normal cells seen on smear**
  - **Bone-marrow hyperplasia; iron accumulates → increased serum ferritin and transferrin saturation**
- Treatment
  - Transfusions
  - **Deferoxamine** (assess iron overload with liver biopsy)
  - May need splenectomy
  - **Bone-marrow transplant** curative

Note

Minor bleeds = von Willebrand

Deep bleeds = hemophilia

HEMORRHAGIC DISORDERS

Evaluation of Bleeding Disorders

History provides the most useful information for bleeding disorders.

- **von Willebrand disease (vWD) or platelet dysfunction → mucous membrane bleeding, petechiae, small ecchymoses**
- **Clotting factors—deep bleeding with more extensive ecchymoses and hematoma**
- Laboratory studies
  - Obtain **platelets**, bleeding time, **PT, PTT**
    - If normal, von Willebrand factor (vWF) testing and thrombin time
    - If abnormal, further clotting factor workup
  - **Bleeding time**—platelet function and interaction with vessel walls; **qualitative platelet defects or vWD** (platelet function analyzer)

- Platelet count—thrombocytopenia is the most common acquired cause of bleeding disorders in children
- PTT—**intrinsic pathway:** from initiation of clotting at level of factor XII through the final clot (prolonged with factor VIII, IX, XI, XII deficiency)
- PT—measures **extrinsic pathway** after activation of clotting by thromboplastin in the presence of Ca^{2+}; **prolonged by deficiency of factors VII, XIII or anticoagulants**; standardized values using the **International Normalized Ratio (INR)**
- Thrombin time—measures the **final step: fibrinogen → fibrin**; if prolonged: **decreased fibrin or abnormal fibrin** or substances that interfere with fibrin polymerization (**heparin or fibrin split products**)
- Mixing studies: if there is a prolongation of PT, PTT, or thrombin time, then add normal plasma to the patient's and repeat labs
  - **Correction of lab prolongation suggests deficiency of clotting factor.**
  - **If not or only partially corrected, then it is due to an inhibitor (most common on inpatient basis is heparin).**
  - **If it becomes more prolonged with clinical bleeding, there is an antibody directed against a clotting factor (mostly factors VIII, IX, or XI).**
  - **If there is no clinical bleeding but both the PTT and mixing study are prolonged, consider lupus anticoagulant (predisposition to excessive clotting).**
- Clotting factor assays—each can be measured; severe deficiency of factors VIII or IX = <1% of normal; moderate = 1–5%; mild = >5%
- Platelet aggregation studies—if suspect a **qualitative platelet dysfunction, ristocetin**

Table 19-3. Clinical Findings in Coagulopathies

	Factor VIII	Factor IX	vWF
Platelet	Normal	Normal	Normal
PT	Normal	Normal	Normal
PTT	↑	↑	↑
Bleeding time	Normal	Normal	↑
Factor VIII	↓	Normal	Normal
Factor IX	Normal	↓	Normal
vWF	Normal	Normal	↓
Sex	Male	Male	Male/female
Treatment	Factor VIII, desmopressin	Factor IX	Fresh frozen plasma, cryotherapy, DDAVP

Hemophilia A (VIII) and B (IX)

- 85% are A and 15% B; no racial or ethnic predisposition
- **X-linked**
- Clot formation is delayed and not robust → **slowing of rate of clot formation**
  - With crawling and walking—**easy bruising**
  - Hallmark is **hemarthroses**—earliest in ankles; in older child, knees and elbows
  - Large-volume blood loss into iliopsoas muscle (inability to extend hip)—vague groin pain and hypovolemic shock
  - Vital structure bleeding—life-threatening
- Labs
  - 2× to 3× **increase in PTT** (all others normal)
  - **Correction with mixing studies**
  - Specific assay confirms:
    - Ratio of VIII:vWF sometimes used to diagnose carrier state
    - Normal platelets, PT, bleeding time, and vW Factor
- Treatment
  - Replace specific factor
  - **Prophylaxis now recommended** for young children with severe bleeding (intravenous via a central line every 2–3 days); prevents chronic joint disease
  - For mild bleed—patient's endogenous factor can be released with **desmopressin** (may use intranasal form)
  - Avoid antiplatelet and aspirin medications
  - DDAVP increases factor VIII levels in mild disease

Note

There is no way to clinically differentiate factors VIII and IX deficiencies. You must get specific factor levels.

von Willebrand Disease (vWD)

- Most common hereditary bleeding disorder; **autosomal dominant**, but more females affected
- Normal situation—vWF adheres to subendothelial matrix, and platelets then adhere to this and become activated; also **serves as carrier protein for factor VIII**
- Clinical presentation—**mucocutaneous bleeding** (excessive bruising, epistaxis, menorrhagia, postoperative bleeding)
- Labs—**increased bleeding time and PTT**
- **Quantitative assay for vWFAg, vWF activity** (ristocetin cofactor activity), plasma factor VIII, determination of vWF structure and platelet count
- Treatment—need to increase the level of vWF and factor VIII
  - Most with type 1 DDAVP **induces release of vWF**
  - For types 2 or 3 need replacement → **plasma-derived vWF-containing concentrates with factor VIII**

Other Bleeding Disorders

Vitamin K deficiency

- **Newborn needs intramuscular administration of vitamin K or develops bleeding diathesis**

- Postnatal deficiency—lack of oral intake, alteration in gut flora (long-term antibiotic use), malabsorption
- Vitamin K is fat soluble so deficiency associated with a decrease in factors **II, VII, IX, and X, and proteins C and S**
- Increased PT and PTT with normal platelet count and bleeding time

Liver disease

- **All clotting factors produced exclusively in the liver, except for factor VIII**
- Decreases proportional to extent of hepatocellular damage
- Treatment—**fresh frozen plasma** (supplies all clotting factors) and/or **cryoprecipitate** (supplies fibrinogen)

PLATELET DISORDERS

Immune Thrombocytopenic Purpura (ITP)

A 4-year-old child previously healthy presents with petechiae, purpura, and excessive bleeding after falling from his bicycle.

Note

With ITP, the physical examination is otherwise normal; **hepatosplenomegaly and lymphadenopathy should suggest another disease**.

- **Autoantibodies** against platelet surface
- Clinical presentation
  - Typically 1–4 weeks after a nonspecific **viral infection**
  - Most 1–4 years of age → **sudden onset of petechiae and purpura with or without mucous membrane bleeding**
  - Most resolve within 6 months
  - **<1% with intracranial hemorrhage**
  - 10–20% develop chronic ITP
- Labs
  - **Platelets <20,000/mm^3**
  - **Platelet size normal to increased**
  - **Other cell lines normal**
  - **Bone marrow—normal to increased megakaryocytes**
- Treatment
  - **Transfusion contraindicated** unless life-threatening bleeding (platelet antibodies will bind to transfused platelets as well)
  - No specific treatment if platelets >20,000 and no ongoing bleeding
  - If very low platelets, ongoing bleeding that is difficult to stop or life-threatening:
  - **Intravenous immunoglobulin for** 1–2 days
    - If inadequate response, then prednisone
  - Splenectomy reserved for older child with severe disease

Oncology 20

Learning Objectives

- ❑ Categorize and describe management of leukemia and lymphomas
- ❑ Describe the epidemiology and management of brain tumors and other malignancies

LEUKEMIA AND LYMPHOMA

Acute Lymphoblastic Leukemia

A 5-year-old patient is brought to the physician's office with the chief complaint of a limp. The patient on physical examination has a low-grade fever, URI symptoms, hepatosplenomegaly, and petechiae.

- 77% of all childhood leukemias
- Onset brief and nonspecific (poor prognosis age <1 or >10 years at diagnosis)
  - Common—**bone and joint pain, especially lower extremities**
  - Then signs and symptoms of **bone marrow failure**—pallor, bruising, epistaxis, petechiae, purpura, mucous membrane bleeding, lymphadenopathy, hepatosplenomegaly, joint swelling
- Diagnosis
  - Peripheral blood:
    - **Anemia**
    - **Thrombocytopenia**
    - **Leukemic cells not often seen early**
  - WBC mostly <10,000/mm^3 (atypical lymphocytes); poor prognosis if >100,000
  - **Best test is bone marrow aspirate → lymphoblasts**
  - If chromosomal abnormalities, poor prognosis
- Treatment
  - **Remission induction** (98% remission in 4–5 weeks; slow response = poor prognosis) with combination drugs
  - Second phase = **central nervous system (CNS) treatment**

Note

ALL is both CALLA (common acute lymphoblastic leukemia antigen) and TdT-positive.

- Intensive systemic *plus* intrathecal chemotherapy
  - **Maintenance phase** 2–3 years
- Complications
  - Majority is **relapse** (15–20%):
    - **Increased intracranial pressure (ICP) or isolated cranial nerve palsies**
    - **Testicular relapse** in 1–2% of boys
  - ***Pneumocystis* pneumonia**
  - Other infections because of immunosuppression
  - **Tumor lysis syndrome**—result of initial chemotherapy (cell lysis): hyperuricemia, hyperkalemia, hypophosphatemia → hypocalcemia (tetany, arrhythmias, renal calcinosis)
    - Treat with hydration and alkalinization of urine; prevent uric acid formation (allopurinol)
- Prognosis: >85% 5-year survival

Hodgkin Lymphoma

A 16-year-old boy presents with complaints of weight loss, fever, and night sweats. On physical examination, he is noted to have a nontender cervical lymph node that is 4–5 cm.

- Most in **15- to 19-year-olds**
- **Ebstein-Barr virus** may play a role; immunodeficiencies may predispose
- Diagnostic hallmark—**Reed-Sternberg cell** (large cell with multiple or multilobulated nuclei)
- Four major histologic subtypes
  - Lymphocytic predominant
  - Nodular sclerosing
  - Mixed cellularity
  - Lymphocyte depleted; now considered to be a high-grade non-Hodgkin lymphoma
- Clinical presentation depends on location
  - **Painless, firm cervical or supraclavicular nodes (most common presenting sign)**
  - **Anterior mediastinal mass**
  - Night sweats, fever, weight loss, lethargy, anorexia, pruritus
- Diagnosis
  - **Excisional biopsy of node (preferred)**
  - Staging from I to IV (single node or site to diffuse disease; multiple tests)
- Treatment
  - Determined by disease stage, large masses, hilar nodes
  - Chemotherapy
  - Radiation
- Prognosis—overall cure of 90% with early stages and >70% with more advanced

Non-Hodgkin Lymphoma

A 6-year-old boy presents to his primary care provider (PCP) with a nonproductive cough. A diagnosis of upper respiratory infection is made. However, the patient's symptoms persist, and he returns to his PCP. At this visit the patient is wheezing, and the PCP makes the diagnosis of reactive airway disease and prescribes an inhaled b2-agonist. The medication does not improve the symptoms; and the patient returns to the PCP for a third time. The patient is now complaining of cough and has a low-grade fever. The patient is diagnosed with clinical pneumonia; and an antibiotic is prescribed. Two days later the patient presents to the emergency department in respiratory distress. A chest roentgenogram shows a large mediastinal mass.

- Malignant proliferation of **lymphocytes of T-cell, B-cell, or intermediate-cell origin**
- **Epstein-Barr virus—major role in Burkitt lymphoma**
- Predisposition with congenital or acquired immunodeficiencies
- Three histologic subtypes
  - **Lymphoblastic** usually T cell, mostly **mediastinal masses**
  - **Small, noncleaved cell lymphoma**—B cell
  - **Large cell**—T cell, B cell, or indeterminate
- Presentation—depends on location
  - Anterior mediastinal mass (respiratory symptoms)
  - Abdominal pain, mass
  - Hematogenous spread
- Diagnosis—prompt because it is a very aggressive disease.
  - Biopsy
  - Any noninvasive tests to determine extent of disease: staging I to IV (localized to disseminated; CNS and/or bone marrow)
- Treatment
  - **Surgical excision of abdominal tumors**, chemotherapy, and monoclonal antibodies ± radiation
  - 90% cure rate for stages I and II

BRAIN TUMORS

Brain tumors are the second most frequent malignancy in children, with mortality 45%. They are more common age <7 years. Most are infratentorial (age 2–10 years, e.g., juvenile pilocytic astrocytoma, medulloblastoma); symptoms depend on the location.

The best initial test for all tumors is head CT scan. The best imaging test overall is MRI.

Some findings of brain tumors in general are severe persistent headaches, onset recurrent seizures, new onset neurologic abnormalities e.g., ataxia, behavioral/personality changes, deterioration of school performance, visual changes, III and VI nerve palsies, abnormal endocrine findings/new onset, papilledema.

Infratentorial Tumors

- **Most common**
- Low-grade, rarely invasive
- Most common—**juvenile pilocytic astrocytoma**
  - Classic site—**cerebellum**
  - Surgery, radiation, and/or chemotherapy
  - With complete resection, 80–100% survival

Others

- Malignant astrocytoma (includes glioblastoma multiforme)
- Medulloblastoma (midline cerebellar)
- Brain stem tumors (diffuse intrinsic with very poor outcome vs. low-grade gliomas)
- Ependymoma (most posterior fossa)

Supratentorial Tumors

Craniopharyngioma

A 14-year-old girl presents to the physician because of short stature. On physical examination, the patient is found to have bitemporal visual field defects. A head CT scan shows calcification at the sella turcica.

- **Most common**; 7–10% of all
- Minimal invasiveness; **calcification on x-ray**
- Major morbidity—**panhypopituitarism, growth failure, visual loss**
- Surgery and radiation; **no role for chemotherapy**

Optic nerve glioma

A 4-year-old boy with neurofibromatosis presents to the ophthalmologist with complaints of decreased visual acuity according to his parents. On physical examination, the patient has proptosis and papilledema.

- **Most frequent tumor of the optic nerve**; benign, slowly progressive
- **Unilateral visual loss, proptosis, eye deviation, optic atrophy, strabismus, nystagmus**
  - Increased incidence in **neurofibromatosis**
  - Treatment—observation:
    - If chiasm is involved—radiation/chemotherapy
    - Surgery if proptosis with visual loss

OTHER MALIGNANCIES

Wilms Tumor

A mother brings her 3-year-old child to the physician because she found an abdominal mass while bathing the child. The child has been in her usual state of health according to the mother. However, on review of the vital signs, the patient is noted to have an elevated blood pressure.

- **Nephroblastoma** (Wilm's tumor)
- **Second most common malignant abdominal tumor**
  - Usual age 2–5 years
  - One or both kidneys (bilateral in 7%)
  - **Associations:**
    - **Hemihypertrophy**
    - **Aniridia**
    - **Genitourinary anomalies**
    - **WAGR**
- Clinical presentation—most are **asymptomatic abdominal mass** (unless invasive at diagnosis, some with ↑ BP due to renal ischemia)
- Diagnosis
  - Best initial test–ultrasound
  - **Abdominal CT scan confirmatory test**
- Treatment
  - Surgery
  - Then chemotherapy and radiation
  - Bilateral renal—unilateral nephrectomy and partial contralateral nephrectomy
- Prognosis—54 to 97% have 4-year survival

Neuroblastoma

A 2-year-old child is brought to the physician because of bluish skin nodules, periorbital proptosis, and periorbital ecchymosis that have developed over the last few days. On physical examination, a hard smooth abdominal mass is palpated.

- **From neural crest cells, due to N-myc Oncogene; can occur at any site**
- 8% of childhood malignancies
- Most are
  - Adrenal
  - Retroperitoneal sympathetic ganglia
  - Cervical, thoracic, or pelvic ganglia
- Firm, palpable mass in flank or midline; **painful; with calcification and hemorrhage**
- Initial presentation often as **metastasis**—long bones and **skull, orbital**, bone marrow, lymph nodes, liver, skin

Note

Patients with neuroblastoma can present with ataxia or opsomyoclonus ("dancing eyes and dancing feet"). These patients may also have Horner syndrome.

- Diagnosis
  - Plain x-ray, CT scan, MRI (overall best)
  - Elevated urine **homovanillic acid (HVA)** and **vanillylmandelic acid (VMA)** in 95% of cases
  - Evaluate for spread—bone scan, bone marrow (neuroblasts) → staging from I (organ of origin) to IV (disseminated)
- Treatment
  - Surgery
  - Chemotherapy and radiation
  - Stem cell transplant (definitive)

Pheochromocytoma

- **Catecholamine-secreting** tumor from chromaffin cells
- **Most common site—adrenal medulla,** but can occur anywhere along abdominal sympathetic chain
- Children age 6–14 years; 20% are bilateral, and some with multiple tumors
- Autosomal dominant; associated with **neurofibromatosis,** *MEN-2A* and *MEN2B*, tuberous sclerosis, Sturge-Weber syndrome, and ataxia-telangiectasia
- Clinical presentation
  - **Episodic severe hypertension**, palpitations and diaphoresis, headache, abdominal pain, dizziness, pallor, vomiting, sweating, encephalopathy
  - Retinal examination—**papilledema, hemorrhages, exudate**
- Labs—significant increase in blood or **urinary levels of catecholamines and, metabolites**
- Diagnosis
  - Most tumors can be localized by **CT scan (best initial test)** and MRI, but extra-adrenal masses are more difficult.
  - Can use **I^{131} metaiodobenzylguanidine** (MBIG) scan → taken up by chromaffin tissue anywhere in body
- Treatment—**removal**, but high-risk
  - **Preoperative alpha and beta blockade** and fluid administration
  - Need prolonged follow up; may manifest later with new tumors

Note

Children with pheochromocytoma excrete predominantly norepinephrine-increased VMA and metanephrine. Children with neuroblastoma usually do not have hypertension, and major metabolites are dopamine and HVA.

Rhabdomyosarcoma

A mother brings her 3-year-old daughter to the physician for evaluation because the young girl has "grapes" growing out of her vagina.

- Almost any site, which determines presentation; determination of specific histologic type needed for assessment and prognosis
  - **Head and neck—40%**
  - **Genitourinary tract—20%**
  - **Extremities—20%**
  - Trunk—10%
  - Retroperitoneal and other—10%

- Increased frequency in **neurofibromatosis**
- Types
  - **Embryonal**—60%
    - Intermediate prognosis
  - **Botryoid** (projects; grapelike)—**vagina**, uterus, bladder, nasopharynx, middle ear
  - Alveolar—15%
    - Very poor prognosis
    - Trunk and extremities
  - Pleomorphic—adult form; very rare in children
- Clinical presentation
  - Mass that may or may not be painful
  - Displacement or destruction of normal tissue
  - Easily disseminates to lung and bone
- Diagnosis—depends on site of presentation
  - Biopsy, CT, MRI, U/S, bone scan
- Treatment—best prognosis with completely resected tumors (but most are not completely resectable)
  - Chemotherapy pre- and postoperatively; radiation

Neurology 21

Learning Objectives

- ❑ Describe the epidemiology and treatment of febrile and other seizure disorders
- ❑ Describe CNS anomalies, neurocutaneous syndromes, and neurodegenerative disorders
- ❑ Recognize and categorize encephalopathies
- ❑ Categorize and describe the epidemiology and genetics of neuromuscular disease

CENTRAL NERVOUS SYSTEM (CNS) ANOMALIES

Neural Tube Defects

Elevated **alpha-fetoprotein** is a marker for neural tube defects.

Spina bifida occulta

- Midline defect of vertebral bodies **without protrusion** of neural tissue; occasionally associated with other anomalies
- Most **asymptomatic and of no clinical consequence**
- May have **overlying midline lumbosacral defect** (patch of hair, lipoma, dermal sinus)

Tethered cord

- **Ropelike filum terminale persists and anchors the conus below L2**
- Abnormal tension—asymmetric lower extremity growth, deformities, bladder dysfunction, progressive scoliosis, diffuse pain, **motor delay**
- Most associated with a **midline skin lesion**
- **MRI needed for precise anatomy**
- Surgical transection

Meningocele

- Meninges herniate through defect in posterior vertebral arches
- **Fluctuant midline mass well covered with skin**; may transilluminate
- Must determine extent of neural involvement with MRI
  - CT scan of head for possible hydrocephalus
  - Surgery

Myelomeningocele

The pediatrician is called to the delivery room because an infant is born with a defect in the lumbosacral area.

- Strong evidence that **maternal periconceptional use of folate** reduces risk by half
- May occur anywhere along the neuraxis, but most are **lumbosacral**
- **Low sacral lesions—bowel and bladder incontinence and perineal anesthesia without motor impairment**

TheFetus.net

Figure 21-1. Arnold-Chiari Malformation, a Defect of the Hindbrain Usually Accompanied by Myelomeningocele

Note

Almost every child with a sacral or lower lumbar spine lesion will achieve some form of **functional ambulation**, and half of those with higher spine defects will have some degree of hip flexor and hip adductor movement.

- Midlumbar lesion—**saclike cystic structure** covered by thin, partially epithelized tissue
  - **Flaccid paralysis** below the level of the lesion is most common; no deep tendon reflexes (DTRs), no response to touch and pain
  - **Urinary dribbling, relaxed anal sphincter**
- 80% associated with **hydrocephalus; type II Chiari malformation**—may have symptoms of hindbrain dysfunction (feeding difficulty, choking, stridor, apnea, vocal cord paralysis, upper extremity spasticity)
- Evaluation and treatment
  - Must evaluate for other anomalies prior to surgery
  - Evaluate renal function
  - **Head CT scan for possible hydrocephalus**
  - Treatment—**ventriculoperitoneal shunt and correction of defect**

Hydrocephalus

A 2-month-old infant is noted to have a head circumference greater than the 95th percentile.

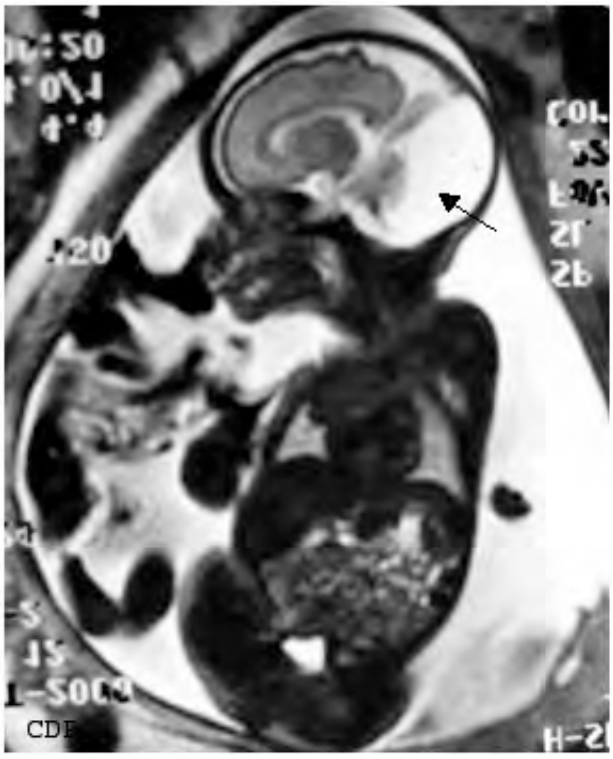
- Definition—**impaired circulation and absorption of CSF** or, rarely, from increased CSF production from a choroid plexus papilloma
- Types
  - **Obstructive** (noncommunicative) versus **nonobstructive** (communicative) from obliteration of subarachnoid cisterns or malfunction of arachnoid villi
    - Obstructive—most are **abnormalities of the cerebral aqueduct** (stenosis or gliosis; congenital, intrauterine infection, mumps, hemorrhage) **or lesions near the fourth ventricle** (brain tumor, Chiari malformation, Dandy-Walker malformation)
  - Nonobstructive—occurs mostly with **subarachnoid hemorrhage**; also with pneumococcal or TB meningitis or leukemic infiltrates
- Clinical presentation—depends on rate of rise of intracranial pressure
  - Infants:
    - **Increased head circumference**
    - **Bulging anterior fontanel**
    - Distended scalp veins
    - Broad forehead
    - **"Setting sun" sign**
    - Increased DTRs
    - Spasticity, clonus
  - Older child (subtler symptoms)
    - Irritability
    - Lethargy
    - Poor appetite

- Vomiting
- **Headache**
- **Papilledema**
- **Sixth-nerve palsy**

- **Treatment for all types of hydrocephalus—shunting**

Dandy-Walker malformation

- **Cystic expansion of fourth ventricle due to absence of roof**
- Associated **agenesis of posterior cerebellar vermis** and corpus callosum
- Presents with increasing head size and **prominent occiput**, long-tract signs, **cerebellar ataxia,** and delayed motor development, positive transillumination



TheFetus.net

Figure 21-2. Dandy Walker Malformation, the Result of Agenesis or Hypoplasia of the Cerebellar Vermis, Cystic Dilatation of the Fourth Ventricle, and Enlargement of the Posterior Fossa

SEIZURES

Seizures are triggered recurrently from within the brain versus somatic disorders that may trigger a seizure from outside the brain. **Epilepsy** is present when **at least 2 unprovoked seizures occur >24 hours apart.**

Febrile seizures

An 18-month-old child is brought to the emergency center after having a generalized tonic-clonic seizure that lasted approximately 5 min. The parents say that the child had been previously well but developed cold symptoms earlier today with a temperature of 39°C (102°F).

- Occurs between age 6 months to 5 years; incidence peaks at age 14–18 months and may reoccur with fever
- Usually positive family history
- Temperature usually increases **rapidly** to >39°C (102°F)
- **Typical: generalized tonic-clonic seizures, <10–15 minutes; brief postictal period**
- **Atypical: >15 minutes, more than one in a day, and focal findings**
- Simple febrile seizure has **no increased risk of epilepsy**—risk for febrile seizures is increased with atypical seizure, family history of epilepsy, initial seizure before age 6 months, abnormal development, or preexisting neurologic disorder
  - Workup/Evaluation
    - Must determine cause of fever, must not look like meningitis
    - **No routine labs, no EEG, no neuroimaging**
  - Treatment—**control fever**

Partial Seizures

Simple

- **Asynchronous tonic or clonic movements; most of the face, neck, and extremities;** average duration 10–20 seconds
- Some have **an aura** and may verbalize during the attack; **no postictal period**
- EEG—**spike and sharp waves or multifocal spikes**
- Treatment—phenytoin and other anticonvulsants

Complex seizures

- **Impaired consciousness at some point,** may be very brief; one-third with aura (always indicates focal onset)
- **Automatisms** common after loss of consciousness (lip-smacking, chewing, swallowing, increased salivation)
- Interictal EEG—**anterior temporal lobe shows sharp waves or focal spikes**
- **MRI—many will show abnormalities in temporal lobe** (sclerosis, hamartoma, cyst, infarction, arteriovenous malformation [AVM], glioma)
- Treatment—**carbamazepine (drug of choice)** and other add-ons

Generalized Seizures

Absence (petit mal)

- **Sudden cessation of motor activity or speech with blank stare and flickering eyes**
- **More in girls; uncommon <5 years of age**
- **No aura**; usually <30 seconds; **no postictal period**
- EEG—**3/second spike and generalized wave discharge**
- Treatment—**ethosuximide (drug of choice)**, valproic acid (second line)

Tonic-clonic seizures

- May have **aura (focal onset; may indicate site of pathology)**; loss of consciousness, eyes roll back, tonic contraction, apnea
- **Then clonic rhythmic contractions** alternating with relaxation of all muscle groups
- Tongue-biting, loss of bladder control
- Semicomatose for up to 2 hours afterward with vomiting and bilateral frontal headache
- Treatment—**valproic acid, phenobarbital, phenytoin, carbamazepine**, and other add-ons

Myoclonic Seizures

- Repetitive seizures—**brief, symmetric muscle contraction** and loss of body tone with falling forward
- Five types, with variable severity, morbidity, and prognosis
- **Treatment—valproic acid** and others

Infantile Spasms

- **Symmetric contractions of neck, trunk, and extremities** (with extension episodes as well)
- Pathophysiology—increased corticotropin-releasing hormone (CRH): neuronal hyperexcitability
- Begin typically at 4–8 months of age
- Types
  - **Cryptogenic**—infant is normal prior to seizure with normal neurologic examination and development; **good prognosis**
  - **Symptomatic**—disease present prior to seizure (e.g., tuberous sclerosis); **poor control and mental retardation**
- EEG—**hypsarrhythmia** (asynchronous, chaotic bilateral spike-and-wave pattern)
- Treatment
  - **Adrenocorticotropic hormone (ACTH); drug of choice**
  - **Prednisone** and add-on of other anticonvulsants if no response

Note

Benign Myoclonus of Infancy

- Often confused with myoclonic seizures
- Clusters confined to the neck, trunk, and extremities
- EEG normal
- Good prognosis
- Goes away after 2 years; no treatment

Neonatal Seizures

  - Because of immaturity of CNS, **tend to have subtle seizures**; therefore, they are difficult to recognize

- Etiology
  - **Hypoxic ischemic encephalopathy most common; seizure usually present within 12–24 hours after birth**
  - CNS **infection**
  - CNS **hemorrhage**
  - **Structural** abnormalities
  - Blood chemistry abnormalities
  - **Inborn errors** of metabolism
  - **Drug withdrawal**
  - Evaluation:
    - CBC; platelets
    - Electrolytes, calcium, magnesium, phosphorus; glucose
    - Lumbar puncture to exclude meningitis or bleed
    - CT scan in term, ultrasound in preterm to diagnose bleed
    - Blood and urine culture may be indicated (+CSF)
    - Consider newborn screen for inborn errors of metabolism, if abnormal results suggestive or no diagnosis
    - Treatment—lorazepam, phenobarbitol

Table 21-1. Neonatal Seizures

Cause	Presentation	Associations
Hypoxic ischemic encephalopathy	12–24 hours	Term; cerebral palsy
Intraventricular hemorrhage	1–7 days	Preterm
Metabolic	Variable	IODM (infant of diabetic mother), inborn errors of metabolism, DiGeorge syndrome
Infection	Variable	TORCH, maternal fever, sepsis/meningitis

NEUROCUTANEOUS SYNDROMES

A 6-year-old presents to the pediatrician for a routine evaluation. The child is noted to have 10 café-au-lait lesions as well as axillary freckling.

Neurofibromatosis (NF; von Recklinghausen Disease)

NF-1

- **Autosomal dominant**; but most with new mutation
- Every organ can be affected; features **present from birth but complications may be delayed into adulthood**
- Diagnosis—a good history and physical examination are needed to make the diagnosis.
  - **Two** of the following are needed:
    - At least 5 café-au-lait spots >5 mm prepubertal or at least 6 café-au-lait spots >15 mm postpubertal
    - Axillary/inguinal freckling
    - >2 iris Lisch nodules (seen on slit lamp only)
    - >2 neurofibromas or one plexiform neurofibroma
    - Osseous lesions, splenoid dysplasia or cortical thinning of long-bones (LE)
    - Optic gliomas
- Complications
  - CNS:
    - Low-grade **gliomas (optic), hamartomas**
    - **Malignant neoplasms** (astrocytoma, neurofibrosarcoma, and others)
    - Transient ischemic attack, hemiparesis, hemorrhage
    - Complex partial or generalized **seizures**
    - **Cognitive defects**, learning disabilities, attention deficit, speech abnormalities, psychiatric disturbances
  - **Renovascular hypertension or pheochromocytoma**
  - Increased incidence **of leukemia, rhabdomyosarcoma, Wilms tumor**
- Treatment
  - Genetic counseling
  - Early detection of treatable conditions
  - Annual ophthalmologic examination
  - Examine family members

NF-2

- Presentation
  - Primary feature—**bilateral acoustic neuromas**
  - Hearing loss
  - Facial weakness
  - Headache
  - Unsteady gait
  - **Skin findings much less common** (glioma, meningioma, schwannoma)
  - CNS tumors common
- Treatment
  - Developmental and cognitive evaluation and diagnosis
  - Prevent pathological fractures if LE cortical thinning present

Tuberous Sclerosis

A 1-month-old infant presents with infantile spasms and has a hypsarrhythmic EEG pattern.

- **Autosomal dominant**; half with new mutations
- Wide range of manifestations within same family
- The younger the patient, the higher the likelihood of mental retardation
- Hallmark is CNS **tubers** found in **convolutions of cerebral hemispheres**; undergo calcification and project into ventricular cavity, causing obstruction of CSF flow and hydrocephalus.
- Clinical presentation
  - Infancy—with **infantile spasms** and characteristic skin lesions
    - **Ash-leaf macule**—hypopigmented; increased with Wood UV lamp
    - CT scan shows **calcified tubers** (but may not see till 3–4 years of age)
  - Childhood—**generalized seizures and skin lesions**
    - **Sebaceous adenoma**—red or clear nodules on nose and cheeks
    - **Shagreen patch**—rough, raised lesion with orange-peel consistency; most in lumbosacral area (midline)
- Diagnosis—**clinical:** characteristic skin lesions and seizure disorder
- Treatment—seizure control
- Complications
  - Retinal lesions—either mulberry tumor from optic nerve head or phakomas (round, flat, gray lesions in area of disc)–visual disturbances
  - Brain tumors much less common (but may see malignant astrocytoma)
  - Half have **rhabdomyoma of the heart** (can detect in fetus with echocardiogram); most spontaneously regress over first 2 years
  - **Renal lesion in most—either hamartoma or polycystic kidneys**
  - Pulmonary—cystic or fibrous changes

Note

Not all babies with a facial nevus have Sturge-Weber syndrome. Obtain a skull x-ray and intraocular pressure.

Sturge-Weber Syndrome (SW)

A newborn is examined in the nursery by the pediatrician. The patient is a product of a term spontaneous vaginal delivery without complications. On physical examination, the patient is noted to have a facial nevus.

- **Facial nevus (port wine stain), seizures, hemiparesis, intracranial calcifications, and mental retardation**
- **Nevus is always present at birth and always involves at least the upper face and eyelid**
- **Glaucoma** in ipsilateral eye
- Presentation
  - **Seizures in most** (focal tonic-clonic, **contralateral to the nevus**); becomes refractory and slowly develops **hemiparesis, mental retardation**
- Diagnosis
  - **Skull x-ray shows occipital-parietal calcifications (serpentine or railroad-track appearance) and intraocular pressure reading initially** (↑)
  - **CT scan to highlight extent and show unilateral cortical atrophy and hydrocephalus ex vacuo**
- Treatment
  - Conservative if seizures are well controlled and development is not severely affected
  - Hemispherectomy or lobectomy—may prevent mental retardation and recalcitrant seizures if done in the first year of life
  - Regular intraocular pressure evaluation
  - Nevus—pulsed laser
  - Special education

ENCEPHALOPATHIES

Cerebral Palsy

- Group of motor syndromes from disorders of early brain development
  - Neurologic function may change or progress with time
  - Some have cognitive dysfunction
  - **Most born at term with uncomplicated labor and delivery**
    - Majority have no identifiable antenatal problems
    - **Only 10% with intrapartum asphyxia**
- **The most obvious manifestation is impaired ability of voluntary muscles (rigidity and spasticity).**
  - Other associations—seizures and abnormalities of speech, vision, and intellect
- Other risk factors—increased risk with intrapartum infection, **low birth weight,** (especially <1,000 g); most of these secondary **to intraventricular hemorrhage and periventricular leukomalacia**

- Diagnosis
  - MRI (location and extent of lesions or abnormalities)
  - If spinal involvement, MRI of spine
  - Hearing and visual evaluation
  - Genetic evaluation
  - Complete neurologic and developmental exams
- Treatment
  - Multidisciplinary team
  - Teach daily activities, exercises, assistance and adaptive equipment, surgical release procedures, communication equipment
  - Spasticity drugs (dantrolene, baclofen, botulinum toxin)
  - Psychological support

NEURODEGENERATIVE DISORDERS

Hallmark

- **Progressive deterioration of neurologic function**
  - Loss of speech, vision, hearing, and/or walking
  - Associated with seizures, feeding difficulties, and cognitive dysfunction
  - Regression of developmental milestones

Friedrich Ataxia

- Abnormal gene encoding for frataxin; autosomal recessive
- Onset of **ataxia** before <10 years of age
  - Slowly progressive
  - Loss of DTRs
  - Extensor plantar reflex
  - Weakness in hands and feet
  - Degeneration of posterior columns—loss of position and vibration sense
- **Explosive, dysarthric speech**
- Skeletal abnormalities, e.g., kyphoscoliosis
- **Hypertrophic cardiomyopathy—refractory congestive heart failure, death**

Wilson Disease

- Inborn error of **copper metabolism**; autosomal recessive
- Liver with or without CNS disease (neurologic, psychiatric)
- Liver symptoms first (any liver pathology), neurologic symptoms later (adolescent to adults)
  - Dystonia, tremors, basal ganglia problems
  - **Kayser-Fleischer rings**—pathognomonic (all will have with neuropsycho symptoms)

  - MRI shows dilated ventricles with atrophy of cerebrum and lesions in thalamus and basal ganglia
- Diagnosis—**Suspect in any child with acute or chronic liver disease, unexplained neurologic disease, or behavioral or psychiatric changes**
  - **Best screen**—serum ceruloplasmin (decreased)
  - Confirm with liver biopsy—increased Cu content
  - Screen family members
- Treatment
  - Chelation with **penicillamine** (slows progression)
  - Definitive treatment with liver transplant

Sphingolipidoses

Tay-Sachs disease

- Deficient β-**hexosaminidase-A**, accumulate GM2
- Mostly in Ashkenazi Jews (carrier rate 1 in 30)
- Normal developmental until 6 months, then lag and lose milestones
- Seizures, hypotonia, blindness
- **Cherry-red macula**

Purine Metabolism Disorders

Lesch-Nyhan disease

- X-linked
- Purine metabolism disorder of purine metabolism → excess uric acid
- Delayed motor development after a few months
- **Self-mutilation and dystonia,** gouty arthritis, tophi, renal calculi
- Choreoathetosis, spasticity
- Diagnosis–**Analyze HPRT enzyme**
- Treatment
  - Manage renal complications, arthritis
  - Behavioral modification
  - Medication for reduction of anxiety and mood stabilization

NEUROMUSCULAR DISEASE

Spinal Muscle Atrophy (SMA)

A pediatrician examines an infant who is on the examination table in frog-leg position, with subdiaphragmatic retractions and absent tendon reflexes.

- **Degenerative disease of motor units beginning in the fetus and progressing into infancy; denervation of muscle and atrophy**
- Types
  - **SMA 1 = severe infantile (Werdnig-Hoffman disease)**
  - SMA 2 = late infancy, slower progression
  - SMA 3 = chronic juvenile (Kugelberg-Welander disease)
- Autosomal recessive
- Clinical presentation—SMA 1 presents in early infancy with
  - **Progressive hypotonia; generalized weakness;** Infant is flaccid, has little movement and poor head control
  - **Feeding difficulty**
  - **Respiratory insufficiency**
  - **Fasciculations of the tongue and fingers**
  - **Absent DTRs**
- Typically appear **brighter** than others of same age
- Diagnosis
  - **Simplest, most effective diagnosis is molecular genetic marker in blood for the *SMN* gene.**
  - EMG—fibrillation potential and other signs of denervation
  - Muscle biopsy shows a characteristic pattern of **perinatal denervation.**
- Treatment is supportive; there is no cure; most die in first 2 years of life

Myasthenia Gravis

A pediatrician examines an infant with poor sucking and swallowing since birth. The infant is noted to be a floppy baby with poor head control. There is associated ocular ptosis and weak muscles on repeated use.

- Immune-mediated neuronal blockade; motor end plate is less responsive due to, decreased number of available **acetylcholine receptors** secondary to **circulating receptor binding antibodies**; generally nonhereditary
- Clinical presentation
  - **Ptosis and extraocular muscle weakness is the earliest and most consistent finding.**
  - Dysphagia and facial weakness, and early infant feeding difficulties
  - Poor head control

Note

Transient Neonatal Myasthenia

- Neonates born to mothers with myasthenia; may have generalized hypotonia and weakness, feeding difficulties, and respiratory insufficiency from days to weeks
- May need ventilation and nasogastric feedings
- After antibodies wane, they are normal and have no risk for disease.

  - Limb-girdle weakness and in distal muscles of hands
  - **Rapid muscle fatigue**, especially late in the day
  - May have respiratory muscle involvement
- Diagnosis
  - **EMG more diagnostic than muscle biopsy**—decremental response to repetitive nerve stimulation, reversed after giving cholinesterase inhibitor (edrophonium) → improvement within seconds
  - CPK is normal.
  - May have anti-acetylcholine (anti-ACh) antibodies (inconsistent)
- Treatment
  - Mild—many need no medication
  - Cholinesterase-inhibiting drugs—either neostigmine bromide PO or pyridostigmine
  - Severe—long-term prednisone; if no response, intravenous immunoglobulin (Ig), then plasmapheresis
  - Thymectomy—most effective if patient has high anti-ACh titers and symptoms for <2 years
- Complications—do not tolerate neuromuscular blockade and aminoglycosides potentiate

Hereditary Motor-Sensory Neuropathies (HMSNs)

HMSN I: Marie-Charcot-Tooth disease

- Progressive disease of peripheral nerves; **peroneal muscle atrophy; peroneal and tibial nerves**
- Autosomal dominant
- Clinical presentation
  - Asymptomatic until late childhood or adolescence but may have problem with gait as early as age 2 years
  - **Clumsy, fall easily; muscles of anterior compartment of lower leg become wasted → stork-like appearance**
  - **Pes cavus, foot drop**
  - **Claw hand** (in worse cases)
  - **Slowly progressive** through life, but normal lifespan and remain ambulatory
- Diagnosis
  - CPK is normal.
  - **Decreased nerve conduction velocities** (motor and sensory)
  - **Sural nerve biopsy** is diagnostic.
  - Blood molecular genetic diagnosis
- Treatment
  - **Stabilize ankles**
  - Surgical ankle fusion
  - Protection from trauma
  - If sensory problems, phenytoin or carbamazepine

Guillain-Barré Syndrome

- **Postinfectious polyneuropathy**—mostly motor; all ages; most with demyelinating neuropathy
- 10 days after a **nonspecific viral illness or *Campylobacter jejuni or Mycoplasma pneumoniae*—Landry ascending paralysis**
  - Symmetric proximal and distal muscles
  - Gradually over days to even weeks
  - May have **tenderness, pain, paresthesias early**
  - **Bulbar involvement** in half—dysphagia, facial weakness, **respiratory insufficiency**
  - May have **autonomic involvement**—blood pressure lability, bradycardia, asystole
  - Spontaneous recovery begins in 2–3 weeks; some have residual weakness; improvement in inverse direction
- Diagnosis
  - Significant **increase in CSF protein** with **normal glucose** and **no cells**
  - Reduced motor and sensory nerve conductions
- Treatment
  - Mostly supportive
  - **Admit all patients** (observe respiratory effort)
    - Mild-observation
  - **Intravenous immunoglobulin** 2–5 days
  - May need plasmapheresis, steroids, interferon, or other immunosuppressives

Muscular Dystrophy

Duchenne

A 3-year-old boy is brought to the pediatrician because he is very clumsy. According to his parents, he has difficulty climbing stairs and frequently falls. On physical examination hypertrophy of the calves is noted.

- Primary myopathy with genetic basis; is progressive and results in degeneration and death of muscle fibers; most common of the neuromuscular diseases in all races and ethnic groups; X-linked recessive
- Clinical presentation
  - First sign may be poor head control in infancy.
  - By year 2, may have subtle findings of hip-girdle weakness
  - **Gower sign** as early as age 3 years but fully developed by **age 5–6 years;** with hip-waddle gait and lordotic posturing
  - **Calf pseudohypertrophy** (fat and collagen) and wasting of thigh muscles
  - Most walk without orthotic devices until age 7–10 years, then with devices until 12; once wheelchair-bound, **significant acceleration of scoliosis**

- Progressive into second decade:
  - Respiratory insufficiency
  - Repeated pulmonary infections
  - Pharyngeal weakness (aspiration)
  - Contractures
  - **Scoliosis** (further pulmonary compromise)
  - **Cardiomyopathy** is a constant feature.
  - **Intellectual impairment** in all; IQ <70 in about 30%; most with **learning disabilities**

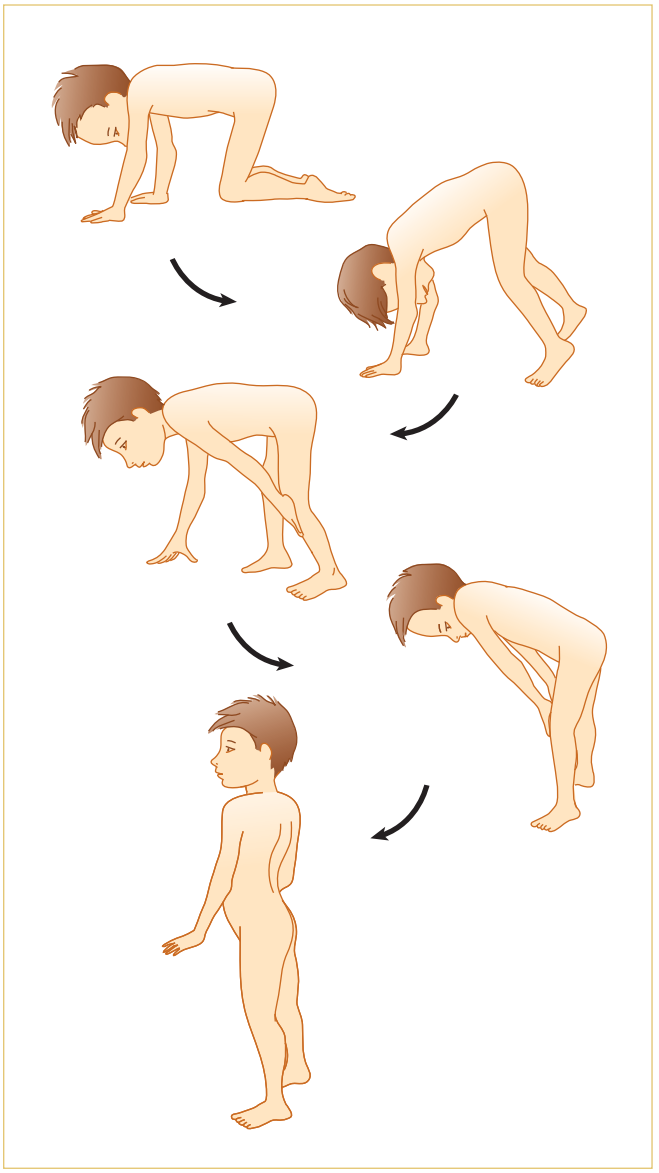


Figure 21-3. Gower Sign in Duchenne Muscular Dystrophy

  - **Death usually around age 18 years** from respiratory failure in sleep, intractable heart failure, pneumonia, aspiration with obstruction
- Lab studies
  - **CPK—15,000–35,000** U/L (normal is <160 U/L) (initial screen for myopathy)
  - **Best initial test—molecular genetic diagnosis: deficiency or defective dystrophin cytoskeletal protein from gene at Xp21.2** (one-third will **not be diagnostic**)
  - **Muscle biopsy** to show the abnormal or absent dystrophin; most accurate test (do in the one-third who do not give a molecular diagnosis)
- Treatment—multidisciplinary team
  - **Digoxin** for heart failure (all patients need cardiology referral)
  - Vigorous treatment of pulmonary infections
  - Maintain good **nutrition**; good calcium supply (prevent osteoporosis)
  - **Physiotherapy**—delay contractions; **orthotic devices**, proper wheelchair, physiatrist

Myotonic Dystrophy

Myotonic dystrophy is the **second most common muscular dystrophy**.

- **Autosomal dominant** inheritance; CTG trinucleotide expansion at 19q13.3; causes multiple dysfunctions in multiple organ systems
- Involves both **striated and smooth muscle**
- Most common findings may be present at birth; the **severe congenital form** occurs in a baby born to a mother with symptomatic disease:
  - **Facial wasting: Inverted V-shaped upper lip, thin cheeks, scalloped concave temporalis muscles, narrow head, high arched palate**
  - **Hypotonia**: mild weakness and progressive wasting of DISTAL muscles especially hands, then dorsal forearm and anterior compartment of lower leg, then atrophy of proximal muscles
  - Progressive difficulty in climbing steps and lastly a Gower sign
  - **Slow progression** through childhood to adulthood but rare to lose ability to walk
  - **NOTE: The distal distribution of muscle wasting is the exception to the general rule of myopathies having a proximal and neuropathies a distal distribution**
  - **Myotonia: not evident until age >5; very slow relaxation of muscle after a contraction, but NOT a painful muscle spasm (difficulty opening fist or relaxing grip)**
- Other problems:
  - Poor speech articulation, slurred
  - Difficulty swallowing, aspiration pneumonia
  - Extraocular muscle weakness; cataracts
  - Slow GI emptying, constipation
  - Ineffective uterine contractions
  - Heart block and arrhythmia (not cardiomyopathy as in other dystrophies)
  - Many endocrine problems
    - Half with intellectual impairment
- Diagnosis: CPK as a screen (in the hundreds compared to MD); EMG classic myotonic findings; best test is DNA (blood); biopsy not needed
- Treatment: supportive

Infectious Disease 22

Learning Objectives

- ❑ Describe the presentation and emergency management of meningitis
- ❑ Describe the presentation and management of pertussis
- ❑ Recognize and describe treatment for mycobacteria, Lyme disease, and Rocky Mountain Spotted Fever
- ❑ Categorize and describe other important mycotic, viral, and helminthic diseases

MENINGITIS

A 6-year-old presents to the physician with the chief complaint of headache, vomiting, neck stiffness, and photophobia. Physical examination reveals an ill-appearing child unable to flex his neck without eliciting pain. Kernig and Brudzinski signs are positive.

Acute Bacterial (Older Than a Neonate)

- First 2 months of life (and some into month 3) represent maternal vaginal flora—group B *Streptococcus, E.coli, Listeria*
- Age 2 months to 12 years—***S. pneumoniae*** (peaks in first 2 years), ***N. meningitidis*** (sporadic or in epidemics; direct contact from a daycare center or a colonized adult family member; increased in college freshmen living in dorms), and HiB (now **uncommon** due to many years of immunization)
- Pathology—meningeal inflammation and exudate
  - Most from hematogenous spread, initially from bacterial colonization of nasopharynx, and a prior or current viral infection may enhance pathogenicity
  - Rarely from an infection at a contiguous site (sinusitis, otitis media [OM], mastoiditis, orbital cellulitis)
- Clinical presentation
  - Several days of **fever, lethargy, irritability, anorexia, nausea, vomiting**
  - Then **meningeal irritation** (photophobia, neck and back pain, and rigidity)
    - **Kernig sign:** flexing of hip 90° and subsequent pain with leg extension (inconsistent)

Note

Infants may not have positive Kernig or Brudzinski sign in meningitis but will have bulging fontanelles on physical examination.

    - **Brudzinski sign:** involuntary flexing of knees and hips after passive flexing of the neck while supine (better test)
  - Increased ICP suggested by headache, emesis, bulging anterior fontanelles, **oculomotor or abducens palsies**, hypertension with bradycardia, apnea, decorticate or decerebrate posturing, stupor, coma
- Diagnosis—**need lumbar puncture (LP) and blood culture in all** (90% have positive blood culture)
  - **Contraindications to immediate LP**
    - Evidence of increased ICP
    - Severe cardiopulmonary problems requiring resuscitation
    - Infection of skin over site
    - Do not delay antibiotics for the CT scan.

Table 22-1. CSF Findings in Various Types of Meningitis

	Bacterial	Partially Treated	Granulomatous (TB)	Aseptic (Viral)
Cells/mL	200–5,000	200–5,000	100–500	100–700
Cytology	Polymorphonuclear neutrophil	Mostly polymorphonuclear neutrophil	Lymphocytes	Mostly lymphocytes
Glucose†	Low	Low	Low	Normal
Protein	High	High	High	Normal to slightly high
Gram stain	Positive	Variable	Negative	Negative
Culture	Positive	Variable	Positive	Negative
CIE or LA	Positive	Positive	Negative	Negative
Pressure	High	High	High	Normal

Definition of Abbreviations: CIE, counterimmunoelectrophoresis; LA, latex agglutination

†CSF glucose concentration should be considered in relation to blood glucose concentration; normally CSF glucose is 50–70% of blood glucose.

- Treatment

Table 22-2. Empiric Antibiotic Therapy Based on Age for Bacterial Meningitis

Age	Most Likely Organisms	Empiric Antibiotics
0-2 months	GBS, *E. coli*, L. monocytogenes	Ampicillin + cefotaxime
2-3 months	Above perinatal organisms + some *S. pneumoniae* + very little *H. influenza* type B	Ampicillin + cefotaxime/ ceftriaxone + vancomycin (assume resistant *S. pneumoniae*)
3 months – 2 years	*S. pneumoniae* + *N. meningitides*	Vancomycin + cefotaxime/ ceftriaxone
2-18 years	*N. meningitides* +	Vancomycin + cefotaxime/ ceftriaxone

Data support the use of IV dexamethasone added to the initial treatment of meningitis due to HiB, beginning with the first dose for 4 doses in children age >6 weeks (this will rarely be the case). Decreased incidence of fever, elevated CSF protein, and 8th cranial nerve damage.

- Complications
  - Increased ICP with herniation and seizures
  - Subdural effusion, especially in infants with HiB, can cause **seizures,** persistent fever; drain if symptomatic.
  - Cranial nerve palsies, stroke, thrombosis of dural venous sinuses
  - Most common sequelae is **hearing loss** (especially with pneumococcus)
  - Less common: mental retardation, developmental delay, visual impairment
- Prevention
  - **Chemoprophylaxis with rifampin for *N. meningitidis* and HiB, but not for *S. pneumoniae***
  - All close contacts regardless of age or immune status

Acute Meningococcemia

- Initially may mimic a viral disease (nonspecific)
- Any organ can be affected by **vasculitis and thromboembolic disease.**
- **Characteristic meningococcal rash** (black central arch and surrounding ring or erythema) often seen before more serious signs develop
- If fulminant—rapid progression: **septic shock, disseminated intravascular coagulation, acidosis, adrenal hemorrhage, renal and heart failure**
- Petechiae and purpura ± meningitis = **purpura fulminans (DIC)**
- Need high dose IV penicillin ASAP
- Chemoprophylaxis for close quarters (dorms, army barracks)

Note

Anything that suggests temporal lobe involvement (i.e., focal seizures, CT scan, MRI, and EEG findings localized to the temporal lobe) is highly suspicious for herpes simplex virus.

Note

- Encephalitis = meningitis + mental status changes
- Consider drug ingestion in differential diagnosis

Viral (Aseptic) Meningitis

- Affects meninges and brain tissue variably; most are self-limited; person-to-person contact in summer and fall; most are enteroviruses
  - Arbovirus = arthropod-borne viruses; vectors are mosquitoes and ticks after biting infected birds or small animals; spreads to humans and other vertebrates
  - Rural exposure more common
  - Herpes simplex: **focal**; progresses to coma and death without treatment
  - Varicella zoster: most common presentation is cerebellar ataxia and acute encephalitis.
  - Cytomegalovirus: in immunocompromised, disseminated disease; or congenital infection but not in immunocompetent host
  - Epstein-Barr virus (EBV), mumps: mild but with 8th-nerve damage
- Clinical
  - **Headache and hyperesthesia in older children**
  - **Irritability and lethargy in infants**
  - **Fever, nausea, vomiting, photophobia, and neck, back, and leg pain**
  - Exanthems, especially **echovirus and coxsackie,** varicella, measles, and rubella
- Complications
  - Guillain-Barré syndrome, transverse myelitis, hemiplegia, cerebellar ataxia
  - Most completely resolve without problems except for the neonate with HSV (severe sequelae)
- Diagnosis
  - **PCR of CSF is the best test.**
  - Viral culture
- Treatment—supportive, except acyclovir indicated for herpes simplex virus (HSV)

Note

Pertussis

Early treatment *may* alter the course of disease. Treatment decreases communicability.

PERTUSSIS

A 10-month-old child who is delayed in immunizations presents with a paroxysmal cough. The patient appears ill and continuously coughs throughout the examination. The patient has facial petechiae and conjunctival hemorrhages. In addition, the patient has post-tussive emesis.

- Cause—*Bordetella pertussis*
  - Endemic; very contagious; aerosol droplets
- Neither natural disease nor vaccination provides complete or lifelong immunity; **wanes after age 8–15 years**
  - Subclinical reinfection
  - Coughing **adolescents and adults are major reservoirs.**
- Clinical presentation of **whooping cough**
  - **Catarrhal phase** (2 weeks)—coldlike symptoms (rhinorrhea, conjunctival injection, cough)

  - **Paroxysmal phase** (2–5 weeks)—increasing to severe coughing paroxysms, inspiratory "whoop" and facial petechiae; post-tussive emesis
  - **Convalescent phase** ≥ 2 weeks of gradual resolution of cough
- Diagnosis
  - **History may reveal incomplete immunizations**
  - **Gold standard is PCR of** nasopharyngeal aspirate 2–4 weeks after onset of cough, or a culture
- Treatment
  - **See immunization chapter**
  - **Supportive care**
  - **Always treat if suspected or confirmed: erythromycin for 14 days** (other macrolides with similar results) only decreases infectious period of patient; it *may* shorten the course of illness; also treat **all household members and any close contacts**

Bartonella (Cat-Scratch Disease)

A 6-year-old presents with a swollen 3×5-cm tender, erythematous, anterior cervical neck node. He denies a history of fever, weight loss, chills, night sweats, or sore throat. The patient's pets include a kitten, a turtle, and goldfish.

- Etiologic agent—*Bartonella henselae*
  - **Most common cause of lymphadenitis lasting >3 weeks**
  - Cutaneous inoculation (arthropod borne by cat flea); kittens transmit better than cats
  - Incubation period 3–30 days
- Clinical presentation
  - One or more 3- to 5-mm **red to white papules along the linear scratch** *plus* hallmark: **chronic regional lymphadenitis**
  - Other nonspecific findings: fever, malaise, headache, anorexia
  - Less common: abdominal pain, weight loss, hepatosplenomegaly, osteolytic lesion
  - Atypical presentation: Parinaud oculoglandular syndrome
- Diagnosis
  - **Clinical with history of scratch from cat**
  - Tissue: **PCR** and Warthin-Starry stain (shows gram-negative bacilli)
  - Serology: variable immunoglobulin IgG and IgM response (not good test)
- Treatment—**Antibiotics** not used as there is a discordance between in vitro and in vivo activity (use only for severe hospitalized cases) (usually self-limiting and resolves in 2–4 months); aspiration of large and painful lesions

Note

Parinaud oculoglandular syndrome consists of:

- unilateral conjunctivitis
- preauricular lymphadenopathy
- cervical lymphadenopathy
- occurs after rubbing the eye after touching a pet

MYCOBACTERIA

Tuberculosis

A 10-year-old child is referred by the school nurse because of a positive tuberculin skin test. The patient has been well, without any associated complaints.

- ***M. tuberculosis***
- High-risk reservoirs—recent immigrants, low SES, HIV, elderly
- Primary complex—affects the **lung** with local infection with hilar adenopathy
- Latent infection—reactive TB skin test and absence of clinical or radiographic findings
- Diagnosis
  - Skin testing
    - Delayed hypersensitivity—Mantoux (PPD) test, (+) most often 4–8 weeks after inhalation
    - Positive reaction (**5, 10, 15** mm), depending on risk factors (*see* margin note)
  - Best—if can get sputum
    - **3 consecutive early A.M. gastric aspirates (still only 50%, even with PCR)**
    - A negative culture **never** excludes the diagnosis.
- Clinical Presentation
  - Primary TB usually asymptomatic in children; healthy host will wall off the organism; occasionally, low-grade fever, mild cough, malaise which resolve in 1 week
  - Infants more likely to have signs and symptoms
  - Reactivation rare, (esp. if acquired <2 years of age) occurs during adolescence
  - Small number with extrapulmonary presentation; symptoms depend on location
- Presentation
  - Primary pulmonary disease
    - Localized nonspecific infiltrate
    - Large adenopathy compared to infiltrate: compression → atelectasis and hyperinflation; most resolve completely
- Extrapulmonary
  - Erosion into blood or lymph = miliary
    - Lungs
    - Spleen
    - Liver
    - Bone and joints—Pott disease (destruction of vertebral bodies leading to kyphosis)
    - **TB meningitis**—mostly affects brainstem; CN III, VI, VII palsies and communicating hydrocephalus
  - If reactivation—fever, anorexia, malaise, weight loss, night sweats, productive cough, hemoptysis, chest pain

Note

Mantoux Test Reactions

- A reaction of >5 mm is positive in those who have been exposed to TB or are immunocompromised.
- >10 mm of induration is positive in high-risk populations.
- For low-risk persons, >15 mm is positive.
- Previous vaccination with bacilli Calmette-Guérin (BCG) may cause a false-positive reaction.
- Patients who are immunocompromised, are malnourished, or received live-virus vaccines may have a false-negative reaction.

- Treatment
  - Latent TB
    - INH × 9 months
  - Primary pulmonary disease
    - INH + rifampin × 6 months, plus pyrazinamide in first 2 months
  - Increased community resistance
    - Add streptomycin, ethambutol or ethionamide
  - In some cases of meningitis, studies have shown decreased morbidity and mortality when **corticosteroids** added to regimen. Use adjunctively in patients with severe miliary disease and pericardial or pleural effusions.

Bacille Calmette-Guérin (BCG) Vaccination in the United States

- **Not routine**—variable efficacy, time-limited efficacy
- Only used in the following situations:
  - High-risk with close or long-term exposures
  - Continuous exposure to resistance strains
- Contraindicated in those with primary or secondary immune deficiencies

Perinatal Tuberculosis

- If mother has (+) PPD → obtain chest x-ray
- If chest x-ray (–) and clinically stable → no separation, no evaluation of baby, INH prophylaxis for mother for 9 months
- If mother has suspected TB at delivery → separate baby from mother until chest x-ray obtained
  - If mother has disease → treat infant with INH with no further separation from mother and treat mother with anti-TB therapy until mother is culture negative for 3 months

LYME DISEASE

A 6-year-old child presents with a rash after camping on Long Island with his family. On physical examination, the rash has a red raised border with central clearing.

Borrelia burgdorferi

- Most common vector-borne disease in the United States
- Most in southern New England, eastern Middle Atlantic states, and upper Midwest, with small endemic area along the Pacific coast
- *Ixodes scapularis,* i.e., the deer tick
- Clinical presentation: history of tick bite is helpful but absent in most; tick is small and often not seen by human eye; history of being in the woods or mountains should give suspicion

  - Early disease
    - **Local: erythema migrans** 3–32 days after bite at site of the bite; **target lesion (must be >10 cm in diameter)** often called "bulls-eye" rash; fever, headache, and malaise most common symptoms; without treatment, lesion resolves in 1–2 weeks
    - **Early disseminated: secondary lesions**, smaller than the primary + constitutional symptoms + lymphadenopathy; uveitis and Bell palsy (may be only finding); carditis (myocarditis, heart block); CNS findings (neuropathy, aseptic meningitis)
  - Late disease: **arthritis** weeks to months later; affecting large joints, more likely to be chronic in adults
- Diagnosis
  - No definitive tests
  - Primarily **clinical and based on history + rash**
  - **Quantitative ELISA test and confirmatory Western blot if the ELISA is positive or equivocal**
- Treatment
  - Early
    - **Doxycycline** 14–21 days (patients >8 years old); **amoxicillin** (patients age <8 years)
  - Ceftriaxone with meningitis or carditis (heart block)
  - Doxycycline or amoxicillin with Bell palsy
- Prognosis—excellent in children with permanent cure

ROCKY MOUNTAIN SPOTTED FEVER

A 17-year-old presents to the emergency department with his friends because of fever, headache, and a rose-colored rash that began on his ankles and is spreading. The patient and his friends have been camping in Virginia.

Rickettsia Rickettsii

- Consider in differential diagnosis of **fever, headache, and rash in summer months, especially after tick exposure**
- Seen now in every state; most in Southeast, especially in **North Carolina**
- Wooded areas, coastal grasses, and salt marshes
- Most April–September; most patients age <10 years
- Ticks are the natural hosts, reservoirs, and vectors (dog tick, wood tick, brown dog tick).
- Clinical presentation
  - Incubation period 2–14 days, then headache, fever, anorexia, myalgias, gastrointestinal (GI) symptoms early
  - After third day—**skin rash**
    - Extremities first (palms, soles)
    - Spreads rapidly
    - Becomes petechial/hemorrhagic
    - Palpable purpura

  - Vascular obstruction, **due to vasculitis and thromboses, leads to gangrene**
  - Hepatosplenomegaly
  - CNS: delirium, coma, and other neurologic findings
  - Myocarditis, acute renal failure, pneumonitis, shock
  - Severe or fatal disease usually due to delay in diagnosis and treatment
- Diagnosis
  - **Strong clinical suspicion**
  - **Confirm with serologic tests;** fourfold increase in antibody titer (acute, convalescence)
- Treatment—**doxycycline or tetracycline in all patients regardless of age** (chloramphenicol in allergy only)

MYCOTIC INFECTIONS

Candida

A newborn infant is noted to have white plaques on his buccal mucosa that are difficult to scrape off with a tongue depressor. When removed, a small amount of bleeding is noted by the nurse. The infant just received a course of empiric antibiotics for suspected Group B β-hemolytic *Streptococcus* infection.

- Most human infections with *C. albicans;* part of normal gastrointestinal tract and vaginal flora of adults
- Oral infection = **thrush;** white plaques; seen with **recurrent or continuing antibiotic treatment and immunodeficiency and normally in breast-fed infants**
  - Diagnosis—**punctate bleeding with scraping**
  - Treatment—oral **nystatin;** if recalcitrant or recurrent, single-dose fluconazole

phil.cdc.gov

Figure 22-1. Diaper Rash Secondary to *Candida Albicans* Infection

- Diaper dermatitis: intertriginous areas of perineum; confluent, papular erythema with **satellite lesions**
  - Diagnosis—skin scrapings; see yeast with KOH prep, but not usually necessary in the presence of clinical findings
  - Treatment—**topical nystatin;** if significant inflammation, add 1% hydrocortisone for 1–2 days
- **Catheter-related fungemia** can affect any organ; may look like bacterial sepsis
  - Diagnosis—buffy coat, catheter tips, urine shows yeast, culture
  - Treatment—remove all catheters; **amphotericin B is drug of choice**
- Chronic mucocutaneous candidiasis—primary defect of T lymphocytes in response to *Candida*; often when **endocrine (diabetes mellitus) and autoimmune disease**

Cryptococcus Neoformans

- Soil contaminated with bird droppings, or in fruits and vegetables
- Predominant fungal infection in **HIV** patients; rare in children and immunocompetent
- Inhalation of spores; in immunocompromised (mostly in HIV patients) disseminated to **brain, meninges**, skin, eyes, and skeletal system; forms granulomas
- **Pneumonia most common presentation**; asymptomatic in many; otherwise, progressive pulmonary disease
- Diagnosis
  - **Latex agglutination—cryptococcal antigen in serum**; most useful for CSF infections
- Treatment
  - Oral fluconazole for 3–6 months if immunocompetent and only mild disease
  - Amphotericin B + flucytosine if otherwise
  - In HIV—lifelong prophylaxis with fluconazole

Coccidioidomycosis (San Joaquin Fever; Valley Fever)

A 14-year-old who lives in Arizona presents to the physician with a 10-day history of fever, headache, malaise, chest pain, and dry cough. He is currently in New York visiting relatives and is accompanied by his aunt. Physical examination reveals a maculopapular rash and tibial erythema nodosum.

- Inhaled arthroconidia from dust; no person-to-person spread
- Types
  - Primary (self-limiting)
  - Residual pulmonary lesions (transient cavity or chest x-ray)
  - Disseminating—can be fatal; more common in males, Filipino/Asians, blood group B
    - Influenza-like symptoms
    - Chest pain

  - **Dry, nonproductive cough**
    - Maculopapular rash
    - **Tibial erythema nodosum**
- Diagnosis
  - Sputum should be obtained via bronchoalveolar lavage or gastric aspirates.
  - Diagnosis is confirmed by culture, **PCR**
- Treatment—most conservative; for those at high risk of severe disease, treatment as with histoplasmosis

Note

Disseminated Coccidiomycosis Triad

- Flu-like symptoms +/– chest pain
- Maculopapular rash
- Erythema nodosum

VIRAL INFECTIONS

Viral Exanthematous Disease

phil.cdc.gov.

Figure 22-2. Typical Appearance of Morbilliform Rash Seen in Measles Infection

Measles

A mother presents to the physician with her adopted daughter, who has just arrived in the United States from a foreign country. The immunization record is not up-to-date. The child has coryza, cough, conjunctivitis, and fever. The mother states that the child also has a rash that began cephalad and spread caudad. On physical examination, a morbilliform rash is seen over the body including the palms. Tiny grayish white dots are seen on the buccal mucosa next to the third molar.

- Rubeola—10-day measles
- RNA *Paramyxovirus*, **very contagious**
- Risk factors—Unimmunized entering high school or college
- Incubation—10–12 days before prodrome appears

- Prodrome—3 C's
  - Cough
  - Coryza
  - Conjunctivitis, then Koplik spots (grayish-white spots on buccal mucosa)
- Final—rash + fever (occur concurrently)
  - Rash—macular; starts at head (nape of neck and behind ears) and spreads downward; fades in same manner
- Diagnosis—mainly clinical
- Treatment—supportive, vitamin A (if deficient)
- Complications—otitis media (most common), pneumonia, encephalitis
- Prevention—immunization

Rubella

A 5-year-old child who has delayed immunizations presents with low-grade fever, a pinpoint rash, postoccipital and retroauricular lymphadenopathy, and rose spots on the soft palate.

- German, 3-day measles
- Risk factors/Etiology—Incubation 14–21 days; contagious 2 days before rash and 5–7 days after rash
- Clinical Presentation
  - Rash similar to measles, **begins on face** and spreads to rest of body, lasts approximately 3 days; concurrent with fever
  - **Retroauricular, posterior, and occipital lymphadenitis** are hallmarks.
  - Forscheimer spots—affect the soft palate and may appear before onset of the rash
  - Polyarthritis (hands) may occur in some patients, especially older females.
- Diagnosis—clinical
- Treatment—supportive
- Prevention—immunization with MMR vaccine
- Complications—congenital rubella syndrome seen if contracted during pregnancy (*see* Newborn chapter)

Roseola

A 15-month-old infant is brought to the physician because of a rash. The mother states that the patient had a fever of 40°C (104°F) for the last 3 days without any source of infection. She explains that the fever has resolved, but now the child has pink, slightly raised lesions on the trunk, upper extremities, face, and neck.

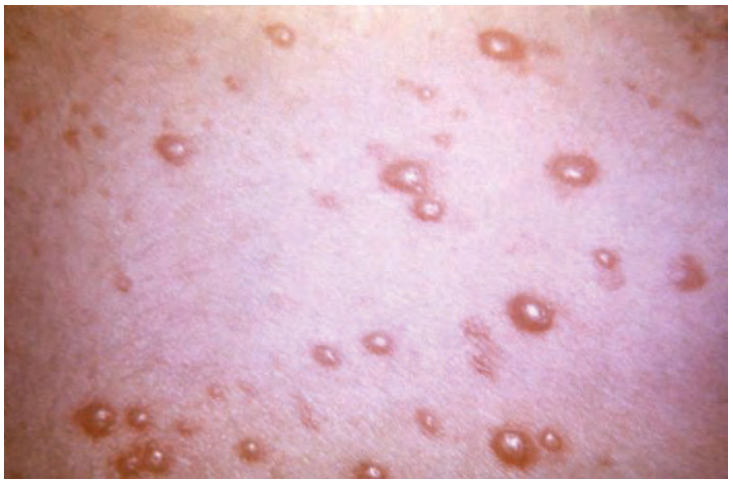
- Also known as exanthem subitum
- Etiology—febrile illness of viral etiology; due to infection with human herpes virus—HHV-6; peaks in children age <5 years, usually 6–15 months; incubation period 5–15 days
- Clinical Presentation
  - High fever (up to 41°C [106°F]) lasting a few days with only signs and symptoms of URI
  - By the 3rd or 4th day, the fever resolves and a maculopapular rash appears on the trunk, arms, neck, and face
    - Characteristic rose-colored rash begins as papules
- Diagnosis and treatment—clinical diagnosis based on age, history, and physical findings. No studies necessary and treatment is supportive.

Mumps

A 4-year-old child is brought to the clinic by his mother with a history of swelling in his face and fever for the last 4 days. His history includes incomplete immunizations due to religious beliefs. Physical examination reveals bilateral, tender facial swelling around the area of the masseter muscle and fever of 39.3°C (102.8°F).

- Etiology/Risk Factors—viral infection due to *Paramyxovirus* transmitted through airborne droplets and respiratory/oral secretions.,
  - Most common in winter/spring
  - Incubation period from 14–24 days
  - Contagious 1 day before and 3 days after swelling appears
  - History usually reveals inadequate or lacking immunizations
- Clinical Presentation
  - Constitutional findings: fever, headache, and malaise
  - Unilateral or bilateral salivary gland swelling, predominantly in the parotids
  - Orchitis (and oophoritis) possible, rare before puberty
    - May result in sterility only if **bilateral**
- Diagnosis—clinical and based upon history/physical findings
- Treatment—supportive
- Meningoencephalomyelitis most common complication; others include pancreatitis, thyroiditis, myocarditis, deafness, and dacryoadenitis

Varicella



phil.cdc.gov

Figure 22-3. Chicken Pox is Characterized by Macules, Papules, Vesicles, and Crusts in Varying Stages of Healing

A 5-year-old child is brought to the emergency center because he has a temperature of 38.9°C (102°F) and is developing a pruritic rash. The rash appears to be in various stages of papules, vesicles, and crusts. It began on his trunk and spread to his extremities.

- Etiology/Risk Factors—due to varicella-zoster virus, a herpes virus
  - Incubation 10–21 days
  - Transmitted through respiratory secretions
  - Remains latent in sensory ganglia after recovery → reactivation in immunosuppressed
- Clinical Presentation—nonspecific symptoms and fever preceeding rash
  - **Pruritic rash in various stages**
    - **Macules → papules → vesicle → open vesicle → crust**
    - Lesions can turn hemorrhagic.
    - **Crops of lesions at same time**
- Clinical diagnosis—no labs
- Treatment
  - Supportive in immunocompetent; treat secondary infection
  - Consider acyclovir and VZIG in immunocomprised or those at risk for severe disease
- Complications—worse in adolescence (scarring)
  - Varicella pneumonia seen in 15–20%
  - Other sequelae include Guillian-Barré syndrome, encephalitis, cerebellar ataxia, postherpetic neuralgia, and Ramsay-Hunt syndrome.
  - Congenital varicella (*see* Newborn chapter)
- Prevention—second vaccine dose recommended

Erythema Infectiosum (Fifth Disease)

A 4-year-old is brought to the physician's office because she developed red cheeks that appear as if someone has slapped her, and a lacy rash on her upper extremities and trunk.

- Etiology—due to Parvovirus B19, a DNA virus; seen most commonly in spring
- Clinical Presentation
  - Mild systemic symptoms
  - Arthritis
  - Intensely red "slapped cheek" appearance
  - Lacy, reticular rash over trunk and extremities
  - Sparing of palms and soles
  - Rash may last up to 40 days
- Diagnosis—clinical; labs not routine **except** when diagnosing hydrops, then viral DNA in fetal blood is often helpful
- Complications—aplastic crisis in patients with hemolytic anemia; hydrops fetalis in neonates during materal infection in first trimester

Table 22-3. Common Childhood Infections with Exanthems

	Prodrome	Enanthem	Exanthem	Complications
Measles	• Cough • Coryza • Conjunctivitis • High fever	Koplik spots	Macules:, hairline, face, neck → trunk and extremities	• Otitis media • Pneumonia • Encephalitis • Subacute sclerosing panencephalitis
Rubella	Mild constitutional symptoms	Forscheimer spots	• Similar to measles • Posterior cervical & auricular nodes	Congenital rubella–teratogenic
Mumps	• Headache • Fever • Malaise • Muscle pain	Glandular swelling	Swollen parotid & submandibular glands	• Encephalitis • Orchitis • Pancreatitis
Varicella	• Low-grade fever • Malaise • URI symptoms	None	• Crops of papules, vesicles • Crusts at same time • Central to peripheral	• Superinfection • Zoster • Pneumonia • Hepatitis • Encephalitis • Congenital varicella
Fifth Disease	Mild URI symptoms	None	Slapped cheek → trunk → central clearing-lacey	Aplastic anemia
Roseola	• URI symptoms • Abrupt onset • High fever then breaks	None	Fever falls rapidly → fine macular rash on trunk and spreads to extremities	Febrile seizures
Scarlet Fever	Sore throat	• Exudative pharyngitis • Strawberry tongue	• Fine maculopapular rash (feels like sand paper, especially in antecubitus and inguinal areas) • Pastia lines	• Acute rheumatic fever • Glomerulonephritis

OTHER VIRAL DISEASES

Epstein-Barr Virus

A 22-year-old college student presents to the clinic complaining of fever, fatigue, and sore throat that have not improved for the last 2 weeks. Physical examination reveals generalized adenopathy most prominent in the anterior and posterior cervical nodes.

- Etiology/Risk Factors
  - **Infectious mononucleosis** (90%)
  - First human virus to be associated with **malignancy**
    - Nasopharyngeal carcinoma
    - **Burkitt lymphoma**
    - Others: Hodgkin disease, lymphoproliferative disorders, and leiomyosarcoma in immunodeficiency states
  - Transmitted in **oral secretions** by close contact (kissing disease); **intermittent shedding for life**
  - Incubation period: 30–50 days; most cases in infants and young children are clinically silent
- Clinical presentation
  - Insidious, vague onset: prodrome for 1–2 weeks with fever, fatigue, headache, myalgia, sore throat, abdominal pain
  - Generalized lymphadenopathy (most **in anterior and posterior cervical** and submandibular nodes; less often in axillary, inguinal, **epitrochlear** nodes), splenomegaly (half the cases; 2–3 cm), and a small number with hepatomegaly
  - Moderate to severe pharyngitis with tonsillar exudative enlargement
  - Small number with rashes (maculopapular); most will have rash if treated with **ampicillin or amoxicillin** (immune-mediated vasculitic rash)
- Diagnosis
  - **Atypical lymphocytosis**
  - **Heterophile antibodies (Monospot test)**
  - **IgM to viral capsid (Igm–VcA–EBV) antigen is the most valuable and specific (up to 4 months).**
- Treatment
  - Rest and symptomatic therapy
  - **No contact sports or strenuous activity with splenomegaly**
  - Short course of **steroids** for complications: incipient airway obstruction, thrombocytopenia with hemorrhage, autoimmune hemolytic anemia, seizures, meningitis
- Complications
  - **Splenic hemorrhage or rupture** (very rare); most in second week, most with trauma
  - Swelling of tonsils and oropharyngeal lymphoid tissue: **airway obstruction**
  - Neurological complications rare; Guillain-Barré syndrome
  - Aplastic anemia

Note

Infectious Mononucleosis Triad

- Fatigue
- Pharyngitis
- Generalized adenopathy

Note

Any exam question that mentions **onset of rash after taking ampicillin or amoxicillin for URI-related symptoms, think mono first.**

  - Interstitial pneumonia
  - Myocarditis
- Prognosis
  - Most cases resolve in 2–4 weeks; some disability that comes and goes for a few months is common; and there may be fatigue for a few years
  - There is no evidence of second attacks from EBV and no evidence that EBV is related to chronic fatigue syndrome

Influenza Viruses

A 14-year-old girl is brought to the physician's office by her mother. She has a 2-day history of fever of 39.7°C (103.5°F), headache, sore throat, refusal to eat, myalgia, chills and non-productive cough. Her current temperature in the clinic is 39.3°C (102.8°F).

- Etiology/Risk Factors
  - Three types—A, B, and C, with A and B being the primary pathogens of epidemic disease; now, also since 2009, H_1N_1
  - Migratory avian hosts may be responsible for spread.
  - Annual spread between Northern and Southern hemispheres; origin of new strains often traced to Asia
  - One or two predominant strains spread annually
  - Attack rate highest in the **young**; colder months in temperate climates
  - Transmission by small particle aerosol
- Clinical presentation
  - Predominantly respiratory illness
  - **Abrupt onset** with coryza, conjunctivitis, pharyngitis, and **dry cough**
  - Prominent systemic signs: **fever (2–4 days), myalgia, malaise, headache**
- Diagnosis
  - Virus can be isolated from nasopharynx early in course.
  - Rapid diagnostic test: **ELISA**
  - Can be confirmed serologically with acute and convalescent titers or PCR
- Treatment
  - Rest and adequate fluid intake
  - Control of fever
  - Antiviral drugs: decrease severity and duration if administered within first 48 hours of symptoms
- Complications—otitis media, pneumonia; secondary bacterial infection, myocarditis

Coxsackievirus

A 2-year-old infant is brought to the clinic with a vesicular rash in his mouth and on his palms and soles. Examination reveals a rash on his buttocks.

- Etiology/Risk Factors—due to infection with coxsackievirus A16
- Clinical diagnosis: Characteristic lesions—seen anywhere but especially on the oral mucosa, hands and feet; hand-foot-mouth disease. Rash on the buttocks is common.
- Coxsackievirus B also responsible for viral myocarditis
- Treatment is supportive care

Figure 22-4. Oral Ulcers of Hand-Foot-and-Mouth Disease

Adenovirus

A 12-year-old patient presents with fever, sore throat, and follicular conjunctivitis.

- Etiology/Risk Factors—DNA virus responsible for URIs in infants and children
- Clinical Presentation—Fever, pharyngitis, conjunctivitis, and diarrhea are common.
  - Less common features include pharyngoconjunctival fever, myocarditis, and intussusception.
- Diagnosis—serology, viral culture, or PCR, but not usually necessary
- Treatment—supportive

Poliovirus

- Etiology/Risk Factors—lives in gastrointestinal track
- Clinical Presentation—can cause URI symptoms
  - Paralytic polio
    - Asymmetric flaccid paralysis
- Prevent with vaccination

Acquired Immunodeficiency Syndrome (AIDS)

An 18-month-old has failure to thrive and developmental delay. The patient also has a history of recurrent ear infections, oral thrush, and chronic diarrhea. The patient on physical examination today is noted to have lymphadenopathy.

- Etiology/Risk Factors
  - Most are children born in developing countries; acquired at birth from an HIV-positive mother
  - Breast feeding in developing countries is an important route of transmission.
  - Pregnant females in United States and other developed countries are routinely screened for HIV infection in prenatal labs, unless the patient refuses.
    - Early treatment and prevention of neonatal infection through anti-retroviral therapy and preventive measures during delivery/postpartum period
- Clinical presentation
  - HIV-infected newborns: rapid onset of symptoms and AIDS in first few months of life
  - Initial symptoms may include
    - Lymphadenopathy
    - Hepatosplenomegaly
    - Failure to thrive
    - Chronic diarrhea
    - Interstitial pneumonia
    - Oral thrush
  - Children > adults: recurrent bacterial infections, chronic parotid swelling, lymphocytic interstitial pneumonitis, early progressive neurological deterioration
- Infections
  - **Recurrent bacterial infections with encapsulated organisms and other gram-positive and gram-negative organisms**
  - **Opportunistic infections**; most common is PCP (onset of fever, tachypnea, dyspnea, and marked hypoxemia)
  - **Mycobacterium avian-intracellulare complex**: disseminated disease in severely compromised
  - Oral candidiasis and other invasive fungal infections
  - Viral infections, especially herpes group
- Other problems
  - CNS disease
  - Cardiomyopathy
  - Enteropathy
  - Wasting syndrome, nephropathy
  - Many cutaneous manifestations
  - All hematologic manifestations, malignancies
- Diagnosis
  - **HIV-DNA by PCR**

  - Maternal HIV IgG antibodies cross the placenta
    - Screen will be positive in **all** newborns up to age 18 months so need 2 of 3 ⊕ PCR for HIV in first month of life.
  - In any **child >18 months of age**: test for infection through **IgG Ab by ELISA and then confirm with Western blot to establish the diagnosis.**
- Treatment—infants born to HIV-infected mothers
  - Mother should be on **perinatal triple anti-retroviral** therapy and then IV ZDV at start of labor until cord is clamped
  - Infant **should be started on ZDV (birth)** until neonatal disease is excluded
    - Also start **PCP prophylaxis (TMP-SMZ) at 1 month** until disease excluded
    - Follow CBC, platelets, CD4 and CD8 counts
    - With symptoms or evidence of immune dysfunction, should be treated with **antiretroviral therapy, regardless of age or viral load**
- Prognosis
  - Best single prognostic indicator is the **plasma viral load.**
  - Mortality higher with **CD4 count <15%**
  - Poor prognosis with persistent fever and/or thrush, serious bacterial infection (meningitis), hepatitis, persistent anemia, and/or thrombocytopenia (30% die by age 3)
  - Children with opportunistic infection, encephalopathy, or wasting syndrome have the worst prognosis (75% die by age <3)

HELMINTHIC DISEASES

Ascariasis

A child is brought to the physician's office because his mother found a "worm" while changing his diaper. He also has a chronic cough with pinkish sputum.

- Etiology/Pathogenesis—*Ascaris lumbricoides;* nematode (roundworm)
  - Most prevalent human helminth in the world
  - High prevalence in poor socioeconomic status countries, with use of human waste as fertilizer, and with geophagia (highest in preschool age)
  - Travels to the small intestines → releases larvae → migrates through venous circulation to lungs **and causes pulmonary ascariasis (Loeffler syndrome)** → through alveoli and bronchi to trachea and are swallowed mature in intestine to adult worms
- Clinical Presentation—most asymptomatic or mild
  - **Most common symptom is pulmonary disease—cough and blood-stained sputum**
  - Followed by obstructive intestinal or biliary tract disease
    - May have colicky abdominal pain or bile-stained emesis
  - CBC reveals **significant blood eosinophilia**
  - Can be identified on fecal smear
- Treatment—**albendazole,** mebendazole, or pyrantel pamoate

Note

Loeffler syndrome = pulmonary ascariasis plus hemoptysis

Hookworm

A 5-year-old girl is brought to the physician due to lack of appetite, abdominal pain, and diarrhea. On physical examination a yellow-green pallor is noted.

- Etiology/Risk Factors—*Ancylostoma duodenale* and *Necator americanus* are nematodes transmitted through warm, moist soil; usually in rural areas where human waste is used as fertilizer.
  - Penetrate **through the skin** (leads to intense pruritis at site of entry) or are ingested
  - Migration through veins to lungs and are swallowed → have teeth to attach to mucosa and can remain up to 5 years, where they mate and produce eggs
- Clinical Presentation—Morbidity from **blood loss**
  - **Iron deficiency anemia**
  - Hypoalbuminemia → edema, anasarca
  - Also, cough, colicky abdominal pain, anorexia, diarrhea
  - Physical growth retardation, cognitive and intellectual deficits
  - Green-yellow skin discoloration known as **chlorosis** and seen in chronic infection
  - Labs reveal significant **blood eosinophilia**.
  - Eggs can be identified on fecal smear.
- Treatment—**mebendazole or albendazole** is drug of choice; pyrantel pamoate an alternative
  - **Ferrous sulfate** if iron deficient

Note

Most parasites, ova, and cysts can be identified on fecal smear.

Enterobiasis

A mother brings her 4-year-old child to the physician with a history of always scratching her anus. The mother is embarrassed by this behavior. The child attends daycare and loves to play in the sandbox.

- Etiology—*Enterobius vermicularis* is the parasite implicated in pinworm infection.
  - Small, white, threadlike nematodes
  - Most common helminth in the United States
  - Primarily in institutional/family settings that include children; highest at age 5–14
  - Eggs are ingested from being carried on fingernails, clothing, bedding, or house dust; after ingestion, adult worms within 1–2 months
  - Inhabits cecum, appendix, ileus, and ascending colon; **female migration at night to deposit eggs on perianal region and perineum**
- Clinical Presentation—most common symptoms include **itching and restless sleep** and *no* eosinophilia
- Diagnosis—history and use of **adhesive cellophane tape** (tape test) **at night when child is asleep**
- Treatment—infected person and entire family receive **single oral dose of mebendazole and repeat in 2 weeks**

Adolescence 23

Learning Objectives

- ❏ Describe the epidemiology including morbidity and mortality of diseases of adolescence
- ❏ Answer questions related to adolescent sexuality and sexually transmitted diseases
- ❏ Describe the causes and treatments of acne

MORTALITY/MORBIDITY, SEXUALITY, AND STDS

A 14-year-old girl who has not yet achieved menarche presents to the physician with her concerned mother. The mother is afraid that her daughter is not "normal." On physical examination, the patient appears well nourished and is in the 50th percentile for height and weight. Her breast examination shows the areolar diameter to be enlarged, but there is no separation of contours. Her pubic hair is increased in amount and is curled but is not coarse in texture. The mother and her daughter wait anxiously for your opinion.

Introduction to Adolescence and Puberty

- Definition—period bridging childhood and adulthood
- Begins at age 11–12 years, ends at 18–21; includes puberty
- Physical and psychological/behavioral changes
  - Completes pubertal and somatic growth
  - Develops socially, cognitively and emotionally
    - Moves from concrete to abstract thinking
    - Establishes independent identity
    - Prepares for career
- All adolescents are at increased risk of mortality and morbidity.
  - Mortality
    - Accidents—especially MVAs
    - Suicide—boys are more successful
    - Homicide—more likely in blacks
    - Cancer—Hodgkin lymphoma, bone, CNS

  - Morbidity
    - Unintended pregnancy
    - STDs
    - Smoking
    - Depression
    - Crime
- There are 3 stages of adolescence.
  - *Early (Age 10-14 years)*
    - Physical changes (puberty) including rapid growth, puberty including development of secondary sexual characteristics
    - Compare themselves to peers (develop body image and self-esteem)
    - Concrete thinkers and feel awkward
  - *Middle (Age 15-16 years)*
    - More independent and have a sense of **identity**
    - Mood swings are common.
    - Abstract thinking
    - Relationships are one-sided and narcissistic.
  - *Late (Age >17 years)*
    - Less self-centered
    - Relationships with individuals rather than groups
    - Contemplate future goals, plans, and careers
    - Idealistic; have a sense of right and wrong

Table 23-1. Tanner Stages of Development

	Female	Both	Male
Stage	Breast	Pubic hair	Genitalia
I	Preadolescent	None	Childhood size
II	Breast bud	Sparse, long, straight	Enlargement of scrotum/testes
III	Areolar diameter enlarges	Darker, curling, increased amount	Penis grows in length; testes continue to enlarge
IV	Secondary mound; separation of contours	Coarse, curly, adult type	Penis grows in length/ breadth; scrotum darkens, testes enlarge
V	Mature female	Adult, extends to thighs	Adult shape/size

- Puberty
  - Variability in onset, duration
  - No variability in order of changes
  - Irreversible
  - Physical reflects hormonal

- Variants of development are normal and most cases only require **reassurance** from the physician to the patient and their family.
  - Breast asymmetry and gynecomastia often seen in males at Tanner stage 3
  - Irregular menses due to anovulatory cycles seen in females starting to menstruate

Sexually Transmitted Diseases

Gonorrhea

A 16-year-old girl presents to her physician because of fever, chills, pain, and swelling in the small joints of her hands, and a maculopapular rash on her upper and lower extremities.

- *Neisseria gonorrhoeae* usually infects mucosal membranes of the genitourinary tract and less commonly the oropharynx, rectum, and conjunctiva.
- Clinical presentation includes urethritis, cervicitis, and dysuria.
- Asymptomatic patients are at higher risk for dissemination, including fever, chills, and arthritis.
- Physical examination
  - Males present with dysuria and purulent penile discharge.
  - Females present with purulent vaginal discharge, cervicitis, abdominal pain, and/or dysuria.
  - Rectal gonorrhea may present with proctitis, rectal bleeding, anal discharge, and/or constipation.
- Tests
  - Culture from discharge
  - Blood cultures if dissemination is suspected
  - Gram stain may show intracellular diplococci.
- Check for other STDs, including **syphilis** and **HIV infection**.
- Treat with single-dose ceftriaxone or single-dose azithromycin; treat partners.
  - Alternatives include doxycycline for 7 days (**not** in children <9 years of age).

Note

Untreated GC/Chlamydia may result in PID and/or infertility (due to tubal scarring).

Chlamydia

A 16-year-old boy presents to the emergency center with a persistent penile discharge. The patient states that 1 week ago he saw his family physician for this same problem. At that time the physician gave him an IM shot of penicillin. However, the patient states that the discharge did not resolve with the penicillin therapy. He would like a second opinion.

- Cause of nongonococcal urethritis
- Intracellular obligate parasites
- Most common STD in developed countries
- Mucoid discharge (mostly females) or lymphogranuloma vernerum

- Tests
  - Nucleic acid amplification (**PCR, ELISA**)
  - Culture of infected tissue
- Treatment
  - Single-dose azithromycin or doxycycline for 7 days
  - Erythromycin if pregnant

Trichomonas

A 15-year-old presents to her physician because she has a yellow, foul-smelling vaginal discharge. On physical examination, she is noted to have a "strawberry cervix."

- *Trichomonas vaginalis* is a protozoa resulting in vaginitis
- Girls with multiple sexual partners (although this is the case in all STDs) are at high risk.
- Frothy, foul-smelling vaginal discharge; males asymptomatic
- "Strawberry cervix" due to hemorrhages in the mucosa
- Wet prep shows motile protozoans in females
- In males, examine urine sediment after prostatic massage
- Treat with metronidazole

Herpes

A 17-year-old, sexually active boy presents to the physician because of painful ulcerations on his glans penis and on the shaft of his penis. He has multiple sexual partners and does not use condoms. Fever and inguinal adenopathy are also present.

- HSV 1: nongenital infections of mouth, eye, and lips most common
- HSV 2: genital, neonatal, oral
  - Cervix primary site in girls; penis in boys
  - Tzanck prep—giant multinuclear cells
  - ELISA testing
- Treat with acyclovir, valacyclovir, famciclovir

Table 23-2. Distinguishing Features of Vaginal Discharge

Feature	Bacterial vaginosis	Trichomoniasis	Candida	Chlamydia/ gonorrhea
Discharge	Profuse, malodorous, "fishy"	Gray-green, frothy	Cottage cheese	Purulent
Wet prep	Clue cells, "whiff test" with KOH	Motile Trichomonads	Hyphae seen with KOH prep	WBCs
pH	>4.5	>5	<4.5	—
STD	No	Yes	No	Yes

ACNE

A mother brings her 15-year-old daughter to the dermatologist because she has developed pimples. The mother says that her daughter's face "breaks out" because she drinks soda pop. The daughter is argumentative about this but admits that she does drink soda pop every day at lunch. The mother would like you to tell her daughter to stop drinking soda pop. On physical examination, the patient has open and closed comedones and pimples on her forehead, nose, and cheeks.

- Pathogenesis
  - Due to the bacteria—*Propionibacterium acnes*, which forms free fatty acids within the sebaceous follicle
  - Abnormal keratinization of follicular epithelium and impaction of keratinized cells in sebaceous follicles
  - Increased sebum production—At puberty, significant increase in sebum from increased **adrenal androgens** (mostly DHEAS with some role of testosterone and estrogen)
  - Inflammation from lysosomal enzymes, which phagocytose bacteria
- Description
  - **Open comedone** = blackhead
  - **Closed comedone** = whitehead (more commonly becomes inflammatory)
  - If comedones rupture, inflammatory lesion and inflammatory contents spill into adjacent dermis; if close to the surface, forms a **papule or pustule**; deeper forms a **nodule**
  - With suppuration → giant-cell reaction to keratin and hair; forms **nodulocystic lesion**
- Treatment must be individualized.
  - Cleansing of skin with mild soap
  - Topical therapy used for treatment of comedones and papulopustular acne
    - **Benzoyl peroxide**
    - **Tretinoin (Retin-A): single most effective agent for comedonal acne**
    - **Adapalene** (Differen gel)

- Topical antibiotics: **erythromycin or clindamycin**
- Allow 4–8 weeks to assess effect of above agents

– Systemic treatment is indicated in those who do not respond to topical agents.
  - Antibiotics: especially **tetracycline,** minocycline, doxycycline, erythromycin, clindamycin
  - **Isotretinoin**: for **moderate to severe nodulocystic disease.** Very **teratogenic**; contraindicated in pregnancy**.** Other major side effect is increased **triglycerides and cholesterol**: rule out liver disease prior to start and check triglycerides 4 weeks after starting treatment
  - **A trial of hormonal therapy can be used in those who are not candidates for isotretinoin.**
– Corticosteroid injections may be used to aid in healing painful nodulocystic lesions.
– Dermabrasion may help decrease visible scarring.

Note

Isotretinoin is very **teratogenic** and contraindicated in pregnancy.

Mental Status Examination 1

Learning Objectives

- ❑ List the steps required to perform a mental status examination

The mental status examination is used to describe the clinician's observations and impressions of the patient during the interview. In conjunction with the history of the patient, it is the best way to make an accurate diagnosis.

General Description

- **Appearance:** grooming, poise, clothes, body type (disheveled, neat, childlike, etc.)
- **Behavior:** quantitative and qualitative aspects of the patient's motor behavior (restless, tics, etc.)
- **Attitude toward the examiner:** (cooperative, frank, and seductive)

Mood and Affect

- **Mood:** emotions perceived by the patient (depressed, anxious, angry, etc.)
- **Affect:** patient's present emotional responsiveness (blunted, flat, labile, etc.)
- **Appropriateness:** in reference to the context of the subject (appropriate or inappropriate)

Speech: physical characteristics of speech (relevant, coherent, fluent, etc.)

Perceptual disturbances: experienced in reference to self or the environment (hallucinations, illusions)

- Hallucinations: false sensory perceptions without a stimulus: **auditory** (psychotic disorders), **visual** (drugs, organic diseases), **tactile** (cocaine intoxication, alcohol withdrawal), **olfactory** (seizures)
- Illusions: sensory misperception with a stimulus

Thought

- **Form of thought:** way in which a person thinks (flight of ideas, loose associations, tangentiality, circumstantiality, etc.)
- **Content of thought:** what the person is actually thinking about (delusions, paranoia, and suicidal ideas)

Sensorium and Cognition

- Alertness and level of consciousness (awake, clouding of consciousness, etc.)
- Orientation: time, place, and person
- Memory: recent, remote, recent past, and immediate retention and recall
- Concentration and attention: serial sevens, ability to spell backwards.
- Capacity to read and write: Ask patient to read a sentence and perform what it says.
- Visuospatial ability: copy a figure
- Abstract thinking: similarities and proverb interpretation
- Fund of information and knowledge: calculating ability, name past presidents

Impulse Control: Estimated from history or behavior during the interview

Judgment and Insight: Ability to act appropriately and self-reflect

Reliability: Physician's impressions of the patient's ability to accurately assess his situation

Interviewing Techniques

Open-Ended Questions: Allow the patient to speak in his own words as much as possible.

"Can you describe your pain?"

Closed-Ended Questions: Ask for specific information without allowing options in answering.

"Are you hearing voices?"

Facilitation: Help the patient continue by providing verbal and nonverbal cues.

"Yes, please continue."

Confrontation: Point something out to the patient.

"You seem very upset today."

Leading: Provide the answer in the question.

"Are the voices telling you to hurt yourself?"

Practice Questions

1. A 20-year-old man presents to your office complaining of auditory hallucinations for approximately 7 months in duration. He reports hearing his father's voice and at times his mother's voice as well. The patient appears distressed by the hallucinations and wants your help. Which of the following would be the most appropriate statement at this time?

   (A) "What do the voices say?"
   (B) "Have you taken medication?"
   (C) "Why do you think you hear voices?"
   (D) "How is your relationship with your parents?"
   (E) "Tell me about the voices."

2. A 30-year-old woman comes to see you after her mother's death approximately 3 weeks ago. Since then she has complained of depressed mood and feelings of helplessness. While in your office, she begins to cry. Which of the following would be the next step in the management of this patient?

   (A) Say, "I will come back when you stop crying."
   (B) Say, "Do you feel guilty about your mother's death?"
   (C) Offer tissue and remain silent
   (D) Say, "Go ahead; it is normal to cry."
   (E) Refer to a psychiatrist for further evaluation

1. **Answer: E.** The ideal interviewing technique is to begin with an open-ended question and conclude with closed-ended questions. Choices A, C, D, and E are all open-ended questions. However, the best open-ended question for this patient and the reason he came to see you is choice E.

2. **Answer: C.** One should always express empathy and then give the patient control. By staying silent and offering a tissue, you are doing just that. Choice E is always incorrect.

Defense Mechanisms 2

Learning Objectives

- ❏ List the types of defense mechanisms and the situations in which they are most likely to occur
- ❏ Describe the most common psychological and intelligence tests, and their purpose

Id: Drives (instincts) present at birth. The 2 most important drives are sex and aggression.

Ego: Defense mechanisms, judgment, relationship to reality, object relationships, developed shortly after birth

Superego: Conscience, empathy, and morality are formed during latency period, right vs. wrong

DEFENSE MECHANISMS

Defense mechanisms are the way and means that the **ego** wards off anxiety and controls instinctive urges and unpleasant emotions. They are unconscious (except suppression), discrete, dynamic and irreversible, and may be adaptive or maladaptive.

Types of Defense Mechanisms

Projection: Attributing your own wishes, thoughts, or feelings onto someone else.

"I'm sure my wife is cheating on me."

Denial: Used to avoid becoming aware of some painful aspect of reality.

"I know I do not have cancer."

Splitting: External objects are divided into all good or all bad.

"The morning staff is perfect, the evening staff is terrible."

Blocking: Temporary block in thinking.

"I have known him for years but can never seem to remember his name."

Regression: Return to an earlier stage of development, most immature.

> "Ever since my divorce, my 5-year-old has begun to wet the bed."

Somatization: Psychic derivatives are converted into bodily symptoms.

> "Just thinking of the exam I get butterflies in my stomach."

Introjection: Features of the external world are taken and made part of the self.

> "The resident physician dresses like the attending whom he admires."

Displacement: An emotion or drive is shifted to another that resembles the original in some aspect.

> "I had to get rid of the dog since my husband kicked it every time we had an argument."

Repression: An idea or feeling is withheld from consciousness; unconscious forgetting.

> "I do not remember having had a dog."

Intellectualization: Excessive use of intellectual processes to avoid affective expression or experience.

> "It is interesting to note the specific skin lesions which seem to arise as a consequence of my end-stage disease."

Isolation: Separation of an idea from the affect that accompanies it.

> "As she arrived at the station to identify the body, she appeared to show no emotion."

Rationalization: Rational explanations are used to justify unacceptable attitudes, beliefs, or behaviors.

> "I did not pass the test because it was harder this year than ever before."

Reaction formation: An unacceptable impulse is transformed into its opposite; results in the formation of character traits.

> "Listen to him tell his family he was not afraid, when I saw him crying."

Undoing: Acting out the reverse of an unacceptable behavior; consists of an act.

> "I need to wash my hands whenever I have these thoughts."

Acting out: Behavioral or emotional outburst.

> "My 10-year-old started getting into trouble right after his mother and I got divorced."

Humor: Permits the expression of feelings and thoughts without personal discomfort.

> "So," said the 300-pound man, "they expected me to place my head between my legs in the event of a plane crash when the best I could manage was placing my chin on my chest."

Sublimation: Impulse gratification has been achieved, but the aim or object has been changed from unacceptable to acceptable; allows instincts to be channeled. Most mature of the defenses.

Jack the Ripper becomes a surgeon.

Suppression: Conscious forgetting; only conscious defense mechanism.

"I would rather talk about my operation after the party is over."

Dissociation: Splitting off of the brain from conscious awareness.

"I hardly remember getting to the hospital after my husband was hit by a car."

Practice Question

A nurse, working in a hospice, has been ignoring an elderly female patient who has terminal cancer. When asked why she has been ignoring the patient, the nurse replied, "She wants to be left alone." Which of the following defense mechanisms best explains her response?

(A) Rationalization
(B) Isolation of affect
(C) Intellectualization
(D) Projection
(E) Denial

Answer: D. The nurse is projecting her wishes by stating that the patient wants to be left alone, when in reality it is *she* who wants to be left alone. Rationalization (A) is making excuses for your behavior. Had that been the answer, she would have made excuses, such as she's too busy, etc.

TESTS

Intelligence Tests

Intelligence Quotient (IQ) measures academic performance. Mean IQ is 100 (SD = 15).

$$IQ = MA/CA \times 100$$

Adults: Wechsler Adult Intelligence Scale Revised (WAIS-R)

Children: Wechsler Intelligence Scale for Children Revised (WISC-R), Stanford-Binet

Personality Tests

Objective tests use simple stimuli, do not need much clinical experience: Minnesota Multiphasic Personality Inventory (MMPI).

Projective tests use ambiguous stimuli, need clinical experience, not diagnostic: Rorschach test (inkblot), Thematic Apperception Test (TAT), sentence completion tests, family drawings.

Childhood Disorders 3

Learning Objectives

- ❏ Describe the degrees of intellectual disability and expected level of function
- ❏ List the different types of learning disorders
- ❏ Describe the presentation of autism spectrum disorder
- ❏ Describe the diagnosis and treatment of childhood disorders likely to present to a psychiatrist, including attention deficit hyperactivity disorder, childhood conduct disorder, oppositional defiant disorder, childhood anxiety, and Tourette syndrome
- ❏ List the approaches to treating childhood enuresis

INTELLECTUAL DISABILITY (ID)

Definition. Formerly called mental retardation. Significantly subaverage intellectual function (IQ <70), as measured by a variety of IQ tests. Must be accompanied by concurrent impairment in adapting to demands of school, work, social, and other environments. Onset is age <18.

Risk Factors/Etiology. Associated genetic and chromosomal abnormalities include inborn errors of metabolism (e.g., lipidoses, aminoacidurias, glycogen storage diseases) and chromosomal abnormalities (e.g., cri du chat, Down, fragile X syndromes). Associated intrauterine infections include rubella, cytomegalovirus, and other viruses. Intrauterine exposure to toxins and other insults such as alcohol, hypoxia, or malnutrition may be causal. Postnatal causes include exposure to toxins and infection, poor prenatal care, postnatal exposure to heavy metals, physical trauma, and social deprivation.

Presenting Symptoms

- **Prevalence:** 1% of the population. Occurs at a 1.2:1 male-to-female ratio.
- **Mild ID (IQ 50–69):** Attain academic skills to approximately the sixth-grade level, often live independently in the community or with minimal supervision, may have problems with impulse control and self-esteem, and may have associated conduct disorder, substance-related disorder, or attention deficit hyperactivity disorder.
- **Moderate ID (IQ 35–50):** Attain academic skills to second-grade level, may be able to manage activities of daily living, work in sheltered workshops, live in residential community settings; have significant problems conforming to social norms (those with Down's syndrome are at high risk for early development of Alzheimer's)

- **Severe (IQ 20–35) and profound ID (IQ <20):** Have little or no speech and very limited abilities to manage self-care; require highly supervised care setting.

Physical Examination. Evidence of underlying disorder or injury

Diagnostic Tests. Amniocentesis: May reveal chromosomal abnormalities associated with ID in high-risk pregnancies (mother age >35.)

Treatment. Primary prevention includes genetic counseling, good prenatal care, and safe environments. Treatment of associated general medical conditions may improve overall level of cognitive and adaptive function. Special education techniques may improve ultimate level of function. Behavioral guidance and attention to promoting self-esteem may improve long-term emotional adjustment.

Differential Diagnosis. Includes learning and communication disorders, sensory impairment, autism spectrum disorder, borderline intellectual functioning (IQ 70–100), and environmental deprivation.

LEARNING DISORDERS

Definition. Characterized by learning achievement in specific areas that is substantially below expectations, given the patient's age, intelligence, sensory abilities, and educational experience. Types of learning disorder are reading disorder (most common), mathematics disorder, and disorder of written expression.

Risk Factors/Etiology. Some cases are due to the effects of coexisting general medical conditions such as cerebral palsy on central nervous system (CNS) function. Some general medical conditions and substance-induced conditions are associated with learning disorders, including lead poisoning and fetal alcohol syndrome. Many cases have no obvious etiology.

Presenting Symptoms

- Prevalence: 5% of school-age children
- Onset: usually during elementary school
- Perceptual–motor problems
- Conduct disorder, oppositional defiant disorder, and ADHD
- Poor self-esteem and social immaturity
- School failure and behavioral disturbances

Deficits sometimes persist into adulthood and interfere with occupational function.

Diagnostic Tests. IQ testing and academic achievement tests are the major diagnostic tools.

Treatment. Special education to ensure general learning and maximize skills in the deficient areas is the mainstay of treatment. Counseling of patients and families to improve self-esteem, social behavior, and family functioning is helpful.

Differential Diagnosis. Major rule-outs are environmental deprivation, hearing or vision impairment, and ID.

AUTISM SPECTRUM DISORDERS (ASD)

Definition: A group of disorders characterized by problems with social interaction, behavior, and language.

Risk Factors/Etiology. The cause is CNS damage due to known or unknown factors. Sites of CNS damage specifically associated with ASD are unknown. General medical conditions associated with ASD include encephalitis, maternal rubella, PKU, tuberous sclerosis, fragile X syndrome, and perinatal anoxia. There is no obvious etiology in many cases.

Presenting Symptoms

- **Prevalence:** 0.08% of the general population. Occurs at a 5:1 male-to-female ratio.
- **Onset:** Before 3 years of age
- **Social symptoms:** Lack of peer relationships and a failure to use nonverbal social cues
- **Communication symptoms:** Absent or bizarre use of speech
- **Behavioral symptoms:** Odd preoccupation with repetitive activities, bizarre mannerisms, and rigid adherence to purposeless ritual
- ID is present in 75% of patients with ASD.
- **Physical findings:** Higher incidence of abnormal electroencephalograms (EEGs), seizures, and abnormal brain morphology
- **Course:** Approximately 30% of individuals with ASD become semi-independent in adulthood, but almost all have severe residual disabilities.
- Predictors of a poor outcome are associated ID and failure to develop useful speech.
- Seizures develop by adulthood in 25% of autistic individuals.

Physical Examination. Self-injuries caused by head banging or biting sometimes present.

Treatment. The major treatment is family counseling, special education, and newer antipsychotic medications to control episodes of severe agitation or self-destructive behavior.

Differential Diagnosis. Major rule-outs are ID, hearing impairment, environmental deprivation, selective mutism, and Rett syndrome.

ATTENTION DEFICIT HYPERACTIVITY DISORDER (ADHD)

Definition. ADHD is characterized by inattention, hyperactivity, and impulsivity that interfere with social or academic function. Symptoms last for at least 6 months, and onset occurs before age 12. Symptoms are present in multiple settings. Subtypes are based on the predominance of symptoms of inattention or of hyperactivity and impulsivity.

Risk Factors/Etiology. No specific etiologies have been identified. Other CNS pathology and disadvantaged family and school situations are sometimes present.

Prevalence. 5% of school-age children and 2.5% of adults. Male-to-female ratio is 2:1 in children and 1.6:1 in adults.

Family history. ADHD, mood and anxiety disorders, substance-related disorders, and antisocial personality disorder.

Onset. Usually first recognized when a child enters school, and symptoms usually persist throughout childhood. ADHD, particularly the attention deficit, persists into adulthood in most but not all affected individuals. Hyperactivity tends to diminish in adolescence and adulthood.

Symptoms. Short attention span, constant fidgeting, inability to sit through cartoons or meals, inability to wait in lines, failure to stay quiet or sit still in class, disobedience, shunning by peers, fighting, poor academic performance, carelessness, and poor relationships with siblings.

Common Associated Problems. Low self-esteem, mood lability, conduct disorder, learning disorders, clumsiness, communication disorders, drug abuse, school failure, and physical trauma as a result of impulsivity.

Physical Examination. Perceptual: motor problems and poor coordination may be present.

Diagnostic Tests. IQ tests and various structured symptom-rating scales for use by teachers and parents are often used.

Differential Diagnosis. Major rule-outs are age-appropriate behavior, response to environmental problems, ID, ASD, and mood disorders.

Treatment. Target symptoms are defined before initiating treatment. Psychological, social, and educational interventions include adding structure and stability to home and school environments. Specialized educational techniques include the use of multiple sensory modalities for teaching, instructions that are short and frequently repeated, immediate reinforcement for learning, and minimization of classroom distractions. Pharmacotherapy of choice is stimulant medications, such as methylphenidate and dextroamphetamine. Non-stimulants such as atomoxetine may also be used. They are usually effective in decreasing hyperactivity, inattention, and impulsivity. Other medications include antidepressants and clonidine.

CONDUCT DISORDER

Definition. Persistent violations over at least 6 months in 4 areas: aggression, property destruction, deceitfulness or theft, and rules.

Risk Factors/Etiology. Genetic influences play a role by affecting temperament. Stressful family and school environments have also been implicated.

Prevalence. 4% of school-age children. Seen more in males.

Family History. Antisocial personality disorder, conduct disorder, ADHD, mood disorders, and substance-related disorders.

Onset. Most often during late childhood or early adolescence. In most individuals, symptoms gradually remit.

Key Symptoms. Bullying, fighting, cruelty to people or animals, and rape, vandalism, fire-setting, theft, robbery, running away, school truancy

Complications. Substance-related disorders and school failures

Outcome. Often, antisocial personality disorder, somatic symptom disorders, depressive disorders, and substance-related disorders

Differential Diagnosis. Major rule-outs are environmental problems, ADHD, and oppositional defiant disorder.

Treatment. Healthy group identity and role models are provided by structured sports programs and other programs (e.g., Big Brothers). Structured living settings that place value on group identification and cooperation are useful. Punishment and incarceration are not often effective.

OPPOSITIONAL DEFIANT DISORDER

Definition. Persistent pattern lasting at least 6 months of negativistic, hostile, and defiant behaviors toward adults, including arguments, temper outbursts, vindictiveness, and deliberate annoyance.

Risk Factors/Etiology. High reactivity and increased motor behavior are innate features of temperament that may predispose to this disorder. Inconsistent or poor parenting may also contribute.

Prevalence. 3% of school-age children. Male-to-female ratio is 1:1 after puberty but boys > girls before puberty.

Onset. Usually in latency or early adolescence and may start gradually. Onset later in girls.

Associated Problems. Family conflict and school failure, low self-esteem and mood lability, early onset of substance abuse, ADHD and learning disorders.

Course. Family conflict often escalates after the onset of symptoms.

Outcome. Conduct disorder may follow.

Treatment. Parents should be advised to spend time interacting with a child, to reward desired behavior and not simply punish undesired behavior, and to be consistent in statements and deeds. Alternative caregivers may be indicated in some cases.

Differential Diagnosis. Conduct disorder

CHILDHOOD ENURESIS

Definition. The disorder is characterized by repeated voiding of urine into the patient's clothes or bed in a child at least 5 years of age. It is diagnosed only if the behavior is not due to a medical condition.

Risk Factors/Etiology. Current psychologic stress, family history of enuresis, and urinary tract infections.

Prevalence. 3–5% of children aged 10. Slightly more common in boys. May occur only at night, only during daytime, or both. Often causes emotional turmoil in the child or parents.

Physical Examination. Assessment for urinary tract infection or abnormalities should occur.

Treatment. Appropriate toilet training and avoiding large amounts of fluids before bed are important, as are decreasing emotional stressors. A bell-pad apparatus is the best treatment. Pharmacotherapy includes imipramine and desmopressin (DDAVP) for short-term treatment.

CHILDHOOD ANXIETY

Definition. Normal childhood anxiety:

- **Stranger anxiety:** Fear of strangers in unfamiliar contexts that is present from age 6 months to approximately 2 years.
- **Separation anxiety:** Fear of separation from the caregiver that is present from approximately 1 to 3 years of age.

Risk Factors/Etiology. Excessively close-knit families, excessive expectations of children, and innate temperamental anxiety

Prevalence. 5% of school-age children

Key Symptoms. Prominent physical complaints such as stomachaches and malaise, unrealistic fears (e.g., monsters) and nightmares, phobias such as school phobia and fear of animals or the dark, difficulty sleeping, and self-mutilation such as scratching, nail-biting, and hair-pulling.

Physical Examination. Evidence of nail biting and scratching is sometimes present.

Treatment. Family therapy helps parents recognize and lessen childhood anxiety. Cognitive behavioral therapy is useful to decrease anxiety in older children.

Complications. Social avoidance, low self-esteem, and inhibited social development may occur.

TOURETTE DISORDER

Definition. Childhood onset of multiple motor and vocal tics

Risk Factors/Etiology. Autosomal dominant transmission may occur in some cases. There are associations between ADHD (50%) and obsessive compulsive disorder (OCD) (40%). Abnormalities in the dopaminergic and adrenergic system have been implicated.

Prevalence. 3 per 1,000. More common in males.

Onset. Average age 7 years with motor tics and vocal tics typically appearing at age 11 years

Course. Vocal and motor tics wax and wane over time.

- *Motor tics:* May present as twitching of face, trunk, or extremities or may involve complex behaviors such as pacing, spinning, or touching.
- *Vocal tics:* Usually grunts; coprolalia (cursing) occurs in about 10% of cases.

Associated Problems. ADHD and obsessive-compulsive disorder are each present in about one-third of cases. ADHD occurs before tics whereas OCD symptoms occur after the tics.

Course. Lifelong, with remissions and exacerbations

Treatment. Antipsychotic drugs, including pimozide, haloperidol, olanzapine and risperidone are treatments of choice. Clonidine and clonazepam are sometimes useful.

Practice Question

A 13-year-old boy is referred by his junior high school principal for evaluation of his short attention span and inability to sit quietly in class or on the school bus. He has a quick temper at school and at home, and his peers tease him about his temper. Which of the following is most likely to be an associated finding in this case?

(A) Affectual blunting
(B) Autistic mannerisms
(C) Conduct disturbances
(D) Grandiosity and inflated self-esteem
(E) Intellectual disability

Answer: C. The symptoms are suggestive of ADHD. Conduct disturbances are a common associated finding in individuals with ADHD; drug abuse is also more common. Affect tends to be more labile, and low self-esteem is common. Although ID is seen more often in children with ADHD than in the general population, it is not a common associated finding, and this boy is at the expected grade level for his age. ASD is rarely diagnosed in individuals with ADHD.

Depressive, Bipolar, and Related Disorders

4

Learning Objectives

- ❏ List the diagnostic criteria and treatment approaches for major mood disorders, including major depressive, bipolar, cyclothymic, and persistent depressive disorders
- ❏ Describe the presentation of mood disorders related to triggering phenomenon, including seasonal pattern, grief, peri/postpartum, and death/dying

MAJOR DEPRESSIVE DISORDER (MAJOR DEPRESSION)

A 70-year-old woman was recently admitted after her son informed the doctor that she had been doing very poorly over the past few months. The patient reports a 30-pound weight loss, decreased concentration, feelings of helplessness and hopelessness, decreased energy, depressed mood, and decreased sleep.

Definition. Mood disorder that presents with at least a 2-week course of symptoms that is a change from the patient's previous level of functioning. Must have depressed mood or anhedonia (inability to enjoy oneself).

Risk Factors/Epidemiology. Major depression is seen more frequently in women due to several factors, such as hormonal differences, great stress, or simply a bias in the diagnosis. The typical age of onset is age 40. There is also a higher incidence in those who have no close interpersonal relationships or are divorced or separated. Many studies have reported abnormalities in serotonin, norepinephrine, and dopamine. Other risk factors include family history, exposure to stressors, and behavioral reasons, such as learned helplessness.

Presenting Symptoms

- Depressed mood most of the day
- Anhedonia during most of the day
- Significant weight loss (>5% of body weight)
- Insomnia
- Psychomotor agitation or retardation
- Fatigue or loss of energy nearly every day
- Feelings of worthlessness or guilt
- Diminished ability to concentrate
- Recurrent thoughts about death

Physical Examination. Usually within normal limits; however, may find evidence of psychomotor retardation, such as stooped posture, slowing of movements, slowed speech, etc. May also find evidence of cognitive impairment, such as decreased concentration and forgetfulness.

May also include:

- **Psychotic features:** Worse prognosis
- **Atypical features:** Increased weight, appetite, and sleep

Treatment. Must first secure the safety of the patient, given that suicide is such a high risk. Pharmacotherapy includes antidepressant medications such as SSRIs. Tricyclic antidepressants (TCAs), or monoamine oxidase inhibitors (MAOIs). Electroconvulsive therapy (ECT) may be indicated if patient is suicidal or intolerant to medications. Individual psychotherapy is indicated to help the patient deal with conflicts, sense of loss, etc. Another form of therapy is cognitive therapy, which will change the patient's distorted thoughts about self, future, world, etc.

Differential Diagnosis. Medical disorders: Hypothyroidism, Parkinson's disease, dementia, medications such as hypertensives, pseudodementia, tumors, cerebrovascular accidents. **Mental disorders:** Other mood disorders, substance disorders, and grief.

BIPOLAR I DISORDER

A 19-year-old college student is taken to the school counselor after he fails several classes. The patient is enrolled in numerous classes, most of which have conflicting times. His grades are poor, yet he seems undisturbed by this. He is also enrolled in numerous organizations, such as the chess club, drama club, student government, sports, and at least 2 fraternities. His speech is pressured and he has psychomotor agitation.

Definition. A mood disturbance in which the patient typically experiences symptoms of elevated mood, for at least 1 week that cause significant distress or impairment in his/her level of functioning.

Risk Factors/Epidemiology. Bipolar disorder affects men and women equally and has a mean age of onset of about 18 years. More prevalent among high socioeconomic status. Considered to be the illness with the greatest genetic linkage. Coexisting disorders may include anxiety, alcohol dependence, and substance-related disorders.

Presenting Symptoms

- Abnormal or persistently elevated mood lasting at least 1 week
- Increased self-esteem or grandiosity
- Distractibility
- Excessive involvement in activities
- More talkative than usual
- Psychomotor agitation
- Flight of ideas
- Increased sexual activity
- Increase in goal-directed activity

Physical Examination. Usually within normal limits; however, may find evidence of psychomotor agitation and pressured speech.

Treatment. Must assess patient safety to determine the need for hospitalization. Pharmacotherapy will include mood stabilizers, benzodiazepines, and antipsychotics.

Differential Diagnosis

- **Mental disorders:** Schizophrenia, personality disorders, and bipolar II disorder (includes major depressive episodes and hypomanic but not manic episodes)
- **Medical disorders:** CNS infections, tumors, hyperthyroidism, and medications

PERSISTENT DEPRESSIVE DISORDER (DYSTHYMIA)

Mr. Smith complains of poor appetite, low energy, poor concentration, and difficulty in making decisions, which affects his ability to complete his assignments at work. These symptoms have been present for more than 2 years.

Definition. A chronic disorder characterized by a depressed mood that lasts most of the day and is present on most days for at least 2 years.

Risk Factors/Epidemiology. Patients typically have other psychiatric disorders, such as anxiety, substance abuse, and/or borderline personality disorders.

Treatment. Hospitalization is usually not indicated. Patients may benefit from psychotherapy to help overcome long-term sense of despair and resolve conflicts from childhood. If medications are indicated, SSRIs, TCAs, or MAOIs are usually preferred.

Differential Diagnosis. Differential diagnosis is essentially the same as for major depression.

CYCLOTHYMIC DISORDER

Mrs. McDonald has experienced a 12-year history of periods of feeling great followed by periods of feeling lousy. During her feeling-great periods, she experiences increased sexual drive, euphoric mood, and increased irritability. During her feeling-lousy periods, she experiences insomnia, fatigue, and low self-esteem.

Definition. A chronic disorder characterized by many periods of depressed mood and many periods of hypomanic mood for at least 2 years.

Risk Factors/Epidemiology. Many patients have interpersonal and marital difficulties. It frequently coexists with borderline personality disorder and is seen more frequently in women. Many patients have family history of bipolar disorder. Alcohol and substance abuse are common.

Treatment. Antimanic drugs such as lithium, carbamazepine, and valproic acid are typically the drugs of choice. Psychotherapy will help patients gain insight into their illness and how to cope with it.

Differential Diagnosis. Medical: Seizures, substances, and medications. **Mental:** Other mood disorders, personality disorders. medications.

MAJOR DEPRESSIVE DISORDER WITH SEASONAL PATTERN

A young woman from Minnesota complains of depressed mood and sleep disturbances every winter. Her symptoms resolve in the spring and summer.

Definition. A disorder characterized by depressive symptoms found during winter months and absent during summer months. Believed to be caused by abnormal melatonin metabolism (decreased MSH).

Treatment. Phototherapy

GRIEF, POSTPARTUM DEPRESSION, DEATH AND DYING

Grief

Table I-4-1. Grief Versus Depression

Grief or Bereavement	Depression
Sadness, tearfulness, decreased sleep, decreased appetite, decreased interest in the world	Sadness, tearfulness, decreased sleep, decreased appetite, decreased interest in the world
Symptoms wax and wane	Symptoms pervasive and unremitting
Shame and guilt less common	Shame and guilt are common
Threaten suicide less often	Threaten suicide more often
Symptoms can last up to one year	Symptoms continue for more than one year
Usually return to baseline level of functioning within 2 months	Patients do not return to baseline level of functioning
Treatment includes supportive psychotherapy	Treatment includes antidepressant medication

Peripartum Mood Disorders

Table I-4-2. Postpartum Reactions

Onset	Disorder	Symptoms	Mother's Feelings Toward Baby	Treatment
Onset of mood symptoms within 2 wks after delivery	Postpartum blues or baby blues	Sadness, mood lability, tearfulness	No negative feelings	Supportive, usually self-limited
Onset of mood symptoms occurs during pregnancy or in the 4 wks following delivery	Depressive disorder with peripartum onset	Depressed mood, weight changes, sleep disturbances, and excessive anxiety	May have negative feelings toward baby	Antidepressant medications
Onset of mood and/or psychotic symptoms occurs during pregnancy or in the 4 wks following delivery	Bipolar disorder with peripartum onset Brief psychotic disorder with peripartum onset	Symptoms of depression, mania along with delusions, hallucinations and thoughts of harm	May have thoughts of harming baby	Antipsychotic medication, lithium, and possible antidepressant

Death and Dying

Based on the stages identified by Elisabeth Kubler-Ross. She believed dying patients did not follow a regular series of responses that could be easily identified. She believed most individuals experience stages that are common reactions to death. These stages do not have to occur in order.

Stage 1: Shock and denial
Stage 2: Anger
Stage 3: Bargaining
Stage 4: Depression
Stage 5: Acceptance

Practice Questions

1. A 50-year-old woman is taken to the hospital after neighbors find her wandering the streets mumbling to herself and gesturing. When approached, she begins to cry and expresses thoughts about hurting herself. Examination reveals scratch marks on both her forearms and questionable lacerations on her throat. When questioned, she reports feeling depressed since her husband died 5 months ago. She reports a decrease in concentration and feelings of helplessness, hopelessness, and anhedonia, which resulted in her quitting her job and staying at home. She now has begun to hear her husband's voice asking her to "join" him. Which of the following would be the next step in management?

   (A) Begin a trial of antidepressant medications
   (B) Refer to psychiatry
   (C) Refer for electroconvulsive therapy
   (D) Assess for thoughts about suicide
   (E) Refer to the outpatient department for follow-up

2. Assuming you decide to begin treatment, which of the following is most indicated as initial treatment?

   (A) Individual psychotherapy
   (B) Behavioral therapy
   (C) Fluoxetine
   (D) Risperidone
   (E) Phenelzine

3. A 32-year-old woman was recently diagnosed with advanced breast cancer. Which of the following reactions would you expect to see first?

   (A) Shock and denial
   (B) Anger
   (C) Bargaining
   (D) Depression
   (E) Any of the above

1. **Answer: D.** The most important thing to assess in patients suffering from depression is their suicidal status, which of course determines her prognosis and whether or not you will admit her to the hospital for treatment. You will probably begin a course of pharm-acotherapy, but you need to assess suicidal status first. "Refer to psychiatry" will always be wrong on a test, given that you need to know what to do in these situations. Electroconvulsive therapy might be indicated in her condition but is usually not the first line of treatment.

2. **Answer: D.** Patients with both mood and psychotic symptoms respond to both antidepressants as well as to antipsychotic medication. However, you must treat the worst symptom first. In this case, the antipsychotic would be most indicated to reduce her psychotic symptoms. Choice D is an atypical antipsychotic medication with minimal side effects.

3. **Answer: E.** Because the stages can occur in any order, any one of the above is the answer.

Schizophrenia and Other Psychotic Disorders

5

Learning Objectives

- ❑ List the diagnostic criteria and treatment approaches to schizophrenia and other psychotic disorders

SCHIZOPHRENIA

Definition. Schizophrenia is a thought disorder that impairs judgment, behavior, and ability to interpret reality. Symptoms must be present for at least 6 months to be able to make a diagnosis.

Risk Factors/Etiology. Men have an earlier onset, usually at age 15–25. Many theories have evolved regarding the cause of schizophrenia.

- Schizophrenia has been associated with high levels of dopamine and abnormalities in serotonin.
- Because there is an increase in the number of schizophrenics born in the winter and early spring, many believe it may be viral in origin.

Schizophrenia is more prevalent in low socioeconomic status groups, either as a result of downward drift or social causation.

Prevalence

General population..... 1%	One schizophrenic parent.....12%
Monozygotic twin..... 47%	Two schizophrenic parents 40%
Dizygotic twin..... 12%	First-degree relative.....12%
	Second-degree relative 5–6%

Physical and Psychiatric Presenting Symptoms

- Hallucinations (mostly auditory)
- Delusions (mostly bizarre)
- Disorganized speech or behavior
- Catatonic behavior
- Negative symptoms
- Social and/or occupational dysfunction
- Physical exam usually unremarkable, but may find saccadic eye movements, hypervigilance, etc.

Brain Imaging Findings

- **CT:** lateral and third **ventricular enlargement**, **reduction in cortical volume** (associated with the presence of negative symptoms, neuropsychiatric impairment, increased neurologic signs, and poor premorbid adjustment)
- **MRI:** increased cerebral ventricles
- **PET:** hypoactivity of the frontal lobes and hyperactivity of the basal ganglia relative to the cerebral cortex

Psychologic Tests

- *IQ tests:* Will score lower on all IQ tests, maybe due to low intelligence at the onset or to deterioration as a result of the disease
- **Neuropsychologic:** Tests usually are consistent with bilateral frontal and temporal lobe dysfunction, including deficits in attention, retention time, and problem-solving ability.
- **Personality:** May give abnormal findings, such as bizarre ideations, etc.

Treatment. Hospitalization is usually recommended for either stabilization or safety of the patient. If you decide to use medications, antipsychotic medications are most indicated to help control both positive and negative symptoms. If no response, consider using clozapine after other medications have failed. The suggested psychotherapy will be supportive psychotherapy with the primary aim of having the patient understand that the therapist is trustworthy and has an understanding of the patient, no matter how bizarre.

Differential Diagnosis

- **Substance-induced:** Psychostimulants, hallucinogens, alcohol hallucinosis, barbiturate withdrawal, etc. Consider urine drug screen to rule out.
- **Epilepsy:** Temporal lobe epilepsy
- **Other psychotic disorders:** Schizoaffective, schizophreniform, brief reactive psychosis, delusional disorder
- **Malingering and factitious disorder:** Must assess whether the patient is in control of the symptoms and whether there is an obvious gain
- **Mood disorders:** Look at duration of mood symptoms; these tend to be brief in schizophrenia.
- **Medical:** HIV, steroids, tumors, CVAs, etc. Need medical work-up to rule out.
- **Personality disorders:** Schizotypal, schizoid, and borderline personality disorders have the most similar symptoms. Must look at duration of symptoms as well as patient's level of functioning.

OTHER PSYCHOTIC DISORDERS

Brief Psychotic Disorder

A 35-year-old female Chinese immigrant is brought in by neighbors after she was found wandering in the streets yelling out someone's name. She appears disheveled and grossly disorganized. You learn that she arrived in the U.S. several days ago and upon her arrival, witnessed the death of her 3-year-old son. While in the waiting room, she appears to be responding to internal stimuli.

Presenting Symptoms

- Hallucinations
- Delusions
- Disorganized speech
- Grossly disorganized or catatonic behavior
- Symptoms more than one day but less than 30 days

Risk Factors. Seen most frequently in the low socioeconomic status as well as in those who have preexisting personality disorders or the presence of psychological stressors.

Treatment. Hospitalization is warranted if the patient is acutely psychotic, to assure the safety of her/himself or of others. Pharmacotherapy will include both antipsychotics and benzodiazepines. The benzodiazepines may be used for short-term treatment of psychotic symptoms.

Schizophreniform Disorder

> Mrs. Jones is evaluated at a nearby clinic after she was noticed to be acting inappropriately at work. According to her coworkers, she began acting strangely 3 months ago. At that time she began wearing a hard hat to work and when asked why, replied, "I will not let you read my mind." She also believed that others were talking about her and routinely asked them to stop. On several occasions, she had to be escorted out of the room because she started to argue with others whom she believed were controlling her mind.

Presenting Symptoms

- Hallucinations
- Delusions
- Disorganized speech
- Grossly disorganized or catatonic behavior
- Negative symptoms
- Social and/or occupational dysfunction
- Symptoms are present more than one month but less than 6 months
- Most of the patients return to their baseline level of functioning

Risk Factors. Suicide is a risk factor given that the patient is likely to have a depressive episode after the psychotic symptoms resolve.

Treatment. Must assess whether the patient needs hospitalization, to assure safety of patient and/or others.

Antipsychotic medication is indicated for a 3–6-month course. Individual psychotherapy may be indicated to help the patient assimilate the psychotic experience into his/her life.

Schizoaffective Disorder

A 25-year-old woman is found walking nude in the shopping mall. When asked why, she replies, "I am making it easy for others to have sex with me since I know they all want me." She states she heard a voice telling her she was irresistible and everyone wanted her. When she speaks, she cannot focus on one topic at a time. Her mood is euphoric and her affect labile. She recounts an episode last year, where, although she did not have an elevated or depressed mood, she heard voices she could not describe and believed others were following her. These symptoms lasted for 6+ months and caused her to lose her job.

Presenting Symptoms

- Uninterrupted period of symptoms meeting criteria for major depressive episode, manic episode, or mixed episode
- Symptoms for schizophrenia
- Delusions or hallucinations for at least 2 weeks in the absence of mood symptoms

Prognosis. Better prognosis than patients with schizophrenia. Worse prognosis than patients with affective disorders.

Treatment. First determine if hospitalization is necessary. Use antidepressant medications and/or anticonvulsants to control the mood symptoms. If not effective, consider antipsychotics to help control the ongoing symptoms.

Delusional Disorder

Mr. Smith has been married for 10 years, and during most of those years he believed his wife was trying to poison him to get his money. He frequently complains of stomach pain, which he believes is due to the poison in the food. His thoughts are logical and coherent. He denies any hallucinations. His wife, an independently wealthy woman, does not understand her husband's logic because she has more money than he does.

Presenting Symptoms

- Nonbizarre delusions for at least 1 month
- No impairment in level of functioning
- The patients are usually reliable unless it is in relationship to their delusions.
- Types include erotomanic, jealous, grandiose, somatic, mixed, unspecified.

Risk Factors. Mean age of onset is about age 40. Seen more commonly in women, and most are married and employed. Has been associated with low socioeconomic status as well as recent immigration. Can usually see conditions in limbic system or basal ganglia, if medical causes are determined to be the cause of the delusions.

Treatment. Outpatient treatment is usually preferred, but the patient may need hospitalization while you rule out medical causes. Pharmacotherapy consists of antipsychotic medications, but studies indicate that many patients do not respond to treatment. Individual psychotherapy is recommended, having the patient trust the physician to point out how the delusions interfere with normal life.

Practice Questions

1. A 23-year-old woman was seen today after she complained that her neighbors were talking about her. According to the neighbors, her behavior started 3 weeks ago after she was involved in a car accident. She was not injured in the accident. Since then, she has been following the neighbors for several days and harassing them at work. She believes that the neighbors are putting poison in her food and want to kill her. When asked why, she is unable to give a clear explanation but insists that what she is saying is true. She states that the voice in her head told her it is true and that you should stop asking questions. While in the waiting room, you observe her to be dressed bizarrely and laughing inappropriately. Which of the following is most indicated in management?

   (A) Haloperidol
   (B) Clozapine
   (C) Lorazepam
   (D) Risperidone
   (E) Fluphenazine decanoate

2. If her symptoms do not improve within the next week, which of the following is she at greatest risk of developing?

   (A) Schizophrenia, paranoid type
   (B) Schizoaffective disorder
   (C) Schizophreniform disorder
   (D) Schizotypal personality disorder
   (E) Delusional disorder

1. **Answer: D.** The patient clearly has psychotic symptoms; therefore, you would want to give her medication with the fewest side effects. Choices A and E are typical antipsychotics with many side effects. Choices B and D are atypical antipsychotics; however, clozapine is not used first line in the treatment of psychotic symptoms. Lorazepam is not an antipsychotic medication. However, it can be used in psychotic patients to reduce agitation.

2. **Answer: C.** Because her symptoms have occurred for only 3 weeks, this patient has a diagnosis of brief psychotic disorder. But should the symptoms persist for >1 month, her diagnosis would be schizophreniform disorder. Schizophrenia is given when the symptoms are present for >6 months.

Anxiety Disorders 6

Learning Objectives

- ❑ Describe the presentation, diagnostic criteria, and treatment approaches to anxiety disorders, including panic, phobic, obsessive-compulsive, acute stress, post-traumatic stress, and generalized anxiety disorders

ANXIETY

Anxiety is a syndrome with psychologic and physiologic components. Psychologic components include worry that is difficult to control, hypervigilance and restlessness, difficulty concentrating, and sleep disturbance. Physiologic components include autonomic hyperactivity and motor tension.

Psychodynamic theory posits that anxiety occurs when instinctual drives are thwarted. **Behavioral theory** states that anxiety is a conditioned response to environmental stimuli originally paired with a feared situation. **Biologic theories** implicate various neurotransmitters (especially gamma-aminobutyric acid [GABA], norepinephrine, and serotonin) and various CNS structures (especially reticular activating system and limbic system).

PANIC DISORDER

Definition. Recurrent, unexpected panic attacks are present. Panic attacks are attacks of intense anxiety that often include marked physical symptoms, such as tachycardia, hyperventilation, dizziness, and sweating. Attacks followed by 1 month of fear of having no attacks, changing behavior, etc.

Risk Factors/Etiology. History associated with panic disorder includes separations during childhood and interpersonal loss in adulthood. A majority of individuals with panic disorder, unlike other individuals, have panic symptoms in response to "panicogens" (lactate CO_2, yohimbine, caffeine, and other substances). Studies of twins suggest a genetic component.

Presenting Symptoms

- **Prevalence:** 2% of the population. Occurs at a 1:2 male-to-female ratio.
- **Onset:** Often during the third decade
- **Course:** Severity of symptoms may wax and wane, and may be associated with intercurrent stressors.
- **Key symptoms:** Attacks usually last a few minutes.
- **Associated problems:** Depression, generalized anxiety, and substance abuse

- **Agoraphobia:** Fear or avoidance of places from which escape would be difficult in the event of panic symptoms (public places, being outside alone, public transportation, crowds). More common in women. Often leads to severe restrictions on the individual's travel and daily routine.

Treatment. Pharmacologic interventions include SSRIs, alprazolam, clonazepam, imipramine, and MAOIs (e.g., phenelzine). Psychotherapeutic interventions include relaxation training for panic attacks and systematic desensitization for agoraphobic symptoms.

PHOBIC DISORDERS

Definition. Irrational fear and avoidance of objects and situations

Types of Phobias

- **Specific phobia:** Fear or avoidance of objects or situations other than agoraphobia or social phobia. Commonly involves animals (e.g., carnivores, spiders), natural environments (e.g., storms), injury (e.g., injections, blood), and situations (e.g., heights, darkness).
- **Social anxiety disorder:** Fear of humiliation or embarrassment in either general or specific social situations (e.g., public speaking, "stage fright," urinating in public restrooms).

Treatment. Cognitive-behavioral therapies for phobias include systematic desensitization and assertiveness training. Pharmacotherapy includes SSRIs, buspirone, and beta-blockers (for stage fright).

OBSESSIVE-COMPULSIVE DISORDER (OCD)

Definition. OCD is characterized by recurrent obsessions or compulsions that are recognized by the individual as unreasonable. Obsessions are anxiety-provoking, intrusive thoughts, commonly concerning contamination, doubt, guilt, aggression, and sex. Compulsions are peculiar behaviors that reduce anxiety, commonly hand-washing, organizing, checking, counting, and praying.

Risk Factors/Etiology. May be associated with abnormalities of serotonin metabolism

Presenting Symptoms

- **Prevalence:** 2% of population. Occurs at a 1:1 male-to-female ratio.
- Some evidence of heritability
- **Onset:** Insidious and occurs during childhood, adolescence, or early adulthood
- **Course:** Symptoms usually wax and wane, and depression, other anxieties, and substance abuse are common.

Physical Examination. Chapped hands when hand-washing compulsion is present.

Treatment. Behavioral psychotherapies are relaxation training, guided imagery, exposure, paradoxical intent, response prevention, thought-stopping techniques, and modeling. Pharma-cotherapy includes selective serotonin reuptake inhibitors, TCAs, MAOIs, and SNRIs.

ACUTE STRESS DISORDER/POST-TRAUMATIC STRESS DISORDER

Definition. These disorders are characterized by severe anxiety symptoms and follow a threatening event that caused feelings of fear, helplessness, or horror.

- When this anxiety lasts <1 month (but >2 days) and symptoms occur within 1 month of stressor, it is diagnosed as **acute stress disorder (ASD)**.
- When the anxiety lasts >1 month, it is diagnosed as **post traumatic stress disorder (PTSD)**.

Risk Factors/Etiology. Traumatic events precipitate ASD and PTSD. Premorbid factors, such as personality traits, play an uncertain role.

Presenting Symptoms

- May occur at any age. About 50% of cases resolve within 3 months.
- Usually begin immediately after trauma, but may occur after months or years.
- Three key symptom groups
  - Reexperiencing of traumatic event: dreams, flashbacks, or intrusive recollections
  - Avoidance of stimuli associated with the trauma or numbing of general responsiveness
  - Increased arousal: anxiety, sleep disturbances, hypervigilance
- Anxiety, depression, impulsivity, and emotional lability are common.
- **"Survivor guilt"**: A feeling of irrational guilt about an event sometimes occurs.

Treatment. Counseling after a stressful event may prevent PTSD from developing. Group psychotherapy with other survivors is helpful. Pharmacotherapy includes SSRIs, other antidepressants, and benzodiazepines. Prazosin has been used to reduce nightmares.

GENERALIZED ANXIETY DISORDER

Definition. Excessive, poorly controlled anxiety about life circumstances that continues for more than 6 months. Both psychologic and physiologic symptoms of anxiety are present. General worry is accompanied by somatic symptoms such as irritability, decreased sleep, and poor concentration.

Risk Factors/Etiology. May be a genetic predisposition for an anxiety trait

Presenting Symptoms

- **Prevalence:** 5% of the population. Occurs at a 2:3 male-to-female ratio.
- **Onset:** Often during childhood but can occur later
- **Course:** Usually chronic, but symptoms worsen with stress
- **Associated problems:** Depression, somatic symptoms, and substance abuse

Treatment. Behavioral psychotherapy includes relaxation training and biofeedback. Pharmacotherapy includes SSRIs, venlafaxine, buspirone, and benzodiazepines.

Practice Question

A 31-year-old local politician has a sudden onset of extreme anxiety, tremulousness, and diaphoresis immediately before his first scheduled appearance on national television, and he is unable to go on the air. For the next week he is paralyzed by fear each time he faces an audience, and he cancels all of his scheduled public appearances.

Which of the following is the most likely diagnosis?

(A) Acute stress disorder
(B) Adjustment disorder with anxious mood
(C) Panic disorder
(D) Social anxiety disorder
(E) Specific phobia

Answer: D. This presentation is most suggestive of social anxiety disorder. In this case, exposure to public speaking precipitated intense anxiety. Panic disorder is also characterized by intense anxiety attacks; however, there is no clear precipitant. Specific phobia, situational type, is a less likely diagnosis, because there is no specific cause of the fear other than social exposure. Acute stress disorder is characterized by the presence of intrusive recollections and emotional numbing that follow a life-threatening event. Adjustment disorder with anxious mood is characterized by an adaptation problem that follows a psychologic stressor, of which there is no evidence in this case.

Somatic Symptom and Related Disorders

7

Learning Objectives

- ❏ Differentiate conversion disorder, factitious disorder, and malingering
- ❏ Answer questions about somatic symptom, illness anxiety, and body dysmorphic disorders

SOMATOFORM DISORDERS

Somatoform disorders are characterized by the presentation of physical symptoms with no medical explanation. The symptoms are severe enough to interfere with one's ability to function in social or occupational activities.

SOMATIC SYMPTOM DISORDER

> Mrs. Smith has been married for 10 years, and during all of those years she remembers being sick all of the time. According to her husband, she constantly takes medications for all of her ailments. She has visited numerous physicians and none have been able to correctly diagnose her condition. Today she presents in your office complaining of shortness of breath, chest pain, abdominal pain, back pain, double vision, difficulty walking due to weakness in her legs, headaches, constipation, bloating, decreased libido, and tingling in her fingers.

Definition. A disorder where one or more somatic symptoms that are distressing result in problems in functioning.

Risk Factors/Etiology. Somatization disorder affects women more than men and is usually inversely related to SES. Usually begins by the age of 30. Data suggest that there may be a genetic linkage to the disorder. Within families, male relatives tend to have antisocial personality disorder, whereas female relatives tend to have histrionic personality disorder.

Physical and Psychiatric Presenting Symptoms

- Many physical symptoms affecting many organ systems
- Excessive thoughts, feelings, or behaviors related to the somatic symptoms
- Long, complicated medical histories

- Interpersonal and psychologic problems are usually present.
- Patients will usually seek out treatment and have significant impairment in their level of functioning.
- Commonly associated with major depressive disorder, personality disorders, substance-related disorders, generalized anxiety disorders, and phobias

Treatment. Must have a single identified physician as the primary caretaker. Patient should be seen during regularly scheduled brief monthly visits. Should increase the patient's awareness of the possibility that the symptoms are psychological in nature. Individual psychotherapy is needed to help patients cope with their symptoms and develop other ways of expressing their feelings.

Differential Diagnosis

- **Medical:** MS, myasthenia gravis, SLE, AIDS, thyroid disorders, and chronic systemic infections
- **Psychiatric:** Major depression, generalized anxiety disorder, schizophrenia

CONVERSION DISORDER

A recently married woman presents to the emergency department unable to move her lower extremities. A full workup is done, and no abnormalities are found. When further questioned, she reports being beaten by her husband that morning.

Definition. A disorder in which the individual experiences one or more neurologic symptoms that cannot be explained by any medical or neurologic disorder.

Risk Factors/Etiology. Seen more frequently in young women. Also more common among the lower SES, rural populations, low IQs, and military personnel. Commonly associated with passive-aggressive, dependent, antisocial, and histrionic personality disorder.

Psychiatric and Physical Presenting Symptoms

- One or two neurologic symptoms affecting voluntary or sensory function
- Must have psychologic factors associated with the onset or exacerbation of the symptoms
- Mutism, blindness, and paralysis are the most common symptoms.
- **Sensory system:** Anesthesia and paresthesia
- **Motor system:** Abnormal movements, gait disturbance, weakness, paralysis, tics, jerks, etc.
- **Seizure system:** Pseudoseizures
- **Primary gain:** Keeps internal conflicts outside patient's awareness
- **Secondary gain:** Benefits received from being "sick"
- **La belle indifference:** Patient seems unconcerned about impairment.
- **Identification:** Patients usually model their behavior on someone who is important to them.

Treatment. Psychotherapy to establish a caring relationship with treater and focus on stress and coping skills. Brief monthly visits with partial physical examinations.

Differential Diagnosis

- **Neurologic:** Dementia, tumors, basal ganglia disease, and optic neuritis
- **Psychiatric:** Schizophrenia, depressive disorders, anxiety disorders, factitious
- **Other:** Malingering

ILLNESS ANXIETY DISORDER

A 22-year-old woman presents to the doctor convinced that she has a brain tumor. She reports frequent headaches that are not alleviated with aspirin. She has been to numerous physicians and all have told her that there is nothing wrong with her. She expects that you can help her because she knows that there is something wrong and that you can adequately treat her condition.

Definition. A disorder characterized by the patient's belief that he/she has some specific disease. Despite constant reassurance, the patient's belief remains the same. Symptoms must occur for >6 months.

Risk Factors/Etiology. Men and women are affected equally. Most common onset is between the ages of 20 and 30.

Physical and Psychiatric Presenting Symptoms

- Preoccupation with diseases
- The preoccupation persists despite constant reassurance by physicians.
- The belief is not delusional.
- The preoccupation affects the individual's level of functioning.
- Duration at least 6 months

Treatment. Psychotherapy to help relieve stress and help cope with illness. Frequent, regularly scheduled visits to patient's medical doctor(s).

BODY DYSMORPHIC DISORDER

The mother of a 20-year-old man presents to your office in tears. She insists that you come to her house and see her son, who has been homebound for several years. Her son refuses to leave the house because he believes he is ugly and people will laugh at him. He feels deformed and refuses to let others see him. When you arrive at the house, you find an attractive young man with no observable deformities.

Definition. A disorder characterized by the belief that some body part is abnormal, defective, or misshapen.

Risk Factors/Etiology. Affects women more than men, typically ages 15–20. These women are unlikely to be married. Other disorders that may be found include depressive disorders, anxiety disorders, and psychotic disorders. Family history of depressive disorders and OCDs. May involve serotonergic systems.

Physical and Psychiatric Presenting Symptoms

- Most common concerns involve facial flaws
- Constant mirror-checking
- Attempt to hide the alleged deformity
- Housebound
- Avoids social situations
- Causes impairment in their level of functioning

Treatment. Individual psychotherapy to help deal with stress of alleged imperfections as well as reality testing. Pharmacotherapy may include the use of SSRIs, TCAs, or MAOIs.

Differential Diagnosis

- **Medical:** Some types of brain damage, such as neglect syndrome
- **Psychiatric:** Anorexia, narcissistic personality disorder, OCD, schizophrenia, delusional disorder

FACTITIOUS DISORDER

A 2-year-old girl was hospitalized after her mother complained that the girl had multiple episodes of apnea in the middle of the night. The mother was given an apnea monitor to take home and when she returned, there were numerous episodes registering on the monitor. While in the hospital, the girl had no episodes of apnea. However, shortly after her mother's visit, there were numerous episodes recorded on the monitor.

Definition. A disorder characterized by the conscious production of signs and symptoms of both medical and mental disorders. The main objective is to assume the sick role and eventually hospitalization. Usually diagnosed with physical or psychological symptoms or both. Consists of 2 main types: **imposed on self** and **imposed on others**.

Etiology. Seen more commonly in women and in hospital and health care workers. As children, many of the patients suffered abuse that resulted in frequent hospitalizations, thus their need to assume the sick role.

Physical and Psychiatric Presenting Symptoms

- Typically demand treatment when in the hospital
- If tests return negative, they tend to accuse doctors and threaten litigation.
- Become angry when confronted

Treatment. Usually involves management rather than cure. Must be aware of countertransference when the physician suspects factitious disorder.

Differential Diagnosis. Psychiatric: Other somatoform disorders, antisocial personality disorder, histrionic personality disorder, schizophrenia, substance abuse, malingering, and Ganser's syndrome

MALINGERING

A 40-year-old homeless man presents to the hospital on a cold night complaining of auditory hallucinations telling him to kill himself. When asked about past psychiatric history, he is unable to give any detailed information. He seems concerned about being admitted immediately and refuses all medications, when offered.

Definition. Characterized by the conscious production of signs and symptoms for an obvious gain (money, avoidance of work, free bed and board, etc.). It is not a mental disorder.

Risk Factors/Etiology. Seen more frequently in men, especially in prisons, factories, the military, etc.

Physical and Psychiatric Presenting Symptoms

- Most express subjective symptoms.
- Tend to complain a lot and exaggerate its effect on their functioning and lives
- Preoccupied more with rewards than with alleviation of symptoms

Treatment. Allow the patient to save face by not confronting the patient and by allowing the physician–patient relationship to work. If confronted, patient will become angry and more guarded and suspicious.

Differential Diagnosis. Psychiatric: somatoform disorders

Practice Question

A 40-year-old woman presents to your office and demands to be seen immediately. She schedules appointments to see you on a regular basis as well as irregularly. She routinely goes to the emergency department when she knows you are in the hospital. She calls your service every night and demands that you call her at home. Her frequent complaints include headache, shortness of breath, double vision, burning at urination, weakness in her arms and legs, tingling in her fingers, and palpitations. All of her medical workups have been negative so far.

Which of the following would be the next step in management?

(A) Tell her it is all in her head
(B) Assure her there is nothing wrong with her
(C) Refer her to a psychiatrist
(D) Begin a trial of lorazepam
(E) Schedule regular office visits

Answer: E. Patients with somatic symptom disorder should have only one physician, and that physician must see the patient on a regular basis given that there might be something physically wrong in the future. Also, by limiting the patient's care to one physician, the likelihood of unnecessary tests and treatment is reduced.

Neurocognitive Disorders

8

Learning Objectives

- ❏ Differentiate delirium, dementia, and psychosis
- ❏ List the causes of delirium and describe the diagnostic work-up
- ❏ Define neurocognitive disorder and mild neurocognitive disorder

NEUROCOGNITIVE DISORDERS

Cognition includes memory, language, orientation, judgment, problem solving, interpersonal relationships, and performance of actions. Cognitive disorders have problems in these areas as well as behavioral symptoms.

Definition. Characterized by the syndromes of delirium, neurocognitive disorder, and amnesia, which are caused by general medical conditions, substances, or both.

Risk Factors/Etiology. Very young or advanced age, debilitation, presence of specific general medical conditions, sustained or excessive exposure to a variety of substances.

Presenting Symptoms (Key Symptoms)

- Memory impairment, especially recent memory
- **Aphasia:** Failure of language function
- **Apraxia:** Failure of ability to execute complex motor behaviors
- **Agnosia:** Failure to recognize or identify people or objects
- **Disturbances in executive function:** Impairment in the ability to think abstractly and plan such activities as organizing, shopping, and maintaining a home

DELIRIUM

Definition. Delirium is characterized by prominent disturbances in alertness, as well as confusion and a short, fluctuating course. It is caused by acute metabolic problems or substance intoxication.

Risk Factors/Etiology. Commonly associated with general medical conditions such as systemic infections, metabolic disorders, hepatic/renal diseases, seizures, head trauma. Also associated with high, sustained, or rapidly decreasing levels of many drugs, especially in the elderly and severely ill.

Presenting Symptoms. Delirium occurs in >40% of elderly, hospitalized patients. Key symptoms include agitation or stupor, fear, emotional lability, hallucinations, delusions, and disturbed psychomotor activity.

Physical Examination. Motor abnormalities commonly present, include incoordination, tremor, asterixis, and nystagmus. Incontinence is common. There is often evidence of underlying general medical conditions or substance-specific syndromes.

Diagnostic Tests. EEG often shows generalized slowing of activity, fast-wave activity, or focal abnormalities. Abnormal findings from neuroimaging and neuropsychiatric testing may be present.

Treatment. Correction of physiologic problems is essential. Frequent orientation and reassurance are helpful. Consider protective use of physical restraints and antipsychotic medications.

Differential Diagnosis. Neurocognitive disorder, substance intoxication or withdrawal, and psychotic disorders are the major rule-outs.

NEUROCOGNITIVE DISORDER

Definition. Neurocognitive disorder is characterized by slight (mild) or prominent (severe) memory disturbances coupled with other cognitive disturbances that are present even in the absence of delirium. It is caused by CNS damage and likely to have a protracted course.

Risk Factors/Etiology.

- Neurodegenerative disease such as Alzheimer, Parkinson, Huntington, Pick, and other fronto-temporal degeneration, and Creutzfeldt-Jakob disease are common causes.
- Cerebrovascular disease, intracranial processes such as CNS infections (e.g., HIV), traumatic brain injuries, radiation, and/or tumors should be considered.
- Seizure disorders, metabolic disorders (e.g., disease of protein, lipid, and carbohydrate metabolism; diseases of myelin; Wilson disease; uremic encephalopathy), and endocrinopathies (e.g., hypothyroidism) are often associated with neurocognitive disorder.
- Nutritional deficiencies, including beriberi (thiamine [vitamin B1] deficiency), pellagra (niacin deficiency), and/or pernicious anemia (cobalamin [vitamin B12] deficiency), should be considered.
- Toxins that cause neurocognitive disorder include alcohol, inhalants, sedative–hypnotics, anxiolytics, anticonvulsants, antineoplastic medications, heavy metals, insecticides, and solvents.

Prevalence. 5% of the population age >65 and >20% of the population age >85

Heritability. Some types of neurodegenerative neurocognitive disorders (e.g., Huntington disease).

Key Symptoms. Increasing disorientation, anxiety, depression, emotional lability, personality disturbances, hallucinations, and delusions

Associated Findings. Abnormal findings from neuroimaging and neuropsychiatric testing.

Course. Depending on the etiology, function may stabilize or deteriorate further.

Physical Examination. Evidence of CNS motor pathology is often present. There may be evidence of underlying general medical conditions or substance-specific syndromes.

Diagnostic Tests. EEG may show specific focal abnormalities. Neuroimaging and neuropsychiatric testing may show specific abnormal findings. Folstein Mini-Mental Status Exam is used to detect neurocognitive disorder. Basic laboratory examination for neurocognitive disorder includes B12 and folate levels, RPR, CBC with SMA, and thyroid function tests.

Treatment. Correction or amelioration of underlying pathology is essential. Medication that further impairs cognition should be avoided. Provision of familiar surroundings, reassurance, and emotional support is often helpful.

Differential Diagnosis. Delirium and less severe, age-related cognitive decline must be ruled out.

Specific Neurocognitive Disorders

All neurocognitive disorders may be mild or severe.

Neurocognitive disorder due to Alzheimer disease

- Occupy more than 50% of nursing-home beds
- Found in 50–60% of patients with neurocognitive disorder
- Risk factors: Female, family history, head trauma, Down syndrome
- Neuroanatomic findings: Cortical atrophy, flattened sulci, and enlarged ventricles
- Histopathology: Senile plaques (amyloid deposits), neurofibrillary tangles, neuronal loss, synaptic loss, and granulovacuolar degeneration of neurons
- Associated with chromosome #21 (gene for the amyloid precursor protein)
- Decreased Ach and NE
- Deterioration is generally gradual; average duration from onset to death is ~8 years.
- Focal neurologic symptoms are rare.
- Treatment includes long-acting cholinesterase inhibitors such as donepezil, rivastigmine, galantamine, and memantine..
- Antipsychotic medications may be helpful when psychotic symptoms present but contraindicated to control behavior.

Vascular neurocognitive disorder (multi-infarct neurocognitive disorder)

- Found in 15–30% of patients with neurocognitive disorder
- Risk factors: Male, advanced age, hypertension, or other cardiovascular disorders
- Affects small and medium-sized vessels
- Examination may reveal carotid bruits, fundoscopic abnormalities, and enlarged cardiac chambers.
- MRI may reveal hyperintensities and focal atrophy suggestive of old infarctions.
- Deterioration may be stepwise or gradual, depending on underlying pathology.
- Focal neurologic symptoms (pseudobulbar palsy, dysarthria, and dysphagia are most common)
- Abnormal reflexes and gait disturbance are often present.
- Treatment is directed toward the underlying condition and lessening cell damage.
- Control of risk factors such as hypertension, smoking, diabetes, hypercholesterolemia, and hyperlipidemia is useful.

Table I-8-1. Alzheimer Versus Vascular Neurocognitive Disorder

Alzheimer	Vascular
Women	Men
Older age of onset	Younger than Alzheimer patients
Chromosome 21	Hypertension
Linear or progressive deterioration	Stepwise or patchy deterioration
No focal deficits	Focal deficits
Supportive treatment	Treat underlying condition

Frontotemporal neurocognitive disorder (Pick disease)

- Neuroanatomic findings: Atrophy in the frontal and temporal lobes
- Histopathology: Pick bodies (intraneuronal argentophilic inclusions) and Pick cells (swollen neurons) in affected areas of the brain
- Etiology is unknown.
- Most common in men with family history of Pick disease
- Difficult to distinguish from Alzheimer's
- May see features of Klüver-Bucy syndrome (hypersexuality, hyperphagia, passivity)

Neurocognitive disorder due to Prion disease

- Rare spongiform encephalopathy is caused by a slow virus (prion).
- Presents with neurocognitive disorder, myoclonus, and EEG abnormalities (e.g., sharp, triphasic, synchronous discharges and, later, periodic discharges)
- Symptoms progress over months from vague malaise and personality changes to neurocognitive disorder and death.
- Findings include visual and gait disturbances, choreoathetosis or other abnormal movements, and myoclonus.
- Other prions that cause neurocognitive disorder (e.g., Kuru) may exist.

Neurocognitive disorder due to Huntington disease

- A rare, progressive neurodegenerative disease that involves loss of GABA-ergic neurons of the basal ganglia, manifested by choreoathetosis, neurocognitive disorder, and psychosis.
- Caused by a defect in an autosomal dominant gene located on chromosome 4
- Atrophy of the caudate nucleus, with resultant ventricular enlargement, is common.
- Clinical onset usually occurs at approximately age 40.
- Suicidal behavior is fairly common.

Neurocognitive disorder due to Parkinson disease

- Common, progressive, neurodegenerative disease involving loss of dopaminergic neurons in the substantia nigra
- Clinical onset is usually age 50–65.
- Motor symptoms include resting tremor, rigidity, bradykinesia, and gait disturbances.
- Neurocognitive disorder occurs in 40% of cases, and depressive symptoms are common.
- Destruction of dopaminergic neurons in the substantia nigra is a key pathogenic component and may be caused by multiple factors, including environmental toxins, infection, genetic predisposition, and aging.
- Treatment of Parkinson disease involves use of dopamine precursors (e.g., levodopa, carbidopa), dopamine agonists (e.g., bromocriptine), anticholinergic medications (e.g., benztropine, trihexyphenidyl), amantadine, and selegiline.
- Antiparkinsonian medications can produce personality changes, cognitive changes, and psychotic symptoms.

Neurocognitive disorder with Lewy bodies

Hallucinations, parkinsonian features, and extrapyramidal signs. Antipsychotic medications may worsen behavior. Patients typically have fluctuating cognition, as well as REM sleep behavior disorder.

Note

(LBD) 1 yr ← PD → 1 yr (PDD)

Neurocognitive disorder due to HIV infection

- HIV directly and progressively destroys brain parenchyma.
- Becomes clinically apparent in at least 30% of individuals with AIDS, beginning with subtle personality changes.
- Diffuse and rapid multifocal destruction of brain structures occurs, and delirium is often present.
- Motor findings include gait disturbance, hypertonia and hyperreflexia, pathologic reflexes (e.g., frontal release signs), and oculomotor deficits.
- Mood disturbances in individuals with HIV infection are apathy, emotional liability, or behavioral disinhibition.

Wilson disease

- Ceruloplasmin deficiency
- Hepatolenticular degeneration
- Kayser-Fleischer rings in the eye
- Asterixis

Normal pressure hydrocephalus

- Enlarged ventricles
- Normal pressure
- Neurocognitive disorder, urinary incontinence, and gait apraxia
- Treatment includes shunt placement

Pseudodementia

- Typically seen in elderly patient who has a depressive disorder but appears to have symptoms of neurocognitive disorder; should improve after being treated with antidepressants
- Can usually date the onset of their symptoms

Table I-8-2. Pseudodementia versus Neurocognitive Disorder

Pseudodementia	Neurocognitive Disorder
Acute onset	Insidious onset
Family aware	Family unaware at first
Answers "I don't know" when asked questions	Confabulates when asked questions
Will talk about deficits when asked	Will minimize deficits
Treat with antidepressants	Will not improve with antidepressants

Table I-8-3. Delirium Versus Neurocognitive Disorder

Delirium	Neurocognitive Disorder
Acute onset	Insidious onset
Fluctuating course	Chronic course
Lasts days to weeks	Lasts months to years
Recent memory problems	Recent then remote memory problems
Disrupted sleep-wake cycle	Less disorientation at first
Disorientation	Normal sleep-wake cycle
Hallucinations common	Hallucinations, sundowning
Treat underlying condition	Supportive treatment

MILD NEUROCOGNITIVE DISORDER DUE TO SUBSTANCE/MEDICATION OR ANOTHER MEDICAL CONDITION

Definition. Characterized by prominent memory impairment in the absence of disturbances in level of alertness or the other cognitive problems that are present with delirium or neurocognitive disorder.

Risk Factors/Etiology (General Medical Conditions). Commonly associated with bilateral damage to diencephalic and mediotemporal structures (e.g., mammillary bodies, fornix, hippocampus). It may also be caused by conditions such as thiamine deficiency associated with alcohol dependence, head trauma, cerebrovascular disease, hypoxia, local infection (e.g., herpes encephalitis), ablative surgical procedures, and seizures.

Risk Factors/Etiology (Substances). Alcohol is likely the most common cause.

Table I-8-4. Wernicke Versus Korsakoff Syndromes

	Wernicke	Korsakoff
Course	Acute	Chronic
Reversibility	Yes	No
Presentation	Ataxia, nystagmus, and ophthalmoplegia	Confusion, psychosis, anterograde and retrograde amnesia
Treatment	Thiamine	Thiamine

Physical Examination. Evidence of chronic alcohol abuse is often present.

Treatment. Correction of the underlying pathophysiology (e.g., administration of thiamine in alcohol-induced amnestic disorder) may be effective in reversing or slowing the progression of symptoms.

Differential Diagnosis. Delirium, neurocognitive disorder, and dissociative amnesia are the common rule-outs.

Practice Question

A 65-year-old woman is found by the police in a filthy apartment after they were called by neighbors complaining of an unpleasant odor. Police find spoiled food in the kitchen, clogged sinks and toilets, and a severe infestation of cockroaches. The woman angrily refuses to leave with the police, stating that her neighbors have threatened her with attack and she fears that they will rob her apartment in her absence. Emergency room assessment reveals a very frail and unkempt woman who is completely alert and attentive. She believes it is 10 years earlier than it actually is, and she seems confused about her current finances and social contacts. She is unable to give the current addresses or phone numbers of her children and cannot find her phone book or purse. Physical exam is WNL.

Which of the following disturbances is the most likely diagnosis?

(A) Vascular neurocognitive disorder
(B) Wernicke's syndrome
(C) Pseudodementia
(D) Delirium
(E) Neurocognitive disorder due to Alzheimer's disease

Answer: E. The woman presents with evidence of memory disturbance and severe problems managing her activities. This presentation is most consistent with neurocognitive disorder, which is characterized by memory impairment and other cognitive deficits. Delirium is characterized by problems with arousal and attention in addition to cognitive disturbances. Wernicke's is a less likely diagnosis because no cognitive disturbances other than memory impairment are present in this patient. Pseudodementia occurs quickly and patients are aware of the symptoms. Vascular neurocognitive disorder will often show motor deficits on physical exam.

Dissociative Disorders 9

Learning Objectives

- ❏ Define depersonalization and derealization
- ❏ Describe the presentation of dissociative amnesia with and without fugue
- ❏ Recognize dissociative identity disorder

DISSOCIATION

Dissociation is the fragmentation or separation of aspects of consciousness, including memory, identity, and perception. Some degree of dissociation is always present; however, if an individual's consciousness becomes too fragmented, it may pathologically interfere with the sense of self and ability to adapt. Presenting complaints and findings of dissociative disorders include amnesia, personality change, erratic behavior, odd inner experiences (e.g., flashbacks, déjà vu), and confusion.

DISSOCIATIVE AMNESIA

Definition. Significant episodes in which the individual is unable to recall important and often emotionally charged memories. Dissociative amnesia **with fugue** also involves purposeful travel or bewildered wandering.

Risk Factors/Etiology. Psychological stress. More common in women and younger adults. Onset is usually detected retrospectively by the discovery of memory gaps of extremely variable duration.

Symptoms. Amnesia that may be general or selective for certain events.

Course. The amnesia may suddenly or gradually remit, particularly when the traumatic circumstance resolves, or may become chronic.

Associated Problems. Mood disorders, conversion disorder, and personality disorders are commonly present.

Treatment. Diagnostic evaluation for general medical conditions (e.g., head trauma, seizures, cerebrovascular disease) or substances (e.g., anxiolytic and hypnotic medications, alcohol) that may cause amnesia. Hypnosis, suggestion, and relaxation techniques are helpful. The patient should be removed from stressful situations when possible. Psychotherapy should be directed at resolving underlying emotional stress.

Differential Diagnosis. Major rule-outs are amnestic disorder due to a general medical condition, substance-induced amnestic disorder, and other dissociative disorders.

DISSOCIATIVE IDENTITY DISORDER

Definition. Formerly called multiple personality disorder. Presence of multiple, distinct personalities that recurrently control the individual's behavior, accompanied by failure to recall important personal information.

Risk Factors/Etiology. Childhood sexual abuse has been postulated as a risk factor.

Prevalence. More common in women

Onset. Usually occult; clinical presentation is several years later when disturbances in interpersonal functioning are present.

Key Symptoms. Presence of distinct personalities is often subtle; in some cases, it is discovered only during treatment for associated symptoms.

Associated Problems. Chaotic interpersonal relationships, impulsivity and self-destructive behavior, suicide attempts, substance abuse

Comorbidity. Borderline personality disorder, PTSD, major depressive disorder and other mood disorders, substance-related disorders, sexual disorders, and eating disorders.

Course. Symptoms may fluctuate or be continuous.

Differential Diagnoses. Borderline personality disorder and other personality disorders, bipolar disorder with rapid cycling, factitious disorder, and malingering

Treatment. Psychotherapy to uncover psychologically traumatic memories and to resolve the associated emotional conflict

DEPERSONALIZATION AND DEREALIZATION DISORDER

Definition. Persistent or recurrent feeling of being detached from one's mental processes or body, accompanied by intact sense of reality

Risk Factors/Etiology. Psychologic stress

Prevalence. Episodes of depersonalization are common.

Onset. Usually in adolescence or early adulthood. Stressful events may precede the onset of the disorder.

Key Symptoms

- **Depersonalization:** Often described as an "out-of-body experience"
- **Derealization:** Perception of the environment is often distorted or strange during episodes of depersonalization, accompanied by a feeling of being detached from physical surroundings. *Jamais vu* (a sense of familiar things being strange), déjà vu (a sense of unfamiliar things being familiar), and other forms of perceptual distortion may occur.

Associated Symptoms. Are often during episodes

Treatment. Psychotherapy directed at decreasing anxiety

Differential Diagnosis. Major rule-outs are substance-induced mental disorders with dissociative symptoms, including intoxication, withdrawal, hallucinogen-induced persisting perceptual disorder, panic disorder, and PTSD.

Practice Question

A 19-year-old man is brought to the emergency room by volunteers from a homeless shelter. The man claims that he cannot remember who he is. He says that he found himself in Los Angeles but that he cannot remember where he comes from, the circumstances of his trip, or any other information about his life. He has neither identification nor money, but he has a bus ticket from New York. Physical exam and laboratory testing are unremarkable.

Which of the following is the most likely diagnosis?

(A) Depersonalization disorder
(B) Dissociative amnesia
(C) Dissociative amnesia fugue
(D) Dissociative identity disorder
(E) Substance-induced amnestic disorder

Answer: C. The symptoms of amnesia, unexplained travel, and identity confusion are most suggestive of dissociative fugue. Because of the generalized nature of his amnesia and negative physical findings, substance-induced amnestic disorder an unlikely diagnosis. There is insufficient evidence of distinct alternative personalities to diagnose dissociative identity disorder.

Adjustment Disorders 10

Learning Objectives

- ❑ Recognize and describe treatment approaches to adjustment disorders

ADJUSTMENT DISORDERS

Adjustment disorders are maladaptive reactions to an identifiable psychosocial stressor. They are caused by environmental stressors having an effect on functioning. The risk that a stressor will cause an adjustment disorder depends on one's emotional strength and coping skills.

Prevalence. Extremely common; all age groups

Onset. Within 3 months of the initial presence of the stressor.

Course. Lasts 6 months or less once the stressor is resolved. Can become chronic if stressor continues and new ways of coping with the stressor are not developed.

Key Symptoms. Complaints of overwhelming anxiety, depression, or emotional turmoil associated with specific stressors

Associated Problems. Social and occupational performance deteriorate, erratic or withdrawn behavior.

Treatment

- Remove or ameliorate the stressor.
- Brief psychotherapy to improve coping skills
- Pharmacotherapy: Anxiolytic or antidepressant medications are used to ameliorate symptoms if therapy is not effective.

Differential Diagnosis. Normal reaction to stress. Disorders that occur following stress (e.g., GAD, PTSD, major depressive disorder).

Types.

- Depressed mood
- Anxiety
- Mixed anxiety and depressed mood
- Disturbance of conduct
- Mixed disturbance of emotions and conduct

Practice Question

A 28-year-old woman without previous behavioral problems becomes angry and bitter after her husband of 5 years leaves her to live with his female business partner. One week later, the woman quits her job without giving notice and begins drinking heavily. For the next several weeks, the woman telephones friends and tearfully expresses her feelings. She also makes several threatening calls to her husband's new girlfriend.

Which of the following is the most likely diagnosis?

(A) Adjustment disorder
(B) Alcohol-induced mood disorder
(C) Bipolar I disorder
(D) Bipolar II disorder
(E) Borderline personality disorder

Answer: A. Depression and erratic behavior after an interpersonal stressor are most suggestive of adjustment disorder with mixed disturbance of emotions and conduct. The cause of the symptoms is most likely the stressor and not the physiologic result of alcohol. Bipolar disorders I and II are unlikely diagnoses for an individual who has no history of mood episodes. Borderline personality disorder is a less likely diagnosis for an individual who has no history of past behavioral and interpersonal difficulties.

Used with permission from Williams & Wilkins, *Board Review Series: Psychiatry*, 1997.

Substance-Related and Addictive Disorders

11

Learning Objectives

- ❏ Describe the neuroanatomy of substance-related and addictive disorders
- ❏ Present the epidemiology of addictive disorders
- ❏ Describe the behavioral and pharmacologic approaches to treating addicts

SUBSTANCE ABUSE AND ADDICTION

Definitions

- **Substance use disorder:** negative behavioral, cognitive, and/or physiologic symptoms due to use of a substance, yet use continues despite these adverse consequences
- **Intoxication:** reversible substance-specific syndrome due to recent use of a substance
- **Withdrawal:** substance-specific behavioral, cognitive, and/or physiologic change due to the cessation or reduction in heavy or prolonged substance use

Physical and Psychiatric Examination

- **Substance abuse history:** Includes the substance(s) used, dosage(s), effects, duration and social context of use, and prior experiences with substance detoxification, rehabilitation, and relapse prevention
- **Medical history:** Includes complications of substance abuse
- **Psychiatric history:** Includes other primary psychiatric diagnoses and past treatments
- **Mental status examination:** Includes signs of substance-induced disorders
- **Physical examination:** Includes signs of substance use

Risk Factors/Etiology

- **Family history:** Biological sons of alcoholics are more likely to develop alcoholism than is the general population.
- **Physiology:** Individuals who are innately more tolerant to alcohol may be more likely to develop alcohol abuse.
- **Developmental history:** Poor parenting, childhood physical or sexual abuse, and permissive attitudes toward drug use.
- **Environmental risk factors:** Exposure to drug use through peers or certain occupations, economic disadvantage, and social isolation.
- **Psychiatric disturbances:** Conduct disorder, ADHD, depression, and low self-esteem.

- **Self-medication hypotheses:** Individuals with certain psychologic problems may abuse substances in an effort to alleviate symptoms (e.g., a person suffering from an anxiety disorder uses alcohol to decrease innate anxiety).

Diagnostic Tests

CAGE. Affirmative answers to any 2 of the following questions (or to the last question alone) are suggestive of alcohol abuse:

- Have you ever felt that you should cut down your drinking?
- Have you ever felt annoyed by others who have criticized your drinking?
- Have you ever felt guilty about your drinking?
- Have you ever had a morning drink (eye-opener) to steady your nerves or alleviate a hangover?

Urine drug screen: typically tests for amphetamines, barbiturates, benzodiazepines, cannabinoids, cocaine, methodone, methaqualone, opiates, phencyclidine

Hair testing: typically tests for cocaine, amphetamines, methamphetamines, opiates, PCP, marijuana

Breath: typically tests for alcohol

Blood: increased AST, ALT, and GGT for alcohol abuse

Types of treatment

- **Pharmacotherapy:** medications that work on the reward center, such as naltrexone, varenicline, and bupropion.
- **Psychotherapy:** preferably group therapy such as Alcoholics Anonymous, Narcotics Anonymous
- **Behavioral modification** techniques: disulfiram (aversive conditioning), patch, gum, inhaler (fading)
- **Detoxification units:** typically 5-10 days, provide medications to assure safe withdrawal from substances
- **Rehabilitation programs:** typically 28-day programs, learn about relapse prevention and identification of triggers

Table I-11-1. Blood Alcohol Levels and Effects on Behavior

Blood Alcohol Level	Behavioral Effect
0.05%	Thought, judgment, and restraint are loosened and disrupted
0.1%	Motor actions become clumsy
0.2%	• Motor area of the brain is depressed • Emotional behavior is affected
0.3%	Confused or stuporous
0.4–0.5%	• Coma • At higher levels, death may occur due to respiratory depression

Table I-11-2. Substances of Abuse

Substance	Signs and Symptoms of Intoxication	Treatment of Intoxication	Signs and Symptoms of Withdrawal	Treatment of Withdrawal
Alcohol	Talkativeness, sullenness, gregariousness, moodiness, etc.	Mechanical ventilation, if severe	Tremors, hallucinations, seizures, delirium tremens	Benzodiazepines Thiamine Multivitamin Folic acid
Amphetamines, cocaine	Euphoria, hypervigilance, autonomic hyperactivity, weight loss, papillary dilatation, perceptual disturbances	Short-term use of antipsychotics, benzodiazepines, vitamin C to promote excretion in urine, anti-hypertensives	Anxiety, tremulousness, headache, increased appetite, depression, risk of suicide	Antidepressants
Anabolic steroids	Irritability, aggression, mood changes, psychosis, heart problems, liver problems, etc.	Symptomatic, abstinence	Depression, risk of suicide	SSRIs
Bath salts	Headache, palpitations, hallucinations, paranoia, violence, increased heart rate and blood pressure	Supportive, benzodiazepines	Unknown	Unknown
Benzodiazepines	Inappropriate sexual or aggressive behavior, impairment in memory or concentration	Flumazenil	Autonomic hyperactivity, tremors, insomnia, seizures, anxiety	Benzodiazepines
Cannabis	Impaired motor coordination, slowed sense of time, social withdrawal, conjunctival injection, increased appetite, dry mouth, tachycardia	None	None	None
Ecstasy	Euphoria, mild psychedelia, hyponatremia, seizures, death, rhabdomyolisis, increased heart rate, blood pressure, and temperature	Cyproheptadine, benzodiazepines, dantrolene	Unknown	Unknown
Hallucinogens	Ideas of reference, perceptual disturbances, impaired judgment, dissociative symptoms, pupillary dilatation, tremors, incoordination	Supportive counseling (talking down), antipsychotics, benzodiazepines	None	None

(*Continued*)

Table I-12-2. Substances of Abuse (*Cont'd*)

Substance	Signs and Symptoms of Intoxication	Treatment of Intoxication	Signs and Symptoms of Withdrawal	Treatment of Withdrawal
Inhalants	Belligerence, apathy, assaultiveness, impaired judgment, blurred vision, stupor or coma	Antipsychotics if delirious or agitated	None	None
Opiates	Apathy, dysphoria, papillary constriction, drowsiness, slurred speech, impairment in memory, coma or death	Naloxone	Fever, chills, lacrimation, runny nose, abdominal cramps, muscle spasms, insomnia, yawning	Clonidine, methadone
Phencyclidine (PCP)	Belligerence, assaultiveness, psychomotor agitation, nystagmus, hypertension, seizures, coma, hyperacusis	Talking down, benzodiazepines, antipsychotics	None	None

Practice Question

A 29-year-old man is brought in by judicial order for evaluation of his continued involvement with heroin use. The man denies that he is addicted but is willing to enter treatment to avoid more severe criminal penalties.

Which of the following is essential to determine the presence of heroin use disorder in this individual?

(A) A family history of substance abuse
(B) Numerous arrests for dealing heroin
(C) He vehemently denies that his use of heroin causes him any problems
(D) He spends all his time trying to obtain heroin and can't stop himself from using it
(E) He is not cooperative with treatment planning

Answer: D. Substance use disorder is characterized by the presence of a constellation of symptoms that suggest compulsive substance use, monopolization of time by substance-related activities, social and occupational consequences, and physiologic changes including tolerance and withdrawal. A family history of substance abuse, arrests for drug dealing, denial of substance-related problems, and cooperation with treatment may all occur in individuals with substance dependence, but are not diagnostic when occurring by themselves.

Impulse Control Disorders 12

Learning Objectives

- ❑ Describe the presentation of intermittent explosive disorder, kleptomania, pyromania, gambling disorder, and trichotillomania
- ❑ Describe the treatment approaches for impulse control disorders

IMPULSE CONTROL

In impulse control disorders, patients are unable to resist a negative impulse. Before the act they have increased anxiety and after the act they feel a reduction in anxiety. Impulse control is mediated by the serotonergic system.

INTERMITTENT EXPLOSIVE DISORDER

> The police arrest a 24-year-old man after he beats up an older man, causing severe injury to his head and neck area and requiring more than 100 stitches. When asked why he assaulted the older man, he replies, "He took my potato chips."

Definition. A disorder characterized by discrete episodes of failure to resist aggressive impulses that result in serious assaultive acts or destruction of property. The degree of the aggressive act is typically out of proportion to the stressor. The attacks may occur within minutes or hours and tend to resolve spontaneously.

Risk Factors/Epidemiology. Affects men more than women, especially men in prisons and women in psychiatric facilities. May have genetic linkage because it is seen frequently among first-degree relatives. Patients may have had a history of head trauma, seizures, encephalitis, hyperactivity, or other brain dysfunctions. May be linked to low levels of 5HIAA, abnormalities in the limbic system, or testosterone. The symptoms lessen as the patients age.

Physical and Psychiatric Presenting Symptoms

- Neurologic examination may reveal soft signs, such as right–left ambivalence
- EEG usually normal
- Psychologic tests often normal
- Poor work histories

- Marital difficulties
- Problems with the law

Treatment. Pharmacotherapy consisting of anticonvulsants, antipsychotics, beta-blockers, or SSRIs has been somewhat helpful. Psychotherapy, although not the preferred treatment, may be beneficial. When psychotherapy is used, it must be with pharmacotherapy and in a group setting.

Differential Diagnosis

- **Medical:** Epilepsy, brain tumors, degenerative disease, and endocrine disorders
- **Psychiatric:** Antisocial personality disorder, borderline personality disorder, schizophrenia, and substance intoxication

KLEPTOMANIA

A 25-year-old woman has a history of more than 20 arrests for stealing small items. She comes from a wealthy family and her parents do not understand her behavior. At home she has numerous salt and pepper shakers, napkin rings, and ashtrays, none of which she needs.

Definition. A disorder characterized by the recurrent failure to resist impulses to steal objects that the patient does not need. There is increased anxiety prior to the act, followed by release of anxiety after the act. The act of stealing is the goal.

Risk Factors/Epidemiology. Appears to be more common in women. Symptoms may be linked to stress in the patient's life. Often associated with mood disorders, OCDs, and eating disorders, such as bulimia nervosa. It has been linked to brain disease and ID.

Physical and Psychiatric Presenting Symptoms. May have signs of anxiety and depression. Feel guilty or ashamed of their actions.

Treatment. Insight-oriented therapy may be indicated to help the patients understand their behavior. Behavioral therapy, including aversive conditioning and systematic desensitization, has been helpful in some patients. If pharmacotherapy is indicated, consider SSRIs or anticonvulsants.

Differential Diagnosis

- **Medical:** None
- **Psychiatric:** Antisocial personality disorder, malingering, mania, and schizophrenia

PYROMANIA

A 19-year-old teen with mild ID is arrested after he is found setting the neighbor's garbage cans on fire. Neighbors had observed him in the past starting fires in his own backyard, staring at them for hours, watching them burn.

Definition. A disorder characterized by deliberate fire-setting on more than one occasion. There is anxiety before the act and a release of anxiety after the act, sometimes followed by fascination and gratification. Must rule out arson.

Risk Factors/Epidemiology. Seen more frequently in men who are mildly retarded and may have a history of alcohol abuse. Many have histories of truancy and cruelty to animals.

Physical and Psychiatric Presenting Symptoms. Many watch fires in their neighborhoods and/or set off fire alarms. Lack remorse for the consequences of their actions, and show resentment toward authority figures. May become sexually aroused by the fire.

Treatment. Because no treatment has been proven to be beneficial, incarceration may be indicated.

Differential Diagnosis

- **Medical:** Brain dysfunctions
- **Psychiatric:** Antisocial personality disorder, conduct disorder, mania, and schizophrenia

GAMBLING DISORDER

> A 40-year-old married man and father of two, was fired from his job because of embezzlement of company funds, which he used to gamble with. When found, he did not have the money on him and admitted to losing it at a casino. His wife left him two months ago, and he has not seen his wife or children since then.

In DSM-5, this is now included under Substance-related and Addictive Disorders.

Definition. A disorder characterized by persistent and recurrent gambling behavior that includes a preoccupation with gambling, a need to gamble with more money, attempts to stop gambling and/or to win back losses, illegal acts to finance the gambling, or loss of relationships due to gambling.

Risk Factors/Epidemiology. More common in men, and seen in their parents as well. Increased incidence of alcohol dependence. May be predisposed by death, loss of a loved one, poor parenting, exposure to gambling behavior, and/or divorce. May be linked to mood disorders, OCDs, panic disorder, agoraphobia, and ADHD.

Physical and Psychiatric Presenting Symptoms

- May engage in antisocial behavior to obtain money for gambling
- Appear overconfident
- Suicide attempts
- Multiple arrests and/or incarceration

Treatment. Gamblers anonymous (GA) is the most effective treatment. It involves public confessions, peer pressure, and sponsors. Although pharmacotherapy is usually not indicated, some studies have shown some efficacy with SSRIs.

Differential Diagnosis

- **Medical:** None
- **Psychiatric:** Mania, antisocial personality disorder

TRICHOTILLOMANIA

A 20-year-old woman is rushed to the hospital after she complains of severe abdominal pain. She appears thin and withdrawn and is missing a lot of hair from both her scalp and eyebrows. A physical examination reveals an intestinal obstruction.

In DSM-5, this is now included under Obsessive-Compulsive and Related Disorders.

Definition. A disorder characterized by pulling one's own hair, resulting in hair loss. There is anxiety before the act and a release of anxiety after the act.

Risk Factors/Epidemiology. Affects women more than men. Associated disorders include OCD, obsessive-compulsive personality disorder, and depressive disorders.

Physical and Psychiatric Presenting Symptoms

- Hair loss is significant over all areas of the body.
- Area most affected is the scalp.
- May eat the hair, resulting in bezoars, obstruction, and malnutrition
- Head-banging, nail-biting, and gnawing may be present.
- Examination of the scalp reveals short, broken hairs along with long hairs.

Treatment. Treatment usually consists of behavior-modification techniques to decrease patient's anxiety; as well as pharmacotherapy, such as SSRIs, anticonvulsants, or antipsychotics to help decrease the urges.

Differential Diagnosis

- **Medical:** Alopecia areata, tinea capitis (biopsy would be indicated)
- **Psychiatric:** OCD, factitious disorder

Practice Question

A 22-year-old woman was recently seen at her college graduation hoarding food in her purse and briefcase. When asked why, she replied, "I might be hungry later." She appeared to be of average height and weight, but with poor dentition. She has numerous calluses on the backs of both hands.

Which of the following disorders is she at risk for developing?

(A) Trichotillomania
(B) Kleptomania
(C) Gambling disorder
(D) Pyromania
(E) Intermittent explosive disorder

Answer: B. Patients with bulimia nervosa have an increased incidence of kleptomania. These patients will steal things they do not need.

Eating Disorders 13

Learning Objectives

- ❑ List the diagnostic criteria for anorexia nervosa, bulimia nervosa, and binge eating disorder
- ❑ Describe treatment approaches for the various eating disorders
- ❑ List criteria for admission of a patient with an eating disorder

ANOREXIA NERVOSA

Definition. Characterized by failure to maintain a normal body weight, fear and preoccupation with gaining weight and unrealistic self-evaluation as overweight. Subtypes are restricting (no binge-eating or purging) and binge-eating/purging (regularly engaged in binge-eating/purging).

Risk Factors/Etiology. Biologic factors are suggested by higher concordance for illness in monozygotic twins and the fact that amenorrhea may precede abnormal eating behavior. Psychologic risk factors include emotional conflicts concerning family control and sexuality. A cultural risk factor may be an emphasis on thinness.

Prevalence. 0.5%. Occurs at a 1:10 male-to-female ratio.

Onset. Average age is 17 years. Very late–onset anorexia nervosa has a poorer prognosis. Onset is often associated with emotional stressors, particularly conflicts with parents about independence, and sexual conflicts.

Key Symptoms

- Restricted food intake and maintaining diets of low-calorie foods. Weight loss may also be achieved through purging (i.e., vomiting or taking laxatives, diuretics, or enemas) and exercise.
- Great concern with appearance. Significant amount of time spent examining and denigrating self for perceived signs of excess weight.
- Denial of emaciated conditions
- With binge-eating/purging: Self-induced vomiting; laxative and diuretic abuse

Associated Symptoms. Excessive interest in food-related activities (other than eating), obsessive-compulsive symptoms, depressive symptoms.

Course. Some individuals recover after a single episode, and others develop a waxing-and-waning course.

Outcome. Long-term mortality rate of individuals hospitalized for anorexia nervosa is 10%, resulting from the effects of starvation and purging or suicide.

Physical Examination. Signs of malnutrition include emaciation, hypotension, bradycardia, lanugo (i.e., fine hair on the trunk), and peripheral edema. Signs of purging include eroded dental enamel caused by emesis and scarred or scratched hands from self-gagging to induce emesis. There may be evidence of general medical conditions caused by abnormal diets, starvation, and purging.

Diagnostic Tests

- **Signs of malnutrition:** normochromic, normocytic anemia, elevated liver enzymes, abnormal electrolytes, low estrogen and testosterone levels, sinus bradycardia, reduced brain mass, and abnormal EEG
- **Signs of purging:** metabolic alkalosis, hypochloremia, and hypokalemia caused by emesis; metabolic acidosis caused by laxative abuse

Treatment. Initial treatment should be correction of significant physiologic consequences of starvation with hospitalization if necessary. Behavioral therapy should be initiated, with rewards or punishments based on absolute weight, not on eating behaviors. Family therapy designed to reduce conflicts about control by parents is often helpful. Antidepressants may play a limited role in treatment when comorbid depression is present.

Differential Diagnosis. Major rule-outs are bulimia nervosa, general medical conditions that cause weight loss, major depressive disorder, schizophrenia, OCD, and body dysmorphic disorder.

BULIMIA NERVOSA AND BINGE EATING DISORDER

Definition. Characterized by frequent binge-eating and a self-image that is unduly influenced by weight. Types:

- **Bulimia nervosa:** binge-eating and purging behavior
- **Binge-eating disorder:** binge-eating but no purging behavior

Risk Factors/Etiology. Psychologic conflict regarding guilt, helplessness, self-control, and body image may predispose. Biologic factors are suggested by frequent association with mood disorders.

Prevalence. 2% in young adult females. Occurs at a 1:9 male-to-female ratio

Onset. Usually during late adolescence or early adulthood and often follows a period of dieting

Course. May be chronic or intermittent

Outcome. 70% of cases have remitted after 10 years. Co-occurring substance abuse is associated with a poorer prognosis

Key Symptoms

- **Recurrent episodes of binge-eating in both binge-eating disorder and bulemia.** Obsession with dieting but followed by binge-eating of high-calorie foods. Binges are associated with emotional stress and followed by feelings of guilt, self-recrimination, and compensatory behaviors.
- **Recurrent, inappropriate compensatory behavior in bulemia but not in binge-eating disorder.** After a binge, attempts to prevent weight gain through self-induced vomiting, misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.

- **Self-evaluation is unduly influenced by body shape and weight in bulemia.** Self-castigation for mild weight gain or binges. Attempts to conceal binge-eating or purging, or lies about behaviors.

Associated Problems. Depressive symptoms, substance abuse, and impulsivity (e.g., kleptomania)

Comorbid Disorders. Borderline personality disorder present in about 50%

Physical Examination. Evidence of purging

Diagnostic Tests. Evidence of laxative or diuretic abuse

Treatment. Cognitive and behavioral therapy are major treatment. Psychodynamic psychotherapies are useful for accompanying borderline personality traits. Antidepressant medications, particularly SSRIs, are usually employed.

Differential Diagnosis. Major rule-outs are anorexia nervosa, binge-eating/purging, major depressive disorder with atypical features, and borderline personality disorder.

Practice Question

A 19-year-old woman is hospitalized for dehydration caused by severe, laxative-induced diarrhea. She is depressed about the recent breakup of a romantic relationship. She admits that she uses laxatives because she has been binge-eating frequently and is worried about gaining weight. Although the woman has BMI 16, she believes that she is overweight.

Which of the following is the most likely diagnosis?

(A) Anorexia nervosa
(B) Brief psychotic disorder
(C) Bulimia nervosa
(D) Delusional disorder, somatic type
(E) Major depressive disorder

Answer: A. The patient presents with low body weight, a distorted body image, a fear of obesity, and amenorrhea, all of which strongly suggest anorexia nervosa. Bingeing and purging behavior is commonly present with this disorder. Because this individual has the essential features of anorexia nervosa, the diagnosis of bulimia nervosa is not made. Because the woman shows no evidence of delusions, brief psychotic disorder or delusional disorder are unlikely diagnoses. Although depression commonly accompanies eating disorders, it does not appear to be the primary problem in this woman's case.

Personality Disorders 14

Learning Objectives

- List the most common personality criteria and their diagnostic criteria

PERSONALITY DISORDERS

Personality disorders (PDs) are characterized by personality patterns that are pervasive, inflexible, and maladaptive. There are 3 clusters:

Cluster A: Peculiar thought processes, inappropriate affect

Cluster B: Mood lability, dissociative symptoms, preoccupation with rejection

Cluster C: Anxiety, preoccupation with criticism or rigidity

Risk Factors/Etiology. PDs are the product of the interaction of inborn temperament and subsequent developmental environment. Risk factors include innate temperamental difficulties, such as irritability; adverse environmental events, such as child neglect or abuse; and personality disorders in parents.

Prevalence. All are relatively common. More males have antisocial and narcissistic PDs, more females have borderline and histrionic PDs.

Onset. Usually not diagnosed until late adolescence or early adulthood

Course. Usually very chronic over decades without treatment. Symptoms of paranoid, schizoid, and narcissistic PD often worsen with age; symptoms of antisocial and borderline PD often ameliorate.

Key Symptoms. Long pattern of difficult interpersonal relationships, problems adapting to stress, failure to achieve goals, chronic unhappiness, low self-esteem

Associated Diagnoses. Mood disorders

Treatment. Psychotherapy is the mainstay of treatment. Intensive and long-term psychodynamic and cognitive therapy are treatments of choice for most PDs. Use of mood stabilizers and antidepressants is sometimes useful for Cluster B PDs.

Differential Diagnosis. Major rule-outs are mood disorders, personality change due to a general medical condition, and adjustment disorders.

Cluster A

Paranoid PD: Distrust and suspiciousness. Individuals are mistrustful and suspicious of the motivations and actions of others and are often secretive and isolated. They are emotionally cold and odd.

> A 57-year-old man living in a condominium complex constantly accuses his neighbors of plotting to avoid payment of their share of maintenance. He writes angry letters to other owners and has initiated several lawsuits. He lives alone and does not socialize.

Schizoid PD: Detachment and restricted emotionality. Individuals are emotionally distant. They are disinterested in others and indifferent to praise or criticism. Associated features include social drifting and dysphoria.

> A 24-year-old man lives alone and works nights as a security guard. He ignores invitations from coworkers to socialize and has no outside interests.

Schizotypal PD: Discomfort with social relationships; thought distortion; eccentricity. Individuals are socially isolated and uncomfortable with others. Unlike Schizoid PD, they have peculiar patterns of thinking, including ideas of reference and persecution, odd preoccupations, and odd speech and affect. DSM-5 includes this PD in both psychotic disorders and personality disorders.

> A 30-year-old man is completely preoccupied with the study and the brewing of herbal teas. He associates many peculiar powers with such infusions and says that plants bring him extra luck. He spends all of his time alone, often taking solitary walks in the wilderness for days at a time, collecting plants for teas. He has no history of disorganized behavior. At times he believes that songs on the radio are about his life.

Cluster B

Histrionic PD. Usually characterized by colorful, exaggerated behavior and excitable, shallow expression of emotions; uses physical appearance to draw attention to self; sexually seductive; and is uncomfortable in situations where he or she is not the center of attention.

> A 30-year-old woman presents to the doctor's office dressed in a sexually seductive manner and insists that the doctor comment on her appearance. When the doctor refuses to do so, she becomes upset.

Borderline PD. Usually characterized by an unstable affect, mood swings, marked impulsivity, unstable relationships, recurrent suicidal behaviors, chronic feelings of emptiness or boredom, identity disturbance, and inappropriate anger. If stressed, may become psychotic. Main defense mechanism is splitting.

> A 20-year-old nurse was recently admitted after reporting auditory hallucinations, which have occurred during the last few days. She reports marriage difficulties and believes her husband is to blame for the problem. She has several scars on her wrists and has a history of substance abuse.

Antisocial PD. Usually characterized by continuous antisocial or criminal acts, inability to conform to social rules, impulsivity, disregard for the rights of others, aggressiveness, lack of remorse, and deceitfulness. These have occurred since the age of 15, and the individual is at least 18 years of age.

> A 22-year-old man was recently arrested after he set his mother's house on fire. He has had numerous problems with the law, which started at an early age when he was sent to a juvenile detention center for his behavior at both home and school. He lacks remorse for setting the fire and expresses a desire that his mother would have died in the fire.

Narcissistic PD. Usually characterized by a sense of self-importance, grandiosity, and preoccupation with fantasies of success. This person believes s/he is special, requires excessive admiration, reacts with rage when criticized, lacks empathy, is envious of others, and is interpersonally exploitative.

> A famous actor is outraged when a director questions his acting abilities during rehearsal for a play. The actor responds by walking off the stage and not returning to the stage unless the director apologizes publicly for her behavior.

Cluster C

Avoidant PD. Individuals have social inhibition, feelings of inadequacy, and hypersensitivity to criticism. They shy away from work or social relationships because of fears of rejection that are based on feelings of inadequacy. They feel lonely and substandard and are preoccupied with rejection.

> A 43-year-old man dreads an upcoming company holiday party because he believes that he is incapable of engaging in social conversation or dancing. He believes that he will become an object of pity or ridicule if he attempts such things. He anticipates yet another lonely holiday.

Dependent PD: Submissive and clinging behavior related to a need to be taken care of. Individuals are consumed with the need to be taken care of. They have clinging behavior and worry unrealistically about abandonment. They feel inadequate and helpless and avoid disagreements with others. They usually focus dependency on a family member or spouse and desperately seek a substitute should this person become unavailable. Associated features include self-doubt, excessive humility, poor independent functioning, mood disorders, anxiety disorders, adjustment disorder, and other PDs.

> A 26-year-old man is brought into the emergency room after sustaining severe rectal lacerations during a sadistic sexual episode with his partner. The patient is extremely concerned that the police not be informed because he doesn't want to upset his partner and cause the partner to leave.

Obsessive-Compulsive PD. Individuals are preoccupied with orderliness, perfectionism, and control. They are often consumed by the details of everything and lose their sense of overall goals. They are strict and perfectionistic, overconscientious, and inflexible. They may be obsessed with work and productivity and are hesitant to delegate tasks to others. Other traits include being miserly and unable to give up possessions. This PD should not be confused with OCD, a separate disorder. Associated features include indecisiveness, dysphoria, anger, social inhibition, and difficult interpersonal relationships.

> A 37-year-old woman seeks psychotherapy as a result of an impending divorce. She states that her demands to keep the house spotless, to maintain an extremely detailed and fixed work and recreational schedule, and to observe rigid dietary habits have driven her spouse away.

Normal Sleep and Sleep Disorders

15

Learning Objectives

- Identify the normal sleep cycles
- Describe EEG, ENG, and physiologic phenomenon associated with each stage of sleep
- Categorize different sleep disorders and describe what is known about their causes

NORMAL SLEEP

Sleep is divided into 2 stages: nonrapid eye movement (NREM) and rapid eye movement (REM). There are numerous differences between them.

NREM

NREM is a state of sleep characterized by slowing of the EEG rhythms, high muscle tone, absence of eye movements, and thoughtlike mental activity. The brain is inactive while the body is active. NREM is made up of 4 stages:

Table I-15-1. NREM

Stage	EEG Findings	Distribution
Stage 1	Disappearance of alpha wave and appearance of theta wave	5%
Stage 2	k complexes and sleep spindles	45%
Stage 3	Appearance of delta wave	12%
Stage 4	Continuation of delta wave	13%

REM

REM is a stage of sleep characterized by aroused EEG patterns, sexual arousal, saccadic eye movements, generalized muscular atony (except middle-ear and eye muscles), and dreams. The brain is active and the body is inactive.

Table I-15-2. REM

Stage	EEG Findings	Distribution
REM	Bursts of sawtooth waves	25%

Sleep Facts

Table I-15-3. Sleep Facts (Stage 2–REM)

Stage	Fact(s)
Stage 2	Longest of all the sleep stages
Stages 3 and 4	Also called slow wave or delta sleep Hardest to arouse Tends to vanish in the elderly
REM	Easiest to arouse Lengthens in time as night progresses Increased during the second half of the night

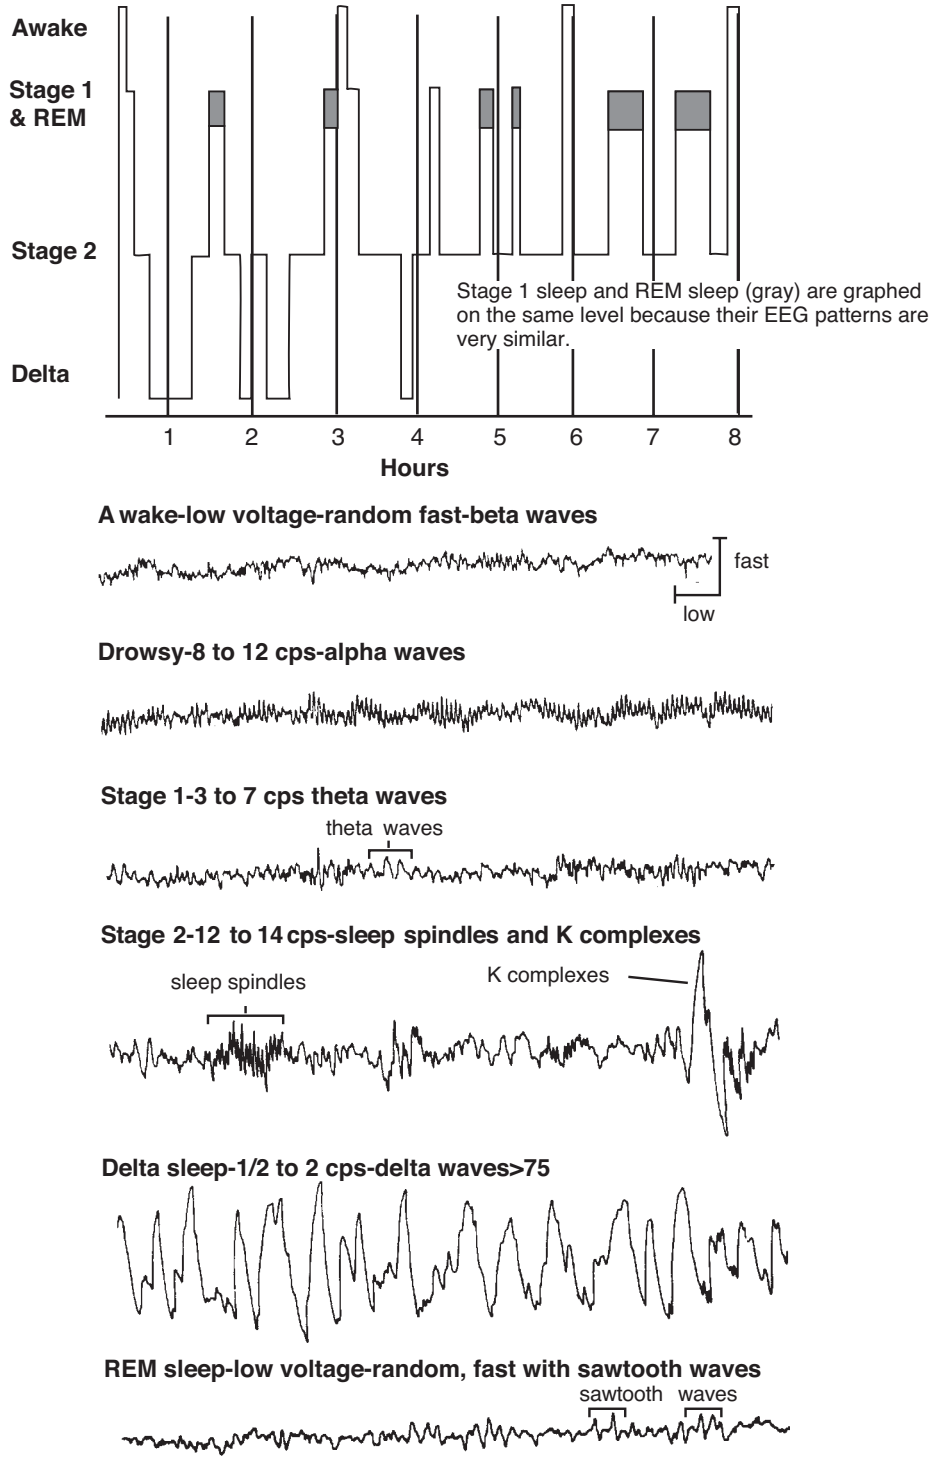

Figure I-15-1. Sleep Architecture Diagram Showing Stages of Sleep in Sequence

Sleep Latency. The time needed before you actually fall asleep. Typically less than 15 minutes in most individuals; however, may be abnormal in many disorders, such as insomnia, etc.

REM Latency. The period lasting from the moment you fall asleep to the first REM period. Lasts approximately 90 minutes in most individuals. However, several disorders will shorten REM latency; these disorders include depression and narcolepsy.

Characteristics of Sleep from Infancy to Old Age

- Total sleep time decreases.
- REM percentage decreases.
- Stages 3 and 4 tend to vanish.

Neurotransmitters of Sleep

- **Serotonin:** Increased during sleep; initiates sleep
- **Acetylcholine:** Increased during sleep; linked to REM sleep
- **Norepinephrine:** Decreased during sleep; linked to REM sleep
- **Dopamine:** Increased toward end of sleep; linked to arousal and wakefulness

Chemical Effects on Sleep

- **Tryptophan:** Increases total sleep time
- **Dopamine agonists:** Produce arousal
- **Dopamine antagonists:** Decrease arousal, thus produce sleep
- **Benzodiazepines:** Suppress Stage 4 and, when used chronically, increase sleep latency
- **Alcohol intoxication:** Suppresses REM
- **Barbiturate intoxication:** Suppresses REM
- **Alcohol withdrawal:** REM rebound
- **Barbiturate withdrawal:** REM rebound
- **Major depression:** Shortened REM latency, increased REM time, suppression of delta, multiple awakenings, and early morning awakening

SLEEP DISORDERS

Narcolepsy

A 35-year-old man was recently hospitalized for the tenth time after he crashed his car into a post. When questioned, he did not remember the cause of the accident and had just had his license suspended. His friends reported occasions when he fell asleep during dinner and during conversations with them.

Definition. A disorder characterized by excessive daytime sleepiness and abnormalities of REM sleep for a period of greater than 3 months. REM sleep occurs in less than 10 minutes. Patients feel refreshed upon awakening.

Physical and Psychiatric Presenting Symptoms

- **Sleep attacks:** Most common symptom
- **Cataplexy:** Pathognomonic sign, consisting of a sudden loss of muscle tone which may have been precipitated by a loud noise or intense emotion. If short episode, the patient remains awake.
- **Hypnagogic and hypnopompic hallucinations:** Hallucinations that occur as the patient is going to sleep and is waking up from sleep, respectively.
- **Sleep paralysis:** Most often occurs during awakening, when the patient is awake but unable to move.
- Report falling asleep quickly at night

Treatment. Forced naps at a regular time of day is usually the treatment of choice. When medications are given, psychostimulants are preferred. If cataplexy is present, antidepressants such as TCAs are preferred. Gamma-hydroxybutyrate (GHB) is also used for narcolepsy–cataplexy by improving the quality of nighttime sleep.

Sleep Apnea

An overweight man reports having difficulties in his marriage because of his snoring at night. During the day, he reports feeling tired despite sleeping for 8 hours at night.

Definition. A disorder characterized by the cessation of airflow at the nose or mouth during sleep. These apneic episodes usually last longer than 10 seconds each. Characterized by a loud snore followed by a heavy pause. Considered pathologic if the patient has more than 5 episodes an hour or more than 30 episodes during the night. In severe cases, patients may experience more than 300 apneic episodes during the night.

Physical and Psychiatric Presenting Symptoms

- Usually seen in obese, middle-aged males
- Sometimes associated with depression, mood changes, and daytime sleepiness
- Spouses typically complain of partner's snoring, and of partner's restlessness during the night
- Complain of dry mouth in the morning
- May have headaches in the morning
- Complain of being tired during the day
- May develop arrhythmias, hypoxemia, pulmonary hypertension, and sudden death

Types of Sleep Apnea

- **Obstructive:** Muscle atonia in oropharynx; nasal, tongue, or tonsil obstruction
- **Central:** Lack of respiratory effort
- **Mixed:** Central at first, but prolonged due to collapse of the airway

Treatment. Continuous positive nasal airway pressure is the treatment of choice. Other treatment includes weight loss, surgery. Sleeping on one's side instead of one's back will help keep the airways open.

Insomnia

While studying over the past week for an important exam, Michael, a third-year medical student, has been unable to sleep for the past several days. At night, he lies awake and imagines himself doing poorly on the exam and failing medical school. During the day, he is tired and frequently falls asleep during his classes.

Definition. A disorder characterized by difficulties in initiating or maintaining sleep.

Risk Factors/Epidemiology. Typically associated with some form of anxiety or anticipatory anxiety. Many patients have underlying psychiatric disorders, such as depression, etc. If due to a psychiatric disorder, seen more frequently in women. Other conditions include PTSD, OCD, and eating disorders.

Physical and Psychiatric Presenting Symptoms

- Predominant complaint is difficulty initiating or maintaining sleep
- Affects the patient's level of functioning
- Frequent yawning and tiredness during the day

Treatment. Consider good sleep hygiene techniques, such as arising at same time of the day, avoiding daytime naps, avoiding evening stimulation, discontinuing CNS-acting drugs, taking hot baths near bedtime, eating meals at regular times, using relaxation techniques and maintaining comfortable sleeping conditions. If these do not work, consider behavioral modification techniques such as stimulus control. If medications are to be used, consider zolpidem, eszopiclone, or zaleplon.

Differential Diagnosis

- **Medical:** Pain, CNS lesions, endocrine diseases, aging, brain-stem lesions, alcohol, diet, medications
- **Psychiatric:** Anxiety, tension, depression, and environmental changes, other sleep disorders

Parasomnias

Table I-15-4. Parasomnias

Disorder	Sleep Stage	Characteristics	Treatment
Nightmares (dream anxiety disorder)	REM	• Memory of the event upon awakening • Increases during times of stress • Reported by 50% of the population	• Usually none indicated, but may use REM suppressants such as TCAs
Night terror (sleep terror disorder)	Stages 3 and 4	• Awakened by scream or intense anxiety • No memory of the event the following day • Seen more frequently in children • More common in boys • Runs in families	• Treatment rarely required • If medication is needed, consider benzodiazepines
Sleeptalking	All stages of sleep	• Common in children • Usually involves a few words • May accompany night terrors and sleepwalking	• No treatment is necessary
Sleepwalking	Stage 3 and 4	• Sequence of behaviors without full consciousness • May perform perseverative behaviors • Usually terminates in awakening followed by confusion • May return to sleep without any memory of the event • Begins at a young age • More common in boys • May find neurologic condition • Sleep deprivation may exacerbate	• Need to assure patient safety • Use drugs to suppress Stages 3 and 4, such as benzodiazepines

Practice Questions

1. An overweight man of average height presents to his doctor's office complaining of feeling tired during the day. He has missed several days of work due to this problem. Which of the following is the most likely diagnosis?

   (A) Narcolepsy
   (B) Insomnia
   (C) Sleep apnea
   (D) Normal sleep pattern
   (E) Hypersomnia

2. Which of the following is the most likely explanation for a young man suddenly falling down but not losing consciousness?

   (A) Syncope
   (B) Cataplexy
   (C) Sleep paralysis
   (D) Medication toxicity
   (E) Hypotensive episode

3. Which of the following is the treatment of choice for insomnia?

   (A) Long-term use of benzodiazepines
   (B) Behavioral techniques
   (C) Drinking coffee before bedtime
   (D) Regular exercises before bedtime
   (E) Frequent naps during the day

1. **Answer: C.** Patients with sleep apnea have multiple episodes of waking up in the middle of the night. Therefore, they are tired during the day. These patients are typically unaware that they wake in the middle of the night.

2. **Answer: B.** Cataplexy is the sudden loss of muscle tone without loss of consciousness. It is differentiated from syncope in that syncope typically includes loss of consciousness. Patients with narcolepsy are usually young and do not have any blood pressure abnormalities.

3. **Answer: B.** Although benzodiazepines are regularly used for the treatment of insomnia, the best treatment includes behavioral techniques such as stimulus control. The patient leaves the bed whenever he is unable to fall asleep, therefore conditioning himself that the bed is only used for sleeping. Choices C, D, and E will tend to cause insomnia.

Human Sexuality 16

Learning Objectives

- ❑ Present epidemiologic information about masturbation and homosexuality
- ❑ List the types of sexual dysfunction and differentiating factors
- ❑ Describe paraphilic disorder and gender dysphoria

SEXUALITY

Sexual identity is based on the person's sexual characteristics, such as external and internal genitalia, hormonal characteristics, and secondary sexual characteristics. **Gender identity** is based on the person's sense of maleness or femaleness and is established by age 3. **Gender role** is based on the external behavioral patterns that reflect the person's inner sense of gender identity. **Sexual orientation** is based on the person's choice of a love object: heterosexual (opposite sex), homosexual (same sex), bisexual (both sexes), or asexual (no sex).

MASTURBATION

Masturbation is a normal precursor of object-related sexual behavior. All men and women masturbate.

- Genital self-stimulation begins in early childhood
- As puberty arrives, sexual interest peaks and masturbation increases.
- Adolescents and adults typically have sexual fantasies while masturbating.
- Commonly seen among adolescents, married couples, and the elderly
- Excessive only if it interferes with daily functioning

HOMOSEXUALITY

Homosexuality was removed from the DSM in 1980 as a mental illness. It is considered a variant of human sexuality, not a pathologic disorder.

- Most homosexuals report feelings toward same sex individuals since adolescence.
- Recent studies indicate it may be due to genetic and biologic causes.
- Greater incidence among monozygotic versus dizygotic twins
- No difference in the sexual practices from those exhibited by heterosexuals.
- Male–male relationships may be less stable than female–female relationships.

- Equal incidence of mental illness when compared with heterosexuals.
- Exceptions (normal during adolescence):
  - Visual comparison of genitalia
  - Mutual masturbation
  - Group exhibitionism
  - Handholding, kissing, etc.

SEXUAL DYSFUNCTIONS

A group of disorders related to a particular phase of the sexual response cycle. These disorders can be psychologic, biologic, or both, and include, desire, arousal, orgasm, and pain.

Table I-16-1. Sexual Dysfunctions

Phase	Characteristics	Disorder	Treatment
Desire	Focuses on the patient's drives, motivation, and desires	**Hypoactive sexual desire:** patients have a decrease or absence of sexual fantasies, desires, etc. **Sexual aversion:** a complete aversion to all sexual contact	Address issues with patient, such as feelings of guilt, poor self-esteem, homosexual impulses, etc. Couples therapy may be indicated if due to marital conflict.
Arousal	Consists of a sense of sexual pleasure with accompanying physiologic changes	**Female sexual arousal:** persistent failure to achieve or maintain adequate lubrication during the sexual act **Impotence:** persistent or recurrent inability to attain or maintain adequate erection until completion of the sexual act	Address issues of guilt, anxiety, and fear. Evaluate for use of medications that cause vaginal dryness, such as antihistamines or anticholinergics. Instruct in relaxation techniques. Must rule out if organic versus psychological. Consider plethysmography or postage stamp test.
Orgasm	Physiologic state in which sexual tension is released and contractions are produced in various organs.	**Female orgasmic disorder and delayed ejaculation:** recurrent or persistent inability to achieve an orgasm either through masturbation or sexual intercourse **Premature ejaculation:** Ejaculation before the man wishes to do so, before penetration, or just after penetration	Address issues of guilt, fear of impregnation, etc. Treatment includes use of vibrators, education, and fantasy. Consider behavioral techniques such as squeeze and stop-and-go. Address issues of anxiety about the sexual act. Consider the use of SSRIs to delay ejaculation.
Pain	Subjective sense of pain associated with the sexual act. Most likely due to dynamic factors.	**Genito-pelvic pain disorder:** Pain associated with sexual intercourse in either male or female. Not diagnosed when organic cause has been found or if due to lack of vaginal lubrication. **Penetration disorder:** involuntary constriction of the outer one-third of the vagina that interferes with the sexual act	Help the woman deal with issues of anxiety and tension about the sexual act. Behavioral techniques, such as the use of dilators and relaxation. Address issues of fear of impregnation, strict upbringing, religion, etc.

PARAPHILIC DISORDER

A 20-year-old man was caught outside his neighbor's window, looking in as she disrobed. Before his arrest, he would wander the subway stations and rub himself up against women as well as expose himself to women who were nearby. All of these activities produced sexual pleasure in the patient.

Definition. A group of disorders that is recurrent and sexually arousing. Usually focus on humiliation and/or suffering and the use of nonliving objects and involve nonconsenting partners. Typically occur for >6 months and are usually distressing and cause impairment in patient's level of functioning.

Risk Factors/ Epidemiology. Affects men more than women. Peak incidence is age 15–25. Tend to have other paraphilias, and as the patient ages, the frequency decreases.

Physical and Psychiatric Presenting Symptoms

- Sexual activity is ritualistic.
- Fantasy is typically fixed and shows very little variation.
- Intense urge to carry out the fantasy

Treatment. Individual psychotherapy is indicated to help the patient understand the reasons why the paraphilia developed. Patient also becomes aware of daily activities and how they are related to the paraphilic behavior. Behavioral techniques, such as aversive conditioning, may be indicated in some situations. Pharmacotherapy consists of antiandrogens or SSRIs to help reduce patient's sexual drive.

Differential Diagnosis. Must distinguish between experimentation and actual paraphilias.

Types of Paraphilic Disorders

- **Exhibitionism:** recurrent urge to expose oneself to strangers
- **Fetishism:** involves the use of nonliving objects usually associated with the human body
- **Frotteurism:** recurrent urge or behavior involving touching or rubbing against a nonconsenting partner
- **Pedophilia:** recurrent urges or arousal toward prepubescent children. Most common paraphilia.
- **Voyeurism:** recurrent urges or behaviors involving the act of observing an unsuspecting person who is engaging in sexual activity, disrobing, etc. Earliest paraphilia to develop.
- **Masochism:** recurrent urge or behavior involving the act of humiliation
- **Sadism:** recurrent urge or behavior involving acts in which physical or psychologic suffering of a victim is exciting to the patient.
- **Transvestic fetishism:** recurrent urge or behavior involving cross-dressing. Usually found in heterosexual men.

GENDER DYSPHORIA

Billy, a 5-year-old boy, was found in his parent's bedroom wearing his mother's clothes. He has been observed going to the bathroom to urinate while sitting on the toilet as well as playing with dolls instead of his trucks and guns. He prefers to wear dresses and hates being a boy.

Definition. Also called gender identity dysphoria. A disorder characterized by a persistent discomfort and sense of inappropriateness regarding the patient's assigned sex.

Risk Factors/Epidemiology. Seen more frequently in men than in women. Cause is unknown. Many believe it may be due to biologic reasons, such as hormones, etc.

Physical and Psychiatric Presenting Symptoms

- Children will have preference for friends of the opposite sex.
- Preoccupied with wearing opposite gender's clothes
- Refuse to urinate sitting down, if a girl, or standing up, if a boy
- Believe they were born with the wrong body
- Routinely request medications or surgery to change their physical appearance
- Women may bind their breasts, have mastectomies, take testosterone to deepen the voice.
- Men may have electrolysis to remove body hair and take estrogens to change the voice, and may have surgeries to remove the penis and create a vagina.

Practice Questions

1. What is the treatment of choice for premature ejaculation?

   (A) Plethysmography
   (B) Dilators
   (C) Squeeze technique
   (D) Postage stamp
   (E) Aversive conditioning

2. What is the most common cause of erectile dysfunction due to a medical condition?

   (A) Pancreatitis
   (B) Diabetes
   (C) Cirrhosis
   (D) Myocardial infarction
   (E) UTI

1. **Answer: C.** The treatment of premature ejaculation typically consists of behavioral techniques aimed at prolonging the time before ejaculation occurs. These include the squeeze-and-go technique. Choices A and D are for the diagnosis of erectile dysfunction. Choice B is for the treatment of pain/penetration disorder.
2. **Answer: B.** Diabetes has been known to be a common cause of erectile dysfunction. Alcohol has been proven to be a common cause of erectile dysfunction in men of all ages.

Psychopharmacology 17

Learning Objectives

- ❑ Describe the classes of drug, mechanism of action, and common adverse effects of typical antipsychotic, atypical antipsychotic, antidepressant, mood-stabilizing, and anxiolytic medications
- ❑ Describe the indications and procedural steps for electroconvulsive therapy

ANTIPSYCHOTIC MEDICATION

Antipsychotic medications (APMs) are used to treat manifestations of psychosis and other psychiatric disorders. The precise mechanism of action is unknown; however, APMs block several populations of dopamine (D2, D4) receptors in the brain. The newer APMs also block some serotonin receptors (5HT), a property that may be associated with increased efficacy.

APMs also variably block central and peripheral cholinergic, histaminic, and alpha-adrenergic receptors.

There are 2 types of APMs:

- **Typical:** work mostly on dopamine receptors, treat the positive symptoms (hallucinations and delusions) and have many side effects (haloperidol, fluphenazine, chlorpromazine, etc.)
- **Atypical:** work mostly on dopamine and serotonin receptors, treat both positive and negative symptoms (flat affect, poor grooming, social withdrawal, anhedonia, etc), and have fewer side effects; always used as first-line agents (risperidone, olanzapine, etc.)

Side Effects

There are several **general groups** of side effects.

Sedation: due to antihistaminic activity

Hypotension: effect is due to alpha-adrenergic blockade and is most common with low-potency APMs.

Anticholinergic Symptoms: dry mouth, blurred vision, urinary hesitancy, constipation, bradycardia, confusion, and delirium

Endocrine Effects: gynecomastia, galactorrhea, and amenorrhea

Dermal and Ocular Syndromes: photosensitivity, abnormal pigmentation, cataracts

Other Effects: cardiac conduction abnormalities (especially with thioridazine), agranulocytosis with clozapine

There are several groups of side effects having to do with **movement**.

Acute Dystonia. (Dystonic Reaction).

- Presentation: Spasms of various muscle groups
- Can be dramatic and frightening to patient
- Can be a major contributing factor to subsequent noncompliance with treatment
- Young men may be at higher risk, seen in 10% patients.
- Treatment: anticholinergics, such as benztropine, diphenhydramine, or trihexyphenidyl
- Can occur within hours after treatment

Akathisia

- Presenting Symptoms: Motor restlessness, "ants in your pants"
- Differential Diagnosis: Often mistaken for anxiety and agitation
- Treatment: lowering the dose, adding benzodiazepines or beta-blockers, switching to other antipsychotic medication
- Can occur several weeks after treatment

Tardive Dyskinesia (TD).

- Characterized by choreoathetosis and other involuntary movements
- Movements often occur first in the tongue or fingers and later involve the trunk.
- Etiology may be a form of "chemical denervation hypersensitivity," which is caused by chronic dopamine blockade in the basal ganglia.
- Patients who take high doses of older antipsychotic medication for long periods of time are at highest risk, and movements gradually worsen with continued use.
- Treatment: Use newer antipsychotic medications.
- Seen more frequently in elderly females
- Can occur after 3–6 months after treatment

The **primary adverse effect** of antipsychotic medication use is neuroleptic malignant syndrome. It is a fairly rare and potentially life-threatening condition characterized by muscular rigidity, hyperthermia, autonomic instability, and delirium. CPK will be elevated.

- Usually associated with high dosages of high-potency antipsychotic medication.
- Treatment: Immediate discontinuation of the medication and physiologic supportive measures; dantrolene or bromocriptine may be used.

ATYPICAL ANTIPSYCHOTIC MEDICATIONS

- Clozapine: gold standard for the treatment of schizophrenia; not used as first-line agent; may cause agranulocytosis (<1%) so monitoring of WBC is essential
- Risperidone: increased risk of movement disorders and elevation of prolactin
- Olanzapine: increased risk of weight gain, metabolic syndrome, diabetes, etc.
- Quetiapine: lowest risk of movement disorders

- Paliperidone: active metabolite of risperidone; fewer side effects than risperidone
- Ziprasidone: prolongation of Qt interval
- Aripiprazole: partial dopamine agonist at low doses, may be used as adjunct for depression
- Asenapine: sedation, akathisia
- Iloperidone: hypotension, dizziness, somnolence
- Lurasidone: somnolence, akathisia, weight gain

How to treat psychotic symptoms:

- First-line: always use atypical agents
- Emergency room: use short-acting intramuscular agent such as haloperidol, fluphenazine, olanzapine, or ziprasidone
- Non-adherant patient: use long-acting antipsychotic medication such as haloperidol, fluphenazine, risperidone, paliperidone, or olanzapine
- Last resort: clozapine
- All meds ineffective: may consider ECT

ANTIDEPRESSANT MEDICATIONS (ADs)

Clinical Guidelines

- Overall efficacy for treatment of major depressive disorder is around 70%.
- Newer ADs should be considered first because of better safety profile.
- Difficult to predict which patient will respond to which antidepressant, so trials of several antidepressants may be necessary before an effective one is found.
- Individual antidepressants differ greatly in their side-effect profiles and must be matched to patient preference and ability to tolerate.
- Older antidepressants are extremely dangerous when an overdose is ingested. When used to treat individuals with depressive symptoms, clinicians should generally prescribe in small quantities and only after determining the absence of suicidal intent.
- If no response to treatment after 4 weeks, or if patient cannot tolerate current antidepressant, switch to another.
- Treatment should continue for 6 months to 1 yr after favorable response.

Untoward Effects

- **Sedation:** due to histamine blockade
- **Hypotension:** due to alpha blockade
- **Anticholinergic effects:** dry mouth, blurry vision, urinary retention, confusion
- **Cardiac:** conduction abnormalities most marked with TCAs
- **Seizures:** bupropion (Wellbutrin)
- **Sexual dysfunction:** anorgasmia and decreased libido with SSRIs; priapism with trazodone (Desyrel)

SSRIs

Inhibit reuptake of serotonin

- **Types:** Fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft), fluvoxamine. (Luvox), citalopram (Celexa), escitalopram (Lexapro)
- Reduced number of serious side effects
- Simple dosing schedules
- Significant incidence of agitation, nausea, vomiting, headache, diarrhea, and sexual dysfunction

'Hybrid' antidepressants

- Venlafaxine: inhibit reuptake of NE and S, used for depression and anxiety, may cause hypertension, blurry vision, diaphoresis, etc.
- Desvenlafaxine: inhibit reuptake of NE and S, active metabolite of venlafaxine therefore fewer side effects
- Duloxetine: inhibit reuptake of NE and S, approved for depression and neuropathic pain
- Bupropion: inhibits reuptake of NE and dopamine, approved for depression and smoking cessation; may cause seizures so avoid using in patients with eating disorders, alcohol withdrawal seizures, or seizure disorders
- Trazodone: S agonist and reuptake inhibitor, approved for depression and insomnia; may cause priapism (prolonged and painful erection)
- Mirtazapine: classified as tetracyclic antidepressant, approved for depression and insomnia; weight gain is main side effect

TCAs

- Inhibit reuptake of NE, S, and dopamine
- Include nortriptyline, amitriptyline, imipramine, desipramine, clomipramine, etc.
- Adverse effects: (especially tertiary TCAs) significant sedation, orthostatic hypotension, and anticholinergic effects. They are the most dangerous antidepressants in overdose.

MAOIs

- Inhibit MAO-A and/or MAO-B in the CNS and have antidepressant efficacy
- Differ by the type of inhibition (i.e., reversible or irreversible), the severity of adverse effects, and the specificity of inhibition (MAO-A or -B)
- Include phenelzine, tranylcypromine, and isocarboxazid
- **Selegiline:** selective inhibitor of MAO-B; currently approved only for treatment of Parkinson's disease
- **Indications:** Second-line treatment for major depressive disorder, depressive disorders with atypical features, and some anxiety disorders.
- **Hypertensive crisis:** may occur with tyramine-rich foods or if certain other medications are ingested, including nasal decongestants, antiasthmatic medications, and amphetamines. Avoid red wine, aged cheese, and chocolate.
- **Adverse effects:** sedation, weight gain, orthostatic hypotension, liver toxicity (with hydrazine MAOIs), and sexual dysfunction.

ELECTROCONVULSIVE THERAPY (ECT)

Indications

- Major depressive episodes that have not responded to antidepressant medication or mood stabilizers
- Major depressive episodes with high risk for immediate suicide
- Major depressive episodes in patients with contraindications to using antidepressant medication
- Major depressive episodes in patients who have responded well to ECT in the past

Untoward effects and contraindications

- Transient memory disturbance: increases in severity over the course of ECT and then gradually resolves over several weeks
- Complications of associated anesthesia and induced paralysis
- Transiently increased intracranial pressure. Therefore, the presence of space-occupying intracranial lesions requires extreme caution.

MOOD-STABILIZING MEDICATIONS

Lithium

Indications

- Bipolar and schizoaffective disorders: First-line medication for treatment and prophylaxis of mood episodes
- Adjunctive treatment of major depressive disorder: May augment responsiveness to antidepressant medications in some patients

Untoward Effects

- Dose-related: Tremor, gastrointestinal (GI) distress, headache
- Dermatologic problems: acne; interferes with patient compliance
- Weight gain: may interfere with patient compliance
- Cardiac conduction: electrocardiogram (ECG) changes usually benign
- Hypothyroidism: 5% of patients develop thyroid problems
- Leukocytosis: usually occurs and seems to be benign
- Polyuria: diabetes insipidus is common and may be troublesome to patients
- Teratogenicity: associated with cardiac abnormalities; contraindicated in first trimester, Ebstein's anomaly (tricuspid valve)
- Nephrotoxic

Toxicity Management

- Keep plasma levels <1.5 mEq/L; optimal 1.0 mEq/L
- Dehydration and hyponatremia predispose to lithium toxicity by increasing serum lithium levels.
- Tremor at therapeutic levels may respond to decreased dosage.
- Lithium levels may increase with ACE inhibitors, NSAIDs, loop and thiazide diuretics

Divalproex

- Treatment of choice for rapid-cycling bipolar disorder, or when lithium is ineffective, impractical, or contraindicated.
- Increasingly popular in emergency settings, may give loading dose
- Time course of treatment response is similar to lithium.
- Efficacy for prophylaxis is unclear.
- Untoward effects: sedation, cognitive impairment, tremor, GI distress, hepatotoxicity, weight gain, possible teratogenicity (spina bifida), and alopecia.

Carbamazepine

- Second-line choice for treatment of bipolar disorder when lithium and divalproex are ineffective or contraindicated
- Rare but serious hematologic and hepatic side effects and significant sedation make carbamazepine less useful.
- May cause agranulocytosis

Lamotrigine

- Approved for bipolar depression
- May cause Steven-Johnson syndrome

ANXIOLYTIC MEDICATIONS

Types

- Benzodiazepines: facilitate transmission of GABA
- Buspirone: S receptor partial agonist

Benzodiazepines

Clinical Guidelines

- Avoid abrupt changes in benzodiazepine dosage.
- Use lower dosages for the elderly.
- Do not mix with alcohol or other sedative-hypnotic medications.
- Consider dependency potential.
- May cause confusion, problems with memory, and falls (especially in the elderly)
- Abrupt discontinuation may cause seizures

Buspirone

- Effective in the treatment of generalized anxiety disorder and social phobia
- Lag time of about 1 week before clinical response
- No additive effect with sedative-hypnotics
- No withdrawal syndrome
- No sedation or cognitive impairment
- Headache may occur.

18 Suicide

Learning Objectives

- ❏ Describe the epidemiology and biological indicators associated with suicide and suicidal gestures
- ❏ Describe the steps required to evaluate a patient's risk of suicide

SUICIDE

Presentations

- Recent suicide attempt
- Complaints of suicidal thoughts
- Admission of suicidal thoughts upon questioning
- Demonstration of possible suicidal behavior

Risk Factors for Suicidal Behavior

- History of suicide threats and attempts
- Perceived hopelessness (demoralization)
- Presence of psychiatric illness/drug abuse
- Males
- Elderly
- Social isolation
- Low job satisfaction
- Chronic physical illness

Emergency Assessment

- Detain until the emergency evaluation is completed
- Take all suicide threats seriously
- Question about suicide ideation, intent, and plan
- Get information from third parties
- Don't identify with the patient
- Emergency treatment decisions about suicidal behavior are based on clinical presentation and presence of risk factors

Psychotherapies 19

Learning Objectives

- ❑ Describe and compare the major forms of psychotherapy and behavioral therapy used in practice today

Table I-19-1. Psychotherapies

Type of Therapy	Goal	Selection Criteria	Duration	Techniques
Psychoanalysis	Resolution of neurosis	Psychologically minded	4–5× per week for years	Free association, defense analysis, interpretation of transference
Insight oriented	Focus on interpersonal goals	Intact reality testing, capacity for insight	1–3× per week for months to years	Defense analysis, interpretation of transference
Supportive	Support reality testing, provide ego support	Healthy patients in time of crises or very ill patients	Days to months to years	Problem solving, suggestion, reinforcement
Behavioral	Modify learned behavior patterns	Those with maladaptive behaviors or psychophysiologic disorders	Time limited	Relaxation techniques, aversive therapy, systematic desensitization, flooding, token economy
Group	Alleviation of symptoms, change relationships, alter family-couple dynamics	Groups target specific disorders, family and couples, personality disorders, etc.	1× per week for weeks to years	Group specific
Cognitive	Change distorted views of self, world, and others	Depressive disorders	1× per week for 15–25 weeks	Assigned readings, homework, behavioral techniques, identification of irrational beliefs and attitudes

Epidemiology & Ethics

Epidemiology 20

Learning Objectives

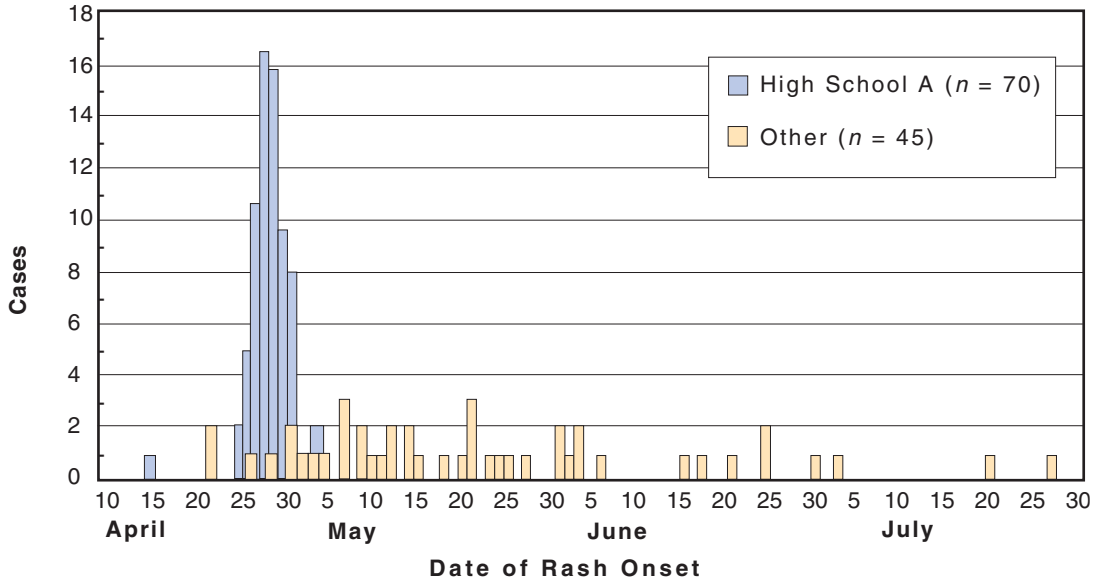
- ❏ Define incidence, prevalence, specific rates, adjusted rates, and other statistical measures, as they relate to morbidity and mortality
- ❏ Perform survival analysis including accounting for potential life lost
- ❏ Describe the types of prevention
- ❏ Show how prevalence, sensitivity, and specificity relate to the value of screening tests
- ❏ Answer questions about study design and bias in research

OVERVIEW

Epidemiology is the study of the distribution and determinants of health-related states within a population. It refers to the patterns of disease and the factors which influence those patterns.

- **Endemic:** the usual, expected rate of disease over time; the disease is maintained without much variation within a region
- **Epidemic:** occurrence of disease in excess of the expected rate; usually presents in a larger geographic span than endemics (**epidemiology** is the **study of epidemics**)
- **Pandemic:** worldwide epidemic.
- **Epidemic curve:** visual description (commonly histogram) of an epidemic curve is disease cases plotted against time; classic signature of an epidemic is a **"spike" in time**

Incubation period is the period of time from the point of infection to the onset of clinical illness.



Reported measles cases by date of rash onset, Elgin, Illinois, April 15 to July 28, 1985

Figure II-20-1. Measles Outbreak

Onsets of illness in patrons and employees: hepatitis A outbreak on a floating restaurant, Florida.

Figure II-20-2. Food-Borne Outbreak

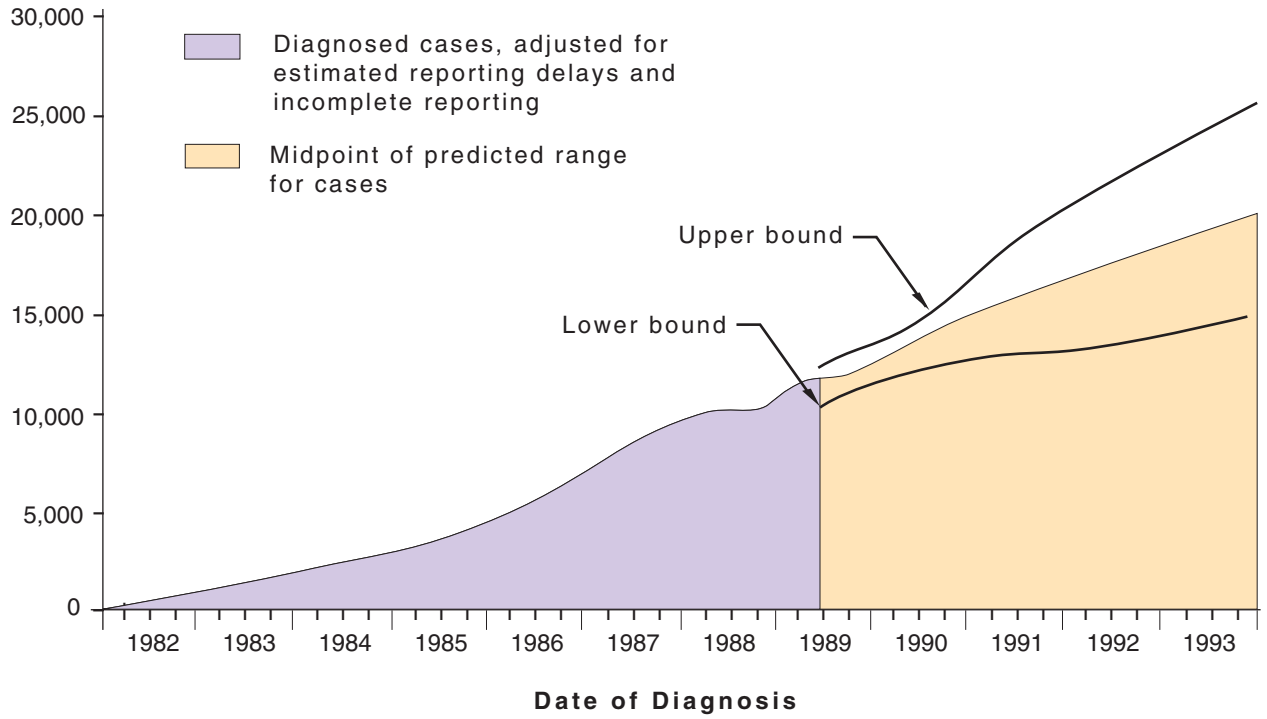


Figure II-20-3. Multiple-Year Increase in AIDS Cases in the United States

Health service interventions are evaluated based the following concepts/metrics:

- **Efficacy:** performance of an intervention under optimal conditions, e.g., prophylactic medications in a clinical trial
- **Effectiveness:** actual results in the real world, e.g., treatment outcomes in the community
- **Efficiency:** a ratio of the benefit compared to the cost associated with an intervention (high efficiency would deliver a greater benefit at minimal cost)

Upper and lower bounds account for uncertainty of the estimate (most commonly 95% confidence intervals).

TYPES OF PREVENTION

The goals of prevention in medicine are to promote health, preserve health, restore health when it is impaired, and minimize suffering and distress. These goals aim to minimize both morbidity and mortality.

- **Primary prevention** is the promotion of health at both individual and community levels; this is done by facilitating health-enhancing behaviors, preventing the onset of risk behaviors, and diminishing exposure to environmental hazards. **Primary prevention efforts decrease disease incidence.**
- **Secondary prevention** is the screening for risk factors and early detection of asymptomatic or mild disease, permitting timely and effective intervention and curative treatment. **Secondary prevention efforts decrease disease prevalence.**

Note

- **Prevalence** is the proportion of population affected by a disease (disease burden).
- **Resource allocation** is often directed at disease prevalence.

- **Tertiary prevention** is the reduction of long-term impairments and disabilities and prevention of repeated episodes of clinical illness. The goals of tertiary prevention are to prevent recurrence and slow progression.

Primordial prevention is a newer concept in disease prevention. It targets the most distal determinants of health (social, economic, environmental, and cultural).

Some examples of **prevention for cardiovascular disease** are as follows:

- **Primary prevention:** health education programs to promote healthy lifestyle and prevent onset of heart disease risk factors, e.g., Hearty Heart nutrition program for elementary school children or smoking cessation program
- **Secondary prevention:** community screening for blood pressure, peripheral artery disease
- **Tertiary prevention:** graded aerobic physical activity program prescribed to patients during recovery from first myocardial infarction

Practice Questions

Response options for Questions 1–4:

A. Quaternary prevention
B. Primary prevention
C. Secondary prevention
D. Tertiary prevention
E. Palliative care

1. Breast self-examination
2. Physical therapy/rehabilitation and ergonomic training program for blue-collar workers recovering from severe back strain injury sustained on the job
3. School-based sexual health education program for middle school students
4. Confidential PPD testing to detect latent TB infection conducted at community clinics by county health department personnel

1. **Answer: C** . Self-screening for early detection leading to early diagnosis and effective, life-saving treatment.
2. **Answer: D**. Rehabilitation following an episode of injury with a concurrent focus on preventing subsequent injury.
3. **Answer: B**. Prevention of onset of risky sexual behaviors.
4. **Answer: C**. Screening to detect TB infection, to be followed by therapy to prevent progression to active TB.

Practice Questions

Response options for Questions 5–7:

A. Hypoendemic
B. Endemic
C. Epidemic
D. Hyperendemic
E. Pandemic

5. Multinational outbreak of influenza
6. Rapid rise in AIDS cases among drug injectors in Bangkok in the late 1980s
7. Long-term, relatively constant rate of occurrence of colorectal cancer in U.S. women

5. **Answer: E**. A pandemic is an epidemic that crosses national borders.
6. **Answer: C**. AIDS appeared suddenly, and the epidemic increased exponentially.
7. **Answer: B**. When disease cases are plotted over time, a flat horizontal line depicts an endemic pattern.

MEASURES OF MORBIDITY AND MORTALITY

Rate

Rate is the frequency of occurrence of epidemiologic events in populations. It is used to compare epidemiologic events among populations.

- Rates allow direct comparisons of "events per identical number of people" in 2+ populations.
- Rates permit comparisons of epidemiologic events occurring in a single population assessed at several points in time.

The rate equation is:

$$\text{Rate} = \frac{\text{Numerator}}{\text{Denominator}} \times \text{Multiplier}$$

where the **numerator** is the number of **epidemiologic events**, the **denominator** is the number of **people in the population of interest**, and the **multiplier** is selected so that the **result of the rate computation generally yields a number from 1–100**.

- For **major vital statistics**, such as birth rate, death rate, and infant mortality rate, the preferred multiplier is 1,000. The result is expressed as a **rate per 1,000.**
- For **individual diseases**, the most common multiplier is 100,000. The result is expressed as a **rate per 100,000.**

It is **essential** that the **numerator is matched with the denominator**. Match on person, place, and time characteristics.

$$\text{Rate} = \frac{\text{Epidemiologic events occuring in a population of persons at a given place at a given time}}{\text{Defined population of persons at a given place at a given time}} \times \text{Multiplier}$$

SPECIFIC AND ADJUSTED RATES

Specific Rates

Specific rates **specify a subset of the total population** that is singled out for special examination or comparison with other subsets of the population. Use the following formula:

$$\text{Specific rate} = \frac{\text{All events in specified subpopulation}}{\text{Specified subpopulation}} \times \text{Multiplier}$$

Common demographic variables used for specific rates are age group, gender, race/ethnicity, highest level of education attained, marital status, and socioeconomic status. Populations can be stratified on 2+ demographic variables at a time.

Matching the numerator and denominator is the most important concept for computing a specific rate. For example:

"Event" of interest:	Cancer deaths
Place:	State of Nevada
Time:	Calendar year, 2006
Rate of interest:	Age-specific rate (rate for a specified age group) for ages 45–64
Formula:	$\frac{\text{Deaths from cancer among persons ages 45–64 in Nevada during 2006}}{\text{Population of Nevada residents ages 45–64, midyear 2006}} \times 100{,}000$

Adjusted Rates (or Standardized)

Adjusted rates are rates calculated after using statistical procedures, in order to minimize demographic differences between populations being compared. Comparisons of rates between 2 groups may be misleading if the composition of the groups differs on important demographic characteristics. Adjustment improves the validity of the comparison, when there is an imbalance of risk factors among 2 populations. In the following example, rate adjustment is clearly essential.

> In the same city, the rate of alcoholism and alcohol abuse is found to be higher among workers in an automobile assembly plant compared with same-age workers at a textile mill.

Adjustment for gender differences is warranted. First, the **2 populations differ on a demographic characteristic**: Automotive workers tend to be men; textile workers tend to be women. Second, the **disorder is related to the same demographic**: Alcohol problems are more prevalent in men. The higher observed rate in automotive workers may be due to the marked differences in gender in the 2 employee populations.

> In the same company, the rate of lung cancer is found to be higher among male factory workers age 50–64 than among male computer programmers age 50–64.

Adjustment for level of education is warranted. First, the 2 populations differ on a demographic characteristic: Factory workers tend to have a low level of education; computer programmers are likely to be college graduates. Second, the disease/disorder is related to the same demographic. The major cause of lung cancer is cigarette smoking. People with lower levels of education have higher smoking rates; college graduates have the lowest smoking rates. The differences in lung rates may reflect expected differences in smoking prevalence rates for workers with different levels of education.

Properties of a board-style adjusted rate problem:

- A significant difference in the rate of disease is declared to exist between 2 groups. The compared rates are unadjusted.
- The groups differ on a key demographic variable.
- The disease is known to be related to the same demographic variable.
- Adjustment will tend to make the observed difference between unadjusted rates disappear.

Table II-20-1. Disease Rates Positively Correlated with Age

		Population A		Population B		Population C	
		Cases	Population	Cases	Population	Cases	Population
Younger	1/1,000	1	1,000	2	2,000	3	3,000
Intermediate	2/1,000	4	2,000	4	2,000	4	2,000
Older	3/1,000	9	3,000	6	2,000	3	1,000
		14	6,000	12	6,000	10	6,000
Crude Rates	Per/1,000	2.3		2.0		1.6	

Practice Questions

8. In the United States, the crude (unadjusted) suicide rate for physicians is significantly higher than the corresponding rate for the general population. What is the most appropriate interpretation of this finding?
   A. Higher suicide rates in physicians are likely to be related to job stress, including life-and-death decision making for patients in the care of the physician.
   B. Higher rates of suicide in physicians are likely to be related to constant exposure to human suffering, trauma, and death.
   C. Physicians have higher rates of suicide than the general population; no further interpretation is possible from the information presented.
   D. While the unadjusted rate of suicide is higher for physicians, failure to adjust for differences between physicians and the general population on socioeconomic status precludes meaningful interpretation of this finding.
   E. The finding of statistical significance proves that physicians are at higher risk for suicide than nonphysicians.

8. **Answer: D**. When a significant relationship is stated but the comparison groups have some obvious demographic difference, look for the answer that suggests conclusions may be invalid unless rates are adjusted or standardized to compensate for the demographic disparities. In this instance, physicians are generally a higher socioeconomic status (SES) group relative to the general population. Suicide rates are elevated for high-SES people. Once adjusted for SES differences, the finding of higher suicide rates in physicians no longer stands.

MEASURES OF MORBIDITY

Prevalence and Incidence

Prevalence: All Cases

Prevalence is the proportion of individuals with existing disease at a point in time (point prevalence). It is also the proportion of individuals with existing disease during a period of time (period prevalence). The **focus is on chronic conditions** (disease burden).

The numerator refers to **all individuals** who have the illness at the time(s) in question.

$$\text{Prevalence} = \frac{\text{Persons with existing disease at a given place at a given time}}{\text{Population of persons at risk for disease at a given place at a given time}} \times \text{Multiplier}$$

Note

Relationship between Incidence and Prevalence:

- Prevalence = Incidence × Duration (conceptual formula, not computational)
- $\text{Duration} = \frac{\text{Prevalence}}{\text{Incidence}}$
- Changes in incidence, duration, or both will ultimately affect prevalence.

Incidence Rate: New Cases

The incidence rate is the rate of new disease events in a population at risk during a period of time. It can be calculated only over a period of time, not at a single point. The focus is on acute conditions.

Incidence is a measure of **risk**.

$$\text{Incidence rate} = \frac{\text{Persons with disease onset at a given place during a specified period of time}}{\text{Population of persons at risk for the disease at a given place during a specified period of time}} \times \text{Multiplier}$$

Attack rate is a type of incidence rate which focuses on a known exposure or risk. If 10 of 100 children who attend daycare A, and 40 of 100 children who attend daycare B develop diarrhea, the attack rate would be 10% for attendance at daycare A and 40% for attendance at daycare B.

Prevalence Pot

A "prevalence pot" is a common portrayal of the concept of prevalence and its relationship to incidence. At the first moment of observation, the count of cases "in the pot" provides an estimate of point prevalence. Incident cases are observed over time. These new cases are added to the pre-existing cases. As long as clinical illness persists, cases remain in the pot.

Prevalence **can be estimated when disease incidence and duration are known**:

$$\text{Prevalence} = \text{Incidence} \times \text{Duration (conceptual formula only)}$$

A disease may have low incidence but long duration, causing prevalence to be higher.

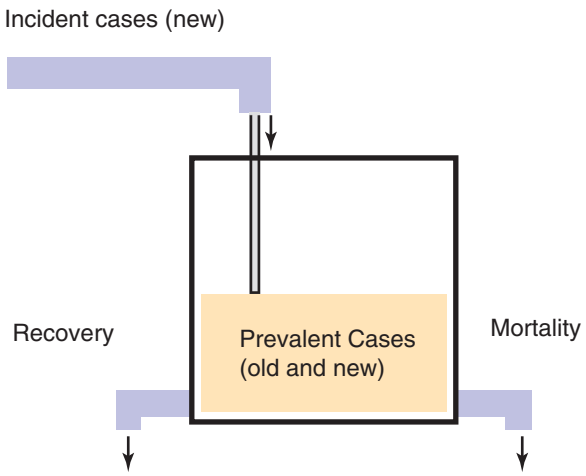

Figure II-20-4. Prevalence Pot Diagram

Cases leave the prevalence pot in one of 2 ways: recovery or death. Changes in prevalence over time can be determined by **monitoring trends in incidence, recovery, and death**.

The **factors affecting prevalence** are as follows:

Increase

- Increase in incidence cases, e.g., improved screening methods
- Longer disease duration, e.g., diabetes
- Better treatment of disease, which results in patients with chronic illness but not "cured," e.g., diabetics

Decrease

- Decrease in incidence cases, e.g., vaccination program
- Shorter disease duration, e.g., high case fatality rate
- Improved treatment of disease, which results in "cured" patients

Practice Questions

9. A pharmaceutical company completes trials on a vaccine for a severe strain of influenza virus demonstrating high vaccine efficacy. The FDA approves the vaccine for use in the United States. As the influenza pandemic approaches U.S. borders, the CDC launches a campaign to vaccinate the population using local public health department personnel throughout the country to ensure the vaccine is available, free of charge, to all people. Assuming a high degree of vaccine coverage is achieved, what is the expected impact of this major public health initiative?

   A. Decreased duration of influenza illness leading to decreased prevalence
   B. Decreased incidence of influenza illness leading to decreased prevalence
   C. Decreased incidence offset by increased duration: no change in prevalence
   D. No change in observed incidence or duration: no change in prevalence
   E. Effects on prevalence cannot be determined from the information provided

10. A new, effective treatment for a common disease, leading to complete cure, is developed. Which of the following impacts on disease occurrence is expected?

   A. Decreased duration of illness, leading to decreased prevalence
   B. Decreased incidence of illness, leading to decreased prevalence
   C. Decreased incidence and duration of illness, leading to decreased prevalence
   D. No change in observed incidence or duration: no change in prevalence
   E. Effects on prevalence cannot be determined from the information provided

11. Which term is used when cost/benefit ratio analysis is used to evaluate public health service interventions?

   A. Efficacy
   B. Effectiveness
   C. Efficiency
   D. Equity
   E. None of the above

9. **Answer: B**. Vaccination decreases the likelihood of development of new infection and clinical disease. In turn, the prevalence during the peak of the influenza season will be decreased. Efficacy reflects how well an intervention performs under ideal circumstances.

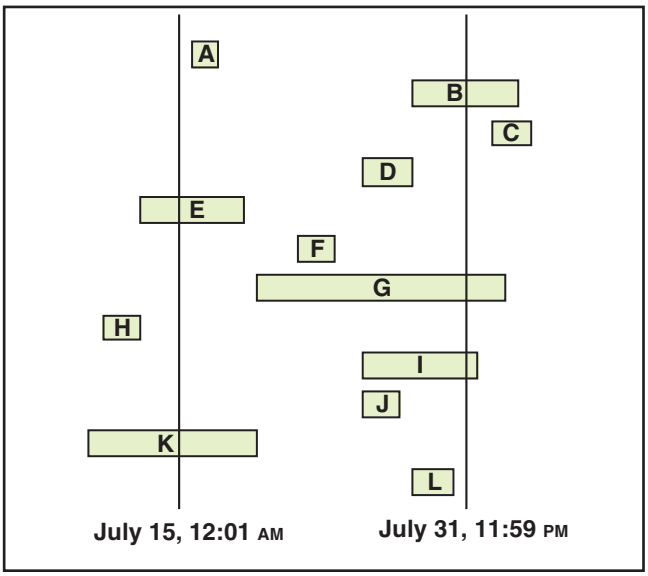
10. **Answer: A**. An effective treatment will move people more quickly toward recovery. Average duration of illness will decrease. Prevalence–the proportion of people ill with the disease at a point in time–will also decrease. This will apply to both acute and chronic diseases. Effectiveness refers to how well an intervention performs in real conditions. Under ideal circumstances, some interventions are relatively efficacious, but less effective in reality.

11. **Answer: C**. Efficiency is the term used to evaluate public health interventions using cost/benefit ratio analysis.

Practice Questions

Questions 12–15

Among 245 college students who dedicated one month of summer break to building homes for Habitat for Humanity, 12 developed back strains on the job. Based on the diagram of these 12 episodes of back strain, answer the following questions:



Response options for Questions 12–15:

A. 2/242	E. 3/245	I. 10/244
B. 2/244	F. 8/242	J. 10/245
C. 2/245	G. 8/244	K. 12/245
D. 3/242	H. 8/245	

12. What is the point prevalence on July 15, 12:01 am?
13. What is the point prevalence on July 31, 11:59 pm?
14. What is the incidence rate for the period July 15–July 31?
15. What is the period prevalence for July 15–July 31?

12. **Answer: C**. On July 15, there were 2 students with symptoms of back strain (E, K).
13. **Answer: E**. On July 31, there were 3 students with symptoms of back strain (B, G, I).
14. **Answer: H**. Eight new cases of back strain had onset between July 15 and July 31 (A, B, D, F, G, I, J, L).
15. **Answer: J**. A total of 10 students had symptoms of back strain at some time from July 15–31, including 2 with onset prior to July 15 (E, K) and 8 with onset during the period July 15–31 (A, B, D, F, G, I, J, L).

VITAL STATISTICS AND RATES

Birth Rate

Birth rate (also called crude birth rate) is the rate of live births in a population during a time period (usually the calendar year).

$$\textbf{Simple formula:}\ \frac{\text{Live births}}{\text{Population}} \times 1{,}000$$

This can be interpreted as **births per 1,000 population**. The U.S. birth rate (in 2010) was 13.0 births/1,000 population.

Fertility Rate

Fertility rate is the rate of live births among women of childbearing age (age 15–49) in a population during a time period (usually the calendar year).

$$\textbf{Simple formula:}\ \frac{\text{Live births}}{\text{Women of childbearing age}} \times 1{,}000$$

This can be interpreted as **births per 1,000 women of child-bearing age**. The U.S. fertility rate (in 2010) was 64.1 births/1,000 women of child-bearing age.

Mortality Rate

Mortality rate (also called death rate or crude death rate) is the rate of deaths in a population during a time period (usually the calendar year).

$$\textbf{Simple formula:}\ \frac{\text{Deaths}}{\text{Population}} \times 1{,}000$$

This can be interpreted as **deaths per 1,000 population**. Mortality rate may be affected by the age structure in different populations, so be sure to account for age structure before comparing mortality rates in different countries. The U.S. mortality rate (in 2010) was 8.4 deaths/1,000 population.

Infant Mortality Rate

Infant mortality rate is the yearly rate of deaths among children age <1 in relation to the number of live births during the same year. Within a population, the infant mortality rate is a key indication of the population's health status.

$$\textbf{Simple formula:}\ \frac{\text{Infant deaths}}{\text{Live births}} \times 1{,}000$$

This can be interpreted as **infant deaths per 1,000 live births**. The U.S. infant mortality rate (in 2010) was 6.14 infant deaths/1,000 live births.

$$\textbf{Neonatal mortality rate:}\ \frac{\text{Infant deaths prior to day 28}}{\text{Live births}} \times 1{,}000$$

$$\textbf{Postneonatal mortality rate:}\ \frac{\text{Infant deaths from day 28–365}}{\text{Live births}} \times 1{,}000$$

Infant mortality rate: neonatal mortality rate + postneonatal mortality rate

Perinatal mortality rate: Stillbirths + $\frac{\text{deaths in the first week of life}}{\text{Live births}} \times 1{,}000$

Infant Mortality

The top 3 causes of infant mortality are **birth defects** (24%), **low birth weight (<1,500 g)/respiratory distress** (18%), and **SIDS** (16%). SIDS rates can be reduced sharply if infants are prevented from sleeping on their stomachs.

Other facts about infant mortality:

- Native Americans have highest rates of SIDS
- Blacks have highest rates of infant mortality due to low birth weight and infections; number 1 killer of black infants is low birth weight
- Hispanic profile is similar to whites, but slightly higher

Sociologic risk factors for children include:

- Maternal immaturity: risk of premature birth increases dramatically below age <19
- Poverty: major risk factor for prematurity and other unfavorable outcomes
- Single-parent family: correlated with child abuse, childhood suicide, truancy, and delinquency

Maternal Mortality Ratio

Maternal mortality ratio is the ratio of deaths in women from all causes associated with childbirth in relation to the number of live births during the same year. The denominator is **per live births**.

Simple formula: $\frac{\text{Maternal deaths}}{\text{Live births}} \times 100{,}000$

This can be interpreted as **maternal deaths per 100,000 live births**; this is an **important index** of maternal care. The U.S. maternal mortality ratio (in 2010) was 7.1 maternal deaths/100,000 live births.

Case Fatality Rate

Case fatality rate (CFR) is the percentage of cases of an illness or medical condition that result in death within a specified time period.

Simple formula: $\frac{\text{Deaths}}{\text{Cases}} \times 100$

This can be interpreted as **proportion of cases which end in death (fatality)**. For instance, in a population of 200 people, 25 become ill, and 5 die from the illness. Therefore, CFR is 5 deaths/25 cases × 100 = 20%.

Proportionate Mortality Rate

Proportionate mortality rate (PMR) is the percentage of deaths from all causes that are due to a specified cause during a specified time period.

$$\textbf{Simple formula: } \frac{\text{Deaths from a specified cause}}{\text{Total deaths}} \times 100$$

This can be interpreted as **proportion of deaths from a specific cause**. The PMR is used for the most common causes of death in a population.

Table II-20-2. Types of Measured Rates

Crude mortality rate	Deaths per population
Cause-specific mortality rate	Deaths from a specific cause per population
Case-fatality rate	Deaths from a specific cause per number of persons with the disease
Proportionate mortality rate (PMR)	Deaths from a specific cause per all deaths

Practice Questions

Response options for Questions 16–18:

A. Birth rate
B. Fertility rate
C. Infant mortality rate
D. Maternal mortality ratio
E. Age-adjusted rate
F. Case-fatality rate
G. Sex-adjusted rate
H. Proportionate mortality rate
I. Age-specific rate
J. Sex-specific rate
K. Age- and sex- and race/ethnicity-specific rate

16. Rate of live births among women of childbearing age
17. Proportion of cases of a disease that die from that disease
18. Rate of homicide in black men, age 15–24

16. **Answer: B**. Restatement of definition of fertility rate
17. **Answer: F**. Restatement of definition of case-fatality rate
18. **Answer: K**. Homicide rate restricted to black men in the age range 15–24

Practice Questions

Questions 19 and 20 are based on the following table

Incidence and Mortality of Disease

Age	Disease A		Disease B		Total	
Groups	Cases	Deaths	Cases	Deaths	Deaths	Population
0–12	2	1	300	1	40	22,000
13–24	101	34	267	0	30	18,000
25–64	50	42	1,042	2	125	50,000
>64	0	0	986	95	303	30,000
Totals	153	77	2,595	98	498	120,000

19. The case-fatality rate for Disease A is

    A. 77/120,000 × 1,000
    B. 77/120,000 × 100,000
    C. 153/120,000 × 100,000
    D. 153/498 × 100
    E. 77/153 × 100

20. The proportionate mortality rate for Disease B is

    A. 98/120,000 × 100,000
    B. 2,595/120,000 × 100,000
    C. 98/2,595 × 100
    D. 98/498 × 100
    E. Cannot be determined

19. **Answer E**. For CFR, denominator is total cases of disease A.

20. **Answer D**. For proportionate mortality, denominator is total deaths.

YEARS OF POTENTIAL LIFE LOST AND SURVIVAL ANALYSIS

YPLL is an indicator of premature death. The YPLL for a particular cause of death is the sum, over all persons dying from the cause, of the years that those persons would have lived had they experienced normal life expectancy.

Assume life expectancy is 75 years. A person who dies at age 65 would be dying 10 years prematurely (75 − 65 = 10 YPLL). For 100 such people, the YPLL calculation would be 100 × (75 2 65) = 1,000 YPLL.

In the United States, the leading cause of YPLL age 65 is unintentional injury.

Survival Analysis

Survival analysis is a class of statistical procedures for estimating the proportion of people who survive in relation to the length of survival time. The starting point is 100% survival. In 2000, the median survival time was age 78.

A survival curve is a curve that starts with 100% of the study population and shows the percentage of the population still surviving at successive times for as long as information is available.

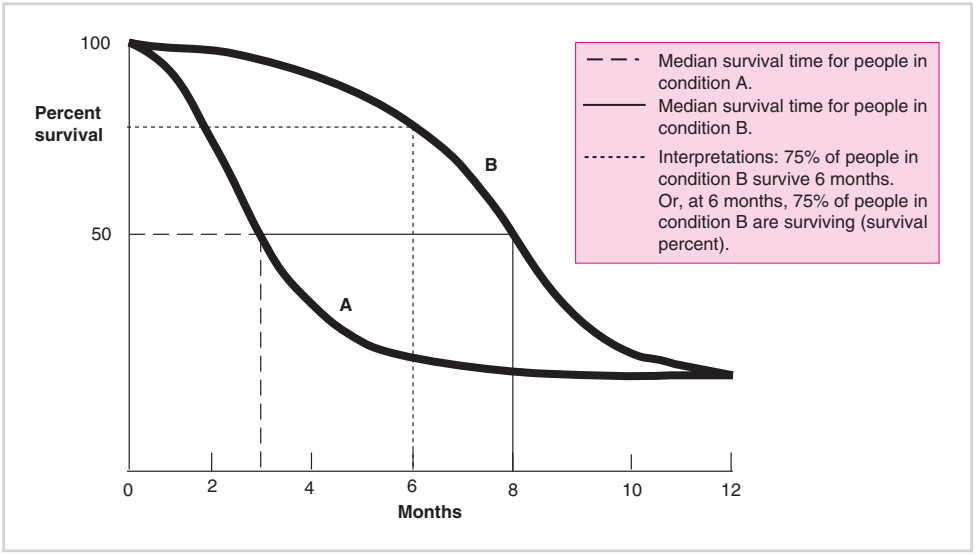


Figure II-20-5. Survival Curve

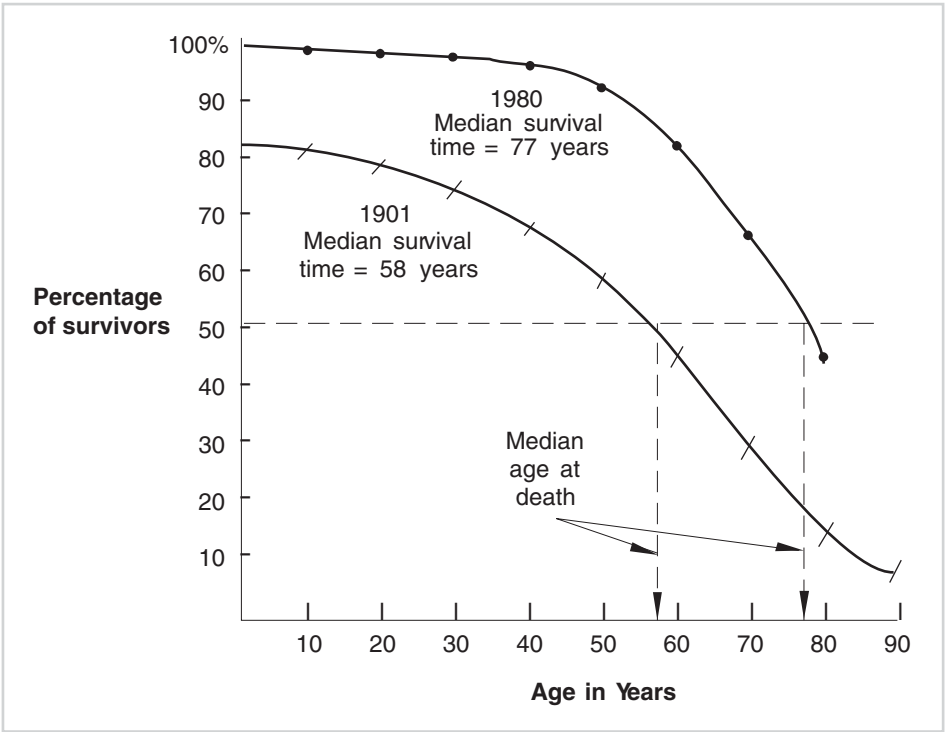

Figure II-20-6. Percentage of Survivors at Specified Ages, 1901 and 1980

SCREENING TESTS

Screening is the process of using tests to permit early detection of risk factors, asymptomatic infection, or early stages of clinical disease, thus permitting early diagnosis and early intervention/treatment. Screening is usually applied to populations of apparently healthy individuals. Illness, if present, is asymptomatic (subclinical, inapparent).

- Screening tests allow for earlier detection and earlier diagnosis. Hopefully, earlier treatment will effect a more favorable clinical course.
- Screening test results are classified as **positive** (presumed by the test to be diseased) or **negative** (presumed by the test to be healthy).

Classic 2 × 2 Table

The 2 × 2 table is the standard form for displaying screening test results in relation to disease status. Disease status categories (diseased and healthy) are diagrammed in the vertical columns. Screening test results (positive, negative) are diagrammed in the horizontal dimension.

Table II-20-3. Classic 2 × 2 Table

	Disease	No Disease	Totals
Positive	True Positive [TP]	False Positive [FP]	TP + FP
Negative	False Negative [FN]	True Negative [TN]	TN + FN
Totals	TP + FN	TN + FP	TP + TN + FP + FN

In the 2 × 2 table, **positive (P) and negative (N) refer to the actual screening test results**, while **true (T) and false (F) refer to the agreement of screening test results with the gold standard**.

- **True Positives:** diseased people correctly classified as positive
- **True Negatives:** healthy people correctly classified as negative
- **False Positives:** healthy people misclassified as positive
- **False Negatives:** diseased people misclassified as negative

Table II-20-4. Screening Results in a 2 × 2 Table

		Disease				
		Present		Absent		Totals
Screening Test Results	Positive	TP	80	FP	40	TP + FP = 120
	Negative	FN	20	TN	60	TN + FN = 80
	Totals	TP + FN = 100		TN + FP = 100		TP + TN + FP + FN = 200

Measures of Screening Test Performance

Sensitivity is the proportion of people with disease who are correctly classified by the screening test as positive. In a 2 × 2 table, sensitivity is located in the left column.

Highly sensitive tests identify most, if not all, possible cases. It is important to consider when there is a consequence associated with missing the detection of disease.

- Sensitivity = TP/All people with disease
- Sensitivity = **TP/(TP + FN)** (in the example above, 80/80 + 20 = 80/100 or 80%)

Specificity is the proportion of healthy people who are correctly classified by the screening test as negative. Specificity is very important in public health screening to minimize FP. In a 2x2 table, specificity is located in the right column.

Highly specific tests identify most, if not all, healthy people (i.e., not diseased); will give few FP results.

- Specificity = TN/All healthy people
- Specificity = **TN/(TN + FP)** (in the example above, 20/20 + 80 = 20/100 or 20%)

Sensitivity and specificity are fixed characteristics of the screening test. Sensitivity and specificity are 2 elements of test validity.

Predictive value represents the percentage of test results that match the diagnosis of the patient. It is predicted by the disease prevalence in the given population.

- **Positive predictive value (PPV)** is the proportion of people with a positive screening test result who are diseased. (i.e., that a person with a positive test is a true positive). In a 2 × 2 table, PPV is located on the top row. **Increased specificity means increased PPV, because FP will be fewer.**
  - PPV = TP/All people with a positive test result
  - PPV = TP/(TP + FP)
- **Negative predictive value (NPV)** is the proportion of people with a negative screening test result who are well. (i.e., that a person with a negative test is a true negative). In a 2 × 2 table, NPV is located on the bottom row. **Increased sensitivity means increased NPV, because FN will be fewer.**
  - NPV = TN/All people with a negative test result
  - NPV = TN/(TN + FN)

Prevalence is the proportion of screened people who have disease. It is something that can be estimated only if the entire population (or representative sample of the population) is screened. Increased prevalence of a disease usually **equals increased PPV and decreased NPV**. Decreased prevalence of a disease usually equals **decreased PPV and increased NPV.**

- Prevalence = (TP + FN)/(TP + TN + FN + FP)

Likelihood ratio is the expression of how many more (or less) likely a test result is to be found in nondiseased (or diseased) compared with diseased (or nondiseased).

- Positive likelihood ratio (LR+) is the proportion of diseased people to that of nondiseased people with a positive test result.

$$\text{LR+} = \frac{\text{Sensitivity}}{1 - \text{specificity}} \text{ OR } \frac{\text{Sensitivity}}{\text{FP/(TN + FP)}} \text{ OR } \frac{\text{Sensitivity}}{\text{FP rate}}$$

- Negative likelihood ratio (LR−) is the proportion of diseased people to that of nondiseased people with a negative test result.

$$\text{LR−} = \frac{1 - \text{sensitivity}}{\text{Specificity}} \text{ OR } \frac{\text{FN/(TP + FN)}}{\text{Specificity}} \text{ OR } \frac{\text{FN rate}}{\text{Specificity}}$$

Screening Test Diagram

The screening test diagram displays the distributions of the screening test measure separately for people with disease and people with no disease. The cutoff point or criterion point divides screened people into test-positive and test-negative categories.

- People with no disease are either correctly classified as TN or misclassified as FP.
- People with disease are either correctly classified as TP or misclassified as FN.

The screening test diagram is a useful model of the real world in which values of screening test measures (such as blood pressure) are generally different for diseased (hypertensive) and nondiseased (normotensive) people, but the distributions overlap.

The measures of screening test performance can be displayed on the screening test diagram by identifying the appropriate areas under the curves. For example, the numerator for sensitivity is TP, whereas the denominator is everyone under the curve labeled "disease."

Sensitivity and specificity are fixed characteristics of the screening test; they are both elements of **test validity**.

Note that changing the cutoff point changes the test.

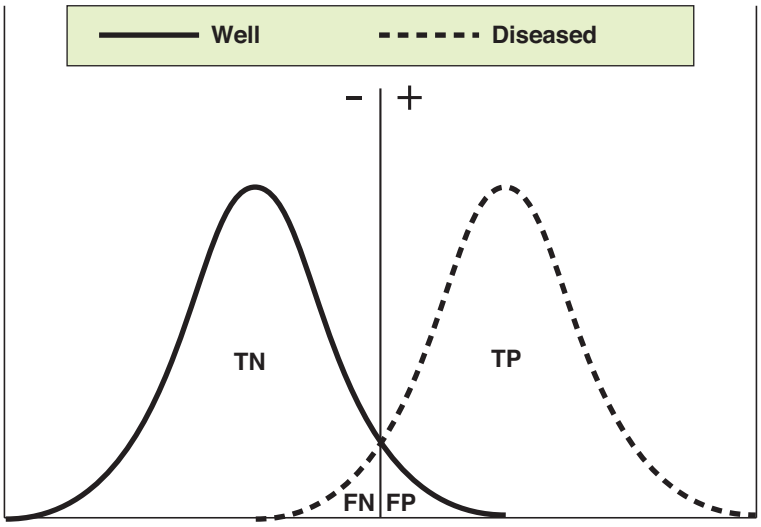

Figure II-20-7. Screening Test Diagram

This is a graphical representation of sensitivity and specificity in a screening test. The area under the curve for the false-negative rate is very low, which implies very high sensitivity. Likewise, the area under the curve for the false-positive rate is low, implying a high specificity.

Reliability indicates the degree of reproducibility (consistency) of screening tests. In other words, does the test yield the same results when performed under the same circumstances by the same personnel? Reliability is sometimes referred as **precision**: poor reliability minimizes a tests value.

Validity indicates the degree in which a test distinguishes healthy from diseased individuals. Sensitivity and specificity are both elements of validity. Validity is sometimes referred as **accuracy**.

Practice Questions

A new screening test is applied to a representative sample of 1,000 people in the population. Based on the data presented in the following table, calculate the requested screening test measures.

	Diseased	Healthy	
Positive	90	60	150
Negative	10	840	850
	100	900	1,000

Response options for Questions 21–27:

A. 90/150
B. 90/100
C. 90/1,000
D. 90
E. 60
F. 10
G. 840/850
H. 840/900
I. 930/1,000
J. 900/1,000
K. 100/1,000
L. Cannot be calculated
M. 60/900
N. 60/150
O. 10/100
P. 10/850

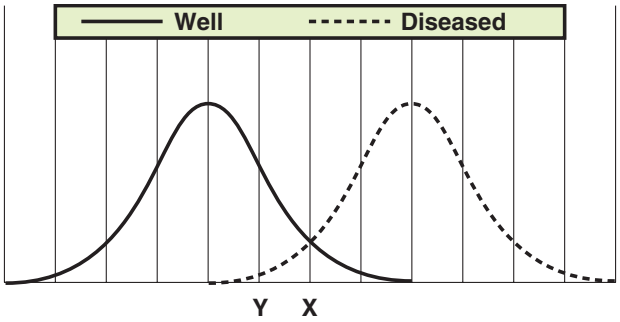
21. What is the sensitivity of the screening test?
22. What is the specificity of the screening test?
23. What is the positive predictive value of the screening test?
24. What is the number of false negative tests?
25. What is the number of false positive test results?
26. What is the prevalence of disease, assuming screening of a representative sample?
27. What is the false positive rate?

21. **Answer: B**. Sensitivity = TP/All diseased people = 90/100
22. **Answer: H**. Specificity = TN/All healthy people = 840/900
23. **Answer: A**. PPV = TP/All test positives = 90/150
24. **Answer: F**. Diseased people misclassified by the test = 10
25. **Answer: E**. False positives = Healthy people who are misclassified by the test = 60
26. **Answer: K**. Prevalence = All diseased people/All screened people = 100/1,000
27. **Answer: M**. False positive rate = FP/All healthy people = 60/900

Practice Questions

Questions 28–33

The CDC is concerned about optimizing the detection of a disease which poses a serious public health threat. CDC health officials are considering lowering the usual screening test cutoff point from X to Y.



28. Moving cutoff in the manner being considered by the CDC causes the number of false positives to

    A. increase
    B. decrease
    C. remain unchanged
    D. cannot be determined

29. Moving the cutoff in the manner being considered by the CDC causes the positive predictive value to

    A. increase
    B. decrease
    C. remain unchanged
    D. cannot be determined

30. Moving the cutoff in the manner being considered by the CDC causes the accuracy to

    A. increase
    B. decrease
    C. remain unchanged
    D. cannot be determined

31. Moving the cutoff in the manner being considered by the CDC causes the sensitivity to

    A. increase
    B. decrease
    C. remain unchanged
    D. cannot be determined

(*Continued*)

Practice Questions (*continued*)

32. Assuming that everyone who receives a positive test result is referred for medical follow-up, moving the cutoff in the manner being considered by the CDC will cause the numbers of screened people who are referred for follow-up to

    A. increase
    B. decrease
    C. remain unchanged
    D. Cannot be determined

33. At Cutoff Point X, sensitivity is

    A. 100%
    B. 85%
    C. 50%
    D. 25%
    E. 0%

28. **Answer: A**. At Y, FP will increase as more well people are misclassified.

29. **Answer: B**. Although there will be more TP at Cutoff Y, there will be a large increase in numbers of FP. The ratio, TP/(TP + FP), will decrease. A positive test result will be less predictive of actual disease.

30. **Answer: B**. X is the point of overlap and the point of maximal accuracy. Moving to Y will decrease accuracy.

31. **Answer: A**. At Y, more diseased people will receive a (correct) positive test result. They will be TP. TP, the numerator for sensitivity, will increase while the denominator (total people with disease) will be unchanged.

32. **Answer: A**. Larger numbers of people would be screened positive at Cutoff Y and referred for follow-up.

33. **Answer: B**. Notice that Cutoff Point X separates the curve of diseased people into 2 areas; above the cutoff point, approximately 85% of diseased people receive a (correct) positive test result. They are true positives. Sensitivity = TP /All people with disease.

Practice Questions

34. A physician interviews an 18-year-old woman who says she has just received a negative syphilis test result from the county health department. She describes her sense of relief. She discloses that she is a sex worker who "works the street" 4–5 nights a week. She has been doing this for the past 18 months. Typically, she has oral or vaginal sex with 5–8 customers per night. For a higher fee she will have sex without requiring her customer to wear a condom. On the basis of these findings, the physician is likely to be most concerning with which of the following screening test measures?

A. Sensitivity
B. Specificity
C. Positive predictive value
D. Negative predictive value
E. Accuracy

35. A 55-year-old man visits his primary care physician with a complaint of urinary infrequency. Examination finds a 1-cm nodule on his prostate gland. The physician orders a prostate-specific antigen (PSA) serum test. By common standards, a PSA level >4 ng/mL is considered abnormal. Using this standard, this test has a sensitivity of 80% and a specificity of 90%. A recently published epidemiologic article found that in a cross-sectional study, 10% of men of this age have prostate cancer. The patient's PSA is tested to be 7 ng/mL. What is your best estimate of the likelihood that this man actually has prostate cancer?

A. 2
B. 53
C. 98
D. 47%
E. Insufficient information

34. **Answer: D**. Disease prevalence affects the predictive value of the test. The greater the prevalence, the higher the PPV of the test. Screening tests are generally performed in high-risk populations (where the PPV is greater). NPV is the proportion of individuals who test negative who are actually free from disease. When the prevalence of disease is high, the negative predictive value will be low. As a result, her negative results are concerning because because she is part of a high prevalence group, and the predictive value of her negative test is low.

35. **Answer: D**. Here, you have to recreate a 2x2 table. You are provided a disease prevalence of 10%. This information can be used to create the lower border of the table using hypothetical numbers. You are also given a sensitivity of 80%, therefore 80% of 10 = 8 for upper right quadrant cell. For the given specificity of 90%, 90% of 90 = 81. Then, fill in the blank fields by deduction.

		Disease Present	Disease Absent		Equation
Test Result	Positive	8	9	17	$PPV = \frac{8}{8+9} = \frac{8}{17} = 47\%$
	Negative	2	81	83	$NPV = \frac{81}{81+2} = \frac{81}{83} = 98\%$
	Equation	10	90	100	

STUDY DESIGNS

When epidemiologists observe the relationship between exposures and disease outcomes in free-living populations, they are conducting **observational studies**. When epidemiologists or clinicians test interventions aimed at minimizing the disease-producing exposures and optimizing health-promoting exposures or factors, they are performing **experimental studies**.

- In observational studies, nature is allowed to take its course; no intervention; not randomized
- In experimental studies, there is an intervention and the results of the study assess the effects of the intervention

Observational Studies

A **case report** is a brief, objective report of a clinical characteristic or outcome from a single clinical subject or event, n = 1; for example, a 23-year-old man with treatment-resistant TB. No control group. A **case series report** is an objective report of a clinical characteristic or outcome from a group of clinical subjects, n >1, i.e., patients at local hospital with treatment-resistant TB. No control group.

In a **cross-sectional study**, the **presence or absence of disease** (and other variables) is determined in each member of the study population or in a representative sample at a particular time. The co-occurrence of a variable and the disease can be examined.

- Disease prevalence rather than incidence is recorded.
- The temporal sequence of cause and effect cannot usually be determined in a cross-sectional study, e.g., who in the community now has treatment-resistant TB.

A **case-control study** identifies a **group of people with the disease and compares them with a suitable comparison group without the disease.** It is almost always retrospective, e.g., comparing cases of treatment-resistant TB with cases of nonresistant TB. A case-control study is very useful for **studying conditions with very low incidence or prevalence.**

- Cannot assess incidence or prevalence of disease
- Can help determine causal relationships

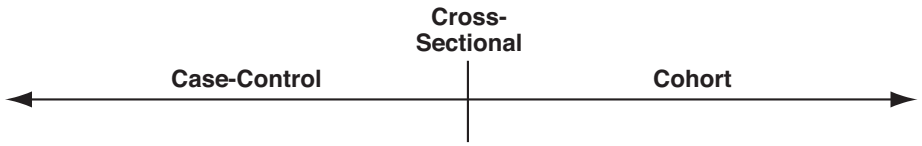


Figure II-20-8. Differentiating Study Types by Time

In a **cohort study**, a population group who has been exposed to the risk factor is identified and followed over time, and compared with a group not exposed to the risk factor. Outcome

is disease incidence in each group, e.g., following a prison inmate population and marking the development of treatment-resistant TB. Cohort studies are **used for more common diseases**.

- Allows you to evaluate whether potential risk factors are related to subsequent outcomes
- Prospective subjects tracked forward in time (may occasionally be retrospective; risk ractor exposure/nonexposure is followed over time past-present)
- Can determine incidence and causal relationships
- Must follow population long enough for incidence to appear
- Historical examples: Framingham study, a long-term study started in 1948, now in the third generation

Analyzing observational studies

For cohort studies, use relative risk and/or attributable risk to measure effect.

Relative risk (RR): Comparative probability asking how much more likely the exposed person is going to get the disease compared to the non-exposed.

- Incidence rate of exposed group **divided by** the incidence rate of the unexposed group. How much greater chance does one group have of contracting the disease compared with the other group?
- For example, if infant mortality rate in whites is 8.9 per 1,000 live births and 18.0 in blacks per 1,000 live births, then the RR of blacks versus whites is 18.0 divided by 8.9 = 2.02. Compared with whites, black infants are 2× as likely to die in the first year of life. **Infant mortality is not a true rate**. The calculation for RR remains unaffected in this calculation.

Attributable risk (AR) (also called absolute risk reduction): Comparative probability asking how many more cases in one group.

- Incidence rate of exposed group minus the incidence rate of the unexposed group
- Using the same example, attributable risk is equal to 18.0 – 8.9 = 9.1. Of every 1,000 black infants, there were 9.1 more deaths than were observed in 1,000 white infants. In this case, attributable risk gives the excess mortality.
- Note that both RR and AR tell us if there are differences but do not tell us why those differences exist.

$$\textbf{AR percentage} = \frac{\text{Incidence in exposed} - \text{Incidence in unexposed}}{\text{Incidence in exposed, e.g., } \frac{18 - 8.9}{18} = 51\% \text{ attributable risk percentage}}$$

This implies that 51% of the excess infant mortality is seen in African American infants.

For case-control studies, use odds ratio.

Odds ratio (OR) (also called relative odds) looks at the increased odds of getting a disease with exposure to a risk factor versus non-exposure to that factor. OR can be calculated from a cohort or case control study.

- Odds of exposure for cases divided by odds of exposure for controls
- Odds that a person with lung cancer was a smoker versus the odds that a person without lung cancer was a smoker

Table II-20-5. Odds Ratio

	Lung Cancer	No Lung Cancer
Smokers	659 (A)	984 (B)
Nonsmokers	25 (C)	348 (D)

$$OR = \frac{A/C}{B/D} = \frac{AD}{BC}$$

Use OR = AD/BC as the working formula. For the above example:

$$OR = \frac{AD}{BC} = \frac{659 \times 348}{984 \times 25} = 9.32$$

The odds of having been a smoker are more than 9× greater for someone with lung cancer compared with someone without lung cancer.

The interpretation of OR is as follows:

- **OR <1:** exposure negatively associated with disease
- **OR = 1:** exposure not related to disease
- **OR >1:** exposure more related to disease

Note

Probability is the likelihood of an event occurring, e.g., the probability of rain today is 75%. **Odds ratio** (or relative odds) looks at the probability the event occurs divided by the probability it will not occur:

0.75/1-0.75 = 0.75/0.25 = 3 to 1 relative odds

Practice Questions

36. How would you analyze the data from this case-control study?

	No Colorectal Cancer	Colorectal Cancer	TOTALS
Family history of colorectal cancer	120	60	180
No family history of colorectal cancer	200	20	220
TOTALS	320	80	400

36. **Answer:** The odds of having colorectal cancer are 5x greater for those who have a family history.

$$OR = \frac{AD}{BC} = \frac{(60)\ (200)}{(120)\ (20)} = 5.0$$

Table II-20-6. Differentiating Observational Studies

Characteristic	Cross-Sectional Study (Prevalence Study)	Case-Control Study	Cohort Study
Time	One time point	Retrospective	Prospective (sometimes retrospective)
Incidence	No	No	Yes
Prevalence	Yes	No	No
Causality	No	Yes	Yes
Role of disease	Measure disease	Begin with disease	End with disease
Assesses	simultaneous assessment of risk factor and disease assess disease burden	Many risk factors for single disease	Single risk factor affecting many diseases
Data analysis	Chi-square to assess association	Odds ratio to estimate association	May calculate relative risk or attributable risk

Table II-20-7. Computational Measures by Type of Observational Study

Measure	Cross-Sectional Study Prevalence Study	Case-Control Study	Cohort Study
Prevalence of disease	Yes	No	No
Prevalence of exposure	Yes	No	No
Odds ratio	No	Yes	Yes
Incidence rate in the exposed	No	No*	Yes
Incidence rate in the nonexposed	No	No*	Yes
Relative risk	No	No	Yes
Attributable risk	No	No	Yes

*In a case control study, calculate the *proportion* (not incidence) of patients with disease who were exposed.

Experimental Studies: Clinical Trials

Clinical trials (intervention studies) use research which involves the administration of a test regimen to evaluate its safety and efficacy. In clinical trials, subjects who do not receive the intervention under study are called the **control group**. The goal is to have a source of comparison to ensure the experiment group is being affected by the intervention and not by other factors (most often a placebo group). To reduce confounding, control group subjects must be as similar as possible to intervention group subjects.

To obtain approval from the FDA, 3 phases of clinical trials must be passed:

Phase 1: testing safety in healthy volunteers

Phase 2: testing protocol and dose levels in small group of patient volunteers

Phase 3: (considered the definitive test): testing efficacy and occurrence of side effects in larger group of patient volunteers

In a **randomized controlled clinical trial** (RCT), subjects are randomly allocated into "intervention" and "control" groups to receive (or not) receive an experimental procedure or intervention. RCTs are generally regarded as the **most scientifically rigorous** studies available in epidemiology.

Double-blind RCT is the type of study least subject to bias, but also the most expensive to conduct. Double-blind means that neither subjects nor researchers who have contact with them know whether the subjects are in the treatment or comparison group.

Community trials are experiments in which the unit of allocation to receive a preventive or therapeutic regimen is an entire community or political subdivision. Does the treatment work in real world circumstances?

Crossover studies are studies in which, for ethical reasons, no group involved can remain untreated. All subjects receive intervention but at different times (e.g., AZT trials). Assume double-blind design, i.e., group A receives AZT for 3 months and group B is the control. Then, for the second 3 months, group B receives AZT and group A is the control.

Table II-20-8. Comparison of Case-Control and Cohort Studies

Case-Control Study	Cohort Study
Small number of subjects	Large number of subjects
Lower cost	Higher cost
Short time period	Longer time period
One disease: multiple past exposures	**One exposure: multiple future diseases**
Low prevalence or high prevalence diseases	High incidence diseases only
Potential for recall bias	Potential for selection bias

STUDY DESIGNS: BIAS IN RESEARCH

Bias versus Confounding

Bias is a type of error in study design. Confounding is universally present in observational studies. The **factor being examined is related to other factors of less interest**. Unanticipated factors obscure a relationship or make it seem like there is one when there is not. More than one explanation can be found for the presented results. An example would be comparing the relationship between exercise and heart disease in 2 populations when one population is younger and the other is older. Are the differences in heart disease due to exercise or to age?

Confounding is not an error, it simply needs to be accounted for in observational studies using multiple regression models. Multiple regression models adjust for any number of variables simultaneously e.g. gender, age, race, socioeconomic status etc. Confounding factors affect the exposure and measured outcome. Confounding may cause the researcher to over or underestimate the association with the exposure and the outcome. Randomized clinical trials are the best study design to avoid confounding.

Types of Bias

Selection bias (sampling bias): the sample selected is **not representative of the population**. For example:

- Predicting rates of heart disease by gathering subjects from a local health club
- Using only hospital records to estimate population prevalence (Berkson's bias)
- People included in study are different from those who are not (nonrespondent bias)

Measurement bias (or information bias): information is gathered in a manner which distorts the information. For example:

- Measuring patients' satisfaction with their respective physicians by using leading questions, such as, "You don't like your doctor, do you?"
- Subjects' behavior is altered because they are being studied (Hawthorne effect). This is a factor only when there is no control group in a prospective study.

Experimenter expectancy (Pygmalion effect): experimenter's expectations are inadvertently communicated to subjects, who then produce the desired effects. Can be avoided by **double-blind design**, where neither the subject nor the investigators know which group receives the intervention under study and which group is the control.

Lead-time bias: gives a false estimate of survival rates. For example, patients seem to live longer with the disease after it is uncovered by a screening test. Actually, there is no increased survival, but because the disease is discovered sooner, patients who are diagnosed seem to live longer.

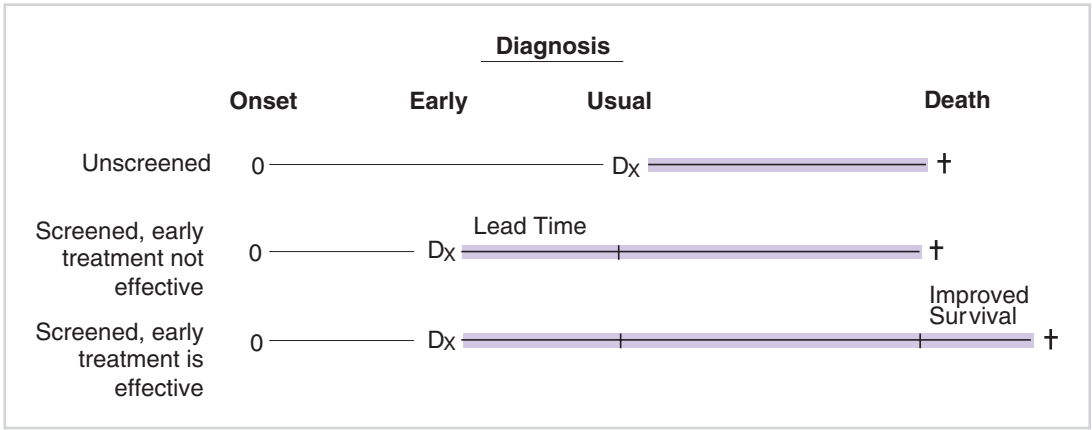

Figure II-20-9. Diagnosis, Time, and Survival

Recall bias: subjects fail to accurately recall events in the past. For example, how many times last year did you kiss your mother? This is a likely problem in retrospective studies.

Late-look bias: individuals with severe disease are less likely to be uncovered in a survey because they die first. For example, a recent survey found that persons with AIDS reported only mild symptoms.

Table II-20-9. Type of Bias in Research and Important Associations

Type of Bias	Definition	Important Associations	Solutions
Selection	Sample not representative	Berkson's bias, nonrespondent bias	Random, independent sample
Measurement	Gathering the information distorts it	Hawthorne effect	Control group/placebo group
Experimenter expectancy	Researcher's beliefs affect outcome	Pygmalion effect	Double-blind design
Lead-time	Early detection confused with increased survival	Benefits of screening	Measure "back-end" survival
Recall	Subjects cannot remember accurately	Retrospective studies	Confirm information with other sources
Late-look	Severely diseased individuals are not uncovered	Early mortality	Stratify by severity

Practice Questions

Response options for Questions 37–41:

A. 520/695
B. 600/1,000
C. 520/600
D. 695/1,000
E. 80/305
F. (520/695)/(80/305)
G. (520 × 225)/(175 × 80)
H. (520/695) – (80/305)
I. Cannot be determined for this type of study

	Disease	Well	
Exposed	520	175	695
Nonexposed	80	225	305
	600	400	1,000

37. Assume the table represents a cross-sectional study: What is the relative risk?

38. Assume the table represents a case-control study: What is the odds ratio?

39. Assume the table represents a cross-sectional study: What is the prevalence of disease?

40. Assume the table represents a disease outbreak investigation: What is the attack rate for people who did not eat the food?

(*Continued*)

Practice Questions (*continued*)

41. A study compares the effectiveness of a new medication for treatment of latent TB infection with the standard medication, isoniazid. Subjects with latent TB infection are sorted with equal likelihood of selection to receive the new medication or isoniazid. Neither the subjects themselves nor the clinicians know the treatment condition for each patient. This study is best described as a

    A. double-blind randomized cohort study
    B. randomized controlled trial with crossover design
    C. double-blind randomized clinical trial
    D. double-blind randomized clinical trial with crossover design
    E. double-blind quasi-experimental trial

37. **Answer: I**. Cannot calculate relative risk from a cross sectional study. Relative risk is calculated from a cohort study.

38. **Answer: G**. Odds ratio = A*D/B*C = 520*225/175*80

39. **Answer: B.** Add exposed and non-exposed with disease for numerator; denominator is population at risk = 600/1000.

40. **Answer: E.** Attack rate for those who did not eat the food = number of people who did not eat the food who became ill over the total number at risk = 80/305

41. **Answer C:** This is the classic description of a double-blinded randomized clinical trial. "sorted with equal likelihood of selection" = randomized

Practice Questions

42. A group of 200 hypertensive subjects and a comparable group of 200 normotensive subjects are recruited and enrolled into a longitudinal study to examine the effect of a diagnosis of hypertension on subsequent occurrence of coronary heart disease. Study subjects are followed for 5 years. Final data are presented below. What is the attributable risk for hypertension? Indicate answer per 1,000.

	CHD	No CHD	Total
Hypertension	25	175	200
No hypertension	10	190	200
Total	35	365	400

    A. 75/100
    B. 250/1,000
    C. 35/1,000
    D. 125/1,000
    E. Cannot be computed for this type of study

(*Continued*)

Practice Questions (*continued*)

43. A study is conducted relating percentage of calories from fat in the habitual diet to subsequent incidence of clinical diabetes mellitus. Four groups of initally well persons are selected from the community to represent persons within each of 4 categories of fat intake. The percentages of daily calories from fat are: <20%, 20.40%, 35.49%, >50%. The groups are followed longitudinally for 5 years and assessed annually for diabetes. The type of study design is best described as a

    A. case-series trial
    B. case-control study
    C. cross-sectional study
    D. cohort study
    E. community trial

44. Alcohol consumption and cigarette smoking both contribute causally to the occurrence of esophageal cancer. These risk factors are not independent; in fact, they operate synergistically. A study of cigarette smoking in relation to esophageal cancer that fails to stratify or otherwise control for level of alcohol consumption would be guilty of which of the following threats to validity?

    A. Ascertainment bias
    B. Confounding
    C. Design bias
    D. Lead time bias
    E. Observer bias
    F. Recall bias
    G. Response bias
    H. Selection bias

42. **Answer: A.**

43. **Answer: D.**

44. **Answer: B.**

21 Biostatistics

Learning Objectives

- List the basic principles of probability and describe the connection to statistics
- Demonstrate how to calculate mode, mean, median, standard error, and standard deviation, and describe how they differ
- Describe the purpose of inferential statistical tests, such as student T test, chi-square, and analysis of variance
- Select an appropriate statistical test for a set of data to be analyzed

PROBABILITY

Combine probabilities for **independent events by multiplication**. Events are independent if the occurrence of one tells you nothing about the occurrence of another.

- If the chance of having blond hair is 0.3 and the chance of having a cold is 0.2, the chance of meeting a blond-haired person with a cold is $0.3 \times 0.2 = 0.06$ (or 6%).
- If events are nonindependent, then multiply the probability of one times the probability of the second, given that the first has occurred. For example, if one has a box with 5 white and 5 black balls in it, the chance of picking 2 black balls is $(5/10) \times (4/9) = 0.5 \times 0.44 = 0.22$ (or 22%).

Combine probabilities for **mutually exclusive events by addition**. Mutually exclusive means that the occurrence of one event precludes the occurrence of the other (i.e., cannot both happen).

- If a coin lands heads, it cannot be tails; the two are mutually exclusive. So if a coin is flipped, the chance that it will be either heads or tails is $0.5 + 0.5 = 1.0$ (or 100%).
- If two events are not mutually exclusive, the combination of probabilities is accomplished by adding the two together and subtracting out the multiplied probabilities. If the chance of having diabetes is 10%, and the chance of someone being obese is 30%, the chance of meeting someone who is obese or had diabetes is $0.1 + 0.30 - (0.1 \times 0.30) = 0.37$ (or 37%).

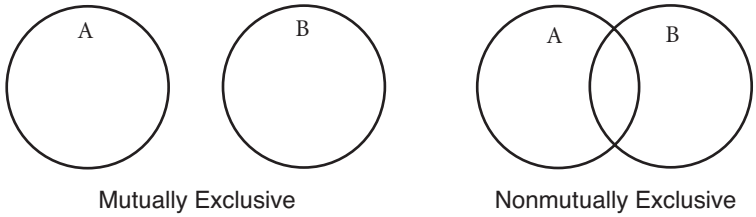

Figure II-21-1. Venn Diagram Representations of Mutually Exclusive and Nonmutually Exclusive Events

Practice Questions

Survival Rates After Surgery

N	1 Year	2 Year	3 Year	4 Year
183	90%	75%	50%	40%

1. What is the average life expectancy after surgery?
2. If a patient survives for 2 years, what is the chance of surviving for 3 years?
3. In an effort to evaluate healthy lifestyle influences at home, a study is conducted to see how many pediatric patients have parents who exercise regularly. Parents at pediatric offices are questioned and it is concluded that 40% of pediatric patients have parents who exercise regularly. Assuming the events are independent, what is the probability that 2 pediatric patients with parents who exercise regularly will come into the office on the same day?

   (A) 0.16
   (B) 0.4
   (C) 0.8
   (D) 0.96
   (E) 0.08
   (F) 0.04

1. 3 years
2. 50/75
3. **Answer: A.** This requires the multiplication rule.

DESCRIPTIVE STATISTICS

Measures of Central Tendency

Measures (indices) of central tendency are **identifiers for the center of a distribution (or data) set.** These measures **determine a value in the middle of the data, around which the rest of the data are centered.**

Mean (or average) is the sum of the values of the observations divided by the numbers of observations.

$$\text{Mean} = \frac{\text{Sum of the observed measurements}}{\text{Number of observations}}$$

Median is the measurement below which half of the observations fall, e.g., the 50th percentile. The simplest division of a set of measurements is into 2 parts: upper and lower half. The point on the scale that divides the group in this way is the median.

Mode is the most frequently occurring value in a set of observations.

Normal Distribution

Normal distribution is **continuous frequency distribution of infinite range**, defined by a specific mathematical function with the following properties:

- A continuous, symmetrical distribution; both tails extend to infinity
- Arithmetic mean, mode, and median are identical
- Shape is completely determined by the mean and standard deviation
- Also called Gaussian distribution or "bell-shaped" curve

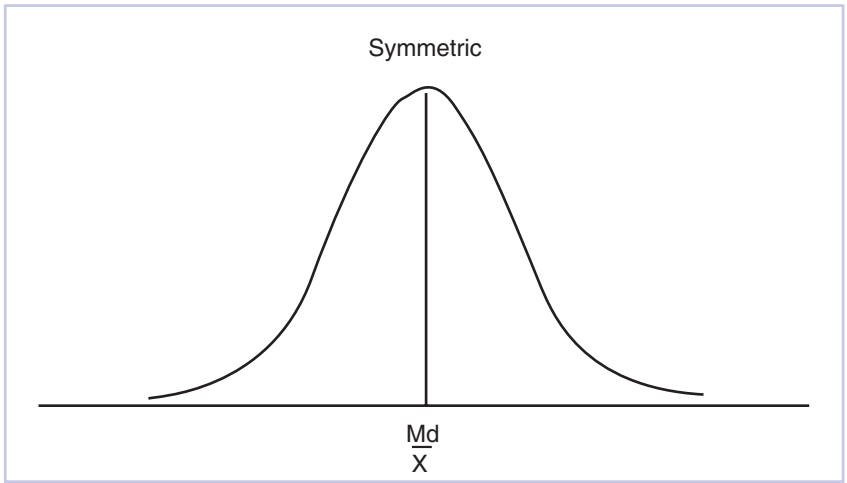

Figure II-21-2. Measures of Central Tendency

Note

If a distribution is skewed, increasing the sample size will not affect the "skewness."

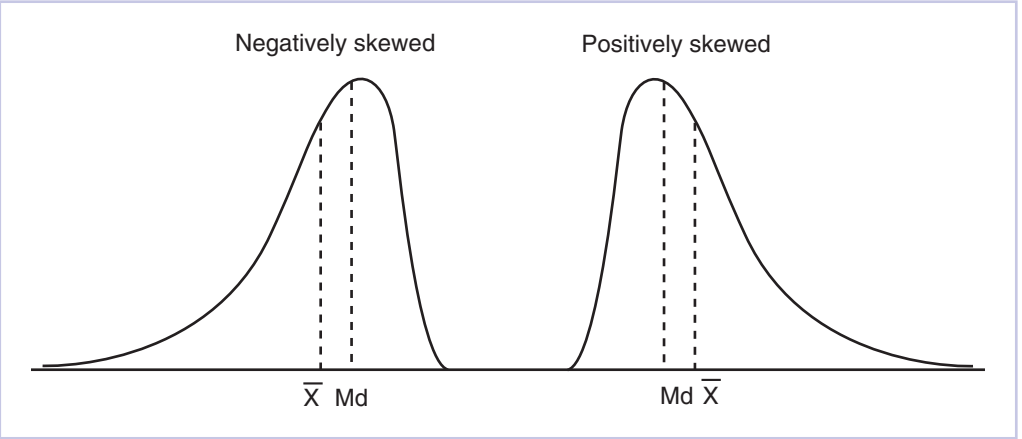

Figure II-21-3. Skewed Distribution Curves

Negative skewed is also called left skewed tail (in the negative direction). Mean is less than median. **Positive skewed** is also called right skewed tail (in the positive direction). Mean is greater than the median.

Dispersion of Data

The dispersion of data helps us identify the spread, or the variation, of the data.

Range is the difference between the largest and smallest values in a distribution.

Variance is a measure of the variation shown by a set of observations, defined by the sum of the squares of deviations scores of each value divided by the number of degrees of freedom in the set of observations or n – 1.

Standard deviation (s or sd) is the most widely used measure of dispersion of a frequency distribution. It is equal to the positive square root of the variance. Whereas the **mean tells where the group of values are centered**, the **standard deviation is a summary of how widely dispersed the values are around the center**.

$$s = \sqrt{\frac{\sum(X - \bar{X})^2}{n - 1}}$$

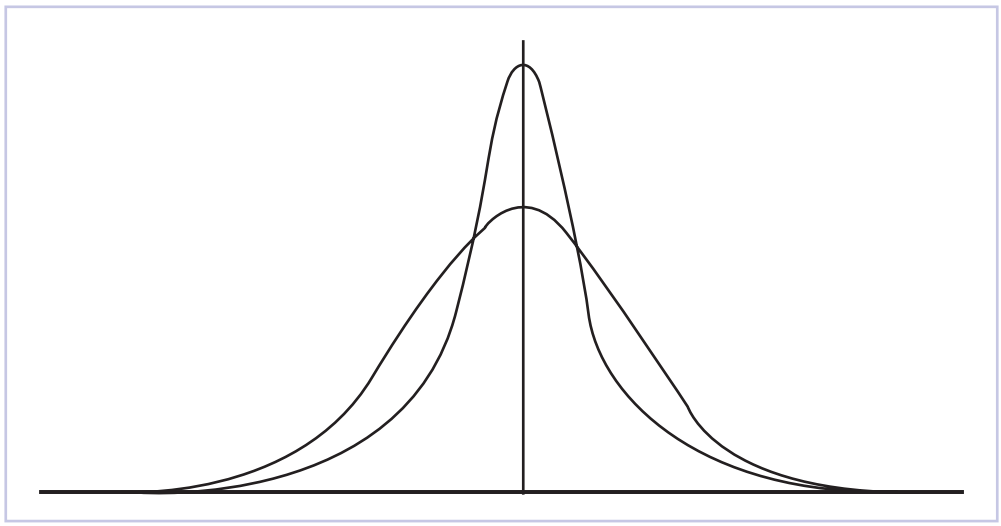

Figure II-21-4. Comparison of Two Normal Curves with the Same Means, but Different Standard Deviations

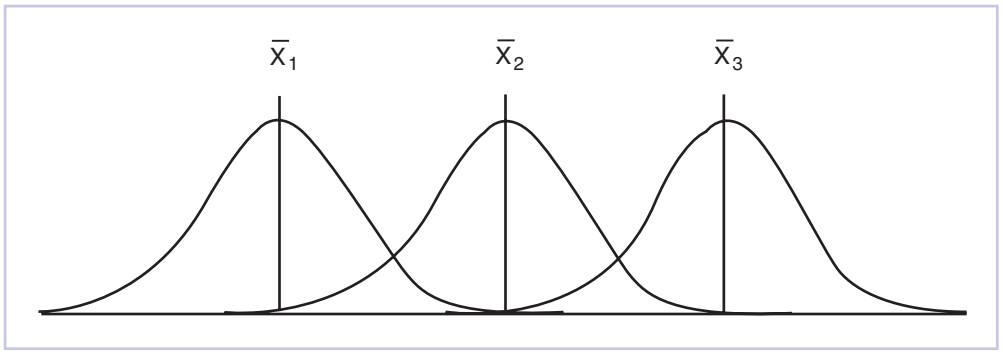

Figure II-21-5. Comparison of Three Normal Curves with the Same Standard Deviations, but Different Means

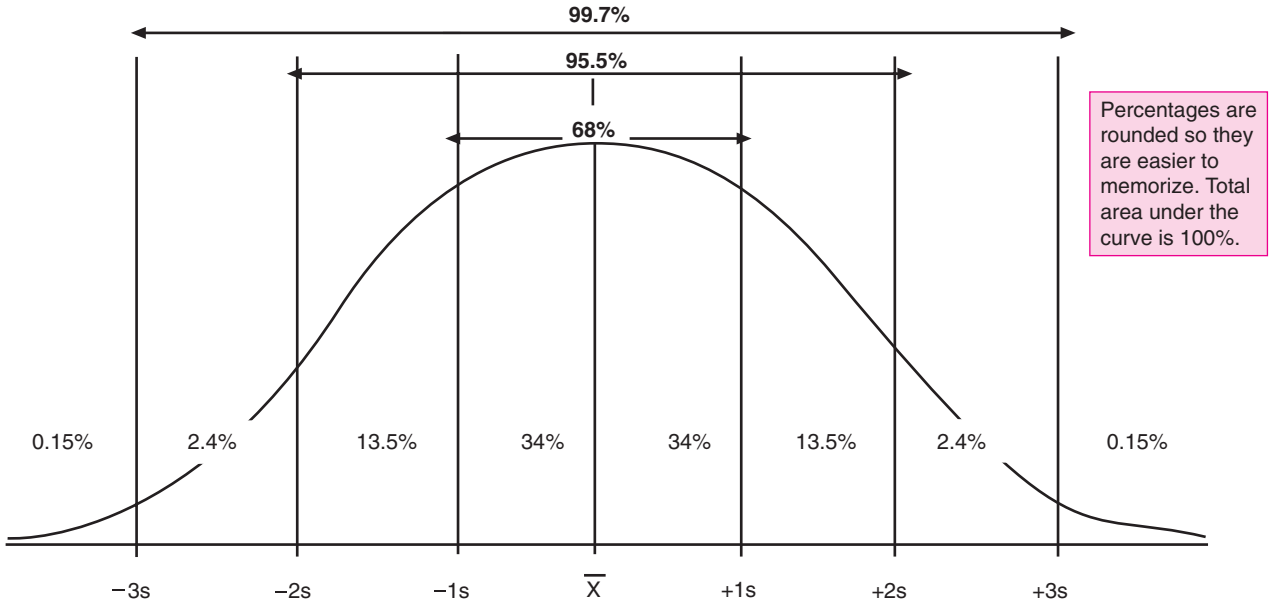

Figure II-21-6. Percentage of Cases within 1, 2, and 3 Standard Deviations of the Mean in a Normal Distribution

The sd is stated in score units. The normal curve has the property that within 1 sd a certain proportion of the cases is included. The property is as follows:

- Between the mean and the value of 1 sd from the mean in either direction, there will be 34% of the cases; there will be 68% of the cases between the score at 1 sd above and 1 sd below the mean.
- Within 2 sd of the mean are 95.5% of the cases.
- Between 1 sd and 2 sd from the mean in either direction, there will be 13.5% of the cases, or 27% for both.
- Within 3 sd of the mean are 99.7% of the cases.
- And between 2 sd and 3 sd from the mean there will be almost 2.5% of the cases, 4.7% for the two extremes together.

There will be a few cases, of course, 0.3%, beyond 3s from the mean both above and below the mean.

You must know these figures for the exam. For example: What percentage of the cases are below 2s below the mean? (2.5%)

Note

On the exam you will not be asked to calculate sd and variance, but you must know what they are and how they relate to the normal curve.

INFERENTIAL STATISTICS

The purpose of inferential statistics is to designate **how likely it is that a given finding is simply the result of chance**. Inferential statistics would not be necessary if investigators studied all members of a population. However, because we can rarely observe and study entire populations, we try to select samples that are representative of the entire population in order to be able to generalize the results from the sample to the population.

Inferential statistics focuses on drawing conclusions about an entire population (i.e., parameter) based on information in a sample.

Confidence Intervals

Confidence intervals are a way of admitting that any measurement from a sample is only an estimate of the population. Although the estimate given from the sample is likely to be close, the true values for the population may be above or below the sample values.

A confidence interval specifies **how far above or below a sample-based value the population value lies within a given range**, from a possible high to a possible low. The true mean, therefore, is most likely to be somewhere within the specified range.

Confidence interval of the mean

The confidence interval contains 2 parts: an estimate of the quality of the sample for the estimate (or the standard error of the mean), and the degree of confidence provided by the interval specified (or the standard or Z-score). The confidence interval of the mean can be calculated as follows:

$$\textbf{Mean} \pm \textbf{appropriate Z-score} \times \textbf{standard error of the mean} = \bar{X} \pm Z\,(S/\sqrt{N})$$

Increasing the sample size will narrow the confidence interval, i.e., improve the precision of the estimate.

Standard error of the mean is the standard deviation divided by the square root of the sample size. It demonstrates the sample mean deviation from the true population mean.

- If the sd is larger, the chance of error in the estimate is greater.
- If the sample size is larger, the chance of error in the estimate is less.

The **Z-score or sd score** is a score from a normal distribution with a mean of 0 and a standard deviation of 1. Any distribution can be converted into a Z-score distribution using the formula:

$$Z = (\bar{X} - X)/S$$

$$Z = \textbf{Sample mean} - \textbf{population mean/Standard deviation}$$

The Z-score distribution is easy to use for calculations because it has simple values. All points in a Z-score distribution are represented in sd units. **Positive scores are above the mean**, while **negative scores are below the mean**. Therefore, a Z-score of +2.0 is exactly 2 standard deviations above the mean; a Z-score of .1.5 is exactly 1.5 standard deviations below the mean.

Z-scores are used in computing confidence intervals to set the level of confidence. Recall that in a normal distribution, 95.5% of the cases are within two standard deviations (2 sd) of the mean. To get 95% confidence and 99% confidence, all we need to know is what symmetric Z-score to use to contain exactly 95% and 99% of the cases.

- For 95% confidence = 1.96; for calculation purposes, use **Z-score of 2.0** (most commonly used)
- For 99% confidence = 2.58; for calculation purposes, use **Z-score of 2.5**

Note that a 99% confidence interval will be wider than a 95% interval.

Confidence intervals for RR and odds ratios

If the given confidence interval contains 1.0, then there is no statistically significant effect of exposure. For example:

Relative Risk	95% Confidence Interval	Interpretation
1.57	(1.1–2.25)	Statistically significant (increased risk); 57% increased risk with the intervention
1.65	(0.89–2.34)	Not statistically significant (risk is the same); the confidence interval includes 1 (null value)
0.76	(0.56–0.93)	Statistically significant (decreased risk); 24% reduced risk with the intervention

Hypothesis Testing

A hypothesis is a statement that postulates a difference between 2 groups. Inferential statistics is used to evaluate the possibility that this difference occurred by chance.

- **Null hypothesis** says the findings are the **result of chance or random factors**. If you want to show that a drug works, the null hypothesis will be that the drug does not work. The p value (see below) is the chance of getting the result assuming the null hypothesis is true.
  - **One-tailed, i.e., directional** or 1-sided such that one group is greater than or less than the other. For example, Group A is not < Group B, or Group A is not > Group B.
  - **Two-tailed, i.e., nondirectional** or 2-sided such that 2 groups are not the same. For example, Group A = Group B. (most commonly used)
- **Alternative hypothesis** says what is left after defining the null hypothesis. In this example, the drug actually does work.

Significance Testing

To test your hypothesis, you would draw a random sample from a population (e.g., men with hypertension) and make an inference. But before you sample, you set a significance level, alpha, which is the risk of error you are willing to tolerate.

Customarily, the level of significance is set at 0.05 and the risk is associated with the rejection of the null hypothesis, even though it is true (e.g., type I error).

Interpretation

p-value

Both the p-value and alpha level symbolize significance, and they are very similar (usually set at 0.05).

They are only slightly different in that p-value measures the strength or magnitude (i.e., significance) of the data against the null hypothesis, whereas alpha level represents risk and is independent of data.

A p-value is used to interpret output from a statistical test; focus on the p-value. The p-value refers to 2 things: first, it is a standard against which we compare our results, and second, it

is a result of computation. The **computed p-value is compared with the p-value criterion to test statistical significance**. If the computed value is less than the criterion, we have achieved statistical significance. In general, the smaller the p the better. The p value of a **1-sided t test is exactly half the p value of a 2-sided t test**. One-sided t tests are not commonly used.

The *p*-value criterion is traditionally set at $p \leq 0.05$. (Assume that these are the criteria if no other value is explicitly specified.) Using this standard:

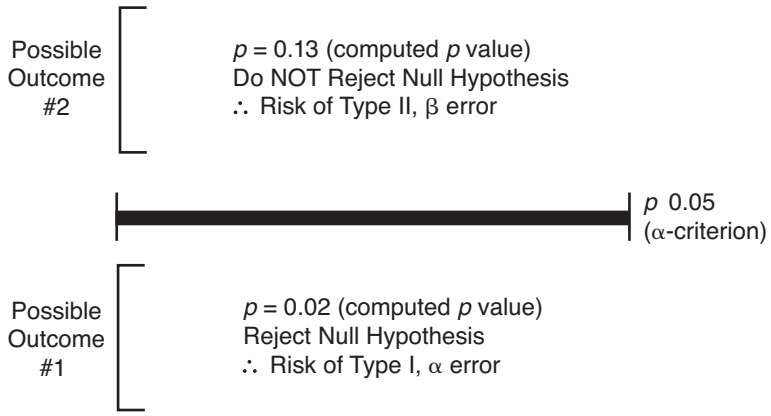

Figure II-21-7. Making Decisions Using *p* -Values

- If $p \leq 0.05$, reject the null hypothesis (reached statistical significance).
- If $p > 0.05$, do not reject the null hypothesis (has not reached statistical significance).

Therefore:

- If $p = 0.13$, fail to reject the null hypothesis, i.e., decide that the drug does not work.
- If $p = 0.02$, reject the null hypothesis, i.e., decide that the drug works.

Types of error

Just because we reject the null hypothesis, we are not certain that we are correct. For some reason, the results given by the sample may be inconsistent with the full population. If this is true, any decision we make on the basis of the sample could be in error. There are 2 types of error we could make:

- **Type I error** (α error): **rejecting the null hypothesis when it is really true**, i.e., assuming a statistically significant effect on the basis of the sample when there is none in the population or asserting that the drug works when it does not.
  - The chance of a type I error is given by the p-value. If p (or a) = 0.05, then the chance of a Type I error is 5 in 100, or 1 in 20.
- **Type II error** (β error): failing to reject the null hypothesis when it is really false, i.e., declaring no significant effect on the basis of the sample when there really is one in the population or asserting the drug does not work when it really does.
  - The chance of a Type II error cannot be directly estimated from the p-value.

The alpha level criterion can also be considered the probability of making a type I error. The alpha level criterion is set up in advance of the test. Beta is the probability of making a type II error.

Note

For odds ratio and relative risk, the **null value = 1**.

Power is the capacity to detect a difference if there is one. Increasing sample size (n) increases power. The **general standard for power in a study is 80% or greater**.

Power = 1-beta

When a study with **low power finds a non-statistically significant result**, it is difficult to interpret, i.e., perhaps the study was not designed with enough power to detect a difference. The study result is then better termed inconclusive. In other words, when a study with higher power finds no association, one is more confident with the results of the study.

Meaning of the p-value

- Provides criterion for making decisions about the null hypothesis.
- Quantifies the chances that a decision to reject the null hypothesis will be wrong.
- Tells statistical significance, not clinical significance or likelihood of benefit.
- Generally, p-value is considered statistically significant if it is equal to or less than 0.05.

Limits to the p-value

- Does not tell us the chance that an individual patient will benefit
- Does not tell us the percentage of patients who will benefit
- Does not tell us the degree of benefit expected for a given patient

Types of Scale

To convert the world into numbers, we use 4 types of scale: nominal, ordinal, interval, and ratio scales.

Table II-21-1. Types of Scales in Statistics

Type of Scale	Description	Key Words	Examples
Nominal (Categorical)	Different groups	This or that	Gender, comparing among treatment interventions
Ordinal	Groups in sequence	Comparative quality, rank order	Olympic medals, class rank in medical school
Interval	Exact differences among groups	Quantity, mean, and standard deviation	Height, weight, blood pressure, drug dosage
Ratio	Interval + true zero point	Zero means zero	Temperature measured in degrees Kelvin

A **nominal scale** puts people into boxes without specifying the relationship between the boxes. Sex is a common example, with 2 groups: male and female. Any time you can say it's either this or that, you are dealing with a nominal scale.

Numbers can also be used to express **ordinal** or rank-order relations. For example, we say Ben is taller than Fred. Now we know more than just the category in which to place someone.

We know something about the relationship between the categories (quality). What we do not know is how different the 2 categories are (quantity). Class rank in medical school and medals at the Olympics are examples of ordinal scales.

An **interval scale** (or numeric scale) uses a scale graded in equal increments. In the scale of length, we know that one inch is equal to any other inch. Interval scales allow us to say not only that two things are different, but by how much. If a measurement has a mean and a standard deviation, treat it as an interval scale.

The best measure is the **ratio scale**. This scale orders things and contains equal intervals, as do the previous 2 scales, but it has one additional quality: a true zero point. In a ratio scale, zero is a floor, i.e., you cannot go any lower. Measuring temperature using the Kelvin scale yields a ratio scale measurement.

SELECTING A STATISTICAL TEST

Table II-21-2. Types of Scales and Basic Statistical Tests

	Variables		
Name of Statistical Test	Interval	Nominal	Comment
Pearson Correlation	2	0	Is there a linear relationship?
Chi-square	0	2	Any # of groups
t-test	1	1	2 groups only
One-way ANOVA	1	1	2 or more groups
Matched pairs *t*-test	1	1	2 groups, linked data pairs, before and after
Repeated measures ANOVA	1	1	More than 2 groups, linked data

Meta-analysis is a statistical way of **combining the results of many studies** to produce one overall conclusion. It is a mathematic literature review.

Correlation Analysis (r, ranges from –1 to +1)

A **positive value** means that 2 variables go together in the same direction, e.g., MCAT scores have a positive correlation with medical school grades. A **negative value** means the presence of one variable is associated with the absence of another variable, e.g., there is a negative correlation between age and quickness of reflexes.

- The further from zero, the stronger the relationship (r = 0).
- A zero correlation means that 2 variables have no linear relation to one another, e.g., height and success in medical school.

There are 2 types of correlation:

- **Pearson correlation** compares 2 interval level variables
- **Spearman correlation** compares 2 ordinal level variables

Note

Correlation, by itself, does not mean causation. A correlation coefficient indicates the **degree** to which 2 measures are related, not *why* they are related. It does not mean that one variable necessarily causes the other.

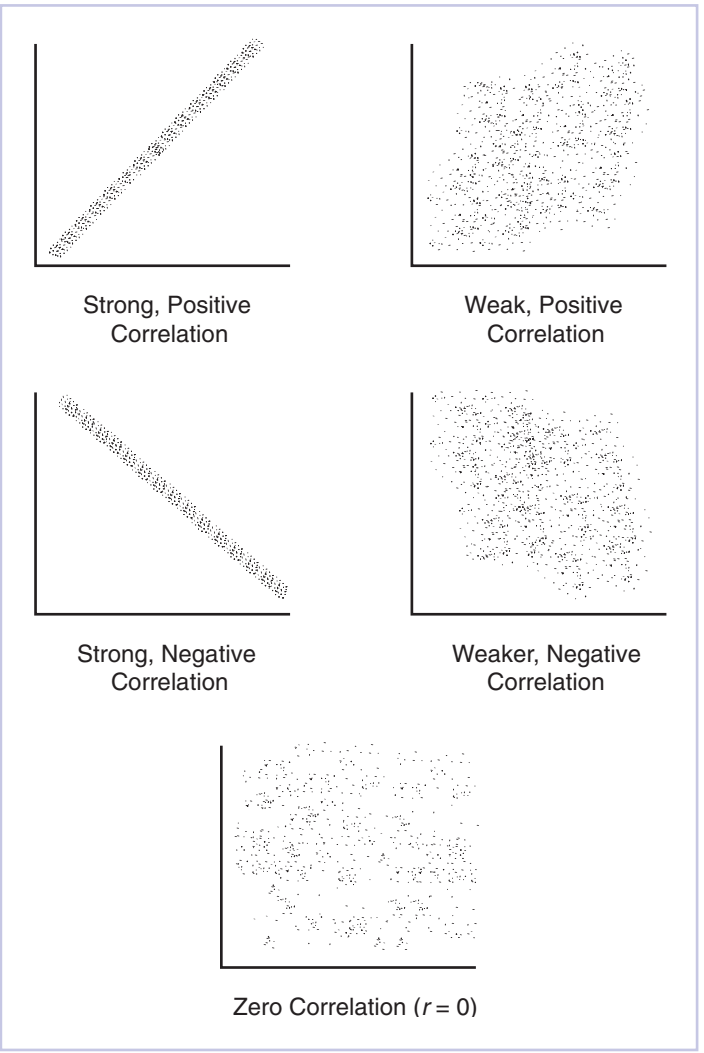

Figure II-21-8. Scatter Plots and Correlations

To graph a correlation using a scatterplot, know that a scatterplot will show points that approximate a line. Be able to interpret scatter plots of data: positive slope, negative slope, and which of a set of scatterplots indicates a stronger correlation.

t-Tests

The output of a t-test is a t-statistic. It **compares the means of 2 groups** from a single nominal variable, using means from an interval variable to see whether the groups are different. It is used for 2 groups only, i.e., compares 2 means. For example, do patients with MI who are in psychotherapy have a reduced length of convalescence compared with those who are not in therapy?

- **Pooled t-test**: regular t-test, assuming the variances of the 2 groups are the same
- **Matched pairs t-test**: if each person in one group is matched with a person in the second; applies to before and after measures and linked data

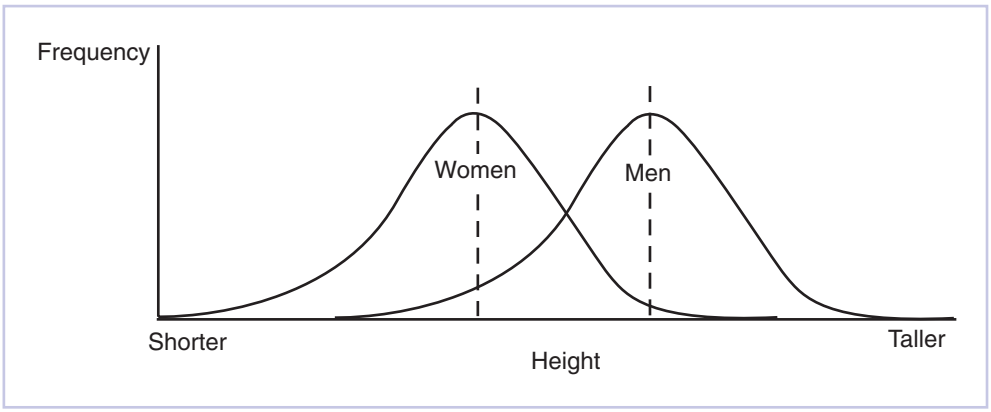

Figure II-21-9. Comparison of the Distributions of Two Groups

Analysis of Variance

Output from an analysis of variance (ANOVA) is one or more "F" statistic, which is converted to a *p* value.

- **One-way** compares means of many groups (2+) of a single nominal variable using an interval variable. Significant *p*-value means that at least 2 of the tested groups are different
- **Two-way** compares means of groups generated by 2 nominal variables using an interval variable. Can test effects of several variables at the same time.
- Repeated measures ANOVA: multiple measurements of same people over time

Chi-Square

Chi-square tests to see whether 2 nominal variables are independent, e.g., testing the efficacy of a new drug by comparing the number of recovered patients given the drug with those who are not.

- Nominal data (or categorical data) only
- Any number of groups

Chi-square is an example of nonparametric test. T test is an example of parametric test, i.e., it involves scores or measurements that come from **normal distributions**. Nonparametric testing is used for categorical data.

Table II-21-3. Chi-Square Analysis for Nominal Data

	New Drug	Placebo	Totals
Recovered	45	35	80
Not Recovered	15	25	40
Totals	60	60	120

Practice Questions

1. The American Medical Association commissions a health study of a representative sample of U.S. physicians. Enrolled physicians complete detailed surveys and undergo an extensive battery of medical tests. For a number of analyses, physicians are classified by subspecialty. Although numerous physiologic measures are assessed, the following questions describe analyses of just one of these, mean fasting plasma glucose. Select the appropriate statistical test for a comparison of mean fasting plasma glucose values for representative samples of surgeons and cardiologists.

   A. *t*-test
   B. Matched pairs *t*-test
   C. One-way ANOVA
   D. Two-way ANOVA
   E. Chi-square

2. An experimenter conducts a test of a new medication compared with the current standard medication. Alpha is selected to be 0.05. At the conclusion of the trial, the sample of patients receiving the new medication shows more improvement than the comparison group on the standard medication. The *p*-value is 0.002. What will the experimenter conclude?

   A. Do not reject the null hypothesis.
   B. The new medication has more clinical benefits than the standard medication.
   C. The likelihood that a type I error has actually been committed is less than the maximum risk the experimenter was willing to accept.
   D. The result is not significant.
   E. A type II error has been committed.

3. Body mass index (BMI) is found to correlate to the following physiologic measures. For which measure is the correlation the strongest?

   A. Physical activity ($r = -0.56$)
   B. Percentage of calories from complex carbohydrates ($r = -0.32$)
   C. Systolic blood pressure ($r = +0.43$)
   D. Triglycerides ($r = +0.37$)
   E. LDL cholesterol ($r = +0.49$)

4. A new treatment for elevated cholesterol is piloted on a sample of 100 men, ages 45–59 with total serum cholesterol in the range of 260–299 mg/dL at entry. Following 3 months on the medication, the mean cholesterol for the treatment group was 250 mg/dL with a standard deviation of 20 mg/dL. What is the 95% confidence interval on the mean for this study?

   A. 210–290 mg/dL
   B. 230–270 mg/dL
   C. 246–254 mg/dL
   D. 248–252 mg/dL
   E. 249–251 mg/dL

Practice Questions

5. The Wechsler Adult Intelligence Scale–Revised (WAIS-R) is a standardized IQ test with a mean of 100 and a standard deviation of 15. A person with an IQ of 115 is at what percentile of IQ?

   A. 50th
   B. 68th
   C. 84th
   D. 95th
   E. 99th

6. From a published article describing the results of the study presented above, the following data table is abstracted. This table presents the relative risks (RR) of clinical diabetes for each of the categories of fat intake relative to the baseline category of <20%. Interpret the study findings from the tabular data.

	% of Calories from Fat	RR for Diabetes	95% Confidence Interval
Baseline	<20	1	—
Level 2	20–34	1.3	0.8–1.8
Level 3	35–49	2	1.6–2.6
Level 4	>50	3	2.7–3.3

   A. Levels 2, 3, and 4 have significantly elevated risks for diabetes relative to baseline.
   B. Levels 2 and 3 are significantly different from each other.
   C. Levels 3 and 4 are significantly different from baseline and risk elevating.
   D. Levels 3 and 4 are not significantly different from each other.
   E. RR for levels 2, 3, and 4 are numerically different but not significantly different from baseline.

1. **Answer: A**. T test is used to compare means of glucose levels in these 2 groups. ANOVA is used for 3+ groups.
2. **Answer: C**. The p value <0.05 (less than 1 in 20) is the probability of obtaining this result based on chance alone assuming the null hypothesis is true.
3. **Answer: A**. R = –0.56 has the strongest negative correlation of the choices. Choose the number closest to –1.0 or +1.0.
4. **Answer: C**. 95% confidence interval can be estimated by mean + or –2* (standard deviation/square root n) 2*(20/square root 100) = 2*(20/10) = 4. 250 + or – 4 = 246 to 254 mg/dL
5. **Answer: C**.
6. **Answer: C**. Level 2 confidence intervals contain 1 (not statistically significant). Level 3 and 4 confidence intervals do not contain 1 (statistically significant).

Ethics 22

Learning Objectives

- Identify some important Supreme Court cases related to medical ethics, and explain their significance
- Distinguish between the ethical and legal principles, and explain how they affect medical practice

SELECTED IMPORTANT COURT CASES

Karen Ann Quinlan: Substituted Judgment Standard

In the Quinlan case, Karen Ann was in a persistent vegetative state, being kept alive only by life support. Karen's father asked to have her life support terminated according to his understanding of what Karen Ann would want. The court found that "if Karen herself were miraculously lucid for an interval . . . and perceptive of her irreversible condition, she could effectively decide upon discontinuance of the life support apparatus, even if it meant the prospect of natural death."

The court therefore allowed termination of life support, not because the father asked, but because it held that the father's request was most likely the expression of Karen Ann's own wishes.

Substituted judgment begins with the premise that decisions belong to the competent patient by virtue of the rights of autonomy and privacy. In this case, however, the patient is unable to decide, and a decision-maker who is the best representative of the patient's wishes must be substituted. In legal terms, the patient has the right to decide but is incompetent to do so. Therefore, the decision is made for the patient on the basis of the best estimate of his or her subjective wishes.

The key here is *not* who is the closest next of kin, but who is most likely to represent the patient's own wishes.

Brother Fox *(Eichner vs Dillon)*: Best Interest Standard

The New York Court of Appeals, in its decision of *Eichner vs Dillon,* held that trying to determine what a never-competent patient would have decided is practically impossible. Obviously, it is difficult to ascertain the actual (subjective) wishes of incompetents.

Therefore, if the patient has always been incompetent, or no one knows the patient well enough to render substituted judgment, the use of substituted judgment standard is questionable, at best.

Under these circumstances, decisions are made for the patient using the **best interest standard**. The object of the standard is to decide what a hypothetical "reasonable person" would decide to do after weighing the benefits and burdens of each course of action.

Note here the issue of who makes the decision is less important. All persons applying the best-interest standard should come to the same conclusions.

Infant Doe: Foregoing Lifesaving Surgery, Parents Withholding Treatment

As a general rule, parents cannot withhold life- or limb-saving treatment from their children. Yet, in this exceptional case they did.

Baby Boy Doe was born with Down syndrome (trisomy 21) and with a tracheo-esophageal fistula. The infant's parents were informed that surgery to correct his fistula would have "an even chance of success." Left untreated, the fistula would soon lead to the infant's death from starvation or pneumonia. The parents, who also had two healthy children, chose to withhold food and treatment and "let nature take its course."

Court action to remove the infant from his parents' custody (and permit the surgery) was sought by the county prosecutor. The court denied such action, and the Indiana Supreme Court declined to review the lower court's ruling. Infant Doe died at 6 days of age, as Indiana authorities were seeking intervention from the U.S. Supreme Court.

This case is simply an application of the best-interest standard. The court agreed with the parents that the burdens of treatment far outweighed any expected benefits.

Roe vs Wade (1973): The Patient Decides

Known to most people as the "abortion legalizing decision," the importance of this case is not limited to its impact on abortion.

Faced with a conflict between the rights of the mother versus the rights of the putative unborn child, the court held that in the first trimester, the mother's rights are certainly paramount, and that states may, if they wish, have the mother's rights remain paramount for the full term of the pregnancy.

Because the mother gets to decide, even in the face of threats to the fetus, by extension, all patients get to decide about their own bodies and the health care they receive. In the United States, the locus for decision-making about health care resides with the patient, not the physician.

Note that courts have held that a pregnant woman has the right to refuse care (e.g., blood transfusions) even if it places her unborn child at risk.

Tarasoff Decision: Duty to Warn and Duty to Protect

A student visiting a counselor at a counseling center in California states that he is going to kill someone. When he leaves, the counselor is concerned enough to call the police but takes no further action. The student subsequently kills the person he threatened. The court found the counselor and the center liable because they did not go far enough to warn and protect the potential victim.

The counselor should have called the police and then should also have tried in every way possible to notify the potential victim of the potential danger.

In similar situations, first try to detain the person making the threat, next call the police, and finally notify and warn the potential victim. All three actions should be taken, or at least attempted.

LEGAL ISSUES RELATED TO MEDICAL PRACTICE

This section lays out a set of rules that constitute the general consensus of legal opinion. Apply these rules to individual situations as they arise.

Rule #1: Competent patients have the right to refuse medical treatment.

Incompetent patients have the same rights, but must be exercised differently (via a surrogate).

- Patients have an almost absolute right to refuse. Patients have almost absolute control over their own bodies. The sicker the patient, the lesser the chance of recovery, the greater the right to refuse treatment.

Rule #2: If a patient is incompetent to make decisions, the physician may rely on advance directives.

Advance directives can be oral.

- Living will: written document expressing wishes
  - Care facilities must provide information at time of admission
  - Responsibility of the institution, not the physician
  - Only applies to end-of-life care
- Health power of attorney: designating the surrogate decision-maker
  - "Speaks with the patient's voice"
  - Beats all other decision rules
- In end-of-life circumstances, if power of attorney person *directly* contradicts the living will, follow the living will.

Rule #3: Assume the patient is competent unless clear behavioral evidence indicates otherwise.

Competence is a legal, not a medical issue.

- A diagnosis, by itself, tells you little about a patient's competence.

- Clear behavioral evidence would be:
  - Patient is grossly psychotic and dysfunctional
  - Patient's physical or mental state prevents simple communication
- If you are unsure, assume the patient is competent. The patient does not have to prove to you that he is competent. You have to have clear evidence to assume that he is not.

Rule #4: When surrogates make decisions for a patient, they should use the following criteria and in this order:

- Subjective standard
  - Actual intent, advance directive
  - What did the patient say in the past?
- Substituted judgment
  - Who best represents the patient?
  - What would patient say if he or she could?
- Best-interest standard
  - Burdens versus benefits
  - Interests of patient, not preferences of the decision-maker

Note

Family matters only to the degree that reflects the patient's wishes. Family's own wishes are not relevant.

Rule #5: Feeding tube is a medical treatment and can be withdrawn at the patient's request.

A feeding tube is not considered killing the patient, but rather stopping treatment at a patient's request.

- A competent person can refuse even lifesaving hydration and nutrition.

Rule #6: Do nothing to actively assist the patient to die sooner.

Active euthanasia and assisted suicide are on difficult ground.

- Passive, i.e., allowing to die = OK
- Active, i.e., killing = NOT OK

On the other hand, do all you can to reduce the patient's suffering (e.g., giving pain medication).

Rule #7: The physician decides when the patient is dead.

If the physician thinks continued treatment is futile (the patient has shown no improvement), but the surrogate insists on continued treatment, the treatment should continue. If there are no more treatment options (the patient is cortically dead), and the family insists on treatment, there is nothing the physician can do; treatment must stop.

Rule #8: Never abandon a patient.

Lack of financial resources or lack of results are never reasons to stop treatment of a patient. An annoying or difficult patient is still your patient; you cannot ever threaten abandonment.

Rule #9: Keep the physician–patient relationship within bounds.

Intimate social contact with anyone who is or has been a patient is prohibited. AMA guidelines say, "for at least 2 years."

- Do not date parents of pediatric patients or children of geriatric patients.
- Do not treat friends or family.
- Do not prescribe for colleagues unless a physician/patient relationship exists.

- If patients are inappropriate, gently but clearly let them know what acceptable behavior would be.
- Any gift from a patient beyond a small token should be declined.

Rule #10 Stop harm from happening

Beyond "do no harm," you must stop anyone from hurting himself or others. Take whatever action is required to prevent harm.

- Harm can be spreading disease, physical assault, psychological abuse, neglect, infliction of pain or anything which produces notable disress.
- You must also protect your patient, or anyone not your patient, from being hurt by another.

Rule #11: Always obtain informed consent.

Full, informed consent requires that the patient has received and understood 5 pieces of information:

  - Nature of procedure
  - Purpose or rationale
  - Benefits
  - Risks
  - Availability of alternatives

There are 4 exceptions to informed consent:

  - Emergency
  - Waiver by patient
  - Patient is incompetent
  - Therapeutic privilege (unconscious, confused, physician deprives patient of autonomy in interest of health)

- Gag clauses which prohibit a physician from discussing treatment options that are not approved violate informed consent and are illegal.
- Consent can be oral.
- A signed paper the patient has not read or does not understand does NOT constitute informed consent.
- Written consent can be revoked orally at any time.

Rule #12: Special rules apply with children.

Children younger than 18 years are minors and are legally incompetent.

- Exceptions: emancipated minors
  - If older than 13 years and taking care of self, i.e., living alone, treat as an adult.
  - Marriage makes a child emancipated, as does serving in the military.
  - Pregnancy or giving birth, in most cases, does not.
- Partial emancipation
  - Many states have special ages of consent: generally age 14 and older
  - For certain issues only:
    - Substance drug treatment
    - Prenatal care
    - Sexually transmitted disease treatment
    - Birth control

Rule #13: Parents cannot withhold life- or limb-saving treatment from their children.

If parents refuse permission to treat child use the following guidelines:

- If immediate emergency, go ahead and treat.
- If not immediate, but still critical (e.g., juvenile diabetes), generally the child is declared a ward of the court and the court grants permission.
- If not life-or limb-threatening (e.g., child needs minor stitches), listen to the parents

Note that the child cannot give permission. A child's refusal of treatment is irrelevant.

Rule #14: For the purposes of the exam, issues governed by laws that vary widely across states cannot be tested.

This includes elective abortions (minor and spousal rights differ by locality) and legal age for drinking alcohol (vary by state).

Rule #15: Good Samaritan Laws limit liability in nonmedical settings.

- Not required to stop to help
- If help offered, shielded from liability provided:
  - Actions are within physician's competence
  - Only accepted procedures are performed.
  - Physician remains at scene after starting therapy until relieved by competent personnel
  - No compensation changes hands

Rule #16: Confidentiality is absolute.

Physicians cannot tell anyone anything about their patient without the patient's permission. Additionally, the physician must strive to ensure that others *cannot* access patient information.

- Getting a consultation is permitted, as the consultant is bound by confidentiality, too. However, watch the location of the consultation. Be careful not to be overheard (e.g., not elevator or cafeteria).
- If you receive a court subpoena, show up in court but do not divulge information about your patient.
- If patient is a threat to self or other, the physician MUST break confidentiality
  - Duty to warn and duty to protect (Tarasoff case)
  - A specific threat to a specific person
  - Suicide, homicide, and abuse are obvious threats.
  - Infectious disease should generally be treated as a threat, but be careful. Here issue is usually getting the patient to work with you to tell the person who is at risk
  - In the case of an STD, the issue is not really whether to inform a sexual partner, but how they should be told. Best advice: Have patient and partner come to your office.

Rule #17: Patients should be given the chance to state DNR (Do Not Resuscitate) orders, and physicians should follow them.

DNR refers only to cardiopulmonary resuscitation.

- Continue with ongoing treatments.
- Most physicians are unaware of DNR orders.
- DNR decisions are made by the patient or surrogate.

- Have DNR discussions as part of your first encounter with the patient.
- Do not ask the patient about "do not resuscitate" wishes. Explain what is entailed.

Rule #18: Committed mentally ill patients retain their rights.

Committed mentally ill adults legally are entitled to the following:

- They must have treatment available.
- They can refuse treatment.
- They can command a jury trial to determine "sanity."
- They lose only the civil liberty to come and go.
- They retain their competence for conducting business transactions, marriage, divorce, voting, driving
- The words "sanity" and "competence" are legal, not psychiatric, terms. They refer to prediction of dangerousness, and medicopsychological studies show that health care professionals cannot reliably and validly predict such dangerousness.

Rule #19: Detain patients to protect them or others.

Emergency detention can be effected by a physician and/or a law enforcement person for 48 hours, pending a hearing. A physician can detain; only a judge can commit. With children, special rules exist. Children can be committed only if:

- They are in imminent danger to self and/or others.
- They are unable to care for their own daily needs.
- The parents have absolutely no control over the child, and the child is in danger (e.g., fire-setter), but not because the parents are unwilling to discipline a child.

Rule #20: Remove from patient contact any health care professionals who pose a risk to patients.

The patient, not professional solidarity, comes first.

- Types of risks
  - Infectious disease (TB)
  - Substance-related disorders
  - Depression (or other psychological issues)
  - Incompetence
- Actions
  - Insist that they take time off
  - Contact their supervisors if necessary

Rule #21: Focus on what is the best ethical conduct, not simply the letter of the law.

The best answers are those that are both legal and ethical.

Practice Questions

- Should physicians answer questions from insurance companies or employers? (Not without a release from the patient)
- Should physicians answer questions from the patient's family without the patient's explicit permission? (No)

- What information can the physician withhold from the patient? (Nothing. If patient may react negatively, figure out how to tell patient to mitigate negative outcome)
- What if the family requests that certain information be kept from the patient? (Tell the patient, but first find out why they don't want the patient told)
- Who owns the medical record? (Health care provider, but patient must be given access or copy upon request)

What should the physician do in each of these situations?

- Patient refuses lifesaving treatment on religious grounds? (Don't treat)
- Wife refuses to consent to emergency lifesaving treatment for unconscious husband citing religious grounds? (Treat, no time to assess substituted judgment)
- Wife produces card stating unconscious husband's wish to not be treated on religious grounds? (Don't treat)
- Mother refuses to consent to emergency lifesaving treatment for her daughter on religious grounds? (Treat)
- What if the child's life is at risk, but the risk is not immediate? (Court takes guardianship)
- From whom do you get permission to treat a girl who is 17 years old? (Her guardian)

From whom does the physician obtain consent in each case?

- A 17-year-old girl's parents are out of the country and the girl is staying with a babysitter? (If a threat to health, the physician can treat under doctrine of *in locum parentis*)
- A 17-year-old girl who has been living on her own and taking care of herself? (The girl herself)
- A 17-year-old girl who is married? (The girl herself)
- A 17-year-old girl who is pregnant? (Her guardian)
- A 16-year-old daughter refuses medication but her mother consents, do you write the prescription? (Yes)
- The 16-year-old daughter consents, but the mother refuses? (No)
- The mother of a minor consents, but the father refuses? (Yes, only one permission needed)
- When should the physician provide informed consent? (Always)
- Must informed consent be written? (No)
- Can written consent be revoked orally? (Yes)
- Can you get informed consent from a schizophrenic man? (Yes, unless there is clear behavioral evidence that he is incompetent)
- Must you get informed consent from a prisoner if the police bring in the prisoner for examination? (Yes)

Interpretation of Medical Literature 23

Learning Objectives

- Critique a journal article, i.e., assess whether appropriate statistical tests were used, what biases or assumptions were inherent in the research study design, and what class of evidence was presented

INTRODUCTION

The purpose of this chapter is to provide you with an approach to reading and understanding research articles and pharmaceutical advertisements. It is based on principles of epidemiology.

An understanding of these concepts is fundamental to the comprehension of medical literature. We have sacrificed depth for the sake of brevity since our goal was to provide a few fundamental tools and avoid complexity

Research Abstract 1

Wedge Resection or Lobectomy: Comparison of Tumor Recurrence Rates and Overall Survival in NSCLC Patients Receiving Preoperative Chemotherapy

Wedge resection for non-small-cell lung cancer (NSCLC) stage I patients still remains controversial with many physicians. The primary outcomes of tumor recurrence and overall survival (OS) remain unclear when compared to complete lobectomy, which has traditionally been considered a far more effective procedure. However, a recent compilation of case reports and case series reports have validated impressive tumor recurrence and OS rates that were previously only believed to be seen in patients receiving lobectomy. Our primary objective was to compare and analyze the tumor recurrence rates and OS for both wedge resection and lobectomy in patients with stage 1 NSCLC following preoperative chemotherapy.

Methods

We systematically reviewed individual case reports and case series reports from 152 institutions in the United States for patients who first received preoperative chemotherapy and then underwent either wedge resection (248 patients) or lobectomy (329 patients). A propensity score algorithm was used to reduce the confounding that can occur when examining the effects and variables related to both treatment measures. Following the procedures, tumor recurrence and OS was assessed at 3 and 5 years in all patients.

Results

Preoperative mortality related to chemotherapy complications for patients scheduled to have wedge resection or lobectomy was 0.8% and 1.5%, respectively (P = 0.22). Perioperative mortality in patients undergoing lobectomy was 3.8% versus 0.8% in those receiving wedge resection (P = 0.02). During the predetermined follow-up times at 3 and 5 years, overall tumor recurrence (both locoregional and metastases) were assessed:

At the 3 year follow-up, overall tumor recurrence was 5.9% for wedge resection and 4.2% for lobectomy (P = 0.41).

At the 5-year follow-up, overall tumor recurrence was 6.3% for wedge resection and 6.1% for lobectomy (P = 0.29).

When comparing the OS for wedge resection with lobectomy the 3-year OS rates were 82% vs 71%, respectively; (P = .09) and 5-year OS rates were 69% v 68%, respectively; (P = .29). Wedge resection was not found to be an independent predictor of tumor recurrence (hazard ratio, 1.23; 99% CI, 0.96 to 1.15) or OS (hazard ratio, 1.43; 99% CI, 0.92 to 1.23).

Conclusion

Wedge resection and lobectomy are associated with similar overall tumor recurrence and overall survival rates when performed after preoperative chemotherapy. However, postoperative complications and mortality are significantly lower in patients receiving wedge resection compared to lobectomy. Since patients generally maintain superior overall lung function with wedge resection, we recommended that wedge resection be performed in all eligible patients with Stage 1 NSCLC unless there is a compelling reason to perform a lobectomy.

Practice Questions

1. Information from the abstract most strongly supports which of the following conclusions?

   (A) Both wedge resection and lobectomy have lower mortality and tumor recurrence rates when patients first receive preoperative chemotherapy.

   (B) Perioperative mortality was lower in patients undergoing wedge resection.

   (C) Postoperative complications were lower in patients undergoing wedge resection.

   (D) Pulmonary function tests at 1 year were significantly higher in patients receiving wedge resection.

   (E) The overall survival for wedge resection at 3 years was proven to be higher than that of lobectomy.

The correct answer is choice B. You are asked to determine which answer choice is most strongly supported by the information provided in the abstract. In this type of question, the correct answer is found in the abstract itself and the reader needs only to interpret the information. Of the answer choices, choice B is most supported by the information provided in the drug abstract. The statement, "Perioperative mortality was lower in patients undergoing wedge resection" is supported by the data provided in the Results section. We are told that perioperative mortality in those receiving lobectomy was 3.8% versus 0.8% for those receiving wedge resection (P = 0.02). This data shows that mortality in those receiving a lobectomy was almost 5x higher than seen in those receiving wedge resection. Furthermore, the p value is 0.02, which shows statistical significance.

The stated objective of the researchers was to "compare and analyze the tumor recurrence rates and OS for both wedge resection and lobectomy in patients with stage I NSCLC following preoperative chemotherapy." In other words, researchers assessed tumor recurrence and OS in patients receiving 2 different surgical procedures. Since all patients received preoperative chemotherapy, one cannot draw a conclusion about the impact of preoperative chemotherapy based on the information presented (**choice A**). Remember, there would have to be a subset of patients who did not receive preoperative chemotherapy in order for a comparative analysis to be performed.

Postoperative complications (**choice C**) were not discussed in the abstract.

A clinician could reasonably conclude that pulmonary function tests would be higher at 1 year in patients receiving wedge resection when compared with lobectomy (**choice D**). However, this "reasonable assumption" is not supported, as data regarding lung function at 1 year was not presented in the abstract.

Choice E states "The overall survival for wedge resection at 3 years was proven to be higher than that of lobectomy." In the Results section of the abstract, it says, "When comparing the OS for wedge resection with lobectomy, the 3-year OS rates were 82% vs 71%, respectively; (P = .09)." At first glance it may appear to be a correct statement; however, the p value is 0.09. Therefore, the 2 percentages are not statistically different.

2. Which of the following best describes the type of study performed?

   (A) Case-control study
   (B) Crossover study
   (C) Meta-analysis
   (D) Propensity-matched analysis
   (E) Randomized, controlled clinical trial

The correct answer is choice D. You are asked to determine what type of study/analysis the researchers performed. The researchers reviewed individual case reports and case series reports from a number of institutions. After reviewing and compiling the data, they used an algorithm to reduce confounding variables and subsequently analyze the data. Based on this information, we can conclude that the researchers performed a **propensity-matched analysis**. Propensity score matching (PSM) is used in the statistical analysis of observational data. PSM is a statistical matching technique which attempts to approximate the effect of a treatment by accounting for the covariates that predict receiving a given treatment. This type of statistical analysis is used to reduce bias caused by confounding variables. Propensity scores (obtained from a propensity-matched analysis) are valuable when attempting to draw causal conclusions from observational studies (such as case reports) where the "treatment" or "independent variable" was not originally randomly assigned.

Case-control studies (**choice A**) are retrospective observational studies used to identify risk factors that are believed to be associated with a particular disease or condition. Subjects are initially classified as having or not having the disease in question and then their histories are explored to identify the presence or absence of any risk factors. Data are usually analyzed by means of an odds-ratio, and interpreted such that if something occurs in the history of the diseased group, but not in the non-diseased group, then it will be identified as a risk factor.

Cross-over studies (**choice B**) are clinical trials in which 2 comparison groups (for example) both receive the drug being tested and the comparative intervention (often a placebo) at different times. This interventional study will generally begin with one group (group A) receiving the investigational drug while a comparison group (group B) receives a placebo. Then, at some predetermined time, there will be a washout period and then Group A is switched to the placebo, while the Group B is given the investigational drug. This study design allows comparison of those on and off the drug, but also satisfies the ethical requirement that everyone in the study is exposed to whatever benefit the experimental drug may provide.

A meta-analysis (**choice C**) will meticulously examine several interventional clinical studies on a particular disease state (or treatment measure) and then combine the results using an acceptable statistical methodology. The results will be presented as if they were from 1 large study. The classical meta-analysis compares 2 types of treatment measures while multiple treatment meta-analysis (or network meta-analysis) can provide estimates of treatment efficacy of multiple treatment regimens, even when direct comparisons are unavailable. One of the key differences between a meta-analysis and a propensity matched analysis is that a meta-analysis is used with interventional studies, and a propensity-matched analysis is used with observational reports or studies.

A randomized, controlled clinical trial (**choice E**) is a type of interventional study where a researcher will administer a medication or treatment measure to one group of participants and evaluate its effects against a control group who receives another treatment measure or placebo. Subjects in the study are randomly allocated into "intervention" and "control" groups to receive or not receive an experimental preventive or therapeutic procedure or intervention. In the "wedge resection" analysis, researchers compiled the results from several observational

studies. The data evaluated was derived from case reports where patients were NOT originally assigned to receive either a wedge resection or lobectomy.

3. The next step in follow-up of these research results would be to conduct which type of study?

   (A) Case-control study
   (B) Cohort study
   (C) Cross sectional study
   (D) Randomized, controlled clinical trial
   (E) Replication in a different biological model

The correct answer is D. In the current study, researchers reviewed and compiled the data from numerous case reports and case series reports. They then attempted to draw causal conclusions from these observational studies where the treatment was not originally randomly assigned. Using this approach, researchers are able to determine if further investigation is warranted. In this particular analysis, researchers identified a higher than expected overall survival rate and lower than expected tumor recurrence rate associated with a procedure (wedge resection) that is believed to be associated better postoperative lung function as compared to lobectomy. Since the results of their analysis essentially showed no real difference in overall tumor recurrence rates and overall survival rates, the next step would be to further validate these results with an interventional study, such as a prospective, randomized controlled trial (RCT). In an RCT, researchers will likely randomly assign patients to receive either wedge resection or lobectomy following preoperative chemotherapy. Researchers will then be able to determine if there is a statistical difference between the two treatment options.

Case-control studies (**choice A**) are retrospective observational studies used to identify risk factors that are believed to be associated with a particular disease or condition. Subjects are initially classified as having or not having the disease in question and then their histories are explored to identify the presence or absence of any risk factors.

Cohort studies (**choice B**) are observational studies in which subjects are classified as having or not having a risk factor and then followed forward in time so incidence rates for the two groups can be compared. Although cohort studies are a type of prospective study, the next step would be to use an "interventional" prospective study, such as a randomized controlled clinical trial.

Cross sectional studies (**choice C**) are observational studies used to assess the prevalence of a disease in a given population and the factors which co-occur with that disease at a particular time.

Replication in a different model (**choice E**) is a type of study generally used in early animal testing of experimental medications. For example, early animal testing for a new compound may involve a small number of rats. Once data is obtained from a single animal test, there is still a lot of information that needs to be obtained and questions that need answered before this new compound (experimental drug) can be considered for human trials. Therefore, researchers often perform several different types of animal tests using a variety of rat species followed by testing in other animal models.

Research Abstract 2

Mekanib Improved Overall Survival and Decreased Vemurafenib-Resistance in BRAF-mutated Metastatic Melanoma

BRAF mutations have been observed in approximately 50% of all malignant melanomas. The most predominant BRAF mutations found in melanoma are those that introduce an amino acid substitution at valine 600. Approximately 80–90% of these mutations are classified as BRAF V600E. Other predominant BRAF mutations include V600K, V600R and V600D. All of these mutations result in heightened BRAF kinase activity and amplified phosphorylation of downstream targets, which in particular includes MEK. BRAF inhibitor therapy (with vemurafenib or dabrafenib) is associated with well-documented clinical benefit in most patients with BRAF V600E-mutated melanoma (and other subtypes). However, resistance to these drugs and tumor progression generally occurs in patients within the first year. It is believed that BRAF mutations stimulate melanoma cell proliferation and survival predominantly through activation of MEK. The purpose of this study was to determine if the addition of the allosteric MEK1/MEK2 inhibitor mekanib (KAP071714) to vemurafenib delayed expected vemurafenib resistance as well as improved progression free survival (PFS) and overall survival (OS) in comparison to dacarbazine.

Methods

This was a phase 3, multicenter, double-blinded, randomized clinical trial comparing the effectiveness of mekanib (KAP071714) in 447 total participants with previously untreated, metastatic melanoma with the BRAF V600E mutation. Patients were randomly assigned into two cohorts. Cohort A (222 participants): received dacarbazine (1000 mg per square meter of body-surface area intravenously every 3 weeks); Cohort B (225 participants): received vemurafenib (960 mg orally twice daily) + mekanib (150 mg orally daily). PFS was the primary end point and OS was a secondary end point.

Results

Median PFS was 11.6 months in the mekanib group and 2.3 months in the dacarbazine group (hazard ratio for disease progression or death in the mekanib group, 0.23; 95% confidence interval [CI], 0.18 to 0.28; $P<0.007$). At 15 months, the rate of overall survival was 78% in the mekanib group and 42% in the dacarbazine group (hazard ratio for death, 0.43; 95% CI, 0.33 to 0.53; $P = 0.02$). Elevated hepatic enzymes, rash, diarrhea, and hypertension were the most common toxic effects in the mekanib group. Nausea, vomiting alopecia, facial flushing, myalgia, leukopenia and hepatotoxicity were the most common toxic effects in the dacarbazine group. Eight patients in the mekanib group and 15 patients in the dacarbazine group withdrew from the study due to severe side effects. Secondary skin neoplasms were not observed in either group.

Conclusion

Mekanib, as compared with traditional dacarbazine chemotherapy, improved rates of PFS and OS among patients with the BRAF-mutated metastatic melanoma as well as delayed vemurafenib drug resistance. Mekanib should be considered for use in conjunction with vemurafenib for the treatment of BRAF-mutated metastatic melanoma.

(Funded by SMILE Pharmaceuticals, ClinicalTrials.gov number NCT0123456789101112)

Practice Questions

1. Information from the abstract above most strongly supports which of the following conclusions about mekanib?

   (A) In the treatment of select cases of metastatic melanoma, mekanib alone provides higher rates of PFS and OS than dacarbazine alone.

   (B) Mekanib does not produce severe side effects.

   (C) Mekanib produces fewer side effects than dacarbazine.

   (D) Metastatic melanoma patients with BRAF V600K mutations have improved PFS and OS rates when taking vemurafenib + mekanib versus dacarbazine.

   (E) Most metastatic melanoma patients appropriately prescribed vemurafenib and mekanib are likely to complete their treatment regimen.

The correct answer is choice E. You are being asked to determine which answer choice is most supported by the information provided in the abstract. While several answer choices might "look good," you will be able to eliminate the incorrect answer choices once you examine the meaning of each statement. Of the answer choices, choice E is most supported by the information provided in the drug abstract. The Results section indicates that "Eight patients in the mekanib group and 15 patients in the dacarbazine group withdrew from the study due to severe side effects." Of the 225 patients originally enrolled in the mekanib + vemurafenib arm of the study, 217 persons or 96% of the original study group completed the study. Hence, you can reasonably conclude that most metastatic melanoma patients appropriately prescribed vemurafenib and mekanib are likely to complete their treatment regimen.

The statement, "In the treatment of select cases of metastatic melanoma, mekanib alone provides higher rates of PFS and OS than dacarbazine alone" can be eliminated (**choice A**) since the study was not designed to evaluate mekanib versus dacarbazine. This study evaluated mekanib PLUS vemurafenib versus dacarbazine.

"Mekanib does not produce severe side effects" (**choice B**) is an incorrect statement because the abstract only lists a few of the most common side effects. It does not mention the severe (and less common) side effects. These findings are likely to be found in the body of the published study. Remember, this is an abstract and only provides limited information.

"Mekanib produces fewer side effects than dacarbazine" (**choice C**) is incorrect because the abstract only lists a few of the most common side effects for both drugs. It does not outline the number and frequency of occurrence of side effects. These findings are likely to be found in the complete study.

The statement "Metastatic melanoma patients with BRAF V600K mutations have improved PFS and OS rates when taking vemurafenib + mekanib versus dacarbazine" can be eliminated (**choice D**), because the study was only performed in metastatic melanoma patients with BRAF V600E mutations. Hence, the reader cannot draw conclusions about the effect of vemurafenib plus mekanib in this patient population.

2. In the conclusion section of the abstract, the authors indicate that when mekanib was added to vemurafenib the drug delayed vemurafenib drug resistance. Which of the following is the most likely reason that the reader should question the validity of this claim?

   (A) Insufficient follow-up of study participants
   (B) Insufficient information on adverse effects and drug-drug interactions
   (C) Lack of an appropriate control group
   (D) Subject attrition
   (E) Use of hazard ratio instead of relative risk

The correct answer is choice C. You are asked to determine the most likely reason why one should question the validity of the claim that mekanib delays vemurafenib-resistance. The correct answer is lack of an appropriate control group. In order for researchers to conclude that mekanib decreases vemurafenib resistance, the control group must be vemurafenib alone and the study group must be vemurafenib PLUS mekanib. In this study, the control group was dacarbazine and study group was vemurafenib plus mekanib; hence, there is not an appropriate control group to answer the question "Does mekanib delay vemurafenib resistance?" In other words, there is no data available to support the claim that the addition of mekanib did in fact decrease vemurafenib resistance. Furthermore, the background states that "resistance to these drugs (vemurafenib and dabrafenib) and tumor progression generally occurs in patients within the first year" and the Results section states that the median PFS was 11.6 months in the mekanib group. The median PFS is a little less than a year; hence, the reader should actually question if mekanib actually provided any benefit at all.

The Results section provides information about median PFS and survival rates at 15 months. The length of the study was sufficient to assess the effects it was designed to assess (**choice A**).

The Results section provides information on adverse effects but does not provide any information on drug-drug interactions (**choice B**). Although a drug interaction could potentially decrease the effectiveness of mekanib, the most likely reason to question the validity of the claim (in the question stem) is because of a lack of an appropriate control group.

The Results section states that "Eight patients in the mekanib group and 15 patients in the dacarbazine group withdrew from the study due to severe side effects." Out of an original 447 patients, only 23 patients withdrew from the study. Hence, the subject attrition rate is low for this study (**choice D**).

By definition, the hazard ratio is a measure of relative risk over time in situations where the researchers are interested not only in the total number of events, but also in the timing of these events. For example, the event of interest may be subject death or it could be a non-fatal event such as readmission or symptom change. The use of a hazard ratio in this particular study is appropriate (**choice E**).

3. In the background section of the abstract, researchers state that purpose of the study was to determine if the addition of the allosteric MEK1/MEK2 inhibitor mekanib (KAP071714) to vemurafenib-delayed drug resistance as well as improved progression free survival (PFS) and overall survival (OS) in comparison to dacarbazine. Which of the following study design changes could have been made to appropriately evaluate all the specified outcomes?

   (A) Add a vemurafenib-only cohort to the study
   (B) Prescribe all 3 medications to each participant but at different dosage ranges
   (C) Replace the dacarbazine cohort with a vemurafenib-only cohort
   (D) Use a crossover study instead of a randomized clinical trial
   (E) No changes were needed since the study was properly designed to meet the specified outcomes

The correct answer is choice A. You are asked to determine what changes could have been made to the original study design so that the 3 initial study outcomes could be appropriately evaluated. Based on the purpose outlined in the question stem, the 3 outcomes being evaluated are as follows:

1. Decreased vemurafenib resistance when mekanib is added
2. Improved PFS for vemurafenib + mekanib compared to dacarbazine
3. Improved OS for vemurafenib + mekanib compared to dacarbazine

The current study design appropriately evaluates PFS and OS between vemurafenib + mekanib AND dacarbazine because participants were administered either vemurafenib + mekanib OR dacarbazine. However, the only way to assess whether mekanib decreases vemurafenib-resistance is to evaluate this regimen against a vemurafenib-only cohort. Hence, in order to appropriately evaluate all 3 outcomes described in the question stem, there would need to be 3 cohorts:

1. Dacarbazine only
2. Vemurafenib only
3. Vemurafenib + mekanib

If researchers prescribed all 3 medications to each participant but at different dosage ranges (**choice B**), then none of the initial 3 outcomes could have been measured because there is no comparison against either dacarbazine only or vemurafenib only.

If researchers replaced the dacarbazine cohort with a vemurafenib-only cohort (**choice C**), then researchers would be able to assess the "resistance outcome." However, they would not be able to assess the effects of mekanib + vemurafenib against dacarbazine.

In cross-over studies, all subjects receive both interventions unless it is a placebo-controlled study then all participants receive treatment and placebo. If a crossover study design were used with the existing study, then group A (for example) would receive dacarbazine only and group B would receive vemurafenib + mekanib. Then at some predetermined point there would be a washout period, and group B would receive dacarbazine only and group A would receive vemurafenib + mekanib. This type of study design (**choice D**) would not be able to assess the "vemurafenib resistance outcome" as outlined above.

Research Abstract 3

Efficacy of Imiquimod in Sustained Lesion Clearance in Actinic Keratosis

Actinic keratosis (AK) is a UV light-induced precancerous lesion of thick, scaly or crusty skin that may progress to invasive squamous cell carcinoma. AK is the most common lesion with malignant potential to arise on the skin. Topical fluorouracil has traditionally been the treatment of choice. However, a number of case reports indicated recently that the topical immune response modifier imiquimod successfully detected and cleared both clinical and subclinical lesions across the entire sun-exposed fields of the face and/or balding scalp for a sustained period of time. The purpose of this study was to evaluate the efficacy of topical imiquimod 5% in the field directed treatment of AK against clinical and subclinical lesions, and to determine patient satisfaction with topical imiquimod in the treatment of AK.

Methods

Twenty seven AK patients (with lesions on the face and/or balding scalp) from 9 dermatology practices in Florida were treated with imiquimod 5% twice weekly at bedtime for a period of 12–18 weeks depending on physician preference. Information from their individual findings are summarized here. Lesions were counted before, during, and 3 months post-treatment. Patients compared the imiquimod 5% regimen with their previous AK therapies (if applicable) in terms of treatment duration and side effect profile.

Results

Nineteen of the 27 patients have previously used 1+ prior AK treatments including 5-flurouracil, diclofenac, and photodynamic therapy. The patients had a median of 12 AK lesions on clinical presentation and a median Lmax (maximum lesion count during treatment) of 22. The Lmax initially increased in all patients once treatment stated since imiquimod unmasked previously invisible lesions. The median lesion count was zero 3 months after treatment was completed. At 6 and 12 months of follow-up, the median absolute reduction in AK lesions from Lmax with imiquimod 5% was 20 and 18, respectively. The median percentage reduction in lesions from Lmax to 6 and 12 months was 91% and 82%, respectively. All patients (when asked by the physician) indicated that imiquimod 5% was easy-to-use and that the duration of treatment was better than that of previous AK therapies. Nineteen of the patients considered the side-effect profile of this drug more favorable than that of their prior AK treatments (if applicable).

Conclusion

Imiquimod 5% dosed twice weekly for 12-18 weeks is able to successfully detect and eliminate both clinical and subclinical lesions across the entire sun-exposed fields of the face and balding scalp for sustained long-term efficacy. Imiquimod had a higher patient satisfaction rating than fluorouracil. Imiquimod 5% is thus recommended as a first-line treatment for patients with AK.

Practice Questions

1. Information from the abstract most strongly supports which of the following conclusions about the use of imiquimod in actinic keratosis (AK)?

   (A) Imiquimod had a higher patient satisfaction rating than fluorouracil.
   (B) Imiquimod is a first-line treatment for patients with AK.
   (C) Imiquimod is effective at detecting subclinical AK lesions.
   (D) Imiquimod is equally as effective as topical fluorouracil in the treatment of AK
   (E) Imiquimod is more effective in the treatment of AK than topical fluorouracil

The correct answer is choice C. Choice C is most supported by the information provided in the drug abstract. The statement, "Imiquimod is effective at detecting subclinical AK lesions" is supported by the data provided in the introdution and Results section of the abstract. We are told that "a number of case reports indicated that the topical immune response modifier imiquimod successfully detected and cleared both clinical and subclinical lesions across the entire sun-exposed fields of the face and/or balding scalp for a sustained period of time." The Results section states that "The Lmax initially increased in all patients once treatment stated since imiquimod unmasked previously invisible lesions."

This abstract provides information based on individual case reports. **Choices A, D**, and **E** would generally be the findings of a randomized controlled clinical trial (RCT) where subjects are randomly allocated into "intervention" and "control" groups to receive or not receive an experimental procedure/intervention. RCTs are generally regarded as the most scientifically rigorous studies available in epidemiology.

Choice B may be a true statement, but the information presented in the abstract is based off of the findings of 27 individual case reports. Further study would be needed to justify this statement being true.

2. With respect to the development of invasive squamous cell carcinoma, the use of imiquimod in actinic keratosis (AK) patients as described in this abstract is considered to be what type of prevention?

   (A) Primary prevention
   (B) Secondary prevention
   (C) Tertiary prevention
   (D) Quaternary prevention
   (E) This is a form of curative treatment for squamous cell carcinoma.

The correct answer is A. Disease prevention and health promotion can take different forms. Health professionals and community officials often approach prevention in different ways, so the needs of each person as well as the general population are met. There are different types of prevention activities that can be considered when working with individual patients or with an entire community. It is important that both clinicians and community lead understanding the target population and what type of prevention are necessary to impact people at all levels.

Primary prevention employs the use of preventative measures so that a person does not contract the disease. Primary prevention will decrease both the incidence and prevalence of the disease. In this case, the disease is invasive squamous cell carcinoma. AK is a UV light-induced precancerous lesion of the skin that may progress to invasive squamous cell carcinoma. Preventative measures, such as treatment of a precancerous (AK) lesions, can be employed to prevent the onset of this

condition. Thus, by definition, imiquimod is classified as a primary preventative measure for invasive squamous cell carcinoma.

Secondary prevention (**choice B**) is a form of prevention that is used after the disease has occurred but before the person notices that anything is wrong. Screening for invasive squamous cell carcinoma in high risk individuals is an example of secondary prevention.

According to the CDC, tertiary prevention (**choice C**) targets the person who already has symptoms of the disease. The goals of tertiary prevention are to: (a) prevent damage and pain from the disease, (b) slow down progression of the disease, (c) prevent the disease from causing other complications, (d) give better care to patients with the given disease, and (e) increase the quality of life for a patient with the disease.

Quaternary prevention (**choice D**) is the use of methods to mitigate or avoid consequences of unnecessary or excessive interventions in the health system; the classic example is mitigating the use of antibiotics in children with viral illness.

In this abstract, imiquimod would be a curative treatment measure (**choice E**) for AK and a primary preventative measure for invasive squamous cell carcinoma.

3. Which of the following best describes the type of study performed in this abstract?

   (A) Case-control study
   (B) Case series report
   (C) Cross-over study
   (D) Meta-analysis
   (E) Randomized, controlled clinical trial

The correct answer is choice B. The researchers reviewed individual case reports from 9 dermatology practices in Florida. After reviewing and compiling the data from these cases, the authors of the abstract compiled the data from each of the case reports and "Information from their individual findings are summarized here" in this abstract. Based on this information, the information presented in the abstract was most likely derived from a case series report.

A case series report is a type of study that tracks subjects with a known exposure, such as patients who have received a similar treatment (imiquimod) or examines their medical records for exposure and outcome. Case series reports are objective reports of a clinical characteristic or outcome from a group of clinical subjects. For example, patients from 9 dermatology practices diagnosed with actinic keratosis and treated with imiquimod. In a case series report, there is no control group.

Case-control studies (**choice A**) are retrospective observational studies used to identify risk factors that are believed to be associated with a particular disease or condition. Subjects are initially classified as having or not having the disease in question and then their histories are explored to identify the presence or absence of any risk factors. Data are usually analyzed by means of an odds-ratio, and interpreted such that if something occurs in the history of the diseased group, but not in the non-diseased group, then it will be identified as a risk factor.

Cross-over studies (**choice C**) are clinical trials in which 2 comparison groups (for example) both receive the drug being tested and the comparative intervention (often a placebo) at different times. This interventional study will generally begin with one group (group A) receiving the investigational drug while a comparison group (group B) receives a placebo. Then, at some predetermined time, there will be a washout period and then group A is

switched to the placebo while group B is given the investigational drug. This study design allows comparison of those on and off the drug, but also satisfies the ethical requirement that everyone in the study is exposed to whatever benefit the experimental drug may provide.

A meta-analysis (**choice D**) will meticulously examine several interventional clinical studies on a particular disease state (or treatment measure) and then combine the results using an acceptable statistical methodology. The results will be presented as if they were from one large study. The classical meta-analysis compares two types of treatment measures while multiple treatment meta-analysis (or network meta-analysis) can provide estimates of treatment efficacy of multiple treatment regimens, even when direct comparisons are unavailable. A meta-analysis a compilation of interventional studies while a case series report is a compilation of case reports.

In a randomized, controlled clinical trial (**choice E**), a researcher will administer a treatment measure to one group of participants and evaluate its effects against a control group who receives another treatment measure or placebo. Subjects are randomly allocated into "intervention" and "control" groups to receive or not receive an experimental procedure/intervention. In the "imiquimod" abstract, researchers compiled the results from several case reports and evaluated. In this study, patients were NOT originally assigned to receive either imiquimod or another treatment measure, such as fluorouracil.

4. The next step in following up the results presented in this abstract would be to conduct which type of study?

   (A) Case-control study
   (B) Cohort study
   (C) Cross sectional study
   (D) Randomized, controlled clinical trial
   (E) Replication in a different biological model

The correct answer is D. In the current study, researchers reviewed and compiled the data from numerous case reports. They then attempted to draw causal conclusions from these individual case reports where the treatment was not originally randomly assigned. Using this approach, researchers are able to determine if further investigation is warranted. In this particular analysis, imiquimod successfully detected and eliminated both clinical and subclinical actinic keratosis lesions across the entire sun-exposed fields of the face and balding scalp for sustained long-term efficacy. Based on these results, the next step would be to further validate these findings with an interventional study, such as a prospective, randomized controlled trial (RCT). In an RCT, researchers will randomly assign patients to receive either imiquimod or some other existing treatment measure (such as fluorouracil). Researchers will then be able to determine if there is a statistical difference between the 2 treatment options.

Case-control studies (**choice A**) are retrospective observational studies used to identify risk factors that are believed to be associated with a particular disease or condition. Subjects are initially classified as having or not having the disease in question and then their histories are explored to identify the presence or absence of any risk factors. This type of study would not be an appropriate next step in research.

Cohort studies (**choice B**) are observational studies in which subjects are classified as having or not having a risk factor and then followed forward in time so incidence rates for the two groups can be compared. Although cohort studies are a type of prospective study, the next step would be to use an "interventional" prospective study (to determine the efficacy of imiquimod over fluorouracil), such as a randomized controlled clinical trial.

Cross sectional studies (**choice C**) are observational studies used to assess the prevalence of a disease in a given population and what factors co-occur with this disease at a particular time.

Replication in a different model (**choice E**) is generally used in early animal testing of experimental medications. For example, early animal testing for a new compound may involve a small number of rats. Once data is obtained from a single animal test, a lot of information still needs to be obtained before the new compound (experimental drug) could be considered for human trials. Therefore, researchers perform several types of animal testing using a variety of rat species and then other animal models.

5. Which of the following raises the most concern about the validity of the study results?

   (A) Expectancy bias
   (B) Late-look bias
   (C) Measurement bias
   (D) Proficiency bias
   (E) Recall bias
   (F) Selection bias

The correct answer is F. First determine the type of study here and then identify what bias is likely going to affect the reported results. This study would be best classified as a case series report. A case series report is a type of study that tracks subjects with a known exposure, such as patients who have received a similar treatment (imiquimod) or examines their medical records for exposure and outcome. Case series reports are objective reports of a clinical characteristic or outcome from a group of clinical subjects.

Case series reports are particularly susceptible to selection bias (sample selected is not representative of the general population). Examples of case series reports include those that report on a number of patients with a certain illness and/or a treatment of an illness with a single agent. Since case series reports are based on a limited number of individual case reports, they may not appropriately represent the wider population. Internal validity of case series studies is usually very low, due to the lack of a comparator group exposed to the same array of intervening variables.

Expectancy bias (**choice A**) exists when a researcher knows which subjects are in a treatment or a placebo group; this knowledge may cause the researcher, unwittingly, to interact with subjects differently. For example, if the researcher thinks a subject is receiving a better treatment, he is more likely to think the subject is getting better, and may perceive effects over and above the physiologic effects of the drugs administered. The way to avoid expectancy bias is a double-blind design, where neither subjects nor the researchers know where each subject is placed. This is not the case here because the "visible" lesions are either present or absent.

Late-look bias (**choice B**) is a problem when gathering information about some types of severe diseases. The problem is that the most severe cases will die or become inaccessible before their information can be gathered. This is not the answer here because AK is a pre-malignant condition and mortality is not an issue.

With measurement bias (**choice C**), something about how the information is gathered affects the information collected. This can occur because survey questions use inappropriate wording that slants respondents to a particular answer, or because just knowing that they are being measured causes people to act differently than they would if they were not observed. The classic example of measurement bias is the Hawthorne effect where a subjects' behavior is altered simply because they are being studied.

Proficiency bias (**choice D**) is an issue when comparing the effects of different treatments administered at multiple sites. Simply stated, the physicians at one site may have more skill with a given procedure than other physicians do. This means that the different skill level of the physicians delivering treatment might affect patient outcomes more than the treatment selection itself. This was not a comparative study and only one drug (imiquimod) was administered.

Recall bias (**choice E**) is a problem in retrospective studies, such as a case-control study, where people are asked to remember what happened in the past and report it in the present. If people do not remember, and say so, then there is missing data. But often, people will invent answers, either from a desire to please the researcher or because the memory of the past changes over time. In this case, the AK lesions are document by the physician and not "recalled" by the patient.

Type of Bias in Research and Important Associations

Type of Bias	Definition	Important Associations	Solutions
Selection	Sample not representative	Berkson's bias, nonrespondent bias	Random, independent sample
Measurement	Gathering the information distorts it	Hawthorne effect	Control group/placebo group
Experimenter expectancy	Researcher's beliefs affect outcome	Pygmalion effect	Double-blind design
Lead-time	Early detection confused with increased survival	Benefits of screening	Measure "back-end" survival
Recall	Subjects cannot remember accurately	Retrospective studies	Multiple sources to confirm information
Late-look	Severely diseased individuals are not uncovered	Early mortality	Stratify by severity
Confounding	Unanticipated factors obscure results	Hidden factors affect results	Multiple studies, good research design
Design	Parts of study do not fit together	Non-comparable control group	Random assignment

Pharmaceutical Ad 1

Tazofect

(tanzopanib 10 and 20 mg capsules)

For newly diagnosed and treatment-resistant EGFR-mutated NSCLC, an effective treatment is now available to improve progression-free survival (PFS)!

- Tazofect is indicated for treatment of EGFR-mutated NSCLC
- Tazofect has shown efficacy in PIK3CA, PTEN, and KRAS-mutated NSCLC

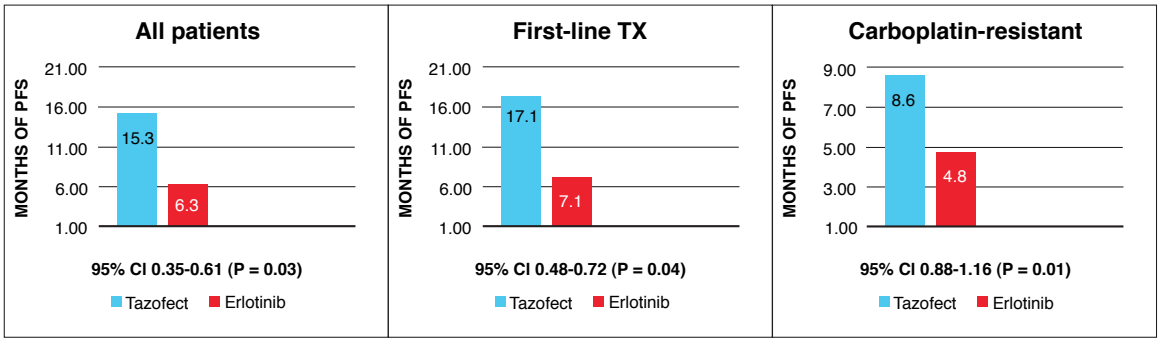
Tazofect is like extra time in a capsule...

...so your patients have more time to do what they want to do!

Tazofect has been proven to:

- Increase PFS by an average of 9 months in all NSCLC study participants (first-line and erlotinib resistant)
- Increase PFS by an average of 10 months in first line NSCLC study participants over those receiving Tarceva® (erlotinib)
- Almost double the PFS in carboplatin resistant NSCLC study participants over those receiving Tarceva® (erlotinib)

The side effect profiles for both Tazofect and erlotinib were similar.



- The effects of Tazofect (10-20 mg qd) and erlotinib (150-200 mg qd) in subjects with EGFR exon 19 deletions or exon 21 (L858R) substitution mutations are presented above. The results were taken from a phase 3, randomized, double blinded multicenter clinical trial. Per protocol, each of these agents was continued until clinically significant disease progression occurred plus an additional 2 months unless mortality occurred. The average follow-up time for patients who completed the study in both Tazofect groups was 17.3 months and 8.3 months in both erlotinib groups.
- Of the 800 initial participants enrolled in the phase 3, randomized, double blinded multicenter trial, 225 (of 398) participants completed the study in the Tazofect group and 388 (of 402) participants completed the study in the erlotinib group.
- Of the original number of study participants, 103 Tazofect patients and 102 erlotinib patients were classified as carboplatin-resistant.

Increased progression-free survival!

HIGHLIGHTS OF PRESCRIBING INFORMATION

Please see Tazofect (tanzopanib) drug package insert for complete prescribing information

Indications and Usage: Tazofect (tanzopanib) is a kinase inhibitor indicated for first-line treatment of NSCLC with EGFR exon 19 deletions and EGFR exon 21 (L858R) substitution mutations in patients age 18 years and older.

Mechanism of Action: Tanzopanib is a kinase inhibitor that acts by inhibiting intracellular tyrosine kinase domain of epidermal growth factor receptor (EGFR) thus resulting in cell cycle arrest and angiogenesis inhibition. Tanzopanib has an elimination half-life of approximately 28 hours in patients with normal hepatic and renal function.

Dosage and Administration: Treatment of NSCLC with EGFR exon 19 deletions and EGFR exon 21 (L858R) substitution mutations in patients aged 18 years and older with normal hepatic and renal function: 10-20 mg daily until clinically significant disease progression.

Contraindications: Hypersensitivity to tanzopanib; use in patients with severe hepatic impairment, active infection and thrombocytopenia.

Warnings and Precautions: May cause reactivation of tuberculosis and hepatitis B. Use caution in patients receiving other chemotherapeutic agents, thyroid disorders, dehydration, mild to moderate renal and hepatic dysfunction

Adverse Reactions:

Common (≥5%): elevated AST & ALT (15%), diarrhea (15%), fatigue (13%), elevated bilirubin (12%), infection (10%), cough (8%), thrombocytopenia (7%)

Less common (<5%): hepatorenal syndrome (2%), hepatotoxicity (2%), toxic epidermal necrolysis (1%), Stevens-Johnson syndrome (1%), acute renal failure (1%), hypothyroidism (1%), hemolytic anemia (<1%)

Practice Questions

1. The data provided in the drug advertisement most strongly supports which of the following conclusions?

   (A) In the treatment of cancer, Tazofect and erlotinib can be used interchangeably.

   (B) Tazofect is not indicated for treatment of EGFR exon 19 insertion in non-small cell lung cancer.

   (C) Tazofect should be considered for use in patients with PIK3CA mutated NSCLC.

   (D) The combination of Tazofect and erlotinib will improve the PFS to a greater extent than either agent alone.

   (E) The dose of Tazofect should be adjusted in patients with hepatic dysfunction.

The correct answer is B. The key to answering this type of question is to first rapidly scan the drug ad and highlights of prescribing information so that you are able to obtain a general sense of how the content is arranged. Then read the question and quickly search for each of the answer choices in the body of the drug ad itself. In the Indications section of the prescribing information, the following is stated. "Tazofect (tanzopanib) is a kinase inhibitor indicated for first-line treatment of NSCLC with EGFR exon 19 deletions and EGFR exon 21 (L858R) substitution mutations in patients aged 18 years and older." There is no mention of "EGFR exon 19 insertions." That is not to say that the drug cannot be used in NSCLC patients with EGFR exon 19 insertions. However, Tazofect is not indicated (FDA approved) for use in these patients by the FDA. Hence this is a true statement and the correct answer.

Both Tazofect and erlotinib are indicated for EGFR exon 19 deletions or exon 21 (L858R) substitution mutations. Also both drugs are noted to have similar side effect profiles (as indicated in the primary drug ad). However, erlotinib is also indicated for the treatment of pancreatic cancer. Since erlotinib has a broader range of clinical indications and choice A states "in the treatment of cancer," these agents are not interchangeable. It should also be pointed out that almost half of the Tazofect patients dropped out of the trial. Without knowing the reasons why, it would not be advisable to interchange Tazofect with erlotinib. Choice A is a false statement.

Choice C states that "Tazofect should be considered for use in patients with PIK3CA mutated NSCLC." Although the main drug ad states that "Tazofect has shown efficacy in PIK3CA, PTEN and KRAS Mutated NSCLC," there is no data in the prescribing information or drug ad itself to support this claim. Also what exactly does "shown efficacy" mean? The drug may be marginally effective in a small percentage of PIK3CA patients, for example. In other words, there is no data to support this claim in the drug ad. Choice C is an incorrect statement.

Choice D states that "The combination of Tazofect and erlotinib will improve the PFS to a greater extent than either agent alone." There is no information indicating whether the combination of the 2 agents will provide more benefit, less benefit or the same benefit as either agent used alone. Choice D is an incorrect statement.

Choice E refers to making a dosing adjustment in patients with hepatic dysfunction. In the prescribing information section, there is a contraindication for use in severe hepatic impairment as well as a precaution about use in patients with mild-moderate hepatic dysfunction. However, there is no information provided in the drug ad related to a dosing adjustment in patients with hepatic dysfunction. Choice E is an incorrect statement.

2. Consider the following statement: "Tazofect was proven to provide approximately double the PFS in carboplatin resistant NSCLC study participants over those receiving Tarceva® (erlotinib)." When evaluating the drug ad and highlights of prescribing information, which of the following provides the best evidence that this statement is inaccurate?

   (A) Number of patients treated in the carboplatin resistant group for both drugs
   (B) The calculation of months of PFS for the carboplatin resistant graph
   (C) The confidence interval for the carboplatin resistant graph
   (D) The p value for the carboplatin resistant graph
   (E) The y axis data points for the carboplatin resistant graph

The correct answer is C. You are asked to evaluate a statement found on the main drug ad and then indicate what information provided in the drug ad invalidates this statement. Of all the answer choices, the data provided on the confidence interval for the carboplatin resistant graph provides the best evidence that the statement is inaccurate. A confidence interval gives an estimated range of values which is likely to include an unknown parameter (such as actual PFS), the estimated range being calculated from a given set of sample data. In the original statement, the drug company claimed that their drug (Tazofect) was proven to provide approximately double the PFS in carboplatin resistant NSCLC study participants over those receiving Tarceva3® (erlotinib). However, the confidence interval provided with the carboplatin resistant graph contains the number 1. If the 95% confidence interval for a study includes 1.0, then there is >1 in 20 chance that random variation in outcome incidence among the study groups (Tazofect-study and erlotinib-control) is what produced the observed correlation between treatment and outcome. In the instance the p value is also likely to be >0.05. In summary if the confidence interval contains the relative risk of 1.00, the result is not significant. As discussed, this should also lead the reader to believe that the P-value (provided on the same graph, choice D) is also inaccurate. However, without the data seen with the confidence interval, the reader would have no way of suspecting that the provided P-value is also likely inaccurate. Therefore, choice C is the best answer

In the key under the 3 graphs, it is stated that 103 Tazofect patients and 102 erlotinib patients were classified as carboplatin resistant. This is a sufficient number of patients in each group (**choice A**).

The statement makes reference to the number of months of PFS in the Tazofect group being "almost double" the erlotinib group in carboplatin resistant patients. The PFS for Tazofect is 8.6 months and the PFS for erlotinib is 4.8 months. This statement could have been phrased differently, but is not completely inaccurate (**choice B**).

When comparing the data points on the y-axes of the 3 graphs, the y-axis on the carboplatin resistant group was clearly manipulated so that a more "profound graphical representation" of the actual results is evident. Although this should cause the reader to question the integrity of the authors, choice C is still the best answer.

3. Shortly after Tazofect is released for use in the general population, the FDA and drug manufacturer begin to receive numerous reports of complete treatment failure in both carboplatin resistant patients and first line therapy patients as well as higher than expected percentages of adverse events in all patients. Which of the following is the most likely reason for these reports on Tazofect?

   (A) Insufficient follow-up of study participants
   (B) Insufficient information on adverse effects
   (C) Insufficient information on drug indications
   (D) Subject attrition
   (E) Type II error was committed

The correct answer is choice D. In the question stem we are told that shortly after the drug is used in the general population there are reports of treatment failure in both carboplatin resistant patients and first line treatment patients. We are also told that higher-than-expected percentages of adverse events are occurring. The question is asking for the most likely cause of this occurrence. The most likely reason based on the data provided in the drug ad and highlights of prescribing information is subject attrition. Under the 3 graphs it is stated that "Of the 800 initial participants enrolled in the phase 3, randomized, double blinded multicenter trial, 225 (of 398) participants completed the study in the Tazofect group and 388 (of 402) participants completed the study in the erlotinib group." Approximately half (225/398 participants) of the original Tazofect study participants never completed the trial. Furthermore, the authors did not provide an explanation as to why they did not complete the study. Is it likely that they did not complete the trial because of severe adverse effects and/or death?

Without knowing the reasons why the participants never completed the trial, it is difficult to evaluate the safety and efficacy of Tazofect in both first line therapy and carboplatin resistant patients. Also, it is quite possible that only a small percentage of the 103 participants in the carboplatin resistant arm of the study never completed the study. Without more information, it is hard for the reader to make a valid conclusion. In summary, the authors should have indicated why almost half of the study participants never completed the study; hence, the primary reason why these reports are occurring (due to treatment failures and increased adverse effect occurrence) is directly related to the circumstances surrounding the high level of subject attrition in this trial.

The phase 3 trial for Tazofect lasted in each patient until clinically significant disease progression occurred plus an additional 2 months unless mortality occurred. Furthermore, the average follow-up time for patients who completed the study was listed. The length of the study was sufficient to assess the effects it was designed to assess. Choice A is an incorrect response.

At the bottom of the highlights of prescribing information page of the drug ad, there is an extensive list of adverse effects and percentage of occurrence of each of these side effects. Hence, sufficient information on these adverse effects was provided. Choice B is an incorrect response. However, this information was based on the number of patients who completed the clinical trial. Since almost half of the study participants (in the Tazofect arm) never completed the trial, an accurate accounting of side effect appearance was not available. This is directly related to subject attrition.

At the top of the highlights of prescribing information page of the drug ad, it clearly states that "Tazofect (tanzopanib) is a kinase inhibitor indicated for first-line treatment of NSCLC with EGFR exon 19 deletions and EGFR exon 21 (L858R) substitution mutations in patients aged 18 years and older." The drug is NOT indicated for use in carboplatin resistant patients. Although there is a graph on the first page of the drug ad and comments about proven effects, the drug ad never claimed that the drug was "indicated" for use in carboplatin patients. Choice C is an incorrect response.

A type II or beta error is where the researcher fails to reject the null hypothesis when it is really false. In other words, the researcher declared that there was no significant effect on the basis of the sample when there really is one in the population. The likely impact of this type of error is that the drug (Tazofect) would NOT obtain FDA approval and the general population would not receive this medication. Choice E is an incorrect response.

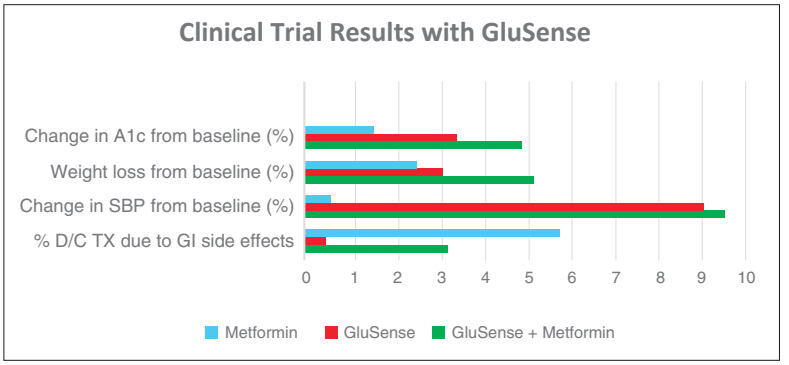
Pharmaceutical Ad 2

GluSense™ ... because it makes sense!

(Glugliflozin 75 mg, 150 mg and 300 mg tablets)

Diabetes is a complex disease ...

GluSense is a simple treatment measure with proven therapeutic outcomes!



- The clinical effects of GluSense (150-mg qd), metformin (1000 mg bid) and combination therapy (GluSense 150 mg qd + metformin 1000 mg bid) in patients with newly diagnosed type 2 diabetes who failed to meet glycemic goals with diet and exercise alone are presented above. The results were taken from a phase 3, randomized, double-blinded multicenter clinical trial.
- Each therapy was administered in conjunction with a structured diet and exercise program.
- A baseline A1c, body weight and systolic blood pressure reading were obtained at the onset of the trial and every 8 weeks during the trial. All participants were enrolled in the study for 12 months.
- Of the 1600 initial participants enrolled in the trial, 462 (of 510) participants in the metformin-only group completed the study, 358 (of 533) of the GluSense-only group completed the study, and 313 (of 577) in the GluSense + metformin group completed the study.
- The primary reason (as stated by the patient) for withdrawing from the study was unwanted side effects.

GluSense demonstrated greater reductions in A1c, weight loss & blood pressure than metformin alone at 52 weeks!

- GluSense is indicated for treatment of T2DM as monotherapy & in combination with metformin.
- GluSense has shown efficacy when used in conjunction with other oral hypoglycemic agents.

The treatment your T2DM patients have always needed is finally here!!

SMILE Pharmaceuticals

Smile for life with SMILE Pharmaceuticals

GluSense has been proven to:

- Reduce A1c in T2DM patients by an average of 3.4% as monotherapy (P<0.001) & in combination with metformin an average of 4.9% (P<0.002) – mean baseline A1c = 8.05%
- Reduce baseline weight in T2DM patients by an average of 3.1% as monotherapy (P<0.02) & in combination with metformin an average of 5.2% (P<0.03) – mean baseline weight = 182 lbs (87.3 kg)
- Reduce baseline systolic blood pressure in T2DM patients by an average of 9.1% as monotherapy (P<0.006) & in combination with metformin an average of 9.6% (P<0.001) – mean baseline SBP = 177 mm Hg.

Additional product information provided below

HIGHLIGHTS OF PRESCRIBING INFORMATION

Please see GluSense (glugliflozin) drug package insert for complete prescribing information.

Indications and Usage: GluSense (glugliflozin) is an SGLT2 inhibitor with insulin-sensitizing properties, indicated for the treatment of type 2 diabetes in conjunction with diet and exercise as monotherapy, and in combination with metformin in patients aged 18 years and older.

Mechanism of Action: Glugliflozin is an SGLT2 inhibitor with insulin-sensitizing properties. This agent has a dual mechanism of action. It acts by:

- Inhibiting the sodium-glucose cotransporter 2 (SGLT2), thereby reducing glucose reabsorption and increasing urinary glucose excretion
- Decreasing insulin in the periphery and liver, resulting in increased insulin-dependent glucose disposal and decreased hepatic glucose output. Glugliflozin is an agonist for peroxisome proliferator-activated receptor-gamma (PPARγ). Activation of PPARγ nuclear receptors in the liver, skeletal muscle, and adipose tissue modulates the transcription of a number of insulin responsive genes involved in the control of glucose and lipid metabolism.
- Other: antagonizes peripheral alpha-1 adrenergic receptors

Pharmacokinetics

- Glugliflozin has an elimination half-life of approximately 16 hours in patients with normal hepatic and renal function.
- Following oral administration of glugliflozin, Tmax occurs within 3 hours.
- Glugliflozin is extensively metabolized by hydroxylation and oxidation; the metabolites also partly convert to glucuronide or sulfate conjugates.
- Following oral administration of glugliflozin, approximately 15–20% of the drug dose is recovered in the urine.

Dosage and Administration: Treatment of type 2 diabetes in patients aged 18 years or older who have failed to meet glycemic goals with diet and exercise alone:

- Monotherapy: 150-300 mg PO qd; start at 75 mg PO qd and increase by 75 mg qwk; max dose 450 mg/day
- Combination with metformin: same as monotherapy and standard metformin dose of 2000 mg daily (in divided doses)

Contraindications: Type 1 diabetes mellitus, hypersensitivity to glugliflozin and/or sulfonamides; NYHA class III or IV heart failure, severe hepatic impairment, hyperkalemia, use with medications causing hyperkalemia and diabetic ketoacidosis

Warnings and Precautions: May cause hypoglycemia, hypotension, and AST/ALT elevation. Caution use in elderly patients with poorly controlled diabetes and patients with past history of cardiovascular disease.

Adverse Reactions (for a complete list, see drug package insert)

Common (≥5%):	Less Common (<5%):
Hyperkalemia	Fatigue
Hypoglycemia	Hepatic dysfunction
Orthostatic hypotension	Thirst
Dizziness	Fainting
Tachycardia	Mental impairment
Hyperhidrosis	Pancreatitis

Drug Interactions (see drug package insert)

Practice Questions

1. The data provided in the drug advertisement most strongly supports which of the following conclusions?

   (A) GluSense is a substitute for diet and exercise in type 2 diabetes due to its weight loss properties.

   (B) GluSense is recommended for use in patients with a history of myocardial infarction.

   (C) GluSense is safer to use in patients with type 2 diabetes than metformin.

   (D) The antihypertensive effects of GluSense are comparable to some currently available antihypertensive medications.

   (E) The combination use of GluSense and a sulfonylurea is recommended for those who initially fail sulfonylurea monotherapy.

The correct answer is D. This type of question generally requires a process of elimination. The statement "The antihypertensive effects of GluSense are comparable to some currently available antihypertensive medications" is most strongly supported by the drug ad. Relevant information to support this statement can be found in several places: First in the table, GluSense is associated with 9.1% decrease in average systolic blood pressure. This percentage decrease is comparable to the diuretics, low-moderate doses of ACE inhibitors, alpha antagonists as well as varying doses of other drugs from different drug classes. Second, the mechanism of action section of the highlights of prescribing information states that this drug antagonizes peripheral alpha-1 adrenergic receptors. This is the same mechanism of action as drugs like terazosin and doxazosin. Finally, the side effects of the drug (orthostatic hypotension, dizziness, and tachycardia) also support its antihypertensive properties since these are side effects commonly seen in alpha antagonists. Hence, out of all of the answer choices, this statement is most strongly supported by the drug ad.

There are several places which indicate GluSense is used in conjunction with diet and exercise, such as the key under the chart on the main ad page and in the Indications and Usage section in the highlights of prescribing information. Although the drug promotes weight loss, GluSence is not a substitute for diet and exercise (**choice A**).

The Warnings and Precautions section states that GluSense should be used cautiously in patients with past history of cardiovascular disease. Furthermore, in Contraindications, it is stated that GluSense is contraindicated for use in patients with NYHA Class III or IV heart failure. Since myocardial infarction (**choice B**) is a form of cardiovascular disease and a common precipitating cause of heart failure, GluSense would not be recommended for use in these cases. GluSense may potentially be used "cautiously" in patients with a mild form of cardiovascular disease but is not "recommended."

The drug ad does not have a safety profile comparison between GluSense and metformin (**choice C**). The only related comparison between the drugs is the appearance of severe GI side effects leading to withdrawal from the study.

The only statement relating to the use of GluSense and another drug is found in the main area of the drug ad: "GluSense has shown efficacy when used in conjunction with other oral hypoglycemic agents." It does not specify the names or drug classes of the other agents (**choice E**). Furthermore, it does not provide any data to support this claim.

2. Of the initial trial participants, 175 persons from the GluSense-only group and an even large number from the GluSense and metformin group withdrew from the study. Which of the following is the most likely reason for participant withdrawal?

   (A) Appearance of drug interactions
   (B) Hypersensitivity to sulfonamides
   (C) Severe hypoglycemia
   (D) Severe hypotension
   (E) Severe GI side effects

The correct answer is C. You are asked to determine the most likely reason why participants withdrew from the study. In the key under the graph on page 1, it states "The primary reason (as stated by the patient) for withdrawing from the study was unwanted side effects." However, it is not stated what side effect caused them to withdraw. Therefore, you must determine the most likely reason based on information provided in the drug ad. The Adverse Reactions section of the highlights of prescribing information provides only a "partial" list of side effects with a percent occurrence above and below 5% so this section alone cannot be used to answer the question. The correct answer can be derived from the section on the bottom right of the main drug ad. It states that GluSense has been proven to reduce A1c in type 2 diabetes (T2DM) patients by an average of 3.4% as monotherapy ($P<0.001$) and in combination with metformin an average of 4.9% ($P<0.002$). The mean baseline A1c was 8.05% for study participants. If the mean baseline A1c was 8.05%, that means that some patients likely started with an A1c around 7%. Remember that an A1c 6% is an average daily glucose level of 126 mg/dL. If you lower this A1c by 3.4% (GluSense only) or 4.9% (Glusense + metformin), the resulting A1c levels are 3.6% and 2.1%, respectively. Since the A1c is a long-term average of the daily blood glucose levels, it is likely that this agent caused severe hypoglycemia in participants; hence, the likely reason for withdrawal from the study. Furthermore, it is stated that hypoglycemia is one of the most common adverse effects. Choice C is the best answer choice.

The drug ad does not specifically mention any problems with drug-drug interactions (**choice A**) in the clinical trial and there is a comment indicating that the reader should please see GluSense (glugliflozin) drug package insert for complete prescribing information. Based on this information, it is unlikely that drug-drug interactions are the primary reason for patient withdrawal.

The Contraindications section states that GluSense is contraindicated for use in patients with sulfonamide hypersensitivity (**choice B**). However, there is nothing which would lead the reader to believe this is the primary reason for withdrawal from the study.

The bottom right of the ad states that GluSense has been proven to reduce baseline SBP (systolic blood pressure) in T2DM patients by an average of 9.1% as monotherapy ($P<0.006$) and in combination with metformin an average of 9.6% ($P<0.001$). The mean participant baseline SBP was 177 mm Hg. Even if the starting blood pressure was 100 mm Hg, the patient would still not be hypotensive with a 9.6% drop in blood pressure. Note, too that orthostatic hypotension is listed as a common side effect, but with the information presented it is unlikely that was the primary reason for patient withdrawal (**choice D**).

It is unlikely that severe GI side effects (**choice E**) were the primary reason for participant withdrawal since the table shows that the GluSense-alone arm had almost no withdrawals from study. GluSense also improved the GI side effect withdrawal rate for patients receiving metformin when the 2 medications were combined.

3. A 64-year-old man comes to the physician with complaints of increasing polyuria and polydipsia. His past medical history is significant for type 2 diabetes, hypertension, hyperlipidemia, and a myocardial infarction 4 years ago. Allergy history includes an anaphylactic reaction to levofloxacin. He is currently receiving metformin 1000 mg 2x daily, enalapril 10 mg daily, pravastatin 20 mg daily, and spironolactone 25 mg twice daily. Physical examination shows blood pressure of 126/82 mm Hg, heart rate 62/min, height 172.7 cm (5 feet, 8 inches), weight 88.6 kg (195 lbs), and BMI 29.6.

   Laboratory studies show:

   - Blood glucose: 215 mg/dL
   - A1c: 10.5%
   - Albumin: 3.8 g/dL
   - Creatinine: 1.3 mg/dL
   - AST: 20 IU/L
   - ALT: 22 IU/L
   - Sodium: 138 mEq/L
   - Potassium: 4.9 mEq/L
   - Calcium: 9.6 mg/dL
   - Ejection fraction: 66%

   If the attending physician is considering the addition of GluSense to this patient's medication regimen, which of the following is a contraindication for prescribing this medication?

   (A) Allergy contraindication
   (B) Cardiovascular contraindication
   (C) Drug interaction contraindication
   (D) Hepatic contraindication
   (E) Renal contraindication
   (F) There is no contraindication in this patient and the medication can be prescribed

The correct answer is C. You are being asked for the most likely reason to not prescribe this medication to a given patient. Therefore, you need to look for either an absolute or relative contraindication for prescribing this medication in the drug ad. The Contraindications section states that GluSense is contraindicated for "use with medications causing hyperkalemia." The patient is currently receiving enalapril and spironolactone. Both of these medications are associated with the development of hyperkalemia. Furthermore, the patient's potassium level is 4.9 mEq/L, which is at the high level of normal. The patient is likely to become hyperkalemic once starting this medication. Based on this information, a drug-drug interaction (choice C) between GluSense and both enalapril and spironolactone is the most likely contraindication for use of this medication in this patient. Choice C is correct and choice F is incorrect.

The patient has a history of anaphylaxis to the fluoroquinolone levofloxacin. Although GluSense is contraindicated for use in patients with a sulfonamide allergy, there is no allergy contraindication for using this medication in patients with a fluoroquinolone allergy (**choice A**).

The only cardiovascular contraindication (**choice B**) listed for GluSense is NYHA Class III or IV heart failure. This patient has a normal ejection fraction of 66% (normal 55-70%) so does not meet the cardiovascular contraindication criteria for this drug. Although the patient's past history of myocardial infarction predisposes him to heart failure, the patient currently does

not have heart failure so there is no contraindication. However, there is a warning for use of GluSense in patients with cardiovascular disease. As indicated, this patient has a past history of a myocardial infarction as well as hyperlipidemia and hypertension. Therefore, this medication should be used cautiously in this patient. If GluSense is prescribed, the patient should be monitored closely but there is no cardiovascular contraindication for the use of this drug in this patient.

The patient has normal hepatic function (AST: 20 IU/L (normal <35 IU/L) and ALT 22 IU/L (normal <35 IU/L)); hence, there is no hepatic contraindication for using GluSense in this patient (**choice D**).

The patient has normal renal function (creatinine: 1.3 mg/dL (normal 0.5-1.4 mg/dL)); hence, there is no renal contraindication for using GluSense in this patient (**choice E**).

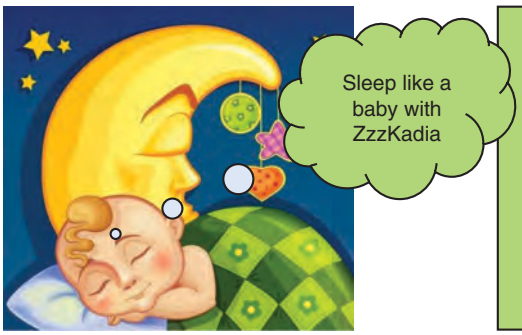
Pharmaceutical Ad 3

Zzzkadia™

(Zlideplon 2.5, 5, 7.5 mg tablets)

The only orexin receptor antagonist with $GABA_BZ$ receptor modulator properties indicated for long-term treatment of insomnia!

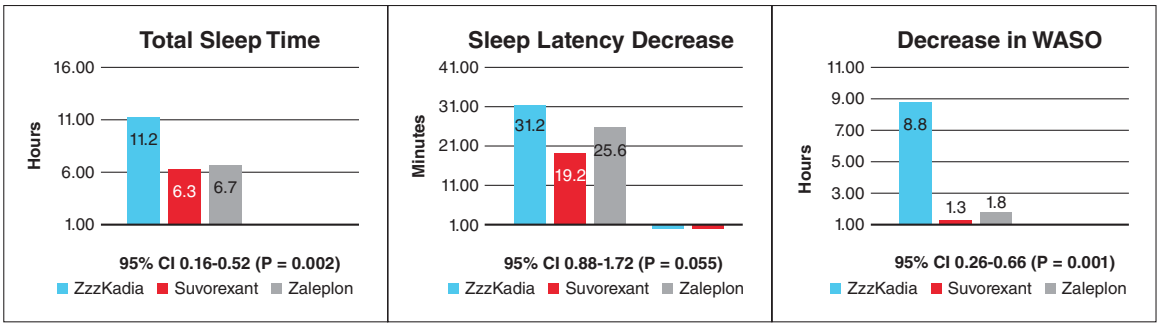
- TIndicated for long-term treatment of insomnia
- Shown to be non-addicting
- The most effective sedative/hypnotic available



ZzzKadia has been proven to:

- Increase mean total sleep times (TST) by 5.7 hours compared to 1.3 hours with suvorexant and 1.1 hours with zaleplon
- Significantly decrease sleep latency (SL) over both suvorexant and zaleplon
- Significantly decrease wake time after sleep onset (WASO) over both suvorexant and zaleplon

Most common side effects: headache, dizziness, lightheadedness, daytime drowsiness, somnolence, and nightmares



- The effects of ZzzKadia (5 mg HS), Suvorexant (10 mg HS) and Zaleplon (5 mg HS) were evaluated in participants age 35-70 with a DSM-5 diagnosis of insomnia disorder who have not previously used prescription sedative/hypnotics. The results were taken from a 16-week phase 3, randomized, double blinded multicenter clinical trial. Per protocol, patients were instructed to take 10 minutes prior to bedtime 5 times per week maximum.
- Of the 651 initial participants enrolled in the study 137 (of 222) ZzzKadia, 198 (of 220) suvorexant and 192 (of 209) zaleplon participants completed the study.
- Following the study, each of the medications was discontinued and 93% of all participants (who completed the trial) requested further treatment due to the reemergence of severe insomnia as well as side effects ranging from autonomic hyperactivity to psychomotor agitation to seizures.

Increased total sleep time!

Additional product information provided below

SMILE Pharmaceuticals

Smile for life with SMILE Pharmaceuticals

Improved daytime function!

HIGHLIGHTS OF PRESCRIBING INFORMATION

Please see ZzzKadia (Zlideplon) drug package insert for complete prescribing information.

Indications and Usage: ZzzKadia (Zlideplon) is an orexin receptor antagonist with $GABA_BZ$ receptor modulator properties indicated for first-line treatment of short-term insomnia and insomnia disorder (according to DSM-5 diagnostic criteria) in patients age 35 years and older.

Mechanism of Action: Zlideplon is an orexin receptor antagonist with $GABA_BZ$ receptor modulator properties. Specifically zildeplon is a selective dual antagonist of orexin receptors OX1R and OX2R that promotes sleep by reducing wakefulness and arousal. It also exerts its action through subunit modulation of the $GABA_BZ$ receptor chloride channel macromolecular complex. Zildeplon also binds to the brain omega-1 receptor located on the alpha subunit of the GABA-A/chloride ion channel receptor complex and potentiates t-butyl-bicyclophosphorothionate (TBPS) binding. Zlideplon has an elimination half-life of approximately 10 hours in patients with normal hepatic function.

Dosage and Administration: Treatment of short-term insomnia and insomnia disorder in patients age 35 years and older with normal hepatic and renal function: 2.5-5 mg PO at bedtime. Maximum dose per day is 7.5 mg.

Contraindications: Hypersensitivity to zlideplon or sulfonylureas; abrupt discontinuation or use in patients with severe hepatic impairment.

Warnings and Precautions: Use caution in the patient who is sensitive to sulfonylureas; has a past history of depression or substance use disorder; drives or operates heavy machinery, or has altered CYP3A4 function (especially CYP3A4 poor metabolizers).

Adverse Reactions:

Common (>5%): orthostatic hypotension (25%), tachycardia (18%), headache (15%), dizziness (13%), lightheadedness (12%), daytime drowsiness (10%), hypotension (9%), somnolence (8%), decreased coordination (7%); memory impairment (5%) and nightmares (5%)

Less common (<5%): hepatotoxicity (2%), toxic epidermal necrolysis (1%), Stevens-Johnson syndrome (1%), diarrhea (1%), paresthesia (1%), and ocular pain (<1%)

Practice Questions

1. The data provided in the drug advertisement most strongly supports which of the following claims?

   (A) The dose of ZzzKadia should be adjusted in patients with hepatic dysfunction.
   (B) Zzzkadia improves daytime function.
   (C) ZzzKadia is indicated for long-term treatment of insomnia.
   (D) ZzzKadia is the most effective sedative/hypnotic.
   (E) ZzzKadia significantly decrease sleep latency (SL) over both suvorexant and zaleplon.

The correct answer is D. Of the 3 medications studied (ZzzKadia, suvorexant, zaleplon), ZzzKadia is significantly more effective than the other 2 agents in terms of total sleep time (TST) and wake time after sleep onset (WASO). These facts are supported by both the confidence intervals and p values provided.

In the prescribing information section, there is a contraindication for use in severe hepatic impairment as well as a precaution about use in patients with altered CYP3A4 function (especially CYP3A4 poor metabolizers). Although a dosage adjustment in patients with renal dysfunction is likely, there is no information provided in the drug ad related to a dosing adjustment in patients with hepatic dysfunction (**choice A**).

The side effects for this drug include headache (15%), dizziness (13%), lightheadedness (12%), daytime drowsiness (10%), somnolence (8%), decreased coordination (7%) and memory impairment (5%). There is no indication that this drug improves daytime function (**choice B**).

In the main drug ad it is stated that "the results were taken from a 16-week phase 3, randomized, double blinded multicenter clinical trial." This timeframe does not constitute long-term efficacy (**choice C**). Furthermore, in the indications section of the prescribing information it is stated that ZzzKadia is indicated for the treatment of short-term insomnia and insomnia disorder (according to DSM-5 diagnostic criteria).

Choice E refers to the stated decrease in sleep latency (SL) over both suvorexant and zaleplon. This statement is false based on the confidence interval provided for SL. If the given confidence interval (for relative risk or odds ratio) contains 1.0 (as seen in the SL graph), then there is no statistically significant effect of exposure. If the confidence interval for an OR does not contain the number "1" then the following rules apply to the odds ratio:

- If OR > 1, the exposure is associated with a higher risk of outcome
- If OR < 1, the exposure is associated with a lower risk of outcome

2. Although not mentioned in the mechanism of action for ZzzKadia, this drug most likely has which of the following pharmacological properties?

   (A) Alpha 1 antagonist
   (B) Beta 1 agonist
   (C) Beta 2 antagonist
   (D) Muscarinic 2 agonist
   (E) Muscarinic 3 antagonist

The correct answer is A. You are being asked to determine the additional pharmacological effects of ZzzKadia, which is currently described as an orexin receptor antagonist with $GABA_BZ$ receptor modulating properties. The best way to answer this question is to review the adverse effects and match several of these effects to the correct answer choice. Since most of the

CNS-related adverse effects are caused by interaction with the orexin and GABA receptors, the focus should be on the non-CNS related effects. The high incidence of orthostatic hypotension (25%), tachycardia (18%) and hypotension (9%) suggests that the drug has some cardiovascular effects. Of the answer choices, only alpha 1 antagonists (such as terazosin) would cause these cardiovascular effects.

Beta 1 agonists (**choice B**) are likely to cause increased heart rate, conduction velocity and force of contraction leading to hypertension (not hypotension).

Beta 2 antagonists (**choice C**) will block the beta-2 receptors found on blood vessels which are responsible for vessel dilation. Hence, blood pressure will not change or may increase.

Muscarinic 2 receptors are primarily located on the heart and when stimulated lead to decreased heart rate. However a muscarinic 2 receptor antagonist (**choice D**) will block these receptors leading to tachycardia and increased blood pressure secondary to the unopposed beta 1 receptor effects.

Muscarinic 3 receptors are non-innervated receptors located on blood vessels. Antagonism (**choice E**) of these receptors would cause not change in blood pressure since stimulation (via nitrous oxide endothelium-derived relaxing factor) leads to dilation.

3. Consider the following statement: "ZzzKadia has been shown to be non-addicting!" When evaluating the drug ad and highlights of prescribing information for ZzzKadia, which of the following provides the best evidence that this statement is inaccurate?

   (A) Long drug half-life
   (B) Presence of euphoric symptoms
   (C) Presence of severe side effects
   (D) Presence of withdrawal symptoms
   (E) This is an accurate statement

The correct answer is D. You are being asked why ZzzKadia is likely an addictive substance with abuse potential. The first step is to understand the definition of abuse potential. According to the FDA, abuse potential refers to a "drug that is used in nonmedical situations, repeatedly or even sporadically, for the positive psychoactive effects it produces. These drugs are characterized by their CNS activity. Examples of the psychoactive effects they produced include sedation, euphoria, perceptual and other cognitive distortions, hallucinations, and mood changes. Drugs with abuse potential often (but not always) produce psychic or physical dependence (leading to withdrawal when substance is removed) and may lead to the disorder of addiction."

In the main drug ad, the following is stated "Following the study, each of the medications was discontinued and 93% of all participants (who completed the trial) requested further treatment due to the reemergence of severe insomnia as well as side effect ranging from autonomic hyperactivity to psychomotor agitation to seizures". Based on this information and the FDA definition of abuse potential, when ZzzKadia is abruptly withdrawn physical side effects (including CNS effects) are seen.

Half-life and the presence of severe side effects (**choices A and C**) have no established impact on abuse potential.

Euphoric symptoms (**choice B**) are probably the most common reason why prescription and illicit drugs are abused. Euphoria is defined as an intense feeling of well-being, elation, happiness, excitement and joy. However, there are no euphoric symptoms listed in the adverse

effects of for this drug. Pharmacologically-induced euphoria is most commonly seen with stimulants, opioids and cannabinoids.

4. A 42-year-old woman comes to the physician because of a persistent inability to fall asleep and/or stay asleep each night (4-5 nights per week) over the past 8-9 months. She states that she is continually exhausted during the day and her work as a pharmacist is "really suffering." She indicates that she normally works 3 shifts, 12 hours each, plus one 8-hour shift per week. She denies using alcohol or illicit drugs. Physical examination is normal. Based on the information presented in the drug ad for ZzzKadia, which of the following is the most appropriate initial statement to the patient?

   (A) "Before I prescribe you a prescription medication for your insomnia, let's try some natural remedies found at a local health and wellness store."

   (B) "I am thinking that ZzzKadia would be perfect for you. Although it does have some serious side effects, you are not likely to experience them due to your relatively young age."

   (C) "I do not recommend prescribing you any medication at this time since you do not have insomnia disorder."

   (D) "I do not recommend ZzzKadia for you; however, suvorexant or zaleplon may be an appropriate treatment option."

   (E) "ZzzKadia is a new drug that will be perfect for you; however, it does have some serious side effects."

The correct answer is D. According to the DSM-5, the diagnostic criteria for insomnia disorder are as follows:

- Predominant complaint of dissatisfaction with sleep quality or quantity associated with 1 or more of the following: difficulty initiating sleep, difficulty maintaining sleep, or early-morning awakening with inability to return to sleep
- Sleep disturbance cause clinically significant distress or impairment in social, occupational or other important areas of functioning
- The sleep difficulty occurs at least 3 nights per week
- The sleep difficulty is present for at least 3 months
- The sleep difficulty occurs despite adequate opportunity for sleep
- The insomnia is not better explained by another disorder or is attributed to effects of a substance (drug abuse, medication).

Based on this information, the patient meets the DSM-5 criteria for insomnia disorder, which is commonly treated with pharmacological therapy. Although ZzzKadia is indicated for treatment of insomnia disorder (as seen in the Indications section), this drug would not be recommended for this patient since she works 12 hour shifts and the average total sleep time with ZzzKadia is 11.2 hours. Furthermore, the drug has a half-life of approximately 10 hours. Assuming that the patient was able to awaken earlier than 11.2 hours, the pharmacological effect (and CNS side effects) would likely be present in the patient while she was working in the pharmacy. However the average total sleep time with both suvorexant and zaleplon are 6.3 and 6.7 hours, respectively. Either of these medications (currently approved for insomnia by the FDA) would likely be an appropriate treatment option.

Choice A is incorrect since you would not see non-FDA approved medications on the exam.

Patient Safety and Quality Improvement

Clinical Applications of Patient Safety and Quality Improvement

24

Learning Objectives

- ❑ Define the principles of patient safety, system-based practice, and continuous quality improvement
- ❑ Recognize and classify the different types of medical error
- ❑ Describe the types of reporting systems which can identify and analyze medical errors

PRINCIPLES OF PATIENT SAFETY

Case: Within the past 2 years, a major tertiary care referral hospital experiences separate cases of a blood transfusion reaction due to incompatibility, 2 inpatient falls leading to significant injury, a wrong-site surgery, and a medication-dosing error causing a patient death.

- What is the most probable single underlying cause behind these medical errors?

  Systems failures due to the complexity of health care delivery

Health care is not a single system, but rather multiple systems which all interact. These clinical microsystems are defined as a group of clinicians and staff working together with a shared clinical purpose to provide health care for a population of patients. Individual health care organizations contain multiple microsystems which evolve over time. It is the complexity of these systems that predispose patients to harm from medical error.

Health care in the United States is capable of achieving incredible results for even the most severely ill patients. However, it does not do so reliably and consistently. Medical errors plague our health delivery systems. The Institute of Medicine (IOM) estimates that 44,000–98,000 patients die each year in the United States from preventable medical errors. This translates to more annual deaths than motor vehicles accidents, HIV, and breast cancer. In addition to the toll that this takes in the form of human suffering, medical errors also represent a significant source of inefficiency and increased cost in the health care system.

The causes of these adverse events are not usually from people intentionally seeking to harm patients, but rather from the complexity of the health care system together with the inherent capability for human error. The causes of these errors are varied, and can include failures made in administering medication, performing surgery, reporting lab results and making a diagnosis, to name a few. The most severe of these medical errors are referred to as **sentinel events.** A sentinel event is an adverse event in which death or serious harm to a patient has occurred; it usually refers to an event that is not at all expected or acceptable (e.g., operating on the wrong patient or body part, abduction of an infant from the hospital, patient suicide while admitted to the hospital). The choice of the word *sentinel* reflects the egregiousness of the injury (e.g., amputation of the wrong leg) and the likelihood that investigation of such an event will reveal serious problems in current policies or procedures.

It is unacceptable for patients to suffer preventable harm caused by a health care system whose purpose is to provide healing and comfort. Improving patient safety is the responsibility of every health care professional and requires a comprehensive team effort. Collectively, health care needs to learn from past errors and develop systems of care which prevent future errors from harming patients (e.g., process of root cause analysis).

Systems in health care delivery can be redesigned to **make it difficult for health care personnel to do the wrong thing** and **easier to consistently do the right thing**.

UNDERSTANDING MEDICAL ERROR

Classifications of Medical Errors

Medical errors can be classified as **errors of commission** (doing something wrong) or **errors of omission** (failing to do the right thing). Errors of omission are more difficult to recognize than errors of commission, but are thought to represent a larger percentage of medical errors.

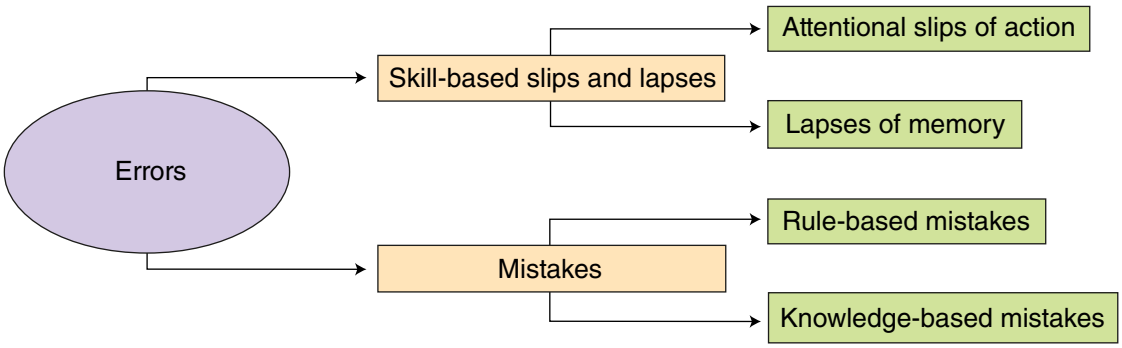
Examples are ordering a medication for a patient with a documented allergy to that medication (**error of commission**), and failing to prescribe low-dose unfractionated heparin as venous thromboembolism prophylaxis for a patient undergoing hip replacement surgery (**error of omission**).

> Case: A 47-year-old man presents to the outpatient clinic with complaints of shoulder pain and is diagnosed with arthritis. The clinician treating him administers a shoulder corticosteroid injection without reviewing the patient's medication list prior to the procedure. The patient has been taking Coumadin for atrial fibrillation and develops hemarthrosis.

- Error classified as a lapse or omission

Lapses are missed actions or omissions (e.g., forgetting to monitor serum sodium in a patient undergoing diuresis for congestive heart failure). Lapses are not directly observable (i.e., you cannot directly 'see' a lack of memory). **Slips** are observed actions that are not carried out as intended (e.g., accidentally injecting a medication intravenously when it was meant to be given subcutaneously). **Mistakes** are a specific type of error brought about by a faulty plan or incorrect intentions; the intended action is wrong (e.g., barium swallow on a patient with suspected esophageal perforation or giving steroids to a patient with acute glaucoma).

The figure below clarifies the relationship further.



Case: After an unexpected 3-hour delay in the operating room due to a problem in the electrical system, an operating room team rushes to get started in order to complete the scheduled elective procedures. The team elects not to perform the mandatory sponge count at the end of the first surgery in order to get the next case started sooner. The patient returns 2 weeks later with abdominal pain and is found on x-ray to have a retained foreign object (a sponge) in the abdominal cavity.

- Error due to **'violation' in policy**

Violations are conscious failures to adhere to procedures or regulation. Violations differ from slips, lapses and mistakes because they are deliberate actions, i.e., intentionally doing something against the rules. Reasons for violations may include time constraints, unfamiliarity with policy, or motivation by personal gain. A health care professional may consider that a violation is well-intentioned; however, if it results in an adverse event it would still technically constitute a 'violation' rather than an error.

Case: A 65-year-old man presents to the emergency department with sudden epigastric pain. He has a history of alcoholism, and the treating physician suspects a diagnosis of pancreatitis. Despite the fact that the patient denies alcohol use for several years, has normal blood levels of pancreatic enzymes, and has an abnormal EKG, he is treated for pancreatitis and the actual diagnosis of myocardial infarction is delayed.

- Error due to **'anchoring bias'**

Anchoring bias describes when a clinician relies on and clings steadfastly to the initial diagnostic impression, despite subsequent information to the contrary. In many cases the features of a patient's presentation allow the clinician to make a correct initial diagnostic impression; however, in certain cases subsequent developments in the patient's course will prove inconsistent with the first impression. Anchoring bias refers to the tendency to hold on to the initial diagnosis, even in the face of disconfirming evidence.

Case: A 33-year-old woman with a breast lump is asked if it is tender. When she says that it is tender, the clinician confirms the suspected diagnosis of a cyst. No further history is obtained and the clinician fails to realize there has been an increase in size, associated adenopathy and fixation to the chest wall (hence the tenderness), all suggesting breast cancer.

- Error due to **'confirmation bias'**

Confirmation bias may accompany anchoring, and refers to the tendency to focus on evidence that supports an initial diagnosis, rather than to look for evidence that refutes it or provides greater support to an alternative diagnosis.

Case: A 24-year-old sexually active woman is seen by her ob/gyn physician for complaints of abdominal pain. She is evaluated briefly and treated for a UTI without any other tests being performed. The next day, the patient presents to the emergency department and is diagnosed with a ruptured appendicitis.

- Error defined as **'premature closure'**

Premature closure is acceptance of a diagnosis before it has been fully vetted by considering alternative diagnoses or searching for data that contradict the initial diagnosis. In this case the physician finds a cause that fits the clinical picture and ceases to search for other diagnostic possibilities.

Case: A 4-week-old infant is brought to the emergency department by his parents after he develops an episode of emesis with an observed period of apnea. Three other infants were seen there earlier this week with the flu. The infant is discharged home with instructions for flu management, but the parents return with him later, reporting that he had another episode of apnea. The patient is further evaluated and subsequently transferred to the children's hospital with the clinical diagnosis of apnea from gastroesophageal reflux.

- Cognitive error classified as **'availability bias/heuristic'**

Availability bias/heuristic is the tendency to make the diagnosis of a current patient biased by recent or vividly recalled cases or events, rather than on prevalence or probability.

Case: During her third visit to an outpatient clinic for shortness of breath, a 57-year-old woman with documented pneumonia is treated with antibiotics and sent home. She later presents to the emergency department with exacerbation of dyspnea and is admitted to the medical service, where she is found to have hypoxia from heart failure.

- Error due to **'diagnosis momentum'**

Diagnosis momentum is a bias that occurs when the diagnosis considered by one clinician becomes a definitive diagnosis as it is passed from one clinician to the next; it then becomes accepted without question by clinicians down the line. It is the medical equivalent of "following the crowd."

Case: A patient with a known heroin addiction presents with abdominal pain. The treating physician assumes the pain to be a sign of opiate withdrawal and manages the patient accordingly with admission to the inpatient med-psychiatry ward. Later during the hospital stay the patient's pain increases and he develops peritonitis from a missed bowel perforation.

- Error related to **'framing effects'**

Framing effects: Diagnostic decision-making unduly biased by subtle cues and collateral information. This can lead to diagnostic error by allowing the way the story is framed to influence the diagnosis.

Human Factors that Cause/Influence Medical Errors

An understanding of medical error requires comprehension of the personal situations and factors associated with the risk of error. Human beings have limited memory and attention capacity. People can make errors when distracted or overtasked. The risk of error is exacerbated by conditions of fatigue, stress, and illness.

Case: A 9-year-old-boy is admitted to the pediatric oncology service for the treatment of a hemolytic malignancy, and is started on chemotherapy ordered from the pharmacy. The hospital pharmacist is working a double shift because 2 other pharmacists called in sick. The hospital is particularly busy and the pharmacist has not had a break all day. He accidentally sends the wrong dose of chemotherapy to the floor, after which the patient develops a hypotensive reaction. The patient is successfully resuscitated with fluids and supportive care.

- What contributed to this adverse patient event?

The risk of medical error is increased when health care professionals work under less than ideal circumstances, especially when well-designed safety systems are not in place. Poor working conditions include:

- Inexperience (especially when combined with lack of supervision)
- Time pressures
- Poor safety procedures (e.g., lack of staffing, lack of safety policies)
- Poorly designed human-equipment interfaces (e.g., difficult to program infusion pumps)
- Inadequate information (e.g., missing or outdated labs, illegible written orders, failure to communicate change in status, language barriers)

A helpful acronym which can be used by health care providers to assess their suitability to provide patient care is **IM SAFE**.

Illness
Medication
Stress
Alcohol
Fatigue
Emotion

The following actions have been demonstrated to limit errors caused by human factors.

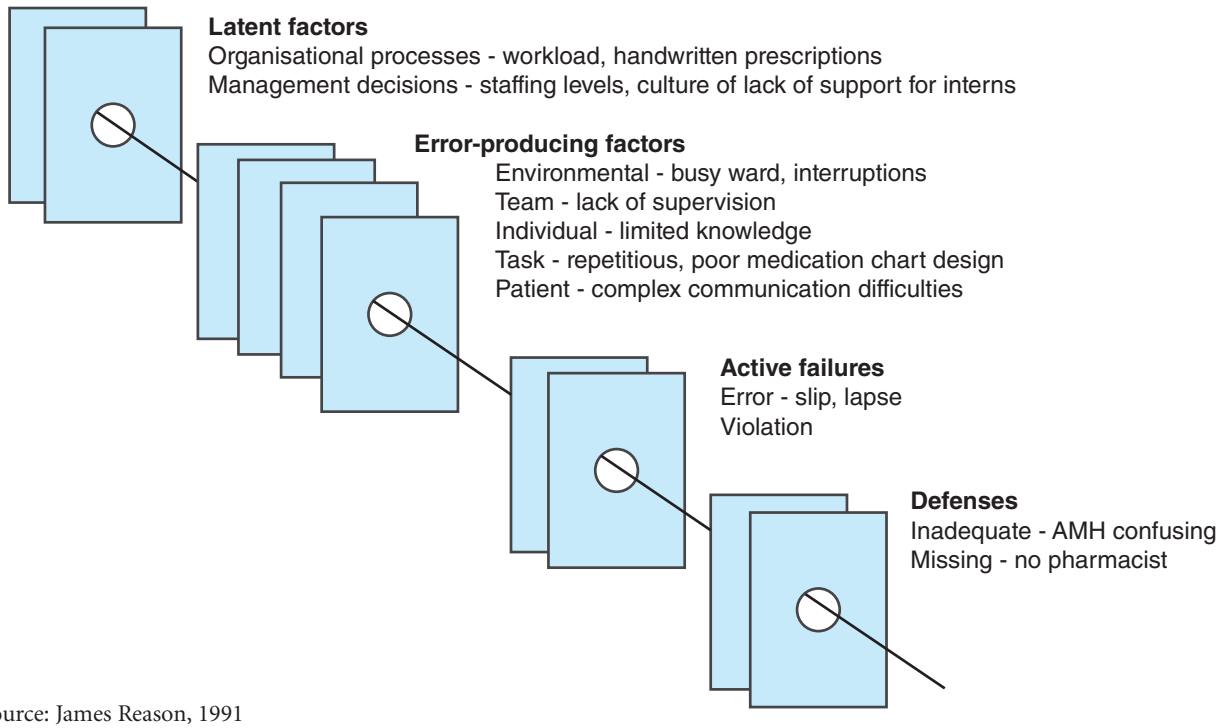
- Avoid reliance on memory or vigilance.
- Simplify processes when possible.
- Standardize common procedures and processes.
- Routinely use checklists.

SYSTEMS-BASED PRACTICE

Lessons from high-reliability organizations (e.g., aviation, nuclear power plants) emphasize the importance of approaching errors on a **systems level** rather than a personal level with blame. It is easier to redesign the conditions under which people work than to attempt to change fallible human nature. When a system fails (i.e., medical error occurs), the immediate question should be **why did it fail**, not 'who caused it to fail.'

A classic example of a systems-based approach to patient safety is the removal of concentrated potassium from general hospital wards. This action was intended to prevent the inadvertent preparation of IV solutions with concentrated potassium, an error that had produced small but consistent numbers of deaths for many years. This particular approach is called a 'forcing function,' where the system is redesigned in a way that forces an individual to avoid making the error due to process design, rather than relying on individual memory. Think of a car that won't allow you to start the engine unless your foot is on the brake.

The "Swiss-cheese model of error" (James Reason, 1991) helps to identify the multiple factors that can often contribute to an error resulting in patient harm.



Source: James Reason, 1991

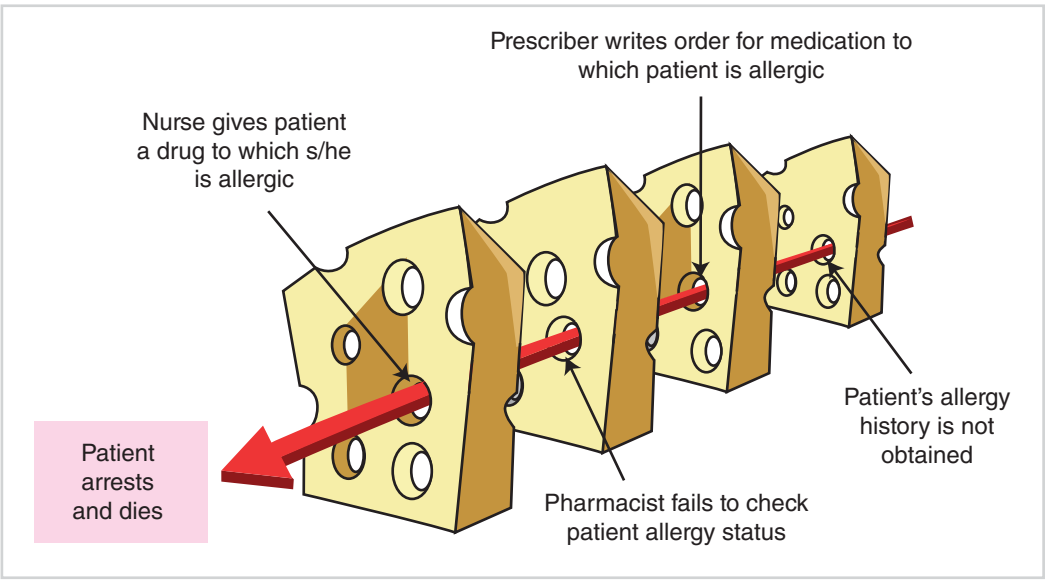
The layers represent barriers which prevent human error from causing patient harm. In a perfect world, these defenses would be impenetrable and patients would always be safe. In reality, these defenses have holes (hence, 'Swiss cheese'), which represent latent hazards (e.g., poor system design, lack of supervision, equipment defects). Occasionally the holes line up and a patient is injured.

Patient harm can be avoided by building systems with successive layers of protection (e.g., awareness, alarms, policies) and removal of latent errors (i.e., plug the holes).

Case: A 45-year-old man presents for treatment of acute sinusitis. He is prescribed antibiotics, after which he suffers a severe allergic reaction requiring hospitalization. Despite attempts of resuscitation, the patient sustains a cardiac arrest and dies. Later review of his medical record reveals a documented allergy to the antibiotic that was prescribed.

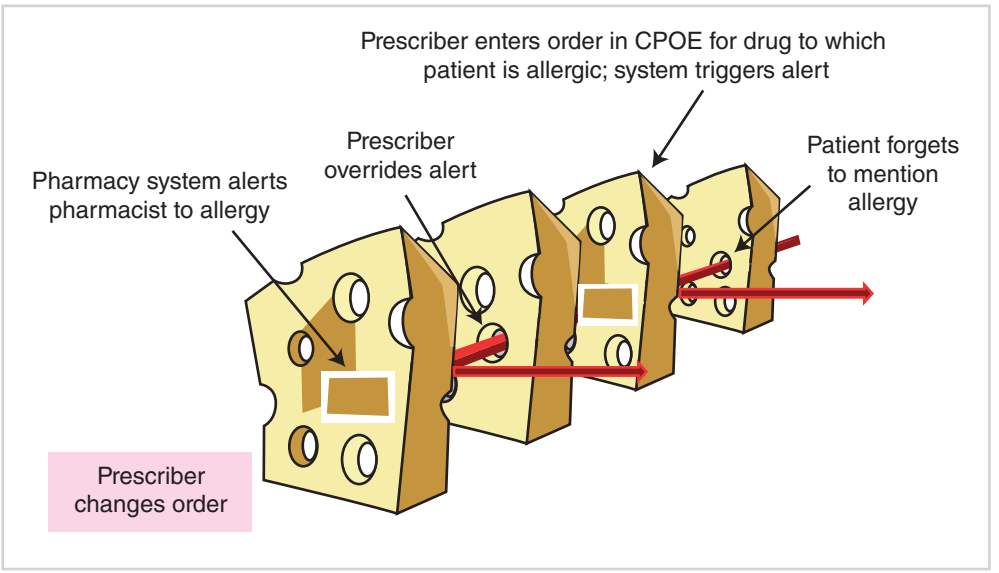
- How do we learn from this event to prevent a similar occurrence in the future?

An example of the "Swiss cheese model" follows below.



This example details a **medication error**. The patient's medication allergy is not obtained in the initial history, thus leading to the wrong medication being prescribed by the clinician, filled by the pharmacist, and administered by the nurse. The final result is the patient's death.

Applying 'systems-thinking' here, the question to be addressed is, "How can the system be redesigned so it is able to absorb the error before it reaches the patient?"



A systems-based redesign seeks not to *remove* the possibility of error, but rather to **create/reinforce barriers to harm**. For this case, one example would have been to implement a computer physician order entry (CPOE) based on the patient's electronic health record, which could have alerted the prescriber and pharmacist to the allergy.

Disclosure of Medical Errors

Known medical errors should be openly disclosed to the affected patient or, in certain circumstances, their families. During error disclosure, it is crucial to prepare the appropriate environment for disclosure. Be sure to arrange to have the proper time, place, and people involved, including arrangement of follow-up care and psychosocial support.

> Case: A 29-year-old man is brought to the emergency department after falling from a ladder. He is evaluated in the trauma bay and subsequently admitted to the hospital with a bilateral calcaneal fracture and stable L4/L5 compression fracture of the spine. The nurse notices that the blood pressure cuff used on the patient had blood stains on it from a prior patient treated for a motor vehicle collision. The prior patient was known to have hepatitis C. Somehow the cuff was not changed or cleaned before being used on the new patient, thus potentially exposing him to hepatitis C.
>
> • What information should be conveyed to the patient who was exposed?

An error disclosure should include the following 3 elements:

1. Accurate description of the events and their impact on the patient
2. Sincere apology showing care and compassion
3. Assurance that steps are being taken to prevent the event from happening in the future

Often the most senior physicians responsible for the patient and most familiar with the case will make the official disclosure.

Clinical Pearl

Be aware of the **second victim** of medical error: the health care professionals involved in the adverse event. Studies report that these individuals often have strong feelings of self-doubt, self-disappointment, shame, and fear, and in fact directly blame themselves for the event.

Without the proper support, this can lead to significant depression, and in extreme cases, suicide. It is important to support colleagues who have been involved in medical error, and to seek counseling and support for yourself if you yourself have been involved. As much as possible, the goal is to learn from the error and move on.

QUALITY IMPROVEMENT PRINCIPLES

Only 5% of patient harm is directly due to individual incompetence or poor intentions. People need to be accountable, but system-based changes are needed to truly transform care. Blaming individuals and taking punitive actions for honest mistakes/errors do little to improve the overall safety of the health system. The most effective approach is to **find out how the error happened**, rather than who did it, and then **fix the system** to prevent a similar error from causing harm to patients in the future.

> Case: Two days after undergoing a hysterectomy for uterine fibroids, a woman is restarted on her outpatient dose of rivaroxaban (a new oral anticoagulant). The patient has a known history of deep venous thrombosis, for which she receives pain control via an epidural catheter. Before removal of the epidural catheter, the anesthesia intern on the pain service reviews the medication list for anticoagulants, yet does not realize that rivaroxaban is an anticoagulation agent. Five days after removal of the catheter, the patient develops an epidural hematoma and sustains paraplegia.

- What should be done with the intern to improve safety in the future?

  Find out *how* the intern made this error (i.e., how the system allowed the error to occur and result in harm to the patient) and then fix the system to prevent a similar error from causing injury to patients in the future.

Error Reporting

Collecting data on medical errors is essential for improving patient care. Reporting errors provides this data and allows opportunities to improve care by learning from failures of the healthcare system. Error reporting is facilitated by

- Anonymous reporting
- A simple and easy-to-use system
- Timely feedback
- Absence of punitive actions

Note that while 'near misses' do not necessarily need to be disclosed to patients, they should be reported to the system so they can be studied and used to inform system changes. It is important to prevent what was a 'near miss' this time from potentially harming a patient in the future.

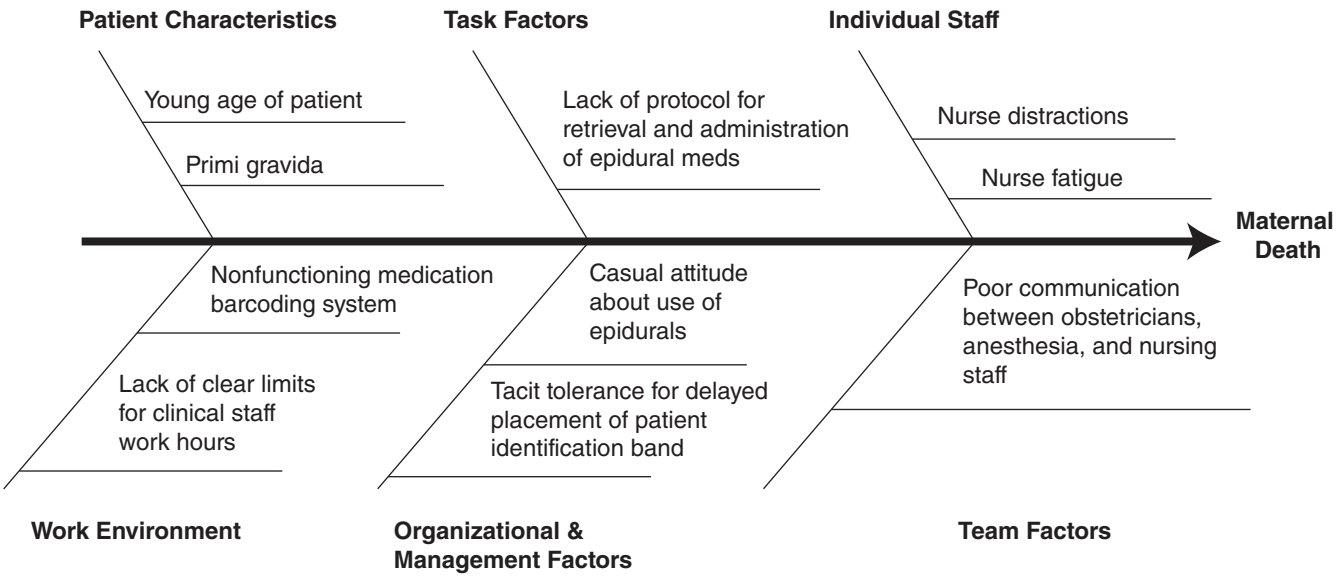
Root Cause Analysis

"Root cause analysis" (RCA) is a retrospective approach to studying errors. It allows a team to identify problems in the system or process of care. It should be conducted by a knowledgeable team (consisting of representatives from all the specialties/professions involved in the event), focus on systems/process analysis rather than individual performance, and identify potential improvements that can be made to reduce the chance of similar errors in the future.

Case: A 16-year-old patient comes to deliver her baby. During the process of her care, an infusion intended exclusively for the epidural route is connected instead to the peripheral IV line and infused by pump. Within minutes, the patient experiences cardiovascular collapse. A cesarean section results in the delivery of a healthy infant, but the medical team is unable to resuscitate the mother.

- Describe an effective approach to studying this error so that future cases of patient harm are prevented.

The fishbone diagram (also known as a 'Cause and Effect' or Ishikawa diagram) is used to explore all the potential causes that result in a poor outcome. An example is as follows:



In the case presented here, systemic problems identified by the RCA would include medications being kept in the room, communication problems, inexperienced staff, and technology failures. Many solutions were then generated, including the removal of barriers to barcode scanning and changing the current medication ordering and dispensing policy. Another consideration would be to add a 'forcing function,' by redesigning the Luer lock on the epidural bag to be unable to connect to an IV line.

Failure Mode and Effects Analysis

The Failure Mode and Effects Analysis (FMEA) is a systematic tool that allows practitioners to anticipate what might go wrong with a device, product or process; determine the impact of that failure; and determine the likelihood of failure being detected before it occurs. Unlike the retrospective nature of RCA, the FMEA is a proactive approach to patient safety. It produces a risk priority number (RPN) based on the probability and relative impact of a failure.

$$\text{RPN} = \textbf{severity of the effect} \times \textbf{probability of occurrence of the cause} \times \textbf{probability of the detection}$$

For example: inadvertent esophageal intubation during elective surgery can severely affect patient outcome (rating of 10), but it has a low level of occurrence (2) and can be detected fairly easily (3).

Therefore, RPN for this failure mode = $\mathbf{10 \times 2 \times 3 = 60}$.

BUILDING A SAFER HEALTH SYSTEM

In 2001 the IOM provided 6 aims to improve patient safety and quality; health care should be **S**afe, **T**imely, **E**quitable, **E**fficient, **E**ffective, and **P**atient-centered (STEEEP). Basic concepts for building a health care system which achieves these aims include:

- Standardizing care whenever possible, reducing reliance on memory (e.g., using checklists for important steps)
- Using systems-based approaches to build safety nets into the health care delivery process to compensate for human error
- Openly report and study errors (e.g., using RCA to learn from error)
- Engaging with patients (i.e., patient education is a powerful tool for safety)
- Improving communication and teamwork

Surgery

Patient safety in surgery is similar to patient safety in non-surgical settings, and involves many of the same issues including medication error, hospital-acquired infection (HAI), and readmissions. It also includes some errors specific to procedures including wrong-site surgery, retained foreign objects, and surgical site infections.

A **wrong-site procedure** is an operation or procedure done on the wrong part of the body or on the wrong person. It can also mean the wrong surgery or procedure was performed. Wrong-site procedures are rare and preventable, but they do still occur. Using a standard system of confirming the patient, site, and intended procedure with the medical team and patient before the procedure starts is a widely employed method of reducing or eliminating these types of errors.

> Case: A 59-year-old man with unresectable lung cancer presents to the emergency department with acute shortness of breath. A chest radiograph demonstrates a right sided malignant pleural effusion. The thoracic surgeon intending to drain the pleural effusion mistakenly places the chest tube on the left side after reading an x-ray of another patient. Post-procedure chest x-ray shows a persistent pleural effusion on the right lung. A second chest tube is then placed, this time in the patient's right chest. The patient remains stable and his breathing improves. The left chest tube is removed after confirmation that there is no air leak. There are no further sequelae.
>
> - How could this adverse event be prevented?

A team supported by the World Health Organization's "**Safe Surgery Saves Lives**" program designed a surgical safety checklist designed to improve team communication and consistency of care with the intent of reducing complications and deaths associated with surgery. The premise of the safe surgical checklist is that many common surgical complications are preventable. Implementation of the checklist was associated with significant reductions in the rates of death and complications including wrong-site surgery.

Among other benefits, the surgery checklist helps ensure appropriately administered antibiotic prophylaxis which reduces the incidence of surgical wound infection. The timing of antibiotic administration is critical to efficacy.

- The first dose should be given preferably within 30 minutes before incision.
- Re-dosing at 1 to 2 half-lives of the antibiotic is recommended for the duration of the procedure.
- In general, postoperative administration is not recommended.

Antibiotic selection is influenced by the organism most likely to cause a wound infection in the specific procedure.

Common Elements of Safe Surgery Checklist

- Confirm patient identity, planned procedure and marking of site
- Review patient allergies
- Ensure necessary equipment is present (e.g., pulse-oximetry)
- Introduce team members to each other
- Review critical steps of the procedure
- Address need for preoperative antibiotics
- Determine airway risk
- Determine estimated blood loss

Medications

Medication errors occur when a patient receives the wrong medication or where the patient receives the right medication but in the wrong dosage or manner (e.g., medication given orally instead of IV, or correct medication given at the wrong time). These errors represent one of the most common causes of preventable patient harm.

> Case: A 54-year-old woman (Susan Jones) is admitted to the hospital and diagnosed with metastatic breast cancer for which chemotherapy is administered. During her hospitalization she mistakenly receives an anticoagulation medication intended for the woman next to her in the room who has a similar name (Suzanne Jonas). The mistake is recognized after the first dose and the medication discontinued without any complications. Later during the same admission, she is inadvertently given an overdose of Dilaudid when the verbal order of 2 mg is administered intravenously instead of orally. She experiences lethargy and hypotension which resolve with supportive care during a brief stay in the ICU.
>
> - What are the risk factors contributing to the occurrence of these medication errors?

Several factors can increase the risk of medication errors:

- Inadequate confirmation of patient identity prior to medication administration
- Look-alike and sound-alike (rifampin/rifaximin) medications

Look-alike Medications

- Illegible hand-written prescriptions/orders can result in a pharmacist or nurse administering the wrong drug or wrong dose of medication
- Use of certain abbreviations can result in misinterpretation of the order

The Joint Commission recently created a **"Do Not Use"** list of abbreviations for health professionals.

Official "Do Not Use" List[1]		
Do Not Use	*Potential Problem*	**Use Instead**
U, u (unit)	Mistaken for "0" (zero), the number "4" (four) or "cc"	Write "unit"
IU (International Unit)	Mistaken for IV (intravenous) or the number 10 (ten)	Write "International Unit"
Q.D., QD, q.d., qd (daily) Q.O.D., QOD, q.o.d, qod (every other day)	Mistaken for each other Period after the Q mistaken for "I" and the "O" mistaken for "I"	Write "daily" Write "every other day"
Trailing zero (X.0 mg)* Lack of leading zero (.X mg)	Decimal point is missed	Write X mg Write 0.X mg
MS MSO4 and MgSO4	Can mean morphine sulfate or magnesium sulfate Confused for one another	Write "morphine sulfate" Write "magnesium sulfate"

[1] Applies to all orders and all medication-related documentation that is handwritten (including free-text computer entry) or on pre-printed forms.

Source: jointcommission.org

The "**5R's**" describe a strategy used to help prevent medication error by confirming the following 5 items prior to administering any medication.

- Right drug
- Right patient
- Right dose
- Right route
- Right time

Performing **medication reconciliation** (a review of the patient's complete medication list during any transition of care) is also intended to prevent inadvertent inconsistencies in the medication regimen.

Other systems changes that have saved countless lives:

- Removal of high-risk medications from certain clinical settings
- 'Unit dose administration,' in which medications packaged in ready-to-use units are prepared by the pharmacy and delivered to the clinical floor (this practice has resulted in fewer medication errors compared with having nurses perform mixing and dispensing on the floor)

The **integration of information technology** has also helped to reduce medication errors. Studies have shown that Computerized Physician Order Entry (CPOE) is an effective means of reducing medication error. It involves entering medication orders directly into a computer system rather than on paper or verbally. CPOE can decrease prescribing errors by automatically alerting the prescriber or pharmacist to allergies, potential drug-drug interactions or an incorrect dose.

Other technologies that have been designed to improve medication errors include barcoding to confirm correct patient identity and smart-pumps to prevent inappropriate dosage of IV medications.

Infections

Hospital-acquired infections (HAI) can be avoided. They are preventable, adverse events which may be caused by failing to adhere to evidence-based prevention strategies. Common HAIs include UTI (most common 35-40%), hospital-acquired pneumonia/ventilator-acquired pneumonia (15-20%), surgical site infection (20%), and central line infection (10-15%).

> Case: A 42-year-old man has surgery to repair a right inguinal hernia. His post-operative course is complicated by excessive post-op pain requiring IV narcotics. Ten hours after surgery he develops pubic pain. He has not voided since before surgery. A bedside ultrasound confirms a distended bladder indicating acute urinary retention. A urinary catheter is placed by a new nurse who is not familiar with sterile technique. The catheter immediately yields 800 cc of urine and the patient's pubic pain resolves. The patient requests to have the catheter left in place over the next 2 days. On post-operative day 3 the patient develops a fever to 101°C. A urine analysis and culture reveal an acute urinary infection.
>
> - What steps can be taken to reduce the likelihood of this complication?

There are some common approaches which can help to reduce HAI:

- Hand washing
- Use of sterile technique
- Use of preoperative prophylactic antibiotics (SSI)
- Elevating the head of the bed (ventilation associated pneumonia)
- Limiting use and duration of indwelling urinary catheters (UTI)
- Following evidence-based protocols for central line placement
  - Hand washing prior to procedure
  - Wearing a cap, mask, sterile gown and gloves
  - Preparation of site with chlorhexidine
  - Use of sterile barrier
  - Removal of the line as soon as possible

Pressure Ulcers

Pressure, or decubitus, ulcers are often preventable. Approaches to avoid this complication include performing risk assessments to identify vulnerable patients (e.g. paraplegics, diabetics, malnutrition, immobility, etc.).

> Case: A 65-year-old woman with type 2 diabetes and BMI 44 is being treated in the hospital for diabetic ketoacidosis. She has a urinary catheter in place to monitor urine output and does not get out of bed to go to the bathroom. She has refused ambulation or getting out of bed to a chair due to feeling very fatigued. Later during the hospital stay she develops a fever. Physical exam reveals a stage III infected decubitus ulcer over the sacral prominence.
>
> - How could this complication have been prevented?

Preventive activities for high-risk patients include daily inspection of skin, appropriate skin care and minimizing pressure through frequent repositioning and use of pressure relieving surfaces (e.g., airbeds).

Patient Falls

Patient falls are a common cause of injury, both within and outside of health care settings. More than one-third of adults over 65 fall each year. Injuries can include bone fractures and head injury/intracranial bleeding, which both can lead to death.

Case: A 70-year-old woman is admitted to the nursing home after being treated in the hospital for a hip fracture sustained during a fall at home. She had an intramedullary nail placed and is currently able to ambulate with a walker. In addition to her hypertension medication, anxiolytic, dementia pills and a beta-blocker, she also takes post-operative pain medication every 4-6 hours. The patient was also placed on warfarin for DVT prophylaxis. On her way to the bathroom at night, she slips and falls, sustaining a head injury and significant intracranial hemorrhage.

- What steps can be taken to reduce the risk of serious injury from a fall?

Performing a fall risk assessment will help to select patients who can benefit from preventative resources (e.g. one-to-one observation, non-slip flooring, lowering the bed height). It is important to identify patients at high risk of sustaining serious injury from a fall. The following are known risk factors for patient fall:

- Advanced age (age >60)
- Muscle weakness
- Use of >4 prescription medications
- Impaired memory
- Difficulty walking (e.g., use of a cane or walker).

Unplanned Readmissions

Unplanned hospital readmissions following discharge are recognized as a serious cause of decreased quality and often result from complications or poor coordination of care. Improving communication, reinforcing patient education, and providing appropriate support to patients at risk for readmissions are all strategies to reduce unplanned readmissions.

Case: A 79-year-old patient is admitted to the cardiology service and treated for acute CHF. He is started on a new medication regimen including a diuretic which relieves his symptoms and improves his cardiac function. He is discharged home, though he returns to the hospital 10 days later with another episode of CHF. During the readmission, the team notices that the patient never filled his new prescriptions and was not taking the prescribed diuretic while at home.

- What actions can be taken to prevent this from happening again?

Recommendations to improve the discharge process and prevent readmissions are as follows:

- Provide timely access to care following a hospitalization
- Communicate and coordinate care plan with patients and other providers
- Improve the discharge planning and transition processes
- Ensure patient education and support to optimize home care

Teamwork

Providing safe health care relies on health care professionals working together as a team. Well-functioning teams deliver higher quality and safer care. The need for improved teamwork has led to the application of teamwork training principles, originally developed in aviation, to a variety of health care settings. Simple changes to behavior and culture have had a profound impact on the culture of teamwork and safety in patient care.

Case: A resident responds to a cardiac code 10 minutes late because he was not aware that he was on code-duty. Upon arrival the patient is actively having chest compressions performed by a physician assistant. A nurse brings in the cardiac arrest cart and a respiratory technician places on oxygen mask on the patient and begins bag-mask ventilation. The resident asks for a blood pressure and heart rate to be checked. The respiratory tech and physician assistant both attempt to find a pulse on the patient's wrist, interrupting chest compressions and ventilation. The nurse simultaneously lowers the bed to place electrodes for an ECG which makes the oxygen mask fall off to the floor. The ECG demonstrates ventricular fibrillation and the resident calls to "shock the patient." No one is certain how to work the defibrillator. The patient expires.

- How can teamwork be improved to achieve a better outcome during the next cardiac code?

Effective teams share the following characteristics:

- Common purpose/shared mental model
- Measurable goals
- Effective leadership
- Effective communication
- Mutual support
- Respect value of all team members

Briefs and **huddles** are effective tools for teamwork. The team *brief* is used for planning, and is a short 'time-out' prior to starting the delivery of care in order to discuss team formation, assign essential roles, establish expectations and climate, and anticipate outcomes and likely contingencies. The *huddle* is used for team problem-solving, and is performed on an ad hoc basis to reestablish situational awareness, reinforce plans already in place, and assess the need to adjust the plan.

Clinical Communication Skills

Communication failures have been identified as a root cause in the majority of serious patient safety events. Patient safety and quality in health care improve when physicians communicate effectively with colleagues, patients, and families. Several techniques have been developed to enhance clinical communication skills.

Case: A 25-year-old woman is admitted to the ICU following a motor vehicle collision, during which she sustained a significant head injury. She is intubated and monitored for increased ICP. The nurse coming on the night shift notices that the patient's pupils are dilated, and she is uncertain if this is a change in the patient's status. The nurse pages the resident on-call to see the patient. The resident evaluates the patient but does not speak with the nurse and is not aware of the nurse's concern of a change in status. No intervention is taken. The following morning during rounds the neurosurgical team finds the patient brain dead from herniation.

- How could communication be improved to prevent this error?

SBAR is a form of structured communication first developed for use in naval military procedures. It has been adapted for health care as a helpful technique used for communicating critical information that requires immediate attention and action concerning a patient's condition.

The following is an example of SBAR communication:

- **S**ituation: What is going on with the patient? "I am calling about Mr. Smith in room 432 who is complaining of shortness of breath."
- **B**ackground: What is the clinical background or context? "The patient is a 67-year-old man post-operative day one from a left total hip replacement. He has no previous history of pulmonary or cardiac disease."
- **A**ssessment: What do I think the problem is? "His breath sounds are decreased bilaterally and his oxygenation is only 87% on room air. He was getting IV Ringer's lactate at a rate of 150 cc/hour, in addition to 5 liters fluid replacement and 4 units of blood in the operating room. I would like to rule out acute pulmonary congestion from fluid overload."
- **R**ecommendation: What would I do to correct it or what action is being requested? "I've already started supplemental oxygen and I feel strongly that the patient should be assessed for pulmonary overload, his fluids stopped and potentially given a diuretic. Are you available to come in?"

Case: During resuscitation of a cardiac code, the physician running the code states that she thinks epinephrine should be given intravenously. The nurse is uncertain if this was an order and believes that the doctor may have been just thinking out loud. No epinephrine is given. The doctor mistakenly assumes that the drug was administered and that it was not effective in reviving the patient. Precious time is lost until it is realized that no medication has been given.

- What communication technique can be used to avoid this error?

A **call-out** is a strategy used to communicate important or critical information. The goals of a call-out are to inform all team members simultaneously during team events, help team members anticipate next steps, and help create a shared mental model.

Case: A hospital lab technician phones a nurse to inform him of a critical serum calcium value in one of his patients. The nurse mistakenly hears a different number and believes the calcium to be only mildly elevated. The patient develops a symptomatic arrhythmia and requires transfer to the ICU for further appropriate care.

- How can techniques in effective communication be used to prevent this error?

A **read-back or check-back** is a communication technique commonly used in the military and aviation industry, and is now increasingly employed in health care to guard against miscommunication. Safety organizations encourage health care professionals to make a routine practice of reading back verbal orders or critical labs to ensure accuracy.

Case: During a clinical rotation on the pediatric ICU, you are invited by the chief resident to observe the operative repair of a congenital heart lesion in the pediatric cardiac surgery operating room. When you arrive in the OR the patient is already intubated and anesthetized, and procedures are underway to prep the patient for surgery. During the start of the case you see that an operative team member inserts the urinary catheter with a clear breach in sterile technique. This is neither noticed by the team member inserting the catheter nor mentioned by anyone else in the room. Being new to this setting, you are unaware whether different practices for sterile insertion are used in pediatric patients.

- What would you do to address your concern?

Critical language is a form of assertive structured communication which provides key words that enable members of the team to speak when patient safety concerns arise. These key phrases are uniformly understood by all to mean "stop and listen to me; we have a potential problem."

The acronym **CUS** is used to remember these key words.

- "I'm **c**oncerned"
- "I'm **u**ncomfortable"
- "I think this is a **s**afety issue"

Speaking up for patient safety is the responsibility of every member of the health care team. It is important to speak up for the patient. It may be intimidating to speak up when you are the most junior member of the team and at times uncertain if a safety issue is actually in question; however, as people with the privilege of caring for others, health care workers have to value our responsibility to the patient above all else. **Speak up if you witness an error or the potential for an error**. Make sure to report adverse events so others can study and learn from them—informing system-based approaches to improving patient safety.

Handoffs

Errors during handoffs and sign-outs can be mitigated by ensuring an accurate and effective transfer of pertinent patient information to the receiving health care professional. This has immediate applications to on-call sign-outs and changes of shift, but it also affects other scenarios such as hospital- and unit-floor-transfers.

> Case: A diabetic patient with an ankle fracture is signed-out to the covering intern from a team member in a hurry to leave the hospital. Later that night the patient develops sinus tachycardia thought be related to pain, and the covering intern orders more pain medication. Unknown to the covering intern, the patient was found earlier to have an incidental pulmonary embolism. This information was forgotten during the hurried sign-out. The patient develops chest pain, dyspnea and ultimately dies from progression of the PE.
>
> - How can this adverse event be avoided in the future?

An effective handoff encompasses the following principles:

- Active process
- Prioritize sick patients
- Verbal + written
- Have a set system
- Limit distractions
- Allow sufficient time
- Ensure updated information

Quality Improvement Roadmap

The methods used to approach quality and process improvement are as follows:

1. Identify the problem.
2. Measure the problem.
3. Organize a team.
4. Flowchart the process.
5. Develop a range of interventions to fix the problem.
6. Measure the impact of the interventions.

Case: A hospital is interested in reducing the number of medication errors in the inpatient geriatric unit. The current medication ordering system has been in place for 15 years and consists of written orders on slips of paper being sent to pharmacy by pneumatic tubes, and then receiving the medication in a batched collection system on the unit. Nurses are required to then sort through the batched medications to identify the correct one for their patient(s). Over the past year, the severity of the admitted geriatric patients has increased, along with the number of medications required. There have been reports of possible increased rates of medication errors over the past 6 months.

- How will you approach improving the current process?

The following tools are commonly used in quality improvement:

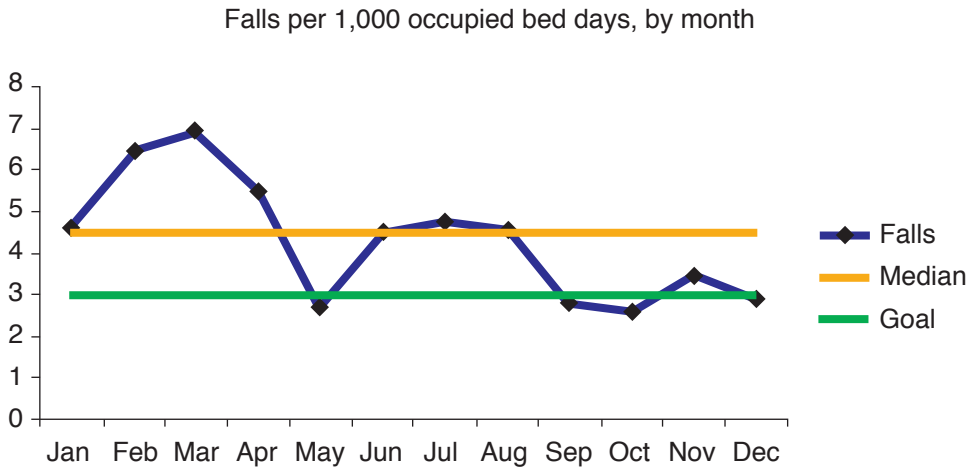
Flow chart: map of all the steps in the current clinical process being evaluated

- Flow charting a process helps the team clearly see the complexity of the process and the opportunities for improvement.

Pareto analysis: process of rank-ordering quality improvement opportunities to determine which of the various potential opportunities should be approached first

Run chart (time plot): graphical record of a quality characteristic measured over time

- Run charts help the team determine if a change is a true improvement over time or just a random fluctuation.
  - A trend is defined as ≥5 consecutive points constantly increasing or constantly decreasing. If a trend is detected, it might indicate a non-random pattern that should be investigated.
  - A shift is a run containing ≥6 data points all above or all below the median and indicates a non-random pattern that should be investigated.



AHRQ.gov

Sample Run Chart Plotting Patient Falls

Control chart: method used to distinguish between variations in a process due to common causes and those due to special causes. It is constructed by obtaining measurements of some characteristic of a process, summarizing with an appropriate statistic, and grouping the data by time period, location, or other process variables.

- Common cause variation is an inherent part of every process. It is random and due to natural or ordinary fluctuations in the system.
- Reducing variation improves the predictability of outcomes and helps reduce the frequency of adverse outcomes for patients.
- Special cause variation is due to irregular or unnatural causes that are neither predictable nor inherent to the process. Special cause variation should be identified and eliminated before making QI changes to a process.

There are many different types of control charts, depending on the statistic analyzed on the chart.

Interventions can take many forms, including automation, standardized process, and checklists. A forcing function is a very effective intervention for patient safety, as it does not rely on human memory or vigilance. A forcing function is an aspect of a design that prevents a target action from being performed. Examples are:

- Computer system that does not allow a drug to be ordered at a dose outside known safety parameters
- Enteral tubing designed to prevents accidental connections with IV ports

Measurements of quality include structure, process, outcomes, and balancing measures.

- **Structure** refers to equipment, resources, or infrastructure (e.g., number of ICU beds, certified infectious disease specialist on staff, ratio of nurses to patients)
- **Process measures** relate to an action involved in the care of patients that is believed to be associated with a particular outcome (e.g., use of preoperative antibiotics to reduce surgical site infections, using 2 means of patient identification prior to blood transfusion).
  - Typically easier to measure than outcome measures, and often serve as surrogates to outcomes
- **Outcome measures** reflect results related directly to the patient (e.g., survival, infection rates, number of admissions for heart failure)
- **Balancing measures** monitor for unintended consequences of a change or intervention made to a process or system. Some well-intended interventions can create unanticipated negative results in quality and safety.
  - For example, alarms have been placed on a number of medical devices and equipment to alert for problems (e.g., oxygen saturation falling below a set level). One negative result has been 'alarm fatigue.' Studies indicate that 85-99% of hospital alarms do not require clinical attention, but failure to respond to the rare critical alarm has resulted in patient death. This is a type of 'boy who cried wolf' phenomenon, where the frequency and prevalence of hospital alarms reduces our attention to them. Strategies are in place to customize alarms to alleviate some of the problem.

Quality models are specific techniques used in improving patient care.

PDSA (plan-do-study-act) refers to a rapid cycle of activities involved in achieving process or system improvement. It is a form of trial and error and consists of planning an intervention, trying it out (i.e. small scale pilot), observing results (e.g. data collection of quality measures), and acting on what is learned (e.g. implement change system-wide or go back to the planning stage with a new intervention).

Six Sigma is a data-driven, patient-centered approach focused on reducing variability. This organized and systematic method for strategic process improvement uses a step-by-step DMAIC method.

- **Define**: define the problem
- **Measure**: measure key quality metric
- **Analyze**: identify root causes
- **Improve**: determine optimal solutions
- **Control**: strive for sustainability of implemented change

Lean process focuses on removing waste from the process or system and adopting a value-added philosophy of patient care. Value-stream maps are created to optimize activities that add value from the patient point-of-view and remove activities that do not.

The following are steps that any health care practitioner can apply to improve safety and quality for patients.

- Follow safety protocols (e.g., hand washing)
- Speak up when there are safety concerns (e.g., medical errors and near misses)
- Practice good communication skills (e.g., SBAR)
- Educate patients about their care
- Take care of yourself (e.g., get appropriate sleep and control stress)
- Practice patient-centered care/recognize opportunities to enhance value for patients

CARE WELL DONE

The case below describes the incredible potential of the health care system. Applying the principles of patient safety and quality improvement to clinical care will enable health care to move closer to the goal of getting it right for every patient, every time.

> A 3-year-old girl falls into an icy fishpond in a small Austrian town in the Alps. She is lost beneath the surface for 30 minutes before her parents find her on the pond bottom and pull her up. CPR is started immediately by the parents on instruction from an emergency physician over the phone, and EMS arrives within 8 minutes. The girl has a body temperature of 36° C and no pulse. Her pupils are dilated and do not react to light. A helicopter takes the patient to a nearby hospital, where she is wheeled directly to an operating room. A surgical team puts her on a heart-lung bypass machine, her body temperature increases almost 10 degrees, and her heart begins to beat. Over the next few days her body temperature continues to rise to normal and her organs start to recover. While she suffered extensive neurologic deficits during this event, by age 5 with the help of extensive outpatient therapy, she recovers completely and is like any other little girl her age.

CHAPTER SUMMARY

- Medical errors result from the complexity of health care combined with the reality of human failure. Although accountability and responsibility are important, simply blaming people for errors they did not intend to commit does not address underlying failures in the system and is an ineffective way of improving safety.
- System-based redesigns in health care delivery are required and hold the greatest potential for advancing patient safety and quality improvement.
- Improving communication, teamwork and the culture of safety are effective methods in improving patient safety.
- Safety is a team effort requiring everyone on the care team to work in partnership with one another and with patients and families.

High Yield Facts

- Systems-based approaches to improving health care are superior to individual-level efforts or blame
- Preoperative checklists can prevent perioperative complications and safety events
- Evidence-based bundles (protocols) prevent central line infection
- Limiting the duration of urinary catheters decreased hospital acquired infections
- Head-of-bed elevation and oral care prevents ventilator associate pneumonia
- Medication reconciliation helps to prevent medication errors during transitions
- Hand hygiene is an important component of infection control
- Avoid the use of hazardous abbreviations
- Computerized physician order entry helps improve medication safety
- Identification of high risk patients is a key step in fall prevention
- Team training and communication can improve quality and safety

Practice Questions

1. A 36-year-old woman with HIV/AIDS and B-cell lymphoma is hospitalized for *Clostridium difficile*–associated diarrhea. Following treatment, the patient is discharged home with a prescription for a 14-day course of oral vancomycin. She is unable to fill the prescription at her local pharmacy because of a problem with her insurance coverage. While awaiting coverage approval, she receives no treatment. Her symptoms soon return, prompting an emergency department visit where she is diagnosed with toxic megacolon. Which of the following should be addressed in order to bring about changes that improve patient safety?

   (A) Prescribing physician
   (B) Pharmacist
   (C) Insurance company
   (D) Patient
   (E) Discontinuity of care

The answer is E. The main failure in this case occurred upon transition of care from the hospital to home. Addressing the discontinuities in care which arise at the time of transition has the greatest potential to improve patient safety.

Rather than dispensing blame to any of the parties involved in the error (**choices A–D**), focus should be given to implementing systems-based transformations to support patients during a transition (e.g. post-discharge telephone follow-up to identify and resolve potential medication issues early).

2. A 23-year-old man with a history of depression is admitted to the inpatient psychiatry ward after his third attempt at suicide with an intentional drug overdose. The patient is stabilized medically; however, he is put under 24-hour monitoring by the nursing staff due to repeated attempts at self-harm. During a change of shift, there is a mistake in communication and no one is assigned to the patient. The mistake is noticed 15 minutes into the new shift, and a member of the nursing team is assigned to watch the patient. Fortunately, during that 15-minute period, the patient made no attempt to harm himself. Which of the following statements is correct about this event?

   (A) This is a sentinel event and should be reported to the medical board.
   (B) This is a sentinel event and should be reported to the hospital and family.
   (C) This is a near-miss and should be reported to the hospital.
   (D) This is a near-miss and should be reported to the patient and family.
   (E) This is a near-miss and no reporting is required since the patient was not harmed.

The answer is C. The event described is a near-miss; there was an error which fortunately did not result in patient harm. Most near-misses need not be disclosed to patients or families (**choice D**), but they should be reported to the hospital so that the error can be studied and thus prevented in the future. A sentinel event (**choices A and B**) is an adverse event resulting in serious or permanent injury to a patient.

3. An 85-year-old woman is being transferred to an acute rehabilitation facility following a hospital admission for hip replacement surgery. Postoperatively during her hospital stay, she is started on deep vein thrombosis (DVT) prophylaxis medication with plans to continue the medication upon discharge. The intern and nurse who are discharging the patient fail to convey this new medication to the receiving treatment team at the rehabilitation center. The patient is not continued on her anticoagulation medication and sustains a DVT, leading to a fatal pulmonary embolus 3 weeks after transfer. Which of the following actions will facilitate quality improvement and the prevention of a similar error in the future?

   (A) Determine which staff member(s) failed to order the medication
   (B) Develop a process to increase the use of medication reconciliation
   (C) Send a memo to all staff about the importance of DVT prophylaxis
   (D) Educate patients about the dangers of DVT following hip surgery
   (E) Conduct monthly audits to monitor medication errors at transitions of care

The answer is B. The goal of quality improvement (QI) is to achieve improvement by measuring the current status of care and then developing systems-based approaches to making things better. It involves both prospective and retrospective reviews and specifically attempts to avoid attributing blame. QI seeks to create systems to prevent errors from happening. In this case, developing a process to increase the use of medication reconciliation would be following the principles of QI. The other interventions in the answer choices are QA-based and/or simply not as effective in creating and sustaining a positive change. Quality assurance (QA) is an older term describing a process that is reactive and retrospective in nature; it is a form of 'policing' to ensure that quality standards have been followed. It often relies on audits and traditionally has focused on punitive actions for failures in quality, i.e., determining who was at fault after something goes wrong. QA has not proven to be very effective in transforming care.

Population Health Management 25

Learning Objectives

- ❑ Define population health and value-based care
- ❑ Describe how population health management principles can be put into practice

DEFINING POPULATION HEALTH

What is population health?

Case example: A 65-year-old woman presents to the emergency department at 3:00 AM with the acute onset of an asthma attack. She is treated with steroids and nebulizer treatments to stabilize her respiratory status. This is the third such presentation in the past 9 months. During her course of treatment it becomes evident that the patient is not able to get time off from work to see her primary care physician during clinic hours, did not receive an influenza vaccination this year, and continues to smoke 1 pack of cigarettes per day.

- What day-to-day factors are present which impact this patient's health outcomes with asthma?
- How would you to help to optimize her long-term management of asthma?

Health care in the United States has traditionally focused on the management of acute medical problems such as trauma, myocardial infarction, and stroke. Incredible advances have been made in these areas and outcomes from acute presentation of disease have steadily improved over the years, with outcomes among some of the best observed in any health system in the world.

However, the health care system here has lagged significantly in the area of disease prevention and health maintenance. Major disparities in access to preventative care services such as prenatal care, cancer screening and diabetes management; together with social inequalities with respect to patient education and income; as well as persistent individual behaviors such as poor diet, lack of exercise and cigarette smoking have contributed to the very poor overall health status observed in the United States.

BIG GEMS (mnemonic for determinants of health)

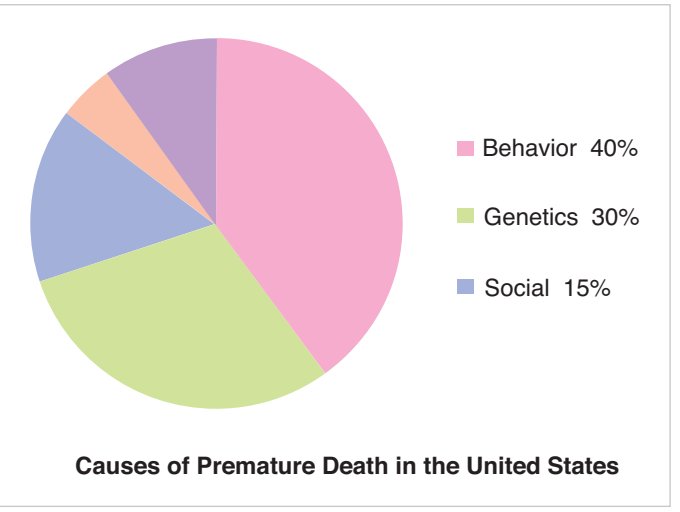
- **B**ehavior
- **I**ncome
- **G**enetics
- **G**eography
- **E**nvironment
- **M**edical care
- **S**ocial-cultural

Problems with patient safety and variations in care that do not follow evidence-based standards further erode the value of patient care. Ironically, the United States spends more on health care than any other nation in the world, yet ranks among the lowest in health measures, compared to other developed nations. Furthermore, the current rate of health care spending in the United States is unsustainable.

Population health is an approach to health care which addresses both individual and public health concerns in order to achieve optimal patient results. It is an approach to patient care which understands that health is influenced by several factors outside of traditional health care delivery models, including (but not limited to) social, economic, and environmental factors.

Population health management is fundamental to the transformation of health care delivery. Its principles recognize the importance of focusing attention not only on improving individual patient care, but also on improving the health of an entire population. In fact, direct health care accounts for only a small proportion of premature deaths in the United States.

- For example, the leading causes of premature death—smoking (435,000 deaths/year), obesity (400,000 deaths/year), and alcohol abuse (85,000 deaths/year)—are all preventable through interventions driven by population health management.

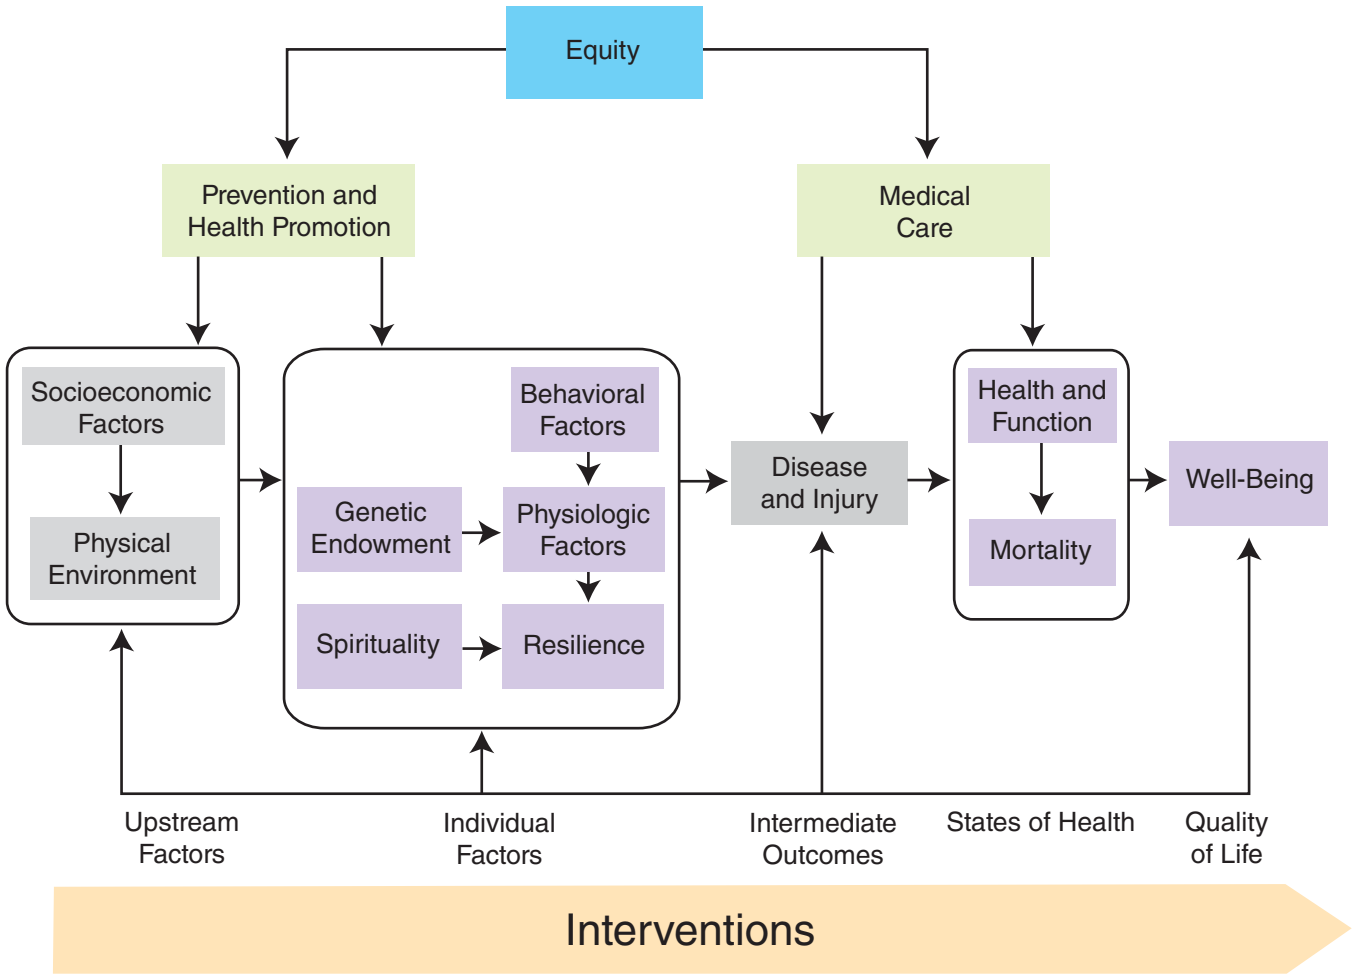


Causes of Premature Death in the United States

Population health management is, in effect, about coordinating care and improving access in order to enhance patient/family engagement and reduce variation in care to achieve better long-term outcomes at a reduced cost. The Institute for Healthcare Improvement (IHI) lists improving the health of the population as one of the 3 dimensions of its Triple Aim approach to optimizing health system performance.

IHI Triple Aim:

- Improve the patient experience of care (including quality and satisfaction)
- **Improve the health of populations**
- Reduce the per capita cost of health care



Source: Adapted from Stiefel M. Nolan KA. Guide to Measuring the Triple Aim: Population Health, Experience of Care, and Per Capita Cost. IHI Innovation Series white paper.Cambridge, Massachusetts: Institute for Healthcare Improvement; 2012. (Available on www.IHI.org)

IHI Population Health Composite Model

Population health management focuses on high-risk patients who are responsible for the majority of health care utilization while simultaneously addressing preventative and chronic care needs of the entire population. One of the first steps in this process is to define the target population (e.g., a hospital or clinic's entire service area or any subset, whether economic, geographic or demographic, or individuals with certain health conditions). Another important step is to identify the specific health status and needs of that group and deploy interventions and prevention strategies to improve the health of the group. The interventions target individuals, but they affect the entire population.

The incorporation of technology (e.g., electronic health records) and innovations in health care (e.g., digital home health monitoring) provide the infrastructure to support efforts in successful population health management. A key factor for the success of population health programs is

automation, as managing populations can be highly complex. Technology-enabled solutions are essential to the efficient management of a program.

Let's say a primary care clinic is interested in improving population health for its diabetic patients.

- First, the clinic analyzes the patient registry generated by its electronic health records to identify high-risk type 2 diabetic patients who are not compliant with their medication and who frequently fail to keep their clinic appointments.
- Next, those patients are offered enrollment in a home hemoglobin A1C monitoring program, using a system which digitally records hemoglobin A1C levels taken in the home and then electronically transfers the results to the clinic.
- The system sends an alert to the clinical team when patients' hemoglobin A1C levels are consistently higher than a predetermined threshold.
- A nurse coordinator contacts these patients by phone to help manage medication compliance, answer patient questions, and encourage timely follow-up with clinic visits.
- A nutritionist works with patients to encourage healthy dietary choices, while a social worker addresses any financial constraints to following medical recommendations.

VALUE-BASED CARE

The traditional health care system operates under a **fee-for-service model**, where a fee is collected for each provision of health care service. For example, hospitals and physicians collect a fee each time a patient comes to the hospital for the treatment of congestive heart failure (CHF), including any diagnostic tests or procedures (e.g. chest x-ray, B-type natriuretic peptide, cardiac angiogram).

A new model of health care in the United States, supported by legislation, is accountable care. Under the Accountable Care Act, the fee-for-service model is being replaced with **value-based care**, where health care professionals are rewarded for keeping entire populations of patients healthy.

Using the CHF example, a value-based system would reward health care professionals for encouraging lifestyle changes that prevent hospital admissions for CHF, such as promoting a heart healthy diet, monitoring home fluid intake, and motivating patients to engage in regular exercise. Instead of rewarding exclusively for the treatment of acute medical problems, the new system provides incentives for the health care system to maintain healthy populations, prevent disease, and avoid acute medical problems through the active monitoring and management of chronic disease. **Quality in health care is measured by outcomes achieved**, rather than the *volume* of services delivered.

Note: Value in patient care can be defined as quality of care divided by total cost of care.

Strategies that increase quality and reduce unnecessary costs result in improved value for patients. Unnecessary costs may be generated from the following examples:

- Duplication of services (e.g., a surgeon orders a routine pre-operative ECG for a patient undergoing elective surgery, not realizing the same test was done 1 week ago in the primary care physician's office and was normal)
- Non evidence-based care (e.g., ordering antibiotics for a viral infection)
- Avoidable inefficiencies in care (e.g., a patient returns to the hospital with acute CHF 1 week after being treated for the same condition because he was unaware that a new diuretic had been started in the hospital and was therefore never filled upon discharge)

Failures in preventive health also lead to avoidable health care spending, as in hospitalization for the treatment of acute pneumonia in a patent who did not receive an influenza vaccination. Shifting the focus from volume of care to value of care will improve the overall status of health care in the United States and contain the currently unsustainable costs of care.

It is important **not to confuse value-based care** with **rationing of care**, which seeks to reduce needed services in order to preserve resources. Value-based care seeks to reduce unnecessary or unwanted waste in care which increases cost without increasing quality of care to the patient.

- Studies, for instance, have shown that performing stress cardiac imaging or advanced non-invasive imaging in patients without symptoms on a serial or scheduled pattern (e.g., every 1–2 years or at a heart procedure anniversary) rarely results in any meaningful change in patient management. This practice may, in fact, lead to unnecessary invasive procedures and excess radiation exposure without any proven impact on patients' outcomes.
  - An exception to this rule would be for patients >5 years after a bypass operation.
- Similarly, using antibiotics for a sore throat or runny nose that is due to a viral infection not only provides no immediate benefit to the patient, it may also increase harm from adverse drug reactions or development of antibiotic resistant bacterial strains.

Many health care organizations are developing guidelines and recommendations to promote value-based care. These approaches motivate patients and their clinicians to follow effective care practices and guide them away from unnecessary and ineffective care; the result is greater value and effectiveness of healthcare utilization. For example, Choosing Wisely™ (choosingwisely.org) is a national initiative of the American Board of Internal Medicine Foundation which promotes conversations between patients and physicians about unnecessary medical tests/procedures that increase cost without enhancing patient outcomes.

Population health management employs value-based care principles by promoting preventive care, encouraging care patterns that have been proven effective, and reducing waste and unnecessary care.

Value equation in health care:

$$\uparrow \text{value} = \frac{\uparrow \text{quality}}{\downarrow \text{cost}}$$

IMPLEMENTATION OF POPULATION HEALTH MANAGEMENT

The goal of population health management is to keep a patient population as healthy as possible. The components required to achieve this goal include the following:

- Delivery of patient care through multidisciplinary teams
- Coordination of care across care settings
- Increased access to primary care
- Patient education in disease self-management
- Emphasis on health behaviors and lifestyle choices
- Meaningful use of health information technology for data analysis, clinical communication, and outcome measurement

This requires clinicians to identify target populations of patients who may benefit from additional services, such as patients who require reminders for preventative care appointments or patients not meeting management goals. Continual access to patient data and analysis of outcomes is the key to providing proactive, preventive care.

Steps in Population Health Management:

Step 1: Define population

Step 2: Identify care gaps

Step 3: Stratify risks

Step 4: Engage patients

Step 5: Manage care

Step 6: Measure outcomes

Several advances in technology are required to perform effective population health management and accomplish risk stratification; identify gaps in care; achieve patient education, compliance education, disease state monitoring; ensure general wellness; as well as to implement and assess specific interventions targeted to selected populations.

- The electronic health record can produce integrated, accessible population-wide data systems capable of generating reports that drive effective quality and care management processes.
- Web-based tools designed to educate patients about their condition, promote self-care, and encourage preventative behaviors have been used successfully to reduce hospitalization rates by enabling patients to take charge of their health.
- Telemedicine programs have been implemented to establish remote care in order to facilitate patient outreach, allow patient follow-up after discharge from the hospital, and improve health care in rural populations.
- The automation of processes and programs is essential in order to make population health management feasible, scalable, and sustainable, such as a health IT system which targets patients in greatest need of services, generates alerts to those patients seeking appropriate and timely appointments with clinicians, and alerts clinicians in real-time to patient care needs.

However, technology alone will not be sufficient for population health management; effective **teamwork** in patient care is also important. Effective population health involves establishing multidisciplinary care teams to coordinate care throughout the entire continuum of care. High-performance clinical care teams can manage a greater number of patients and more comprehensively respond to patient care needs compared with individual clinicians working in isolation. Care teams can include physicians, nurses, nurse practitioners, physician assistants, pharmacists, patient navigators, medical assistants, dieticians, physical therapists, social workers, and care managers, and others.

The **patient-centered medical home** (**PCMH**) is one emerging model used to deliver patient-centered, value-based care, and it plays an important role in population health management. The medical home model emphasizes care coordination and communication beyond episodic care in order to transform primary care. It stresses prevention, early intervention and close partnerships with patients to tightly manage chronic conditions and maintain health. The PCMH is not necessarily a physical place, but rather an organizational model that delivers the core functions of primary health care. Key principles in this model include:

- Access to a personal physician who leads the care team within a medical practice
- Adoption of a whole-person orientation to providing patient care
- Integrated and coordinated care
- Focus on quality and safety

The medical home is intended to result in more personalized, coordinated, effective and efficient care. Many of the goals of PCMH directly support efforts in population health.

In 2006, the Massachusetts General Hospital (MGH) worked with the U.S. Centers for Medicare and Medicaid to establish 1 of 6 population health demonstration projects nationwide. During the 3-year demonstration, the MGH implemented strategies to improve health care delivery to its most vulnerable high risk patients—those with multiple health conditions and chronic disease. The hospital system took steps to address the needs of 2,500 of their highest-risk patients.

- Each patient was assigned to a comprehensive care team consisting of a primary care physician, experienced nurse case manager, social worker, and pharmacist.
- A non-clinical community resource specialist was employed to work with the care teams in addressing non-clinical factors influencing health outcomes (for example, if the patient was not able to come to the primary care office for a scheduled visit because of transportation issues, this specialist connected the patient to local transportation resources).

This structure of care allowed clinicians to focus the majority of their time on patients' medical needs. The results revealed a decrease in hospital readmissions by 20%, and a decrease in emergency room visits by 13% for the patients enrolled in the program. Satisfaction was extremely high among both patients and caregivers, and the system was associated with significant cost-savings. This is one example of using population health to increase quality while decreasing costs, thereby increasing value in patient care.

CHAPTER SUMMARY

- Population health management is an important strategy for improving the quality of patient outcomes, containing costs, and promoting health maintenance.
- Successful population health management requires data-driven clinical decision-making, transformations in primary care leadership, meaningful use of health technology and patient-family engagement.
- Accountable care involves an integrated, proactive approach to improving the quality of health in identified patient populations.

High Yield Topics

- Understanding and managing population risk (e.g., identifying care gaps)
- Care teams coordinating home health between clinic visits as well as during clinic encounters
- Informatics: sharing information seamlessly with EHR and patient portals
- Engaging patients in health maintenance: screening, prevention and behavioral health
- Measuring outcomes
- Reducing waste in the system (e.g., duplication, non-value added interventions)
- Improving chronic care: keeping patients out of hospital (optimize home and outpatient care)

KEY DEFINITIONS

- **Care cycle**: array of health services and care settings which address health promotion, disease prevention, and the diagnosis, treatment, management, and rehabilitation of disease, injury, and disability
- **Clinical care pathway**: integrated, multidisciplinary outline of anticipated care placed in an appropriate timeframe to help patients with a specific condition/set of symptoms move progressively through a clinical experience to positive outcomes
- **Clinical outcome**: end result of a medical intervention, such as survival or improved health
- **Clinical variation**: variation in the utilization of health care services that cannot be explained by variation in patient illness or patient preferences (Wennberg JH 2010)
- **Continuum of care**: concept involving an integrated system of care which guides and tracks patients over time through a comprehensive array of health services spanning all levels of intensity of care
- **Cost-effectiveness analysis**: analytic tool in which the costs and effects of at least 1 alternative are calculated and presented, as in a ratio of incremental cost to incremental effect; the effects are health outcomes (e.g., cases of disease prevented, years of life gained, or quality-adjusted life years) rather than monetary measures (e.g., cost-benefit analysis) (Gold et al. 1996)

- **Evidenced-based medicine**: applying the best available research results (evidence) when making decisions about health care
  - Health care professionals who perform evidence-based practice use research evidence, along with clinical expertise and patient preferences. Systematic reviews (summaries of health care research results) provide information which aids in the process of evidence-based practice.
    - For example, a health care provider recommends acetaminophen to treat arthritis pain in a patient who has recently had stomach bleeding. The health care provider makes this recommendation because research shows that acetaminophen is associated with less risk for stomach bleeds than other common pain relievers. The health care provider's recommendation is an example of evidence-based practice.
- **Health**: a state of complete physical, mental and social well-being, and not merely the absence of disease or infirmity (WHO definition)
- **Health inequity**: those inequalities in health deemed to be unfair or to stem from some form of injustice; the dimensions of being avoidable or unnecessary have often been added to this concept (Kawachi, Subramanian, and Almeida-Filho 2002)
- **Health-related quality of life**: impact of the health aspects of an individual's life on his quality of life or overall well-being (Gold et al. 1996)
- **Intervention**: any type of treatment, preventive care, or test that a person could take or undergo to improve health or to help with a particular problem
  - Health care interventions include drugs (prescription drugs or drugs that can be bought without a prescription), foods, supplements (such as vitamins), vaccinations, screening tests (to rule out a certain disease), exercises (to improve fitness), hospital treatment, and certain kinds of care (such as physical therapy).
- **Life expectancy**: average amount of time a person will live after a certain starting point, such as birth or the diagnosis of a disease
  - The calculation is based on statistical information comparing people with similar characteristics, such as age, gender, ethnicity, and health. In the United States, for example, the life expectancy from birth for men and women combined is 78.1 years. In England, it is 78.7, and in China it is 72.9 years.
- **Patient-centered**: approach to patient care that focuses on the priorities, preferences, and best interests of the patient
  - It is a partnership among practitioners, patients, and their families to ensure that (a) decisions respect patients' wants, needs, and preferences, and (b) patients have the education and support needed to make decisions and participate in their own care.
- **Patient centered medical home:** care delivery model whereby patient treatment is coordinated through the primary care physician to ensure that the patient receives the necessary care when and where she needs it, in a manner she can understand
  - The goal is to have a centralized setting which facilitates partnerships between individual patients, their personal physician, and when appropriate, their family. Care is facilitated by registries, information technology, health information exchange, and other means to assure that patients get optimal care.

- **Population**: any group of individuals for whom consideration of health or health care at the level of the group is likely to advance health
- **Population health**: health of a population as measured by health status indicators, and as influenced by social, economic, and physical environments; personal health practices; individual capacity and coping skills; human biology; early childhood development; and health services (Dunn and Hayes 1999)
- **Public health**: activities that a society undertakes to assure the conditions in which people can be healthy; these include organized community efforts to prevent, identify, and counter threats to the health of the public (Turnock 2004)
- **Quality of life**: a broad construct reflecting a subjective or objective judgment concerning all aspects of an individual's existence, including health, economic, political, cultural, environmental, aesthetic, and spiritual aspects (Gold, Stevenson, and Fryback 2002)
- **Quality measure**: clinical quality measures (CQMs) are a mechanism for assessing observations, treatment, processes, experience, and/or outcomes of patient care
  - In other words, CQMs assess "the degree to which a provider competently and safely delivers clinical services that are appropriate for the patient in an optimal timeframe.
- **Registry**: organized system which uses observational study methods to collect uniform data (clinical and other) to evaluate specified outcomes for a population defined by a particular disease, condition, or exposure, and that serves 1 or more predetermined scientific, clinical, or policy purposes
- **Risk factor**: aspect of personal behavior/lifestyle, environmental exposure, or inborn/inherited characteristic that, on the basis of epidemiologic evidence, is known to be associated with health-related condition(s) considered important to prevent. (Last 2001)
- **Screening:** using tests or other methods of diagnosis to find out whether a person has a specific disease/condition before it causes any symptoms
  - For many diseases (e.g., cancers), starting treatment earlier leads to better results. The purpose of screening is to find the disease so that treatment can be started as early as possible. For example, a breast exam and mammogram are both screening tests used to find small breast cancers.
- **Social determinant***:* proposed or established causal factor in the social environment which affects health outcomes (e.g., income, education, occupation, class, social support)
- **Target population**: entire service area or any subset, whether economic, geographic, or demographic, or individuals with certain health conditions
- **Upstream determinants**: features of the social environment, such as socioeconomic status and discrimination that influence individual behavior, disease, and health status

Practice Questions

1. A 59-year-old man with a history of type 2 diabetes is diagnosed with diabetic retinopathy and referred to ophthalmology for additional management. The patient's primary care physician is interested in reducing the number of patients in the practice who develop similar long-term complications from type 2 diabetes mellitus. Which one of the following is the most important next step?

   (A) Develop an intervention to monitor blood glucose levels for all patients in the practice

   (B) Utilize the patient registry to identify high-risk patients comprising the target population

   (C) Train staff in the clinic to identify early signs of retinopathy

   (D) Request to have an ophthalmologist perform fundoscopic exams on all patients in the practice

   (E) Place a sign in the office depicting the dangers of diabetes

Answer: B. One of the first steps in designing a population health management program is to define the target population and identify common risk factors or gaps in care. Ideally, this should be done prior to implementing any intervention, so that it is clear which patients have the greatest need for the intervention and what risk factor(s) the intervention should address.

- Monitoring blood glucose for all patients, even those without diabetes or not at risk for diabetes, may not be a practical use of resources.
- Training staff to identify retinopathy or having an ophthalmologist perform fundoscopic exams will identify patients who already have long-term complications, rather than adjusting behaviors to prevent complications.
- A sign depicting the dangers of diabetes is not a proactive measure, does not optimally engage patients in self-care, and may only help those who are already in the clinic.

2. An 8-year-old boy is brought to the emergency department by his mother after he develops acute shortness of breath and wheezing. The boy appears anxious but is alert and responsive. He is afebrile and responds well to supplemental oxygen and initial respiratory treatment. He has a history of asthma and has presented with similar symptoms 4 times in the past 12 months. The mother smokes 1-2 packs of cigarettes per day while at home with her son. Which of the following addresses an upstream determinant of health amenable to population health management to improve the patient's long-term outcome?

   (A) Rapid use of nebulizer treatments in the emergency department

   (B) Administration of weight adjusted dose of steroid treatment

   (C) Asking the mom to purchase an inhaler to keep at the home

   (D) Parent education on second-hand smoking risk and enrollment in a smoking cessation program

   (E) Prophylactic antibiotics

Answer: D. Educating parents about the risks of second-hand smoke to children—especially one with a history of asthma—and offering parents enrollment in a smoking-cessation program may have a dramatic benefit to the health of the child and help prevent future asthma attacks. Use of nebulizers or steroids in the emergency department may be necessary to treat the acute episode of care; however, will not help prevent future attacks. The use of antibiotics without indications of bacterial infection (e.g. no fever) is not warranted.

Trauma 1

Learning Objectives

- ❑ List the ABCs of evaluating a trauma patient
- ❑ Demonstrate a head-to-toe review of a trauma patient
- ❑ Provide basic information about treatment of burns, bites, and stings

PRIMARY SURVEY: THE ABCs

Airway

The first step in the evaluation of trauma is airway assessment and protection.

- An airway is considered protected if the patient is conscious and speaking in a normal tone of voice.
- An airway is considered unprotected if there is an expanding hematoma or subcutaneous emphysema in the neck, noisy or "gurgly" breathing, or a Glasgow Coma Scale <8.

An airway should be secured before the situation becomes critical. **In the field** an airway can be secured by intubation or cricothyroidotomy. This is called a "definitive airway." **In the emergency department**, it is best done by rapid sequence induction and orotracheal intubation, with monitoring of pulse oximetry. In the presence of a cervical spine injury, orotracheal intubation can still be done as long as the head is secured and in-line stabilization is maintained during the procedure. Another option in that setting is nasotracheal intubation over a fiberoptic bronchoscope. If severe maxillofacial injuries preclude the use of intubation or intubation is unsuccessful, cricothyroidotomy may become necessary.

In the pediatric patient population (age <12), tracheostomy is preferred over cricothyroidotomy due to the high risk of airway stenosis, as the cricoid is much smaller than in the adult.

Breathing

Breath sounds indicate **satisfactory ventilation**; absence or decrease of breath sounds may indicate a pneumothorax and/or hemothorax and necessitate chest tube placement. **Pulse oximetry** indicates **satisfactory oxygenation**; hypoxia may be secondary to airway compromise, pulmonary contusion, or neurological injury impairing respiratory drive and necessitate intubation. Measurement of CO2 (capnography) is also very useful.

Circulation

Clinical signs of shock include the following:

- Low BP (<90 mm Hg systolic)
- Tachycardia (heart rate >100 bpm)
- Low urinary output (<0.5 ml/kg/h)

Patients in shock will be pale, cold, shivering, sweating, thirsty, and apprehensive.

In the trauma setting, shock is either hypovolemic (secondary to hemorrhage and the most common scenario) or cardiogenic (secondary to pericardial tamponade or tension pneumothorax due to chest trauma).

Hemorrhagic shock tends to cause collapsed neck veins due to low central venous pressure (CVP), while cardiogenic shock tends to cause elevated CVP with jugular venous distention. Both processes may occur simultaneously.

In pericardial tamponade, there is typically no respiratory distress, while in tension pneumothorax there is significant dyspnea, loss of unilateral breath sounds, and tracheal deviation.

Treatment of hemorrhagic shock includes volume resuscitation and control of bleeding, in the OR or ED depending on the injury and available resources. Volume resuscitation is initially with 2L of Lactated Ringer's solution unless blood products are immediately available.

In the setting of trauma, transfusion of blood products should be in a 1:1:1 ratio between packed RBCs, fresh frozen plasma, and platelets. Resuscitation should be continued until BP and heart rate normalize and urine output reaches 0.5–1.0 ml/kg/hr. In the setting of uncontrolled hemorrhage, permissive hypotension is recommended to prevent further blood loss while awaiting definitive surgical repair, but a mean arterial pressure >60 mm Hg should be maintained to ensure adequate cerebral perfusion.

The preferred route of fluid resuscitation in the trauma setting is 2 large bore peripheral IV lines, 16-gauge or greater. If this cannot be obtained, percutaneous subclavian or femoral vein catheters should be inserted; an acceptable alternative is a saphenous vein cut-down. In children age <6, intraosseus cannulation of the proximal tibia or femur is the alternate route.

Pericardial tamponade is generally a clinical diagnosis and can be confirmed with U/S. Management requires evacuation of the pericardial space by pericardiocentesis, subxiphoid pericardial window, or thoracotomy. Fluid and blood administration while evacuation is being set up is helpful to maintain an adequate cardiac output..

Tension pneumothorax is a clinical diagnosis based on physical exam. Management requires immediate decompression of the pleural space, initially with a large-bore needle which converts the tension to a simple pneumothorax and followed by chest tube placement.

In the non-trauma setting, shock can also be hypovolemic because of massive fluid loss such as bleeding, burns, peritonitis, pancreatitis, or massive diarrhea. The clinical picture is similar to trauma, with hypotension, tachycardia, and oliguria with a low CVP. Stop the bleeding and replace the blood volume.

Intrinsic cardiogenic shock is caused by myocardial damage (e.g. myocardial infarction or fulminant myocarditis). The clinical picture is hypotension, tachycardia, and oliguria with a high CVP (presenting as distended neck veins). Treat with pharmacologic circulatory support. Differential diagnosis is essential, because additional fluid and blood administration in this setting could be lethal, as the failing heart becomes easily overloaded.

Vasomotor shock (from anaphylaxis, high spinal anesthesia, or spinal cord transection) causes circulatory collapse. Patients are flushed, "pink and warm" with a low CVP. Treatment with phenylephrine and fluids is aimed at filling dilated veins and restoring peripheral resistance.

Secondary Survey

After the ABC's have been evaluated and any immediate life-threatening emergencies addressed, trauma evaluation continues with the secondary survey which is composed of a complete physical exam to evaluate for occult injuries followed by chest x-ray and pelvic x-ray. The secondary survey may be augmented with further imaging studies depending on the mechanism of injury and findings on examination. Any change that occurs requires complete re-evaluation.

A REVIEW FROM HEAD TO TOE

Head Trauma

- Penetrating head trauma as a rule requires surgical intervention and repair of the damage.
- Linear skull fractures are left alone if they are closed (no overlying wound).
- Open fractures require wound closure. If comminuted or depressed, treat in the OR.
- Anyone with head trauma who has become unconscious gets a CT scan to look for intracranial hematomas. If negative and neurologically intact, they can go home if the family will awaken them frequently during the next 24 hours to make sure they are not going into coma.

Signs of a fracture affecting the base of the skull include raccoon eyes, rhinorrhea, otorrhea or ecchymosis behind the ear (Battle's sign). CT scan of the head is required to rule out intracranial bleeding and should be extended to include the neck to evaluate for a cervical spinal injury. Expectant management is the rule and antibiotics are not usually indicated.

Neurologic damage from trauma can be caused by 3 components:

- Initial blow
- Subsequent development of a hematoma that displaces the midline structures
- Later development of increased intracranial pressure (ICP) due to cerebral edema

There is no treatment for the first (other than prevention), surgery can relieve the second, and medical measures can prevent or minimize the third.

Acute epidural hematoma occurs with modest trauma to the side of the head, and has classic sequence of trauma, unconsciousness, a lucid interval (a completely asymptomatic patient who returns to his previous activity), gradual lapsing into coma again, fixed dilated pupil (90% of the time on the side of the hematoma), and contralateral hemiparesis with decerebrate posturing. CT scan shows a biconvex, lens-shaped hematoma. Emergency craniotomy produces dramatic cure. Because every patient who has been unconscious gets CT scan, the full-blown picture with the fixed pupil and the contralateral hemiparesis is seldom seen.

Acute subdural hematoma has the same sequence, but the force of the trauma is typically much larger and the patient is usually much sicker (not fully awake and asymptomatic at any point), due to more severe neurologic damage. CT scan will show semilunar, crescent-shaped hematoma. If midline structures are deviated, craniotomy will help, but prognosis is bad. If there is no deviation, therapy is centered on preventing further damage from subsequent increased ICP.

Invasive ICP monitoring, head elevation, modest hyperventilation, avoidance of fluid overload, and diuretics such as mannitol or furosemide can decrease ICP. However, do not diurese to the point of lowering systemic arterial pressure, as **cerebral perfusion pressure = mean arterial pressure minus intracranial pressure**. Hyperventilation is recommended when there are signs of herniation, and the goal is pCO2 35 mm Hg. Sedation is used to decrease brain activity and oxygen demand. Moderate hypothermia is currently recommended to further reduce cerebral oxygen demand.

Diffuse axonal injury occurs in more severe trauma. CT scan shows diffuse blurring of the gray-white matter interface and multiple small punctate hemorrhages. Without hematoma there is no role for surgery. Therapy is directed at preventing further damage from increased ICP.

Chronic subdural hematoma occurs in the very old or in severe alcoholics. A shrunken brain is rattled around the head by minor trauma, tearing venous sinuses. Over several days or weeks, mental function deteriorates as hematoma forms. CT scan is diagnostic, and surgical evacuation provides dramatic cure.

Hypovolemic shock cannot happen from intracranial bleeding: there isn't enough space inside the head for the amount of blood loss needed to produce shock. Look for another source.

Neck Trauma

For the purpose of evaluating penetrating neck trauma, the neck has been divided into 3 zones.

- From caudad to cephalad, **zone 1** extends from the clavicles to the cricoid cartilate
- **Zone 2** from the cricoic cartilage to the angle of the mandible
- **Zone 3** from the angle of the mandible to the base of the skull

Penetrating trauma to the neck mandates surgical exploration in all cases where there is an expanding hematoma, deteriorating vital signs, or signs of esophageal or tracheal injury such as coughing or spitting up blood.

- For injuries to zone 1, evaluate with angiography, esophagogram (water-soluble, followed by barium if negative), esophagoscopy, and bronchoscopy to help decide if surgical exploration is indicated and to determine the ideal surgical approach.
- Historically, all penetrating injuries to zone 2 mandated surgical exploration, with a recent trend toward selective exploration based on physical exam.
  - If the patient is stable with low index of suspicion of a significant injury, use the above diagnostic modalities to evaluate situation and potentially avoid unnecessary surgical exploration.
  - If the patient's condition changes, however, urgent surgical exploration is indicated.
- For injuries to zone 3, evaluate with angiography for vascular injury.

In all patients with severe blunt trauma to the neck, the integrity of the cervical spine has to be ascertained. Unconscious patients and conscious patients with midline tenderness to palpation should be evaluated initially with CT scan, and potentially followed with MRI depending on findings. Conscious patients with no symptoms (are not intoxicated, have not used drugs, or have no 'distracting' injury) can be clinically evaluated for a cervical spinal injury; however if CT scan of the head is being obtained, it is generally accepted to extend the study to include the cervical spine.

Spinal Cord Injury

Complete transection is unlikely to be on the exam because it is too easy: nothing works, sensory, or motor, below the level of the injury.

Hemisection (Brown-Sequard) is typically caused by a clean-cut injury such as a knife blade, and results in ipsilateral paralysis and loss of proprioception and contralateral loss of pain perception caudal to the level of the injury.

Anterior cord syndrome is typically seen in burst fractures of the vertebral bodies. There is loss of motor function and loss of pain and temperature sensation on both sides caudal to the injury, with preservation of vibratory and positional sense.

Central cord syndrome occurs in the elderly with forced hyperextension of the neck, such as arear-end collision. There is paralysis and burning pain in the upper extremities, with preservation of most functions in the lower extremities.

Management necessitates precise diagnosis of cord injury, best done with MRI. There is some evidence that high-dose corticosteroids immediately after the injury may help, but that concept is still controversial. Further surgical management is too specialized for the exam.

Chest Trauma

Rib fractures can be deadly in the elderly, because pain impairs respiratory effort, which leads to hypoventilation, atelectasis, and ultimately, pneumonia. To avoid this cycle, treat pain from rib fractures with a local nerve block or epidural catheter, in addition to oral and IV analgesics.

Figure I-1-1. X-ray of Multiple Rib Fractures due to Trauma

Simple pneumothorax results from penetrating trauma such as a weapon or the jagged edge of a fractured rib. There is typically moderate shortness of breath with absence of unilateral breath sounds and hyperresonance to percussion. Diagnosis is confirmed with chest x-ray and management consists of chest tubeplacement.

Hemothorax happens the same way but the affected side will be dull to percussion due to blood accumulation in the pleural space. The blood can originate directly from the lung parenchyma or from the chest wall, such as an intercostal artery. Diagnosis is confirmed with chest x-ray. Chest tube placement is necessary to enable evacuation of the accumulated blood to prevent late development of a fibrothorax or empyema, but surgery to stop the bleeding is sometimes required. If the lung is the source of bleeding, it usually stops spontaneously as it is a low pressure system.

In some cases where a systemic vessel such as an intercostal artery is the source of bleeding, thoracotomy is needed to stop the hemorrhage. Indications for thoracotomy include:

- Evacuation of >1,500 mL when the chest tube is inserted
- Collecting drainage of >1 L of blood over 4 hours, i.e., 250 mL/hr

Severe blunt trauma to the chest may cause obvious injuries such as rib fractures with a flail chest or sucking chest wound, as well as less apparent injuries such as pulmonary contusion, blunt cardiac injury, diaphragmatic injury, and aortic injury.

Sucking chest wounds are obvious from physical exam, as there is a flap that sucks air with inspiration and closes during expiration. Untreated, it will lead to a deadly tension pneumothorax. Initial management is with a partially occlusive dressing secured on 3 sides, with one open side acting as a one-way valve. This allows air to escape but not enter the pleural cavity (to prevent iatrogenic tension pneumothorax and multiple fractures within each rib).

Flail chest occurs with multiple rib fractures that allow a segment of the chest wall to cave in during inspiration and bulge out during expiration (paradoxical breathing). The real problem is the underlying pulmonary contusion. Contused lung is very sensitive to fluid overload, thus treatment includes fluid restriction and pain management. Pulmonary dysfunction may develop, thus serial chest x-rays and arterial blood gases have to be monitored.

Pulmonary contusion can show up right away after chest trauma with "white-out" of the affected lung(s) or can be delayed up to 48 hours. If a respirator is needed, bilateral chest tubes should be considered to prevent a tension pneumothorax from developing as the multiple broken ribs may have punctured the lung. Significant force is necessary to result in a flail chest, so traumatic dissection or transection of the aorta should be evaluated for using a CT angiogram. Finally, ARDS may develop in this scenario.

Blunt cardiac injury should be suspected with the presence of sternal fractures. ECG monitoring will detect any abnormalities. Although serum troponin level was historically obtained, elevations do not generally change management and are therefore not indicated, as treatment is focused on the complications of the injury such as arrhythmias.

Traumatic rupture of the diaphragm shows up with bowel in the chest (by physical exam and x-rays), almost always on the left side (the liver protects the right hemidiaphragm). All suspicious cases should be evaluated with laparoscopy. Surgical repair is typically done from the abdomen.

Traumatic rupture of the aorta is the ultimate "hidden injury." It most commonly occurs at the junction of the arch and the descending aorta where the relatively mobile aorta is tethered

by the ligamentum arteriosum. Such an injury requires a significant deceleration injury and is totally asymptomatic until the hematoma contained by the adventitia ruptures resulting in rapid death. Suspicion should be triggered by one of the following:

- Mechanism of injury
- Widened mediastinum on chest x-ray
- Presence of atypical fractures such as the first rib, scapula, or sternum, which requires great force to fracture

Diagnosis is made with CT angiogram. Surgical repair is indicated once the patient has been stabilized and more immediate live-threatening injuries have been managed. This can be done in an open or endovascular fashion.

Traumatic rupture of the trachea or major bronchus is suggested by developing subcutaneous emphysema in the upper chest and lower neck, or by a large "air leak" from a chest tube. Chest x-ray and CT scan confirm the presence of air outside the bronchopulmonary tree, and fiberoptic bronchoscopy is necessary to identify the injury and allow intubation past the injury to secure an airway. Surgical repair is indicated

Differential diagnosis of **subcutaneous emphysema** also includes rupture of the esophagus and tension pneumothorax.

Air embolism should be suspected when sudden death occurs in a chest trauma patient who is intubated and on a respirator. It also can occur when the subclavian vein is opened to the air (e.g. supraclavicular node biopsies, central venous line placement or lines that become disconnected), also leading to sudden cardiovascular collapse and cardiac arrest. Immediate management includes cardiac massage, with the patient positioned in Trendelenburg with the left side down. Prevention includes the Trendelenburg position when the great veins at the base of the neck are to be accessed.

Fat embolism may also produce respiratory distress in a trauma patient who may not have necessarily suffered chest trauma. The typical setting is the following:

- Patient with multiple traumatic injuries (including several long bone fractures) develops petechial rashes in the axillae and neck; fever, tachycardia, and low platelet count
- At some point patient shows a full-blown picture of respiratory distress, with hypoxemia and bilateral patchy infiltrates on chest x-ray

The mainstay of therapy is respiratory support, and therefore precise diagnosis is not needed and rarely confirmed. Other therapies for this syndrome including heparin, steroids, alcohol, or low-molecular-weight dextran have been discredited.

Abdominal Trauma

For the sake of evaluation and management, abdominal trauma is divided into penetrating and blunt trauma based on the mechanism of injury. **Penetrating trauma** is further differentiated into gunshot wounds and stab wounds as the pattern of injury based on mechanism is quite different.

- Gunshot wounds to the abdomen require exploratory laparotomy for evaluation and possible repair of intra-abdominal injuries, not to "remove the bullet." Any entrance or exit wound below the level of the nipple line is considered to involve the abdomen.
- Stab wounds allow a more individualized approach. If it is clear that penetration has occurred, e.g. protruding viscera, exploratory laparotomy is mandatory.
- The same is true if hemodynamic instability or signs of peritoneal irritation develop.

In the absence of the above, local wound exploration may be performed in the ED to assess whether or not the anterior rectus fascia has been penetrated.

- If the fascia is not violated, the intra-abdominal cavity likely has not been penetrated and no further intervention is necessary.
- If the fascia has been violated, surgical exploration is indicated to evaluate for bowel or vascular injury, even in the setting of hemodynamic stability and lack of peritoneal findings on physical examination. If there is any question, perform CT.

Blunt trauma to the abdomen with obvious signs of internal injury requires emergent surgical evaluation via exploratory laparotomy. Signs of internal injury include abdominal distention and significant abdominal pain with guarding or rigidity on physical examination consistent with peritonitis. The occurrence of blunt trauma even without obvious signs of internal injury requires further evaluation because internal hemorrhage or bowel injury can be slow and therefore present in a delayed fashion.

Signs of internal bleeding include a drop in BP, a fast and/or thready pulse, a low CVP, and low urinary output. Patients tend to be cold, pale, anxious, shivering, thirsty, and perspiring profusely. These signs of shock occur when 25–30% of blood volume is acutely lost, ~1,500 ml in the average-size adult. There are few places in the body that this volume of blood can be lost without being obvious on physical or radiographic exam.

- The head is too small without causing a lethal degree of intracranial pressure.
- The neck could contain a significant amount of blood, but such a hematoma would be obvious on physical exam.
- The pericardial sac cannot contain the significant an amount of blood loss without resulting in pericardial tamponade and rapid clinical deterioration.
- The pleural cavities could easily accommodate several liters of blood, with relatively few local symptoms, but that significant a hemothorax would be obvious on chest x-ray, which is routinely performed in the secondary survey of a trauma patient.
- The arms and legs would also be obviously deformed by a large hematoma if present.

That leaves the abdomen, retroperitoneum, thighs (secondary to a femur fracture), and pelvis as the only places where a volume of blood significant enough to cause shock could "hide" in a blunt trauma patient that has become unstable. The femurs and pelvis are always checked for fractures in the initial survey of the trauma patient by physical exam and pelvic x-ray. So a patient who has experienced blunt trauma who has become hemodynamically unstable with normal chest and pelvic x-rays likely has intra-abdominal bleeding.

Diagnosis can be quickly utilizing the "FAST" exam: **F**ocused **A**bdominal **S**onography for **T**rauma. Bedside U/S evaluates the perihepatic space, perisplenic space, pelvis, and pericardium for free fluid. Fluid is not typically present in these locations, therefore in combination with a clinical suspicion such as hypotension following blunt trauma, should trigger the consideration of an internal injury.

- An unstable patient with these findings should be taken to the OR for immediate surgical exploration.
- A stable patient in whom the diagnosis is less definite should be taken for a more definitive study, i.e., CT scan. CT will show the presence of intra-abdominal fluid and can accurately delineate the source, typically the liver or spleen.

Additionally, grading scores exist for the extent of injury to these solid organs, with specific guidelines as to when a surgical intervention is indicated versus observation. The details of

these guidelines are outside the scope of the exam. Generally speaking, a patient with intra-abdominal bleeding injury from the liver or spleen can be observed as long as they are hemodynamically stable or respond to fluid and blood product administration; the moment instability is mentioned in a vignette, surgical exploration is indicated.

If surgical exploration is indicated for penetrating or blunt trauma, certain principles must be employed.

- Prolonged surgical time and ongoing bleeding can lead to the "triad of death": hypothermia, coagulopathy, and acidosis. The longer a patient is open, these component worsen and precipitate each other, resulting in a vicious cycle ultimately leading to death. Accordingly, the "damage control" approach has been adopted: immediate life-threatening injuries are addressed, less urgent injuries are temporized. Obviously repair of a major vascular structure with ongoing bleeding takes precedence.
  - Next comes control of contamination from injury to the GI tract. If a bowel resection is necessary, reconstruction can be delayed as only the contamination is life-threatening, not the inability to digest food.
  - If hypothermia, coagulopathy, or acidosis is setting in and injuries have been controlled, the operation is terminated and the abdomen is packed with gauze pads and closed with a temporary closure. The patient is resuscitated in the ICU, and returns to the OR at a later date when warm, not coagulopathic, and not acidotic for definitive reconstruction and abdominal closure.
- If coagulopathy does develop during surgical exploration, it is objectively treated with transfusion of RBCs, fresh frozen plasma, and platelets in equal quantities (1:1:1 ratio). This most realistically mimics the replacement of whole blood and enable not only adequate quantities of hemoglobin, but adequate clotting factors to reverse the developing coagulopathy and enable control of hemorrhage.
- The abdominal compartment syndrome is when the pressure in the peritoneal cavity is elevated and leads to end-organ injury. This occurs when a significant amount of fluid is administered in an effort to resuscitate a patient in hypovolemic shock. Bowel edema develops, increasing intra-abdominal pressure, which is detrimental for several reasons.
  - First, the elevated pressure leads to decreased perfusion pressure to the viscera, contributing to acute kidney injury and possibly bowel and hepatic ischemia.
  - Second, the upward pressure of the viscera on the diaphragm prevents adequate expansion of the lungs and ventilation, contributing to respiratory failure.
  - Therefore, if bowel edema is observed or intra-abdominal pressure is elevated following surgical exploration, the abdomen is not closed, rather left open as described in the damage-control approach.
  - Similarly, if a patient is not surgically explored but undergoes a significant volume resuscitation and abdominal compartment syndrome develops, a decompressive laparotomy may be indicated. Incidentally, this can occur in non-trauma scenarios requiring massive fluid resuscitation, most notable severe pancreatitis.

A **ruptured spleen** is the most common source of significant intra-abdominal bleeding in blunt abdominal trauma. Often there are additional diagnostic hints, such as fractures of lower ribs on the left side. Given the limited function of the spleen in the adult, a splenic injury resulting in hemodynamic instability or requiring significant blood product transfusion is an indication for splenectomy. Post-operative immunization against encapsulated bacteria is mandatory (Pneumococcus, *Haemophilus influenza* B, and meningococcus). However, lesser injuries to the spleen which can be repaired easily are attempted.

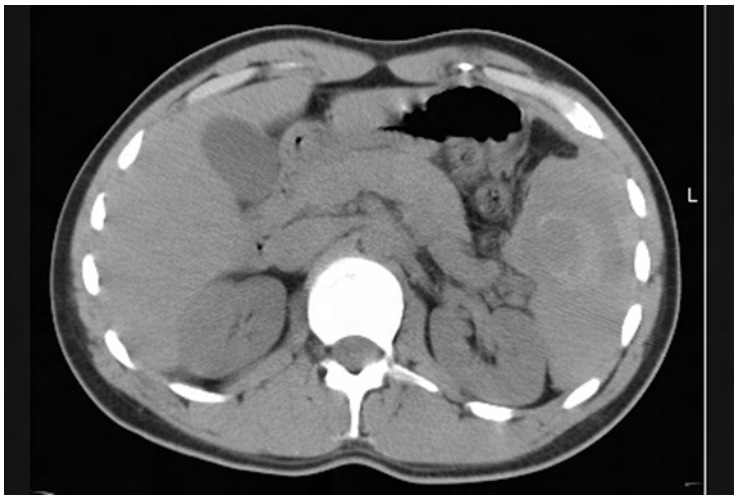

Figure I-1-2. CT Scan of Abdomen in 21-Year-Old Man demonstrating Ruptured Spleen and Hemoperitoneum

Pelvic Fracture

The pelvis is a complex ring, much like a pretzel, in that it cannot be fractured in only one location; multiple fractures are typically present. These can range from minor to life-threatening. Minor fractures with small pelvic hematomas incidentally identified on CT scan are typically monitored.

In **pelvic fracture with ongoing significant bleeding** causing hemodynamic instability, management is complex.

- The first step for an obvious pelvic fracture in an unstable patient is external pelvic wrapping for stabilization of the pelvis, which limits the potential space for ongoing blood loss.
- The next step is *not* surgical exploration but rather angiography.
  - This is because it is incredibly difficult (often impossible) to identify the source of bleeding in the pelvis where a deep cavity contains significant organs and vessels including the complex sacral venous plexus.
  - However, interventional radiologists can angiographically identify an arterial source of bleeding and potentially embolize the branch vessels and control hemorrhage.
  - If no arterial bleeding is identified, the ongoing blood loss is presumed to be venous in origin, and the internal iliac arteries are prophylactically embolized to prevent the inflow to these bleeding veins.

In any pelvic fracture, associated injuries have to be ruled out. These include rectum (do a rectal exam and rigid proctoscopy), vagina in women (do a pelvic exam); urethra in men (do a retrograde urethrogram), and bladder (addressed in the next section)

Urologic Injury

The hallmark of urologic injury is blood in the urine of someone who has sustained penetrating or blunt abdominal trauma. Gross hematuria in that setting must be investigated with appropriate studies.

Penetrating urologic injuries as a rule are surgically explored and repaired.

- Blunt urologic injuries may affect the kidney, in which case the associated injuries tend to be lower rib fractures. If they affect the bladder or urethra, the usual associated injury is pelvic fracture.
- Urethral injuries occur almost exclusively in men, is typically associated with a pelvic fracture, and may present with blood at the meatus.
  - Other clinical findings include a scrotal hematoma, the sensation of wanting to void but inability to do so, and a "high-riding" prostate on rectal exam (i.e., it is not palpable on rectal exam).
  - The key issue in any of these is that a **Foley catheter should not be inserted**, as it might compound an existing injury, but a retrograde urethrogram should be performed instead.
    - If Foley catheter placement has been attempted and resistance met, this should be a clue that a urethral injury may be present and attempt should be aborted.
- Bladder injuries can occur in either sex, are usually associated with pelvic fracture, and are diagnosed by retrograde cystogram or CT cystography.
  - The x-ray study must include post-void films to enable visualization of an extraperitoneal leak at the base of the bladder that might be obscured by a bladder full of dye. Management is surgical repair with protection by a decompressive suprapubic cystostomy or indwelling Foley catheter.
- Renal injuries secondary to blunt trauma are usually associated with lower rib fractures. They are assessed by CT and most of the time can be managed without surgical intervention.
  - A rare but fascinating potential sequela of injuries affecting the renal pedicle is the development of an arteriovenous fistula leading to CHF. Should renal artery stenosis develop after trauma, renovascular hypertension is another potential sequela.
- Scrotal hematomas can attain alarming size, but typically do not need specific intervention unless the testicle is ruptured. The latter can be assessed with sonogram.
- Fracture of the penis (fracture of the corpora cavernosa, fracture of the tunica albuginea) occurs to an erect penis, typically as an accident during vigorous intercourse (with woman on top). There is sudden pain and development of a large penile shaft hematoma, with a normal appearing glans.
  - Frequently, the true history will be concealed by an embarrassed patient who concocts a cover story. Emergency surgical repair is required. If not done, impotence will ensue as either arteriovenous shunts or painful erections.

Injury to the Extremities

In penetrating injuries of the extremities, the main issue is whether a vascular injury has occurred or not. Anatomic location provides the first clue.

- When there are no major vessels in the vicinity of the injury, only tetanus prophylaxis and irrigation of the wound is required.
- If the penetration is near a major vessel and the patient is asymptomatic, Doppler studies or CT angiogram is performed and will guide the need for a surgical intervention.
- If there is an obvious vascular injury (absent distal pulses, expanding hematoma) surgical exploration and repair are required.

Simultaneous injuries of arteries and bone pose the challenge of the sequence of operative repair. One perspective is to stabilize the bone first, then do the delicate vascular repair which could otherwise be disrupted by the bony reduction and fixation. However during the orthopedic repair, ongoing ischemia is occurring as the arterial flow is disrupted.

A good solution, if proposed on the exam, is to place a vascular shunt, which allows temporary revascularization during the bony repair, with definitive vascular repair completed subsequently. A fasciotomy should usually be added because the prolonged ischemia could lead to a compartment syndrome.

High-velocity gunshot wounds (e.g. military or big-game hunting rifles) produce a large cone of tissue destruction that requires extensive debridements and potential amputations.

Crushing injuries of the extremities resulting in myonecrosis pose the hazard of hyperkalemia and renal failure as well as potential development of compartment syndrome. Aggressive fluid administration, osmotic diuretics, and alkalinization of the urine with sodium bicarbonate are good preventive measures for the acute kidney injury, and a fasciotomy may be required to prevent or treat compartment syndrome.

BURNS

Chemical burns require massive irrigation to remove the offending agent. Alkaline burns (Liquid Plumr, Drano) are worse than acid burns (battery acid). Irrigation must begin as soon as possible at the site where the injury occurred (tap water, shower). Do not attempt to neutralize the agent.

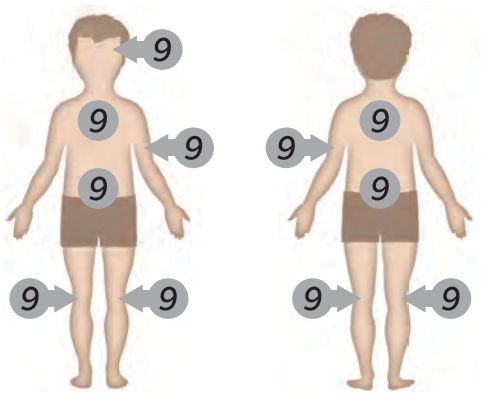
High-voltage electrical burns are always deeper and worse than they appear to be. Massive debridements or amputations may be required. Additional concerns include myonecrosis-induced acute kidney injury, orthopedic injuries secondary to massive muscle contractions (e.g., posterior dislocation of the shoulder, compression fractures of vertebral bodies), and late development of cataracts and demyelinization syndromes. Of course cardiac electrical integrity and function must be evaluated.

Respiratory burns (inhalation injuries) occur with flame burns in an enclosed space (a burning building, car, plane) and are chemical injuries caused by smoke inhalation. Burns around the mouth or soot inside the throat are suggestive clues. Diagnosis is confirmed with fiberoptic bronchoscopy, but the key issue is whether respiratory support is necessary, and is guided by serial arterial blood gases. Intubation should be initiated if there is any concern about adequacy of the airway. The routine use of tracheostomy and antibiotic/steroids therapy has been discredited, but levels of carboxyhemoglobin have to be monitored. If elevated, 100% oxygen will shorten its half-life.

Circumferential burns of the extremities can lead to tissue edema and restriction of arterial inflow, resulting in ischemia and compartment syndrome secondary to eschar. This can also occur in circumferential burns to the chest, with resultant limitations in ventilation. Escharotomies done at the bedside with no need for anesthesia will provide immediate relief.

Scalding burns in children should always raise the suspicion of child abuse, particularly if the pattern of the burn does not fit the description of the event given by the parents. A classic example is burns of both buttocks, which are typically produced by holding a small child by arms and legs, and dunking him into boiling water.

- Burns result in the loss of skin integrity and increase insensible fluid losses, leading to profound hypovolemia.
- In the first 48 hours after burn, fluid needs can be estimated by calculations that take into account the extent of the burn and provide an estimated amount of IV fluid that is needed.
- Once fluid resuscitation has been initiated, adjust based on urinary output determining the adequacy of resuscitation.
- The extent of burns in the adult is estimated by the use of the "**rule of nines**," where the head and each of the upper extremities are each assigned 9% of body surface; each lower extremity is assigned two 9% units; and trunk is assigned 4 units of 9% each.
- For purposes of most of this calculation, second- and third-degree burns are counted.



The most widely used calculation is the modified Parkland formula, in which body weight in kilograms is multiplied by the percentage of burn (as a whole number), and multiplied by 4 ml. The number obtained is the amount of Lactated Ringer's (LR) required in the first 24 hours, half of which should be infused in the first 8 hours and the other half in the next 16 hours.

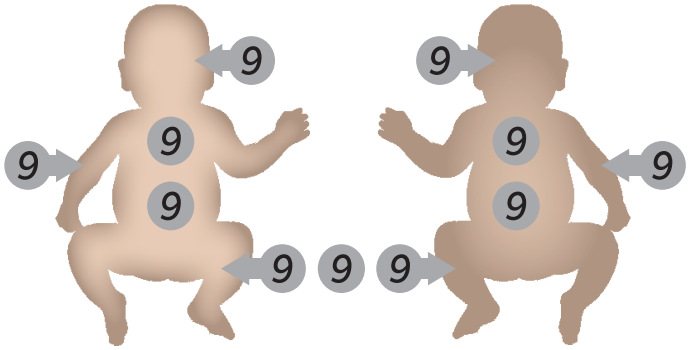
Parkland Formula

BW (kg) × % of burn (up to 50%) × 4 cc RL
Infuse ½ first 8 hours, infuse ½ next 16 hours

Alternative strategy: Initiate a predetermined rate of infusion, typically 1,000 ml/h of LR for anyone whose burns >20% of body surface, and then adjust as needed to produce the desired urinary output. Fluids containing dextrose are avoided to prevent an osmotic diuresis that would render urine output unreliable as an indicator of intravascular volume status.

Estimation of fluid needs in burned babies differs from the adult in several measures.

- Babies have bigger heads and smaller legs; thus the "rule of 9s" for them assigns two 9s to the head, and both legs share a total of three 9's instead of 4.
- Third-degree burns in babies look deep bright red rather than the leathery, dry, gray appearance present in adults.
- Babies need proportionally more fluid than adults, therefore formulas and calculations in the baby use 4-6 ml/kg/%.
- A reliable predetermined rate of infusion for babies is 20 ml/kg/hour.



Other aspects of burn care include tetanus prophylaxis, cleaning of the burn areas, and the use of topical agents. The standard topical agent is silver sulfadiazine. If deep penetration is necessary (e.g. a thick eschar or a burn ovar cartilage), mafenide acetate is the choice. Burns near the eyes are covered with triple antibiotic ointment (silver sulfadiazine is irritating to the eyes).

- In the early period, all pain medication is given intravenously.
- After an initial day or two of NG suction, intensive nutritional support is provided, preferably via the gut, with high calorie/high nitrogen diets.
- After 2 or 3 weeks of wound care and general support, the burned areas that have not regenerated are grafted. Rehabilitation starts on day 1.
- When possible, early excision and skin grafting is recommended to save costs and minimize pain, suffering, and complications.

BITES AND STINGS

Tetanus prophylaxis and wound care are required for all bites. **Dog bites** are considered provoked if the dog was petted while eating or otherwise teased. No rabies prophylaxis is required, other than observation of the dog for developing signs of rabies. Because bites to the face are very close to the brain, it might be prudent to start immunization and then discontinue it if observation of the dog is reassuring.

Unprovoked dog bites or bites from wild animals raise the issue of potential rabies. If the animal is available, it can be euthanized and the brain examined for signs of rabies. Otherwise, rabies prophylaxis with immunoglobulin plus vaccine is mandatory.

Snakebites do not necessarily result in envenomation, even if the snake is poisonous (up to 30% of bitten patients are not envenomated). The most reliable signs of envenomation are

severe local pain, swelling, and discoloration developing within 30 minutes of the bite. If present, draw blood for typing and crossmatch (they cannot be done later if needed), coagulation studies, and liver and renal function. Treatment is based on antivenin. The currently preferred agent for crotalids is CROFAB, of which several vials are usually needed.

Antivenin dosage relates to size of the envenomation, not size of the patient (children get the same dosages as adults). Surgical excision of the bite site or fasciotomy is very rarely needed. The only valid first aid is to splint the extremity during transportation. Do not make cruciate cuts, suck out venom, wrap with ice, or apply a tourniquet.

Bee stings kill many more people in the United States than snakebites because of an anaphylactic reaction. Wheezing and rash may occur, and hypotension when present is caused by vasomotor shock ("pink and warm" shock). Epinephrine is the drug of choice (0.3–0.5 ml of 1:1,000 solution). The stingers should be removed without squeezing them.

Black widow spiders are black, with a red hourglass on their belly. Bitten patients get nausea, vomiting, and severe generalized muscle cramps. The antidote is IV calcium gluconate. Muscle relaxants also help.

Brown recluse spider bites are often not recognized at the time. In the next several days, a skin ulcer develops, with necrotic center and a surrounding halo of erythema. Dapsone is helpful. Surgical debridement of all necrotic tissue is needed. Skin grafting may be needed subsequently.

Human bites are bacteriologically the dirtiest bite one can get. They require extensive irrigation and debridement (in the OR) and antibiotics. A classic human bite is the sharp cut over the knuckles on someone who punched someone else in the mouth and was cut by the teeth of the victim. They often show up in the ED with a cover story, but should be recognized because they need specialized orthopedic care.

Orthopedics 2

Learning Objectives

- ❏ Describe the diagnostic and treatment approach to common pediatric and adult orthopedic problems
- ❏ Answer questions about bone tumors

PEDIATRIC ORTHOPEDICS

- Congenital dysplasia of the hip runs in families, and should be ideally diagnosed right after birth. Children have uneven gluteal folds, and physical examination of the hips show that they can be easily dislocated posteriorly with a jerk and a "click," and returned to normal with a "snapping." If signs are equivocal, sonogram is diagnostic (do not order x-rays; the hip is not calcified in the newborn). Treatment is abduction splinting with a Pavlik harness for ~6 months.
- Hip pathology in older children may present as hip or knee pain. **Legg-Calve-Perthes** disease is avascular necrosis of the capital femoral epiphysis and occurs around age 6, with insidious development of limping, decreased hip motion, and hip or knee pain. Patients walk with an antalgic gait and passive motion of the hip is guarded. Diagnosis is confirmed by AP and lateral hip x-rays. Treatment is controversial, usually containing the femoral head within the acetabulum by casting and crutches.
- **Slipped capital femoral epiphysis** (**SCFE**) is an orthopedic emergency.
  - The typical patient is a chubby (or lanky) boy around age 13 who complains of groin or knee pain, and who ambulates with a limp.
  - When sitting with the legs dangling, the sole of the foot on the affected side points toward the other foot.
  - On physical exam there is limited hip motion, and as the hip is flexed the thigh goes into external rotation and cannot be rotated internally.
  - X-rays are diagnostic, and surgical treatment pins the femoral head back in place.
- A **septic hip** is an orthopedic emergency.
  - It is seen in toddlers who have had a febrile illness, and then refuse to move the hip. They hold the leg with the hip flexed, in slight abduction and external rotation, and do not let anybody move it passively.
  - White blood cell count and erythrocyte sedimentation rate are elevated.
  - Diagnosis is made by aspiration of the hip under general anesthesia, and further open drainage is performed if pus is obtained.

- **Acute hematogenous osteomyelitis** is seen in small children who have had a febrile illness and presents as severe localized pain in a bone with no history of trauma to that bone. X-rays will not show anything for several weeks. MRI reveals prompt diagnosis. Treatment is IV antibiotics.
- **Genu varum (bow-legs)** is normal up to age 3; no treatment is needed. Persistent varus age >3 is most commonly Blount disease, a disturbance of the medial proximal tibial growth plate, for which surgery is corrective.
- **Genu valgus (knock-knee)** is normal between ages 4–8; no treatment is needed.
- **Osgood-Schlatter disease (osteochondrosis of the tibial tubercle)** is seen in teenagers with persistent pain right over the tibial tubercle, which is aggravated by contraction of the quadriceps. Physical exam shows localized pain right over the tibial tuberclein the absence of knee swelling. Treatment is initially with rest, ice, compression, and elevation. If conservative management fails, treatment is immobilization of the knee in an extension or cylinder cast for 4–6 weeks.
- **Club foot (talipes equinovarus)** is seen at birth. Both feet are turned inward and there is plantar flexion of the ankle, inversion of the foot, adduction of the forefoot, and internal rotation of the tibia. Serial plaster casts started in the neonatal period provide sequential correction starting with the adducted forefoot, then the hindfoot varus, and last the equinus. About 50% of patients with club foot are fully corrected this way. The other 50% require surgery after age 6–8 months but before age <1–2 years.
- **Scoliosis** is seen primarily in adolescent girls whose thoracic spines are curved toward the right. The most sensitive screening finding is to look at the girl from behind while she bends forward, a hump will be noted over her right thorax. The deformity progresses until skeletal maturity is reached (at the onset of menses skeletal maturity is ~80%). In addition to the cosmetic deformity, severe cases develop decreased pulmonary function. Bracing is used to arrest progression; severe cases may require surgery. Early treatment is mandated.

Fractures

Remodeling occurs to an astonishing degree in children's fractures, thus degrees of angulation that would be unacceptable in the adult may be acceptable in children when these fractures are reduced and immobilized. Also, the healing process is much faster than in the adult. The only areas where children have special problems include supracondylar fractures of the humerus and fractures of any bone that involve the growth plate or epiphysis.

Supracondylar fractures of the humerus occur with hyperextension of the elbow in a child who falls on the hand with the arm extended. The injuries are particularly dangerous due to the proximity of the brachial artery and ulnar nerve. Although these fractures are treated with standard casting or traction and rarely need surgery), they require careful monitoring of vascular and nerve integrity and vigilance regarding development of compartment syndrome.

Figure I-2-1. Supracondular Fracture of the Humerus

Fractures that involve the **growth plate** or epiphysis can be treated by closed reduction if the epiphyses and growth plate are displaced laterally from the metaphysis but they are in one piece (i.e., the fracture does not cross the epiphyses or growth plate and does not involve the joint). If the growth plate is fractured into two pieces, open reduction and internal fixation will be required to ensure precise alignment and even growth to avoid chronic deformity of the extremity.

Figure I-2-2. Salter Harris Grade III Fracture

ADULT ORTHOPEDICS

X-rays for suspected fracture in adults should always include the following:

- Two views at 90° to one another
- Joints above and below the broken bone
- If suggested by the mechanism of injury, bones that are in "the line of force," which might also be broken (e.g. the lumbar spine must be evaluated for fracture following a fall from a significant height with foot fractures)

As a general rule, broken bones that are not badly displaced or angulated or that can be satisfactorily aligned by external manipulation can be immobilized in a cast ("closed reduction"). Broken bones that are severely displaced or angulated or that cannot be aligned easily require surgical intervention to reduce and fix the fracture ("open reduction and internal fixation").

Clavicular fracture is typically at the junction of middle and distal thirds. It is treated by placing the arm in a sling. Figure-of-8 bandage treatment is now less popular.

Anterior dislocation of the shoulder is by far the most common shoulder dislocation. Patients hold the arm close to their body but rotated outward as if they were going to shake hands. There may be numbness in a small area over the deltoid, from stretching of the axillary nerve. AP and lateral x-rays are diagnostic. Some patients develop recurrent dislocations with minimal trauma.

Posterior shoulder dislocation is rare and occurs after massive uncoordinated muscle contractions, such as epileptic seizure or electrical burn. The arm is held in the usual protective position (close to the body, internally rotated). Regular x-rays can easily miss it; axillary views or scapular lateral views are needed.

Colles' fracture results from fall on an outstretched hand, often in old osteoporotic women. The deformed and painful wrist looks like a "dinner fork." The main lesion is an older, dorsally displaced, dorsally angulated fracture of the distal radius. Treatment is with close reduction and long arm cast.

Figure I-2-3. X-ray demonstrating Colles Fracture with "Dinner-fork" Deformity

Monteggia fracture results from a direct blow to the ulna (i.e., on a raised protective arm hit by a nightstick). There is diaphyseal fracture of the proximal ulna, with anterior dislocation of the radial head. **Galeazzi fracture** is the mirror image: the distal third of the radius gets the direct blow and has the fracture, and there is dorsal dislocation of the distal radioulnar joint. In both of these, the broken bone often requires open reduction and internal fixation, whereas the dislocated one is typically handled with closed reduction.

Fracture of the scaphoid (carpal navicular) affects a young adult who falls on an outstretched hand. Chief complaint is typically wrist pain, with physical exam revealing localized tenderness to palpation over the anatomic snuff box. In undisplaced fractures, x-rays are usually negative, but thumb spica cast is indicated just with the history and physical findings. X-rays will show the fracture 3 weeks later. If original x-rays show displaced and angulated fracture, open reduction and internal fixation are needed. Scaphoid fractures are notorious for a very high rate of nonunion secondary to avascular necrosis.

Metacarpal neck fracture (typically the fourth or fifth, or both) happens when a closed fist hits a hard surface (like a wall). The hand is swollen and tender, and x-rays are diagnostic. Treatment depends on the degree of angulation, displacement, or rotary malalignment: close reduction and ulnar gutter splint for the mild ones; Kirschner wire or plate fixation is indicated for bad fractures.

Hip fracture typically occurs in the elderly following a fall. The hip hurts, and the patient's position in the stretcher is classic: the affected leg is shortened and externally rotated. Specific treatment depends on specific location (as shown by x-rays).

Femoral neck fracture, particularly if displaced, compromises the very tenuous blood supply of the femoral head. Faster healing and earlier mobilization can be achieved by replacing the femoral head with a prosthesis.

Reproduced with permission from the HWB Foundation, www.hwbf.org/, courtesy of Dr. Alexander Chelnokov.

Figure I-2-4. Femoral Neck Fracture on X-ray of the Hip

Intertrochanteric fracture is less likely to lead to avascular necrosis, and is usually treated with open reduction and pinning. The unavoidable immobilization that ensues poses a very high risk for deep venous thrombosis and pulmonary emboli, thus post-op anticoagulation is recommended.

Figure I-2-5. Intertrochanteric Fracture of the Hip Noted on X-ray

Femoral shaft fracture is often treated with intramedullary rod fixation.

- If bilateral and comminuted, it may produce enough internal blood loss to lead to shock (external fixation may help while the patient is stabilized).
- If open, it is an orthopedic emergency, requiring OR irrigation and closure within 6 hours.
- If multiple, fat embolism syndrome may develop, in which severe respiratory distress occurs secondary to marrow fat entering the blood stream and embolizing to the pulmonary vasculature.
- Treatment is supportive care.

Knee injury typically produces swelling of the knee; knee pain without swelling is unlikely to be a serious knee injury. Collateral ligament injury is usually sustained when the force of impact is the side of the knee, a common sports injury. Medial blows disrupt the lateral ligament and vice versa.

- The knee will be swollen and there is localized pain by direct palpation on the affected side.
- With the knee flexed 30°, passive abduction or adduction will produce pain on the torn ligaments and allow further displacement than the normal leg.

- Abduction demonstrates the medial injuries (valgus stress test), whereas adduction diagnoses the lateral injuries (varus stress test). Isolated injuries are treated with a hinged cast.
- When several ligaments are torn, surgical repair is preferred.

Anterior cruciate ligament injury is more common than posterior injury.

- There is severe knee swelling and pain.
- With the knee flexed 90°, the leg can be pulled anteriorly, like a drawer being opened (anterior drawer test).
- A similar finding can be elicited with the knee flexed at 20° by grasping the thigh with one hand, and pulling the leg with the other (Lachman test).

Posterior cruciate ligament injury produces the opposite findings. MRI is diagnostic. Sedentary patients may be treated with immobilization and rehabilitation, whereas athletes require arthroscopic reconstruction.

Meniscal tear is difficult to diagnose clinically and on x-rays, but is beautifully demonstrated on MRI.

- Protracted pain and swelling after a knee injury
- Possible "catching and locking" which limits knee motion, and a "click" when the knee is forcefully extended
- Repair is done, trying to save as much meniscus as possible
- Complete meniscectomy leads to the late development of degenerative arthritis

Injuries to the medial meniscus, medial collateral, and anterior cruciate often occur simultaneously.

Tibial stress fracture is seen in young men subjected to forced marches. There is tenderness to palpation over a very specific point on the bone, but x-rays are initially normal. Treat with a cast, and repeat the x-rays in 2 weeks. Non–weight bearing with crutches is another option.

Leg fracture involving the tibia and fibula is often seen when a pedestrian is hit by a car. Physical exam shows angulation; x-rays are diagnostic. Casting takes care of the ones that are easily reduced; intramedullary nailing is needed for the ones that cannot be aligned. The lower leg (along with the forearm) is one of the most common locations for development of the compartment syndrome. Increasing pain after a long leg cast has been applied always requires immediate removal of the cast and appropriate assessment.

Rupture of the Achilles tendon is seen in out-of-shape middle-age men who subject themselves to severe strain (tennis, for instance). As they plant the foot and change direction, a loud popping noise is heard (like a rifle shot), and they fall clutching the ankle. Limited plantarflexion is still possible; but pain, swelling, and limping bring them to medical attention. Palpation of the tendon reveals a gap. Casting in equinus position allows healing in several months; surgery achieves a quicker cure.

Fracture of the ankle occurs when falling on an inverted or everted foot. In either case, both malleoli break. AP, lateral, and mortise x-rays are diagnostic. Open reduction and internal fixation is needed if the fragments are displaced.

Orthopedic Emergencies

Compartment syndrome occurs most frequently in the forearm or lower leg.

- Precipitating events include prolonged ischemia followed by reperfusion, crushing injuries, or other types of trauma.
- In the lower leg, by far the most common cause is a fracture with closed reduction.
- The patient has pain and limited use of the extremity; the compartment feels very tight and tender to palpation.
- The most reliable physical finding is excruciating pain with passive extension.
- Pulses may be normal.
- Emergency fasciotomy is required for treatment.

Pain under a cast is always handled by removing the cast and examining the limb.

Open fracture in which a broken bone protrudes from the wound requires irrigation in the OR and suitable reduction within 6 hours from the time of the injury. It is called compound or open fracture.

Posterior dislocation of the hip occurs when the femur is driven backward, such as in a head-on car collision where the knees hit the dashboard. The patient has hip pain and lies in the stretcher with the leg shortened, adducted, and internally rotated (in a broken hip the leg is also shortened, but it is externally rotated). Because of the tenuous blood supply of the femoral head, emergency reduction is needed to avoid avascular necrosis.

Gas gangrene occurs with deep, penetrating, dirty wounds. In about 3 days the patient is extremely sick, looking toxic and moribund. The affected site is tender, swollen, discolored, and has gas crepitation. Treatment includes IV penicillin, extensive emergency surgical debridement, and possibly hyperbaric oxygen.

Associated neurovascular injuries

The **radial nerve** can be injured in oblique fractures of the middle to distal thirds of the humerus. If a patient comes in unable to dorsiflex (extend) the wrist, and regains function when the fracture is reduced and the arm is placed on a hanging cast or coaptation sling, no surgical exploration is needed. However, if nerve paralysis develops or remains after reduction, the nerve is entrapped and surgery has to be done.

Popliteal artery injury can occur in posterior dislocations of the knee. Following reduction of the dislocation, the popliteal artery must be evaluated with U/S, because even if distal pulses which were absent return following reduction of the dislocation, there may be an intimal flap or local dissection that may need either further evaluation with CT angiogram or surgical exploration. If pulses remain absent or an obvious injury is identified on U/S, surgical exploration is indicated. Delayed restoration of flow may require a prophylactic fasciotomy.

Injury patterns—the second hidden fracture

The direction of force that produces an obvious injury may produce another one that is less obvious and needs to be sought.

- **Falls from a height** landing on the feet may have obvious foot or leg fractures, but fractures of the lumbar or thoracic spine may be less obvious and must be assessed.
- **Head-on automobile collisions** may produce obvious injuries in the face, head, and torso, but if the knees hit the dashboard, the femoral heads may be driven backward into the pelvis or out of the acetabulum and thus cause a fracture or dislocation.

The presence of **facial fractures or closed head injuries** mandates evaluation of the cervical spine initially with CT scan and further with MRI if pain or neurological symptoms persist.

Common Hand Problems

Carpal tunnel syndrome occurs following performance of repetitive hand work such as typing and presents with numbness and tingling in both hands in the distribution of the median nerve (radial 3½ fingers). The symptoms can be reproduced by hanging the hand limply for a few minutes, or by tapping, percussing or pressing the median nerve over the carpal tunnel (Tinel's sign). The diagnosis is clinical, but the American Academy of Orthopaedic Surgery recommends that wrist x-rays (including carpal tunnel view) be done to rule out other pathology. Initial treatment is splinting and anti-inflammatory agents. If these conservative measures fail, surgery is indicated following electromyography and nerve conduction velocity.

Figure I-2-8. Thenar Atrophy is a Feature of Carpal Tunnel Syndrome

Trigger finger is more common in women and presents with acute finger flexion and the inability to extend it unless pulled with the other hand, which results in a painful "snap." Steroid injection is the first line of therapy; surgery is the treatment of last resort.

De Quervain tenosynovitis is seen in young mothers who, as they carry their baby, force their hand into wrist flexion and thumb extension to hold the baby's head. They complain of pain along the radial side of the wrist and the first dorsal compartment. On physical exam the pain can be reproduced by asking her to hold the thumb inside her closed fist, then forcing the wrist into ulnar deviation. Splint and anti-inflammatory agents can help, but steroid injection is most effective. Surgery is rarely needed.

Dupuytren contracture occurs in older men of Norwegian ancestry and in alcoholics. There is contracture of the palm of the hand, and palmar fascial nodules can be felt. Surgery may be needed when the hand can no longer be placed flat on a table.

A **felon** is an abscess in the pulp of a fingertip, caused by a neglected penetrating injury. Patients complain of throbbing pain, and have all the classic findings of an abscess, including fever. Because the pulp is a closed space with multiple fascial trabecula, pressure can build up and lead to tissue necrosis; thus surgical drainage is urgently indicated.

Gamekeeper thumb is an injury of the ulnar collateral ligament sustained by forced hyperextension of the thumb (historically suffered by gamekeepers when they killed rabbits by dislocating their necks with a violent blow with the extended thumb—nowadays seen as a skiing injury when the thumb gets stuck in the snow or the ski strap during a fall). On physical exam there is collateral laxity at the thumb-metacarpophalangeal joint, and if untreated it can be dysfunctional and painful, and lead to arthritis. Casting is usually effective.

Jersey finger is an injury to the flexor tendon sustained when the flexed finger is forcefully extended (as in someone unsuccessfully grabbing a running person by the jersey). When making a fist, the distal phalanx of the injured finger does not flex with the others.

Mallet finger is the opposite: the extended finger is forcefully flexed (a common volleyball injury), and the extensor tendon is ruptured. The tip of the affected finger remains flexed when the hand is extended, resembling a mallet. For both of these injuries, splinting is usually the first line of treatment.

Traumatically amputated digits are surgically reattached whenever possible. The amputated digit should be cleaned with sterile saline, wrapped in a saline-moistened gauze, placed in a sealed plastic bag, and the bag placed on a bed of ice. The digit should not be placed in antiseptic solutions or alcohol, should not be put on dry ice, and should not be allowed to freeze. With the use of electric nerve stimulation to preserve muscular function, entire amputated extremities can be reattached.

Back Pain

Lumbar disk herniation occurs most commonly at L4–L5 or L5–S1. Peak age incidence is the fourth decade of life.

- Patients often describe several months of vague aching pain (the "discogenic pain" produced by pressure on the anterior spinal ligament) before they have the sudden onset of the "neurogenic pain" precipitated by a forced movement.
- The latter is extremely severe, "like an electrical shock that shoots down the leg" (exiting on the side of the big toe in L4–L5, or the side of the little toe in L5–S1), and it is exacerbated by coughing, sneezing, or defecating (if the pain is not exacerbated by those activities, the problem is not a herniated disk). Patients cannot ambulate, and they hold the affected leg flexed.
- Straight leg-raising test reproduces excruciating pain and MRI confirms the diagnosis.
- Treatment for most patients is bed rest, physical therapy, and pain control, enhanced by a regional nerve block; surgical intervention is needed if neurologic deficits are progressing; emergency intervention is needed in the presence of the cauda equine syndrome (distended bladder, flaccid rectal sphincter, or perineal saddle anesthesia).

Figure I-2-9. Spine MRI Showing Lumbar Disc Herniation of L4-L5 Interspace

Ankylosing spondylitis is seen in men in the third and fourth decades of life who complain of chronic back pain and morning stiffness. The pain is worse at rest, and improves with activity. Symptoms are progressive, and x-rays reveal a "bamboo spine." Anti-inflammatory agents and physical therapy are effective. Many of these patients have the HLA B-27 antigen, which is also associated with uveitis and inflammatory bowel disease.

Metastatic malignancy should be suspected in the elderly who have progressive back pain that is worse at night and unrelieved by rest or positional changes. Weight loss is often an additional finding. The most common pathology is lytic breast cancer metastases in women and blastic prostate metastases in men. Most lesions are identifiable on x-ray, but MRI is a more sensitive diagnostic tool.

Leg Ulcers

Diabetic ulcer is typically indolent and located at pressure points (heel and metatarsal head). It starts because of the neuropathy, and does not heal because of the microvascular disease. It can sometimes heal with good blood glucose control and wound care, but often becomes chronic and sometimes leads to amputation due to osteomyelitis.

Figure I-2-10. Gross Appearance of a Large Diabetic Foot Ulcer

Ulcer from arterial insufficiency is usually as far away from the heart as it can be, i.e., at the tip of the toes. It looks dirty, with a pale base devoid of granulation tissue. The patient has other manifestations of arteriosclerotic occlusive disease (absent pulses, trophic changes, claudication, or rest pain). Workup begins with Doppler studies looking for a pressure gradient, though in the presence of microvascular disease this may not be present (and these lesions are less amenable to surgical therapy). Further evaluation with CT angiogram may be necessary, and ultimately, formal angiography leading to angioplasty, stenting, or surgical revascularization.

Venous stasis ulcer develops in chronically edematous, indurated, and hyperpigmented skin above the medial malleolus. The ulcer is painless, with granulating bed. The patient has varicose veins, and suffers from frequent bouts of cellulitis. Duplex scan is useful in the workup. Treatment revolves around physical support to keep the veins empty: support stockings, Ace bandages, and Unna boot. Surgery may be required (vein stripping, grafting of the ulcer, injection sclerotherapy); endovascular ablation with laser or radiofrequency may also be used.

wikipedia.org.

Figure I-2-11. Venous Stasis Ulcers

Marjolin's ulcer is a squamous cell carcinoma of the skin that has developed in a chronic leg ulcer. The classic setting is one of many years of healing and breaking down, such as seen in untreated third-degree burns that underwent spontaneous healing, or in chronic draining sinuses secondary to osteomyelitis. A dirty-looking, deeper ulcer develops at the site, with heaped up tissue growth around the edges. Biopsy is diagnostic. Treatment is wide local excision and skin grafting if necessary.

Foot Pain

Plantar fasciitis is a very common but poorly understood problem affecting older, overweight patients who complain of disabling, sharp heel pain every time their foot strikes the ground.

- The pain is worse in the mornings.
- X-rays show a bony spur matching the location of the pain, and physical exam shows exquisite tenderness to palpation over the spur, although the bony spur is not likely the cause of the problem as many asymptomatic people have similar spurs.
- Spontaneous resolution occurs over several months, during which time symptomatic treatment is offered.

Morton's neuroma is an inflammation of the common digital nerve at the third interspace, between the third and fourth toes. The neuroma is palpable and exquisitely tender to palpation. The cause is typically the use of pointed, high heel shoes (or pointed cowboy boots) that force the toes to be bunched together. Management includes analgesics and more sensible shoes, but surgical excision can be performed if conservative management fails.

Gout produces the typical swelling, redness, and exquisite pain of sudden onset at the first metatarsal-phalangeal joint in a middle-age obese man with high serum uric acid. Uric acid crystals are identified in fluid from the joint. Treatment for the acute attack is indomethacin and colchicine; treatment for chronic control is allopurinol and probenicid.

Figure I-2-12. Gross Appearance of Acute Gout

TUMORS

Children and Young Adults

Primary malignant bone tumors are diseases of young people. They present with persistent low-grade pain for several months.

- **Osteogenic sarcoma** is the most common primary malignant bone tumor.
  - It is seen in ages 10–25, usually around the knee (lower femur or upper tibia).
  - A typical "sunburst" pattern is often described on x-rays.
- **Ewing sarcoma** is the second most common.
  - It affects younger children (ages 5–15) and it grows in the diaphyses of long bones.
  - A typical "onion skinning"–type pattern is often seen on x-rays.

Adults

Most malignant bone tumors in adults are metastatic, from the breast in women (lytic lesions) and from the prostate in men (blastic lesions). Localized pain is an early finding. X-rays can be diagnostic, CT scans give more information, and MRI is even more sensitive. Lytic lesions commonly present as pathologic fractures.

- **Multiple myeloma** is seen in old men and presents with fatigue, anemia, and localized pain at specific places on several bones. X-rays are diagnostic, showing multiple, punched-out lytic lesions.
  - They also have Bence-Jones protein in the urine and abnormal immunoglobulins in the blood, best demonstrated by serum proptein electrophoresis (SPEP).
  - Treatment is chemotherapy; thalidomide can be used in the event that chemotherapy fails.
- **Soft tissue sarcoma** has relentless growth of soft tissue mass over several months. It is firm and typically fixed to surrounding structures.
  - It can metastasize hematogenously to the lungs but does not invade the lymphatic system.
  - MRI delineates the extent of the mass and invasion of local structures.
  - Incisional biopsy to obtain tissue is diagnostic.
  - Treatment includes wide local excision, radiation, and chemotherapy.

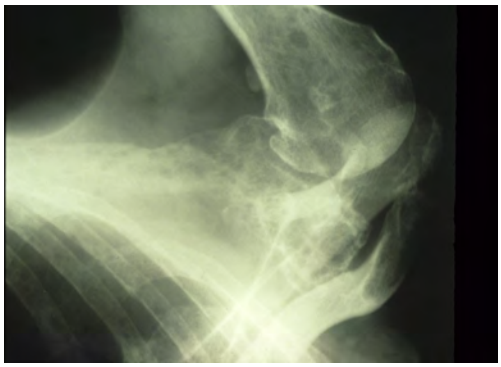

Figure I-2-13. Shoulder X-ray Showing Punched-out Lesions of Multiple Myeloma

Pre-Op and Post-Op Care 3

Learning Objectives

- ❑ List the appropriate steps in a preoperative assessment
- ❑ Recognize and describe the treatment approach to post-operative complications

PREOPERATIVE ASSESSMENT

Cardiac Risk

Ejection fraction <35% (normal 55%) poses prohibitive cardiac risk for elective non-cardiac operations. Incidence of peri-operative myocardial infarction (MI) could be as high as 75-85%, and mortality for such an event as high as 50–90%.

Goldman's index of cardiac risk assigns the following:

- 11 points to jugular venous distention (evidence of CHF)
- 10 points to recent MI (within 6 months)
- 7 points each to either premature ventricular contractions (≥5 per min) or a rhythm other than sinus rhythm
- 5 points to age >70
- 4 points to emergency nature of surgery
- 3 points each to either aortic valve stenosis, poor medical condition, or surgery within the chest or abdomen

The risk of life-threatening cardiac complications is only 1% with total score up to 5. The risk becomes 5% if the points total up to 12, increases to 11% with counts up to 25, and reaches 22% when the points >25.

Jugular venous distention, which indicates the presence of CHF, is the worst single finding predicting high cardiac risk. If at all possible, treatment with ACE inhibitors, beta-blockers, digitalis, and diuretics should precede surgery.

Recent MI is the next worse predictor of cardiac complications. Operative mortality within 3 months of the infarct is 40%, but drops to 6% after 6 months. Therefore delaying surgery longer than 6 months from MI is the best course of action. If surgery cannot be safely delayed, admission to the ICU before surgery is recommended to optimize cardiac performance.

Note

Do not memorize the specific percentages with respect to cardiac complications. Just get an idea of what contributes to cardiac risk.

Pulmonary Risk

Smoking is by far the most common cause of increased pulmonary risk, and the problem is compromised ventilation (high Pco_2, low forced expiratory volume in 1 second [FEV_1]), rather than compromised oxygenation. The smoking history, or the presence of chronic obstructive pulmonary disease (COPD), should lead to evaluation.

- Start with pulmonary function tests, and, if abnormal, obtain an arterial blood gas.
- Cessation of smoking for 8 weeks and intensive respiratory therapy (physical therapy, expectorants, incentive spirometry, humidified air) should precede surgery.

Hepatic Risk

Predictors of mortality are stratified by the Child-Pugh classification system. The contributing factors can be remembered as **A**scites, **B**ilirubin, **C**lotting (prothrombin time), **D**iet (serum albumin) and **E**ncephalopathy (presence/absence) predict surgical mortality as follows:

- **~40% mortality** is predictable with bilirubin >2 mg/dL, albumin <3 g/dL, prothrombin time >16 sec, or encephalopathy.
- **~80–85% mortality** is predictable if 3 of the above are present (close to 100% if all 4 exist), or with either bilirubin alone >4 mg/dL, albumin <2 g/dL, or blood ammonia concentration >150 mg/dl.

Nutritional Risk

Severe nutritional depletion is identified by one or more of the following:

- Loss of 20% of body weight over 6 months
- Serum albumin <3 g/dL
- Anergy to skin antigens
- Serum transferrin level <200 mg/dl

Operative risk is multiplied significantly in those circumstances. Surprisingly, as few as 4–5 days of preoperative nutritional support (preferably via the gut) can make a big difference, and 7–10 days would be optimal if the surgery can be deferred that long.

Metabolic Risk

Diabetic coma is an absolute contraindication to surgery. Rehydration, return of urinary output, and at least partial correction of the acidosis and hyperglycemia must be achieved before surgery.

POSTOPERATIVE COMPLICATIONS

Fever

Malignant hyperthermia develops shortly after the onset of the anesthetic (typically attributed to halothane or succinylcholine). Temperature >104°F and metabolic acidosis, hypercalcemia, and hyperkalemia also occur. A family history may exist. Treatment is IV dantrolene,

100% oxygen, correction of the acidosis, and cooling blankets. Monitor post-operatively for the development of myoglobinuria.

Bacteremia is seen within 30–45 minutes of invasive procedures (instrumentation of the urinary tract is a classic example), and presents as chills and a temperature spike as high as 104°F. Draw multiple sets of blood cultures and start empiric antibiotics.

Although rare, severe wound pain and very high fever within hours of surgery should alert you to the possibility of gas gangrene in the surgical wound. Immediately remove surgical dressings and examine the wound. Gas gangrene is not subtle, and should prompt immediate return to the OR for wound reopening and washout.

Postoperative fever 101–103° F is caused (sequentially in time) by atelectasis, pneumonia, UTI, deep venous thrombophlebitis, wound infection, or deep abscesses. ("Wind, water, walking, wound")

Atelectasis is the most common source of fever on the first post-operative day. Assess the risk for the other causes listed above, listen to the lungs, do a chest x-ray, improve ventilation (deep breathing and coughing, postural drainage, incentive spirometry), and perform a bronchoscopy if necessary.

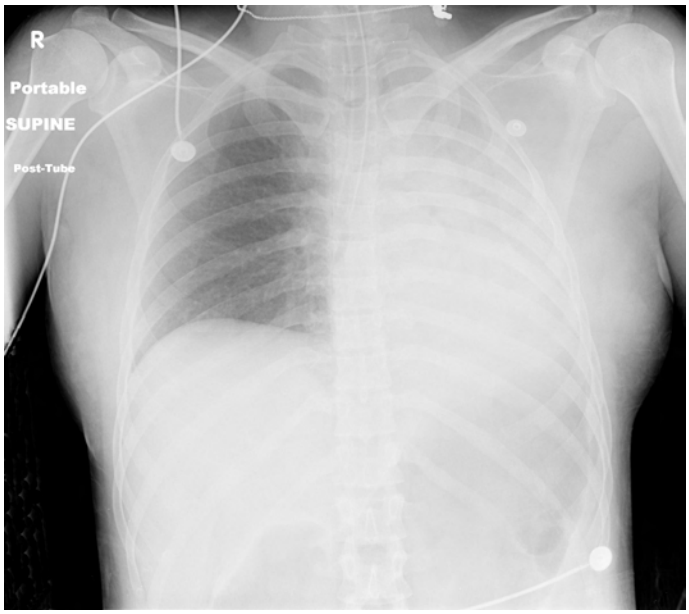

Figure I-3-1. Total Left Sided Ateltectasis

Pneumonia will happen in about 3 days if atelectasis is not resolved. Fever will persist, leukocytosis will be present, and chest x-ray will demonstrate an infiltrate(s). Obtain sputum cultures and treat with appropriate antibiotics.

UTI typically produces fever starting on post-operative day 3. Work up with a urinalysis and urinary cultures and treat with appropriate antibiotics.

Deep thrombophlebitis typically produces fever starting around post-operative day 5. Physical exam is not sensitive for this pathology, so obtain U/S with Doppler studies of the deep leg and pelvic veins. Treatment is systemic anticoagulation initially with heparin or unfractionated low molecular weight heparin and transitioned to a long term anticoagulant, typically Warfarin.

Wound infection typically begins to produce fever around post-operative day 7. Physical exam will reveal erythema, warmth, tenderness, and fluctuance.

- If only cellulitis is present, treat with antibiotics.
- If an abscess is present or suspected, the wound must be opened and drained.
- If it is unclear, use both U/S and CT scan to diagnose.

Deep abscesses (i.e. intra-peritoneal: subphrenic, pelvic, or subhepatic) start producing fever around post-operative days 10–15. CT scan of the appropriate body cavity is diagnostic. Percutaneous image-guided drainage is therapeutic.

Chest Pain

Perioperative myocardial infarction (MI) may occur during the operation (triggered most commonly by hypotension), in which case it is detected by the ECG monitor (ST depression, T-wave flattening). When it happens post-operatively, it is typically within the first 2–3 days, presenting as chest pain in one-third of patients and with the complications of the MI in the rest. The most reliable diagnostic test is serum troponin-I levels. Mortality is 50-90%and greatly exceeds that of MI not associated with surgery. Treatment is directed at the complications. Thrombolysis cannot be used in the peri-operative setting, but emergency angioplasty and coronary stenting can be life-saving.

Pulmonary Embolism

Pulmonary embolus (PE) typically occurs around post-operative day 7 in elderly and/or immobilized patients. The pain is pleuritic, sudden onset, and is accompanied by shortness of breath. The patient is anxious, diaphoretic, and tachycardic, with prominent distended veins in the neck and forehead (a low CVP virtually excludes the diagnosis). Arterial blood gases demonstrate hypoxemia and often hypocapnia. Diagnosis is with CT angiogram, which is a spiral CT with a large IV contrast bolus timed to pulmonary artery filling.

Treatment is systemic anticoagulation with heparin, and should be started immediately following diagnosis.

- In decompensating patients with a high index of suspicion, consider starting treatment even prior to confirming the diagnosis.
- If a PE recurs while anticoagulated or if anticoagulation is contraindicated, place an inferior vena cava (Greenfield) filter to prevent further embolization from lower extremity deep venous thromboses.

Prevention of thromboembolism will in turn prevent PE. Sequential compression devices should be used on anyone who does not have a lower extremity fracture or significant lower extremity arterial insufficiency. In moderate or high risk patients, prophylactic anticoagulation is indicated with lower dose heparin (typically 5000 units every 8-12 hours until mobile). Risk factors include age > 40, pelvic or leg fractures, venous injury, femoral venous catheter, and anticipated prolonged immobilization.

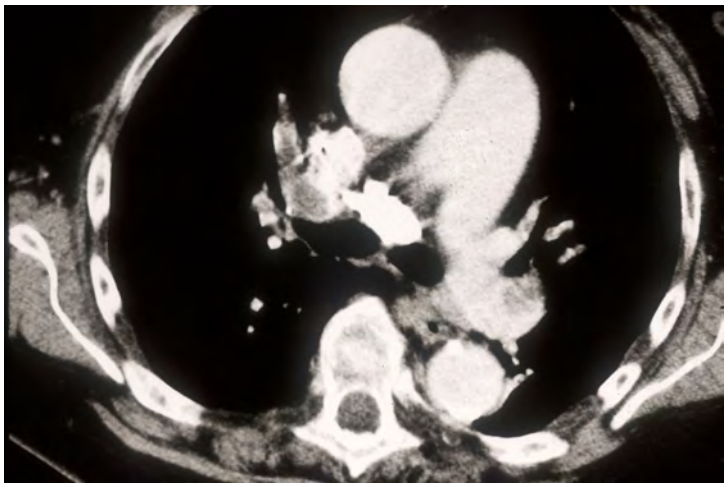

Figure I-3-2. Spiral CT of Chest Demonstrating Pulmonary Embolus

Other Pulmonary Complications

Aspiration is a distinct hazard in awake intubations in combative patients with a full stomach. It can be lethal right away or lead to a chemical injury of the tracheobronchial tree and subsequent pulmonary failure and/or pneumonia. Prevention includes strict restriction of oral intake prior to surgery and antacids before induction. Therapy starts with bronchoscopic lavage and removal of acid and particulate matter followed by bronchodilators and respiratory support. Steroids usually don't help and so are not necessarily indicated. Antibiotics are only indicated if a patient demonstrates evidence of the resultant pneumonia, i.e. leukocytosis, sputum production and culture, and focal consolidation on chest x-ray.

Intraoperative tension pneumothorax can develop in patients with traumatized lungs once they are subjected to positive-pressure breathing. They become progressively more difficult to ventilate with rising airway pressure, BP steadily declines, and CVP steadily rises. If the abdomen is open, quick decompression can be achieved through the diaphragm but this is not recommended. A better approach is to place a needle through the anterior chest wall into the pleural space. Formal chest tube has to be placed following acute decompression.

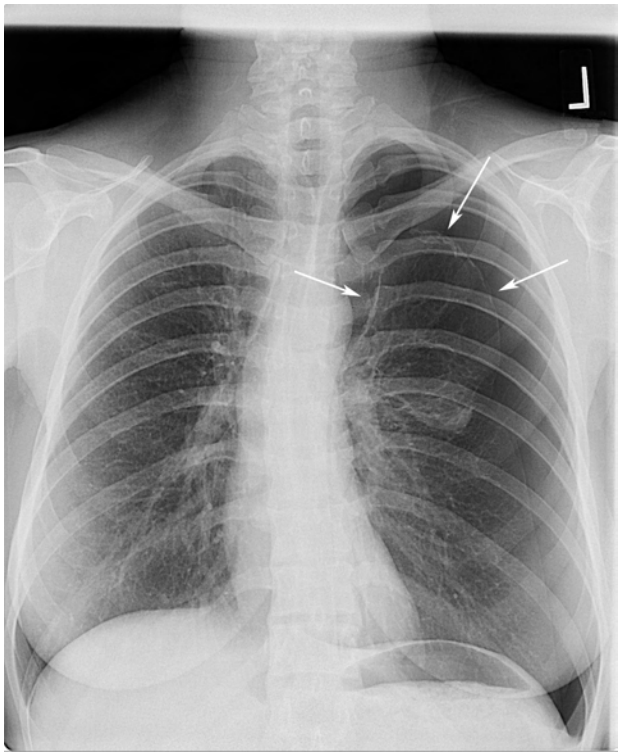

Figure I-3-3. Complete Left-sided Pneumothorax

Disorientation/Coma

Hypoxia is the first suspect when a post-operative patient becomes confused and disoriented. Sepsis is another prime cause. Check arterial blood gases and provide respiratory support if airway protection is threatened.

Adult respiratory distress syndrome (ARDS) is seen in patients with a complicated post-op course, often complicated by sepsis as the precipitating event. There are bilateral pulmonary infiltrates and hypoxia, with no evidence of CHF. The centerpiece of therapy is positive end-expiratory pressure (PEEP) with low volume ventilation as excessive ventilatory volumes have been demonstrated to result in barotrauma. A source of sepsis must be sought and corrected.

Delirium tremens (DTs) is very common in the alcoholic whose drinking is suddenly interrupted by surgery. During post-operative day 2 or 3, the patient gets confused, has hallucinations, and becomes combative. IV benzodiazepines are the standard therapy, but oral alcohol is available at most hospitals for this indication (less commonly used).

Acute hyponatremia can produce confusion, convulsions, and eventually coma and even death ("water intoxication"). This can be inadvertently induced by the liberal administration of sodium-free IV fluids (like D5W) in a postoperative patient with high levels of antidiuretic hormone (ADH; triggered by the response to trauma). Therapy, which includes hypertonic saline and osmotic diuretics, is controversial. Unfortunately mortality is high, especially in young women; the best management is prevention by including sodium in IV fluids.

Hypernatremia can also be a source of confusion, lethargy, and potentially coma, and rapidly induced by large, unreplaced water loss. Surgical damage to the posterior pituitary with unrecognized diabetes insipidus is a good example. Unrecognized osmotic diuresis can also do it. Rapid replacement of the fluid deficit is needed, but to "cushion" the impact on tonicity many prefer to use D5½ or D5⅓ normal saline (NS), rather than D5W.

Ammonium intoxication is a common source of coma in the cirrhotic patient with bleeding esophageal varices who undergoes a portocaval shunt.

Urinary Complications

Postoperative urinary retention is extremely common, particularly after surgery in the lower abdomen, pelvis, perineum, or groin. The patient feels the need to void, but cannot do it. Bladder catheterization should be performed 6-8 hours post-operatively if no spontaneous voiding has occurred. Indwelling (Foley) catheter placement is indicated at the second (some say third) consecutive catheterization.

Zero urinary output typically is caused by a mechanical problem, rather than a biologic one. Look for plugged or kinked catheter and flush the tubing to dislodge any clot that may have formed.

Low urinary output (<0.5 ml/kg/hr) in the presence of normal perfusing pressure (i.e., not because of shock) represents either fluid deficit or acute kidney injury.

- A low-tech diagnostic test is a fluid challenge: a bolus of 500 ml of IV fluid infused over 10 or 20 minutes. Dehydrated patients will respond with a temporary increase in urinary output, whereas those in renal failure will not do so.
- A more scientific test is to measure urinary sodium: it will be <10 or 20 mEq/L in the dehydrated patient with normally functional kidneys, while it will exceed 40 mEq/L in cases of renal failure.
- An even more scientific test is to calculate the fractional excretion of sodium, or FeNa. In order to calculate the FeNa, plasma and urinary sodium and creatinine must be measured. In acute kidney injury, the ratio >2; in hypovolemia it is <1.

Abdominal Distention

Paralytic ileus is to be expected in the first few days after abdominal surgery. Bowel sounds are absent or hypoactive and there is no passage of gas. There may be mild distension, but there is no pain. Paralytic ileus is prolonged by hypokalemia.

Early mechanical bowel obstruction because of adhesions can happen during the postoperative period. What was probably assumed to be paralytic ileus not resolving after 5-7 days is most likely an early mechanical bowel obstruction. X-rays will show dilated loops of small bowel and air-fluid levels. Diagnosis is confirmed with an abdominal CT scan that demonstrates a transition point between proximal dilated bowel and distal collapsed bowel at the site of the obstruction. Surgical intervention is needed to correct the problem.

Ogilvie syndrome or pseudo-obstruction is a poorly understood (but very common) condition that could be described as a "paralytic ileus of the colon."

- It does not follow abdominal surgery but is classically seen in elderly sedentary patients (Alzheimer, nursing home) who have become further immobilized owing to surgery elsewhere (broken hip, prostatic surgery).

- Patients develop abdominal distention without tenderness, and x-rays show a massively dilated colon.
- After fluid and electrolyte correction, it is imperative that mechanical obstruction be ruled out radiologically or by endoscopy, before giving IV neostigmine to restore colonic motility. A long rectal tube is also commonly used.
- This is a functional obstruction, not an anatomic one.

Wound

Wound infections are typically seen around post-operative day 7.

Wound dehiscence is typically seen around post-operative day 5 after open laparotomy. The wound looks intact, but large amounts of pink, "salmon-colored" fluid are noted to be soaking the dressing; this is peritoneal fluid. Reoperation is needed to avoid peritonitis and evisceration.

Evisceration is a catastrophic complication of wound dehiscence, where the skin itself opens up and the abdominal contents rush out. It typically happens when the patient (who may not have been recognized as having a dehiscence) coughs, strains, or gets out of bed. The patient must be kept in bed, and the bowel be covered with large sterile dressings soaked with warm saline. Emergency abdominal closure is required.

Fistula of the GI tract is recognized because bowel contents leak out through a wound or drain site. It may harm the patient in a number of ways.

- If it does not empty completely to the outside but leaks into a cavity which then leaks out, an abscess may develop and lead to sepsis; complete drainage is the required treatment.
- If it drains freely, sepsis is not encountered (patient is typically afebrile with no signs of peritoneal irritation) though there are 3 other potential problems:
  - Fluid and electrolyte loss
  - Nutritional depletion
  - Erosion and digestion of the abdominal wall
- These problems are related to location and volume of the fistula:
  - Nonexistent in the distal colon
  - Present but manageable in low-volume fistula (up to 200–300 ml/day)
  - Upper GI fistulas (stomach, duodenum, upper jejunum)
  - Daunting in high-volume (several liters per day) fistulas in upper GI tract
- Fluid and electrolyte replacement, nutritional support (preferably elemental diets delivered beyond the fistula), and compulsive protection of the abdominal wall (frequent dressing changes, suction tubes, "ostomy" bags) are done to keep the patient alive until nature heals the fistula. Nature will do so if none of the following are present to prevent wound healing (**mnemonic: FRIENDS**):
  - Foreign body
  - Radiation injury
  - Infection or inflammatory bowel disease
  - Epithelialization
  - Neoplasm
  - Use of steroids

Fluids and Electrolytes

Hypernatremia invariably means that the patient has lost water (or other hypotonic fluids) and has developed hypertonicity. Every 3 mEq/L that the serum sodium concentration is >140 represents roughly 1 L of water lost.

- If the problem happens slowly (i.e., over several days), the brain will adapt and the only clinical manifestations will be those of volume depletion.
- Treatment requires volume repletion, but done in such a way that volume is corrected rapidly (in a matter of hours) while tonicity is only gently "nudged" in the right direction (and goes back to normal in a matter of days). This is achieved by using D5½ NS rather than D5W.
- If the hypernatremia develops rapidly (i.e., in osmotic diuresis, or diabetes insipidus), it will produce CNS symptoms (the brain has not had time to adapt), and correction can be safely done with more diluted fluid (D5⅓ NS, or even D5W).

Hyponatremia means that water has been retained and hypotonicity has developed, but there are 2 different scenarios (easily distinguishable by the clinical circumstances).

- In one scenario, a patient who starts with normal fluid volume adds to it by retaining water because of the presence of inappropriate amounts of ADH (e.g., post-op water intoxication, or inappropriate ADH secreted by tumors).
- In the other scenario, a patient who is losing large amounts of isotonic fluids (typically from the GI tract) is forced to retain water if he has not received appropriate replacement with isotonic fluids.
- Rapidly developing hyponatremia (water intoxication) produces CNS symptoms (the brain has not had time to adapt), and requires careful use of hypertonic saline (3% or 5%).
- In slowly developing hyponatremia from inappropriate ADH, the brain has time to adapt, and therapy should be water restriction.
- In the case of the hypovolemic, dehydrated patient losing GI fluids and forced to retain water, volume restoration with isotonic fluids (NS or Lactated Ringer's) will provide prompt correction of the hypovolemia and allow the body to slowly and safely unload the retained water and return the tonicity to normal.

Hypokalemia develops slowly (over days) when potassium is lost from the GI tract (all GI fluids have lots of K), or in the urine (because of loop diuretics, or too much aldosterone), and it is not replaced. Hypokalemia develops very rapidly (over hours) when potassium moves into the cells, most notably when diabetic ketoacidosis is corrected. Therapy is obviously potassium replacement. Remember that the safe "speed limit" of IV potassium administration is 10 mEq/hr.

Hyperkalemia will occur slowly if the kidney cannot excrete potassium (renal failure, aldosterone antagonists), and it will occur rapidly if potassium is being dumped from the cells into the blood (crushing injuries, dead tissue, acidosis). The ultimate therapy for hyperkalemia is hemodialysis, but while waiting for it we can help by "pushing potassium into the cells" (50% dextrose and insulin), sucking it out of the GI tract (NG suction, exchange resins such as Kayexelate if the patient's bowels are working), or neutralizing its effect on the cellular membrane (IV calcium). The latter provides the quickest protection.

Metabolic acidosis can occur from any of the following:

- Excessive production of fixed acids (diabetic ketoacidosis, lactic acidosis, low-flow states)
- Loss of buffers (loss of bicarbonate-rich fluids from the GI tract)
- Inability of the kidney to eliminate fixed acids (renal failure)

In all 3 cases, blood pH is low (<7.4), serum bicarbonate is low (<25), and there is a base deficit. When abnormal acids are piling up in the blood, there is also an "anion gap" (serum sodium exceeds by >10 or 15 the sum of chloride and bicarbonate), which does not exist when the problem is loss of buffers.

Treatment in all cases must be directed at the underlying cause, though in all cases administration of bicarbonate (or bicarbonate precursors, like lactate or acetate) would temporarily help correct the pH. Bicarbonate therapy, however, is ideal only when the initial problem is bicarbonate loss (it corrects the pH and it addresses the underlying problem). In other cases it risks producing a "rebound alkalosis" once the underlying problem is corrected. Thus correction of the underlying problem—rather than bicarbonate administration—is the preferred therapy. In long-standing acidosis, renal loss of K leads to a deficit that does not become obvious until the acidosis is corrected. One must be prepared to replace K as part of the therapy of acidosis.

Metabolic alkalosis occurs from loss of acid gastric juice, or from excessive administration of bicarbonate (or precursors). There is a high blood pH (>7.4), high serum bicarbonate (>25), and a base excess. In most cases, an abundant intake of KCl (5–10 mEq/h) will allow the kidney to correct the problem. Only rarely is ammonium chloride or 0.1 N HCl needed.

Respiratory acidosis and alkalosis result from impaired ventilation (acidosis) or abnormal hyperventilation (alkalosis). They are recognized by abnormal PCO_2 (low in alkalosis, high in acidosis) in conjunction with the abnormal pH of the blood. Therapy must be directed at improving ventilation (in acidosis) or reducing it (in alkalosis).

General Surgery 4

Learning Objectives

- ❏ Demonstrate understanding of surgical diseases of the gastrointestinal and endocrine systems
- ❏ Explain surgical treatment approaches for diseases of the breast
- ❏ Answer questions about surgical hypertension

DISEASES OF THE GASTROINTESTINAL SYSTEM

Upper Gastrointestinal System

Esophagus

Gastroesophageal reflux may produce vague symptoms, difficult to distinguish from other sources of epigastric distress. When the diagnosis is uncertain, pH monitoring is best to establish the presence of reflux and its correlation with the symptoms. In more typical cases, an overweight individual complains of burning retrosternal pain and "heartburn" that is brought about by bending over, wearing tight clothing, or lying flat in bed at night; and relieved by the ingestion of antacids or over-the-counter H2 blockers. If there is a long-standing history, the concern is the damage that might have been done to the lower esophagus (peptic esophagitis) and the possible development of Barrett's esophagus. In that setting, endoscopy and biopsies are the indicated tests as Barrett's is a precursor to malignancy.

Surgery for gastroesophageal reflux is:

- Appropriate in long-standing symptomatic disease that cannot be controlled by medical means (using laparoscopic Nissen fundoplication)
- Necessary when complications have developed (ulceration, stenosis) (using laparoscopic Nissen fundoplication)
- Imperative if there are severe dysplastic changes (resection is needed)

Motility problems have recognizable clinical patterns, such as crushing pain with swallowing in uncoordinated massive contraction; or the suggestive pattern of dysphagia seen in achalasia, where solids are swallowed with less difficulty than liquids. Manometry studies are used for the definitive diagnosis. Barium swallow is typically done first to evaluate for an obstructing lesion.

Achalasia is seen more commonly in women. There is dysphagia that is worse for liquids; the patient eventually learns that sitting up straight and waiting allows the weight of the column

of liquid to overcome the sphincter. There is occasional regurgitation of undigested food. X-rays show megaesophagus. Manometry is diagnostic. The most appealing current treatment is balloon dilatation done by endoscopy, however recurrence is high and many patients ultimately require an esophagomyotomy (Heller).

Cancer of the esophagus shows the classic progression of dysphagia starting with meat, then other solids, then soft foods, eventually liquids, and finally (in several months) saliva. Significant weight loss is always seen. Squamous cell carcinoma is seen in men with a history of smoking and drinking. Adenocarcinoma is seen in people with long-standing gastroesophageal reflux. Diagnosis is established by endoscopy and biopsy. Endoscopic U/S and CT/PET scan are used to assess local and lymph node involvement and therefore operability, but most cases present late and therefore are inoperable.

Mallory-Weiss tear is a mucosal laceration typically at the junction of the esophagus and stomach. It occurs after prolonged, forceful vomiting and presents with bright red hematemesis. Endoscopy establishes diagnosis, and allows treatment with endoscopic clipping or coagulation.

Boerhaave's syndrome also results from prolonged, forceful vomiting but leads to esophageal perforation. There is continuous, severe, wrenching epigastric and low sternal pain of sudden onset, soon followed by fever, leukocytosis, and a very sick-looking patient. Contrast swallow (Gastrografin) is diagnostic, and emergency surgical repair should follow. Delay in diagnosis and treatment has grave consequences due to the morbidity of mediastinitis.

Instrumental perforation of the esophagus is by far the most common reason for esophageal perforation. Shortly after completion of endoscopy, symptoms as described above will develop. There may be emphysema in the lower neck (virtually diagnostic in this setting). Contrast studies and prompt repair are imperative.

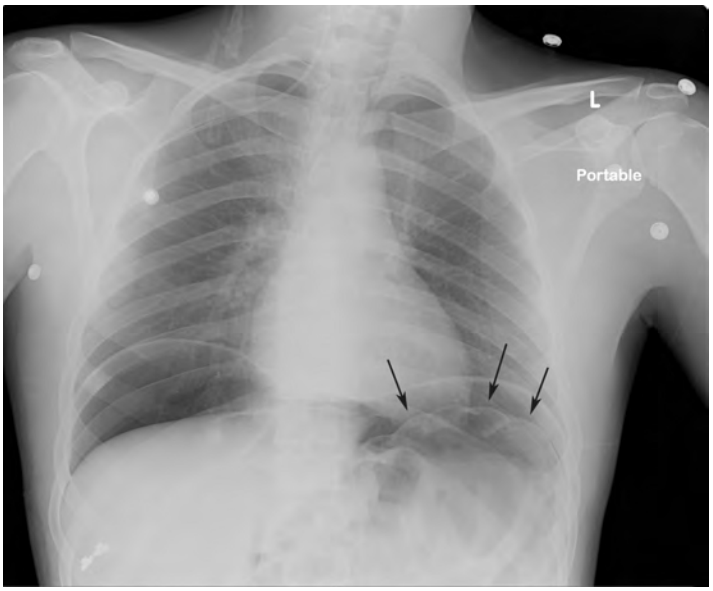

Figure I-4-1. Upright Chest X-ray Demonstrating Free Air under the Diaphragm due to Colonic Perforation during Endoscopy

Stomach

Gastric adenocarcinoma is more common in the elderly. Symptoms include:

- Anorexia
- Weight loss
- Vague epigastric distress or early satiety
- Occasional hematemesis

Endoscopy and biopsies are diagnostic. CT scan helps assess operability. Surgery is the best therapy.

Gastric lymphoma is almost as common as gastric adenocarcinoma. Presentation and diagnosis are similar, but treatment is chemotherapy. Surgery is only indicated if perforation is feared as the tumor melts away. Low-grade lymphomatoid transformation (MALTOMA) can be reversed by eradication of *H. pylori*.

Mid and Lower Gastrointestinal System

Small bowel and appendix

Mechanical intestinal obstruction is typically caused by adhesions in those who have had a prior laparotomy. There is colicky abdominal pain and protracted vomiting, progressive abdominal distention (if it is a low obstruction), and no passage of gas or feces. Early on, high-pitched bowel sounds coincide with the colicky pain (after a few days there is silence). X-rays show distended loops of small bowel, with air-fluid levels. Treatment starts with NPO, NG suction, and IV fluids, hoping for spontaneous resolution, while watching for early signs of strangulation. Surgery is done if conservative management is unsuccessful, within 24 hours in cases of complete obstruction or within a few days in cases of partial obstruction.

Strangulated obstruction occurs due to compromised blood supply leading to bowel ischemia. It starts as described above, but eventually the patient develops fever, leukocytosis, constant pain, signs of peritoneal irritation, and ultimately full-blown peritonitis and sepsis. Emergency surgery is required.

Mechanical intestinal obstruction caused by an incarcerated hernia has the same clinical picture and potential for strangulation as described above, but the physical exam shows the irreducible hernia that used to be reducible. Because we can effectively eliminate the hernia (we cannot effectively eliminate adhesions), all of these undergo surgical repair, but the timing varies: emergently after proper rehydration in those who appear to be strangulated; electively in those who can be reduced manually and have viable bowel.

Carcinoid syndrome is seen in patients with a small bowel carcinoid tumor with liver metastases. It includes diarrhea, flushing of the face, wheezing, and right-sided heart valvular damage (look for prominent jugular venous pulse). Diagnosis is made with 24-hour urinary collection for 5-hydroxyindolacetic acid.

(Hint: Whenever syndromes produce episodic attacks or spells, the offending agent will be at high concentrations in the blood only at the time of the attack. A blood sample taken afterward will be normal. Thus, a 24-hour urinary collection is more likely to provide the diagnosis.)

The **classic picture of acute appendicitis** begins with anorexia, followed by:

- Vague periumbilical pain that several hours later becomes sharp, severe, constant, and localized to the right lower quadrant of the abdomen
- Tenderness, guarding, and rebound found to the right and below the umbilicus (not elsewhere in the belly)
- Modest fever and leukocytosis in the 10,000–15,000 range, with neutrophilia and immature forms

Emergency appendectomy is the indicated treatment.

Doubtful presentations that could be acute appendicitis include those that do not have all the classic findings described above. CT scan has become the standard diagnostic modality for those cases.

Colon

Cancer of the right colon typically presents with anemia (hypochromic, iron deficiency) in the right age group (age 50–70). Stools will be 4+ for occult blood. Colonoscopy and biopsies are diagnostic; surgery (right hemicolectomy) is treatment of choice.

Cancer of the left colon typically presents with bloody bowel movements and obstruction. Blood coats the outside of the stool, there may be constipation, stools may have narrow caliber. Flexible proctosigmoidoscopic exam (45 or 60 cm) and biopsies are usually the first diagnostic study. Before surgery is done, full colonoscopy is needed to rule out a synchronous second primary lesion more proximally. CT scan helps assess operability and extent.

Colonic polyps may be premalignant. In descending order of probability for malignant degeneration are familial polyposis (and variants such as Gardner's), familial multiple inflammatory polyps, villous adenoma, and adenomatous polyp. Polyps that are not premalignant include juvenile, Peutz-Jeghers, isolated inflammatory, and hyperplastic.

Chronic ulcerative colitis (CUC) is managed medically. Surgical indications include disease present >20 years (high incidence of malignant degeneration), severe interference with nutritional status, multiple hospitalizations, need for high-dose steroids or immunosuppressants, or development of toxic megacolon (abdominal pain, fever, leukocytosis, epigastric tenderness, massively distended transverse colon on x-rays, with gas within the wall of the colon). Definitive surgical treatment of CUC requires removal of affected colon, including all of the rectal mucosa (which is always involved).

Pseudomembranous enterocolitis is caused by overgrowth of *Clostridium difficile* in patients who have been on antibiotics. Any antibiotic can do it. Clindamycin was the first one described, and, currently, Cephalosporins are the most common cause. There is profuse, watery diarrhea, crampy abdominal pain, fever, and leukocytosis. Diagnosis is best made by identifying the toxin in the stool. Stool cultures take too long, and the pseudomembranes are not always seen on endoscopy. The culpable antibiotic should be discontinued, and no antidiarrheals should be used. Metronidazole is the treatment of choice (oral or IV), with vancomycin (oral) an alternative. A virulent form of the disease, unresponsive to treatment, with WBC >50,000/μL and serum lactate above 5mg/dL, requires emergency colectomy.

Anorectal Disease

In **all anorectal disease, cancer should be ruled out** by proper physical exam (including proctosigmoidoscopic exam), even though the clinical presentation may suggest a specific benign process.

Hemorrhoids typically bleed when they are internal (can be treated with rubber band ligation), or hurt when they are external (may need surgery if conservative treatment fails). Internal hemorrhoids can become painful and produce itching if they are prolapsed.

Anal fissure happens to young women. There is exquisite pain with defecation and blood streaks covering the stools. The fear of pain is so intense that patients avoid bowel movements (and get constipated) and may even refuse proper physical examination of the area. Examination may need to be done under anesthesia (the fissure is usually posterior, in the midline). A tight sphincter is believed to cause and perpetuate the problem, thus therapy is directed at relaxing it: stool softeners, topical nitroglycerin, local injection of botulinum toxin, steroid suppositories, or lateral internal sphincterotomy. Calcium channel blockers such as diltiazem ointment 2% TID topically for 6 weeks have had an 80-90% success rate, as compared to only 50% success for botulinum toxin.

Crohn's disease often affects the anal area. It starts with a fissure, fistula, or small ulceration, but the diagnosis should be suspected when the area fails to heal and gets worse after surgical intervention (the anal area typically heals very well because it has excellent blood supply—failure to do so should suggest Crohn's disease). Surgery, in fact, should *not be done* in Crohn's disease of the anus. A fistula, if present, could be drained with setons while medical therapy is underway. Remicade helps healing.

Ischiorectal abscess (perirectal abscess) is very common. The patient is febrile, with exquisite perirectal pain that does not let him sit down or have bowel movements. Physical exam shows all the classic findings of an abscess (rubor, dolor, calor, and fluctuance) lateral to the anus, between the rectum and the ischial tuberosity. Incision and drainage are needed, and cancer should be ruled out by proper examination during the procedure. If patient is a poorly-controlled diabetic, necrotizing soft tissue infection may follow; significant monitoring is mandatory.

Fistula-in-ano develops in some patients who have had an ischiorectal abscess drained. Epithelial migration from the anal crypts (where the abscess originated) and from the perineal skin (where the drainage was done) form a permanent tract. Patient reports fecal soiling and occasional perineal discomfort. Physical exam shows opening (or openings) lateral to the anus, a cordlike tract may be felt, and discharge may be expressed. Rule out necrotic and draining tumor, and treat with fistulotomy.

Squamous cell carcinoma of the anus is more common in HIV, and in patients with receptive sexual practices. A fungating mass grows out of the anus, metastatic inguinal nodes are often felt. Diagnose is with biopsy. Treatment starts with the Nigro chemoradiation protocol, followed by surgery if there is residual tumor. Currently the 5-week chemo-radiation protocol has a 90% success rate, so surgery is not commonly required.

Gastrointestinal Bleeding

General statistics of GI bleeding show that 3 of 4 cases originate in the upper GI tract (from the tip of the nose to the ligament of Treitz). One of 4 originates in the colon or rectum, and very few arise from the jejunum and ileum. GI bleeding arising from the colon comes from angiodysplasia, polyps, diverticulosis, or cancer, all of which are diseases of older people. Even hemorrhoids become more common with age. Therefore:

- When a young patient presents with GI bleed, the odds are overwhelming that it comes from the upper GI tract.
- When an older patient presents with GI bleed, it could be from anywhere (an "equal opportunity bleeder"), as the upper GI is the most common source overall (3/4), but age makes that old patient a good candidate for lower GI bleeding.

Vomiting blood always denotes a source in the upper GI tract. The same is true when blood is recovered by a NG tube in a patient who presents with bleeding per rectum. The best next diagnostic test in that setting is upper GI endoscopy. Be sure to look at the mouth and nose first.

Similarly, melena (black, tarry stool) always indicates digested blood, thus it must originate high enough to undergo digestion. Start workup with upper GI endoscopy.

Red blood per rectum could come from anywhere in the GI tract (including upper GI, as it may have transited too fast to be digested). The first diagnostic maneuver if the patient is actively bleeding at the time is to pass an NG tube and aspirate gastric contents. If blood is retrieved, an upper source has been established (follow with upper endoscopy as above). If no blood is retrieved and the fluid is white (no bile), the territory from the tip of the nose to the pylorus has been excluded, but the duodenum is still a potential source and upper GI endoscopy is still necessary. If no blood is recovered and the fluid is green (bile tinged), the entire upper GI (tip of the nose to ligament of Treitz) has been excluded, and there is no need for an upper GI endoscopy.

Active bleeding per rectum, when upper GI has been excluded, is more difficult to work up. Bleeding hemorrhoids should always be excluded first by physical exam and anoscopy. Colonoscopy is not helpful during an active bleed as blood obscures the field. Once hemorrhoids have been excluded, management is based on rate of bleeding.

- If the bleeding >2 mL/min (1 unit of blood every 4 hours), an angiogram is useful as it has a very good chance of finding the source and may allow for angiographic embolization.
- If the bleeding is slower, i.e. <0.5 mL/min, wait until the bleeding stops and then do a colonoscopy.
- For bleeding in between, do a tagged red-cell study
  - If the tagged blood collects somewhere indicating a site of bleeding, an angiogram may be productive.
    - The curse of the tagged red-cell study is that it is a slow test, and by the time it is finished, the patient is often no longer bleeding and the subsequent angiogram is useless. In that case, at least there is some degree of localization of bleeding to indicate which side of the colon to resect if the patient rebleeds or emergently begins to exsanguinate.
  - If the tagged red cells do not show up on the scan, a subsequent colonoscopy is planned. Some practitioners always begin with the tagged red-cell study, regardless of the estimated rate of bleeding.

With increasing frequency in clinical practice, when bleeding is not found to be in the colon, capsule endoscopy is done to localize the spot in the small bowel. Of course this is done only when the patient is stable and upper and lower GI sources have been ruled out.

Patients with a recent history of blood per rectum, but not actively bleeding at the time of presentation, should start workup with upper GI endoscopy if they are young (overwhelming odds); but if they are old they need both an upper and a lower GI endoscopy (typically performed during the same session).

Blood per rectum in a child is most commonly a Meckel's diverticulum; start workup with a technetium scan looking for the ectopic gastric mucosa in the distal ileum.

Massive upper GI bleeding in the stressed, multiple trauma, or complicated post-op patient is probably from stress ulcers. Endoscopy will confirm. Angiographic embolization is the best therapeutic option. Better yet, they should be avoided by maintaining the gastric pH above 4 with prophylactic H2 blockers or proton pump inhibitors, which is now commonly done in the ICU setting.

Acute Abdomen

Acute abdominal pain can be caused by perforation, obstruction, or inflammatory/ischemic processes. Each of these groups has some common identifying characteristics.

- Acute abdominal pain caused by **perforation** has sudden onset and is constant, generalized, and very severe. The patient is reluctant to move, and very protective of his abdomen. Except in the very old or very sick, impressive generalized signs of peritoneal irritation are found: tenderness, muscle guarding, rebound, and lack of bowel sounds. Free air under the diaphragm on upright x-rays confirms the diagnosis. Perforated peptic ulcer is the most common example. Emergency surgery is indicated.
- Acute abdominal pain caused by **obstruction** of a narrow duct (ureter, cystic, or common bile) has sudden onset of colicky pain, with typical location and radiation according to source. The patient moves constantly, seeking a position of comfort. There are few physical findings, and they are limited to the area where the process is occurring.
- Acute abdominal pain caused by **inflammatory process** has gradual onset and slow buildup (at the very least a couple of hours, more commonly 6-12 hours). It is constant, starts as ill-defined and eventually localizes to the site of pathology, and often has typical radiation patterns. There are physical findings of peritoneal irritation in the affected area, and (except for pancreatitis) systemic signs such as fever and leukocytosis.

Ischemic processes affecting the bowel are the only ones that combine severe abdominal pain with blood in the lumen of the gut.

Spotaneous bacterial peritonitis (SBP) should be suspected in the child with nephrosis and ascites, or the adult with ascites who has a "mild" generalized acute abdomen with equivocal physical findings, and perhaps some fever and leukocytosis. Cultures of the ascitic fluid will yield a single organism (in garden-variety acute abdomens, a multiplicity of organisms grow). Treat with antibiotics, not with surgery.

Treatment for a generalized acute abdomen is exploratory laparotomy, with no need to have a specific diagnosis as to the exact nature of the process. With the exception of patients in whom SBP is suspected, other etiologies that mimic an acute abdomen must be ruled out

before proceeding to exploration. These include myocardial ischemia (obtain an ECG), lower lobe pneumonia (perform a chest x-ray), PE (suspect in an immobilized patient), and abdominal processes that do not require surgical exploration, such as pancreatitis (check serum amylase and lipase) and urinary stones (perform a non-contrast CT scan of abdomen).

Acute pancreatitis should be suspected in the alcoholic who develops an "upper" acute abdomen. The classic picture has rapid onset for an inflammatory process (a few of hours), and the pain is constant, epigastric, radiating straight through to the back, with nausea, vomiting, and retching. Physical findings are relatively modest, found in the upper abdomen. Diagnose with serum amylase and lipase, CT if diagnosis is not clear. Treat with NPO, NG suction, IV fluids. (More details in pancreatic disease section.)

Biliary tract disease should be suspected in the obese multiparrous female patient ages 30-50 ("fat, female, forty, fertile") who presents with right upper quadrant abdominal pain.

Ureteral stones produce sudden onset colicky flank pain radiating to inner thigh and scrotum or labia, sometimes with urinary symptoms like urgency and frequency; and with microhematuria discovered on urinalysis. Non-contrast CT scan is the best diagnostic test.

Acute diverticulitis is one of the very few inflammatory processes giving acute abdominal pain in the left lower quadrant (in women, the fallopian tube and ovary are other potential sources).

- Patients are typically middle-aged and present with fever, leukocytosis, physical findings of peritoneal irritation in the left lower quadrant, occasionally with a palpable tender mass.
- CT scan with oral and IV contrast is diagnostic.
- Treatment is NPO, IV fluids, and antibiotics.
- Most will cool down.
- Emergency surgery is needed for those who do not demonstrate evidence of free perforation of fistulization (most often to the bladder, presenting with pneumaturia).
- Radiologically guided percutaneous drainage of an abscess may be helpful and help prevent emergent surgical resection but if successful, usually will require elective resection.
- Colonoscopy is indicated around 6 weeks after an episode of diverticulitis to rule out an underlying malignancy (endoscopy earlier in the presence of active inflammation increases the likelihood of perforation and decreases the diagnostic sensitivity).
- Elective resection of the involved colon is indicated for those who have had complications, multiple attacks, or continuing discomfort.

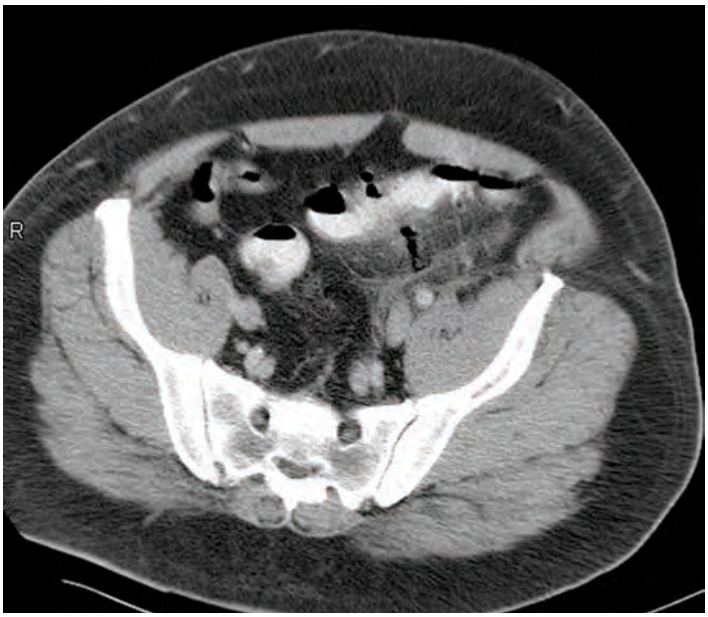

Figure I-4-2. Abdominal CT scan of 56-year-old Man with Acute Diverticulitis of Sigmoid Colon

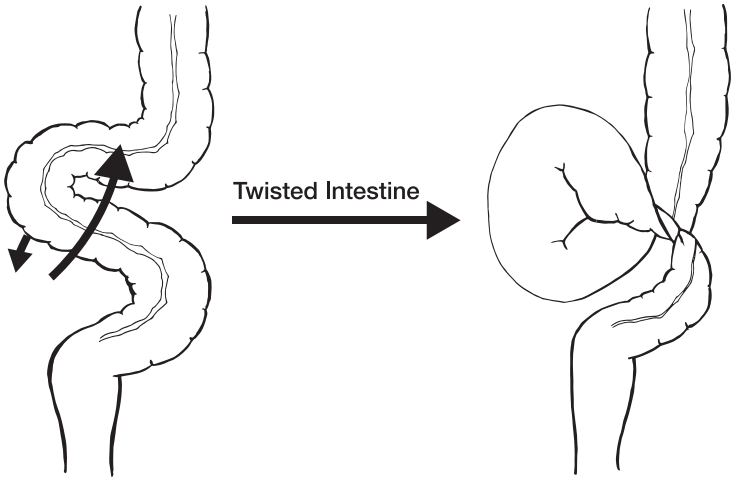
Volvulus of the sigmoid is seen in older patients. It presents with signs of intestinal obstruction and severe abdominal distention. X-rays are diagnostic, as they show air-fluid levels in the small bowel, very distended colon, and a huge air-filled loop in the right upper quadrant that tapers down toward the left lower quadrant with the shape of a "parrot's beak."



Proctosigmoidoscopic exam resolves the acute problem and asses for mucosal ischemia; leaving a rectal tube allows for complete decompression and prevents immediate recurrence. Recurrent cases need elective sigmoid resection.

Mesenteric ischemia is also seen predominantly in the elderly, but the real key is the development of an acute abdomen in someone with atrial fibrillation or a recent MI (the source of the clot that breaks off and lodges in the superior mesenteric artery). Because the very old do not mount impressive acute abdomens, often the diagnosis is made late, when there is blood in the bowel lumen (the only condition that mixes acute pain with GI bleeding), and lactic acidosis and sepsis have developed. In very early cases, arteriogram and embolectomy might save the day, whereas once bowel ischemia is present, surgical resection is mandatory.

Hepatobiliary

Liver

Primary hepatoma (hepatocellular carcinoma) is seen in the United States in patients with cirrhosis. Patients develop vague right upper quadrant discomfort and weight loss. The specific blood marker is α-fetoprotein (AFP). CT scan will show location and extent. Resection is done if technically possible.

Metastatic cancer to the liver outnumbers primary cancer of the liver in the United States by 20:1. It is found by CT scan if follow-up for the treated primary tumor is under way, or suspected because of rising carcinoembryonic antigen (CEA) in those who had colonic cancer. If the primary is slow growing and the metastases are confined to one lobe, resection can be done. Other means of control include radiofrequency ablation (RFA).

Hepatic adenoma may arise as a complication of birth control pills, and is important because it has a tendency to rupture and bleed massively inside the abdomen. CT scan is diagnostic. If symptomatic, oral contraceptives should be stopped immediately; emergency surgery is required for patients presenting with signs of rupture and massive hemorrhage. Patients may not resume birth control pills.

Pyogenic liver abscess is seen most often as a complication of biliary tract disease, particularly acute ascending cholangitis. Patients develop fever, leukocytosis, and a tender liver. Sonogram or CT scan are diagnostic. Percutaneous drainage is required.

Amebic abscess of the liver favors men, all of whom have a "Mexico connection." (It is very common there, and seen in the U.S in immigrants.) Presentation and imaging diagnosis are similar to pyogenic liver abscesses, but can be treated with Metronidazole and rarely require drainage. Definitive diagnosis is maden by serology (the ameba does not grow in the pus), but because the test takes weeks to be reported, empiric treatment is started in those clinically suspected. If they improve, it is continued; if not, drainage is indicated.

Jaundice

Jaundice may be hemolytic, hepatocellular, or obstructive.

- **Hemolytic** jaundice is usually low level (bilirubin of 6-8 mg/dL, but not 35 or 40), and all the elevated bilirubin is unconjugated (indirect), with no elevation of the conjugated (direct) fraction. There is no bile in the urine. Workup should determine what is chewing up the red cells.
- **Hepatocellular** jaundice has elevation of both fractions of bilirubin, and very high levels of transaminases with only a modest elevation of the alkaline phosphatase. Hepatitis is the most common example, and workup should proceed in that direction (serologies to determine specific type).

- **Obstructive** jaundice has elevations of both fractions of bilirubin, modest elevation of transaminases, and very high levels of alkaline phosphatase. The first step in the workup is an U/S looking for dilatation of the biliary ducts, as well as further clues as to the nature of the obstructive process. In obstruction caused by stones, the stone that is obstructing the common duct is seldom seen, but stones are seen in the gallbladder, which because of chronic irritation cannot dilate. In malignant obstruction, a large, thin-walled, distended gallbladder is often identified (Courvoisier-Terrier sign).
  - Obstructive jaundice caused by **stones** should be suspected in the obese, fecund woman in her forties, who has high alkaline phosphatase, dilated ducts on sonogram, and nondilated gallbladder full of stones. The next step in that case is an endoscopic retrograde cholangiopancreatography (ERCP) to confirm the diagnosis, perform a sphincterotomy, and remove the common duct stone. Cholecystectomy should usually follow during the same hospitalization.
  - Obstructive jaundice caused by a **tumor** could be caused by adenocarcinoma of the head of the pancreas, adenocarcinoma of the ampulla of Vater, or cholangiocarcinoma arising in the common duct itself.
    - Once a tumor has been suspected by the presence of dilated gallbladder in the sonogram, the next test should be CT scan. Pancreatic cancers that have produced obstructive jaundice are often big enough to be seen on CT. If the CT is negative, ERCP is the next step.
    - Ampullary cancers or cancers of the common duct by virtue of their strategic location produce obstruction when they are still very small, and therefore may not be seen on CT, but endoscopy will show ampullary cancers and the cholangiography will show intrinsic tumors arising from the duct (apple core) or small pancreatic cancers.
    - The recent advent of endoscopic U/S has given us another diagnostic pathway to locate and biopsy these tumors. Percutaneous biopsy is not indicated to avoid seeding the abdominal wall with tumor; if cancer is suspected and a tumor is identified on CT or ERCP, it should be resected if no contraindications are present (i.e. evidence of metastatic disease).

Ampullary cancer should be suspected when malignant obstructive jaundice coincides with anemia and positive blood in the stools.

- Can bleed into the lumen like any other mucosal malignancy, at the same time that it can obstruct biliary flow by virtue of its location.
- Given that combination, endoscopy should be the first test.

Pancreatic cancer is seldom cured, even when resectable by the Whipple operation (pancreatoduodenectomy).

Ampullary cancer and cancer of the lower end of the common duct have a much better prognosis (about 40% cure).

Gallbladder

Gallstones are responsible for the vast majority of biliary tract pathology. There is a spectrum of biliary disease caused by gallstones, as noted below. Although the obese woman in her forties is the "textbook" victim, incidence increases with age so that eventually they are common across all ethnic groups. Asymptomatic gallstones are left alone.

Figure I-4-3. Gallstones Noted on CT Scan of Abdomen

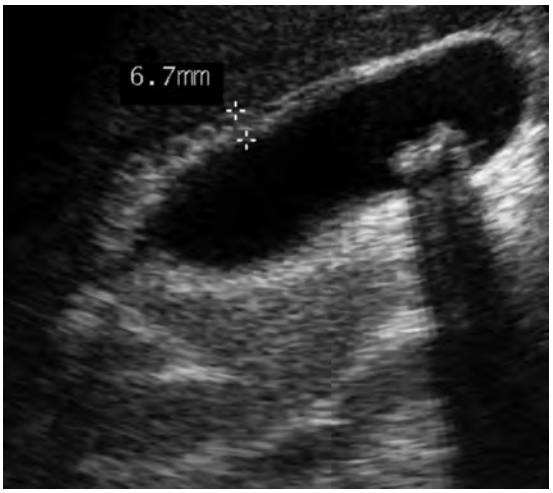


Figure I-4-4. Gallstones and a Thickened Gallbladder Wall Noted on U/S

Biliary colic occurs when a stone temporarily occludes the cystic duct. This causes colicky pain in the right upper quadrant radiating to the right shoulder and back, often triggered by ingestion of fatty food, accompanied by nausea and vomiting, but without signs of peritoneal irritation or systemic signs of inflammatory process. The episode is self-limited (10, 20, maybe 30 minutes), or easily aborted by anticholinergics. U/S establishes diagnosis of gallstones and elective laparoscopic cholecystectomy is indicated.

Acute cholecystitis starts as a biliary colic, but the stone remains at the cystic duct until an inflammatory process develops in the obstructed gallbladder.

- Pain becomes constant, there is modest fever and leukocytosis, and there are physical findings of peritoneal irritation in the right upper quadrant.
- Liver function tests are minimally affected.
- U/S is diagnostic in most cases (gallstones, thick-walled gallbladder, and pericholecystic fluid).
- In equivocal cases, a radionuclide scan (HIDA) might be needed, and would show tracer uptake in the liver, common duct, and duodenum, but not in the occluded gallbladder.
- NPO, IV fluids, and antibiotics "cool down" most cases, allowing elective laparoscopic cholecystectomy to follow.
- Physicians typically endeavor to do it in the same hospital admission, as an urgent case, though it is not a "middle of the night" true emergency.
- If the patient doesn't respond (men and diabetics often do not), emergency cholecystectomy will be needed. Emergency percutaneous cholecystostomy may be the best temporizing option in the very sick with a prohibitive surgical risk.

Acute ascending cholangitis is a far more deadly disease, in which stones have reached the common duct producing partial obstruction and ascending infection.

- Patients are often older and much sicker.
- Temperature spikes to 104–105°F, with chills, and very high white blood cell count indicating sepsis.
- There is some hyperbilirubinemia but the key finding is extremely high levels of alkaline phosphatase.
- Charcot's triad is the presence of fever, jaundice, and right upper quadrant pain and is suggestive of ascending cholangitis; Reynolds pentad is those 3 symptoms plus altered mental status and evidence of sepsis (most commonly, hypotension), which further suggests the diagnosis.
- IV antibiotics and emergency decompression of the common duct is lifesaving; this is performed ideally by ERCP, alternatively percutaneous through the liver by percutaneous transhepatic cholangiogram (PTC), or rarely by surgery.
- Eventually cholecystectomy has to be performed.

Obstructive jaundice without ascending cholangitis can occur when stones produce complete biliary obstruction, rather than partial obstruction. Presentation and management were detailed in the jaundice section.

Biliary pancreatitis is seen when stones become impacted distally in the ampulla, temporarily obstructing both pancreatic and biliary ducts. The stones often pass spontaneously, producing a mild and transitory episode of cholangitis along with the classic manifestations of pancreatitis (elevated amylase or lipase). U/S confirms gallstones in the gallbladder. Medical management (NPO, NG suction, IV fluids) usually leads to improvement, allowing elective cholecystectomy to be done later. If not, ERCP and sphincterotomy may be required to dislodge the impacted stone.

Pancreas

Acute pancreatitis is seen as a complication of gallstones (as described above), or in alcoholics. Acute pancreatitis may be edematous, hemorrhagic, or suppurative (pancreatic abscess). Late complications include pancreatic pseudocyst and chronic pancreatitis.

Reproduced with permission from VGHTC, Gastroenterology Section.

Figure I-4-5. Grey-Turner Sign Can Be seen in Acute Pancreatitis

Acute edematous pancreatitis occurs in the alcoholic or the patient with gallstones. Epigastric and midabdominal pain starts after a heavy meal or bout of alcoholic intake, is constant, radiates straight through to the back, and is accompanied by nausea, vomiting, and (after the stomach is empty) continued retching. There is tenderness and mild rebound in the upper abdomen. Serum amylase and lipase are elevated, and often serum hematocrit levels are high due hypovolemia. Resolution usually follows a few days of pancreatic rest (NPO, NG suction, IV fluids).

Acute severe pancreatitis is a much more deadly disease. It starts as the edematous form does, but an early lab clue is lower hematocrit (the degree of amylase elevation does not correlate with the severity of the disease). Other findings have been catalogued (Ranson's criteria):

- At the time of presentation, elevated WBC count, elevated blood glucose, and low serum calcium
- By the next morning, hematocrit is even lower, continued low serum calcium (in spite of calcium administration), increased blood urea nitrogen, and eventual metabolic acidosis and low arterial PO_2

Prognosis at that time is terrible, and intensive supportive therapy is needed in the ICU. This includes significant IV fluid hydration, possibly mechanical ventilation, and enteral feeding (distal to the pancreas). A common final pathway for death is the development of multiple pancreatic abscesses; try to anticipate them and drain if possible. If drained fluid is positive for bacteria (often gram-negative), the antibiotic of choice is IV carbopenem (imipenem or meropenem).

Necrosectomy is the best way to deal with necrotic pancreas, but timing is crucial. Most practitioners will wait as long as possible before necrosectomy is offered, as it requires the dead tissue to delineate well and mature for dissection. Patients do far better by waiting at least 4 weeks before debridement of the dead pancreatic tissue. Many pancreatic abscesses are not amenable to percutaneous or open drainage and will require open drainage or debridement.

Pancreatic abscess (acute suppurative pancreatitis) may become evident in someone who was not getting CT scans, because persistent fever and leukocytosis develop ~10 days after the onset of pancreatitis and sepsis develops. Imaging studies done at that time will reveal the collection(s) of pus, and percutaneous drainage and imipenem or meropenem will be indicated.

Pancreatic pseudocyst can be a late sequela of acute pancreatitis, or of pancreatic (upper abdominal) trauma. In either case, ~5 weeks elapses between the original problem and the discovery of the pseudocyst. There is a collection of pancreatic juice outside the pancreatic ducts (most commonly in the lesser sac), and the pressure symptoms thereof (early satiety, vague symptoms, discomfort, a deep palpable mass). CT or U/S will be diagnostic. Treatment is dictated by the size and age of the pseudocyst.

- Cysts ≤6 cm or those that have been present <6 weeks are not likely to have complications and can be observed for spontaneous resolution.
- Larger (>6 cm) or older cysts (>6 weeks) are more likely to cause obstruction, bleed, or infection, and they need to be treated.

Treatment involves drainage of the cyst. The cyst can be drained percutaneously to the outside, drained surgically into the GI tract, or drained endoscopically into the stomach.

Chronic pancreatitis is a devastating disease. People who have repeated episodes of pancreatitis (usually alcoholic) eventually develop calcified burned-out pancreas, steatorrhea, diabetes, and constant epigastric pain. The diabetes and steatorrhea can be controlled with insulin and pancreatic enzymes, but the pain is resistant to most modalities of therapy and can be incredibly debilitating. If ERCP shows specific points of obstruction and dilatation, operations that drain the pancreatic duct may help.

Hernias

All abdominal hernias should be electively repaired to avoid the risk of intestinal obstruction and strangulation. Exceptions include:

- Asymptomatic umbilical hernia in patients age <5 (they typically close spontaneously)
- Esophageal sliding hiatal hernias (not "true" hernias)

Hernias that become irreducible need emergency surgery to prevent strangulation. Those that have been irreducible for years need elective repair.

Figure I-4-6. Gross Appearance of Large Umbilical Hernia

DISEASES OF THE BREAST

In all breast disease, cancer must be ruled out even if the presentation suggests benign disease. The only sure way to rule out cancer is to get tissue for the pathologist. Age correlates best with the odds for cancer:

- Virtually unknown in the teens
- Rare in young women
- Quite possible by middle age
- Very likely in the elderly

Women with family history are at risk from an earlier age.

Mammography is not a substitute for tissue diagnosis, but an adjunct to physical examination. Breast mass that might be missed by palpation may be seen in x-rays, and vice versa.

- As a regular screening exam, mammography should be started at age 40 (earlier if there is family history).
- Mammogram is not done age <20 (breast is too dense) or during lactation (all you see is milk), but it can be done if needed during pregnancy.
- Mammographically or U/S-guided core biopsies have become the most convenient, effective, and inexpensive way to biopsy breast masses, whether they are palpable or are discovered by screening mammogram.
- MRI is useful for screening younger patients with denser breast tissue, but its exact indications are still controversial.

Fibroadenoma is seen in young women (late teens, early twenties) as a firm, rubbery mass that moves easily with palpation. Fine-needle aspirate (FNA) or core biopsy is sufficient to establish diagnosis. Removal is optional but generally recommended (most women want them out). Giant juvenile fibroadenoma is seen in very young adolescents, where it has very rapid growth. Removal is needed to avoid deformity and distortion of the breast.

Cystosarcoma phyllodes is seen in the late 20s; it grows over many years, becoming very large, replacing and distorting the entire breast, yet not invading or becoming fixed. Most are benign, but it has the potential to become outright malignant sarcoma. Core or incisional biopsy is needed (FNA is not sufficient), and removal is mandatory.

Mammary dysplasia (fibrocystic disease, cystic mastitis) is seen in the 30s and 40s (goes away with menopause), with bilateral tenderness related to menstrual cycle (worse in the last 2 weeks) and multiple lumps that seem to come and go (they are cysts) also following the menstrual cycle.

- If there is no "dominant" or persistent mass, mammogram is all that is needed.
- If there is a persistent mass (presumably a cyst but potentially a tumor), further steps are required; aspiration is done (not FNA, but aspiration with a bigger needle and syringe).
  - If clear fluid is obtained and the mass goes away, that's it.
  - If the mass persists or recurs after aspiration, formal biopsy is required. If bloody fluid is aspirated, send for cytology and a formal biopsy.
- A simple cyst can also be diagnosed with U/S.

Intraductal papilloma is seen in young women (20s–40s) with bloody nipple discharge. Mammogram is needed to identify other potential lesions, but it will not show the papilloma (they are tiny). Galactogram or U/S may be diagnostic and guide surgical resection. However, any patient with a bloody nipple discharge is cancer until proven otherwise.

Mastititis and **breast abscesses** are most commonly seen in lactating women; what appears to be a breast abscess at other times is cancer until proven otherwise. Mastitis is treated with oral antibiotics alone, whereas incision and drainage is needed to drain a true abscess.

Breast cancer should be suspected in any woman with a palpable breast mass, and the index of suspicion increases with the patient's age. Other strong indicators of cancer include:

- Ill-defined fixed mass
- Retraction of overlying skin

- Recent retraction of the nipple
- Eczematoid lesions of the areola
- Reddish orange peel skin over the mass (inflammatory cancer)
- Palpable axillary nodes

A history of trauma does not rule out cancer.

Breast cancer during pregnancy is diagnosed exactly as if pregnancy did not exist, and is treated the same way with the following exceptions:

- No radiotherapy during the pregnancy
- No chemotherapy during the first trimester

Termination of the pregnancy is not necessary.

The radiologic appearance of breast cancer in mammogram includes an irregular, speculated mass, asymmetric density, architectural distortion or fine microcalcifications that were not there in a previous study.

Treatment of resectable breast cancer starts with lumpectomy (partial mastectomy) plus post-op radiation or total mastectomy; either way, axillary sentinel lymph node sampling is performed simultaneously. The sentinel node biopsy is performed only when nodes are not palpable on physical exam. Lumpectomy is an ideal option when the tumor is small, in a relatively large breast, and away from the nipple and areola.

Infiltrating ductal carcinoma is the common standard form of breast cancer. Other variants (lobular, medullary, mucinous) have slightly better prognosis, and are treated the same way as the standard infiltrating ductal. Lobular has higher incidence of bilaterality, but not high enough to justify bilateral mastectomy in all cases.

Inflammatory cancer is a clinical presentation of advanced breast cancer. It has a much worse prognosis and is treated with chemotherapy prior to surgery. The surgery for inflammatory breast cancer is almost always a modified radical mastectomy. Inflammatory breast cancer is also one of the few times where radiation is added following a total mastectomy. It mimics mastitis.

Ductal carcinoma in situ cannot metastasize (thus no axillary sampling is needed) but has very high incidence of recurrence if only local excision is done. Total mastectomy is recommended for multicentric lesions throughout the breast; because of the possibility of missing an invasive focus in multicentric disease, many practitioners add a sentinel node biopsy in those patients. Lumpectomy followed by radiation is used if the lesion(s) are confined to one quarter of the breast.

Inoperable cancer of the breast is treated with chemotherapy with or without radiation, and is sometimes rendered operable. Inoperability is based on local extent (not metastases). Adjuvant systemic therapy should follow surgery in virtually all patients, particularly if axillary nodes are positive. Chemotherapy is used in most cases, and hormonal therapy is added if the tumor is receptor-positive.

- Premenopausal women receive tamoxifen
- Postmenopausal women receive an aromatase-inhibitor (e.g. anastrozole)
- Frail, old women with less-aggressive tumors and women with small, low-risk tumors may be offered hormonal therapy alone if their tumors are estrogen-receptor positive

Persistent headache or back pain (with areas of localized tenderness) in women who recently had breast cancer suggests metastasis. MRI is diagnostic. Brain metastases can be radiated or resected. The vertebral pedicles are the favorite location in the spine.

Figure I-4-8. Peau d'Orange is Seen in Some Cases of Breast Cancer

DISEASES OF THE ENDOCRINE SYSTEM

Thyroid nodules in euthyroid patients could be cancer, but incidence is low and indiscriminate thyroidectomy is not justified. FNA is the diagnostic method of choice.

- If read as benign, continue to follow the patient but do not intervene.
- If read as malignant or indeterminate, follow with a thyroid lobectomy.
- The need for further surgery is determined by the histologic diagnosis given from a frozen section.
- A total thyroidectomy should be performed in follicular cancers, so that if needed, radioactive iodine can be used in the future to treat blood-borne metastases.

Thyroid nodules in hyperthyroid patients are almost never cancer, but they may be the source of the hyperfunction ("hot adenomas"). Clinical signs of hyperthyroidism include:

- Weight loss in spite of ravenous appetite
- Palpitations
- Heat intolerance
- Moist skin
- Fidgety and hyperactive behavior
- Tachycardia
- Atrial fibrillation or flutter (occasional)

Laboratory confirmation can be done with thyrotropin (TSH; low) or thyroxine (T4; high). Nuclear scan will show if the nodule is the source. Most hyperthyroid patients are treated with radioactive iodine, but those with a "hot adenoma" have the option of surgical excision of the affected lobe.

Hyperparathyroidism is most commonly found by serendipitous discovery of high serum calcium in blood tests (rarely seen in the full florid "disease of stones, bones, and abdominal groans"). Repeat calcium determinations, look for low phosphorus, and rule out cancer with bone metastases. If findings persist, do parathyroid hormone (PTH) determination (and interpret in light of serum calcium levels).

- Asymptomatic patients become symptomatic at a rate of 20% per year; thus elective intervention is justified.
- Ninety percent have single adenoma.
- Removal is curative (sestamibi scan may help localize the culprit gland before surgery).

Cushing's syndrome presents with a round, ruddy, hairy face, buffalo hump, supraclavicular fat pads, obese trunk with abdominal stria, and thin weak extremities, classically in a patient with a normal previous appearance. Osteoporosis, diabetes, hypertension, and mental instability are also present. Workup starts with an overnight low-dose dexamethasone suppression test.

- Suppression at low dosage rules out the disease.
- If no suppression, measure 24-hour urine-free cortisol; if elevated, move to a high-dose suppression test.
  - Suppression at a higher dose identifies pituitary microadenoma.
  - No suppression at higher dose identifies adrenal adenoma (or paraneoplastic syndrome).
- Do appropriate imaging studies (MRI for pituitary, CT scan for adrenal) and remove the offending adenoma.

Zollinger-Ellison syndrome (gastrinoma) shows up as virulent peptic ulcer disease, resistant to all usual therapy (including eradication of *Helicobacter pylori*), and more extensive than it should be (several ulcers rather than one, ulcers extending beyond first portion of the duodenum). Some patients also have watery diarrhea. Measure gastrin and do a secretin test; if values are equivocal, locate the tumor with CT scan (with contrast) of the pancreas and nearby areas and resect it. Omeprazole helps those with metastatic disease.

Insulinoma produces CNS symptoms because of low blood sugar, always when the patient is fasting. Differential diagnosis is with reactive hypoglycemia (attacks occur after eating), and with self-administration of insulin. In the latter the patient has reason to be familiar with insulin (some connection with the medical profession, or with a diabetic patient), and in plasma assays has high insulin but low C-peptide. In insulinoma both are high. Do CT (with contrast) of pancreas to locate the tumor and then resect it. Glucagonoma produces severe migratory necrolytic dermatitis, resistant to all forms of therapy, in a patient with mild diabetes, mild anemia, glossitis, and stomatitis. Glucagon assay is diagnostic, CT scan is used to locate the tumor, resection is curative. Somatostatin and streptozocin can help those with metastatic, inoperable disease.

SURGICAL HYPERTENSION

Primary hyperaldosteronism can be caused by an adenoma or by hyperplasia. In both cases the key finding is hypokalemia in a hypertensive (usually female) patient who is not on diuretics. Other findings include modest hypernatremia and metabolic alkalosis. Aldosterone levels are high, whereas renin levels are low. Appropriate response to postural changes (more aldosterone when upright than when lying down) suggests hyperplasia (which is treated medically), whereas lack of response (or inappropriate response) is diagnostic of adenoma. Adrenal CT scans localize it, and surgical removal provides cure.

Pheochromocytoma is seen in thin, hyperactive women who have attacks of pounding headache, perspiration, palpitations, and pallor (i.e., extremely high but paroxysmal BP). By the time patients are seen, the attack has subsided and pressure may be normal, leading to a frustrating lack of diagnosis. Patients who have sustained hypertension are easier to diagnose.

- Start the workup with a 24-hour urinary determination of vanillylmandelic acid (VMA), metanephrines (more specific), or free urinary catecholamines.
- Follow with a CT scan of the adrenal glands and retroperitoneum; if negative, a radionuclide study may be necessary to identify extra-adrenal sites.
- Tumors are usually large.
- Surgery requires careful pharmacologic preparation with alpha-blockers, followed by beta-blockers.

Coarctation of the aorta may be recognized at any age, but patients are typically young and have hypertension in the arms, with normal pressure (or low pressure, or no clinical pulses) in the lower extremities. Chest x-ray shows scalloping of the ribs (erosion from large collateral intercostals). CT angiogram (CTA) is diagnostic and surgical correction is curative.

Renovascular hypertension is seen in 2 distinct groups: **young women with fibromuscular dysplasia,** and **old men with arteriosclerotic occlusive disease**.

In both groups hypertension is resistant to the usual medications, and a telltale faint bruit over the flank or upper abdomen suggests the diagnosis. Workup is multifactorial, but Duplex scan of the renal vessels and CTA have prominent roles. Therapy is imperative in the young women—usually balloon dilatation and stenting—but it is much more controversial in the old men who may have short life expectancy from the other manifestations of the arteriosclerosis.

Pediatric Surgery 5

Learning Objectives

- ❑ Demonstrate understanding of common surgical problems in children within the first 24 hours of birth, within the first 2 months of life, and later in infancy

BIRTH—FIRST 24 HOURS

Most congenital anomalies require surgical correction, but in most of them other anomalies have to be looked for first. In some cases clusters are seen.

Esophageal atresia presents with excessive salivation noted shortly after birth or choking spells when first feeding is attempted. A small NG tube is passed, and it will be seen coiled in the upper chest when x-rays are done. If there is normal gas pattern in the bowel, the baby has the most common form of the 4 types, in which there is a blind pouch in the upper esophagus and a fistula between the lower esophagus and the tracheobronchial tree.

Before therapy is undertaken, rule out associated anomalies (the vertebral, anal, cardiac, tracheal, esophageal, renal, and radial [VACTER] constellation):

- Look at the anus for imperforation
- Check the x-ray for vertebral and radial anomalies
- Do echocardiogram looking for cardiac anomalies
- Do U/S for renal anomalies

Primary surgical repair is preferred, but if it has to be delayed, do a gastrostomy to protect the lungs from acid reflux.

Imperforated anus may be the clinical presentation (noted on physical exam) for the VACTER collection of anomalies. If so, the others have to be ruled out as detailed above.

For the imperforated anus itself, look for a fistula nearby (to vagina or perineum).

- If present, repair can be delayed until further growth (but before toilet training time).
- If not present, do a colostomy for high rectal pouches (and definitive repair at a later date)
  - A primary repair can be done right away if the blind pouch is almost at the anus.
  - The level of the pouch is determined with x-rays taken upside down (so that the gas in the pouch goes up), with a metal marker taped to the anus.

Congenital diaphragmatic hernia is always on the left and results in bowel residing in the chest. The real problem is not the mechanical one, but the hypoplastic lung that still has fetal-type circulation. Repair must be delayed 3–4 days to allow maturation. Babies are in respiratory distress, and need endotracheal intubation, low-pressure ventilation (careful not to hyperinflate the contralateral lung), sedation, and NG suction. Difficult cases may require extracorporeal membrane oxygenation (ECMO). Many patients currently are diagnosed before birth by U/S.

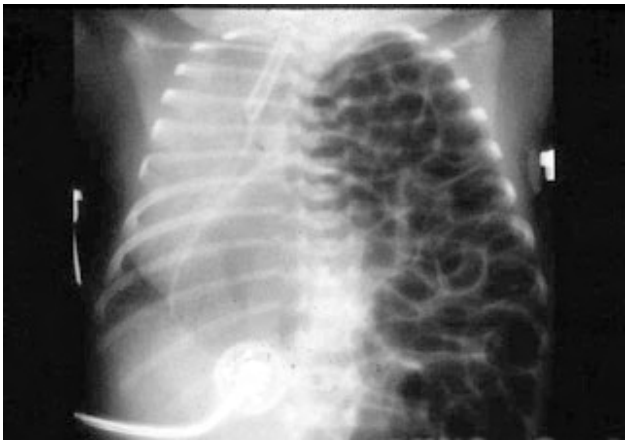

Figure I-5-1. Congenital Diaphragmatic Hernia with Bowel Contents in the Thoracic Cavity

Gastroschisis and omphalocele present with an abdominal wall defect in the abdomen.

- In gastroschisis, the cord is normal (it reaches the baby), the defect is to the right of the cord (lateral), there is no protective membrane, and the bowel looks angry and matted.
- In omphalocele, the cord goes to the defect (central), which has a thin membrane under which one can see normal-looking bowel and a little slice of liver.

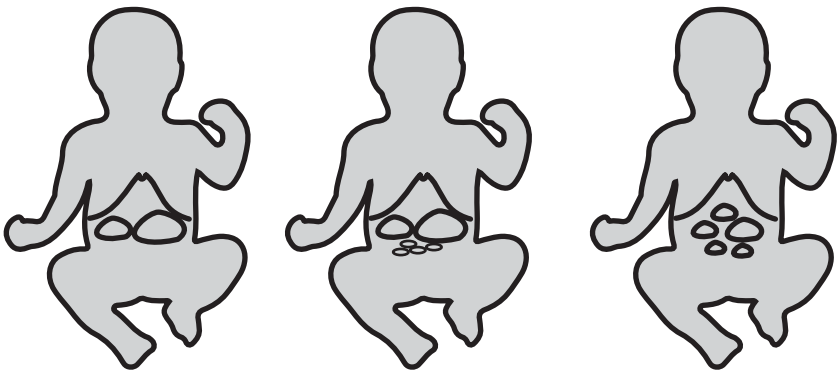
Small defects can be closed primarily, but large ones require construction of a Silastic "silo" to house and protect the bowel. The contents of the silo are then squeezed into the belly, a little bit every day, until complete closure can be done in about a week. Babies with gastroschisis also need vascular access for parenteral nutrition, because the angry-looking bowel will not work for about 1 month. If the skin can be closed and not the fascia, then the patient is left with a ventral hernia repaired at a later date.

Exstrophy of the urinary bladder is also an abdominal wall defect, but over the pubis (which is not fused), with a medallion of red bladder mucosa, wet and shining with urine. The baby has to be transferred immediately to a specialized center where a repair can be done within the first 1–2 days of life. Delayed repairs do not work.

Green vomiting in the newborn has ominous significance. A serious problem exists. **Green vomiting and a "double-bubble" picture in x-rays** (a large air-fluid level in the stomach and a smaller one to its right in the first portion of the duodenum) are found in duodenal atresia, annular pancreas, or malrotation. All of these anomalies require surgical correction, but malrotation is

the most dangerous because the bowel can twist on itself, cut off its blood supply, and die. If, in addition to the double bubble, there is a little normal gas pattern beyond, the chances of malrotation are higher. Malrotation is diagnosed with contrast enema (safe, but not always diagnostic) or upper GI study (more reliable, but more risky). Although described here as a problem of the newborn, the first signs of malrotation can show up at any time within the first few weeks of life.

Intestinal atresia also shows up with green vomiting, but instead of a double bubble there are multiple air-fluid levels throughout the abdomen. There may be more than one atretic area, but no other congenital anomalies have to be suspected because this condition results from a vascular accident in utero.



A FEW DAYS OLD—FIRST 2 MONTHS OF LIFE

Necrotizing enterocolitis is seen in premature infants when they are first fed. There is feeding intolerance, abdominal distention, and a rapidly dropping platelet count (in babies, a sign of sepsis). Treatment is to stop all feedings, initiate broad-spectrum antibiotics, IV fluids, and nutrition. Surgical intervention is required if they develop abdominal wall erythema, air in the portal vein, intestinal pneumatosis (presence of gas in the bowel wall), or pneumoperitoneum, all signs of intestinal necrosis and perforation.

Meconium ileus is seen in babies who have cystic fibrosis (often hinted at by the mother having it). They develop feeding intolerance and bilious vomiting. X-rays show multiple dilated loops of small bowel and a ground-glass appearance in the lower abdomen. Gastrografin enema is both diagnostic (microcolon and inspissated pellets of meconium in the terminal ileum) and therapeutic (Gastrografin draws fluid in, dissolves the pellets).

Reproduced with permission from Auckland District Health Board, © Crown

Figure I-5-2. Meconium Ileus with Perforation (Free Air) seen on Plain Abdominal X-ray

Hypertrophic pyloric stenosis shows up age ~3 weeks, more commonly in first-born boys, with non-bilious projectile vomiting after each feeding. The baby is hungry and eager to eat again after he vomits. By the time they are seen they are dehydrated, with visible gastric peristaltic waves and a palpable "olive-size" mass in the right upper quadrant. If the mass cannot be felt, U/S is diagnostic. Therapy begins with rehydration and correction of the hypochloremic, hypokalemic metabolic alkalosis, followed by pyloromyotomy.

Biliary atresia should be suspected in babies age 6- to 8 weeks who have persistent, progressively increasing jaundice (which includes a substantial conjugated fraction). Do serologies and sweat test to rule out other problems, and do HIDA scan after 1 week of phenobarbital (which is a powerful choleretic). If no bile reaches the duodenum even with phenobarbital stimulation, surgical exploration is needed.

- 1/3 of cases can get a long-lasting surgical derivation
- 1/3 of cases need liver transplant after surviving for a while with a surgical derivation
- 1/3 of cases need transplant right away

Hirschsprung's disease (aganglionic megacolon) can be recognized in early life, or may go undiagnosed for many years. The cardinal symptom is chronic constipation. With short segments, rectal exam may lead to explosive expulsion of stool and flatus, with relief of abdominal distention. In older children in whom differential diagnosis with psychogenic problems is an issue, presence of fecal soiling suggests the latter. X-rays show distended proximal colon (the normal one) and "normal-looking" distal colon, which is the aganglionic part. Diagnosis is made with full-thickness biopsy of rectal mucosa. Ingenious operations have been devised to preserve the unique sensory input of the motor-impaired rectum, while adding the normal propulsive capability of the innervated colon.

LATER IN INFANCY

Intussusception is seen in chubby, healthy looking babies ages 6- to 12 months, who have episodes of colicky abdominal pain which makes them double up and squat. The pain lasts for ~1 minute, and the child looks perfectly happy and normal until he gets another colic episode. Physical exam shows a vague mass on the right side of the abdomen, an "empty" right lower quadrant, and "currant jelly" stools. Barium or air enema is both diagnostic and therapeutic. If reduction is not achieved radiologically (or if there are recurrences), surgery is done.

Child abuse should always be suspected when injuries cannot be properly accounted for. Some classic presentations include:

- Subdural hematoma plus retinal hemorrhages (shaken baby syndrome)
- Multiple fractures in different bones at different stages of healing
- All scalding burns, particularly burns of both buttocks (child was held by arms and legs and dipped into boiling water)

Refer to the proper authorities.

Meckel's diverticulum should be suspected in lower GI bleeding in the pediatric age group. Diagnose with a radioisotope scan looking for gastric mucosa in the lower abdomen.

Cardiothoracic Surgery 6

Learning Objectives

- ❑ Answer questions about the surgical correction of congenital and acquired heart problems
- ❑ Describe surgical issues related to diseases of the lung

CONGENITAL HEART PROBLEMS

Vascular ring produces symptoms of pressure on the tracheobronchial tree and pressure on the esophagus.

- The first include stridor and episodes of respiratory distress with "crowing" respiration, during which the baby assumes a hyperextended position.
- The latter revolve around some difficulty swallowing. (If only the respiratory symptoms are present, one should think of tracheomalacia.)

Barium swallow shows typical extrinsic compression from the abnormal vessel. Bronchoscopy shows segmental tracheal compression and rules out diffuse tracheomalacia. Surgery divides the smaller of the two aortic arches.

Morphologic cardiac anomalies (congenital or acquired) are best diagnosed with an echocardiogram.

Left-to-right shunts share the presence of a murmur, overloading of the pulmonary circulation, and long-term damage to the pulmonary vasculature. The volume and consequences of the shunt are different at different locations, as noted below.

An **atrial septal defect** has a very minor, low-pressure, low-volume shunt. Patients typically grow into late infancy before they are recognized. A faint pulmonary flow systolic murmur and fixed split second heart sound are characteristic. A history of frequent colds is elicited. Echocardiogram is diagnostic. Closure can be achieved surgically or by cardiac catheterization.

Small, restrictive ventricular septal defects low in the muscular septum produce a heart murmur, but otherwise few symptoms. They are likely to close spontaneously within the first 2 or 3 years of life.

A **ventricular septal defect** (VSD) in the more typical location (high in the membranous septum) leads to trouble early on. Within the first few months there will be "failure to thrive," a loud pansystolic murmur best heard at the left sternal border, and increased pulmonary vascular markings on chest x-ray. Diagnose with an echocardiogram and treat with surgical closure.

Patent ductus arteriosus becomes symptomatic in the first few days of life. There are bounding peripheral pulses and a continuous "machinery-like" heart murmur. Echocardiogram is diagnostic. In premature infants who have not gone into CHF, closure can be achieved with indomethacin. Those which do not close, babies who are in heart failure, or full-term babies need surgical ligation.

Right-to-left shunts share the presence of a murmur, diminished vascular markings in the lung, and cyanosis. Although 5 are always described (all beginning with the letter T), 3 of them are rather rare and will not be reviewed (one of them, truncus arteriosus, is fascinating because it is cyanotic but it kills by overloading the pulmonary circulation, like the noncyanotic shunts do). The common ones follow.

- **Tetralogy of Fallot** (VSD, pulmonary stenosis, overiridng aorta, and right ventricular hypertrophy), although crippling, often allows children to grow up into infancy. It is also the most common cyanotic anomaly, and thus any exam question in which a child age 5–6 is cyanotic is bound to be tetralogy. The children are small for their age, have a bluish hue in the lips and tips of their fingers, clubbing, and spells of cyanosis relieved by squatting. There is a systolic ejection murmur in the left third intercostal space, a small heart, diminished pulmonary vascular markings on chest x-ray, and ECG signs of right ventricular hypertrophy. Echocardiogram is diagnostic, treatment is surgical repair.
- **Transposition of the great vessels** leads to severe trouble early on. Children are kept alive by an atrial septal defect, ventricular septal defect, or patent ductus (or a combination), but die very soon if not corrected. Suspect this diagnosis in a child age 1-2 days with cyanosis who is in deep trouble, and ask for echocardiogram. The technical details of the surgical correction are mind-boggling, and you do not have to know them.

ACQUIRED HEART DISEASE

Aortic stenosis produces angina, syncope, and dyspnea. There is a harsh midsystolic heart murmur best heard at the right second intercostal space and along the left sternal border. Start workup with an echocardiogram. Surgical valvular replacement is indicated if there is a gradient >50 mm Hg, or at the first indication of CHF, angina, or syncope.

Chronic aortic insufficiency produces wide pulse pressure and a blowing, high-pitched, diastolic heart murmur best heard at the second intercostal space and along the left lower sternal border, with the patient in full expiration. Patients are often followed with medical therapy for many years, but should undergo valvular replacement at the first evidence on echocardiogram of beginning left ventricular dilatation.

Acute aortic insufficiency because of endocarditis is seen in young drug addicts who suddenly develop CHF and a new, loud diastolic murmur at the right second intercostal space. Emergency valve replacement and long-term antibiotics are needed.

Mitral stenosis is caused by a history of rheumatic fever many years before presentation. It produces dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, cough, and hemoptysis. There is a low-pitched, rumbling diastolic apical heart murmur. As it progresses, patients become thin and cachectic and develop atrial fibrillation. Workup starts with echocardiogram. As symptoms become more disabling, mitral valve repair becomes necessary with a surgical commissurotomy or mitral valve replacement.

Mitral regurgitation is most commonly caused by valvular prolapse. Patients develop exertional dyspnea, orthopnea, and atrial fibrillation. There is an apical, high-pitched, holosystolic heart murmur that radiates to the axilla and back. Workup and surgical indications are as above, with repair of the valve (annuloplasty) preferred over prosthetic replacement.

Coronary disease can happen to anybody (including women), but the typical patient is as follows:

- Middle-age sedentary man
- Has family history, smoking history, type II diabetes and/or hypercholesterolemia

Progressive, unstable, disabling angina is the main reason to do cardiac catheterization and evaluate as a potential candidate for revascularization. Intervention is indicated if ≥1 vessels have ≥70% stenosis and there is a good distal vessel. Preferably, the patient should still have good ventricular function (you cannot resuscitate dead myocardium).

The general rule is that the simpler the problem, the more it is amenable to angioplasty and stent; whereas more complex situations do better with surgery.

- Single vessel disease (that is not the left main or the anterior descending) is perfect for angioplasty and stent.
- Triple vessel disease makes multiple coronary bypass (using the internal mammary for the most important vessel) the best choice.

Post-operative care of heart surgery patients often requires that cardiac output be optimized. If cardiac output is considerably under normal (5 liters/min, or cardiac index 3), the pulmonary wedge pressure (or left atrial pressure, or left end-diastolic pressure) should be measured. Low numbers (0–3) suggest the need for more IV fluids. High numbers (≥20) suggest ventricular failure.

Chronic constrictive pericarditis produces dyspnea on exertion, hepatomegaly, and ascites, and shows a classic "square root sign" and equalization of pressures (right atrial, right ventricular diastolic, pulmonary artery diastolic, pulmonary capillary wedge, and left ventricular diastolic) on cardiac catheterization. Surgical therapy relieves it.

LUNG

A **solitary "coin" lesion** found on a chest x-ray has an 80% chance of being malignant in people age >50, and even higher if there is a significant history of smoking. A very expensive workup for cancer of the lung, however, can be avoided if an older chest x-ray shows the same unchanged lesion; it is unlikely to be cancer. Therefore, seeking an older x-ray is always the first step when a solitary pulmonary nodule is detected.

Suspected **cancer of the lung** requires what is potentially an expensive and invasive workup to confirm diagnosis and assess operability. It starts with a chest x-ray (which may have been ordered because of persistent cough or hemoptysis) showing a suspicious lesion. Assuming no older x-ray is available or the lesion was not present on a previous film, 2 noninvasive tests should be done first: sputum cytology and CT scan (chest and upper abdomen).

Diagnosis of cancer of the lung, if not established by cytology, requires bronchoscopy and biopsies (for central lesions) or percutaneous biopsy (for peripheral lesions). If unsuccessful with those, video-assisted thoracic surgery (VATS) and wedge resection may be needed. How far one goes in that sequence depends on the following:

- Probability of cancer (higher in elderly, with history of smoking and noncalcified lesion in CT)
- Assurance that surgery can be done (residual pulmonary function will suffice)
- Chances that the surgery may be curative (no metastases to mediastinal or carinal nodes, the other lung, or the liver)

The interplay of these factors determines the specific sequence of workup beyond sputum cytology and CT scan in each patient.

Small cell cancer of the lung is treated with chemotherapy and radiation, and therefore assessment of operability and curative chances of surgery are not applicable. Operability and possibility of surgical cure applies only to non–small cell cancer.

The operability of lung cancer is predicated on residual function after resection. If clinical findings (COPD, shortness of breath) suggest this may be the limiting factor, do pulmonary function studies.

- Determine FEV1
- Determine fraction that comes from each lung (by ventilation-perfusion scan)
- Figure out what would remain after pneumonectomy

A minimum FEV_1 of 800 mL is mandatory for a patient to undergo lung resection, as the worst case scenario is that a pneumonectomy will need to be performed and could potentially leave a marginal patient ventilator dependent. If <800 mL, do not continue expensive tests; the patient is not a surgical candidate. Treat with chemotherapy and radiation instead.

Potential cure by surgical removal of lung cancer depends on extent of metastases.

- Hilar metastases can be removed with the pneumonectomy.
- Nodal metastases at the carina or mediastinum preclude curative resection.
- CT scan may identify nodal metastases.
- The addition of PET scan has helped define the presence of an actively growing tumor in enlarged nodes.
- Endobronchial U/S has emerged as a mainstay of diagnosis by obtaining tissue samples from mediastinal nodes; cervical mediastinal exploration ("mediastinoscopy") is now rarely needed.
- Metastases to the contralateral lung, adrenal gland, or liver would also be evident in the CT and be a contraindication to surgical resection.

Vascular Surgery 7

Learning Objectives

- ❑ List the common procedures, including indications, complications, and alternatives, in vascular surgery

Subclavian steal syndrome is rare but fascinating (medical school professors love it, thus it is likely to appear on exams). An arteriosclerotic stenotic plaque at the origin of the subclavian (proximal to the takeoff of the vertebral) allows enough blood supply to reach the arm for normal activity, but does not allow enough to meet higher demands when the arm is exercised. When that happens, the arm sucks blood away from the brain by reversing the flow in the vertebral.

Clinically the patient describes claudication of the arm (coldness, tingling, muscle pain) and posterior neurologic signs (visual symptoms, equilibrium problems) when the arm is exercised. Vascular symptoms alone would suggest thoracic outlet syndrome, but the combination with neurologic symptoms identifies the subclavian steal. Duplex scanning is diagnostic when it shows reversal of flow. Bypass surgery is curative.

Abdominal aortic aneurysm (AAA) is typically asymptomatic, found as a pulsatile abdominal mass on examination (between the xiphoid and the umbilicus), or found on x-rays, U/S, or CT scans done for another diagnostic purpose, usually in an older man. Size is the key to management; if an aneurysm is found by physical exam, U/S or CT scan is needed to provide precise measurements.

- If aneurysm is ≤4 cm, it can be safely observed; chance of rupture is almost zero
- If aneurysm is ≥5 cm, patient should have elective repair because chance of rupture is very high

Aneurysms that grow 1 cm per year or faster also need elective repair. Most AAAs are now treated with endovascular stents inserted percutaneously. The 10-year outcome has been encouraging; limiting factors to this modality are specific anatomic criteria (neck of aneurysm, landing zone, and tortuosity of vascular tree) and available resources (angiography team and equipment). Open AAA repair involves an interposition graft within the aneurysm sac and carries ~10-15% peri-operative morbidity, with MI, renal failure, and bowel ischemia being the most severe culprits.

Surgery for a ruptured AAA carries very high morbidity and mortality, thus efforts are made to predict and anticipate rupture, and not wait for it to occur.

- A tender AAA is at risk to rupture, so immediate repair is indicated.
- Excruciating back pain in a patient with a large AAA means that the aneurysm is already leaking. Retroperitoneal hematoma is already forming, and blowout into the peritoneal cavity is imminent; emergency surgery is required.

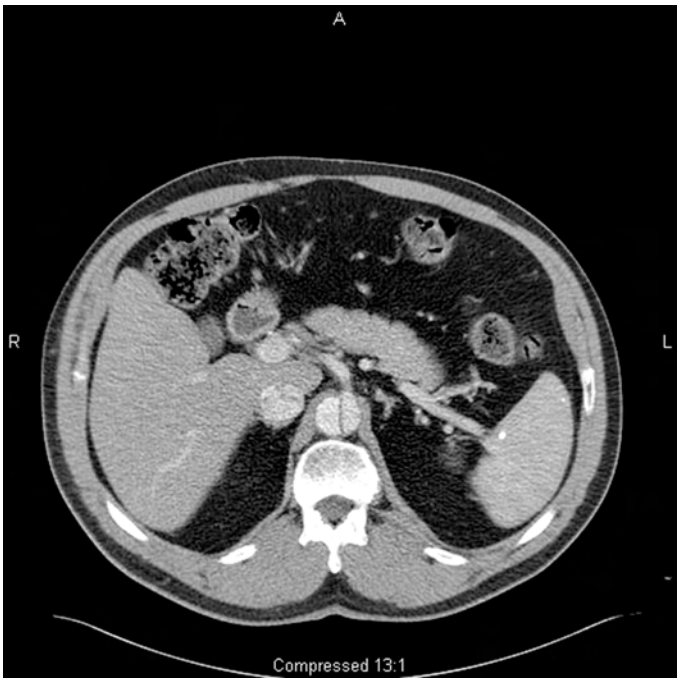


Figure I-7-1. CT Scan of 52-year-old Man with an Abdominal Aortic Aneurysm Involving the Celiac Artery

Arteriosclerotic occlusive disease of the lower extremities has an unpredictable natural history (except for the predictable negative impact of smoking), and therefore there is no role for "prophylactic" surgery in claudication. Surgery is done only to relieve disabling symptoms or to save the extremity from impending necrosis (rest pain). The first clinical manifestation is pain brought about by walking and relieved by rest (intermittent claudication). If the claudication does not interfere significantly with the patient's lifestyle, no workup is indicated. Smoking cessation, exercise, and the use of cilostazol can help the patient in the long run.

The workup of **disabling intermittent claudication** starts with Doppler studies looking for a pressure gradient.

- If there isn't a significant gradient, the disease is in the small vessels and not amenable to surgery. If there is one, CTA or magnetic resonance angiogram is performed to identify specific areas of stenosis or complete obstruction, and to look for good distal vessels to which a bypass graft could be anastmosed.
- Short stenotic segments can be treated with angioplasty and stenting.
- More extensive disease may require bypass grafts, sequential stents or longer stents.
- When multiple lesions are present, proximal ones are usually repaired before distal ones are addressed.
- Grafts originating at the aorta (aortobifemoral) are done with prosthetic material.
- Bypasses between more distal vessels (femoropopliteal, or beyond) are usually done with reversed saphenous vein grafts.

Rest pain is the penultimate stage of the disease (the ultimate is ulceration and gangrene). The clinical picture is rather characteristic. The patient seeks help because he "cannot sleep." It turns out that pain in the calf is what keeps him from falling asleep. He has learned that sitting up and dangling the leg helps the pain, and a few minutes after he does so, the leg that used to be very pale becomes deep purple. Physical exam shows shiny atrophic skin without hair, and no peripheral pulses. Workup and therapy are as detailed above.

Arterial embolization from a distant source is seen in patients with atrial fibrillation (a clot breaks off from the atrial appendage) or those with a recent MI (the source of the embolus is the mural thrombus). The patient suddenly develops the 6 Ps:

- Painful
- Pale
- Cold ("poikilothermic")
- Pulseless
- Paresthetic
- Paralytic lower extremity

Urgent evaluation and treatment should be completed within 6 hours. Doppler studies will locate the point of obstruction. Early incomplete occlusion may be treated with clot busters. Embolectomy with Fogarty catheters is effective for complete obstructions, and fasciotomy should be added if several hours have passed before revascularization to prevent compartment syndrome from reperfusion edema.

Dissecting aneurysm of the thoracic aorta occurs in the poorly controlled hypertensive. The episode resembles an MI, with sudden onset of extremely severe, tearing chest pain that radiates to the back and migrates down shortly after its onset. There may be unequal pulses in the upper extremities, and chest x-ray shows a widened mediastinum. ECG and cardiac enzymes rule out an MI. Definitive diagnosis should be sought by noninvasive means such as CTA or MRA, but TEE is useful as well. Type A dissections (involving the ascending aorta) are treated surgically, whereas Type B (those in the descending only) are managed medically with control of the hypertension in the ICU.

Figure I-7-2. Peripheral Vascular Disease noted on Angiogram of the Lower Extremities

Skin Surgery 8

Learning Objectives

- ❑ List the common procedures, including indications, complications, and alternatives, in dermatology

Cancer of the skin is typically seen in blond, blue-eyed, fair-skinned people who live where the sun is fierce, and who by virtue of occupation or hobby are out in the sun all day.

- Basal cell carcinoma: 50% of cases
- Squamous cell carcinoma: 25% of cases
- Melanoma: ≥15% of cases (incidence is rising)

They have preferred presentations (detailed below), but diagnosis in all is done by obtaining tissue from a biopsy of the lesion (shave, punch or excisional biopsy). Excisional biopsy is the most accurate in diagnosis, especially when melanoma is suspected. Because they share etiology, they often coexist, and patients frequently have multiple lesions over the years.

Basal cell carcinoma may show up as a raised waxy lesion or as a nonhealing ulcer. It has a preference for the upper part of the face (above a line drawn across the lips). It does not metastasize, but can kill by relentless local invasion ("rodent ulcer"). Local excision with negative margins (1 mm is enough) is curative, but other lesions may develop later.

Squamous cell carcinoma of the skin shows up as a nonhealing ulcer, has a preference for the lower lip (and territories below a line drawn across the lips), and can metastasize to lymph nodes. Excision with wider margins is needed (0.5–2 cm), and node dissection is done if they are involved. Radiation treatment is another option.

Melanoma usually originates in a pigmented lesion. A mnemonic to identify them is **ABCD**.

- Asymmetric (A)
- Irregular borders (B)
- Different colors (C) within the lesion
- Diameter (D) >0.5 cm

Melanoma should also be suspected in any pigmented lesion that changes in any way (grows, ulcerates, changes color and/or shape, bleeds, etc.). The biopsy report must give not only the diagnosis, but also the depth of invasion. The prognosis of melanoma is directly related to the thickness or depth of invasion (Breslow measurement); the deeper the thickness/depth of invasion, the worse the prognosis.

Table I-8-1. Breslow Measurements

Thickness/Depth	Surgical Margins Required
MIS (melanoma in-situ)	0.5 cm
<1 mm	1 cm
1-2 mm	1-2 cm
>2 mm	2 cm

Melanoma-in-situ (non-invasive melanoma) carries an excellent prognosis and can be effectively treated with local excison (5 mm margins).

- Lesions <1 mm in depth have a good prognosis and require only local excision with 1 cm margins.
- Lesions 1–2 cm in depth have a worse prognosis and require resection with 1-2 cm margins.
- Deeper lesions (>2 mm) require excision with wide margins (2 cm).
- Lesions >4 mm have a terrible prognosis.
- Lesions 1–4 mm benefit most from aggressive therapy, including node dissection.
- Patients with lesions >1 mm deep and without palpable nodes on exam should undergo sentinel lymph node biopsy.

Metastatic malignant melanoma (from a deep, invasive primary) is a bizarre, unpredictable, and fascinating disease. Melanoma metastasizes to all the usual places (lymph nodes, liver, lung, brain, and bone), but it also metastasizes to remote and bizarre locations (e.g. the muscle of the left ventricle, the wall of the duodenum…anywhere!).

Furthermore, it has no predictable timetable. Some patients are full of metastases and dead within a few months of diagnosis, while others go 20 years between resection of their primary tumor and the sudden explosion of metastases. Interferon is the current adjuvant systemic therapy for high-risk melanoma. Newer drugs such as ipilimumab and vemurafenib are being explored for treatment.

Ophthalmology 9

Learning Objectives

- ❑ List the common procedures, including indications, complications, and alternatives, in ophthalmology

CHILDREN

Amblyopia is a vision impairment caused by interference with the processing of images by the brain during the first 6 or 7 years of life. The most common expression of this phenomenon is the child with strabismus. Faced with two overlapping images, the brain suppresses one of them. If the strabismus is not corrected early on, there will be permanent cortical blindness of the suppressed eye, even though the eye is perfectly normal. Should an obstacle impede vision in one eye during those early years (for instance a congenital cataract), the same problem will develop.

Strabismus is verified by showing that the reflection from a light comes from different areas of the cornea in each eye. Strabismus should be surgically corrected when diagnosed, to prevent the development of amblyopia. When reliable parents relate that a child did not have strabismus in the early years but develops it later in infancy, the problem is an exaggerated convergence caused by refraction difficulties. In that case corrective glasses instantly resolve the problem. True strabismus does not resolve spontaneously.

A **white pupil in a baby** is an ophthalmologic emergency, as it may be caused by a retinoblastoma. Even if the white pupil is caused by a less lethal problem, like a congenital cataract, it should be attended to in order to prevent amblyopia.

ADULTS

Glaucoma is a very common source of blindness, but because of its silent nature is unlikely to be discovered by regular physicians (or to be tested for in an exam). One variant, however, should be recognized by every physician who might encounter it. **Acute closed angle glaucoma** shows up as very severe eye pain or frontal headache, typically starting in the evening when the pupils have been dilated for several hours (watching a double feature at the movies, or watching television in a dark room).

- Patient may report seeing halos around lights
- On physical exam the pupil is mid-dilated and does not react to light; cornea is cloudy with greenish hue; and eye feels "hard as a rock"

- Emergency treatment is required (ophthalmologists will drill a hole in the iris with a laser beam to provide a drainage route for the fluid that is trapped in the anterior chamber).
- While waiting for the ophthalmologist, administer systemic carbonic anhydrase inhibitors (such as Diamox) and apply topical beta-blockers and alpha-2–selective adrenergic agonists. Mannitol and pilocarpine may also be used.

Orbital cellulitis is another ophthalmologic emergency. The eyelids are hot, tender, red, and swollen; and the patient is febrile—but the key finding when the eyelids are pried open is that the pupil is dilated and fixed, and the eye has very limited motion. There is pus in the orbit, and emergency CT scan and drainage have to be done.

Chemical burns of the eye require massive irrigation, like their counterparts elsewhere in the body. Start irrigation with plain water as soon as possible, and do not wait until arrival at the hospital. Once the eye has been pried open and washed under running water for about 30 minutes, get the patient to the ED. At the hospital, irrigation with saline is continued, corrosive particles are removed from hidden corners, and before the patient is sent home, pH is tested to assure that no harmful chemicals remain in the conjunctival sac. As is true elsewhere in the body, alkaline burns are worse than acid burns.

Retinal detachment is another emergency that should be recognized by all physicians. The patient reports seeing flashes of light and having "floaters" in the eye. The number of floaters gives a rough idea of the magnitude of the problem.

- The person with 1 or 2 floaters may only have vitreous tugging at the retina, with little actual detachment.
- The person who describes dozens of floaters, or "a snow storm" within the eye, or a big dark cloud at the top of his visual field has a big horseshoe piece of the retina pulled away, and is at risk of ripping out the rest. Emergency intervention, with laser "spot welding," will protect the remaining retina.

Embolic occlusion of the retinal artery is also an emergency, although little can be done about it. The patient (typically elderly) describes sudden loss of vision from one eye. In about 30 minutes the damage will be irreversible, but the standard recommendation is for the patient to breathe into a paper bag, and have someone repeatedly press hard on the eye and release while he is in transit to the ED (the idea is to vasodilate and shake the clot into a more distal location, so that a smaller area is ischemic).

Newly diagnosed diabetics need ophthalmologic evaluation if they have type II, because they may have had it for years before diagnosis was made. Retinal damage may have already occurred, and proper treatment may prevent its progression. Young people diagnosed with type I are about 20 years away from getting eye problems.

Otolaryngology (ENT) 10

Learning Objectives

- ❏ List the most important ENT emergencies and describe the presenting features of each
- ❏ Describe the common neck masses and ENT tumors including prognosis
- ❏ Recognize and present treatment options for pediatric ENT problems

NECK MASSES

Neck masses can be congenital, inflammatory, or neoplastic. Congenital masses are seen in young people, and typically have been present for years before they become symptomatic (get infected) and medical help is sought. The timetable of inflammatory masses is typically measured in days or weeks. After a few weeks an inflammatory mass has reached some kind of resolution (drained or resolved). The timetable of neoplastic masses is typically several months of relentless growth.

Congenital

Thyroglossal duct cyst is located on the midline, at the level of the hyoid bone, and originates from the foramen cecum in the tongue (pulling at the tongue retracts the mass). It is typically 1–2 cm in diameter. Surgical removal includes the cyst, the middle segment of the hyoid bone, and the track that leads to the base of the tongue (Sistrunk procedure).

Branchial cleft cyst occurs laterally, along the anterior edge of the sternomastoid muscle, anywhere from in front of the tragus to the base of the neck. It is typically several centimeters in diameter, and sometimes has a little opening and blind tract in the skin overlying it.

Cystic hygroma is found at the base of the neck as a large, mushy, ill-defined mass that occupies the entire supraclavicular area and seems to extend deeper into the chest. Indeed, it often extends into the mediastinum, and therefore CT scan before attempted surgical removal is mandatory.

Inflammatory versus Neoplastic

Most recently discovered enlarged lymph nodes are benign, and so an extensive workup should not be undertaken right away. Complete history and physical should be followed by an appointment in 3 to 4 weeks. If the mass is still there, workup then follows.

Persistent enlarged lymph node (a history of weeks or months) could still be inflammatory, but neoplasia has to be ruled out. There are several patterns that are suggestive of specific diagnosis, as detailed below.

Lymphoma is typically seen in young people; they often have multiple enlarged nodes (in the neck and elsewhere) and have been suffering from low-grade fever and night sweats. FNA can be done, but usually a node has to be removed for pathologic study to determine specific type. Chemotherapy is the usual treatment.

Metastatic tumor to supraclavicular nodes invariably comes from below the clavicles (and not from the head and neck). Lung or intraabdominal tumors are the usual primaries. The node itself may be removed to help establish a tissue diagnosis. It is commonly on the left side (Virchow's node).

Squamous cell carcinoma of the mucosae of the head and neck is seen in older men who smoke, drink, and have rotten teeth. Patients with AIDS are also prime candidates. Often the first manifestation is a metastatic node in the neck (typically to the jugular chain). The ideal diagnostic workup is a triple endoscopy (or panendoscopy) looking for the primary tumor.

- Biopsy of the primary establishes the diagnosis, and CT scan demonstrates the extent.
- FNA of the node may be done, but open biopsy of the neck mass should never be performed, as an incision in the neck will eventually interfere with the appropriate surgical approach for the tumor.

Treatment involves resection, radical neck dissection, and very often radiotherapy and platinum-based chemotherapy. Other presentations of squamous cell carcinoma include persistent hoarseness, persistent painless ulcer in the floor of the mouth, and persistent unilateral earache.

OTHER TUMORS

Acoustic nerve neuroma should be suspected in an adult who has sensory hearing loss in one ear, but not the other (and who does not engage in sport shooting that would subject one ear to more noise than the other). MRI is the best diagnostic modality.

Facial nerve tumors produce gradual unilateral facial nerve paralysis affecting both the forehead and the lower face, as opposed to sudden onset paralysis which suggests Bell's palsy. Gadolinium-enhanced MRI is the best diagnostic study.

Parotid tumors are visible and palpable in front of the ear, or around the angle of the mandible. Most are pleomorphic adenomas, which are benign but have potential for malignant degeneration. They do not produce pain or facial nerve paralysis. A hard parotid mass that is painful or has produced paralysis is a parotid cancer.

- FNA of these tumors may be done, but open biopsy is absolutely contraindicated.
- A formal superficial parotidectomy (or superficial and deep if the tumor is deep to the facial nerve) is the appropriate way to excise—and thereby biopsy—parotid tumors, preventing recurrences and sparing the facial nerve.
- Enucleation alone leads to recurrence.
- In malignant tumors the nerve is sacrificed and a nerve interposition graft performed.

PEDIATRIC ENT

Foreign bodies are the cause of unilateral ENT problems in toddlers. A 2-year-old with unilateral earache, unilateral rhinorrhea, or unilateral wheezing has a little toy truck (substitute for your favorite toy if you wish) in his ear canal, up his nose, or into a bronchus. The appropriate endoscopy under anesthesia will allow extraction.

Figure I-10-1. Airway Foreign Body Noted on Chest X-ray

ENT EMERGENCIES AND MISCELLANEOUS

Ludwig's angina is an abscess of the floor of the mouth, often the result of a bad tooth infection. The usual findings of an abscess are present, but the special issue here is the threat to the airway. Incision and drainage are done, but intubation and tracheostomy may also be needed to protect the airway.

Bell's palsy produces sudden paralysis of the facial nerve for no apparent reason. Although not an emergency per se, current practice includes the use of antiviral medications—and as is the case for other situations in which antivirals are used, prompt and early administration is the key to their success. Steroids are also typically prescribed.

Facial nerve injuries sustained in multiple trauma produce paralysis right away. Patients who have normal nerve function at the time of admission and later develop paralysis have swelling that will resolve spontaneously.

Cavernous sinus thrombosis is heralded by the development of diplopia (from paralysis of extrinsic eye muscles) in a patient suffering from frontal or ethmoid sinusitis. This is a serious emergency that requires hospitalization, IV antibiotics, CT scans, and drainage of the affected sinuses.

Epistaxis in children is typically from nosepicking; the bleeding comes from the anterior septum, and phenylephrine spray and local pressure controls the problem. In teenagers the prime suspects are cocaine abuse (with septal perforation) or juvenile nasopharyngeal angiofibroma.

Posterior packing may be needed for the former, and surgical resection is mandatory for the latter (the tumor is benign, but it eats away at nearby structures).

In the elderly and hypertensive, nosebleeds can be copious and life-threatening. BP has to be controlled, and posterior packing is usually required. Sometimes angiographic or surgical ligation of feeding vessels is the only way to control the problem.

Dizziness may be caused by inner ear disease or cerebral disease. When the inner ear is the culprit, the patients describe the room spinning around them (vertigo). When the problem is in the brain, the patient is unsteady but the room is perceived to be stable. In the first case meclizine, Phenergan, or diazepam may help. In the second case, neurologic workup is in order.

Neurosurgery 11

Learning Objectives

- ❏ List differential diagnoses for neurosurgical presenting complaints
- ❏ Describe neurosurgical treatment options for cerebrovascular occlusive disease
- ❏ Describe primary and metastatic brain tumors, treatment options, and prognosis
- ❏ Provide an approach to treating chronic pain syndromes

DIFFERENTIAL DIAGNOSIS BASED ON PATIENT HISTORY

The timetable and mode of presentation of neurologic disease may provide the first clues as to its nature.

- **Vascular problems** have sudden onset without headache when they are occlusive, and with very severe headache when they are hemorrhagic.
- **Brain tumors** have a timetable of months, and produce constant, progressive, severe headache, sometimes worse in the mornings. As intracranial pressure increases, blurred vision and projectile vomiting are added. If the tumor presses on an area of the brain associated with a particular function, deficits of that function may be evident.
- **Infectious problems** have a timetable of days or weeks, and often an identifiable source of infection in the history.
- **Metabolic problems** develop rapidly (hours or days) and affect the entire CNS. Degenerative diseases usually have a timetable of years.

VASCULAR OCCLUSIVE DISEASE

Transient ischemic attack (TIA) is sudden, transitory loss of neurologic function that comes on without headache and resolves spontaneously within 24 hours, leaving no neurologic sequelae. The specific symptoms depend on the area of the brain affected, which is in turn related to the vessels involved. The most common origin is high-grade stenosis (≥70%) of the internal carotid, or ulcerated plaque at the carotid bifurcation.

- The importance of TIAs is that they are predictors of stroke, and timely elective carotid endarterectomy may prevent or minimize that possibility.
- Workup starts with noninvasive Duplex studies.
- Carotid endarterectomy is indicated if the lesions are found in the location that explains the neurologic symptoms.
- Angioplasty and stent can be performed in high risk surgical patients.

Ischemic stroke also has sudden onset without headache, but the neurologic deficits are present >24 hours, leaving permanent sequelae. Except for very early strokes, ischemic stroke is no longer amenable to revascularization procedures. An ischemic infarct may be complicated by a hemorrhagic infarct if blood supply to the brain is suddenly increased. Vascular workup will eventually be done to identify lesions that might produce another stroke (and treat them), but for the existing infarct, assessment is by CT scan, and therapy is centered on rehabilitation.

There is a current movement to reeducate physicians to recognize very early stroke and treat it emergently with clot busters. CT scan is done first to rule out extensive infarcts or the presence of hemorrhage. IV infusion of tissue-type plasminogen activator (t-PA) is best if started within 90 minutes up to 3 hours after the onset of symptoms.

Intracranial Bleeding

Hemorrhagic stroke is seen in the uncontrolled hypertensive who complains of very severe headache of sudden onset and goes on to develop severe neurologic deficits. CT scan is used to evaluate the location and extent of the hemorrhage, and therapy is directed at control of the hypertension and rehabilitation efforts.

Subarachnoid hemorrhage can be caused by rupture of an intracranial aneurysm as well as trauma or even spontaneous bleeding. The amount of pressure the free blood exerts on the brain determines severity of symptoms and thereby outcome.

- With **significant pressure exertion**, especially when caused by an aneurysm, patients complain of severe, sudden onset headache—"the worst of their life." Physical exam can demonstrate nuchal rigidity due to meningeal irritation. Evaluation begins with CT scan and may require magnetic resonance angiogram (MRA) or formal angiogram to delineate the neurovascular anatomy. Treatment is either open clipping of the aneurysm or endovascular coiling with good results.
- With **minimal pressure exertion** on the brain, patients are not very symptomatic and do not necessarily seek medical attention or are not fully evaluated; they tend to re-present in a delayed fashion, usually 7-10 days after the "sentinel bleed." When this happens, the degree of intracranial hematoma is often significant, and patients are not always salvageable. Accordingly, a very high index of suspicion at initial presentation can be life-saving.

BRAIN TUMOR

Brain tumor may offer no clue as to location if it presses on a "silent area" of the brain. The only history will be progressively increasing headache for several months, worse in the mornings, and eventually accompanied by signs of increased intracranial pressure:

- Blurred vision
- Papilledema
- Projectile vomiting
- Bradycardia and hypertension (due to Cushing reflex) at the extreme end of the spectrum

Brain tumor can be visualized very well on CT scan, but MRI gives better detail and is the preferred study. While awaiting surgical removal, treat any increased intracranial pressure with high-dose steroids (i.e., dexamethasone).

Clinical localization of brain tumors may be possible by virtue of specific neurologic deficits or symptom patterns. For example, the motor strip and speech centers are often affected in tumors that press on the lateral side of the brain, producing symptoms on the opposite side of the body (people speak with the same side of the brain that controls their dominant hand). Other classic clinical pictures include the following:

- **Tumor at the base of the frontal lobe** produces inappropriate behavior, optic nerve atrophy on the side of the tumor, papilledema on the other side, and anosmia (Foster-Kennedy syndrome).
- **Craniopharyngioma** occurs in children who are short for their age, and they show bitemporal hemianopsia and a calcified lesion above the sella on x-rays.
- **Prolactinomas** produce amenorrhea and galactorrhea in young women. Diagnostic workup includes ruling out pregnancy (pregnancy test), ruling out hypothyroidism, determination of prolactin level, and MRI of the sella. Therapy is with bromocriptine. Transnasal, trans-sphenoidal surgical removal is reserved for those who wish to get pregnant, or those who fail to respond to bromocriptine.
- **Acromegaly** is recognized by the huge hands, feet, tongue, and jaws. (On the exam, images typically show both hands on either side of the face in a frontal view, and a long prominent jaw in a lateral view.) Additionally, there is hypertension, diabetes, sweaty hands, headache, and the history of wedding bands or hats that no longer fit. Workup starts with determination of somatomedin C, and pituitary MRI. Surgical removal is preferred, but radiation is an option.
- **Pituitary apoplexy** occurs when there is bleeding into a pituitary tumor, with subsequent destruction of the pituitary gland. The history may have clues to the long-standing presence of the pituitary tumor (headache, visual loss, endocrine problems), and the acute episode starts with a severe headache, followed by signs of increased compression of nearby structures by the hematoma (deterioration of remaining vision, bilateral pallor of the optic nerves) and pituitary destruction (stupor and hypotension). Steroid replacement is urgently needed, and eventually other hormones will need to be replaced. MRI or CT scan will show the extent of the problem.
- **Tumor of the pineal gland** produces loss of upper gaze and the physical finding known as "sunset eyes" (Parinaud syndrome).
- **Brain tumor in children** is most commonly in the posterior fossa. It produces cerebellar symptoms (stumbling around, truncal ataxia) and the children often assume the knee-chest position to relieve their headache.
- **Brain abscess** shows many of the same manifestations of brain tumors (it is a space-occupying lesion), but much more quickly (a week or two). There is fever, and usually an obvious source of the infection nearby, like otitis media and mastoiditis. It has a very typical appearance on CT, thus the more expensive MRI is not needed. Actual resection is required.

PAIN SYNDROMES

Trigeminal neuralgia (tic douloureux) produces extremely severe, sharp, shooting, "like a bolt of lightning," pain in the face brought about by touching a specific area, and lasting about 60 seconds. Patients are in their sixties, and have a completely normal neurologic exam. The only finding on physical may be an unshaven area in the face (the trigger zone, which the patient avoids touching). MRI is done to rule out organic lesions. Treatment with anticonvulsants is often successful. If not, radiofrequency ablation can be done.

Reflex sympathetic dystrophy (**causalgia**) develops several months after a crushing injury. There is constant, burning, agonizing pain that does not respond to the usual analgesics. The pain is aggravated by the slightest stimulation of the area. The extremity is cold, cyanotic, and moist. A successful sympathetic block is diagnostic, and surgical sympathectomy is curative.

Urology 12

Learning Objectives

- ❏ Describe treatment options for urologic emergencies, including stones and retention
- ❏ List common congenital urologic diseases and their treatment
- ❏ Answer questions about urological tumor
- ❏ Outline the causes and treatments of urinary incontinence

UROLOGIC EMERGENCIES

Testicular torsion is seen in young adolescents. There is severe testicular pain of sudden onset, but no fever, pyuria, or history of recent mumps. The testis is swollen, exquisitely tender, "high riding," and with a "horizontal lie." The cord is not tender. This is one of the few urologic emergencies, and time wasted doing any tests is tantamount to malpractice. Immediate surgical intervention is indicated. After the testis is untwisted, an orchiopexy is done to prevent recurrence; simulataneous contralateral orchiopexy is also indicated.

Acute epididymitis can be confused with testicular torsion. It is seen in young men old enough to be sexually active, and it also starts with severe testicular pain of sudden onset. There is fever and pyuria, and although the testis is swollen and very tender, is in the normal position. The cord is also very tender. Acute epididymitis is treated with antibiotics, but the possibility of missing a diagnosis of testicular torsion is so dreadful that sonogram is done to rule it out.

The combination of **obstruction and infection of the urinary tract** is the other condition (besides testicular torsion) that is a dire emergency. Any situation in which these two conditions coexist can lead to destruction of the kidney in a few hours, and potentially to death from sepsis. A typical scenario is a patient who is being allowed to pass a ureteral stone spontaneously, and who suddenly develops chills, fever spike (104–105°F), and flank pain. In addition to IV antibiotics, immediate decompression of the urinary tract above the obstruction is required. This is accomplished by the quickest and simplest means (in this example, ureteral stent or percutaneous nephrostomy), deferring more elaborate instrumentations for a later, safer date.

UTI (cystitis) is very common in women of reproductive age and requires no elaborate workup. Patients have frequency, painful urination, with small volumes of cloudy and malodorous urine. Empiric antimicrobial therapy is used. More serious infection such as pyelonephritis, or UTI in children or young men, requires urinary cultures and a urologic workup to rule out concomitant obstruction as the reason for the serious infection.

Pyelonephritis produces chills, high fever, nausea and vomiting, and flank pain. Hospitalization, IV antibiotics (guided by cultures), and urologic workup (IVP or sonogram) are required.

Acute bacterial prostatitis is seen in older men who have chills, fever, dysuria, urinary frequency, diffuse low back pain, and an exquisitely tender prostate on rectal exam. IV antibiotics are indicated, and care should be taken not to repeat any more rectal exams. Continued prostatic massage could lead to septic shock.

CONGENITAL UROLOGIC DISEASE

Posterior urethral valve is the most common reason a newborn boy doesn't urinate during day 1 of life (also look for meatal stenosis). Gentle catheterization can be done to empty the bladder (the valves will not present an obstacle to the catheter). Voiding cystourethrogram is the diagnostic test, and endoscopic fulguration or resection will get rid of them.

Hypospadias is easily noted on physical exam. The urethral opening is on the ventral side of the penis, somewhere between the tip and the base of the shaft. Circumcision should never be done on such a child, inasmuch as the skin of the prepuce will be needed for the plastic reconstruction that will eventually be done.

UTI in children should always lead to a urologic workup. The cause may be vesicoureteral reflux, or some other congenital anomaly. **Vesicoureteral reflux** and infection produce burning on urination, frequency, low abdominal and perineal pain, flank pain, and fever and chills in a child. Start treatment of the infection (empiric antibiotics first, followed by culture-guided choice), and do IVP and voiding cystogram looking for the reflux. If found, use long-term antibiotics until the child "grows out of the problem."

Low implantation of a ureter is usually asymptomatic in little boys but has a fascinating clinical presentation in little girls. The patient feels normally the need to void, and voids normally at appropriate intervals (urine deposited into the bladder by the normal ureter); but is also wet with urine all the time (urine that drips into the vagina from the low implanted ureter). If physical examination does not find the abnormal ureteral opening, IVP will show it. Corrective surgery is done.

Ureteropelvic junction (UPJ) obstruction can also produce a fascinating clinical presentation. The anomaly at the UPJ allows normal urinary output to flow without difficulty, but if a large diuresis occurs, the narrow area cannot handle it. Thus the classic presentation is an adolescent who goes on a beer-drinking binge for the first time in his life, and develops colicky flank pain.

TUMORS

Hematuria is the most common presentation for cancers of the kidney, ureter, or bladder. Actually most cases of hematuria are caused by benign disease, but except for the adult who has a trace of urine after significant trauma, any patient presenting with hematuria needs a workup to rule out cancer. Workup should begin with CT scan and continue with cystoscopy, which is the only reliable way to rule out cancer of the bladder.

Renal cell carcinoma in its full-blown picture produces hematuria, flank pain, and a flank mass. It can also produce hypercalcemia, erythrocytosis, and elevated liver enzymes. That

full-blown picture is rarely seen today, since most patients are worked up as soon as they have hematuria. CT gives the best detail, showing the mass to be heterogenic solid tumor (and alerting the urologist to potential growth into the renal vein and the vena cava). Surgery is the only effective therapy and may include partial nephrectomy, radical nephrectomy, or even inferior vena cava resection.

Cancer of the bladder (transitional cell cancer in most cases) has a very close correlation with smoking (even more so than cancer of the lung), and usually presents with hematuria. Sometimes there are irritative voiding symptoms, and patients may have been treated for UTI even though cultures were negative and they were afebrile. Although cystoscopy is the best way to diagnose these, it should be preceded by CT scan. Both surgery and intravesical BCG have therapeutic roles, and a very high rate of local recurrence makes life-long close follow-up a necessity.

Prostatic cancer incidence increases with age. Most are asymptomatic, and have to be sought by rectal exam (rock-hard discrete nodule) and prostatic specific antigen (PSA; elevated levels for age group). Surveillance frequently stops at age 75, beyond which survival is not affected by treatment. Transrectal needle biopsy (guided by sonogram when discovered by PSA) establishes diagnosis. CT helps assess extent and choose therapy. Surgery and/or radiation are choices. Widespread bone metastases respond for a few years to androgen ablation, surgical (orchiectomy) or medical (luteinizing hormone-releasing hormone agonists, or antiandrogens like flutamide).

Testicular cancer affects young men, in whom it presents as a painless testicular mass. Because benign testicular tumors are virtually nonexistent, biopsy is not done, and a radical orchiectomy is performed by the inguinal route. Blood samples are taken pre-op for serum markers (α-fetoprotein [AFP] and β-human chorionic gonadotropin [β-HCG]), which will be useful for follow-up. Further surgery for lymph node dissection may be done in some cases. Most testicular cancers are exquisitely radiosensitive and chemosensitive (platinum-based chemotherapy), offering many options for successful treatment in advanced, metastatic disease.

RETENTION AND INCONTINENCE

Acute urinary retention is very common in men who already have significant symptoms from benign prostatic hypertrophy. It is often precipitated during a cold, by the use of antihistamines and nasal drops, and abundant fluid intake. The patient wants to void but cannot, and the huge distended bladder is palpable.

- An indwelling bladder catheter needs to be placed and left in for at least 3 days.
- First line of long-term therapy is alpha-blockers. 5-alpha-reductase inhibitors are used for very large glands (>40 g).
- Minimally invasive procedures are under evaluation.
- The traditional transurethral resection of the prostate (TURP) is rarely done.

Postoperative urinary retention is also very common, and sometimes it masquerades as incontinence. The patient may not feel the need to void because of post-op pain, medications, etc., but will report that every few minutes there is involuntary release of small amounts of urine. A huge distended bladder will be palpable, confirming that the problem is overflow incontinence from retention. Indwelling bladder catheter is needed.

Stress incontinence is also very common in middle-age women who have had many pregnancies and vaginal deliveries. They leak small amounts of urine whenever intra-abdominal pressure suddenly increases. This includes sneezing, laughing, getting out of a chair, or lifting a heavy

object. They do not have any incontinence during the night. Examination will show a weak pelvic floor, with the prolapsed bladder neck outside of the "high-pressure" abdominal area.

- For early cases, pelvic floor exercises may be sufficient.
- For advanced cases with large cystoceles, surgical repair of the pelvic floor is indicated.
- For extreme cases, surgical reconstruction of the pelvic floor may be needed.

STONES

Passage of ureteral stones produces the classic colicky flank pain, with irradiation to the inner thigh and labia or scrotum, and sometimes nausea and vomiting. Most stones are visible on non-contrast CT scan. Although there is an array of fancy gadgetry available to deal with urinary stones, intervention is not always needed.

- Small stones (≤3 mm) at the ureterovesical junction have a 70% chance of passing spontaneously. Such cases can be handled with analgesics, plenty of fluids, and watchful waiting.
- On the other hand, a 7-mm stone at the UPJ only has a 5% probability of passing. Intervention will be required.

The most common tool used is extracorporeal shock-wave lithotripsy (ESWL). Sometimes ESWL cannot be used (pregnant women, bleeding diathesis, stones that are several centimeters large). Other options include basket extraction, sonic probes, laser beams, and open surgery. Although there is specific therapy for the prevention of recurrences in defined types of stones, abundant water intake is universally applicable.

MISCELLANEOUS

Pneumaturia is almost always caused by fistulization between the bladder and the GI tract, most commonly the sigmoid colon, and most commonly from diverticulitis (second possibility is cancer of the sigmoid, and cancer of the bladder is a very distant third). Workup starts with CT scan, which will show the inflammatory diverticular mass. Sigmoidoscopy is needed later to rule out cancer. Surgical therapy is required.

Impotence can be organic or psychogenic.

- **Psychogenic impotence** has sudden onset, is partner- or situation-specific, does not interfere with nocturnal erections (which can be tested with a roll of postage stamps), and can be effectively treated with psychotherapy only if it is done promptly.
- **Organic impotence**, if caused by trauma, will also have sudden onset, specifically related to the traumatic event (after pelvic surgery, because of nerve damage, or after trauma to the perineum, which involves arterial disruption).
  - Because of chronic disease (arteriosclerosis, diabetes), organic impotence has very gradual onset, going from erections not lasting long enough, to being of poor quality, to not happening at all (including absence of nocturnal erections).
  - Sildenafil, tadalafil, and vardenafil have become first choice therapy in many cases, but there are many other options, including vascular surgery (well-suited for those with arterial injury), suction devices (can be used on almost everybody), and prosthetic implants.

Organ Transplantation 13

Learning Objectives

- ❏ Describe the policies related to waiting lists for organ transplantation
- ❏ Describe the common complications in organ transplantation

Selection of donors has been liberalized tremendously to help alleviate the acute shortage of organs. Virtually all brain-dead patients are potential candidates, regardless of age. Donors with specific infections (e.g., hepatitis) can be used for recipients who have the same disease. Even donors with metastatic cancer can donate corneas.

The general rule for regular physicians is that all potential donors are referred to the harvesting teams, and they will exclude the few that cannot be used at all.

A positive HIV status is the only absolute contraindication to organ donation, though recent reports of donating to HIV+ recipients may change that policy.

Transplant rejection can happen in 3 ways: **hyperacute**, **acute**, and **chronic rejection**.

Hyperacute rejection is a vascular thrombosis that occurs within minutes of reestablishing blood supply to the organ. It is caused by preformed antibodies. It is prevented by ABO matching and lymphocytotoxic crossmatch, and thus it is not seen clinically.

Acute rejection (most common) occurs after the first 5 days, and usually within the first 3 months. Episodes occur even though the patient is on maintenance immunosuppression. Signs of organ dysfunction suggest it, and biopsy confirms it.

- In the case of the **liver**, technical problems are more commonly encountered than immunologic rejection. Thus, the first goal when liver function deteriorates post-transplant (rising g-glutamyltransferase [GGT], alkaline phosphatase, and bilirubin) is to rule out biliary obstruction by U/S and vascular thrombosis by Doppler.
- In the case of the **heart**, signs of functional deterioration occur too late to allow effective therapy, thus routine ventricular biopsies (by way of the jugular, superior vena cava, and right atrium) are done at set intervals. The first line of therapy for acute rejection is steroid boluses. If unsuccessful, antilymphocyte agents (OKT3) have been used though their high toxicity is a problem. Newer anti-thymocyte serum is tolerated better.
- Efforts are underway to come up with cellular MRI as a non-invasive way to diagnose rejection, without the need for biopsy. The field of allotransplantation is in continuous flux.

Chronic rejection is seen years after the transplant, with gradual, insidious loss of organ function. It is poorly understood and irreversible. Although we have no treatment for it, patients suspected of having it have the transplant biopsied in the hope that it may be a delayed (and treatable) case of acute rejection.

SECTION II

Surgical Vignettes

Trauma 1

PRIMARY SURVEY: THE ABCs

Airway

1. A patient involved in a car accident is fully conscious, and his voice is normal.

A very brief vignette, but in terms of the airway, the airway is fine.

2. A patient with multiple stab wounds arrives in the ED fully conscious, and he has normal voice, but he also has an expanding hematoma in the neck.

3. A patient with multiple stab wounds arrives in the ED fully conscious, and he has a normal voice, but he also has subcutaneous air (emphysema) in the tissues in the neck and upper chest.

The airway may be fine now, but it is going to be compromised soon. Intubation is indicated now before an emergency situation develops. Orotracheal intubation with rapid-sequence anesthetic induction and pulse oximetry (or topical anesthesia) is preferred in the setting of a trauma center. Blind nasotracheal intubation is often performed by paramedics in the field. The patient with subcutaneous emphysema requires fiberoptic bronchoscopy (more details follow).

4. A patient involved in a severe car accident has multiple injuries and is unconscious. He is breathing spontaneously but his breathing sounds gurgled and noisy.

Altered mental status is the most common indication for intubation in the trauma patient. Unconscious patients with Glasgow coma scale ≤8 may not be able to maintain or protect their airway. Orotracheal intubation would be preferred here, but no anesthetic is needed.

5. An unconscious patient is brought in by the paramedics with spontaneous but noisy and labored breathing. They relate that at the accident site the patient was conscious, but was complaining of neck pain and was unable to move his lower extremities. He lost consciousness during the ambulance ride, and efforts to secure a nasotracheal airway were unsuccessful.

Although it is obvious that the patient has a cervical spine injury, his airway has to be managed first. Orotracheal intubation can still be performed with manual in-line cervical immobilization or over a flexible bronchoscope. Some prefer nasotracheal intubation in this setting if facial injuries do not preclude it.

6. A patient involved in a severe automobile crash is fully awake and alert, but he has extensive facial fractures and is bleeding briskly into his airway, and his voice is masked by gurgling sounds.

Securing an airway is mandatory, but the orotracheal route may not be suitable. Cricothyroidotomy is probably the best choice under these circumstances (except in the pediatric population because of the high-risk of airway stenosis in children, in whom a tracheostomy should be performed because the cricoid cartilage is much smaller than in the adult).

Breathing

7. An unconscious trauma patient has been rapidly intubated in the ER. He has spontaneous breathing and bilateral breath sounds, and his oxygen saturation by pulse oximetry is above 95.

As far as breathing is concerned, he is moving air (physical examination) and getting oxygen into his blood (oximetry). Deterioration could occur later, but right now we are ready to move to C in the ABCs.

Circulation

8. A 22-year-old man arrives in the ED with multiple gunshot wounds to the abdomen. He is diaphoretic, pale, cold, shivering, and anxious. He asks for a blanket and a drink of water. His BP is 60/40 mm Hg, pulse 150/min, and thready.

We recognize the picture of shock. In the trauma setting, shock is most commonly hypovolemic caused by bleeding, but other possibilities are pericardial tamponade or tension pneumothorax. Although each of these could occur with transabdominal gunshot wounds, it is less likely (than a direct thoracic injury), so most likely the source of shock is bleeding.

Management includes several simultaneous interventions:

- Large-bore IV lines
- Foley catheter
- Preparation of blood products for immediate exploratory laparotomy for control of bleeding
- Fluid and blood administration

The old emphasis on fluid resuscitation first has given way to a preference for control of the bleeding site as the first order of business, particularly when surgery will have to be done anyway. When surgery might or might not be needed as with blunt trauma, fluid resuscitation is still performed first, in part as a diagnostic test (patients who respond promptly and remain stable are probably no longer bleeding).

9. During a bank robbery an innocent bystander is shot multiple times in the abdomen. When the emergency medical technicians arrive, they find him to be in shock. A fully staffed trauma center is 2 miles away from the site of the shooting.

An ambulance can travel 2 miles in 2 minutes—maybe 3. The point of the vignette is that elaborate attempts to start an IV at the site and begin to infuse Ringer's lactate would waste precious time that would be best spent moving the patient to a place where the urgently needed laparotomy can be done ("scoop and run").

10. A 19-year-old male is shot in the right groin during a drug deal gone bad. He staggers to the hospital on his own, and arrives in the ED with BP 90/70 mm Hg and pulse 105/min. Bright red blood is squirting from the groin wound.

The point of this vignette is that control of the bleeding by direct local pressure is the first order of business before volume resuscitation is started. Finger pressure is used in the civilian setting, where typically there is a single patient and multiple health care workers. In the military combat setting, where the ratio is reversed, tourniquets are life-saving.

11. A car accident victim arrives at the ED both unconscious and with spontaneous but noisy breathing. His BP is 80/60 mm Hg, pulse 95/min. Head and neck veins are not obviously distended. While the anesthesia team is intubating him, another team is placing a central line for central venous pressure (CVP) measurement, and others are examining his chest and abdomen.

The emphasis on control of bleeding first and fluid replacement later cannot be implemented if we do not know yet where the bleeding is coming from, and whether it might stop spontaneously or not. In a case like this, two large (16-gauge) peripheral lines should be started, and Ringer's lactate should be rapidly infused.

At one time central venous lines were deemed essential for fluid resuscitation, but short, wide catheters in peripheral veins work better, and placing them does not interfere with other ongoing therapeutic and diagnostic maneuvers. Central lines should only be used when no other access is available or there is a need for monitoring. Percutaneous femoral vein catheter is an acceptable alternative when peripheral IVs are hard to start. Saphenous vein cut-downs, which were very popular in the 1950s, have also made a comeback as a suitable route.

12. A 4-year-old child has been shot in the arm in a drive-by shooting. The site of bleeding has been controlled by local pressure, but he is hypotensive and tachycardic. Two attempts at starting peripheral IVs have been unsuccessful.

Up to age 6, the access of last resort is intraosseous cannulation in the proximal tibia and femur. The initial bolus of Ringer's lactate would be 20 ml/kg of body weight.

13. During a wilderness trek, a 22-year-old man is attacked by a bear and bitten repeatedly in the arms and legs. His trek companion manages to kill the bear and to stop the bleeding by applying direct pressure, but when paramedics arrive 1 hour later, they find the patient to be in a state of shock. Transportation to the nearest hospital will take at least 2 hours.

All the training that paramedics took to enable them to infuse IV fluids has not been wasted. In the urban setting we now prefer rapid transportation to the hospital ("scoop and run"), but in this case prompt and vigorous fluid resuscitation is in order. The preferred fluid is Ringer's lactate, infusing at least 2 liters in the first 20–30 minutes.

14. A 22-year-old gang member arrives in the ED with multiple gunshot wounds to the chest and abdomen. He is diaphoretic, pale, cold, shivering, anxious, and asking for a blanket and a drink of water. His BP is 60/ 40 mm Hg and pulse 150/min and thready.

Hypovolemic shock is still the best bet, but the inclusion of chest wounds raises the possibility of pericardial tamponade or tension pneumothorax. As a rule, if significant findings are not included in the vignette, they are not present. Thus, as given, this is still a vignette of hypovolemic shock, but you may be offered in the answers the option of looking for the missing clinical signs: distended neck veins (or a high measured CVP) would be common to both tamponade and tension pneumothorax; and respiratory distress, tracheal deviation, and absent breath sounds on a hemithorax that is hyperresonant to percussion would specifically identify tension pneumothorax.

15. A 22-year-old gang member arrives in the ED with multiple gunshot wounds to the chest and abdomen. He is diaphoretic, pale, cold, shivering, anxious, and asking for a blanket and a drink of water. His BP is 60/40 mm Hg and pulse 150/min and thready. He has distended veins in his neck and forehead. He is breathing okay and has bilateral breath sounds and no tracheal deviation.

This is clearly describing the presentation of pericardial tamponade. Although the FAST exam or a formal transthoracic echocardiogram could confirm the diagnosis, it is clinically apparent and time is of the essence. Management entails evacuation of the blood in the pericardial space. This could be done by pericardiocentesis or pericardial window. If positive, follow with thoracotomy and then exploratory laparotomy. Fluid administration or blood transfusions would also help the patient with pericardial tamponade, but only as a temporizing measure while preparations are being made to evacuate the pericardial sac.

16. During a domestic dispute a young woman is stabbed in the chest with a 6-inch-long butcher knife. On arrival at the ED she is found to have an entry wound just to the left of the sternal border, at the fourth intercostal space. BP is 80/50 mm Hg and pulse 110/min. She is cold, pale, and perspiring heavily. She has big distended neck and facial veins, but she is breathing normally and has bilateral breath sounds.

There is no question that this is pericardial tamponade, and the location of the entry wound leaves no doubt as to the source: a stab wound to the heart. That will need to be repaired, and performing the median sternotomy will automatically open the pericardial sac and relieve the tamponade. Many trauma surgeons will not bother with previous pericardiocentesis or pericardial window, and will go straight to the OR.

17. A 22-year-old gang member arrives in the ED with multiple gunshot wounds to the chest and abdomen. He has labored breathing and is cyanotic, diaphoretic, cold, and shivering. His BP is 60/40 mm Hg and pulse 150/min and thready. He is in respiratory distress and has big distended veins in his neck and forehead, his trachea is deviated to the left, and the right side of his chest is hyperresonant to percussion, with no breath sounds.

This vignette describes a tension pneumothorax. Management entails immediate decompression using a large-bore needle or IV catheter placed into the right pleural space, followed by chest tube placement on the right side. Watch out for a trap which offers chest x-ray as an answer choice. Although this would confirm the diagnosis, it is clinically apparent and time is of the essence. Patient will die if sent to x-ray. Exploratory laparotomy will follow.

18. A 22-year-old man is involved in a high-speed, head-on automobile collision. He arrives in the ED in coma, with fixed, dilated pupils. He has multiple obvious fractures in both upper extremities and in the right lower leg. His BP is 70/50 mm Hg, with a barely perceptible pulse 140/min. His CVP is zero.

We have pointed out that shock in the trauma setting is caused by bleeding (the most common source), pericardial tamponade, or tension pneumothorax. This case fits right in, but the presence of obvious head injury might lead you into a trap: the question will offer you several kinds of intracranial bleeding (acute epidural hematoma, acute subdural hematoma, intracerebral bleeding, subarachnoid hemorrhage, etc.) as answer choices, all of which would be wrong. Intracranial bleeding can indeed kill you, but not by blood loss. There isn't enough

room in the head to accommodate the amount of blood needed to go into shock (roughly a liter and a half in the average size adult). Thus, you need to look for another source (we will elaborate in the section on abdominal trauma).

19. A 72-year-old man who lives alone calls 911 saying that he has severe chest pain. He cannot give a coherent history when picked up by the EMTs, and on arrival at the ED he is cold and diaphoretic and his BP is 80/65mm Hg. He has an irregular, feeble pulse at 130/min. His neck and forehead veins are distended, and he is short of breath.

Many findings are similar to above cases but in the absence of trauma: old man, chest pain, straightforward cardiogenic shock from massive MI. Management entails electrocardiogram (ECG), check coronary enzymes, admit to coronary care unit, etc. Do not drown him with enthusiastic fluid "resuscitation," but use thrombolytic therapy if offered.

20. A 17-year-old girl is stung many times by a swarm of bees. On arrival to the ED she has BP 75/20 mm Hg and pulse 150/min, but she looks warm and flushed rather than pale and cold. CVP is low.

21. Twenty minutes after receiving a penicillin injection, a man breaks into hives and develops wheezing. On arrival at the ED his BP 75/20 mm Hg and pulse 150/min, but he looks warm and flushed rather than pale and cold. CVP is low.

22. In preparation for an inguinal hernia repair, a patient has a spinal anesthetic placed. His level of sensory block is much higher than anticipated, and shortly thereafter his BP becomes 75/20 mm Hg, but he looks warm and flushed rather than pale and cold. CVP is low.

All of these vignettes describe vasomotor shock due to anaphylaxis or inhibition of the sympathetic nervous system. Management is vasoconstrictors and volume replacement.

A REVIEW FROM HEAD TO TOE

Head Trauma

1. An 18-year-old man arrives in the ED with an ax firmly implanted into his head. Although it is clear from the size of the ax blade and the penetration that he has sustained an intracranial wound, he is awake and alert and hemodynamically stable.

The management of penetrating wounds is fairly straightforward. There will be exceptions, but as a rule the damage done to the internal organs (in this case the brain) will need to be repaired surgically. This man will go to the OR, and it will be there, under anesthesia and with full control, that the ax will be removed. An important detail when the weapon is embedded in the patient and part of it is sticking out is not to remove it in the ED or at the scene of the accident.

2. In the course of a mugging, a man is hit over the head with a blunt instrument. He has a scalp laceration, and CT scan shows an underlying linear skull fracture. He is neurologically intact and gives no history of having lost consciousness.

The rule in skull fractures is that if they are closed (no overlying wound) and asymptomatic, they are left alone. If they are open (like this one), the laceration has to be cleaned and closed, but if not comminuted or depressed, it can be done in the ER.

3. In the course of a mugging, a man is hit over the head with a blunt instrument. He has a scalp laceration, and CT scan shows an underlying comminuted, depressed skull fracture. He is neurologically intact and gives no history of having lost consciousness.

This one goes to the OR for cleaning and repair, and possible craniotomy.

4. A pedestrian is hit by a car. When brought to the ED he has minor bruises and lacerations but is otherwise quite well, with a completely normal neurologic exam. However, the ambulance crew reports that he was unconscious at the site, and although he woke up during the ambulance ride and is now completely lucid, he does not remember how the accident happened.

Anyone who has been hit over the head and has become unconscious gets a CT scan, looking for intracranial hematomas. If the CT scan and the neurologic exam are normal, he can go home—provided his family is willing to wake him up frequently over the next 24 hours to make sure he is not going into coma.

5. A pedestrian is hit by a car. He arrives in the ED in coma. He has ecchymosis around both eyes (raccoon eyes).

6. A pedestrian is hit by a car. He arrives in the ED in coma. He has clear fluid dripping out of his nose.

7. A pedestrian is hit by a car. He arrives in the ED in coma. He has clear fluid dripping from the ear.

8. A pedestrian is hit by a car. He arrives in the ED in coma. He has ecchymosis behind the ear.

Cases 5–8 are vignettes of basal skull fracture; they all require CT scan because the patient is in a coma. The scan will show the fractures, but nothing will actually be done about them. Typically, the leak of CSF will stop by itself, and although there is a higher risk of meningitis, prophylactic antibiotics have not proven to be of use. The CT scan should be extended to include the neck because the most important feature of these 4 vignettes is that the patients sustained significant trauma to the head and thus are at risk for lesions of the cervical spine.

9. A 14-year-old boy is hit over the side of the head with a baseball bat. He loses consciousness for a few minutes, but he recovers promptly and continues to play. One hour later he is found unconscious in the locker room. His right pupil is fixed and dilated. There are signs of contralateral hemiparesis.

This vignette describes an acute epidural hematoma, most likely on the right side. Diagnosis is made with CT scan, which will show a lens-shaped hematoma and deviation of the midline structures to the opposite side. Management is emergency surgical decompression via craniotomy. It has a good prognosis if treated, but fatal within hours if it is not.

10. A 32-year-old man is involved in a head-on, high-speed automobile collision. He is unconscious at the site, regains consciousness briefly during the ambulance ride, and arrives at the ED in deep coma with a fixed, dilated right pupil and contralateral hemiparesis.

This could be an acute epidural hematoma, but acute subdural is a better bet (big-time trauma, sicker patient). Diagnosis is made with CT scan, which will show a semilunar, crescent-shaped hematoma. Given the lateralizing signs, it will also show deviation of the midline structures to the opposite side. Be sure to check the cervical spine also!

Management requires an emergency craniotomy with evacuation of the clot often leading to significant improvement, particularly when the brain is being pushed to the side, but ultimate prognosis is poor because of accompanying parenchymal injury.

11. A man involved in a high-speed, head-on automobile collision is in coma. He has never had any lateralizing signs, and CT scan shows a small crescent shaped hematoma, but there is no deviation of the midline structures.

Another subdural hematoma, but without lateralizing signs and evidence of displacement of the midline structures, surgery has little to offer. Management will probably be directed at controlling ICP, as detailed in the next vignette.

12. A patient involved in a head-on, high-speed automobile collision arrives in the ED in deep coma, with bilateral fixed dilated pupils. CT scan of the head shows diffuse blurring of the gray-white mass interface and multiple small punctate hemorrhages. There is no single large hematoma or displacement of the midline structures.

The CT findings are classic for diffuse axonal injury. Prognosis is terrible, and surgery cannot help. Therapy will be directed at preventing further injury from increased ICP. Probably ICP monitoring will be in order. First-line measures to lower ICP include head elevation, hyperventilation, and avoidance of fluid overload. Mannitol and furosemide are next in line.

Do not overdo the treatment. Lowering ICP is not the ultimate goal; preserving brain perfusion is. Thus, diuretics which lead to systemic hypotension, or measures which produce excessive cerebral vasoconstriction may be counterproductive. Hyperventilation is indicated when there are clinical signs of herniation, and the goal is PCO_2 of 35. Lowering oxygen demand may also help. Sedation has been used for that purpose, and hypothermia is currently advocated for the same reason.

13. A 77-year-old man "becomes senile" over a period of 3 or 4 weeks. He used to be active and managed all of his financial affairs. Now he stares at the wall, barely talks, and sleeps most of the day. His daughter recalls that he fell from a horse about a week before the mental changes began.

This vignette is suspicious for a chronic subdural hematoma due to venous bleeding. Diagnosis is made with CT scan, and management is surgical decompression via craniotomy. Spectacular improvement is expected if recognized and treated appropriately.

14. A 45-year-old man is involved in a high-speed automobile collision. He arrives at the ED in coma with fixed, dilated pupils. He has multiple other injuries, including fractures of the extremities. His BP is 70/50 mm Hg with a feeble pulse 130/min. What kind of intracranial bleeding is responsible for the low BP and high pulse rate?

This very same vignette was presented in the review of shock. Shock does not result from intracranial bleeding (not enough room in the head for sufficient blood loss to cause shock). Look for an answer of significant blood loss to the outside (could be scalp laceration), or inside (abdomen, pelvic fractures).

Neck Trauma

15. A man has been shot in the neck and his BP is rapidly deteriorating.

Not much detail, but the point is that penetrating wounds anywhere in the neck need immediate surgical exploration if the patient is unstable (i.e., if vital signs are deteriorating).

16. A 42-year-old man is shot once with a .22-caliber revolver. The entrance wound is in the anterior left side of the neck, at the level of the thyroid cartilage. X-rays show that the bullet is embedded in the right scalene muscle. He is spitting and coughing blood and has an expanding hematoma under the entrance wound. His BP responded promptly to fluid administration, and he has remained stable.

A clear-cut case of a penetrating wound in the middle of the neck (zone II) that has alarming symptoms and therefore follows the rule (rather than the exception) for all penetrating injuries: immediate surgical exploration is required. This is true even though he is stable. The middle of the neck is packed with structures that should not have holes in them and are easily accessible via surgical exploration.

17. A young man is shot in the upper part of the neck. Evaluation of the entrance and exit wounds indicates that the trajectory is all above the level of the angle of the mandible. A steady trickle of blood flows from both wounds, and does not seem to respond to local pressure. The patient is drunk and combative but seems to be otherwise stable.

Now we are getting into the exceptions. In this very high level of the neck (Zone III) there is no trachea or esophagus to worry about, but only pharynx—injuries to which are less consequential. Vascular injuries are the only potential problem, but getting to them surgically is not easy. Thus angiography is a better choice, both for diagnosis and potentially for embolization.

18. A young man suffers a gunshot wound to the base of his neck. The entrance and exit wounds are above the clavicles but below the cricoid cartilage. He is hemodynamically stable.

This is another part of the neck (Zone I, or the thoracic outlet) that is crammed with vital structures that should be promptly repaired if they are injured. But precise preoperative diagnosis would help plan the incision and surgical approach. If the patient is stable, the standard workup includes angiography, soluble-contrast esophagogram, esophagoscopy, and bronchoscopy.

19. In the course of a bar fight, a young man is stabbed once in the neck. The entrance wound is in front of the sternomastoid muscle on the right, at the level of the thyroid cartilage. The patient is completely asymptomatic, and his vital signs are completely normal.

In stab wounds to the upper and middle zones of the neck, completely asymptomatic patients can be closely observed but investigate if any symptoms arise.

20. A patient who was the unbelted right front-seat passenger in a car flies through the windshield when the car crashes into a telephone pole at 30 miles an hour. He arrives in the ED strapped to a headboard and with sandbags on both sides of the neck. He has multiple facial lacerations but is otherwise stable.

    Examination of the neck reveals persistent pain and tenderness to palpation over the posterior midline of the neck. Neurologic examination is normal.

Every patient with head injuries from blunt trauma is at risk for cervical spine injury. The paramedics transport everyone as if they had such injury. Neurologic deficits provide a clear answer (more about those later), but in the patient who arrives neurologically intact, we don't want to make the diagnosis by allowing neurologic deficits to develop. Persistent local pain over the suspected area should trigger radiologic evaluation, which is best done with a CT scan of the neck.

Spinal Cord Injury

21. An 18-year-old street fighter gets stabbed in the back, just to the right side of the midline. He has paralysis and loss of proprioception distal to the injury on the right side, and loss of pain perception distal to the injury on the left side.

Probably no one in real life will have such a neat, clear-cut syndrome, but for purposes of the exam this is a classic spinal cord hemisection, better known as Brown-Séquard syndrome.

22. A patient involved in a car accident sustains a burst fracture of the vertebral bodies. He develops loss of motor function and loss of pain and temperature sensation on both sides distal to the injury, while showing preservation of vibratory sense and position.

Anterior cord syndrome.

23. An elderly man is involved in a rear-end automobile collision in which he hyperextends his neck. He develops paralysis and burning pain on both upper extremities while maintaining good motor function in his legs.

Central cord syndrome.

Management for cases 21–23 requires making the precise diagnosis. CT scans are good to look at the cervical bones. To evaluate the cord, MRI is better. Beyond that, the specific and complicated management of spinal cord injuries is unlikely to be tested on the examination.

Chest Trauma

24. A 75-year-old man slips and falls at home, hitting his right chest wall against the kitchen counter. He has an area of exquisite pain to direct palpation over the seventh rib, at the level of the anterior axillary line. Chest x-ray confirms the presence of a rib fracture, with no other abnormal findings.

A plain rib fracture is the most common chest injury. It is bothersome but manageable in most people, but it can be hazardous in the elderly as splinting and hypoventilation leads to atelectasis and can ultimately lead to pneumonia. The key to treatment is local pain relief, best achieved by nerve block and epidural catheter. Beware of the wrong answers that call for strapping or binding.

25. A 25-year-old man is stabbed in the right chest. He is moderately short of breath and has stable vital signs. There are no breath sounds on the right, which is hyperresonant to percussion.

This vignette describes an uncomplicated pneumothorax. Diagnosis is made with chest x-ray; is this case, as opposed to a tension pneumothorax, there is time to get an x-ray if the option is offered. Ultimately, management is with insertion of a chest tube. If given an option for location, it should be placed at the fifth intercostal space in the mid-axillary line, above the rib.

26. A 25-year-old man is stabbed in the right chest. He is moderately short of breath and has stable vital signs. The base of the right chest has no breath sounds and is dull to percussion. He has faint distant breath sounds at the apex.

Given these findings, this case sounds more like hemothorax. Diagnosis is again made with chest x-ray, and if confirmed, treatment is still with a chest tube. This allows drainage to enable ventilation, assess quantity of bleeding, and drain blood because if blood is allowed to remain in the pleural space, it will lead to adhesions and form a fibrothorax or get infected and create and empyema.

27. A 25-year-old man is stabbed in the right chest. He is moderately short of breath and has stable vital signs. There are no breath sounds at the right base, and only faint distant breath sounds at the apex. The right base is dull to percussion. Chest x-ray confirms the presence of a hemothorax. A chest tube placed at the right pleural base recovers 120 ml of blood and drains another 20 ml in the next hour.

The point of this case is that most hemothoraces do not need exploratory surgery. Bleeding is typically from the lung parenchyma (low pressure) and stops by itself. It also can be from the intercostal artery. A chest tube is all that is needed. Key clue: little blood retrieved, even less afterward.

28. A 25-year-old man is stabbed in the right chest. He is moderately short of breath, has BP of 95/70 mm Hg, pulse 100/min. No breath sounds are heard over the right chest, which is dull to percussion. Chest x-ray shows a large hemothorax on the right. A chest tube placed at the right pleural base recovers 1,250 ml of blood.

The exception is bleeding from a systemic vessel or a major vessel in the pulmonary circuit which will need surgical exploration to repair or ligate. The most likely culprit is an intercostal artery. One or more of the following is required for proceeding with surgical exploration:

- Immediate drainage >1.5 L
- >250 mL/hour for 4 hours
- Hemodynamic instability with high output

29. A 25-year-old man is stabbed in the right chest. He is moderately short of breath and has stable vital signs. There are no breath sounds at the right base, and only faint distant breath sounds at the apex. The right base is dull to percussion. Chest x-ray confirms the presence of a hemothorax. A chest tube placed at the right pleural base recovers 350 ml of blood. Over the ensuing 4 hours he continues to drain 200–300 mL of blood/hour.

Another example of bleeding from a systemic vessel (most likely an intercostal) that will require a thoracotomy.

30. A 25-year-old man is stabbed in the right chest. He is moderately short of breath, has stable vital signs. No breath sounds on the right. Hyperresonant to percussion at the apex of the right chest, dull at the base. Chest x-ray shows one single, large air-fluid level.

This describes a hemopneumothorax. Chest tube placement would ideally be at the base to make sure all the blood is drained. Subsequent management criteria as in the previous vignettes.

31. A worker has been injured at an explosion in a factory. He has multiple cuts and lacerations from flying debris, and he is obviously short of breath. The paramedics at the scene of the accident ascertain that he has a large, flaplike wound in the chest wall, about 5 cm in diameter, and he sucks air through it with every inspiratory effort.

The classic sucking chest wound. It needs to be covered to prevent further air intake (Vaseline gauze is ideal), but must be allowed to let air out. Taping the dressing on 3 sides creates a one-way flap that allows air to escape but not enter. Once in the hospital, he will need a chest tube.

32. A 54-year-old woman crashes her car against a telephone pole at high speed. On arrival at the ED she is in moderate respiratory distress. She has multiple bruises on the chest, and multiple sites of point tenderness over the ribs. X-rays show multiple rib fractures on both sides. On closer observation it is noted that a segment of chest wall on the left side caves in when she inhales, and bulges out when she exhales.

Paradoxical breathing as described essentially makes the diagnosis of flail chest. Diagnosis is easy, but management requires a long discussion. Management of severe blunt trauma to the chest from a deceleration injury has 3 components:

- Treatment of the obvious lesion
- Monitoring for other pathology that may not become obvious until a day or two later
- Actively investigating the potential presence of a silent killer, traumatic transection of the aorta

In this case, the obvious lesion is flail chest. The problem there is the underlying pulmonary contusion, which is treated with fluid restriction, diuretics, and close monitoring of blood gases. Should blood gases deteriorate, the patient needs to be placed on a respirator and get bilateral chest tubes (because lungs punctured by the broken ribs could leak air once positive pressure ventilation is started, which could lead to a tension pneumothorax).

Monitoring is needed over the next 48 hours for possible signs of pulmonary or myocardial contusion. Repeated chest x-rays, blood gases, EKGs, and troponins are needed.

Traumatic transection of the aorta is best diagnosed with CTA of the chest.

33. A 54-year-old woman crashes her car into a telephone pole at high speed. On arrival at the ED she is breathing well. She has multiple bruises over the chest, and multiple sites of point tenderness over the ribs. X-rays show multiple rib fractures on both sides, but the lung parenchyma is clear and both lungs are expanded. Two days later her lungs "white out" on x-rays and she is in respiratory distress.

This is a classic presentation of pulmonary contusion. It does not always show up right away, may become evident 1 or 2 days after the trauma. Management consists of fluid restriction, diuretics, and respiratory support. The latter is essential with intubation, mechanical ventilation, and PEEP if needed.

34. A 33-year-old woman is involved in a high-speed automobile collision. She arrives at the ED gasping for breath, cyanotic at the lips, with flaring nostrils. There are bruises over both sides of the chest, and tenderness suggestive of multiple fractured ribs. BP is 60/45 mm Hg and pulse 160/min and thready. She has distended neck and forehead veins and is diaphoretic. Her left hemithorax has no breath sounds and is hyperresonant to percussion.

A variation on an old theme: classic picture for tension pneumothorax—but where is the penetrating trauma? The fractured ribs can act as a penetrating weapon.

Management. Needle through the upper anterior chest wall to decompress the pleural space, followed by chest tube on the left. Do not fall for the option of getting x-ray first, though you need it later to verify the correct position of the chest tube. This is a deceleration injury. You also need to look for traumatic transection of the aorta with a CTA as discussed.

35. A 54-year-old woman crashes her car against a telephone pole at high speed. On arrival at the ED she is breathing well. She has multiple bruises over the chest, and is exquisitely tender over the sternum at a point where there is a gritty feeling of bone grating on bone, elicited by palpation.

Obviously this describes a sternal fracture (which a lateral chest x-ray will confirm), but the point is that she is at high risk for myocardial contusion and for traumatic rupture of the aorta. Diagnosis of cardiac contusion is made by ECG, and management of arrhythmias as they develop. Serum troponin levels are not always useful as they will not change management. But the real important test would be CTA looking for an aortic rupture given the mechanism of injury.

36. A 53-year-old man is involved in a high-speed automobile collision. He has moderate respiratory distress. Physical examination shows no breath sounds over the entire left chest. Percussion is unremarkable. Chest x-ray shows multiple air fluid levels in the left chest.

This is classic for traumatic diaphragmatic rupture with resultant migration of intra-abdominal contents into the left chest; the right side is protected by the liver so it always occurs to the left.

A nasogastric (NG) tube curling up into the left chest might be an added tidbit. In suspicious cases, laparoscopic evaluation is indicated. Management is surgical repair either through the abdomen (more common) or chest dependent on the surgeon

37. A motorcycle daredevil attempts to jump over the 12 fountains in front of Caesar's Palace Hotel in Las Vegas. As he leaves the ramp at very high speed, his motorcycle turns sideways and he hits the retaining wall at the other end, literally like a rag doll. At the ED he is found to be remarkably stable, although he has multiple extremity fractures. Chest x-ray shows fracture of the left first rib and widened mediastinum.

What is it? This is a real case. Classic for traumatic rupture of the aorta: massive trauma, fracture of a hard-to-break bone (could be first rib, scapula, or sternum), and the telltale hint of widened mediastinum.

Diagnosis is with spiral CT scan. Management is emergency surgical repair.

38. A 34-year-old woman suffers severe blunt trauma in a car accident. She has multiple injuries to her extremities, head trauma, and pneumothorax on the left side. Shortly after initial examination it is noted that she is developing progressive subcutaneous emphysema all over her upper chest and lower neck.

Three things can give thoracic subcutaneous emphysema. One is rupture of the esophagus, but the setting there is always after endoscopy (for which it is diagnostic). The second one is tension pneumothorax, but there the alarming findings are all the others already reviewed—the emphysema is barely a footnote. That leaves the third (which is the case): traumatic rupture of the trachea or major bronchus.

Diagnosis is with chest x-ray to confirm the presence of air in the tissues. Fiberoptic bronchoscopy will confirm diagnosis and level of injury and to secure an airway. Surgical repair thereafter.

39. A patient who had received a chest tube for a traumatic pneumothorax is noted to be putting out a very large amount of air through the tube (a large air leak), and his collapsed lung is not expanding.

Another presentation for a major bronchial injury.

40. A patient who sustained a penetrating injury of the chest has been intubated and placed on a respirator, and a chest tube has been placed in the appropriate pleural cavity. The patient had been hemodynamically stable throughout, but then suddenly goes into cardiac arrest.

A typical scenario for air embolism, from an injured bronchus to a nearby injured pulmonary vein, and from there to the left ventricle. Immediate management includes cardiac massage, followed by thoracotomy.

41. During the performance of a supraclavicular node biopsy under local anesthesia, suddenly a hissing sound is heard, and the patient drops dead.

42. A patient who is receiving total parenteral nutrition through a central venous line becomes frustrated because the nurses are not answering his call button, so he gets up and out of bed, and disconnects his central line from the IV tubing. With the open catheter dangling, he takes two steps in the direction of the nurses station, and drops dead.

Two more examples of air embolism. Other thoracic calamities such as tension pneumothorax or continued bleeding will produce severe deterioration of vital signs, but there will be a sequence from being okay to becoming terribly ill. When vignettes give you sudden death, think of air embolism. This is very uncommon.

43. A patient who sustained severe blunt trauma, including multiple fractures of long bones, becomes disoriented about 12 hours after admission. Shortly thereafter he develops petechial rashes in the axillae and neck, fever, and tachycardia. A few hours later he has a full-blown picture of respiratory distress with hypoxemia. Chest x-ray shows bilateral patchy infiltrates, and his platelet count is low.

This is not a chest injury, but is included here because its main problem is respiratory distress. You probably recognized already the fat embolism syndrome. It is not clear how specific the lab finding of fat droplets in the urine is, but it does not matter: the mainstay of therapy is respiratory support—which is needed regardless of the etiology of the respiratory distress. Heparin, steroids, alcohol, and low-molecular-weight dextran have all been used, but are of questionable value.

Abdominal Trauma

44. A 19-year-old gang member is shot in the abdomen with a .38-caliber revolver. The entry wound is in the epigastrium, to the left of the midline. The bullet is lodged in the psoas muscle on the right. He is hemodynamically stable, the abdomen is moderately tender.

No diagnostic tests are needed. A penetrating gunshot wound of the abdomen gets exploratory laparotomy every time. Preparations before surgery include an indwelling bladder catheter, a large-bore venous line for fluid administration, and a dose of broad-spectrum antibiotics.

45. At exploratory laparotomy for the patient described in the previous question, examination shows clean, punched-out entrance and exit wounds in the transverse colon.

If there is gross fecal contamination, do a colostomy. With minimal contamination, primary repair is usually okay.

46. A 19-year-old gang member is shot once with a .38-caliber revolver. The entry wound is in the left mid-clavicular line, 2 inches below the nipple. The bullet is lodged in the left paraspinal muscles. He is hemodynamically stable, but he is drunk and combative and physical examination is difficult to perform.

What is it? The point here is to remind you of the boundaries of the abdomen; though this seems like a chest wound, it is also abdominal. The belly begins at the nipple line. The chest does not end at the nipple line, though. Belly and chest are not stacked up like pancakes: they are separated by a dome. This patient needs all the stuff for a penetrating chest wound (chest x-ray, chest tube if needed), plus the exploratory laparotomy.

47. A 42-year-old man is stabbed in the belly by a jealous lover. The wound is lateral to the umbilicus, on the left, and omentum can be seen protruding through it.

The general rule is that penetrating abdominal wounds get a laparotomy. That is true for gun-shot wounds, but it is also true for stab wounds if it is clear that peritoneal penetration took place.

48. In the course of a domestic fight, a 38-year-old obese woman is attacked with a 4-inch-long switchblade. In addition to several superficial lacerations, she was stabbed in the abdomen. She is hemodynamically stable, and does not have any signs of peritoneal irritation.

This is probably the only exception to the rule that penetrating abdominal wounds have to be surgically explored—and that is because this in fact may not be penetrating at all! (The blade was short, the woman is well padded.) Local wound exploration of the wound tract in the ED may show that no abdominal surgery is needed (i.e. the anterior rectus fascia has not been violated). But if there is any suspicion of intra-abdominal injury, obtain an abdominal CT.

49. A 31-year-old woman smashes her car against a wall. She has multiple injuries including upper and lower extremity fractures. Her BP is 75/55 mm Hg, pulse rate 110/min, and CVP 0. On physical examination she has a tender abdomen, with guarding and rebound on all quadrants.

50. A 31-year-old woman smashes her car against a wall. She has multiple injuries including upper and lower extremity fractures. Her BP is 135/75 mm Hg and pulse 82/min. On physical examination she has a tender abdomen, with guarding and rebound on all quadrants.

Solid organs will bleed when smashed. Hollow viscera will spill their contents. Often they both happen, but one can exist without the other. Here we have 2 vignettes with plenty of clues to suggest that abnormal fluid is loose in the belly. In one case there is also bleeding, in the other there is not; but the presence of "acute abdomen" after blunt abdominal trauma mandates laparotomy. They will both need it.

51. A 26-year-old woman has been involved in a car wreck. She has fractures in both upper extremities, facial lacerations, and no other obvious injuries. Chest x-ray is normal. Shortly thereafter she develops hypotension, tachycardia, and dropping hematocrit. Her CVP is low.

Obviously blood loss, but the question is where. The answer is easy: it has to be in the abdomen. To go into hypovolemic shock one has to lose 25–30% of blood volume, which in the average size adult will be nearly 1.5 L (25–30% of 5 L).

In the absence of external hemorrhage (scalp lacerations can bleed that much), the bleeding has to be internal. That much blood cannot fit inside the head, and would not go unnoticed in the neck (huge hematoma) or chest (a good decubitus x-ray can spot anything >150 ml, and even in other positions 1.5 L would be obvious). Only massive pelvic fractures, multiple femur fractures, or intra-abdominal bleeding can accommodate that much blood. The first two would be evident in physical examination and x-rays. The belly can be silent. Thus the belly is invariably the place to look for that hidden blood.

Diagnosis. We have a choice here. The old, invasive way was the diagnostic peritoneal lavage. The newer, noninvasive ways are the CT scan or sonogram. CT scan is best, but it cannot be done in the patient who is "crashing." (The exam questions still assume that fast CT scanners are not available in every emergency department in the nation. Under this assumption, only hemodynamically stable patients can get the CT scan.) Try to gauge from the question whether the patient is stable—do CT scan—or literally dying on your hands, in which case diagnostic peritoneal lavage or sonogram is performed in the ED or the OR.

Management. Most likely finding will be ruptured spleen. If stable, observation with serial hemoglobin and hematocrit levels every 6 hours for 48 hours. If not, exploratory laparotomy.

52. A 27-year-old intoxicated man smashes his car against a tree. He is tender over the left lower chest wall. Chest x-ray shows fractures of the 8th, 9th, and 10th ribs on the left. He has a BP of 85 over 68 and a pulse rate 128/min, which do not respond satisfactorily to fluid and blood administration. He has a positive peritoneal lavage, and at exploratory laparotomy a ruptured spleen is found.

You are unlikely to be asked technical surgical questions, but when dealing with a ruptured spleen, remove it. Further management includes administration of Pneumovax and also immunization for *Haemophilus influenza* B and meningococcus.

53. A multiple trauma patient is receiving massive blood transfusions as the surgeons are attempting to repair many intraabdominal injuries. It is then noted that blood is oozing from all dissected raw surfaces, as well as from his IV line sites. His core temperature is normal.

Signs of coagulopathy in this setting require a shotgun approach to treatment. Empiric administration of both fresh-frozen plasma and platelet packs is recommended, in a 1:1 ratio with packed RBCs.

54. During the course of a laparotomy for multiple trauma, the patient develops a significant coagulopathy, a core temperature below 34°C, and refractory acidosis.

This combination of hypothermia, coagulopathy, and acidosis is referred to as the "triad of death." It requires that the abdomen be packed and temporarily closed immediately (as long as major vascular injuries and GI tract injuries leading to contamination have been controlled).

55. An exploratory laparotomy for multiple intraabdominal injuries has lasted 3.5 hours, during which time multiple blood transfusions have been given, and several liters of Ringer's lactate have been infused. When the surgeons are ready to close the abdomen they find that the abdominal wall edges cannot be pulled together without undue tension. Both the belly wall and the abdominal contents seem to be swollen.

This is the abdominal compartment syndrome. All the fluid that has been infused has kept the patient alive, but at the expense of creating a lot of edema in the operative area. Forced closure would produce all kinds of problems. The bowel cannot be left exposed to the outside either, so the standard approach is to close the wound with an absorbable mesh over which formal closure can be done later, or with a nonabsorbable plastic cover that will be removed later.

56. In postoperative day 1, a trauma patient develops a very tense and distended abdomen, and the retention sutures are cutting through the abdominal wall. He also develops hypoxia and renal failure.

This is also the abdominal compartment syndrome that was not obvious at the end of the operation, but has developed thereafter. The abdomen will have to be decompressed by opening the incision and using a temporary cover as described above.

Pelvic Fracture

57. In a rollover motor vehicle accident, a 42-year-old woman is thrown out of the car and subsequently becomes crushed underneath it. At evaluation in the ED it is determined that she has a pelvic fracture. She arrived hypotensive, but responded promptly to fluid administration. CT scan shows no intraabdominal bleeding but a pelvic hematoma.

Nonexpanding pelvic hematomas in a patient who has become hemodynamically stable are left alone. Depending on the type of fracture, the orthopedic surgeons may eventually do something to stabilize the pelvis, but at this time the main issue is to rule out the potential associated pelvic injuries: rectum, bladder, and vagina. Physical examination and a Foley catheter will do it.

58. In a rollover motor vehicle accident, a 42-year-old woman is thrown out of the car and subsequently becomes crushed underneath it. At evaluation in the ED it is determined that she has a pelvic fracture. She arrived hypotensive but did not respond to fluid resuscitation. Hemodynamic parameters have continued to deteriorate. FAST exam performed at the ED shows no intraabdominal bleeding.

A tough situation. People can bleed to death from pelvic fracture so it makes sense to do something about it. But that is easier said than done. Surgical exploration is not the answer; these injuries are typically not in the surgical field afforded by a laparotomy. Ateriographic evaluation might reveal arterial bleeding amenable to embolization. Angiographic therapy is not effective for venous bleeding. External pelvic fixation might be the only helpful intervention. A reasonable sequence to give in the examination, as the answer to this vignette, would be external pelvic fixation first, followed by a trip to the angiography suite (interventional radiology) for possible angiographic embolization of both internal iliac arteries.

Urologic Injury

59. A young man is shot point blank in the lower abdomen, just above the pubis. He has blood in the urine, and no evidence of rectal injury.

60. A woman is shot in the flank, and when a Foley catheter was inserted in ED, the urine was found to be grossly bloody.

The hallmark of urologic injuries is blood in the urine after trauma. These two are clear-cut. The therapy is also clear. Penetrating urologic injuries are like most penetrating injuries elsewhere: they need surgical repair.

61. A 22-year-old man involved in a high-speed automobile collision has multiple injuries, including a pelvic fracture. On physical examination there is blood at the meatus.

What is it? The vignette will be longer, but the point is that pelvic fracture plus blood at the meatus in a male means either bladder or urethral injury, most likely the latter. Evaluation starts with a retrograde urethrogram because urethral injury would be compounded by insertion of a Foley catheter.

62. A 19-year-old man is involved in a severe automobile accident. Among many other injuries he has a pelvic fracture. He has blood at the meatus, scrotal hematoma, and the sensation that he wants to urinate but cannot. Rectal examination shows a high-riding prostate.

What is it? This is a more complete description of a posterior urethral injury.

Diagnosis. You already know: retrograde urethrogram.

63. A 19-year-old man is involved in a motorcycle accident. Among many other injuries he has a pelvic fracture. He has blood at the meatus and scrotal hematoma.

This is an anterior urethral injury.

64. A 22-year-old man involved in a high-speed automobile collision has multiple injuries, including a pelvic fracture. At the initial physical examination no blood is seen at the meatus. A poorly informed intern attempts insertion of a Foley catheter, but resistance is met.

Back out! Although the blood at the meatus or the perineal hematoma were not there to warn you, this is also a urethral injury. Do the retrograde urethrogram.

65. A 22-year-old woman involved in a high-speed automobile collision has multiple injuries, including a pelvic fracture. Insertion of a Foley catheter reveals gross hematuria.

What is it? It most likely is a bladder injury.

Assessment will require retrograde cystogram or CT cystography. When done, obvious intraperitoneal extravasation may be seen (rupture at the dome), but if "negative" you need another film after the bladder is empty. Ruptures at the trigone leak retroperitoneally, and the leak may be obscured by the bladder full of dye.

66. A patient involved in a high-speed automobile collision has multiple injuries, including rib fractures and abdominal contusions (but no pelvic fracture). Insertion of a Foley catheter shows that there is gross hematuria.

What is it? The blood most likely is coming from the kidneys.

Diagnosis is with CT scan. For management, the rule is that traumatic hematuria from blunt trauma to the kidney does not need surgery, even if the kidney is smashed. Surgery is done only if the renal pedicle is avulsed or the patient is exsanguinating.

67. A patient involved in a high-speed automobile collision has multiple injuries, including rib fractures and abdominal contusions. Insertion of a Foley catheter shows that there is hematuria, and retrograde cystogram is normal. CT scan shows renal injuries that do not require surgery. Six weeks later the patient develops acute shortness of breath and a flank bruit.

What is it? This is a weird one, but so fascinating that some medical school professors may not be able to resist the temptation to include it. The patient developed a traumatic arteriovenous fistula at the renal pedicle, and subsequent heart failure. Management is arteriogram and surgical correction.

68. A 35-year-old man is about to be discharged from the hospital where he was under observation for multiple blunt trauma sustained in a car wreck. It is then discovered that he has microscopic hematuria.

69. A 4-year-old falls off his tricycle. In the ensuing evaluation he is found to have microscopic hematuria.

Gross traumatic hematuria always has to be investigated, in both children and adults, while microscopic hematuria following trauma does not. At one time it was felt that microscopic hematuria following trauma in children was suggestive of congenital abnormalities and thus deserved mandatory investigation. That is no longer considered absolute. Obviously, any kind of hematuria—needs to be followed.

70. A 14-year-old boy slides down a banister, not realizing that there is a big knob at the end of it. He smashes the scrotum and comes to the ED with a scrotal hematoma the size of a grapefruit. He can urinate normally, and there is no blood in the urine.

What is it? The issue in scrotal hematomas is whether the testicle is ruptured or not.

Diagnosis. U/S will tell.

Management. If ruptured, surgery will be needed, usually orchiectomy. If intact, only symptomatic treatment.

71. A 41-year-old man presents to the ED reporting that he slipped in the shower and injured his penis. Examination reveals a large penile shaft hematoma with normal appearing glans.

What is it? A classic description of fracture of the tunica albuginea (fracture of the corpora cavernosa)—including the usual cover story given by the patient. These always happen during sexual intercourse, usually with woman on top—but the patient is too embarrassed to explain the true details.

Management. This is a urologic emergency. Prompt surgical repair is needed.

Injury to the Extremities

72. A 25-year-old man is shot with a .22-caliber revolver. The entrance wound is in the anteriolateral aspect of his thigh, and the bullet is seen by x-rays to be embedded in the muscles, posterolateral to the femur.

73. A 25-year-old man is shot with a .22-caliber revolver. The entrance wound is in the anteromedial aspect of his upper thigh, and the exit wound is in the posterolateral aspect of the thigh. He has normal pulses in the leg, and no hematoma at the entrance site. X-rays show the femur to be intact.

74. A 25-year-old man is shot with a .22-caliber revolver. The entrance wound is in the anteromedial aspect of his upper thigh, and the exit wound is in the posterolateral aspect of the thigh. He has a large, expanding hematoma in the upper, inner thigh. The bone is intact.

Apart from the obvious need to fix a bone that might have been shattered by a bullet, the issue in low-velocity gunshot wounds (or stab wounds) of the extremities is the possibility of injury to major vessels. In the first vignette, the anatomy precludes that possibility. Thus that patient only needs cleaning of the wound and tetanus prophylaxis. The bullet can be left where it is.

In the second patient, the anatomy of the area makes vascular injury very likely, and lack of symptoms does not exclude that possibility. At one time, all of these would have been surgically explored. Arteriogram then became the preferred diagnostic modality, and, currently CTAis a highly sensitive non-invasive alternative.

In the third example, it is clinically obvious that there is a vascular injury. Surgical exploration is in order. Arteriogram preceding surgical exploration is done only in parts of the body where the very specific site of the vascular injury dictates the use of a particular incision versus another (for instance at the base of the neck and thoracic outlet).

75. A young man is shot through the arm with a .38-caliber revolver. The path of the bullet goes right across the extremity, from medial to lateral sides. He has a large hematoma in the inner aspect of the arm, no distal pulses, radial nerve palsy, and a shattered humerus.

That he will need surgery is clear, but the issue here is what to do first. A very delicate vascular repair, and an even more fragile nerve reanastomosis, would be at risk of disruption when the orthopedic surgeons start manipulating, hammering, and screwing the bone. Thus the usual sequence begins with fracture stabilization, then vascular repair (both artery and vein if possible), and last nerve repair. The unavoidable delay in restoring circulation will make a fasciotomy mandatory. Temporary shunting the arterial injury to allow distal perfusion is a good solution if offered as a choice, but is easier said than done in real life.

76. In a hunting accident, a young man is shot in the leg with a high-powered, big-game hunting rifle. He has an entrance wound in the upper outer thigh that is 1 cm in diameter, and an exit wound in the posteromedial aspect of the thigh that is 8 cm in diameter. The femur is shattered.

Even though the major vessels are not in the path of this bullet, this young man will need to go to the OR to have extensive debridement of the injured tissues. High-velocity bullets (military weapons and big-game hunting rifles) produce a cone of destruction.

77. A 6-year-old girl has her hand, forearm, and lower part of the arm crushed in a car accident. The entire upper extremity looks bruised and battered, although pulses are normal and the bones are not broken.

In addition to possible hyperkalemia, crushing injuries lead to two concerns; the myoglobinemia–myoglobinuria–acute renal failure issue, and the delayed swelling that may lead to a compartment syndrome. For the first, plenty of fluids, osmotic diuretics (mannitol), and alkalinization of the urine help protect the kidney. For the latter, fasciotomy is the answer.

BURNS

1. You get a phone call from a frantic mother. Her 7-year-old girl spilled Drano all over her arms and legs. You can hear the girl screaming in pain in the background.

Management. The point of this question is that chemical injuries—particularly alkalis—need copious, immediate, profuse irrigation. Instruct the mother to do so right at home with tap water, for at least 30 minutes before rushing the girl to the ED. Do not pick an option where you would be "playing chemist," i.e., soak an alkaline burn with an acid or vice versa.

2. While trying to hook up illegally to cable TV, an unfortunate man comes in contact with a high-tension electrical power line. He has an entrance burn wound in the upper outer thigh, and an exit burn lower on the same side.

Management. The issue here is that electrical burns are always much bigger than they appear to be. There is deep tissue destruction. The patient will require extensive surgical debridement, but there is also another item (more likely to be the point of the question): myoglobinemia, leading to myoglobinuria and to renal failure. Patient needs lots of IV fluids, diuretics (osmotic if given that choice, i.e., mannitol), perhaps alkalinization of the urine.

If asked about other injuries to rule out, they include posterior dislocation of the shoulder and compression fractures of vertebral bodies (from the violent muscle contractions), and late development of cataracts and demyelinization syndromes.

3. A man is rescued by firemen from a burning building. On admission it is noted that he has burns around the mouth and nose, and the inside of his mouth and throat look like the inside of a chimney.

What is it? There are two issues here: carbon monoxide poisoning and respiratory burns, i.e., smoke inhalation producing a chemical burn of the tracheobronchial tree. Both will happen with flame burns in an enclosed space. The burns in the face are an additional clue that most patients rarely have in real life but will be mentioned on the exam to point you in that direction.

For the first issue we determine blood levels of carboxyhemoglobin, and put the patient on 100% oxygen (oxygen therapy will shorten the half-life of carboxyhemoglobin). For the second issue, diagnosis can be made with bronchoscopy, but the actual degree of damage—and the need for supportive therapy—is more likely to be revealed by monitoring of blood gases.

Management. Revolves around respiratory support, with intubation and use of a respirator, if needed.

4. A patient has suffered third-degree burns to both of his arms when his shirt caught on fire while lighting the backyard barbecue. The burned areas are dry, white, leathery, anesthetic, and circumferential all around arms and forearms.

What is it? You are meant to recognize the problem posed by circumferential burns: the leathery eschar will not expand, while the area under the burn will develop massive edema, thus circulation will be cut off. (Or in the case of circumferential burns of the chest, breathing will be compromised.) Note that if the fire was in the open space of the backyard, respiratory burn is not an issue.

Management. Compulsive monitoring of Doppler signals of the peripheral pulses and capillary filling. Escharotomies at the bedside at the first sign of compromised circulation. In deeper burns, fasciotomy may also be needed. If the chest wall is involved and respiration impaired, emergent escharotomy is necessary.

5. A toddler is brought to the ED with burns on both of his buttocks. The areas are moist, have blisters, and are exquisitely painful to touch. The parents report that the child accidentally pulled a pot of boiling water over himself.

What is it? Burns, of course. There are several issues. First: how deep. The description is classic for second-degree burns. (Note that in kids third-degree burn is deep bright red, rather than white leathery as in the adult.) How did it really happen? Scalding burns in kids always brings up the possibility of child abuse, particularly if they have the distribution that you would expect if you grabbed the kid by the arms and legs and dunked him in a pot of boiling water.

Management. For the burn is Silvadene (silver sulfadiazine) cream. Management for the social problem requires reporting to authorities for child abuse.

6. An adult man who weighs x kilograms sustains second- and third-degree burns over–whatever. The burns will be depicted in a front-and-back drawing, indicating what is second-degree (moist, blisters, painful) and what is third-degree (white, leathery, anesthetic). The question will be about fluid resuscitation.

The first order of business will be to figure out the percentage of body surface burned. The rule of nines is used. In the adult, the head is 9% of body surface, each arm is 9%, each leg has two 9%s, and the trunk has 4 9%s.

7. An adult who weighs x kilograms has third-degree burns over… (the calculated surface turns out to be >20%). Fluid administration should be started at a rate of what?

If you are simply asked how fast should the infusion start, rather than what is the calculated total for the whole day, the answer is Ringer's lactate (without sugar) at 1,000 ml/h.

8. An adult man who weighs x kilograms has third-degree burns over… (a set of drawings provides the area). How much is the estimated amount of fluid that will be needed for resuscitation?

If asked this way, remember the old Parkland formula:

> 4 ml of Ringer's lactate (without sugar) per kilogram of body weight, per percentage of burned area (up to 50%) "for the burn," plus about 2L of 5% dextrose in water (D5W) for maintenance

Give one half in the first 8 hours, the second half in the next 16 hours. Day 2 requires about one half of that calculated amount, and is the time when colloids should be given if one elects to use them. By day 3 there should be a brisk diuresis, and no need for further fluid.

Remember that these amounts are only a guess, to be fine-tuned by the actual response of the patient (primarily hourly urinary output). Higher amounts are needed in patients who have respiratory burn, electrical burns, or recent escharotomies.

The use of the formulas is now less frequently done, since physicians typically end up adjusting the rate of fluid administration on the basis of the urinary output after initial resuscitation.

9. After suitable calculations have been made, a 70-kg adult with extensive third degree burns is receiving Ringer's lactate at the calculated rate. In the first 3 hours his urinary output is 15, 22, and 18 ml.

Most experts aim for an hourly urinary output of at least 0.5 ml/kg, or preferably 1 ml/kg body weight per hour. For patients with electrical burns the flow should be even higher (1 to 2 ml/kg per hour); thus by any criteria this patient needs more fluid.

10. After suitable calculations have been made, a 70-kg adult with extensive third degree burns is receiving Ringer's lactate at the calculated rate. In the first 3 hours his urinary output is 325, 240, and 270 ml.

The opposite of the previous vignette. Somebody is trying to drown this poor guy. The calculation was too generous; the rate of administration has to be scaled back.

11. During the first 48 hours after a major burn, a 70-kg patient received vigorous fluid resuscitation and maintained a urinary output between 45 and 110 ml/h. On postburn day 3—after IV fluids have been discontinued—urinary output reaches 270 to 350 ml/h.

This is the expected. Fluid is coming back from the burn area into the circulation. He does not need more IV fluids to replace these losses.

12. An 8-month-old baby who weighs x kilograms is burned over…areas (depicted in a front-and-back drawing). Second-degree burn will look the same as in the adult; third-degree burn will look deep bright red.

In babies the head is bigger and the legs are smaller, thus the head has two 9%s, whereas both legs add up to 3 (rather than 4) 9%s. Proportionally, fluid needs are greater in children than in adults. Therefore:

- If asked for the rate in the first hour, it should be 20 ml/kg.
- If asked for 24-hour calculations, the formula calls for 4 to 6 ml/kg/%.

13. A patient with second- and third-degree burns over 65% of his body surface is undergoing proper fluid resuscitation. The question asks about management for the burned areas, and other supportive care.

First of all, tetanus prophylaxis. Then suitable cleaning, and use of topical agents. The standard one is silver sulfadiazine. If deep penetration is desired (thick eschar, cartilage), mafenide acetate is the choice (do not use everywhere; it hurts and can produce acidosis). Burns near the eyes are covered with triple antibiotic ointment. Pain medication is given IV.

After about 2–3 weeks, grafts will be done to the areas that did not regenerate. After an initial day or two of NG suction, intensive nutritional support is needed (via the gut, high calorie/high nitrogen). Rehabilitation starts on day 1.

14. A 42-year-old woman drops her hot iron on her lap while doing the laundry. She comes in with the shape of the iron clearly delineated on her upper thigh. The area is white, dry, leathery, anesthetic.

What is the issue? A current favorite of burn treatment is the concept of early excision and grafting. After fluid resuscitation, the typical patient with extensive burns spends 2–3 weeks in the hospital consuming thousands of dollars of health care every day, getting topical treatment to the burn areas and intensive nutritional support in preparation for skin grafting.

In very extensive burns there is no alternative. However, less extensive burns can be taken to the OR and excised and grafted on day 1, saving tons of money. You will not be asked on the exam to provide the fine judgment call for the borderline case that might be managed that way (the experts are routinely doing it in burns under 20% and daring to include patients with as much as 40%), but the vignette is a classic one in which the decision is easy: very small and clearly third-degree.

Management. Early excision and grafting.

BITES AND STINGS

1. A 6-year-old child tries to pet a domestic dog while the dog is eating, and the child's hand is bitten by the dog.

This is considered a provoked attack, and as far as rabies is concerned, only observation of the pet is required (for development of signs of rabies). Tetanus prophylaxis and standard wound care is all that is needed for the child. Had the bite been to the face, and thus near the brain, treatment should be started and then discontinued if it is proven to be not necessary.

2. During a hunting trip, a young man is bitten on the leg by a coyote. The animal is captured and brought to the authorities alive.

Observation of a wild animal for behavioral signs of rabies is impractical. But having the animal available will allow it to be killed and the brain examined for signs of rabies, thus hopefully sparing the hunter the necessity of getting vaccinated. Had the bite been to the face, and thus near the brain, treatment should be started and then discontinued if it is proven to be not necessary.

3. While exploring caves in the Texas hill country, a young man is bitten by bats (that promptly fly away).

Now we do not have the animal to examine. Rabies prophylaxis is mandatory (immunoglobulin plus vaccine).

4. During a hunting trip a hunter is bitten in the leg by a snake. His companion, who is an expert outdoorsman, reports that the snake had elliptical eyes, pits behind the nostrils, big fangs, and rattlers in the tail. The patient arrives at the hospital 1 hour after the bite took place. Physical examination shows 2 fang marks about 2 cm apart, and there is no local pain, swelling, or discoloration.

The description of the snake is indeed that of a poisonous rattlesnake, but even when bitten by a poisonous snake, up to 30% of patients are not envenomated. The most reliable signs of envenomation are excruciating local pain, swelling, and discoloration (usually fully developed within 30 minutes)—none of which this man has. Continued observation (about 12 hours) is all that is needed, plus the standard wound care (including tetanus prophylaxis).

5. During a hunting trip, a hunter is bitten in the leg by a snake. His companion, who is an expert outdoorsman, reports that the snake had elliptical eyes, pits behind the nostrils, big fangs, and rattlers in the tail. The patient arrives at the hospital 1 hour after the bite took place. Physical examination shows two fang marks about 2 cm apart, as well as local edema and ecchymotic discoloration. The area is very painful and tender to palpation.

This patient is envenomated. Blood should be drawn for typing and crossmatch, coagulation studies, and renal and liver function. The mainstay of therapy is antivenin, of which several vials have to be given. The product currently preferred is CroFab. Surgical excision of the bite site and fasciotomy are only needed in extremely severe cases.

6. While playing in the backyard of her south Texas home, a 6-year-old girl is bitten by a rattlesnake. At the time of hospital admission she has severe signs of envenomation.

The point of this vignette is to remind you that snake antivenin is one of the very few medicines for which the dose is *not* calculated on the basis of the size of the patient. The dose of antivenin depends on the *amount of venom injected*, regardless of the size and age of the victim.

7. During a picnic outing, a young girl inadvertently bumps into a beehive and is stung repeatedly by angry bees. She is seen 20 minutes later and found to be wheezing, hypotensive, and madly scratching an urticarial rash.

Epinephrine is the drug of choice (0.3 to 0.5 ml of 1:1000 solution). The stingers have to be carefully removed.

8. While rummaging around her attic, a woman is bitten by a spider that she describes as black, with a red hourglass mark in her belly. The patient has nausea and vomiting and severe generalized muscle cramps.

Black widow spider bite. The antidote is IV calcium gluconate. Muscle relaxants also help.

9. A patient seeks help for a very painful ulceration that he discovered in his forearm on arising this morning. Yesterday he spent several hours cleaning up the attic, and he thinks he may have been "bitten by a bug." The ulcer is 1 cm in diameter, with a necrotic center with a surrounding halo of erythema.

Probably a brown recluse spider bite. Dapsone will help. Local excision and skin grafting may be needed. All necrotic tissue must be debrided/excised.

10. A 22-year-old gang leader comes to the ED with a small, 1-cm deep sharp cut over the knuckle of the right middle finger. He says he cut himself with a screwdriver while fixing his car.

What is it? The description is classic for a human bite. No, nobody actually bit him—he did it by punching someone in the mouth and getting cut with the teeth that were smashed by his fist. The imaginative cover story usually comes with this kind of lesion. The point of management is that human bites are bacteriologically the dirtiest that one can get and antibiotics are given. Rabies shots will not be needed, but surgical exploration by an orthopedic surgeon will be required as well as antibiotics.

Orthopedics 2

PEDIATRIC ORTHOPEDICS

1. In the newborn nursery it is noted that a child has uneven gluteal folds. Physical examination of the hips reveals that one of them can be easily dislocated posteriorly with a jerk and a "click," and returned to normal position with a "snapping." The family is concerned because a previous child had the same problem.

What is it? Developmental dysplasia of the hip (congenital dislocation of the hip)

Diagnosis. The physical examination should suffice, but if there is any doubt, do a sonogram.

Management. Abduction splinting with Pavlik harness

2. A 6-year-old boy has insidious development of limping with decreased hip motion. He complains occasionally of knee pain on that side. He walks into the office with an antalgic gait. Passive motion of the hip is guarded.

What is it? In this age group, Legg-Calve-Perthes disease (avascular necrosis of the capital femoral epiphysis). Remember that hip pathology can show up with knee pain. Management is AP and lateral x-rays for diagnosis. Contain the femoral head within the acetabulum by casting and crutches.

3. A 13-year-old obese boy complains of pain in the groin (it could be the knee) and is noted by the family to be limping. He sits in the office with the sole of the foot on the affected side pointing toward the other foot. Physical examination is normal for the knee, but shows limited hip motion. As the hip is flexed, the leg goes into external rotation and cannot be rotated internally.

What is it? Forget the details: a bad hip in this age group is slipped capital femoral epiphysis, an orthopedic emergency. Management is AP and lateral x-rays for diagnosis. The orthopedic surgeons will pin the femoral head in place.

4. A young toddler has had the flu for several days, but until 2 days ago he was walking around normally. He now absolutely refuses to move one of his legs. He is in pain and holds the leg with the hip flexed, in slight abduction and external rotation, and you cannot examine that hip—he will not let you move it. He has elevated sedimentation rate.

What is it? Another orthopedic emergency: septic hip. Aspiration of the hip under general anesthesia to confirm the diagnosis, and open arthrotomy is performed for drainage.

5. A child with a febrile illness but no history of trauma has persistent, severe localized pain in a bone.

What is it? Acute hematogenous osteomyelitis. X-ray will not show anything for 2 weeks. MRI is diagnostic. Then give antibiotics.

6. A 2-year-old child is brought in by concerned parents because he is bowlegged.

7. A 5-year-old child is brought in by concerned parents because he is knockkneed.

Genu varum (bow-leg) is normal up to age 3. Genu valgus (knock-knee) is normal ages 4–8. Thus, neither of these children needs therapy. Should the varum deformity (bow-legs) persist beyond its normal age range, i.e., age >3, Blount disease is the most common problem (a disturbance of the medial proximal tibial growth plate). In that case, surgery can be performed.

8. A 14-year-old boy says he injured his knee while playing football. Although there is no swelling of the knee joint, he complains of persistent pain right over the tibial tubercle, which is aggravated by contraction of the quadriceps. Physical examination shows localized tenderness right over the tibial tubercle.

This is another one with a fancy name: Osgood-Schlatter disease (osteochondrosis of the tibial tubercle). It is usually treated with immobilization of the knee in an extension or cylinder cast for 4–6 weeks, if more conservative management fails (rest, ice, compression, and elevation).

9. A baby boy is born with both feet turned inward. Physical examination shows that there is plantar flexion of the ankle, inversion of the foot, adduction of the forefoot, and internal rotation of the tibia.

This is the complex deformity known as club foot (fancy name: talipes equinovarus). The child needs serial plaster casts started in the neonatal period. The sequence of correction starts with the adducted forefoot, then the hindfoot varus, and finally the equinus. About 50% of patients respond completely and need no surgery; those who require surgery are operated on age >6–8 months, but <1–2 years.

10. A 12-year-old girl is referred by the school nurse because of potential scoliosis.

The thoracic spine is curved toward the right, and when the girl bends forward a "hump" is noted over her right thorax. The patient has not yet started to menstruate.

Management. This is too complicated for the exam, but the point is that scoliosis may progress until skeletal maturity is reached. Baseline x-rays are needed to monitor progression. At the onset of menses skeletal maturity is ~80%, so this patient still has a way to go. Bracing may be needed to arrest progression. Pulmonary function could be limited if there is large deformity.

Fractures

11. A 4-year-old falls down the stairs and fractures his humerus. He is placed in a cast at the nearby "doc in the box," and he is seen by his regular pediatrician 2 days later. At that time he seems to be doing fine, but AP and lateral x-rays show significant angulation of the broken bone.

Nothing else is needed. Except for rotational deformities, children have such tremendous ability to heal and remodel broken bones that almost any reasonable alignment and immobilization will end up with a good result. In fact, fractures in children are no big deal—with a few exceptions that are illustrated in the next few vignettes.

12. An 8-year-old boy falls on his right hand with the arm extended, and he breaks his elbow by hyperextension. X-rays show a supracondylar fracture of the humerus. The distal fragment is displaced posteriorly.

This type of fracture is common in children, but it is important because it may produce vascular or nerve injuries—or both—and end up with a Volkmann contracture. Although it can usually be treated with appropriate casting or traction (and rarely needs surgery), the answer revolves around careful monitoring of vascular and nerve integrity, and vigilance regarding development of a compartment syndrome.

13. A child sustains a fracture of a long bone, involving the epiphyses and growth plate. The epiphyses and growth plate are laterally displaced from the metaphyses, but they are in one piece, i.e., the fracture does not cross the epiphyses or growth plate and does not involve the joint.

14. A child sustains a fracture of a long bone that extends through the joint, the epiphyses, the growth plate, and a piece of the metaphyses.

In the first example, even though the dreaded growth plate is involved it has not been divided by the fracture. Treatment by closed reduction is sufficient.

In the second example, there are 2 pieces of growth plate. Unless they are very precisely aligned, growth will be disturbed. Open reduction and internal fixation will be needed.

ADULT ORTHOPEDICS

1. A man who fell from a second floor window has clinical evidence of fracture of his femur. The vignette gives you a choice of x-rays to order.

Here are the rules:

- Always get x-rays at 90° to each other (for instance, AP and lateral).
- Always include the joints above and below.
- If appropriate (this case is), check the other bones that might be in the same line of force (here, the lumbar spine).

2. While playing football, a college student fractures his clavicle. The point of tenderness is at the junction of the middle and distal thirds of the clavicle.

Place the arm in a sling or figure of 8 splint. Young women may request fixation by surgery, to achieve a better cosmetic result.

3. A 55-year-old woman falls in the shower and hurts her right shoulder. She shows up in the ED with her arm held close to her body, but rotated outward as if she were going to shake hands. She is in pain and will not move the arm from that position. There is numbness in a small area of her shoulder, over the deltoid muscle.

What is it? Anterior dislocation of the shoulder, with axillary nerve damage.

Management. Get AP and lateral x-rays for diagnosis. Reduce.

4. After a grand mal seizure, a 32-year-old epileptic notices pain in her right shoulder, and she cannot move it. She goes to the nearby "doc in a box," where she has x-rays and is diagnosed as having a sprain and given pain medication. The next day she still has the same pain and inability to move the arm. She comes to the ED with the arm held close to her body, in a normal (i.e., not externally rotated, but internally rotated) protective position.

What is it? Posterior dislocation of the shoulder. Very easy to miss on regular x-rays.

Management. Get x-rays again but order axillary view or scapular lateral.

5. An elderly woman with osteoporosis falls on her outstretched hand. She comes in with a deformed and painful wrist that looks like a "dinner fork." X-rays show a dorsally displaced, dorsally angulated fracture of the distal radius and small, nondisplaced fracture of the ulnar stylus.

This is the famous Colles' fracture. It is treated with close reduction and long arm cast.

6. During a rowdy demonstration and police crackdown, a young man is hit with a nightstick on his outer forearm that he had raised to protect himself. He is found to have a diaphyseal fracture of the proximal ulna, with anterior dislocation of the radial head.

Another classic with a fancy name: Monteggia fracture. The patient needs closed reduction of the radial head, and possible open reduction and internal fixation of the ulnar fracture.

7. Another victim of the same melee has a fracture of the distal third of the radius and dorsal dislocation of the distal radioulnar joint.

This one is Galeazzi fracture and is quite similar to Monteggia in terms of the resultant instability. The fractured radius may need open reduction and internal fixation, while the dislocated joint may be manipulated back into proper position and casted in supination.

8. A young adult falls on an outstretched hand and comes in complaining of wrist pain. On physical examination, he is distinctly tender to palpation over the anatomic snuff-box. AP and lateral x-rays are read as negative.

Another classic, this is a fracture of the scaphoid bone (carpal navicular). These are notorious because x-rays will not show them for 2–3 weeks, and they have a high rate of nonunion. The history and physical findings (the tenderness in the snuff-box) are sufficient to indicate the use of a thumb spica cast, with repeat x-rays 3 weeks later.

9. A young adult falls on an outstretched hand and comes in complaining of wrist pain. On physical examination he is distinctly tender to palpation over the anatomic snuff-box. AP, lateral, and oblique x-rays show a displaced and angulated fracture of the scaphoid.

Displaced and angulated; will need open reduction and internal fixation.

10. During a barroom fight, a young man throws a punch at somebody, but misses and ends up hitting the wall. He comes in with a swollen and tender right hand. X-rays show fracture of the fourth and fifth metacarpal necks.

Metacarpal necks, typically the fourth or the fifth (or both), take the brunt of one's anger when trying to hit somebody but miss. Treatment depends on the degree of angulation, displacement, or rotary malalignment. Closed reduction and ulnar gutter splint for the mild ones, Kirschner-wire or plate fixation for the bad ones.

11. A 77-year-old man falls in the nursing home and hurts his hip. He shows up with the affected leg shortened and externally rotated. X-rays show that he has a displaced femoral neck fracture.

The point of this vignette is that blood supply to the femoral head is compromised in this setting, and the patient is better off with a metal prosthesis put in, rather than an attempt at fixing the bone.

12. A 77-year-old man falls in the nursing home and hurts his hip. He shows up with the affected leg shortened and externally rotated. X-rays show that he has an intertrochanteric fracture.

These can be fixed with less concern about avascular necrosis. Open reduction and pinning are usually performed. Immobilization in these old people often leads to deep venous thrombosis and pulmonary embolus; thus an additional choice for postoperative anticoagulation may be offered in the question.

13. The unrestrained front-seat passenger in a car that crashes sustains a closed fracture of the femoral shaft.

There are many ways to deal with fractured femurs, but intramedullary rod fixation is commonly done.

14. The unrestrained front-seat passenger in a car that crashes sustains closed comminuted fractures of both femoral shafts. Shortly after admission, he develops BP 80/50 mm Hg, pulse 110/min, and venous pressure 0. The remainder of the physical examination and x-ray survey (chest, pelvis) are unremarkable. Sonogram of the abdomen done in the ED was negative.

This is a throwback to the trauma vignettes to remind you that femur fractures may bleed into the tissues sufficiently to cause hypovolemic shock. Fixation will diminish the blood loss, and fluid resuscitation and blood transfusions will take care of the shock.

15. The unrestrained front-seat passenger in a car that crashes sustains closed comminuted fractures of both femoral shafts. Twelve hours after admission, he develops disorientation, fever, and scleral petechia. Dyspnea is evident shortly thereafter, at which time blood gases show Po2 of 60.

Another repeated topic: fat embolism. Respiratory support is the centerpiece of the treatment.

16. A college student is tackled while playing football, and he develops severe knee pain. When examined shortly thereafter, the knee is swollen, and he has pain on direct palpation over the medial aspect of the knee. With the knee flexed at 30°, passive abduction elicits pain in the same area, and the leg can be abducted further out than the normal, contralateral leg (valgus stress test).

17. A college student is tackled while playing football, and he develops severe knee pain. When examined shortly thereafter, the knee is swollen, and he has pain on direct palpation over the lateral aspect of the knee. With the knee flexed at 30°, passive adduction elicits pain in the same area, and the leg can be adducted further out than the normal, contralateral leg (varus stress test).

The medial collateral ligament is injured in the first example, whereas the second example depicts an injury to the lateral collateral ligament. A hinged cast is the usual treatment for either isolated injury. When several ligaments are torn, surgical repair is preferred.

18. A college student is tackled while playing football, and he develops severe knee swelling and pain. On physical examination with the knee flexed at 90°, the leg can be pulled anteriorly, like a drawer being opened. A similar finding can be elicited with the knee fixed at 20° by grasping the thigh with one hand, and pulling the leg with the other.

This is a lesion of the anterior cruciate ligament, shown by the anterior drawer test and the Lachman test. Further definition of the extent of internal knee injuries can be done with MRI.

Sedentary patients may be treated just with immobilization and rehabilitation, but athletes require arthroscopic reconstruction.

19. A college athlete injured his knee while playing basketball. He has been to several physicians who have prescribed pain medication and a variety of splints and bandages, but he still has a swollen knee and knee pain. He describes catching and locking that limit his knee motion, and he swears that when his knee is forcefully extended there is a "click" in the joint. He has been told that his x-rays are normal.

Meniscal tears may be difficult to diagnose clinically, but MRI will show them beautifully. Arthroscopic repair is done, trying to save as much of the meniscus as possible. If complete meniscectomy is done, late degenerative arthritis will ensue. Some orthopedic surgeons prefer to repair meniscal injuries with an open operation.

20. A young recruit complains of localized pain in his tibia after a forced march at boot camp. He is tender to palpation over a very specific point on the bone, but x-rays are normal.

What is it? Stress fracture. The lesson here is that stress fractures will not show up radiologically until 2 weeks later. Treat as if he has a fracture (cast) and repeat the x-ray in 2 weeks. Non–weight bearing (crutches) is another option.

21. A pedestrian is hit by a car. Physical examination shows the leg to be angulated midway between the knee and the ankle. X-rays confirm fractures of the shaft of the tibia and fibula.

Casting takes care of the ones that can be easily reduced. Intramedullary nailing is needed for the ones that cannot be aligned.

22. A pedestrian is hit by a car. Physical examination shows the leg to be angulated midway between the knee and the ankle. X-rays confirm fractures of the shaft of the tibia and fibula. Satisfactory alignment is achieved, and a long leg cast applied. In the ensuing 8 hours the patient complains of increasing pain. When the cast is removed, the pain persists, the muscle compartments feel tight, and there is excruciating pain with passive extension of the toes.

Compartment syndrome is a distinct hazard after fractures of the leg (the forearm and the lower leg are the two places with the highest incidence of compartment syndrome). Fasciotomy is needed here.

23. An out-of-shape, recently divorced 42-year-old man is trying to impress a young woman by challenging her to a game of tennis. In the middle of the game, a loud "pop" is heard (like a gunshot), and the man falls to the ground clutching his ankle. He limps off the courts, with pain and swelling in the back of the lower leg, but still able to dorsiflex his foot. When he seeks medical help the next day, palpation of his Achilles tendon reveals an obvious defect right beneath the skin.

This is a classic presentation for rupture of the Achilles tendon. Casting in equinus position will allow healing after several months, or open surgical repair may do it sooner.

24. While running to catch a bus, an old man twists his ankle and falls on his inverted foot. AP, lateral, and mortise X-rays show displaced fractures of both malleoli.

A very common injury. When the foot is forcefully rotated (in either direction), the talus pushes and breaks one malleolus and pulls off the other one. Open reduction and internal fixation is needed in this case because the fragments are displaced.

Orthopedic Emergencies

25. A middle-aged homeless man is brought to the ED because of very severe pain in his forearm. He passed out after drinking a bottle of cheap wine and fell asleep on a park bench for an indeterminate time, probably over 12 hours. There are no signs of trauma, but the muscles in his forearm are very firm and tender to palpation. Passive motion of his fingers and wrist elicit excruciating pain. Pulses at the wrist are normal.

Classic compartment syndrome. Emergency fasciotomy is needed. Note that normal pulses do not rule out this diagnosis.

26. A patient presents to the ED complaining of moderate but persistent pain in his leg under a long leg plaster cast that was applied 6 hours earlier for a fracture.

The point of this vignette is that you do not do anything for pain under a cast, not even pain medication. The cast must be removed right away. It may be too tight, it may be compromising blood supply, or it may have rubbed off a piece of skin. Your only acceptable option is to remove the cast.

27. A young man involved in a motorcycle accident has an obvious open (compound) fracture of his right thigh. The femur is sticking out through a jagged skin laceration.

An open fracture is an orthopedic emergency. This patient may need to have other problems treated first (abdominal bleeding, intracranial hematomas, chest tubes, etc.), but the open fracture should be in the OR getting cleaned and reduced within 6 hours of the injury.

28. A front-seat passenger in a car that had a head-on collision relates that he hit the dashboard with his knees, and complains of pain in the right hip. He lies in the stretcher in the ED with the right lower extremity shortened, adducted, and internally rotated.

What is it? Another orthopedic emergency: posterior dislocation of the hip. The blood supply of the femoral head is tenuous, and delay in reduction could lead to avascular necrosis.

Management. X-rays and emergency reduction.

29. A healthy 24-year-old man steps on a rusty nail at the stables where he works as a horse breeder. Three days later he is brought to the ED moribund, with a swollen, dusky foot, in which one can feel gas crepitation.

What is it? Gas gangrene. Management is a lot of IV penicillin and immediate surgical debridement of dead tissue, followed by a trip to the nearest hyperbaric chamber for hyperbaric oxygen treatment.

30. A 48-year-old man breaks his arm when he falls down the stairs. X-rays demonstrate an oblique fracture of the middle to distal thirds of the humerus. Physical examination shows that he cannot dorsiflex (extend) his wrist.

Fractures of the humeral shaft can injure the radial nerve, which courses in a spiral groove right around the posterior aspect of that bone. However, surgical exploration is not usually needed. Hanging arm cast or coaptation splint are used, and the nerve function returns eventually. However, if the nerve was okay when the patient came in, and becomes paralyzed after closed reduction of the bone, the nerve is entrapped and surgery has to be performed.

31. A football player is hit straight on his right leg, and he suffers a posterior dislocation of his knee.

The point here is that posterior dislocation of the knee can nail the popliteal artery. Attention to integrity of pulses, Doppler studies or CT angio, and prompt reduction are the key issues.

32. A window cleaner falls from a third-story scaffold and lands on his feet. Physical examination and x-rays show comminuted fractures of both calcanei.

Compression fractures of the thoracic or lumbar spine are the associated, hidden injuries that have to be looked for in this case.

33. In a head-on automobile collision, the unrestrained front-seat passenger strikes the dashboard and windshield. He comes in with facial lacerations, upper extremity fractures, and blunt trauma to his chest and abdomen.

In the confusion of dealing with multiple traumas, it is possible to miss less-obvious injuries. In this scenario, as the knees strike the dashboard, the femoral heads may drive backward into the pelvis, or out of the acetabulum.

34. The unrestrained front-seat passenger in a car that crashes at high speed is brought into the ED with multiple facial fractures and a closed head injury.

The ultimate hidden injury (because of the devastating complications if missed) is the fracture of the cervical spine. A CT scan must be done to rule it out.

Common Hand Problems

35. A 43-year-old secretary who types a lot at work complains about numbness and tingling in the hand, particularly at night. On physical examination, when asked to hang her hand limply in front of her, numbness and tingling are reproduced over the distribution of the median nerve (the radial side 3 1/2 fingers). The same happens when her median nerve is pressed over the carpal tunnel, or when it is percussed.

Carpal tunnel syndrome is diagnosed clinically, and this vignette is typical. The American Academy of Orthopedic Surgery recommends that wrist x-rays (including carpal tunnel view) be done, primarily to rule out other things. Initial treatment is splints and anti-inflammatories. If surgery is needed, electromyography and nerve conduction velocity should precede it.

36. A 58-year-old woman describes that she awakens at night with her right middle finger acutely flexed, and she is unable to extend it. She can do it only by pulling on it with her other hand, at which time she feels a painful "snap."

This is trigger finger. Steroid injections are tried first, and surgery is performed if needed.

37. A young mother complains of pain along the radial side of the wrist and the first dorsal compartment. She relates that the pain is often caused by the position of wrist flexion and simultaneous thumb extension that she assumes to carry the head of her baby. On physical examination the pain is reproduced by asking her to hold her thumb inside her closed fist, and then forcing the wrist into ulnar deviation.

De Quervain tenosynovitis. Splints and antiinflammatories can help, but steroid injection is best. Surgery is rarely needed.

38. A 72-year-old man of Norwegian ancestry has a contracted hand that can no longer be extended and be placed flat on a table. Palmar fascial nodules can be felt.

Dupuytren contracture. Surgery may be needed.

39. A 33-year-old carpenter accidentally drives a small nail into the pulp of his index finger, but he pays no attention to the injury at the time. Two days later he shows up in the ER, with throbbing pulp pain, fever, and all the signs of an abscess within the pulp of the affected finger.

This kind of abscess is called a *felon*, and like all abscesses it has to be drained. There is an urgency to it, however, because the pulp is a closed space and the process is equivalent to a compartment syndrome.

40. A young man falls while skiing, and as he does he jams his thumb into the snow. Physical examination shows collateral laxity at the thumb metacarpophalangeal joint.

This one is "gamekeeper's thumb." The injury was to the ulnar collateral ligament of the thumb. If not treated it can be dysfunctional and painful, and can lead to arthritis. Casting is usually done.

41. Two thieves grab a woman's purse and run away with it. She tries to grab one of the offenders by his jacket, but he pulls away, hurting the woman's hand in the process. Now, when she makes a fist, the distal phalanx of her ring finger does not flex with the others.

42. While playing volleyball, a young woman injures her middle finger. She cannot extend the distal phalanx.

Two classic tendon injuries, with appropriate names: jersey finger (to the flexor), and mallet finger (to the extensor). Splinting is usually the first line of treatment.

43. While working at a bookbinding shop, a young man suffers a traumatic amputation of his index finger. The finger was cleanly severed at its base.

Replantation of severed digits is no longer "miracle surgery." It is commonly done at specialized centers, and regular physicians should know how to handle the amputated part. The answer is to clean it with sterile saline, wrap it in saline-moistened gauze, place it in a plastic bag, and place the bag on a bed of ice.

The digit should not be placed in antiseptic solutions or alcohol, put in dry ice, or allowed to freeze.

Back Pain

44. A 45-year-old man complains of aching back pain for several months. He was told previously that he had muscle spasms, and was given analgesics and muscle relaxants. He comes in now because of the sudden onset of very severe back pain that came on when he tried to lift a heavy object. The pain is like an electrical shock that shoots down his leg; it is aggravated by sneezing, coughing, and straining, and it prevents him from ambulating. He keeps the affected leg flexed. Straight leg-raising gives excruciating pain.

What is it? Lumbar disk herniation. Peak age incidence is in age 40s, and virtually all those cases are at L4–L5 or L5–S1.

- If the "lightning" exits the foot by the big toe, it is L4–L5.
- If the "lightning" exits by the little toe, it is L5–S1.

Management is MRI for diagnosis. Bed rest and pain control will take care of most of these. Use neurosurgical intervention only if there is progressive weakness or sphincteric deficits.

45. A 46-year-old man has sudden onset of very severe back pain that came on when he tried to lift a heavy object. The pain is like an electrical shock that shoots down his leg, and it prevents him from ambulating. He keeps the affected leg flexed. Straight leg-raising test gives excruciating pain. He has a distended bladder, flaccid rectal sphincter, and perineal saddle area anesthesia.

The cauda equina syndrome is a surgical emergency.

46. A young man began to have chronic back pain at age 34. Pain and stiffness have been progressive. He describes morning stiffness, and pain that is worse at rest, but improves with activity. Two years ago, he was treated for uveitis.

Think ankylosing spondylitis. X-rays will eventually show "bamboo spine." Antiinflammatory agents and physical therapy are used.

47. A 72-year-old man has had a 20-pound weight loss, and he complains of low back pain. The pain is worse at night and is unrelieved by rest or positional changes.

Suggestive of metastatic malignancy. If advanced, x-rays will show it. At a higher cost, an MRI will make a reliable, early diagnosis.

Leg Ulcers

48. A 67-year-old diabetic has an indolent, unhealing ulcer at the heel of the foot.

What is it? Ulcer at a pressure point in a diabetic is caused by neuropathy. Once it has happened, it is unlikely to heal because the microcirculation is poor also. The infection would be osteomyelitis.

Management is to control the diabetes, keep the ulcer clean, keep the leg elevated, and be resigned to the idea that the foot may need to be amputated. The other common location is the first metatarsophalangeal joint.

49. A 67-year-old smoker with high cholesterol and coronary disease has an indolent, unhealing ulcer at the tip of his toe. The toe is blue, and he has no peripheral pulses in that extremity.

What is it? Ischemic ulcers are at the farthest away point from where the blood comes.

Management. Doppler studies looking for pressure gradient, MRI angio or CT angio. Lack of pulses is concerning for an inherent vascular problem; revascularization (i.e. stenting or surgical bypass) may be possible, and then the ulcer may heal.

50. A 44-year-old obese woman has an indolent, unhealing ulcer above her right medial malleolus. The skin around it is thick and hyperpigmented. She has frequent episodes of cellulitis, and has varicose veins.

What is it? Venous stasis ulcer.

Management. Duplex scanning, Unna boot, support stockings. Varicose vein surgery or endoluminal ablation may ultimately be needed.

51. A 40-year-old man has had a chronic draining sinus in his lower leg since he had an episode of osteomyelitis at age 12. In the last few months he has developed an indolent, dirty-looking ulcer at the site, with "heaped up" tissue growth at the edges.

52. Ever since she had an untreated third-degree burn to her lower leg at age 14, a 38-year-old immigrant from Latin America has had shallow ulcerations at the scar site that heal and break down all the time. In the last few months she has developed an indolent, dirty-looking ulcer at the site, with "heaped up" tissue growth around the edges, which is steadily growing and shows no sign of healing.

Both of these are classic vignettes for the development of squamous cell carcinoma at long-standing, chronic irritation sites. The name Marjolin ulcer has been applied to these tumors. Obviously biopsy is the first diagnostic step, and wide local excision (with subsequent skin grafting) is the appropriate therapy.

Foot Pain

53. An older, overweight man complains of disabling, sharp heel pain every time his foot strikes the ground. The pain is worse in the mornings, preventing him from putting any weight on the heel. X-rays show a bony spur matching the location of his pain, and physical examination shows exquisite tenderness right over that heel spur.

Although all the signs point to that bony spur as the culprit, this is in fact plantar fasciitis—a very common but poorly understood problem that needs symptomatic treatment until it resolves spontaneously within 12 to 18 months. Podiatrists often remove the spur anyway; although the spur is not the initial problem, its removal can accelerate recovery.

54. A woman who usually wears high-heeled, pointed shoes complains of pain in the forefoot after prolonged standing or walking. Physical examination shows a very tender spot in the third interspace, between the third and fourth toes.

This one is a Morton neuroma, which is an inflammation of the common digital nerve. If conservative management (more-sensible shoes, among other things) does not suffice, the neuroma may be excised.

55. A 55-year-old obese man suddenly develops swelling, redness, and exquisite pain at the first metatarsal–phalangeal joints.

Gout. The diagnosis of the acute attack is done with identification of uric acid crystals in fluid from the joint. Treatment of the acute attack relies on indomethacin and colchicine. Long-term control of serum uric acid levels is done with allopurinol or probenecid.

TUMORS

1. A 16-year-old boy complains of low-grade but constant pain in the distal femur present for several months. He has local tenderness in the area, but is otherwise asymptomatic. X-rays show a large bone tumor breaking through the cortex into the adjacent soft tissues and exhibiting a "sunburst" pattern.

2. A 10-year-old complains of persistent pain deep in the middle of the thigh. X-rays show a large, fusiform bone tumor, pushing the cortex out and producing periosteal "onion skinning."

Primary malignant bone tumors are also diseases of young people. Our vignettes illustrate each of these, but this is such a specialized field that you may just be asked to diagnose "malignant bone tumor" without picking the specific kind.

- Most common: osteogenic sarcoma
  - Seen in ages 10–25
  - Usually occurs around the knee (lower femur or upper tibia)
- Second-most common: Ewing's sarcoma
  - Seen in younger children (ages 5–15)
  - Grows in the diaphyses of long bones

Management. Do not mess with these and do not attempt biopsy. Referral is needed, both to an orthopedic surgeon (every 3 years) and to a specialist on bone tumors.

3. A 66-year-old woman picks up a bag of groceries, and her arm snaps broken.

What is it? A pathologic fracture (i.e., for trivial reasons) means bone tumor, which in the vast majority of cases will be metastatic. Get x-rays to diagnose this particular broken bone, whole body bone scans to identify other metastases, and start looking for the primary. In women, breast (lytic bone lesions). In men, prostate. Lung is second most common in both men and women.

4. A 60-year-old man complains of fatigue and pain at specific places on several bones. He is found to be anemic, and x-rays show multiple punched out lytic lesions throughout the skeleton.

Multiple lytic lesions in an old anemic man suggest multiple myeloma. X-rays are diagnostic and additional tests include: Bence-Jones protein in the urine and abnormal immunoglobulins in the blood. The latter are detectable by serum electrophoresis and better yet by immunoelectrophoresis.

Management. Chemotherapy is the usual treatment. Thalidomide is used for refractory cases.

5. A 58-year-old woman has a soft tissue tumor in her thigh. It has been growing steadily for 6 months. It is located deep into the thigh, is firm, is fixed to surrounding structures, and measures ~8 cm in diameter.

What is it? Soft tissue sarcoma is the concern.

Diagnosis. Start with MRI. Leave biopsy and further management to the experts.

Pre-Op and Post-Op Care 3

PREOPERATIVE ASSESSMENT

Cardiac Risk

1. A 72-year-old man with a history of multiple myocardial infarctions is scheduled to have an elective sigmoid resection for diverticular disease. A preoperative radionuclide ventriculography shows an ejection fraction <0.35.

This is a "no-go" situation in which cardiac risk in noncardiac surgery is prohibitive. With this ejection fraction, the incidence of perioperative MI is 75–85%, and the mortality for such an event is around 55–90%. Probably the only option here is not to operate, but to continue with medical therapy for the diverticular disease. Should he develop an abscess, percutaneous drainage would be the only possible intervention.

2. A 72-year-old chronically bedridden man is being considered for emergency cholecystectomy for acute cholecystitis that is not responding to medical management. He had a transmural MI 4 months ago, and currently has atrial fibrillation, 8–10 premature ventricular beats/min, and jugular venous distention.

This patient is a compendium of almost all of the items that Goldman has compiled as predictors of operative cardiac risk. In fact he adds up to 50 points, and anything >25 points (class IV) gives a mortality in excess of 22%. Here again the best option would be to treat the cholecystitis in a different way (percutaneous cholecystostomy tube being the obvious choice).

3. A 72-year-old man is scheduled to have an elective sigmoid resection for diverticular disease. In the preoperative evaluation it is noted that he has venous jugular distention.

Now we have fewer items, but CHF is the worst one on the list (the other one here is his age). The failure has to be treated first: ACE inhibitors, beta-blockers, digitalis, and diuretics.

4. A 72-year-old man is scheduled to have an elective sigmoid resection for diverticular disease. In the preoperative evaluation it is ascertained that he had a transmural MI 2 months ago.

The next worst Goldman finding is the recent MI (<6 months). Time is the best therapy for that one. Mortality is highest within 3 months of the MI (near 40%), but is brought down considerably >6 months (6%). Waiting is the obvious choice here. If our hand is forced and earlier operation becomes mandatory, admission to the ICU the day before surgery is recommended, to "optimize" all the cardiac parameters.

5. A 72-year-old man who needs to have elective repair of a large abdominal aortic aneurysm has a history of severe, progressive angina.

For many years it was believed that coronary revascularization prior to major surgery improved the risk of the latter. Current reviews of the available evidence suggest that it does not. The planned surgery for the aneurysm can be done first if it is more urgent than addressing the angina.

Pulmonary Risk

6. A 61-year-old man with a 60 pack-year smoking history and physical evidence of chronic obstructive pulmonary disease (COPD) needs elective surgical repair of an abdominal aortic aneurysm. He currently smokes 1 pack per day.

Smoking is by far the most common cause of increased pulmonary risk, and the main problem is compromised ventilation (high Pco2 and low FEV1) rather than compromised oxygenation. Start the evaluation with FEV1. If it is abnormal, perform blood gases. Cessation of smoking for 8 weeks and intensive respiratory therapy (physical therapy, expectorants, incentive spirometry, humidified air) should precede surgery.

Hepatic Risk

7. A cirrhotic is bleeding from a duodenal ulcer. Surgical intervention is being considered. His bilirubin is 3.5, prothrombin time 22 seconds, and serum albumin 2.5. He has ascites and encephalopathy.

Please don't! Any one of those items alone (bilirubin >2, albumin <3, prothrombin >16, and encephalopathy) predicts a mortality >40%. If 3 of them are present, the number is 85%. If all 4 are present, the number is 100%.

8. A cirrhotic with a blood ammonia concentration >150 ng/dl needs an operation.

9. A cirrhotic with an albumin level <2 needs an operation.

10. A cirrhotic with a bilirubin >4 needs an operation.

Another way to look at liver risk is to see if any one of the previously listed findings is deranged to an even greater degree. Any one of these 3 examples would carry a mortality of about 80%. A deranged prothrombin time is slightly kinder to the patient, predicting only 40–60% mortality. Death, incidentally, occurs with high-output cardiac failure with low peripheral resistance.

Nutritional Risk

11. An elderly gentleman needs palliative surgery for an advanced cancer of the colon. He has lost 20% of his body weight over the past 2 months, and his serum albumin is 2.7. Further testing reveals anergy to injected skin-test antigens and a serum transferrin level <200 mg/dl.

Any one of these 4 findings indicates severe nutritional depletion. All 4 leave no doubt as to the enormous operative risk that this man represents. Surprisingly, as few as 4–5 days of preoperative nutritional support (preferably via the gut) can make a big difference, and 7–10 days would be optimal if there is no big hurry to operate.

Metabolic Risk

12. An elderly diabetic man presents with a clinical picture of acute cholecystitis that has been present for 3 days. He is profoundly dehydrated, in coma, and has blood sugar 950, severe acidosis, and ketone bodies "all over the place."

The treatment of diabetes is not within the scope of this surgical review, but we should point out that someone in overt diabetic ketoacidotic coma is not a surgical candidate, no matter how urgent the operation might be. The metabolic problem has to be addressed first in this case (although aiming for complete correction to normal values would be unrealistic as long as that rotten gallbladder is there). Temporization of the cholecystitis can be achieved with a percutaneous cholecystostomy tube with cholecystectomy performed when acidosis has resolved.

POSTOPERATIVE COMPLICATIONS

Fever

1. Shortly after the onset of a general anesthetic with inhaled halothane and muscle relaxation with succinylcholine, a patient develops rapid rise in body temperature, exceeding 104° F. Metabolic acidosis and hypercalcemia are also noted. A family member died under general anesthesia several years before, but no details are available.

A classic case of malignant hyperthermia. The history should have been a warning, but once the problem develops, treat with IV dantrolene plus the obvious support measures: 100% oxygen, correction of the acidosis, cooling blankets, watch for myoglobinuria.

2. Forty-five minutes after completion of a cystoscopy, a patient develops chills and a fever spike of 104° F.

This early on after an invasive procedure, and this high fever, means bacteremia. Take blood cultures times 3, and start empiric antibiotic therapy.

3. On postoperative day 1 after an abdominal procedure, a patient develops a fever of 102°F.

Fever on day 1 means atelectasis, but all the other potential sources have to be ruled out. Management includes the following:

- Chest x-ray
- Look at wound and IV sites
- Inquire about urinary tract symptoms
- Improve ventilation: deep breathing and coughing, postural drainage, incentive spirometry

The ultimate therapy for major, recalcitrant atelectasis is bronchoscopy.

4. On postoperative day 1 after an abdominal procedure, a patient develops a fever of 102° F. The patient is not compliant with therapy for atelectasis, and by postoperative day 3 still has daily fever in the same range.

Now a pneumonic process has developed in the atelectatic segments. Chest x-ray, sputum cultures, and appropriate antibiotics are needed.

5. A patient who had major abdominal surgery is afebrile during the first 2 postoperative days, but on day 3 he has a fever spike to 103° F.

6. A patient who had major abdominal surgery is afebrile during the first 4 postoperative days, but on day 5 he has a fever spike to 103° F.

7. A patient who had major abdominal surgery is afebrile during the first 6 postoperative days, but on day 7 he has a fever spike to 103° F.

Every potential source of post-op fever always has to be investigated, but the timing of the first febrile episode gives a clue as to the most likely source. The mnemonic used (sequentially) is the "4 Ws": wind (for atelectasis), water (for urine), walking (for the veins in the leg), and wound. Thus UTI, thrombophlebitis, and wound infection are the likely culprits in these vignettes. Urinalysis and urinary culture, Doppler studies, and physical examination are the respective tests.

8. A patient who had major abdominal surgery has a normal postoperative course, with no significant episodes of fever, until the 10th day when he begins to spike temperatures up to 102 and 103°F every day.

Now deep abscess (intra-abdominal: typically pelvic or subphrenic) is the most likely source, and CT scan is performed to diagnose; management is percutaneous drainage.

Chest Pain

9. On postoperative day 2 after an abdominoperineal resection for rectal cancer, a 72-year-old man complains of severe retrosternal pain, radiating to the left arm. He also becomes short of breath and tachycardic.

10. During the performance of an abdominoperineal resection for rectal cancer, unexpected severe bleeding is encountered, and the patient is hypotensive on and off for almost 1 hour. The anesthesiologist notes ST depression and T wave flattening in the ECG monitor.

Perioperative MI happens within the first 3 days, and the biggest triggering cause is hypovolemic shock. These two are fairly typical scenarios, although the classic chest pain picture is often obscured by other ongoing events. When thinking MI everybody does an ECG, but the most reliable diagnostic test is serum troponin.

11. On postoperative day 7 after pinning of a broken hip, a 76-year-old man suddenly develops severe pleuritic chest pain and shortness of breath. When examined, he is found to be anxious, diaphoretic, and tachycardic, and he has prominent distended veins in his neck and forehead.

Chest pain this late post-op is pulmonary embolus (PE). This patient is obviously at high risk, and the findings are classic. If they give you a similar vignette in which the venous pressure is low, it virtually excludes this diagnosis. Arterial blood gases are your first test, and hypoxemia and hypocapnia are the obligatory findings (in their absence, it is not a PE either). CTA is the gold standard diagnostic test of choice. Therapy starts with heparinization. The very active natural fibrinolytic mechanism in the lung makes the use of clot-busters less clearly indicated, but if PEs recur during anticoagulation, a vena cava filter (Greenfield) is needed.

This man already had a PE. It is too late to think about preventive measures on him, but read the narrative portion of this book for a brief review of those.

Other Pulmonary Complications

12. An awake intubation is being attempted in a drunk and combative man who has sustained gunshot wounds to the abdomen. In the struggle the patient vomits and aspirates a large amount of gastric contents with particulate matter.

The nightmare of every anesthesiologist. Aspiration can kill a patient right away, or produce chemical injury to the tracheobronchial tree ("chemical pneumonitis"). This is an inflammatory problem, not an infectious one, so antibiotics are not immediately indicated. However the irritation results in pulmonary failure and increases the risk of secondary pneumonia. Prevention is best (empty stomach, antacids before induction), but once it happens, lavage and removal of particulate matter is the first step (with the help of bronchoscopy), followed by bronchodilators and respiratory support. Steroids are not useful.

13. A trauma patient is undergoing a laparotomy for a seat belt injury. He also sustained several broken ribs. Halfway through the case it becomes progressively difficult to "bag" him, and his BP steadily declines, while the CVP steadily rises. There is no evidence of intraabdominal bleeding.

Intraoperative tension pneumothorax. The lung was punctured by one of the broken ribs. The best approach is immediate thoracic needle decompression. The formal chest tube can be placed later.

Disorientation/Coma

14. Eighteen hours after major surgery, a patient becomes disoriented.

Very brief vignette, but out of the very long list of things that can produce post-op disorientation, the most lethal one if not promptly recognized and treated is hypoxia. So, unless it is clear from the vignette that we can blame metabolic problems (uremia, hyponatremia, hypernatremia, ammonium, hyperglycemia, delirium tremens [DTs], or our own medications), the safest thing to ask for first is blood gases.

15. In the second week of a stormy, complicated postoperative period in a young patient with multiple gunshot wounds to the abdomen, he becomes progressively disoriented and unresponsive. He has bilateral pulmonary infiltrates, and a Po_2 of 65 while breathing 40% oxygen. He has no evidence of CHF.

The reason for the mental changes are obvious: he is not getting enough oxygen in his blood, but the rest of the findings specifically identify adult respiratory distress syndrome (ARDS). The centerpiece of therapy for ARDS is PEEP, with care not to use too much volume, which may damage the lungs. Another issue is why does he have ARDS? In an older patient we can blame preexisting lung disease, and when there has been trauma to the chest, that can be the cause—but when those are not present, we have to think of sepsis as the precipitating event.

16. An alcoholic man checks in to have an elective colon resection for recurrent diverticular bleeding. He swears to everyone that he has not touched a drop of alcohol for the past 6 months. On postoperative day 3 he becomes disoriented and combative, and claims to see elephants crawling up the walls. The wife then reveals that the patient actually drank heavily up until the day of hospital admission.

These are obviously DTs. The standard management relies on benzodiazepines. In the past surgeons used IV alcohol (5% alcohol/5% dextrose), but this is most uncommon today. Most hospitals allow oral intake of alcohol for such scenarios.

17. Twelve hours after completion of an abdominal hysterectomy, a 42-year-old woman becomes confused and lethargic, complains of severe headache, has a grand mal seizure, and finally goes into a coma. Review of the chart reveals that an order for D5W, to run in at 125 ml/h, was mistakenly implemented as 525 ml/h.

A classic example of water intoxication. The laboratory finding that will confirm it will be a very low serum sodium concentration. Mortality for this iatrogenic condition is very high, and therapy very controversial. Very careful use of hypertonic saline is probably a reasonable answer.

18. Eight hours after completion of a trans-sphenoidal hypophysectomy for a prolactinoma, a young woman becomes lethargic, confused, and eventually comatose. Review of the record shows that her urinary output since surgery has averaged 600 ml/h, although her IV fluids are going in at 100 ml/h.

The reverse of the previous vignette. Large, rapid, unreplaced water loss from surgically induced diabetes insipidus. The lab will show significant hypernatremia, and the safest therapy would use 1/3 or 1/4 normal saline to replace the lost fluid, although in this acute setting D5W would be acceptable.

19. A cirrhotic patient goes into coma after an emergency portocaval shunt for bleeding esophageal varices.

Brief but obvious: the culprit here will be ammonia. If there is also hypokalemic alkalosis and high cardiac output–low peripheral resistance, overt liver failure has occurred.

Urinary Complications

20. Six hours after undergoing a hemorrhoidectomy under spinal anesthesia, a 62-year-old man complains of suprapubic discomfort and fullness. He feels the need to void but has not been able to do so since the operation. There is a palpable suprapubic mass that is dull to percussion.

By far the most common post-up urinary problem is inability to void, and men are the likely victims. In-and-out bladder catheterization is the answer. Some authors recommend leaving an indwelling Foley catheter if catheterization has to be repeated in 6 hours, others wait until it has been done twice before suggesting it.

21. A man has had an abdominoperineal resection for cancer of the rectum, and an indwelling Foley catheter was left in place after surgery. The nurses are concerned because even though his vital signs have been stable, his urinary output in the last 2 hours has been zero.

In the presence of renal perfusing pressure, an output of zero invariably means a mechanical problem. In this case the catheter is plugged or kinked. More ominous—but much more rare—possibilities include both ureters having been tied off or thrombosis of the renal vessels.

22. Several hours after completion of multiple surgery for blunt trauma in an average-size adult, the urinary output is reported in 3 consecutive hours as 12 ml/h, 17 ml/h, and 9 ml/h. His BP has hovered around 95 to 130 systolic during that time.

His kidneys are perfusing, but he is either behind in fluid replacement or has gone into renal failure. A fluid challenge would suggest which situation exists. A bolus of 500 ml given in 10–20 minutes should produce diuresis in the dehydrated patient but not in renal failure.

The more elegant way, however, and the answer for the exam, is to look at urinary sodium. The dehydrated patient will be retaining sodium, and the urine will be <10 or 20 mEq/L. In renal failure the figure will be >40. An even more elegant calculation is the fractional excretion of sodium, which in renal failure >1.

Abdominal Distention

23. Four days after exploratory laparotomy for blunt abdominal trauma with resection and reanastomosis of damaged small bowel, a patient has abdominal distention, without abdominal pain. He has no bowel sounds and has not passed flatus, and his abdominal x-rays show dilated loops of small bowel without air fluid levels.

Probably paralytic ileus, which can be expected under the circumstances. NPO and NG suction should be continued until peristaltic activity resumes. Should resolution not be forthcoming, mechanical obstruction should be ruled out with a CT scan of the abdomen that will demonstrate a transition point between the proximal, dilated bowel and the distal collapsed bowel at the site of obstruction. Hypokalemia should also be ruled out.

24. An elderly gentleman with Alzheimer's disease who lived in a nursing home is operated on for a fractured femoral neck. On postoperative day 5 it is noted that his abdomen is grossly distended and tense, but not tender. He has occasional bowel sounds. X-rays show a very distended colon and a few distended loops of small bowel.

In the elderly who are not very active to begin with and are now further immobilized, massive colonic dilatation (Ogilvie syndrome) is commonly seen. Correct the fluids and electrolytes first. Neostigmine can dramatically improve colon motility, but it has significant side effects. Colonoscopy is a common successful treatment.

Wound

25. On postoperative day 5 after a laparotomy, it is noted that large amounts of salmon-colored clear fluid are soaking the dressings.

The classic presentation of a wound dehiscence. Patient must go to the OR for repair.

26. The nurses report that on postoperative day 5 after a laparotomy, a patient has been draining clear pink fluid from his abdominal wound. A medical student removes the dressing and asks the patient to sit up so he can get out of bed and be helped to the treatment room. When the patient complies, the wound opens widely and a handful of small bowel rushes out.

This one is evisceration, a rather serious problem. Put the patient back in bed, cover the bowel with large moist dressings soaked in warm saline (moist and warm are the key), and make arrangements to rush him to the OR for reclosure.

27. On postoperative day 7, the inguinal incision of an open inguinal herniorrhaphy is found to be red, hot, tender, and boggy (fluctuant). The patient reports fever for the past 2 days.

Wound infection. This far advanced there is sure to be pus, and the wound has to be opened. If it were just a bit of redness early on, antibiotics might still be able to abort the process. If there is doubt as to the presence or absence of pus, a sonogram is diagnostic.

28. Nine days after a sigmoid resection for cancer, the wound drains a brown fluid that everybody recognizes as feces. The patient is afebrile, and otherwise doing quite well.

A fecal fistula, if draining to the outside, is inconvenient but not serious. It will close eventually with little or no therapy. If feces were accumulating on the inside, the patient would be febrile and sick, and would need drainage and probably a diverting colostomy.

29. Eight days after a difficult hemigastrectomy and gastroduodenostomy for gastric ulcer, a patient begins to leak 2–3 L of green fluid per day through the right corner of his bilateral subcostal abdominal wound.

If patient is febrile, with an acute abdomen, and sick, he needs to be explored. The problem is serious. However, if all the gastric and duodenal contents are leaking to the outside, further immediate surgery is not the answer.

- Provide massive fluid and electrolyte replacement
- Provide nutritional support, with elemental nutrients delivered into the upper jejunum.
  - Total parenteral nutrition [TPN] is second choice but less effective and greater potential risk

The goal is eventual healing without having to operate again. The abdominal wall has to be protected from the digestion caused by the leaking GI fluids. Somatostatin or octreotide may diminish the volume of GI fluid loss.

Fluids and Electrolytes

30. Eight hours after completion of a trans-sphenoidal hypophysectomy for a prolactinoma, a young woman becomes lethargic, confused, and eventually comatose. Review of the record shows that her urinary output since surgery has averaged 600 ml/h, although her IV fluids are going in at 100 ml/h. A serum sodium determination shows a concentration 152 mEq/L.

An elevated concentration of serum sodium invariably means that the patient has lost pure water (or hypotonic fluids). Every 3 mEq/L above the normal of 140 represents 1 L lost. This woman is 4 L shy, which fits her history of a diuresis of 500 ml/h more than the intake she is getting. As previously noted, she could be given 4 L of D5W, but many would prefer a similar amount of 5% dextrose in half normal saline, or 5% dextrose in one-third normal saline.

31. Several friends go on a weekend camping trip in the desert. On day 2 they lose their way as well as all connection via electronic devices. They are rescued a week later. One of them is brought to your hospital--awake and alert--with obvious clinical signs of dehydration. Serum sodium concentration is 155 mEq/L.

This gentleman has also lost water, about 5 L, but has done so slowly, by pulmonary and cutaneous evaporation over 5 days. He is hypernatremic, but his brain has adapted to the slowly changing situation. Were he to be given 5 L of D5W, the rapid correction of his hypertonicity would be dangerous. Five liters of 5% dextrose in half normal saline would be a much safer plan.

32. Twelve hours after completion of an abdominal hysterectomy, a 42-year-old woman becomes confused and lethargic, complains of severe headache, has a grand mal seizure, and finally goes into coma. Review of the chart reveals that an order for D5W to run in at 125 ml/h was mistakenly implemented as 525 ml/h. Her serum sodium concentration is 122 mEq/L.

In the surgical patient with normal kidneys, hyponatremia invariably means that water (without sodium) has been retained, thus the body fluids have been diluted. In this case a lot of IV water was given, and the antidiuretic hormone (ADH) produced as part of the metabolic response to trauma has held onto it. Rapidly developing hyponatremia (water intoxication) is a big problem (the brain has no time to adapt), and once it has occurred the therapy is very controversial. Most authors would recommend hypertonic saline (either 3% or 5%) given 100 ml at a time, and reassessing the situation (clinical and lab) before each succeeding dose.

33. A 62-year-old woman comes in for her scheduled chemotherapy administration for her metastatic cancer of the breast. Although she is quite asymptomatic, the lab reports that her serum sodium concentration is 122 mEq/L.

In this setting, water has also been retained (by ADH produced by the tumor), but so slowly that the brain has kept up with the developing hypotonicity. Rapid correction would be lethal and ill advised. Water restriction, on the other hand, will slowly allow the abnormality to be reversed.

34. A 68-year-old woman comes in with an obvious incarcerated umbilical hernia. She has gross abdominal distension, is clinically dehydrated, and reports persistent fecaloid vomiting for the past 5 days. She is awake and alert, and her serum sodium concentration is 118 mEq/L.

Hyponatremia means water retention, but in this case the problem began with loss of isotonic (sodium-containing) fluid from her gut. As her extracellular fluid became depleted, she has retained whatever water has come her way: tea and Coke that she still was able to drink early on, and endogenous water from catabolism. Thus she is now volume-depleted at the same time that she is hyponatremic (hypotonic). She desperately needs volume replacement, but we do not want to correct her hypotonicity too quickly. Thus lots of isotonic fluids (start with 1 or 2 L/h of normal saline or Ringer's lactate, depending on her acid-base status) would be the way to go (use clinical variables to fine-tune). Once her volume is replenished, she will unload the retained water and correct her own tonicity.

35. A patient with severe diabetic ketoacidosis comes in with profound dehydration and a serum potassium concentration 5.2 mEq/L. After several hours of vigorous therapy with insulin and IV fluids (saline, without potassium), his serum potassium concentration is reported as 2.9.

Severe acidosis (or alkalosis, for that matter) results in the loss of potassium in the urine. While the acidosis is present, though, the serum concentration is high because potassium has come out of the cells in exchange for hydrogen ion. Once the acidosis is corrected, that potassium rushes back into the cells, and the true magnitude of the potassium loss becomes evident. He obviously needs potassium. (Under most circumstances, 10 mEq/h is a safe "speed limit." In this setting, 20 mEq/h can be justified.)

36. An 18-year-old woman slips and falls under a bus, and her right leg is crushed. On arrival at the ED she is hypotensive, and she receives several units of blood. Over the next several hours she is in and out of hypovolemic shock, and she develops acidosis. Her serum potassium concentration, which was 4.8 mEq/L at the time of admission, is reported to be 6.1 a few hours later.

Let's count the ways in which potassium has been pouring into her blood: it came out of the crushed leg, it came in with the blood transfusions, and it came from the cells when she became acidotic. With low perfusing pressure (in and out of shock), the kidneys have not been doing a great job of eliminating it. We will have to do that. In addition to improving her BP, we can "push potassium into the cells" with insulin and 50% dextrose. We can help dispose of it with exchange resins, and we can neutralize it with IV calcium. Hemodialysis is the ultimate weapon.

37. An elderly alcoholic, diabetic man, with marginal renal function, sustains multiple trauma while driving under the influence of alcohol. In the course of his resuscitation and multiple surgeries, he is in and out of shock for prolonged periods of time. Blood gases show a pH of 7.1 and Pco2 of 36. His serum electrolytes are sodium 138, chloride 98, and bicarbonate 15.

This man has every reason to develop metabolic acidosis, and he will do so by retention of fixed acids (rather than by loss of bicarbonate). The main driving force in this case is the state of shock, with lactic acid production; but the diabetes, alcohol, and bad kidney are also contributing.

The lab shows that indeed he has metabolic acidosis (low pH and low bicarbonate), he is trying to compensate by hyperventilating (low Pco2), and he shows the classic anion gap (the sum of his chloride and bicarbonate is 25 mEq shy of the serum sodium concentration—instead of the normal 10 to 15).

As for the therapy, the classic treatment for metabolic acidosis is either bicarbonate or a bicarbonate precursor such as lactate or acetate. But in cases like this, reliance on such therapy tends to eventually produce alkalosis once the low flow state is corrected. Thus the emphasis here should be in fluid resuscitation. However, the choice of fluid is critical: a lot of saline would not be a good idea (too much chloride). A lot of Ringer's lactate would be a better choice.

38. A patient who has had a subtotal gastrectomy for cancer, with a Billroth 2 reconstruction, develops a "blowout" of the duodenal stump, and a subsequent duodenal fistula. For the past 10 days he has been draining 750–1,500 mL/d of green fluid. His serum electrolytes show sodium 132, chloride 104, and bicarbonate 15. The pH in his blood is 7.2, with Pco_2 35.

Again, metabolic acidosis, but now with a normal anion gap. He has been losing lots of bicarbonate out of the fistula. The problem would not have developed if his IV fluid replacement had contained lots of bicarbonate (or lactate, or acetate), but the use of those agents is indicated now for the therapy of the existing abnormality.

39. A patient with severe peptic ulcer disease develops pyloric obstruction and has protracted vomiting of clear gastric contents (i.e., without bile) for several days. His serum electrolytes show sodium 134, chloride 82, potassium 2.9, and bicarbonate 34.

The classic hypochloremic, hypokalemic, metabolic alkalosis secondary to loss of acid gastric juice. This man needs to be rehydrated (choose saline rather than Ringer's lactate), and he needs lots of potassium chloride (10 mEq/h will give him plenty, and will be a safe rate). Very rarely is ammonium chloride (or diluted, buffered hydrochloric acid) needed.

General Surgery 4

DISEASES OF THE GASTROINTESTINAL SYSTEM

Upper Gastrointestinal System

Esophagus

1. A 62-year-old man describes epigastric and substernal pain that he cannot characterize well. At times his description sounds like gastroesophageal reflux, at times it does not. Sonogram of the gallbladder, ECG, and cardiac enzymes have been negative.

What is it? The question is, is it gastroesophageal reflux?

Diagnosis. Esophageal pH monitoring.

2. A 54-year-old obese man gives a history of burning retrosternal pain and heartburn that is brought about by bending over, wearing tight clothing, or lying flat in bed at night. He gets symptomatic relief from antacids but has never been formally treated. The problem has been present for many years, and seems to be progressing.

What is it? The description is classic for gastroesophageal reflux disease (GERD).

Management. The diagnosis is not really in doubt, and with that clinical picture alone thousands of patients are treated with symptomatic medication—but the academicians writing exam questions would want you to recommend endoscopy and biopsies to assess the extent of esophagitis and potential complications, specifically, Barrett's esophagus.

3. A 54-year-old obese man gives a history of burning retrosternal pain and heartburn that is brought about by bending over, wearing tight clothing, or lying flat in bed at night. He gets symptomatic relief from antacids but has never been formally treated. The problem has been present for many years, and seems to be progressing. Endoscopy shows severe peptic esophagitis and Barrett's esophagus.

Management for Barrett's has evolved, and the diagnosis alone is no longer considered an indication for surgery. In this patient who has not had formal medical management, that should be the first step. Continued symptoms would warrant consideration for fundoplication. Dysplastic changes would require resection.

4. A 54-year-old obese man gives a history of many years of burning retrosternal pain and heartburn that is brought about by bending over, wearing tight clothing, or lying flat in bed at night. He gets brief symptomatic relief from antacids, but in spite of faithful adherence to a strict program of medical therapy, the process seems to be progressing. Endoscopy shows severe peptic esophagitis with no dysplastic changes.

Management: He has failed medical management, and has no dysplastic changes. He needs a fundoplication. Whether or not performed, he needs endoscopy surveillance with biopsies to follow progression of the esophagitis.

5. A 47-year-old woman describes difficulty swallowing, which she has had for many years. She says that liquids are more difficult to swallow than solids, and she has learned to sit up straight and wait for the fluids to "make it through." Occasionally she regurgitates large amounts of undigested food.

It sure sounds like achalasia. The diagnosis is suggested by a barium swallow (usually the first test) and confirmed by manometry studies. Endoscopic Botox injection, balloon dilation and surgery are the therapeutic options.

6. A 54-year-old black man with a history of smoking and drinking describes progressive dysphagia that began 3 months ago with difficulty swallowing meat, progressed to other solid foods, then soft foods, and is now evident for liquids as well. He locates the place where the food "sticks" at the lower end of the sternum. He has lost 30 pounds of weight.

A classic for carcinoma of the esophagus (progressive dysphagia, weight loss). Given the detail of race, age, sex, and habits, it is probably squamous cell cancer. Had the history been long-standing reflux, it would suggest adenocarcinoma.

The diagnosis is made the same way for both: endoscopy and biopsies—but the endoscopist wants a "road map" first: barium swallow. The sequence is barium swallow, then endoscopy with U/S and biopsies, then CT scan (to assess extent and limitations to respectability such as metastatic disease).

7. A 24-year-old man spends the night cruising bars and drinking heavily. In the wee hours of the morning he is quite drunk, and he starts vomiting repeatedly. He initially brings up gastric contents only, but eventually he vomits bright red blood.

8. A 24-year-old man spends the night cruising bars and drinking heavily. In the wee hours of the morning he is quite drunk and starts vomiting repeatedly. Eventually he has a particularly violent episode of vomiting, and he feels a very severe, wrenching epigastric pain and low sternal pain of sudden onset. On arrival at the ED 1 hour later he still has the pain, is diaphoretic, has fever and leukocytosis, and looks quite ill.

What is it? Two vignettes that have the same beginnings, with one leading to bleeding (Mallory-

Weiss tear), and the other one to perforation (Boerhaave syndrome).

Management. For the patient who is bleeding, endoscopy to ascertain the diagnosis and occasionally treat. Bleeding will typically be arterial and brisk, but self-limiting. Photocoagulation can be used if needed, and rarely a discreet mucosal tear is identified that can be clipped. The patient with perforation is facing a potentially lethal problem. Gastrografin swallow will confirm the diagnosis, and emergency surgical repair will follow. Prognosis depends on time elapsed between perforation and treatment, and degree of mediastinal contamination that has occurred.

9. A 66-year-old man has an upper GI endoscopy done as an outpatient to check on the progress of medical therapy for gastric ulcer. Six hours after the procedure, he returns complaining of severe, constant retrosternal pain that began shortly after he went home. He looks prostrate and very ill, is diaphoretic, has a fever of 104°F, and a respiratory rate of 30. There is a hint of subcutaneous emphysema at the base of the neck.

What is it? Instrumental perforation of the esophagus. The setting plus the air in the tissues are virtually diagnostic. Do Gastrografin swallow and emergency surgical repair. Severe pain after endoscopy is a perforation until proven otherwise.

Stomach

10. A 72-year-old man has lost 40 pounds of weight over a 2- or 3-month period. He gives a history of anorexia for several months, and of vague epigastric discomfort for the past 3 weeks.

What is it? Cancer of the stomach is a possibility, along with other etiologies.

Diagnosis. Imaging studies followed by endoscopy and biopsies.

Management. Surgery will be done for cure if possible, for palliation if not.

Mid and Lower Gastrointestinal System

Small bowel and appendix

11. A 54-year-old man has had colicky abdominal pain and protracted vomiting for several days. He has developed progressive moderate abdominal distention, and has not had a bowel movement or passed any gas for 5 days. He has high-pitched, loud bowel sounds that coincide with the colicky pain, and x-rays show distended loops of small bowel and air-fluid levels. Five years ago he had an exploratory laparotomy for a gunshot wound of the abdomen.

What is it? Mechanical intestinal obstruction, caused by adhesions.

Management. NG suction, IV fluids, and careful observation.

12. A 54-year-old man has had colicky abdominal pain and protracted vomiting for several days. He has developed progressive moderate abdominal distention, and has not had a bowel movement or passed any gas for 5 days. He has high-pitched, loud bowel sounds that coincide with the colicky pain, and x-rays show distended loops of small bowel and air-fluid levels. Five years ago he had an exploratory laparotomy for a gunshot wound of the abdomen. Six hours after being hospitalized and placed on NG suction and IV fluids, he develops fever, leukocytosis, abdominal tenderness, and rebound tenderness.

What is it? He has strangulated obstruction, i.e., a loop of bowel is dying—or dead—from compression of the mesenteric blood supply.

Management. Emergency surgery.

13. A 54-year-old man has had colicky abdominal pain and protracted vomiting for several days. He has developed progressive moderate abdominal distention, and has not had a bowel movement or passed any gas for 5 days. He has high-pitched, loud bowel sounds that coincide with the colicky pain, and x-rays show distended loops of small bowel and air-fluid levels. On physical examination a groin mass is noted, and he explains that he used to be able to "push it back" at will, but for the past 5 days has been unable to do so.

What is it? Mechanical intestinal obstruction caused by an incarcerated (potentially strangulated) hernia.

Management. After suitable fluid replacement he needs urgent surgical intervention.

14. A 55-year-old woman is being evaluated for protracted diarrhea. On further questioning she gives a bizarre history of episodes of flushing of the face, with expiratory wheezing. A prominent jugular venous pulse is noted on her neck.

What is it? Carcinoid syndrome.

Diagnosis. Twenty-four-hour urinary collection for 5-hydroxy-indolacetic acid, perform a CT scan to assess liver metastasis, and plan resection based upon the results.

15. A 22-year-old man develops anorexia followed by vague periumbilical pain that several hours later becomes sharp, severe, constant, and well localized to the right lower quadrant of the abdomen. He has abdominal tenderness, guarding, and rebound to the right and below the umbilicus, temperature 99.6° F, and white blood cell count 12,500, with neutrophilia and immature forms.

What is it? A classic for acute appendicitis.

Management. Perform emergency appendectomy. If the case had not been typical, do CT scan. In children and women of child-bearing age for whom the presentation is not typical, U/S can also make the diagnosis and prevent radiation exposure,

Colon

16. A 59-year-old man is referred for evaluation because he has been fainting at his job where he operates heavy machinery. He is pale and gaunt, but otherwise his physical examination is remarkable only for 4+ occult blood in the stool. Lab shows hemoglobin 5 g/dl.

What is it? Cancer of the right colon.

Diagnosis. Colonoscopy and biopsies.

Management. Blood transfusions and eventually right hemicolectomy.

17. A 56-year-old man has bloody bowel movements. The blood coats the outside of the stool, and has been present on and off for several weeks. For the past 2 months he has been constipated, and his stools have become of narrow caliber.

What is it? Cancer of the distal, left side of the colon.

Diagnosis. Endoscopy and biopsies. If given choices, start with flexible proctosigmoidoscopy (with the 45-cm or 60-cm instrument that any MD can handle). Eventually full colonoscopy (to rule out a second primary) will be needed before surgery.

18. A 77-year-old man has a colonoscopy because of rectal bleeding. A villous adenoma is found in the rectum, and several adenomatous polyps are identified in the sigmoid and descending colon.

The issue with polyps is which ones are premalignant, and thus need to be excised. Premalignant include, in descending order of potential for malignant conversion, familial polyposis (and all variants, such as Gardner), familial multiple inflammatory polyps, villous adenoma, and adenomatous polyp. Benign, which can be left alone, include juvenile, Peutz-Jeghers, isolated, inflammatory, and hyperplastic.

19. A 42-year-old man has suffered from chronic ulcerative colitis for 20 years. He weighs 90 pounds and has had at least 40 hospital admissions for exacerbations of the disease. Because of a recent relapse, he has been placed on high-dose steroids and Imuran. For the past 12 hours he has had severe abdominal pain, temperature of 104°F, and leukocytosis. He looks ill and "toxic." His abdomen is tender, particularly in the epigastric area, and he has muscle guarding and rebound. X-rays show a massively distended transverse colon, and there is gas within the wall of the colon.

What is it? Toxic megacolon.

Management. Emergency surgery for the toxic megacolon, but the case illustrates all of the other indications for surgery in chronic ulcerative colitis. The involved colon has to be removed, and that always includes the rectal mucosa.

20. A 27-year-old man is recovering from an appendectomy for gangrenous acute appendicitis with perforation and periappendicular abscess. He has been receiving Clindamycin and Tobramycin for 7 days. Eight hours ago he developed watery diarrhea, crampy abdominal pain, fever, and leukocytosis.

What is it? Pseudomembranous colitis from overgrowth of *Clostridium difficile*.

Diagnosis. The diagnosis relies primarily on identification of toxin in the stools. Cultures take too long, and proctosigmoidoscopic exam does not always find typical changes.

Management. Clindamycin has to be stopped, and antidiarrheal medications (diphenoxylate combined with atropine, paregoric) should not be used. Metronidazole is the usual drug of choice. An alternate drug is vancomycin. Failure of medical management, with a marked leukocytosis and serum lactate above 5 mmol/L, is an indication for emergency colectomy.

Anorectal Disease

21. A 60-year-old man known to have hemorrhoids reports bright red blood in the toilet paper after evacuation.

22. A 60-year-old man known to have hemorrhoids complains of anal itching and discomfort, particularly toward the end of the day. He has mild perianal pain when sitting down and finds himself sitting sideways to avoid the discomfort.

What is it? The rule is that internal hemorrhoids bleed but do not hurt, whereas external hemorrhoids hurt but do not bleed.

Management. It is not reassurance and hemorrhoid remedies prescribed over the phone! In all anorectal problems, cancer has to be ruled out first! The correct answer is proctosigmoidoscopic examination (digital rectal exam, anoscopy, and flexible sigmoidoscope). Once the diagnosis has been confirmed, internal hemorrhoids can be treated with rubber-band ligation, whereas external hemorrhoids or prolapsed hemorrhoids require surgery.

23. A 23-year-old woman describes exquisite pain with defecation and blood streaks on the outside of the stools. Because of the pain she avoids having bowel movements and when she finally does, the stools are hard and even more painful. Physical examination cannot be done, as she refuses to allow anyone to even draw apart her buttocks to look at the anus for fear of precipitating the pain.

A classic description of anal fissure. Even though the clinical picture is classic, cancer still has to be ruled out. Examination under anesthesia is the correct answer. Medical management includes stool softeners and topical agents. A tight sphincter is believed to cause and perpetuate the problem, and injections with paralyzing agents (botulin toxin) have been proposed. If it gets to surgery, lateral internal sphincterotomy is the operation of choice.

Fissures are preferably treated by calcium channel blockers such as diltiazem ointment 2% topically 3x/daily for 6 weeks, or cortisone suppositories. They have an 80-90% success rate. Botox has a 50% rate of healing.

24. A 28-year-old man is brought to the office by his mother. In the last 4 months he has had 3 operations–done elsewhere–for a perianal fistula, though after each one the area has not healed, and in fact the surgical wounds have become bigger. The patient now has multiple unhealing ulcers, fissures, and fistulas all around the anus, with purulent discharge. There are no palpable masses.

Another classic. The perianal area has a fantastic blood supply and heals beautifully even though feces bathe the wounds. When it does not, immediately think of Crohn's disease.

You must still rule out malignancy (anal cancer does not heal either if not completely excised). A proper examination with biopsies is needed. The specimens should confirm Crohn's. Fistulotomy is not recommended. Most fistulae will get draining setons which will ensure adequate drainage of infection while medical management controls the disease. Remicade in particular has shown to help heal these fistulae.

25. A 44-year-old man shows up in the ED at 11 pm with exquisite perianal pain. He cannot sit down, reports that bowel movements are very painful, and has been having chills and fever. Physical examination shows a hot, tender, red, fluctuant mass between the anus and the ischial tuberosity.

Another very common problem: ischiorectal abscess. The treatment for all abscesses is drainage. This one is no exception. But cancer also has to be ruled out. Thus the best option would be an answer that offers examination under anesthesia and incision and drainage. If the patient is diabetic, incision and drainage would have to be followed by very close in-hospital follow-up.

26. A 62-year-old man complains of perianal discomfort and reports that there are fecal streaks soiling his underwear. Four months ago he had a perirectal abscess drained surgically. Physical examination shows a perianal opening in the skin, and a cordlike tract can be palpated going from the opening toward the inside of the anal canal. Brownish purulent discharge can be expressed from the tract.

What is it? A pretty good description of fistula-in-ano.

Management. First rule out cancer with proctosigmoidoscopy (necrotic tumors can drain). Then schedule elective fistulotomy.

27. A 55-year-old HIV-positive man has a fungating mass growing out of the anus, and rock-hard, enlarged lymph nodes in both groins. He has lost a lot of weight, and looks emaciated and ill.

What is it? Squamous cell carcinoma of the anus.

Diagnosis. Biopsies of the fungating mass.

Management. Nigro protocol is combined preoperative chemotherapy and radiation for 5 weeks with 90% cure rate. Surgery is done only if Nigro fails to cure the cancer.

Gastrointestinal Bleeding

28. A 33-year-old man vomits a large amount of bright red blood.

What is it? Pretty skimpy vignette, but you can already define the territory where the bleeding is taking place: from the tip of the nose to the ligament of Treitz.

Diagnosis. Don't forget to look at the mouth and nose and then proceed with upper GI endoscopy.

29. A 33-year-old man has had 3 large bowel movements that he describes as made up entirely of dark red blood. The last one was 20 minutes ago. He is diaphoretic and pale, and has a BP of 90 over 70 and pulse rate of 110.

The point of the vignette is that something needs to be done to define the area from which he is bleeding: with the available information, it could be from anywhere in the GI tract (a vast territory to investigate). Fortunately, he seems to be bleeding right now, thus the first diagnostic move is to place an NG tube and aspirate after you have looked at the nose and mouth.

30. A 33-year-old man has had 3 large bowel movements that he describes as made up entirely of dark red blood. The last one was 20 minutes ago. He is diaphoretic and pale, and has a BP of 90 over 70 and a pulse rate of 110. An NG tube returns copious amounts of bright red blood.

What is it? The area has been defined (tip of the nose to ligament of Treitz). Proceed with endoscopy.

31. A 65-year-old man has had 3 large bowel movements that he describes as made up entirely of dark red blood. The last one was 20 minutes ago. He is diaphoretic and pale, and has a BP of 90 over 70 and a pulse rate of 110. An NG tube returns clear, green fluid without blood.

What is it? If the NG tube had returned blood, the boundaries would have been tip of the nose to ligament of Treitz. Clear fluid, without bile, would have exonerated the area down to the pylorus, and if there is bile in the aspirate, down to the ligament of Treitz—provided you are sure that the patient is bleeding now. That's the case here. So, he is bleeding from somewhere distal to the ligament of Treitz.

Further definition of the actual site is no longer within reach of upper endoscopy, and except for anoscopy looking for bleeding hemorrhoids, lower endoscopy is notoriously unrewarding during massive bleeding. If he is bleeding at >2 ml/min (about 1 U of blood every 4 hours), some physicians go straight to the emergency angiogram. Those same physicians would wait and do a colonoscopy later if the bleeding is <0.5 mL/min, and they would resort to a tagged red-cell study for the cases in between. There is another school of thought that always begins with the tagged red-cell study, regardless of estimated rate of bleeding. If the question offers that choice in this setting (upper GI source has been ruled out, and bleeding hemorrhoids have been sought), it would be safe to pick it.

32. A 72-year-old man had 3 large bowel movements that he describes as made up entirely of dark red blood. The last one was 2 days ago. He is pale, but has normal vital signs. An NG tube returns clear, green fluid without blood.

What is it? The clear aspirate is meaningless because he is not bleeding right now. So the guilty territory can be anywhere from the tip of the nose to the anal canal. Across the board, 75% of all GI bleeding is upper, and virtually all the causes of lower GI bleeding are diseases of the old: diverticulosis, polyps, cancer, and angiodysplasias. So, when the patient is young, the odds overwhelmingly favor an upper site. When the patient is old, the overall preponderance of upper is balanced by the concentration of lower causes in old people—so it could be anywhere.

Diagnosis. Angiography is not the first choice for slow bleeding or bleeding that has stopped. Even the proponents of radionuclide studies don't have much hope if the patient bled 3 days ago. The first choice now is endoscopies, both upper and lower.

33. A 7-year-old boy passes a large bloody bowel movement.

What is it? In this age group, Meckel diverticulum leads the list.

Diagnosis. By radioactively labeled technetium scan (not the one that tags red cells, but the one that identifies gastric mucosa).

34. A 41-year-old man has been in the ICU for 2 weeks being treated for idiopathic hemorrhagic pancreatitis. He has had several percutaneous drainage procedures for pancreatic abscesses, chest tubes for pleural effusions, and bronchoscopies for atelectasis. He has been in and out of septic shock and respiratory failure several times. Ten minutes ago he vomited a large amount of bright red blood, and as you approach him he vomits again what looks like another pint of blood.

What is it? In this setting it has to be stress ulcer.

Management. It should have been prevented by keeping the pH of the stomach above 4 with H2 blockers, antacids, or both; but once the bleeding takes place, the diagnosis is made as usual with endoscopy. Treatment will be difficult (start with endoscopic attempts—laser and such), and it may require angiographic embolization of the left gastric artery.

Acute Abdomen

35. A 59-year-old man arrives in the ED at 2 am, accompanied by his wife who is wearing curlers on her hair and a robe over her nightgown. He has abdominal pain that began suddenly about 1 hour ago, and is now generalized, constant, and extremely severe. He lies motionless on the stretcher, is diaphoretic, and has shallow, rapid breathing. His abdomen is rigid, very tender to deep palpation, and has guarding and rebound tenderness in all quadrants.

What is it? Definitely an acute abdomen. The time and circumstances attest to the severity and rapid onset of the problem. The physical findings are impressive. He has generalized acute peritonitis. The best bet is perforated peptic ulcer—but we do not need to prove that.

Management. The acute abdomen does not need a precise diagnosis to proceed with surgical exploration. Lower lobe pneumonia and MI have to be ruled out with chest x-ray and ECG, and it would be nice to have a plain x-ray or CT scan of the abdomen and a normal lipase—but the best answer of this vignette should be prompt emergency exploratory laparotomy.

36. A 62-year-old man with cirrhosis of the liver and ascites presents with generalized abdominal pain that started 12 hours ago. He now has moderate tenderness over the entire abdomen, with some guarding and equivocal rebound. He has mild fever and leukocytosis.

What is it? Peritonitis in the cirrhotic with ascites, or the child with nephrosis and ascites, could be spontaneous bacterialperitonitis—which does not need surgery—rather than acute peritonitis secondary to an intraabdominal catastrophe that requires emergency operation. This is very uncommon.

Diagnosis. Cultures of the ascitic fluid (aspirate via paracentesis) will yield a single organism. Treatment will be with the appropriate antibiotics.

37. A 43-year-old man develops excruciating abdominal pain at 8:18 pm. When seen in the ED at 8:50 pm, he has a rigid abdomen, lies motionless on the examining table, has no bowel sounds, and is obviously in great pain, which he describes as constant. X-ray shows free air under the diaphragm.

What is it? Acute abdomen plus perforated viscus equals perforated duodenal ulcer in most cases. Although I am exaggerating the sudden onset by giving the exact minute, vignettes of perforated peptic ulcer will have a pretty sharp time of onset.

Management. Emergency exploratory laparotomy.

38. A 44-year-old alcoholic man presents with severe epigastric pain that began shortly after a heavy bout of alcoholic intake, and reached maximum intensity over a period of 2 hours. The pain is constant, radiates straight through to the back, and is accompanied by nausea, vomiting, and retching.

    He had a similar episode 2 years ago, for which he required hospitalization.

What is it? Acute pancreatitis.

Diagnosis. Serum amylase and lipase determinations. CT scan will follow if the diagnosis is unclear, or in a day or two if there is no improvement.

Management. NPO, NG suction, IV fluids.

39. A 43-year-old obese mother of 6 children has severe right upper quadrant abdominal pain that began 6 hours ago. The pain was colicky at first, radiated to the right shoulder and around toward the back, and was accompanied by nausea and vomiting. For the past 2 hours the pain has been constant. She has tenderness to deep palpation, muscle guarding, and rebound in the right upper quadrant. Her temperature is 101°F, and she has a WBC count of 16,000. She has had similar episodes of pain in the past brought about by ingestion of fatty food, but they all had been of brief duration and relented spontaneously or with anticholinergic medications.

What is it? Acute cholecystitis.

Diagnosis. Sonogram should be the first choice. If equivocal, an HIDA scan (radionuclide excretion scan).

Management. Start medical management (antibiotics, NPO, IV fluids) with the intention of doing laparoscopic cholecystectomy within the same hospital admission.

40. A 52-year-old man has right flank colicky pain of sudden onset that radiates to the inner thigh and scrotum. There is microscopic hematuria.

What is it? Ureteral colic (included here for differential diagnosis).

Diagnosis. Specific CT scan for ureteric colic is CT-KUB. This is a noncontrast CT scan that allows for visualization of a ureteric calculus.

41. A 59-year-old woman has a history of 3 prior episodes of left lower quadrant abdominal pain for which she was briefly hospitalized and treated with antibiotics. She began to feel discomfort 12 hours ago, and now she has constant left lower quadrant pain, tenderness, and a vaguely palpable mass.

    She has fever and leukocytosis.

What is it? Acute diverticulitis.

Diagnosis. In acute diverticulitis, CT scan is the gold standard investigation. After 6 weeks of cooling off, however, all cases must get a colonoscopy to rule out perforated colon cancer.

Management. Treatment is medical for the acute attack (antibiotics, NPO), but elective sigmoid resection is advisable for recurrent disease (like this woman is having). Percutaneous drainage of abscess is indicated if one is present. Emergency surgery (resection or colostomy) may be needed if she gets worse or does not respond to treatment.

42. An 82-year-old man develops severe abdominal distension, nausea, vomiting, and colicky abdominal pain. He has not passed any gas or stool for the past 12 hours. He has a tympanitic abdomen with hyperactive bowel sounds. X-ray shows distended loops of small and large bowel, and a very large gas shadow that is located in the right upper quadrant and tapers toward the left lower quadrant with the shape of a parrot's beak.

What is it? Volvulus of the sigmoid.

Management. Endoscopic intervention will relieve the obstruction. Eventually, surgery to prevent recurrences should be considered. If the patient has an acute abdomen, this means dead gut, and laparotomy is mandated.

43. A 79-year-old man with atrial fibrillation develops an acute abdomen. He has a silent abdomen, with diffuse tenderness and mild rebound. There is a trace of blood in the rectal exam. He has acidosis and looks quite sick. X-rays show distended small bowel and distended colon up to the middle of the transverse colon.

What is it? Acute abdomen in an elderly person who has atrial fibrillation brings to mind embolic occlusion of the mesenteric vessels. Acidosis frequently ensues, and blood in the stool is often seen. Unfortunately not much can be done, as the bowel is usually dead. Young, aggressive vascular surgeons would call for an angiogram to perform emergency embolectomy, assuming the case is seen very early before the bowel dies.

Hepatobiliary

Liver

44. A 53-year-old man with cirrhosis of the liver develops malaise, vague right upper quadrant abdominal discomfort, and 20-pound weight loss. Physical examination shows a palpable mass that seems to arise from the left lobe of the liver. α-fetoprotein is significantly elevated.

45. A 53-year-old man develops vague right upper quadrant abdominal discomfort and a 20-pound weight loss. Physical examination shows a palpable liver with nodularity. Two years ago he had a right hemicolectomy for cancer of the ascending colon. His carcinoembryonic antigen (CEA) had been within normal limits right after his hemicolectomy, but is now 10 times normal.

What is it? Both are good descriptions of cancer in the liver, included to remind you that α-fetoprotein goes with primary hepatoma, whereas CEA goes with metastatic tumor from the colon.

Diagnosis. Both would start with CT scan (with contrast) to define location and extent of tumor.

Management. In the primary hepatoma, resection would be performed if a tumor-free anatomic segment can be left behind. In the metastatic tumor, resection is done if there are no other metastases, it is surgically possible, and the primary is relatively slow growing.

46. A 24-year-old woman develops moderate, generalized abdominal pain of sudden onset, and shortly thereafter faints. At the time of evaluation in the ED she is pale, tachycardic, and hypotensive. The abdomen is mildly distended and tender, and she has hemoglobin 7 g/dl. There is no history of trauma. On inquiring as to whether she might be pregnant, she denies the possibility because she has been on birth control pills since she was age 14, and has never missed taking them.

What is it? Bleeding from a ruptured hepatic adenoma, secondary to birth control pills.

Management. It's pretty clear that she is bleeding into the belly, but CT scan will confirm it and probably show the liver adenoma as well. Surgery will follow. She will not be allowed to take birth control pills in the future.

47. A 44-year-old woman is recovering from an episode of acute ascending cholangitis secondary to choledocholithiasis. She develops fever and leukocytosis and some tenderness in the right upper quadrant. A sonogram reveals a liver abscess.

Not much of a diagnostic challenge here, but the issue is management, and it is included to contrast it with the handling of the patient in the next vignette. This is a pyogenic abscess, it needs to be drained which can usually be done by the radiologists percutaneously, other laparoscopic drainage can be performed.

48. A 29-year-old migrant worker from Mexico develops fever and leukocytosis, as well as tenderness over the liver when the area is percussed. He has mild jaundice and an elevated alkaline phosphatase. Sonogram of the right upper abdominal area shows a normal biliary tree and an abscess in the liver.

What is it? This one is an amebic abscess—very common in Mexico.

Management. Alone among abscesses, this one in most cases does not have to be drained, but can be effectively treated with Metronidazole. Get serology for amebic titers, but don't wait for the report (it will take 3 weeks). Start the patient on Metronidazole. Prompt improvement will tell you that you are on the right track. When the serologies come back, the patient will be well and your diagnosis will be confirmed. Don't fall for an option that suggests aspirating the pus and sending it for culture; you cannot grow the ameba from the pus.

Jaundice

49. A 42-year-old woman is jaundiced. She has a total bilirubin of 6, and laboratory reports that the unconjugated, indirect bilirubin is 6 and the direct, conjugated bilirubin is 0. She has no bile in the urine.

What is it? The vignette in the exam will be adorned with other evidence of hemolysis, but you do not need it to make the diagnosis. This is hemolytic jaundice.

Management. Try to figure out what is chewing her red cells.

50. A 19-year-old college student returns from a trip to Cancun, and 2 weeks later develops malaise, weakness, and anorexia. A week later he notices jaundice.

When he presents for evaluation his total bilirubin is 12, with 7 indirect and 5 direct. His alkaline phosphatase is mildly elevated, and the transaminases are very high.

What is it? Hepatocellular jaundice.

Management. Get serologies to confirm diagnosis and type of hepatitis.

51. A patient with progressive jaundice that has been present for 4 weeks is found to have a total bilirubin of 22, with 16 direct and 6 indirect, and minimally elevated transaminases. The alkaline phosphatase was twice the normal value 2 weeks ago, and now is about 6 times the upper limit of normal.

What is it? A generic example of obstructive jaundice.

Management. Sonogram, looking for dilated intrahepatic ducts, possibly dilated extrahepatic ducts as well, and if we get lucky, a finding of gallstones.

52. A 40-year-old obese mother of 5 children presents with progressive jaundice, which she first noticed 4 weeks ago. She has a total bilirubin of 22, with 16 direct and 6 indirect, and minimally elevated transaminases. The alkaline phosphatase is about 6 times the upper limit of normal. She gives a history of multiple episodes of colicky right upper quadrant abdominal pain, brought about by ingestion of fatty food.

What is it? Again, obstructive jaundice, with a good chance of being caused by stones.

Management. Start with the sonogram. If you need more tests after that, endoscopic retrograde cholangiopancreatography (ERCP) is the next move, which could also be used to remove the stones from the common duct. Cholecystectomy will eventually have to be performed.

53. A 66-year-old man presents with progressive jaundice, which he first noticed 6 weeks ago. He has total bilirubin of 22, with 16 direct and 6 indirect, and minimally elevated transaminases. The alkaline phosphatase is about 6 times the upper limit of normal. He has lost 10 pounds over the past 2 months, but is otherwise asymptomatic. A sonogram shows dilated intrahepatic ducts, dilated extrahepatic ducts, and a very distended, thin-walled gallbladder.

What is it? Malignant obstructive jaundice. "Silent" obstructive jaundice is more likely to be caused by tumor (although most patients with pancreatic tumor have dull constant pain). A distended gallbladder is an ominous sign: when stones are the source of the problem, the gallbladder is thick-walled and nonpliable.

Diagnosis. You already have the sonogram. Next move is CT scan. Follow with ERCP if the CT is not diagnostic.

54. A 66-year-old man presents with progressive jaundice, which he first noticed 6 weeks ago. He has a total bilirubin of 22, with 16 direct and 6 indirect, and minimally elevated transaminases. The alkaline phosphatase is about 6 times the upper limit of normal. He is otherwise asymptomatic. A sonogram shows dilated intrahepatic ducts, dilated extrahepatic ducts, and a very distended, thin-walled gallbladder. Except for the dilated ducts, CT scan is unremarkable. ERCP shows a narrow area in the distal common duct, and a normal pancreatic duct.

What is it? Malignant, but lucky: probably cholangiocarcinoma at the lower end of the common duct. He could be cured with a pancreatoduodenectomy (Whipple operation).

Management. Get brushings of the common duct for cytologic diagnosis.

55. A 64-year-old woman presents with progressive jaundice, which she first noticed 2 weeks ago. She has a total bilirubin of 12, with 8 direct and 4 indirect, and minimally elevated transaminases. The alkaline phosphatase is about 10 times the upper limit of normal. She is otherwise asymptomatic, but is found to be slightly anemic and to have positive occult blood in the stool. A sonogram shows dilated intrahepatic ducts, dilated extrahepatic ducts, and a very distended, thin-walled gallbladder.

What is it? Again malignant, but also lucky. The coincidence of slowly bleeding into the GI tract at the same time that she develops obstructive jaundice points to an ampullary carcinoma, another malignancy that can be cured with radical surgery.

Management. Endoscopy with U/S assistance.

56. A 56-year-old man presents with progressive jaundice, which he first noticed 6 weeks ago. He has a total bilirubin of 22, with 16 direct and 6 indirect, and minimally elevated transaminases. The alkaline phosphatase is about 8 times the upper limit of normal. He has lost 20 pounds over the past 2 months, and has a persistent, nagging mild pain deep into his epigastrium and in the upper back. His sister died at age 44 from a cancer of the pancreas. A sonogram shows dilated intrahepatic ducts, dilated extrahepatic ducts, and a very distended, thin-walled gallbladder.

What is it? Bad news. Cancer of the head of the pancreas. Terrible prognosis.

Diagnosis. Nowadays, endoscopic U/S has become a standard part of the pancreatic head mass work-up. U/S-guided FNAC is increasingly being used for diagnosis. Endoscopic retrograde cholangiopancreatography (ERCP) has a limited role in placing stents to decompress the bile duct if total bilirubin is >20.

Gallbladder

57. A white, obese 40-year-old mother of 5 children gives a history of repeated episodes of right upper quadrant abdominal pain brought about by the ingestion of fatty foods, and relieved by the administration of anticholinergic medications. The pain is colicky, radiates to the right shoulder and around to the back, and is accompanied by nausea and occasional vomiting. Physical examination is unremarkable.

What is it? Gallstones, with biliary colic.

Management. Sonogram. Elective cholecystectomy will follow.

58. A 43-year-old obese mother of 6 children has severe right upper quadrant abdominal pain that began 6 hours ago. The pain was colicky at first, radiated to the right shoulder and around toward the back, and was accompanied by nausea and vomiting. For the past 2 hours the pain has been constant. She has tenderness to deep palpation, muscle guarding, and rebound in the right upper quadrant. Her temperature is 101° F, and WBC count 12,000. Liver function tests are normal.

What is it? If you are alert, you will recognize the picture of acute cholecystitis. A similar vignette was presented in the acute abdomen section. It is repeated here to contrast it with the next one. She will get a cholecystectomy, as previously mentioned.

59. A 73-year-old obese mother of 6 children has severe right upper quadrant abdominal pain that began 3 days ago. The pain was colicky at first but has been constant for the past 2.5 days. She has tenderness to deep palpation, muscle guarding, and rebound in the right upper quadrant. She has temperature spikes of 104 and 105°F, with chills. WBC count is 22,000, with a shift to the left. Her bilirubin is 5, and she has an alkaline phosphatase of 2,000 (~20x normal).

What is it? Acute ascending cholangitis.

Diagnosis. The diagnosis is already clear. Sonogram might confirm dilated ducts.

Management. This is an emergency, and many things will be needed at once. The therapy is based on IV antibiotics plus emergency decompression of the biliary tract. To achieve the latter, ERCP is the first choice, but percutaneous transhepatic cholangiogram (PTC) is another option (and surgery is a distant third choice).

60. A white, obese 40-year-old mother of 5 children gives a history of repeated episodes of right upper quadrant abdominal pain brought about by the ingestion of fatty foods, and relieved by the administration of anticholinergic medications. The pain is colicky, radiates to the right shoulder and around to the back, and is accompanied by nausea and occasional vomiting. This time she had a shaking chill with the colicky pain, and the pain lasted longer than usual. She has mild tenderness to palpation in the epigastrium and right upper quadrant. Laboratory determinations show a bilirubin of 3.5, an alkaline phosphatase 5 times normal, and serum lipase 3 times normal value.

What is it? She passed a common duct stone and had a transient episode of cholangitis (the shaking chill, the high phosphatase) and a bit of biliary pancreatitis (the high amylase).

Management. As in many of these cases, start with sonogram. It will confirm the diagnosis of gallstones. If she continues to get well, elective cholecystectomy will follow. If she deteriorates, she may have the stone still impacted at the ampulla of Vater, and may need ERCP and sphincterotomy to extract it.

Pancreas

61. A 33-year-old alcoholic man shows up in the ED with epigastric and midabdominal pain that began 12 hours ago shortly after the ingestion of a large meal. The pain is constant and very severe, and radiates straight through to the back. He vomited twice early on, but since then has continued to have retching. He has tenderness and some muscle guarding in the upper abdomen, is afebrile, and has mild tachycardia. Serum lipase is 1,200, and his hematocrit is 52%.

What is it? Acute pancreatitis.

Management. Put the pancreas at rest: NPO, NG suction, IV fluids.

62. A 56-year-old alcoholic man is admitted with a clinical picture of acute upper abdominal pain. The pain is constant, radiates straight through the back, and is extremely severe. He has a serum amylase of 800, a hematocrit of 40%, WBC count of 18,000, blood glucose of 150 mg/dl, and serum calcium of 6.5. He is given IV fluids and kept NPO with NG suction. By the next morning, his hematocrit has dropped to 30%, the serum calcium has remained below 7 despite calcium administration, his blood urea nitrogen (BUN) has gone up to 32, and he has developed metabolic acidosis and a low arterial Po2.

What is it? He has acute severe pancreatitis. In fact, he is in deep trouble, with at least 8 of Ranson's criteria predicting 80 to 100% mortality.

Management. Very intensive support will be needed, but the common pathway to death from complications of hemorrhagic pancreatitis frequently is by way of pancreatic abscesses that need to be drained as soon as they appear. Thus serial CT scans will be required. In very selected patients there is a role for necrosectomy to get rid of dead pancreatic tissue.

63. A 57-year-old alcoholic man is being treated for acute hemorrhagic pancreatitis. He was in the ICU for 1 week, required chest tubes for pleural effusion, and was on a respirator for several days, but eventually improved enough to be transferred to the floor. Two weeks after the onset of the disease, he begins to spike fever and to demonstrate leukocytosis. He looks septic.

What is it? Pancreatic abscess.

Diagnosis. CT scan.

Management. Drainage and appropriate antibiotics.

64. A 49-year-old alcoholic man presents with ill-defined upper abdominal discomfort and early satiety. On physical examination he has a large epigastric mass that is deep within the abdomen and actually hard to define. He was discharged from the hospital 5 weeks ago, after successful treatment for acute pancreatitis.

65. A 55-year-old woman presents with vague upper abdominal discomfort, early satiety, and a large but ill-defined epigastric mass. Five weeks ago she was involved in an automobile accident in which she hit the upper abdomen against the steering wheel.

What is it? The 2 presentations of pancreatic pseudocyst.

Management. You could diagnose it on the cheap with a sonogram, but CT scan is probably the best choice. Small cysts (< 6 cm) which have not been present too long (<6 weeks) can be watched waiting for spontaneous resolution. Bigger or older cysts could have serious complications (obstruction, infection, bleeding) and they need intervention. Internal surgical derivation (cystogastrostomy or cystojejunostomy) is the standard surgical treatment. Radiologically guided external drainage is option, often used for infected pseudocysts. The latest and very appealing (if technically feasible) is endoscopic cystogastrostomy, which can only be done for cysts with a completely liquid content without debris.

66. A disheveled, malnourished individual shows up in the ED requesting medication for pain. He smells of alcohol and complains bitterly of constant epigastric pain, radiating straight through to the back, that he says he has had for several years. He has diabetes, steatorrhea, and calcifications in the upper abdomen in a plain x-ray.

What is it? Chronic pancreatitis.

Management. I hope they ask you to recognize this vignette, but not to manage it. There is precious little that can be done for these unfortunate individuals. Stopping the alcoholic intake is the first step (easier said than done). Replacement of pancreatic enzymes and control of the diabetes are obvious needs. Sometimes the pancreatic enzymes will relieve the pain, but if they do not, the pain will be very difficult to eradicate. Various operations can be performed that would be guided by the anatomy of the pancreatic ducts; thus, if forced to go to further diagnostic tests, pick ERCP.

Hernias

67. A 9-month-old baby girl is brought in because she has an umbilical hernia. The defect is 1 cm in diameter, and the contents are freely reducible.

Although we routinely recommend elective surgical repair of all hernias (to prevent the ghastly complication of strangulation), there are some exceptions. This is one. Umbilical hernias in children age <5 years may still close spontaneously. Only observation is needed here. If present at age 5 years, repair is usually performed.

68. An 18-year-old man has a routine physical examination as part of his college registration, and the examination reveals that he has a right inguinal hernia. The external inguinal ring is about 2.5 cm in diameter, and a hernial bulge can be easily seen and felt going down into his scrotum when he is asked to strain. He is completely asymptomatic and was not even aware of the presence of the hernia.

Elective surgical repair is in order. Even though he is asymptomatic, he should not be exposed to the risk of bowel strangulation. They will not ask you about specific technical details. The hernia is probably indirect. All routine unilateral first-time hernias can be repaired by open or laparoscopic approach with a mesh. Laparoscopy is often favored for repair of recurrent inguinal, bilateral inguinal, and incisional hernias.

69. A 72-year-old farmer is forced by his insurance company to have a physical examination to be issued a life insurance policy. He has been healthy all his life, and "has never been to the doctor." At the examination it is found that he has a large, left inguinal hernia that reaches down into the scrotum. Bowel sounds can be easily heard over it. The hernia is not reducible, and he says that many years ago he used to be able to "push it back," but for the last 10 or 20 years he has not been able to do so.

A hernia that cannot be pushed back in (reduced) is incarcerated, and one that has compromised blood supply is strangulated. The latter is an emergency. The former is also an emergency if the irreducible state is of new onset, because one does not want to wait for overt signs of dead or compromised bowel before operating. But if he has been this way for 10 or 20 years, obviously the bowel is alive and well. Elective repair is still indicated, before he runs out of good luck and gets into trouble.

DISEASES OF THE BREAST

1. An 18-year-old woman has a firm, rubbery mass in the left breast that moves easily with palpation.

What is it? Fibroadenoma.

Management. The underlying concern in all breast masses is cancer, and the best predictor of the likelihood of malignancy is age. At age 18, the chances of malignancy are very remote; thus, the least invasive way to make the diagnosis is, in order, either sonogram, fine-needle aspirate (FNA) or core needle biopsy, or surgical excision. Sonogram happens to be quite diagnostic for fibroadenomas (more so than for other conditions). Reassurance alone would not be a good choice! Do not order a mammogram either. At age 18, mammograms are useless (breast too dense). Sonogram is the only imaging technique suitable for the very young breast. Once diagnosis is confirmed, excision is optional.

2. A 14-year-old girl has a firm, movable, rubbery mass in her left breast that was first noticed 1 year ago and has since grown to be about 6 cm in diameter.

What is it? Giant juvenile fibroadenoma.

Management. At age 14 chances of cancer are virtually zero. That avenue does not have to be explored. But the rapid growth requires resection to avoid cosmetic deformity.

3. A 27-year-old immigrant from Mexico has a 12- × 10- × 7-cm mass in her left breast. It has been present for 7 years, and has been slowly growing to its present size. The mass–firm, rubbery, completely movable–is not attached to chest wall or to overlying skin. There are no palpable axillary nodes.

What is it? Cystosarcoma phyllodes, a benign condition that can turn into an outright malignant sarcoma.

Management. After tissue diagnosis, proceed with margin-free resection.

4. A 35-year-old woman has a 10-year history of tenderness in both breasts, related to menstrual cycle, with multiple lumps on both breasts that seem to "come and go" at different times in the menstrual cycle. She now has a firm, round, 2-cm mass that has not gone away for 6 weeks.

What is it? Palpable cyst in fibrocystic disease (cystic mastitis, mammary dysplasia).

Management. Start with mammogram to see if there are other nonpalpable lesions. Once we can zero in on this one, tissue diagnosis (i.e., biopsy) becomes impractical when there are lumps every month. Aspiration of the cyst is the answer here (this is not FNA, this is aspiration

of fluid to empty a cyst, not aspiration of a solid mass to get cells). If the mass goes away and the fluid aspirated is clear, that's all. If the fluid is bloody it goes to cytology. If the mass does not go away, or recurs, she needs biopsy.

5. A 34-year-old woman has been having bloody discharge from the right nipple, on and off for several months. There are no palpable masses.

What is it? Intraductal papilloma.

Management. Although cancer is a concern with bloody nipple discharge, the most common cause of this complaint happens to be benign intraductal papilloma. The concern over cancer must be ruled out; the way to detect cancer that is not palpable is with mammogram. That should be the first choice. If negative, one may still wish to find and resect the intraductal papilloma to provide symptomatic relief and further exclude malignancy given the bloody discharge. Resection can be guided by galactogram, sonogram, or done as a retroareolar exploration.

6. A 26-year-old lactating mother has cracks in the nipple and develops a fluctuating, red, hot, tender mass in the breast, along with fever and leukocytosis.

What is it? Sounds like an abscess—and in this setting it is. Usually, only lactating breasts are entitled to develop abscesses. On anybody else, a breast abscess is a cancer until proven otherwise.

Management. No point on doing a mammogram on a lactating breast (even if she were older). Incision and drainage is the treatment for all abscesses, this one included. But, if an option includes drainage with biopsy of the abscess wall, go for that one.

7. A 49-year-old woman has a firm, 2-cm mass in the right breast, which has been present for 3 months.

What is it? This could be anything. Age is the best determinant for risk for cancer of the breast.If she had been 72, you go for cancer. At 22, you favor benign.

Management. Mammogram to explore for other non-palpable lesions (don't want to miss anything) and then multiple core biopsies of the known 2-cm mass are needed.

8. A 34-year-old woman in month 5 of pregnancy reports a 3-cm firm, ill-defined mass in her right breast that has been present and growing for 3 months.

The diagnosis of possible breast cancer in the pregnant patient is done the same way as if she had not been pregnant. Yes, you can do the mammogram and appropriate biopsies; but the radiologist will probably use sonogram to guide the biopsies, and no, you do not need to terminate the pregnancy.

9. A 69-year-old woman has a 4-cm hard mass in the right breast with ill-defined borders, movable from the chest wall but not movable within the breast. The skin overlying the mass is retracted and has an "orange peel" appearance.

10. A 69-year-old woman has a 4-cm hard mass in the right breast under the nipple and areola with ill-defined borders, movable from the chest wall but not movable within the breast. The nipple became retracted 6 months ago.

11. A 72-year-old woman has a red, swollen breast. The skin over the area looks like orange peel. She is not particularly tender, and it is debatable whether the area is hot or not. She has no fever or leukocytosis.

12. A 62-year-old woman has an eczematoid lesion in the areola. It has been present for 3 months, and it looks to her like "some kind of skin condition" that has not improved or gone away with a variety of lotions and ointments.

These are all classic presentations of breast cancer. The hard masses are likely invasive breast adenocarcinoma. The red, orange peel skin is likely inflammatory breast cancer, and the eczematoid areolar lesion is likely Paget's disease of the breast (a rare form of breast cancer). They all need mammograms for further evaluation and multiple core biopsies of suspicious breast lesions. The suspicious skin lesions (e.g. orange peel, eczematoid) can be confirmed with dermal punch biopsies.

13. A 42-year-old woman hits her breast with a broom handle while doing her housework. She noticed a lump in that area at the time, and 1 week later the lump is still there. She has a 3-cm hard mass deep inside the affected breast, and some superficial ecchymosis over the area.

What is it? A classic trap for the unwary. It is cancer until proven otherwise. Trauma often brings the area to the attention of the patient—but is not the cause of the lump. Proceed as with the others.

14. A 58-year-old woman discovers a mass in her right axilla. She has a discrete, hard, movable, 2-cm mass. Physical examination of her breast is negative, and she has no enlarged lymph nodes elsewhere.

What is it? A tough one, but another potential presentation for cancer of the breast. It could be lymphoma but also may be lymph node metastasis from an occult primary. She needs a mammogram (we are now looking for an occult primary in the breast) and possible U/S. The

node will eventually have to be biopsied. MRI of the breast is now in the work-up for occult primary breast cancer, as many are lobular cancers which are not always visualized by mammogram or even U/S.

15. A 60-year-old woman has a routine, screening mammogram. The radiologist reports an irregular area of increased density, with fine microcalcifications, that was not present 2 years ago on a previous mammogram.

Management. You will not be asked to read difficult x-rays (particularly mammograms), but you should recognize the description of a malignant radiologic image—which this one is. Thus, we go back to our old issue: we need tissue diagnosis. The mammographer will obtain multiple core biopsies.

16. A 44-year-old woman has a 2-cm palpable mass in the upper outer quadrant of her right breast. A core biopsy shows infiltrating ductal carcinoma. The mass is freely movable, and her breast is of normal, rather generous size. She has no palpable axillary nodes, and the mammogram showed no other lesions.

Treatment of operable breast cancer begins (but does not end) with surgery. With a small tumor far away from the nipple, the standard option is segmental resection (lumpectomy) and axillary node sampling (i.e. sentinel node biopsy) to help determine the need for adjuvant systemic therapy. Why go after the axillary nodes when they are not palpable? Because palpation is notoriously inaccurate in detecting microscopic metastasis to the lymph nodes which may be present in the early stages of an invasive breast cancer. Afterward, radiation therapy has to be given to the breast (otherwise, lumpectomy would have an unacceptably high rate of local recurrence).

17. A 62-year-old woman has a 4-cm hard mass under the nipple and areola of her smallish left breast. A core biopsy has diagnosed infiltrating ductal carcinoma. There are no palpable axillary nodes, and the mammogram shows no other lesions.

Lumpectomy is an ideal option when the tumor is small (in relation to the size of the breast), is located where most of the breast can be spared, and can be performed in a way that maintains the cosmetic appearance of the breast. A total mastectomy (also called simple mastectomy) is the choice here. Axillary sampling of sentinel nodes is also required (i.e. sentinel node biopsy if no palpable nodes). Radiation is typically not needed when the whole breast is removed unless in rare circumstances where the mass is very large (e.g., ≥5 cm) or if the lymph nodes contain metastasis. The old (unmodified) radical mastectomy is no longer done.

18. A 44-year-old woman has a 2-cm palpable mass in the upper outer quadrant of her right breast. A core biopsy shows lobular cancer.

19. A 44-year-old woman has a 2-cm palpable mass in the upper outer quadrant of her right breast. A core biopsy shows medullary cancer of the breast.

If they tease you with breast cancers that are not the standard infiltrating ductal carcinoma, here are the rules: lobular has a higher incidence of bilaterality (but not enough to justify bilateral mastectomy), and inflammatory has terrible prognosis. All the other variants of invasive cancer have a little better prognosis than infiltrating ductal, and they are all treated the same way anyway.

20. A 52-year-old woman has a suspicious area on mammogram. Multiple radiologically guided core biopsies show ductal carcinoma in situ.

No axillary sampling is needed if the lesion is confined to one quadrant. Lumpectomy and radiation should be performed. If there are multicentric lesions all over the breast, total mastectomy (also called simple mastectomy) is needed, and sentinel node biopsy should be done.

21. A 32-year-old woman in the seventh month of pregnancy is found to have a 2-cm mass in her left breast. Mammogram shows no other lesions, and core biopsy reveals infiltrating ductal carcinoma.

Again, pregnancy imposes very little limitations to our handling of breast cancer. The only no-no's are: no radiation therapy during the pregnancy, and no chemotherapy during the first trimester. Termination of the pregnancy is not needed.

22. A 44-year-old woman arrives in the ED because she is "bleeding from the breast." Physical examination shows a huge, fungating, ulcerated mass occupying the entire right breast, and firmly attached to the chest wall. The patient maintains that the mass has been present for only "a few weeks," but a relative indicates that it has been there at least 2 years, maybe longer.

An all-too-frequent tragic case of neglect and denial, as well as a significant psychiatric issue. Obviously, this is a far advanced cancer of the breast. Tissue diagnosis is still needed, and either a core or an incisional biopsy is in order, but the likely question here is what to do next. This is inoperable, and incurable as well, but palliation can be offered. Chemotherapy is the first line of treatment, perhaps accompanied by radiation. In many cases the tumor will shrink enough to become operable for palliation.

23. A 37-year-old woman has a lumpectomy and axillary sentinel node sampling for a 3-cm infiltrating ductal carcinoma. The pathologist reports clear surgical margins and metastatic cancer in both of the sentinel axillary nodes that were removed. The tumor is positive for estrogen and progesterone receptors.

Very rarely is surgery alone sufficient to cure breast cancer. Virtually all patients are given subsequent adjuvant systemic therapy. The need for it is underscored by the finding of involved axillary nodes. Chemotherapy is mandatory here, followed by radiation (because she had a lumpectomy) and finally, hormonal therapy, which, given her age, should be tamoxifen. If the sentinel lymph node dissection (SLND) is positive for metastasis, levels I and II lymph node dissection must also be done.

24. A 66-year-old woman has an MRM for infiltrating ductal carcinoma of the breast. The pathologist reports that the tumor measures 1 cm in diameter and that 1 of 2 sentinel axillary nodes removed are positive for metastasis. The tumor is estrogen and progesterone receptor positive.

The hormonal therapy of choice for post-menopausal women is an aromatase inhibitor (e.g., anastrazole). This should follow chemotherapy in this case, or it could be the only treatment if her general health precludes the use of chemo. As a general rule, all invasive cancers should be treated locally by surgery/radiation therapy and systemically by chemo/hormonal therapy. The only subgroup of women who will be spared chemotherapy are those who are node-negative, have tumor <1 cm in size, have hormone receptors on the cancer, and typically are post-menopausal.

25. A 44-year-old woman complains bitterly of severe headaches that have been present for several weeks and have not responded to the usual over-thecounter headache remedies. She is 2 years post-op from MRM for T3 N2 M0 cancer of the breast, and she had several courses of post-op chemotherapy, which she eventually discontinued because of the side effects.

A classic: severe headache in someone who a few years ago had extensive cancer of the breast means brain metastases until proven otherwise. Don't get hung up on the TNM classification; if the numbers are not 1 for the tumor and 0 for the nodes and metastases, the tumor is bad. Do MRI of the brain and use high-dose steroids and radiation.

26. A 39-year-old woman completed her last course of postoperative adjuvant chemotherapy for breast cancer 6 months ago. She comes to the clinic complaining of constant back pain for about 3 weeks. She is tender to palpation over 2 well-circumscribed areas in the thoracic and lumbar spine.

A variation on the above theme. Now bone metastases, instead of brain metastases—at least until proven otherwise. What do you do? MRI for diagnosis. Local radiation to the metastases may help, and a variety of orthopedic supports can be used to prevent collapse of the vertebral pedicles.

DISEASES OF THE ENDOCRINE SYSTEM

1. A 62-year-old woman was drinking her morning cup of coffee at the same time she was applying her makeup, and she noticed in the mirror that there was a lump in the lower part of the neck, visible when she swallowed. She consults you for this, and on physical examination you ascertain that she indeed has a prominent, 2-cm mass on the left lobe of her thyroid as well as 2 smaller masses on the right lobe. They are all soft, and she has no palpable lymph nodes in the neck.

Management. Most thyroid nodules are benign, and surgical removal to ascertain the diagnosis is a big operation—thus surgery has to be reserved for selected cases. Worrisome features include: young, male, single nodule, history of radiation to the neck, solid mass on sonogram, and cold nodule on scan. In centers with sufficient experience, the last 2 tests are omitted in preference for FNA and cytology. This case does not sound malignant, but you cannot be sure. If given the option among the answers, go for the FNA.

2. A 21-year-old man is found on a routine physical examination to have a single, 2-cm nodule in the thyroid gland. His thyroid function tests are normal. An FNA is read as indeterminate.

Management. Surgery is done for the FNAs that are read as malignant and those that are indeterminate.

3. A 32-year-old woman has a thyroid lobectomy done for a 2-cm mass that had been reported on a FNA as a "follicular neoplasm, not otherwise specified." The specimen is given for frozen section to a pathologist with a great deal of experience in thyroid disease and in the reading of frozen sections. The intraoperative diagnosis is follicular cancer.

Management: A total thyroidectomy should be completed.

4. An automated blood chemistry panel done during the course of a routine medical examination indicates that an asymptomatic patient has a serum calcium of 12.1 in a lab where the upper limit of normal is 9.5. Repeated determinations are consistently between 10.5 and 12.6. Serum phosphorus is low.

What is it? Parathyroid adenoma.

Diagnosis. Had this question been written 20 years ago, the vignette would have described a patient with a disease of "stones and bones and abdominal groans," and you would have cleverly asked for a serum calcium as your first test. Nowadays most parathyroid adenomas are identified when they are still asymptomatic, because of the widespread use of automated blood chemistry

panels. Across the board, most cases of hypercalcemia are caused by metastatic cancer, but that would not be the case on asymptomatic people. Your next move here is parathyroid hormone (PTH) determination and sestamibi scan to localize the adenoma. Surgery will follow.

5. A 32-year-old woman is admitted to the psychiatry unit because of wild mood swings. She is found to be hypertensive and diabetic and to have osteoporosis. (She had not been aware of such diagnosis beforehand.) It is also ascertained that she has been amenorrheic and shaving for the past couple of years. She has gross centripetal obesity, with moon facies and buffalo hump, and thin, bruised extremities. A picture from 3 years ago shows a person of very different, more normal appearance.

What is it? Cushing's syndrome. The appearance is so typical that you will probably be given before and after photographs on the exam, with a brief vignette. The presenting symptom may be any one of those listed.

Diagnosis. Start with the overnight dose dexamethasone suppression test. If she suppresses at a low dose, she is an obese, hairy woman, but she does not have the disease. If she does not suppress at the low dose, verify that 24-hour urine-free cortisol is elevated, and then go to high-dose suppression tests. If she suppresses at a high dose, do an MRI of the head looking for the pituitary microadenoma, which will be removed by the transnasal, trans-sphenoidal route. If she does not suppress at the higher dose, do a CT or MRI of adrenals looking for the adenoma there.

6. A 28-year-old woman has virulent peptic ulcer disease. Extensive medical management including eradication of *Helicobacter pylori* fails to heal her ulcers. She has several duodenal ulcers in the first and second portions of the duodenum. She has watery diarrhea.

What is it? Gastrinoma (Zollinger-Ellison syndrome).

Diagnosis. Start by measuring serum gastrin. If the value is not clearly normal or abnormal, a secretin stimulation test is added. Later CT scans (with vascular and GI contrast) of the pancreas and nearby areas to find the tumor, and surgery to remove it.

7. A second-year medical student is hospitalized for a neurologic workup for a seizure disorder of recent onset. During one of the convulsions, it is determined that his blood sugar is extremely low. Further workup shows that he has high levels of insulin in the blood with low levels of C-peptide.

What is it? Exogenous administration of insulin. If the C-peptide had been high along with the insulin level, the diagnosis would have been insulinoma. Had it been a baby with high insulin levels and low blood sugar, nesidioblastosis.

Management. In this case, psychiatric evaluation and counseling (he is faking the disease to avoid taking the USMLE). If it had been insulinoma, CT scan (with vascular and GI contrast) looking for the tumor in the pancreas, to be subsequently removed surgically.

8. A 48-year-old woman has had severe, migratory necrolytic dermatitis for several years, unresponsive to all kinds of "herbs and unguents." She is thin and has mild stomatitis and mild diabetes mellitus.

What is it? Glucagonoma.

Diagnosis. Determine glucagon levels. Eventually CT scan (with vascular and GI contrast) looking for the tumor in the pancreas. Surgery will follow. If inoperable, somatostatin can help symptomatically, and streptozocin is the indicated chemotherapeutic agent.

SURGICAL HYPERTENSION

1. A 45-year-old woman comes into your office for a regular checkup. On repeated determinations you confirm the fact that she is hypertensive. When she was in your office 3 years ago, her BP was normal. Laboratory studies at this time show a serum sodium of 144 mEq/L, a serum bicarbonate of 28 mEq/L, and a serum potassium concentration of 2.1 mEq/L. The woman is taking no medications of any kind.

What is it? Hyperaldosteronism. Possibly adenoma.

Diagnosis. Start with determination of aldosterone and renin levels. If confirmatory (aldosterone high, renin low), proceed with determinations lying down and sitting up to differentiate hyperplasia (appropriate response to postural changes—not surgical) from adenoma (no response or wrong response to postural changes—surgical). Treat the first with Aldactone. Pursue the second with imaging studies (CT or MRI) and surgery.

2. A thin, hyperactive 38-year-old woman is frustrated by the inability of her physicians to help her. She has episodes of severe pounding headache, with palpitations, profuse perspiration, and pallor, but by the time she gets to her doctor's office she checks out normal in every respect. In addition, she has paroxismal hypertension.

What is it? Suspect pheochromocytoma.

Diagnosis. The most sensitive test is the 24-hour urinary metanephrine test (90% effective). The vanillylmandelic acid (VMA) test is next best, at 80% effective. Follow with CT scan of adrenal glands. Surgery will eventually be done, with careful pharmacologic preparation with alpha-blockers.

3. A 17-year-old man is found to have a BP of 190 over 115. This is checked repeatedly in both arms, and it is always found to be elevated, but when checked in the legs it is found to be normal.

What is it? Coarctation of the aorta.

Diagnosis. Start with a chest x-ray, looking for scalloping of the ribs. Then CTA and ultimately surgery.

4. A 23-year-old woman has had severe hypertension for 2 years, and she does not respond well to the usual medical treatment for that condition. A bruit can be faintly heard over her upper abdomen.

5. A 72-year-old man with multiple manifestations of arteriosclerotic occlusive disease has hypertension of relatively recent onset and refractory to the usual medical therapy. He has a faint bruit over the upper abdomen.

What are they? Two examples of renovascular hypertension; the first one caused by fibromuscular dysplasia, the second one secondary to arteriosclerosis.

Diagnosis. Start with Duplex scanning of the renal vessels. CT angio may also be helpful.

Management. Once the diagnosis has been made, the decision for therapy is easy in the young woman: she has many years of potential life, and her hypertension must be cured. Angiographic balloon dilation with stenting is the first choice, surgery the other alternative. In the elderly man the decision is far more complex. Treatment of the renovascular hypertension makes sense only if other manifestations of the arteriosclerosis are not going to kill him first.

Pediatric Surgery 5

AT BIRTH—THE FIRST 24 HOURS

1. Within 8 hours after birth, it is noted that a baby has excessive salivation. A small, soft NG tube is inserted, and the baby is taken to x-ray to have a "babygram" done. The film shows the tube coiled back on itself in the upper chest. There is air in the GI tract.

What is it? Tracheoesophageal (TE) fistula, the most common type, with proximal blind esophageal pouch and distal TE fistula.

Management. First, rule out the associated anomalies (VACTER: vertebral, anal, cardiac, TE, and renal/radial). The vertebral and radial will be seen in the same x-ray you already took, you need echocardiogram for the heart, sonogram for the kidneys, and physical examination for the anus. Then off to surgery.

2. A newborn baby is found on physical examination to have an imperforate anus.

Management. This is part of the VACTER group, so rule out the other components. For the anal problem, if there is a fistula to the vagina or perineum, repair can be safely done later, as the GI tract is not obstructed. If there is no fistula, one has to ascertain the level of the blind pouch. This is done with an x-ray while holding the baby upside down, with a metal marker taped to the anal dimple. Low imperforate anus can be corrected with a very simple operation. High imperforate anus needs a colostomy, and repair at a later date.

3. A newborn baby is found to be tachypneic, cyanotic, and grunting. The abdomen is scaphoid, and there are bowel sounds heard over the left chest. An x-ray confirms that there is bowel in the left thorax. Shortly thereafter, the baby develops significant hypoxia and acidosis.

What is it? Congenital diaphragmatic hernia.

Management. The main problem is the hypoplastic lung. It is better to wait 36 to 48 hours to do surgery to allow transition from fetal circulation to newborn circulation. Meanwhile, the trick is to keep the kid alive with endotracheal intubation, low-pressure hyperventilation (careful not to blow up the other lung), sedation, and NG suction.

4. At the time of birth, it is noted that a child has a large abdominal wall defect to the right of the umbilicus. There is a normal cord, but protruding from the defect is a matted mass of angry-looking edematous bowel loops.

5. A newborn baby is noted to have a shiny, thin, membranous sac at the base of the umbilical cord (the cord goes to the sac, not to the baby). Inside the sac, one can see part of the liver and loops of normal bowel.

What are they? The first one is gastroschisis, the second one omphalocele. Medical school professors love to emphasize differential diagnosis of somewhat similar problems. Chances are all you'll be expected to do is to identify the correct one.

Management. Intuitive. You've got to get those intestines back into the belly, and the technical details are best left to the pediatric surgeons. They will be on the lookout for atresias (which babies with gastroschisis can have) or multiple defects (which are seen with omphalocele), and they will close small defects directly. Very often, however, the defects are large, most of the bowel is outside the abdomen, and there is no room to "push it in." In those cases a silicon "silo" is used to house the bowel and gradually return it to the abdomen. The baby with gastroschisis will also need vascular access for IV nutrition (the angry bowel will not work for about 1 month).

6. A newborn is noted to have a moist medallion of mucosae occupying the lower abdominal wall, above the pubis and below the umbilicus. It is clear that urine is constantly bathing this congenital anomaly.

What is it? Extrophy of the urinary bladder.

What's the point of the vignette? These are very rare anomalies that only very highly specialized centers can repair. The problem is that unless the repair is done within the first 48 hours, it will not have a good chance to succeed. It takes time to arrange for transfer of a newborn baby to a distant city. If a day or 2 are wasted before arrangements are made, it will be too late.

7. Half an hour after the first feed, a baby vomits greenish fluid. The mother had polyhydramnios, and the baby has Down syndrome. X-ray shows a "double bubble sign": a large air-fluid level in the stomach, and a smaller one in the first portion of the duodenum. There is no gas in the rest of the bowel.

What is it? It can be 2 things, but first some general points. Kids vomit, burp, and regurgitate all the time (ask any parent), but the innocent vomit is clear-whitish. Green vomiting in the newborn is bad news. It means something serious. The 2 conditions that this could be are duodenal atresia and annular pancreas. Malrotation is also possible, but I expect that one to be presented to you as in the next vignette.

Management. With complete obstruction, surgery will be needed, but these kids have lots of other congenital anomalies, look for them first.

8. Half an hour after the first feed, a baby vomits greenish fluid. X-ray shows a "double-bubble sign": a large air-fluid level in the stomach, and a smaller one in the first portion of the duodenum. There is air in the distal bowel, beyond the duodenum, in loops that are not distended.

What is it? Now you have 3 choices: it could be an incomplete obstruction from duodenal stenosis or annular pancreas, or it could be malrotation.

Management. If you are dealing with incomplete obstruction, you have time to do what's needed, i.e., it is a lesser emergency. But if it is malrotation the bowel could twist and die, so that one is a super-emergency. How can you tell? A contrast enema is safe but not always diagnostic. An upper GI study is riskier but more reliable.

9. A newborn baby has repeated green vomiting during the first day of life, and does not pass any meconium. Except for abdominal distention, the baby is otherwise normal. X-ray shows multiple air-fluid levels and distended loops of bowel.

What is it? Intestinal atresia.

Management. This one is caused by a vascular accident in utero; thus, there are no other congenital anomalies to look for, but there may be multiple points of atresia.

A FEW DAYS OLD—THE FIRST 2 MONTHS OF LIFE

1. A very premature baby develops feeding intolerance, abdominal distention, and a rapidly dropping platelet count. The baby is 4 days old, and was treated with indomethacin for a patent ductus arteriosus.

What is it? Necrotizing enterocolitis.

Management. Stop all feedings, broad-spectrum antibiotics, IV fluids/nutrition. Surgical intervention if the baby develops abdominal wall erythema, air in the portal vein, or pneumoperitoneum.

2. A 3-day-old, full-term baby is brought in because of feeding intolerance and bilious vomiting. X-ray shows multiple dilated loops of small bowel and a ground-glass appearance in the lower abdomen. The mother has cystic fibrosis.

What is it? Meconium ileus.

Management. Gastrografin enema may be both diagnostic and therapeutic, so it is the obvious first choice. If unsuccessful, surgery may be needed. The kid has cystic fibrosis, and management of the other manifestations of the disease will also be needed.

3. A 3-week-old baby has had "trouble feeding" and is not quite growing well. He now has bilious vomiting and is brought in for evaluation. X-ray shows a classic "double bubble," along with normal-looking gas pattern in the rest of the bowel.

What is it? Malrotation. The vignette is repeated here because they can show up at any time within the first few weeks of life. Proceed with urgent diagnostic studies.

4. A 3-week-old first-born, full-term baby boy began to vomit 3 days ago. The vomiting is projectile, has no bile in it, and follows each feeding, and the baby is hungry and eager to eat again after he vomits. He looks somewhat dehydrated and has visible gastric peristaltic waves and a palpable "olive size" mass in the right upper quadrant.

What is it? Hypertrophic pyloric stenosis.

Management. Check electrolytes; hypokalemic, hypochloremic metabolic alkalosis may have developed. Correct it, rehydrate, and do a pyloromyotomy.

5. An 8-week-old baby is brought in because of persistent, progressively increasing jaundice. The bilirubin is significantly elevated, and about 2/3 of it is conjugated, direct bilirubin. Serology is negative for hepatitis, and sweat test is normal.

What is it? Biliary atresia.

Management. HIDA scan after 1 week of phenobarbital is the best test. Surgical derivation will be tried, but 2/3 of these kids end up with liver transplant.

6. A 2-month-old baby boy is brought in because of chronic constipation. The kid has abdominal distention, and plain x-rays show gas in dilated loops of bowel throughout the abdomen. Rectal examination is followed by explosive expulsion of stool and flatus, with remarkable improvement of the distention.

What is it? Hirschsprung disease (aganglionic megacolon).

Diagnosis. Barium enema will define the normal-looking aganglionic distal colon and the abnormal-looking, distended, normal proximal colon; but the diagnosis is established with full thickness biopsy of the rectal mucosa.

LATER IN INFANCY

1. A 9-month-old, chubby, healthy-looking little boy has episodes of colicky abdominal pain that makes him double up and squat. The pain lasts for about 1 minute, and the kid looks perfectly happy and normal until he gets another colic episode. Physical examination shows a vague mass on the right side of the abdomen, an "empty" right lower quadrant, and currant jelly stools.

What is it? Intussusception.

Management. Barium enema or air enema are both diagnostic and therapeutic in most cases. It should be your first choice. If reduction is not achieved radiologically, do surgery.

2. A 1-year-old baby is referred to the University Hospital for treatment of a subdural hematoma. In the admission examination it is noted that the baby has retinal hemorrhages.

3. A 3-year-old girl is brought in for treatment of a fractured humerus. The mother relates that the girl fell from her crib. X-rays show evidence of other older fractures at various stages of healing in different bones.

4. A 1-year-old child is brought in with second-degree burns of both buttocks. The stepfather relates that the child fell into a hot tub.

What are they? Classic vignettes of child abuse.

Management. Notify the proper authorities.

5. A 7-year-old boy passes a large bloody bowel movement.

What is it? Meckel diverticulum.

Diagnosis. Do a radioisotope scan looking for gastric mucosa in the lower abdomen.

Cardiothoracic Surgery 6

CONGENITAL HEART PROBLEMS

1. A 6-month-old baby has occasional stridor, and episodes of respiratory distress with "crowing" respiration during which he assumes a hyperextended position. The family has also noted mild difficulty in swallowing.

The combination of pressure on the esophagus and pressure on the trachea identifies a vascular ring. Barium swallow will show a typical extrinsic compression from the abnormal vessel. Bronchoscopy confirms the segmental tracheal compression and rules out diffuse tracheomalacia. Surgical repair is done by dividing the smaller of the double aortic arches.

2. A patient who has prosthetic aortic and mitral valves needs extensive dental work.

Antibiotic prophylaxis is needed to protect those valves from bacterial contamination. Pretty brief vignette, but the point is that somewhere along the line, you might be expected to remember that these patients need antibiotic prophylaxis for subacute bacterial endocarditis.

3. During a school physical exam, a 12-year-old girl is found to have a heart murmur. She is referred for further evaluation. An alert cardiology fellow recognizes that she indeed has a pulmonary flow systolic murmur, but he also notices that she has a fixed split second heart sound. A history of frequent colds and upper respiratory infections is elicited.

What is it? Atrial septal defect.

Management. Echocardiography to establish the diagnosis. Closure of the defect by open surgery or cardiac catheterization.

4. A 3-month-old boy is hospitalized for "failure to thrive." He has a loud, pansystolic heart murmur best heard at the left sternal border. Chest x-ray shows increased pulmonary vascular markings.

What is it? Ventricular septal defect.

Management. Echocardiography and surgical correction.

5. Because of a heart murmur, an otherwise asymptomatic 3-month-old baby is diagnosed with a small, restrictive ventricular septal defect located low in the muscular septum.

This particular variant has a good chance to close spontaneously within the first 2 or 3 years of life.

6. A 3-day-old premature baby has trouble feeding and pulmonary congestion. Physical examination shows bounding peripheral pulses and a continuous, machinery-like heart murmur. Shortly thereafter the baby goes into overt heart failure.

What is it? Patent ductus arteriosus.

Management. Echocardiography and surgical closure. In premature infants, surgery is usually reserved for patients who did not close their ductus with indomethacin, but with overt heart failure there is no time to wait. In full-term infants, closure can be achieved with intraluminal coils or surgery.

7. A premature baby girl has mild pulmonary congestion, signs of increased pulmonary blood flow on x-ray, a wide pulse pressure, and a precordial machinery-like murmur. She is not in congestive failure.

Same diagnosis of patent ductus, but with no urgency, and being premature, she is a clear candidate for medical treatment with indomethacin.

8. A 6-year-old boy is brought to the United States by his new adoptive parents from an orphanage in Eastern Europe. The boy is small for his age and has a bluish hue in the lips and tips of his fingers. He has clubbing and spells of cyanosis relieved with squatting. He has a systolic ejection murmur in the left third intercostal space. Chest x-ray shows a small heart and diminished pulmonary vascular markings. ECG shows right ventricular hypertrophy.

What is it? Tetralogy of Fallot. Cyanotic children could have any of the 5 conditions that begin with the letter "T":

- Tetralogy or transposition of the great vessels (common)
- Truncus arteriosus, total anomalous pulmonary venous connection, or tricuspid atresia (rare)

If the baby went home after birth, and later was found to be cyanotic, bet on tetralogy. If he was blue from the moment of birth, bet on transposition.

Management. Even if all you can recognize from the vignette is that the child has cyanosis, start with an echocardiogram as a good diagnostic test. The intricate details of surgical correction are bound to be beyond the level of knowledge expected on the exam.

ACQUIRED HEART DISEASE

1. A 72-year-old man has a history of angina and exertional syncopal episodes. He has a harsh midsystolic heart murmur best heard at the right second intercostal space and along the left sternal border.

What is it? Aortic stenosis with the triad of angina, dyspnea, and syncope.

Diagnosis: Echocardiogram

Management. Surgical valvular replacement is indicated if there is a gradient of >50 mm Hg, or at the first indication of CHF, angina, or syncope.

2. A 72-year-old man has been known for years to have a wide pulse pressure and a blowing, high-pitched, diastolic heart murmur best heard at the right second intercostal space and along the left lower sternal border with the patient in full expiration. He has had periodic echocardiograms, and in the most recent one there is evidence of beginning left ventricular dilatation.

What is it? Chronic aortic insufficiency.

Management. Aortic valve replacement.

3. A 26-year-old drug-addicted man develops CHF over a short period of a few days. He has a loud, diastolic murmur at the right, second intercostal space. A physical examination done a few weeks ago, when he had attempted to enroll in a detoxification program, was completely normal.

What is it? Acute aortic insufficiency caused by endocarditis.

Management. Emergency valve replacement, and antibiotics for a long time.

4. A 35-year-old woman has dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, cough, and hemoptysis. She has had these progressive symptoms for about 5 years. She looks thin and cachectic and has atrial fibrillation and a low-pitched, rumbling diastolic apical heart murmur. At age 15 she had rheumatic fever.

What is it? Mitral stenosis.

Management. Start with echocardiogram. Eventually, surgical mitral valve repair.

5. A 55-year-old woman has been known for years to have mitral valve prolapse. She now has developed exertional dyspnea, orthopnea, and atrial fibrillation. She has an apical, high-pitched, holosystolic heart murmur which radiates to the axilla and back.

What is it? Mitral regurgitation.

Management. Start with the echocardiogram, eventually surgical repair of the valve (annuloplasty), or possibly valve replacement.

6. A 55-year-old man has progressive, unstable, disabling angina that does not respond to medical management. His father and 2 older brothers died of heart attacks age <50. The patient stopped smoking 20 years ago, but still has a sedentary lifestyle, is a bit overweight, has type 2 diabetes mellitus, and has high cholesterol.

What is it? It's a heart attack waiting to happen—but the point of this vignette is the management: this man needs a cardiac catheterization to see whether he is a suitable candidate for coronary revascularization.

7. A 55-year-old man has progressive, unstable, disabling angina that does not respond to medical management. His father and 2 older brothers died of heart attacks age <50. The patient stopped smoking 20 years ago, but still has a sedentary life style, is a bit overweight, has type 2 diabetes mellitus, and has high cholesterol. Cardiac catheterization demonstrates 70% occlusion of 3 coronary arteries, with good distal vessels. His left ventricular ejection fraction is 55%.

Management. The patient is lucky. He has good distal vessels (smokers and diabetics often do not) and enough cardiac function left. He clearly needs coronary bypass, and with triple-vessel disease he is clearly not a good candidate for angioplasty.

8. A postoperative patient who underwent open heart surgery is determined to have a cardiac index of 1.7 L/min/m2, and a left ventricular end-diastolic pressure of 3 mm Hg.

The postoperative management of open heart surgery is a little too esoteric for the exam, but a little bit of applied physiology is not. You should be able to recognize a dangerously low cardiac index, without a high end-diastolic pressure—a clear indication for increased fluid intake.

9. A 72-kg patient who had a triple coronary bypass is determined on postoperative day 2 to have a cardiac output of 2.3 L/min. His pulmonary wedge pressure is 27 mm Hg. The cardiac output is low, but in this case, the ventricle is failing.

LUNG

1. On a routine pre-employment physical examination, a chest x-ray is done on a 45-year-old chronic smoker. A solitary pulmonary nodule is found in the upper lobe of the right lung.

What is it? The concern, of course, is cancer of the lung.

Diagnosis. Find an older chest x-ray if one is available (from ≥1 year ago). The workup for cancer of the lung is expensive and invasive. On the other hand, cancer of the lung grows and kills in a predictable way, over a matter of several months. If an older x-ray has the same unchanged lesion, it is not likely cancer. No further workup is needed now, but the lesion should be followed with periodic x-rays.

2. A 65-year-old man with a 40 pack-year history of smoking gets a chest x-ray because of persistent cough. A peripheral, 2-cm solitary nodule is found in the right lung. A chest x-ray taken 2 years ago was normal.

After age 50, "coin lesions" have an 80% chance of being malignant. In this patient it is almost certainly cancer of the lung. These vignettes typically have already had a chest x-ray done, thus the next step in management consists of noninvasive ways to establish the diagnosis and some idea of the extension of the tumor (about 2/3 of patients are already beyond surgical stage when first seen). If other findings do not dictate a different approach, start with sputum cytology and CT scan (including the upper abdomen to detect liver metastases). The next step if needed would be biopsy of the mass—by bronchoscopy if it is central, percutaneously if it is peripheral.

3. A 66-year-old man with a 40 pack-year history of smoking gets a chest x-ray because of persistent cough. A peripheral 2-cm solitary pulmonary nodule is found in the right lung. A chest x-ray taken 2 years ago was normal. CT scan shows no calcifications in the mass, no liver metastases, and no enlarged peribronchial or peritracheal lymph nodes. Sputum cytology, bronchoscopy, and percutaneous needle biopsy have not been diagnostic. The man has good pulmonary function and is otherwise in good health.

Management. In dealing with cancer of the lung, 3 issues are at play:

- Establishing the diagnosis, which sometimes requires very invasive steps
- Ascertaining whether surgery can be done, i.e., will the patient still be functional after some lung tissue is removed
- Does the surgery have a fair chance to cure him? (It will not if the tumor is extensive.)

Here is an example of a man who could stand lung resection (peripheral lesion, good function) and who stands a good chance for cure (no node metastases in the CT scan). Diagnostic steps should be VATS or wedge resection to remove the wedge of tissue one suspects for malignancy.

4. A 72-year-old chronic smoker with severe COPD is found to have a central, hilar mass on chest x-ray. Sputum cytology establishes a diagnosis of squamous cell carcinoma of the lung. His forced expiratory volume in 1 second (FEV1) is 1,100 ml, and a ventilation–perfusion scan shows that 60% of his pulmonary function comes from the affected lung.

Management. The history and physical suggested that the main limiting factor would be pulmonary function, so that issue was properly evaluated first. It takes an FEV1 of at least 800 ml to survive surgery and not be a pulmonary cripple afterward. If this patient underwent a pneumonectomy (which he would need for a central tumor), he would be left with FEV1 440 ml. No way. Don't do any more tests. He is not a surgical candidate. You already have a diagnosis to pursue chemotherapy and radiation.

5. A 62-year-old chronic smoker has an episode of hemoptysis. Chest x-ray shows a central hilar mass. Bronchoscopy and biopsy establish a diagnosis of squamous cell carcinoma of the lung. His FEV1 is 2,200 ml, and a ventilation–perfusion scan shows that 30% of his pulmonary function comes from the affected lung.

Management. This patient could tolerate a pneumonectomy, but we still have to determine the extent of his disease. CT scan alone may be able to establish that he does not have metastasis. CT plus PET scan may be required in some cases where the status of the mediastinal nodes is not clear, and if the PET scan cannot provide an answer, an endobronchial U/S to sample nodes would be the next step in management.

6. A 33-year-old woman undergoes a diagnostic workup because she appears to have Cushing syndrome. Chest x-ray shows a central 3-cm round mass on the right lung. Bronchoscopy and biopsy confirm a diagnosis of small cell carcinoma of the lung.

Management. Radiation and chemotherapy. Small cell lung cancer is not treated with surgery, and thus we have no need to determine FEV1 or nodal status.

Vascular Surgery 7

1. A 54-year-old right handed laborer notices coldness and tingling in his left hand as well as pain in the forearm when he does strenuous work. What really concerned him, though, is that in the last few episodes he also experienced transitory vertigo, blurred vision, and difficulty articulating his speech.

This is subclavian steal syndrome. A combination of claudication of the arm with posterior brain neurologic symptoms is classic for this rare but fascinating (and thus favorite question) condition. Duplex scanning will demonstrate retrograde flow through the vertebral artery when the patient exercises the arm. Surgical bypass resolves the problem.

2. A 62-year-old man is found on physical examination to have a 6-cm pulsatile mass deep in the abdomen, between the xiphoid and the umbilicus.

This is an abdominal aortic aneurysm. He needs elective surgical repair, but because our decisions are based so much on the size of the aneurysm, we need more precise measurement. CT scan is indicated.

3. A 62-year-old man has vague, poorly described epigastric and upper back discomfort. He is found on physical examination to have a 6-cm pulsatile mass deep in the abdomen, between the xiphoid and the umbilicus. The mass is tender to palpation.

This is an abdominal aortic aneurysm that is beginning to leak. Get an immediate vascular surgery consultation as surgical repair is necessary.

4. A 68-year-old man is brought to the ED with excruciating back pain that began suddenly 45 minutes ago. He is diaphoretic and has a systolic BP 90. There is an 8-cm, pulsatile mass palpable deep in the abdomen, above the umbilicus.

The aneurysm is rupturing right now. He needs immediate, emergency surgery.

5. A wealthy, retired man has claudication when walking more than 15 blocks.

Vascular surgery and angioplastic stenting are palliative procedures; they do not cure arteriosclerotic disease.

Claudication has an unpredictable course; thus, there is no indication for early operation or intervention. No expensive workup is needed. If he smokes, he should quit, and he would benefit from a program of exercise and the use of cilostazol.

6. A 56-year-old postman describes severe pain in his right calf when he walks 2 or 3 blocks. The pain is relieved by resting 10 or 15 minutes, but recurs if he walks again the same distance. He cannot do his job this way, and he does not qualify yet for retirement, so he is most anxious to have this problem resolved. He does not smoke.

This patient needs help. Start with Doppler studies. If he has a significant gradient, CT angio or MRI angio comes next, followed by bypass surgery or stenting.

7. A patient consults you because he "cannot sleep." On questioning it turns out that he has pain in the right calf, which keeps him from falling asleep. He relates that the pain goes away if he sits by the side of the bed and dangles the leg. His wife adds that she has watched him do that, and she has noticed that the leg, which was very pale when he was lying down, becomes deep purple several minutes after he is sitting up. On physical examination the skin of that leg is shiny, there is no hair, and there are no palpable peripheral pulses.

Rest pain. Definitely he needs the studies to see whether vascular surgery could help him.

8. A 45-year-old man shows up in the ED with a pale, cold, pulseless, paresthetic, painful, and paralytic lower extremity. The process began suddenly 2 hours ago. Physical examination shows no pulses anywhere in that lower extremity. Pulse at the wrist is 95/min, grossly irregular.

What is it? Embolization by the broken-off tail of a clot from the left atrium. Start with Doppler studies. If he has complete occlusion, do embolectomy with Fogarty catheters, and if he was ischemic for several hours, add a fasciotomy to prevent compartment syndrome. Incomplete occlusion may be treated with clot busters.

9. A 74-year-old man has sudden onset of extremely severe, tearing chest pain that radiates to the back and migrates down shortly after its onset. His BP is 220/110 mm Hg, and he has unequal pulses in the upper extremities and a wide mediastinum on chest x-ray. ECG and cardiac enzymes are negative for MI.

This is dissecting aneurysm of the thoracic aorta. Spiral CT scan is the best study to confirm the diagnosis in a noninvasive way. If the aneurysm is in the ascending aorta, emergency surgery should be performed. If it is in the descending aorta, intensive therapy in the ICU for the hypertension is the preferable option.

Skin Surgery

8

1. A 65-year-old West Texas farmer of Swedish ancestry has an indolent, raised, waxy, 1.2-cm skin mass over the bridge of the nose that has been slowly growing over the past 3 years. There are no enlarged lymph nodes in the head and neck.

2. A 71-year-old West Texas farmer of Irish ancestry has a non-healing, indolent, punched out, clean-looking 2-cm ulcer over the left temple that has been slowly becoming larger over the past 3 years. There are no enlarged lymph nodes in the head and neck.

Basal cell carcinoma has 2 potential configurations: waxy raised lesion or punched out ulcer, but both have a preference for the upper part of the face.

Diagnosis is made with full-thickness biopsy at the edge of the lesion (punch or knife) or complete excision with narrow margin of uninvolved skin. Management is surgical excision with clear margins, but conservative width. Alternatives include electrodessication with curettage or ablation.

3. A blond, blue-eyed, 69-year-old sailor has a non-healing, indolent 1.5-cm ulcer on the lower lip that has been slowly enlarging, for the past 8 months. He is a pipe smoker, and he has no other lesions or physical findings.

What is it? Squamous cell carcinoma. The location is classic.

Diagnosis. Biopsy, as described before.

Management. He will need surgical resection with wider (~1 cm) clear margins. Local radiation therapy is another option.

4. A red-headed, highly freckled, 23-year-old woman who worships the sun consults you for a concerning skin lesion on the shoulder. She has a pigmented lesion that is asymmetric, with irregular borders of different colors within the lesion. It measures 1.8 cm.

What is it? The classic ABCD that alerts you to melanoma or a forerunner (dysplastic nevus).

Management. Excisional biopsy with narrow margin preferred. Once diagnosis is confirmed, definitive treatment is wide local excision with margins based on depth of invasion (Breslow). Sentinel lymph node biopsy is indicated for lesions 1–4 mm Breslow thickness.

5. A 35-year-old blond, blue-eyed man left his native Minnesota at age 18 and has been living an idyllic life as a crew member for a sailing yacht charter operation in the Caribbean. He has multiple nevi all over his body, but one of them has changed recently.

What is it? Change in a pigmented lesion is the other tip off to melanoma. It may be growth, or bleeding, or ulceration, or change in color—whatever. Manage as above.

6. A 44-year-old man has unequivocal signs of multiple liver metastases, but no primary tumor has been identified by multiple diagnostic studies of the abdomen and chest. The only abnormality in the physical examination is a missing toe, which he says was removed at age 18 for a black tumor under the toenail.

What is it? A classic vignette for malignant melanoma (the alternate version has a glass eye, and history of enucleation for a tumor). No self-respecting malignant tumor would have this time interval, but melanoma will.

7. A 32-year-old gentleman had a 3.4-mm deep melanoma removed from the middle of his back 3 years ago. He now has… (a tumor in a weird place, like his left ventricle, his duodenum, his ischiorectal area–anywhere!).

The point of this vignette is that invasive melanoma (it has to be deep) metastasizes to all the usual places (lymph nodes plus liver-lung-brain-bone) but it is also the all-time-champion in going to weird places where few other tumors dare to go. Because tumor behavior is unpredictable in any given patient, doctors tend to be aggressive in resecting these metastasis.

Ophthalmology 9

CHILDREN

1. A 1-year-old child is suspected of having strabismus. You verify that indeed the corneal reflection from a bright light in your examining room comes from different places from each of his eyes.

2. A 2-year-old child is diagnosed with a congenital cataract obstructing his vision in the right eye.

What is the point of these vignettes? To remind you that the brain "learns" to see what the eyes see during early infancy (up to about age 7). If one eye cannot see (any kind of obstruction) or the brain does not like what they see (double vision), the brain will refuse to process the image and that cortical "blindness" will be permanent (the concept of amblyopia).

Management. The problem has to be surgically corrected as early as possible.

3. A young mother is visiting your office for routine medical care. She happens to have her 18-month-old baby with her, and you happen to notice that one of the pupils of the baby is white, whereas the other one is black.

What is it? An ophthalmologic and potentially life-and-death emergency. A white pupil (leukocoria) at this age can be retinoblastoma. This kid needs to see the ophthalmologist not next week, but today or tomorrow. If it turns out to be something more innocent, like a cataract, the kid still needs it corrected to avoid amblyopia.

ADULTS

1. A 53-year-old woman arrives in the ED complaining of extremely severe frontal headache and nausea. The pain started about an hour ago, shortly after she left the movies where she watched a double feature. On further questioning, she reports seeing halos around the lights in the parking lot when she left the theater. On physical examination the pupils are mid-dilated and do not react to light. The corneas are cloudy with a greenish hue, and the eyes feel "hard as a rock."

What is it? A classic description of acute glaucoma. Not the most common type (most are asymptomatic—but you cannot write a vignette for those), but one that requires immediate treatment.

Management. An ophthalmologist is needed right away—but start treatment with systemic carbonic anhydrase inhibitors, topical beta-blockers, and alpha-2–selective adrenergic agonists. Mannitol and pilocarpine may also be used.

2. A 32-year-old woman presents in the ED with swollen, red, hot, tender eyelids on the left eye. She has fever and leukocytosis. When prying the eyelids open, you can ascertain that her pupil is dilated and fixed and that she has very limited motion of that left eye.

What is it? Orbital cellulitis.

Management. Another ophthalmologic emergency that requires immediate consultation, but if asked what to do, CT scan will be indicated to assess the extent of the orbital infection, and surgical drainage will follow.

3. A frantic mother reaches you on the phone, reporting that her 10-year-old boy accidentally splashed Drano (clogged drain remover) on his face. He is screaming in pain, complaining that his right eye hurts terribly.

Management. Copious irrigation is the main treatment for chemical burns. The point of this vignette is to remind you that time is a key element. If the mother is instructed to bring the boy to the ED, his eye will be cooked to a crisp by the time he arrives. The correct answer here is to instruct the mother to pry the eye open under the cold water from the tap at home, and irrigate for about 30 minutes before bringing the child to the hospital. You will do more irrigation in the ED, remove solid matter, and eventually recheck the pH before the child goes home. Do not forget to check the eyelid for remaining bits of Drano.

4. A 59-year-old, myopic gentleman reports "seeing flashes of light" at night when his eyes are closed. Further questioning reveals that he also sees "floaters" during the day, that they number 10 or 20, and that he also sees a cloud at the top of his visual field.

What is it? This is retinal detachment; 1–2 floaters would not mean that but >12 is an ominous sign. The "cloud" at the top of the visual field is hemorrhage settling at the bottom of the eye.

Management. Another ophthalmologic emergency. The retina specialist will use laser treatment to "spot weld" the retina and prevent further detachment.

5. A 77-year-old man suddenly loses sight from the right eye. He calls you on the phone 10 minutes after the onset of the problem. He reports no other neurologic symptoms.

What is it? Embolic occlusion of the retinal artery.

Management. Another ophthalmologic emergency—although little can be done for the problem, he has to get to the ED instantly. It might help for him to take an aspirin and breathe into a paper bag en route, and have someone press hard on his eye and release it repeatedly.

6. A 55-year-old man is diagnosed with type 2 diabetes mellitus. On questioning about eye symptoms, he reports that sometimes after a heavy dinner the television becomes blurry, and he has to squint to see it clearly.

What is it? The blurry TV is no big deal: the lens swells and shrinks in response to swings in blood sugar—the important point is that he needs to start getting regular ophthalmologic follow-up for retinal complications. It takes 10–20 years for these to develop, but type 2 diabetes may have been present that long before it was diagnosed.

Otolaryngology (ENT) 10

NECK MASSES

Congenital

1. A 15-year-old girl has a round, 1-cm cystic mass in the midline of her neck at the level of the hyoid bone. When the mass is palpated at the same time that the tongue is pulled, there seems to be a connection between the two. The mass has been present for at least 10 years, but only recently bothered the patient because it got infected.

What is it? Thyroglossal duct cyst.

Management. Sistrunk operation (removal of the mass and the track to the base of the tongue, along with the medial segment of the hyoid bone). Some people insist that the location of the normal thyroid must be ascertained first with radioisotope scanning.

2. An 18-year-old woman has a 4-cm, fluctuant round mass on the side of her neck, just beneath and in front of the sternocleidomastoid. She reports that it has been there at least 10 years, although she thinks that it has become somewhat larger in the last year or two. A CT scan shows the mass to be cystic.

This is a branchial cleft cyst. Do elective surgical removal.

3. A 6-year-old child has a mushy, fluid-filled mass at the base of the neck that has been noted for several years. The mass is ~6 cm in diameter, occupies most of the supraclavicular area and seems by physical examination to go deeper into the neck and chest.

What is it? Cystic hygroma.

Management. Get a CT scan to see how deep the mass goes. Cystic hygromas can extend down into the chest and mediastinum. Surgical removal will eventually be done.

Inflammatory Versus Neoplastic

4. A 22-year-old woman notices an enlarged lymph node in her neck. The node is in the jugular chain, measures ~1.5 cm, is not tender, and was discovered by the patient yesterday. The rest of the history and physical examination are unremarkable.

Management. Before you spend a lot of money doing tests, let time be your ally. Schedule the patient to be rechecked in 3 weeks. If the node has gone away by then, it was inflammatory and nothing further is needed. If it's still there, it could be neoplastic and something needs to be done. Three weeks of delay will not significantly impact the overall course of a neoplastic process.

5. A 22-year-old woman seeks help regarding an enlarged lymph node in her neck. The node is in the jugular chain, measures ~2 cm, is firm, not tender, and was discovered by the patient 6 weeks ago. There is a history of low-grade fever and night sweats for the past 3 weeks. Physical examination reveals enlarged lymph nodes in both axillas and in the left groin.

What is it? Lymphoma.

Management. Tissue diagnosis will be needed. You can start with FNA of the available nodes, but eventually node biopsy will be needed to establish not only the diagnosis but also the type of lymphoma.

6. A 72-year-old man has a 4-cm hard mass in the left supraclavicular area. The mass is movable and not tender and has been present for 3 months. The patient has had a 20-pound weight loss in the past 2 months, but is otherwise asymptomatic.

What is it? Malignant metastases to a supraclavicular node from a primary tumor below the neck (Virchow's node). The vignette may include a few clues to suggest which one.

Diagnosis. Look for the obvious primary tumors: lung, stomach, colon, pancreas, kidney. The node itself may eventually be biopsied.

7. A 69-year-old man who smokes and drinks and has rotten teeth has a hard, fixed, 4-cm mass in his neck. The mass is just medial and in front of the sternocleidomastoid muscle, at the level of the upper notch of the thyroid cartilage. It has been there for at least 6 months, and it is growing.

What is it? Metastatic squamous cell carcinoma to a jugular chain node, from a primary in the mucosa of the head and neck (oropharyngeal–laryngeal territory).

Management. Don't biopsy the node! FNA is okay, but the best answer is triple endoscopy (examination under anesthesia of the mouth, pharynx, larynx, esophagus, and tracheobronchial tree), also known as a panendoscopy. CT scan will follow, to determine extent and operability. Most patients get combined therapy that includes radiation, platinum-based chemotherapy, and surgery if possible.

Squamous Cell Cancer—Other Presentations

8. A 69-year-old man who smokes and drinks and has rotten teeth has hoarseness that has persisted for 6 weeks in spite of antibiotic therapy.

9. A 69-year-old man who smokes and drinks and has rotten teeth has a painless ulcer in the floor of the mouth that has been present for 6 weeks and has not healed.

10. A 23-year-old man with AIDS has a painless ulcer in the floor of the mouth that has been present for 6 weeks and has not healed. He does not smoke or drink.

11. A 69-year-old man who smokes and drinks and has rotten teeth has a unilateral earache that has not gone away in 6 weeks. Physical examination shows serous otitis media on that side, but not on the other.

What are they? These are all different ways for squamous cell carcinoma of the mucosa of the head and neck to show up. They all need triple endoscopy to find and biopsy the primary tumor and to look for synchronous second primaries. Although the classic candidate for this disease is the older man who smokes and drinks, patients with AIDS also have very high incidence—with similar presentations.

OTHER TUMORS

1. A 52-year-old man complains of hearing loss. When tested he is found to have unilateral sensory hearing loss on one side only. He does not engage in any activity (such as sport shooting) that would subject that ear to noise that spares the other side.

What is it? Unilateral versions of common ENT problems in the adult suggest malignancy. In this case, acoustic nerve neuroma. Note that if the hearing loss had been conductive, a cerumen plug would be the obvious first diagnosis.

Diagnosis. MRI looking for the tumor.

2. A 56-year-old man develops slow, progressive paralysis of the facial nerve on one side. It took several weeks for the full-blown paralysis to become obvious, and it has been present now for 3 months. It affects both the forehead and the lower face.

What is it? Gradual, unilateral nerve paralysis suggests a neoplastic process.

Diagnosis. Gadolinium-enhanced MRI.

3. A 45-year-old man presents with a 2-cm firm mass in front of the left ear, which has been present for 4 months. The mass is deep to the skin, and it is painless. The patient has normal function of the facial nerve.

What is it? Pleomorphic adenoma (mixed tumor) of the parotid gland.

Diagnosis. FNA is appropriate, but the point of the question will be to bring out the fact that parotid masses are never biopsied in the office or under local anesthesia. Look for the option that offers referral to a head and neck surgeon for formal superficial parotidectomy which serves as a diagnostic and therapeutic tool.

4. A 65-year-old man presents with a 4-cm hard mass in front of the left ear, which has been present for 6 months. The mass is deep to the skin, and it is fixed. He has constant pain in the area, and for the past 2 months has had gradual progression of left facial nerve paralysis. He has rock-hard lymph nodes in the left neck.

This one is parotid cancer, but the point is the same: let the experts manage it.

PEDIATRIC ENT

1. A 2-year-old has unilateral earache.

2. A 2-year-old has unilateral foul-smelling purulent rhinorrhea.

3. A 2-year-old has unilateral wheezing, and the lung on that side looks darker on x-rays (more air) than the other side.

What are they? Unilateral versions of common bilateral ENT conditions in toddlers suggest foreign body (small toys). Appropriate x-rays, physical examination or endoscopies, and extraction—obviously under anesthesia.

ENT EMERGENCIES AND MISCELLANEOUS

1. A 45-year-old woman with a history of a recent tooth infection shows up with a huge, hot, red, tender fluctuant mass occupying the left lower side of the face and upper neck, including the underside of the mouth. The mass pushes up the floor of the mouth on that side. She is febrile.

What is it? Ludwig's angina (an abscess of the floor of the mouth).

Management. The special issue is the need to maintain an airway. Incision and drainage are needed, but intubation or tracheostomy may also be required.

2. A 29-year-old woman calls your office at 10 AM with the history that she woke up that morning with one side of her face paralyzed.

Obviously Bell's palsy. The latest trend is to start these patients right away on antiviral medication and steroids.

3. A patient with multiple trauma from a car accident is being attended to in the ED. As multiple invasive things are done to him, he repeatedly grimaces with pain. The next day it is noted that he has a facial nerve paralysis on one side.

What is it? Trauma to the temporal bone can certainly transect the facial nerve, but when that happens the nerve is paralyzed right there and then. Paralysis appearing late is from edema. The point of the vignette is that nothing needs to be done.

4. Your office receives a phone call from Mrs. Rodriguez, a middle-aged patient whom you have treated repeatedly over the years for episodes of sinusitis. In fact, 6 days ago you started her on decongestants and oral antibiotics for what you diagnosed as frontal and ethmoid sinusitis. Now she tells you over the phone that ever since she woke up this morning, she has been seeing double.

What is it? Cavernous sinus thrombosis, or orbital cellulitis.

Management. This is a real emergency. She needs immediate hospitalization, high-dose IV antibiotic treatment, and surgical drainage of the paranasal sinuses or the orbit. CT scan will be needed to guide the surgery, but I expect that the thrust of the question will be directed at your recognition of the serious nature of this problem.

5. A 10-year-old girl has epistaxis. Her mother says that she often picks her nose.

What is it? Bleeding from the anterior part of the septum.

Management. Phenylephrine spray and local pressure.

6. An 18-year-old boy has epistaxis. The patient denies picking his nose. No source of anterior bleeding can be seen by physical examination.

What is it? In this age group either septal perforation from cocaine abuse, or posterior juvenile nasopharyngeal angiofibroma. The former may need posterior packing. The latter needs to be surgically removed (they are benign, but they eat away at nearby structures).

7. A 72-year-old, hypertensive man, on aspirin for arthritis, has a copious nosebleed. His BP is 220/115 mm Hg when seen in the ED. He says he began swallowing blood before it began to come out through the front of his nose.

What is it? Obviously epistaxis secondary to hypertension.

Management. These are serious problems that can end up with death. Medical treatment to lower the BP is clearly needed, and may be the option offered in the answers, but getting the ENT people there right away should also be part of the equation. Posterior packing is needed, emergency arterial ligation or angiographic embolization may be required.

8. A 57-year-old man seeks help for "dizziness." On further questioning he explains that he gets light-headed and unsteady, but the room is not spinning around.

What is it? Neurologic, probably vascular occlusive—but not inner ear. Direct your management and workup in that direction.

9. A 57-year-old man seeks help for "dizziness." On further questioning, he explains that the room spins around him.

What is it? This one is in the vestibular apparatus. I could not even begin to tell you how to work it up, but seek the answers that look like either symptomatic treatment (meclizine, Phenergan, diazepam) or an ENT workup.

Neurosurgery 11

VASCULAR OCCLUSIVE DISEASE

1. A 62-year-old right-handed man has transient episodes of weakness in the right hand, blurred vision, and difficulty expressing himself. There is no associated headache, the episodes have sudden onset, lasting about 5 or 10 minutes at the most, and they resolve spontaneously, leaving no neurologic sequela.

What is it? Transient ischemic attacks in the territory of the left carotid artery, caused by stenosis or an ulcerated plaque at the left carotid bifurcation.

Management. Start workup with Duplex scanning. If stenosis exceeds 70% proceed to carotid endarterectomy.

2. A 61-year-old man presents with a 1-year history of episodes of vertigo, diplopia, blurred vision, dysarthria, and instability of gait. The episodes have sudden onset, last several minutes, have no associated headache, and leave no neurologic sequela.

What is it? Another version of transient ischemic attacks, but now the vertebrals may be involved.

Management. Start with Duplex scanning.

3. Last week, a 60-year-old diabetic man had abrupt onset of right third nerve paralysis and contralateral hemiparesis. There was no associated headache. The patient is alert, but the neurologic deficits have not resolved.

What is it? Neurologic catastrophes that begin suddenly and have no associated headache are vascular occlusive. The vernacular for this man's problem is "a stroke."

Management. Vascular surgery in the neck is designed to prevent strokes, not to treat them once they happen. There are very rare exceptions, but revascularization of an ischemic brain area risks making it bleed and get worse. This patient will get a CT scan to assess the extent of the infarct and supportive treatment with emphasis on rehabilitation. Eventually his neck vessels will be looked at by Duplex to see whether a second stroke elsewhere may be preventable. If the vignette had given the patient a very early stroke, where IV infusion of tissue-type plasminogen activator (tPA) could be started within 90 minutes of the onset of symptoms, your choice would've been a CT scan (to rule out extensive or hemorrhagic infarcts), followed by the tPA infusion.

Intracranial Bleeding

4. A 64-year-old black man complains of a very severe headache of sudden onset and then lapses into a coma. Past medical history reveals untreated hypertension, and examination reveals a stuporous man with profound weakness in the left extremities.

What is it? Neurologic catastrophes of sudden onset, with severe headache, are vascular hemorrhagic. This man has bled into his head. In the vernacular, he has also suffered "a stroke."

Management. Again supportive with eventual rehabilitation efforts if he survives. CT scan is the universal first choice to see blood inside the head (we use it in trauma for the same purpose). This man will get one, to see exactly where he bled, and how bad it is.

5. A 39-year-old woman presents to the ED with a history of a severe headache of sudden onset that she says is different and worse than any headache she has ever had before. Her neurologic examination is completely normal, so she is given pain medication and sent home. She improves over the next few days, but 10 days after the initial visit she again gets a sudden, severe, and singular diffuse headache, and she returns to the ED. This time she has some nuchal rigidity on physical exam.

What is it? This one is a classic: subarachnoid bleeding from an intracranial aneurysm. The "sentinel bleed" that is not identified for what it is is a common feature. The "sudden, severe, and singular" nature of the pain are classics. And the nuchal rigidity betrays the presence of blood in the subarachnoid space.

Diagnosis. We are looking for blood inside the head, thus start with CT. Angiograms will eventually follow, in preparation for surgery to clip the aneurysm or endovascular coiling.

BRAIN TUMOR

1. A 31-year-old nursing student developed persistent headaches that began approximately 4 months ago, have been gradually increasing in intensity, and are worse in the mornings. For the past 3 weeks, she has been having projectile vomiting. Thinking that she may need new glasses, she seeks help from her optometrist, who discovers that she has bilateral papilledema.

What is it? Brain tumor. Neurologic processes that develop over a period of a few months and lead to increased ICP spell out tumor. Morning headaches are typical. If the tumor is in a "silent" area of the brain, there may be no other neurologic deficits.

Management. If given the option, pick MRI as your diagnostic test. If it is not offered, pick CT scan. Measures to decrease ICP while awaiting surgery include high-dose steroids (Decadron).

2. A 42-year-old right-handed man has a history of progressive speech difficulties and right hemiparesis for 5 months. He has had progressively severe headaches for the last 2 months. At the time of admission he is confused and vomiting and has blurred vision, papilledema, and diplopia. Shortly thereafter his BP goes up to 190 over 110, and he develops bradycardia.

What is it? Again brain tumor, but now with 2 added features: there are localizing signs (left hemisphere, parietal, and temporal area), and he manifests the Cushing reflex of extremely high ICP.

Management. As above, but as an emergency.

3. A 42-year-old man has been fired from his job because of inappropriate behavior. For the past 2 months he has gradually developed very severe, "explosive" headaches that are located on the right side, above the eye. Neurologic examination shows optic nerve atrophy on the right, papilledema on the left, and anosmia.

What is it? Brain tumor in the right frontal lobe. A little knowledge of neuroanatomy can help localize tumors. The frontal lobe has to do with behavior and social graces, and is near the optic nerve and the olfactory nerve. If you want the fancy name, this is the Foster-Kennedy syndrome.

Management. MRI and neurosurgery.

4. A 12-year-old boy is short for his age, has bitemporal hemianopsia, and has a calcified lesion above the sella in x-rays of the head.

What is it? Craniopharyngioma.

Management. Get the fancy MRI and proceed with craniotomy.

5. A 23-year-old nun presents with a history of amenorrhea and galactorrhea of 6 months' duration. She is very concerned that others might think that she is pregnant, and she vehemently denies such a possibility.

What is it? Prolactinoma.

Management. First confirm that she indeed is not pregnant or hypothyroid. Then, since you suspect a functioning tumor of an endocrine gland, measure the appropriate hormone. So, here you want a prolactin level. You also want to see the tumor. The top choice for that is MRI. Bromocriptine therapy is favored by most, with surgery reserved for those who do not respond or who wish to become pregnant.

6. A 44-year-old man is referred for treatment of hypertension. His physical appearance is impressive: he has big, fat, sweaty hands, large jaw and thick lips, a large tongue, and huge feet. He is also found to have a touch of diabetes. In further questioning he admits to headaches, and he relates that his wedding ring no longer fits his finger.

What is it? Acromegaly. Appearance is so striking that the vignette is likely to come with a picture (or two: front including his hands, and lateral showing the large jaw).

Management. Somatomedin C determination, MRI, and eventually pituitary surgery or radiation therapy.

7. A 15-year-old girl has gained weight and become "ugly." She shows a picture of herself taken a year ago, where she was a lovely young woman. Now she has a hairy, red, round face full of pimples; her neck has a posterior hump, and her supraclavicular areas are round and convex. She has a fat trunk and thin extremities. She has mild diabetes and hypertension.

What is it? Cushing's syndrome. This one will also come with a picture, rather than a description. (Or two pictures, the before and after.)

Management. The sequence already described in the endocrine section: overnight low-dose dexamethasone suppression test. If no suppression, 24-hour urinary cortisol. If cortisol is high, do high-dose dexamethasone suppression test. If she suppresses at high dose, do MRI of the sella, and follow with trans-sphenoidal pituitary surgery.

8. A 27-year-old woman develops a severe headache of sudden onset, making her stuporous. She is taken to the hospital, where she is found at admission to have a BP of 75 over 45. Funduscopic examination reveals bilateral pallor of the optic nerves. Relatives indicate that for the past 6 months, she has been complaining of morning headaches, loss of peripheral vision, and amenorrhea. After she developed the severe headache, and just before she went into a deep stupor, she told her relatives that her peripheral vision had suddenly deteriorated even more than before.

What is it? Pituitary apoplexy. (She has bled into a pituitary tumor.)

Management. Steroid replacement is urgently needed. Other hormones will need to be replaced eventually. MRI or CT scan will determine extent of the problem.

9. A 32-year-old man complains of progressive, severe generalized headaches that began 3 months ago, are worse in the mornings, and lately have been accompanied by projectile vomiting. He has lost his upper gaze, and he exhibits the physical finding known as "sunset eyes."

What is it? Another classic. This tumor is in the pineal gland, and if you want the fancy name it is Parinaud syndrome.

Management. MRI to start. The neurosurgeons will take care of the rest.

10. A 6-year-old boy has been stumbling around the house and complaining of severe morning headaches for the past several months. While waiting in the office to be seen, he assumes the knee-chest position as he holds his head. Neurologic examination demonstrates truncal ataxia.

What is it? Tumor of the posterior fossa. Most brain tumors in children are located there, and cerebellar function is affected.

Management. MRI, neurosurgery.

11. A 23-year-old man develops severe headaches, seizures, and projectile vomiting over a period of 2 weeks. He has low-grade fever, and was recently treated for acute otitis media and mastoiditis.

What is it? Brain abscess. Signs and symptoms suggestive of brain tumor that develop in a couple of weeks with fever and an obvious source of infection spell out abscess.

Management. These are seen in CT as well as they would on MRI, and the CT is cheaper and easier to get…so pick CT if offered. Then the abscess has to be resected.

SPINAL CORD

1. A 52-year-old woman has constant, severe back pain for 2 weeks. While working in her yard, she suddenly falls and cannot get up again. When brought to the hospital she is paralyzed below the waist. Two years ago she had a mastectomy for cancer of the breast.

What is it? Most tumors affecting the spinal cord are metastatic, extradural. In this case the source is obvious, and the sudden onset of the paralysis suggests a fracture with cord compression or transection.

Management. Typically, an x-ray of the affected area is done right away, and it will show a huge, bony metastasis and the fracture that it has produced. But the best imaging to see what has happened to the cord (compressed? transected?) is the MRI. Neurosurgeons may be able to help if the cord is compressed rather than transected.

2. A 45-year-old man gives a history of aching back pain for several months. He has been told that he had muscle spasms, and was given analgesics and muscle relaxants. He comes in now because of the sudden onset of very severe back pain that came on when he tried to lift a heavy object. The pain is "like an electrical shock that shoots down his leg," it is worse with sneezing and straining, and it prevents him from ambulating. He keeps the affected leg flexed. Straight leg-raising test gives excruciating pain.

What is it? Lumbar disk herniation. Peak incidence is age 40s, and virtually all of these are at L4–L5 or L5–S1.

- If the "lightning" exits the foot by the big toe, it is L4–L5.
- If the "lightning" exits by the little toe, it is L5–S1.

Management. MRI for diagnosis. Bed rest and pain control will take care of most of these cases. Neurosurgical intervention is done only if there is progressive weakness or sphincteric deficits.

3. A 79-year-old man complains of leg pain brought about by walking and relieved by rest. On further questioning it is ascertained that he has to sit down or bend over for the pain to go away. Standing at rest will not do it. Furthermore, he can exercise for long periods of time if he is "hunched over," such as riding a bike or pushing a shopping cart. He has normal pulses in his legs.

What is it? The symptom is neurogenic claudication. The disease is spinal stenosis.

Management. Get MRI and refer to pain clinic. Pain control can usually be obtained with steroid and analgesic injections under x-ray guidance. Surgery is rarely needed for these.

4. A business executive who has been a T6 paraplegic for many years is held at a business meeting for several hours beyond the time when he would normally have done his in-and-out self-catheterization of the urinary bladder. He develops a pounding headache, profuse perspiration, and bradycardia. BP is 220/120 mm Hg.

The classic picture of autonomic dysreflexia. Obviously his bladder needs to be emptied, but he also needs alpha-adrenergic blocking agents and may benefit from calcium-channel blockers (such as nifedipine).

PAIN SYNDROMES

1. A 60-year-old man complains of extremely severe, sharp, shooting, "like a bolt of lightning" pain in his face that is brought about by touching a specific area, and which lasts about 60 seconds. His neurologic examination is normal, but it is noted that part of his face is unshaven because he fears to touch that area.

What is it? Tic douloureux (trigeminal neuralgia).

Management. Rule out organic lesions with MRI. Treat with anticonvulsants.

2. Several months after sustaining a crushing injury of his arm, a patient complains bitterly about constant, burning, agonizing pain that does not respond to the usual analgesic medications. The pain is aggravated by the slightest stimulation of the area. The arm is cold, cyanotic, and moist.

What is it? Causalgia (reflex sympathetic dystrophy).

Management. A successful sympathetic block is diagnostic, and surgical sympathectomy will be curative.

Urology 12

UROLOGIC EMERGENCIES

1. A 14-year-old boy presents in the ED with very severe pain of sudden onset in his right testicle. There is no fever, pyuria, or history of recent mumps. The testis is swollen, exquisitely painful, "high riding," and with a "horizontal lie." The cord is not tender.

What is it? Testicular torsion, a urologic emergency.

Management. Emergency surgery to save the testicle (bilateral orchiopexy). Do not waste time doing diagnostic studies.

2. A 24-year-old man presents in the ED with very severe pain of recent onset in his right scrotal contents. There is a fever of 103°F and pyuria. The testis is in the normal position, and it appears to be swollen and exquisitely painful. The cord is also very tender.

What is it? Acute epididymitis.

Management. This is the condition that presents the differential diagnosis with testicular torsion. Torsion is a surgical emergency epididymitis is not. This patient does not need to be rushed to the OR; all he needs is antibiotic therapy.

Should a diagnosis of testicular torsion be missed, the medicolegal implications are so severe that urologists routinely do a sonogram when they are sure the problem is epididymitis—just to absolutely, unequivocally rule out torsion.

3. A 72-year-old man is being observed with a ureteral stone that is expected to pass spontaneously. He develops chills, a temperature spike to 104°F, and flank pain.

What is it? Obstruction of the urinary tract alone is bad. Infection of the urinary tract alone is bad. But the combination of the two is horrible—a true urologic emergency. That's what this patient has.

Management. Massive IV antibiotic therapy, but the obstruction must also be relieved right now. In a septic patient, stone extraction would be hazardous, so the option in addition to antibiotics would be decompression by ureteral stent or percutaneous nephrostomy.

4. An adult woman relates that 5 days ago she began to notice frequent, painful urination, with small volumes of cloudy and malodorous urine. For the first 3 days she had no fever, but for the past 2 days she has been having chills, high fever, nausea, and vomiting. Also in the past 2 days she has had pain in the right flank. She has had no treatment whatsoever up to this time.

What is it? Pyelonephritis.

Management. UTI should not occur in men or in children, and thus should trigger a workup looking for a cause. Women of reproductive age, on the other hand, get cystitis all the time, and they are treated with appropriate antibiotics without great fuss. However, when they get flank pain and septic signs it's much more serious. This woman needs hospitalization, IV antibiotics, and at least a sonogram to make sure that there is no concomitant obstruction.

5. A 62-year-old man presents with chills, fever, dysuria, urinary frequency, diffuse low back pain, and an exquisitely tender prostate on rectal exam.

What is it? Acute bacterial prostatitis.

Management. This vignette is supposed to elicit from you what you would not do. The treatment for this man is intuitive: he needs IV antibiotics—but what should not be done is any more rectal exams or any vigorous prostatic massage. Doing so could lead to septic shock.

6. A 33-year-old man has urgency, frequency, and burning pain with urination. The urine is cloudy and malodorous. He has mild fever. On physical examination the prostate is not warm, boggy, or tender.

The first part of this vignette sounds like prostatitis, which would be common and not particularly challenging; but if the prostate is normal on examination the ante is raised: The point of the vignette becomes that men (particularly young ones) are not supposed to get urinary tract infections. This infection needs to be treated, so ask for urinary cultures and start antibiotics—but also start a urologic workup. Do not start with cystoscopy (do not instrument an infected bladder, you could trigger septic shock). Start first with a sonogram.

CONGENITAL UROLOGIC DISEASE

1. You are called to the nursery to see an otherwise healthy-looking newborn boy because he has not urinated in the first 24 hours of life. Physical examination shows a big distended urinary bladder.

What is it? Kids are not born alive if they have no kidneys (without kidneys, lungs do not develop). This represents some kind of obstruction. First look at the meatus: it could be simple meatal stenosis. If it is not, posterior urethral valves is the best bet.

Management. Drain the bladder with a catheter if it passes easily (it will pass through the valves). Voiding cystourethrogram for diagnosis, endoscopic fulguration or resection for treatment.

2. A bunch of newborn boys are lined up in the nursery for you to do circumcisions. You notice that one of them has the urethral opening in the ventral side of the penis, about midway down the shaft.

What is it? Hypospadias.

The point of the vignette is that you don't do the circumcision. The foreskin may be needed later for reconstruction when the hypospadias is surgically corrected.

3. A newborn baby boy has one of his testicles down in the scrotum, but the other one is not. On physical examination the missing testicle is palpable in the groin. It can easily be pulled down to its normal location without tension, but it will not stay there; it goes back up.

What is it? This is a retractile testicle, due to an overactive cremasteric reflex.

Management. Nothing needs to be done now. Even truly undescended testicles may spontaneously descend during the first year of life. Those that do not require orchidopexy.

4. A 9-year-old boy gives a history of 3 days of burning on urination, with frequency, low abdominal and perineal pain, left flank pain, and fever and chills.

What is it? Little boys are not supposed to get UTI. There is more than meets the eye here. A congenital anomaly has to be ruled out.

Management. Treat the infection of course, but do IVP and voiding cystogram looking for reflux. If found, long-term antibiotics while the child "grows out of the problem."

5. A mother brings her 6-year-old girl to you because "she has failed miserably to get proper toilet training." On questioning you find out that the little girl perceives normally the sensation of having to void and voids normally and at appropriate intervals, but also happens to be wet with urine all the time.

What is it? A classic vignette: low implantation of one ureter. In little boys there would be no symptoms, because low implantation in boys is still above the sphincter, but in little girls the low ureter empties into the vagina and has no sphincter. The other ureter is normally implanted and accounts for her normal voiding pattern.

Management. If the vignette did not include physical exam, that would be the next step, which might show the abnormal ureteral opening. Often physical examination does not reveal the anomaly, and imaging studies would be required (start with IVP). Surgery will follow.

6. A 16-year-old boy goes on a beer-drinking binge for the first time in his life. Shortly thereafter he develops colicky flank pain.

What is it? Another classic. Ureteropelvic junction obstruction.

Management. Start with U/S (sonogram). Repair will follow.

TUMORS

1. A 62-year-old man reports an episode of gross, painless hematuria. Further questioning determines that the patient has total hematuria rather than initial or terminal hematuria.

What is it? The blood is coming anywhere from the kidneys to the bladder, rather than the prostate or the urethra. Either infection or tumor can produce hematuria. In older patients without signs of infection, cancer is the main concern, and it could be either renal cell carcinoma or transitional cell cancer of the bladder or ureter.

Management. Do a CT scan and cytoscopy.

2. A 70-year-old man is referred for evaluation because of a triad of hematuria, flank pain, and a flank mass. He also has hypercalcemia, erythrocytosis, and elevated liver enzymes.

What is it? Full-blown picture of renal cell carcinoma (very rarely seen nowadays).

Management. Do a CT scan.

3. A 55-year-old chronic smoker reports 3 instances in the past 2 weeks when he has had painless, gross, total hematuria. In the past 2 months he has been treated twice for irritative voiding symptoms, but has not been febrile, and urinary cultures have been negative.

What is it? Most likely bladder cancer but must exclude renal etiology.

Management. Do a CT scan and cytoscopy.

4. A 59-year-old black man has a rock-hard, discrete, 1.5-cm nodule felt in his prostate during a routine physical examination.

5. A 59-year-old black man is told by his primary care physician that his prostatic specific antigen (PSA) has gone up significantly since his last visit. He has no palpable abnormalities in his prostate by rectal exam.

What are they? The two classic presentations for early cancer of the prostate.

Management. Transrectal needle biopsy, guided by the examining finger in the first case, and guided by sonogram in the second. Eventually surgical resection or radiotherapy after the extent of the disease has been established.

6. A 62-year-old man had a radical prostatectomy for cancer of the prostate 3 years ago. He now presents with widespread bony pain. Bone scans show metastases throughout the entire skeleton, including several that are very large and very impressive.

Management. Significant, often dramatic palliation can be obtained with orchiectomy, although it will not be long-lasting (1 or 2 years only). An expensive alternative is luteinizing hormone-releasing hormone agonists, and another option is antiandrogens (flutamide).

7. A 78-year-old man comes in for a routine medical checkup. He is asymptomatic. When a physician had seen him 5 years earlier, a PSA had been ordered, but he notices as he leaves the office this time that the study has not been requested. He asks if he should get it.

Management. For many years PSA was not done after age 75. Improved longevity and better treatments for early prostatic cancer have led to a more flexible approach. Also, with the advent of robotic prostatectomy, the surgery is so much safer and with better outcomes that PSA is now being offered selectively.

8. A 25-year-old man presents with a painless, hard testicular mass. It is clear in the physical examination that the mass arises from the testicle rather than the epididymus. To be sure, a sonogram was done. The mass was indeed testicular.

What is it? Testicular cancer.

Management. This will sound horrible, but here is a disease where we shoot to kill first—and ask questions later. The diagnosis is made by performing a radical orchiectomy by the inguinal route. That irreversible, drastic step is justified because testicular tumors are almost never benign.

Beware of the option to do a trans-scrotal biopsy: that is a definite no-no. Further treatment will include lymph node dissection in some cases (too complicated a decision for you to know about) and platinum-based chemotherapy. Serum markers are useful for follow-up: α-fetoprotein and β-human chorionic gonadotropin (β-HCG), and they have to be drawn **before** the orchiectomy (but they do not determine the need for the diagnostic orchiectomy—that still needs to be done).

9. A 25-year-old man is found on a pre-employment chest x-ray to have what appears to be a pulmonary metastasis from an unknown primary tumor. Subsequent physical examination discloses a hard testicular mass, and the patient indicates that for the past 6 months he has been losing weight for no obvious reason.

What is it? Obviously same as above—but with metastasis. The point of this vignette is that testicular cancer responds so well to chemotherapy that treatment is undertaken regardless of the extent of the disease when first diagnosed. Manage exactly as the previous case.

RETENTION AND INCONTINENCE

1. A 60-year-old man shows up in the ED because he has not been able to void for the past 12 hours. He wants to, but cannot. On physical examination his bladder is palpable halfway up between the pubis and the umbilicus, and he has a big, boggy prostate gland without nodules. He gives a history that for several years now he has been getting up 4 or 5 times a night to urinate. Because of a cold, 2 days ago he began taking antihistaminics, using "nasal drops," and drinking plenty of fluids.

What is it? Acute urinary retention, with underlying benign prostatic hypertrophy.

Management. Indwelling bladder catheter, to be left in for at least 3 days. Further management will be based on the use of alpha-blockers. Other options include 5-alpha-reductase inhibitors for large glands, or newly developed noninvasive interventions. The traditional TURP is rarely done now.

2. On postoperative day 2 after surgery for repair of bilateral inguinal hernias, a patient reports that he "cannot hold his urine." Further questioning reveals that every few minutes he urinates a few milliliters of urine. On physical examination there is a large palpable mass arising from the pelvis and reaching almost to the umbilicus.

What is it? Acute urinary retention with overflow incontinence.

Management. Indwelling bladder catheter.

3. A 42-year-old woman consults you for urinary incontinence. She is the mother of 5 children. Ever since the birth of her last child 7 years ago, she leaks a small amount of urine whenever she sneezes, laughs, gets out of a chair, or lifts any heavy objects. She relates that she can hold her urine all through the night without any leaking whatsoever.

What is it? Stress incontinence.

Management. If she has no physical findings, she can be taught exercises that strengthen the pelvic floor. If she has a large cystocele, she will need surgical reconstruction.

STONES

1. A 72-year-old man who in previous years has passed 3 urinary stones is now again having symptoms of ureteral colic. He has relatively mild pain which began 6 hours ago but does not have much nausea and vomiting. CT scan shows a 3-mm ureteral stone just proximal to the ureterovesical junction.

Management. Urologists have a huge number of options to treat stones, including laser beams, shock waves, ultrasonic probes, baskets for extraction—but there is still a role for "watching and waiting." This man is a good example; it is a small stone, almost at the bladder. Give him time, medication for pain, and plenty of fluids, and he will probably pass it.

2. A 54-year-old woman has a severe ureteral colic. CT scan shows a 7-mm ureteral stone at the ureteropelvic junction.

Management. Whereas a 3-mm stone has a 70% chance of passing, a 7-mm stone only has a 5% probability of doing so. This one will have to be smashed and retrieved. The best option among choices offered would be shock-wave lithotripsy (SWL). (Contraindications to SWL include pregnancy, bleeding diathesis, and stones that are several centimeters big.)

MISCELLANEOUS

1. A 72-year-old man has for the past several days noticed bubbles of air coming out with the urine when he urinates. He also gives symptoms suggestive of mild cystitis.

What is it? Pneumaturia caused by a fistula between the bowel and the bladder. Most commonly from sigmoid colon to dome of the bladder, caused by diverticulitis. Cancer (also originating in the sigmoid) is the second possibility.

Management. Intuitively you would think that either cystoscopy or sigmoidoscopy would verify the diagnosis, but real life does not work that way: those seldom show anything. Contrast studies (cystogram or barium enema) are also typically unrewarding. The test to do is CT scan. Because ruling out cancer of the sigmoid is important, the sigmoidoscopic examination would be done at some point, but not as the first test. Eventually surgery will be needed.

2. A 32-year-old man has sudden onset of impotence. One month ago he was unexpectedly unable to perform with his wife after an evening of heavy eating and heavier drinking. Ever since then he has not been able to achieve an erection when attempting to have intercourse with his wife, but he still gets nocturnal erections and can masturbate normally.

What is it? Classic psychogenic impotence: young man, sudden onset, partner-specific.

Management. Curable with psychotherapy if promptly done.

3. Ever since he had a motorcycle accident where he crushed his perineum, a young man has been impotent.

4. Ever since he had an abdominoperineal resection for cancer of the rectum, a 52-year-old man has been impotent.

Organic impotence has sudden onset only when it is related to trauma. Vascular injury explains the first of these two, and vascular reconstruction may help. Nerve injury accounts for the second, and only prosthetic devices can help there.

5. A 66-year-old diabetic man with generalized arteriosclerotic occlusive disease notices gradual loss of erectile function. At first he could get erections, but they did not last long; later the quality of the erection was poor; and eventually he developed complete impotence. He does not get nocturnal erections.

This is the classic pattern of organic impotence (not related to trauma). A wide range of therapeutic options exists, but probably the first choice now is sildenafil, tadalafil, and vardenafil.

Organ Transplantation 13

1. A 62-year-old man who had a motorcycle accident has been in a coma for several weeks. He is on a respirator, has had pneumonia on and off, has been on vasopressors, and shows no signs of neurologic improvement. The family inquires about brain death and possible organ donation.

At one time the medical profession was very fussy about who was accepted as an organ donor. Nowadays, with 65,000 patients on transplant waiting lists and many dying every day for lack of organs, almost anybody is taken. The rule now is that all potential donors are referred to the local organ harvesting organization. Donors with specific infections (such as hepatitis) can be used for recipients with the same infection. Even donors with metastatic cancer are eligible for eye donation.

A positive HIV status remains the only absolute contraindication to a patient serving as an organ donor.

2. Ten days after liver transplantation, levels of g-glutamyltransferase (GGT), alkaline phosphatase, and bilirubin begin to go up. There is no U/S evidence of biliary obstruction or Doppler evidence of vascular thrombosis.

3. On week 3 after a closely matched renal transplant, there are early clinical and laboratory signs of decreased renal function.

4. Two weeks after a lung transplant, the patient develops fever, dyspnea, hypoxemia, decreased FEV1, and interstitial infiltrate on chest x-ray.

There are 3 kinds of rejection. **Hyperacute rejection** happens within minutes of re-establishing blood supply, produces thrombosis, and is caused by preformed antibodies. ABO matching and lymphocytotoxic crossmatch prevents it, and thus we do not see it clinically—and you will not encounter it on the exam.

Acute rejection is the one we deal with all the time. It occurs after the first 5 days, and usually within the first few months. Signs of organ dysfunction (as in these vignettes) suggest it, but biopsy is what confirms it. In the case of the heart, there are no early clinical signs; thus biopsies there are done routinely at set intervals. Once diagnosed, the first line of therapy is steroid boluses. If unsuccessful, antilymphocyte agents are used (anti-thymocyte serum).

5. Several years after a successful (renal, hepatic, cardiac, pulmonary) transplantation, there is gradual, insidious loss of organ function.

The third form, **chronic rejection**, is poorly understood and irreversible. There is no treatment for it, but the correct answer for such vignette would be to do biopsy. Late acute rejection episodes could be the problem, and those can be treated.
