Electrocoagulation may be used via a transanal approach after administering general anesthesia and placing the patient in the lithotomy position. The rectal lesion and a 1-cm margin are fulgurated. Recurrence rates approach 50–80%; therefore patients may require repeat treatments.

Cryotherapy, another alternative modality, results in a large amount of foul-smelling discharge. Photodynamic therapy has limited availability. Laser vaporization using neodymium:yttrium-aluminum-garnet laser provides palliation but is associated with a 14% recurrence rate and is costly.

COMPLICATIONS

Complications of surgical management of rectal cancer may include those common to any major intra-abdominal operation, such as infection, bleeding, wound problems, deep venous thrombosis/pulmonary embolism, myocardial infarction, pneumonia, and renal failure. There are, however, several complications that are related to rectal cancer. There is a 50% incidence of impotence in men following resection for rectal cancer. Therefore, it is critical to discuss this situation with the patient before the resection and to record the preoperative status of his sexual function. If a man is impotent after surgery, it is advisable to wait 1 year before undergoing implantation of a penile prosthetic device. This delay is recommended not only to ensure that the malignancy has been cleared but also to allow the patient sufficient time to overcome psychological impediments such as a change in body image from pelvic surgery or from a colostomy. Women may also suffer from impaired sexual function, especially if the vagina is distorted during the rectal resection.

A possible permanent colostomy is often not preferred by patients. Its placement, however, must be explained in a way that the patient understands that he or she may be left with this if reconstruction is not technically possible.

Anastomotic leak, which occurs in up to 20% of patients, can be avoided by constructing the anastomosis with well-vascularized tissue without tension. Interestingly, young, muscular men have a higher incidence of anastomotic leaks, which may result from the technical challenge of operating in a narrow pelvis or from strong sphincters that may stress the anastomosis. The latter may be addressed by dilating the anal sphincter in the operating room at the end of the procedure. Anastomotic leaks usually present between 4 and 7 days postoperatively. Symptoms may include fever, tachycardia, arrhythmias, tachypnea, enterocutaneous fistula, or diffuse peritonitis. When a leak is suspected, the patient should be made NPO and blood should be sent for a complete blood count, electrolytes, and type and cross-match. An upright chest x-ray will diagnose pneumoperitoneum. Abdominal series may demonstrate extraluminal air. CT scan of the abdomen and pelvis with water-soluble contrast material may demonstrate abscess formation, extraluminal air, and the actual leak. Barium should be avoided because leakage of barium creates a destructive peritonitis. A leak may be managed with intravenous antibiotics and bowel rest in a patient without peritonitis. An abscess may be drained percutaneously. An enterocutaneous fistula may be treated with total parenteral nutrition and local wound care. If a large leak is demonstrated or the patient experiences peritonitis, exploratory laparotomy with diverting ileostomy or colostomy should be performed. The anastomosis is rarely taken down and should not be reconstructed in the presence of sepsis.

Massive venous bleeding from the presacral space may result intraoperatively from lateral dissection onto the pelvic sidewall or sacrum. Ligation of the iliac vessels is discouraged and may be hazardous. If massive bleeding is encountered, a surgical metal "tack" may be driven into the sacrum to compress the venous space. Additionally, the pelvis may be packed for 24–48 hours, at which time the patient is returned to the operating room for pack removal and closure.

Urinary dysfunction may occur after rectal resection. Many men have coexisting prostatic hypertrophy. Because low rectal dissection approaches the membranous urethra, Foley catheters usually are kept in place for 5 days. Patients may be discharged with indwelling catheters, especially if they have undergone partial prostatectomies or seminal vesiculectomies. Women may experience urinary incontinence if the anterior aspect of the vagina, which contains the neurologic control of the urethra, is transected.

OBSTRUCTING, METASTATIC, AND RECURRENT RECTAL CANCER

Obstructing Cancer of the Rectum

For obstructing cancers of the rectum, a loop ileostomy, performed as an open or a laparoscopic procedure, is constructed for diversion. Usually, the tumor is staged as a T3 or N1 lesion; the patient is treated with neoadjuvant chemoradiation and considered for subsequent surgical resection.

Metastatic Rectal Cancer

The management of hepatic and pulmonary metastases is not described in this chapter (see Chap. 36). Nonetheless, if a patient presents with incurable metastatic disease and life expectancy is greater than 6 months, it is reasonable to consider a palliative rectal resection. If the rectal lesion is staged as T3 or N1, we recommend neoadjuvant chemoradiation because this addresses both the primary lesion and the metastasis and may provide some palliation of obstruction, bleeding, or pain. Other options include rectal stents or laser destruction of the tumor to maintain an adequate lumen. It is important to understand the patient, his or her desires, and general state of health when recommending treatment at this stage of cancer.

Recurrent Rectal Cancer

Local recurrence of rectal adenocarcinoma is seen in up to 30% of patients. Although recurrence may be seen at the distal margin of the anastomosis, most develop from residual cancer on the pelvic wall. The time course for recurrences to present through the anastomosis is approximately 18 months. By their nature, these tumors are fixed to the pelvic wall and surrounding viscera. They cause significant symptoms, such as intractable pelvic pain, bleeding, cramping or constipation, urinary tract dysfunction, and chronic pelvic sepsis.

When patients present with these symptoms or with a rising CEA level, a workup including CT scan of the abdomen and pelvis, ERUS, MRI of the pelvis, and PET scan may be helpful. A careful pelvic examination is mandatory. A biopsy, either via sigmoidoscopy or CT-guided, should be used to confirm the diagnosis pathologically. If external radiation has not been used before, it should be considered. The surgeon should review the imaging studies and determine which organs are involved, such as the vagina, uterus, prostate, bladder, sacrum, and small intestine, which will require en bloc resection. Urology consult should be obtained if there is any question of prostate or bladder involvement; ureteral stents should be placed preoperatively. Removal of the rectum and urinary bladder with surrounding lymphatic tissue results in a permanent colostomy and ileal conduit.

INTRAOPERATIVE RADIATION THERAPY

Intraoperative radiation therapy (IORT) may be considered in patients with pelvic sidewall recurrence. This is performed in an operating room–radiation therapy suite. Resection with negative microscopic margins and absence of vascular invasion independently predicts improved local control and survival after resection and IORT.[62] The major morbidities of IORT include peripheral neuropathy and ureteral stenosis.

PALLIATION

These tumors are difficult to palliate, let alone cure. Surgical resection combined with aggressive multimodality therapy is advocated to avert the morbidity of pelvic disease and to prolong survival in a subset of patients, with survival rates up to 30%.[63] Most patients, however, will not be offered curative surgery on the basis of comorbidities, poor performance status, distant metastases, or locally unresectable disease on preoperative imaging. These patients may be offered palliative intervention. Miner and colleagues demonstrated that in patients who underwent surgery with palliative intent, improvement was noted in 40% with bleeding, 70% with obstruction, and 20% with pain.[64] When considering the effective use of surgery for these patients, decision making is complex because one must balance palliation of symptoms, comorbidities, and patient desires and goals. Seeking the input of a multidisciplinary treatment group, including medical oncologists and radiation oncologists, is invaluable.

CHEMORADIATION

Patients with rectal cancer who undergo surgery with intention to cure and without evidence of gross disease postoperatively may still develop local recurrence or distant metastases. Up to 10% of patients who undergo TME with tumor-free radial and distal margins may develop local failure. The goal of adjuvant therapy is to eliminate the micrometastatic disease present at the time of surgery.

Adjuvant Chemoradiation

In 1990, the National Institutes of Health consensus statement concluded that "combined postoperative chemotherapy and radiotherapy improves local control and survival in stages II and III patients and is recommended." Most of the information regarding chemotherapy for colorectal cancer comes from trials of colon cancer rather than for rectal cancer. The NSABP C-04 (National Surgical Adjuvant Breast and Bowel Project C-04) trial studied stages II and III colon cancer patients and demonstrated that 5-fluorouracil (5-FU) and leucovorin treatment had a significantly better 5-year survival rate (74 vs 69%) compared with 5-FU and levamisole.[65]

Several trials have suggested a benefit for adjuvant chemoradiation for rectal cancer in patients with resected stage II or III cancers. The GITSG (Gastrointestinal Tumor Study Group) trial demonstrated that combined chemoradiation resulted in an improvement in overall survival as well as a decrease in local recurrence.[66] The NCCTG (North Central Cancer Treatment Group) trial demonstrated that the addition of chemotherapy to radiation reduced both local recurrence (13 vs 25%) and distant metastases (28 vs 46%) and improved survival.[67]

Radiation therapy used alone as adjuvant therapy may improve local recurrence and survival rates. A theoretical reason to use postoperative radiation therapy is that more appropriate patient selection can be achieved because pathologic staging is performed prior to radiation. Disadvantages include radiating the neorectum and small bowel and a lower tendency of patients to complete their radiation. While none of the trials in the 1980s and 1990s demonstrated increased survival, one study did show a decrease in local recurrence.

Neoadjuvant Chemoradiation

There are a number of potential advantages for using neoadjuvant chemoradiation. They include the ability to deliver higher doses of chemotherapy with radiation. Another advantage is not only to downstage the tumor, which has been noted in 60–80% of patients, but also to achieve a pathologic complete response, which occurs in 15–30% of patients. The ability to "shrink" the tumor facilitates surgical resection, thereby allowing one to achieve negative margins and perform a sphincter-preserving operation in patients who otherwise would require an APR. Additional advantages include radiating tissues with a greater oxygen supply, not radiating the anastomosis, and decreased likelihood of developing radiation enteritis because small bowel is less likely to enter the pelvis. Finally, patients are more likely to complete the course of radiation therapy because it precedes their surgical resection.

The Dutch Colorectal Cancer Group demonstrated a significantly decreased rate of local recurrence at 2 years in patients who received preoperative radiotherapy (20 Gy over 5 days) followed by TME compared with TME alone (2.4 vs 8%).[39] The Swedish trial was the first and only study to demonstrate a survival benefit (58%) for stage III rectal cancer patients receiving preoperative radiation (short course of 5 Gy over 5 days) followed by surgery compared with patients who underwent surgery alone (48%).[68] The Swedish trial also demonstrated a decreased rate of local recurrence in the radiation-treated group (11%) compared with 27% in the surgery-alone group. Furthermore, a meta-analysis concluded that preoperative radiation therapy plus surgery compared with surgery alone significantly reduced the 5-year overall mortality rate, cancer-related mortality rate, and local recurrence rate.[69]

In the German Rectal Cancer Trial published in the *New England Journal of Medicine*, Sauer et al randomly assigned patients with clinical stage II or III rectal cancer to preoperative (421 patients) or postoperative (402 patients) chemoradiotherapy based on a concurrent long course of radiotherapy (5040 cGy delivered in fractions of 180 cGy per day, 5 days per week) and 5-FU (120-hour continuous intravenous infusion during the first and fifth weeks).[70] Six weeks later, TME was performed, followed by four cycles of 5-FU 1 month postoperatively. Despite the preponderance of distal tumors in the preoperative chemoradiation group, there was no difference in overall survival or disease-free survival at 4 years. On the other hand, patients receiving preoperative chemoradiotherapy had a 6% local recurrence rate as compared to a 13% local recurrence rate in those receiving postoperative chemoradiotherapy. Moreover, the group treated with

preoperative chemoradiotherapy had a higher incidence of sphincter preservation and lower treatment-related toxicities (27 vs 40%). Differences in local recurrence, sphincter preservation, and treatment toxicities were all statistically significant. A Polish rectal cancer trial from 2004 compared preoperative short-course radiotherapy (5 days of 5 Gy) versus conventional radiotherapy (28 fractions of 1.8 Gy for a total of 50.4 Gy) to ascertain whether there was a difference in sphincter preservation. The surgical resection was based on the tumor status at the time of surgery not before the radiotherapy. This allowed for the surgical decision to be made after tumor shrinkage for patients who received the longer course of radiotherapy. Between 1999 and 2002 the study enrolled 316 patients. Tumor shrinkage was on average 1.9 cm greater in the long-course group and this was statistically significant. However, sphincter preservation in the short-course group was 61% and in the long-course group 58%. In other words, whether the patient received short- or long-course radiotherapy, it did not impact sphincter preservation.[71] There was also no difference in survival, local control or late complications. Furthermore, this Polish trial reported no differences in anorectal or sexual function between the short- or long-course radiotherapy.[72] A French group in conjunction with the EORTC (European Organisation for Research and Treatment of Cancer) group studied "the addition of chemotherapy to preoperative radiotherapy and the use of postoperative chemotherapy in the treatment of rectal cancer." Patients with clinical stage T3 or T4 rectal adenocarcinoma were randomized to four groups: preoperative radiotherapy, preoperative chemoradiotherapy, preoperative radiotherapy with postoperative chemotherapy, and preoperative chemoradiotherapy with postoperative chemotherapy. The primary end point of this study, which enrolled 1011 patients, was overall survival. The main secondary end point was local recurrence. The results showed that there was no difference in overall survival between the groups that received chemotherapy preoperatively or those that received it postoperatively. There was, however, a difference in local recurrence. In the patients who received pre-op, post-op, or pre-op and post-op chemotherapy, the local recurrence rates were 8.7, 9.6, and 7.6%, respectively whereas the radiotherapy-alone group had a local recurrence rate of 17.1%. This was statistically significant and it suggests that there is a benefit to local control by adding preoperative chemotherapy to the regimen. It is not clear whether the addition of postoperative chemotherapy to a patient who has already received preoperative chemotherapy with the radiation treatment has any survival benefit.[73]

Our current practice is to recommend preoperative staging with ERUS or MRI to all patients with rectal adenocarcinoma and then to offer chemoradiation to medically fit patients with curative intent who have T3-T4 or N-positive rectal carcinoma. Some patients with bulky T2 lesions near the sphincters should also be considered for neoadjuvant chemoradiotherapy in order to improve sphincter preservation (Table 40-8). Neoadjuvant therapy then is followed by TME with APR or TME with an end-to-side or colonic J-pouch reconstruction. Postoperatively, patients who have had involved lymph nodes either by preoperative staging or on the final pathology report are encouraged to have additional postoperative chemotherapy. Postoperative chemotherapy in node-negative patients or patients who have had a complete response is determined on a case by case basis.

SURVEILLANCE

After curative resection, long-term follow-up includes routine screening for rectal recurrence and metachronous colorectal neoplasms. Between 60 and 84% of recurrences are seen in the first 24 months and 90% within 48 months. Median time to recurrence is 11–22 months. Local recurrence rates

TABLE 40-8: CURRENT RECOMMENDATIONS FOR CHEMORADIATION IN RECTAL CANCER PATIENTS AFTER RADICAL RESECTION

Stage I	No adjuvant therapy
Stage II or III	Neoadjuvant chemoradiation
Low/midlesion	5-FU–based chemotherapy or other investigational agents with XRT (180 cGy 5 d/wk × 30 treatments)
	Rest for 4–8 wk
	Total mesorectal excision
	Rest for 4 wk
	Chemotherapy in appropriate patients for 4–6 mo
High lesion	Pre- or post-op chemoradiation therapy
	Total mesorectal excision
Stage IV	LAR or APR for palliation/prevention of obstruction or bleeding
	Adjuvant chemotherapy
	5-FU + leucovorin ± irinotecan or oxaliplatin with individualized XRT

APR, abdominoperineal resection; 5-FU, 5-fluorouracil; LAR, low anterior resection; XRT, radiation therapy.

range between 4 and 50%. Survival rates vary according to stage (see Table 40-4). Median survival after recurrences are detected is 40 months.

Patients are seen postoperatively at 2 weeks and then every 3 months for 2 years. At each visit, the patient undergoes DRE and sigmoidoscopy, and a CEA level is obtained. As per the National Comprehensive Cancer Network (NCCN) guidelines we recommend at 1 year postresection, a colonoscopy and abdominopelvic CT. Either a chest CT or chest x-ray is also performed. A CT scan is performed annually until 3 years postoperatively. Colonoscopy frequency is determined by the findings at 1 year. If there are no polyps and no recurrence, the follow-up interval can be lengthened. After 2 years, patients continue to be followed every 6 months with CEA levels and physical examinations until 5 years after the surgery. At 5 years, if the patient has had no recurrence, he or she may be followed yearly with clinic visits and may undergo colonoscopy every 3 to 5 years. Of course, closer observation is indicated for patients at high risk for subsequent cancer formation, such as patients with IBD, polyposis syndromes, or a strong family history of colorectal cancer.

PERSPECTIVE ON RECTAL AND ANAL CANCER

Julio Garcia-Aguilar

CANCER OF THE RECTUM

Introduction

For many years the treatment of rectal cancer has involved removal of the rectum and the mesorectal envelope through a laparotomy, an operation commonly known as *total mesorectal excision* (TME).[1] For surgeons performing this procedure, the main surgical consideration was whether to preserve the sphincter and restore continuity of the bowel or remove the entire rectum and anal canal leaving the patient with a permanent colostomy. In recent years, an improved understanding of the biology of rectal cancer and the causes of local recurrence,[2,3] coupled with advances in imaging,[4] surgical techniques,[5,6] and the use of radiation and systemic chemotherapy[7] have expanded the available surgical options. Selection between the different surgical therapies is based predominately on the stage and location of the tumor. Other factors such as patient age, overall health, functional status, and personal wishes and expectations also need to be taken into consideration when deciding on an appropriate surgical approach.

Patient Evaluation

Treatment decisions in patients with rectal cancer can be influenced by the presence of synchronous tumors, by the locoregional extension of the disease, and by the presence of distant metastasis. Therefore, every patient should undergo a complete evaluation before outlining a treatment plan.

A complete colonoscopy is important to exclude synchronous polyps and cancers, but locoregional staging is essential to guide the initial therapy. A digital rectal examination (DRE) provides useful information because the mobility of the tumor in relation to the rectal wall is an indication of the depth of tumor invasion. The DRE is particularly useful in assessing the relationship of the tumor to the levator muscle and the external anal sphincter, and deciding between the different treatment options. A proctoscopic examination is the best method to assess the distance of the tumor from the anal verge, the only anatomical landmark that can be seen simultaneously with the distance marks of the rigid scope.

In addition to a thorough clinical examination, every rectal cancer patient should undergo adequate local and regional staging with the help of the best available imaging technology.[4] Endorectal ultrasound (ERUS) is a useful technique for staging early rectal cancer as it provides detailed images of the different layers of the rectal wall and demonstrates the disruption of those layers by the tumor. Magnetic resonance imaging (MRI) is most useful for staging locally advanced rectal cancer because it provides a broader view of the pelvis and the best images of the fascia propria of the rectum. The new-generation computed tomography (CT) scanners also provide high-resolution cross-sectional images of the rectum, the mesorectum, and surrounding pelvic structures, and can be used for the locoregional staging of rectal cancers when high-quality MRI is not available. A chest x-ray and a CT scan of the abdomen and pelvis are also commonly included in any patient assessment to diagnose metastatic disease. Occasionally, other tests such as a triple-phase CT of the liver or a positron emission tomography-CT (PET-CT) may be necessary to confirm the diagnosis of liver or pulmonary metastasis.

Choosing the Surgical Approach

At the completion of the evaluation, the surgeon must decide whether the patient requires a TME or can be treated with a local form of therapy, such as local excision (LE). To make the right choice, the surgeon should take into consideration both the location and characteristics of the tumor and the overall status of the patient.

LOCAL EXCISION

Patients with early-stage rectal cancer, that is, tumors localized to the bowel wall that have not penetrated beyond the muscularis propria and do not involve the mesorectal lymph nodes, can potentially be treated with LE, thus avoiding some

of the mortality, morbidity, and functional consequences of removing the entire rectum.[8] Local excision of low rectal cancers can be performed by a conventional transanal excision (TAE) or by transanal endoscopic microsurgery (TEM), an operation that uses a special operating proctoscope, endoscopic imaging, and long surgical instruments similar to those used for laparoscopy.[9] The oncologic outcomes are similar with both LE techniques for tumors of the same stage and location.[10] However, the advantage of TEM is that it permits the use of LE in tumors located in the mid and upper rectum, which would otherwise be out of reach using TAE. But this advantage is relative as LE should only be considered for patients with early-stage distal rectal cancers in whom a TME would otherwise require a coloanal anastomosis or an abdominoperineal resection (APR) of the rectum.

The initial decision to perform LE should be based on clinical staging and imaging studies; only patients with small mobile tumors, localized to the rectal wall and without mesorectal nodes suspicious for lymph node metastasis according to optimal imaging, should be considered for LE.[8] However, the decision to accept LE as the only treatment should be based on the pathologic examination of the LE specimen. For fit and healthy patients treated with curative intent, LE as the only form of therapy should only be offered for distal T1N0 rectal cancers with favorable histologic features (well or moderately differentiated, without lymphovascular invasion, mucinous component, or signet ring cells) and negative resection margins. Patients with positive margins or tumors with unfavorable histologic features should be offered a TME. Patients found to have T2 tumors after an LE should be offered a TME because the 5-year survival rate after LE as the only form of therapy for T2 tumors is lower compared to TME.[11] Two prospective phase II trials have suggested that postoperative radiation and chemotherapy decrease the risk of local recurrence after LE for T2 rectal cancer provided the surgical margins are negative and the mesorectum is free of nodes in preoperative imaging staging.[12,13]

Patients with clinically staged T2N0 tumors, that is, those with a complete break of the submucosa but no penetration into the perirectal fat and without evidence of mesorectal nodes in ERUS imaging, deserve special consideration. While still potentially resectable for cure with LE, these tumors carry a significant risk of occult nodal metastasis, and, if confirmed to be T2 tumors on histopathologic examination, they are associated with a high rate of local recurrence when they are treated with LE alone. Therefore, chemoradiation (CRT) before LE has been explored as an option for patients with distal uT2uN0 rectal cancer interested in an organ preservation approach.[8] The ACOSOG Z6041 (American College of Surgeons Oncology Group Z6041) trial investigated the efficacy of CRT before LE in this subset of rectal cancer patients, but the long-term oncologic outcomes for these patients are not available yet, and therefore CRT before LE for ultrasound-staged T2N0 tumors should still be considered an experimental treatment.[14]

TOTAL MESORECTAL EXCISION

The majority of rectal cancer patients with tumors that have penetrated the muscularis propria or metastasized to the mesorectal lymph nodes require the removal of the rectum and the mesorectal envelope. This operation should be performed by sharp dissection within the areolar space between the fascia propria of the rectum and the presacral fascia. A blunt dissection increases the risks of tearing the mesorectum potentially leaving nests of cancer cells behind or causing bleeding from inadvertent tearing of the presacral veins. The risks of injuring the hypogastric nerves or the branches of the pelvic plexuses are also considerably reduced if they are visualized and protected during a sharp mesorectal excision along well-defined anatomical planes. Rectal perforation with the associated risks of pelvic infection, tumor cell spillage, and compromised sphincter preservation are also less likely when the dissection is performed outside the fascia propria of the rectum. The importance of performing a sharp mesorectal excision has been highlighted by a number of pathologic audits that have linked the completeness of the mesorectal excision to the risk of local and distant tumor recurrence.[3]

The need to remove the entire mesorectum for tumors located in the upper rectum has been a matter of controversy for years. There is now conclusive evidence that rectal cancers rarely spread distally in the mesorectum beyond 5 cm, measured from the lower end of the tumor.[15] Therefore, for tumors located in the upper rectum, the mesorectum can be safely transected transversely, without coning, approximately 5 cm distal to the lower margin of the tumor. This operation is often called *tumor-specific mesorectal excision*. For tumors located in the mid or lower rectum, a 5-cm mesorectal clearance requires a complete TME.[16]

The mesorectum tapers distally as the rectum approaches the levator hiatus and ends slightly above the level of the anorectal ring. Distal to that point, the muscularis propria of the rectum is in contact with the levator muscle. For most mid and distal rectal cancers, the rectum is transected below the end of the mesorectum and the intestinal continuity is reestablished by a double-stapling technique. Whenever possible, a colonic J-pouch or a side-to-end anastomosis should be performed to provide some reservoir capacity and reduce, at least temporarily, the urgency and frequency associated with the sphincter-saving procedure. For patients with tumors located close to the anorectal ring, the surgeon must decide whether removal of the tumor with a negative margin is compatible with sphincter preservation or requires an APR of the rectum. For many years the decision between these two surgical options was based primarily on the possibility of obtaining a negative distal resection margin in the bowel wall. While a 2-cm margin of normal rectal wall distal to the tumor is desirable, a margin as short as 1 cm does not seem to increase the risk of recurrence, particularly in patients treated with neoadjuvant CRT.[17] In recent years surgeons have learned that in most patients with very distal rectal cancers, the need for an APR of the rectum is due to the inability to obtain a negative circumferential resection margin rather than a negative distal margin. In general, an APR of the rectum becomes necessary when a distal rectal cancer has penetrated beyond the muscularis propria and infiltrates the levator muscle or the external anal sphincter. In these patients, the dissection in the intersphincteric plane in an attempt to preserve the sphincter will

result in a positive circumferential resection margin with the consequent risk of local tumor recurrence. Tumor fixation on DRE is a good indicator of tumor infiltration of the levator muscle or the external anal sphincter, but high-resolution MRI and CT scans that provide axial, saggital, and coronal views can demonstrate the relationship of the tumor to the levator muscle and the external anal sphincter with a high degree of accuracy.

Historically, an APR of the rectum has been associated with higher local recurrence rates compared to the sphincter-saving procedures.[18] This difference has been attributed in part to the higher rate of positive circumferential resection margins associated with the APR in tumors that infiltrate the levator muscle or the external anal sphincter.[19] When the pelvic dissection is carried out distally to the level of the levator hiatus or beyond and the upper portion of the levator muscle is not removed, the risk of leaving tumor behind is very high. Therefore, when performing an APR for rectal cancer that infiltrates the levators or the external sphincter, the mesorectal dissection should stop at the upper level of the levators. During the perineal dissection, the levators should be divided at the apex of the ischiorectal fossa where they insert in the white line of the obturator fascia. This operation, known as a *cylindrical APR*, has been shown to decrease the risk of local recurrence compared to conventional APR.[20] Some surgeons prefer to perform the perineal portion of the APR with the patient in the prone-jackknife position because it provides better visualization of all anatomical structures, improved ergonomics, and better use of assistants.

Some patients with low rectal cancers that do not infiltrate the levator muscle or the external sphincter but are too close to the pelvic floor to perform a double-stapling technique are still potential candidates for a sphincter-saving procedure with a hand-sewn coloanal anastomosis. In this procedure the dissection of the portion of the rectum distal to the tumor is performed through the anus. This transanal approach provides simultaneous visualization of the distal end of the tumor and the anatomical landmarks in the anal canal, in particular the dentate line and the anal verge. A circular incision is made in the rectal wall at least 1 cm below the level of the tumor. This incision is carried though the mucosa, submucosa, and muscularis propria/internal sphincter until the intersphincteric space is reached. The transanal dissection is carried out in the intersphincteric space separating the distal rectum from the levator muscle posteriorly and laterally and from the urethra and the prostate or vagina anteriorly, provided that the intersphincteric space is free of tumor. This transanal dissection of the distal portion of the rectum can be performed before or after the transabdominal mesorectal dissection. If the mesorectal dissection has been performed from the pelvis first, the transanal dissection is continued until the rectum is totally mobilized. When the transanal approach is the first step of the operation, the lumen of the distal rectum is closed with interrupted sutures and the patient is repositioned to perform the abdominal and pelvic aspects of the operation. Either way, once the specimen is removed, the distal end of the colon is anastomosed to the anal canal with interrupted absorbable stitches. Patients with distal rectal cancer treated with a TME and a sphincter-saving procedure should receive a loop ileostomy because of the high risk of anastomotic leak.

MINIMALLY INVASIVE TME

In most centers a TME is performed though a midline or low transverse laparotomy. However, many surgeons use minimally invasive techniques for the treatment of rectal cancer because of the potential gains of a faster recovery and improved short-term quality-of-life outcomes.

The length of the incision in rectal cancer surgery is dictated by the need to mobilize the left colon and take down the splenic flexure rather than by the mesorectal dissection. Therefore, dividing the inferior mesenteric artery and vein, taking down the splenic flexure, and mobilizing the left colon laparoscopically or with the help of a hand-assisted device, help reduce the length of the incision even if the mesorectal dissection is performed open through a low midline or low transverse incision. A laparoscopic or robotic mesorectal dissection reduces the size of the abdominal incision even further and expedites recovery without compromising the quality of the operation or the oncologic outcomes compared to open mesorectal dissection.[21,22]

For a laparoscopic TME, the patient is placed in a modified lithotomy position with the legs in stirrups and the hips fully extended. The patient needs to be well secured to the operating table to avoid sliding when the table is placed in steep Trendelenburg's position and/or lateral rotation. Once the pneumoperitoneum is created by either a Veress needle in the left upper quadrant or by placing the Hasson trocar in the periumbilical area, additional trocars are placed in the right upper, right lower, and left lower quadrants. Once the peritoneum is inspected and the presence of peritoneal carcinomatosis excluded, the operation begins by identifying the inferior mesenteric artery and its branches at the root of the left colon mesentery. A space is developed underneath the superior rectal vessels, and, once the left ureter is identified, the vessels are divided with a stapling device, between vascular clips, or with a bipolar energy device. Care has to be taken to avoid injuring the hypogastric plexus that lies close to the aorta. Next, the inferior mesenteric vein is dissected and divided close to the ligament of Treitz. The mesentery of the sigmoid and descending colon is lifted from the retroperitoneal structures by blunt dissection, from the inferior border of the pancreas to the pelvic inlet. The lateral attachments of the colon to the parietal peritoneum along the line of Told are divided from the pelvic inlet to the splenic flexure. Finally, the splenic flexure is completely mobilized after separating the omentum from the left side of the transverse colon. Some surgeons routinely take down the splenic flexure and mobilize the entire left colon in every patient undergoing a sphincter-saving TME for rectal cancer to ensure a tension-free anastomosis using the end of the descending colon. The blood supply of the left colon is never an issue provided the left branch of the middle colic vessels and the marginal vessels are preserved.

Once the colon is completely mobilized, the mesorectal dissection starts by applying traction anteriorly from the stump of the superior rectal vessels to open the areolar space behind the fascia propria of the rectum at the level of the promontory. The hypogastric nerves, clearly identified at this level in their course toward the pelvic sidewalls, should be carefully separated from the fascia propria of the rectum and brushed posteriorly and laterally. The peritoneum is opened on both sides of the rectum all the way to the cul-de-sac, and the rectum is lifted from the concavity of the sacrum by sharply dividing the areolar attachments of the fascia propria of the rectum to the presacral fascia. The lateral stalks are divided next using electrocautery, although armonic scalpel or bipolar coagulation can also be used. The anterior dissection to separate the rectum from the urogenital organs is performed last. The anterior dissection can be performed in different planes, depending on the location of the tumor. For anterior tumors the dissection should be carried in front of Denonvilliers' fascia to avoid dissecting into the tumor. For other tumors, the dissection can be safely performed behind Denonvilliers' fascia.

The laparoscopic TME is a technically demanding procedure because of the two-dimensional visualization, the use of long and rigid instruments, the difficulty handling the rectum and providing traction and countertraction during the dissection, and the unnatural position for the surgeon. Consequently conversion rates for laparoscopic TME in prospective randomized trials have been high.[21] The robotic da Vinci (Intuitive Surgical, Inc., Sunnyvale, CA) platform eliminates some of these difficulties by providing tridimensional visualization, articulating instruments that resemble the human wrist, improved scale of motion, enhanced surgeon control of camera and instruments, and improved ergonomics. A number of retrospective case series have reported that a robotic TME is safe and provides similar outcomes compared to open or laparoscopic TME.[23] However, the changes in patient position needed to take advantage of the gravity required to keep the small bowel away from the area of dissection represents a handicap to the use of the robot because it requires more than one docking of the instruments to the patient. Therefore, most surgeons perform a hybrid procedure with laparoscopic control of the vessels, mobilization of the left colon, and takedown of the splenic flexure and robotic mesorectal dissection. Robotic techniques are still evolving, and with new instrumentation and improved trocar placement it may be possible to perform the entire operation without the need to reposition the patient.

Use of Neoadjuvant CRT

Another important consideration for patients with rectal cancer is the use of neoadjuvant CRT to improve local tumor control. Information accumulated over several decades has proven that for patients with locally advanced rectal cancer the use of pelvic radiation with or without chemotherapy decreases the risk of local recurrence. For many years, pelvic radiation was given after surgery for patients with tumors found at surgery to penetrate the perirectal fact or involve the regional lymph nodes.[24] With recent advances in imaging techniques that can accurately stage tumors before surgery, patients diagnosed with locally advanced rectal cancer now receive pelvic radiation, usually associated with sensitizing chemotherapy, prior to surgery. Indeed there is now conclusive evidence suggesting that the use of neoadjuvant CRT is more effective for local tumor control and safer than adjuvant CRT.[25]

Current guidelines in the United States recommend that all patients with clinical stage II or III rectal cancers should be treated with 5 weeks of hyperfractionated radiation and sensitizing chemotherapy, followed by TME 6–8 weeks later, and postoperative adjuvant chemotherapy.[26] In Europe, where most rectal cancer patients are staged with phased-array MRI, patients are stratified into three different risk groups according to the penetration of the tumor into the mesorectum and its relationship to the fascia propria of the rectum.[27] Patients with early rectal cancer are treated with TME alone. Patients with T3 or node-positive rectal cancer that is not close to the fascia propria of the rectum are treated by short course radiation (5 cGy/d for 5 consecutive days) followed by TME 1 week later. Patients with locally advanced tumors that are close to or reach the fascia propria of the rectum are treated with hyperfractionated radiation and sensitizing chemotherapy followed by TME, or extended surgery as needed to achieve an R0 resection, 6 weeks after completion of the CRT.

Patients With Metastatic Disease

Almost one-third of rectal cancer patients present with distant metastasis at the time of diagnosis. The treatment options in these patients are multiple and need to be individualized according to the local-regional stage and the symptoms of the primary tumor, the extent and potential resectability of the metastatic disease and the comorbid conditions, and performance status of the patient. Treatment decisions in these patients require a multidisciplinary approach with input from several medical and surgical specialists.

Patients with distant metastases that are resectable or borderline resectable at the time of diagnose often require multimodality therapy, including systemic chemotherapy, neoadjuvant CRT of the primary tumor, and surgery for the primary and the metastatic disease. The sequence and timing of these interventions need to be individualized according to the tumor and the patient, but also according to the response of the tumor to the different treatments. Asymptomatic patients should be treated initially with systemic chemotherapy with reevaluation after 2 months to assess tumor response and plan the surgery for both the primary tumor and the distant metastasis. Depending on the tumor response, some patients benefit from additional cycles of chemotherapy. Patients with locally advanced primary rectal cancers that approach the circumferential resection margin and have a high risk for local recurrence often need short-course radiation (5 Gy/d for 5 days) or CRT before surgery.

Fit and otherwise healthy patients may be candidates for synchronous resections of the primary tumor and the distant metastasis, particularly if the rectal resection can be performed laparoscopically. However synchronous resections are associated with high morbidity and some patients are better treated by

staged resections. If the decision is to perform staged resections, the primary tumor should be treated first because the inability to achieve a curative resection for the rectal primary, or the finding of unexpected peritoneal disease at the time of the first procedure, may impact the treatment plan for the distant metastasis.

A number of rectal cancer patients with resectable metastasis present with obstructive symptoms, rectal bleeding, or rectal pain at the time of diagnosis. While patients with severe symptoms may require an intervention such as tumor resection, diverting stoma, stenting, or even electrocoagulation, many of them experience a significant symptomatic improvement after a few weeks of CRT. Once the CRT is completed, patients can be treated with systemic chemotherapy.

In the past, asymptomatic patients with unresectable metastasis were offered surgery to treat or prevent debilitating complications related to the primary tumor such as obstruction, bleeding, or perforation. But multiple studies have proven that the proportion of these patients requiring an operation to treat complications is relatively small. Therefore asymptomatic patients with unresectable metastasis should also be treated initially with systemic chemotherapy. The treatment of the primary tumor will depend on the response to the chemotherapy and the development of symptoms. Patients with unresectable distant metastasis and symptoms either at diagnosis or after systemic chemotherapy may require local palliative interventions. These palliative procedures may include resection, diverting stoma, stenting, tumor ablation by laser or electrocautery, or even CRT, depending on the type and severity of the symptoms, the size of the tumor, the performance status, the comorbid conditions, and life expectancy of the patient.

CANCER OF THE ANUS

In the last three decades of the 20th century, anal cancer changed from being a disease primarily treated by surgery to a disease treated with chemotherapy and radiation. These changes resulted in improved patient survival and quality of life. However, they have been paralleled by a dramatic increase in the incidence of anal cancer due primarily to the AIDS epidemics.

The surgeon still plays a pivotal role in the management of patients with anal cancer at different levels. The surgeon can play a role in the primary prevention of anal cancer by diagnosing and treating precancerous conditions, diagnosing and directing the initial therapy, following the patient to assess the tumor response to the multimodality therapy, and diagnosing and treating the recurrences. Therefore surgeons should be familiar with all aspects of the disease, from the etiology and pathogenesis to the treatment of advanced disease. All of these aspects are well covered in Chap. 42.

The term *cancer of the anus* includes a number of different neoplasms with different etiology, pathogenesis, treatment, and prognosis that have in common only their anatomical locations. Therefore a precise understanding of the embryology, anatomy, and histopathology of the anal region is essential. The anal canal extends from the anorectal ring, represented by the impromptu of the puborectalis in the distal rectal wall, to the anal verge, which corresponds to the palpable groove created by the distal end of the internal anal sphincter. Outside the anal verge is the anal margin, which corresponds to a circular area of skin extending 5 cm from the anal verge around the anus. Tumors with their center located in the anal canal are considered cancers of the anal canal, but in some cases the classification of an adenocarcinoma as rectal or anal, or a squamous cell carcinoma as originating in the anal canal or in the anal margin, may be difficult. However, this distinction may be relatively irrelevant, because an adenocarcinoma invading the distal rectum and anal canal should be treated as a distal rectal cancer with neoadjuvant CRT and APR of the rectum and anal canal, while a squamous cell carcinoma of the anal margin extending to the anal canal should be treated primarily with CRT.

As emphasized in Chap. 42, the anal canal is a complex embryologic region where different types of epithelia overlap over a significant distance. For example, squamous epithelium could be found several centimeters within the rectum. Therefore it is not unusual to find a squamous cell carcinoma located entirely within the distal rectum. In addition, there are cases of squamous cell carcinoma located exclusively in the mesorectal lymph nodes secondarily invading the rectum without conclusive evidence of a primary tumor in the anal canal per se. These considerations are important, because tumors in the anorectal region should be treated according to their histology. In other words, a squamous cell carcinoma of the distal rectum should be treated as a squamous cell carcinoma of the anal canal.

One of the most controversial issues in the management of patients with anal cancer is primary prevention by diagnosing and treating precancerous conditions. As described in Chap. 42, a number of institutions are now performing anal Pap smear in high-risk patients groups. Patients with positive Pap smear are often referred to surgeons for high-resolution anoscopy. These procedures are only performed at a handful of institutions and the data are still limited, but the diagnosis and ablation of areas of high-grade squamous intraepithelial lesions (H-SIL) seems to reduce the risk of invasive squamous cell carcinoma of the anus in high-risk patients. The true effectiveness of this intervention, measured as the number of cancers prevented and the complications caused, is still to be proven. It is likely that the recently introduced prophylactic and therapeutic vaccine will prevent anal cancer with less discomfort and potential complications than the surgical or ablative therapies.

Shortly after the introduction of multimodality therapy as definitive therapy, patients were typically followed for 6–8 weeks after the completion of the CRT. A biopsy of the tumor bed was performed, and an APR of the rectum was recommended if the biopsy was positive. However, these premature biopsies led to many unnecessary permanent colostomies. As a result patients are now followed clinically with DRE and anoscopy, and biopsies are reserved for patients with persistent or recurrent palpable, visible, or symptomatic lesions. In most institutions follow-up examinations are performed at 3–4 months for the first 3 years and every 6 months for 2 additional years. The benefit of using ultrasound in the follow-up has not proven to be effective.

Not every patient with squamous cell carcinoma of the anus responds to multimodal therapy, and 20–30% of tumors will never disappear completely or will relapse after an apparent

initial complete response. Surgery is the best treatment for patients who have failed multimodality therapy, but only 30% of those who have a surgical resection survive 5 years.[28–34] A radical resection with negative resection margins is the main prognostic factor and the only hope for cure in these patients, and therefore every effort should be made to diagnose recurrences early when they are still resectable and to plan the operation adequately to remove the entire tumor en block with negative margins. An APR in patients with anal cancer, particularly in those with squamous cell carcinoma of the anus who have failed multimodality treatment, usually requires a wider skin excision and complete removal of the ischiorectal fat and the levator muscle. These patients are therefore at a greater risk of infection and dehiscence of the perineal wound with the consequent morbidity. Therefore many of these patients benefit from a reconstruction of the perineum using either a rectus muscle flap or unilateral or bilateral gluteal flaps. In some patients salvage surgery requires extensive exenterative procedures with more complex reconstructions involving multiple specialists.[30–34]

PERSPECTIVE ON RECTAL CANCER

Mark Welton

INTRODUCTION

Dr Goldberg and Dr Bleday have admirably summarized the current literature regarding the diagnosis, evaluation, and treatment of rectal cancer. In broad strokes, I agree with what they say and wish primarily to highlight a few important issues.

ANATOMIC LANDMARKS

In the description of the anatomy, the authors emphasize their preference for the anorectal ring as the anatomic landmark when evaluating the level of the tumor. Yet in other sections of the chapter, the anal verge and the dentate line are mentioned as the distal landmark rather than the anorectal ring. This is consistent with the confusion that exists in colorectal and general surgery and confounds and confuses recommendations made for approaching rectal tumors. I personally prefer the dentate line because it is a clear tissue transition not altered by patient body habitus. Consider, for example, a lesion at 5 cm from the anal verge. Heavyset patients may have a longer distance from the anal verge to the dentate line (4 cm), leaving the lesion quite close to the dentate line (1 cm above). In contrast, the distance from anal verge to the dentate may be very short in thin patients (1 cm), and the lesion may actually reside relatively high in the rectum (4 cm above the dentate line). This variability holds true for the other landmark mentioned, the anorectal ring. The muscular funnel that comprises the anal sphincters may be long in young muscular patients and shorter in others. These variations lead to unclear recommendations as to how to approach lesions at various heights. The literature would benefit from a standardization of landmarks so that authors and clinicians attempting to follow the recommendations in articles could compare outcomes across studies.

PREOPERATIVE ASSESSMENT

I agree with the authors' recommendation for a CT scan of the chest, abdomen, and pelvis in the preoperative evaluation of patients with rectal cancer and would add that a preoperative PET scan adds value when used selectively to assess abnormalities identified on CT scans. This approach is preferred to the routine use of PET scans as it is more cost-effective. It is better than a follow-up CT in 3 months after surgery in that it allows for earlier identification and treatment of metastatic and may obviate the need for surgical intervention.

TNM STAGING

The 7th edition of the American Joint Committee on Cancer (AJCC) TNM (tumor-node-metastasis) staging system published in 2010 developed new classifications of stages II and III tumors following the recommendations of the Hindgut Taskforce.[1,2] As noted by the authors, the tumors are evaluated about depth of tumor invasion (T), nodal involvement (N), and distant metastases (M). Stage 0 tumors are T0 or Tis, N0 and M0. Stage I is T1 or T2, N0, M0. Stage II is T3 or T4, N0, M0. Stage III is Any T stage, N1 or N2, and M0. Stage IV is Any T stage, Any N stage, and M1. Stages II and III can be subdivided and these subdivisions were modified in the 7th edition based on the Surveillance, Epidemiology, and End Results (SEER) and the National Cancer Data Base (NCDB) data. Traditionally stage II was divided into IIA and IIB, T3, N0, M0, and T4, N0, M0, respectively. Stage III was separated into three stages: IIIA (T1 or T2, N1, M1); IIIB (T3 or T4, N1, M0); and IIIC (Any T, N2, M0). T4bN0 is associated with poorer survival and is now classified as IIC (previously IIB). In contrast, the following three tumors appear to have somewhat better survivals upgrading their classifications to IIIB, T1 or T2, N2a, T1 or T2, N2b and T3, N2a. Finally, T4b, N1a and T4b, NIb are IIIC (previously IIIB). These reclassifications are important for prognostication and treatment planning.

PERIOPERATIVE MANAGEMENT

Perioperative management is an arena in which data appear to drive practice less rigorously than in other realms in

surgery despite the push to practice evidence-based, outcomes-driven medicine. A case in point is the issue of bowel preparation. The authors note despite the lack of evidence supporting oral mechanical bowel preparation and evidence from Cochrane reviews and a meta-analysis from Pineda et al that oral mechanical bowel preparation may be harmful, it is still their preference to mechanically bowel-prep their patients prior to surgery.[3,4] They are not alone in this practice. Nearly 99% of colorectal surgeons surveyed in 2003 did the same.[5] Unfortunately, this survey predates the larger discussion and simply reinforces the need to educate the practicing physicians. We abandoned routine oral mechanical bowel preparation at our institution over 3 years ago because there are no data to support its routine use. We have continued oral mechanical bowel preparation when intraoperative colonoscopy is planned for tumor localization or clearing of the proximal bowel. Oral mechanical bowel preparation is associated with increased anastomotic leaks and wound complications in many series. This may result from dehydration, increased intraoperative fluid requirements (secondary to the dehydration), decreased core temperature (secondary to rehydration), and overresuscitation leading to edematous bowel. We have not noted any negative impact on bowel handling on either open or laparoscopic cases as suggested by the authors. Many other centers have abandoned routine oral mechanical bowel preparation based on the literature for all cases and simply perform one or two preoperative enemas to clear the distal bowel of feces to allow passage of a stapler. Others have eliminated bowel preparation for all right-sided lesions. The issue is far from settled as highlighted by a debate at the SSAT in 2009 when the presentation to eliminate oral mechanical bowel preparation won the debate unanimously and yet not one individual out of 250 attending did agree to change their practice based on the data. A large multicenter North American trial is still desired.

Wound infection rates are impacted by factors other than oral mechanical bowel preparation. The Surgical Care Improvement Project (SCIP) has outlined recommendations that have been adopted by the Centers of Medicare and Medicaid Services (CMS) and the Centers for Disease Control (CDC) as performance measures. These recommendations emphasize appropriate timing of antibiotic delivery, within 60 minutes of incision, discontinuation of antibiotics within 24 hours (although there are no data to support more than one preoperative dose with appropriate intraoperative redosing as needed),[6] appropriate hair removal, maintenance of normothermia, and "early" removal of urinary catheters.[7–11] In teaching hospitals the discontinuation of antibiotics proved to be a challenge. Therefore we moved to a single dose of ertapenem when appropriate as it provides a 24-hour coverage obviating the need for any postoperative "prophylaxis." The timing of urinary catheter removal has not been well studied in the colorectal population, and colorectal pelvic cases are explicitly exempted from the urinary catheter removal performance measure.

LOCAL EXCISION

The authors provide an excellent discussion of the controversies surrounding local excision of rectal cancers as would be expected, given Dr Bleday's leading role in defining patient populations appropriately treated in this fashion. Articles by You and others highlight the potential risks and benefits of transanal excision.[12–16] It appears T1 lesions within 5 cm of the dentate line with favorable histology and clear margins seem appropriately treated in this fashion. Whether T2 lesions may be treated in this fashion if they meet the aforementioned criteria and are treated with either preoperative combined modality therapy (chemotherapy plus radiation therapy) or postoperative therapy remains unclear. The potential for decreased operative morbidity and mortality with local excision is clear. Recently the presumed functional benefit and improved quality of life (QOL) associated with transanal excision were questioned when local excision was compared to low anterior resection (LAR).

It is clear that appropriate patient selection and adherence to preoperative selection criteria are critical, and ultimately this is an individual decision made after lengthy informed discussions with the patient and the patient's family. Unfortunately the current selection criteria are still lacking an ability to predict who will fail locally or with distant disease, and we await biologic markers. However, even with improved markers, questions will remain regarding treatment of primary rectal tumors by local excision in attempts to preserve gastrointestinal continuity. For instance, in a patient with markers that predict a high likelihood of early metastasis, does the method of removing the primary rectal tumor impact development of systemic disease and overall survival? Are local excision and early chemotherapy to treat microscopic disease preferable to a large operation because of the potential for immunosuppression associated with a more invasive procedure?

As with any other operative approach, surgical technique (and most likely surgeon volume and possibly hospital volume) plays a role. This is clear in total mesorectal excision (TME), and it seems reasonable to assume that it would be true for local excision approaches, whether TEM or transanal excision. This issue is at the heart of the dilemma in that surgeons often feel that their personal experience is not equal to that published in large series where technique and selection may be harder to define.

The authors give a nice description of transcoccygeal surgery. I have not had the opportunity to use this approach feeling the morbidity of a transsacral colocutaneous fistula outweighs the potential benefits. Selected patients with significant comorbidities and increasing operative risk might be candidates for this approach. My practice has been to proceed with an LAR or abdominoperineal resection (APR) instead of the transcoccygeal approach.

QUALITY OF LIFE

Quality of life (QOL) is a much-understudied subject in the treatment of rectal cancer. We are just starting to accumulate

data to help us answer how best to treat these patients with a focus on long-term QOL issues. QOL impacts our decisions to perform lateral lymph node dissections, provide pelvic radiation therapy, create a colonic J-pouch, and pursue palliative procedures. The experience in North America with lateral pelvic node dissection, as highlighted by the authors, suggests that the complications associated with the procedure outweigh potential benefits. However, a true comparison of TME plus lateral pelvic node dissection versus TME plus pelvic irradiation in the treatment of patients with rectal cancer with a focus on local failure, overall survival, and QOL is lacking.

Pelvic radiation for the treatment of rectal cancer is standard of care for T3 or T4 lesions and Any T with nodal disease. However, there is clearly room to define the functional impact of radiation therapy on the function of the residual rectum. Many patients suffer frequent bowel movements after resection of the rectum with clustering of their movements (LAR syndrome). Radiation therapy negatively impacts the reservoir function of the rectum, leaving some to question the routine use of radiation after a well-performed TME.

Colonic J-pouches favorably impact the frequency of bowel movements in the first year. The pouch does not appear to be associated with significant long-term benefit and many patients have difficulty evacuating the pouches, leaving some to question the advisability of creating a pouch for short-term benefit. One note of caution, the authors state that they select either sigmoid or descending colon to create the pouch. In Western cultures the surgeon needs to be sure that the sigmoid is healthy and not involved with diverticular disease that would limit distensibility of the pouch.

Palliation of the primary rectal lesion in a patient with established distant disease is a challenging problem that is best approached with a multispecialty team, often a tumor board. We have chosen to be aggressive in our treatment of metastatic disease in the well-selected patient, believing the metastatic disease presents the biggest challenge to overall survival. In a patient with an asymptomatic primary, we have offered chemotherapy to treat the metastatic disease looking for a tumor response. In those patients where a response is seen, we may proceed with chemoradiation therapy of the primary if indicated by imaging studies. If the metastatic disease does not progress during this time interval, we may then proceed with resection of the primary with simultaneous resection of the metastatic disease, especially if we are able to achieve these goals laparoscopically with the assistance of an experienced laparoscopic liver surgeon. We may also proceed with resection of the primary alone or metastatic disease in staged procedures. We are ever vigilant regarding the primary tumor and local invasion of surrounding structures, believing the pain associated with local invasion a significant issue that we control poorly. If the primary appears to be encroaching on the sidewalls, we offer resection for palliation.

We have been aggressive, as have the authors, with locally advanced primary or recurrent disease believing posterior exenteration, pelvic exenteration, and exenteration including sacrectomy to be the best methods to control the tumor and associated symptoms in those with locally advanced disease.

Finally, whenever possible, we have preferred stenting of the primary rectal tumor in the patient with advanced metastatic disease to fecal diversion as it avoids a stoma and the morbidity of surgery with associated time loss due to hospitalization and recovery.

TECHNIQUE

The description of TME is excellent, and the importance of this technique cannot be understated. Pathologic assessment of the specimen and evaluation of the adequacy of mesorectal excision has been shown to predict 5-year survival.[17]

I do not perform oral mechanical bowel preparation routinely, reserving that for cases in which I anticipate intraoperative colonoscopy might be necessary to localize a lesion. I provide one dose of ertapenem and no postoperative prophylactic antibiotics because no data support its use. Unless contraindicated, 5000 units of subcutaneous heparin and sequential compression stockings are used routinely. All vessels are taken with an electrosurgical device unless there is difficulty with hemorrhage. No drains are placed routinely as no data support this practice and increased complications are seen with routine usage.[18,19]

POSTOPERATIVE CARE

Postoperative care is another arena in which major advances and challenges to the traditional dogma await young investigators. One example is "early refeeding." Experience in laparoscopic surgery started to challenge our beliefs; 80–90% of patients tolerated liquids within 24 hours of laparoscopic procedures.[20,21] This practice was expanded to the open patient population. A meta-analysis found a statistically significant decrease in infection rates and lengths of stay and increased rates of vomiting.[22] A Cochrane review suggested that early refeeding is safe and may reduce post-operative complications.[23] We have practiced a patient-controlled diet for 18 years offering on postoperative day 1 a postsurgical diet (tea, coffee, chicken broth, toast, crackers, juice, English muffin, bagel). This is followed by a regular diet of choice (diabetic, etc.) emphasizing chicken, fish, rice, bread, pasta, and potatoes. The patient is encouraged to eat what sounds good and small meals (six per day) and avoid rich foods and foods that have "always made [them] sick."

CANCER OF THE ANUS

Joshua I. S. Bleier • Najjia N. Mahmoud • Robert D. Fry

Cancers of the anus are rare problems with diverse histology. While squamous cell carcinoma (SCC) of the anal canal remains by far the most common of these neoplasms and the main focus of this chapter, the anus may also harbor tumors such as adenocarcinoma, melanoma, and basal cell carcinoma. The treatment of anal cancer has undergone dramatic changes in the past 30 years. Multimodality treatment consisting of radiation and chemotherapy has replaced abdominoperineal resection or wide local excision as the mainstay of therapy. Five-year survival rates now exceed 80% and radical surgery is reserved for cancers of the anal canal that do not respond to chemoradiation or that subsequently recur locally. Our understanding of the etiology and epidemiology of anal SCC and its precursor lesions has also profoundly changed in the past few decades, yielding new initiatives in both therapy and prevention that may further alter the future treatment of this disease. The importance of the surgeon's role in the detection and diagnosis of anal cancer remains undiminished. The surgeon is the clinician most likely to diagnose the disease, delegate treatment, and provide follow-up care. Anal cancer is clearly a disease that benefits from multidisciplinary intervention. Because of this, the treatment of anal cancer serves as a paradigm for the multimodality treatment of cancer.

ANAL CANAL ANATOMY AND HISTOLOGY

The anal canal extends from the top of the anorectal ring (a palpable convergence of the internal sphincter, deep external sphincter, and puborectalis muscle) to the anal verge (the junction of the anal canal and the hair-bearing keratinized skin of the perineum). The lining of the anal canal is comprised of columnar cells, transitional epithelium, and non–hair bearing squamous epithelium. Tumors distal or beyond the verge have been historically been termed anal margin tumors (Fig. 42-1A).

The anal transition zone, or transformation zone (ATZ) is a unique anatomic region, which has a variable histologic makeup. It is a 1- to 2-cm region which begins at the dentate line and extends proximally. This zone, similar to the transformation zone of the cervix, contains a transitional epithelium containing columnar cells with variable amounts of squamous metaplasia. These metaplastic cells may be found as high as 6–10 cm proximal to the dentate line. This may, in part, explain the existence of rare "intra-anal" SCCs that have been found in the mid-low rectum. Tumors arising in the anal canal above and within the ATZ are typically nonkeratinizing SCCs. Those originating below this level are generally keratinizing.[1]

Because of the complex gross and histologic anatomy of this region, classification of anal neoplasms has been confusing and inconsistent. According to the World Health Organization (WHO) classification, anal canal lesions consist of squamous cell (cloacogenic) variants, including keratinizing, nonkeratinizing, and basaloid tumors. Other anal canal neoplasms include adenocarcinoma, carcinoid, lymphoma, and melanoma.[2] Anal margin tumors include SCC, giant condyloma (verrucous carcinoma), and basal cell carcinoma.[2]

A more current *clinical* classification scheme is more progressively in use which is more broadly understood by all practitioners who may treat patients with anal pathology.[3] This classification divides the area into three anatomic regions: intra-anal, perianal, and skin (Figs. 42-1B and C). Intra-anal lesions are contained fully within the anal canal and cannot be seen on external view. Lesions may be made partially visible with gentle distraction of the area. Perianal lesions are fully visible, and lie within a 5-cm radius of the anal opening. Skin lesions lie outside this 5-cm radius. Henceforth in this chapter, we will use the updated terms to refer to the location of these tumors.

The dentate line provides an anatomic reference point for lymphatic drainage of the anal canal and margin. Above the dentate line, drainage is primarily via the superior rectal lymphatics to the inferior mesenteric nodes and laterally along the middle and inferior rectal vessels to the internal iliac nodal basin. Lesions distal to the dentate line drain to the inguinal and femoral lymphatics. Tumors in the ATZ may follow both lymphatic routes. Patients with unexplained inguinal lymphadenopathy should undergo a careful examination of the anal canal.

ANAL SQUAMOUS CELL CARCINOMA

Incidence and Epidemiology

In the last two decades of the twentieth century, the incidence of anal cancer nearly doubled; in the year 2000 approximately 3400 new cases were reported in the United States. During the ensuing 9 years, this figure has risen even faster—in 2009, it is estimated that there will be 5290 new cases, reflecting a trend that mirrors increases in human immunodeficiency virus (HIV) infection.[4–7] Although this number represents only 1–2% of all large bowel cancers, the rise in incidence underscores a significant and serious change in the epidemiology of the problem.[5] Squamous cell cancers of the anus are thought to have a viral etiology that is similar to that of cervical cancer. There is much evidence to suggest that high-risk sexual activity in the era of the HIV is responsible for the potentiation of the viruses that cause anal SCC and that the rise in incidence is directly linked to this phenomenon.

Until the past decade, the highest rates of anal SCC were described in women with numbers increasing after 30 years of age to plateau at an incidence of 5.0/100,000 after age 85.[8] The ratio of females to males affected was approximately 2:1.[9] However, in the past decade men under the age of 45 who have sex with men have constituted the group with both the greatest number of reported cases as well as the greatest increase in disease incidence. Currently in the United States, anal cancer occurs more frequently in males than in females.[9]

Considered as a group, men who practice anoreceptive intercourse have an incidence of anal SCC of 35/100,000—a rate identical to that of cervical cancer prior to routine cervical cytological screening.[9] Although not yet listed as an acquired immunodeficiency syndrome (AIDS)-defining illness like cervical cancer, an argument may be made that anal SCC should have similar emphasis. The United States AIDS-Cancer registry is a survey that linked AIDS-related cancer registries in 11 states or metropolitan areas for the period of time between 1995 and 1998 and included over 309,000 HIV-infected

patients.[10] The relative risk of SCC-type anogenital cancers in this population was much higher than that of the general population. The relative risks for cervical, vulvar or vaginal, and penile cancers were 5.4, 5.8, and 3.7, respectively, while the risk for anal cancer in women was 6.8 and for men 37.9.[10] Subset analysis of affected individuals revealed that those less than 30 years of age, compared to the healthy, HIV-negative, human papillomavirus- (HPV) negative population, had dramatically elevated relative risks of anal cancer of 134 for women and 162.7 for men. Analyzing the data by HIV exposure history showed that homosexual contact resulted in the highest relative risk of anal SCC, with other categories such as intravenous (IV) drug abuse, heterosexual contact among women, and blood transfusion somewhat less.[11]

Etiology, Pathogenesis, and Risk Factors

HUMAN PAPILLOMAVIRUS

HPV is a double-stranded papova DNA virus with a predilection for mucoepithelial tissues. More than 100 HPV strains have been identified, but only approximately 30 have been isolated in cancers of the anogenital region.[12] The majority of those exposed clear the virus, however, chronic HPV infection results in either anogenital warts (condyloma acuminata) or squamous intraepithelial lesions (SILs).[12] Condylomata are generally associated with HPV 6 and 11 and their subtypes and consist of fleshy growths that harbor and generate infectious viruses and have virtually no malignant potential.[12]

It is estimated that between 10 and 40% of HIV-positive males who have sex with males (MSM) will develop chronic infection with HPV strains with malignant potential. The most commonly isolated oncogenic HPV viruses are HPV 16, 18, 31, 33, and 35, which are strongly associated with invasive cancer and are commonly found in both anal and cervical cancer.[13] In a case-control study of 388 patients with anal cancer from Denmark and Sweden, 88% of anal cancers harbored HPV DNA.[14]

HPV infection is the most common sexually transmitted viral disease. Transmission is not prevented by safer-sex practices. These oncogenic viruses may lead to premalignant changes and uncontrolled cellular proliferation, via integration in host-cell genome and loss of cell-cycle regulation.[15]

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

There is an increased incidence of both anal SCC as well as its precursor lesion, high-grade squamous intraepithelial lesion (HSIL) in patients with HIV infection. Progression to high-grade dysplasia is accelerated in patients with a low CD4 count (<200).[16] Data collected in case-control studies among homosexual men and heterosexual women with high-risk behaviors show a direct correlation between HIV seropositivity, HPV prevalence, and anal cancer and its precursors. Anal HPV infection is found in nearly 92% of HIV-positive MSM compared to 66% in HIV-negative MSM. Early epidemiologic evidence among homosexual men in the San Francisco Bay area documents a dramatic rise in anal SCC between 1973 and 1999, when the relative risk increased from 3.7 to 20.6.[17] Similar studies conducted in New York city between the years 1979 and 1985 show a 10-fold increase in anal SCC in men 20–49 years of age that coincided with the explosion of HIV in this population.[18]

Since the advent of highly active antiretroviral therapy (HAART), morbidity and mortality in the HIV population have decreased dramatically, both due to opportunistic infections and malignancies. Thus, it might be hypothesized that the incidence of HPV-related diseases and anal SCC would decrease in this group. However the opposite appears to be true; increasing incidence of anal cancer in the HIV-positive population in the HAART era have been shown by multiple groups. A report by Piketty et al using the French Hospital database on HIV[19] showed an increase in incidence, especially in the MSM population. In another recent publication, a Surveillance, Epidemiology and End Results (SEER)-based analysis showed that over the period from 1992 to 2003, anal cancer was the only malignancy increasing in incidence among HIV-positive individuals in the United States.[20]

However, HPV, HSIL, and anal cancer do not seem to be phenomena linked exclusively to homosexual men. Similar findings occur in HIV-infected male heterosexual IV drug users who deny anal-receptive sex. In this cohort, a high rate of HPV infection coincides with an elevated rate of HSIL as well as anal cancer.[21] Heterosexual women who are HIV-positive or have progressed to AIDS have high rates of HSIL as well.[10] When HIV-positive and HIV-negative cohorts (both male and female) with similar HPV risk factors are compared, the rates of both HSIL and anal cancer are dramatically increased in the HIV-positive groups.[10,11,18,22]

Although this trend includes both men and women with HIV, HIV-positive MSM is the highest risk group with an incidence of anal cancer higher than 78/100,000 person years.[23]

SMOKING

Cigarette smoking is a well-known risk factor for anal SCC that is independent of sexual practices. The risk increases two- to fivefold over that of the general population.[18,24] It is speculated based on data demonstrating an increased incidence in premenopausal women of 5.6 with a 6.7% linear increase per pack-year, that smoking may have some antiestrogenic effect permissive for the disease in the estrogen-sensitive tissues of the anal canal.[25] This hypothesis is supported by the finding that no-risk increase was demonstrated by this study in either postmenopausal female or male smokers.

CHRONIC INFLAMMATION

At one time, benign anorectal conditions such as hemorrhoids, fissures, and fistulas were thought to predispose to

the development of SCC. The etiology or common mechanism was presumed to be prolonged exposure of the anal epithelium to chronic inflammatory conditions. Patients with inflammatory bowel disease were believed to be at increased risk, particularly when anal fistulas were present. In 1994, Frisch examined this issue in a large population and found no evidence to support a causal relationship between benign anorectal conditions and anal cancer up to 13 years after resolution of the benign condition.[26] In another large population study, Frisch and Johansen identified 9602 Danish patients with a diagnosis of either Crohn's disease or ulcerative colitis with a mean follow-up of 10 years.[27] Only two patients developed anal SCC during this time. Both patients had the disease longer than 15 years. Although long-term irritable bowel disease patients may be at slightly increased risk of anal SCC, short- and mid-term risk is not significantly different from that of the general population.[27]

Anal Intraepithelial Neoplasia or Squamous Intraepithelial Neoplasia

DIAGNOSIS AND TREATMENT

Anal intraepithelial neoplasia (AIN) is widely believed to be the precursor lesion for SCC of the anus. The terms carcinoma in situ (CIS), Bowen's disease, AIN, anal dysplasia, and squamous intraepithelial lesion (SIL) have all been used to refer to the same spectrum of pathology; nomenclature varies by pathologist. There is a growing effort to make this pathological definition more uniform, and prognostically, lesions can be lend themselves to be divided into normal, low-grade squamous epithelial lesions (LSILs), HSIL, and invasive cancer.[3] In the United States, the Bethesda criteria for anal intraepithelial lesions (AIN) lists two dominant categories—HSIL and LSIL.[13] In the European literature, HSIL is known as AIN 3, whereas LSIL consists of AIN 1 and 2.[13]

The incidence of anal cancer among HIV-positive homosexual men is 75–80/100,000 (a rate of 0.8/100,000 in the general population), more than twice the incidence of cervical cancer in women (35/100,000) prior to the introduction of routine cervical Pap smear cytology evaluations.[10,17] Because of the dramatic reduction in cervical cancer (8/100,000 currently) attributed to the detection of dysplasia, it is widely believed that the same result could be seen in high-risk anal cancer populations if similar detection and ablation methods are used.

Previously, wide local excision had been the treatment of choice for HSIL (Bowen's disease). It was assumed, based on anecdotal evidence that a percentage of patients with HSIL progresses to invasive cancer. This led to attempts to surgically clear patients of the disease.

A 1999 survey of the practice patterns of members of the American Society of Colon and Rectal Surgeons revealed that 86–95% of surgeons treated HSIL with wide local excision.[28] A distinction was made between microscopic disease and other manifestations. Most HSIL found incidentally in hemorrhoidectomy specimens were considered microscopic asymptomatic disease and simply followed without re-excision (74%).[28] This survey coincided with other investigations highlighting the multifocal nature of HSIL and the difficulty presented by wide local excision under these circumstances. In one review of 34 patients undergoing wide local excision for macroscopically evident HSIL, 19 had positive margins at the time of initial resection, and 12 of the 19 had recurrent HSIL within 1 year.[29] Even with a microscopically complete initial resection, 2 of 15 patients eventually developed HSIL. Although none of these individuals subsequently developed anal cancer, five developed significant surgical complications of resection including anal stenosis and incontinence.[29]

More structured techniques using mapping biopsies, intraoperative frozen section and selective wide-local excision yielded excellent results and long-term control, however recurrent disease still occurred.[30]

The true incidence of HSIL and its resultant progression to invasive SCC are not clearly known, however the rapid increase in incidence of SIL and anal SCC in clearly high-risk populations, combined with the potential morbidity of a radical surgical approach have led many to adopt a policy of either very specific ablative therapy or close and frequent observation.

Anal screening (Pap smear) was first described in the 1990s as a direct corollary of the cervical Pap smear, and has since been promoted as a diagnostic and screening tool in high-risk populations.[31] However, evidence demonstrating a resulting decrease in the incidence of anal cancer similar to that of cervical cancer has not been forthcoming. Still, only a very short time has passed since the institution of the technique. The use of anal cytology as a screening technique has not gained the recognition afforded cervical Pap smears. Lack of recognition by clinicians of the increased incidence of anal cancer, limitation of the problem to high-risk populations, lack of knowledge of techniques, cost, and a dearth of supporting outcomes data may all conspire to limit the use of the technique. Ongoing outcome studies may clarify the role of anal Pap smear for high-risk patients.

In the early 1990s high-resolution anoscopy (HRA) was developed at the University of California, San Francisco (UCSF). Like anal Pap cytologies, HRA is a direct application of the technology for cervical intraepithelial detection and ablation to anal dysplasia. The technique can be done in either the office, or for more extensive disease, in the operating room.

After obtaining a Pap smear, a digital rectal examination is performed followed by placement of a cotton swab covered in gauze soaked in 3% acetic acid. The swab is held in place for 1 minute after which an anoscope is inserted, permitting examination of the anal canal by a colposcope providing 6- to 25-times magnification. Special attention is directed to the area surrounding the ATZ. Applying acetic acid causes these often unapparent lesions to become opaque or "acetowhite." Lugol's iodine solution is then placed in the anal canal to further highlight these areas. HSILs fail to take up Lugol's, rendering the area yellow to tan, whereas normal tissue or

LSILs stain dark brown or black.[31] This approach, combined with the magnification, allows visualization of vascular changes such as punctate appearance, mosaicism, and atypical vessels characteristic of dysplastic change.[31] Suspicious lesions are then destroyed by electrocautery.

Pineda et al published a retrospective review of 246 patients being treated for HSIL with HRA and targeted ablation over a 10-year period. In this group, 81% of patients had extensive, or circumferential lesions, and 79% were immunocomprised due to HIV. Recurrent HSIL occurred after ablation in 57% at an average of 19 months of follow-up, but only 25% of those patients required surgery. In this high-risk group, under careful surveillance, 1.2% of patients progressed to invasive cancer.[32] This series represent the largest report of patients followed with HRA and targeted surgical ablation. It is especially notable for a much lower rate of progression to invasive cancers compared to other studies detailing expectant management *without* the use of HRA surveillance, where progression to invasive cancer ranges from 8.5 to 13%.[33,34]

HRA may provide objective evidence of the presence of disease that office examination alone does not. Whether ablative therapies should follow documentation of HSIL by any method remains unknown and controversial. There have been no randomized controlled trials to date which can clearly characterize the appropriate approach for this group. Slow progression from HSIL to invasive cancer, heterogeneity in follow-up, and lack of broad expertise in surveillance techniques make these studies impractical to perform. Nevertheless, it is clear that special attention needs to be paid to these highest-risk groups.

HUMAN PAPILLOMAVIRUS VACCINES

Both prophylactic and therapeutic vaccines to HPV have completed Phase III trials targeting cervical cancer, testing both types of vaccine in high-risk populations.[13,35]. Prophylactic or preventive vaccines are typically made from structural viral proteins, while therapeutic vaccines are made from the early viral replication proteins E6 and E7. In 2006, the Food and Drug Administration (FDA) granted approval to the first vaccine designed to prevent cervical cancer. Gardisil (Merck & Co., Inc, Whitehouse Station, NJ) is a recombinant vaccine against HPV types 6, 11, 16, and 18. It is currently approved for use in females, 9–26 years of age and requires a series of three injections over a 6-month period. A total of 21,000 patients in four randomized trials demonstrated a dramatic, nearly 100% prevention rate in genital warts, and vulvar, vaginal, and cervical precancerous lesions caused by the serotypes against which the vaccine is directed. The vaccine is only effective, however, in patients not previously exposed to the viruses included in the vaccine, and it confers no protection against viruses not covered by the vaccine. Scattered reports of adverse side effects to Gardasil have been reported, including syncope, headache, and anaphylaxis raising some concern regarding its use. However, the significance of these events is yet to be determined.

A recent double-blind placebo-controlled randomized clinical trial (RCT) involving over 4000 HPV genotype-naïve males showed that the quadrivalent vaccine was 86% effective in preventing persistent HPV infection, and 90% effective against genotype-specific condyloma.[35] Although the potential usefulness of this vaccine can be extrapolated, further studies in high-risk population will be needed to determine efficacy and effects on SIL and cancer prevention.

Cervarix (GSK) is a bivalent vaccine targeted against HPV 16 and 18. It has been licensed for use in females as young as 10 years of age. No registration for treatment indications in males has been sought.[35]

Other studies have combined aerosolized delivery mechanisms with intramuscular injections to maximize antibody titers against the virus. Although the practicality of prevention of dysplasia and cancer by vaccines is unclear at this time, results from these studies may clarify the situation in the near future.

Stressgen Biotechnologies, Inc. has developed a therapeutic vaccine for anal HSIL that has completed Phase II clinical trials in HIV-negative patients.[13] The vaccine is a recombinant fusion protein called HspE7. The immune response generated by the vaccine seems to be CD8 dependent alone—CD4 cells do not seem to be involved. Of those patients receiving 500 μg doses, 76% showed regression of their HSIL to LSIL, one of the primary endpoints of the study. Approximately 7 months elapsed before the first complete responses began to appear. Even so, results seem durable with 86% of this group remaining in remission at 15 months. Although the study samples are small and this approach has yet to be validated in HIV-positive immunocompromised patients, early evidence supports an optimistic outlook for the field of HPV therapeutic vaccines.[13]

Pathology, Diagnosis, and Staging of Anal Squamous Cell Cancer

PATHOLOGY

Nearly 80% of anal canal tumors are either SCCs or histologic variants of SCC. The great variation in terminology results from the histologically diverse microscopic anatomy and the fact that many tumors, especially in the anal transition zone, have a mixed histologic appearance, including squamous, basaloid, and rarely glandular elements. The WHO designates all squamous carcinoma variants in this location as "cloacogenic."[2] Tumors of the distal anal canal (anal), and particularly of the anal margin (perianal), are generally comprised predominantly of squamous cells, with fewer basaloid and no glandular characteristics.[36] The more distal in the anal canal the squamous tumor arises, generally the more likely it is to contain keratinizing cells. Tumors of the proximal anal canal and ATZ are usually composed of nonkeratinizing cells.[36] It is important to note that the difference in the cellular characteristics of these anal canal cancers does not result in a different mode of treatment. There are

no data to suggest differences in outcome between squamous and basaloid histologic types in anal canal cancers. Perianal (anal margin) tumors, however, are typically treated like skin cancers, by local excision.

The treatment of anal cancer has undergone major changes within the past 30 years. Currently chemotherapy and radiation are usually the sole treatment for patients with this disease. Prior to 1974, the standard of care was either wide local excision if the tumor was judged to be superficial, or abdominoperineal resection (APR) for tumors invading the sphincter. Outcomes were poor, with overall survival rates after APR ranging from 30–70%, depending on tumor grade, stage, and size.[8] The local recurrence rate after wide resection or APR was reported to be 25–35% with a 100% local recurrence rate for tumors invading through the submucosa in a series from Singh and associates at Roswell Park Memorial Institute.[37] Perineal or pelvic recurrence occurs in 50–70% of patients undergoing APR, with less than 10% dying of distant disseminated disease.[9] In 1974, Norman Nigro at Wayne State University used radiation and fluoropyrimidines in anal canal cancer as a way to reduce local recurrence following APR.[38] He observed that often there was no residual cancer in the resected specimen. Thus began an exciting and revolutionary time in the treatment of this disease that resulted in a radical shift in treatment.

DIAGNOSIS AND STAGING

Over 50% of patients present with a complaint of rectal bleeding. Delays in diagnosis are common because the tumor is often mistaken by both patients and physicians for benign conditions such as hemorrhoids or fissures (Fig. 42-2). Pain, tenesmus, and pruritus may be present. The initial physical examination should include a digital rectal examination, proctoscopy, and inspection of the inguinal lymph nodes. A biopsy of the anal mass is necessary to confirm the diagnosis. Inguinal masses should be aspirated with a fine needle for diagnosis and staging. Because the current nonoperative approach to anal cancer management is highly effective, excisional biopsy of suspected anal SCCs and inguinal node dissection for adenopathy should generally be avoided. The staging process includes CT of the chest, abdomen, and pelvis, and a transanal ultrasound to assess depth of invasion and aid in establishing the size of the tumor (Figs. 42-3A and B). In addition, the use of positron emission tomography (PET)/CT is becoming more standard is the pretreatment staging. This allows for anatomic and metabolic correlation of primary tumor as well as sensitive assessment for inguinal or distant nodal metastases. Importantly, post-therapy response to PET is predictive of long-term outcomes.[39]

The IUCC staging system for anal cancer was updated in 1997 and adopted by the AJCC[7] (Table 42-1). In contrast to staging parameters for other gastrointestinal (GI) lesions, it is based on size rather than depth of invasion. Anal margin tumors are staged and treated the same as skin cancers (Fig. 42-4).

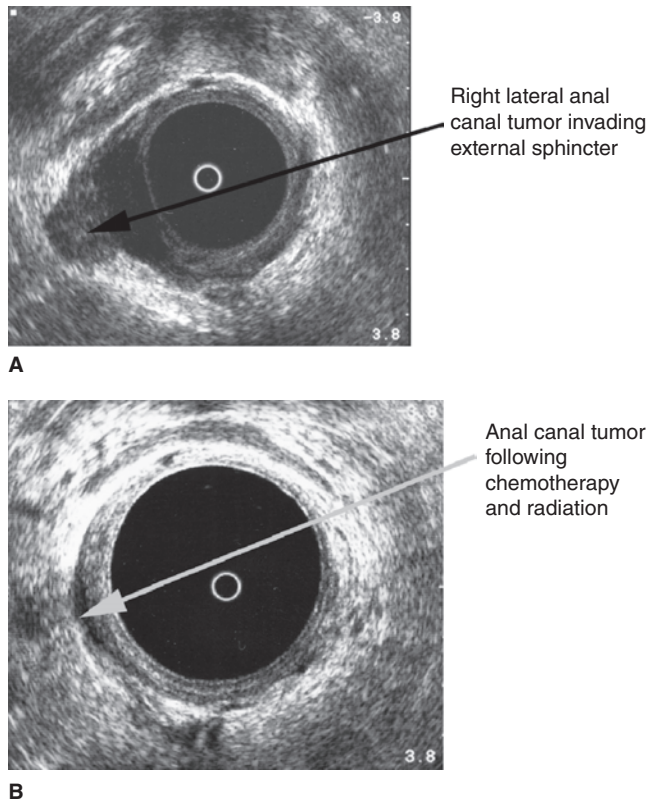

FIGURE 42-3 **A.** Endoanal ultrasound of a squamous cell carcinoma (SCC) of the anal canal invading the anal sphincters prior to chemoradiation. **B.** The patient shown 4 months after 4500 Gy radiation, cisplatin, and 5-fluorouracil. The patient has had a complete clinical response to therapy.

TABLE 42-1: AJCC STAGING SYSTEM FOR ANAL (CANAL) CARCINOMA

Primary Tumor (T)

TX: Primary tumor cannot be assessed
T0: No evidence of primary tumor
Tis: Carcinoma in situ
T1: Tumor 2 cm or less in greatest dimension
T2: Tumor more than 2 cm but no more than 5 cm in greatest dimension
T3: Tumor more than 5 cm in greatest dimension
T4: Tumor of any size that invades adjacent organ(s) (eg, vagina, urethra, or bladder[a])

Regional Lymph Nodes (N)

NX: Regional lymph nodes cannot be assessed
N0: No regional lymph node metastasis
N1: Metastasis in perirectal lymph node(s)
N2: Metastasis in unilateral internal iliac and/or inguinal lymph node(s)
N3: Metastasis in perirectal and inguinal lymph nodes and/or bilateral internal iliac and/or inguinal lymph nodes

Distant Metastasis (M)

MX: Distant metastasis cannot be assessed
M0: No distant metastasis
M1: Distant metastasis

Stage Groupings

Stage 0:
Tis, N0, M0
Stage I:

A number of reviews in the literature prior to and during the introduction of chemoradiotherapy for anal SCC document the strong correlation between tumor size, lymphatic spread, and prognosis.[40] In a 1984 report from the M.D. Anderson Cancer Center, 132 patients treated by APR for anal SCC were studied. For patients with tumors 1–2 cm in size, survival was 78%; 3- to 5-cm tumors had survival of 55%; and patients with tumors greater than 6 cm experienced survival of only 40%.[40] Other reviews suggest that survival for large tumors is considerably worse, at less than 20%, and that generally overall survival is diminished when tumor size is greater than 5 cm, whether the tumor is treated by excision or chemoradiotherapy.[41–44] Recently, analysis of the completed Radiation Treatment Oncology Group (RTOG) 98-11, which represents the largest prospective trial database showed that pretreatment tumor size greater than 5 cm predicted colostomy requirement.[45]

The presence of regional nodal metastases is a poor prognostic indicator regardless of treatment modality. Although survival in the face of nodal metastases has improved significantly with the use of chemoradiation, patients who present with metastatic disease have a significant survival disadvantage.[40,41] Prior to the routine use of chemoradiotherapy, a report in which surgery was done with and without preoperative radiation demonstrated a 5-year survival rate of 44% for node-positive patients compared to 74% for node-negative patients.[40] Other studies confirm comparatively poor survival for patients with nodal metastases.[41]

Surgical Management

Operative therapy for anal SCC has largely been supplanted by chemoradiation and is now the exception rather than the rule. Historically, the failure rate for APR has depended rather predictably on the size of the primary tumor. This procedure was often accompanied by prophylactic inguinal node dissection, but the morbidity and lack of efficacy caused inguinal lymphadenectomy to be abandoned. Failure rates for APR range from 40 to 70%, with local failure rates of 40% and median survival time after recurrence of only 1 year.[8]

Although chemotherapy and radiation have been shown to result in higher disease-free survival rates, when chemoradiotherapy is refused or contraindicated, there may still be a role for local excision in some cases of anal canal carcinoma. A retrospective analysis of local excision at the University of Minnesota revealed a direct correlation between survival and tumor size. For tumors greater than 2.5 cm, 5-year survival rates were 60%.[46] Although the sample size was small, the authors advocated local resection with curative intent for small (<1 cm) well-differentiated tumors confined to the submucosa.[46] Corman and Haggitt reported a similar experience, with all tumors confined to the submucosa being cured by local excision or APR, and those invading more deeply suffering eventual local recurrence.[47] Longo and colleagues recorded a 62% failure rate in stage I–III tumors undergoing solely local excision, in which all patients with stage II and III tumors recurred.[48] Tumor accessibility, full-thickness excision, depth of invasion, and negative margins seem imperative technical considerations when considering local resection. Even so, very few candidates are suitable for this approach.

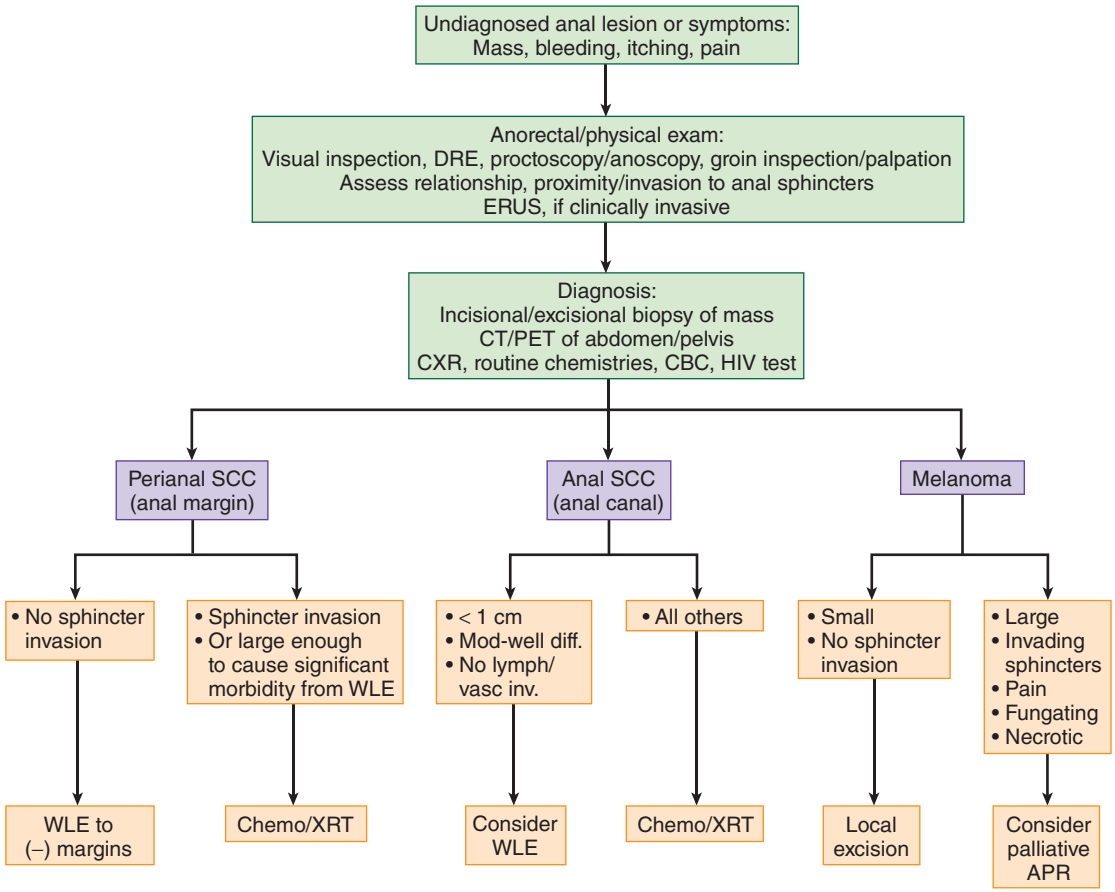

FIGURE 42-4 Basic treatment algorithm for most common anal neoplasms.

Chemoradiation

The treatment of anal (canal) carcinoma has changed radically since the late 1970s, with the advent of chemoradiation protocols. In 1974 Norman Nigro defined a treatment protocol involving the administration of 5-fluorouracil (5-FU), mitomycin-C, and preoperative radiation to shrink anal canal tumors.[38] Fluoropyrimidines were known at the time to enhance the effect of radiation, and there was some evidence that mitomycin had an antineoplastic effect on squamous cell tumors. Nigro's protocol was neoadjuvant, and the radiation (30 Gy total) was given in 15 sessions over a 3-week period. The 5-FU was administered at a dose of 1000 mg/m^2/d, for 4 days starting on the first day of radiation therapy, as a continuous infusion. It was then repeated on days 29 through 32. Mitomycin-C (15 mg/m^2) was administered as a single dose on treatment day one.[38] Of the three patients in the initial report, two underwent APR 6 weeks after treatment. The third refused surgery and remained disease-free. No evidence of tumor was found in the specimens of the two patients who underwent surgery.[38]

Following the dramatic results reported by Nigro's group, others followed suit, treating patients with both radiation alone and with multimodality therapy followed by surgical excision. In 1983, Michaelson and associates at Memorial Sloan-Kettering Cancer Center (MSKCC) reported that 52% of patients treated with both chemotherapy and radiation had a complete pathological response, and another 22% had only microscopic disease at operation.[49] All of these patients had undergone APR or wide local excision following treatment. After Nigro's 1974 publication, a number of other investigators examined the effects of multimodality therapy. Most used 5-FU and mitomycin-C as the chemotherapeutic regimen, although several made dose and infusion modifications, and nearly all increased the radiation dose. Maximal doses were in the range of 50 Gy. Because of such variability among therapies, meta-analysis is difficult. However, direct comparison between studies is useful.[38]

Preliminary studies done by Nigro and others set the stage for prospective Phase II studies. Among these, Martenson and colleagues reported on an Eastern Cooperative Oncology Group (ECOG) study of 50 patients receiving 40 Gy of radiation with a 10–13 Gy boost to the tumor.[50] Bolus 5-FU and mitomycin-C was given during radiation, and biopsy of the tumor or tumor site was performed 6–8 weeks later. APR was performed if the biopsy was positive. Of 46 patients completing treatment, 34 (74%) had a complete response and 11 had a partial response.[50] Eighty

TABLE 42-2: RANDOMIZED PHASE III TRIALS OF RADIATION AND CHEMOTHERAPY FOR ANAL (CANAL) CANCER

	Study Arms	Radiation Dose	Chemotherapy	Number of Eligible Patients	Stoma-Free Survival	Local Failure Rate	Overall Survival
EORTC[50]	Radiation alone	45 Gy + 15–20 Gy boost if CR/PR	None	103	22%	69%	56%
	Radiation + 5-FU/Mit-C	45 Gy + 15–20 Gy boost if CR/PR	5-FU, Mit-C	103	41% ($p = .002$)	42% ($p = .02$)	56% NSS
UKCCCR[49]	Radiation alone	45 Gy + 15–20 Gy boost if CR/PR	None	285	N/A	59%	58% (3 y)
		45 Gy + 15–20 Gy boost if CR/PR	5-FU, Mit-C	145	59%	36% ($p < .0001$)	65% (3 y) NSS
RTOG/ ECOG[51]	Radiation + 5-FU	45 Gy	5-FU	145	59%	36%	67%
	Radiation + 5-FU/Mit-C	45 Gy	5-FU, Mit-C	146	71% ($p = .0019$)	18% ($p = .0001$)	76% ($p = .18$)

CR/PR, complete response or partial response; 5-FU, 5-fluorouracil; Mit-C, mitomycin-C; NSS, not statistically significant; N/A, not available.

percent had no locoregional recurrence and 58% were disease-free at 7 years.[50]

The RTOG and ECOG reported on an intergroup trial of 79 patients treated with combined radiation and chemotherapy in 1989. The radiation dose was 40.8 Gy and only 8 patients had evidence of disease requiring APR at the completion of therapy. At 3 years, overall survival and local control rates were 73% and 71%, respectively.[51]

Further series from MSKCC supported the ECOG and intergroup study. Forty-two patients were treated with a total dose of 30 Gy and the 5-FU/mitomycin-C combination.[52] Eighteen patients had positive biopsy results after treatment but only half of these had local recurrence on follow-up. The 5 year disease-free survival rate was 82%.[52]

In all of these small Phase II trials, disease-free survival, colostomy-free survival, and local disease control compared very favorably to the standard surgical approach. However, the toxicities encountered were significant. In the ECOG study, 37% of patients suffered severe toxicities including severe neutropenia, moist desquamation of the perianal skin, and diarrhea.[50] Treatment toxicities like these gave rise to questions regarding the necessity of chemotherapy in anal cancer in spite of its early promise. Concurrent studies examined the role of radiation alone, often in doses substantially higher than those used with chemotherapy. At the Institute Curie, 183 patients receiving a dose between 60 and 65 Gy showed a 59% 5-year survival rate with a local control rate of 69%.[53] A similar 5-year survival rate of 61% was demonstrated in a review of 147 patients from the Hospital Tenon.[43] Local control in this study was 71%. Complications of higher-dose radiation included anal ulceration and stenosis requiring surgery in 5–15% of cases.

In the late 1990s three Phase III trials reported direct comparisons between radiation alone and radiation with concurrent chemotherapy (Table 42-2). In 1996, the United Kingdom Coordinating Committee on Cancer Research (UKCCCR) published the largest prospective randomized study of chemotherapy and radiation versus radiation alone.[54] The trial enrolled 585 patients, assigning them to either combined therapy or radiation, and then assessed them at 6 weeks. Poor responders were offered APR while those responding well received boost radiotherapy and reassessment. Those patients receiving only radiation had a local failure rate of 59%, whereas those with multimodality therapy recorded a 36% local failure rate with a mean follow-up time of 42 months. Although the early morbidity of combination therapy was higher than that with radiation alone (including two deaths from sepsis), the late morbidity rate was the same. Both the local failure rate as well as the number of patients requiring salvage surgery was halved compared to radiation alone. In all, 29/174 patients who had received combined therapy with a boost required salvage APR, compared to 72/188 who had received radiation alone. Although the local failure rate for radiation alone was higher, overall survival between the groups was not statistically significant (58% radiation vs 65% chemoradiation at 3 years).[54]

The results of the European Organization for Research and Treatment of Cancer (EORTC) supported those of the UKCCCR trial.[55] Patients with locally advanced (T3–T4) cancers were randomized to radiation alone (45 Gy plus a boost of 15–20 Gy) versus combination therapy with 5-FU/mitomycin-C. With the addition of chemotherapy, the local failure rate dropped from 69% to 42% and colostomy-free

survival increased from 22% to 41%. Early and late complication rates were similar except for anal ulcers, which were slightly increased in the combined group. As in the UKCCCR trial, although local control and colostomy-free survival rates were much improved over that of radiation alone, the rate of distant spread was unchanged. Overall survival between the two groups in this study was 56% at 5 years.[55]

In 1996, Flam and colleagues explored further the role of mitomycin-C as a radiation sensitizing agent in a phase III RTOG/ECOG trial.[56] Three hundred ten patients were enrolled and randomized to receive either radiation/5-FU or radiation/5-FU and mitomycin-C. They concluded that although the addition of mitomycin-C produced slightly greater toxicity, at 4 years the disease-free survival was higher (73% vs 51%; $p = .0003$) and the colostomy rate was lower (9% vs 22%; $p = .002$). While the 5-FU/mitomycin-C/radiation group had a good overall survival of 76%, this was not statistically different from that of the comparison group at 67% ($p = .18$). However, the role of mitomycin-C was validated.[56]

The RTOG/ECOG study also examined the ability to salvage patients with residual cancer in their post-treatment biopsy with additional chemotherapy and radiation. Of the 24 patients on the trial eligible to undergo salvage, 12 were rendered free of disease with a 9-Gy boost, 5-FU, and cisplatin (100 mg/m^2).[56] It has been suggested that the patients who underwent salvage chemoradiotherapy in this trial may have been free of disease secondary to radiation-induced apoptosis if the period prior to biopsy had been extended. It is unclear whether cisplatin was actually responsible for the results, but interest in the agent was sparked, given the treatment-limiting toxicities of mitomycin-C. Cisplatin is well known as a radiation sensitizer and effective agent in the treatment of SCC in other areas such as cervix, head and neck, and esophagus. There have been two Phase II trials of high-dose radiation and 5-FU in combination with cisplatin for anal canal cancer. These studies showed complete response rates of 70–95% with reduced toxicity compared to mitomycin-C.[50,57]

RTOG 98-11 was a Phase III study designed to directly compare the efficacy of cisplatin-based therapy to the standard mitomycin-based regimen, in the setting of large SCC primaries (T2 or larger), a group known to have decreased response to chemoradiotherapy. The authors hypothesized that induction chemotherapy with fluorouracil and cisplatin would shrink the primary tumor, and render subsequent concurrent chemoradiotherapy more effective. Primary outcome measure was 5-year disease-free survival, while secondary end points were overall survival, time to relapse, and colostomy rate. After a median follow-up of 2.51 years, as compared to standard (mitomycin) therapy, the cisplatin group showed decreased 5-year disease-free survival (54 vs 60%), worse 5-year overall-survival (70 vs 75%), higher 5-year local recurrence and distant metastasis rates (33 and 19% vs 25 and 15%), respectively. Colostomy rates were *significantly* better in the mitomycin group (10 vs 19%, $p = .02$).[58]

Based on these data, the authors conclude that cisplatin-based therapy failed to achieve improved disease-free survival compared to a standard mitomycin-based regimen, and in fact, worsened colostomy rates.[58] Currently, at the University of Pennsylvania, a mitomycin-based regimen, without induction, is the standard treatment.

Treatment for anal cancer does not differ in the HIV-positive population. Combined chemotherapy and radiation is the best approach to this disease in the setting of HIV/AIDS. Studies have consistently documented responses to standard therapy that equal those in the HIV-negative population.[10,17]

Thus, for any stage of invasive SCC of the anal canal, the primary mode of treatment should be chemoradiotherapy with a 5-FU/mitomycin-based regimen and external beam radiotherapy. Surgery is reserved for in situ (wide local excision), residual or recurrent disease (APR).

Newer Modalities for Radiotherapy

The above series of randomized trials firmly established concurrent chemoradiotherapy with 5-FU and mitomycin-C as standard of care for anal cancer. This approach has resulted in very effective disease control (5-year overall survival 50–61% and 5-year colostomy-free survival from 76 to 78%).[54–56,58] The tradeoff, however is that this sphincter-sparing approach has significant toxicity. The EORTC trial and UKCCCR trial reported significant acute dermatologic toxicity on 49–76% of patients, and acute GI toxicity in 33–45%.[54,55]

The technique of intensity-modulated radiation therapy (IMRT) is a new way to plan and deliver conformal radiation. Using advanced imaging and computer-guided techniques, radiation dosage can be delivered with higher accuracy to target tissue while sparing normal nearby tissues. A multicenter US group conducted a prospective cohort study using concurrent 5-FU/mitomycin C and IMRT techniques on 53 patients with SCC of the anus.[59] Outcomes showed a favorable toxicity profile when compared with classic controls, as exemplified by the outcomes of the RTOG 98-11 (Table 42-3).[58] There was decreased dermatologic toxicity(grade 3, 38 vs 78%, and no grade 4), and fewer patients needed breaks in treatment; in addition 57% of patients requiring breaks left for less than or equal to 4 days of treatment. GI toxicity was similarly decreased with only 15.1% experiencing grade 3 toxicity compared to 34% in the RTOG trial.[58]

Cancer response rates were similar in this study compared to controls; there was a 92.5% complete response (CR), with failures associated with advanced stage, although not statistically so. Survival rates were also comparable, with 18-month colostomy-free survival, and overall survival at 83.7 and 93.4%, respectively.

Further randomized trials need to be conducted to validate standard concurrent chemoradiotherapy with IMRT techniques; however at the University of Pennsylvania we use conformal radiation techniques as standard therapy.

TABLE 42-3: RECENT TRIALS OF CHEMORADIATION FOR ANAL (CANAL) CANCER

Study	N	Stage	Follow-Up (Months)	Chemotherapy	Radiation	CR	Stoma-free Survival	Local Control	Survival

Treatment of Inguinal Nodal Metastases

Palpable inguinal lymph nodes (LN) should be biopsied or evaluated by fine-needle aspiration (FNA) at the onset of treatment for staging. Several reviews have confirmed the poor prognostic outlook conferred by inguinal LN metastases. In 1970, Stearns and Quan reviewed the MSKCC experience with anal canal cancer and noted that only 14% of patients with synchronous nodal metastases survived for 5 years.[60] Similarly, O'Brien and colleagues reported in 1982 that none of the 52% of patients presenting with synchronous LN involvement survived more than 3 years after diagnosis.[61] Both Stearns and O'Brien observed independently that patients presenting with metachronous LN metastases had better survival following therapeutic inguinal lymph node dissection. In the MSKCC review, 75% of patients survived longer than 5 years after groin dissection.

The use of radiation on the inguinal lymph nodes, both prophylactically and for treatment, was explored by Papillon.[66] In 1974, he reported on 19 patients with synchronous inguinal nodal involvement who underwent groin irradiation for disease control. Eleven of the 19 had no evidence of disease at 3 years. Cummings and associates treated nodal disease in a similar fashion and showed that 87% of patients had good disease control or cure without groin dissection.[67]

With the use of radiation fields expanded to include inguinal, internal, and external iliac nodes, the current treatment paradigm is to treat inguinal nodal metastases with chemotherapy and radiation concurrently with the primary tumor. Metachronous lymph node involvement is treated with salvage chemotherapy and radiation if dose limits have not been exceeded, as well as groin dissection if warranted.

Recurrent Disease and Salvage Therapy

The goal of early detection of local post-treatment recurrence is to prevent lymphatic spread of disease and maximize salvage. Most clinicians advocate a thorough physical examination including a digital rectal examination and anoscopy every 3–4 months for at least 2 years. An additional strategy involves the use of endoanal ultrasound (EAUS) inspection. At the Hospital of the University of Pennsylvania, the current protocol is EAUS every 4 months for 3 years, followed by every 6 months for 2 years. Suspicious tissue or lymph nodes are biopsied with the aid of ultrasound guidance.

There is some evidence that local regression of disease following radiation therapy can occur up to 6–9 months following chemoradiation. Routine biopsy of the anal canal

following treatment is no longer recommended within this time period. Rousseau and associates advise allowing the anal canal to heal completely, reserving biopsy for nonhealing ulcers and recurrent or enlarging anal canal masses after a period of at least 6 months following therapy.[68] After this point, any disease detected is residual and salvage therapy is warranted.

In spite of success with nonoperative anal (canal) cancer management, depending on the stage of disease, 10–30% of patients will recur, most locally. The treatment of recurrent or persistent disease is APR with negative margins. In a retrospective analysis of salvage therapy for recurrent disease following chemotherapy with radiation, Allal and colleagues found that APR results in a 53% actuarial 5-year survival rate versus 28% in those who did not receive additional treatment.[69] Pocard and colleagues' data from St. Antoine University Hospital examined salvage APR in 21 patients who had either residual disease after sphincter conservation or recurrence. The group found an actuarial 5-year survival benefit of 30%.[70] Factors resulting in failure were lymphadenopathy, positive margins, and distant disease. Longo and associates compared salvage with chemoradiation versus APR and found that only 27% of patients treated with additional combined therapy survived long term, whereas 57% of those in the APR group did[71] (Table 42-4).[44,72,73] Similarly, a recent retrospective review from the University of Toronto looked at a cohort of 40 patients who underwent surgical salvage after failure of chemoradiotherapy and found an overall survival of 41 months, with 5-year overall- and disease-free survival 39 and 30%, respectively.[74]

Patients with recurrence die of locoregional complications including ureteral obstruction, perineal sepsis and necrosis, bowel obstruction, and venous thrombosis. Contraindications for salvage surgery include medical debilitation, known distant metastases, invasion of the pelvic sidewalls, and obvious inguinal lymphadenopathy. The preoperative assessment should include a chest x-ray and an MRI or CT scan of the abdomen and pelvis. A multidisciplinary approach is appropriate for local invasion of resectable structures such as the urinary bladder, cervix, vagina, or the sacrum. A team including urologists, neurosurgeons, orthopedic surgeons, and plastic surgeons may be required. Recurrences close to the pelvic sidewall may be indistinguishable intraoperatively from fibrosis and scarring from prior radiation or surgery. An intraoperative frozen section may be useful if one is considering placing afterloading catheters or delivering intraoperative brachytherapy to these areas. The role and long-term outcomes of brachytherapy as a treatment adjunct for salvage surgery has not yet been validated.

The complications of salvage pelvic surgery may be severe and debilitating and include perineal wound dehiscence and necrosis. Tissue coverage in previously irradiated fields improves wound healing and many consider it essential for postexenteration reconstruction. Pedicle and rotational flaps may be fashioned from the gluteus, gracilis, or rectus abdominis muscles.

There is little published regarding long-term follow-up in patients salvaged with radiation or chemoradiation following local excision of anal cancer. Patients who undergo primary excision for anal canal carcinoma do so for a number of reasons, usually inadvertently, including polypectomy, hemorrhoidectomy, or excisional biopsy, as well as local excision with intent to cure. Although it is unclear at this point whether further treatment for completely excised, early-stage lesions is appropriate, patients with positive margins, or those with tumors harboring vascular or lymphatic invasion with poorly differentiated characteristics are candidates for further therapy. A retrospective analysis from MSKCC in 1999 reviewed 14 patients who received postoperative chemoradiation (either 30 or 45–50 Gy) after local excision.[75] Actuarial 5-year local control rates were 93% with no difference between outcomes in the higher- and lower-dose groups. Longo and associates published the largest single retrospective analysis of outcomes in 1994, reviewing chemoradiation following local excision.[48] The overall local control rate at 5 years was 79% in 109 patients receiving a median dose of 42 Gy. Stratification of the data by stage revealed a 90% local control rate with stage I, 54% with stage II, and 100% with stage III (6/6 patients).[48] There have been no prospective

studies comparing local excision alone versus chemoradiation for T1 favorable-histology tumors.

More recently, a multicenter group from France looked at their experience with adjuvant treatment of very early anal (canal) tumors. Of 62 patients with either Tis or T1 anal SCC, 26 had undergone primary excision followed by adjuvant radiation as compared to 43 patients treated with definitive radiation alone. Local recurrence rates were higher for the former group (3/23 vs 3/43). Local control was obtained in all six local failures via APR. Long-term survival was no different.[76] There are no data to clearly show superiority of local excision of anal SCC over definitive chemoradiation. However, current studies suggest that tumors that are incompletely excised, those with poor histologic characteristics, and those that are stage II and above are candidates for chemoradiation following excision.[68,71,75] As with primary therapy, giving chemotherapy (principally infusional 5-FU with mitomycin-C or cisplatin) seems to promote effective local control at lower radiation doses.

Anal (canal) carcinoma metastasizes in 10–20% of patients late in the course of disease and prognosis is exceedingly poor.[9] Liver and lung metastases predominate and cisplatin-based chemotherapy is the only strategy shown to be somewhat effective.[68]

PERIANAL (ANAL MARGIN) CANCER

Squamous cell carcinoma of the perianal area is at least five times less common than anal (canal) carcinoma, and for the most part, is treated by primary surgical excision similarly to skin cancers. These tumors arise on the perianal skin beyond the anal verge. They are usually well- or moderately differentiated keratinized SCCs and generally have a favorable prognosis.[9] Metastases are late and rare, and recurrences are typically locoregional. Symptoms include pain, bleeding, itching, and palpable mass. In a study from Denmark, Jensen and associates noted a 6-month median duration of symptoms prior to diagnosis, with an erroneous initial diagnosis made in 29% of cases.[6] Because these tumors are fairly slow growing and uncommon, they are frequently mistaken for hemorrhoids or other benign conditions at initial presentation.

Diagnosis is often suspected by the experienced clinician on inspection, but biopsy prior to definitive treatment is imperative. If the lesion is small, excisional biopsy can be accomplished with adequate margins (1 cm). If the tumor is larger, a small incisional biopsy allows accurate classification of the tumor and appropriate preoperative counseling.

Metastases to the inguinal lymph nodes occur in 15–25% of patients. The rate of nodal metastases is directly proportional to the size of the tumor. Papillon and Chassard reported that for tumors less than 2 cm in size, the rate of nodal metastasis was 0%, for those 2–5 cm 24%, and for those greater than 5 cm 67%.[77] Cummings and colleagues found that those with tumors less than 5 cm in size had 0% nodal metastases, whereas metastases occurred in 25% of those with tumors 5 cm or larger.[67]

Surgery

Although surgical excision (either local excision or APR, depending on location) is considered the standard of care for perianal (anal margin) tumors, outcome data for this rare neoplasm are primarily retrospective. In most studies, overall and disease-specific survival is considered for all stages together and subgroup analysis for large numbers of patients is not available. Unfortunately, evaluation of local recurrence data is similarly limited by the small numbers of patients affected; however, in general a trend toward increased recurrence in larger tumors is apparent.[78]

Surgical treatment of the primary perianal tumor is accomplished by wide local excision with 1-cm margins. At MSKCC, Greenall and associates reported a series of 51 patients with perianal squamous cell carcinoma (anal margin).[42] Five-year survival was 88%, although local recurrence was 46%. Local recurrences were amenable to re-excision. Inguinal nodal dissection was employed for metachronous inguinal nodal metastases. Thirteen patients in this series underwent APR as initial treatment. The local recurrence rates for these patients were identical to those of the local excision group. Tumor size was the most important factor for local control and survival (Fig. 42-5). In 1979, Cleveland

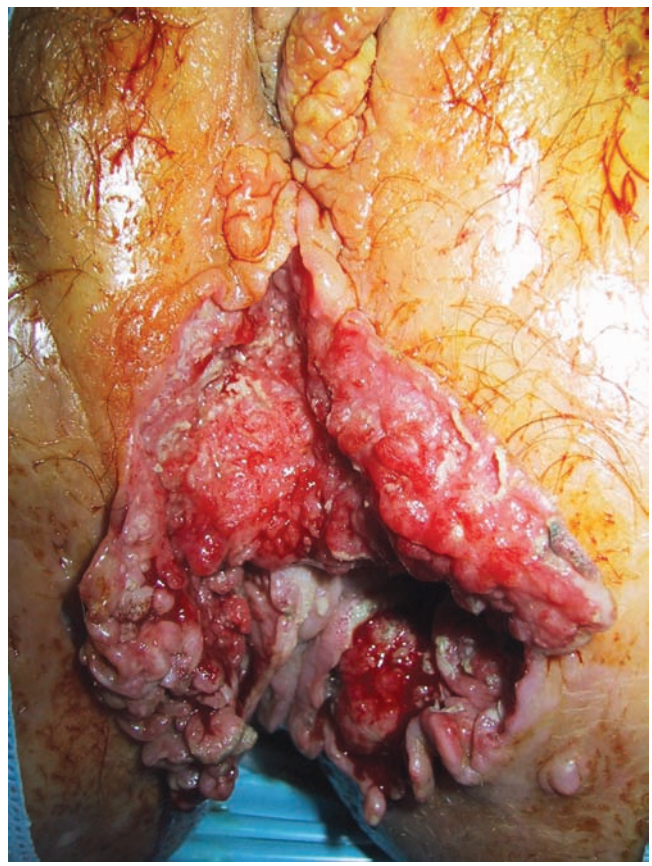

FIGURE 42-5 Deeply ulcerating anal margin tumor. (Used, with permission, from Charles Friel, MD.)

clinic reviewed their experience with surgery for anal margin tumors over a 20-year period.[79] Eight patients were identified for whom follow-up was available. A disease-specific survival rate of 70% was noted after 8 years, with a local recurrence rate of 30%. At the University of Chicago, a 19% local recurrence rate was noted in 16 patients undergoing surgical therapy alone.[80] Two of 11 patients recurred following local excision, and 1 of 3 recurred after APR. Of 27 patients with either stage I perianal (anal margin) cancer or carcinoma in situ treated at the Mayo Clinic between 1950 and 1970, 5-year survival rates were 100%, although local recurrence rates were unavailable.[81]

After surgery alone (local excision or APR), the overall survival rate for all stages is 60–90% with a local recurrence rate of approximately 30%. Survival rates after surgery for recurrence are unknown.[9,78]

Radiotherapy

The optimal treatment of perianal (anal margin) tumors is dependent on location. Significant challenges and functional problems may result when the anal sphincters are present within the boundaries of optimal surgery. If adequate excision compromises the sphincters, APR is an option. However, many surgeons and oncologists would advocate a more conservative approach and use radiotherapy. Cummings and associates demonstrated local control rates of 100% for anal margin tumors less than 5 cm in size with a dose of 50 Gy over 4 weeks.[67] Local control rates were inversely proportional to the size of the tumor. For those tumors 5–10 cm, 70% local control was achieved, but for tumors greater than 10 cm, only 40% sustained a durable response. Similar results were reported by Papillon and Chassard at Centre Leon Berard in France.[77] In this review, a 78% overall survival rate was achieved using external beam radiation (40 Gy cobalt 60 source) with a perineal field. Again, those with tumors greater than 5 cm in size fared considerably worse, with overall survival rates less than 50%.[77]

There have been numerous retrospective reviews of the response of perianal (anal margin) tumors to radiation in the past 40 years documenting stage-specific local recurrence rates, disease-specific survival rates, and overall survival rates. Overall, local control rates of 52–87% are typical, with 5-year overall survival rates ranging from 52 to 90%.[78] T1 and T2 tumors have better local control rates with overall and disease-specific survival rates ranging from 82 to 100%.[78]

It is difficult to evaluate the sphincter preservation rate from these reviews. Small numbers and retrospective design limits direct comparison of this technique to surgery alone. There are no prospective studies comparing surgery alone to radiotherapy. Although the addition of chemotherapy (5-FU and mitomycin-C or cisplatin) seems logical, there are few data to support that approach. The rationale for these agents is extrapolated from the prospective trials of chemoradiation in the setting of anal (canal) carcinoma. Even so, it is reasonable to believe that primary radiotherapy with or without chemotherapy for perianal (anal margin) tumors in close proximity to the anal sphincters, where adequate excision may compromise function, will result in both sphincter preservation and good local control. It is also reasonable to expect that surgical salvage for recurrence after primary radiotherapy is a possibility, with rates of local control of approximately 50%. Long-term disease-specific survival following this scenario is unknown.

LESS COMMON ANAL NEOPLASMS: ANAL MELANOMA

Melanoma of the anus and rectum is a rare malignancy accounting for less than 1% of all colorectal and anal neoplasms.[82] The majority of GI melanomas are metastases; autopsy studies have shown GI metastases in up to 30% of patients with extraintestinal primaries.[83] Primary GI melanoma predominantly affects the anorectum and esophagus. Although there is a female predominance, with an almost 1:2 ratio, there is evidence that the median age of affected males is significantly less (57 vs 71 years).[79] Cagir and colleagues examined the epidemiology and demographics of anorectal melanoma using the Surveillance, Epidemiology and End Results (SEER) database. These investigators note a recent emergence of a bimodal age distribution of anorectal melanoma for all patients, with males occupying the younger aspect of the curve. Survival rates were slightly better in this group (63 vs 51% at 1 year and 41 vs 27% at 2 years; $p < .01$).[84] The most common symptoms include bleeding, itching, the presence of a mass, pain, tenesmus, or changes in bowel habits. Like anal SCC, misidentification of the tumor as a hemorrhoid is a common mistake. Diagnosis is frequently made following hemorrhoidectomy or local excision of the perianal mass. The tumor can appear small and polypoid, or large and ulcerating. About 30% of these tumors are amelanotic and unpigmented making immediate recognition of the problem difficult.[82] On pathology, 70% of lesions show some evidence of melanin production either grossly or microscopically.[82] Commonly, anal melanoma arises at the mucocutaneous junction. Occasionally, the lesion arises more proximally, within the rectal mucosa. Although the origin of these tumors is speculative, they are believed to arise in areas of heterotopic anal canal epithelium in the rectum, or to start from proximal microscopic mucosal spread from a small lesion located more distally.[82]

Staging and Prognosis

Like melanoma of the skin, anorectal melanoma is staged by depth or thickness of the lesion. Lymphatic metastases can occur in the inguinal, mesorectal, and internal iliac nodal distribution. Mesorectal lymph node metastases are found in 40–60% of patients at initial presentation and inguinal

adenopathy is present in at least 20% of patients.[85,86] Distant spread occurs to the bone, lung, and liver.

Regardless of stage, 5-year survival rates for patients diagnosed with anorectal melanoma are very poor, averaging about 6%. The median survival time following diagnosis is 12–18 months.[82]

Surgery

In recent years, local excision has replaced APR for the treatment of anal melanoma. A 64-year review, concluding in 1995, of the anorectal melanoma experience at MSKCC demonstrated a trend toward increased survival for patients with localized, node-negative disease, and for those that were resectable, the authors advocated radical surgery.[86] A more recent report of the last 20 years of the MSKCC experience showed no disease-specific or overall survival for any surgical approach.[87] Other outcomes data comparing local recurrence rates and survival are similar, and do not demonstrate a survival difference between the two approaches; therefore the preservation of fecal continence is a priority when possible. A number of retrospective series published from 1990 to 2003 reviewing institutional experience with local excision and APR found that 5-year survival rates range from 0 to 29% for those undergoing wide local excision, and from 0 to 26% for those undergoing APR. Most authors now recommend wide local excision with negative margins for those patients without anal sphincter involvement.[82]

Even though survival differences are minimal between local and radical approaches, local recurrence rates may be higher after local excision. A study from the M.D. Anderson Cancer Center found that recurrence after local excision was significantly higher than recurrence after APR (58 vs 29%), and that median survival times were the same (~19 months for both groups).[88] Patients with local recurrence in this study developed synchronous regional and distant disease. Roumen in the Netherlands also reported an increased rate of local recurrence with local excision, but no overall survival disadvantage.[89]

Inguinal lymph node dissection in anorectal melanoma is usually reserved for those with clinically positive nodes and is a palliative intervention. Prophylactic nodal dissection does not seem to provide a survival benefit and there currently is no clear indication for it. The role of sentinel lymph node mapping in this disease is not clear. The benefits of the technique are now well established in cutaneous melanoma, but it has not been investigated in anorectal melanoma and is not currently routinely performed.

Adjuvant Therapy

High-dose interferon-α (IFN-α) is currently used in the treatment of cutaneous melanoma. It confers a survival benefit in this group, improving disease-free survival rates.[82] However, there are no data demonstrating its efficacy in anorectal melanoma, and current reports of adjuvant chemotherapy in this setting are anecdotal. In fact, two large meta-analyses show no consistent benefit from the use of IFN-α.[90,91]

Aggressive multidrug chemotherapeutic regimens show some potential efficacy, but toxicities with these approaches are considerable.[92,93] Temozolomide, whose metabolite is dacarbazine has shown efficacy against cutaneous melanoma,[94] and is being investigated for use in anal melanoma. Innovative new approaches, guided by molecular targets are also underinvestigation,[95] but currently, there is no data to guide effective adjuvant chemotherapy.

External beam irradiation for symptomatic pelvic and local recurrences and metachronous inguinal nodal disease has been incorporated into the palliative treatment of anorectal melanoma, but again, no data are available to assess overall efficacy. It seems reasonable, however, to extrapolate treatment paradigms from cutaneous melanoma to anorectal melanoma in stage IV disease.

The surgical treatment of anorectal melanoma has changed over time, evolving from radical to local excision. No survival benefit is conferred by APR in most studies, and in most reviews survival is quite poor in spite of surgical excision, with median survival less than 20 months from the time of diagnosis. Although adjuvant chemotherapy is shown to be effective in cutaneous melanoma, lack of data hinders acceptance of this therapy in anorectal melanoma.

ANAL ADENOCARCINOMA

Anal adenocarcinomas are uncommon, comprising 10% of all anal (canal) carcinomas.[82] Symptoms of bleeding, pain, and change in bowel habits are nonspecific and similar to other anal canal and distal rectal neoplasms. Anal adenocarcinomas may occasionally arise from chronic anal fistulas.

Although outcomes data are few, anal adenocarcinoma has a poor prognosis when compared to rectal cancers or anal SCC. In small series, 5-year survival rates range from 64% to less than 5%.[96,97] These neoplasms have a high rate of both local and distant failure.[97]

Treatment is similar to therapy for adenocarcinoma of the rectum. Neoadjuvant chemoradiation followed by surgical excision is recommended. Postoperative adjuvant chemotherapy may be prudent, as it is in rectal adenocarcinoma, to reduce the risk of distant spread.

PAGET'S DISEASE

Paget's disease was first described in 1874 by Sir James Paget, who reported 15 cases involving the nipple.[98] To date, less than 200 cases of perianal Paget's have been documented in the literature since Darier and Couillaud reported the first case in 1893.[98]

Paget's has a female predominance (1.5:1) with a median presentation age of 65 years.[99] The disease is usually

present for an extended period of time prior to diagnosis because the symptoms are nonspecific and often mistaken for a benign dermatitis. Paget's occurs in apocrine, hair-bearing areas. Erythematous, pruritic, scaling plaques with well-defined serpiginous borders are a typical feature of the disease. These lesions may also appear ulcerated and crusty with a serous discharge. The disease can be found in both the anal canal and margin.[82,98] Histologically, Paget's disease is defined by the presence of large intraepidermal anaplastic tumor cells lying separately or in small clusters. Perianal Paget's cells are foamy and vacuolar in appearance and stain light blue with hematoxylin and eosin. They are positive for periodic acid-Schiff, mucicarmine, Alcian blue, and cytokeratin 7.[82]

The pathogenesis of Paget's disease is still somewhat unclear. Because it can be associated with the presence of rectal adenocarcinoma, it is speculated that Paget's represents a downward extension of the tumor or that a "neoplastic milieu" may create an environment hospitable to the presence of multiple GI primary tumors. Another hypothesis holds that it is a primary tumor of the apocrine glandular elements of the distal anal canal and margin. Others have suggested that Paget's may arise from a neoplastic pluripotent epidermis basal cell.[82]

Perianal Paget's is associated with an underlying visceral malignancy in 20–86% of cases.[82,98,99] Colorectal adenocarcinoma is the most common synchronous tumor, but urogenital, breast, and bile duct carcinomas have also been reported. Screening for other malignancies is imperative. A colonoscopy and prostate examination are basic preventive and diagnostic tests that can be helpful. Some authors recommend computed tomography of the abdomen and pelvis as well.[98]

Complete excision is the treatment for Paget's disease. The extent of the disease is usually determined by taking circumferential biopsies of the anal canal and margin. After the disease is *mapped*, wide local excision is performed. Often, the procedure creates large defects that may require skin grafts or flaps (rotational, island, or myocutaneous). Because excision to negative margins is critical to cure, techniques to ensure this may be required. Surgeons may obtain frozen sections of the margins of the specimen in the operating room prior to reconstruction. Others prefer to cover the wound with saline-soaked gauze, admit the patient to the hospital, and await permanent pathology results for up to 2–3 days prior to reconstruction. If a large flap reconstruction is placed in the anal canal, some recommend diversion with a colostomy or ileostomy at the time of the perineal excision.

Recurrence rates as high as 61% have been reported following excision of perianal Paget's disease.[100] Re-excision is the usual recommendation, although in cases in whom underlying rectal or anal adenocarcinoma exist, radiation followed by APR is advisable. Although recurrence rates are high, the prognosis of Paget's limited to the perianal area with no concomitant neoplasm is very good.[82] Because of the association with additional visceral neoplasms, continued surveillance is required for patients with perianal Paget's disease. Physical examination, including a prostate and pelvic examination, and periodic colonoscopy are probably prudent. Biopsies of new lesions at the edges of the flap or graft may reveal residual disease. Local excision of these recurrences and continued surveillance is required.

BUSCHKE-LÖWENSTEIN TUMORS

Buschke-Löwenstein tumors are also referred to as giant condylomas and were first described in 1925 by Buschke and Löwenstein as "carcinoma-like condylomata acuminata."[101] They are rare entities belonging to a wider group of lesions called verrucous carcinomas, which include oral and cutaneous fungating condylomata. The key feature of giant condyloma that differentiates it from benign anal condyloma is the presence of local invasion.

Although the natural history of these lesions is poorly understood, the etiology is assumed to be similar to that of condyloma.[101] Human papillomavirus (HPV) has been isolated from the tumors. Histologically, the lesions are benign in appearance and do not invade the basement membrane as carcinomas do. Instead, they destroy surrounding tissue by expansion rather than direct invasion (Fig. 42-6). The tumor does not metastasize. Deaths from untreated Buschke-Löwenstein tumors have occurred following deep invasion into unresectable pelvic structures followed by superinfection and recurrent sepsis. The overall mortality rate from this rare entity is 20%.[102]

The literature consists almost entirely of case reports,[103] thus, there are no consistent treatment guidelines. Primary treatment consists of surgical resection to clear margins.[102] However, adequate surgery may be impossible when the tumor deeply invades the pelvis. There have been several case reports demonstrating the efficacy of intralesional injection of interferon-α 2b.[101] At least three reported cases of deeply infiltrating giant condylomata have completely responded to

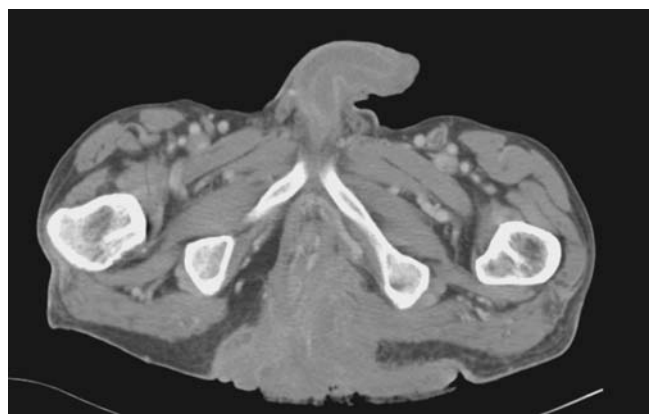

FIGURE 42-6 Buschke-Löwenstein tumor. Local invasion of pelvis, rectum, anal sphincters, and gluteus muscles.

long-term therapy, including one patient who would have required hemipelvectomy with limb amputation to achieve negative margins. Interferon-α 2b may be a good alternative or supplement to radical resection in select cases. Long-term outcomes are not available.

GASTROINTESTINAL STROMAL TUMORS

Gastrointestinal stromal tumors (GISTs) are of mesynchymal origin, believed to be derived from the interstitial cells of Cajal. Immunohistochemical analysis shows the majority to be positive for CD34 and CD117 (*c-kit*). The vast majority of GISTs affect the stomach and small bowel; only 5% of GISTs affect the anorectum, and purely anal GIST comprise only 2–8% of these.[104] Because there are so few, most reports consider anal and rectal GISTs together for analysis.

Current assessment of prognosis for GIST is based on certain clinicopathologic features; tumor size greater than 5 cm, and mitoses greater than 5/high-power field (HPF) predict malignant behavior and decreased survival. Other factors such as pleomorphism, tumor necrosis, and infiltration of muscularis propria and symptoms are indicative of more aggressive behavior, but effects on survival are less clear.[104,105]

Due to the exceeding rarity of this tumor, few data-driven recommendations can be given but extrapolation from management of rectal GISTs demonstrates that surgical excision is recommended for all tumors. Smaller tumors (<2 cm) may be excised locally, while larger, or more locally invasive tumor may require APR for an R0 resection. Local recurrence is common after limited resection, up to 60% in one series,[104] while radical resection yielded 100% recurrence-free survival. Anecdotally, salvage APR for local recurrence after limited excision may yield affective long-term disease control. However, there is no data available to show that extent of surgery can affect overall survival.

While adjuvant therapy with molecularly targeted tyrosine kinase inhibitors like imatinib (Gleevec) and sunitinib (Sutent) for advanced or metastatic disease is becoming standard of care for most GISTs, however there is no data yet to support or extrapolate its use in anal GISTs.

KAPOSI'S SARCOMA

Although Kaposi's sarcoma (KS) is the most common malignancy in AIDS, the incidence of anorectal KS is still quite small in this population. Current HAART treatment makes this number continue to fall.[106] Anal KS usually presents as pedunculated or round purplish-red anal lesions that can easily be mistaken for prolapsing hemorrhoidal tissue. Treatment is primarily medical, with chemotherapy directed at the tumor, as well as appropriate antiretroviral therapy. Use of external beam radiation has also been described for cutaneous anal lesions.[107]

HEPATIC ABSCESS AND CYSTIC DISEASE OF THE LIVER

Kathleen K. Christians • Henry A. Pitt

INTRODUCTION

The differential diagnosis of cystic lesions of the liver includes bilomas, abscesses, parasitic disease, simple cysts, polycystic liver disease (PCLD), biliary cystadenoma, and cystadenocarcinoma.[1] The disease spectrum includes infectious, traumatic, congenital, and neoplastic hepatic lesions that are relatively uncommon. While significant improvements have been made in the diagnosis, treatment, and outcome of many of these cystic hepatic lesions, controversy continues regarding the best treatment option. Many classification systems exist for these lesions; however, the one used in this chapter is presented in Table 43-1.

PYOGENIC LIVER ABSCESS

The first description of a hepatic abscess is credited to Hippocrates in the year 4000 BC. Ochsner's classic 1938 paper[2] described this disease as one that occurred in young males with pylephlebitis, usually due to appendicitis, and resulting in liver abscess. At that time, pyogenic liver abscesses carried a case-fatality rate of 77%[2] and open surgical drainage remained the treatment of choice for many years. In 1953, McFadzean and associates[3] in Hong Kong advocated closed aspiration and antibiotics for treatment of solitary pyogenic liver abscess; however, this treatment did not gain widespread acceptance until imaging advancements in the 1980s allowed for precise localization and a percutaneous approach to treatment. In recent decades, the predominant etiology of pyogenic liver abscess has changed from pylephlebitis to a biliary origin, and more recent reports from Asia and the United States have noted an increase in incidence of cryptogenic liver abscesses. Fortunately, advanced imaging techniques and improved therapeutic modalities have decreased the case-fatality rate for this disease to 6–26%.[4,5]

Etiology

Kupffer cells act as a filter for the clearance of microorganisms in the liver. These organisms reach the liver through the bloodstream, biliary tree, or direct extension. Abscesses occur when normal hepatic clearance mechanisms fail or the system is overwhelmed. Parenchymal necrosis and hematoma secondary to trauma, obstructive biliary processes, ischemia, and malignancy also promote invasion of microorganisms.

In order to appropriately treat the abscess, source control is required. Six distinct categories have been identified as potential sources: (1) bile ducts, causing ascending cholangitis; (2) portal vein, causing pylephlebitis from appendicitis or diverticulitis; (3) direct extension from a contiguous disease; (4) trauma due to blunt or penetrating injuries; (5) hepatic artery due to septicemia; and (6) cryptogenic[6,7] (Fig. 43-1).

Biliary disease accounts for 35–40% of all pyogenic liver abscesses, and 40% of pyogenic liver abscesses of biliary origin are related to an underlying malignancy.[6] Obstruction of the biliary tree is the norm, and cholangitis is present in up to one-half of these patients.[8] Intrahepatic stones and related biliary stricture are predominant in Eastern series whereas malignant biliary obstruction is more common in the West.[7] Any manipulation of the biliary tree—namely cholangiography, percutaneous transhepatic stents, endoscopic stent placement, and biliary-enteric anastomoses—also predispose patients to cholangitis and pyogenic liver abscess. Malignancy contributes to poor nutrition and immunosuppression, potentiating the whole process.

Intestinal pathology is responsible for 20% of all pyogenic liver abscesses. Transient bacteremia due to bacterial translocation or frank gastrointestinal perforation causes overwhelming numbers of microorganisms to spread via the portal venous system to the liver. In the preantibiotic era, 43% of Ochsner's 622 patients seeded the liver through the portal vein, and appendicitis was the most common source (34%).[2] Today, appendicitis accounts for only 2% of

IV. Traumatic hepatic cysts

all pyogenic liver abscesses. Diverticulitis, perforated colon cancers, and abscesses elsewhere in the abdomen and pelvis remain common causes of pyogenic liver abscesses. Primary and metastatic liver tumors may also become colonized with enteric flora.

Contiguous extension of gangrenous cholecystitis, perforated ulcers, and subphrenic abscesses is also a reported source for pyogenic liver abscess. In addition, liver trauma causes parenchymal necrosis and clot, which creates an ideal milieu for the seeding and proliferation of microorganisms and subsequent abscess formation. Ablative procedures for tumors can create this same environment. Microorganisms can then seed these areas of necrosis through intraoperative contamination, biliary-enteric anastomoses, external drains involving the biliary tree, or percutaneous drains placed near the site of trauma or ablation.

Arterial embolization of bacteria via the hepatic artery causes approximately 12% of pyogenic liver abscesses. Intravenous drug abuse accounts for most of these cases, but hepatic artery chemoembolization and umbilical artery catheterization have also been cited. Arterial embolization can also occur from distant infection in the heart, lungs, kidneys, bones, ears, and teeth.[9]

Cryptogenic abscesses occur in 10–45% of patients, depending on the aggressiveness of investigation used to define the source.[9,10] Patients with cryptogenic abscesses usually have comorbidities such as diabetes, immunosuppression, or malignancy. Abscesses in these patients tend to be solitary and usually contain a single anaerobe.

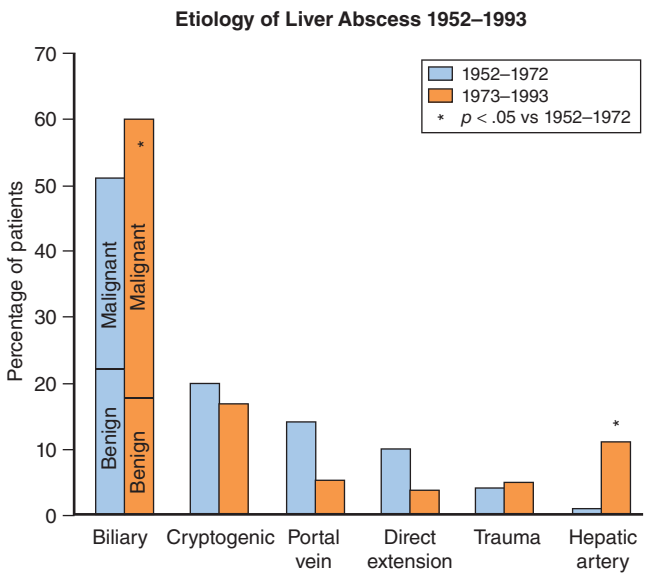

FIGURE 43-1 Comparison of etiology of pyogenic liver abscesses treated during 1952–1972 and 1973–1993 at the Johns Hopkins Hospital. (Reproduced, with permission, from Huang CJ, Pitt HA, Lipsett PA, et al. Pyogenic hepatic abscess: changing trends over 42 years. *Ann Surg.* 1996;223:600–609.)

Incidence

Pyogenic liver abscess affected 5–13 patients per 100,000 admissions before 1970 and accounts for approximately 15 cases per 100,000 admissions today. Seeto and Rocky[11] reported an incidence nearly twofold that of earlier reports (22 per 100,000). This rising incidence is attributed to a more aggressive management approach to hepatobiliary and pancreatic cancers as well as major improvements in diagnostic imaging.[7,12]

Predisposing Factors

Pyogenic liver abscesses occur more frequently in adults with comorbid conditions, including diabetes mellitus, cirrhosis, pancreatitis, inflammatory bowel disease, pyelonephritis, and peptic ulcer disease. Solid-organ cancers as well as lymphoma and leukemia are present in 17–36% of patients with liver abscesses.[9] Branum and associates reported an increased incidence in patients with underlying malignancy and immunosuppression.[13] Civardi and colleagues[14] as well as Lambiase and coworkers[15] have reported series of patients with liver abscesses and underlying acquired immune deficiency. The combination of chemotherapy and steroid use is thought to be responsible in these cases.

In addition to comorbidities, age plays a role in the development of pyogenic liver abscess. The age of pyogenic liver abscess patients has increased since 1938. This disease has now become one of the middle-aged and elderly with a reported mean age of 47–65 years. Older patients are more likely to have a biliary etiology or underlying malignancy, whereas younger patients are more likely to be alcoholic males with a cryptogenic origin. Polymicrobial or anaerobic infections with multidrug-resistant organisms, a pleural effusion, inappropriate initial antibiotic selection, and a greater severity of illness on admission occur more frequently in older patients.

Underlying malignancy is more prevalent in older patients and is a risk factor for developing anaerobic infections. Age and an APACHE II (Acute Physiology and Chronic Health Evaluation II) score of greater than 15 on admission are risk factors for case fatality in older patients. The case-fatality rate in older patients is related to host conditions, rather than characteristics of the abscess itself. Clinicians should apply an aggressive approach for older patients exhibiting a poor response to primary treatment, particularly in those with a greater severity of illness on admission.[16]

In children, pyogenic liver abscesses tend to occur in the setting of host-defense abnormalities or immune disorders. Complement deficiencies, chronic granulomatous disease, leukemia, and other malignancies place these children at increased risk for liver abscess. Hepatic abscesses are also seen in sickle cell anemia, congenital hepatic fibrosis, PCLD, and after liver transplant (Table 43-2).[9]

Pathology

The source of the liver abscess is predictive of the number, location, and size of the abscess affecting a given patient. In general, portal, traumatic, and cryptogenic hepatic abscesses are solitary and large, while biliary and arterial abscesses are multiple and small. Huang and associates[7] reported that 63% of patients had abscesses involving the right lobe, 14% had abscesses involving the left lobe, and 22% had bilobar disease. The number of bilateral and multiple abscesses have increased as more patients present with a biliary etiology. Bilateral disease may be seen in 90% of patients with an arterial or biliary source. In contrast, those with intra-abdominal infections frequently present with right lobe abscesses due to preferential flow from the superior mesenteric vein. Fungal abscesses are usually multiple, bilateral, and miliary.[9]

TABLE 43-2: PREDISPOSING FACTORS FOR PYOGENIC LIVER ABSCESSES

Children	Adults
Chronic granulomatous disease	Diabetes mellitus
Complement deficiencies	Cirrhosis
Leukemia	Chronic pancreatitis
Malignancy	Peptic ulcer disease
Sickle cell anemia	Inflammatory bowel disease
Polycystic liver disease	Jaundice
Congenital hepatic fibrosis	Pyelonephritis
Posttransplant liver failure	Malignancy
Necrotizing enterocolitis	Leukemia and lymphoma
Chemotherapy and steroid therapy	Chemotherapy and steroid therapy
Acquired immunodeficiency syndrome	Acquired immunodeficiency syndrome

Bacteriology

Diagnostic confirmation of a pyogenic liver abscess involves aspiration of the abscess itself and obtaining blood cultures that are positive. Abscess cultures are positive for growth in the majority (80–97%), whereas blood cultures are positive in only 50–60% of cases.[11,14] *Escherichia coli*, *Klebsiella* species, enterococci, and *Pseudomonas* species are the most common aerobic organisms cultured in recent series, whereas *Bacteroides* species, anaerobic streptococci, and *Fusobacterium* species are the most common anaerobes.[12] Huang and colleagues[7] cited the increased use of indwelling biliary stents as the cause of an increasing incidence of *Klebsiella*, streptococcal, staphylococcal, and pseudomonal species in liver abscesses. They also noted the presence of fungi in 22% of cultures taken between 1973 and 1993 compared to only 1% between 1952 and 1972. Broad-spectrum antibiotic use in the treatment of cholangitis was thought to be the causative factor. *Candida* fungal abscesses are also found in cancer patients who have undergone cytotoxic chemotherapy. *Mycobacterium tuberculosis* is a common infecting organism in the acquired immune deficiency syndrome[8] (Table 43-3).

The species of microorganism found in a hepatic abscess is related to the source. The biliary tree gives rise to abscesses predominantly composed of *E. coli* and *Klebsiella*. *E. coli*, enterococci, and anaerobes are the main organisms

TABLE 43-3: ORGANISMS ISOLATED FROM PYOGENIC LIVER ABSCESSES

Category of Organism	% of Patients

recovered from abscesses related to the intestinal tract. Anaerobes are the usual microorganisms found in cryptogenic liver abscesses in Western countries. Negative cultures may relate to poor anaerobic culture technique or the use of broad-spectrum antibiotics prior to abscess drainage. In series where careful attention is paid to anaerobic organism recovery, anaerobes may be detected in 10–17%, most often *B. fragilis*.[17] If suspected bacterial cultures are repeatedly negative, amebic and parasitic organisms must be considered because they are difficult to identify by routine staining and culture techniques.[9]

Klebsiella pneumoniae is the number one pathogen found in pyogenic liver abscesses in Taiwan and Korea and usually occurs in a monobacterial as opposed to mixed bacterial setting. Investigation into the K antigen serotype revealed that the K1 serotype accounts for 60% of *K. pneumoniae* strains causing liver abscess in these countries. The reason why liver abscess caused by K1 serotype *K. pneumoniae* strains has been emerging has not been elucidated. In contrast, this particular serotype is rarely found in clinical isolates from Western countries. In Taiwan and Korea, the average age to develop a *K. pneumoniae* liver abscess is 55–60 years. These abscesses are twice as likely to be diagnosed in men than in women and are much more likely to be cryptogenic in origin (64%). Diabetes is a known risk factor for developing *K. pneumoniae* liver abscess and is a significant risk factor for embolic complications, especially endophthalmitis.[17,18]

Diagnosis

The clinical presentation of pyogenic liver abscess is usually subacute and nonspecific, leading to delays in presentation, diagnosis, and treatment. In Seeto and Rocky's review[11] of 142 patients with pyogenic liver abscesses, the classic triad of fever, jaundice, and right upper quadrant (RUQ) tenderness was present in fewer than 10% of patients overall.

Clinical Presentation

Most patients have fever (92%) and 50% have abdominal pain, but only half have pain in the right upper quadrant. Diarrhea occurs in less than 10% of patients. The liver may be tender (65%) and enlarged (48%), and the patient may appear jaundiced (54%). Other nonspecific complaints include malaise, anorexia, and nausea. If the diaphragm is involved, pleuritic chest pain, cough, or dyspnea may occur. If the abscess ruptures, peritonitis and sepsis may be presenting features [7,8,11] (Table 43-4).

Laboratory Evaluation

Leukocytosis is present in 70–90%, an elevated alkaline phosphatase in 80%, and an elevated bilirubin and transaminases in 50–67% of patients. Anemia, hypoalbuminemia, and prolonged prothrombin time are seen in 60–75% of patients.[7,8,11,12]

Radiology

Plain films such as chest radiographs are abnormal in 50% of patients. Findings may include an elevated right hemidiaphragm, a right pleural effusion, and/or right lower lobe atelectasis. Abdominal films may show hepatomegaly, air-fluid levels in the presence of gas-forming organisms, or portal venous gas if pylephlebitis is the source (Fig. 43-2). Ultrasound (US) will distinguish solid from cystic lesions and is cost-effective and portable. US is 80–95% sensitive but has limited utility in the morbidly obese and in lesions that are located under the ribs or located in an inhomogeneous liver.

Computed tomography (CT) is more sensitive (95–100%) than US in detecting hepatic abscesses. On CT examination, an abscess is of lower attenuation than the surrounding liver, and the wall of the abscess may enhance with intravenous

contrast administration. Lesions are detectable to around 0.5 cm with CT and are not limited by shadowing from ribs or air. CT and US may be used to evaluate and potentially treat the source of infection by percutaneous drainage (Figs. 43-3A and B; Figs. 43-4A through 4-4C). Radionuclide scanning with technetium 99m (^{99m}Tc) is no longer used and has been completely replaced by CT and US. On the other hand, cholangiography, usually through an indwelling biliary stent, may visualize the abscess (Fig. 43-5).

Treatment

The appropriate treatment for pyogenic liver abscesses requires treatment of the abscess itself and concomitant treatment of the source. Drainage of a pyogenic abscess is essential for cure in most cases. Although antibiotics alone may be curative, patients sustain higher risk of failure and complications such as abscess rupture. Percutaneous transhepatic drainage is relatively low-risk and successful treatment method for both polymicrobial liver abscesses and *K. pneumoniae* liver abscesses.[17] Steps in management include antibiotic administration, radiologic confirmation by US or CT, and drainage. Exceptions to this strategy include multiple small abscesses and miliary fungal abscesses. These abscesses are treated with intravenous antibiotics and antifungals respectively, without a drainage procedure.

ANTIBIOTICS

After confirmatory imaging with US or CT, abscesses are aspirated, blood cultures are drawn, and broad-spectrum intravenous antibiotics are administered until sensitivities allow a more selective antibiotic choice. Serologic testing should also be performed if an amebic abscess is suspected.[8]

Classic antibiotic regimens include an aminoglycoside, clindamycin, and either ampicillin or vancomycin. Fluoroquinolones can replace aminoglycosides, and metronidazole can be used instead of clindamycin, especially if an amebic source is suspected. Single-agent therapy with ticarcillin-clavulanate, imipenem-cilastatin, or piperacillin-tazobactam is also acceptable.[12] Treatment used to be given for 4–6 weeks; however, many studies now document success with only 2 weeks of antibiotic therapy.[9] Empiric antibiotics should include anaerobic coverage in

older pyogenic liver abscess patients, particularly in the setting of malignancy.[16]

K. pneumoniae is intrinsically resistant to ampicillin. Metronidazole is ineffective against aerobic organisms, and regimens containing first-generation cephalosporins have been shown to be inferior in treatment of *K. pneumoniae* liver abscess. A combination of an aminoglycoside and either an extended spectrum β-lactam, such as piperacillin, or second- or third-generation cephalosporin is preferred for patients with *K. pneumoniae* liver abscess.[17]

In the setting of multiple abscesses of less than 1.5 cm and no concurrent surgical disease, patients may be treated with IV antibiotics alone. However, multiple small abscesses frequently imply biliary tract disease and may require biliary drainage for source control. Similarly, fungal abscesses are miliary in nature and not amenable to percutaneous or surgical drainage.

FIGURE 43-5 Cholangiogram via a transhepatic stent in a patient with biliary obstruction secondary to recurrent gastric cancer. It shows a communicating liver abscess.

ANTIFUNGALS

Candidal liver abscess is a rare disease reported most commonly in patients with hematologic malignancies during periods of neutropenia resolution. Most of the candidal liver abscesses in patients with hematologic malignancies are a manifestation of disseminated candidiasis and have high mortality rates. They can also be acquired by fungemia from the portal vein or an ascending retrograde infection from the biliary tree. In patients with hematologic malignancies, the yield of positive culture is often less than 50% with the diagnosis usually based on microscopic examination or histopathology from deep tissues. Higher doses of amphotericin B (2–9 g) are recommended by most experts because a cumulative dose of less than 2 g correlated with residual lesions at autopsy. Cases of hepatosplenic candidiasis have been successfully treated with fluconazole. Symptoms improved at 3–8 weeks, but resolution of the lesions on CT scan was noted after at least 1 month of fluconazole.[19]

Candida glabrata often has reduced susceptibility to both azoles and amphotericin B, and opinions on best therapy are divided. Both *C. Krusei* and *C. glabrata* appear susceptible to caspofungin, and this agent appears to be a good alternative. Although fungemia due to *C. glabrata* has been treated successfully with fluconazole (6 mg/kg/d), many experts prefer amphotericin B deoxycholate (>0.7 mg/kg/d). On the basis of pharmacokinetics predictions, fluconazole (12 mg/kg/d; 800 mg/d for the 70-kg patient) may be a suitable alternative, particularly in less critically ill patients.[20]

ASPIRATION AND PERCUTANEOUS CATHETER DRAINAGE

Needle aspiration and percutaneous catheter drainage of liver abscesses have similar mortality rates; however, recurrence rates and the requirement for surgical intervention may be greater in those who undergo aspiration alone.[11] Needle aspiration is less invasive, less expensive, and avoids all of the complications associated with catheter care. Giorgio and colleagues[21] reported a series of 115 patients with a 98.3% success rate for needle aspiration, no mortality, and no procedure-related morbidity. A randomized controlled trial by Rajak et al[22] in 1998 compared percutaneous needle aspiration to catheter drainage and also found no major complications and no deaths. They did, however, report only 60% success with needle aspiration versus a 100% success rate with catheter drainage.[22] The highest rate of recurrence (15%) occurred in patients with biliary tract disease and obstructive lesions, whereas the recurrence rate with cryptogenic abscesses was less than 2%. This observation suggests that the underlying lesion should influence the type of therapy chosen.[11]

Patients in whom percutaneous drainage is not appropriate include those with (1) multiple large abscesses; (2) a known intra-abdominal source that requires surgery; (3) an abscess of unknown etiology; (4) ascites; and (5) abscesses that would require transpleural drainage.[6] An example of a patient managed by percutaneous drainage is provided in Figs. 43-6A through 43-6D.

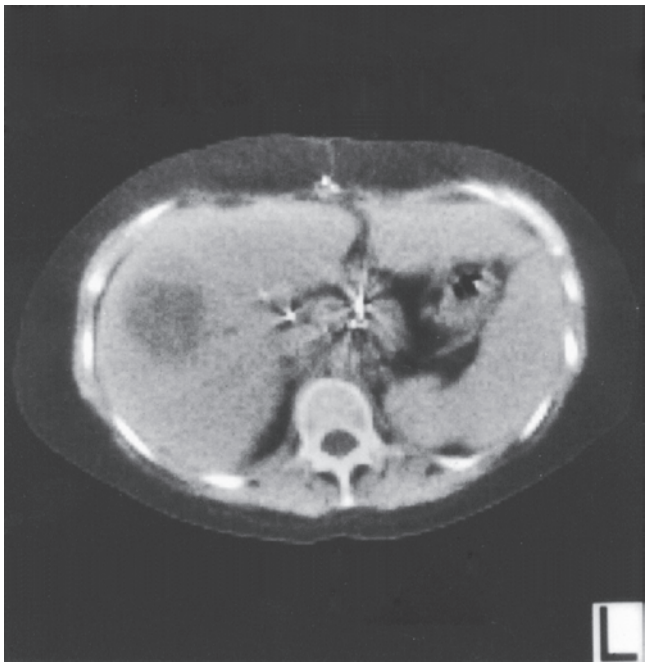
SURGICAL DRAINAGE

Surgical drainage was the widely accepted treatment for liver abscesses for many years following Ochsner's 1938 report.[2] Abscesses were drained extraperitoneally via a 12th rib resection to avoid contamination of the peritoneal cavity. With the advent of systemic antibiotics, transperitoneal surgical exploration also was considered a safe surgical approach. The transperitoneal approach advantages include the ability to: (1) treat the inciting pathology in the remainder of the abdomen/pelvis; (2) gain access and exposure of the entire liver for evaluation and treatment; and (3) access the biliary tree for cholangiography and bile duct exploration.

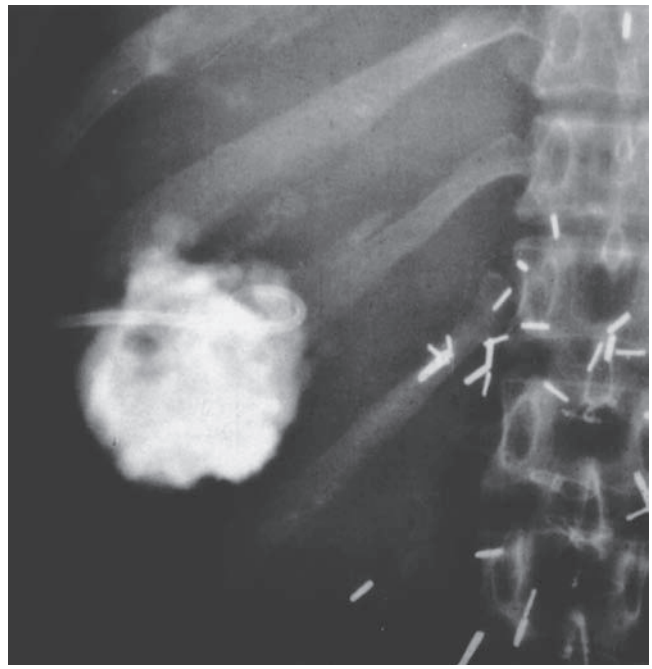
Since the 1980s, treatment has shifted to a less invasive approach using percutaneous needle aspiration or catheter drainage to treat pyogenic abscesses. Surgical drainage is currently reserved for patients who have failed nonoperative therapy, those who need surgical treatment of the underlying source, those with multiple macroscopic abscesses, those on steroids, or those with concomitant ascites.[7]

Complications

Up to 40% of patients develop complications from pyogenic liver abscesses, with the most common being generalized sepsis. In addition to sepsis, morbidity can include pleural effusions,

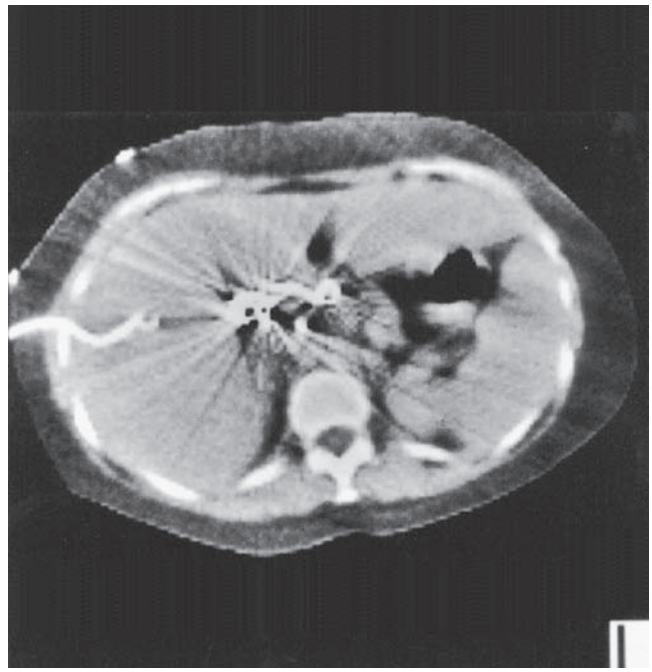


A



B

C



D

FIGURE 43-6 **A.** CT demonstrating a pyogenic abscess in the right hepatic lobe. **B.** Contrast injected into the abscess cavity through a percutaneously placed drainage catheter. **C.** Sinogram performed 2 weeks later revealing a decrease in the size of the abscess cavity. **D.** CT after 4 weeks demonstrating complete resolution of the abscess. (Reproduced, with permission, from Pitt HA. Liver abscess. In: Zuidema GD, Tureotte JG, eds. *Shackleford's Surgery of the Alimentary Tract*. 3rd ed. Philadelphia, PA: WB Saunders; 1991:444.)

empyema, and pneumonia. Abscesses may also rupture intraperitoneally, which is frequently fatal. Usually, however, the abscess does not rupture but develops a controlled leak, resulting in a perihepatic abscess. Pyogenic abscesses may also cause hemobilia and hepatic vein thrombosis.[9]

Bacteremia is extremely common (95%) in *K. pneumoniae* liver abscess as opposed to other types of pyogenic liver abscesses (50%). As a result, end-organ seeding and distant abscesses are common. Extrahepatic abscesses occur in 7–12% of patient with *K. pneumoniae* liver abscesses with the most commonly reported organ being the eye. Endophthalmitis occurs in to 6–61% of cases and commonly occurs after liver abscess drainage. Disseminated intravascular coagulation (DIC), septic pulmonary emboli, and acute renal failure are also well-accepted complications of *K. pneumoniae* liver abscess.[17]

Outcome

Between the 1950s and 1990, mortality rates varied from as low as 11% to as high as 88%.[6] High mortality rates came from delay or failure to diagnose the abscess, failure to detect smaller intrahepatic abscesses, ineffective surgical drainage, lack of source control, associated malignancy, immune insufficiency, or other major comorbid conditions. No general consensus has been reached regarding risk factors due to the variability of the patient population being studied (Table 43-5).

The prognosis for *K. pneumoniae* is better than that for other pyogenic liver abscesses regarding mortality (6–17%) and disease relapse. Prognosticators for mortality in *K. pneumoniae* liver abscess include abscess more than 5 cm, concomitant sepsis, intrahepatic gas formation, APACHE III score of more than 40, delayed/inadequate abscess drainage, use of antimicrobials alone, thrombocytopenia, and diabetes.[17] The main concern in this type of liver abscess is no longer mortality but catastrophic disability due to irreversible ocular or neurological complications. The *K. pneumoniae* genotype K1 is an emerging pathogen capable of causing septic ocular or central nervous system (CNS) complications from pyogenic liver abscess independent of host underlying diseases.[18] The outcome for patients who develop endophthalmitis is grim because despite rapid intervention, visual acuity outcome is poor.[17]

TABLE 43-5: FACTORS ASSOCIATED WITH A POOR OUTCOME IN PATIENTS WITH PYOGENIC LIVER ABSCESSES

Age >70 y	WBC count >20.000/mm^3
Diabetes mellitus	Increasing bilirubin
Associated malignancy	Increasing SGOT
Biliary etiology	Albumin <2 g/dL
Multiple abscesses	Aerobic abscess
Septicemia	Significant complication
Polymicrobial bacteremia	

SGOT, serum glutamic oxaloacetic transaminase; WBC, white blood (cell) count.

AMEBIC LIVER ABSCESS

Amebic liver abscess is caused by the parasitic protozoan *Entamoeba histolytica.* The disease was described in association with blood and mucus diarrheal stools in the fifth century BC by Hippocrates and other practitioners. In 1890, Sir William Osier described the first North American case when, after an attack of dysentery while in Panama, a physician's stool and abscess fluid were both found to contain amebae. Councilman and LaFleur of Johns Hopkins Hospital went on to detail the pathogenic role of amebae and coined the terms "amebic dysentery" and "amebic liver abscess" in 1891.[23] Amebic liver abscess is the most common extraintestinal form of invasive amebiasis and an estimated 100,000 people succumb to this disease each year.[24]

Etiology

Two species of ameba infect humans. *Entamoeba dispar* is associated with an asymptomatic carrier state and not with disease. *E. histolytica* is responsible for all forms of invasive disease. The life cycle involves cysts, invasive trophozoites, and fecally contaminated food or water to initiate the infection.[25,26] Fecal-oral transmission occurs; the cyst passes through the stomach into the intestine unscathed, and pancreatic enzymes start to digest the outer cyst wall. The trophozoite is then released into the intestine and multiplies there. Normally, no invasion occurs, and the patient develops amebic dysentery or becomes an asymptomatic carrier. In a small number of cases, the trophozoite invades through the intestinal mucosa, travels through the mesenteric lymphatics and veins, and begins to accumulate in the hepatic parenchyma, forming an abscess cavity. Liquefied hepatic parenchyma with blood and debris gives a characteristic "anchovy paste" appearance to the abscess.[12]

Incidence

Worldwide, an estimated 500 million people are carriers of *E. histolytica* or *E. dispar*, 50 million people have active disease and 50,000–100,000 die annually. The vast majority of these infections are acquired in the developing world. Amebiasis is common in Africa, Indochina, and Central and South America. Up to 5% of diarrheal illness in Mexico is due to *Entamoeba* disease.[25] The overall prevalence in the United States is 4% per year. High-risk groups in the United States include sexually active homosexual men, immigrants, tourists who travel to endemic areas, institutionalized people, and those with human immunodeficiency virus (HIV).[27] Children also have been known to infect entire families. Amebiasis follows a bimodal age distribution. One peak is

at age 2–3 years, with a case-fatality rate of 20%, and the second peak is at over the age of 40 years, with a case-fatality rate of 70%.[25] Those living in developing countries have a greater risk and an earlier age of infection than those in developed regions. Low socioeconomic status and unsanitary conditions are significant independent risk factors for infection.[27] Amebic liver abscess is 10 times as common in men as in women and is a rare disease in children.[26]

Pathology

Roughly 90% of people who become infected with *E. histolytica* are asymptomatically colonized, and factors that control the invasiveness of this organism are not completely understood. *E. histolytica* cysts can last for days in a dried state at temperatures of 30°C. These cysts are resistant to the effects of gastric acid pH but become stimulated to form trophozoites in the alkaline pH of the bowel. Trophozoites are found in the colon and in the feces of humans and mammals. Humans become reservoirs, and transmission occurs by ingesting food and water contaminated with amebic cysts, or occasionally through person-to-person contact. Incubation takes 1–4 weeks. Left untreated, asymptomatic individuals may shed cysts for many years.

Invasive amebiasis can include anything from amebic dysentery to metastatic abscesses. The most common form of the invasive disease is colitis. The majority (70–80%) of patients experience a gradual onset of symptoms with worsening diarrhea, abdominal pain, weight loss, and stools containing blood and mucus. Trophozoites invade and induce apoptosis in colonic mucosa, resulting in "buttonhole" ulcers with undermined edges. Trophozoites are actually found in the edge of the ulcers.

The most common extraintestinal site of amebiasis is the liver, occurring in 1–7% of children and 50% of adults (usually males) with invasive disease.[25] Trophozoites reach the liver through the portal system, causing focal necrosis of hepatocytes and multiple microabscesses that coalesce into a single abscess. The central cavity of the lesion contains a homogenous thick liquid that is typically red-brown and yellow in color and similar to anchovy paste in consistency.[28]

Diagnosis

The definitive diagnosis of amebic liver abscess is by detection of *E. histolytica* trophozoites in the pus and by finding serum antibodies to the ameba.[28] The differential diagnosis should include pyogenic liver abscess, necrotic adenoma, and echinococcal cyst.

CLINICAL PRESENTATION

Ninety percent of amebic liver abscesses occur in young adult males. The presentation may be acute, with fever and RUQ pain, or subacute, with weight loss and, less frequently, fever and abdominal pain. The usual case of amebic liver abscess does not present with concurrent colitis, but patients may have had dysentery within the last year. Alcohol abuse is common.[29] Eighty percent of patients with amebic liver abscess present with symptoms that develop within 2–4 weeks, including fever, cough, and a dull aching pain in the RUQ or epigastrium. Diaphragmatic involvement causes right-sided pleural pain or pain referred to the shoulder. Gastrointestinal symptoms of nausea, vomiting, abdominal cramping, abdominal distention, diarrhea, and constipation occur in 10–35%. Hepatomegaly with point tenderness over the liver or subcostal region is common[26] (Table 43-6). In contrast to pyogenic liver abscesses, amebic liver abscesses are more likely to occur in males younger than 50 years who have immigrated or traveled to a country where the disease is endemic. The patient will also not be jaundiced or have biliary disease or diabetes mellitus[26] (Table 43-7).

LABORATORY EVALUATION

Patients may present with a mild to moderate elevation of the white blood cell count and anemia. Acutely, alkaline

Diarrhea	Jaundice
Abdominal tenderness	Septic shock
Hepatomegaly	Palpable mass

phosphatase will be normal and alanine aminotransferase levels will be elevated. The opposite is true in patients with chronic disease.[26] Jaundice is rare. Because amebic abscesses involve destruction of liver parenchyma and are often larger than pyogenic liver abscesses, patients may have an elevated prothrombin time.[9] If colitis is present, wet mount preps of stool samples contain trophozoites 30% of the time in one sample and 70% of the time if three samples are tested. Liver abscesses are associated with positive stool samples in 40–50% of cases.[25]

RADIOLOGY

Chest radiographs are abnormal in two-thirds of patients with amebic liver abscess and frequently show pleural effusion, infiltrates, or an elevated hemidiaphragm.[9] Ultrasound, CT, and magnetic resonance imaging (MRI) are all excellent methods for detecting amebic liver abscesses but are nonspecific.[26]

In 75–80% of cases, only a single abscess is present and located in the right lobe. Ten percent are in the left lobe and the rest are multiple. Six percent may present as a caudate lobe abscess. Only 40% have typical sonographic features of amebic liver abscess, and serial scanning shows no change in the ultrasound features despite adequate treatment. The mean time to resolution is 7 months, and 70% have findings that persist for more than 6 months. Eventually, resolution may be complete or result in a small residual cystic cavity that resembles a simple cyst of the liver.[30]

SEROLOGY

Serum antibodies are positive in 85% of patients with invasive colitis and 99% with liver abscesses.[31] Countries with a high prevalence of amebiasis also have a high prevalence of positive serologies in asymptomatic individuals. Therefore serologies help exclude the diagnosis only in appropriately chosen populations. Patients with *E. dispar* infection will have negative serologies. Biopsies of the edge of an ulcer or the wall of an abscess reveal trophozoites with periodic acid-Schiff stain.[25]

DIAGNOSTIC ASPIRATION

Serologic data are usually available within 24–48 hours; therefore the need to aspirate a suspected amebic abscess is questionable. Diagnostic aspirations are usually done when amebic serologies are negative and a pyogenic cause needs to be ruled out. The fluid of an amebic abscess is odorless, and Gram stain and cultures are negative. Amebae are recovered in 33–90% of aspirates, and wall scrapings increase the yield.

The diagnosis of invasive amebiasis is most commonly attempted by a combination of stool testing for ova and parasites (O&P) and serologic testing, possibly coupled with colonoscopy and biopsy of intestinal lesions or drainage of liver abscesses. Numerous studies have demonstrated the inadequacies of microscopic examination for *E. histolytica* for the diagnosis of both amebic colitis and liver abscess. Antigen detection or polymerase chain reaction (PCR) to detect *E. histolytica* in the stool is a better approach than O&P but requires fresh or frozen stool specimens (vs preserved), and PCR is impractical in the developing world. The detection of amebic markers in the sera of patients with amebic colitis and liver abscess remains only a research tool at the present time.[27]

Treatment

Since the introduction of metronidazole in the 1960s, surgical drainage of amebic liver abscesses has become virtually unnecessary. Drainage procedures, regardless of the approach, are reserved for those cases in which the diagnosis is questionable or when complications occur.

ANTIBIOTICS

Noninvasive infections can be treated with paromomycin. Nitroimidazoles, especially metronidazole, are the mainstays of treatment for invasive amebiasis. Nitroimidazoles with longer half-lives (secnidazole, tinidazole, and ornidazole) are better tolerated and can be given for shorter periods, but these are not available in the United States.[26] Metronidazole reaches high concentrations in the liver, stomach, intestine, and kidneys. This antibiotic crosses the placenta and blood-brain barrier and is contraindicated in the first trimester of pregnancy. The drug is also excreted in milk; thus breast-feeding should be discontinued during use. Serious side effects are rare. Positive responses to metronidazole should be seen by the third day of treatment. At 5 days, an 85% cure rate is achieved, and this response may be increased to 95% by 10 days. Approximately 5–15% of patients with amebic liver abscess may be resistant to metronidazole.[30] Parasites persist in the intestine in up to 40–60% of patients who get a nitroimidazole; thus nitroimidazole treatment should be followed with paromomycin or diloxanide furoate to cure luminal infection or risk relapse from residual infection in the intestine.[26]

In summary, amebic liver abscess is usually managed by the administration of metronidazole or tinidazole, followed

by treatment with a luminal amoebicide (paromomycin or diloxanide furoate).[24]

THERAPEUTIC ASPIRATION

Blessmann and colleagues[32] reported a prospective, randomized trial of patients with amebic abscesses that were treated with metronidazole alone or with US-guided aspiration of the fluid plus medication. Fever, RUQ pain, liver tenderness, and laboratory studies such as erythrocyte sedimentation rate, white blood cell count, hemoglobin, C-reactive protein, and abscess size were obtained on admission and daily thereafter. Abscess aspiration resulted in improved liver tenderness within the first 3 days, but no other difference was demonstrable between the two groups. The authors concluded that this minor benefit was insufficient to justify routine needle aspiration. They advocated drug treatment alone for uncomplicated abscesses with a diameter up to 10 cm and located in the right lobe of the liver.

Therapeutic aspiration may occasionally be required as an adjunct to antiparasitic treatment. Drainage should be considered in patients who have no clinical response to drug therapy within 5–7 days or those with a high risk of abscess rupture defined as having a cavity diameter of greater than 5 cm or lesions located in the left lobe.[33] A 2009 Cochrane Review[34] attempted to lay to rest the controversy surrounding percutaneous needle aspiration of uncomplicated amebic liver abscesses. The authors found that percutaneous needle aspiration did not help patients with uncomplicated amebic liver abscess. Benefits were observed in resolution time of pain and tenderness, but no additional benefit was found with percutaneous needle aspiration plus metronidazole versus metronidazole alone for uncomplicated amebic liver abscesses in hastening clinical and radiologic resolution.[34] Bacterial coinfection of amebic liver abscess has been observed; therefore addition of antibiotics, drainage, or a combination of both, to nitroimidazole therapy may be necessary.[26]

DRAINAGE

Percutaneous or surgical drainage should be reserved for cases in which the diagnosis of amebic liver abscess is in question or when complications occur.

Percutaneous. Image-guided percutaneous catheter drainage has replaced surgical intervention as the procedure of choice for decreasing the size of an abscess. Percutaneous drainage remains most useful for treating pulmonary, peritoneal, and pericardial complications. The high viscosity of amebic abscess fluid, however, requires a large-diameter catheter for adequate drainage, and this may cause more discomfort for the patient. Secondary infections related to the indwelling catheter are always a risk of this intervention.[9]

Surgical. Surgical drainage of amebic liver abscesses has largely been replaced by antibiotic therapy. The most common indication for surgical intervention is to manage abscesses that have failed to respond to more conservative therapy. Laparotomy is indicated for life-threatening hemorrhage that may or may not be related to abscess rupture, or when the amebic abscess erodes into a neighboring viscus and control of the involved viscus is necessary. Sepsis due to a secondarily infected amebic abscess also warrants operative intervention if percutaneous treatment fails.[9]

COMPLICATIONS

Complications from amebic abscesses occur secondary to rupture of the abscess into the peritoneum, pleural cavity, or pericardium (Fig. 43-7). Extrahepatic sites also have been described in the lungs, brain, skin, and genitourinary tract, presumably from hematogenous spread.[26] Ruptured amebic liver abscesses occur in 2–17% of patients and are associated with mortality rates between 12 and 50%.[30]

Peritonitis associated with amebiasis is due to rupture in the majority (78%) and less commonly secondary to necrotizing or perforated amebic colitis (22%). The liver abscess usually adheres to the diaphragm and the anterior abdominal wall, or the omentum and bowel tend to wall it off. Rupture into the colon or stomach also may occur. Free rupture into the peritoneal cavity is uncommon and occurs in moribund patients or those with poor nutrition.[30]

Thoracic amebiasis (empyema, bronchohepatic fistulas, and pleuropulmonary abscess) is the most common complication, followed by pericardial amebiasis (acute pericarditis with

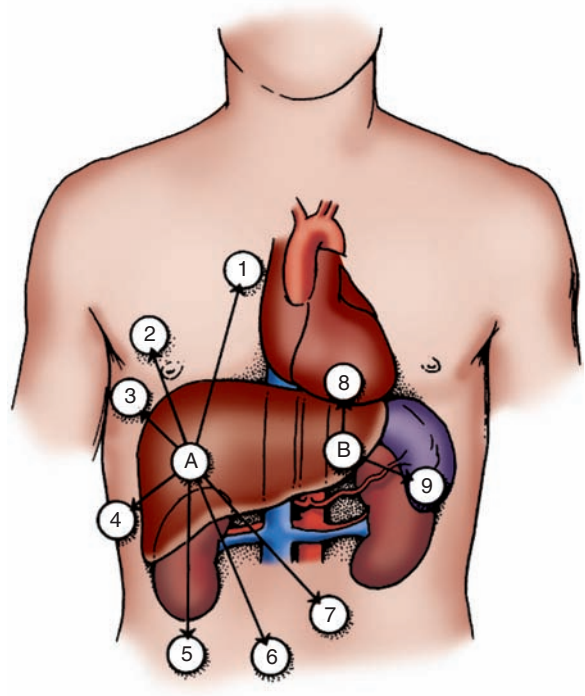

FIGURE 43-7 Paths of extension of amebic liver abscesses located within **(A)** the right hepatic lobe (labels 1–7) and **(B)** the left hepatic lobe (8, 9).

tamponade).[25] Transdiaphragmatic involvement manifests as dyspnea and dry cough. On examination, right basilar crackles and a pleural rub may be heard. Plain films show atelectasis and blunting of the costophrenic angle. If the abscess ruptures into the pleural cavity, it usually occurs suddenly, collapsing the lung, filling up the pleural space, and whiting out the lung on chest x-ray. Treatment requires drainage of the pleural cavity with tube thoracostomy. If the abscess ruptures into the bronchi, this complication causes sudden onset of coughing with expectoration of copious brown sputum. Surgical intervention is not required, as the abscess is usually walled off from the pleural and peritoneal cavities. Postural drainage, bronchodilators, and antiamebic drugs may suffice.

Left lobe abscesses are more likely to involve the pericardium. Complications range from asymptomatic effusions, to cardiac tamponade, to intrapericardial rupture. If pericardial thickening or effusion is noted on imaging, some experts believe that this is an indication for aspiration of a left lobe liver abscess. When tamponade develops, aspiration of the pericardium, drainage of the liver abscess, and antiamebic drugs are indicated.[30] Cerebral amebiasis is seen in up to 8% of autopsies. These patients are severely ill from sepsis and may experience seizures.[25]

Outcome

The majority of patients with amebic liver abscess defervesce within 3–4 days of treatment[29]; however, if left untreated, amebic liver abscesses are often fatal. Mortality rates of 0–18% are reported, with higher rates occurring secondary to a delay in diagnosis, or when secondary bacterial infection or complications (abscess rupture) occur. Independent risk factors for mortality include serum bilirubin greater than 3.5 mg/dL, encephalopathy, hypoalbuminemia defined as less than 2.0 g/ dL, and the presence of multiple abscess cavities.[35] Abscess aspiration is a risk factor for secondary bacterial infection; however in recent reports, secondary bacterial infection rates have decreased from 10–20% to 0–4% (Table 43-8).

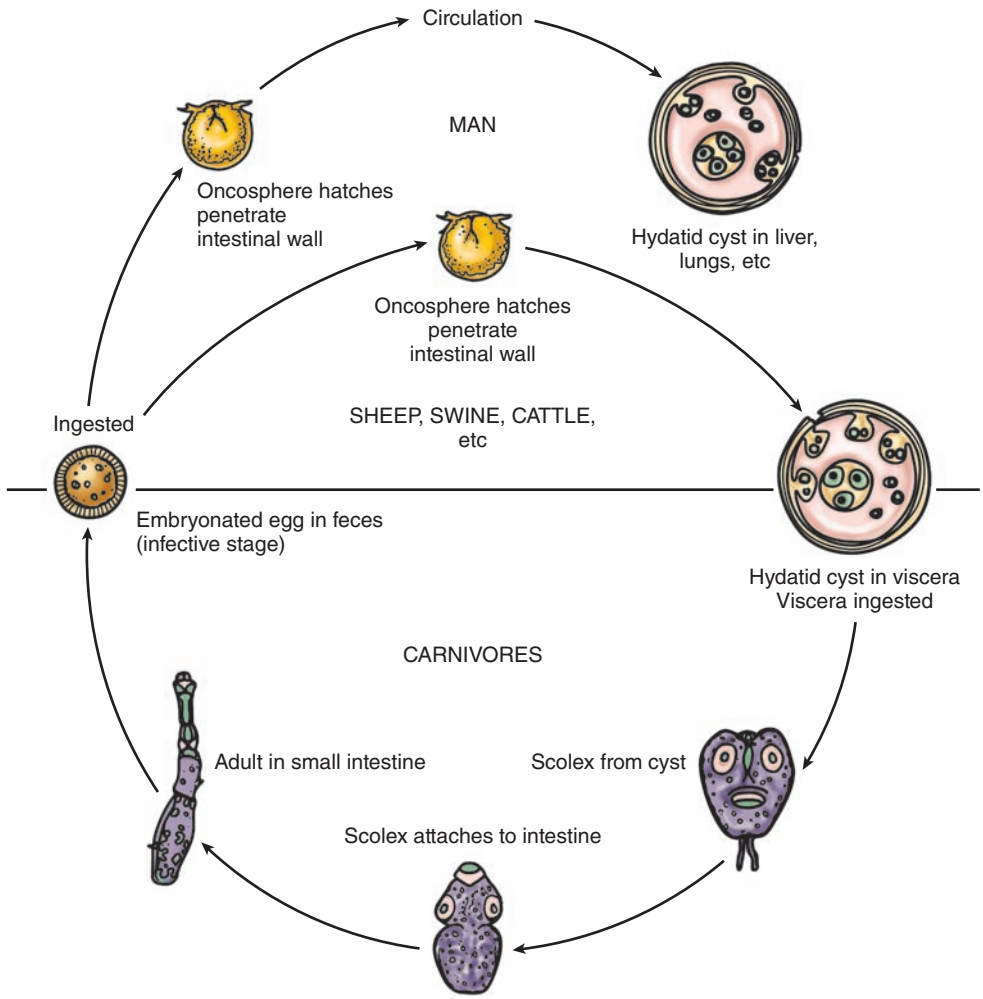

FIGURE 43-8 Life cycle of *Echinococcus granulosus.* (Modified from Melvin DM et al. *Common Blood and Tissue Parasites of Man. Life Cycle Charts*. Atlanta, Georgia: Center for Disease Control, 1979.)

HYDATID LIVER CYST

Echinococcosis (hydatid disease) is a zoonosis caused by the larval stage of *Echinococcus granulosus* (also known as *Taenia echinococcus).* Humans are accidental intermediate hosts, whereas animals can be both intermediate and definitive hosts. The two main types of hydatid disease are caused by *E. granulosus* and *E. multilocularis.* The former is commonly seen in the Mediterranean, South America, the Middle East, Australia, and New Zealand, and is the most common type of hydatid disease in humans.[36] In humans, 50–75% of the cysts occur in the liver, 25% are located in the lungs, and 5–10% distribute along the arterial system. Infection with echinococcal organisms is the most common cause of liver cysts in the world.[37]

Etiology

The life cycle of *E. granulosus* has two hosts. The definitive host is usually a dog or some other carnivore. The adult worm of the parasite lives in the proximal small bowel of the definitive host attached by hooklets to the mucosa. Eggs are released into the host's intestine and excreted in the feces. Sheep are the most common intermediate host, and these animals ingest the ovum while grazing. The ovum loses the protective chitinous layer and is digested in the duodenum. The released hexacanth embryo (oncosphere) passes through the intestinal wall into the portal circulation and develops into cysts within the liver. The definitive host eats the viscera of the intermediate host to complete the cycle (Fig. 43-8).

Humans may become intermediate hosts through contact with the definitive host (usually a dog) or by ingestion of contaminated water or vegetables. Once in the liver, cysts grow to 1 cm in the first 6 months and 2–3 cm annually thereafter. Once the parasite passes through the intestinal wall into the portal venous or lymphatic system, the liver is the first line of defense and thus is the most frequently involved organ.

Incidence

The incidence of hydatid liver cysts in the United States is approximately 200 cases per year, with an increased frequency in immigrant populations. Hydatid liver disease affects all age groups, both sexes equally, and no predisposing pathologic conditions are associated with infection. Public education about the life cycle and transmission of the disease has helped decrease the incidence. Washing hands after contact with canines, eliminating the consumption of vegetables grown at ground level from the diet, and stopping the practice of feeding entrails of slaughtered animals to dogs have all aided in decreasing the incidence of the disease.[9]

Pathology

Hydatid liver cysts tend to expand slowly and without symptoms and are thus frequently very large on presentation. Single lesions are noted in 75% and are predominantly located within the right lobe (80%).[36] Even though the lesion is single, half contain daughter cysts and are multilocular.

The typical hydatid cyst has a three-layer wall surrounding a fluid cavity. The outer layer is the pericyst, a thin, indistinct fibrous tissue layer representing an adventitial reaction to the parasitic infection. The pericyst acts as a mechanical support for the hydatid cyst and is the metabolic interface between the host and the parasite. As the cyst grows, bile ducts and blood vessels stretch and become incorporated within this structure. This explains the biliary and hemorrhagic complications of cyst growth and difficulties with resection. Over time, the pericyst calcifies.[9]

The outer layer of the cyst itself is the ectocyst or laminated membrane and is bluish-white, gelatinous, and about 0.5 cm thick. This membrane is a cuticular chitinous structure without nuclei and acts as a barrier for bacteria and an ultrafilter for protein molecules.

The inner layer or endocyst is the germinal membrane, responsible for the production of clear hydatid fluid, the ectocyst, brood capsules, scoleces, and daughter cysts. The endocyst is 10–25 μm thick and attached tenuously to the laminated membrane. The absorptive function of the inner layer is important for cyst nutrition. The inner layer also has a proliferative function producing the ectocyst and scoleces.[38] This germinal layer forms small cellular masses that give rise to brood capsules, in which future worm heads develop. They enlarge and develop into invaginated protoscoleces with four suckers and a double row of hooks—a protoscolex. The protoscolex fully differentiates and matures attached by a pedicle to the capsule wall. Brood capsules and freed protoscoleces are released into the fluid of the original cyst and together with calcareous bodies, form hydatid sand.

Hydatid sand is made up of around 400,000 scoleces per milliliter of fluid. The protoscolex can differentiate in two directions. In the definitive host, the scolex becomes an adult tapeworm. In the intermediate host, including humans, each of the released protoscoleces is capable of differentiating into a new hydatid cyst. Development of brood capsules from the germinal layer indicates complete biologic development of the cyst, which occurs after 6 months of growth.

Daughter cyst formation is a defense reaction. Hydatid cysts in humans are long-standing, large, and liable to injury. Any injury may cause daughter cyst formation. Daughter cysts are replicas of the mother cyst, and their size and number are variable. In uncomplicated cysts, the cyst cavity is filled with sterile, colorless, antigenic fluid containing salt, enzymes, proteins, and toxic substances.[38] The formation of daughter cysts is called *endogenic vesiculation*.

Ectogenic vesiculation occurs when a small rupture or defect in the laminated membrane occurs and the germinal layer passes through and creates a satellite hydatid cyst. This process is uncommon in *E. granulosus* but is characteristic for the larval stage of *E. multilocularis.* Because the liver parenchyma in humans cannot sequester *E. multilocularis* and the process of ectogenic vesiculation is fulminant, multiple vesicles are formed in all directions. The infected parenchyma has a multilocular appearance, and the center becomes necrotic, spongy, and filled with a gelatinous fluid similar to that of a mucoid liver carcinoma. Hepatic insufficiency is common and the disease is often lethal.[38]

Diagnosis

The diagnosis of uncomplicated hydatid liver cyst depends on the index of clinical suspicion. Most uncomplicated cysts are asymptomatic. Symptoms may arise due to a toxic reaction from the presence of the parasite or local mechanical effects.

CLINICAL PRESENTATION

The clinical features of hydatid liver disease depend on the site, size, stage of development, whether the cyst is alive or dead, and whether the cyst is infected.[38] Pain in the RUQ or epigastrium is the most common symptom, whereas hepatomegaly and a palpable mass are the most common signs. Nonspecific fever, fatigue, nausea, and dyspepsia may also be present[39] (Table 43-9). Approximately one-third of patients will have eosinophilia, and only 20% will present with jaundice and hyperbilirubinemia.

SEROLOGY

No single biochemical test definitively establishes the diagnosis. The Casoni and Weinberg tests are no longer used owing to their low sensitivities. Determination of specific antigens and immune complexes of the cyst with enzyme-linked immunosorbent assay (ELISA) give a positive result in more than 90% of patients. Specific IgE antibodies are demonstrated with ELISA and radioallergosorbent test (RAST) if active disease is present. The arc 5 antibody test involves precipitation during immunoelectrophoresis of the blood of patients with the antigen. Positivity for this test is 91%. Sbihi and colleagues[40] reported that purified fractions enriched in antigens 5 and B and glycoproteins from hydatid fluid yielded a sensitivity of 95% with a specificity of 100%.

RADIOLOGY

Chest radiographs may show an elevated diaphragm and concentric calcifications in the cyst wall, but they are of limited value. Ultrasound and CT are considered the first choice for imaging (Figs. 43-9A through 43-9D). Classic findings of hydatid cysts are calcified thick walls, often with daughter cysts.[41] Ultrasound defines the internal structure, number, and location of the cysts and the presence of complications. The specificity of ultrasound in hydatid disease is around 90%.[39] The classification proposed by Gharbi and associates[42] provides a morphologic description. Type I has a pure fluid collection. Type II has a fluid collection with a split wall (floating membrane). Type III reveals a fluid collection with septa (honeycomb image). Type IV has heterogenous echographic patterns and type V has reflecting thick walls. Differential imaging characteristics of hepatic cysts is presented in Table 43-10.

CT gives similar information to ultrasound, but more specific information about the location and depth of the cyst within the liver. Daughter cysts and exogenous cysts are also clearly visualized, and cyst volume can be estimated. CT is imperative for operative management, especially when a laparoscopic approach is used.[39] MRI provides structural details of the hydatid cyst, but adds little more than ultrasound or CT, and is more expensive. Endoscopic retrograde cholangiopancreatography (ERCP) may show communication between the cysts and bile ducts and can be used to drain the biliary tree before surgery. The routine use of ERCP is advocated by some to completely define the bile duct anatomy and to visualize any clinically silent connections between the bile ducts and cysts.[41]

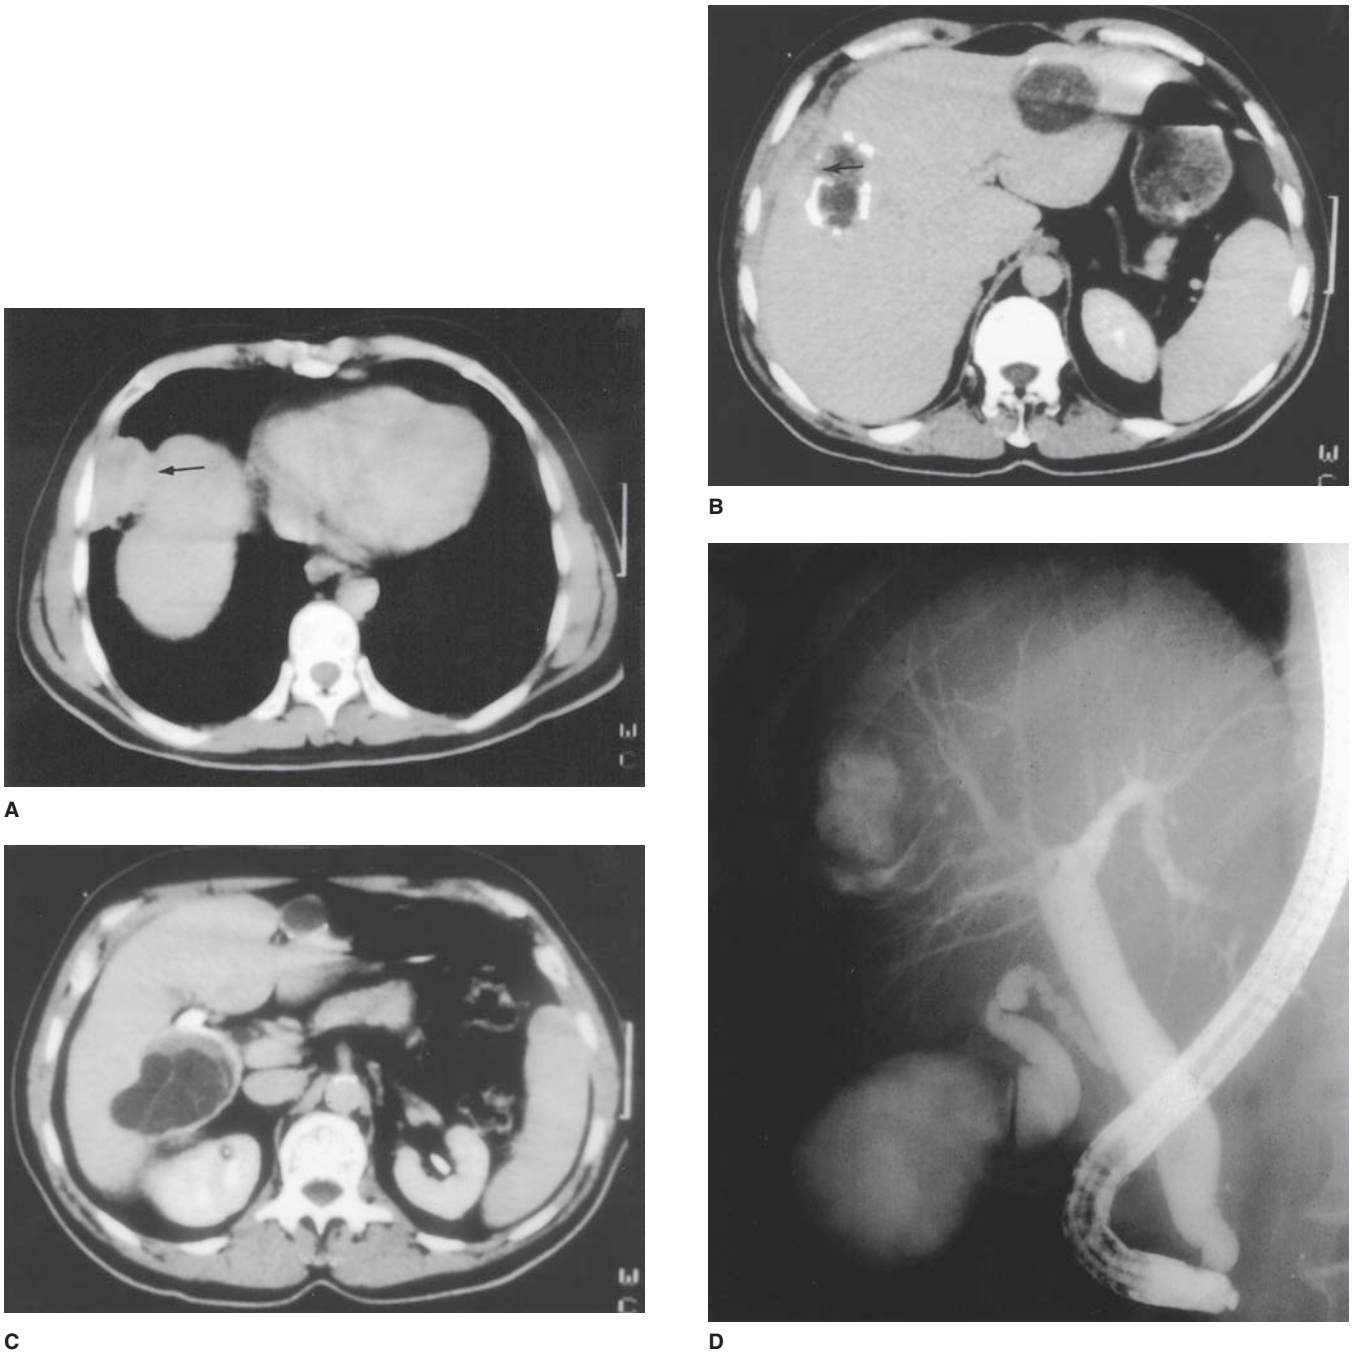

FIGURE 43-9 **A.** CT scan demonstrating rupture of hydatid cyst through the diaphragm (*arrow*) into the pleural space. **B.** CT scan in the same patient demonstrating a heavily calcified hydatid cyst (*arrow*) with diaphragmatic penetration and a lightly calcified cyst on the left. **C.** CT scan in the same patient showing a third calcified cyst near the gallbladder fossa and a small superficial fourth cyst on the left. **D.** Endoscopic retrograde cholangiopancreatography (ERCP) in the same patient demonstrating biliary communication in the cyst that also penetrates the diaphragm.

Treatment

Most echinococcal cysts are asymptomatic on presentation, but potential complications such as pulmonary infection, cholangitis, rupture, and anaphylaxis give good reason to consider treatment for all. Medical, surgical, and percutaneous approaches may be part of the treatment armamentarium.[41] Small cysts (<4 cm) located deep in the parenchyma of the liver, if uncomplicated, can be managed conservatively.[39] Basic principles include (1) eradication of the parasite within the cyst, (2) protection of the host against spillage of scoleces, and (3) management of complications.[41]

TABLE 43-10: DIFFERENTIAL IMAGING AND CHARACTER OF HEPATIC CYSTS

	Pyogenic	Amebic	Hydatid	Congenital	Cystadenoma
Number	Single or multiple	One or few	Usually single	Single or multiple	Single with loculations
Wall thickness	Thick	Thick	Thick	Thin	Variable
Wall character	Uniform or multiloculated	Usually uniform	Uniform, daughter cysts; 50% calcified	Uniform	Septations common may be irregular
Cyst contents	Usually pus with blood	Red-brown; like anchovy paste	Clear or bilious; gelatinous	Usually clear water density	Usually green-brown mucinous

ANTIHELMINTICS

Medical therapy for echinococcosis is limited to the benzimidazoles (mebendazole and albendazole) and used alone is only 30% successful. Albendazole is readily absorbed from the intestine and metabolized by the liver to an active form. Mebendazole is poorly absorbed and is inactivated by the liver. Albendazole is thus the drug of choice for medical therapy. Greater success rates may be seen in extrahepatic manifestations of the disease and with the alveolar form caused by *E. multilocularis*. Given for at least 3 months preoperatively, albendazole reduces the recurrence rate when cyst spillage, partial cyst removal, or biliary rupture has occurred. Duration of therapy in these instances is at least 1 month.[41]

PERCUTANEOUS ASPIRATION AND DRAINAGE

Surgical dictum has stated that percutaneous puncture of a hydatid cyst is a dangerous and contraindicated activity. It was believed that the risk of anaphylaxis, communication with the biliary tree, and spillage outweighed any potential advantages. In 1983, Fornage[43] challenged this axiom and reported an accidental puncture of a hydatid cyst by US that had no clinical consequences. Many successful reports followed thereafter.[38,44] The most frequently used protoscolecidal agents for percutaneous treatment are 15–20% saline, 95% ethanol, a combination of 30% saline and 95% ethanol, and mebendazole solution. PAIR technique stands for *p*uncture of the cyst wall, *a*spiration of cyst content, *i*njection, and *r*e-aspiration of a scolecoidal agent. PAIR involves initial puncture of the cyst under ultrasound or CT guidance, aspiration of cyst content, injection of contrast material to opacify the cyst, infusion of scolecoidal drug, followed by povidone-iodine infusion. The catheter stays clamped for 30 minutes, and then povidone-iodine is infused again. The catheter is preserved for drainage. Except in the case of povidone-iodine infusion, aspiration can be followed by sclerotherapy or infusion of alcohol or a scolecidal such as albendazole. Recently, a modified PAIR technique was created to introduce concomitant evacuation of cyst contents while infusing scolicidal agent via a specially designed coaxial catheter system. The simultaneous aspiration/infusion process allows almost complete washout of cyst content, reducing chances of any scoleces surviving, and the maintenance of the intracystic pressure minimizes risk of biliary fistula formation.[45] The PAIR technique has been combined with albendazole therapy with 70% success rates and a low rate of recurrence. In 1997 Filice and Brunetti[46] reported a series of 163 patients with 231 cysts treated percutaneously. No complications were reported and long-term results were good.

Indications for percutaneous treatment of liver hydatid cysts include types I and II cysts; types III and IV cysts with drainable material; suspected fluid collections; infected hydatid cysts; inoperable patients; pregnant women; and patients with multiple, disseminated, or symptomatic cysts. Contraindications include subgroups of types III and IV (hydatid cysts with heterogeneous echo pattern), ruptured liver cysts into the biliary system or peritoneum, cysts inaccessible to puncture, and children younger than 3 years. Type V cysts are not eligible for any intervention other than simple follow-up. Recurrence rates vary between 0 and 4%. Overall complication rates in percutaneous drainage range from 15 to 40%. Major complications (anaphylactic shock) are rare (0.1–0.2%). Minor complications (urticaria, itching, hypotension, fever, infection, fistula, rupture into the biliary system) range from 10 to 30%. Cyst-biliary complications after PAIR and caused by cyst decompression can be handled endoscopically or by cyanoacrylate infusion. Cholangiography or ERCP is recommended before any attempt for percutaneous drainage to inject contrast material and make any communication visible. Overall mortality rates are as low as 0.1%.[45]

Despite these reports, percutaneous treatment is not benign. Spillage, anaphylaxis, and recurrence can be life threatening. Complete aspiration of all cyst contents, especially multivesicular disease, is difficult, and complete sterilization with protoscolecidal agents is uncertain. If the protoscolecidal agent enters the biliary tree, serious damage also can occur within the liver. Exogenous vesiculation may also go undiscovered. Long-term results are unknown.[38]

SURGERY

Surgery remains the treatment of choice for uncomplicated hydatid disease of the liver, although there is much debate about the most appropriate surgical technique that can offer

total extirpation of the parasites with minimal postoperative complications.[45] The objectives of surgical treatment are to (1) inactivate the scoleces, (2) prevent spillage of cyst contents, (3) eliminate all viable elements of the cyst, and (4) manage the residual cyst cavity. The surgical procedure varies from a radical resective open approach (pericystectomy or hepatic resection) to a conservative approach (drainage or obliteration of the cavity or both) that can potentially even be done laparoscopically[39] (Fig. 43-10). One of the most important end points of hydatid cyst surgery may be recurrence. Dissemination of protoscoleces-rich fluid during surgery and incomplete removal of the germinative membrane from the cyst cavity is a major cause of recurrence (8.5–25%) of postoperative cases.[47]

Scolicidal Agents. Early on, surgical management of hydatid cysts via cyst evacuation resulted in a high rate of peritoneal implantation. This problem prompted the use of scolicidal agents for injection into the cyst and for use in the surrounding peritoneum. Formalin, hypertonic saline, chlorhexidine, cetrimide, hydrogen peroxide, polyvinylpyrrolidone-iodine,

FIGURE 43-10 **A.** Open-cyst evacuation demonstrating cyst aspiration (*upper left*), removal of daughter cysts (*upper right*), resection of active cyst lining (*lower left*), and packing with omentum (*lower right*). **B.** Pericystectomy demonstrating removal of a calcified pericyst (*top right*), closure of a small bile duct (*middle left*), and closure of the cavity over a drain (*lower right*). (Reproduced, with permission, from Cameron JL, Sandove C. *Atlas of Surgery.* Philadelphia, PA: BC Decker; 1990:215–221.)

silver nitrate, and ethyl alcohol are among some of the many agents that have been used.[39,41,45] However, formalin caused sclerosing cholangitis when it entered the biliary tract. Hypertonic saline has to be used carefully to avoid biliary injection and hypernatremia. The safety of the other agents in the biliary tree has not been established. No agent should be injected pre-evacuation due to high intracyst pressure. The World Health Organization (WHO) regards the use of scolicidal agents for intraoperative killing of infectious material as questionable, as there is no agent that is both effective and safe. According to WHO, ethanol (70–95%), hypertonic saline (15–20%), and cetrimide solution (0.5%) are deemed substances with relatively low risk.[47] Recently, chlorhexidine gluconate 0.04% (Chx-Glu) was found to be nontoxic, without harmful effects on the biliary tract, and is not affected by dilution in the cyst fluid. In addition, Chx-Glu is commonly available, easily prepared, inexpensive, and was 100% effective on protoscoleces and germinative membrane, and may become the preferred scolicidal in the future.[47]

Open-Cyst Evacuation. The safest surgical approach is open-cyst evacuation. Peripherally located cysts are the most easily treated, and either abdominal or flank approaches may be used depending on cyst location. Before opening the cyst, the field is lined with hypertonic (20%) saline-soaked gauze to guard against spillage. The cyst is then opened, and the contents are aspirated with a suction device that is capable of generating high negative pressures. The cyst is then opened completely, and any remaining debris is meticulously cleared. The cavity may then be irrigated with a scolicidal agent.[41] Recurrence rate of this procedure is 10–30%.[45]

Laparoscopic Cyst Evacuation. Peripherally located echinococcal hepatic cysts may be safely managed by laparoscopic cyst evacuation.[48] The lesions best suited for this approach are situated anteriorly and do not have thick calcified walls. A right lateral approach also works for cysts in segments VI and VII. A trocar (11 mm) is inserted just above the cyst, and 10% povidone-iodine–soaked sponges are placed as the scolicidal agent. The cyst is aspirated with a 14-gauge needle. The endocyst then shrinks back from the wall and rests at the bottom of the cyst. The 11-mm trocar is then exchanged for an 18-mm trocar, and the germinal membrane is aspirated. The laparoscopic camera is inserted directly into the cyst to explore for residual daughter cysts or biliary fistulae. The remaining cavity is irrigated with 20% saline solution, and the cyst wall is excised. The cavity may be plugged with omentum or closed over a closed-suction drain.[48]

The most difficult part of the laparoscopic approach is the initial cyst puncture and aspiration of the cyst fluid. Indications for laparoscopic excision of liver echinococcosis have changed over the years. Currently, the only excluding criteria for laparoscopic intervention include deep intraparenchymal cysts or posteriorly situated cysts, more than three cysts, and cysts with thick and calcified walls. Postoperative morbidity ranges from 8 to 25% and morality in most series is 0% with recurrence rates of 0–9% (vs 12–63% morbidity, 0–3% mortality, and 0–30% recurrence in open series). Major complications (ie, anaphylaxis) are, however, more common in laparoscopic interventions as a result of peritoneal spillage during debridement and removal of cyst contents. Major drawbacks to the comparison of laparoscopic versus open procedures include the small studies, lack of randomization, and bias related to careful selection of laparoscopic candidates.[45]

Pericystectomy. Pericystectomy involves complete resection of the cyst wall without entering the cyst cavity. This procedure is done through a plane outside of the pericyst or along the cyst wall itself. Preoperative localization of the bile ducts and vascular system is imperative. If a bile duct connection is suspected, preoperative ERCP should be obtained. Intraoperative ultrasound should be used. Pericystectomy decreases the risk of spillage of cyst contents into the peritoneal cavity and also lowers the risk of recurrence. The disadvantage to this approach is the potential for bleeding and/or damage to bile ducts in proximity to the cyst wall.[41] Gunay and associates[37] reported 0% recurrence rates, a lower incidence of biliary fistulae, and shorter hospitalization compared with more conservative procedures. The procedure also precludes management of the cavity and facilitates detection of recurrence.

Liver Resection/Transplantation. Some experts have argued that formal resection for benign disease is excessive and unnecessary, whereas others have stressed that resection is very safe. Multiple cysts within proximity to a major blood supply or to each other, or a cyst in a relatively safe location (ie, segments II/III) are candidates for resection provided a complete resection can be achieved. *E. multilocularis* infection may also lead to fulminant hepatic failure from sclerosing cholangitis, biliary sclerosis, or Budd-Chiari syndrome, and in these rare cases orthotopic liver transplant may be necessary.[41] Among these various treatment options, criteria for uncomplicated and complicated patients are presented in Table 43-11. A recent study also discovered lymphatic spread of larval *E. multilocularis* from the liver to regional lymph nodes and suggests the routine removal of regional nodes to reduce the risk of persistent infection.[49]

Complications

Complications from hydatid cysts are seen in one-third of patients. Most commonly, the cyst ruptures internally or externally, followed by secondary infection, anaphylactic shock, and liver replacement, in order of decreasing frequency.[37] Viable hydatid cysts are space-occupying lesions with a tendency to grow. In confined areas such as the CNS, even small cysts can cause severe symptoms. In less confined areas, symptoms depend on the site and size of the cyst. Symptoms result from direct pressure or distortion of neighboring structures or viscera. Compressive atrophy of the surrounding hepatocytes and

fibrosis occurs, and these cysts may grow to such an enormous size that they replace an entire lobe.

As the cysts enlarge, they may also rupture. If rupture of only the endocyst occurs, the content is retained within the pericyst. A communicating rupture is a rupture into the biliary or bronchial tree.[38] Hydatid liver cysts cause compression of the biliary system leading to decubitus lesions and biliary communication in up to 80% of cases. This communication may be very difficult to find and result in biliary leakage/fistulae postoperatively. Bile leakage is the main source of cavity-related complications in conservative surgery. If not properly drained, this may result in abscess or bile peritonitis. If drained effectively, an external biliary fistula may develop. From 12 to 33.3% with biliary fistulae require biliary drainage postoperatively and rates are higher in conservative versus radical surgery. The complication rates for radical surgery range from 17 to 20%. Retention cysts in conservative surgery may lead to misdiagnosis of early recurrence and result in unnecessary operations.[50]

A free rupture occurs when hydatid contents rupture throughout the peritoneal, pleural, or pericardial cavity. Acute symptomatic rupture into the peritoneal cavity occurs in 1–4% of patients and may precipitate anaphylactic shock.[38]

Outcome

Medical therapy alone results in recurrence rates of 70–80% and is not recommended. Medical treatment is used in combination with a drainage procedure or in patients who are not surgical candidates. Uncomplicated cases that undergo open surgical, laparoscopic, and percutaneous drainage have recurrence rates around 10%. Early local recurrence and cavity-related complications are the main problems affecting the success of the surgical management of hydatid liver disease. These problems are rare for complete resections due to complete removal of the cyst wall containing the germinal epithelium and daughter cyst. Conservative operations are easier and safer but are associated with a high incidence of local recurrence (10%) and cavity-related complications (37%). Older cysts have an increased risk of exogenic daughter cyst formation, which is an important risk factor for early local recurrence. Another important risk factor for early local recurrence, especially in conservative surgery, is pre- and intraoperative undetected satellite cysts that exist around pericysts or exogenic vesiculations. Because the disease is endemic to many locations, the potential for reinfestation remains, so long-term serologic and imaging studies are necessary. Rupture into the pleural or peritoneal cavity portends a recurrence rate of up to 25%.[41]

Uncomplicated cases undergoing elective procedures such as laparoscopic or percutaneous cyst aspiration should have morbidity rates between 15 and 30% and essentially no mortality. In patients with complicated disease that requires open evacuation, pericystectomy, or resection, morbidity is as high as 50%; however, mortality should still remain less than 5%. Septic shock, peritoneal rupture, and comorbid conditions (ie, malnutrition) play a major role in increasing mortality rates.

CONGENITAL LIVER CYSTS

Simple

The incidence of simple hepatic cysts in 1695 patients referred for abdominal or pelvic ultrasound was 2.5% with a sharp increase noted at the age of over 60 years.[51] In a separate European study[52] of more than 26,000 patients undergoing upper abdominal ultrasound, simple cysts were found in 2.8%, and most (>92 %) were over the age of 40. The female to male ratio was 1.5:1.

Solitary benign cysts are believed to be congenital and thought to arise from abnormal development of intrahepatic bile ducts in utero. The aberrant ducts enlarge slowly and may result in symptoms later in life. In a study from the Mayo Clinic[53] from 1907 through 1971, only 24% of simple cysts were symptomatic, and they usually became symptomatic in the fourth or fifth decade of life. Abdominal pain and mass were noted most frequently and were present in

more than 50%. Less commonly, symptoms were related to mass effect, resulting in nausea, vomiting, early satiety, and jaundice. Physical examination revealed hepatomegaly or a palpable abdominal mass. Laboratory values should be normal, but occasionally hyperbilirubinemia may be seen. Simple solitary cysts are bluish in color, and contain clear, straw-colored fluid. Echinococcal disease should be ruled out by serology.[54]

Ultrasound is the most accurate imaging modality, with greater than 90% sensitivity and specificity. On ultrasound, the cysts appear as anechoic masses with smooth margins and thin, imperceptible walls. Ultrasound also differentiates between cystic and solid lesions and can assess for intra- and extrahepatic biliary dilation in the jaundiced patient. CT imaging reveals nonenhancing, fluid (water) density lesions with a thin, uniform wall (Fig. 43-11). On MRI, simple cysts are well-circumscribed lesions that are hypointense on T1-weighted images and hyperintense on T2-weighted images.[52]

Most simple cysts are found incidentally and are asymptomatic, and 80–95% remain asymptomatic. In the setting of symptoms, percutaneous aspiration can aid in diagnosis but is associated with 100% recurrence within a 2-year period. If sclerosants are added, a 17% recurrence rate can be achieved.[54]

Success of surgical treatment for cystic liver disease is judged by relief of symptoms rather than by complete disappearance of the cystic lesion on imaging studies. Once the benign nature of the cyst is established, a permanent internal cyst "drain" is the mainstay of surgical therapy and complete cyst excision is not necessary.[55] If the cyst protrudes from the liver and no biliary connection is demonstrated, the accessible wall on the liver surface may be excised and the remaining cyst lining allowed to drain freely into the peritoneal cavity. If the cyst has a biliary connection, suspicion should be high that the lesion is a biliary cystadenoma rather than a simple cyst. In general, cyst excision or unroofing and resection have a 0–20% recurrence rate and a mortality rate of 0–5% (Table 43-12).[54]

  A. Aspiration with sclerosis
  B. Open surgery
    1. Partial unroofing
    2. Unroofing with resection
    3. Liver transplant

Unroofing the cyst by a laparoscopic approach can also be done with an overall success rate of more than 90% and a 10% rate of symptomatic cyst recurrence. Proponents of the laparoscopic approach report excellent exposure, less postoperative pain, and success rates similar to those of cases done open.[54] Gamblin et al reported the largest series of laparoscopic liver resections for cystic lesions that included 51 patients. The authors routinely left the back wall of the cyst behind and untreated. Patients experienced minimal postoperative pain, short hospital stays (median 2 days, range 1–11) resolution of symptoms (pain resolved in all), had a low recurrence rate (2 of 51 required reoperation), and no 90-day mortalities. Median follow-up was 13 months. A growing body of literature supports the equivalency of many laparoscopic and open procedures regarding outcomes and advantages in avoiding a laparotomy, especially in benign disease. These authors proposed minimally invasive cyst excision as the standard of care for management of these benign hepatic cysts.[56]

Polycystic

Polycystic liver disease (PCLD) is an autosomal dominant disorder, often found in association with polycystic renal disease (40%).[57] PCLD is the most frequent extrarenal manifestation of autosomal dominant polycystic kidney disease. It also exists in an autosomal dominant pattern that is not associated with polycystic renal disease, but may have cysts that develop in other organs in addition to the kidneys.

Cysts in PCLD are epithelial-lined growths arising from biliary epithelium that usually do not communicate with the biliary tree. The majority of patients are asymptomatic and do not require treatment. Their prognosis is directly related to the severity of the accompanying renal disease.[58]

If PCLD becomes symptomatic, it is usually secondary to hepatomegaly. Symptoms may include abdominal fullness, distention and pain, or bowel and biliary obstruction. Complications such as bleeding, infection, rupture, portal hypertension, and Budd-Chiari syndrome have been reported, but they are rare. Malignant transformation has been reported, but it infrequently occurs. Hepatic function is typically preserved, so progression to liver failure is uncommon.[58]

Routine imaging of cysts in PCLD is similar to that of simple cysts. Unenhanced CTs show multiple, homogenous, hypoattenuating lesions with a regular outline (Fig. 43-12). Contrast-enhanced CT images have no cyst wall or enhancement of cyst contents. MRI demonstrates very low-signal intensity on T1-weighted images and does not enhance after administration of gadolinium. Because the cyst content is purely fluid and homogeneous, high-signal intensity is demonstrated on T2-weighted images.[57]

Development of symptoms in PCLD is most often due to hepatomegaly, and therefore treatment needs to result in a reduction in liver size. Percutaneous aspiration with sclerotherapy may be used in those who are not surgical candidates or in lesions that are not surgically accessible, but long-term results of this approach are poor.

If a small number of large cysts exist, laparoscopic unroofing with the aid of intraoperative ultrasound may be successful. Deeper cysts may be accessed and unroofed through the back wall of more superficially located cysts. However, because the rigid architecture is found in PCLD, unroofing alone may not be enough to provide hepatic collapse and relief of symptoms. In addition, if too many cysts are unroofed, the peritoneum's absorptive capacity may be exceeded and cause ascites. Unroofing is not useful in patients with a large number of smaller cysts because it cannot be adequately performed.

A combination of cyst unroofing and liver resection may achieve the best results in terms of reducing liver volume. Resection should include the most cysts with the least loss of hepatic function. Morbidity for this approach is greater, but long-term results are improved. Orthotopic liver transplant is occasionally indicated if symptoms are disabling or hepatic function is compromised. If patients have associated renal failure, the liver transplant may be combined with renal transplant.[58]

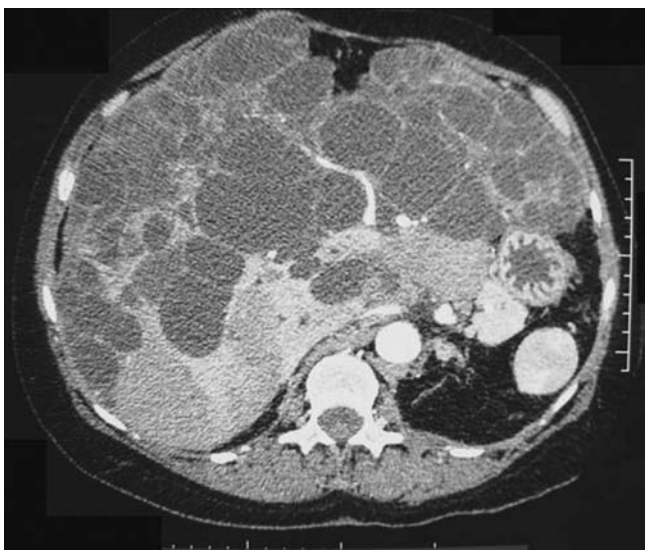

FIGURE 43-12 CT demonstrating polycystic liver disease (PCLD).

NEOPLASTIC CYSTS

Neoplastic cysts are acquired cysts that occur less commonly than simple cysts, usually in females, in the fifth decade of life. Their etiology is unknown. Cystic neoplasms are frequently large, resulting in abdominal discomfort and a palpable mass on examination. Cystic neoplasms appear as multiloculated lesions with papillary projections inside the cyst cavity. Invasion of the surrounding tissue suggests malignancy, as does the presence of a predominantly solid (vs cystic) component. Ten percent of neoplastic cysts are malignant. Definitive diagnosis requires intraoperative biopsy of the cyst wall. Incomplete resection will result in nearly 100% recurrence.[54]

Laboratory investigation is normal in most, although some patients present with elevated liver enzymes. Serum alpha-fetoprotein (AFP) and carcinoembryonic antigen (CEA) levels are usually normal. In some patients, CA 19-9 has been found to be elevated fivefold. In general, hemorrhagic cyst fluid suggests cystadenocarcinoma, whereas bilious or mucinous fluid suggests cystadenoma.[59]

Cystadenoma

Cystadenomas comprise less than 5% of all intrahepatic cysts of biliary origin.[60] Hepatobiliary cystadenoma with mesenchymal stroma occurs exclusively in young and middle-aged women and has potential to transform into cystadenocarcinoma. In contrast, hepatobiliary cystadenoma without mesenchymal stroma occurs in both sexes equally, at a mean age of 50, and has no clear association with cystadenocarcinoma.[59] These tumors are lined with columnar epithelium and frequently have papillary infoldings[60] (Fig. 43-13, negative path). If symptoms are present, they may include abdominal pain (60–80%), jaundice, cholangitis, fullness, or bloating.[1]

Cystadenomas have a septated, multilocular appearance on US and CT (see Figs. 43-13A through 43-13C).[54] CT will reveal well-demarcated cystic lesions, usually with internal septations; the walls are rarely calcified, and the presence of polypoid protrusions or wall excrescences should trigger the concern for cystadenocarcinoma.[1] MRI shows typical

features for a fluid-containing loculated mass with homogeneous low-signal intensity on T1-weighted images and homogeneous high-signal intensity on T2-weighted images. However, signal intensity of mucinous fluids varies depending on protein concentration. On T1-weighted images, the signal intensity may change from hypointense to hyperintense as protein concentration increases. On T2-weighted images signal intensity of mucinous fluids can decrease from hyperintense to highly hypointense with increasing protein concentration and viscosity. Blood products also have different signal characteristics on MRI. The distinction between cystadenoma and cystadenocarcinoma remains difficult on the basis of imaging findings alone as the presence/absence of septae, mural nodules, and papillary projections are variable between lesions. Magnetic resonance cholangiopancreatography (MRCP) does, however, appear helpful in evaluating the relationship of the lesion to bile ducts.[61] ERCP will usually demonstrate communication with the biliary tree, often at the proximal left hepatic duct.

Serum CEA and CA 19-9 levels are usually within normal ranges and cannot be considered as significant parameters to discriminate between malignant and benign liver tumors.[61] The diagnosis of intrahepatic biliary cystadenoma can be suggested on the basis of cyst fluid analysis (CFA), but this relies on adequate sampling and correlation with clinical and radiologic findings. CA 19-9 and CEA have been shown to be elevated in intrahepatic biliary cystadenoma and normal in simple cysts. Immunohistochemical analysis of intrahepatic biliary cystadenoma has shown the presence of CA 19-9 and CEA in the epithelium; however, the premalignant progression is based on the histologic presence of intestinal metaplasia characterized by the presence of numerous goblet cells. This has led to the recommendation that patients with suspected intrahepatic biliary cystadenoma based on CFA should undergo cyst wall sampling to determine whether a premalignant (intestinal metaplasia + atypia) or malignant diagnosis requiring resection exists.[62] Other authors, however, believe that percutaneous biopsy for preoperative diagnosis rarely produces a definitive diagnosis and the risk of peritoneal dissemination in the case of malignancy is prohibitive.

Neoplastic cysts with no signs of malignancy may be enucleated. This technique requires removal of the entire cyst, the cyst's surrounding wall, and a small rim of liver parenchyma.[54] Formal hepatic resection also is an appropriate treatment. Aspiration, sclerosis, marsupialization, and internal drainage must be avoided. Inadequate excision leads to recurrence in all cases[60] (Table 43-13).

Cystadenocarcinoma

Devaney and colleagues[63] divided cystadenocarcinoma (Fig. 43-14, positive path) into three subtypes: (1) cystadenocarcinoma with mesenchymal stroma arising from cystadenoma with mesenchymal stroma, occurring exclusively in females and following a relatively indolent course; (2)

cystadenocarcinoma without mesenchymal stroma not associated with cystadenoma, occurring in males and following an extremely aggressive course; and (3) cystadenocarcinoma without mesenchymal stroma, occurring in females and with a poorly understood clinical course.[64] Resection is the only appropriate treatment for malignant biliary cystadenocarcinoma.[54] With complete resection, the clinical course for cystadenocarcinoma is better than that for hepatocellular carcinoma or cholangiocarcinoma.[64] In the rare patient with a symptomatic cystadenocarcinoma with peritoneal metastasis, palliative unroofing of the cyst may be indicated.

TRAUMATIC CYSTS

In recent years, the management of hepatic trauma has undergone major changes. The frequent use of dual-phase CT imaging to assess patients with abdominal trauma has resulted in the detection of even the most minor of liver injuries. In the hemodynamically unstable patient, damage control laparotomy—the control of bleeding and contamination with packing off of the abdomen to postpone definitive treatment—has gained popularity, while formal anatomic hepatic resection has fallen out of favor. More and more American Association for the Surgery of Trauma grades IV and V liver injuries are also being managed nonoperatively. Mortality rates have fallen to 7–12%,[65] but a different set of management problems is being created. One such problem is the traumatic cyst.

Traumatic cysts are acquired cysts that occur from continued bile leakage from an injured intrahepatic bile duct after abdominal trauma. When an injured biliary structure continues to leak into a hematoma cavity, a cyst containing bile and blood may form.[54] These cysts lack a true epithelial lining and are considered pseudocysts (Fig. 43-15). Some traumatic cysts may resolve spontaneously,[58] while others may grow until compressive symptoms are caused. Presentation is typically delayed, and abdominal pain or fullness may occur months or sometimes years after the trauma.[54]

Because of the proximity of the right hepatic artery to the cystic duct, this artery is vulnerable to injury when the critical view of safety is not achieved during laparoscopic cholecystectomy. Combined injury to the bile duct and hepatic artery during laparoscopic cholecystectomy may result in development of intrahepatic abscess, recurrent cholangitis with

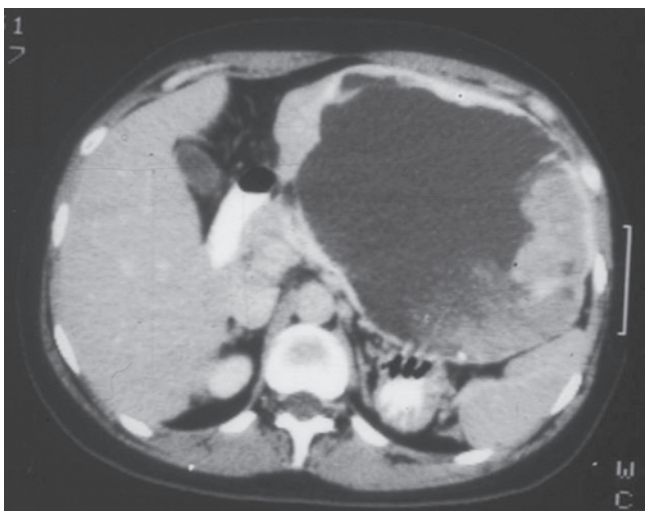

FIGURE 43-14 CT scan demonstrating a cystadenocarcinoma.

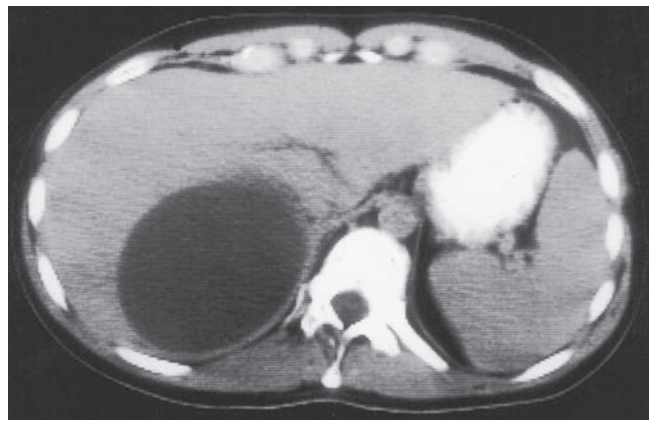
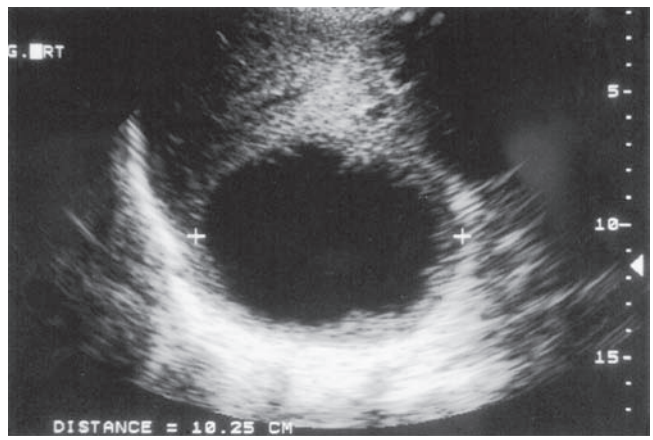


A



B

FIGURE 43-15 **A.** CT scan demonstrating a traumatic hepatic cyst 4 months after blunt liver trauma. **B.** Ultrasound in the same patient demonstrating a thickened cyst wall.

secondary biliary cirrhosis or ischemic necrosis, and atrophy of the liver.[66] The incidence of liver necrosis with or without abscess is reported as high as 75% in patients with combined biliary and arterial injury.[67] Patients with bile duct injuries after cholecystectomy should be evaluated for concomitant hepatic arterial injury and will frequently require hepatic resection to treat secondary biliary cirrhosis. An intact portal circulation is mandatory for oxygenation of the hepatic parenchyma when the hepatic artery has been injured; therefore portal blood flow must also be examined in any case of combined bile duct and hepatic artery injury following cholecystectomy. These combined portal and arterial injuries in the setting of bile duct injury tend to present earlier and often require formal hepatectomy.[68]

TREATMENT

Treatment is reserved for those who are symptomatic. Options include aspiration, unroofing, and excision. Bile leaks must be sought and controlled.[58] Small bilomas may be observed, whereas larger collections usually require percutaneous drainage at the time of diagnosis. Once the cavity is collapsed, spontaneous closure of the fistula is the rule.

BENIGN AND MALIGNANT PRIMARY LIVER NEOPLASMS

Clifford S. Cho • Yuman Fong

BENIGN LIVER TUMORS

Introduction

Benign tumors of the liver include hepatic hemangioma, hepatocellular adenoma, focal nodular hyperplasia (FNH), and other less common lesions arising from hepatic epithelial or mesenchymal tissues (Table 44-1). Benign tumors of the liver may be found in up to 20% of the population,[1] and are more than twice as common as malignant lesions. As a consequence of increased availability and utilization of abdominal computed tomography (CT) and magnetic resonance imaging (MRI), they are now being diagnosed with increasing frequency. Hemangiomas and FNH have an entirely benign natural history and therefore do not warrant resection; adenomas carry a risk of growth, hemorrhage, or malignant transformation and should be treated operatively. Correct identification of these lesions is therefore imperative, and establishment of a definitive diagnosis is often the primary challenge in managing this group of patients.

Diagnostic uncertainty is common, and has been reported to be the indication for operation in as many as 40% of patients undergoing resection.[2,3] Contemporary clinical, laboratory, and radiographic studies are often incapable of definitively distinguishing benign from malignant liver lesions. Symptoms, physical examination findings, and liver function tests are nonspecific. Tumor markers are normal in many patients with malignancy, and therefore should not be relied upon to identify a benign process. Hepatic ultrasonography is commonly employed, but often nonspecific. Currently, the most accurate radiographic modalities are CT and MRI. These are often complementary tests, and are usually diagnostic for hemangioma. MRI is becoming the diagnostic test of choice, with recent studies demonstrating an accuracy of 85–95%.[4] CT and MRI have traditionally been less helpful in distinguishing adenoma from FNH,[3,5] but recent advances in MRI contrast agents selectively excreted by hepatocytes suggest that use of such agents may permit reasonable differentiation of FNH, which retains contrast enhancement on delayed imaging, from adenoma, which does not.[6] Table 44-2 presents the MRI and CT characteristics of the more common benign lesions.

A liver biopsy may be indicated when noninvasive tests are not diagnostic. The precise indications for preoperative liver biopsy remain controversial; in our practice, liver biopsy is generally reserved for cases in which diagnostic uncertainty persists after a thorough clinical and radiographic evaluation. Biopsy may be performed by percutaneous or laparoscopic fine-needle aspiration (FNA) or core needle biopsy. The diagnostic accuracy of liver biopsy may be as low as 40%; therefore, the potential benefits of biopsy must be balanced against the risk of iatrogenic bleeding and the potential for tumor seeding of the peritoneal cavity if the lesion is malignant.[7,8] In a recent study from the Memorial Sloan-Kettering Cancer Center (MSKCC), 30 of 68 patients (44%) who underwent resection of a benign liver tumor had a preoperative percutaneous biopsy, but the preoperative biopsy provided the correct diagnosis in only 11 of the 30 cases (37%).[9]

Indications for resection of benign tumors include diagnostic uncertainty with a suspicion of malignancy, severe mass-related symptoms due to lesion size, and in the case of hepatic adenoma, the risk of hemorrhage, rupture, or malignant degeneration. The decision to resect is based on patient history, the radiographic appearance of the tumor, and the surgeon's clinical judgment. Because of the predominance of hemangioma, the majority of patients with benign liver tumors may be safely observed.[2,9] The safety of nonoperative management of asymptomatic patients with FNH or hemangioma was illustrated in a large study in which 388 patients diagnosed with either hemangioma or FNH by thorough radiographic evaluation were followed with observation alone.[2] After a median follow-up of 32 months, 87% of patients demonstrated complete stability in their tumor size, and no patients developed tumor rupture. Figure 44-1 presents a flow diagram of our basic management approach for presumed benign tumors of the liver.

When surgical resection is indicated, a variety of approaches can be considered. These approaches include open or laparoscopic resection or enucleation. When malignancy cannot be excluded, resection should be performed with a margin of

normal surrounding parenchyma. Resection is also necessary when the tumor lies deep within the liver, as enucleation is generally not feasible in this circumstance. Enucleation for benign tumors is often appropriate, and is our preferred approach for tumors known to be hemangioma.[10] Laparoscopic resection is appropriate for selected patients with benign tumors, with retrospective studies verifying the safety of laparoscopic subsegmental, segmental, and lobar resections.[11,12]

Hemangioma

EPIDEMIOLOGY AND ETIOLOGY

Hemangiomas are the most common benign tumors of the liver; autopsy series suggest that they may be present in up to 7% of the population.[13] Their pathogenesis is unknown. Hemangiomas of the liver may be associated with hemangiomas of other organs, and may be multifocal within the liver.[14] Recent data suggest that there is no difference in the incidence of liver hemangioma between men and women, and sex hormones do not appear to play a role in the growth of these lesions.[15,16] An updated review from MSKCC of 115 patients with liver hemangioma found that 35% of the patients were male.[10] A recent case-control study found no association between liver hemangioma and the patient's reproductive history or use of oral contraceptives.[15]

PATHOLOGY

The typical cavernous hemangioma is a red-blue, soft, spongy mass that usually measures between 1 and 2 cm in diameter. When these lesions are greater than 4 cm in size, they are

TABLE 44-2: RADIOGRAPHIC FEATURES OF BENIGN TUMORS OF THE LIVER

	Triphasic Contrast-Enhanced CT			MRI		
	Precontrast	Arterial Phase	Delayed Phase	T1	T2	Delayed Sequence
Hemangioma	Well-defined hypodensity	Peripheral nodular enhancement	Centripetal enhancement	Hypointense	Hyperintense	Centripetal enhancement
Focal nodular hyperplasia	Well-defined hypo/isodensity	Homogeneous enhancement	Increased scar uptake	Hypo/isointense	Isointense with possible increased scar signal	Retains gadobenate dimeglumine contrast enhancement
Hepatocellular adenoma	Isodensity; fat, hemorrhage or necrosis may be present	Homogeneous enhancement	Possible prolonged hyperdense enhancement	Mixed, may be hyperintense	Mixed, may be hyperintense	Does not retain gadobenate dimeglumine contrast enhancement

referred to as giant hemangiomas. Histologically, these lesions are sharply defined but not encapsulated, and are made up of large, cavernous vascular spaces partly or completely filled with blood separated by minimal connective tissue stroma. The amount of stromal tissue is variable, and some lesions may exhibit extensive areas of necrosis and fibrosis. Thrombosis is common, and dystrophic calcification may be present within the lesion.

The microscopic interface between a hemangioma and the surrounding liver parenchyma is one that has been well described, and may influence the ease with which they can be enucleated.[17,18] Zimmermann has described four distinct patterns of tumor-parenchymal interface: (1) a fibrous interface characterized by relatively avascular capsule-like fibrous lamellae, (2) an interdigitating interface characterized by a mixture of parenchymal and hemangioma components without a capsule-like interface, (3) a compression interface characterized by direct apposition between hemangioma and parenchyma, and (4) an irregular or spongy interface characterized by a highly irregular border with numerous parenchymal foci interspersed between dilated blood channels.[18] The fibrous interface is the most common interface in large hemangiomas, and the presence of this capsule-like avascular fibrous interface facilitates operative enucleation of these lesions.

DIAGNOSIS

Although cavernous hemangioma can be diagnosed by biopsy, percutaneous biopsies should be performed with caution because of their risk of hemorrhage and their suboptimal diagnostic accuracy. In a recent study from MSKCC, 8 of 55 patients (15%) resected for hemangioma underwent preoperative percutaneous biopsy.[10] The diagnosis of hemangioma was established by biopsy in only three of 13 patients (23%).

The diagnosis of hemangioma is most often rendered through the use of high-quality CT and MRI. Noncontrast CT images will reveal a well-defined hypodense mass that may contain areas of calcification or central scarring. Contrast-enhanced images using arterial and portal venous phase series will usually demonstrate a typical pattern of peripheral nodular enhancement (Fig. 44-2).[19,20] In a study of 38 patients with 50 liver hemangiomas, five specific CT criteria were found to be diagnostic of hemangioma: (1) a low-density lesion on an unenhanced scan, (2) early peripheral contrast enhancement, (3) progressive centripetal opacification from the periphery toward the center, (4) a delay of at least 3 minutes before total opacification, and (5) an eventual isodense appearance. In this study, 38 of the 50 lesions (76%) demonstrated all five criteria, and the presence of criteria 4 and 5 plus any other two criteria was considered diagnostic.[20]

When hemangioma is clinically suspected but CT fails to confirm the diagnosis, MRI should be performed. Hemangiomas typically exhibit hypointense signal intensity compared with the surrounding liver tissue on T1-weighted imaging, and hyperintense signal intensity on T2-weighted imaging. The pattern of gadolinium enhancement is similar to that seen on contrast-enhanced CT imaging. MRI may be more sensitive than CT in detecting subtle enhancement, and recent studies have demonstrated that MRI has a diagnostic accuracy as high as 96% for hepatic hemangioma.[4,21]

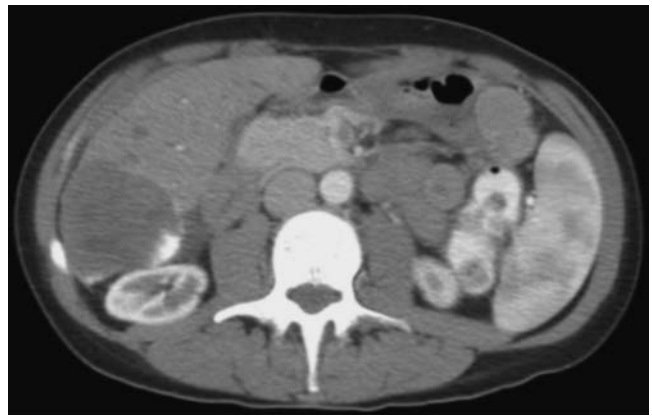

FIGURE 44-2 Arterial phase computed tomographic appearance of hepatic hemangioma of the right hemiliver. Note the nodular peripheral contrast enhancement.

Several other radiographic tests are available for the diagnosis of liver hemangioma, but are generally not indicated. Because of the accuracy of CT and MRI, Tc-99m-labeled red blood cell scans are infrequently necessary. However, in circumstances where both CT and MRI are not diagnostic, this test may be helpful and is certainly superior to ultrasound or even biopsy.[22] Use of positron emission tomography (PET) has also been described in the diagnosis of hepatic and peripheral hemangiomas.[10,23] Limited available data suggest that hemangiomas are not ^{18}F-fluorodeoxyglucose (FDG)-avid, suggesting that PET may be helpful in differentiating hemangioma from metabolically active malignancies.

TREATMENT

Most patients with hepatic hemangiomas should be managed nonoperatively. The natural history of these lesions is usually one of stability. Only rarely do patients develop symptoms attributable to hemangioma, and the onset of spontaneous rupture is reportable. Only 30 reports of spontaneous intra-abdominal rupture of hepatic hemangiomas have been cited in the literature.[24] Size alone should not be used as a criterion for resection, as recent reports have demonstrated that even large lesions may be safely managed nonoperatively.[2,25] In a recent study from the Netherlands, 38 of 49 patients discovered to have hepatic hemangiomas were followed nonoperatively. In this study, the median diameter of nonoperatively managed lesions was 6 cm. The median follow-up was 52 months, during which time no patient experienced a complication or developed symptoms attributable to the lesion.[25]

Three criteria we use as indications for resection of hemangioma are the presence of severe symptoms, an inability to confidently exclude malignancy, and the development of

complications. Controversy persists as to whether resection is advisable for symptom relief. Bismuth's group reported that 7 of 14 patients (50%) who underwent treatment of hemangioma for symptom relief had persistent symptoms following treatment, prompting them to advise caution against resection.[26] However, it should be noted that 6 of the 14 patients treated for symptomatic hemangioma underwent embolization or hepatic arterial ligation rather than surgical excision; of the seven patients with persistence of symptoms, five were from the embolization or ligation group. Data from MSKCC and others suggest that between 75 and 96% of carefully selected patients who undergo resection or enucleation for symptoms will have relief,[9,10,14,27,28] but it is imperative that these patients be carefully selected. Other pancreaticobiliary and upper gastrointestinal (GI) causes for the symptoms must be investigated, and the symptoms should be carefully matched to the size and nature of the hemangioma. Lesion size appears to be associated with the likelihood of symptoms. The median lesion size among patients resected for symptoms at MSKCC was 14 cm. In our experience, hemangiomas less than 4 cm in size are almost exclusively asymptomatic, and symptomatic lesions tend to be larger within the right hemiliver than within the left.[10]

Another indication for surgical resection of hepatic hemangioma is the development of tumor-related complications. As noted above, intra-abdominal hemorrhage is extremely uncommon, but when it does occur, it should be considered a life-threatening emergency treated with a combination of angiography with embolization and surgery. Intratumoral bleeding has been reported as a complication of hemangioma, and is often thought to be associated with the development of symptoms. Although this complication is not life threatening, onset of symptoms will often lead to diagnosis of the lesion and eventual surgical evaluation. Kasabach-Merritt syndrome is another complication of large hemangiomas characterized by thrombocytopenia and consumptive coagulopathy.[30] Its pathophysiology is thought to involve activation of the clotting cascade by platelets trapped within the hemangioma. Controversy exists as to the most appropriate intervention for this condition. Recommended treatments have included immunosuppressive agents, radiation, surgical resection, and even transplantation.[29,30]

When surgical intervention is indicated, both resection and enucleation have been advocated. Multiple studies have documented that the majority of cases are treated by enucleation.[10,27,31] In a recent study from MSKCC, enucleation was performed for 31 of 52 patients (60%) undergoing operative treatment for hemangioma.[10] We believe that this technique decreases both operative time and operative blood loss. In a recent analysis of 52 patients undergoing surgical resection of hemangioma, enucleation was associated with a lower rate of postoperative complications and a similar rate of transfusion.[31] Hepatic hemangioma is suited for enucleation because of its benign nature and the fibrous cleavage plane that often exists between the hemangioma and the surrounding hepatic parenchyma.

The technique for enucleation of hepatic hemangiomas has previously been described in detail.[10,32] In general, hepatic inflow control is initially achieved by use of the Pringle maneuver. The hepatic artery ipsilateral to the tumor is identified and dissected proximally to the level of the proper hepatic artery. For large lesions of the right or left hemiliver, ligation of the ipsilateral artery can result in some shrinkage in tumor size. Smaller lesions do not require arterial ligation and may be adequately devascularized with a more selective ligation of distal branch vessels. Once arterial inflow has been controlled, a small hepatotomy should be performed a few millimeters from the edge of the hemangioma. Division of this parenchyma will allow entry into the compressed sheath of liver tissue that usually defines the border between hemangioma and normal parenchyma. Gentle dissection within this sheath is usually possible, and small blood vessels or bile ducts encountered during parenchymal transaction can be easily controlled with clips or suture ligatures.

Focal Nodular Hyperplasia

EPIDEMIOLOGY AND ETIOLOGY

Focal nodular hyperplasia (FNH) presents as a nodule composed of benign-appearing hepatocytes within a liver that is otherwise histologically normal.[33] The second most common benign tumor of the liver, FNH typically presents as a solitary lesion and is often discovered incidentally. It occurs most commonly in young women, with a female-to-male ratio of 8:1. The average age of patients at the time of diagnosis is 35 years.[34]

The pathogenesis of this lesion is not well understood, but thought to be a reactive process to a vascular injury or malformation. The presence of large arteries within a central fibrous scar and the absence of portal venous structures are characteristic of FNH. Some have postulated that this abnormal vascular anatomy results in chronic malperfusion and secondary hyperplasia of the surrounding hepatocytes.[35] Controversy exists as to whether this lesion, or its natural history, is associated with the use of oral contraceptives.[36,37] Contemporary data suggest that neither the presence, size, nor number of lesions is influenced by the use of oral contraceptives. In an analysis of 216 women with FNH, oral contraceptive use and pregnancy were not associated with lesion growth.[38] During follow-up, only four lesions (2%) increased in size, and none of the 12 patients who became pregnant experienced growth or complications related to their lesion.

PATHOLOGY

FNH grossly appears as a discrete pale mass with lobulations and abundant septae. A thin capsule often surrounds the tumor, which is usually free of necrosis or hemorrhage. A central scar is characteristic of FNH. More than one central scar may be apparent, and dilated blood vessels are often

evident within the scar. These dilated vessels represent the large central arteries that are typical of this lesion.

Technically, FNH is not a neoplastic process, but a hyperplastic one. FNH is categorized into typical and atypical types. Typical, or classic FNH, is characterized by a central stellate fibrous region that contains abnormal arteries but not portal veins, and is multinodular with nearly normal-appearing hepatocytes and mildly proliferative bile ducts.[37] These bile ducts are generally located at the junction of the abnormal hepatocytes and fibrous regions. Atypical FNH are histologically classified as FNH, but do not exhibit one of the classic features of typical FNH; for example, they may lack a central scar, or may harbor a portal vein within the central vascular region. These atypical lesions have been further divided into three subtypes: (1) telangiectatic; (2) FNH with cytologic atypia; and (3) mixed hyperplastic or adenomatous FNH.[34,37]

DIAGNOSIS

FNH does not require surgical resection; therefore, it is critical to differentiate this lesion from other hypervascular lesions such as hepatocellular adenoma, hepatocellular carcinoma, and various metastatic lesions. Radiographic imaging is the current mainstay for diagnosis; however, percutaneous biopsy may be warranted in situations where radiographic diagnosis is not definitive.

Increased availability and recent improvements in contrast administration and image detection have resulted in increased utilization and accuracy of CT imaging for the diagnosis of FNH. The typical FNH will appear as a well-demarcated hypointense lesion on noncontrast images. In the arterial phase, the lesion will become uniformly hyperattenuating because of the homogenous enhancement of the entire lesion with the exception of the central scar. This pattern is similar to that of hemangioma; however, within an FNH, the enhancement is uniform throughout the lesion rather than from the periphery. In the portal phase, the lesion will become more isointense, and the central scar may show enhancement as a result of gradual diffusion of the contrast material into the fibrous scar.[39]

Currently, the most sensitive test for the diagnosis of FNH is MRI with gadolinium enhancement, which has reported sensitivity and specificity rates of about 75 and 98%, respectively.[6,37,40] In general, FNH is hypointense on T1-weighted images, and slightly hyperintense on T2-weighted images. Similar to CT findings, FNH will show brisk and homogenous enhancement with gadolinium. During later phases, the central scar will enhance and may even become hyperintense as contrast washes out of the lesion (Fig. 44-3). Other tissue-specific contrast agents have been recently investigated.[37] These agents are specific for Kupffer cells and hepatocytes and may further increase the ability to identify FNH with MRI.[6]

When imaging studies are equivocal, percutaneous biopsy may permit diagnosis of FNH in a majority of cases.[37] In one study, a histologic diagnosis of FNH was made by percutaneous biopsy in 58% of lesions with nondiagnostic radiographic imaging characteristics.[41] The typical FNH can be diagnosed with core biopsy when benign-appearing hepatocytes, a prominent arterial supply, absence of a portal vein, and peripheral bile duct hyperplasia are observed histologically.

TREATMENT

When the diagnosis of FNH is confirmed, treatment should be nonoperative in the vast majority of patients. FNH is not a neoplastic process, and cannot be considered premalignant. As noted above, growth of these lesions is uncommon, and does not clearly appear to be related to the use of oral contraceptives or pregnancy.[38] Therefore, resection should not be recommended as a prophylactic measure against tumor enlargement and rupture. Patients have on rare occasion been reported to present with symptoms attributable to FNH.[9,42] After careful diagnostic review, resection in such a setting may be warranted for highly selected cases. Subsegmental resections are generally preferable for FNH, and minimally invasive approaches should be considered.

Hepatocellular Adenoma

EPIDEMIOLOGY AND ETIOLOGY

Like FNH, hepatocellular adenoma also occurs predominantly in young women; however, unlike FNH, it is a neoplastic process that is clearly associated with the use of oral contraceptive

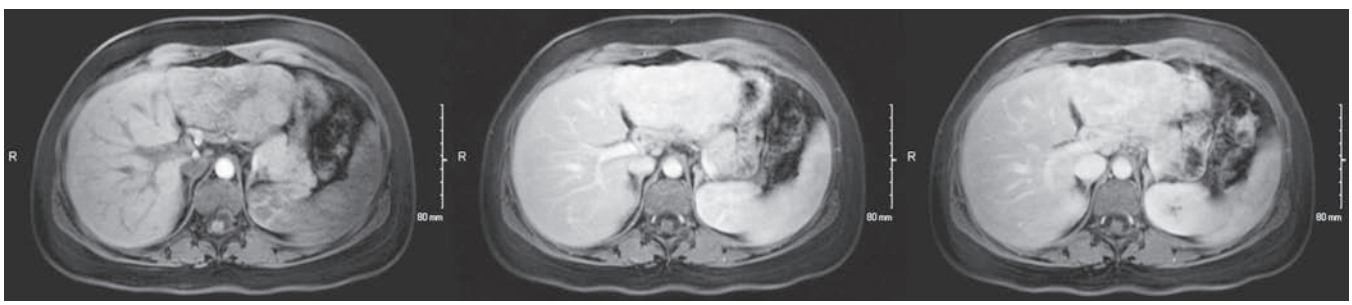

FIGURE 44-3 MRI appearance of a large left lateral section focal nodular hyperplasia. Note the gradual contrast washout from the lesion and enhancement of the central scar on delayed sequences.

pills (OCPs), as well as with type 1 glycogen storage disease and diabetes.[43] Hepatocellular adenoma was rarely reported before the introduction of oral contraception, and is believed to be four times more common in women who use OCPs compared with those who do not.[43] The risk of developing hepatocellular adenoma is proportional to the duration of OCP use; patients who have used OCPs for more than 9 years have a risk of developing hepatocellular adenoma that is 25 times that of the general population. Complications from hepatocellular adenoma have also been associated with the use of OCPs. A review of 237 patients found that those taking OCPs presented with larger tumors (97% >5 cm vs 75% >5 cm) and were more likely to present with tumor rupture or hemorrhage than those not taking OCPs (65 vs 25%).[44]

A majority of hepatocellular adenomas will be symptomatic at presentation, and complications associated with these lesions include tumor growth, rupture with intraperitoneal hemorrhage, and malignant transformation. The risk of rupture and intraperitoneal hemorrhage may be as high as 30–50%.[45,46] In a review of 54 patients with hepatocellular adenoma, 21 patients (39%) were diagnosed after the onset of hemorrhage into the tumor or peritoneal cavity, and only four patients (7%) had the lesion discovered incidentally.[47] In a recent multicenter retrospective analysis of 124 patients with hepatocellular adenoma, tumor rupture was reported in 31 cases (25%), and the risk of rupture was associated with increasing tumor size, recent OCP use, or hormonal replacement therapy (within 6 months). Average tumor size for nonruptured adenoma in this series was 7.2 cm, compared with 10.5 cm for ruptured adenoma.[48] When hemorrhage does occur, intra-abdominal blood may be observed in up to 60% of patients. Hepatocellular adenoma should be considered a premalignant condition. Published reports of patients who have been followed with serial radiographic studies have described the development of hepatocellular carcinoma within previous hepatocellular adenoma.[45,46,49] In these studies, an increase in the serum alpha-fetoprotein (AFP) level was found to be an indicator of malignant transformation.[45,46,49] In the aforementioned multicenter analysis of 124 patients with hepatocellular adenoma, malignancy was detected in 5 cases (4%).[48]

PATHOLOGY

Hepatocellular adenomas present as solitary lesions in approximately 75% of cases. Multiple adenomas are common in patients with glycogen storage disease or hepatic adenomatosis. Adenomas may vary from 1 cm to greater than 20 cm in size. Grossly, adenomas are sharply demarcated from the normal parenchyma and appear light in color. Unlike FNH, hemorrhage is commonly evident on gross examination.

Microscopically, adenomas consist of cords of cells that closely resemble normal hepatocytes; indeed, histologic differentiation between adenoma and normal liver tissue can be difficult. However, adenoma cells are larger than normal hepatocytes and may contain large amounts of glycogen and lipid.[50] Adenomas are devoid of bile ducts, and this key histologic feature helps to distinguish hepatocellular adenoma from FNH on biopsy. Hepatocytes within an adenoma are separated by dilated sinusoids that represent the arterial blood supply of the lesion which, like FNH, typically lacks a portal venous supply. Adenomas characteristically have little fibrous connective tissue support and generally lack a tumor capsule.

DIAGNOSIS

The most important diagnosis to exclude in the evaluation of hepatocellular adenoma is FNH, as their treatments are radically different. Hepatocellular adenomas are often first detected by ultrasonography during evaluation for right upper quadrant abdominal symptoms.[50] Adenomas are typically hyperechoic on ultrasound, which may be a result of their high lipid content. Other findings may include significant heterogeneity due to intratumoral hemorrhage, or calcifications due to hemorrhage and necrosis. These findings may identify the lesion, but are not specific enough to diagnose hepatocellular adenoma.

Multiphasic CT is more specific than ultrasonography for adenoma.[51] Nonenhanced images may identify areas of fat or hemorrhage that are typical of adenoma. The majority of adenomas will appear sharply demarcated and are hypo- or isoattenuating. Areas of old hemorrhage and necrosis will appear as discrete foci of hypoattenuation on nonenhanced imaging. Arterial phase contrast images may show some degree of peripheral enhancement due to the larger peripheral feeding vessels. However, approximately 80% of cases will show rapid homogenous enhancement.[50] Unlike FNH, contrast enhancement in adenoma usually does not persist due to a component of arteriovenous shunting (Fig. 44-4).

Findings on MR imaging have been reported to be more variable than those of CT.[50,52,53] Adenomas have been described as hyperintense, isointense, and hypointense on T1-weighted imaging.[52,53] Heterogeneity is again common, with regions of increased signal intensity occurring due to fat, hemorrhage, and necrosis. Inconsistency is also reported for T2-weighted imaging, but the majority of adenomas will be hyperintense relative to the liver on T2 imaging.[53] Dynamic gadolinium-enhanced MRI may also be used to demonstrate early arterial enhancement. Since adenomas have a scarcity of Kupffer cells, Kupffer cell–specific agents will result in decreased signal intensity on T2-weighted imaging.[53]

If diagnostic uncertainty persists after a thorough imaging evaluation, percutaneous biopsy should be considered, especially if the possibility of FNH remains within the differential diagnosis. Percutaneous FNA and core biopsy have been shown to be accurate in the diagnosis of hepatocellular adenoma.[43] As noted earlier, the absence of bile ducts within the lesion is one of the critical elements that differentiates FNH from hepatocellular adenoma.

TREATMENT

In general, patients with any size hepatocellular adenoma should undergo surgical therapy in order to prevent the risk of tumor growth and rupture, and to prevent the risk

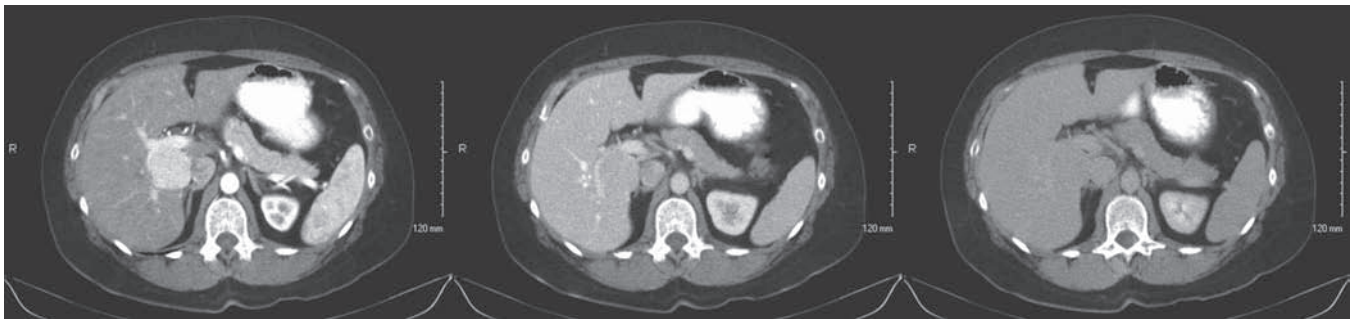

FIGURE 44-4 Computed tomographic appearance of hepatic adenoma of the right hemiliver. Note the rapid homogenous contrast enhancement seen on arterial phase images and rapid contrast washout seen on delayed images.

of malignant degeneration. Some have recommended initial discontinuation of OCP use with follow-up imaging to assess for evidence of regression.[9] This approach may be reasonable in selected patients, but it must be emphasized that regression is unpredictable, and continued growth, rupture, and malignant transformation even after discontinuation of OCPs have been reported.[43–45]

Miscellaneous Benign Tumors

NODULAR REGENERATIVE HYPERPLASIA

Nodular regenerative hyperplasia is an uncommon lesion associated with conditions of chronic liver disease. Cirrhosis and portal hypertension may be present in up to 50% of cases.[54] Radiographically, these lesions appear similar to FNH; however, portal venous phase images may show almost complete contrast washout, rendering these lesions almost imperceptible.[36] Given the rarity of this entity, their natural history is poorly understood, but tumor growth and rupture are extremely rare. Percutaneous biopsy can be obtained to confirm the diagnosis of nodular regenerative hyperplasia, which should be managed nonoperatively.

PELIOSIS HEPATITIS

Hepatic peliosis is an uncommon disorder histologically characterized by multiple, small, blood-filled sinuses. Peliosis occurs most commonly in immunocompromised transplant recipients, AIDS patients, and patients on long-term corticosteroid therapy.[55,56] Radiographically, they present as diffuse hypodense areas distributed throughout the liver. CT and MRI will typically show enhancement on early phase images, and may progress from central to peripheral enhancement on delayed imaging.[57] Rupture with intraperitoneal hemorrhage has been reported from this condition.[58,59] The optimal treatment for bleeding from this lesion has been angiographic embolization. As this is a diffuse condition of the liver resulting from identifiable causes, ultimate treatment should be directed toward the specific etiology.

BILE DUCT ADENOMA

Bile duct adenomas are benign lesions that appear as small and well-demarcated white subcapsular lesions ranging from several millimeters to 1 or 2 cm in maximal dimension. These are typically diagnosed incidentally at the time of operation. Pathologically, these appear as well-differentiated bile ductular structures surrounded by a fibrous stroma. These lesions are typically asymptomatic and appear to be entirely benign.[60,61]

MALIGNANT LIVER TUMORS

Introduction

Malignant tumors of the liver may arise from the hepatocyte, the bile duct epithelium, and the endothelial cells within the liver. The most common primary liver malignancy is hepatocellular carcinoma (HCC), which represents the most common solid organ cancer worldwide. As a group, malignant tumors of the liver present major diagnostic and therapeutic challenges. Although surgery can be potentially curative, most hepatobiliary cancers are discovered at a stage too advanced to permit complete resection.

Over the last two decades, considerable advances have been made in the diagnosis and treatment of these tumors. Enhancements in imaging have permitted earlier detection and more accurate staging of disease. The morbidity associated with surgical resection has decreased, and improving short- and long-term results are now being achieved with extensive but rational resections. Contemporary surgical therapy is guided by improved imaging techniques and a better understanding of disease biology. Furthermore, novel palliative treatments such as radiotherapy and ablative techniques have extended the limits of tumor eradication and treatment.

Hepatocellular Carcinoma

The therapeutic challenge of HCC arises from three factors. First, it is usually associated with cirrhosis, which limits the

range of treatment options and increases the morbidity of any given therapy. Second, HCC is usually asymptomatic at early stages, during which it has a great propensity for intravascular or intrabiliary extension; as a result, HCC typically presents at an advanced stage with consequently few effective therapeutic options. Third, HCC has been resistant to most conventional forms of cytotoxic chemotherapy, limiting the array of nonoperative forms of treatment.

EPIDEMIOLOGY AND ETIOLOGY

There are nearly 500,000 new cases of HCC diagnosed yearly (Table 44-3).[62] The incidence of HCC increases with age, and is four to eight times more common in males than in females. HCC is strongly associated with chronic liver injury; therefore, its geographic distribution closely mirrors that of viral hepatitis. The etiologic association between hepatitis B (HBV) infection and HCC is well established. A landmark study examined the relationship between HBV infection and HCC among 22,707 male subjects in Taiwan, 15.2% of whom were chronic HBV carriers as evidenced by detection of HB_sAg in their serum. Of the 116 cases of HCC that developed during a mean follow-up period of 7 years, 113 occurred in patients positive for HB_sAg. This study demonstrated that HCC was related not simply to a history of HBV infection but to the chronic carrier state, and that the relative risk of developing HCC was 200-fold greater in individuals with evidence of HBV infection compared with uninfected individuals.[63]

The hepatitis C virus (HCV) has also been associated with HCC. Antibodies to HCV have been found in as many as 76% of patients with HCC in Japan, Italy, and Spain[64] and in 36% in the United States.[65] Unlike HBV-associated HCC, which rarely occurs before the development of cirrhosis, HCV-associated HCC does not necessarily arise in the setting of advanced liver disease. Additionally, the incidence of HCC in chronic carriers of HCV is estimated to be as high as 5% per year, compared with 0.5% per year for HBV carriers.[66]

Chemical carcinogens have also been linked to HCC. Nitrites, hydrocarbons, solvents, organochlorine pesticides, primary metals, and polychlorinated biphenyls have been implicated in development of HCC.[67] Colloidal thorium dioxide (Thorotrast), which emits high level α, β, and γ radiation and was used as an angiographic agent in the 1930s, has been linked to angiosarcoma, cholangiocarcinoma, and HCC. Of all the chemicals linked to the development of HCC, the most important is ethanol. Alcohol abuse has been associated with the development of HCC, in addition to carcinomas of the larynx, mouth, and esophagus. Ethanol is believed to produce HCC through the development of hepatic cirrhosis or as a cocarcinogen with other agents such as HBV, HCV, hepatotoxins, and tobacco[68–73] rather than through any direct effect on hepatocytes.

Aflatoxins produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus* have also been linked to HCC. These are fungi that grow on grains, peanuts, and other food products, and are the most common cause of food spoilage in the tropics. These fungi produce aflatoxins designated B_1, B_2, G_1, and G_2. Aflatoxin B_1 is the most hepatotoxic, and chronic exposure to these mycotoxins can promote HCC.[74]

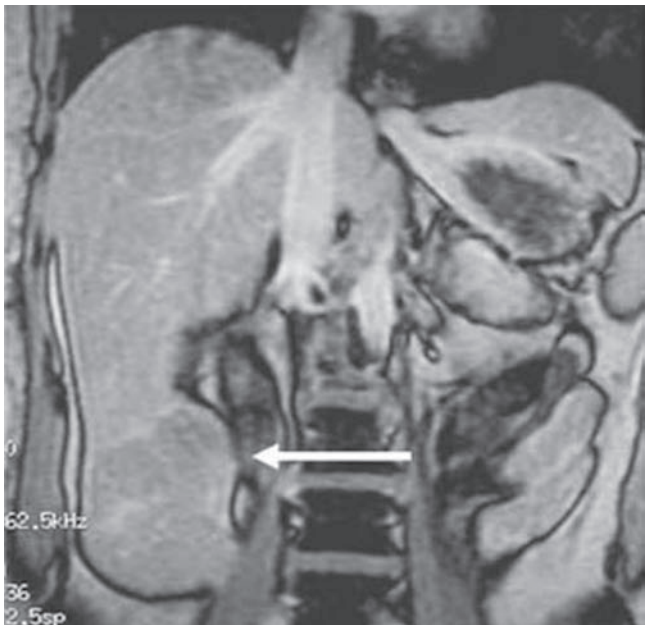
Congenital conditions may also lead to the development of HCC. Genetic diseases such as hemochromatosis, Wilson's disease, hereditary tyrosinemia, type 1 glycogen storage disease, hepatic porphyria of both intermittent and cutanea tarda types, familial polyposis coli, ataxia telangiectasia, familial cholestatic cirrhosis, biliary atresia, congenital hepatic fibrosis, neurofibromatosis, situs inversus, fetal alcohol syndrome, α-antitrypsin deficiency, and Budd-Chiari syndrome[75] have all been linked to a higher incidence of HCC. Ultimately, the unifying etiology of HCC for these conditions is chronic liver injury and inflammation.

TABLE 44-3: FACTORS ASSOCIATED WITH THE DEVELOPMENT OF HCC

Infection	Hepatitis B virus
	Hepatitis C virus
Cirrhosis	Laennec's (alcohol-induced)
	Autoimmune hepatitis
	Primary biliary cirrhosis
Environmental	Aflatoxins
	N-nitrosylated compounds
	Pyrrolizidine alkaloids
	Thorotrast
Metabolic disorders	Alpha1-antitrypsin deficiency
	Citrullinemia
	Familial cholestatic cirrhosis
	Galactosemia
	Hemochromatosis
	Hereditary tyrosinemia
	Porphyria cutanea tarda
	Type 1 and 3 glycogen storage disease
	Wilson's disease

PATHOLOGY

HCC has been histologically graded as well differentiated, moderately differentiated, and poorly differentiated. The well-differentiated variety may be difficult to distinguish from a regenerating nodule on biopsy. HCC can also be classified into three distinct patterns of growth that are associated with resectability and therefore have a significant influence on long-term outcome (Fig. 44-5). The hanging type is attached to the normal liver by a small vascular stalk, even when tumors are large. Because of this anatomic configuration, these are easily excised with minimal loss of functional hepatic parenchyma. The pushing type is generally well demarcated and often encapsulated by a fibrous capsule. These displace rather than infiltrate normal vasculature and typically do not invade the major vessels. Even when large, they are often resectable. Finally, the infiltrative type has a very indistinct tumor-to-liver interface,



A

FIGURE 44-5 Growth patterns of hepatocellular carcinoma. **A.** "Hanging" type. MRI demonstrating a mass (*arrow*) that is attached by a stalk to the right lobe of the liver. **B.** "Pushing" type. These are generally encapsulated, well-circumscribed tumors (*arrow*). **C.** "Infiltrating/invading" type. This lesion has diffusely infiltrated the entire left two-thirds of the liver. Note the left biliary ductal dilation (*arrow*).

and tends to have a much greater degree of vascular infiltration and invasion even when the tumor is relatively small. Because of the indistinct interface, resection of infiltrative-type HCC is occasionally complicated by positive margins. The practical nature of this gross pathologic classification scheme is reinforced by the distinctive radiologic appearance of these three different growth patterns on imaging and the resulting ability to categorize HCC preoperatively.[76]

An important pathologic determination involves the distinct appearance and clinical behavior of the fibrolamellar variant of HCC (Table 44-4). On gross and radiologic inspection, fibrolamellar HCC is generally well demarcated,

TABLE 44-4: COMPARISON OF STANDARD HCC WITH FIBROLAMELLAR VARIANT HCC

Characteristic	HCC	Fibrolamellar HCC
Male:Female	4:1–8:1	1:01
Median age	55	25
Tumor morphology	Invasive	Well-circumscribed
Resectability	<25%	50–75%
Cirrhosis	90%	5%
AFP elevation	80%	5%
HBV positivity	65%	5%

often encapsulated, and contains a central fibrotic area that can sometimes make differentiation of fibrolamellar HCC and FNH difficult. This variant generally occurs in young patients without underlying cirrhosis.[77] AFP, which is commonly elevated in usual cases of HCC, is not elevated in fibrolamellar HCC. Other serum markers that are often elevated in fibrolamellar HCC include neurotensin and vitamin B_{12}-binding protein.[78] The fibrolamellar variant of HCC is associated with prolonged survival compared with typical HCC, which is likely due to the well-demarcated nature of their tumors and the greater range in treatment options for patients without underlying cirrhosis.[79]

CLINICAL PRESENTATION

Despite the fact that they are generally slow-growing tumors, most cases of HCC present at an advanced stage that is no longer amenable to potentially curative therapies. Because the liver is relatively hidden behind the right costal cartilages, tumors can reach a substantial size before becoming palpable. Furthermore, the large functional reserve of the liver generally masks any small impairment resulting from local parenchymal disturbances by tumor. Small HCC tumors are usually therefore asymptomatic, and are discovered by screening programs[80–82] or incidentally during imaging performed for other abdominal conditions.

As a result, the majority of HCC cases present with local symptoms resulting from large tumor mass. Patients usually complain of a dull and vague right upper quadrant pain that is sometimes attributable to the shoulder. Hepatomegaly is a frequent accompanying finding. The liver edge is often hard and irregular because of both the tumor and the usual accompanying cirrhosis. A vascular bruit can be heard over the liver in about 25% of cases.[83] General symptoms of malignancy, including anorexia, nausea, lethargy, and weight loss, are common. The most common clinical presentation is the triad of right upper quadrant pain, a palpable mass, and weight loss.[84–86] Central necrosis of large tumors can lead to fever, and HCC can occasionally present as pyrexia of unknown origin. For the majority of patients, the presentation of HCC will also be the first presentation of their underlying cirrhosis. In one study population in which 90% of patients were eventually found to have cirrhosis, fewer than 10% of patients were thought at first evaluation for HCC to have chronic liver disease on the basis of their history and clinical examination.[85]

Hepatic decompensation is another common presentation for HCC, with patients seeking medical attention as a result of symptoms of liver failure like ascites, jaundice, or encephalopathy. This acute decompensation of liver function is usually a consequence of replacement of functional parenchyma by tumor in a patient with previously compensated cirrhosis. HCC also has a great propensity for vascular invasion and intravascular growth; hepatic failure can also result from portal vein occlusion secondary to intravascular tumor thrombus.[87–89] A rare cause of liver failure is Budd-Chiari syndrome resulting from direct invasion and occlusion of the hepatic vein and inferior vena cava by tumor and tumor thrombus. Gastrointestinal hemorrhage often complicates the clinical course of patients with HCC and is the presenting finding in 10% of cases.[89] In approximately half of these cases, bleeding is from esophageal varices[89] that can result from portal hypertension due to cirrhosis alone or cirrhosis with the added contribution of intraportal tumor thrombus. Patients with bleeding esophageal varices have an extraordinarily poor prognosis, with a median survival measurable in weeks.[88] In one study, nearly a quarter of patients with HCC died of massive variceal hemorrhage.[87] Gastrointestinal bleeding can also occur from other causes, such as a benign peptic ulcer or direct invasion of the alimentary tract by tumor.[89] The most dramatic presentation of HCC is tumor rupture, which is the initial presenting event in 2–5% of HCC patients (Fig. 44-6). Symptoms of tumor rupture include acute abdominal pain and swelling, and signs include abdominal distension, guarding, rebound tenderness, and ileus. Patients also commonly have signs of hemodynamic instability or overt hypovolemic shock. Diagnosis is confirmed by findings of tumor mass and peritoneal blood through imaging, laparotomy, or paracentesis.[90–94]

Up to half of HCC patients initially present with jaundice, which is most commonly due to hepatic insufficiency.[84,95–97] On rare occasions (fewer than 10% of jaundiced patients), jaundice associated with HCC is a result of biliary obstruction by extraluminal or intraluminal tumor or tumor-induced hemobilia.[84,98–102] In the clinical evaluation of jaundice for patients with HCC, it is critically important to distinguish hepatocellular failure from obstruction. The former etiology usually indicates that the patient is beyond any therapy, while the latter can often be treated with effective palliation and possible cure.[99,101,103–107]

In rare cases (<5%), HCC can present with paraneoplastic syndromes attributable to hormonal or immune effects of tumor.[108] The most important of these are hypoglycemia, erythrocytosis, hypercalcemia, and hypercholesterolemia. Porphyria cutanea tarda, virilization and feminization syndromes, carcinoid syndrome, hypertrophic osteoarthropathy, hyperthyroidism, and osteoporosis can also occur.[109–111]

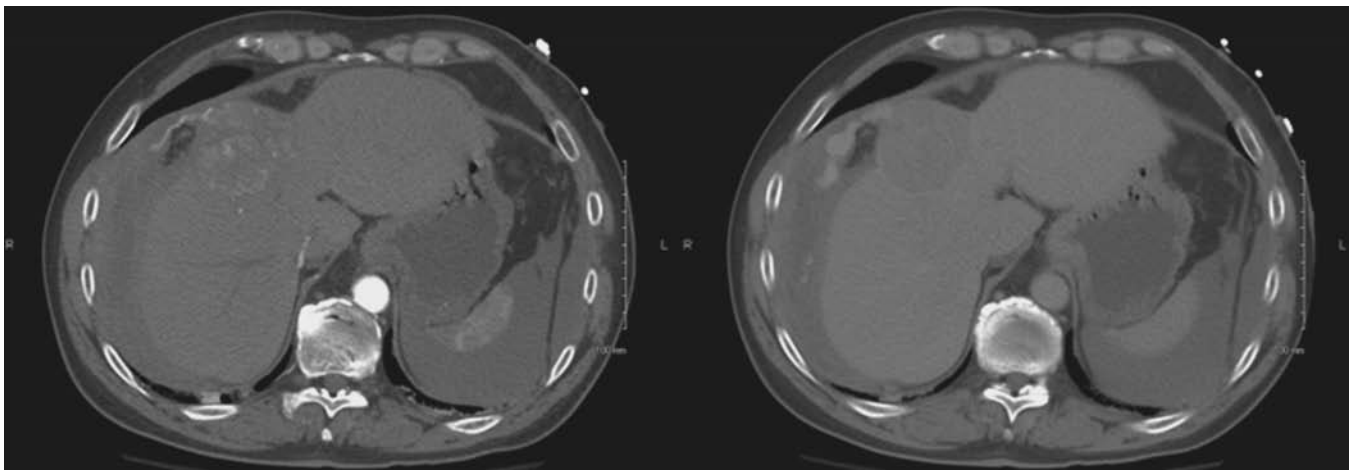

FIGURE 44-6 Computed tomographic appearance of ruptured hepatocellular carcinoma. Note the acute extravasation of contrast seen on early arterial phase images with pooling of blood seen on delayed images.

DIAGNOSIS

For patients with suspected HCC, the aims of diagnostic investigations are (1) verification of diagnosis; (2) determination of extent of disease; and (3) estimation of functional liver reserve.

Verification of Diagnosis. Diagnosis of HCC can usually be established noninvasively with a combination of history, physical examination, imaging, and laboratory blood tests. There is little diagnostic doubt in a patient with a liver mass consistent with a HCC on CT or MRI and a serum AFP greater than 500 ng/dL. This combination of findings is diagnostic, and treatment can be initiated without the need for a tissue diagnosis. The presence of cirrhosis or hepatitis infection (as documented by presence of HB_sAg or HCV in the blood) serves to further confirm the diagnosis.

In the patient with a space-occupying lesion on ultrasonography or CT with a nondiagnostic AFP level, the role of percutaneous needle biopsy has been debated. There is little doubt that needle biopsy can be diagnostic for HCC; however, iatrogenic complications of biopsy are not infrequent. Hemorrhage or tumor rupture can occur, and there is also a risk of tumor spillage and seeding of the needle biopsy tract.[112] In cases of potentially resectable HCC where the diagnostic certainty is high, we typically proceed to surgical exploration without a biopsy. Indeed, in this clinical scenario, the histologic appearance of the non-neoplastic liver may have a greater impact on surgical planning; if the presence of advanced cirrhosis will preclude safe resection, we will biopsy the nontumoral liver for histologic evaluation.

In patients with nondiagnostic AFP who are not surgical candidates (and therefore not candidates for curative therapy), tumor biopsy is performed for those who may be candidates for palliative therapy. In such cases, fine-needle aspirate for cytologic evaluation has been shown to yield a higher percentage of correct diagnoses compared with microhistology of core needle biopsy specimens (86 vs 66%).[113] Patients who are not candidates for palliative therapy do not need a definitive diagnosis, and biopsy is discouraged for this cohort.

Extent of Disease Evaluation. The two issues that must be resolved by the extent of disease evaluation are (1) whether the disease is isolated to the liver, and (2) whether the distribution of tumor within the liver is amenable to surgical resection. The most common sites of HCC metastases include lung, peritoneum, adrenal, and bone. Chest radiography is therefore mandatory. Cross-sectional imaging such as CT or MRI of the abdomen and pelvis should be scrutinized for peritoneal and adrenal sites of disease. Many centers consider bone scans to be mandatory prior to liver resection; this should certainly be performed for patients with pain that could be attributable to bony metastases. The presence of extrahepatic disease gravely alters the prognosis, as it eliminates the potentially curative treatment option of hepatectomy.

The extent of liver involvement is usually determined by CT. In the evaluation of HCC, cross-sectional imaging is used to determine the number and distribution of liver tumors and to identify radiographic evidence of vascular invasion. In this regard, triple phase (noncontrast, arterial phase, and portal phase) CT images should be obtained. HCC tumors are generally highly vascular; however, some tumors may become isodense with the surrounding liver on contrast-enhanced images, and some tumors are only visible during the noncontrast-enhanced phase. HCC has a great propensity for vascular invasion and extension, and tumor thrombus in the portal vein, hepatic vein, or vena cava is not unusual. Scans should therefore be scrutinized for evidence of vascular invasion, since therapy and prognosis can be significantly altered by the presence of such findings. If vascular invasion is suspected but not proven by CT, Doppler ultrasonography or MRI is indicated.

At some centers, hepatic angiography is a standard component of the diagnostic evaluation of HCC.[114,115] Some have even advocated routine use of lipiodol injected angiographically to

further delineate hepatic extent of disease.[116] This lipid is preferentially retained in HCC because of its particle size. There is no doubt that these angiographic methods are highly sensitive in detecting the presence of tumor. However, with current helical CT or MRI, the incremental yield of this invasive diagnostic modality is minor. We rely on angiography for select circumstances in which small tumors are suspected but not visible by conventional cross-sectional imaging (eg, a patient with a very high AFP level with only minimal disease seen on CT).

Determination of Functional Liver Reserve. Various liver function tests, alone or in combination, have been touted as useful for predicting risks of liver resection and other treatments for HCC. Various single serum measures of liver function have been suggested to be useful predictors of perioperative outcome, including serum bilirubin[117] and serum alanine aminotransferase (ALT).[118] A doubling of bilirubin has been suggested as a contraindication for liver resection.[119] Others have used a platelet count less than 50,000, or a prolonged prothrombin time greater than 4 seconds over control, to be relative contraindications for hepatic resection.[119] Most investigators have not relied on a single parameter, but use a combination of clinical and biochemical parameters to gauge safety of hepatectomy and other liver-directed treatments. The most clinically useful system is the Child-Turcotte-Pugh (Child) classification, which is a point scoring system for evaluation of liver function based on serum bilirubin, coagulation profile, serum albumin, presence or absence of ascites and encephalopathy, and nutritional status (Table 44-5).[120,121] Functionally, well-compensated cirrhosis is classified as Child classification grade A; decompensating cirrhosis is grade B; decompensated cirrhosis is grade C. Generally, partial hepatectomy is offered only to patients who are Child A and the most favorable class B patients.[122] In general, class C patients are only offered supportive care, since even nonsurgical ablative methods such as transarterial embolization are associated with procedure-related mortality in one-third of patients.[123]

Many sophisticated dynamic measures of liver function have also been used in attempts to quantitate hepatic function. Investigators have used the elimination of certain dyes that are exclusively cleared by the liver, such as bromosulphthalein or indocyanine green, as measures of hepatic function. Galactose clearance and [^{14}C] aminopyrine clearance have also been used to evaluate the metabolic capacity of the liver. Of these, the most commonly utilized evaluations in clinical practice are indocyanine green retention at 15 minutes[124] and the [^{14}C] aminopyrine breath test,[125] although controversy still exists concerning their utility.[126] We do not use these tests on a routine basis in our care of patients with HCC, and have found clinical Child-Turcotte-Pugh classification sufficiently discriminatory for selecting patients for therapies.

Another relatively simple test that may be predictive of perioperative outcome, and which we use on occasion, is hepatic venous wedge pressure. By passing a venous catheter through the vena cava into the hepatic vein, the hepatic venous pressure can be directly ascertained. With balloon occlusion of the hepatic vein, the hepatic venous wedge pressure, which is a reflection of portal pressure, can be determined. These measurements have been touted as useful in segregating Child-Turcotte-Pugh B patients who may have favorable results from resection versus those likely to have major complications.[127]

TABLE 44-5: CHILD-TURCOTTE-PUGH GRADING SYSTEM FOR CIRRHOSIS

Criterion	1 Point	2 Points	3 Points
Bilirubin (mg/dL)	<2.0	2.0–2.9	>2.9
INR	<1.7	1.7–2.3	>2.3
Albumin (g/dL)	>3.5	2.8–3.4	<2.8
Ascites	Absent	Mild	Moderate–severe
Encephalopathy	Absent	Mild (grade 1–2)	Moderate–severe (grade 3–4)

Child-Turcotte-Pugh class A: 5–6 points; B: 7–9 points; C: 10–15 points.

POTENTIALLY CURATIVE TREATMENT

Therapies for HCC can be separated into resection, ablation, radiation therapy, systemic chemotherapy or immunotherapy, and supportive care. Resectional therapy represents the only potentially curative option. We will begin with a discussion of these, particularly emphasizing recent advances and comparison of partial hepatectomy with total hepatectomy or liver transplantation.

Partial Hepatectomy. Partial hepatectomy represents the most common procedure for HCC performed with curative intent (Table 44-6). The liver is normally a very resilient organ with remarkable regenerative capacity. In a noncirrhotic liver, routine recovery can be expected even after resection of over two-thirds of functional parenchyma.[128] In the United States, nearly half of the patients with HCC will have no associated cirrhosis.[129] Operative mortality at most major centers is generally less than 5%, and very extensive procedures are justified by the low risk and the potential for long-term survival and cure. Resection is associated with a 5-year survival estimate of nearly 40% (Fig. 44-7).[126–130] For patients without cirrhosis, partial hepatectomy is a relatively safe procedure, and is the treatment of choice for HCC.

In contrast, most cases of HCC worldwide are associated with cirrhosis. The associated cirrhosis greatly increases the risk of partial hepatectomy. This increase in risk is partly a result of intraoperative factors. These patients will usually have rigid and hard hepatic parenchyma and established varices that are difficult to manipulate and prone to hemorrhage. Additionally, these patients will have thrombocytopenia and coagulation defects that further exacerbate their risk of bleeding. Postoperatively, the liver may not regenerate, resulting in liver failure. Furthermore, postoperative exaggeration of portal hypertension may lead to ascites and variceal bleeding. It is understandable; therefore, that resection is associated with

TABLE 44-6: OUTCOMES AFTER LIVER RESECTION FOR HCC

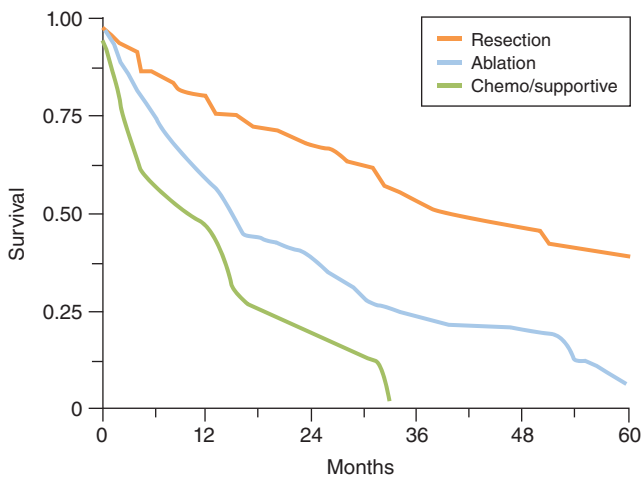

FIGURE 44-7 Survival curve for 154 patients undergoing hepatectomy for hepatocellular carcinoma at Memorial Sloan-Kettering Cancer Center. (Used with permission from Fong Y, et al. An analysis of 412 cases of hepatocellular carcinoma at a Western center. *Ann Surg.* 1999;229[6]:792.)

increased morbidity and mortality in these patients. Even for a cirrhotic patient with well-compensated liver function, we are reluctant to remove more than 20–25% functional parenchyma.[126,136–139] Until recently, even at centers with a low mortality for partial hepatectomy in the noncirrhotic population, partial hepatectomy for patients with cirrhosis was associated with a 10% mortality or more.[134,140–144] This explains the nihilistic view adopted by some for this disease, and explains the interest in treating this disease by total hepatectomy and liver transplantation. Nevertheless, even in this period of time, cirrhotic patients who survive the operation have a 5-year survival of approximately 30%.[137–141] Over the last decade, a number of series have demonstrated increasing safety of partial hepatectomy in cirrhotic patients. Due to improvements in patient selection, surgical technique, and perioperative support, the mortality at most major centers treating HCC has been reduced to less than 5%.[129,131,132,135]

Patient selection for surgery is primarily driven by hepatic function. As discussed above, the most commonly used clinical selection criteria for a patient's fitness for surgery relies on the Child-Turcotte-Pugh score. Few surgeons are willing to perform hepatic resection for patients with Child C cirrhosis. Most surgeons will only consider resection for patients with class A liver functional reserve and the best class B patients.

The major changes in operative conduct that have improved perioperative outcome include the willingness to use inflow occlusion during resection and the willingness to accept nonanatomic resection. Temporary occlusion of the hepatic artery and portal vein during liver resection by clamping the gastrohepatic ligament has been a useful technique for reducing blood loss during hepatectomy for patients without cirrhosis.[145] In the past, surgeons have been reluctant to use such inflow occlusion (the Pringle maneuver) in cirrhotic patients because of fears that cirrhotic parenchyma will not tolerate even transient ischemia. Recent studies have indicated that the reluctance to use this technique is largely unfounded, and that the cirrhotic liver can tolerate a Pringle maneuver for well over 30 minutes.[146,147] The most important change in operative technique has been the willingness to use limited, nonanatomic resections. For patients without cirrhosis, most major centers adhere to the anatomic boundaries of the various segments during liver resection for cancer. Hemihepatectomies, sectionetomies, and segmentectomies are preferred over wedge and other nonanatomic resections because limited resections are more likely to result in a positive microscopic margin.[148] In the cirrhotic liver, however, a smaller resection margin is acceptable if it will reduce the chance of postoperative liver failure. The smallest resection that will remove all gross tumors is generally used at most centers.

As the safety of resections has improved, increasing experience in the treatment of HCC has resulted in long-term results that allow for the analysis of prognostic factors. Many factors that in years past were thought to be contraindications to surgical resection have not been substantiated by these data. It is now clear that multiple lesions do not preclude surgical resection.[132,134,135,138] Presentation with intraductal tumor and obstructive jaundice does not preclude long-term survival after surgical resection. Therefore, it is very important in a patient who presents with HCC and jaundice to distinguish biliary obstruction from hepatic insufficiency as the cause for the jaundice. Synchronous direct invasion of adjacent organs such as the diaphragm by HCC is also not an absolute contraindication to resectional surgery.[149,150]

One cohort with a particularly poor prognosis is comprised of those with major intravascular extension of tumor (Fig. 44-8). Even though tumor thrombus can be treated with liver resection and thrombus extraction, the risk of disseminated disease is extremely high.[151] If the tumor thrombus involves the vena cava or main portal vein, liver resections accompanied by venous tumor thrombectomies are unlikely to yield long-term survival.

A number of staging systems have been proposed for purposes of postoperative risk stratification.[152–158] In a recent analysis of the MSKCC experience, the median disease-specific survival of 184 patients with HCC treated with partial hepatectomy was 54 months. Incorporating the prognostically informative variables of patient age, operative blood loss, microscopic resection margin status, presence of satellite lesions, presence of vascular invasion, tumor size, and AFP, we developed a nomogram that appears to permit far more accurate prediction of individual recurrence-free and overall survival outcomes than is permissible using conventional staging systems (Fig. 44-9).[135]

FIGURE 44-8 Vascular invasion of hepatocellular carcinoma. These tumors have propensity for intravascular extension. Note the tumor thrombus in the portal vein (*arrow*).

Neoadjuvant Therapy. Many groups have attempted to treat HCC with local or systemic therapies prior to surgical resection. The rationale for such neoadjuvant therapies is that (1) large primary tumors may be sufficiently reduced in bulk to make resection safer, and (2) local and systemic microscopic disease may be reduced or eradicated to improve long-term outcomes. In this regard, methods that have been employed to achieve these goals include transarterial chemoembolization,[159,160] combined chemotherapy (doxorubicin and 5-fluorouracil) and radiation therapy (2100 cGy), a combination of hepatic artery ligation, hepatic artery infusion of chemotherapeutic agents, radioimmunotherapy, and fractionated regional radiotherapy,[161] and transarterial yttrium 90 microspheres.[162,163]

In a French study, preoperative administration of lipiodol/doxorubicin-based transarterial chemoembolization (TACE) prior to partial hepatectomy in 49 patients resulted in tumor downstaging in 42% and total tumoral necrosis in 50%, with five patients being converted from unresectable to resectable disease. A trend toward improved survival was observed among patients demonstrating a partial or complete response

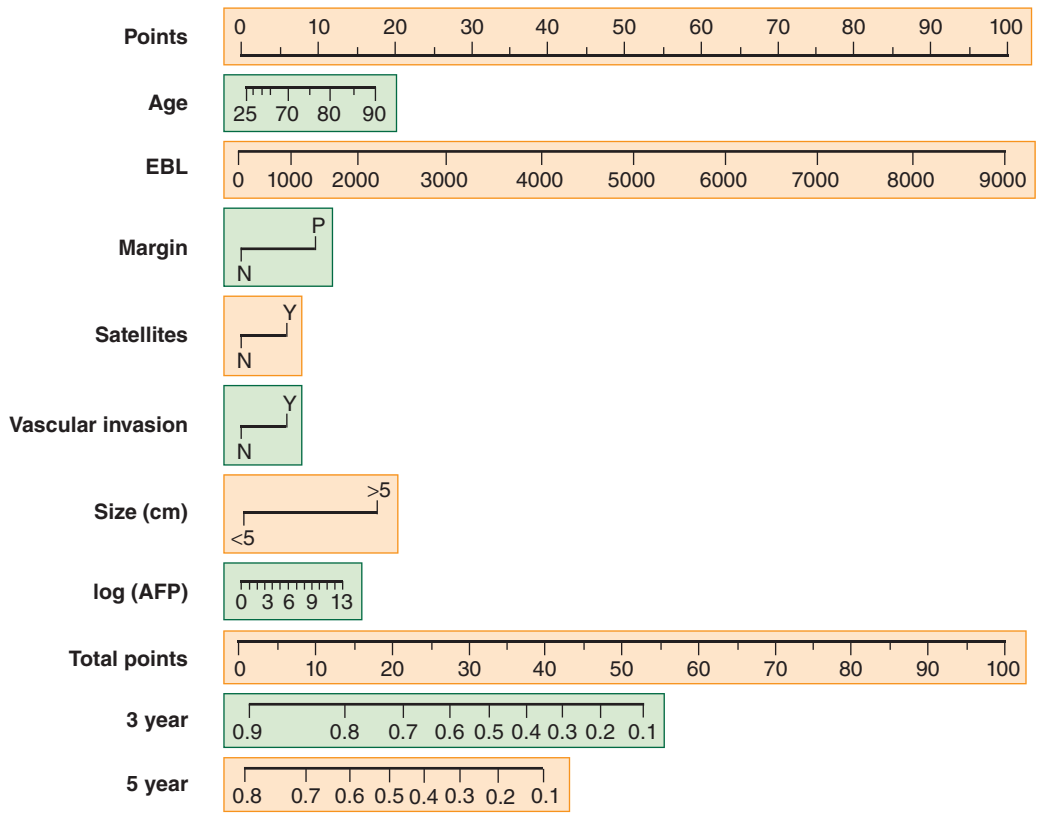

FIGURE 44-9 Prognostic nomogram for prediction of overall survival following resection of hepatocellular carcinoma. The individual patient's values are located on each variable axis and a line is drawn upward to determine the number of points received for each variable. A line is drawn downward from the sum of these numbers on the "Total Points" axis to obtain the likelihood of 3-year and 5-year survival. (Used with permission from Cho CS, Gonen M, Shia J, et al. A novel prognostic nomogram is more accurate than conventional staging systems for predicting survival after resection of hepatocellular carcinoma. *J Am Coll Surg.* 2008;206[2]:288.)

to neoadjuvant TACE compared with those demonstrating no response or those not undergoing resection alone, suggesting that response to preoperative therapy may enhance proper selection of patients for operative intervention.[164] Another investigative form of preoperative treatment is immunoembolization. In a comparison of 39 patients treated with neoadjuvant transarterial immunoembolization using the immunogenic *Streptococcus pyogenes* preparation OK-432 versus neoadjuvant TACE, enhanced tumoral necrosis was observed among patients treated with transarterial immunoembolization. Two- and 3-year disease-free survival after resection were 85 and 51% after transarterial immunoembolization and 56 and 47% after TACE, respectively.[165] In a randomized analysis of 91 patients with HCC assigned to resection alone versus neoadjuvant chemoembolization or immunotherapy followed by resection, overall survival was 18 months after resection alone versus 36.3 months after neoadjuvant therapy followed by resection.[166] Although these strategies are promising, their analyses have involved relatively small numbers of patients, and the use of neoadjuvant therapy remains investigative.

An alternative neoadjuvant strategy to improve outcomes after resection that has been adopted more widely is preoperative portal vein embolization (PVE). Embolization of the portal vein nourishing the portion of liver in which the tumor resides results in compensatory hypertrophy of the contralateral hemiliver. Single-institution analyses have identified improved postoperative mortality and morbidity among patients treated with preoperative PVE with no compromise in oncologic outcomes.[167–169]

Adjuvant Therapy. Approximately one-third of patients can expect to remain durably free of disease after partial hepatectomy for HCC; the fact that the majority of patients will recur indicates the prevalence of microscopic residual disease at the time of liver resection.[170,171] This has motivated keen interest in developing effective adjuvant therapy directed at microscopic residual disease.

In a Chinese study, 61 patients with resected HCC were randomized to no further therapy or postoperative hepatic infusion of lipiodol and cisplatin with systemic epirubicin. Interestingly, patients receiving adjuvant therapy appeared to have a higher extrahepatic recurrence rate and worse outcomes.[172] Another study of 57 patients with resected HCC randomized to hepatic arterial infusional and systemic epirubicin versus no further treatment demonstrated no differences in overall and disease-free survival.[173]

Although TACE is used extensively for the treatment of unresectable disease, randomized studies have not supported the use of this modality in the adjuvant setting. Indeed, three studies have demonstrated worse survival for those treated after resection with chemoembolization.[174–176] There have been two positive randomized trials of adjuvant therapy after resection for HCC. The first involves the use of the retinoid-derivative polyprenoic acid, which had been shown to inhibit hepatocarcinogenesis in rodents.[177] In a study randomizing patients after curative resection or percutaneous ethanol injection for HCC to polyprenoic acid or placebo, significantly higher numbers of patients receiving placebo developed additional HCC. This compound is not currently available in the United States, but these data encourage further study of this and other retinoid derivatives in adjuvant treatment for HCC and in chemoprevention of patients at high risk for development of HCC. Another positive adjuvant study involved the use of radioembolization employing transarterial delivery of ^{131}I-lipiodol. This compound has demonstrated significant activity against small HCC, but problems with dosimetry have limited its use for patients with bulky unresectable disease. In a prospective, randomized study, 21 patients who received 50 mCi of transarterial^{131} I-lipiodol within 6 weeks of liver resection were compared with 22 patients receiving no adjuvant therapy. Three-year survival rates for the treated group and the control group were 85 and 46%, respectively.[178] These findings await larger multicenter studies to confirm long-term survival improvement and to demonstrate the feasibility of delivering radioembolization in other centers.

Until recently, no systemic chemotherapy regimen had demonstrated efficacy for HCC. However, a large prospective multicenter randomized trial involving 602 patients confirmed a survival advantage associated with the use of the multikinase inhibitor sorafenib for patients with advanced unresectable HCC.[179] Median survival and time to radiographic progression were 10.7 and 5.5 months, respectively, in the sorafenib group compared with 7.9 and 2.8 months, respectively in the placebo control group. Whether sorafenib may offer benefit in an adjuvant setting for patients having undergone resection of HCC is presently under investigation.

Total Hepatectomy and Liver Transplantation. From a theoretical standpoint, total hepatectomy with liver transplantation is the most attractive therapeutic option for HCC (Table 44-7). This treatment allows for tumor resection with the widest possible margins, and permits removal of diseased and tumorigenic parenchyma that may contain microscopic metastatic disease and be predisposed to the formation of additional primary tumors. Initial experience with liver transplantation for HCC was disappointing. Several studies demonstrated that large tumors, multiple tumors, and the presence of microscopic and/or macroscopic vascular invasion were associated with poor outcomes.[180–183] Indeed, early comparative analyses did not uniformly identify improved outcomes associated with transplantation as compared to resection. A landmark study defining the appropriate role for transplantation described 3-year post-transplant survival estimates of 85% for highly selected patients with small tumor burden.[184]

TABLE 44-7: OUTCOMES AFTER LIVER TRANSPLANTATION FOR HCC

Author/Year	n	Operative Mortality	Survival 1-y	Survival 3-y	Survival 5-y

This work motivated the introduction of the so-called "Milan criteria" (single tumors ≤5 cm in maximal dimension or no more than three tumors each ≤3 cm in maximal dimension), which have been adopted by the United Network of Organ Sharing (UNOS) as a system of selecting HCC patients eligible for liver transplantation. As a result of these defined criteria, there is also accumulating experience with the use of neoadjuvant locoregional therapies such as TACE and percutaneous ablation as means to downstage patients to meet transplantation eligibility.[185–187]

Attempts to compare partial hepatectomy and liver transplantation for HCC have been challenging because of the fundamental differences in patient populations selected for each treatment modality. Patients selected for partial hepatectomy generally have good liver function and can have tumors of enormous size.[188–190] Partial hepatectomy for patients with small tumors also results in very favorable outcomes. For a patient with a tumor that is less than 5 cm in size, the 5-year overall survival is 45–57%.[129,191,192] In light of organ shortages and costs of liver transplantation, partial hepatectomy should be regarded as the curative treatment of choice for patients without cirrhosis or with Child's A classification cirrhosis. Indeed, survival outcomes after partial hepatectomy among patients with preserved hepatic function with HCC meeting Milan criteria are comparable to those observed after transplantation.[193] For patients with severe liver dysfunction, total hepatectomy and transplantation is the better option and may indeed be the only viable option.

Palliative Therapy. The majority of patients presenting with HCC will not have disease amenable to potentially curative surgical intervention. The presence of underlying liver disease often renders them not treatable by partial hepatectomy, and most patients present with disease burden beyond accepted eligibility criteria for total hepatectomy and orthotopic liver transplantation. If the disease is nevertheless completely or largely confined to the liver, local tumor ablative therapies (including percutaneous ethanol injection, radiofrequency ablation, and cryoablation) and embolization (chemoembolization or radioembolization) can result in reasonable local control of disease. Two randomized trials comparing chemoembolization to symptom control have demonstrated a significant survival benefit associated with the use of palliative chemoembolization.[194,195] Nonrandomized studies have suggested that a similar survival benefit may be expected with the use of radiofrequency ablation for properly selected cases.[196] As outlined earlier, systemic sorafenib has also been associated with an incremental survival benefit for patients with unresectable HCC.[179]

Intrahepatic Cholangiocarcinoma

EPIDEMIOLOGY AND ETIOLOGY

Cancers of the bile duct are uncommon, with approximately 4000 cases diagnosed in the United States annually.[197] Bile duct carcinoma may occur anywhere along the biliary tree, and is commonly divided into distal, proximal, and intrahepatic varieties. It is a disease of the elderly, with the majority of patients diagnosed older than 65 years of age, and the peak incidence occurs in the eighth decade of life.[198] In the absence of therapeutic intervention, bile duct cancers are rapidly fatal, and the majority of patients will die within a year of diagnosis. Death usually results from hepatic failure or biliary sepsis.[197,199,200] Long-term survival is highly dependent on the efficacy of surgical therapy. Indeed, it has been shown that location within the biliary tree has no impact on survival, provided that complete resection is achieved.[201] However, it is more likely that a patient with distal bile duct cancer can be resected with curative intent, which explains the relatively favorable prognosis of distal tumors.

Conditions resulting in chronic biliary inflammation have been associated with an increased incidence of cholangiocarcinomas. These conditions include primary sclerosing cholangitis, choledochal cysts, and chronic biliary infections.

Primary Sclerosing Cholangitis. In Western nations, the disease most often associated with development of cholangiocarcinoma is primary sclerosing cholangitis (PSC). This is an autoimmune disease characterized by inflammation of the periductal tissues. In advanced cases, it is characterized by multifocal strictures of the intrahepatic and extrahepatic bile ducts.[185–187] The majority (70–80%) of patients with PSC also have associated inflammatory bowel disease, typically in the form of ulcerative colitis.[185] In a longitudinal study of patients with PSC, 8% of patients developed clinically apparent cholangiocarcinoma over a 5-year period.[185] Indeed, a high incidence (30–40%) of occult cholangiocarcinoma has been found in autopsy or explant specimens from patients with PSC.[202,203] Cholangiocarcinoma presenting in patients with PSC is often multifocal and prone to recurrence, and typically not amenable to treatment by partial hepatectomy. Liver transplantation is often the only effective treatment for these patients, not only because of the likelihood of multifocal cancer, but also because of the baseline hepatic insufficiency that often results from the underlying inflammatory disease.[204,205]

Choledochal Cysts or Caroli's Disease. The increased risk of cholangiocarcinoma in patients with congenital cystic disease of the biliary tree is well recognized.[206,207] The reason for the malignant transformation is thought to be related to chronic inflammation and bacterial contamination within areas of cystic dilatation.[206,208–210] Early excision of the choledochal cyst significantly reduces the risk of cancer.[206,208] Fifteen percent to 20% of adult patients with unexcised choledochal cysts, or cysts previously treated with bypass, will be found to harbor cholangiocarcinoma.[206,208]

Pyogenic Cholangiohepatitis and Other Hepatic Infections. In Asia, chronic infections of the liver can predispose patients to the development of cholangiocarcinoma. Pyogenic cholangiohepatitis or oriental cholangiohepatitis

results from chronic portal bacteremia and portal phlebitis, which gives rise to intrahepatic pigment stone formation. This hepatolithiasis then leads to recurrent episodes of cholangitis and biliary stricture formation.[211,212] Those who do not succumb to sepsis will have an estimated 10% risk of developing cholangiocarcinoma.[212] In southeast Asia, biliary parasites (*Clonorchis sinensis, Opisthorchis viverrini*) are also associated with an increased risk of cholangiocarcinoma.[213] In areas where these parasites are endemic, the incidence of cholangiocarcinoma is as high as 87 per 100,000.[213]

Environmental Toxins. Several radionuclides and chemical carcinogens, including thorium, radon, nitrosamines, dioxin, and asbestos, have also been implicated in the genesis of cholangiocarcinomas.

PATHOLOGY AND CLASSIFICATION

Cholangiocarcinoma can arise anywhere within the biliary tree. Approximately 10% of cholangiocarcinoma cases arise within the intrahepatic bile ducts.[214–217] Extrahepatic cholangiocarcinomas are more common and can occur along the entire length of the extrahepatic biliary system from the confluence of the hepatic ducts to the ampulla. Some have classified these extrahepatic tumor into proximal (hilar), mid, and distal bile duct tumors. We agree with the convention of dividing cholangiocarcinomas into intrahepatic, perihilar, and distal subgroups, thus eliminating the mid-duct group.[218]

Peripheral or intrahepatic cholangiocarcinoma is diagnosed in 1000–2000 patients in the United States annually.[219] Clinical presentation is similar to that for HCC, with the most common symptoms being right upper quadrant pain, epigastric pain, and weight loss.[214,219] In fact, difficulty can be encountered in distinguishing peripheral cholangiocarcinomas from HCC or metastatic tumors from unknown origin. Jaundice occurs in only 24% of patients with peripheral cholangiocarcinoma compared with 71% of patients with hilar tumors.[219] Because the tumor is usually asymptomatic in early stages, most patients have advanced disease at presentation. On cross-sectional imaging by CT or MRI, peripheral cholangiocarcinoma is often confused with HCC or metastatic tumor from unknown primary. Unlike HCC, AFP levels will be normal. Search for alternative primary cancers that may have produced liver metastases will not be fruitful. A solitary lesion not associated with the gallbladder, in a patient with no cirrhosis and no other primary cancer, and with a normal serum AFP, should raise suspicion of a peripheral cholangiocarcinoma. Intrahepatic metastases and tumor growth along the biliary tract frequently occur, and can make it even more difficult to distinguish these tumors from metastatic disease originating from a distant site.

The segregation of extrahepatic cholangiocarcinomas into perihilar and distal subtypes is practical for purposes of operative planning. Tumors that are proximal to the cystic duct–common duct junction typically require a liver resection for extirpation; these represent approximately 40–60% of cases of cholangiocarcinoma, and include the hilar cholangiocarcinomas or so-called "Klatskin tumors."[200,201,218–221] Tumors that are distal to the cystic duct typically require pancreaticoduodenectomy for extirpation. Fewer than 10% of patients will present with multifocal or diffuse involvement of the biliary tree.[222]

Lymph node metastases are common with peripheral cholangiocarcinoma, and the assessment of hilar lymph node appears to provide useful prognostic information.[223,224] The (primary) tumor, (regional lymph) node, (remote) metastases (TNM) staging of intrahepatic or peripheral cholangiocarcinoma is the same as that for HCC.

TREATMENT

Partial Hepatectomy. Whenever possible, surgical resection is the treatment of choice. In a series of 42 patients with intrahepatic cholangiocarcinoma, survival was indistinguishable from that of 70 patients with hilar cholangiocarcinomas.[225] Median survival was 12 months, and no patient survived more than 42 months. Others have reported more favorable results. In a series of 20 patients with peripheral cholangiocarcinoma undergoing surgery over a 10-year period, median survival was 21 months.[214] Four patients lived more than 3 years, and a single patient was alive 5 years after resection. In our own report of 32 cases of resected peripheral cholangiocarcinoma, median survival was 59 months with an actuarial 5-year survival of 42%. Vascular invasion and intrahepatic satellite lesions were predictors of worse survival ($p < .05$).[214] In a recent update of the MSKCC experience, the median disease-specific survival for 82 patients with intrahepatic cholangiocarcinoma treated with surgical resection was 36 months. This stands in contrast to a median disease-specific survival of only 9 months for patients with disease not amenable to partial hepatectomy; unfortunately, only a third of patients with intrahepatic cholangiocarcinoma evaluated at MSKCC were ultimately found to have resectable disease. The presence of multiple tumors, tumors greater than or equal to 5 cm, and nodal metastases was found to be associated with worse survival after resection on multivariate analysis.[224]

Total Hepatectomy and Liver Transplantation. Historically, outcomes after liver transplantation for patients with cholangiocarcinoma have been suboptimal; in 1991, an actuarial 5-year survival rate of 17% was reported for 109 intrahepatic and extrahepatic cholangiocarcinoma patients transplanted at various centers throughout the world. In this series, there were no significant differences in recurrence rates for hilar and peripheral tumors.[226] More recently, encouraging outcomes have been observed with the use of liver transplantation for selected patients with hilar cholangiocarcinoma following a course of neoadjuvant chemoradiation.[227,228] The Mayo Clinic has utilized a protocol of external beam radiation therapy, chemosensitizing 5-FU, and capecitabine chemotherapy followed by staging laparotomy and, for patients without evidence of hilar nodal or distant metastases, liver transplantation for patients with unresectable hilar cholangiocarcinoma or hilar cholangiocarcinoma arising in a setting of primary

sclerosing cholangitis.[229,230] Estimated actuarial 5-year survival of patients completing this therapy was 82%, which compared favorably to the 21% 5-year survival observed among a cohort of 26 patients with hilar cholangiocarcinoma who underwent conventional surgical resection at the same institution. Whether this promising strategy could be applied for patients with peripheral cholangiocarcinoma remains unknown.

Chemotherapy. Data for chemotherapy or radiation in treatment of this disease is not encouraging. Response rates with 5-fluorouracil (5-FU) and 5-FU-based systemic chemotherapy regimens have been generally poor.[231] A 5% complete response and 46% partial response for the treatment of peripheral cholangiocarcinoma was reported with a regimen of initial whole-liver irradiation to 2100 cGy in seven fractions, doxorubicin, cisplatin, and ^{131}I anticarcinoembryonic antigen (CEA) antibody. Although the median survival was 14 months from diagnosis and 10 months from treatment, no patient survived more than 2 years from the onset of diagnosis.[232] A recent phase II clinical trial examining the use of hepatic arterial floxuridine and dexamethasone for patients with unresectable intrahepatic cholangiocarcinoma and HCC identified a radiographic response rate of 47.1% with 2-year survival estimates of 67%, suggesting that liver-directed chemotherapeutic regimens may hold some palliative promise for patients with unresectable intrahepatic cholangiocarcinoma.[233]

Other Primary Malignancies of the Liver

HEPATOBLASTOMA

Hepatoblastoma affects approximately 1 in 100,000 children and is the most common primary malignant liver tumor in children.[234,235] It is usually diagnosed before the age of 3 years, with a 2:1 male predominance. Patients usually present with abdominal swelling,[234,235] and the serum AFP is elevated in over 75% of cases. CT scans will reveal a vascular mass that is often (50%) speckled with calcifications.[236] Overall long-term survival varies between 15 and 37%.[236–239] Poor prognosis is associated with unresectable tumors and tumors demonstrating aneuploidy and anaplastic characteristics.[237,240,241]

Complete resection is possible in 50–65% of children with hepatoblastoma, and is associated with cure rates between 30 and 70%.[240,241] Unlike adult primary liver tumors, chemotherapy may produce a response in a significant number of patients with hepatoblastoma. Preoperative chemotherapy has been used with some success in converting unresectable tumors to resectability.[242,243] Adjuvant chemotherapy has also been used following resection of hepatoblastoma. In one report, 20% of 24 patients with hepatoblastoma were relapse-free 8–42 months after surgical resection coupled with adjuvant vincristine, doxorubicin, 5-FU, and cyclophosphamide.[244] Radiation therapy has been used in the treatment of unresectable hepatoblastomas, but its utility is yet to be proven.[242,245] Orthotopic liver transplantation should be considered for children with unresectable hepatoblastoma if the tumor does not become resectable after preoperative chemotherapy. In a report of 18 patients undergoing liver transplantation for unresectable hepatoblastoma, tumors recurred in six patients, but five have survived disease-free for more than 2 years with actuarial survival rates of approximately 50%.[226]

ANGIOSARCOMA

These malignant mesenchymal tumors of the liver are also referred to as hemangiosarcomas. Approximately 25 cases occur in the United States each year.[246] Peak incidence is in the sixth and seventh decades, with 85% of cases occurring in males.[247] Presenting symptoms are as for any liver tumor, and most commonly include abdominal pain, abdominal swelling (usually due to hepatomegaly), liver failure, nausea, anorexia, emesis, and jaundice. These malignant tumors have been associated with exposure to Thorotrast, arsenic, or vinyl chloride.

Angiosarcomas are aggressive neoplasms; partial hepatectomy can result in long-term survival, but most patients present with advanced tumors not amenable to complete resection. Distant metastases are found at initial presentation in half of patients. Most patients die within 6 months of diagnosis. Even with resectable tumors, few patients survive more than 1–3 years after complete resection due to the onset of metastatic disease. Results of radiation therapy and chemotherapy or both have been disappointing.[247] Results of orthotopic liver transplantation for treatment of angiosarcoma have also been poor, with disease recurrences reported in 9 of 14 transplant patients with tumors classified as either angiosarcomas or epithelioid tissue sarcomas. The 2-year survival rate was 15%, with no patient surviving more than 28 months after transplantation.[226]

The liver can occasionally be the primary site for rhabdomyosarcoma,[248] although this is more common in children than adults. Hepatic metastases from a gastrointestinal or uterine primary need to be ruled out before the diagnosis of primary leiomyosarcoma of the liver can be made. Surgical resection is the treatment of choice for these primary hepatic sarcomas,[248] and unresectable disease typically portends an unfavorable prognosis. Undifferentiated sarcomas of the liver are very rare and usually occur in children between the ages of 6 and 15 years.[249,250] Most undifferentiated sarcomas of the liver present at an advanced stage, when surgical resection is not possible. These patients rapidly succumb to their disease, as they are generally not responsive to radiotherapy or chemotherapy.[250]

EPITHELIOID HEMANGIOENDOTHELIOMA

Epithelioid hemangioendothelioma is another malignant soft tissue tumor of endothelial cell origin.[246,248,251] Factor VII immunohistochemical staining differentiates hemangioendothelioma from other nonvascular tumors. Unlike infantile hemangioendothelioma, which is benign, the adult variety is malignant and highly aggressive. Average age at presentation is 50 years. Afflicted patients usually present with nonspecific

complaints that include pain and an abdominal mass. In contrast to angiosarcoma, there is a female predominance (63% of patients).[248] Vinyl chloride exposure has also been implicated as a possible etiology of epithelioid hemangioendothelioma in some patients.[251]

Radical surgery has been advocated for cases of resectable epithelioid hemangioendothelioma.[246] Unfortunately, these tumors are almost always diffuse and multifocal, and therefore unlikely to be cured by partial hepatectomy. Percutaneous biopsy is undertaken when this diagnosis is suspected. Intraoperative frozen section analysis is not typically helpful, as special immunostaining is often needed for definitive diagnosis. Patients with hemangioendotheliomas should be considered for total hepatectomy and liver transplantation. In a series of patients who underwent orthotopic liver transplantation for epithelioid hemangioendothelioma, 7 of 21 patients developed disease recurrence.[226] The actuarial survival rate was 82% at 2 years and 43% at 5 years.

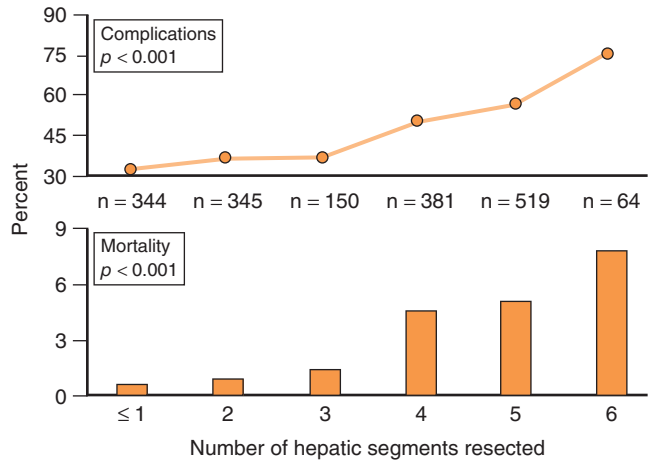

FIGURE 44-10 Perioperative complications and mortality stratified by the number of hepatic segments resected. (Used with permission from Jarnagin WR, Gonen M, Fong Y, et al. Improvement in perioperative outcome after hepatic resection: analysis of 1803 consecutive cases over the past decade. *Ann Surg.* 2002;236[4]:402.)

Technical Considerations in Hepatic Resection

The past two decades have seen a dramatic improvement in perioperative outcome after hepatic resection. High-volume centers now routinely report operative mortality rates of less than 5%, and often as low as 2–3%.[129,232–234] A recent review of over 1800 resections from MSKCC also documented a significant improvement in blood loss, transfusion requirements, and postoperative length of stay in patients undergoing hepatic resection over a 10-year time period.[254] There is no single factor solely responsible for this reduction in morbidity and mortality; better patient selection, the evolution of hepatobiliary surgery as an area of specialization, advances in anesthetic technique, and optimization of operative technique have all contributed to these improved results.

A better appreciation of the segmental nature of hepatic anatomy has resulted in an increasing use of anatomically based resections and, more importantly, an increased use of parenchymal-sparing segmental resections. In a study from MSKCC, the number of hepatic segments resected was a strong predictor of outcome and, along with operative blood loss, was an independent predictor of both the morbidity and mortality of hepatic resection.[234,255] As the number of resected segments increased, there was an almost linear rise in the rate of complications and postoperative mortality (Fig. 44-10). We have observed a significant increase in the proportion of segmental resections performed over the last decade, resulting in a decline in the number of segments resected. Both of these factors correlated closely with the observed reduction in mortality and the overall improvement in perioperative outcome.

Data from this and other studies suggest that measures aimed at preserving hepatic parenchyma without compromising the oncologic integrity of the resection have a significant influence on operative morbidity and mortality. In selected patients, parenchymal-sparing segmental resections offer the same benefit as more extensive lobar resections with less risk. The use of segmental resections allows a complete but less extensive resection to be performed in patients with limited disease, and permits greater flexibility for those with more extensive disease or decreased hepatic functional reserve. Additionally, anatomically based segmental resections have been shown to be superior to nonanatomic wedge resections with respect to blood loss and tumor clearance.[256–258]

For major hepatic resections, we typically begin by establishing control of the vascular inflow. Several different techniques for vascular inflow control during hepatic resection have been described.[259] In the 1950s, the technique of extrahepatic portal dissection and transection, prior to parenchymal division, became a common practice.[260] This technique consists of individual dissection and ligation of the ipsilateral hepatic artery and portal vein within the hilus of the liver. This extrahepatic technique is still commonly employed today, with division of the inflow being performed with the use of stapling devices or suture ligation.[261,262] Some have noted, however, that this extrahepatic method for inflow control is time consuming, and can result in inadvertent injury to aberrant vascular or biliary structures.[257]

The technique of intrahepatic vascular inflow control was first reported by Couinaud and Launois.[259,263,264] This technique is based on the anatomic observation that the structures of the portal triad enter the liver together as a pedicle, carrying the enveloping Glisson's capsule with them into the hepatic parenchyma. Thus, within the liver, all three structures of the porta are contained within a very strong and well-formed sheath (pedicle), which can be isolated and divided *en masse* within the liver. No such well-characterized sheath exists outside the liver; therefore, the extrahepatic portal structures are

isolated and divided individually. The technique of pedicle ligation is ideally suited for right-sided tumors situated away from the hilus and requiring a right hemihepatectomy. For tumors close to the hilus, pedicle ligation may compromise the resection margin and is therefore inappropriate. For major left hemihepatectomies, pedicle ligation may be used but extrahepatic control is typically employed, as the longer extrahepatic course of the left hepatic inflow allows for relatively easy extrahepatic dissection.

Two different methods have been reported for intrahepatic ligation of the portal pedicle during hepatic hemihepatectomy.[263,264] These methods differ with respect to the direction from which the pedicle is approached, and the sequence for division of the parenchyma and the pedicle. In the posterior approach (or hepatotomy method), hepatotomies are created both anterior and posterior to the hilum on the side of resection (Fig. 44-11). A clamp or other instrument is used to isolate the pedicle sheath, and the pedicle is then transected with a vascular stapler prior to division of the hepatic parenchyma (Fig. 44-12). In the anterior approach (or transection method), the hepatic parenchyma is initially divided along the line of the main hepatic fissure under Pringle inflow occlusion until the pedicle is identified. Once identified, the pedicle is isolated from within the liver and divided. Regardless of approach, both techniques obviate the need for extrahepatic dissection within the hilus of the liver.

With either approach, the technique of pedicle ligation for right hemihepatectomy first involves mobilization of the right liver off the inferior vena cava. Initial division of the lowermost retrohepatic veins draining the caudate process is essential. Failure to do this can result in tearing of these veins during pedicle isolation.[265] Once the liver has been mobilized, the gallbladder is removed and the hilar plate lowered. A hepatotomy is created anterior to the hilum, extending from the right side of the gallbladder fossa. A second parallel incision is made in the caudate process just posterior to the hilum. The hepatic parenchyma is further dissected and a finger or clamp passed to connect the two hepatotomies to encircle the portal pedicle with a tape or vessel loop. With traction, the right and left main pedicles can be exteriorized. After confirming adequate and appropriate isolation with clamping, the pedicle is divided with either an Endo GIA (Covidien, Mansfield, MA) or TA stapler (Ethicon Surgical, Cincinnati, OH).[257] This technique may also be used for segmental resections, as further dissection of the hepatic parenchyma after initial isolation of the main pedicle permits isolation of pedicle branches to individual hepatic sections or segments.

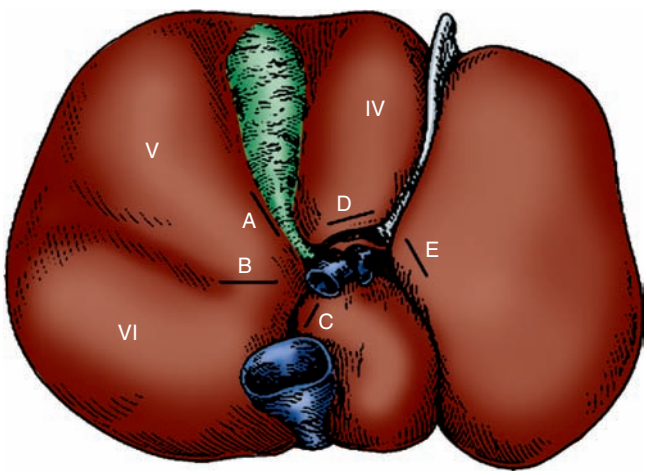

FIGURE 44-11 Hepatotomy placement for pedicle ligation. **A** and **C.** Right hepatectomy. **A** and **B.** Right anterior sectorectomy. **B** and **C.** Right posterior sectorectomy. **D** and **E.** Left hepatectomy.

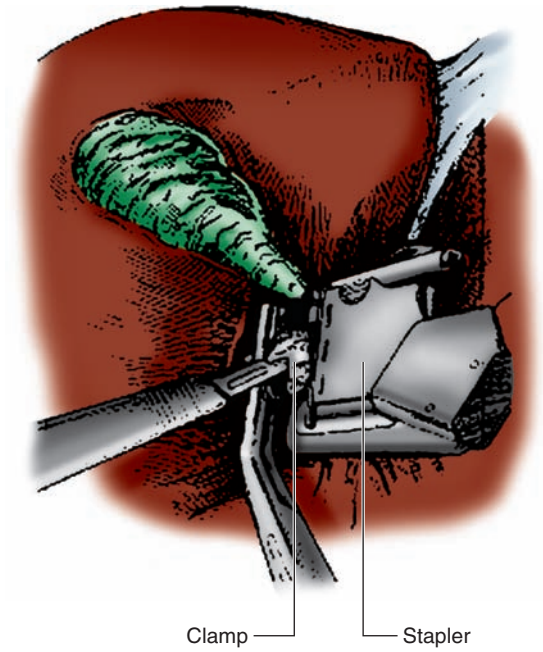

FIGURE 44-12 Placement of stapling device after isolation of the right portal pedicle.

Once inflow control has been achieved, control of the hepatic venous outflow is undertaken; this may again be achieved intrahepatically during parenchymal transection, or outside of the liver. In general, we prefer to obtain extrahepatic control except for bulky tumors that involve the junction of the hepatic vein with the inferior vena cava, in which case hepatic vascular isolation may be appropriate. In almost all cases, with satisfactory control of central venous pressure and careful dissection of the major veins, extrahepatic outflow control can be achieved.

Once the vascular inflow and outflow have been controlled, the liver parenchyma may be transected with any variety of techniques or instruments. Our preferred approach is to crush the parenchyma with a clamp to expose the intrahepatic bile ducts and vessels, which are then individually ligated and divided. Over the past decade, a number of devices have been described for parenchymal transection. The ultrasonic dissector, water-jet dissector, harmonic scalpel, stapling devices, and most recently radiofrequency coagulators have all been used for parenchymal transection.

The majority of reports regarding the use of these instruments are descriptive, and little data exist to suggest that one technique is better than another with respect to intraoperative blood loss.[32,257,266–268] In the setting of cirrhosis and significant steatosis, the crushing technique for parenchymal transection is probably not ideal because the liver tissue tends to fracture and small vascular or biliary structures are more easily torn. In these situations, the use of noncrushing instruments such as the harmonic scalpel, which simultaneously coapt and coagulate, may be beneficial.

HEPATIC COLORECTAL METASTASES: RESECTION, PUMPS, AND ABLATION

Michael A. Choti

INTRODUCTION

Colorectal cancer (CRC) is the third most commonly diagnosed cancer in the United States.[1] In spite of an increasing emphasis on screening and prevention of this disease, more than 140,000 new cases will have been diagnosed in 2010, comprising approximately 10% of new cancer diagnoses. Although mortality from this disease has improved over the past two decades, more than 40% of patients with colorectal cancer eventually die of their cancer.[1,2] Among those patients with advanced disease, more than half will develop liver metastases, more than any other organ, and many will have disease recognizably confined to this organ. Specifically, approximately 20–40% of patients with metastatic CRC have liver-only metastases at the time of presentation or recurrence, accounting for about 30,000 patients per year in the United States.[3,4]

While not supported by randomized trials, a preponderance of uncontrolled studies have demonstrated that complete resection in patients with liver metastases is associated with dramatically improved survival compared with patients not undergoing surgical therapy. Advances in imaging technology, surgical techniques, and systemic chemotherapy have brought steady improvements in long-term outcome in patients undergoing resection, with 5-year overall survival exceeding 50%. In addition, other surgically delivered locoregional strategies offer promising directions in improving outcomes in these patients, including ablation, and intra-arterial chemotherapy. Herein, an overview is provided of the important clinical issues relating to the surgical management of patients with colorectal liver metastases.

PREOPERATIVE EVALUATION OF THE PATIENT WITH HEPATIC METASTASES

The extent of evaluation and staging of a patient with hepatic metastases should be determined based on the available treatment options. In patients for whom further treatment is not being considered, either due to comorbid conditions or patient choice, an extensive evaluation for the extent of disease may be unjustified. In patients for whom only non-curative systemic chemotherapy is being considered, an evaluation should establish a baseline to facilitate monitoring of the response to treatment at all sites. In those who are or may become candidates for local therapy directed to the liver, it is important to exclude the presence of extrahepatic disease, particularly in the majority of these patients who are asymptomatic from their liver disease.

When evaluating the patient for extrahepatic disease, computed tomography (CT) is the imaging modality used most frequently. Abdominal CT can detect other intra-abdominal disease, while chest CT is most sensitive for identifying pulmonary metastases, detecting 95% of lesions greater than 1 cm in diameter.[5–7] While controversial, chest CT should be strongly considered prior to resection of liver metastases, even in patients with a normal chest x-ray.[6] The ability of CT imaging to detect extrahepatic disease within the abdominal cavity or pelvis is lower, with a sensitivity reported between 22 and 41%.[8,9] Similarly, magnetic resonance imaging (MRI) can be useful in evaluating evidence of extrahepatic disease.[8] In addition, MRI may be useful to characterize indeterminate liver lesions. While most consider a high-quality contrast CT sufficient, some have suggested MRI may be the most sensitive for preoperative staging.[10]

One of the most informative imaging modalities for the assessment of metastatic sites is whole body positron emission tomography (PET). Unlike standard cross-sectional imaging, PET provides functional information related to metabolic activity. Although a number of positron-emitting radiopharmaceuticals have been developed,[18]F-fluorodeoxyglucose (FDG) PET is the most widely used in oncology.[11] When administered intravenously, [18]F-FDG is taken up and accumulated in metabolically active cells. Malignant tissue with relatively increased uptake can be seen as areas of increased signal relative to the surrounding less metabolically active normal tissue.

A wide spectrum of malignancies may be successfully staged by FDG-PET, including colorectal, lung, and breast cancer.[12] PET has been reported to have a sensitivity as high as 92–100%, with a specificity of 85–100%.[13] In patients with colorectal liver metastases in whom resection is planned, preoperative FDG-PET appears to be especially useful to exclude extrahepatic disease.[14,15] Recent studies report identifying such additional disease which alters the patient management in up to 25% of the patients.[15,16] Accordingly, FDG-PET is recommended by the National Comprehensive Cancer Network as a routine component of the preoperative evaluation in patient being considered for surgical therapy for liver metastases from CRC.[6]

When considering any local therapy of the liver, it is particularly important to carefully evaluate the extent of intrahepatic disease and determine the location of metastases relative to major vascular pedicles within the liver. Multiple bilobar metastases as well as involvement of hilar structures or the presence of periportal or celiac nodal disease may preclude resection. Not infrequently, patients who are considered preoperatively to be candidates for resection are found at operation to be unresectable because of previously unrecognized additional hepatic lesions. High-quality contrast-enhanced cross-sectional imaging is imperative for an adequate assessment of the liver prior to surgery. In addition, advanced postacquisition imaging techniques—such as three-dimensional reconstruction, volume-rendering, and digital subtraction angiography—may improve the ability to view the relationship of metastases to vital structures and determine resectability.

The goal of the preoperative evaluation is to identify the best candidates for resection and exclude those who will be found at operation to have unresectable disease, thereby obviating unnecessary laparotomy in the latter group. In one report from Johns Hopkins, the non-therapeutic laparotomy rate decreased from 15% in the 1990s to approximately 5% in the more recent years.[17]

INTRAOPERATIVE ASSESSMENT: IOUS AND LAPAROSCOPY

Intraoperative exploration and evaluation of the extent of disease within the abdominal cavity and liver is critical prior to proceeding with surgical resection. The abdominal cavity, including peritoneal surfaces and pelvis should be inspected and palpated if accessible to rule out extrahepatic disease or locoregional recurrence. Special attention should be paid to porta hepatis and periportal nodal region.[18,19] Nodal involvement in the periportal area is associated with a significantly poorer long-term outcome.[18,20] It probably represents a manifestation of disseminated disease and should preclude curative resection in most cases.

Bimanual and bidigital palpation of the liver is then carried out. In most cases, metastases from CRC are firmer than the surrounding liver and palpable. In some patients, however, a fibrotic or fatty liver, sometimes related to the use of preoperative chemotherapy, may reduce the ability to palpate small metastases. In some cases, an indentation or dimple on the capsule of the liver can provide a clue of the presence of a small metastasis below the surface, particularly in patients following a significant response to chemotherapy.

Intraoperative ultrasonography (IOUS) is the most sensitive modality currently available for detecting otherwise occult liver metastases. Even in the era of high-quality preoperative imaging, IOUS sensitivity is reported to be superior to other imaging modalities.[21,22] The sensitivity of IOUS to detect additional lesions depends on multiple factors, including the quality and timing of the preoperative imaging, associated liver disease, and tumor echogenicity.[22–24] In one study, van Vledder et al demonstrated in 213 patients undergoing surgical exploration for CRC liver metastases between 1998 and 2009, IOUS alone detected additional tumors in 10% of patients. Detection rate was found to be higher in those patients with multiple metastases (>3) and those in whom the index known lesions were hypoechoic[22] (Fig. 45-1). Moreover, they found patients with isoechoic index lesions were associated with significantly higher rate of early intrahepatic recurrence, a surrogate for missed lesions.

By improving the capability of detecting clinically occult metastases, patients with multiple unresectable metastases may be spared unnecessary hepatic resection. IOUS may also contribute to improved survival by helping to detect and excise or ablate otherwise occult residual disease. Moreover, IOUS facilitates the careful examination of intrahepatic vascular structures and their relationship to the hepatic tumors, often facilitating safer resections with more adequate resection margins.[25–27]

Laparoscopic evaluation of the liver and abdominal cavity just prior to laparotomy has been used in a variety of gastrointestinal malignancies.[28–30] This approach is used to potentially identify additional patients who have unresectable disease, reducing the number of patients unnecessarily undergoing full surgical exploration. With recent refinements in laparoscopic ultrasonographic devices, intraoperative hepatic ultrasonography can now compliment visual laparoscopic assessment.[29,31] Laparoscopic staging for potentially resectable hepatic colorectal metastases is more controversial and less frequently used. First, non-therapeutic laparotomy rates are lower in this disease than in most other gastrointestinal cancers, resulting in less potential benefit. Yet some continue to recommend it, particularly among those at higher risk.[32,33] In one report of 103 consecutive patients evaluated with potentially resectable disease, laparoscopy identified 14 of 26 patients with unresectable disease, 10 of whom were spared an unnecessary laparotomy.[33] Despite such enthusiastic initial reports, the role of laparoscopy prior to surgical exploration for patients with isolated hepatic metastases remains to be defined.

SURGICAL RESECTION

Hepatic resection is acknowledged as the most effective therapy for patients with colorectal metastases confined to the liver. A more accurate understanding of liver structure, based on functional segmental anatomy, as well as advances

in operative technique and postoperative care, has resulted in the capability to perform even major hepatectomy with very low morbidity and mortality. Thus, the goal of surgery should be complete removal of all metastatic disease. Several issues should be addressed when considering hepatic resection for our patients: (1) How do we select patients for resection? (2) What surgical techniques are recommended? (3) What are the long-term outcomes and prognostic factors? (4) How can we expand the role of liver resection to those with disease that is initially considered to be unresectable? and (5) What is the role of adjuvant or neoadjuvant chemotherapy for patients undergoing hepatic resection?

Selecting Patients for Surgical Resection

Indications for surgical resection of hepatic colorectal metastases have undergone a major shift in the last decade. Previously, hepatectomy was not recommended in patients who had more than three or four metastases, hilar adenopathy, metastases within 1 cm of major vessels such as the vena cava or main hepatic veins, or extrahepatic disease. More recent studies demonstrate, however, that patients with these clinicopathologic factors can achieve long-term survival following hepatic resection and therefore should not be excluded from surgical consideration.[34–37] Specifically, a small number of metastases[38–40] and wide margin status are no longer considered necessary for defining resectability.[41,42] Similarly, contiguous extension to adjacent anatomical structures and local or regional recurrence at the site of the primary colorectal cancer are not contraindications to resection. An increasing number of studies also indicate that although survival may be reduced in patients with extrahepatic or periportal lymph node metastases, complete resection of these sites in conjunction with resection of hepatic metastases can result in long-term survival.[18,43–47]

Data such as these have led to a shift in the definition of resectability from criteria based on the characteristics of the metastases (tumor number, size, etc.) to new criteria based on whether a macroscopic and microscopic complete (R0) resection of the liver disease, can be achieved. Currently, hepatic colorectal metastases should be defined as resectable when it is anticipated that (1) all disease can be completely resected, (2) two adjacent liver segments can be spared, (3) adequate vascular inflow and outflow and biliary drainage can be preserved, and (4) the volume of the liver remaining after resection is sufficient.

The health and function of the nontumor bearing liver is clearly one of the most important factors impacting resectability and outcomes following liver resection. In patients undergoing surgery for hepatic metastases, cirrhosis is rarely present. However, increasing use of prolonged preoperative chemotherapy can result in significant steatosis, steatohepatitis, and sinusoidal dilatation. In some situations, these pathologic changes can be associated with increased postoperative morbidity. Assessment of hepatic functional reserve is important when deciding whether resection should be pursued. Staging the extent of hepatic dysfunction using the functional Child-Pugh and model for end-stage liver disease (MELD) classification system may be helpful.[48] Thrombocytopenia can be useful to estimate the extent of portal hypertension. Measurement of the indocyanine green retention rate can also provide an estimate of underlying liver function.[49] Although this test is used in some centers, it is not employed with great frequency in most cases. Imaging techniques may shed light on the extent of cirrhosis in some cases. Specifically, CT scan or MRI can identify loss of liver volume or hepatic contour changes indicative of more extensive cirrhosis; visualization of portal vein collaterals, splenomegaly, or ascites can indicate more advanced disease.

The size of the remnant volume considered safe varies with the condition of the hepatic parenchyma. In healthy livers, a

remnant liver volume greater than 20–25% of the estimated total liver volume is considered adequate.[50,51] In contrast, patients with cirrhosis need a greater remnant liver volume (>40%) in order to avoid postoperative liver failure. CT or MRI can now provide an accurate, reproducible method for preoperatively measuring the volume of the future liver remnant.[52] In cases where major hepatectomy is planned and there is concern regarding insufficient liver volume, these patients should be considered for ipsilateral portal vein embolization (PVE) to induce hypertrophy of the contralateral liver lobe.[51] PVE has been shown to increase the size of the future liver remnant. However, no strong evidence to date has clearly demonstrated improved outcomes following PVE compared to no PVE, particularly in the non-cirrhotic patient. Likely, the selective use of PVE may enable the performance of an extended hepatectomy in a subset of patients who otherwise would not have been candidates for safe resection.

In addition to tumor- and liver-related factors, patient comorbidities also need to be considered. Patients with an increased American Society of Anesthesiology (ASA) score have been shown to have a significantly higher morbidity and mortality as compared to those patients with an ASA of 1.[48,53] These patients with higher ASA scores reflect more underlying cardiac disease, renal insufficiency, and other conditions which place this patient population at greater risk for postoperative complications.

Techniques for Liver Resection

Whether for removal of colorectal metastases or other indications, the objective of a liver resection is to remove the involved portion of liver with an acceptable surgical margin and preserve sufficient hepatic reserve. Major hepatic resections can be divided into left and right hepatectomy (or hemihepatectomy) or extended hepatectomy, depending on the number of liver segments removed.[54] All or part of the caudate lobe can be included as part of a major liver resection or can be resected separately. When performing major hepatic resection, the vascular structures supplying the liver being removed are typically isolated extrahepatically prior to parenchymal dissection. The relevant portal pedicle can be secured at the hilum, either as a group within the intrahepatic hilum or by individual isolation of the portal vein and hepatic artery.[55,56] Selective extrahepatic ligation of inflow allows for the demarcation of the portion of the liver to be removed.

Minor resections can be either nonanatomic wedge resections or segmental resections. Wedge resections typically make no attempt at isolating vascular structures supplying the area being removed and are generally reserved for small peripheral lesions. When such resections are being performed for colorectal metastases, care must be taken to achieve an adequate resection margin as wedge resections are more often associated with positive or close margins.[56] Hepatic segmentectomy can be considered an anatomic minor resection. Such resections can be of a single segment or multiple adjacent segments (bisegmentectomy, sectorectomy, or sectionectomy) in one or both hemilivers. Provided adequate tumor margins are achieved, segmental resections have the advantage of preserving hepatic parenchyma compared to major liver resections. Intrahepatic anatomic landmarks visualized with intraoperative ultrasonography can be used to plan segmental resections and vascular pedicles are typically controlled within the liver substance. Temporary total inflow occlusion (Pringle maneuver) can be helpful during these types of resections.

A variety of techniques have been described for the division of the liver parenchyma.[26,57–60] The traditional method utilizes blunt parenchymal dissection either manually, or with a crushing clamp. Vascular and biliary structures are identified within the liver and ligated or clipped. Other dissection techniques utilize devices such as the ultrasonic Cavitron or a saline jet irrigator to divide the liver by disrupting the parenchyma. Newer devices use saline-enhanced radiofrequency energy to achieve coagulative necrosis of the liver substance to achieve hemostasis during or before the dissection.[58,59] Other devices thermally precoagulate the resection plane to achieve complete hemostasis prior to transection.[60] Surgical stapling devices have also greatly improved the ease in which liver resection can be performed.[61] In addition to facilitating division of the extrahepatic vascular pedicles, staplers can be used to divide larger pedicles within the liver parenchyma. The superiority of any one single method has not been established and the choice of technique should be determined by the individual surgeon's expertise.

Results of Liver Resection for Colorectal Metastases

Perioperative mortality of liver resection for colorectal metastases has markedly decreased in recent years, approximating 1% in most recent reported series.[62–68] In experienced hands, even major hepatic resections, which are performed in about half of these cases, result in perioperative mortalities of less than 3%.[62,64,65] The recommendation is that major liver resection be performed at centers and by surgeons with more than occasional experience with such procedures. One study analyzing the short-term outcome for liver resections in the state of Maryland indicated a clear relationship between hospital procedure volume and perioperative mortality.[65] Among 606 patients, the in-hospital mortality was 1.5% in the high-volume hospitals (defined as more than 15 resections per year) compared to a 9.6% mortality in centers performing less than eight resections per year. Although operative mortality should be uncommon, significant complications have been reported in 15–30% of patients.[64,67,69,70] The morbidity associated specifically with liver resection includes hemorrhage, perihepatic abscess, bile leak and/or fistula, pleural effusion, and hepatic failure.

The long-term survival reported following hepatic resection with curative intent for metastatic colorectal cancer has improved significantly in the last decade. While older series report 5-year survival rates of 25–40%,[69,71,72] more contemporary series report

TABLE 45-1: LARGEST SERIES REPORTING SHORT- AND LONG TERM OUTCOMES AFTER CURATIVE INTENT SURGICAL THERAPY FOR COLORECTAL LIVER METASTASES

Authors (Year Published)	Number of Patients Included	Mortality	Morbidity	5-Year Disease-free Survival	5-Year Overall Survival
Nordlinger et al (1992)[76]	1568	2%	23%	15%	28%
Fong et al (1999)[63]	1001	3%	31%	—	37%
Malik et al (2007)[68]	700	3%	30%	31%	45%
de Jong et al (2009)[77]	1669	—	—	30%	47%
House et al (2010)[75]	1600	2%	44%	27–33%	37–51%

5-year survival in excess of 50%.[62,73–75] Recent large multi-institutional collective series demonstrate trends in improved long-term outcome[63,68,76,77] (Table 45-1).

Prognostic Factors Following Resection for Colorectal Metastases

Although surgical resection results in prolonged survival and perhaps cure in some patients, the majority eventually develop recurrent disease. For this reason, many authors have attempted to identify factors that might improve patient selection, thereby improving the long-term outcome of those resected.[78,79]

Pathologic features of the primary tumor appear to correlate with long-term outcome following liver resection. Both nodal status and histologic grade of the primary tumor are associated with poorer outcome following liver resection in several reported series.[62,63,72] Features of the hepatic metastatic disease, including the number, size, and location of the metastases, correlate with prognosis in many series.[62,63,73,75] Fong et al report that the number and size of metastases, as well as the preoperative carcinoembryonic antigen (CEA) and disease-free interval each independently correlated with survival by multivariate analysis.[33] Although these data suggest that the prognosis appears worse in patients with an increased number of metastases, long-term survival can be achieved, at least in selected patients, with resection of even four or more metastatic lesions. There are insufficient data to allow a definitive threshold to be established at present.[78]

Technical factors at the time of surgery can also impact on the prognosis. These are of particular significance as they are often under the control of the surgeon. A positive histologic surgical resection margin has been found to be associated with poor long-term survival and higher risk of local recurrence.[41,62,80] The optimal width of the negative surgical margin, however, remains controversial. Some investigators have reported an improved survival when clearance margins were 1 cm or greater[72] while others have shown no differences, provided the margin is grossly negative.[41,81] In recent reports, some have challenged the need even for microscopically negative margins, particularly following preoperative chemotherapy.[42] The type of resection performed (wedge resection, segmentectomy, or hemihepatectomy) and the technique of parenchymal dissection do not appear to affect long-term recurrence rates, independent of margin status.[62,63,75]

Liver Resection in the Presence of Extrahepatic Colorectal Metastases

Extrahepatic disease, even when limited and resectable is generally acknowledged to be associated with worse prognosis following liver resection of colorectal metastases, with many in the past considering this a contraindication to surgery.[63,71] However, reduced surgical morbidity as well as the development of more effective systemic chemotherapy regimens have prompted many to recommend resection of all disease when possible, including extrahepatic sites.[45,47] Certainly, local extension to adjacent structures and locoregional recurrence should not be considered true extrahepatic disease and are not contraindication to surgery if complete resection is possible. In contrast, offering hepatic resection in the presence of extrahepatic metastases is somewhat more controversial. The lungs are the second most frequent site of metastatic disease, accounting for approximately 20% of those with metastases from colorectal cancer, and about 5–10% of patients who present with metastatic disease will have both liver and lung metastases. In the past, multiple studies have reported favorable long-term survival rates after resection of localized lung-only disease.[82,83] More recently, however, several centers have reported their results for patients undergoing combined lung and liver resection.[84,85] These studies have reported 5-year survival rates in excess of 30%. Prognosis following resection of pulmonary and liver metastasis does not appear to be affected by synchronous versus metachronous presentation. Several studies have reported no significant difference in survival between patients who present with simultaneous versus synchronous disease.[86] Patients with multiple pulmonary metastases (>3) have a significantly higher risk for disease-specific death compared with other patients.

Perihepatic lymph nodes are felt to be "metastases from metastases" and are generally associated with a poor outcome.

Until recently, many considered such nodal involvement an absolute contraindication to hepatic resection.[87] However, more recent studies have reported long-term survival in some patients with such nodal metastases and have concluded that this patient population may still benefit from hepatic resection.[18,47,88,89]

Metastatic spread to the peritoneal surfaces can occur in 15–20% of patients with advanced colorectal cancer and is not uncommonly seen in those with liver metastases. Although usually a particularly ominous indicator of poor prognosis, some centers have reported success with cytoreductive surgery and intraperitoneal chemotherapy.[90] Surgical therapy of combined liver and peritoneal metastases has been advocated by some.[91] However, concomitant peritoneal disease should be considered a contraindication for resection of liver metastases.

Elias et al[92] reported that the 5-year survival rate following hepatectomy for colorectal liver metastasis and simultaneous resection of extrahepatic disease with curative intent was 29%, including selected cases with pulmonary, nodal, and peritoneal metastasis. Patients with peritoneal disease or extrahepatic disease at multiple sites were found to have worse survival rate than patients with single-site extrahepatic disease.[92] In contrast, multiple studies have shown that patients with only pulmonary metastases have the most favorable outcome following liver and lung resection.[82,83]

While preoperative factors may be generally instructive, these factors should not be used to exclude patients from surgical consideration. Patients with one or multiple negative prognostic factors can still derive a significant survival advantage from hepatic resection of their colorectal metastases. However, the presence of disseminated extrahepatic disease, probably including periportal nodal disease or lack of control of the locoregional primary disease, is generally considered a contraindication to resection with curative intent. In patients with metastatic disease confined to the liver in whom surgical resection can completely and safely remove all evident disease with negative margins, surgical resection should be advocated.

ROLE OF SYSTEMIC CHEMOTHERAPY IN PATIENTS UNDERGOING SURGICAL THERAPY OF LIVER METASTASES

Current combination chemotherapy regimens incorporating oxaliplatin or irinotecan in addition to 5-fluorouracil (5-FU) and leucovorin (LV) or capecitabine have produced response rates in excess of 40%.[93–95] The addition of biologic agents such as those targeting epithelial and vascular endothelial growth factor pathways has been shown to further improve response rates and increase survival in the metastatic setting.[96,97] The impressive results of these regimens have led to much enthusiasm for their use in combination with hepatic resection.

Optimal integration of chemotherapy and surgical therapy of liver metastases is an important and controversial topic. While extensive randomized controlled trials have shown the benefit of postoperative adjuvant chemotherapy in locoregional colon cancer,[98–100] the role of chemotherapy combined with potentially curative resection of liver metastases is less well studied. Specifically, integration of chemotherapy may include (1) postoperative adjuvant therapy in the resected patient, (2) neoadjuvant or perioperative chemotherapy in the patient with initially resectable disease, and (3) preoperative chemotherapy in the initially unresectable patient in order to achieve a conversion to a resectable state.

Postoperative Adjuvant Chemotherapy

It has been known for decades that adjuvant chemotherapy improves disease-free and overall survival in earlier-stage colon cancer.[99,100] In stage III patients, the risk of relapse with surgery alone is reduced by 40% with 5-FU-based adjuvant therapy, and the risk of death is reduced by 30%.[99] The addition of oxaliplatin to infusion 5-FU/LV (FOLFOX regimen) significantly improves disease-free survival.[98] However, the role of adjuvant chemotherapy is not as clearly defined after potentially curative resection of liver metastases (stage IV with no evidence of disease). Given that these patients have overall higher risk of recurrence than stage III patients, the rationale for use of adjuvant therapy in this setting is clear, yet few studies have evaluated whether chemotherapy improves outcomes following liver resection. Two European randomized trials closed early because of slow accrual. A pooled analysis of these included 278 patients who had undergone complete resection of the primary tumor and up to four liver or lung metastases and randomized patients to receive either six cycles of bolus 5-FU/LV or surgery alone.[101] There was a trend toward improved 5-year progression-free survival with chemotherapy compared with surgery alone, but the results did not reach statistical significance. Portier et al reported a French trial of 173 patients who were randomized to 6 months of postoperative bolus 5-FU/LV versus observation following R0 resection.[102] The 5-year disease-free survival was 34% for patients in the chemotherapy group and 27% for patients in the surgery-alone group (OR 0.66, $p = .028$). There was a trend toward increased 5-year overall survival with chemotherapy (51 vs 41% with surgery alone), but this difference did not reach statistical significance. These trials were conducted with bolus 5-FU/LV, the standard regimen at the time; the benefit of more effective postoperative oxaliplatin-based regimens such as FOLFOX as well as with biologic therapies has yet to be determined.

Intrahepatic infusional chemotherapy also has been proposed as adjuvant therapy following liver resection, based in part on the high risk of intrahepatic recurrence and the ability of regional chemotherapy to deliver higher drug concentrations within the liver. Several studies have examined the role of adjuvant hepatic artery infusion (HAI) using 5-FU or floxuridine (FUDR) with or without systemic chemotherapy.[103] This therapy was compared with either observation or systemic chemotherapy with bolus 5-FU/LV. Two small

trials demonstrated some benefit for HAI over this systemic chemotherapy alone.[103] Although some improved efficacy was observed in these studies as well as phase II studies, comparisons with newer, more active systemic regimens in randomized trials are lacking.[104] In addition, the toxicity and technical aspects of implanting and maintaining a hepatic arterial pump have limited its applicability in practice. One recent cooperative trial in the United States closed early after failing to accrue many patients, and the current role for adjuvant therapy using regional infusion chemotherapy in this disease is limited outside of a clinical trial.

Perioperative Chemotherapy in the Initially Resectable Patient

The use of preoperative chemotherapy for patients with initially resectable hepatic metastases has generated significant controversy. Several arguments have been made in favor of preoperative chemotherapy (Table 45-2). First, it provides some time for biologically aggressive disease to declare itself, potentially avoiding unnecessary surgery. Second, determination of response in the macroscopic disease provides prognostic information[105–108] as well as potentially allowing for modification of the postoperative therapy based on response. Finally, neoadjuvant chemotherapy may allow a smaller resection or increase the possibility of an R0 resection. Achieving negative margins is important when resecting for curative intent and the rate of positive surgical margins may be lower with preoperative systemic chemotherapy than with immediate resection.[42]

While theoretically appealing, the use of preoperative chemotherapy in an initially resectable patient may have some disadvantages (Table 45-2). Some consider it important to offer the surgical therapy first in order to avoid a lost opportunity. If neoadjuvant therapy fails to stabilize the disease, it may progress to an unresectable status. This situation is rare, however, with most series reporting less than 10% occurrence. In addition, patients in this group may have less to gain from aggressive surgical therapy given the poor prognosis that early progression may indicate.[106] Another disadvantage of preoperative chemotherapy is the risk of chemotherapy-associated liver injury, which could increase the morbidity of surgery.[109–112] Seen in two forms, vascular sinusoidal dilatation and fatty liver changes (steatosis or steatohepatitis), hepatotoxicity can be limited with shorter duration of chemotherapy.

Another potential disadvantage of neoadjuvant chemotherapy is related to the complete radiologic response that can be observed in some lesions. In one study, van Vledder et al found 23% of patients receiving preoperative chemotherapy had at least one disappearing liver metastases.[113] This finding was more common in small lesions, in patients with multiple metastases, and in those with longer chemotherapy duration (Fig. 45-2). Only approximately one-half were found at the time of surgery and, when not identified, the majority of these were not treated. In most cases local recurrence developed in these sites. Similarly, Benoist et al, reported the presence of residual disease at the site of a radiologic complete response in 82%.[114] Thus, if the hepatic lesions are rendered so small that the surgeon can no longer find them, perhaps the patient may have been done a disservice by preoperative chemotherapy.

The impact of perioperative chemotherapy in conjunction with liver resection was reported in a randomized, multiinstitution trial sponsored by the European Organization for Research and Treatment of Cancer (EORTC 40983).[115] In this study, 364 chemonaive patients with up to four colorectal liver metastases (median of 1) were randomized

TABLE 45-2: NEOADJUVANT CHEMOTHERAPY PRIOR TO HEPATECTOMY IN THE INITIALLY RESECTABLE PATIENT WITH COLORECTAL LIVER METASTASES

Potential Advantages	Potential Disadvantages
1. Allows time for other sites to declare themselves	1. Tumors may progress to unresectable status
2. Allows for earlier therapy of occult micrometastatic disease	2. Split regimen may have detrimental effect
3. Allows for in vivo gauge of chemoresponsiveness, facilitating postoperative chemotherapy planning	3. Chemotherapy-associated hepatotoxicity
4. Response may allow for smaller resection	4. Potential for increased postoperative complications
5. Response is a prognostic factor	5. Response may hinder finding all sites of metastatic disease

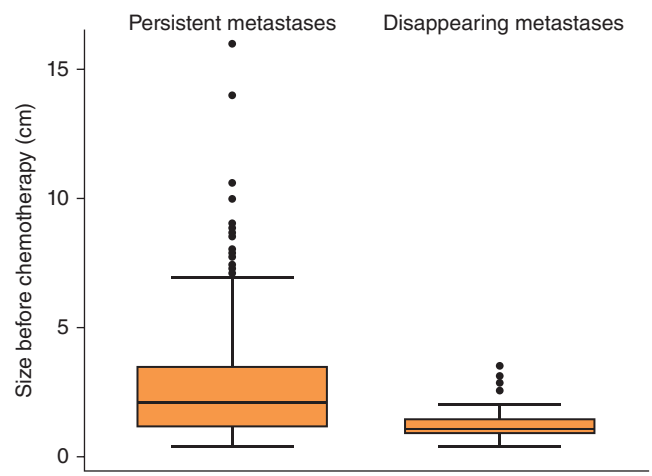

FIGURE 45-2 Comparison of the size of metastases prior to chemotherapy among those that radiologically disappeared versus those that remained visible following chemotherapy. (van Vledder MG, de Jong MC, Pawlik TM, Schulick RD, Diaz LA, Choti MA. Disappearing colorectal liver metastases after chemotherapy: should we be concerned? *J Gastrointest Surg.* 2010 Nov;14[11]:1691–1700.)

to either perioperative chemotherapy with six cycles of FOLFOX before surgery and six cycles after surgery, or to surgery alone. Difference in 3-year progression-free survival between groups was 7.3% in randomized patients ($p = .058$), 8.1% in eligible patients ($p = .041$), and 9.2% in patients successfully undergoing resection ($p = .025$). There were no differences in perioperative mortality between the treatment groups, but postoperative complications occurred significantly more often in those who received neoadjuvant therapy (25 vs 16%), including increased risk of biliary fistula and intra-abdominal infection. These findings support a role for chemotherapy in patients undergoing liver resection, although the benefit was perhaps less than may be expected based on the benefit seen with chemotherapy in stage III disease. Overall survival was not significant, so it is unclear whether perioperative FOLFOX actually contributes to cure or simply delays recurrence. Furthermore, the trial was not designed to test the value of preoperative versus postoperative chemotherapy and did not definitively answer the important question about the optimal sequencing of chemotherapy around curative liver resection.

Converting Unresectable to Resectable Disease With Preoperative Chemotherapy

The prospect of converting initially unresectable metastases to resectable disease has become more attainable with improved response rates from modern systemic regimens. Combination chemotherapy, including FOLFOX and FOLFIRI, achieves radiologic response rates of approximately 50%.[97,116] More aggressive regimens (eg, FOLFOXIRI) as well as the addition of targeted therapies increase response rates even further.[117–119]

The goal of tumor downsizing with a chemotherapeutic response is to be able to remove the gross residual disease of all original sites of disease. Liver metastases located near major vascular pedicles which need to be salvaged are ideal candidates (Fig. 45-3). Currently, it is estimated that approximately one-fourth of patients with liver metastases are initially resectable and conversion from unresectable to resectable disease through tumor downsizing can be achieved in approximately 20% of those initially considered unresectable.[120,121]

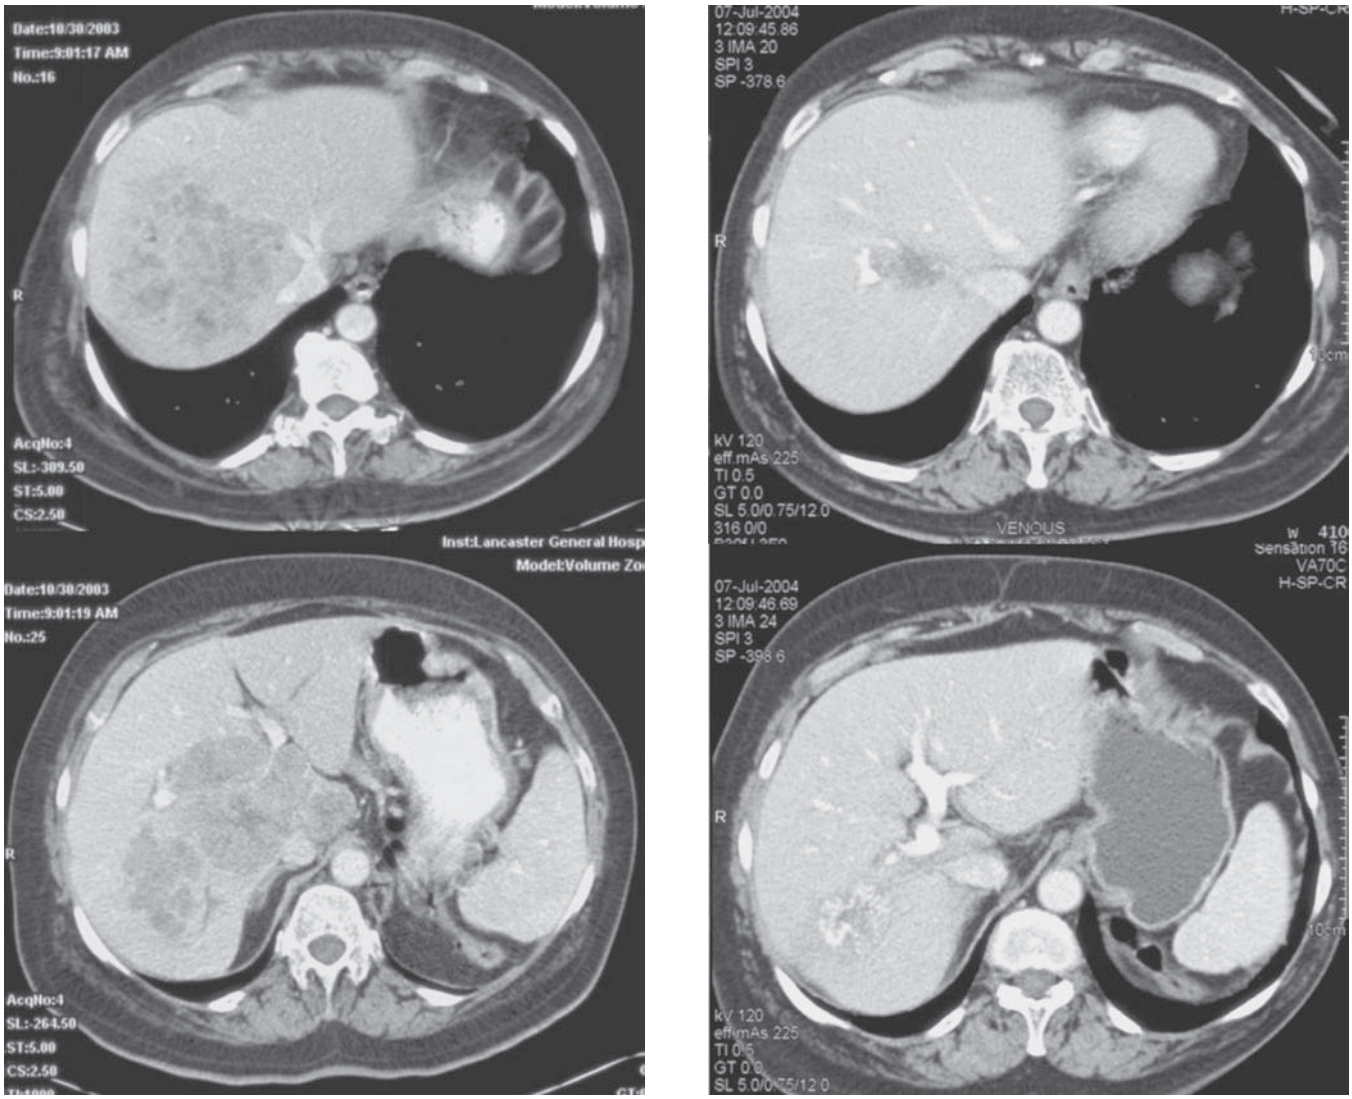
Outcomes following liver resection in initially unresectable patients following chemotherapy response appear similar to initially resectable patients. In one report, 5- and 10-year overall survival rates were 33% and 23%, respectively in initially unresectable patients who subsequently underwent resection.[120] In a more recent study, unresectable patients with liver-only disease were randomized to either FOLFOX or FOLFIRI in combination with cetuximab.[122] Complete resection was achieved in 34% overall and was comparable in both groups.

Strategies for tumor downsizing and resection need to be further refined. We still do not know what circumstances indicate optimally converted patients. For example, it is unclear whether all areas where the tumor initially existed should be resected. Furthermore, it is still unclear what role ablation might play in such a setting. The optimal duration of preoperative chemotherapy in this setting also remains uncertain. For example, should patients be treated until disease is resectable or to a maximal response? It is likely that residual visible disease is of benefit in identifying all initial sites that need to be resected to prevent recurrent disease. Similarly, it is unclear how to manage disease in the case of complete radiologic response. Should patients undergo surgery at that time or wait until some disease becomes radiologically evident?

ABLATIVE THERAPIES

Although surgical resection may afford the best potential for cure in patients with hepatic metastases, many patients may not be candidates for surgical resection for a variety of reasons. Novel methods for local ablation have been developed with a goal of increasing the number of patients eligible for local, potentially curative therapy. The early experiences with metastasis ablation have been primarily with hepatic cryosurgery. This technique relies on the destruction of a defined area within the liver by freeze or thawing, using probes cooled by liquid nitrogen to subzero temperatures. Placement and monitoring of the freezing process is monitored with ultrasound. More recently, radiofrequency ablation (RFA) has been applied for the treatment of liver tumors in much the same manner as cryotherapy. With this technique, a needle-probe is inserted within the selected tumor under image guidance and electric current is employed to generate heat, resulting in interstitial thermal destruction. RFA can be performed laparoscopically or percutaneously, as well as via open laparotomy. Advantages of RFA over cryotherapy include the smaller probe and fewer related complications. For these reasons, RFA has replaced cryotherapy as the preferred method of interstitial ablation in many centers. While most studies report outcomes of RFA for treatment of colorectal metastases, newer ablative approaches are being used with increasing frequency. These include microwave ablation and nonthermal irreversible electroporation. While potentially promising, these newer ablative modalities await larger controlled reports to determine their role in therapy of hepatic colorectal metastases.

When performing ablation of colorectal metastases, RFA in particular, careful planning of the zone of destruction is necessary to achieve complete necrosis of the target lesion.[123] In some cases when using an expandable multielectrode RFA needle of sufficient size, complete ablation can be achieved with a single application, deploying the electrode from the center of the tumor. In cases of larger lesions, multiple overlapping applications may be required.[124] Tumor size as well as location can preclude effective ablation with curative intent. Tumor sizes larger than 3 cm are associated with an increased incidence of local recurrence.[125] Similarly, tumors near major



A B

FIGURE 45-3 Computed tomographic images in a patient with metastatic colorectal cancer. **A.** Bulky liver-only disease in patient initially considered unresectable. **B.** Converted to resectable status following response to preoperative systemic chemotherapy (FOLFOX with bevacizumab).

vascular structures such as the vena cava are more difficult to achieve long-term local control with ablation.

Once the target tumor is identified with the IOUS transducer during a surgical ablation, the RFA electrode needle is inserted under ultrasound guidance (Fig. 45-4). Optimally, the electrode is advanced in a track parallel and within the plane of the transducer, so the entire path of the needle can be visualized. Monitoring during thermal ablation can be performed using a variety of methods. Some RFA devices have the capacity to measure tissue temperatures with thermistors located at the tips of the electrodes. Alternatively, tissue impedance and current can be monitored during treatment. The ablation zone is visualized by ultrasound during treatment. Typically, local miniscule gas bubble formation results in hyperechogenicity within the treated tissue.

The optimal method for evaluating the efficacy of RFA treatment using imaging modalities is not well defined. The presence of residual viable tumor tissue after RFA can be detected using contrast-enhanced CT or MRI.[126,127] However, as with other ablative approaches, interpretation of these images can be difficult at times, as a hypoattenuating lesion may persist for months to years despite complete tumor destruction. In most cases, a local recurrence is characterized by an increase in the lesion size on serial scans, or evidence of new areas of contrast enhancement. FDG-PET may be useful in assessing recurrent disease provided it is acquired after the postablation inflammation has subsided, typically after 3 months.[127]

Unlike hepatic resection where long-term efficacy is relatively established, evidence of the benefit of ablation for treatment

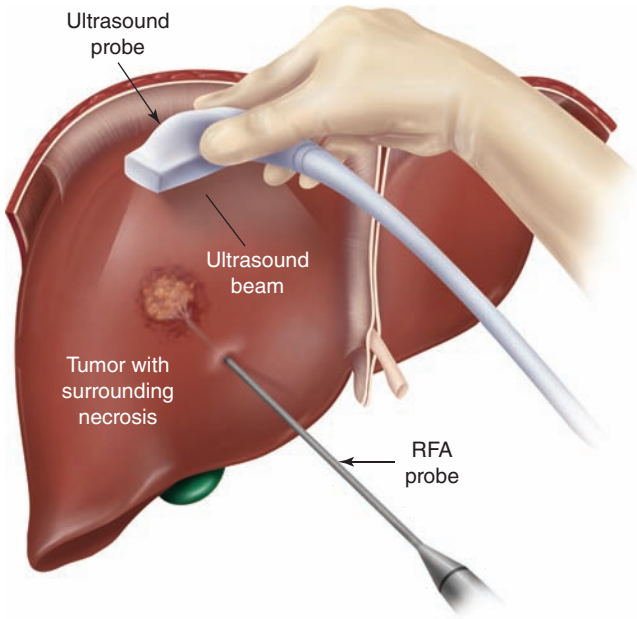


FIGURE 45-4 Operative radiofrequency ablation under IOUS guidance.

of hepatic colorectal metastases has been limited and inconsistent.[123] There are no published randomized controlled trials examining its use in this disease so the data are largely based on single-arm, retrospective, and prospective studies.

Local recurrence rates published in the literature range from less than 10% to as high as 40–50%.[73,123,128,129] Data on the survival benefit of RFA have been similarly contradictory. Some studies have reported 5-year survival of less than 20% following RFA whereas other studies have reported 5-year survival rates in the range of 40% or more.[123] In addition, several studies have attempted to compare outcome of resection versus ablation, most demonstrating RFA to be associated with a worse disease-free and overall survival compared with resection. One must realize, however, that important prognostic and treatment-related variables differ between the two cohorts when compared retrospectively. In a review of RFA for colorectal cancer by the American Society of Clinical Oncology (ASCO), the authors recognized a scarcity of quality evidence and emphasized a compelling need for more clinical trials to determine the efficacy and utility of RFA in these patients.[123]

REGIONAL CHEMOTHERAPY: HEPATIC ARTERIAL INFUSION

Chemotherapy delivered systemically to treat hepatic metastases may be limited by the incapability to deliver high concentrations of drug to tumor cells without systemic toxicity. This provides the rationale for regional chemotherapy. The normal liver derives its blood supply from both the hepatic arterial and portal venous vessels. Macroscopic hepatic tumors, however, derive most of their afferent blood supply from the hepatic artery.[130] Directing a high-dose infusion of chemotherapy into the hepatic artery therefore increases the concentration of drug to which the tumor is exposed, proportional to the hepatic parenchyma, as well as to the body as a whole, and should thereby improve the therapeutic index.[131] Drugs such as fluorodeoxyuridine (FUDR), an active metabolite of 5-FU, which are rapidly metabolized within the liver on the first pass, are the most commonly used regional chemotherapeutic agents.[132]

While evidence regarding the role of HAI therapy was summarized earlier, several older randomized trials have compared the results of continuous HAI chemotherapy alone to systemic chemotherapy in patients with unresectable liver metastases.[133–135] Most reported increased response rates compared to systemic therapy but survival benefit was inconsistent, in part because of inadequate sample sizes, crossover study designs, or inadequately administered systemic chemotherapy.

In 2003, Kerr et al reported a European trial randomizing 290 patients to systemic versus HAI 5-FU.[136] While the study was criticized for the technique and study design, the median overall survival was no different between treatment groups. In another randomized multi-institutional trial, Kemeny et al reported a higher response rate with HAI FUDR with dexamethasone (47%) compared to the systemic group receiving 5-FU/LV (24%), along with an improved overall survival in the HAI group (24.4 vs 20 months, $p = .003$).[103] As with HAI therapy in the adjuvant setting, limited level 1 evidence exists comparing regional infusion chemotherapy to current combination systemic regimens. While response rates are high with this approach, even following tumor progression on systemic therapies, the biliary toxicity and technical aspects of implanting and maintaining an hepatic arterial pump have limited its applicability in current practice beyond few centers with experience in this approach.

SUMMARY

Surgical therapies for hepatic colorectal metastases have been shown to be increasingly safe and effective resulting in more frequent and aggressive application of this local approach. Preoperative and intraoperative assessment and planning are important to achieve safe and complete resection of all evident disease. Current methods for increasing the ability to offer liver resection include preoperative chemotherapy, staged resection, preoperative portal vein embolization, and ablative strategies. Perioperative chemotherapy may play a role in the optimal treatment of initially resectable disease, but the sequencing of chemotherapy and surgery remains unclear.

In the near future, we are likely to see expanding use of local therapies of hepatic metastases, particularly as systemic chemotherapy improves. Minimally invasive approaches for resection, including laparoscopic resection, will likely be increasingly utilized, as well as other nonextirpative techniques. However, until the role of cytoreduction or incomplete local therapies is defined, complete, curative-intent therapy must be advocated.

46A

PERSPECTIVE ON LIVER SURGERY

Steven A. Curley

Interest and experience with surgical treatment of the liver has expanded dramatically over the past two decades. The size of the pool of surgeons who routinely perform liver-directed surgery has also increased. These changes and expansion have been fueled by improved description, understanding, and study of segmental liver anatomy and the numerous potential variations in hepatic arterial, portal venous, hepatic venous, and bile duct anatomy. A key example is the description of segmental hepatic anatomy by Couinaud with an appreciation of the vascular anatomy and associations with the eight segments of the liver (Fig. 46A-1).

As with many other types of potentially complex surgical procedures, operations on the liver now occur more commonly because of enhanced safety. Procedures and techniques have evolved to minimize blood loss which reduces the morbidity related to transfusion of multiple units of blood. Hepatobiliary surgeons can be as idiosyncratic as any other group of surgical specialists; each individual surgeon has his or her own favorite technique or techniques for hepatic transection. The number of possible techniques to perform liver transection safely has grown based on the interest from medical device manufacturers to produce novel equipment to permit liver parenchymal transection while minimizing blood loss. It is not unusual for there to be an array of equipment in the operating room of the modern hepatobiliary surgeon with the goal being to perform the operation with maximum safety and improved patient outcome.

The liver is unusual in the human body as it has a dual blood supply, the portal vein and the hepatic artery. It has been known for almost a 100 years that occlusion of the portal vein and hepatic artery during operation on the liver, be it for a traumatic injury to the liver or for elective resection of a portion of the liver, can reduce blood loss. Advances in our understanding using this technique have led to the realization that inflow occlusion of the hepatic blood supply can be performed safely for carefully controlled periods even in patients with cirrhotic livers. Furthermore, intermittent occlusion followed by brief periods of reperfusion of the liver will increase the total time of inflow occlusion that can be achieved while still successfully limiting blood loss and reducing the risk for ischemic liver injury.

HEPATIC ABSCESS AND CYSTIC DISEASE OF THE LIVER

Despite an ever expanding selection of antibiotic agents, pyogenic liver abscess is as common a problem today as it was in the preceding century. If anything, treatment of pyogenic liver abscess with antibiotic therapy is more difficult and has been complicated by the indiscriminate use of antibiotics over the past several decades. Iatrogenic etiologies of liver abscess may have also been increased by the more invasive and aggressive approaches to benign and malignant pancreatic and biliary tract diseases. Endoscopic retrograde cholangiopancreatography, placement of internal stents, or percutaneous placement of external stents in patients with biliary obstruction can increase the likelihood of the development of a pyogenic liver abscess. Furthermore, immunocompromised patients, such as those receiving cytotoxic chemotherapy for malignant disease, are at increased risk to develop hepatic abscess. The primary treatment approach continues to be medical antibiotic therapy and percutaneous interventional radiology aspiration or drainage of abscesses when possible. However, there is still an occasional role for surgical drainage of a complex or multiloculated abscess.

Amebic liver abscess is an extremely common problem worldwide. It should not be forgotten in patients treated in the United States because of the number of people who travel to high-risk areas or who have immigrated to the United States from endemic regions. This is particularly true in the southern, southwestern, and western United States. The diagnosis of amebic liver abscess should be entertained in patients with imaging evidence of a hepatic abscess and an appropriate history and risk group. Treatment is generally medical therapy with occasional need for aspiration or percutaneous drainage.

An echinococcal or hydatid cyst of the liver is an extremely common cause of cystic liver disease worldwide. It is critical to consider this in the differential diagnosis of a patient with a liver cyst because aspiration and spillage of the cyst contents can produce an anaphylactic reaction and spread of the scoleces throughout the peritoneal cavity. This diagnosis should

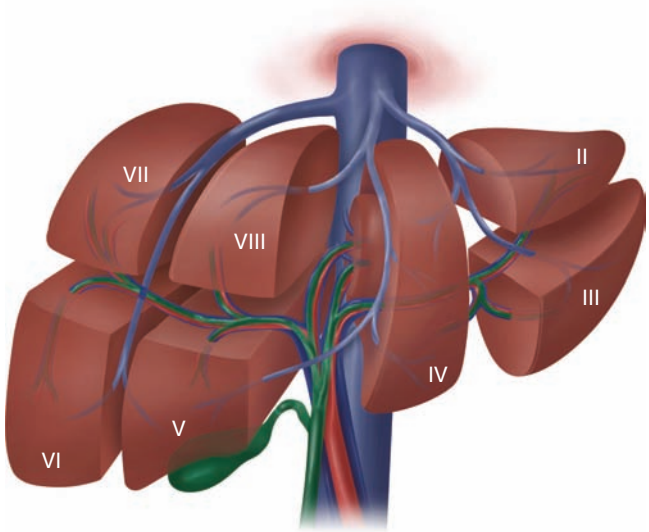

FIGURE 46A-1 The junctional division of the liver and the segments according to Couinaud's nomenclature.

be considered in individuals living in high-risk areas of the world, and once again, may arise in immunocompromised individuals. Management of small cysts involves medical therapy with benzimidazoles. However, this is rarely successful alone, and treatment of larger lesions may also require very careful percutaneous aspiration of all cyst contents followed by installation of the cyst cavity with protoscolecidal agents. Surgical treatment still has a primary role in management of hydatid cysts of the liver and may include resection of the area of the liver bearing the cyst or complete drainage of the cyst while preventing spillage of cyst contents.

Simple liver cysts are diagnosed frequently in patients who are undergoing upper abdominal ultrasound or axial body imaging for some other diagnostic purpose. It is particularly common in patients with malignant disease during staging to be referred to a hepatobiliary surgeon with a finding of cystic lesions in the liver. The question arises from many oncologists as to whether or not these are worrisome and a concern for metastatic disease is often raised. Asymptomatic simple cysts essentially are a radiographic finding and do not require any therapeutic intervention. In the unusual case of giant cysts that are causing pain or compression on adjacent structures, either an open or laparoscopic unroofing of the cyst can be performed as long as there is no connection to the biliary tract. A laparoscopic approach is my preferred treatment for patients with symptomatic simple cysts of the liver as the recovery time is rapid and the symptom relief rate without recurrence of symptoms exceeds 95%. If a biliary tract connection is recognized, concern must be raised for a possible biliary cystadenoma or cystadenocarcinoma. Most of the cystic neoplasms are benign, but complete resection of both benign and malignant neoplastic cysts of the liver is mandatory to prevent a local recurrence of disease. Cystadenoma or cystadenocarcinoma should be suggested if aspiration of a cyst reveals either bile-stained or mucinous fluid.

BENIGN AND MALIGNANT PRIMARY LIVER NEOPLASMS

Similar to asymptomatic simple cysts of the liver, patients with solid benign tumors of the liver are often referred to hepatobiliary surgeons after either a transcutaneous ultrasound or an axial body imaging technique reveals a single or multiple solid lesions. Cavernous hemangiomas, hepatocellular adenomas, and focal nodular hyperplasia may be found in almost one in five patients undergoing a liver imaging technique. It is not uncommon for an individual patient to have more than one type of benign hepatic tumor. Like asymptomatic simple cysts, hemangiomas and focal nodular hyperplasia of the liver are usually only radiographic findings and not associated with symptoms. In those unusual situations where these lesions are large or symptomatic, surgical resection with either an open or laparoscopic approach is indicated. Parenthetically, a significant proportion of early laparoscopic resections were performed for benign solid tumors of the liver that may have not required any type of resection. A benign solid or cystic neoplasm of the liver in an area that is technically feasible to resect with a laparoscopic approach is not an indication for a resection if the lesion is asymptomatic. Hepatic adenomas can grow in size over time and have been associated with two potentially catastrophic outcomes, rupture of the lesion with intraperitoneal hemorrhage or transformation into malignant hepatocellular carcinoma (HCC). Taking female patients off oral contraceptives or other forms of estrogen replacement therapy may lead to reduction in the size of hepatic adenomas, but most hepatobiliary surgeons agree that lesions larger than 4–5 cm should be treated with surgical resection.

HCC is one of the most common solid tumors worldwide. There are estimates that anywhere between ½ and 1 million new patients are diagnosed annually worldwide with this particularly lethal malignancy. Most cases of HCC are associated with concomitant liver injury or established cirrhosis. The chronic liver injury can arise from a number of environmental or hereditary causes, but the most common etiologic agents are chronic hepatitis B and/or C infection and alcohol abuse. The presence of cirrhosis may limit the role of the hepatobiliary surgeon even in patients with reasonably early-stage disease. Surgical treatment is still considered the gold standard in therapy for HCC but only a small minority of patients are candidates for surgical treatment approaches. These treatments include orthotopic liver transplantation based on defined patient-inclusion criteria, resection in patients with adequate functional hepatic reserve remaining after an anatomic or nonanatomic liver resection, and thermal ablation techniques in patients with small lesions but cirrhosis too severe to permit resection. As pointed out in the chapter by Cho and Fong, the 5-year survival rates after resection for HCC have ranged from approximately 20 to 75%. In orthotopic liver transplant series that accrued patients after proper patient selection criteria were established the 5-year survival rates vary from 45 to 75%.

Unfortunately, in most large treatment centers that see a large volume of HCC patients, less than 10% are candidates for surgical treatment. The reasons for exclusion from surgical

treatment may include presentation with advanced-stage or metastatic disease, major vascular invasion by tumor, paucity of organs for transplantation, and severity of cirrhosis too great to permit surgical treatment. There have been numerous types of regional and systemic therapies used to treat HCC in patients who are not candidates for surgical treatment. This is a highly resistant and aggressive disease and sadly very few patients who are not candidates for surgical treatment survive more than 2 years, much less having a chance at 5-year survival. Worldwide, the overall mortality rate for HCC in all patients exceeds 94%, so it is clear that better screening programs to diagnose patients at an earlier stage of disease would be highly desirable. It is not clear if such screening programs would be cost effective but this will become an issue due to the increased incidence of this disease in both modern and less developed regions of the world. Similarly, programs aimed at prevention of disease are crucial. Hepatitis B vaccinations have made an impact on the incidence of this cancer in portions of the world where chronic hepatitis B infection is hyperendemic. There is no vaccine for hepatitis C and this virus is supplanting hepatitis B virus as the most common cause of HCC worldwide. Education and prevention are important factors, but clearly better treatments are also needed for this lethal disease. Currently the oral agent sorafenib, a multiple tyrosine kinase inhibitor, has become a standard therapy for patients with advanced and unresectable HCC. However, use of sorafenib enhances survival by an average of less than 3 months, so more effective therapeutic agents for patients with advanced disease must be sought and developed.

Cholangiocarcinomas may arise from the extrahepatic bile ducts, the intrahepatic bile ducts, or the gallbladder. As with HCC, complete surgical resection of cholangiocarcinoma offers the patient the best opportunity for long-term survival. For extrahepatic bile duct cancer and gallbladder cancer, identifying the association of tumors in the bile ducts with key vascular, lymphatic, and hepatic structures is critical to optimize the resection. An excellent example is the importance of caudate resection in patients with hilar cholangiocarcinoma as direct extension of these cancers along small bile ducts directly into the caudate is a common site of failure in patients undergoing a resection that does not include the caudate. Resection of regional lymph nodes is recommended in patients with gallbladder cancer and cholangiocarcinoma and is important for staging. It is not clear that adjuvant therapy significantly improves the long-term outcome of patients but some small studies of systemic chemotherapy or chemoradiation therapy have suggested improved local disease control and possibly an improved median disease-free survival time. Cholangiocarcinomas generally arise in patients with no evidence of cirrhosis or concomitant risk factors for the development of chronic liver injury so major liver resection can be performed more frequently in this patient population. Discussion in the surgical literature has ranged widely regarding the volume of liver that must be resected as part of an operation for cholangiocarcinoma, particularly for gallbladder cancer or hilar cholangiocarcinoma. My general philosophy and data from our experience indicates that major extended hepatectomy should only be performed if this is the procedure that is required to permit complete resection of the tumor with negative resection margins. As previously noted, resection of the caudate is important as a component of the resection of patients with hilar cholangiocarcinoma, but the volume of other liver that must be resected should be based on leaving as much normal, non-malignant liver as possible after the resection.

HEPATIC COLORECTAL METASTASES: RESECTION, PUMPS, AND ABLATION

HCC is the most common reason for hepatic resection or surgical treatment of malignant liver tumors in parts of the world where chronic hepatitis B and C virus infections are common. In most western countries, surgical resection of colorectal cancer liver metastases is a primary focus of many hepatobiliary surgeons. Following the report in the late 1980s of a retrospective analysis of tumor registry data, it was recognized that patients undergoing hepatic resection of colorectal metastases can achieve long-term disease-free and overall survival. While there has not been, and likely never will be a randomized prospective controlled clinical trial comparing resection of colorectal cancer liver metastases with nonsurgical treatment, it is accepted by both the surgical and medical oncology communities that properly selected patients should be considered for surgical treatment of their colorectal cancer liver metastases. Like cholangiocarcinoma, most patients with colorectal cancer liver metastases have relatively normal liver function. This being said, it has been recognized in the last decade that patients with steatohepatitis, caused either by obesity and dietary excesses or iatrogenically by the extensive and prolonged use of neoadjuvant chemotherapy that causes hepatic inflammation, can increase the risk of complications and even mortality related to liver failure after major hepatic resection. Many hepatobiliary surgeons prefer to proceed directly with resection of colorectal cancer liver metastases if the patient has technically resectable disease and an adequate functional hepatic volume remaining after the operation. Others advocate for the use of short courses of neoadjuvant therapy to assess the biological response in the tumors to potentially effective systemic agents. Ultimately, hepatobiliary surgeons will operate on some colorectal cancer patients who have received extensive systemic therapy. It has now been recognized that patients who initially present with clearly unresectable disease but who have a dramatic response to systemic therapy may be considered candidates for resection and can achieve 5-year survival rates in excess of 35% following operation. Ongoing clinical trials internationally will be important to understand the role of neoadjuvant and adjuvant therapy after surgical resection of colorectal cancer liver metastases. Surgeons and patients should be encouraged to enter these trials to provide much needed information on optimal multidisciplinary treatment of stage IV colorectal cancer.

The early retrospective studies indicated that approximately one-third of patients treated with surgical resection achieved a 5-year overall survival. Improved patient selection, routine use

of intraoperative ultrasonography to detect small lesions not found on preoperative imaging studies, and improved surgical techniques have produced 5-year survival rates of almost 60% in more recent studies. Additionally, we now know that even a small tumor-free resection margin can be associated with improved patient outcomes, so aggressive surgical approaches should be considered even in tumor that is near major central portal or hepatic venous structures. The routine but selective use of preoperative portal vein embolization (PVE) to induce compensatory hypertrophy in the future liver remnant has also improved the ability to perform major extended hepatectomies safely. The compensatory hypertrophy that occurs after PVE is rapid and most patients can undergo an operation 4–6 weeks after PVE. We, and other surgical groups, have also been aggressive about applying staged hepatic resections in properly selected patients. Performing a two-stage liver resection with or without PVE is associated with long-term survival in over one-third of the treated patients. It is important to recognize that discussing such an aggressive surgical approach is considered reasonable and rational because the 5-year survival rate in patients with unresectable colorectal cancer liver metastases treated with active chemotherapeutic drugs continues to be 5% or less. Furthermore, the surgical mortality rate in high volume centers is less than 3%.

As noted previously, intraoperative ultrasonography is critical for the hepatobiliary surgery performing resection for colorectal cancer, or for other solid tumor liver metastases. Despite improvements in axial body imaging, I still find additional small tumors not seen on preoperative imaging studies in up to 10% of patients undergoing resection. These lesions may be in area of the liver that is planned to be resected or may be on the contralateral side of the liver requiring wedge resection, staged resection, or concomitant thermal ablation of the additional small tumors. I routinely map the location of major intrahepatic portal and hepatic venous structures. This allows the safe application of linear vascular staplers in patients with nonsteatotic or noncirrhotic livers. I also use ultrasonic dissection devices combined with saline-enhanced cautery devices to perform a safe and relatively bloodless liver transection. Inflow occlusion can be applied judiciously, but many patients require no inflow occlusion when using vascular stapling and other liver transection techniques. I am not an advocate for any specific technique as being superior, I am a firm believer that all surgeons should be well versed in use of equipment available for safe hepatic transection and should use techniques with which they are comfortable and confident in their results.

Prior to 2000, there were a paucity of active systemic chemotherapeutic agents in the United States to treat stage IV colorectal cancer. In the 1980s and 1990s, surgical placement of hepatic artery infusion (HAI) pumps was a treatment that was often considered in patients with stage IV colorectal cancer confined to the liver that was not resectable. Unfortunately, regional chemotherapy, while associated with increased rates of measurable partial response, was not associated with an improved long-term survival rate. Additionally, there were toxicities peculiar to HAI chemotherapy, including chemical hepatitis and biliary sclerosis. There have been trials published supporting the use of adjuvant HAI chemotherapy which may reduce the likelihood of recurrence of disease in the liver after liver resection, but this approach has not gained general acceptance. Currently, HAI therapy is performed at few centers in the country and should be considered only as part of a clinical trial.

Tumor ablation techniques continue to evolve. Radiofrequency ablation (RFA) has been applied to treat unresectable HCC as well as unresectable liver metastases from colon and other types of solid malignancies. In my mind it would not be appropriate to consider a trial that would randomize patients with resectable colorectal cancer to resection versus thermal tumor ablation. Well-trained hepatobiliary surgeons can perform resection with low-morbidity and mortality rates and even the most meticulous application of thermal tumor destruction techniques such as RFA, laser tumor ablation, or microwave tumor ablation are associated with incomplete tumor destruction in as few as 5% and as many as 20% of patients. Nonetheless, thermal ablation has permitted treatment of patients with otherwise unresectable disease and we have learned how to apply to it appropriately in patients. The risk of incomplete tumor destruction is much higher in tumors larger than 4 cm in diameter or in lesions that abut major vascular structures. Tumors that are near major hilar structures should not be treated with thermal ablation techniques unless some special circumstance allows installation and infusion of cooled solutions into the biliary system to prevent bile duct injury. This is somewhat extreme and while technically feasible, should not be considered routinely and should be performed only as part of clinical trials in the hands of experienced practitioners. I do commonly perform concomitant RFA of small contralateral tumors in patients undergoing right or left hepatectomy or extended right or left hepatectomy. This must be applied judiciously as a surrounding zone of normal hepatic parenchyma will be destroyed by the ablation technique and consideration must always be given to the amount of liver volume that will remain following a combined resection and ablation procedure.

SUMMARY

Surgeons should understand the role and timing of application of surgical treatment for localized hepatic infections. Similarly, patients are often referred after a benign tumor of the liver is encountered during some type of imaging study. These generally do not require surgical treatment but certain lesions, particularly hepatic adenomas, do require close follow-up evaluation and symptomatic or large lesions can be treated by either laparoscopic or open surgical resection. The surgical treatment of primary and metastatic solid tumors that are confined to the liver will continue to have an important role. This remains the gold standard for treatment for these patients and offers the best opportunity for long-term disease-free and overall survival. We must continue to take the lead in investigation of neoadjuvant and adjuvant multidisciplinary approaches in both primary and metastatic hepatic malignancies in an attempt to improve further the outcomes for our patients.

PERSPECTIVE ON LIVER SURGERY

Richard S. Swanson

RESECTION OF COLORECTAL CANCER METASTATIC TO THE LIVER

Chapter 45 expertly describes the preoperative evaluation, patient selection, integration of chemotherapy, and results of resection for colorectal cancer (CRC) metastatic to the liver. Below are comments about the technique of resection.

Most liver resections can be done with a right subcostal incision extended vertically in the midline to the xyphoid process. Patients prefer this incision to the rooftop or "Chevron" incision that rarely is needed. Inspection and palpation should exclude extrahepatic disease and assess intrahepatic disease. At this point, intraoperative ultrasound (IOUS) should be performed to determine the size and location of all tumor nodules. IOUS can help plan the resection to maximize the chance of obtaining a negative margin. With no contraindication to resection, the appropriate resection can be performed. Resections depend on the segments that need to be removed. A diagram of Couinaud's segments is in Fig. 46B-1.

The nomenclature for resections depends on the segments removed as summarized in Table 46B-1. Right hepatectomy is the most common major liver resection and it is described in detail below.

Right Hepatectomy

The right side of the liver is mobilized by dividing the right triangular ligament and the anterior and posterior leaflets of the right coronary ligament. The inferior vena cava (IVC) is exposed and small branches from the liver to the IVC are ligated and divided to facilitate exposure and avoid tearing. At this point, attention is focused on the porta hepatis for the hepatoduodenal dissection.

The gallbladder is removed and the bile duct is traced to the liver. The hepatic artery is identified and the right hepatic artery (RHA) isolated, usually anterior to the hepatic duct but occasionally posterior to the hepatic duct. The RHA is ligated and divided, carefully protecting the main and left hepatic arteries. The right hepatic duct is divided and the hepatic duct can be lifted anteriorly to the left to expose the portal vein (Fig. 46B-2). The junction of left and right portal vein (RPV) is exposed cautiously and a vessel loop is placed around the RPV. It is preferable to ligate and divide the RPV with sutures or a vascular stapler that ligates and cuts. At this point, inflow control is achieved and the liver will quickly demarcate such that the right liver will discolor. It now is reasonable to maximize outflow control.

An alternative method to achieve inflow control is to isolate and ligate the right portal pedicle intrahepatically. This can be done by incising the capsule in segments four and six and placing a finger around the pedicle in the liver. IOUS can monitor this technique. A vascular stapler can be applied to control the inflow.

The liver is rotated anteriorly and to the left. Small veins emptying directly from the liver into the IVC are ligated and divided. This might require suture ligation of the veins at the IVC as these branches are quite short. The surgeon should work from caudad to cephalad to secure these branches; usually there are about four pairs. A broad fibrous band of tissue extends from the IVC to the liver just caudad to the right hepatic vein (RHV). This tissue has small veins in it or next to it. There can be a larger accessory RHV in or next to this tissue. This band needs to be divided to expose the RHV (Fig. 46B-3).

Careful sharp and blunt dissection usually can isolate the RHV outside the liver such that it can be divided with clamps or a vascular stapler. The vascular stapler with 2.5-mm staples works well; clamps and Prolene sutures occasionally slip or tear producing significant bleeding. With inflow and outflow control, the parenchyma is transected to obtain a 1-cm margin. If the central venous pressure (CVP) is kept low, then backbleeding will be minimized. To minimize the risk of air embolism when the CVP is low during transection, the patient should be kept in a Trendelenberg position. There are several methods for parenchymal transection. The standard technique is "finger fracture" that requires fracturing the parenchyma with the index finger and thumb to define vessels and bile ducts. The vessels and ducts are ligated or clipped and the liver is expeditiously transected (Fig. 46B-4). Variations of the finger fracture technique

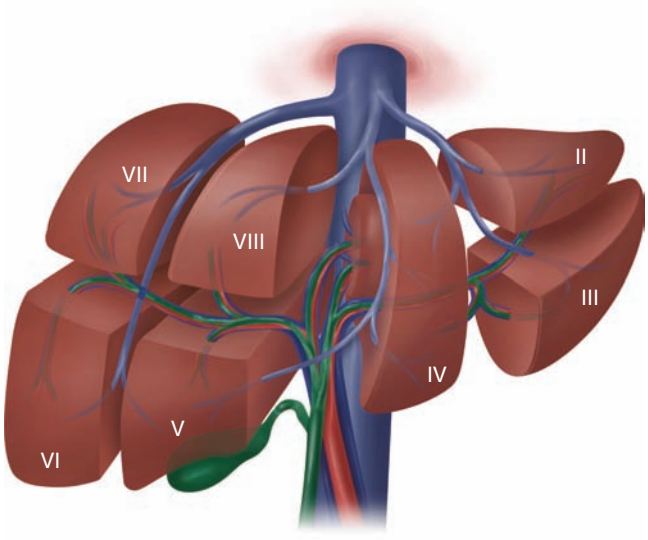

FIGURE 46B-1 The functional division of the liver and the segments according to Couinaud's nomenclature.

use a Kelly clamp, closed scissors, or a metal suction device. The key is to use a method that works well for the surgical team such that one surgeon can do the fracturing while another surgeon secures the vessels. During this maneuver, bleeding can be minimized by occluding inflow at the porta hepatis as a Pringle maneuver with clamping for 10–15 minutes with 2–5 minutes of unclamping. This maneuver can be repeated until the liver has been divided. A normal liver without steatohepatitis should tolerate 45 minutes of normothermic ischemia.

Other devices have been designed to divide the parenchyma. These include the ultrasonic dissector, the water jet dissector, the saline-linked radiofrequency (RF) dissecting sealer, the bipolar vessel sealing device, and the harmonic scalpel. Each device has its proponents. Some use these devices to meticulously and slowly divide the complete parenchyma of the liver, suturing, tying, or clipping vessels or ducts. Others use these devices to divide a portion of the parenchyma; when they are deep in the parenchyma and when the margin is not

TABLE 46B-1: DEFINITIONS OF LIVER RESECTION

Definition	Couinaud's Segments Removed
Right hepatectomy	V, VI, VII, VIII
Left hepatectomy	II, III, IV
Right trisegmentectomy (right lobectomy)	IV, V, VI, VII, VIII
Left trisegmentectomy	II, III, IV, V, VIII
Left lateral liver resection (left lobectomy)	II, III

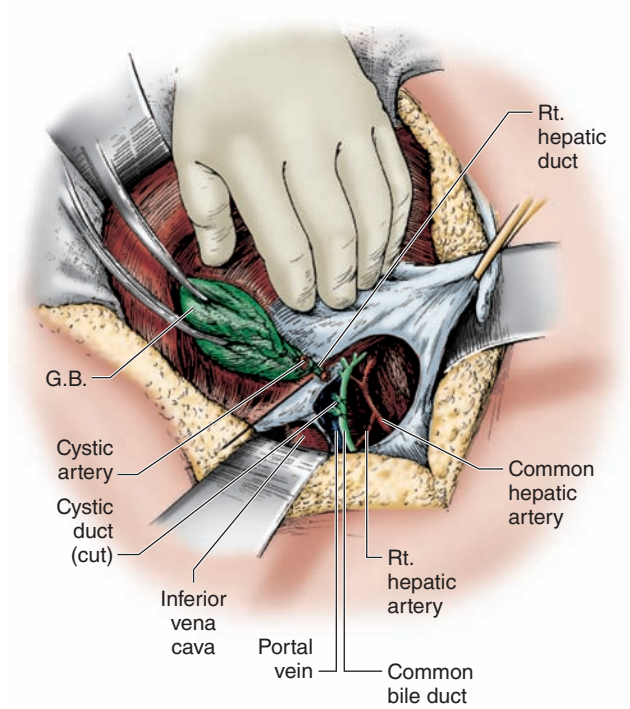

FIGURE 46B-2 Hepatoduodenal dissection.

an issue, these surgeons switch to a finger fracture technique to finish the dissection. To expedite deep parenchymal division, many will use vascular staplers. Vascular staplers control vessels efficiently and they can be used for parenchymal transection. To perform transection of the right liver can require over 15 vascular stapler cartridges. The parenchymal transection can be performed in less than 10 minutes without the need for a Pringle maneuver. The staplers can rip vessels if not guided appropriately. The firm metal blade of the stapler should be introduced carefully; there should be no force required to introduce the stapler. The obvious argument against staplers is cost. If the stapler companies would reduce the costs of the staplers, many surgeons would use multiple loads of the vascular stapler to divide the liver. If two experienced surgeons use finger fracture, the cost of transection is small and the resection can be performed with little blood loss. If a liver surgeon performs finger fracture with an inexperienced resident, the time for transection and the blood loss can be considerable. The RF resection device (such as the Habib) ablates liver tissue that then can be cut with a knife or a bipolar cautery device. The problem with these devices are twofold: (1) cost—one RF resection device can cost as much as 30 or more stapler cartridges; and (2) vessels less than 5 mm in diameter can be ablated but larger vessels can bleed significantly from the holes of the electrodes. The RF resection devices are very effective for peripheral nonanatomic wedge resections and left lateral liver resections. Theoretically, the radiofrequency ablation (RFA) can treat microscopic tumor cells at the margin. The first

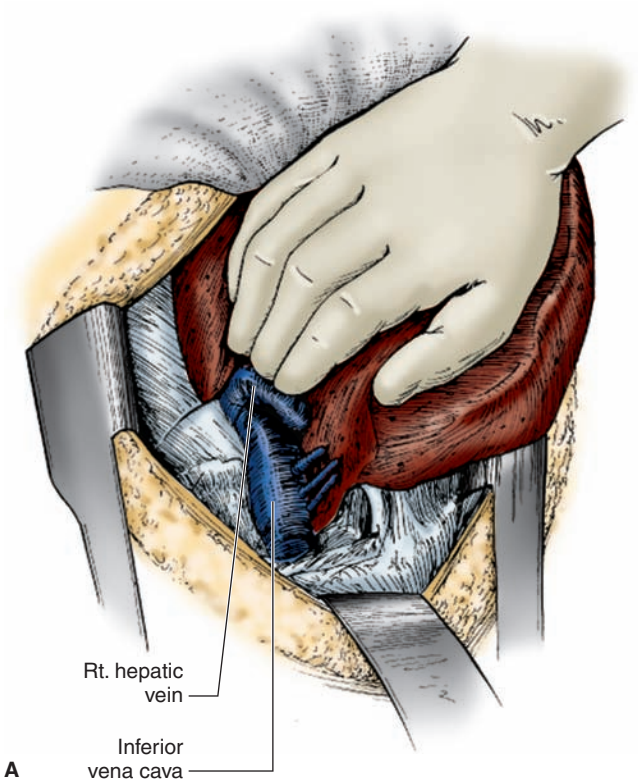

FIGURE 46B-3 **A** and **B.** Retrohepatic dissection to achieve control of hepatic veins.

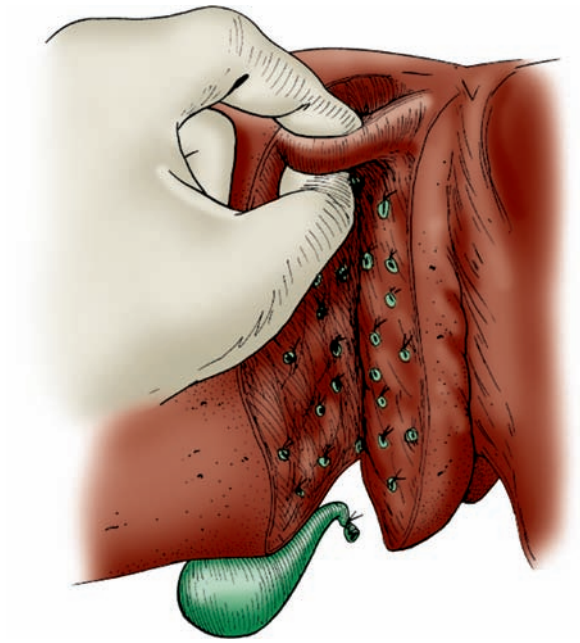

FIGURE 46B-4 Finger fracture technique. Posterosuperior intraparenchymal dissection of the RHV.

laparoscopic liver resection with a RF resection device was done at the Brigham and Women's Hospital (BWH),[1] but now most laparoscopic liver resections at the BWH are done with the staplers or a variation of the finger fracture method.

The above operation can be performed with a laparoscope either as a complete laparoscopic procedure or as a hand-assisted laparoscopic liver resection.[2,3] Multiple methods of parenchymal transection can be performed laparoscopically. The vascular staplers work well with the use of a handport. A reason to use staplers to transect the liver during open liver resection is to become familiar with this technique for laparoscopic resection. The intra-abdominal pressure with pneumoperitoneum can tamponade some of the smaller venous bleeding. This nuisance bleeding can be controlled with the Argon Beam Coagulator, topical sealants, or with sutures as necessary. The Argon Beam Coagulator should be used with caution as a venous embolus with Argon does not dissipate as quickly as carbon dioxide. Draining the right upper quadrant usually is done for several days if there is concern about a possible bile leak.

Patients should be discharged in 4–5 days. Blood transfusions should be avoided, if possible, as the survival rate decreases after liver resection if transfusion is used.

Left Hepatectomy

Left hepatectomy essentially is the mirror image to right hepatectomy. A hilar dissection controls inflow (Fig. 46B-5). If the caudate lobe needs to be removed, it can be freed from the IVC facilitating isolation of the left hepatic vein (LHV). A stapler can be used to divide it. Alternatively, the parenchyma

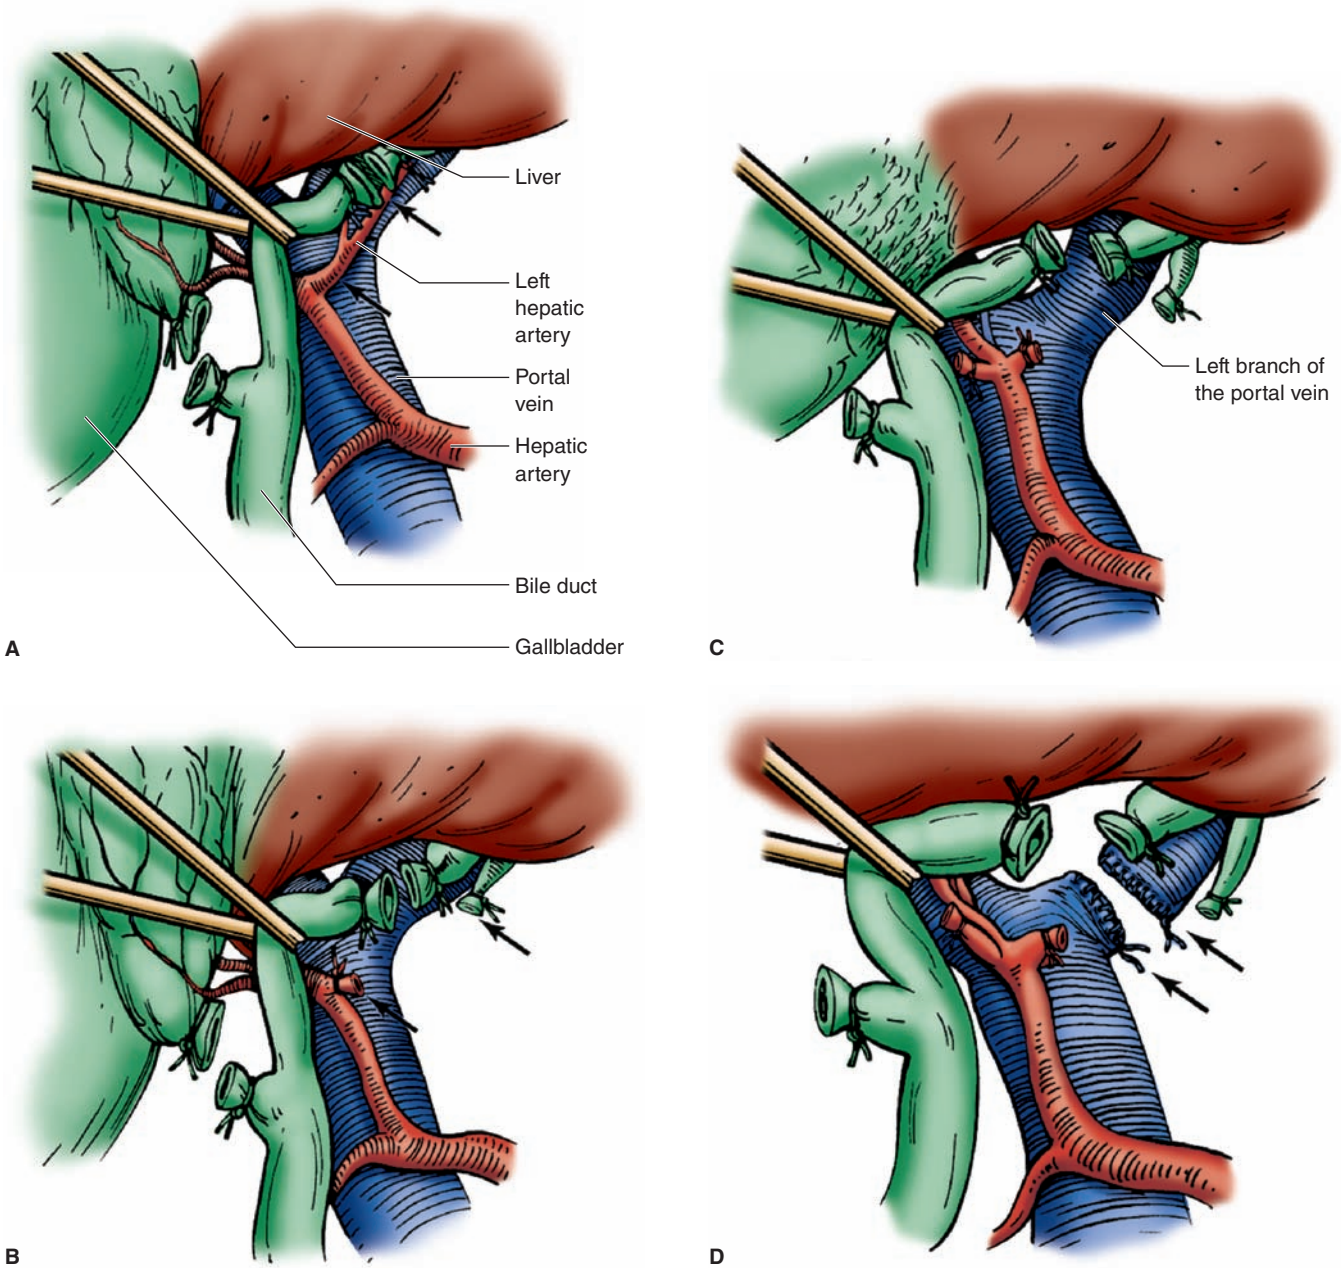

FIGURE 46B-5 Hilar dissection in left hepatectomy. **A.** Division of cystic duct and left hepatic duct; **B.** Division of left hepatic artery; **C.** Exposure of left portal vein; **D.** Division of left portal vein.

can be divided and the LHV can be secured during the parenchymal dissection (Fig. 46B-6).

PUMPS FOR TREATMENT OF COLORECTAL METASTASES TO THE LIVER

Administering chemotherapy directly into the hepatic artery via a catheter introduced through the femoral artery has been practiced for over 30 years. Toward the end of the 1970s, a totally self-contained implantable pump was developed that allowed continuous arterial infusion of chemotherapy via a catheter placed in the gastroduodenal artery at the junction of the hepatic artery. The rationale for HAI chemotherapy takes advantage of the observation that CRC metastases in the liver derive the majority of their blood supply from the hepatic artery, not the portal vein.[4] Further, the drug most commonly used for HAI, fluorodeoxyuridine (FUDR), has over 95% uptake in the liver on first pass as compared to 5-fluorouracil (5-FU) that has less than 50% uptake on first pass.[5] This major difference allows HAI with FUDR at 100–400 times the concentration of systemic 5-FU.

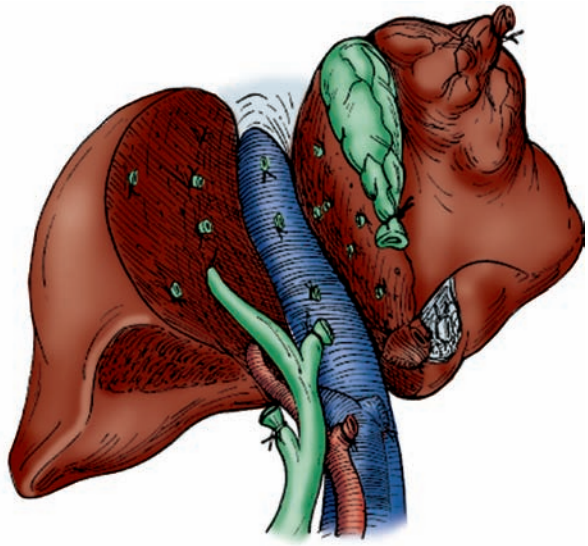

FIGURE 46B-6 Completed transection of the parenchyma in left hepatectomy.

Randomized studies evaluating HAI with FUDR versus systemic 5-FU conducted in the 1980s showed response rates of 30–50% with HAI FUDR but did not conclusively demonstrate a survival benefit with this technique.[5-10] Thus, the appropriate role for this treatment continues to be debated. The literature is clear that the frequency and severity of complications decrease with increasing experience of the surgeon. These complications include pump malfunction, pocket problems, catheter occlusion or dislodgement, and arterial complications (hemorrhage, thrombosis, or perfusion problems).[10] Currently, the indications for HAI chemotherapy are twofold: (1) for the treatment of unresectable liver-only metastases from CRC; and (2) as an adjunct after the resection of CRC metastatic to the liver. Both indications are controversial. With no definitive randomized study showing a clear benefit to HAI chemotherapy, a multi-institutional trial of HAI with FUDR versus systemic 5-FU-based chemotherapy was conducted in the 1990s. The HAI chemotherapy group had about a 3-month median survival time advantage over the systemic therapy group.[11] However, this trial was criticized by many medical oncologists because (1) the survival time advantage was considered too short to argue for pump implantation; and (2) newer systemic agents provide longer survival times than the systemic regimen used in this trial. A single-institution randomized trial showed a survival advantage at 2 years with HAI chemotherapy after liver resection versus no HAI chemotherapy.[12] This trial was criticized because there was not a significant long-term survival advantage in the HAI group. At the moment, HAI chemotherapy is not widely used principally because most oncologists are not comfortable managing pump chemotherapy and they feel systemic chemotherapy is adequate.

The technique of pump implantation requires insertion of a catheter into the gastroduodenal artery with the tip close to the junction with the hepatic artery. The pump is placed in the subcutaneous space on the abdominal wall. The gallbladder is removed to obviate chemical cholecystitis. Potential arterial branches from the hepatic artery to the stomach or duodenum are interrupted to avoid chemical duodenitis or gastritis.

ABLATION OF COLORECTAL METASTASES TO THE LIVER

RFA is a treatment that destroys tumors in situ by protein denaturation and thermal coagulation. It has been used to treat tumors since the early 1900. Beer used RF coagulation through a cystoscope to treat bladder tumors in 1908. Cushing used RFA to treat intracranial tumors in 1926. In 1990, two groups independently used ultrasound to guide RFA treatment of liver tumors. RFA uses alternating current with a frequency between 10 kHz and 900 MHz. Tissue adjacent to the electrode dies from the heat generated in the tissue by RF energy; the electrode itself does not become hot but it delivers RF energy that causes mechanical friction in the tissue that leads to thermal ablation.[13]

Resection is the best treatment for CRC metastatic to the liver. RFA is used as an alternative to resection when (1) comorbid disease precludes resection, or (2) anatomical considerations preclude resection. Examples of the latter indication principally are twofold. First, if a discrete number of metastases are located in different segments such that resection of the lesions would result in inadequate residual liver volume, then RFA would be reasonable. Second, if several lesions in one-half of the liver can be removed with an ipsilateral hepatectomy but a lesion deep in the contralateral half of the liver cannot be removed, an ipsilateral hepatectomy with RFA of the lesion in the contralateral liver would be appropriate.

RFA can be performed percutaneously in an imaging suite with computed tomography (CT) scan or ultrasound guidance, or in the operating room either open or laparoscopically with ultrasound guidance. Complication rates associated with RFA in one large review and one single-institution study were 7 and 2.4%, respectively.[14,15] The reported procedure-related mortality rate is 0.5% (10 deaths in 1931 patients).[14] Complications are more frequent in those undergoing open RFA versus percutaneous RFA. Complications include abscess, biloma, bile duct injury, pleural effusion, and pain.[16,17]

Some claim that RFA for solitary CRC metastases is associated with infrequent local recurrences. The M.D. Anderson group recently examined this issue. With a median follow-up time of 31 months, they found a 37% local recurrence rate for RFA treatment of solitary metastases as compared to a 5% local recurrence for resection ($p = .0001$).[18] The subset with smaller tumors—less than 3 cm in diameter—had a 31% local recurrence rate with RFA compared to 3% with resection. Clearly, RFA of CRC metastases to the liver is not equivalent to resection; RFA should be considered investigational or—at best—an inferior, second-choice treatment.

BENIGN AND MALIGNANT PRIMARY TUMORS

Cho and Fong appropriately state that imaging modalities should differentiate hemangiomas, focal nodular hyperplasia (FNH), adenomas, and cancers. When it is difficult to confirm the diagnosis of a benign (or malignant) tumor,[19–23] a biopsy can be considered; however, as the authors state, liver biopsies of suspected tumors notoriously are inaccurate, and complications such as bleeding and spread of tumor can occur. The inadequate accuracy and bleeding complications of liver biopsy particularly become relevant when attempting to distinguish the atypical FNH that does not need resection from the adenoma that does.

Focal Nodular Hyperplasia

FNH is the second most common solid tumor or the most common nonvascular benign tumor of the liver. It possibly comes from a polyclonal hyperplastic response to locally altered blood flow.[24] Resection infrequently is necessary to diagnose or treat pain. Pain usually is from a source other than the FNH; thus, a search for other causes is mandatory. If pain is from the FNH, the FNH usually is large but a small FNH can cause pain.

Hepatocellular Adenomas

Hepatocellular adenomas (HCAs) typically occur in young females who are taking oral contraceptive pills (OCPs). The initial management is to stop the OCP which should shrink the tumor. This action both confirms diagnosis and treats the tumor. In general, all adenomas greater than 5 cm or symptomatic should be resected. But this approach generates questions that cannot be answered adequately because the natural history of adenomas is not well known. These questions include:

If an adenoma shrinks to less than 5 cm with cessation of the OCP, can it safely be observed? Probably, but adenomas less than 5 cm can bleed or transform into hepatocellular carcinomas (HCCs).[25]

Will small adenomas cause trouble during pregnancy? Probably not. Dokmak et al reported 11 patients followed through pregnancy with no problems.[26] But adenomas less than 5 cm can bleed and transform,[25] and pregnancy is associated with a significant increase in estrogen that stimulates the growth of adenomas. It probably is reasonable to monitor a pregnant patient with a small adenoma by using ultrasound of the liver during pregnancy.

Does adenomatosis of the liver (defined by most as >10 adenomas) demand a liver transplant? The literature certainly is not clear about this issue. The Mayo Clinic used a definition of adenomatosis to be more than three tumors and they recommended observing adenomas less than 3 cm in diameter and resecting adenomas greater than 5 cm.[27] Others have reported selective transplantation for adenomatosis.[28]

Can small adenomas be treated by percutaneous RFA? The literature does not have adequate information to answer this question.

Regenerative Nodular Hyperplasia

These tumors do not need treatment but they are becoming an increasing clinical problem because they are associated with chemotherapy given before resection of CRC metastatic to the liver. Wicherts et al found regenerative nodular hyperplasia in 22% who had six cycles of preoperative chemotherapy containing oxaliplatin. Distinguishing these tumors from other tumors becomes an issue, and these tumors are associated with an increase in postoperative hepatic morbidity (50 vs 29%).[29]

Hepatocellular Carcinoma

The best treatment of HCC is resection but the cirrhosis generally associated with HCC makes resection difficult. As Cho and Fong note, it is difficult to use preoperative information to determine whether or not a minimally cirrhotic liver can tolerate resection. In selected cases, preoperative portal vein embolization (PVE) might demonstrate whether or not a chronically damaged liver has the ability to grow. If 4–6 weeks after PVE the future liver remnant does not grow, then liver resection probably would not be tolerated. At this point, this strategy is speculation at best.

After resection, RFA is a second choice for treatment of HCC. Ideally, HCC should be resected with a healthy negative margin, but this approach can be difficult from a bleeding standpoint as well as from a liver function standpoint. To minimize bleeding and theoretically optimize tumor control as well as liver function, it is reasonable to use a RF resection device to ablate a plane of liver tissue at the edge of the tumor. Theoretically, this should kill microscopic tumor at the margin, and minimize bleeding during resection.

HEPATIC ABSCESSES AND CYSTIC DISEASES OF THE LIVER

Chapter 43 expertly discusses hepatic abscesses and cystic diseases of the liver. Given the advances in laparoscopy, the management of cystic diseases of the liver particularly has evolved. Patients with large liver cysts who have symptoms typically have pain. A search for other causes of pain is reasonable as most liver cysts do not cause pain. If pain appears to be due to a large liver cyst, then a magnetic resonance imaging (MRI) with magnetic resonance cholangiopancreatography (MRCP)

is reasonable specifically to examine the cyst lining and any possible communication with the biliary tree. If the lining does not have nodularity and there is no obvious communication with the biliary tree, then laparoscopy with aspiration of the cyst contents followed by generous laparoscopic resection of protruding cyst wall can provide significant tissue for frozen section analysis. While awaiting frozen section analysis, the remainder of the cyst lining can be examined and biopsied if there is any concerning tissue. If frozen section reveals a simple cyst, then the remaining lining can be cauterized to minimize recurrence of the cyst. If frozen section reveals cystadenoma, then the remaining epithelium should be removed. If it technically is not possible to remove the epithelium laparoscopically, then open resection should be considered. An alternative is to cauterize laparoscopically the remaining epithelium in the cyst. This should kill any residual cystadenoma which should prevent cystadenocarcinoma from occurring. We have used this approach selectively although there are no long-term large series demonstrating the efficacy of this strategy. If frozen section reveals cystadenocarcinoma, then formal resection to obtain negative margins—either by open or laparoscopic technique—should be performed.

PORTAL HYPERTENSION

J. Michael Henderson

Portal hypertension is present when portal venous pressure exceeds 10 mm Hg. This chapter addresses the causes, evaluation, and treatment options for patients with portal hypertension. While the emphasis is on surgical aspects, this group of patients requires a multidisciplinary approach and surgical therapy must inevitably be viewed in this context. The major clinical presentations that will be addressed are variceal bleeding, ascites, end-stage liver disease, and the pulmonary syndromes. Whatever the presentation of portal hypertension, be it an incidental finding or one of the above clinical presentations, it demands full investigation. In the United States, the etiology is most commonly cirrhosis, but other etiologies such as prehepatic portal or splenic vein thrombosis or other intraparenchymal liver disease such as schistosomiasis or hepatic fibrosis should be considered. Definition of the cause is important as prognosis depends on the underlying liver disease, and a full evaluation to allow development of a treatment plan for variceal bleeding, ascites, or end-stage liver disease is paramount at initial presentation. The focus of this chapter is on emphasizing the role of a multidisciplinary team approach to managing patients with portal hypertension.

HISTORY

Portal hypertension was recognized by the Greeks[1,2], was highlighted by Shakespeare in his character of Falstaff, and has played a role through much of history. The evolution of the treatment of portal hypertension was driven by surgeons until the 1980s. Nicolai Eck, a Russian Army surgeon, performed an end-to-side portacaval shunt in 1883 in an animal model. Pavlov, the great Russian physiologist, conducted animal studies that showed the detrimental effect of diverting portal flow, describing meat intoxication (encephalopathy) and liver failure. Vidal, a French surgeon is credited with performing the first portal systemic shunt in a human in 1903. Morison and Talma operated on patients with portal hypertension with procedures such as omentopexy and splenic transposition, but their failure to recognize cirrhosis as the cause of portal hypertension led to poor results.

In the 1940s, Whipple and the Columbia Presbyterian group in New York initiated an era of success for portal decompression.[3] The next 40 years saw many refinements to decompressive shunts, Drapanas with mesocaval shunts,[4] Warren and Inochuchi with selective variceal decompression,[5,6] and Sarfeh with partial shunts.[7] This era saw many randomized trials documenting efficacy of shunts.

Endoscopic therapy was the next major advance in managing variceal bleeding, being first done by surgeons with rigid esophagoscopes.[8] In the 1980s, three surgeons, Johnston, Terblanche,[9] and Paquet,[10] bridged the gap from rigid to flexible variceal sclerotherapy. Another surgeon, Steigmann,[11] moved the field forward by introducing variceal band ligation.

Over the last three decades, the more recent advances have been made by nonsurgeons. A better understanding of the pathophysiology, the ability to better evaluate liver diseases, the introduction of pharmacologic therapy, development of the radiologic shunt, and coming of age of liver transplantation are the main contributors to this progress. Lebrec and his colleagues in the 1980s introduced beta-blockers to reduce portal hypertension,[12] and this has become the primary treatment for reducing the risk of an initial variceal bleed and first-line treatment for those who have bled. Transjugular intrahepatic portosystemic shunt (TIPS), pioneered by Rösch,[13] has led to shunts being more safely placed by the radiologist than the surgeon with lower early morbidity and mortality.

However, two surgeons, Starzl[14] and Calne,[15] revolutionized the whole field of hepatology with their persistence in developing liver transplantation through the 1960s to 1980s, and bringing it to a clinical reality. Transplantation has not only offered a treatment for patients with end-stage liver disease and portal hypertension, but has also opened the doors to further investigation.

It is around this history of portal hypertension that many of the investigative and treatment options discussed in this chapter are built.

PATHOPHYSIOLOGY

The pathophysiology of portal hypertension[16,17] has been clarified over the past two decades in animal models documenting the sequential changes in the splanchnic and systemic circulations. The sequence of events is as follows:

- Block to portal flow leads to increased portal pressure.
- Splanchnic vascular bed response.
  - **(a)** Initial increased vasoconstrictor and decreased vasodilator response increases intrahepatic resistance.
  - **(b)** Secondarily, the vasodilator response dominates, with increase in splanchnic inflow.
- Collaterals develop between the portal circulation and the systemic circulation.
- Plasma volume expansion occurs with the development of a systemic hyperdynamic circulation.

The splanchnic vascular response leads to increased flow in the gut and thus major clinical manifestations of collaterals in multiple locations: at the umbilicus, in the retroperitoneum, hemorrhoidal, and at the gastroesophageal junction.

The systemic hemodynamic changes result in cardiac outputs in the 10–15 L/min range, systolic blood pressures in the 100–110 range, and a low calculated total systemic vascular resistance. These changes have significant management implications for fluid resuscitation and patient management. It is important for the managing physician to understand these pathophysiologic changes and their impact on patient care.

COMPLICATIONS

The major complications of portal hypertension are as follows:

- Variceal bleeding
- Ascites
- End-stage liver disease
- Hepatopulmonary syndromes

This chapter will address the etiology, evaluation methods, specific therapies, and overall treatment strategies for each of these complications. An important distinction in patients with portal hypertension is between those with ascites and encephalopathy, which are markers of advanced liver disease, and patients with variceal bleeding, which may occur in patients with a normal liver (portal vein thrombosis) or early in the course of cirrhosis. The implication of this is that the range of treatment options is considerably broader for variceal bleeding than it is for patients with ascites and encephalopathy.

ETIOLOGY

Figure 47-1 illustrates the wide range of etiologies for portal hypertension.[18] In the United States and Europe, approximately 90% of patients with portal hypertension have cirrhosis, with a small percentage having portal vein thrombosis (PVT) or hepatic fibrosis. The latter are important to differentiate because they have normal liver function and a much better prognosis. Worldwide, schistosomiasis is an important etiology

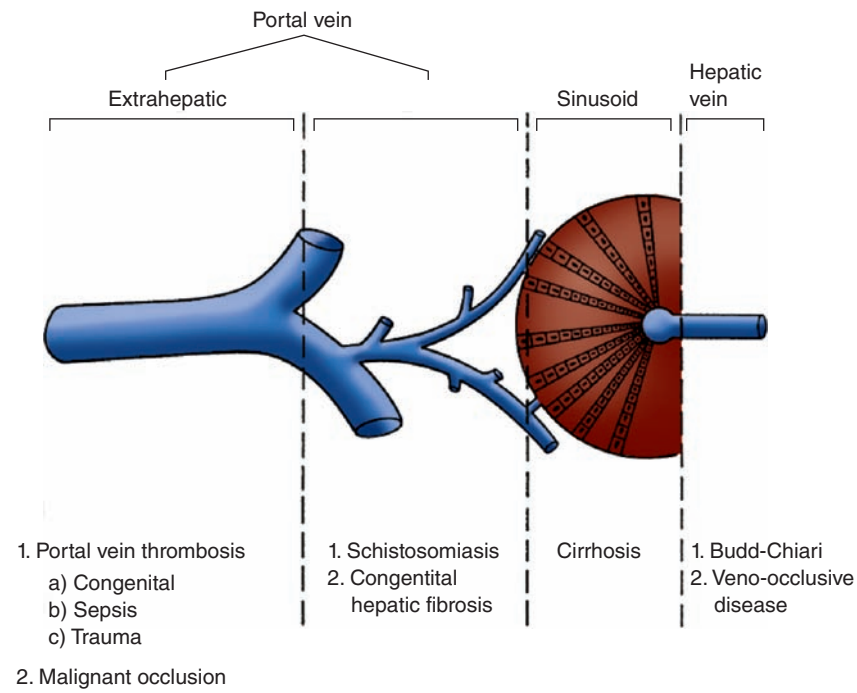

FIGURE 47-1 Sites for obstruction in portal hypertension. In the United States and Europe, most patients have a sinusoidal block secondary to cirrhosis. Other causes must be considered.

of portal hypertension, occurring mainly in the Middle and Far East and South America. It is characterized by fibrosis of the terminal portal venules, and in the absence of concurrent hepatitis, these patients have normal liver function.

Cirrhosis covers a broad spectrum of disease by etiology and severity. Alcoholic liver disease and hepatitis are the most common etiologies, with other causes, such as the cholestatic liver diseases of primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC), and the metabolic liver diseases such as hemochromatosis, Wilson's disease, and α1-antitrypsin deficiency, contributing a small percentage. Whatever may be the etiology of the cirrhosis, full evaluation of activity and stage of the disease is an important part of initial patient evaluation. Different etiologies may have different natural histories which is important in developing a treatment plan.

EVALUATION

The evaluation of patients with portal hypertension has the following essential components, and should be done at initial presentation:

- Assessment of the liver disease
- Assessment of the portal circulation
- Upper gastrointestinal (GI) endoscopy

Liver evaluation[19,20] is based on clinical findings and laboratory studies. Jaundice, ascites, encephalopathy, and malnutrition define a patient with end-stage liver disease. Some patients with variceal bleeding do not show these clinical signs and have well-preserved liver function. Laboratory tests add objectivity, the most useful indicators being serum bilirubin, albumin, prothrombin time, and creatinine. The two main scoring systems for liver disease severity are the Child-Pugh score[19] (Table 47-1) and the Model for End-stage Liver Disease (MELD) score[20] (Equation 47-1). Specific serologic markers may be useful in defining etiology for viral hepatitis, or for some of the metabolic diseases with antimitochondrial antibody, iron studies, α1-antitrypsin, or ceruloplasmin levels. In addition, alpha-fetoprotein (AFP) should be measured in all such patients as a screening test for hepatoma.

TABLE 47-1: CHILD-PUGH SCORE

Parameter	1 Point	2 Points	3 Points
Serum bilirubin (mg/dL)	<2	2–3	<3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Prothrombin time (↑ S)	1–3	4–6	>6
Ascites	None	Slight	Moderate
Encephalopathy	None	1–2	3–4

Grades: A, 5–6 points
B, 7–9 points
C, 10–15 points

Equation 47-1

MELD Score

$$\text{Score} = 0.957 \times \log_e \text{creatinine (mg/dL)} + 0.378 \times \log_e \text{bilirubin (mg/dL)} + 1.120 \log_e \text{INR}$$

When a patient has portal hypertension, usually shown by varices, a cause must be found. If clinical and laboratory studies do not fit, imaging and a liver biopsy may be indicated. Quantitative liver testing with studies such as indocyanine green clearance, galactose elimination capacity, and monoethylglycinexylidide (MEGX) formation are advocated by some, but have not proved to be clinically useful.

Imaging is initially with ultrasound to show overall liver morphology and potentially to pick up focal lesions suggestive of hepatoma. Contrast-enhanced computed tomography (CT) scan or magnetic resonance imaging (MRI) may be required for morphologic assessment. Liver biopsy may be required to confirm that some patients do have underlying cirrhosis, and in cases of focal lesions, to differentiate hepatocellular carcinoma from regenerative nodules. In the latter case a biopsy of the uninvolved liver is performed as well as the focal lesion to assess for cirrhosis.

Vascular anatomy is evaluated with imaging modalities of escalating complexity depending on information required for management.[21–23] Doppler ultrasound can assess the hepatic artery, portal and hepatic veins and this may be all that is required. Documenting size, directional flow, velocities, and wave-form patterns of the portal and hepatic veins is a standard procedure. Tributaries to the portal vein—the superior mesenteric and splenic veins, and large collaterals such as the coronary and umbilical vein may also be readily defined. The most important information that the clinician needs to know is the patency (or thrombosis) of the portal vein. Hepatic artery patency, course, and resistive index can be assessed with Doppler ultrasound.

The next level of complexity for evaluating the liver circulation is with CT scan or MRI. These two modalities may be combined with CT or MR angiography (MRA). The speed of scanners, new contrast-enhancing agents, and the increasingly advanced software for data reconstruction allow sophisticated imaging of the liver's arterial and venous anatomy. These methods have improved preoperative planning for living donor liver transplantation and liver resection.

Finally, angiography still plays a role for direct pressure measurement and clarification when the prior modalities are unclear. Portal pressure is measured indirectly from the hepatic veins by measuring wedged and free hepatic vein pressures, with the difference being the hepatic venous pressure gradient (HVPG).[24] This is done using a balloon occlusion technique akin to a Swan-Ganz catheter measurement in the pulmonary circulation. Normal HVPG is 6–8 mm Hg, and in cirrhosis it will be greater than 10 mm Hg. There has been resurgence of interest in HPVG to measure response to pharmacologic therapy. Direct portal pressure measurement also can be done by the transjugular, transhepatic route. This method, useful in

the acute situation particularly when combined with TIPS, is not used for repeated measurements.

Upper GI endoscopy is used to assess varices. All patients with cirrhosis should have an upper endoscopy. This recommendation is based on epidemiologic studies that have shown the following:

- Thirty percent of patients with cirrhosis develop portal hypertension.
- Thirty percent of patients with portal hypertension will bleed from varices within 2 years.
- The rate of development of varices in patients with cirrhosis is approximately 8% per year.

Endoscopy should focus on the presence of varices; the size, extent, and tortuosity; and the presence or absence of red color signs. Large varices with red color signs are at greater risk of bleeding. In patients with cirrhosis and upper GI bleeding, endoscopy may be both diagnostic and therapeutic with banding. Following an acute variceal bleed, the extent of varices should be assessed after stabilization. Grading systems for varices have been developed and validated by the Japanese[25] and Italians.[26] Finally, the gastric mucosa should be evaluated for evidence of portal hypertensive gastropathy with congestion and cobble stoning.[27] Gastric varices may also be seen, with isolated gastric varices being more problematic than gastric varices in continuity with esophageal varices.[28]

MANAGEMENT OF VARICEAL BLEEDING

Figure 47-2 illustrates a management algorithm for variceal bleeding that requires a multidisciplinary team, and may vary from center to center depending on available expertise. The team should have a predetermined, step-wise management plan for patients with variceal bleeding. This algorithm will form the basis for further discussion of patients.

The following therapies are available for treating variceal bleeding:

- Pharmacotherapy
- Endoscopic therapy
- Decompressive shunts—radiologic or surgical
- Devascularization operations
- Liver transplantation

Pharmacologic therapy plays a role in preventing the initial bleed, managing the acute variceal bleed, and as first-line treatment in preventing rebleeding.

Noncardioselective beta-blockers (Inderal [propranolol hydrochloride] or nadolol) were shown by Lebrec and his colleagues in the early 1980s to reduce portal hypertension.[12] Patients with moderate- to large-size varices should be placed on one of these drugs for prophylaxis prior to their first bleed. Not all patients tolerate beta-blockers or are responsive to them, with a noncompliance or fallout rate of about 20%. The target for treatment is greater than 20% or less than 12 mm Hg reduction in HVPG. If this is achieved, patients will not bleed.[29]

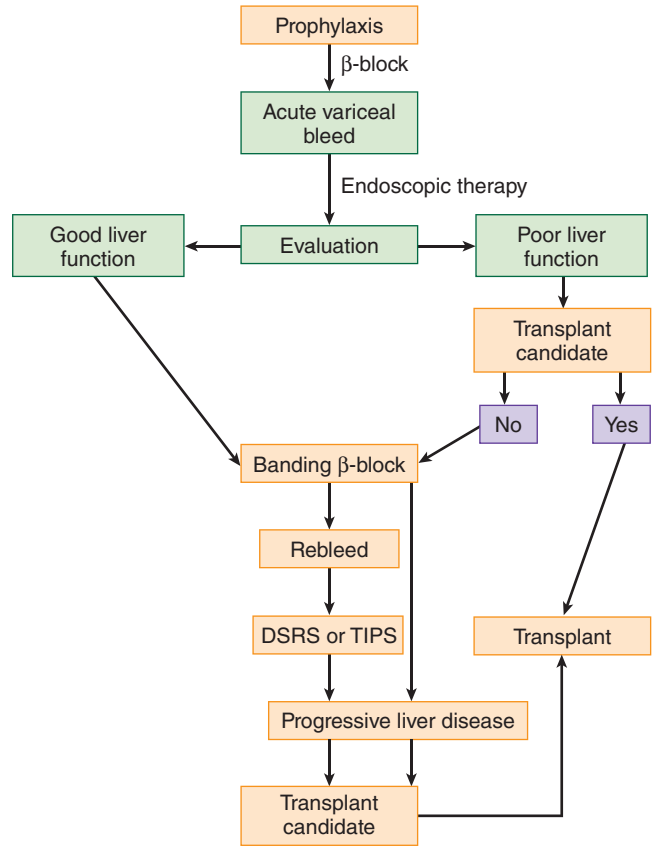

FIGURE 47-2 Algorithm for management of patients with variceal bleeding.

Propranolol or nadolol are used as initial therapy to prevent rebleeding, with the same caveats for tolerance, response rates, and targets for therapy. Many other pharmacologic agents have been evaluated such as long-acting nitrates, serotonin antagonists, and calcium channel blockers. None of these have been shown to be as efficacious as the beta-blockers, and while combination therapy has been beneficial in some studies, it has been limited by side effects.[29,30]

Pharmacologic therapy for acute variceal bleeding was initially with vasopressin. It has been largely replaced by terlipressin, or somatostatin or one of its analogs. These drugs effectively reduce portal pressure in the patient with acute variceal bleeding.

Endoscopic Therapy

The current standard for endoscopic therapy for esophageal varices is endoscopic banding.[11] This has largely replaced endoscopic sclerotherapy because it has fewer side effects, obliterates varices faster, and can be easily applied. Multiband ligators can be fitted on the end of the endoscope and allow the firing of six to eight bands in a spiral fashion onto columns of

varices. The varix is sucked into the end of the applicator, and the band fired around its base. The bands will slough off in 5–7 days with less ulceration over the varices than induced by sclerotherapy, and hence a lower initial rebleeding rate. Endoscopic banding can be used in the patient with acute variceal bleeding if the bleeding varix can be identified. A course of banding—usually two to three sessions—is then applied over the next month to 6 weeks in an attempt to obliterate the varices at the gastroesophageal junction. Occasionally, endoscopic sclerotherapy with injection of a sclerosing solution may be a useful adjunct to complete the obliteration of smaller varices that cannot be banded.

Many prospective, randomized controlled trials have documented better control of bleeding with endoscopic banding than sclerotherapy, with lower morbidity. However, the mortality was not significantly different between banded and sclerosed patients in these trials.[31]

From a practical point of view, patients with an acute variceal bleed should have their bleeding controlled with an endoscopic session, have their varices obliterated with a course of banding, and be placed on a noncardioselective beta-blocker for long-term management. This constitutes first-line treatment.

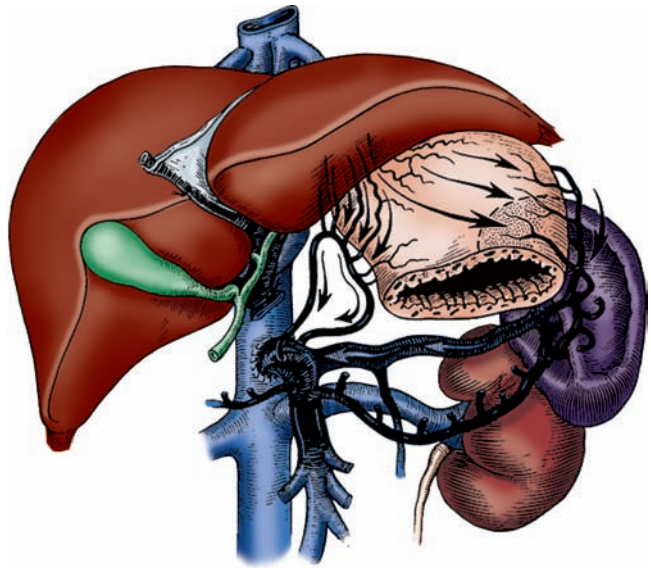

FIGURE 47-3 End-to-side portacaval shunt. This shunt decompresses varices and the splanchnic circulation. Sinusoidal pressure remains high in the cirrhotic liver.

Decompressive Shunts

This component of management of variceal bleeding has changed dramatically over the last two decades. Decompression is considered second-line treatment and is reserved for patients who rebleed through pharmacologic therapy and endoscopic banding or whose varices remain "high risk." Very few surgical shunts are performed at the current time, and patients requiring decompression are usually managed with a radiologically placed shunt—TIPS.

Surgical shunts are largely of historic interest and fall into three groups: total, partial, and selective shunts.

Total Shunts

Figures 47-3 and 47-4 illustrate total shunts,[32,33] with two physiologically different types. Figure 47-3 shows a classic end-to-side portacaval shunt in which the portal vein is divided close to the hilus of the liver and the splanchnic end anastomosed to the side of the vena cava. This decompresses the splanchnic portal hypertension but leaves the obstructed sinusoids under high pressure. As such, it will not relieve ascites but will control variceal bleeding.

Figure 47-4 illustrates the second group of total shunts, which are either side-to-side portacaval shunts with direct vein-to-vein or a short interposition graft, or the other interposition shunts such as mesocaval or mesorenal as illustrated. These shunts need to be at least 10 mm in diameter, usually being 12–15 mm, to fully decompress portal hypertension and be classified as a total shunt. Pathophysiologically, these shunts differ from the end-to-side portacaval shunt in that the intact upper end of the portal vein serves as a decompressive outflow from the high-pressure–obstructed liver sinusoids. Hence, in addition to controlling variceal bleeding, these shunts also control ascites.

These total shunts (>10 mm in diameter) divert all portal flow away from the liver and the major debate has been the

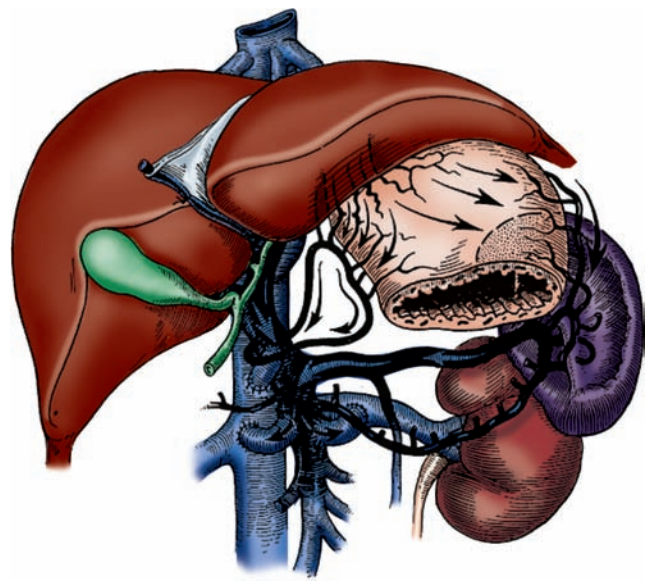

FIGURE 47-4 Side-to-side portal systemic shunts. Portacaval, mesocaval, and mesorenal shunts are shown. The portal vein acts as an outflow from obstructed sinusoids, decompressing the liver as well as varices and the splanchnic circulation.

effect that this has on hepatic function. Data are conflicting as to the severity of the portoprival syndrome (diversion of all portal flow), its effect on liver function, and its role in causing encephalopathy. It is almost certainly the severity of the underlying liver disease, which is the dominant factor in whether a shunt accelerated liver failure.

The technical aspects of a side-to-side portacaval shunt are relatively straightforward. The portal vein and inferior vena cava are approached from the right side, usually through a long right subcostal incision. Sufficient length of the portal vein is mobilized in the right edge of the hepatoduodenal ligament. The inferior vena cava is mobilized from the lower border of the liver to the renal veins. This will usually allow for a direct side-to-side portacaval anastomosis. When the caudate lobe is particularly large, either a segment of this may be excised, or a short interposition graft may be used. These vessels are familiar territory to the transplant surgeon, who can perform this operation in the few patients in whom it is indicated.

The only indication for a total portal systemic shunt at present is for patients with acute Budd-Chiari syndrome in which the congested intrahepatic sinusoids need to be decompressed using a side-to-side total shunt.[34]

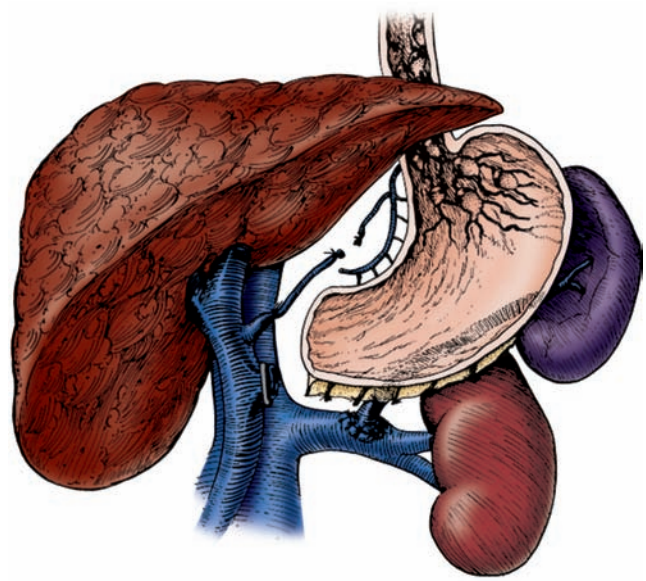

FIGURE 47-5 Distal splenorenal shunt (DSRS). Varices are decompressed transplenic to the left renal vein. Portal hypertension is maintained in the splanchnic bed to keep prograde portal flow to the liver.

Partial Shunts

Partial shunts are side-to-side shunts whose diameter is reduced to 8 mm. Sarfeh and associates in the 1980s systematically reduced the size of polytetrafluoroethylene (PTFE) interposition grafts between the portal vein and the inferior vena cava down to 8 mm diameter, showing that at this size there is a greater than 90% control of variceal bleeding and maintained portal perfusion in 80% of patients.[7] This shunt has been used in a randomized trial compared to TIPS.[35,36] The surgical approach is similar to that used for a side-to-side portacaval shunt, with the PTFE graft being approximately 2–3 cm long, and beveled at each end to give a larger anastomosis.

Selective Shunts

Selective shunts are most commonly the distal splenorenal shunt (DSRS) (Fig 47-5).[5] This shunt leaves the spleen in situ, divides the splenic vein at its junction with the superior mesenteric vein, and anastomoses the splenic vein to the left renal vein. This selectively decompresses gastroesophageal varices. Portal hypertension is maintained in the splanchnic and portal veins to maintain portal flow to the liver in Child's class A and B+ patients. Control of bleeding has been at 94%, with good portal perfusion maintained in 90% of patients initially. Portal flow is preserved in greater than 90% of patients with nonalcoholic liver disease long term, but loss of portal flow occurs in 50% of alcoholic patients. The overall incidence of encephalopathy has been around 15% following this operation.[37–41]

DSRS is done through a long left subcostal incision. The pancreas is approached through the lesser sac, taking down the gastrocolic omentum to the short gastric vessels, and the splenic flexure of the colon. The pancreas is then mobilized along its inferior margin over it whole length to the left of the superior mesenteric vessels. The splenic vein is identified and carefully dissected out from the posterior surface of the pancreas over sufficient length to allow it to come down to the left renal vein without kinking. The operation is completed by interrupting the other collateral pathways between the portal vein and the shunt, particularly the coronary vein.

Postoperative management for all of these surgical procedures requires attention to detail. Patients should be managed in a monitored environment for 24 hours to make sure they are hemodynamically stable and there is no early postoperative bleeding. Limiting intravenous (IV) fluids and sodium helps minimize the risk of ascites. Infection prophylaxis, nutrition, and careful monitoring of hepatic function are important. Shunt patency should be documented prior to hospital discharge with imaging studies.

Transjugular Intrahepatic Portal Systemic Shunt

TIPS has matured over the last two decades, and is now the most widely used method for decompressing portal hypertension in patients with variceal bleeding or ascites.[42–44] It is an important part of the repertoire for the multidisciplinary team managing these patients. Figure 47-6 shows the principles of TIPS. The technical approach to TIPS is

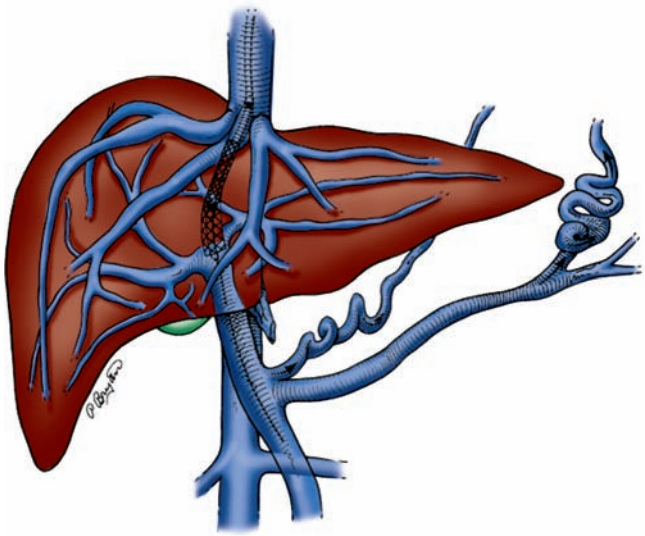

FIGURE 47-6 Transjugular intrahepatic portal systemic shunt (TIPS). This side-to-side shunt has variable hemodynamic effect depending on its diameter.

direct puncture of the internal jugular vein (IJV), passage of a catheter through the right atrium into one of the major hepatic veins—usually the right vein—followed by a transparenchymal puncture of the liver to cannulate the portal vein. The catheter is passed into the portal vein and pressure is measured. The portal vein puncture may be aided by ultrasound definition of its location. The intraparenchymal track is then dilated and the track stented with an expandable metal stent in the 10- to 12-mm-diameter range. Pressures are again measured and the goal is to decrease the gradient between the portal vein and the right atrium to less than 10 mm Hg. The technical success rate is high (>90%) with a low procedural morbidity and mortality (<10%). Patients are usually in the hospital for 1–2 days and the shunt patency should be documented the day after the procedure with a Doppler ultrasound.

The major issue with TIPS is its restenosis and thrombosis rates, which requires careful monitoring, and dilation and/or shunt extension when detected. The risk of early thrombosis seems to be related to bile duct puncture as the parenchymal track is developed. Covered TIPS stents have reduced thrombosis and stenosis rates. While a Doppler ultrasound will document patency, it has not proved to be a sensitive method for documenting stenoses, which requires direct measurement of the pressure gradient. Reintervention rates to maintain patency were high with uncovered stents, ranging from 40 to 80%, but have fallen to about 20% with covered stents.[45] The overall published rebleeding rates for TIPS are around 20%, and this was reduced to 13% in the covered stent trial.[45] Most centers have developed standard follow-up protocols to monitor TIPS, which call for repeated Doppler ultrasound. New encephalopathy rates are around 30%. Most of this encephalopathy appears to be relatively easily controlled with lactulose and/or some minimal protein restriction.

Devascularization Procedures

These operations approach the problem of variceal bleeding by interrupting inflow to the varices. The components are splenectomy, gastric and esophageal devascularization, and possibly esophageal transaction (Fig. 47-7).[46] The effectiveness of these procedures appears to depend on the aggressiveness of the operation. Popularized by Sugiura in Japan[46] and Hassab in Egypt, good results have been obtained in these countries. The advantage of these procedures is that portal hypertension is maintained with portal flow to the cirrhotic liver. Control of variceal bleeding in the originators' hands has been greater than 90%,[47] but higher rebleeding rates (~30%) have been seen in Europe and the United States.[48] These results are probably related to applying this operation to poorer-risk patients who are not candidates for other operations and inadequate operative devascularization. More recent application of devascularization procedures by Orozco and colleagues in Mexico has achieved good results with a 10% rebleeding rate.[49]

From a technical perspective, the original Sugiura operation combined an abdominal and a thoracic procedure either as a single- or two-stage approach. More recently, most surgeons have approached devascularizations purely from an abdominal approach. Standard devascularization operations include splenectomy, but Orozco and colleagues have published data indicating this is not essential. The whole of the greater curve should be devascularized, at least 7 cm of the distal esophagus, and finally the upper two-thirds of the lesser curve of the stomach. Attempts are made to keep the vagus

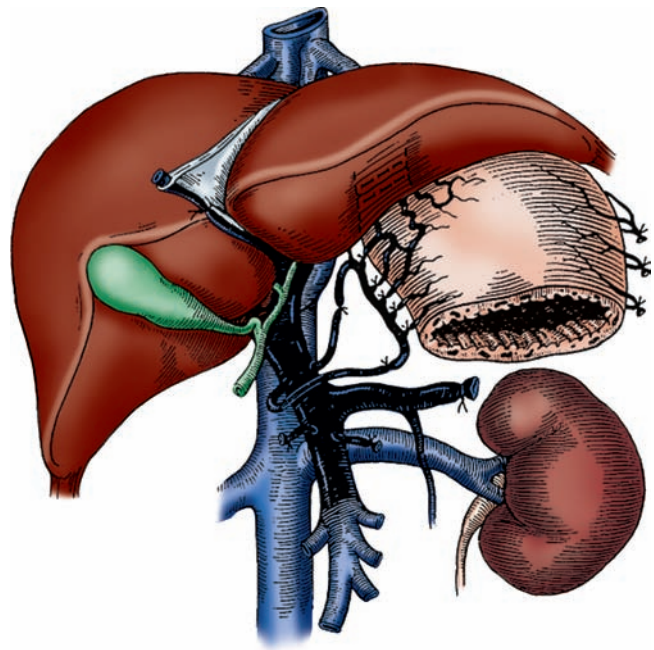

FIGURE 47-7 Gastroesophageal devascularization for variceal bleeding. Splenectomy, gastric and esophageal devascularization, and esophageal transection are the components of these operations.

nerve intact and the devascularization has the appearances of a proximal gastric vagotomy as the operation is completed. Because many of these patients have received sclerotherapy or banding prior to operative intervention, most do not need an esophageal transection, which can be difficult with the thickened esophagus.

Devascularization can be useful when patients have extensive portal and splenic venous thrombosis and there are no other operative or radiologic options. Extensive devascularization will reduce the risk of bleeding in such patients, and this remains the main indication for this operation.

Postoperative management requires attention to detail to minimize the risk of ascites as these patients still have portal hypertension. Follow-up endoscopy around 6 months is often helpful to document if there are any residual varices, treat them endoscopically at that time, or document the completeness of the devascularization procedure.

Overall, the bleeding rates can be reduced to less than 20% with this procedure and encephalopathy rates are low.

Liver Transplant

Liver transplant is the most commonly used operation for patients with portal hypertension at the present time,[50–52] and has been *the* major advance in the treatment of patients with advanced liver disease and sequelae of portal hypertension. The major issues are patient selection, timing of transplant, expanding the donor pool, and outcomes.

Patient selection has evolved over the past two decades. The indication for transplant is end-stage liver disease, but definition of this in the field of hepatology is a moving target. Variceal bleeding per se is not necessarily an indication of end-stage liver disease but other manifestations of portal hypertension such as ascites and encephalopathy are clinical indicators of end-stage liver disease. Patient selection also depends on other variables such as comorbid medical conditions and a psychosocial suitability for transplant particularly in the alcoholic and other chemical dependency patient populations. The increase in the incidence of hepatoma, particularly in the hepatitis C population, has also changed indications for patient selection for liver transplant. Standards for patient listing have been set by the United Network for Organ Sharing (UNOS), with evolving indications proposed by individual liver centers considered by regional review boards.

The timing of transplant is dictated by the severity of the underlying liver disease. Prioritization for organs occurs on the basis of MELD scores, with the sickest patients receiving cadaveric organs first based on bilirubin, prothrombin time, and serum creatinine. Timing is dictated by these objective criteria rather than individual physician decisions in day-to-day patient management. The donor pool for liver transplant has expanded with increasing public awareness of the need for organ donation, the use of "expanded donor" criteria with concomitant documentation that these organs do work, and the application of living donor transplant. The direct impact of these changes on the donor pool, the systems of organ allocation and prioritization, and individual center philosophies and priorities for their patients have changed and will continue to change the role of liver transplantation in portal hypertension.

The outcomes with liver transplant have continued to improve. The fear that pushing organs to the sickest patients would lead to poorer outcomes has not been fulfilled. Hospital mortality remains at less than 10%, despite transplanting in sicker and sicker patients and despite using more marginal organs. This is testimony to the advances in the fields of organ preservation and overall patient management during and following liver transplantation. The expectation therefore for outcomes is less than 10% hospital mortality and an 80+% 1-year survival with a 60–65% 5-year survival for liver transplant.

Technical aspects of liver transplant have focused on use of whole organ grafts, partial segmental grafts, living donor grafts, techniques of caval preservation, alternative methods of revascularization, and improved methods for biliary reconstruction. In addition to these technical advances in the transplant field itself, the increasing number of surgeons who have developed this expertise also represent the pool of surgeons with the ability to conduct some of the operative procedures described earlier in this chapter.

The management and longer-term follow-up of patients with portal hypertension coming to liver transplant is likewise an evolving field. Improvement in methods of immunosuppression, infection prophylaxis and treatment, patient monitoring to reduce the risk of transplant-related malignancy, and long-term health maintenance after transplant are ongoing fields of investigation and improvement. The net result of all of these advances is that patients with Child's class C cirrhosis, variceal bleeding, and advanced liver disease can now look forward to a reasonable chance of long-term survival, whereas 15–20 years ago, they had a 15–20% chance of long-term survival.

MANAGEMENT STRATEGIES

Variceal Bleeding

The treatment options just described need to be used appropriately in treatment strategies for

- Prophylaxis
- Acute variceal bleeding
- Prevention of rebleeding

Prophylaxis

Beta-blockers should be used for all patients with medium or large varices to reduce their risk of an initial bleed. Bleeding risk can be reduced from 30% to 18–20% with beta-blocker treatment. Multiple randomized controlled trials have documented this benefit. Patients with cirrhosis should have a screening endoscopy to assess for varices and initiate treatment if appropriate.[29,30]

Endoscopic therapy for prophylaxis should only be used for large varices and patients intolerant to beta-blockers.[53] Surgical therapy or radiologic shunts are not indicated in prophylaxis prior to an initial variceal bleed.[30]

Acute Variceal Bleeding

Acute variceal bleeding may require several treatment modalities and outcome has improved in the past decade.[54] Most important is the overall management of the patient rather than the specific therapies. Airway protection, appropriate fluid resuscitation, adequate monitoring, and antibiotic prophylaxis are all now standard of care for such patients. Transfusion of blood for bleeding, blood products for coagulopathy must be carefully monitored with a target of under- rather than over-resuscitation. Pharmacologic therapy with intravenous octreotide (50 μg/h) will reduce portal pressure and should be initiated on suspicion of a variceal bleed. Early endoscopy, both for diagnosis and initial banding therapy, is the mainstay of treatment.[55] Endoscopic banding can be done provided the varix is visualized and can be sucked into the end of the scope. In the occasional patient in whom endoscopic therapy cannot be performed, balloon tamponade should be used to control bleeding. Inflation of the gastric balloon alone, pulled gently up into the gastric fundus, will usually suffice to control bleeding. If that fails to control the bleeding, the esophageal balloon may need to be inflated to 40 mm Hg. Placement of a tamponade balloon mandates further reintervention within 24 hours, and this is usually an indication for an emergency TIPS procedure.

TIPS is required in fewer than 10% of patients with acute variceal bleeding.[42] Emergency TIPS placement needs to be treated in the same way as if the patient were going to the operating room. Airway protection, careful monitoring, and appropriate fluid management and resuscitation are required. While the radiologist is concentrating on the technical aspects of placing an accurate decompressing TIPS shunt, the patient overall management team needs to assure all other aspects of care are completed.

The patient with an acute variceal bleeding episode still carries a significant mortality risk, death most commonly resulting from decompensation of the underlying liver disease. A major bleed requires an intensive care unit (ICU) admission, but once stable, patients can be transferred to a regular hospital floor. Early evaluation and follow-up endoscopy to initiate an elective course of banding is the next step in overall patient management.

Prevention of Rebleeding

The first-line treatment for prevention of rebleeding is a course of variceal banding and concomitant pharmacologic therapy with a beta-blocker no matter what the underlying cause is.[29,30] The first elective banding episode should be performed within 3 or 4 days of the acute bleeding episode and as many bands placed as necessary to obliterate the columns of varices in the distal esophagus. Subsequently one or two banding sessions will probably be required to obliterate these varices. A beta-blocker is started with the target of reducing the pulse rate by 20% and with the plan to use this for long-term therapy.

Overall patient care also mandates a full evaluation of the patient at this point.[56,57] An understanding of the etiology of the liver disease, its severity, its likely natural history, and looking for other complications of portal hypertension should be completed at this stage. Several possible case scenarios may emerge:

- Good-risk patients—Child's A patients or MELD less than 10. Patients who still look like a Child's A patient after a variceal bleed and have MELD scores less than 10 probably have well-compensated liver disease. These patients should be treated with first-line treatment, but if they rebleed or have failure to obliterate their varices with banding, they may be a candidate for decompression with TIPS or DSRS.
- Indeterminate patients—Child's B or MELD 10–16. The majority of patients will fall into this category after their variceal bleed with some disturbance in their liver laboratory numbers, possibly developing ascites, and having an unpredictable course for their liver disease. From a management perspective, the question is whether these patients will improve to Child's A, remain Child's B patients, or move toward end-stage disease. Their initial treatment is with endoscopic banding and a beta-blocker. Subsequent treatment depends on the course of their liver disease.
- End-stage liver disease—Child's C or MELD greater than 16. If initial evaluation shows Child's C cirrhosis and patients clearly are not improving with routine clinical management, consideration needs to be given to full transplant evaluation. The severity of the bleeding episode may play some role in whether or not these patients' disease will return to a compensated level or whether they will continue to deteriorate secondary to the acute bleeding episode.

Failure of first-line treatment can occur in several scenarios. The main reasons are (1) the patient may have a further acute variceal bleed, (2) the patient may have recurring small bleeding episodes that are not transfusion-requiring, or (3) the patient may fail to have the varices obliterated and continue to have large varices with risk factors. Patients with any of the above scenarios, who also have advanced liver disease, are candidates for liver transplantation, possibly using TIPS as a bridge. Any of the above occurring in patients with well-compensated liver disease (Child's class A) may lead to variceal decompression with DSRS or TIPS.

Decompression with TIPS versus a surgical shunt has been evaluated in two randomized controlled trials. Rosemurgy and associates[36] studied the relative benefits of TIPS versus the 8-mm portacaval H-graft shunt. In their "all comers" study of 132 patients, 50% of their population were Child's class C patients. They showed a significantly lower rebleeding

rate, and significantly lower rate of need for transplant with the surgical shunt compared to the TIPS group, but no significant difference in survival.

A randomized trial compared DSRS to TIPS at five clinical centers in 140 Child's class A and B patients who failed first-line treatment.[58] Data showed no significant difference in rebleeding rates (5.5% DSRS group, 10.5% TIPS group), no significant difference in the times to first encephalopathy episode with 50% of patients in each group having at least one episode of encephalopathy by 5 years, and no significant difference in survival between the two groups. However, the reintervention rate in the TIPS group was significantly ($p < .001$) higher at 82% compared to a reintervention rate of 11% in the DSRS group. The rate of total thrombosis was significantly higher in the TIPS group compared to the DSRS group. This study used uncovered TIPS stents, which was all that was available at the time of this National Institutes of Health (NIH)-funded trail. The excellent results were achieved through intensive surveillance in the TIPS group compared to the DSRS patients to achieve the low rebleeding rate. A cost-effectiveness analysis of patients in this trial showed TIPS may be more cost-effective than DSRS in good risk Child's AB patients.[59]

Studies of TIPS with covered stents have shown significant advantages compared to uncovered stents for rates of stenosis and rebleeding.[60] This has now become the standard for variceal decompression when needed.

Ascites

The management of ascites is primarily medical with dietary salt restriction and diuretics (spironolactone and furosemide).[61] When ascites becomes refractory to such a regimen, large-volume paracentesis or TIPS may be considered, but these are a bridge to transplant. As indicated above, refractory ascites is one of the major clinical signs of end-stage liver disease. Four randomized trials have shown benefit and better control of ascites with TIPS compared to large-volume paracentesis, but survival benefit was only shown in two of four studies.[62–65]

Other surgical methods that have been used to manage ascites are side-to-side total portal systemic shunts and peritoneovenous shunts. The only indication currently to use a side-to-side (>10 mm) portacaval shunt for ascites is in patients with acute Budd-Chiari syndrome in whom decompression of the liver sinusoids with this operation will not only relieve their ascites, but will also stop the centrilobular hepatocyte necrosis and allow the liver to recover. The question to be answered in such a patient with acute Budd-Chiari syndrome is whether the same result can be achieved with TIPS.

Peritoneovenous shunts are seldom indicated in 2010 because the alternatives for managing intractable ascites, large-volume paracentesis, TIPS, and liver transplant are more satisfactory. Peritoneovenous shunts, with either a pressure-activated or a patient-activated pumping valve, were introduced in the 1970s and proved to be effective in the short term, but have largely been abandoned because of complications. Occlusion occurs in over half by 6 months, disseminated intravascular coagulation is triggered by reinfusion of ascites, and infection is a significant risk in this susceptible population.[66] Patients with complications from their intractable ascites, such as leakage at an umbilical hernia, are best managed with repeated paracentesis and/or TIPS.

The surgeon's role in treating patients with ascites is now limited to liver transplant which is the best therapy for patients with intractable ascites. The issue is candidacy for and availability of transplant.

PULMONARY SYNDROMES IN LIVER DISEASE

Lung dysfunction has been recognized in some patients with liver disease and portal hypertension for more than a century, but it is only in the last two decades that two distinct pulmonary vascular disorders have been better understood.[67,68] Hepatopulmonary syndrome (HPS) occurs when there is a pulmonary vascular vasodilation and hypoxemia, whereas portopulmonary hypertension (PPH) occurs when there is pulmonary vasoconstriction and increased pulmonary artery pressure. The major features of these two syndromes are summarized in Table 47-2.

The comparative contributions of liver dysfunction and portal hypertension vary with these syndromes. HPS can occur without severe portal hypertension and has also been recognized in some patients with prehepatic and postsinusoidal blocks. PPH can occur when the degree of liver dysfunction is relatively minor in the presence of established portal hypertension.

Shortness of breath is the most common presentation for either HPS or PPH.[69–72] Increased dyspnea on standing, cyanosis, and finger clubbing are often present with HPS and should lead to evaluation for this syndrome in patients with cirrhosis. Although patients with PPH may present with dyspnea, they are more likely to be asymptomatic. It is important to differentiate these pulmonary syndromes because treatment is different.

TABLE 47-2: PULMONARY SYNDROMES IN LIVER DISEASE

Variables	Hepatopulmonary Syndrome	Portopulmonary Hypertension
Prevalence	8–20% of cirrhosis	3–12% of cirrhosis
Pulmonary vascular changes	Vasodilation	Vasoconstriction
Contributing factors	Liver dysfunction, portal hypertension	Portal hypertension
Place of transplant	Curative	Contraindicated

In HPS, diagnosis is made on patients hypoxemic on room air (PO_2 <70 mm Hg) by a bubble-contrast echocardiogram.[73] If this is positive as judged by delayed visualization of intravenously administered microbubbles in the left cardiac chamber, the patient has HPS. Patients with HPS require oxygen therapy, but the only effective treatment for HPS is liver transplant.

The diagnosis of PPH requires documentation of elevated pulmonary arterial pressures.[74] Echocardiography is used for screening for elevated right heart pressure,[75] but when the estimate is equal to or greater than 40 mm Hg, direct pulmonary artery pressure measurements should be made with right heart catheterization. A mean pulmonary artery pressure of greater than 25 mm Hg with a capillary wedge pressure of less than 15 mm Hg confirms a diagnosis of pulmonary arterial hypertension. Mild degrees of pulmonary arterial hypertension up to 35 mm Hg do not preclude liver transplantation in otherwise acceptable candidates, but pressures greater than 35 mm Hg require aggressive evaluation and treatment. Pulmonary artery pressures greater than 50 mm Hg are an absolute contraindication to liver transplantation.[76] Patients with pulmonary artery pressure greater than 35 mm Hg should receive pharmacologic therapy, with reassessment after 3 months.[77] Response to this treatment may make such patients candidates for liver transplantation.

THE MULTIDISCIPLINARY TEAM

The content of this chapter has involved many specialists to take care of the complications of portal hypertension, including the following:

Hepatologists are in the front line for diagnosing and directing the management for many of the clinical presentations.

Endoscopists play an important role diagnostically and in primary therapy for managing variceal bleeding. Endoscopic banding requires significant expertise.

Radiologists, both imaging and interventional, play roles in diagnosis, directed biopsy, and procedural (TIPS) management of these patients.

Surgeons play a major role in liver transplant but may also have a role in shunting good-risk patients with refractory variceal bleeding.

Pathologists with an interest in liver pathology are important in the accurate diagnosis and staging of disease severity.

Critical care physicians and anesthesiologists are vital team members when patients with portal hypertension have acute events and in their perioperative management. The different pathophysiology of portal hypertension can be challenging in the ICU and operating room.

Nephrologists, cardiologists, and pulmonologists all play a role in the management of some of these patients, and in major centers it is important to have members of all these specialties in the team who understand the pathophysiologic changes of portal hypertension.

Finally, who coordinates? In a complex multidisciplinary team such as described, it is frequently the nurse clinicians or coordinators who help bring these specialists together. Undoubtedly the coordinators are the ones to whom the patients turn for help in navigating their way through management in this complex field.

CHOLECYSTITIS AND CHOLELITHIASIS

Edward D. Auyang • Nathaniel J. Soper

HISTORY AND BACKGROUND

Cholecystectomy is one of the most common surgical procedures performed in the United States with over 600,000 procedures performed each year. Open cholecystectomy, first performed by Carl Langenbuch in 1882, has been the primary treatment of gallbladder disease through the early 1990s.[1] In 1985, the first endoscopic cholecystectomy was performed by Erich Mühe of Böblingen, Germany. Shortly thereafter, pioneers in France and the United States coupled a CCD video camera with a laparoscope to allow the entire surgical team to view the operative field and performed cholecystectomies with laparoscopic equipment. Since then, laparoscopic cholecystectomy has been adopted around the world, and subsequently been recognized as the gold standard for the treatment of gallstone disease.[2–5] In 1992, the National Institutes of Health (NIH) Consensus Development Conference stated that laparoscopic cholecystectomy provides a safe and effective treatment for most patients with symptomatic gallstones.[6] Currently it is estimated that over 80% of cholecystectomies are performed using the laparoscopic approach.

The advantages of laparoscopic over open cholecystectomy have been well documented. These advantages include earlier return of bowel function, less postoperative pain, improved cosmesis, shorter length of hospital stay, earlier return to full activity, and decreased overall cost.[7–11] There has been an increase in the rate of cholecystectomies subsequent to the introduction of laparoscopic cholecystectomy accompanied by evidence of lower clinical thresholds for operative therapy of gallbladder disease.[12–14]

INDICATIONS FOR CHOLECYSTECTOMY

There are multiple indications for cholecystectomy with the most common being symptomatic cholelithiasis (Table 48-1). The diagnosis of symptomatic cholelithiasis is made by radiographic documentation of gallstones, usually using abdominal ultrasound, with the presence of symptoms attributable to a diseased gallbladder. Biliary colic is typically a severe and episodic right upper abdominal or epigastric pain that can radiate to the back. Attacks frequently occur postprandially or awaken the patient from sleep. Often times the postprandial pain will be associated with meals that are high in fat content. Once a patient begins to experience symptoms, there is a greater than 80% chance that he or she will continue to have symptoms in the future or develop a complication. These complications may result from obstruction of the gallbladder outlet, causing acute cholecystitis, or migration of a stone into the common bile duct, causing cholangitis or pancreatitis.

Patients with asymptomatic gallstones have less than 20% chance of ever-developing symptoms, and the risks associated with prophylactic operation outweigh the potential benefit of surgery in most patients.[15,16] Prophylactic cholecystectomy for asymptomatic cholelithiasis can be justified in certain circumstances, such as in patients with sickle cell disease, those undergoing open bariatric surgery, requiring long-term total parental nutrition, or patients who are therapeutically immunosuppressed after solid organ transplantation. Patients with sickle cell disease often have hepatic or vaso-occlusive crises that can be difficult to differentiate from acute cholecystitis.[17] In patients following bariatric surgery, the development of gallstones is markedly increased during the period of rapid weight loss to an incidence of about 30%.[18,19] Removing the gallbladder at the time of bariatric surgery can abolish gallstone-related morbidity relatively easily. This approach has been adopted by many bariatric surgeons during open bariatric procedures, but not during laparoscopic bariatric surgery, because the potential morbidity of an added laparoscopic cholecystectomy in the patient with morbid obesity appears greater than the potential later risk of cholelithiasis-related complications.[20–22] In transplant patients, there is concern that immunosuppression may mask the signs and symptoms of inflammation until overwhelming infection has ocurred.[23] Recommendations in the literature range from mandatory screening and treatment of biliary disease before transplantation, to prophylactic cholecystectomy 6 months post-transplantation, to expectant management of all asymptomatic patients.[24–27] Other possible

TABLE 48-1: INDICATIONS FOR LAPAROSCOPIC CHOLECYSTECTOMY

Symptomatic cholelithiasis
Biliary colic
Acute cholecystitis
Choledocholithiasis
Gallstone pancreatitis
Cholangitis or obstructive jaundice
Asymptomatic cholelithiasis
Sickle cell disease
Total parenteral nutrition
Chronic immunosuppression
No immediate access to health care facilities (eg, missionaries, military personnel, peace corps workers, relief workers)
Incidental cholecystectomy for patients undergoing procedure for other indications
Acalculous cholecystitis
Gallbladder dyskinesia
Gallbladder polyps >10 mm in diameter
Porcelain gallbladder

indications for prophylactic laparoscopic cholecystectomy include individuals who may not have access to modern health care facilities for an extended time period, such as missionaries and military personnel, and patients who are already undergoing an abdominal operation for other reasons. Prophylactic cholecystectomy has been occasionally advocated in diabetics. There is no evidence to support this policy, but good evidence to support a strategy of early cholecystectomy in the symptomatic patient. Diabetics tend to present with acute cholecystitis more frequently once they become symptomatic, and withstand complications less well.

Individuals without gallstones but with typical biliary symptoms, that is, acalculous cholecystitis or gallbladder dyskinesia (GBD), may also be considered for the procedure.[10] GBD is often a diagnosis of exclusion. The Rome Committee, established in 1994, set three criteria to confirm GBD: (1) absence of gallbladder stones, sludge or microlithiasis, (2) abnormal ejection fraction (EF) less than 40% on hepatobiliary iminodiacetic acid (HIDA) scan after 30 minutes of continuous cholecystokinin (CCK) infusion, and (3) positive response without pain for 12 months after cholecystectomy.[28]

Other indications for cholecystectomy include gallbladder polyps and porcelain gallbladder. Gallbladder polyps are typically an incidental finding that affects approximately 5% of the population, with a higher percentage in Asian populations.[29] Polyps that are smaller than 10 mm in diameter have a low likelihood of malignancy and can be followed radiologically. Polyps larger than 10 mm in diameter in patients over 50 years old have a higher likelihood of being malignant and are recommended for cholecystectomy.[29,30] Porcelain gallbladder has an associated risk of gallbladder cancer. Earlier studies estimated the incidence of gallbladder cancer to be between 12 and 60%, but recent studies suggest that the overall risk is lower at 7%.[31] Nevertheless, radiographic evidence of porcelain gallbladder warrants cholecystectomy.

DIAGNOSTIC STUDIES

Serum laboratory tests of patients with biliary disease include total bilirubin, alkaline phosphatase, transaminases, amylase, lipase, and complete blood count (CBC). Elevations in the liver function panel may suggest biliary obstruction. Elevations in amylase and lipase may suggest pancreatitis. With simultaneous elevation of both liver and pancreatic enzymes, gallstone pancreatitis must be ruled out.

In a patient with typical biliary colic, the only diagnostic imaging study necessary prior to laparoscopic cholecystectomy is an abdominal ultrasound revealing gallstones. Ultrasound demonstrates the size and number of stones, the thickness of the gallbladder wall, the presence or absence of pericholecystic fluid, the diameter of the common bile duct (CBD), and other components of the biliary ductal system. Other nonbiliary disorders such as hepatic lesions or steatosis, masses in the pancreas, or renal tumors may also be diagnosed. When ultrasound is negative despite typical biliary symptoms, CCK-stimulated HIDA scan demonstrating a low gallbladder EF with or without pain reproduction suggests gallbladder dyskinesia.[28] If a patient with gallstones has atypical symptoms, however, a more extensive work-up including upper gastrointestinal contrast radiography or endoscopy, computerized tomography, or cardiac and pulmonary evaluation may be appropriate to rule out significant nonbiliary disease processes.

CONTRAINDICATIONS TO LAPAROSCOPIC CHOLECYSTECTOMY

The number of absolute and relative contraindications to performing laparoscopic cholecystectomy has decreased over the past 20 years as minimally invasive surgical instrumentation and skills have improved (Table 48-2). Absolute contraindications include the inability to tolerate general anesthesia or laparotomy, refractory coagulopathy, diffuse peritonitis with hemodynamic compromise, cholangitis, and potentially curable gallbladder cancer. Diffuse peritonitis with hemodynamic compromise represents a surgical emergency in which attempted laparoscopic cholecystectomy is not prudent, because the etiology is not clear or secure, and the pneumoperitoneum may lead to vascular collapse. Standard open laparotomy allows rapid determination of the etiology and more expeditious management of the disorder. Suspicion of gallbladder malignancy mandates that standard open resection be undertaken. This is because of persistent concerns with adequacy of resection and the possibility of gallbladder perforation (occurring in 20–30% of laparoscopic cholecystectomies) with intraperitoneal dissemination of cancer.

TABLE 48-2: CONTRAINDICATIONS TO LAPAROSCOPIC CHOLECYSTECTOMY

Absolute
Unable to tolerate general anesthesia
Refractory coagulopathy
Suspicion of gallbladder carcinoma
Relative
Previous upper abdominal surgery
Cholangitis
Diffuse peritonitis
Cirrhosis and/or portal hypertension
Chronic obstructive pulmonary disease (COPD)
Cholecystoenteric fistula
Morbid obesity
Pregnancy

Relative contraindications are dictated primarily by the surgeon's philosophy and experience. These include previous upper abdominal surgery with extensive adhesions, cirrhosis, portal hypertension, severe cardiopulmonary disease, morbid obesity, and pregnancy. In most patients, little is lost by initiating a laparoscopic cholecystectomy with conversion to laparotomy if the laparoscopic approach is deemed too risky.

Pregnancy is a controversial relative contraindication to laparoscopic cholecystectomy because of the unknown effects of prolonged CO_2 pneumoperitoneum on the fetus. Laparoscopic cholecystectomy can be performed safely during pregnancy, but only with great care.[29] We limit this intervention to the second trimester of gestation after organogenesis is complete and prior to the uterine fundus reaching a size and height that encroaches on the operative field. Open insertion of the initial port or alternative location of the initial port in the right upper quadrant should be used to avoid injury to the gravid uterus, and the insufflation pressure should be limited to less than 12 mm Hg to avoid respiratory embarrassment and decreased vena caval return. Also, maternal hyperventilation with close monitoring of end-tidal CO_2 should be undertaken to prevent fetal acidosis. When visualization of the biliary tree is required, laparoscopic ultrasound is used in place of cholangiography in order to limit fetal radiation exposure. And finally, perioperative consultation with an experienced obstetrician is advisable, as is perioperative fetal heart monitoring.

Early experience suggested that acute cholecystitis was a relative contraindication to performing laparoscopic cholecystectomy. A number of recent reports indicate that laparoscopic cholecystectomy indeed can be done safely for patients with acute inflammation of the gallbladder, but should be performed in this setting only by experienced laparoscopic surgeons. There is clearly a higher rate of conversion in the setting of acute cholecystitis. In particular, after 72 hours the rate of conversion increases significantly. One should not hesitate to convert to an open cholecystectomy if significant adhesions or inflammation are identified during laparoscopy. The timing of cholecystectomy for acute cholecystitis has been a long-standing matter of debate. Based on several prospective studies, early surgical intervention has economic, social, and medical benefits and therefore is the preferred approach for experienced laparoscopic surgeons in the management of acute cholecystitis.[32–36] Our practice is to proceed with laparoscopic cholecystectomy immediately after the diagnosis of acute cholecystitis has been made. In patients who present after 72 hours of symptoms, a laparoscopic cholecystectomy is attempted only if the patient has no pre-existing medical conditions which preclude an open cholecystectomy. If the patient does have significant comorbid illnesses, we continue with antibiotic therapy and possibly a percutaneous cholecystostomy tube and subsequent elective laparoscopic cholecystectomy 6–8 weeks later. Surgeons must be comfortable in their ability to safely perform the procedure laparoscopically; significant concerns based on laparoscopic findings should prompt conversion to open cholecystectomy. Despite the advent of minimally invasive technology, open cholecystectomy continues to be an acceptable method for removal of the gallbladder under any circumstances and should certainly be considered if proper facilities for performance of laparoscopic surgery are not available or if the surgeon is not adequately trained in this technology.

In addition to relative contraindications, there are situations when cholecystectomy, whether laparoscopic or open, should be avoided completely in favor of percutaneous cholecystostomy. Patients in which cholecystostomy should be used include patients who have absolute contraindications to surgery. These include patients with significant respiratory failure resulting in inability to tolerate general anesthesia and those who have had recent exacerbation of a significant comorbid illness such as myocardial infarction (MI).

OPERATIVE TECHNIQUE

Anatomy

The classic anatomy of the biliary tree is present in only 30% of individuals, so it may be said that anomalies are the rule, not the exception. As with any procedure, the knowledge of normal anatomy and common variants is critical to the success of surgical intervention. The cystic duct may join the CBD at an acute angle, travel parallel to the common duct for several centimeters prior to insertion, insert into the right hepatic duct, or be congenitally absent. The cystic artery usually arises from the right hepatic artery, but one must be absolutely sure that the cystic artery is visualized entering the gallbladder wall. Occasionally the right hepatic artery will loop up onto the surface of the gallbladder, and a very short cystic artery will arise. Furthermore, there can often be a posterior cystic artery, which can easily be injured if not recognized. The common bile duct begins at the junction of the cystic duct and the common hepatic duct and passes inferiorly to the ampulla of Vater. Its normal diameter is less than

6 mm, although it may be larger in elderly patients and those with biliary obstruction.

It is important to clearly identify the structures within the hepatocystic triangle, which is the ventral aspect of the area bounded by the gallbladder wall and cystic duct, the liver edge, and the common hepatic duct. Contained within the hepatocystic triangle is the eponymic Calot's triangle: The boundaries of Calot's triangle include the cystic duct, cystic artery, and the gallbladder wall. Aberrant anatomy is a well-recognized risk factor for biliary injury. An aberrant right hepatic duct (RHD) is the most common anomaly causing problems during laparoscopic cholecystectomies. The most dangerous variant is when the cystic duct joins a low-lying aberrant right sectoral duct. Injuries to these ducts are under-reported since occlusion of an aberrant duct may be asymptomatic and even unrecognized (Fig. 48-1).

Patient Preparation

As with any abdominal operation, patients are fasted for a minimum of 8 hours prior to the operation. Patients without major comorbidities are generally scheduled as outpatient procedures. Prophylactic antibiotics are up to the surgeon's discretion; evidence suggests that most patients have a very low risk of perioperative infection.[37] Antiembolic stockings and sequential compression devices are placed on both legs to avoid pooling of blood in the lower extremities by the reverse Trendelenburg position generally used during this operation. Following induction of general endotracheal anesthesia, an orogastric tube may be placed to decompress the stomach. The abdomen is shaved and prepared in standard sterile fashion with particular care taken to rid the umbilicus of all debris.

FIGURE 48-2 Operating room setup.

Laparoscopic Cholecystectomy

OPERATING ROOM SETUP

Most surgeons utilize two video monitors, one on each side of the operating table to facilitate visualization by both surgeon and assistant. Using the American technique, the surgeon stands to the left of the patient, the first assistant stands to the patient's right (Fig. 48-2). If a laparoscopic video camera operator is used, he stands to the left of the surgeon. In the French technique, the patient's legs are abducted and the surgeon stands between the legs.

PNEUMOPERITONEUM

A working space, provided by a pneumoperitoneum, is essential for the surgeon to see and to operate within the abdominal cavity. CO_2 has the advantage of being noncombustible and rapidly absorbed from the peritoneal cavity. It may, however, lead to hypercarbia in patients with significant cardiopulmonary disease.[38] The most common location for initial peritoneal entry is at the midline near the umbilicus. Supraumbilical or infraumbilical incisions may be made in vertical, horizontal, or curvilinear orientations based on surgeon's preference. Pneumoperitoneum can be established by either a closed or an open technique. In the closed technique, CO_2 is insufflated into the peritoneal cavity through a Veress needle, which is subsequently replaced with a laparoscopic port, placed blindly into the abdominal cavity. In the open technique, a laparoscopic port is inserted under direct vision into the peritoneal cavity via a small incision; only after ensuring definitive and safe peritoneal entry is the pneumoperitoneum established. There are advantages and disadvantages to both techniques. Surgeons performing laparoscopic cholecystectomy should learn both and use them selectively based on the patient's body habitus and previous surgical history.

PORT PLACEMENT AND EXPOSURE

Depending on the surgeon's preference, a 5- or 10-mm laparoscope is inserted into the abdomen through the periumbilical port and the abdominal cavity is visually explored. It is generally advantageous to use an angled (30- or 45-degree) laparoscope rather than a 0-degree scope, because the angled scopes enable obtaining multiple views of the same operative field. The patient is then placed in a reverse Trendelenburg position of 30 degrees while rotating the table to the left by 15 degrees. This maneuver allows the colon and duodenum to fall away from the liver edge. The falciform ligament and both lobes of the liver are examined closely for abnormalities. The gallbladder can usually be seen protruding beyond the edge of the liver.

Two small accessory subcostal ports are then placed under direct vision. The first 5-mm trocar is placed along the right anterior axillary line between the 12th rib and the iliac crest. A second 5-mm port is inserted in the right subcostal area in the midclavicular line. Grasping forceps are placed through these two ports to secure the gallbladder. The assistant manipulates the lateral grasping forceps, which are used to grasp the fundus and elevate the liver. The fourth working port is then inserted through an incision in the midline of the epigastrium (Fig. 48-3). This trocar is usually inserted approximately 5 cm below the xiphoid process, but the precise position and angle depends on the location of the gallbladder as well as the size of the medial segment of the left lobe of the liver. Dissecting forceps are then inserted and directed toward the gallbladder neck. One should note that the orientation of the laparoscope is generally parallel to that of the cystic duct when the fundus is elevated, whereas the instruments placed through the other three ports enter the abdomen at right angles to this plane. The surgeon uses a dissecting forceps to raise a serosal fold of the most dependent portion of the fundus. The assistant's heavy grasping forceps are then locked onto this fold using either a spring or ratchet device. With these axillary grasping forceps, the fundus of the gallbladder is then pushed in a

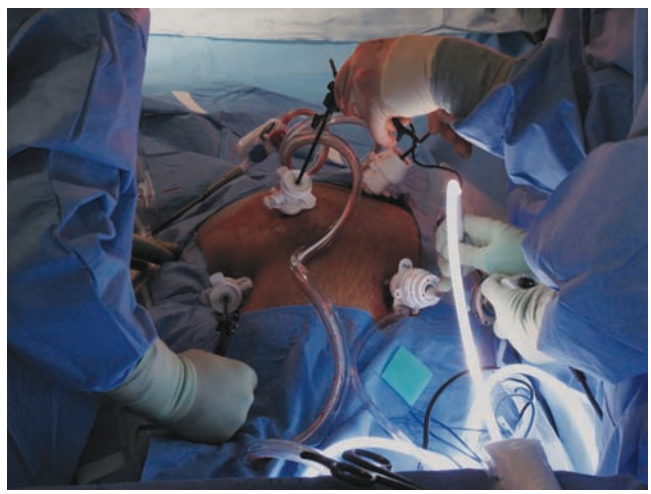

FIGURE 48-3 Port placement.

lateral and cephalad direction, rolling the entire right lobe of the liver cranially.

This maneuver is complicated in patients with a fixed, cirrhotic liver or a heavy, friable liver because of fatty infiltration. In patients with few adhesions to the gallbladder, pushing the fundus cephalad exposes the entire gallbladder, cystic duct, and porta hepatis. Most patients, however, have adhesions between the gallbladder and the omentum, hepatic flexure and/or duodenum. These adhesions are generally avascular and may be lysed bluntly by grasping them with dissecting forceps at their site of attachment to the gallbladder wall and gently *stripping* them down toward the infundibulum. Extreme caution should be taken to avoid damage to surrounding structures. Use of electrocautery may accidentally damage the unvisualized CBD or proximally located duodenum. After exposing the infundibulum, blunt grasping forceps held in the surgeon's left hand and placed through the midclavicular trocar are used to grasp and place traction on the neck of the gallbladder.

DISSECTION

The infundibulum is grasped, placing traction on the gallbladder in a lateral direction to distract the cystic duct from the CBD (Fig. 48-4). Fine-tipped dissecting forceps (Maryland) are used to dissect away the overlying fibroareolar structures from the infundibulum of the gallbladder. The dissection should begin from a known structure, for example, the gallbladder, rather than in an unknown area, to avoid damage to the underlying structures such as a bile duct or hepatic artery. The dissection initially commences 4 or 5 cm proximal to the neck of the gallbladder and proceeds distally, such that a modified "top-down" technique is employed. The objective of the initial dissection is to free the gallbladder from its bed such that there is a window beneath it through which the liver substance can be seen. The hepatocystic triangle is maximally opened and converted into a trapezoid shape by retracting the infundibulum of the gallbladder inferiorly and laterally while maintaining the fundus under traction in a superior and medial direction. A lymph node usually lies on the surface of the cystic artery, and occasionally it is necessary to use a brief application of low-wattage electrosurgical coagulation to obtain hemostasis as the lymph node is bluntly swept away. To expose the reverse of Calot's triangle, the infundibulum of the gallbladder is pulled in a superior and medial direction. The use of an angled laparoscope facilitates viewing both sides of the hepatocystic triangle when used in combination with these retraction techniques. After clearing the structures from the apex of the triangle, the junction between the infundibulum and the origin of the proximal cystic duct can be tentatively identified. The strands of peritoneal, lymphatic, and neurovascular tissue are stripped away from the cystic duct to clear a segment from the surrounding tissue. Curved dissecting forceps are helpful in creating a window around the posterior aspect of the cystic duct to skeletonize the duct itself. Alternatively, the tip of the hook cautery can be used to encircle and expose the duct. It is generally unnecessary and potentially harmful to dissect the cystic duct down to its junction with the CBD. The cystic artery is separated from the surrounding tissue by similar blunt dissection at this time. If the cystic artery crosses anterior to the duct, the artery may require dissection and division prior to approaching the cystic duct. The neck of the gallbladder is thus dissected away from its liver bed, leaving a large window at its base through which the liver parenchyma is visualized. There should be two, and only two, structures (the cystic duct and artery) crossing this window—this is the "critical view of safety," which should be demonstrated prior to clipping or cutting any tubular structures.[38] To reiterate, no structure should be divided until the cystic duct and cystic artery are unequivocally identified. Developing this critical view of safety is an essential step to minimize the chance of bile duct injury during laparoscopic cholecystectomy (Fig. 48-5).[38]

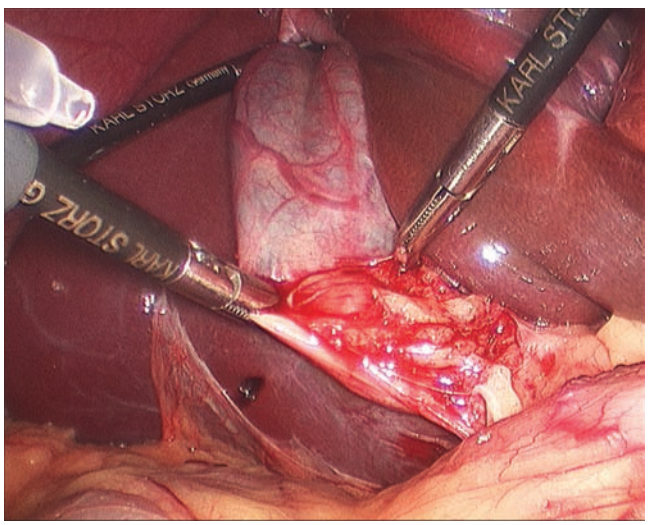

FIGURE 48-4 Retraction of the gallbladder.

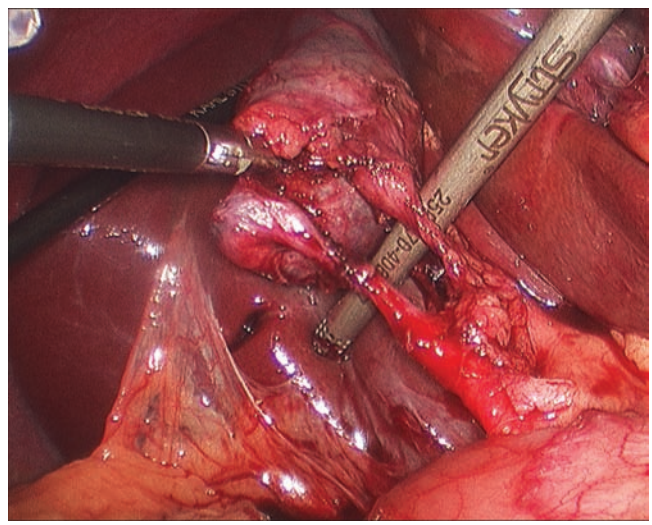

FIGURE 48-5 Critical view of safety.

INTRAOPERATIVE EVALUATION FOR CHOLEDOCHOLITHIASIS

After initially dissecting the proximal cystic duct, the CBD should be imaged if there is any concern for choledocholithiasis or questions regarding the biliary anatomy. This can be achieved by intraoperative cholangiography (IOC) or intracorporeal laparoscopic ultrasonography (LUS). Prior to either procedure, a clip is applied high on the cystic duct at its junction with the gallbladder to prevent stones migrating down the duct during subsequent manipulation. To perform IOC, the anterolateral wall of the cystic duct is incised and dissecting forceps are used to gently compress the cystic duct systematically back toward the gallbladder, thereby milking stones away from the CBD and out of the ductotomy. A 4F or 5F catheter is inserted into the duct through a hollow, 5-mm metal tube that has an appropriate gasket to prevent carbon dioxide leakage around the catheter itself. The cholangiography catheter is inserted into the cystic duct and a clip is applied loosely to secure the catheter in place. If the introducer has grasping jaws, it can be used to secure the catheter into the duct. Alternatively, catheters equipped with balloons proximal to the tip may be used for fixation. Cholangiography can be performed by either real-time fluoroscopy (dynamic) or by obtaining two standard radiographs (static) after injecting 5 and 10 mL of water-soluble contrast medium. The films should be inspected for the following: (1) the length of cystic duct and location of its junction with the CBD, (2) the diameter of the CBD, (3) the presence of luminal filling defects within the CBD, (4) free flow of contrast into the duodenum, and (5) anatomy of the extrahepatic and intrahepatic biliary tree. After the cholangiocatheter is removed, the cystic duct is doubly clipped below the ductotomy with care to avoid the wall of the CBD, and then divided. The posterior jaw of the clip applier must be visualized prior to applying each clip in order to avoid injuring the surrounding structures. Great care should be taken so that the CBD is not tented up into the clip. If the cystic duct is particularly large or friable, it may be preferable to replace one of the clips with a suture, either hand-tied or a preformed loop with slip knot.

Evaluation of the CBD by LUS is an alternative to cholangiography. Several studies[39,40] performed at open cholecystectomy reported intracorporeal ultrasonography to be more accurate than operative cholangiography in assessing the CBD for stones (97–99% vs 89–94%).[41–43] However, few surgeons adopted ultrasound for this purpose. Recently, LUS has been used in several centers during laparoscopic cholecystectomy and is gaining popularity.[43–47] With LUS, the transducer has a higher frequency with improved resolution compared to those used with transabdominal ultrasonography. In experienced hands, LUS appears to be as accurate as cholangiography for demonstrating choledocholithiasis but can be performed more rapidly.[48] In a recent prospective multicenter trial with 209 laparoscopic cholecystectomy patients, the time to perform LUS (7 ± 3 minutes) was significantly less than that of IOC (13 ± 6 minutes).[48] The study showed that LUS was more sensitive for detecting stones but that IOC was better in delineating intrahepatic anatomy and defining anatomical anomalies of the ductal system. The authors concluded that the two methods of duct imaging were complementary. Despite these promising data, more clinical experience will be necessary to establish the appropriate role of LUS for the detection of choledocholithiasis during laparoscopic cholecystectomy.[49,50]

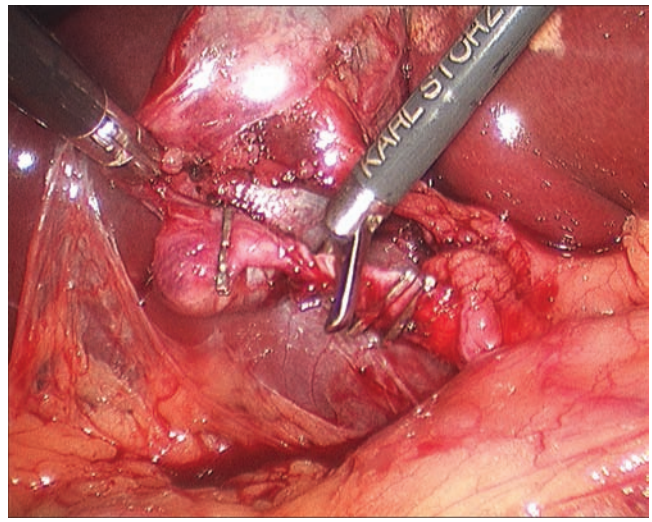

FIGURE 48-6 Clipping the cystic duct.

COMPLETION OF CHOLECYSTECTOMY

The cystic duct is clipped using an endoscopic clip applier and divided using scissors. Two clips are placed proximally on the cystic duct and one clip is placed toward the gallbladder (Fig. 48-6). For cystic ducts that are large or friable, a preformed endoloop is preferable for ligating the distal cystic duct. After the duct is divided, the cystic artery is dissected from the surrounding tissue for an adequate distance to permit placement of three clips. The surgeon must determine that the structure is indeed the cystic artery and not the right hepatic artery looping up onto the neck of the gallbladder or an accessory or replaced right hepatic artery. After an appropriate length of cystic artery has been dissected free, it is clipped proximally and distally prior to transection (Fig. 48-7). Electrocautery should not be used for this division, as the current may be transmitted to the proximal clips leading to subsequent necrosis and hemorrhage.

The ligated stumps of the cystic duct and the artery are then examined to ensure that there is no leakage of either bile or blood and that the clips are placed securely and compress the entire lumen of the structures without impinging on adjacent tissues. A suction-irrigation catheter is used to remove any debris or blood that has accumulated during the dissection. Separation of the gallbladder away from its hepatic bed is then initiated using an electrosurgical probe to coagulate small vessels and lymphatics. While maintaining cephalad traction on the fundus of the gallbladder with the

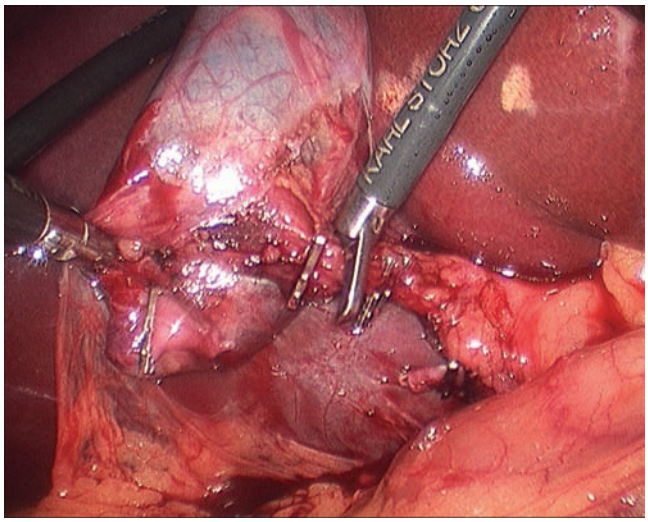

FIGURE 48-7 Clipping the cystic artery.

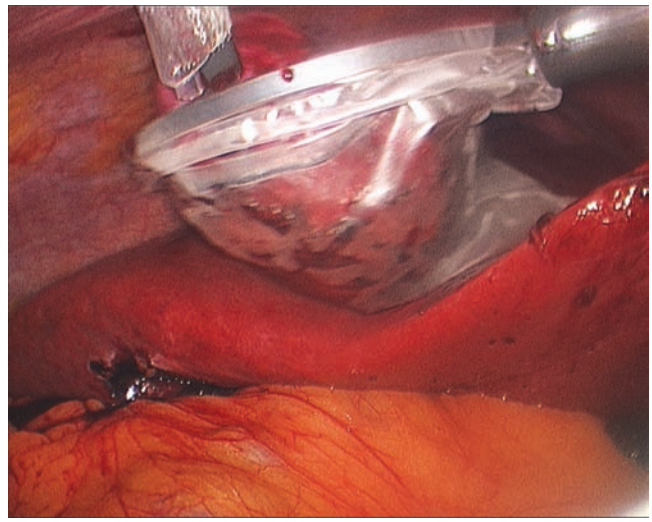

FIGURE 48-9 Placing gallbladder in entrapment bag.

axillary forceps, the midclavicular forceps pulls the neck of the gallbladder anterosuperiorly and then alternatively medially and laterally to expose and place the tissue connecting the gallbladder to its fossa under tension. An electrocautery spatula or hook is used to coagulate and divide the tissue. Intermittent blunt dissection will facilitate exposure of the proper plane (Fig. 48-8).

Dissection of the gallbladder fossa continues from the infundibulum to the fundus, progressively moving the midclavicular grasping forceps cephalad to allow maximal countertraction. The dissection proceeds until the gallbladder is attached by only a thin bridge of tissue. At this point, prior to completely detaching the gallbladder, the hepatic fossa and porta hepatis are once again inspected for hemostasis and bile leakage. Small bleeding points are coagulated and the right upper quadrant is liberally irrigated and then aspirated dry

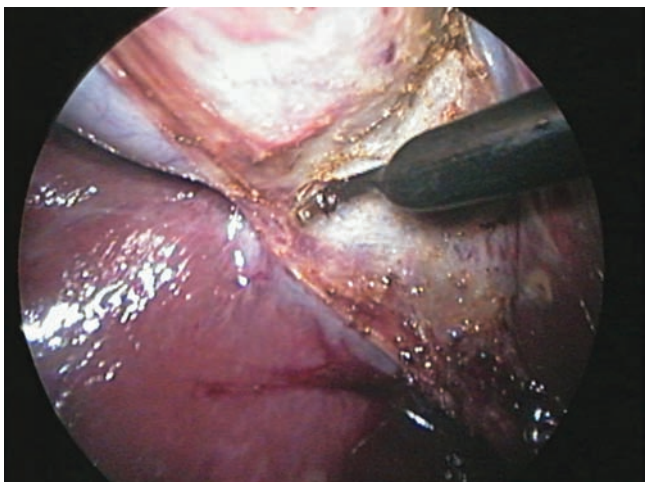

FIGURE 48-8 Dissecting the gallbladder off the liver.

while checking for any residual bleeding or bile leakage. The final attachments of the gallbladder are divided, and the liver edge is again examined for hemostasis.

After the cholecystectomy has been performed, the gallbladder must be removed from the abdominal cavity. The gallbladder may be placed within an entrapment sac prior to extracting it through the abdominal wall (Fig. 48-9). This is recommended particularly if the gallbladder has been perforated intraoperatively or if the specimen is large. If the stone burden is small, the gallbladder can be extracted at the subxiphoid port site. Usually, the gallbladder is most easily removed at the umbilical port site where there are no muscle layers anterior to the fascial plane. Also, if the fascial opening needs to be enlarged because of large or numerous stones, extension of the umbilical incision causes less postoperative pain and has better cosmesis than does enlarging the subxiphoid incision. The laparoscope is removed from the umbilical port and placed through the epigastric port. Large "claw" grasping forceps are introduced through the umbilical port to grasp the infundibulum of the gallbladder. The forceps, trocar, and gallbladder neck are then retracted as a unit through the umbilical incision. The neck of the gallbladder is thus exteriorized through the anterior abdominal wall with the fundus remaining within the abdominal cavity. If the gallbladder is not distended with bile or stones, it can be simply withdrawn with gentle traction. In many cases, a suction catheter introduced through an incision in the gallbladder neck is used to aspirate bile and small stones. Stone forceps can also be placed into the gallbladder to extract or crush calculi if necessary. Occasionally, the fascial incision must be extended to extract larger stones or thick-walled gallbladders.

Each incision is infiltrated with bupivacaine for postoperative analgesia. The fascia of the umbilical incision is closed with one or two large absorbable sutures in an interrupted or figure-of-eight fashion. Closure of the subxiphoid fascia is optional, as visceral herniation is unlikely to occur because of the oblique entry angle of the trocar into the abdominal

cavity and its location anterior to the falciform ligament. The skin of the subxiphoid and umbilical incisions is closed with subcuticular absorbable sutures. The skin incisions at both 5-mm port sites can be closed with absorbable sutures, adhesive strips, or skin closure adhesives. The orogastric tube is removed in the operating room, and the patient is transferred to the postanesthesia care unit. Patients are allowed out of bed as soon as they are fit enough to walk, and more than 90% of patients are discharged from the hospital within 24 hours. Fit patients who have been preoperatively selected may be safely discharged within 6 hours following surgery.[45] Patients are evaluated 1 week following surgery and if sutures are present, they are removed. At this time, more than 95% of patients are back to a normal routine and most return to work immediately following their clinic visit.

ADVANTAGES AND DISADVANTAGES

The advantages of laparoscopic cholecystectomy over other therapies for gallstone disease are multiple (Table 48-3). Unlike nonresective techniques for gallstone ablation, laparoscopic cholecystectomy removes the diseased gallbladder along with its stones. Relative to traditional open cholecystectomy, postoperative pain and intestinal ileus are diminished with laparoscopic cholecystectomy. The small size of the fascial incisions allows rapid return to heavy physical activities. The small incisions are also cosmetically more appealing than is the large incision used during traditional cholecystectomy. The patient can usually be discharged from the hospital either on the same day or the day following operation, and can return to full activity within a few days.[7,11] These factors lead to overall decreased cost of laparoscopic cholecystectomy compared to its traditional open counterpart.[8]

There are, however, several potential disadvantages of laparoscopic cholecystectomy. As opposed to nonresective treatments for gallstones, patients must be acceptable candidates for general anesthesia and possible laparotomy. Three-dimensional depth perception is limited by the two-dimensional monocular image of the videoscope. It is more difficult to control significant hemorrhage using laparoscopic technology than in an open surgical field. There is also less haptic discrimination of structures using laparoscopic instruments as opposed to direct digital palpation during open cholecystectomy. CO_2 insufflation to create the pneumoperitoneum is associated with a number of potential risks, including reduction of vena caval flow and systemic hypercarbia with acidosis.

TABLE 48-3: ADVANTAGES AND DISADVANTAGES OF LAPAROSCOPIC CHOLECYSTECTOMY COMPARED TO OPEN CHOLECYSTECTOMY

Advantages	Disadvantages
Less pain	Lack of depth perception
Smaller incisions	Adhesions/inflammation limit use
Better cosmesis	More difficult to control hemorrhage
Shorter hospitalization	Decreased tactile discrimination (haptics)
Earlier return to full activity	Potential CO_2 insufflation complications
Decreased total costs	Slight increase in bile duct injuries

SPECIAL CONSIDERATIONS

Conversion to Open Operation

Surgeons performing laparoscopic cholecystectomy should not think of conversion to open operation as a complication, but rather a sound clinical judgment, and hence not hesitate to convert to a traditional open cholecystectomy if the anatomy is unclear, if complications arise, or there is failure to make reasonable progress in a timely manner. Some complications requiring laparotomy are obvious, such as massive hemorrhage or major injury to the bile duct. Open laparotomy allows the additional tool of manual palpation and haptic sensation and should be performed when the anatomy cannot be delineated because of inflammation, adhesions, or anomalies. Fistulae between the biliary system and bowel are rare, but may require laparotomy for optimal management. The demonstration of potentially resectable gallbladder carcinoma also dictates an open exploration. Finally, CBD stones that cannot be removed laparoscopically and are unlikely to be extracted endoscopically (because of Billroth II anastomosis, previously failed endoscopic retrograde cholangiopancreatography [ERCP], or an inexperienced endoscopist) should be converted to open operation without hesitation.

Open Cholecystectomy

The technical aspects of performing an open cholecystectomy have not changed significantly since Langenbuch's description of this procedure more than 100 years ago. Although this operation can be performed safely through a midline, paramedian, or right subcostal incision, most surgeons prefer the right subcostal (Kocher) incision. Adequate exposure of the gallbladder and the hepatoduodenal ligament is the key to performing a safe cholecystectomy. Laparotomy sponges may be packed temporarily between the dome of the liver and the diaphragm, and appropriate retractors should be inserted to optimize visualization of the hepatoduodenal ligament and its structures. The hepatic flexure of the colon is packed or retracted inferiorly and the medial segment of the left liver lobe is retracted superiorly. When a large distended gallbladder is encountered, removal can be facilitated by decompressing the gallbladder. Adhesions of omentum

or viscera adjacent to the gallbladder are divided with sharp dissection or electrocautery.

Meticulous dissection and positive identification of the cystic duct, its entry into the CBD, and the cystic artery are mandatory and significantly reduce the likelihood of bile duct injury. Most experienced surgeons prefer to identify these important structures before beginning dissection of the gallbladder from the hepatic bed. The fundus and infundibulum of the gallbladder are grasped with curved clamps. The fundus is retracted anteriorly and superiorly and the infundibulum inferiorly and laterally, exposing the structures of Calot's triangle. Caudal counter-retraction of the hepatoduodenal ligament stretches and exposes the porta hepatis, placing the peritoneum overlying the cystic duct and artery on tension. This maneuver may be accomplished with a retractor, although the left hand of the first assistant effectively retracts the duodenum. The surgeon introduces the left index finger into the foramen of Winslow and palpates for calculi in the CBD. Acute inflammation or chronic scarring may preclude approaching the infundibulum first; many surgeons prefer to dissect the fundus initially (fundus first or top-down technique), and the ductal and vascular structures subsequently, only after the organ has been separated from the liver. Careful ligation of the cystic duct is essential in preventing not only a biliary leak, but also in reducing the possibility of bile duct injury and stricture. Ligation of the cystic duct in close proximity to its junction with the CBD has long been considered an essential component of open cholecystectomy. Experience with laparoscopic cholecystectomy suggests that the length of the cystic duct stump is not a critical factor and probably does not significantly contribute to postcholecystectomy syndrome, a poorly defined clinical entity characterized by pain following gallbladder removal. The cystic artery should be dissected, secured, and divided near the surface of the gallbladder. This will reduce bleeding associated with division of the peritoneum investing the gallbladder and separation of areolar tissue between the gallbladder and the liver. Intraoperative cholangiography can be performed at the discretion of the surgeon.

Throughout the procedure, care should be exercised to minimize spillage of bile into the peritoneal cavity. Drains are not mandatory and are indicated only if the surgeon is concerned about identifying or controlling a possible bile leak. Common pitfalls are usually related to inadequate exposure, severe inflammation, bleeding, and anatomic variants, which can lead to injury of portal structures, including the common bile duct and the hepatic artery or its branches. With a short cystic artery, the right hepatic artery must be carefully identified. Similarly with a short cystic duct, careful dissection and high ligation of the cystic duct near the gallbladder should be employed to avoid injury to the common bile duct. In fact, in the face of severe inflammation with obliteration of normal tissue planes it may be safest to perform a subtotal cholecystectomy, leaving a portion of the infundibulum in situ (after removing all stones) and suture ligating the mucosal side of the cystic duct origin. If there is unintentional gallbladder puncture, a second clamp or purse-string suture can be applied to prevent gallbladder bile and stone spillage. Before closing the abdominal incision, bleeding and bilious drainage must be controlled. Structures in the porta hepatis are re-examined, with special attention to the cystic duct stump. The subhepatic space is irrigated with warm saline and all irrigants are evacuated. The incision is usually closed in one or two layers. The skin can be closed with sutures or staples.

Acute Cholecystitis

Acute cholecystitis may be treated successfully by laparoscopic cholecystectomy. Intervention during the early phase often reveals an inflamed, edematous, thick-walled, and tensely distended organ. To gain adequate traction on the gallbladder with the grasping forceps, it may be necessary to decompress the gallbladder by aspirating its contents with a large-gauge needle or suction irrigator. As long as the inflammation is limited to the gallbladder, laparoscopic cholecystectomy is usually technically feasible. However, if inflammation extends to the porta hepatis, great care must be taken in proceeding with the operation. The normally thin, minimally adherent tissue that invests the cystic duct and artery is markedly thickened and edematous and may not readily separate from these structures with the usual blunt dissection techniques. The duct wall also may be edematous, thus making its external diameter similar to the gallbladder neck and CBD. If the anatomy is unclear, cholangiography must be performed before clipping or dividing tissue. When acute inflammation has been present for several days or weeks before operation, the pericholecystic tissue planes may be obliterated by thick, woody tissue that is difficult to dissect bluntly. The surgeon may therefore need to convert to open cholecystectomy if the minimal access approach is initially attempted during this subacute phase. There is no harm in inserting the laparoscope and assessing the right upper quadrant. The decision to convert to an open operation is a matter of judgment, based on the existing anatomy, local conditions, and the surgeon's experience and confidence in his or her ability to complete the procedure using minimal access techniques.

Several authors have reported performing laparoscopic cholecystectomy[51] in the face of acute inflammation with success but with a higher conversion rate than for elective laparoscopic cholecystectomy.[52–57] Lo and associates reported in their prospective study that despite longer operative times and postoperative stays for early laparoscopic cholecystectomy in patients with acute cholecystitis (treatment within 5 days) versus delayed laparoscopic cholecystectomy (initial conservative treatment followed by laparoscopic cholecystectomy 3–4 months later), the advantage of early laparoscopic cholecystectomy was the reduction in the total hospital stay, from 15 to 7 days. In a second prospective study of 105 patients randomized to early laparoscopic cholecystectomy (within 24 hours of diagnosis of acute cholecystitis) versus delayed laparoscopic cholecystectomy (6–8 weeks later), there was no significant difference in conversion rate (early 21% vs delayed 24%), postoperative analgesic requirement,

or number of postoperative complications. The early group did have a longer operative time (123 vs 107 minutes; $p = .04$), but total hospitalization was shorter (8 vs 12 days; $p = .001$).[57] Rattner and associates retrospectively reviewed 20 patients who underwent attempted laparoscopic cholecystectomy for acute cholecystitis and examined factors that were predictive of a successful procedure.[54] Seven of the 20 patients (35%) required conversion to open cholecystectomy. The interval from admission to cholecystectomy in the successful cases was 0.6 days versus 5 days in the cases requiring conversion to open cholecystectomy. Converted cases also had a significantly higher white blood cell (WBC) count, alkaline phosphatase levels, and Acute Physiology and Chronic Health Evaluation II (APACHE II) scores compared to those undergoing successful laparoscopic cholecystectomy. Ultrasonographic findings such as gallbladder distention, wall thickness, and pericholecystic fluid did not correlate with the success of laparoscopic cholecystectomy.

More recent studies have confirmed that laparoscopic cholecystectomy is an equivalent or better option than open surgery for treating acute cholecystitis.[58,59] In a study of two prospectively randomized groups, Johansson and associates reported that there were no differences in post-operative complications or pain when comparing laparoscopic to open cholecystectomy.[55] Using a cohort of almost 1 million patients from the National Hospital Discharge Surveys from 2000 to 2005, Csikescz and associates reported recently that patients undergoing laparoscopic cholecystectomy for acute cholecystitis have low conversion rates (9.5%), lower morbidity (16 vs 36%), and lower unadjusted mortality (0.4 vs 3%) compared to open cholecystectomy.[56]

It can be concluded that laparoscopic cholecystectomy should be performed immediately after the diagnosis of acute cholecystitis. Delaying surgery allows inflammation to become more intense and neovascularized, thus increasing the technical difficulty of laparoscopic cholecystectomy.

Intraoperative Gallbladder Perforation

Perforation of the gallbladder with bile or stone leakage can be a nuisance but should not ordinarily require conversion to open cholecystectomy. Perforation may occur secondary to traction applied by the grasping forceps or because of electrosurgical thermal injury during removal of the gallbladder from its bed. In our experience, almost one-third of the patients have had intraoperative spillage of bile or stones.[5] Patients with a bile leak have not experienced an increased incidence of infection, prolongation of hospitalization, or postoperative disability, nor adverse long-term complications[60] (mean follow-up of 41 months in 250 consecutive laparoscopic cholecystectomy patients). The only difference between those with and without bile leakage was that the operating time of patients with a gallbladder perforation was approximately 10 minutes longer, presumably because of the time spent in cleaning up the operative field. When perforation does occur, the bile should be aspirated completely and irrigation used liberally. The hole in the gallbladder is best secured with a grasping instrument and then sutured or tied with an endoloop. The stones should be retrieved and removed. Gallbladder spillage, when treated in this manner, results in no adverse short- or long-term complications. Escaped stones composed primarily of cholesterol pose little threat of infection. However, pigment stones frequently harbor viable bacteria and may potentially lead to subsequent infectious complications if allowed to remain in the peritoneal cavity.[61,62] The long-term complications of retained stones, either intra-abdominally with resultant abscess formation or intramurally with resultant port site abscess, have not been prospectively studied, but recent case reports and case series in the surgical literature document a clear potential for long-term infectious complications.[63–66] The relative infrequency of these complications probably does not justify conversion to open operation in the face of spilled stones, but vigilance in avoidance of perforation, a careful search for escaped stones, the aggressive use of irrigation, and liberal use of a plastic retrieval bag for large and friable gallbladders are recommended.[67]

COMPLICATIONS

Laparoscopic Cholecystectomy

Most complications related to laparoscopic removal of the gallbladder are similar to those occurring during traditional open cholecystectomy (Table 48-4). These complications include hemorrhage, bile duct injuries, bile leaks, retained stones, pancreatitis, wound infections, and incisional hernias. Other potential complications are pneumoperitoneum related (gas embolism, vagal reaction, ventricular arrhythmias, or hypercarbia with acidosis) and trocar related (injuries to the abdominal wall, intra-abdominal organ, or major blood vessels). The protective shield on disposable trocars is not an insurance

TABLE 48-4: COMPLICATIONS OF LAPAROSCOPIC CHOLECYSTECTOMY

- Hemorrhage
- Bile duct injury
- Bile leak
- Retained stones
- Pancreatitis
- Wound infection
- Incisional hernia
- Pneumoperitoneum related
  - CO_2 embolism
  - Vaso-vagal reflex
  - Cardiac arrhythmias
  - Hypercarbic acidosis
- Trocar related
  - Abdominal wall bleeding, hematoma
  - Visceral injury
  - Vascular injury

against perforation of intestine or major vessels, especially after previous abdominal operations. Regardless of the make of trocar, during its insertion one should never aim toward the spine or the location of the great vessels, and a hand is used as a brake to prevent inadvertently introducing the trocar too far. Insertion of the initial trocar, especially when performed in a closed fashion, can cause iatrogenic injury to the bowel, bladder, aorta, iliac artery, or vena cava.[68,69] When a trocar injury to a major blood vessel is suspected, the patient must be opened immediately without removing the trocar until the involved blood vessel is isolated. In contrast, if the small-bore Veress needle enters a viscus or blood vessel, the operation can generally be completed and the patient monitored closely for signs of complications in the postoperative period.

The laparoscopic trocars may also lacerate blood vessels in the abdominal wall. Prior to removal, each trocar should be visualized from the peritoneal aspect using the laparoscope. If significant hemorrhage is seen, it can generally be controlled with cautery, intraoperative tamponade with a Foley catheter, or a through-and-through suture on each side of the trocar insertion site.

Most serious complications occur early in the surgeon's experience. For instance, in a multivariate regression analysis of 8839 laparoscopic cholecystectomies in which there were 15 bile duct injuries, the only significant factor associated with an adverse outcome was the surgeon's experience with the procedure.[70] The regression model predicted that a surgeon had a 1.7% chance of a bile duct injury occurring in the first case and 0.17% chance of a bile duct injury in the 50th case.

Of all the potential complications, biliary injuries have received the most attention and are discussed at length elsewhere in this text. Most series quote a major bile duct injury rate of around 0.2% during open cholecystectomy, whereas the incidence of bile duct injuries during laparoscopic cholecystectomy is 0.40% or higher.[34] These injuries can cause major morbidity, prolonged hospitalization, high cost, and litigation.[70,71] In addition to the surgeon's experience and aberrant anatomy, a number of reports mention chronic inflammation with dense scarring, operative bleeding obscuring the field, or fat in the portal area contributing to the biliary injuries.[38,70–72] The classic biliary injury, however, occurs when the CBD or a RHD is mistaken for the cystic duct and is divided between clips. Many surgeons attribute this misidentification to the direction of traction of the gallbladder, that is, pulling the CBD and the cystic duct into alignment, thus making them appear to be one. Other contributing factors to misidentification are a short cystic duct, a large stone in Hartmann's pouch (making retraction and display of the cystic duct difficult), or tethering of the infundibulum to the CBD by acute or chronic inflammation. Constant awareness of these potential misidentifications and technical causes of biliary injuries is the best method of prevention. If a partial bile duct injury occurs and is recognized intra-operatively, an immediate primary repair, possibly in conjunction with a T-tube should be performed. A complete transection of the bile duct is a rare injury and an end-to-end repair is a technically challenging procedure that may require assistance from an experienced hepatobiliary surgeon. When a bile duct injury is discovered in the postoperative period, a coordinated effort by radiologists, endoscopists, and surgeons is necessary to optimize management.[40] There should be no hesitation in asking for the help of a surgeon experienced in biliary repair.

Open Cholecystectomy

Experience with open cholecystectomy is vast, spanning generations of surgeons and having been practiced in virtually every country throughout the world. Over time, this operation has proved to be safe and effective. In a collected series of about 20,000 patients who underwent cholecystectomy between l946 and 1973 at 10 different institutions, from the United States and throughout the world, the overall mortality rate was l.6%. This figure is comparable to a l.7% mortality rate reported for more than 12,000 patients operated on for calculous biliary tract disease between 1932 and 1979 at a single US university center. In this latter group, the operative mortality rate for patients who underwent elective cholecystectomy was 0.1%. More recently, a US population-based study examining the outcome of all open cholecystectomies performed in a 12-month period in two states reported an overall mortality rate of 0.17%.[73] The morbidity rate was 14.7%, which includes all reported complications, including minor problems such as electrolyte imbalances, atelectasis, urinary retention, and other assorted difficulties that can occur following any surgical procedure. In this study, morbidity and mortality were dependent on age as well as disease status. Perhaps the most significant complication that can arise during open or laparoscopic cholecystectomy is bile duct injury. Numerous reports in the literature, including this large population-based study indicate that the risk of bile duct injury during open cholecystectomy is between 0.1 and 0.2%. Similar morbidity and mortality data have been reported by other large series. These data confirm that open cholecystectomy continues to be a very safe operation that can be performed with a very low morbidity and mortality. In elective situations, open cholecystectomy is being performed in many hospitals throughout the world on patients who are admitted the day of surgery, with an overall stay of 2–4 days.

NEW AND INVESTIGATIONAL TECHNIQUES TO PERFORM CHOLECYSTECTOMY

The advent of laparoscopic cholecystectomy provided a dramatic benefit to patients who previously underwent laparotomy for gallbladder disease. While laparoscopy has already set a high bar for cholecystectomy with regards to perioperative and intraoperative outcomes, there are areas of surgical research examining ways that could potentially make the procedure even less invasive.

Single-port Laparoscopic Surgery

Single-port laparoscopy is a recent development in laparoscopic surgery that involves introducing all operative instruments and devices through a single skin incision, usually at the umbilicus.[74–76] The proposed benefit of single-port laparoscopic cholecystectomy over traditional laparoscopic cholecystectomy is by reducing the overall number of abdominal incisions from three or four to one, there will be less perioperative pain and fewer resulting incisional complications. From a technical standpoint, single-port surgery leads to all of the instruments entering the operative field in line with the optics. Triangulation and traction or countertraction are made more difficult, but new instrumentation is being developed to overcome these limitations. There are currently no established standard techniques for performing this procedure and postoperative results are just emerging.

Natural Orifice Translumenal Endoscopic Surgery

Natural orifice translumenal endoscopic surgery (NOTES) is an investigational procedure that aims to reduce and eventually eliminate all abdominal incisions by accessing the peritoneum through natural orifice routes including transoral or transgastric, transvaginal, and transanal or transcolonic. By eliminating abdominal incisions, the hypothesis is that there will be less pain, fewer complications and decreased morbidity associated with abdominal incisions.[77–81] These benefits are proposed to include decreased incisional hernias, wound infections, and post-operative pain, while improving cosmesis. Given the current state of technology and lack of appropriate instrumentation, few pure NOTES cholecystectomies have been performed worldwide.[82–84] NOTES hybrid procedures, where a laparoscopic instrument is used in conjunction with the natural orifice devices, have been performed in greater numbers, though only in a relatively few specialized centers. Results from these procedures are also just being reported and large sets of data are not yet available to evaluate the proposed benefits of NOTES.

CONCLUSION

Cholecystectomy remains one of the most common operations performed in the United States and worldwide. Laparoscopic cholecystectomy is the standard for treatment of gallstone and gallbladder disease. There are numerous advantages of laparoscopic cholecystectomy over open cholecystectomy, including decreased pain, length of stay, recovery time, incisional complications, and improved cosmesis. However, occasionally anatomical or physiological considerations will hinder or preclude the minimal access approach, and conversion to an open operation in such cases reflects sound clinical judgment and should not be considered a complication. Additionally, there are current studies underway to investigate new ways to perform cholecystectomies that may result in additional benefits over traditional laparoscopic cholecystectomy.

CHOLEDOCHOLITHIASIS AND CHOLANGITIS

Antonio di Carlo • David W. McFadden

With advanced endoscopic and laparoscopic techniques being readily accessible to the treating surgeon, determining the wisest path to the successful treatment of choledocholithiasis and cholangitis has become more challenging. Nevertheless, a large number of options allow one to tailor-specific therapy to each individual clinical situation so as to achieve the highest probability of success. In this chapter we attempt to give the reader a better understanding of the methods available for the diagnosis and treatment of common bile duct (CBD) stones and cholangitis so that treatment plans are developed that are patient-specific and have the highest chance of success.

CHOLEDOCHOLITHIASIS

Classification and Epidemiology

A common entity in Western societies, gallstones are found in approximately 15% of Americans and result in 700,000 cholecystectomies a year. The annual cost of medical care for gallstones is almost $6.5 billion (1.3% of US health care costs) compared with chronic liver disease and cirrhosis ($1.6 billion), chronic hepatitis C ($0.8 billion), and diseases of the pancreas ($2.2 billion).[1] CBD (downstream of the confluence of the hepatic ducts) stones have been noted in 10–15% of patients with cholelithiasis, and this incidence increases with age to over 80% in those who are over 90 years old.[2] Choledocholithiasis in Western countries usually results from stones originating in the gallbladder and migrating through the cystic duct. These *secondary bile duct stones* are cholesterol stones in 75% and black pigment stones in 25% of patients. Cholesterol stones are formed in the presence of cholesterol saturation, biliary stasis, and nucleating factors. Behavioral factors associated with cholesterol gallstones include nutrition, obesity, weight loss, and physical activity. Biologic factors linked to gallstones include increasing age, female sex and parity, serum lipid levels, and the Native American, Chilean, and Hispanic race.[1] The formation of black pigment stones is associated with hemolytic disorders, cirrhosis, ileal resection, prolonged fasting, and total parenteral nutrition.[2]

Primary bile duct stones, on the other hand, form within the bile ducts and usually are of the brown pigment variety. These tend to be lower in cholesterol content and higher in bilirubin content as compared with secondary stones. Unlike secondary stones, primary stones are associated with biliary stasis and bacteria.[3] In fact, in the pathogenesis of brown pigment stones, bile infection appears to be the initial event leading to stone formation.[4] Moreover, bacteria have been found in brown pigment stones by electron microscopy but not in black pigment stones. Primary bile duct stones are more common in Asian populations, and these often are associated with *primary intrahepatic stones* in this population.[1] These intrahepatic stones usually are calcium bilirubinate and mixed stones and contain more cholesterol and less bilirubin than the extrahepatic bile duct pigmented stones. The pathogenesis of these intrahepatic stones appears to involve bile infection; biliary stasis; low-protein, low-fat diets and malnutrition; and parasitic infections. However, the role of *Ascaris lumbricoides* and *Clonorchis sinensis* in the formation of intrahepatic stones is controversial. While these parasites are found in many geographic areas, primary intrahepatic stones are found mainly in Southeast Asia. Therefore, in addition to parasitic infections, other factors must play a role in the formation of these stones.[1]

Clinical Presentation and Natural History

Asymptomatic bile duct stones may be found incidentally during evaluation of patients with suspected gallstones. In fact, 5% of common duct stones found during surgery may be unsuspected by preoperative findings and discovered only during intraoperative evaluation of the biliary tree. In one autopsy study of 615 patients over age 60, 1% were found to have bile duct stones.[2] Patients with choledocholithiasis may present with biliary colic, bile duct obstruction, bilirubinuria (or tea-colored urine), pruritus, acholic stools, and jaundice. However, the biliary obstruction usually is incomplete. There may be nausea and vomiting with intermittent or constant epigastric or right upper quadrant pain.[5] The clinical

course may be complicated by acute gallstone pancreatitis, cholangitis, or rarely, hepatic abscess. Infected patients may present with back pain, fever, hypotension, and mental status changes suggestive of cholangitis and ascending cholangitis. An asymptomatic state is also recognized.

CBD stones are covered by a bacterial biofilm of adherent quiescent bacteria residing in a hermetic environment. When stones cause obstruction of the ducts, cytokines released by epithelial cells activate these bacteria to the planktonic and virulent forms.[1] Therefore, bile duct obstruction secondary to stones often is accompanied by bacterial sepsis resulting from activation of the bacterial biofilm on these stones. Sepsis is much less likely to occur in the context of malignant obstruction without choledocholithiasis.

Although a majority of stones will pass spontaneously into the duodenum within hours, prolonged biliary obstruction can lead to biliary cirrhosis and portal hypertension. The average time for choledocholithiasis to lead to biliary cirrhosis is about 5 years, depending on the extent of obstruction.[1] Even with cirrhosis, however, the obstruction should be relieved because some reversal of portal hypertension and secondary biliary cirrhosis may be possible.

Physical examination of patients with choledocholithiasis may be normal or reveal jaundice, scleral icterus, and abdominal tenderness over the right upper quadrant without peritoneal signs. Early in the course, physical examination may not be very different from that of patients with cholecystitis. Severe tenderness may point to acute gallstone pancreatitis, whereas fever, hypotension, and confusion may suggest cholangitis.[6]

Blood tests may reveal elevation of serum alkaline phosphatase, gamma-glutamyl transpeptidase, and bilirubin. Mild elevations of aspartate aminotransferase and alanine aminotransferase can be seen, whereas these are particularly abnormal in the situation of cholangitis. Although bilirubin and aminotransferase levels are high in 70–90% of patients at the onset of symptoms, almost all patients have elevation of alkaline phosphatase and gamma-glutamyl transpeptidase.[6] Elevated amylase and lipase may suggest pancreatitis. Leukocytosis may be seen with cholangitis, pancreatitis, or associated acute cholecystitis. It is worth noting that laboratory evaluation of patients with bile duct stones can be normal repeatedly, and this should not dissuade further evaluation of patients suspected to harbor duct stones.[7]

Evaluation and Management

The evaluation and treatment of choledocholithiasis are best discussed by considering the three clinical circumstances in which patients who may have bile duct stones are seen prior to cholecystectomy, during cholecystectomy, or some time after cholecystectomy.

PREOPERATIVE

The diagnosis of choledocholithiasis cannot be made on the basis of history, physical examination, and laboratory investigations alone. Moreover, the distinction between the symptoms of bile duct stones and gallbladder stones often is difficult. Increasing age, history of fever, cholangitis, and pancreatitis are risk factors for bile duct stones, whereas elevations of serum bilirubin, aspartate aminotransferase, or alkaline phosphatase are independent positive predictors.[1,8]

Transcutaneous ultrasound has been the traditional method of evaluating patients with biliary disease. It is highly accurate in identifying acute calculous cholecystitis and the presence of gallstones greater than 2 mm. Sensitivities and specificities of 48–100% and 64–100%, respectively, have been reported.[9] However, the ability of transcutaneous ultrasound to establish the diagnosis of choledocholithiasis is only about 50%, varying from 30 to 90%.[6,10] The role of ultrasound as a screening test for bile duct stones was evaluated prospectively by Gross and colleagues.[11] Patients who were about to undergo endoscopic retrograde cholangiopancreatography (ERCP) were examined by right upper quadrant sonography to assess the size of the intra- and extrahepatic ducts and for the presence or absence of bile duct stones. The findings were compared with ERCP, percutaneous transhepatic cholangiography, or surgical follow-up. Ultrasound was not found to be accurate in the diagnosis (sensitivity of 25%) or the exclusion (73% negative predictive value) of choledocholithiasis.

Costi and colleagues studied the usefulness of the number and size of gallbladder stones for predicting asymptomatic choledocholithiasis.[12] Ultrasound data of 300 consecutive patients undergoing laparoscopic cholecystectomy were analyzed. Patients were divided into two groups: those with multiple small (<5 mm) gallbladder stones or variable (≤5 mm and >5 mm) stones and those with large (>5 mm) stones only. The classification of stone size was confirmed by surgery in 95% of patients. Moreover, the presence of multiple small and variable gallbladder stones represented a risk factor for synchronous asymptomatic bile duct stones (9.5%) as compared with large stones only (2.5%). In another study, ultrasonography was found to have a positive predictive value (PPV) of 69% and a negative predictive value (NPV) of 78% for choledocholithiasis in patients suspected to have bile duct stones.[13] This compared with serum transaminase tests having predictive values of 68 and 93%, respectively. In comparison to elevated serum transaminases and/or increased amylase levels, ultrasonographic evidence of common bile duct dilatation (>7 mm) has been described to be the best predictor of choledocholithiasis.[14] Nonetheless, it is worth noting that almost half the patients with CBD stones do not have dilated ducts by ultrasonography, hence a negative study has limited value.[15]

In order to predict the presence of bile duct stones more accurately, the combination of clinical, laboratory, and ultrasound risk factors has been used by several investigators.[1,16,17] By multivariate logistic regression analysis, the combination of dilated CBD with evidence of stones by ultrasonography, clinical evidence of cholangitis, elevated aspartate transaminase and bilirubin, the likelihood of having stones in the bile duct was 99%.[17] In the absence of all four of these findings, the probability of synchronous choledocholithiasis in patients with cholelithiasis was only 7%.[17] Unfortunately,

many patients present with only some of these findings, and the prediction of bile duct stones based on these criteria becomes difficult. Moreover, ultrasound sensitivity is in part operator-dependent and altered by bowel gas, making the findings inconsistent.[18]

In 1968, ERCP was introduced as a diagnostic tool to aid in the management of biliary and pancreatic diseases.[19] Five years later, with the development of endoscopic sphincterotomy, ERCP was transformed into a therapeutic modality.[20] Currently, more than 150,000 endoscopic biliary sphincterotomies are performed annually in the United States. Short of intraoperative examination, ERCP has long been considered the standard reference for the diagnosis of CBD stones.[18] The specificity and sensitivity of ERCP were reported in 1982 by Frey and colleagues.[21] ERCP was compared with findings on common duct exploration or cystic duct cholangiography in 72 patients and was found to have a sensitivity of 90%, specificity of 98%, and a 96% accuracy. Interestingly, the interval between performance of the procedure and operation was particularly important in patients with multiple small stones. Since small stones pass more readily from the gallbladder to the common duct and from the common duct to the duodenum, the longer the interval between ERCP and operation, the greater was the chance of discordant findings. With improvements in technique and better radiological equipment, ERCP certainly has improved over time.

Along with the ability to diagnose bile duct stones, ERCP has the advantage of offering therapeutic intervention options in the same setting of diagnosis (Figs. 49-1 and 49-2). That is, after stones in the bile duct are identified,

FIGURE 49-1 Endoscopic retrograde cholangiopancreatography (ERCP) with distal common bile duct (CBD) stone prior to cholecystectomy.

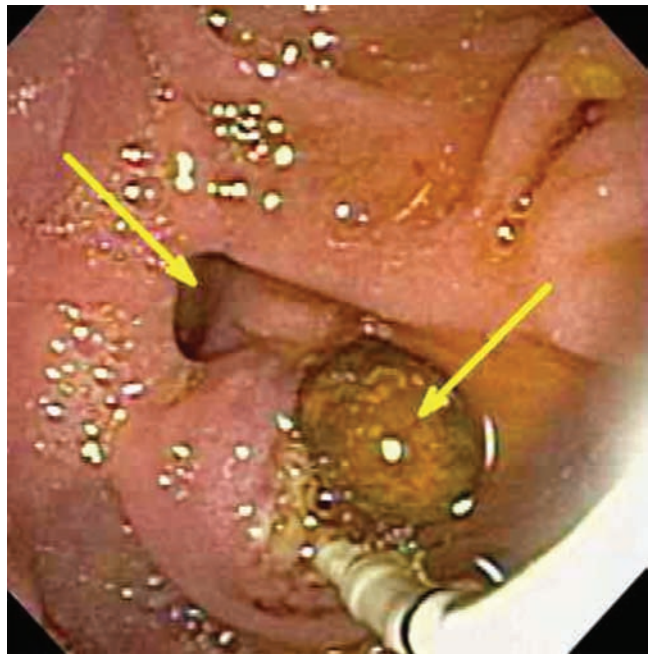

FIGURE 49-2 Endoscopic retrograde cholangiopancreatography (ERCP) and common bile duct (CBD) stone extraction.

endoscopic sphincterotomy and stone extraction can be performed at the same setting. If stones are not found, bile can be collected to test for microlithiasis if clinically appropriate.[18] ERCP *stone extraction* is successful 80–90% of the time using the techniques of sphincterotomy and balloon catheter or Dormia basket stone retrieval.[20,22] The addition of mechanical, electrohydraulic, laser, or extracorporeal shockwave lithotripsy for large stones increases the success rate to over 95%.

Sphincterotomy entails division of the papilla and sphincter muscles to widen the distal end of the CBD with the use of a sphincterotome, a device consisting of a Teflon catheter with exposed cautery wire at the tip. The length of the intraduodenal part of the CBD limits the extent of the cut. *Balloon sphincteroplasty* is a sphincter-preserving alternative to sphincterotomy that uses a high-pressure hydrostatic balloon of either 6 or 8 mm diameter to dilate the papilla. One drawback of sphincteroplasty is the limited size of the papillary opening created as compared with sphincterotomy. Failure rates of 22% for stone extraction with balloon dilatation and the need for mechanical lithotripsy in 31% have been reported.[22] Furthermore, sphincteroplasty has been associated with a pancreatitis rate of 19 times greater than the rate associated with sphincterotomy.[23] A recent study evaluating the use of sphincteroplasty, on the other hand, found that severe pancreatitis only occurred in 1 patient out of 63, whereas the successful stone extraction rate was 84%.[24]

Once the sphincter has been divided, most stones can be removed using a Dormia basket or a balloon catheter. The Dormia basket has better traction than the balloon and consequently is recommended for larger stones (>1 cm). The balloon catheter occludes the bile duct lumen after inflation

and therefore is useful for removal of small stones and gravel. The catheter also can be inserted over a guidewire, making it useful for intrahepatic duct stones. Three situations that may lead to a difficult extraction are stone size greater than 1.5 cm, stone location proximal to a stricture, and multiple stones that are impacted. Alternative approaches to these situations include mechanical lithotripsy, electrohydraulic or laser lithotripsy, and extracorporeal shock wave lithotripsy. Mono-octanoin and methyl tertiary butyl ether (MTBE) have been used in the past to dissolve bile duct stones through nasobiliary drainage catheters or T-tubes. The practice largely has been abandoned because of high complication rates, poor results, and the technical difficulty of performing the dissolution.[22]

Mechanical lithotripsy is the most commonly used and simplest means of fragmenting large bile duct stones or when a significant discrepancy between the stone size and the diameter of the exit passage exists.[25] A large, strong basket is used to trap the stone. The stone then is crushed against a metal sheath by applying tension to the wires by the use of a crank handle. Reimann and colleagues first described the technique in 1982, and since then, many variations in design have become available.[26,27] When stones are extremely large, repeat application of the technique may be needed to further break the stone fragments and thus allow removal. Success rates between 80 and 90% have been reported for clearing the bile duct using the procedure.[28–30] One retrospective study of 162 patients undergoing mechanical lithotripsy found that the probability of bile duct clearance was over 90% for stones less than 1 cm diameter versus 68% for stones greater than 2.8 cm diameter.[31] Garg and colleagues recently presented data on 87 patients with stones greater than 1.5 cm that required mechanical lithotripsy.[32] They analyzed various predictive factors, including size and number of stones, stone impaction, serum bilirubin, presence of cholangitis, and bile duct diameter, in relation to the success or failure of lithotripsy. Impaction of the stones in the bile duct was found to be the only significant factor that predicted failure of mechanical lithotripsy and subsequent bile duct clearance. The composition of the stone also has been found to affect the success of stone removal. Soft stones, such as those found in Oriental cholangitis, are large but amenable to crushing, sometimes even with the Dormia basket.[25] However, calcified stones are hard and resist mechanical crushing.

When mechanical lithotripsy fails, *intraductal shock wave lithotripsy* can be performed using a cholangioscope that is inserted into the bile duct through the instrument channel of the duodenoscope. A flexible lithotripsy probe then is passed into the bile duct through the working channel of the cholangioscope. Shock waves are generated at the tip of the lithotripsy probe using electrical (*electrohydraulic lithotripsy*) or light energy (*laser lithotripsy*).[22] Impulses are fired on the surface of the stones under cholangioscopic guidance until the needed fragmentation is achieved. The main risk of intraductal shock wave therapy is bile duct injury resulting from a misguided shock wave. The avoidance of this complication makes cholangioscopic guidance necessary. Newer devices have a scattered light sensor located at the tip of the probe that allows automatic interruption of the laser pulse when tissue is detected. Nevertheless, the cost of intraductal shock wave lithotripsy and the requirement for two endoscopists experienced in the mother-baby scope system makes the availability of this technique limited to a few major referral centers.[22] Success rates of electrohydraulic and laser lithotripsy have been in the 80–95% range.[33] In a recent report by Arya and colleagues, the use of electrohydraulic lithotripsy was evaluated in 94 patients, with 81 having large stones and 13 having average-sized stones located above a narrow bile duct.[34] A total of 96% had successful fragmentation of their stones, with fragmentation failure secondary to hard stones in two patients and trouble with targeting in two patients. Seventy-six percent of the patients required one treatment session, 14% needed two sessions, and 10% underwent three or more treatments. Complications included cholangitis and/or jaundice in 13 patients, hemobilia in one, mild post-ERCP pancreatitis in one, biliary leak in one, and bradycardia in one patient. No deaths were reported, and the final stone clearance achieved was 90%.

Not approved for bile duct stones in the United States, *extracorporeal shock wave lithotripsy* (ESWL) has gained popularity in Europe and Japan for the treatment of bile duct stones in patients with major medical comorbidities and technical difficulties encountered using the standard methods of endoscopic stone extraction. A drawback with this technique is the need for multiple sessions to achieve complete stone fragmentation.[22] There have been several reports from various countries on ESWL to break down bile duct stones.[33,35–41] Shackman and colleagues, from Germany, reviewed their experience with 313 patients who had failed endoscopic stone extraction with mechanical lithotripsy and subsequently underwent high energy extracorporeal shock wave lithotripsy.[35] Stone targeting was performed by either fluoroscopy (99%) or ultrasonography. Using the technique, complete clearance of the bile duct was achieved in 90% of the patients, with 80% requiring fragment extraction by endoscopy after the shock wave therapy. Spontaneous passage, however, was observed in 10% of the patients. No difference in outcome was noted with regard to size or number of stones, intrahepatic or extrahepatic stone location, or presence or absence of bile duct strictures. Four cases of cholangitis and one case of acute cholecystitis were the rare adverse effects noted. Conversely, a study from Switzerland found that in their 54 patients treated with extracorporeal shock wave therapy for difficult bile duct stones, an intrahepatic location of stones was significantly associated with treatment failure.[37] Interestingly, the study found microhematuria in 95% of the patients treated. In a randomized, prospective study to evaluate ESWL versus laser-induced shock wave lithotripsy for retained bile duct stones, laser therapy achieved stone disintegration more rapidly and with significantly fewer treatment sessions, resulting in a lower cost for therapy.[39] Yasuda and colleagues, from Japan, presented the use of ESWL without preliminary endoscopic sphincterotomy for choledocholithiasis.[42] Fifty-two patients underwent

endoscopic nasobiliary tube insertion followed by extracorporeal therapy. Fragmentation and complete clearance of stones were achieved in 67% without the need for additional treatment. In 25%, fragmentation was not achieved, and endoscopic extraction was required. A favorable response to extracorporeal shock wave therapy was noted in patients with smaller (<1.5 cm) floating stones.

In addition to lithotripsy, *large-balloon dilatation* of the distal bile duct has been reported as a means of removing difficult bile duct stones after standard extraction has been unsuccessful.[43] In a retrospective analysis, 58 patients who failed standard sphincterotomy and standard basket or balloon extraction underwent dilation with a 10–20-mm-diameter balloon (esophageal type) followed by standard basket or balloon extraction. The patients were divided into two groups: 18 patients with a tapered distal bile duct (group 1) and 40 patients with square, barrel-shaped, and/or large (>15 mm) stones (group 2). Stone clearance was successful in 89% of group 1 patients and 95% of group 2 patients. In the two patients in each group in whom extraction was not possible after dilatation alone, mechanical lithotripsy allowed for stone removal. Complication rates were 33% for group 1 and 7.5% for group 2. Complications included mild pancreatitis (two patients), mild cholangitis (two patients), and bleeding (five patients). Although bleeding was mild in two patients, moderate bleeding was noted in three patients in group 1 and was treated without surgery. Interestingly, hyperamylasemia was noted in all patients, and perforation was seen in none. Large-balloon dilatation offers an alternative in managing difficult bile duct stones, and further studies are needed to establish its role as compared with other lithotripsy options.

The management of complicated situations of choledocholithiasis may require several procedures or several sessions of the same procedure for successful clearance of the common bile duct. In such situations, partial stone impaction may lead to biliary stasis and cholangitis. Along with the administration of broad-spectrum antibiotics to cover gram-negative and gram-positive bacteria, it is important to decompress the biliary tree with either a nasobiliary catheter or a biliary stent as a temporizing measure pending more definitive treatment.[22,25] By doing this, serum bilirubin levels are allowed to decrease, and the rate of postprocedure cholangitis becomes similar to that after stone clearance. Interestingly, up to 30% of patients in whom a stent has been left in place for large stones have spontaneous disintegration of the stones, as noted on subsequent ERCP.[25] This may be secondary to the frictional movement of stone against the stent or as a result of improved bile flow with dissolution effects. Furthermore, by adding oral ursodeoxycholic acid to stent placement, 9 of 10 patients have been reported to become stone-free by this combination as compared with 0 of 40 with stent placement only.[44] Although long-term stent placement is an unconventional management option for patients with large, inextricable stones who are at high risk for surgical intervention, this approach should be used with caution. In a long-term follow-up study of 58 elderly patients, 40% of patients treated with permanent stents for endoscopically irretrievable stones developed 34 complications in 23 patients, with cholangitis being the most frequent.[45] At median follow-up of 36 months, 44 patients had died, 9 as a result of biliary-related causes. Hui and colleagues prospectively evaluated 36 high-risk patients with difficult common bile duct stones.[46] Of these, 19 underwent stent placement, and 17 underwent complete stone clearance with electrohydraulic lithotripsy. The actuarial incidence of recurrent acute cholangitis was 8% in the lithotripsy group versus 63% in the stent group. The actuarial mortality also was higher in the stent group compared with the lithotripsy group, 74 and 41%, respectively.

Although ERCP has developed over the years as a relatively safe endoscopic diagnostic and therapeutic tool, there are well-defined, potentially severe, and life-threatening complications associated with it. The reported rates of complications vary widely in different studies, and this may be related in part to study design, with retrospective studies being prone to under-reporting. Furthermore, the complication rates may diverge depending on the patient mix in the study and may be influenced in part by the definitions used for these complications.[19]

The mortality rate after diagnostic ERCP is about 0.2%, and this rate is more than doubled by therapeutic interventions, to 0.5%.[18,19] Cardiopulmonary complications are the leading cause of death and include cardiac arrhythmia, hypoventilation, and aspiration. These may be the result of premorbid conditions or related to medications used during sedation and analgesia. Other significant complications include perforations (0.3–0.6%), bleeding related primarily to sphincterotomy (0.8–2%), cholecystitis (0.2–0.5%), and cholangitis (1%). In a recent meta-analysis, prophylactic antibiotics were not found to be beneficial in reducing infectious complications of ERCP. Moreover, another study failed to show a decrease in the rate of cholangitis in patients with distal bile duct stones or biliary strictures receiving antibiotic prophylaxis.[19]

Pancreatitis is the most common complication seen after ERCP. The consensus definition for ERCP-induced pancreatitis is new or worsened abdominal pain, serum amylase that is greater than three times the upper limits of normal at 24 hours postprocedure and a requirement of at least 2 days of hospitalization. Although the transient elevation of serum pancreatic enzyme levels is frequent, based on the consensus definition of ERCP pancreatitis, the expected rate of this complication is typically between 1 and 7%. Risk factors associated with ERCP-induced pancreatitis include a prior history of ERCP pancreatitis, nondilated biliary ducts, normal bilirubin, young age, female gender, and suspected sphincter of Oddi dysfunction. In fact, the risk of pancreatitis in women with normal bilirubin and suspected sphincter of Oddi dysfunction is 18% compared with 1.1% for the low-risk patient.[19,47] Moreover, one of five episodes of pancreatitis in this setting will be severe, requiring more than a 10-day hospital stay and/or resulting in necrosis, pseudocyst, or abscess formation needing surgery or percutaneous drainage, or death. Since the highest rate of complications appears to exist in the group of patients that is least likely to benefit from

ERCP, the most effective method of reducing post-ERCP pancreatitis would be to avoid unnecessary ERCP.

Pharmacologic methods of pancreatitis prophylaxis have been attempted to reduce this complication after ERCP.[19] Although meta-analyses have suggested that somatostatin and gabexate are useful in reducing pancreatitis rates, multicenter randomized, controlled trials have failed to show effect over that of placebo. Meanwhile, interleukin 10 (IL-10) with its anti-inflammatory activity has been found to have conflicting results in two controlled, prospective trials. The use of nonionic contrast agents has not reduced the rate of pancreatitis. On the other hand, glyceryl trinitrate (GTN) administered by both sublingual and transdermal routes has been shown to decrease post-ERCP pancreatitis in two placebo-controlled trials, supposedly by decreasing sphincter of Oddi pressure. Use of nitrates, however, is limited by their hypotensive effects.

The placement of pancreatic stents has been found to reduce the incidence of postbiliary sphincterotomy pancreatitis in patient suspected of sphincter of Oddi dysfunction. However, in a case-controlled evaluation of pancreatic stent placement after balloon dilatation of the major papillae for bile duct stone removal, a decreased postprocedure hyperamylasemia did not result in a decreased pancreatitis rate.[19]

Based on clinical, laboratory, and ultrasound criteria for common bile duct stones, up to 70% of patients may be found not to have duct stones at the time of preoperative ERCP.[17,48,49] Given this, a large number of patients may be subjected to an unnecessary ERCP and suffer its risks and costs. Several methods have become available to diagnose the presence of bile duct stones accurately prior to having patients undergo ERCP or operative interventions. The most important of these are magnetic resonance cholangiopancreatography (MRCP), endoscopic ultrasound (EUS), and computed tomography (CT).

Sensitivities of conventional CT for choledocholithiasis in the setting of suspected bile duct stones is 76–90%, whereas unenhanced helical CT has been shown to have a sensitivity of 88%, a specificity of 97%, and an accuracy of 94%.[18] When compared with ERCP as the reference standard, CT without biliary contrast material showed poor concordance with ERCP (sensitivity 65% and specificity 84%) but compared better when oral biliary contrast material was given (sensitivity and specificity greater than 90%).[50] CT with intravenous (IV) biliary contrast material in other studies has been found to have a sensitivity of 71–85% and a specificity of 88–95%.[50] Patel and colleagues reported a comparison between noncontrast-enhanced helical CT and the reference standard of EUS and found that CT had both a sensitivity and a specificity of 83% for the detection of common bile duct dilatation in the setting of choledocholithiasis.[51] However, when CT was evaluated for identifying duct stones, it had a sensitivity of only 22% and a specificity of 83%.

Since its introduction over a decade ago, MRCP has significantly influenced the way in which CBD stones are detected and excluded. With sensitivities and specificities that approach those of ERCP, MRCP has emerged as a diagnostic alternative to ERCP for the detection and exclusion of choledocholithiasis.[18] Performed with T_2-weighted sequences, the biliary tract is seen as a bright structure with high-signal intensity without the use of contrast material, instrumentation, or ionizing radiation. Common duct stones are seen as low-signal-intensity filling defects surrounded by high-intensity bile. Improvements in hardware and software for MRCP over the past decade have resulted in the ability to image the entire biliary tract in a single breath-hold of 20 seconds with a resolution that allows visualization of fourth-order intrahepatic bile ducts and small stones. Stones as small as 2 mm can be detected even in the absence of biliary dilatation.[18] In one study of 97 patients, sensitivity of MRCP was 100% for stone diameters of 11–27 mm, 89% for stone diameters of 6–10 mm, and 71% for stone diameters of 3–5 mm.[47] In this study, MRCP had a 91% sensitivity compared with 100% for ERCP, whereas both tests had a specificity of 100%. Although earlier studies reported MRCP sensitivities ranging from 81 to 92% and specificities from 91 to 100% for choledocholithiasis, recent studies with state-of-the-art techniques have found sensitivities of 90–100% with specificities of 92–100%.[18] In a prospective analysis by Ke and colleagues, 267 patients felt to have CBD stones were evaluated by MRCP and ERCP.[52] MRCP was found to have a sensitivity of 100%, a specificity of 96%, and a NPV of 100%. Kejriwal and colleagues retrospectively examined patients with cholelithiasis who underwent MRCP for suspected choledocholithiasis.[53] Patients were considered not to have clinically relevant common duct stones if they had a negative MRCP and did not present for readmission for choledocholithiasis after treatment of their cholelithiasis. MRCP was negative for bile duct stones in 74% of patients (60 of 81) and missed clinically relevant stones in two patients, resulting in a PPV of 95% and a NPV of 97%. With its ability to exclude bile duct stones, MRCP may allow the avoidance of unnecessary diagnostic ERCP. Demertines and colleagues found that even in patients with high and moderate risk of common bile duct stones based on laboratory findings, the performance of MRCP could have resulted in the avoidance of ERCP in 52 and 80% of patients, respectively.[54]

One of the limitations of MRCP is that its resolution remains less than that of ERCP, and therefore, it cannot detect small stones and crystals consistently. Claustrophobia also may influence the use of MRCP, and patients may need sedation or even general anesthesia for its performance. Open magnetic resonance imaging (MRI) may soon alleviate this problem. Patient obesity may diminish the quality of images, whereas morbid obesity, pacemakers, and aneurysm clips preclude entry into the scanner.[18] Conversely, ERCP may be limited by an inability to access and cannulate the papilla and opacify the ductal system. Failed ERCP rates vary greatly among endoscopists and vary from 5 to 20%.[18] Moreover, alterations in the gastrointestinal tract anatomy, such as a Billroth II gastrojejunostomy, may preclude access to the ampulla. MRCP offers a method of evaluating the biliary system for bile duct stones with sensitivities and specificities that approach those of ERCP in a manner that is noninvasive

and avoids the risks and limitations of ERCP. Patients with a positive MRCP then may be considered for more invasive therapeutic procedures.

Another sensitive method of evaluating the biliary system for common bile duct stones is EUS. EUS has been shown to have a diagnostic accuracy of 95% for bile duct stones.[55] With the high ultrasound frequencies used (7.5 and 12 MHz), EUS has a resolution of less than 1 mm, making it the best imaging technique available for the extrahepatic biliary tract. Several studies have found EUS to be similar to ERCP in sensitivity and specificity for the evaluation of choledocholithiasis, with some showing ERCP to be better and others showing EUS to be better.[50] Compared with ERCP, EUS is semi-invasive with almost no procedure-related complications and a negligible failure rate. In fact, several series comprising over 1000 patients have reported no complications.[55] In a prospective study by Buscarini and colleagues, 485 patients suspected to have choledocholithiasis based on clinical, laboratory, and ultrasound, or CT findings underwent EUS.[55] Positive EUS findings were confirmed by surgery or ERCP with sphincterotomy; negative findings were confirmed by clinical follow-up of at least 6 months. EUS findings were verified in 463 patients as follows: 237 true positive, 216 true negative, 2 false positives, and 4 false negatives, and in 4 patients EUS was incomplete (sensitivity 98%, specificity 99%, PPV 99%, NPV 98%, accuracy 97%). No complications were noted in the study. EUS offers higher resolution than MRCP and therefore is better able to detect small stones. It is able to identify bile duct stones as well as microlithiasis and is able to detect pathology that is not seen by ERCP. EUS prior to performing invasive diagnostic or therapeutic techniques would lower the rate of procedure-related complications in patients suspected of having bile duct stones. Cost analysis of EUS followed by ERCP versus ERCP alone is also in favor of EUS as a pretherapeutic procedure.[55]

In patients for whom ERCP is not available, not possible secondary to anatomic considerations, or not successful, an alternative method of cholangiography and nonsurgical therapy is *percutaneous transhepatic cholangiography* (PTC) followed by transhepatic methods of stone removal. A needle is introduced into the intrahepatic bile ducts through the skin, and a cholangiogram is performed, followed by wire insertion and then a catheter over the wire for external biliary drainage and access to the biliary system. The method was introduced in Denmark in the 1970s and has been refined over the years with the addition of several therapeutic options.[56] This technique is particularly useful for evaluating intrahepatic stones or other proximal bile duct disease. After diagnosis of bile duct stones, several therapeutic options are available through the percutaneous route. In 1981, the removal of an 8-mm common bile duct stone by percutaneous transhepatic technique was reported by Fernstrom and colleagues.[57] In 1990, Stokes and colleagues, from Boston, reported a series of 53 patients in whom surgery was contraindicated and ERCP unsuccessful.[58] By inserting a modified Dormia basket via a percutaneous transhepatic route, stones were advanced whole or after fragmentation into the duodenum. Mono-octanoin or MTBE were used in 30 patients to reduce stone size or remove debris. Morbidity and mortality were 12 and 4%, with a success rate of 93%. Transhepatic cholangioscopy and lithotripsy can be performed after PTC and dilatation of the intrahepatic channel with success rates of 90–100% and 5–8% complications.[59] In a series of 12 patients with bile duct stones, PTC in combination with laser or electrohydraulic lithotripsy to deliver stone fragments into the duodenum was found to be successful in all the patients.[60] In another series of 13 patients, laser lithotripsy was used with percutaneous cholangioscopy performed either transhepatic (12 patients) or through the T-tube track.[61] Stone fragmentation was successful in 92%, and stone clearance was possible in all patients. However, 11 patients required the addition of sphincterotomy (either by ERCP or by antegrade method with fluoroscopic monitoring) or stent insertion. Bleeding in two patients accounted for a 15% severe complication rate. Percutaneous transhepatic papillary balloon dilatation was reported recently by a Japanese group for the management of choledocholithiasis.[62] In the five patients in whom the method was used, bile duct stones were able to be pushed into the duodenum in all, with no complications or deaths. Ponchon and colleagues reported percutaneous choledochoscopy for stone extraction in 75 patients, with the transhepatic route used in 48 patients and T-tube tract used in 27 patients.[63] Complete clearance of bile duct stones was accomplished in 69 patients (92%).

Role of Cholecystectomy Following CBD Stone Extraction. After bile duct clearance is achieved by nonoperative methods, cholecystectomy generally is recommended in younger patients to decrease the risk of future cholecystitis and recurrent biliary colic. As many as 24% of patients have been found to require cholecystectomy at follow-up after endoscopic papillotomy at an average of 14 months.[64] Others have argued that sphincterotomy results in gallbladder stasis, bacterial overgrowth, and an increase in bile acids, and these may increase the risk of gallbladder cancer in 10–20 years.[2] On the other hand, Dhiman and colleagues studied the changes in gallbladder emptying and lithogenicity of bile following endoscopic sphincterotomy in patients with choledocholithiasis and gallbladder in situ.[65] Sphincterotomy was found to decrease stasis of gallbladder bile, improve gallbladder emptying, and decrease the lithogenicity of bile as measured by prolongation of nucleation time. Meanwhile, there is much evidence to support leaving the gallbladder in situ after bile duct clearance in high-risk or elderly patients.[66–75] In a study of 191 patients (median age 76 years) in whom the gallbladder was left in situ post-ERCP, only 10 patients (5%) required subsequent uneventful cholecystectomy.[69] Twenty-six percent (49 patients) died during the review period from nonbiliary pathology. Kwon and colleagues followed 146 patients without elective cholecystectomy after endoscopic CBD stone removal for a period of 3 months or more to see if they could identify factors that predict subsequent gallbladder-related symptoms and need of cholecystectomy.[71] Fifty-nine patients had cholelithiasis, whereas 87 patients had no gallbladder stones. During a

mean follow-up of 24 months, seven patients (5%) underwent cholecystectomy, on average, 18 months after ERCP as a result of acute cholecystitis (four patients), biliary pain (two patients), and acute pancreatitis (one patient). Nine patients (6%) died of causes unrelated to biliary disease. Interestingly, Cox regression analysis revealed that the need for subsequent cholecystectomy did not correlate with age, sex, presence of gallbladder stones, number of gallbladder stones, or underlying disease. Kullman and colleagues found that at a median observation time of 42 months, cholecystectomy was needed in 11% (13 patients) of 118 patients with a gallbladder in situ after ERCP bile duct clearance.[72] Forty-nine patients (42%) died within 2–87 months after ERCP during the follow-up period. In another study of 33 elderly patients who were followed for an average of 42 months with gallbladder in situ after successful ERCP for choledocholithiasis, 3% (one patient) required cholecystectomy for acute cholecystitis, and 6% (two patients) had mild right upper quadrant pain, whereas 91% remained asymptomatic.[73] Over the course of the study, 30% of the patients died from nonbiliary causes. The impact of gallbladder status on patient outcome after ESWL for complicated CBD stones was studied by a German group.[70] One-hundred twenty patients with an average age of 68 years (range 28–86 years) were followed for 3–9 years (mean 4 years). Thirty-seven had their gallbladder in situ, 27 had had a cholecystectomy after ESWL, and 56 had already undergone cholecystectomy prior to diagnosis of choledocholithiasis. During the follow-up period, 30% (36 patients) experienced biliary symptoms. However, there was no significant difference in the incidence of these symptoms between the three groups. Repeat ERCP revealed 28 cases of recurrent bile duct stones. Although not reaching statistical significance ($p = .077$), the recurrences occurred more often in the cholecystectomy groups. Given the multiple studies supporting leaving the gallbladder in situ after CBD clearance, it seems reasonable to perform cholecystectomies on high risk or elderly patients as needed rather than prophylactically following nonoperative treatment of bile duct stones.

INTRAOPERATIVE

When patients present to the operating room for cholecystectomy, they may either have CBD stones confirmed by preoperative studies (eg, ERCP, MRCP, or EUS), or they are suspected to have CBD stones by clinical presentation, laboratory values, or transabdominal ultrasound, or they have no suspicion of bile duct stones. At the time of surgery, *intraoperative cholangiography* (IOC) is the method used most often to establish the presence of bile duct stones. IOC was first introduced to open biliary surgery by Mirizzi in the 1930s.[76] With the universal acceptance of laparoscopic cholecystectomy as the treatment of choice for symptomatic gallbladder stones, laparoscopic IOC has developed into a very useful method to evaluate the biliary tree. The technique may be performed by injecting contrast material through a catheter introduced into the cystic duct via a variety of techniques.[78] 14-gauge IV catheter placed through the abdominal wall 3 cm medial to the midclavicular port.[77] Cannulation rates with successful cholangiography are from 75 to 100%, and the use of fluoroscopy has become standard because it is faster, more detailed, and allows real-time surgeon interaction.[77,78] The reported sensitivity, specificity, PPV, NPV, and accuracy for laparoscopic cholangiography are 80–90%, 76–97%, 67–90%, 90–98%, and 95%, respectively, and these are comparable with the values for open IOC.[76] The rate of false-positive IOC results in a recent large review was found to be 0.8% (34 of 4209 patients).

Although approximately 10–15% of patients undergoing laparoscopic cholecystectomy harbor CBD stones, the need for routine IOC is a matter of much debate.[79] In a large Medline literature review, Metcalfe and colleagues found a 4% rate of CBD stones in eight laparoscopic cholecystectomy trials in which routine IOC was performed on 4209 patients without suspected bile duct stones preoperatively.[78] This finding was felt to be consistent with previous reviews. On the other hand, in a total of 5179 patients without suspicion for bile duct stones that did not undergo IOC during laparoscopic cholecystectomy, 32 (0.6%) proceeded to develop symptoms from residual bile duct stones. By extrapolating this data, it would seem that of the 4% of patients with silent CBD stones at laparoscopic cholecystectomy, only 15% go on to develop symptoms from retained stones. In other words, 167 IOCs would have to be performed during laparoscopic cholecystectomy in order to detect one CBD stone that would go on to cause symptoms in patients without preoperative evidence of duct stones. This would result in eight unnecessary bile duct explorations or ERCPs.[78] It is possible that stones that are not manifested preoperatively are of the size that can pass spontaneously into the duodenum, never presenting with symptoms.

Intraoperative ultrasound (IOUS) is a noninvasive way to evaluate the biliary system at the time of surgery. First introduced in the mid-1980s in the time of open cholecystectomy, laparoscopic IOUS came into use in the mid-1990s.[76] Recent experience with laparoscopic IOUS has suggested that it is a very sensitive test for CBD stones and roughly equivalent to IOC in evaluating the biliary ductal system. Moreover, it lacks the potential of common bile duct injury that exists with placement of the cholangiography catheter during IOC and will not cause a false-positive test owing to air introduced into the biliary tree.[78] The use of laparoscopic IOUS has been limited, however, possibly secondary to equipment availability and cost, as well as the expertise and experience required for its use. There appears to be a considerable learning curve associated with the use of laparoscopic IOUS.[80,81]

Once the presence of CBD stones has been established at the time of surgery, there are several treatment options. Depending on local availability and expertise, these may include open or laparoscopic duct exploration and postcholecystectomy nonoperative techniques such as ERCP or PTC. However, before embarking on a means of eradicating the biliary tree of stones, it is worth remembering that only 15% of patients with silent bile duct stones at the time of cholecystectomy present with symptoms of retained stones.[78]

The natural history of choledocholithiasis was revisited in a recent prospective study by Collins and colleagues.[82] Operative cholangiography was attempted in 997 patients undergoing laparoscopic cholecystectomy and was successful in 962 patients. Patients with cholangiogram-positive stones were restudied in 48 and 72 hours and 6 weeks after laparoscopic cholecystectomy through a cystic duct cholangiocatheter left in the cystic duct at the time of surgery. Of the 962 patients, 46 (4.6%) had at least one filling defect, but 12 had normal cholangiograms 48 hours later, giving a 26% possible false-positive cholangiogram rate. At 6 weeks, a further 12 patients had a normal cholangiogram, giving a 26% spontaneous passage rate of bile duct stones. This spontaneous passage was not predictable by either the number or size of stones or the diameter of the bile duct. Only 2.2% of the total population (22 patients) required postoperative endoscopic retrograde cholangiopancreatographic retrieval of persistent common duct calculi. **Thus a treatment decision based on the findings of IOC alone would have resulted in 52% of patients with positive findings undergoing unnecessary intervention.**

The first surgical exploration of the CBD was done in 1890 by Ludwig Courvoisier, a Swiss surgeon who made an incision in the CBD and removed a gallstone.[77,83] Prior to the development of laparoscopic cholecystectomy, patients found to have bile duct stones at surgery underwent *open CBD exploration* with greater than 90% successful duct clearance. ERCP was used for retained stones postoperatively or for patients who would not be able to tolerate extended general anesthesia. At the time of open cholecystectomy, the common duct is opened in the longitudinal direction so as to not compromise the blood supply to the duct. The bile duct is cleared of stones with the use of Fogarty balloons, saline irrigation, stone forceps, and scoops placed into the biliary tract through the opening. Choledochoscopy is particularly useful in evaluating the duct system during and after the clearance of residual stones and in making sure that there is no other ductal pathology. Moreover, a basket can be passed through the working channel of the scope and used under direct vision for stone removal. Although used commonly in the management of CBD stones in the era of open cholecystectomy, open bile duct exploration is used infrequently in the present age of minimally invasive surgery. In a recent series of 326 patients who underwent laparoscopic common bile duct exploration (LCBDE) for choledocholithiasis at the time of cholecystectomy, only five patients were converted to laparotomy and only two for open bile duct exploration and stone extraction.[77]

Over a hundred years after Langenbuch performed the first open cholecystectomy in 1882, laparoscopic cholecystectomy was introduced and soon became the standard treatment of cholecystitis and symptomatic gallstones.[77,83] In the early years after the development of laparoscopic cholecystectomy, LCBDE was used infrequently, and reliance on alternative methods of duct clearance was widespread.[77] With increasing experience in laparoscopic techniques and the demand for single-procedure minimally invasive duct clearance, the use of LCBDE gained greater acceptance among experienced biliary surgeons. Since the development of the technique, thousands of successful LCBDEs have been reported in the literature, and success rates of duct clearance are between 80 and 90%, comparable with the open method of bile duct exploration.[76] The morbidities range from 8 to 10% and are typical of laparoscopic procedures, including nausea, diarrhea, ileus, atelectasis, phlebitis, urinary retention and infection, biliary leak, dislodgement of the T-tube, fluid collections, pulmonary embolus, and myocardial infarctions. Reported mortalities are from 0 to 2%.

The technique of LCBDE has been well described by Petelin.[76,77] Access to the biliary system, after obtaining a cholangiogram, can be either transcystic or transductal using a choledochotomy. Use of the transcystic approach varies from 5 to 98% depending on the series. With this method, the gallbladder is retracted toward the right hemidiaphragm, and if needed, the cystic duct is dilated with either over-the-wire mechanical or pneumatic dilators. The transductal approach is favored for stones greater than 6 mm in diameter, intrahepatic stones, cystic duct diameter less than 4 mm, and cystic duct entrance either posterior or distal. When using the transductal method, a choledochotomy is made on the anterior surface of the CBD with a scissors or scalpel and is limited to 1 cm or the size of the largest stone.

Once the biliary tree has been accessed, choledocholithotomy is performed using several different techniques and is guided by either fluoroscopy or choledochoscopy. Although separate monitors may be used with a choledochoscope, the use of a video mixer to place the laparoscopic and choledochoscopic images on the same screen is helpful. Newer choledochoscopes with 3 mm diameters even can be passed through the cystic duct. Common bile duct clearance is started with irrigation, which allows the flushing of small, less than 3-mm stones and sludge. The administration of 1–2 mg IV glucagon allows relaxation of the sphincter of Oddi and facilitates the irrigation process. Fogarty-type balloons (4F) then can be inserted into the bile duct for retrograde extraction of stones with withdrawal of the inflated balloon. Stones also may be captured with a Dormia-type basket inserted directly through the cystic duct or choledochotomy or through the working port of the choledochoscope. Intraoperative electrohydraulic or laser lithotripsy is useful for large stones or stones that are impacted and not responsive to other methods. Care is needed, however, to avoid injury to the duct by inaccurate application of the lithotripsy device.

If a choledochotomy is used to perform the LCBDE, a T-tube may be left in place for later study of the biliary system, decompression if the biliary tree was not cleared, or access to the biliary system for recurrent stones. On the other hand, laparoscopic suturing with 4-0 or 5-0 Vicryl can be done instead to close the choledochotomy primarily. A recent study found that hospital stay was shorter in a group of patients who underwent primary closure versus placement of a T-tube (5 vs 9 days).[84] There does not appear to be an increase in the incidence of bile leak or peritonitis in patients undergoing primary closure.[77] This further abrogates

the complications of T-tubes, including dislodgement, bacteremia, fracture of the tube, and the possibility of bile leak and peritonitis at the time of T-tube removal. An alternative to T-tube placement is a stent placed in an antegrade fashion into the duct similar to an ERCP-placed stent.[85] An alternative to a T-tube is a modified ureteral catheter placed through the cystic duct and brought out through the abdomen after closure of the choledochotomy.[86] In a study of 30 patients undergoing placement of this modified catheter, no complications related to the catheter were found, and removal was possible at a median of 5 days as compared with 29 days when a T-tube was used.

If LCBDE is unsuccessful, a transcystic catheter may be inserted through the abdominal wall to decompress the biliary system and allow for postoperative cholangiography. If the catheter is further advanced into the duodenum, it can aid in bile duct cannulation at the time of postoperative ERCP.[76] In addition to treating bile duct stones postoperatively following an incomplete laparoscopic duct clearance, the option of converting to an open duct exploration is also available to the operating surgeon.

There are several alternatives to laparoscopic or open duct exploration for bile duct stones encountered at the time of surgery. At the time of cholecystectomy, a *transcystic stent* may be placed over a wire antegrade through the sphincter of Oddi as initial treatment.[87] This allows for decompression of the biliary tree and can be followed postoperatively by ERCP and sphincterotomy with stent removal. Another option is the use of *intraoperative ERCP* (IO-ERCP), allowing the same anesthetic to be used for both the cholecystectomy and the ERCP.[88–90] In one Swedish study by Enochsson and colleagues, 592 patients underwent IOC during laparoscopic cholecystectomy.[90] Thirty-four of these were subjected to IO-ERCP with a 100% common bile duct cannulation rate. This was assisted by the fact that the surgeon, while waiting for the endoscopist, introduced a thin guidewire into the IOC catheter and through the sphincter of Oddi into the duodenum. Bile duct clearance was possible in 94%, and a stent was left in place in the two patients with remaining stones. Operative time was prolonged by 1.5 hours as compared with laparoscopic cholecystectomy, but the length of hospitalization was not significantly longer for IO-ERCP patients. There were no cases of postoperative pancreatitis. In a French report by Meyer and colleagues, 60 patients were treated with laparoscopic cholecystectomy and IO-ERCP for confirmed or suspected CBD stones.[89] The mean operative time for laparoscopic cholecystectomy was 60 minutes (range 40–90 minutes), and general anesthesia was prolonged only 40 minutes (range 30–60 minutes) for performing the IO-ERCP, including the time needed for setting up the endoscopic equipment. The papilla could not be catheterized in two patients. In one, postoperative ERCP was possible, and in the second patient, a small stone passed spontaneously. In one patient, secondary to multiple calculi in CBD, open surgery was performed immediately after IO-ERCP. Final duct clearance was achieved in 100% of patients. The argument for using IO-ERCP versus postoperative ERCP is that the former allows the identification of anatomic problems (such as duodenal diverticulum) that could make later ERCP unsuccessful. Thus the surgeon has the option to convert to open bile duct exploration at the same anesthetic.[88] If one chooses to use IO-ERCP, performing the cholecystectomy prior to the ERCP is important because this avoids endoscopy-induced small bowel distension from interfering with gallbladder visualization. Moreover, transcystic IOC at the time of cholecystectomy may avoid unnecessary ERCP if no stones are visualized by the cholangiogram.

POSTOPERATIVE

Patients presenting with CBD stones after cholecystectomy generally are treated with ERCP[77] (Fig. 49-3). The noninvasive imaging techniques, such as ultrasound and MRI, are not different from those used preoperatively. If a T-tube (or other transabdominal drainage catheter) had been left in place at prior surgery, a cholangiogram can be obtained after surgery to establish the presence of bile duct stones. In situations in which ERCP is not possible or successful, other nonoperative methods can be used. For patients with T-tubes, percutaneous instrumentation under fluoroscopic guidance through the T-tube tract can be used to remove bile duct stones. In one report, 23 of 25 patients underwent successful duct clearance through the T-tube tract for retained stones.[91] A choledochoscope also may be inserted through the T-tube tract to allow for either laser or electrohydraulic lithotripsy and stone extractions.[63] Other percutaneous transhepatic options described in the preoperative section of this chapter also may be used. Combinations and repeated techniques may be needed to achieve duct clearance. In the rare incidences

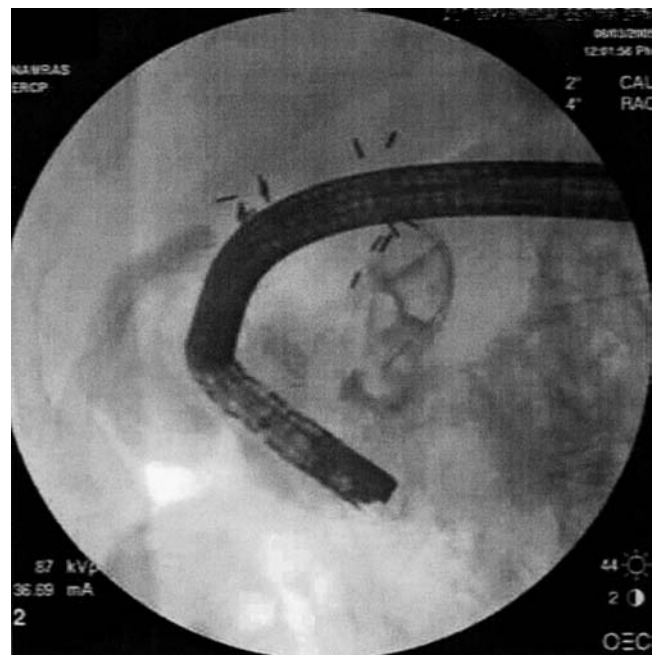

FIGURE 49-3 Multiple retained stones after cholecystectomy, seen on endoscopic retrograde cholangiopancreatography (ERCP).

where the biliary system cannot be cleared of stones nonoperatively, surgical duct exploration is considered, and the need for surgical drainage procedures must be addressed.

SURGICAL BILIARY DRAINAGE PROCEDURES

Surgical biliary drainage procedures must be considered in situations of multiple stones; incomplete removal of all stones; impacted, irremovable distal bile duct stones; markedly dilated CBD; distal bile duct obstruction from tumor or stricture; and reoccurrence after previous bile duct exploration. The methods of surgical drainage include transduodenal sphincteroplasty, choledochoduodenotomy, and choledochojejunostomy (CDJ).

Transduodenal sphincteroplasty (TDS) is useful in the management of choledocholithiasis when there is stone impaction in the ampulla of Vater, papillary stenosis, and multiple stones, particularly in the presence of a nondilated bile duct.[92–94] The duodenum is kocherized completely, and the ampulla is located by passing a biliary Fogarty catheter through the CBD into the duodenum. A longitudinal duodenotomy is made over the ampulla, and the entrance to the pancreatic duct is identified at the 4 o'clock position when possible. Intravenous secretin given at 0.2 g/kg over 1 minute sometimes is helpful in this identification. Absorbable sutures are placed on each side of the ampulla, and the sphincteroplasty is started at 11 o'clock and extended with sequential placement of sutures along the incision. After the opening is wide enough to fit a biliary dilator the size of the common duct, the last ampullary suture is placed at the apex to prevent a duodenal leak. The duodenotomy then is closed in the transverse direction to prevent duodenal stenosis, and a drain is left in the event that the duodenotomy leaks.

In a French review by Suter and colleagues, of the 78 patients who underwent transduodenal sphincterotomy, 26 were operated on urgently.[94] Forty-seven (60%) were jaundiced, 15 (19%) had pancreatitis, and 12 (15%) had cholangitis before surgery. Three patients died, one from pulmonary embolism, one from pulmonary sepsis, and the other from multiorgan failure syndrome complicating preoperative necrotizing pancreatitis. Of the 30 patients (38%) with complications, 20 were directly related to the surgery and included 4 cases of bleeding not requiring transfusion, 17 instances of hyperamylasemia with 1 case of clinical pancreatitis, and 1 case of duodenal fistula that healed after conservative therapy. No deaths were noted that were directly attributable to the TDS. In an older review by Meyhoff, a 10% postoperative mortality was noted after TDS, with four patients developing fatal pancreatitis.[92]

Choledochoduodenostomy (CDD) was first performed by Riedel in 1888 in Europe.[95] Unfortunately, the patient died of anastomotic disruption secondary to a missed stone in the distal CBD. The first successful operation was performed by Sprengel in 1891. CDD is indicated in patients with recurrent stones requiring repeated interventions, impacted or giant stones, biliary sludge, and ampullary stenosis. The funnel syndrome in which a distal bile duct stenosis exists in the presence of CBD stones is one of the most classic indications for CDD.[95] Most of the CBD stones in this situation are primary biliary stones forming as a result of biliary stasis. Any procedure done to remove only the stones has a temporary benefit if the stenosis is not addressed.

CDD can be performed either as an elective or an emergency operation, such as for cholangitis. The side-to-side anastomosis is the most commonly used technique, but an end-to-side is also an option. A CBD diameter of at least 1.2 cm is important in assessing the feasibility of CDD because this allows a wide enough stoma to ensure good biliary drainage and avert stenosis. The anastomosis is created in the most distal portion of the bile duct to decrease the chance of the well-described sump syndrome.[95] After opening the abdomen, the duodenum is kocherized widely to allow for a tension-free anastomosis, and the CBD is dissected completely along its distal anterior surface. A longitudinal duodenotomy is made close to the bile duct along the long axis of the duodenum, perpendicular to the choledochotomy. The CBD incision is made along the long axis of the bile duct as close to the duodenum as possible and of a 2 cm length to prevent stenosis. After performing a CBD exploration and clearing the duct of stones, a side-to-side single-layered anastomosis is made with absorbable suture, and a drain is placed for the possibility of an anastomotic leakage.

The morbidity and mortality rates associated with CDD are 23 and 3%, respectively.[95] Mortality is most commonly from medical complications, such as pulmonary embolism, myocardial infarction (MI), or heart failure. Among the specific operative morbidities, cholangitis and sump syndrome are described most commonly.

The incidence of cholangitis ranges from 0 to 6% in the largest long-term follow-up series.[95] Although once thought to be caused by ascending reflux of duodenal contents into the biliary tree, cholangitis is now believed to be the result of stenosis of the anastomotic stoma. A wide anastomosis avoids stasis and stone retention by allowing entrance and egression of duodenal and biliary contents. Sump syndrome is caused by food and debris accumulating between the stoma and the papilla of Vater. This leads to contamination of the large and small bile ducts with resulting recurrent cholangitis and even secondary biliary cirrhosis.[95] Although the accumulation of debris in the blind segment of the bile duct may cause destruction of the stoma or cholangitis, some believe that the disease is caused by stenosis of the stoma. To avoid the problem, creating a stoma of at least 14 mm, along with placing the anastomosis near the duodenum, is important. Stomal patency is felt to be the most important factor for preventing both cholangitis and sump syndrome.[96] Other complications of CDD include wound infection, anastomotic leak, and intra-abdominal abscess. Long-term studies reveal that 70–80% of patients are asymptomatic 5 years after surgery.[95] In a review of 126 patients undergoing CDD after CBD exploration over a period of 19 years, Deutsch and colleagues reported a 4% mortality rate, with all deaths occurring in patients over 70 years old.[97] Morbidity included wound infections in 18 patients (14%) and bile leak through a drain

for over 2 weeks in 4 patients (3%). Ninety-seven patients (94%) were symptom-free at a follow-up of 1–19 years.

Rameriz and colleagues reported their experience with CDD and transduodenal sphincterotomy for the treatment of choledocholithiasis over a period of 10 years.[98] Of the 591 patients who underwent choledochotomy for bile duct stones, 240 (40.6%) were treated with primary closure over a T-tube, 126 (21.3%) received primary closure over a T-tube along with a TDS, 216 (36.5%) had a supraduodenal CDD, and 9 (1.5%) had both a CDD and a TDS. CDD was performed when the bile duct was more than 12 mm in diameter, and TDS was used if a stone was impacted in the papilla and/or papillary stenosis was noted. Complications included six abdominal abscesses and three external biliary fistulas in the patients undergoing CDD and four abscesses and two episodes of acute pancreatitis in the patients treated with TDS. There was no difference in mortality between the two groups, and after a mean follow-up of 5.6 years, 71.5% of the CDD group and 75.2% of the TDS group were asymptomatic. Symptoms noted in the remainder included dyspepsia, colicky pain, and episodes of cholangitis and resulted in reoperations for residual stones in nine patients, six from the CDD group and three from the TDS group. The same authors previously reported that of the patients who presented with symptoms after CDD and underwent endoscopy, no problems at the anastomosis were noted in patients who presented with dyspepsia, whereas 27% of those with biliary colic had an anastomotic stenosis or sump syndrome, and all the patients with cholangitis had stenosis and residual stones.[99] On the other hand, in a comparison of 190 patients with CDD and 56 patients with TDS over a period of 10 years, Baker and colleagues found an overall mortality of approximately 5% in both groups.[93] The morbidity rates were 11.6% for CDD and 21.4% for TDS. With a mean follow-up of 4.5 years, six patients (3.3%) in the CDD group presented with sump syndrome, cholangitis or both and three patients (5.7%) in the TDS group had cholangitis. In another report by the same authors, an elevated serum alkaline phosphatase level was noted in 22% of CDD patients and 3% of the TDS patients, whereas radiological studies showed that the CDD stoma admitted air and barium more often than the TDS stoma.[100] Interestingly, neither the biochemical nor the radiological findings correlated with long-term symptomatic results after the two procedures.

An alternative to CDD is CDJ, which can be performed with either a loop of jejunum or using a Roux-en-Y configuration. If a loop is used, a side-to-side jejunojejunostomy is used to divert the flow of intestinal contents from the biliary tree. The Roux-en-Y usually is brought retrocolic using a 60-cm afferent limb to protect against intestinal reflux and secondary cholangitis. In either case, an end-to-side CDJ is created using fine absorbable suture. The anastomosis can be decompressed using a T-tube if the remaining bile duct is long enough to allow one, or a transhepatic stent can be used if the remaining bile duct is short. As in the other methods of surgical drainage, a drain is left in place to guard against possible anastomotic leakage.

Gouma and colleagues reported their experience with 43 patients undergoing Roux-en-Y CDJ after complex clearance of the biliary tree for choledocholithiasis.[101] There were no mortalities and only one major complication. Moreover, 98% of the patients had good long-term results with no signs or symptoms related to biliary obstruction or cholangitis. A comparison of CDD and CDJ for choledocholithiasis was evaluated by a French group.[102] One-hundred and thirty patients were included, of which 64 underwent CDD and 66 had a CDJ. No difference in morbidity or mortality was noted between the two groups. Of the 120 patients (58 CDD and 62 CDJ) available for a mean follow-up of 29 months, 107 were symptom-free, 13 patients (6 CDD and 7 CDJ) experienced biliary symptoms suggestive of cholangitis, 8 presented in the first postoperative year, and 5 presented in the second postoperative year. In the CDD group, the cholangitis was secondary to sump syndrome (three patients), anastomotic stricture (one patient), or unknown causes (two patients). Anastomotic strictures (three patient), residual intrahepatic stones (one patient), or unknown causes (three patients) were felt to be the cause of cholangitis in the CDJ group. The authors concluded that CDD is preferable given the similar outcomes because it is easier and faster to perform than CCJ and allows for easy endoscopic interventions if needed in the future. However, often the choice between the two operations is dictated by the anatomy and feasibility of creating a tension-free anastomosis.[103]

One controversy in performing biliary anastomoses is the use of biliary stents. Earlier studies have argued that stents allow for decompression of the bile duct and decreased risk of bile leak, postoperative radiographic evaluation of the biliary tree, and reduced fibrotic narrowing of the anastomosis during early healing.[104] Pitt and colleagues noted a higher success rate with the anastomosis stented for more than 1 month compared with those stented for less than 1 month or not stented at all.[105] Others also have noted good results with the use of stents.[106,107] However, Bismuth and colleagues showed that excellent results could be obtained in 86% of 123 patients undergoing stentless hepaticojejunostomy for benign biliary disorders.[108] Pellegrini and colleagues found that stenting for more than 1 month postoperatively resulted in outcomes no different from anastomoses done without stents.[109] The argument has been raised that stents cause an inflammatory reaction that may predispose to stenosis. DiFronzo and colleagues found that of the 97 patients having either a CDD (77%), CDJ (8%), hepaticoduodenostomy (1%), or hepaticojejunostomy (13%) without the use of stents, only one patient developed an anastomotic leak that resolved spontaneously within 1 week.[104] In the mean follow-up period of 13 months, no postoperative strictures were noted. Meanwhile, Tocchi and colleagues presented their data on performing hepaticojejunostomy (48 patients), CDJ (34 patients), and intrahepatic cholangiojejunostomy (8 patients) without stents in 84 patients over a period of 15 years for benign biliary strictures.[110] Excellent or good results were obtained in 83% of the patients. Anastomotic strictures occurred in 10 patients, 6 within 5 years and 4 at 62, 75, 85, and 96 months. By

multivariate analysis, only postoperative complications and the degree of CBD dilatation proved to be significant independent predictors of outcome. A bile duct dilatation of less than 15 mm was noted in 60% of patients with poor outcome. Although not reaching statistical significance, higher complications and restructures were noted in patients having a CDJ versus hepaticojejunostomy, and the authors changed their practice to performing only higher anastomosis during the study period for even low strictures. Peptic ulcers were noted in only 2.3% of the patients in the entire series, which is not higher than the normal population and does not appear to be related to diverting the flow of bile from the duodenum, as others have suggest.

Laparoscopic approaches to both Roux-en-Y CDJ and CDD have been reported recently. Jeyapalam and colleagues reported six patients who underwent *laparoscopic choledochoduodenostomy* (LCDD).[111] While one patient died of comorbidity, the liver laboratory values returned to normal in all the remaining patients, and the average length of postoperative stay was 6 days. Tang and colleagues selected 12 patients to undergo LCDD for recurrent pyogenic cholangitis.[112] A successful laparoscopic approach was used in all cases, with a mean operating time of 6 hours and a median postoperative length of stay of 7.5 days. One postoperative bile leak was noted and managed conservatively, whereas no patients developed cholangitis or sump syndrome at a mean follow-up of 38 months. Han and colleagues presented similar results in performing laparoscopic Roux-en-Y CDJ for benign disease.[113] One episode of melena that resolved spontaneously was the only postoperative complication in six patients who underwent the surgery. All patients were symptom-free at a 27-month follow up. Despite the proliferation of robotic-assisted surgery, its application to biliary surgery has remained rather limited. The literature thus far includes only two separate case reports. One report describes robotic-assisted CBD exploration.[114] The other report describes a robotic CDJ with an intracorporeal Roux limb construction.[115] The use of minimally invasive surgical drainage procedures is likely to become more widely used as experience increases and technology improves.

SUMMARY

The evaluation and treatment of choledocholithiasis has evolved over the last 100 years. As newer and less invasive techniques emerge, the surgeons will find a variety of options and many paths that can lead to the successful treatment of a patient with CBD stones. Evaluation and diagnosis may involve an examination and simple laboratory tests or evaluation of the biliary tree with MRCP, ERCP, or an IOC. Treatment may be endoscopic, percutaneous, open, or laparoscopic. Given the multiple alternatives available, sometimes it is difficult to decide on the right one for a particular patient. Frequently, the best path is the one the surgeon is most adept at or the one that local expertise can accomplish most safely. Sometimes, however, the safest approach is a transfer to a center where multiple treatment options are available so that the treatment can be tailored to fit each individual situation.

Figures 49-4 and 49-5 show the treatments followed at our institution for preoperative and intraoperative suspected choledocholithiasis (at cholecystectomy).

CHOLANGITIS

Cholangitis is the most rapidly fatal complication of gallstones and occurs as a result of biliary tract bacterial infection in the setting of biliary tree obstruction. Mortality approaches 100% in patients who after failing conservative therapy are not subjected to needed drainage interventions.[116] Early diagnosis and treatment are imperative for a successful outcome.

Pathophysiology

Although bile is normally sterile, when the biliary tree is compromised, such as by a stone, stricture, or endoprosthesis, bacteria then often can be cultured from the bile.[117] Along with the sphincter of Oddi and the bacteriostatic properties of bile, bile flow is an important component of maintaining sterility. Bile duct obstruction results in decreased antibacterial defenses, allowing bacteria to gain access to the biliary tree. Although the route of infection is unclear, ascent from the duodenum or hematogenous is felt to be the possible source.[116] Once colonization has occurred, stasis allows for exponential bacterial growth. As the biliary pressure rises with obstruction, bacteria and their products such as endotoxins leak into the systemic circulation and cause the septicemia of cholangitis.[117]

Patients with partial obstruction have a higher chance of developing cholangitis than those with complete obstruction, and bile duct stones are associated more often with cholangitis than neoplasms causing obstruction. In the United States, secondary choledocholithiasis is the most common cause of cholangitis. Primary bile duct stones are common in areas where Oriental cholangiohepatitis is endemic, including Hong Kong and Southeast Asia.[116] Other causes of cholangitis include obstructing periampullary tumors, tumors metastatic to the porta hepatis or peripancreatic lymph nodes, benign strictures, and primary sclerosing cholangitis. Biliary tract interventions may lead to postprocedural cholangitis, and rare cases of cholangitis may be caused by hemobilia, parasites, and congenital abnormalities of the biliary tree.

Escherichia coli, Streptococcus spp., *Klebsiella* spp., and Enterobacteriaceae are the most common organisms cultured in cholangitis. *Pseudomonas* spp. and skin and oral flora are associated with biliary tract interventions, whereas anaerobes are noted most commonly in the elderly after biliary surgery.[116]

Clinical Presentation and Diagnosis

Charcot's triad of fever, right upper quadrant pain, and jaundice is present in 50–70% of patients with cholangitis

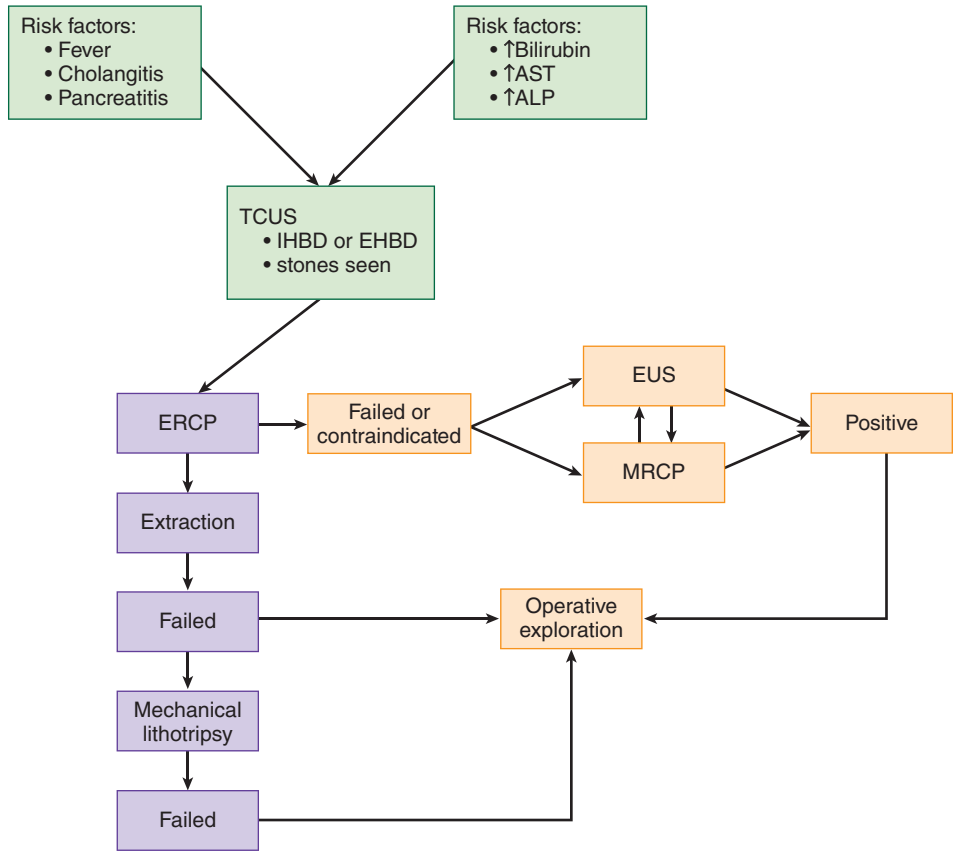

FIGURE 49-4 Algorithm for treatment of preoperative suspected choledocholithiasis.

at presentation, with fever, abdominal pain, and jaundice occurring in 90, 70, and 60% of patients, respectively. Hypotension (20%) and altered mental status (30%) are seen in septic patients and are known as *Reynold's pentad* when presenting in the setting of Charcot's triad. Although peritonitis is uncommon, 65% of patients have right upper quadrant tenderness.[116] Laboratory and radiological studies are important for distinguishing cholangitis from other conditions such as acute cholecystitis, liver abscesses, and pancreatitis. Elevations of serum alkaline phosphatase, gamma-glutamyl transpeptidase, and bilirubin are typical. Mild increases in transaminases may be seen, whereas hyperamylasemia is found in up to 30% of patients. A discussion of imaging studies for the evaluation of choledocholithiasis has been presented in the section on CBD stones. In a patient presenting with signs of cholangitis, the most widely used imaging modalities are ultrasound and CT scan. Ultrasound is highly accurate in diagnosing acute cholecystitis and identifying gallstones. However, its ability to establish the diagnosis of choledocholithiasis is only 50%, varying from 30 to 90%.[6,10] Although the presence of bile duct stones can be inferred by associated bile duct dilatation, a normal ultrasound without duct dilatation does not exclude either choledocholithiasis or cholangitis.[15,116] CT scan is better at determining the level of biliary tract obstruction and has a 94% accuracy in diagnosing choledocholithiasis in the setting of suspected bile duct calculi.[18] MRCP has sensitivities and specificities approaching ERCP in the diagnosis of bile duct stones and is useful in delineating biliary anatomy. However, its use in the setting of acute cholangitis is limited. ERCP is highly accurate in revealing the cause of biliary obstruction and at the same time allows for therapeutic intervention to occur at the same session.[116] Nonetheless, given the well-defined life-threatening complications associated with ERCP and the availability of other noninvasive imaging techniques, ERCP should not be used solely as a diagnostic tool in the setting of acute cholangitis.[116]

TREATMENT

Patients with cholangitis can become extremely ill in a short period of time, and rapid initiation of treatment can be lifesaving. Supportive measures are begun without delay and include fluid resuscitation, correction of electrolyte deficits and coagulopathy, and administration of analgesics.[118] Empirical broad-spectrum antibiotics are started while blood cultures, and when available, bile cultures are sent. Aminoglycosides and ampicillin are associated with gram-negative resistance and nephrotoxicity and are no longer felt to be the ideal regimen. Newer effective therapies include

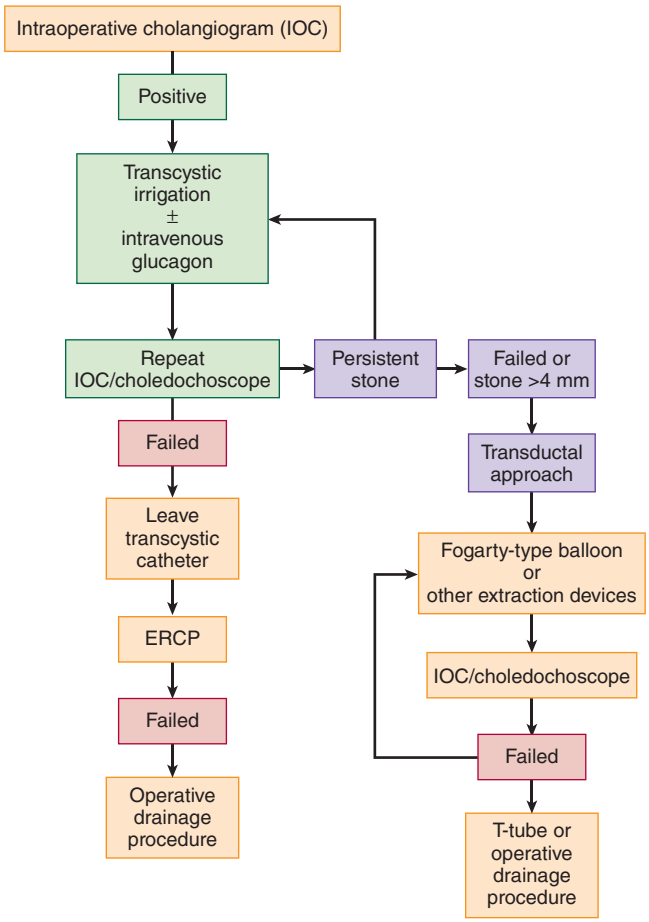

FIGURE 49-5 Algorithm for treatment of intraoperative suspected choledocholithiasis (at cholecystectomy).

combinations of extended-spectrum cephalosporins, metronidazole, and ampicillin; fluoroquinolones as single-agent or in combination with metronidazole; and ureidopenicillins alone or with metronidazole.[116] Anaerobic coverage is felt to be more important in the elderly and those with biliary manipulations. Antibiotics usually are given for 7–10 days, even if biliary decompression has been accomplished during the interim. A retrospective study by van Lent and colleagues evaluated whether continuation of antibiotics is needed after biliary drainage is achieved and signs of inflammation have subsided.[117] Eighty patients who were treated successfully for cholangitis with ERCP were included in the study and followed for 6 months. Forty-one patients received antibiotics for 3 days or less, 19 patients for 4–5 days, and 20 patients for more than 5 days. The three groups were well matched, and the rate of recurrent cholangitis (24%) was not different for the three groups. The authors felt that a 3-day duration of antibiotic therapy may be sufficient in treating cholangitis when adequate drainage has been achieved and fever is abating.

Drainage of the biliary tree is the mainstay of therapy for patients with acute cholangitis.[117] However, the timing and route of biliary decompression vary depending on the response of antibiotics, the cause of the obstruction, and the presence of morbidities.[118] Biliary sepsis will resolve in most patients with conservative therapy, allowing time for a detailed delineation of the biliary anatomy by noninvasive imaging (CT scan or MRI) in order to determine the cause and level of obstruction. However, urgent decompression is needed in the 10–15% of patients who fail to respond within 24 hours to supportive measures and antibiotic therapy.[117] When biliary decompression is not achieved, liver abscesses are inevitable.[117] Mortality approaches 100% in patients who are not subjected to drainage interventions after failing conservative therapy.[119]

The methods of relieving biliary tract obstruction include endoscopic, percutaneous transhepatic, and surgical drainage techniques. With a success rate of 90–98%, ERCP with bile duct clearance is superior to the other methods and is the modality of choice for decompressing the biliary tree during acute cholangitis, particularly if caused by choledocholithiasis.[116,118] In a study of 83 patients with acute cholangitis randomized to undergo either endoscopic or surgical decompression, the mortality was 10% in the endoscopic arm versus 30% in the surgical group.[116] Meanwhile, in an evaluation of 65 patients undergoing endoscopic drainage versus 40 patients receiving traditional surgery for acute cholangitis, 5 operated patients and no individuals subjected to endoscopy died.[120] In comparison with percutaneous drainage, ERCP also has been shown to have lower morbidity, shorter hospitalization, and higher definitive success rates.[116] Sugiyama and colleagues found that in elderly patients (age 80 or older) with acute cholangitis, endoscopic drainage had lower morbidity (16.7%) and mortality (5.6%) than surgical (87.5 and 25%, respectively) or percutaneous drainage (36.4 and 9.1%, respectively).[121]

Various endoscopic treatment options are available from the placement of nasobiliary catheters or biliary stents to sphincterotomy and stone extraction. In patients who have responded to antibiotic therapy, sphincterotomy with bile duct clearance is preferred, whereas drainage catheters are used in those with ongoing sepsis and multiple large stones.[118] In critically ill patients or in those with coagulopathy, concerns about bleeding and increased procedure times are associated with endoscopic sphincterotomy.

In comparing nasobiliary catheters with biliary stents for the treatment of acute cholangitis, a randomized study found both to be equally effective, but stents were more comfortable and avoided the risk of accidental removal.[116]

Percutaneous transhepatic drainage is reserved for patients in whom the papilla is inaccessible or ERCP has failed and for those suspected of hilar cholangiocarcinoma, hepatolithiasis, and intrasegmental cholangitis.[116,118] Although successful in 90% of patients with biliary obstruction, percutaneous drainage has higher rates of morbidity (30–80%) and mortality (5–15%) than endoscopic techniques. As with ERCP, coagulopathy must be corrected prior to the procedure.

Used for almost 100 years, open surgery for acute cholangitis is associated with mortality rates of up to 40%.[116] Surgery may be limited to choledochotomy, decompression, and T-tube

insertion when performed for emergency situations. In patients who have undergone other methods of biliary drainage for the acute situations, surgery offers definitive treatment of the underlying disease and is associated with low mortality when performed electively after the initial treatment.

The need for cholecystectomy after CBD clearance in patients with cholelithiasis has been discussed in the section on choledocholithiasis. To prevent further biliary complications, some have advocated cholecystectomy for patients who are fit after the initial treatment of acute cholangitis. In nonrandomized and retrospective studies, the risk of developing subsequent biliary problems ranges from 4 to 12% in patients with CBD stones.[116] In a study by Boerma and colleagues, 47% of patients who were randomized to a wait-and-see approach after common duct clearance developed biliary symptoms compared with only 2% of patients who were allocated to cholecystectomy within 6 weeks of the endoscopic procedure.[122] Of the wait-and-see patients, 37% eventually needed cholecystectomy. Targarona and colleagues randomized 98 elderly (mean age 80) patients with biliary symptoms to either open cholecystectomy with operative cholangiography and (if necessary) bile duct exploration (48 patients) or to endoscopic sphincterotomy alone (50 patients).[123] There were no significant differences in immediate morbidity (23 and 16%) or mortality (4 and 6%) in the surgery versus endoscopic group. However, at a mean follow-up of 17 months, biliary symptoms recurred in 3 surgical patients, none of whom underwent repeat surgery, and in 10 endoscopic patients, 7 of whom had further biliary surgery. In conclusion, these studies suggest that patients with acute cholangitis should undergo elective cholecystectomy after bile duct clearance if they are able to tolerate an operation. Conversely, in Asian patients in whom bile duct stones may originate from intrahepatic stones, cholecystectomy may not prevent future biliary complications.[116]

HEPATOLITHIASIS

Hepatolithiasis is a primary disease of the biliary ducts and is more refractory to surgical treatment than most other benign diseases of the biliary system.[124,125] The disease is defined as stones in ducts proximal to the confluence of the hepatic ducts regardless of the presence of stones within the gallbladder or CBD. The relative incidence in Western countries is approximately 1%, whereas in Taiwan, South Korea, and China it has been reported to be 20, 18, and 40%, respectively.[126] Originally felt to be common only in Southeast Asia and referred to as *Oriental cholangiohepatitis* and *Hong Kong disease,* the widespread immigration of Asians to the United States has resulted in an increasing number of patients with hepatolithiasis presenting to American surgeons.[124,127] Moreover, the North American experience includes a significant number of Caucasians and Latin Americans. This increasing incidence may be attributed to different etiologies such as primary sclerosing cholangitis, choledochal cysts, and iatrogenic biliary strictures.

The pathogenesis of primary hepatic stones was discussed earlier in the section on choledocholithiasis and appears to involve bile infection; biliary stasis; low-protein, low-fat diets and malnutrition; and parasitic infections.[1] Brown pigment stones (calcium bilirubinate) are the most common stones and cholesterol stones are the most common of the other forms found. Hepatolithiasis presents with recurrent pyogenic cholangitis and sepsis, complicated by parenchymal infection and liver abscesses, obstructive cholangiopathy, and subsequent parenchymal destruction and atrophy of involved lobe.[125,127,128] The natural course of the disease may lead to the development of biliary cirrhosis, portal hypertension, and liver failure and is complicated by cholangiocarcinoma in about 10% of patients.[124,125,129]

The diagnostic procedures used in establishing the diagnosis of hepatolithiasis include ultrasonography, CT scan, MRI, and direct (either endoscopic or percutaneous) cholangiography.[18,125,130,131] Characterizing features include varying combinations of ductal dilatation, intrahepatic and extrahepatic bile duct stones, segmental ductal strictures, and lobar or segmental atrophy. In acute exacerbation, parenchymal or ductal contrast enhancement, abscess formation, or biliary obstruction may be noted.[125]

The management of hepatolithiasis is difficult and far from satisfactory. The principles of treatment are centered on the decompression of abscesses, removal of stones, dealing with recurrences and anticipating the development of malignancy. More than two-thirds of patients undergo multiple surgical procedures, and 10% ultimately require liver transplantation for liver failure.[124] Initial biliary decompression usually can be achieved by endoscopic or percutaneous transhepatic drainage.[128] The goal of definitive treatment is complete removal of all bile duct stones and elimination of bile stasis at the sites of intra- or extrahepatic strictures.

If the stones and strictures are located in a single segment or lobe of the liver, hepatic resection generally is recommended.[124,128,132–135] Interestingly, there appears to be a predisposition for the left lobe of the liver. Resection is particularly important for patients with parenchymal atrophy and stricture of the intrahepatic ducts who may have concomitant cholangiocarcinoma.[124] Even with resection, a significant number of patients will have recurrent disease. Kim and colleagues evaluated their experience with hepatectomy in 44 patients with hepatolithiasis by dividing them into two groups, those with intrahepatic biliary stricture and those without it.[136] At a median follow-up of 65 months, the incidence of residual or recurrent stones was 36% for those with stricture and 11% for those without. The rate in late cholangitis was higher in the stricture group (54%) versus the no-stricture group (6%), as was the initial failure rate (50 vs 31%, respectively). Intrahepatic stricture recurred in 46% of the stricture group versus none in the no-stricture group, with stricture reoccurrence seen at the primary site in two-thirds. Therefore, the importance of including the strictured duct in the hepatic resection is emphasized by this study.

Nevertheless, the number of patients in whom resection is feasible is limited secondary to the diffuse and multifocal

nature of the disease.[132] If stones are located predominantly in the extrahepatic ducts or at the primary convergence and there is minimal stenosis of the intrahepatic ducts, it may be possible to use endoscopic treatment. When stones or strictures are located at the secondary convergence or beyond, surgery and percutaneous transhepatic cholangioscopic lithotripsy have a complete stone clearance rate of 84–100% and 72–92%, respectively.[124] However, the stone recurrence rate is high, ranging from 33 to 40%. Hepaticojejunostomy has been used in the past to prevent biliary-enteric regurgitation and to decrease stagnation of debris and calculi in the intrahepatic ducts. The use of hepaticojejunostomy is controversial and refuted by others, who claim that increased biliary complications occur in patients with hepaticojejunostomies in the setting of hepatolithiasis.[124] However, adding a cutaneous stoma to the Roux limb of the hepaticojejunostomy creates an access point for entering the biliary system for treating future complications.[137] A more appealing alternative to a stoma is the creation of a Hutson loop. This entails tacking the jejunal loop of the biliary-enteric anastomosis to the abdominal wall and clearly marking it with staples or a metal ring such that it can be easily accessed by percutaneous means. We believe that this option should be considered in every patient that undergoes surgery.

With the advent of biliary endoscopy and radiological intervention, percutaneous choledochoscopic removal of intrahepatic stones has been well established.[138] Stones can be removed via cholangioscopic guidance with basket forceps or lithotripsy, and strictures can be dilated. In a study from Hong Kong, 79 patients with intrahepatic stones underwent percutaneous transhepatic choledochoscopy.[138] The success rate was 76.8%, with a complication rate of 21.5%. Cholangitis occurred within 3–5 years in one-third of the patients after the procedure. Another study found that recurrent calculi are more common in the setting of bile duct strictures, and addressing the strictures is mandatory part of treatment.[139] Meanwhile, one study of percutaneous transhepatic cholangioscopic lithotripsy reported a biliary clearance rate of 100%, with a mean of two sessions required and a complication rate of 6.7%.[132] During the follow-up period of 1–127 months (mean 75 months), one recurrence was noted and treated by repeat choledochoscopy. Others have used percutaneous intracorporeal electrohydrolic lithotripsy for hepatolithiasis. Using this technique, in a series of 53 patients, complete clearance of stones was achieved in 92%, and during a mean follow-up of 5 years, 9% had recurrent symptoms of biliary obstruction.[140] Han and colleagues described the use of laparoscopy in the treatment of intrahepatic stones.[129] A flexible choledochoscope, inserted through a choledochotomy, was used for stone removal in 12 patients, with a mean operating time of 288 minutes. Remnant stones were found in only one patient and removed by percutaneous choledochoscopy performed through the T-tube site. No cholangitis or recurrent stones were found at follow-up at 10–45 months.

The most recently documented North American experience describes treating 42 patients between 1986 and 2005 at the University of Toronto.[133] They operated on 17 patients (46%) for indications of lobar atrophy or stones confined to a single lobe. Patients who underwent an operation were found to have less need for reintervention. The incidence of cholangiocarcinoma was 12%, including patients who were diagnosed at initial presentation.

Although the evolution of this disease is unclear, it will likely continue to challenge us. With lessons learned from more common biliary pathologies and the application of novel technologies, we would anticipate better outcomes for our future patients.

CHOLEDOCHAL CYST AND BENIGN BILIARY STRICTURES

Purvi Y. Parikh • Keith D. Lillemoe

Benign conditions of the intra- or extrahepatic bile ducts can range from focal or diffuse dilations (choledochal cyst) to obstructive strictures of the biliary tree. Historically, choledochal cyst disease was considered a disease of childhood but is increasingly being recognized in adults. In the United States, benign biliary strictures most commonly occur as a result of injury after cholecystectomy but also occur in a number of diverse inflammatory conditions affecting the biliary tree. Both conditions represent significant clinical challenges where proper evaluation and management are paramount to prevent serious clinical sequelae.

CHOLEDOCHAL CYST

Choledochal cysts are focal or diffuse dilations of the biliary tree and, aside from biliary atresia, are the most common congenital abnormality of the biliary tree. Choledochal cysts can occur as single or multiple cysts throughout the extra- or intrahepatic bile ducts. The cysts can predispose patients to recurrent cholangitis or pancreatitis, choledocholithiasis, secondary biliary cirrhosis, biliary stricture, and malignancy.

The incidence of choledochal cysts varies significantly throughout the world. Choledochal cysts appear to be most common in Asian countries with an estimated incidence of 1 in 13,000 and have been reported to be as high as 1 in 1000, in reports from Japan. In Western countries, choledochal cysts occur much less frequently, with reported rates that vary from 1 in 150,000 to 1 in 2 million live births.[1] Biliary cysts are four times more common in women compared with men. Approximately 60% of patients with choledochal cysts present during their first decade of life and 25% present in adults.[2] There are a few case reports of choledochal cysts occurring within families but generally do not have a recognized hereditary pattern.

Classification

The anatomy of choledochal cyst disease was first described by Vater in 1723 and in 1959 Alonso-Lej categorized three types of choledochal cysts.[3] The classification system was revised by Todani and colleagues in 1977 to the five cyst categories[4] that are in use today (Table 50-1). A similar classification has been proposed based on bile duct cholangiographic appearance.[5] A further Todani classification reflects the presence or absence of pancreaticobiliary maljunction; however, this revision has not widely been accepted.[6]

Traditionally, the classic type and most common choledochal cyst is type I disease: (A) cystic (Fig. 50-1A), (B) saccular, or (C) fusiform dilation of the extrahepatic biliary tree. Type II cysts are simple diverticula of the common bile duct, which are usually extrahepatic, supraduodenal, and saccular (Fig. 50-1B). A rare combination of type I cystic dilation and type II diverticulum was reported in a few cases representing a mixed type. Type III cysts, also known as *choledochocele*, is a cystic dilation of one segment of the bile duct (Fig. 50-1C). Manning and colleagues[7] described two anatomic variations of intraduodenal choledochocele. The most frequent variety is with the common bile duct and main pancreatic duct entering into the choledochocele separately. The second variety of intraduodenal choledochocele is essentially a diverticulum off the common bile duct at the level of the ampulla of Vater, with the pancreatic duct entering the end of the common bile duct in the usual location. Multiple dilations of the intra- and extrahepatic biliary tree are known as type IV cysts divided into types IVa and IVb. Type IVa represents fusiform extra- and intrahepatic cysts (Fig. 50-1D). Type IVb consists of multiple extrahepatic cysts (Fig. 50-1E). Type V cyst, Caroli's disease, is confined to the entire liver or a solitary lobe, usually on the left (Fig. 50-1F).[2,3] This disease may be associated with periportal fibrosis and cirrhosis leading to subsequent hepatosplenomegaly and portal hypertension.

While Todani's 1977 schema is the most widely accepted classification, it is not without controversy. Some have argued that the term "choledochal cyst" should refer to only type I and IV cysts (which comprise over 90% of biliary cysts).[8] This proposal is based on current understanding of pathogenesis, treatment, malignancy risk, and natural history, which vary substantially with types I and IV cysts versus types II, III, or V cysts. A recent paper from Indiana University questioned

TABLE 50-1: ALONSO-LEJ/TODANI MODIFICATION OF THE CLASSIFICATION OF CHOLEDOCHAL CYSTS

Type I	Classic cyst type characterized by cystic dilation of the common bile duct; most common, comprising 50–80% of all biliary cysts; subdivided into IA (cystic), IB (fusiform), and IC (saccular)
Mixed types I and II	Fusiform dilation of the extrahepatic biliary tree in combination with a separate diverticulum, midportion of the common bile duct, with cystic duct entering in the right of the diverticulum, comprising < 1%
Type II	Simple diverticulum of the extrahepatic biliary tree, comprising 2–3% of all cysts; located proximal to the duodenum
Type III	Cystic dilation of the intraduodenal portion of the extrahepatic common bile duct; also known as a choledochocele; comprise approximately <10%
Type IV	Involve multiple cysts of the intra- and extrahepatic biliary tree; subdivided into types IVa (both intra- and extrahepatic cysts) and IVb (multiple extrahepatic cysts without intrahepatic involvement); type IVA is the second most common type of biliary cyst, comprising 30–40%, type IVB comprising <5%
Type V	Isolated intrahepatic biliary cystic disease, also known as Caroli's disease; associated with periportal fibrosis or cirrhosis; can be multilobar or confined to a single lobe, comprising <10%

whether choledochoceles were truly choledochal cysts. They reviewed 146 patients with choledochal cysts and identified 28 patients with choledochoceles. They concluded that classifications of choledochal cysts should not include choledochoceles because they differ from choledochal cysts regarding age, gender, presentation, pancreatic ductal anatomy, and their management.[9]

Pathogenesis

The cause of choledochal cysts is unknown. While there have been reports of acquired cysts in the literature, most are congenital in nature. There may be multiple mechanisms involved in the creation of biliary cysts, and several theories have been proposed.

The high incidence of biliary cysts in Asia suggests a role for either genetic or environmental factors. The first theory pertains primarily to the pathogenesis of Caroli disease and is related to a defect in maturation with ductal plate malformation. This defect can be either sporadic or inherited, with both autosomal-recessive and, rarely, autosomal-dominant inheritance patterns seen in families. Ductal plates describe the development of intrahepatic liver progenitor cells that are in contact with the mesenchyme of the portal vein and are then remodeled into mature ducts. Defective bile duct plate remodeling during embryogenesis results in inflammation and ulceration of biliary epithelium into larger bile ducts. These ducts then become segmentally dilated in a focal, lobar, or multilobar distribution.[10]

The second theory for the etiology of choledochal cyst formation is that bile duct obstruction or distention in the prenatal or neonatal periods may contribute to biliary cyst formation. The obstruction may be secondary to a stricture, web, or sphincter of Oddi dysfunction. With distal biliary obstruction there is pancreatic juice reflux into the biliary tree, resulting in chronic inflammation and increased bile duct pressure leading to dilation.[11] In animal models, bile duct ligation in neonates leads to cyst formation; in contrast, bile duct ligation in adult animals results in gallbladder distention.[12] In addition, there are case reports of a congenital web at the lower end of the common bile duct and antenatal choledochal cyst with distal common bile duct formation.[13]

The most common proposed theory for choledochal cyst formation is related to pancreaticobiliary maljunction.[14] Pancreaticobiliary maljunction is defined as an extramural junction of the pancreatic and biliary ducts in the duodenum beyond the intramural sphincter function and is characterized by a long common channel. On average, patients with this anomaly have a common channel that is 1.86 cm compared with 0.46 cm in patients with a normal junction.[15] In the literature, pancreaticobiliary maljunction has been reported in 57–96% of patients with choledochal cyst disease (Fig. 50-2).[16] Pancreaticobiliary maljunction is also thought to be a significant risk factor for the development of cholangiocarcinoma in the biliary cyst,[17] as well as the development of gallbladder cancer. Several investigators have speculated on the embryologic etiology of pancreaticobiliary maljunction, hypothesizing that the development of pancreaticobiliary maljunction is a result of an arrest in the migration of the choledochopancreatic junction into the duodenal wall.[18]

Because of the long common channel, patients with pancreaticobiliary maljunction may have increased reflux of pancreatic juice into the biliary tree, because the ductal junction lies outside the sphincter of Oddi and cannot prevent the mixing of bile and pancreatic juices.[19] The mixed juices then have the potential of stagnating in the ducts or gallbladder, resulting in a cycle of inflammation, activation of proteolytic enzymes, theoretical biliary epithelial damage, alterations in bile composition, and ductal distention. It is thought that a combination of these factors contributes to the development of malignancy within the choledochal cyst or gallbladder. Elevated sphincters of Oddi pressures have also been documented in patients with pancreaticobiliary maljunction, resulting in more reflux.[20,21]

On pathology, choledochal cysts have variable microscopic features, with appearance ranging from normal bile

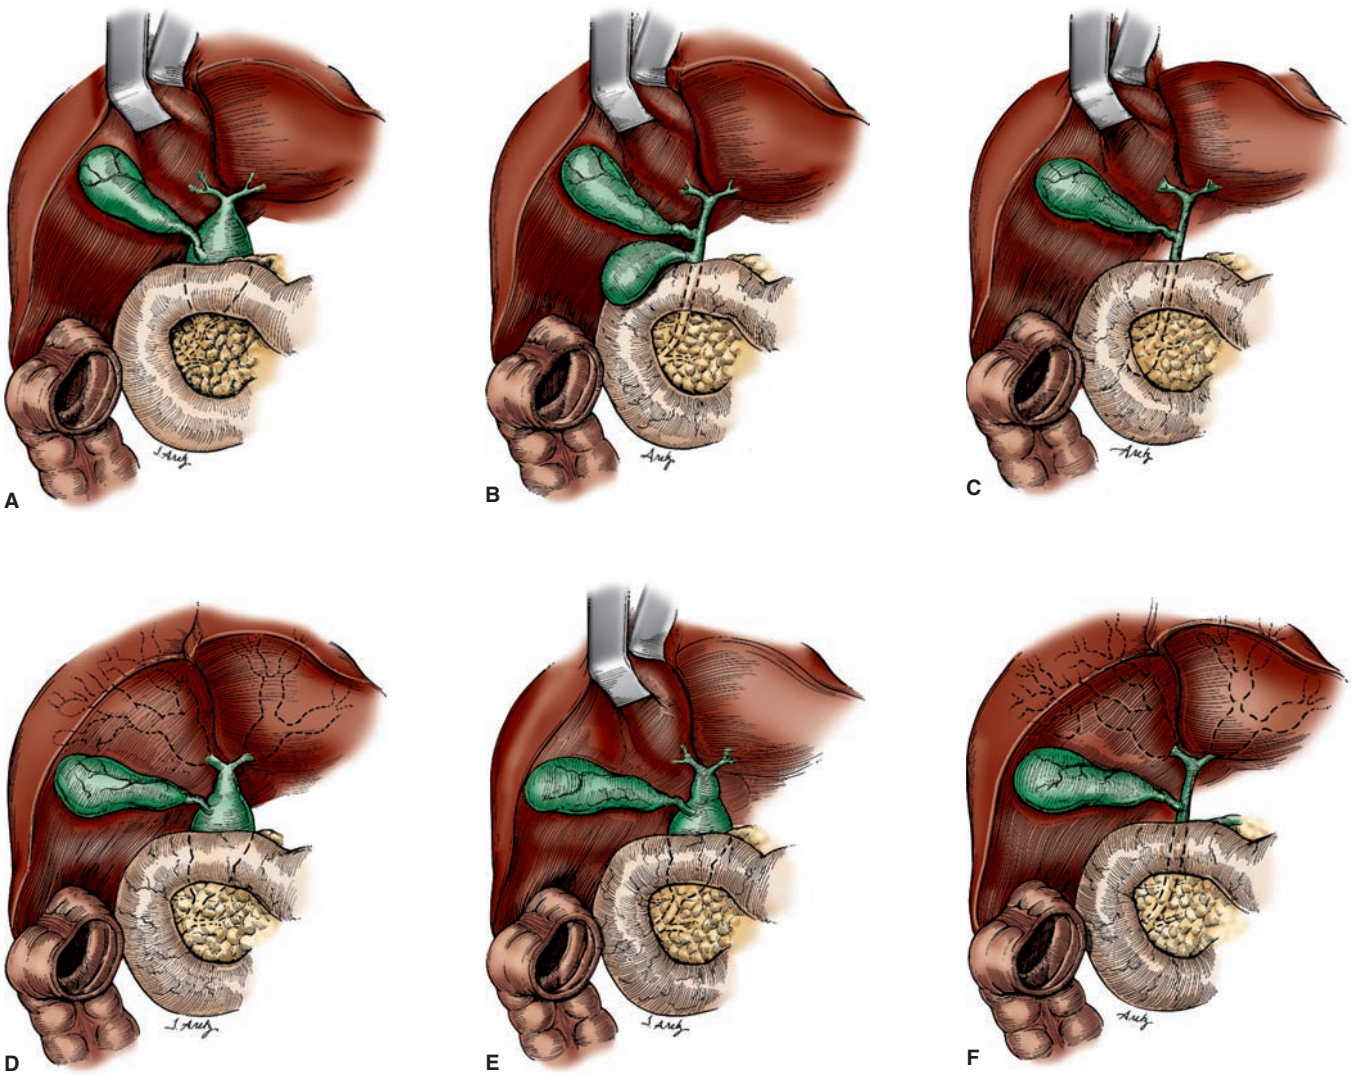

FIGURE 50-1 Illustrations of the Todani classification of choledochal cysts. **A.** Type IA. **B.** Type II. **C.** Type III. **D.** Type IVA. **E.** Type IVB. **F.** Type V.

duct mucosa to carcinoma. In children, the classic histologic appearance is a thick and dense fibrotic cyst wall with evidence of acute or chronic inflammation. In adults, common findings are inflammation, erosions, sparseness of mucin glands, and metaplasia.[1,22] Type III cysts are most often lined by duodenal mucosa, although they sometimes are lined by bile duct epithelium.[22] When malignancy is present, it is most commonly found along the posterior cyst wall.[23]

Presentation

Choledochal cyst disease can present with a vast spectrum of symptoms. The classic triad of presentation of a choledochal cyst is a female child with jaundice, abdominal pain, and right upper quadrant abdominal mass. This triad is found in only a minority of children at the time of presentation. Infants commonly present with elevated conjugated bilirubin (80%), failure to thrive, or an abdominal mass (30%). An abdominal mass becomes less common with increasing age and is rarely appreciated in adults. In adults, abdominal pain and recurrent cholangitis are the most common presentations.[24] The abdominal pain usually mimics that of calculous cholecystitis and many patients do have gallstones either in the cyst or in the gallbladder. Almost 38% of adult patients have had a cholecystectomy before the diagnosis of a choledochal cyst because of right upper quadrant pain, which was attributed to gallbladder disease.[25] Intermittent jaundice and recurrent cholangitis are also common, as is pancreatitis (30%), especially in patients with a type III cyst

FIGURE 50-2 Pancreaticobiliary maljunction.

(choledochocele).[1,9,26] Rarely, choledochal cysts will present as intraperitoneal rupture or bleeding due to erosion into adjacent vessels.

Diagnosis

The diagnosis of a choledochal cyst requires a high level of suspicion. Unless choledochal cyst is considered in the differential diagnosis in patients with ductal dilation, type I cysts may go undiagnosed. Patients with biliary obstruction, either acutely or chronically, may also have biliary dilation that can mimic a type I cyst. In contrast to a type I cyst, an obstructing lesion will often cause elevated alkaline phosphatase and bilirubin, as well as improvement in biliary dilation after appropriate treatment. The presence of pancreaticobiliary maljunction in uncertain cases can also be helpful in making the diagnosis of a type I cyst versus a biliary obstruction.

Ultrasonography is the most common first-line imaging tool and was used in 93% of the pediatric population and 72% of the adult patients in The Johns Hopkins series.[25] While ultrasound is the standard for antenatal and childhood diagnosis, computed tomography (CT) scan may be more appropriate in adult patients, in whom the differential diagnosis is broader. Important considerations on CT scan (Fig.50-3) include assessing the hepatobiliary and pancreatic anatomy, with evaluation for possible biliary malignancy, metastatic disease, and vascular encasement.

Ultimately, when choledochal cyst disease is suspected on imaging, visualization of the pancreatic, intrahepatic,

FIGURE 50-3 **A.** CT scan appearance of type IA choledochal cyst (*arrow* shows sludge within the cyst). **B.** CT scan appearance through the liver demonstrates multiple low-density structures (*arrows*) within the right and left lobe consistent with a type IVA choledochal cyst.

and extrahepatic ductal anatomy is required. Magnetic resonance cholangiopancreatography (MRCP) has become the noninvasive procedure of choice for the diagnosis of choledochal cyst. As quality of MRCP has improved, many surgeons now consider MRCP the only imaging technique needed for diagnosis and operative planning. Park and colleagues[27] retrospectively reviewed 72 adult patients who underwent both MRCP and endoscopic retrograde cholangiopancreatography (ERCP) and found that when compared with ERCP, MRCP was accurate 100% of the time with types IVb and V cysts.

Cholangiography has been considered the gold standard for diagnosis of choledochal cysts but now is necessary as

FIGURE 50-4 Percutaneous cholangiogram via the right hepatic duct. A large type I choledochal cyst is seen. Note the anomalous choledochopancreatic duct junction.

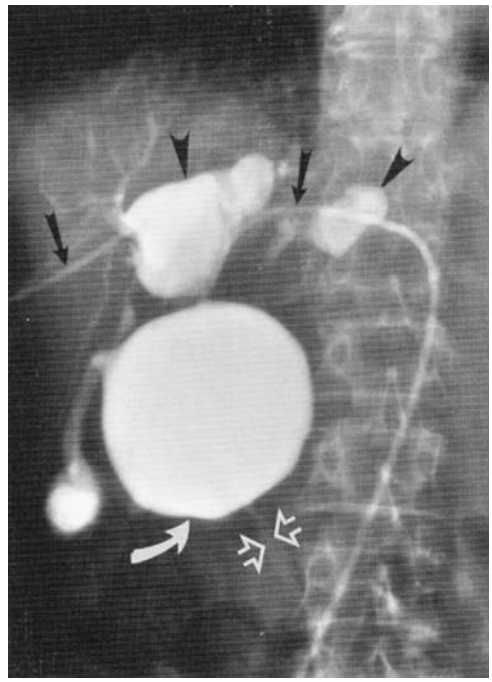

FIGURE 50-5 Type IVA choledochal cyst. Bilateral percutaneous biliary drainage catheters (*arrows*) were placed in this patient, who had extensive intrahepatic biliary duct dilation (*arrow-heads*) and a huge extrahepatic choledochal cyst (*curved arrow*). Note that the biliary catheters exit the cyst and enter the duodenum (*open arrows*).

primarily a therapeutic procedure to place stents to relieve jaundice or cholangitis or to obtain brushings for cytology. Cholangiography can demonstrate areas of cystic dilation, the presence of stones, and exclude complete obstruction of the bile duct (Fig. 50-4). It is also effective in demonstrating the presence of pancreaticobiliary maljunction. Percutaneous transhepatic cholangiography (PTC) or ERCP is typically performed on adults and larger children. In small children, ERCP is not the ideal tool because it involves the use of general anesthesia can lead to pancreatitis and may not define the very proximal biliary anatomy, which tends to be abnormal. Therefore, in children intraoperative cholangiography may be used. The use of MRCP in children is increasing as experience with MRCP grows, and its technological accuracy may rival that of endoscopic evaluation. However, patients with type I or type IV cysts that extend to the hepatic bifurcation, PTC allows for excellent imaging of the entire biliary system and the placement of one or two transhepatic biliary catheters that may be helpful to facilitate complete resection and biliary reconstruction (Fig 50-5). To decrease the high risk of pancreatitis in patients with pancreaticobiliary maljunction and a long channel, it is important to avoid placing the stent through the ampulla while performing PTC.

Management

Once the diagnosis of choledochal cyst is made and the patient's biliary anatomy is delineated through preoperative imaging, several important clinical considerations must be taken into account. If a patient presents with pancreatitis or cholangitis, these problems must be treated supportively prior to considering definitive operative management of the biliary cyst. Because of the extensive sludge or stones that may be present within choledochal cysts and the high incidence of pancreaticobiliary maljunction, these patients are at especially high risk for pancreatitis. Furthermore, there is a risk of pancreatitis during ERCP with ampullary stent placement.

Another important clinical consideration in patients with choledochal cysts is the presence of malignancy. The most common malignancy associated with choledochal cyst disease is cholangiocarcinoma, although other malignant neoplasms have been reported, including gallbladder cancer, adenocarcinoma, and bile duct sarcoma. The incidence of cholangiocarcinoma with biliary cysts varies with patient age and cyst type. The lifetime risk of associated cholangiocarcinoma is as high as 26% in some studies, and, importantly, the rate of malignancy increases with age. Patients discovered in their twenties have only a 2.3% risk of concomitant malignancy, but it increases to 14.6% for patients with choledochal cysts discovered in their thirties and forties.[8,12,22,28] In older untreated patients, the reported incidence of cholangiocarcinoma is as high as 75%.[29]

Types I and IV have a higher risk of cancer, while cancer is rare in types II and III cysts. In type III cysts, cancer risk may be limited to those choledochoceles lined by biliary and not duodenal epithelium.

Historically, choledochal cyst presenting in childhood were often treated with a cyst-enteric bypass leaving the cyst in situ. These patients remain at risk for the development of cancer within the retained cyst.[29] Caroli's disease also carries a risk (about 7%) of cholangiocarcinoma. Most patients with Caroli's disease, however, will present first with compromised liver function or cholangitis before developing malignancy. The Johns Hopkins series had 92 choledochal cyst patients with 8 of them being diagnosed with cancer at the time of surgery or in follow-up. Every cyst type except types II and III was involved with cancer. None of the patients who had a complete cyst excision developed cancer after a mean of 10 years of follow-up. However, this population was still at a greater risk of malignancy than the general population.[25] Malignancy may develop with incompletely resected cysts, at the anastomotic site, or in residual cyst left within the pancreas.[29]

Speculated etiological factors in carcinogenesis associated with biliary cysts include bile stasis, reflux of pancreatic juice mixed with bile, superinfection, or inflammation.[29,30] Cholangiocarcinoma in choledochal cysts is strongly linked to patients with pancreaticobiliary maljunction.[17] There is strong pathologic evidence of a hyperplasia-dysplasia-carcinoma sequence of carcinogenesis in patients with pancreaticobiliary maljunction. While the exact pathways have yet to be elucidated, cells with hyperplasia in patients with pancreaticobiliary maljunction have elevated expression of cellular proliferation markers, including cyclooxygenase-2 and vascular epithelial growth factor.[31] On a molecular level, hyperplastic cells also have a high incidence of K-*ras* mutations (13–63%)[32,33] while dysplastic cells frequently have microsatellite instability (60%)[34] and cancerous lesions often have over expression of cyclin D1[35] and *p53* mutations.[36] Prophylactic cholecystectomy is also advised in all patients with either pancreaticobiliary maljunction or choledochal cyst.

In addition to the continued risk of cancer after excision, the most frequent long-term complication after biliary reconstruction is postoperative biliary stricture at the site of the anastomosis (~25%).[37] Therefore, long-term follow-up should include surveying patients for the development of an anastomotic stricture. Significant elevations in serum alkaline phosphatase levels merit further investigation and treatment to prevent long-term complications from postoperative biliary strictures.

Unfortunately, current methods for screening for malignancy within a choledochal cyst have not proved effective, and therefore expectant management cannot be advised for most patients. Intraductal ultrasound and cytologic brushings of the cyst wall show promise for potentially detecting malignancy. Patients with choledochal cysts who are poor candidates or who refuse biliary reconstructive surgery may be candidates for lesser interventions to treat symptoms caused by gallstones or sludge, such as cholecystectomy or endoscopic treatment.

OPERATIVE MANAGEMENT

Historically, choledochal cysts were managed with biliary-enteric drainage via cyst-enterostomy. Recognition of an increased risk of bile duct and gallbladder cancer at an average of 10 years[29] after enteric drainage has changed the recommended management to complete cyst excision. The current treatment of choice is surgical excision, as it is well documented to lead to a decrease in the rate of malignancy from 16 to less than 1%.[25,29] The main goal of management is therefore to prevent malignant degeneration of the cyst via surgical excision. In newly diagnosed adult patients with biliary cysts, the possibility of an existing cancer needs to be considered.

The operative management of choledochal cysts should first consist of careful exploration of the patient. Upon entry to the abdomen via a midline incision, the initial step should be searching for possible metastatic disease. Once metastatic disease has been excluded, management of the choledochal cyst consists of cholecystectomy and complete cyst excision. If possible, excision should include all remnants of the cyst. Because of the extensive fibrosis that may be present, complete excision of the cyst can be technically challenging. Following cholecystectomy and choledochal cyst excision, the bile duct is reconstructed. Standard methods to reconnect the bile duct include hepaticojejunostomy or hepaticoduodenostomy, although Roux-en-Y hepaticojejunostomy is by far the most commonly used technique.

Enteric interposition grafts have been proposed as an option because of theoretical restoration of physiologic bile flow. Both jejunal interposition grafts and appendiceal interposition grafts between the duodenum and bile duct have been reported in the pediatric surgery literature. The value of these techniques, however, has been questioned because of graft dysfunction from stenosis and kinking.[38]

Successful resection and biliary reconstruction with types I and II choledochal cysts has also been reported using laparoscopic techniques, particularly in children.[39] A recent review of 35 adult patients with choledochal cysts that were resected laparoscopically was done, which showed a 0% mortality, 8.5% conversion rate, and 14.8% morbidity rate. Thus, showing that laparoscopic surgery for choledochal cysts was feasible, safe, and even advantageous.[40] While the choice of performing these procedures via an open or laparoscopic approach should be a matter of preference and technical ability for the surgeon, it is important that the procedure not be compromised by the use of laparoscopy.

Type I Cysts. The surgical approach recommended for type I is complete cyst excision with Roux-en-Y hepaticojejunostomy reconstruction. The technical aspects of this operation involve mobilization of the hepatic flexure and wide Kocher's maneuver to expose the distal portion of the cyst that lies posterior to the duodenal wall (Fig. 50-6A). After the cyst has been exposed, the gallbladder, which usually arises from the midportion of the choledochal cyst, should be dissected away from the hepatic bed (Fig. 50-6B). The

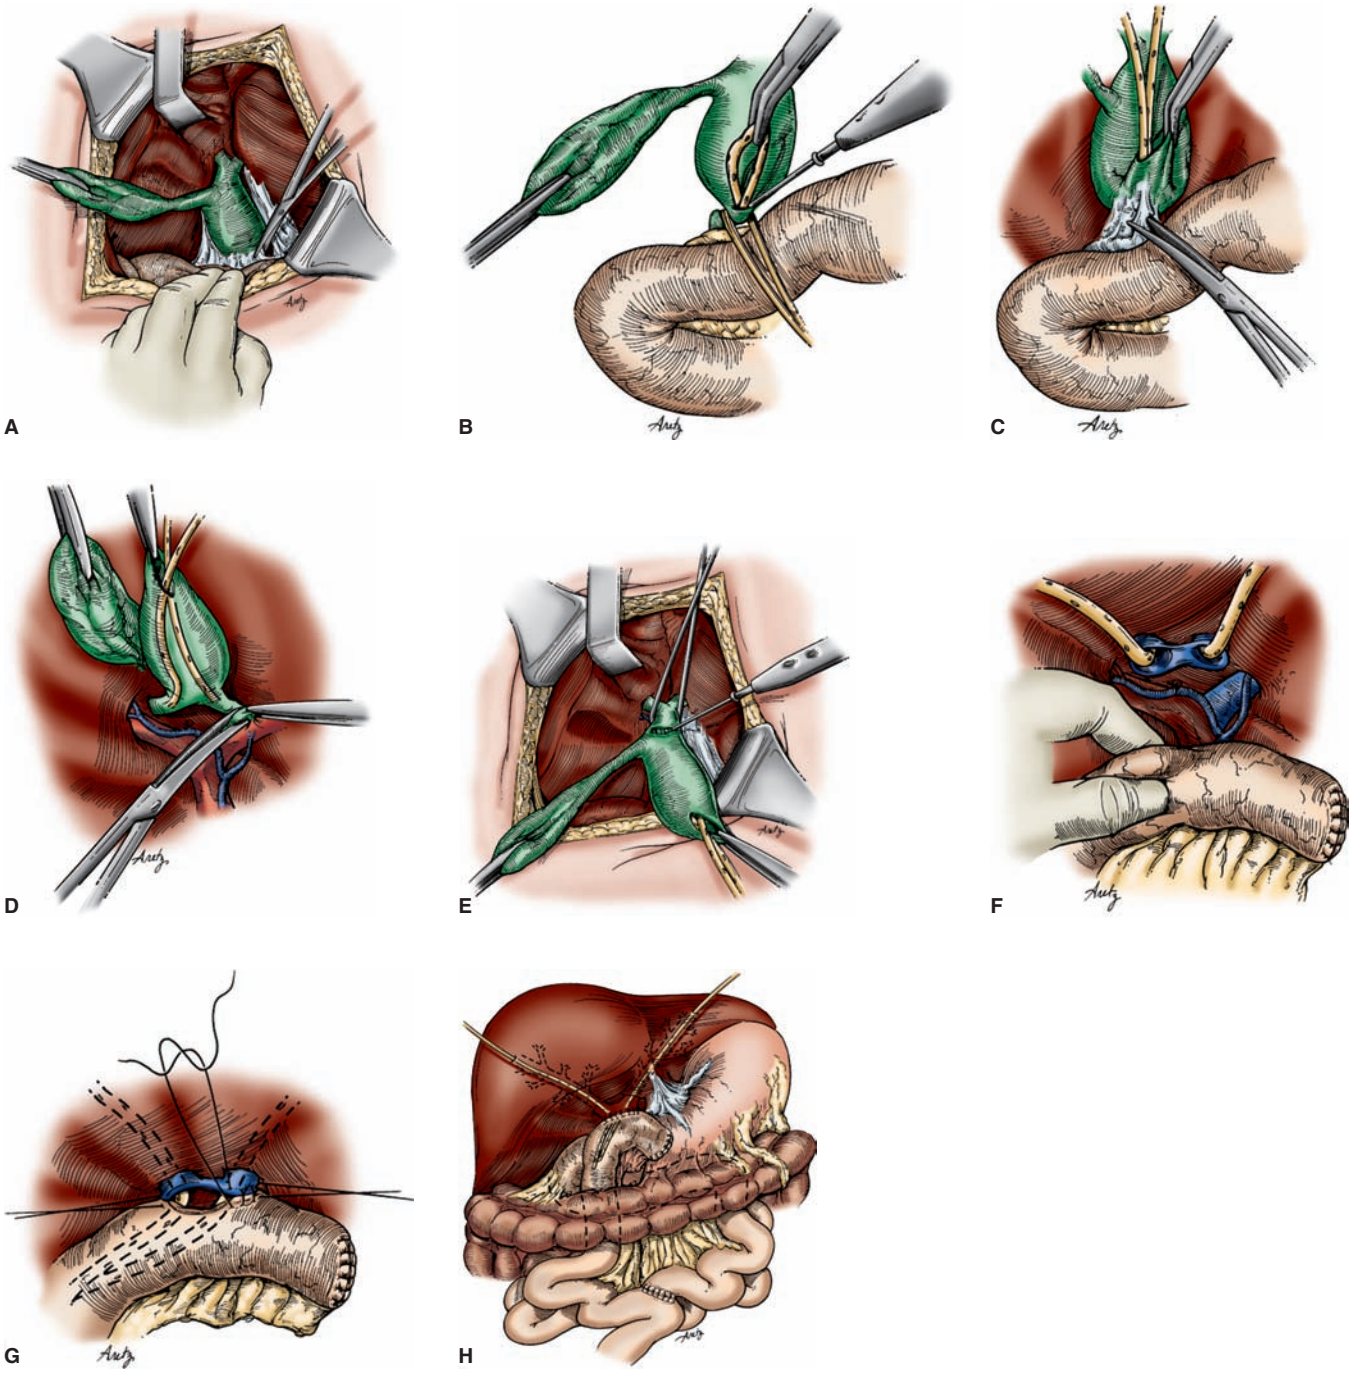

FIGURE 50-6 Type I choledochal cyst resection and biliary reconstruction with Roux-en-Y hepaticojejunostomy. **A.** Exposure of cyst and gallbladder. **B.** Cholecystectomy and anterior dissection of the distal choledochal cyst. **C.** Distal extent of the cyst identified, encircled, and opened. **D.** Posterior dissection proceeds caudad to cephalad. **E.** Dissection proceeds until normal hepatic duct is identified. **F.** Cyst is transected and removed at normal duct. **G.** Excision is complete; reconstruction proceeds with a Roux-en-Y hepaticojejunostomy. If the bifurcation is involved, right and left hepaticojejunostomies can be performed. **H.** One-layer hepaticojejunostomy at the hepatic bifurcation.

procedure then focuses on the distal portion of the choledochal cyst (Fig. 50-6C). Type IB (fusiform) cysts are particularly prone to extend distally within the common bile duct as it enters the dorsal aspect of the pancreas. The goal is then to excise the intrapancreatic portion of the cyst without injuring the pancreatic duct or the long common channel. Resection of the pancreatic head can usually be avoided unless there is documented malignancy. The distal portion of the cyst is encircled and transected as it enters into the pancreas and then reflected cephalad (Fig. 50-6D).

This allows posterior dissection and identification of the portal vein and hepatic artery. The dissection may be facilitated by the presence of a preoperatively placed transhepatic stent. The dissection is continued until the most proximal portion of the duct at the hilum. The cyst is then resected at the hepatic duct confluence or more proximally if the cyst extends into the individual hepatic ducts (Fig. 50-6E). The excised cyst should be examined grossly for malignancy, and then the specimen should be sent for frozen section. If malignancy is present at the surgical margins, the resection may be extended either proximally or distally with the possibility of a pancreaticoduodenectomy to obtain negative margin and adequate lymph node dissection.

Reconstruction of the biliary tree is typically preformed with a Roux-en-Y hepaticojejunostomy at the bifurcation with a single anastomosis or multiple individual anastomoses with each of the hepatic ducts (Fig. 50-6F). A suitable segment of intestine is mobilized with a Roux-en-Y jejunal limb, approximately 60 cm in length, and the anastomosis is created with a standard retrocolic end-to-side Roux-en-Y hepaticojejunostomy, using a single layer of absorbable suture (Fig. 50-6G and 50-6H).

Type II Cysts. The recommended procedure for type II choledochal cysts is complete cyst excision. After the cyst has been exposed, the common bile duct wall defect should be closed transversely with or without a T-tube. A transverse closure helps minimize potential narrowing or stricturing of the common bile duct. These patients should also undergo a cholecystectomy at the time of cyst excision. Recently, resection of type II cysts has been completed successfully via a laparoscopic approach.

Type III Cysts. Because these cysts are unusual and have an overall lower rate of malignant transformation, reports of surgical excision of choledochoceles are uncommon. Primary management of choledochoceles is by ERCP with endoscopic unroofing of the choledochocele and sphincterotomy of the common bile duct.[9,41] Surgical management is much less common in patients with choledochoceles compared to patients with other choledochal cysts. Surgical intervention for choledochoceles is needed for patients where sphincterotomy is very difficult or there is concern for malignancy, although very uncommon.

The surgical approach for choledochoceles involves complete excision of the cyst and is approached via transverse duodenotomy in the second or third portion of the duodenum. Before the duodenotomy, cholecystectomy is performed and then the ampulla can be localized by passing a biliary Fogarty catheter into the duodenum via the transected cystic duct. The anatomy can also be better defined via extensive Kocher's maneuver and intraoperative ultrasound. The common bile duct and pancreatic duct must be identified to prevent injury to the pancreatic duct. After the duodenotomy, the pancreatic duct should be intubated with a small Silastic tube so that the intraduodenal biliary cyst can be excised. The cyst is excised and a sphincterotomy can be done by suturing the duodenal mucosa to the bile duct mucosa and pancreatic duct mucosa individually using interrupted absorbable sutures. A piece of 5 or 8F plastic tubing can be placed into the pancreatic duct and secured with a single absorbable suture as a temporary stent to prevent acute pancreatitis. Finally the duodenotomy is closed in a transverse fashion. It is highly unlikely that a Whipple procedure is required and should be considered only if malignancy is suspected.

Type IV Cysts. Types IVa and IVb cysts are managed similarly to type I cysts regarding cholecystectomy, extrahepatic cyst excision, and biliary enteric anastomosis. However, the procedures are technically more challenging, and complete removal is not always possible for type IV cysts because of multiple extrahepatic cysts and intrahepatic cysts. Furthermore, these patients will most likely need reconstruction proximal to the bifurcation and involve anastomosing individual hepatic ducts. If one lobe of the liver predominantly involves the intrahepatic cyst, hepatic lobectomy should be recommended. In many situations, bilobar cyst disease remains leaving this area at risk for malignancy. The long-term management in this situation is controversial. Intrahepatic disease in type IVa disease and Caroli's disease are prone to secondary biliary cirrhosis, hepatic atrophy, and portal hypertension. If the liver parenchyma is not cirrhotic and there is no evidence of intrahepatic duct malignancy, the hepatic parenchyma should be preserved, even in the setting of stones or strictures. If cirrhosis is unilateral or segmental, resection of the involved parenchyma is necessary. Transhepatic biliary stents may be especially helpful for managing patients with type IV cysts, particularly those with type IVa cysts that extend into the intrahepatic ducts. The stents allow for proper decompression alleviating chronic inflammation and may prevent or facilitate the management of long-term complications of biliary stasis, stones, cholangitis, cirrhosis, and be used for surveillance for malignant transformation.

Oncological principles should be followed in cases in which malignancy is involved. If no metastatic disease is present and the vascular supply to the uninvolved hepatic parenchyma can be preserved, resection of the involved bile ducts and adjacent parenchyma and lymph node dissection is indicated. In rare cases, extensive resections involving combined hepatic and pancreatic resection may be necessary. In cases in which metastatic disease is present, palliative stenting of the bile ducts is indicated.

Type V Cysts. Type V choledochal cyst (Caroli's disease) is a difficult condition to manage, and the specific recommendations are not well defined. Current recommendations are to begin with conservative management treating infectious complications with drainage, stone extraction, antibiotics, and ursodiol. While Caroli's disease may be diffuse and bilobar, it is often confined to a single lobe and typically on the left side. Similar to type IVa cysts, Caroli's disease, if unilateral or segmental involvement with cirrhosis, can be managed by resection of the involved parenchyma, resulting in decreased incidence of recurrent cholangitis, pancreatitis, cholestasis, and the need for invasive procedures. Bilobar Caroli's disease is a challenging problem. The use of ursodiol and antibiotics may improve bile flow and reduce the incidence of biliary stones, sludge, and chol-

angitis. In the absence of cirrhosis or malignancy, Roux-en-Y hepaticojejunostomy with bilateral transhepatic Silastic stents may be indicated to improve biliary drainage. Following operative management, the stents are left in place for 6–12 months, depending on the extent of intrahepatic stones and strictures. Patients that continue to have recurrent cholangitis or recurrent stones often require indefinite transhepatic stenting. Patients with Caroli's disease and progressive liver disease and cirrhosis should be considered for liver transplantation. The timing for when transplantation should be pursued is still under debate. Because patients with Caroli's disease may also have polycystic kidney disease, combined liver-kidney transplants have had excellent outcomes.

OPERATIVE RESULTS

Early postoperative complications include pancreatitis, anastomotic leakage, cholangitis, and wound infection. Most series show morbidity of 9–41% and mortality 0–3.3%.[9,25,40] The median length of stay ranges from 7 to 12 days postoperatively, where patients with a laparoscopic approach had a slightly decreased stay but longer operative time. Late postoperative complications include the formation of intrahepatic strictures and stones, anastomotic stricture, malignancy, cirrhosis, and intrahepatic abscess formation.

However, long-term results following resection of a benign choledochal cyst with biliary reconstruction are generally excellent, especially with type I cysts. The rate of biliary stricture had been found be very low. The management of more proximal cysts can be more challenging, particularly in the presence of extensive intrahepatic stone disease and liver damage. Type IVa cyst patients have the greatest risk for intrahepatic calculi and stricture formation secondary to the intrahepatic cystic disease. A series by Tsuchida and associates examined 103 patients with a mean follow-up of 12.5 years. Patients with type IVa disease with dilated intrahepatic ducts developed strictures at a rate 40%, with virtually all developing cholangitis.[42] In contrast, management with large-bore Silastic transhepatic stenting results in 90% success without recurrent cholangitis.[43] Patients remain at long-term risk for cholangitis, postoperative biliary strictures, intrahepatic stones, pancreatitis, or malignancy.

Summary

Choledochal cyst disease is uncommon. The presentation of the disease is more common in children but has been increasing in the adult population, especially in Western countries. Currently, the diagnosis in adults is based on cross-sectional imaging and cholangiography, primarily CT and MRCP. The consequences of not treating choledochal cyst disease can lead to malignant degeneration. The majority of cases of biliary cysts can be treated effectively with cholecystectomy, cyst excision, and biliary-enteric reconstruction. Long-term follow-up is necessary for surveillance of cancer, cholangitis, intrahepatic stones, and postoperative biliary strictures.

BENIGN BILIARY STRICTURES

Benign biliary strictures include several diverse clinical entities that share the common characteristic of biliary obstruction. Although advances in medical technology have greatly improved their management, bile duct strictures continue to pose a significant clinical challenge. Many of these strictures result from iatrogenic injuries, often in young patients who are otherwise in good health and expected to live for years. Improper management may result in life-threatening complications, including cholangitis, portal hypertension, biliary cirrhosis, and end-stage liver disease. Proper diagnosis and treatment are essential in preventing these complications.

Benign biliary strictures may affect the intra- or extrahepatic bile ducts or both, and may be solitary or multiple. There are numerous etiologies of benign bile duct strictures (Table 50-2). The vast majority of strictures occur following injury to the bile duct during cholecystectomy; however,

TABLE 50-2: ETIOLOGY OF BENIGN BILIARY STRICTURES

Congenital Strictures
Biliary atresia
Postoperative Strictures
Laparoscopic cholecystectomy
Open cholecystectomy
Common bile duct exploration
Injury at other operative procedures
Gastrectomy
Hepatic resection
Portacaval shunt
Biliary-enteric anastomotic stricture
Pancreatic surgery
Liver transplantation
Blunt or penetrating trauma
Endoscopic or percutaneous biliary intubation
Strictures Due to Inflammatory and Other Conditions
Primary sclerosing cholangitis
Chronic pancreatitis
Cholelithiasis and choledocholithiasis
Cholangiohepatitis and other parasitic disease
Sphincter of Oddi stenosis
Duodenal ulcer
Granulomatous lymphadenitis
Secondary sclerosing cholangitis
Toxic drugs
Infectious cholangiopathy from AIDS
Hepatic allograft rejection
Graft-versus-host disease in bone marrow transplantation
Histiocytosis X
Congenital biliary abnormality
Mast cell cholangiopathy

other procedures in the upper abdomen may injure the biliary tract, especially procedures involving the liver, pancreas, and stomach/duodenum. Inflammatory conditions such as pancreatitis, gallstone disease, and primary sclerosing cholangitis are also important causes of benign bile duct strictures.

Postoperative Biliary Stricture

The introduction and widespread use of laparoscopic cholecystectomy in the 1990s resulted in a significant increase in the frequency of biliary injuries and associated bile duct strictures. Postoperative bile duct injuries may present early in the postoperative period with biliary leak, or months to years later with jaundice or cholangitis from biliary stricture. Proper management begins with delineation of biliary anatomy followed by repair. Nonoperative balloon dilation via percutaneous transhepatic or endoscopic routes is appropriate in select patients with intact biliary-enteric continuity. Operative repair, however, remains the mainstay of treatment in patients with benign strictures.

INCIDENCE

Most bile duct injuries and strictures occur in patients following abdominal surgery in the right upper quadrant. Cholecystectomy is performed on over 750,000 patients on an annual basis in the United States and accounts for over 90% of postoperative biliary strictures and injuries. Although the exact incidence of injuries is unknown because many cases go unreported, numerous studies have attempted to define the incidence and mechanisms of bile duct injuries associated with cholecystectomy. An incidence of one to three major bile duct injuries per 1000 cases was consistently reported during the era of open cholecystectomy. Roslyn and colleagues demonstrated a 0.2% incidence of major bile duct injuries from a series of over 42,000 open cholecystectomies.[44] A literature review by Strasberg and associates[45] of over 25,000 open cholecystectomies performed since 1980 revealed a 0.3% incidence of major bile duct injuries. In contrast, in a review of nearly 125,000 laparoscopic cholecystectomies reported in the literature in the years 1991–1993, Strasberg and associates reported an overall incidence of biliary injuries of 0.85% and an incidence of major injuries of 0.52%. Multiple large surveys from numerous centers have estimated the rate of major bile duct injury with laparoscopic cholecystectomy to be 0.4–1.3%.[46–49] Therefore it appears that the incidence of bile duct injury associated with laparoscopic cholecystectomy is two to three times greater than that with open cholecystectomy.

In the early 1990s, many authors ascribed the increased incidence of bile duct injuries with laparoscopic cholecystectomy as a "learning curve" associated with the new technique and projected that the rate of injury associated with laparoscopic cholecystectomy would decline with time. Unfortunately, these projections were not correct, and the rate of bile duct injuries appears now to have stabilized at a level still higher than that of the prelaparoscopic era. A report of over 10,000 cases at US military institutions[46] and nationwide reviews in New Zealand[50] and Italy[48] have demonstrated no significant improvement in the incidence of injury as surgeons have passed through the learning curve. It is likely that the technology and technique associated with laparoscopic cholecystectomy will need fundamental enhancements for the current rate of injury to diminish.

PATHOGENESIS

Several factors are associated with increased risk of bile duct injuries at the time of cholecystectomy. Some of these factors may be pathologic, anatomic variations, and/or technical problems that are unique to the laparoscopic approach. Ultimately, the final common pathway of most injuries is either a technical error or misinterpretation of the anatomy. The "classic" biliary injury during laparoscopic cholecystectomy includes misidentification by the surgeon of the common bile duct as the cystic duct or misidentification of an aberrant right sectoral duct as the cystic duct (Fig. 50-7).

Pathologic Factors. A number of patient-related factors have been associated with bile duct injury. Patients with acute cholecystitis may have severe inflammation in the porta hepatis and Calot's triangle, which can make a laparoscopic approach difficult. Patients with complicated gallstone disease also have a higher risk of injury than those with chronic cholecystitis, symptomatic cholecystitis, or biliary colic. Fletcher and colleagues[47] reported that complex cases, which included patients with acute cholecystitis, cholangitis, and gallstone pancreatitis, are associated with an increased incidence of bile duct injuries (1.7 vs 0.6%) versus other indications for laparoscopic cholecystectomy. These patients are also associated with a higher rate of conversion to open cholecystectomy (29 vs 8%).

Anatomic Variations. Anatomic variations can also contribute to bile duct injury. A congenitally short cystic duct or a duct that appears shortened by an impacted stone may also lead to misidentification of the common bile duct, resulting in injury or transection. Other high-risk congenital anatomic anomalies include a long common wall between the cystic and common bile duct or the cystic duct inserting into the right hepatic duct. The cystic duct has a very variable pattern ranging from joining the common hepatic duct quite high, almost at the biliary confluence, or running parallel to the common hepatic duct before inserting into the common bile duct almost at the level of the pancreas. The risk of bile duct injury also appears to be increased in patients with obesity, chronic inflammation, excessive fat in the dissection area, inadequate exposure, poor or excessive clip placement, injudicious use of electrocautery, and bleeding into the operative field.

Technical Factors. Several technical factors associated with laparoscopic cholecystectomy make it prone to bile duct injury. First, standard laparoscopy gives a limited perspective from its

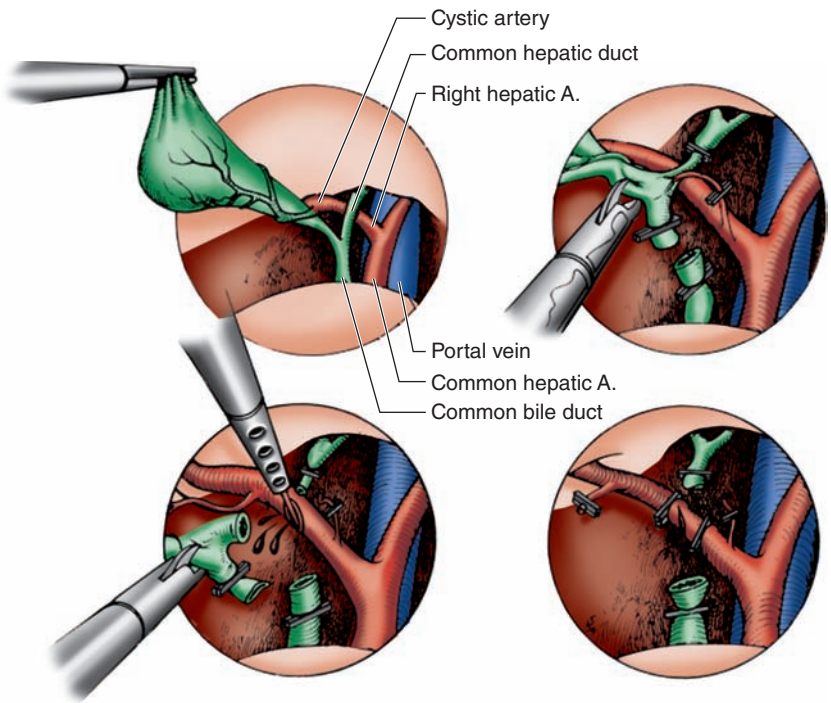

FIGURE 50-7 Classic laparoscopic bile duct injury. Confusion of the common bile duct with the cystic duct leads to clipping and division of the common bile duct. In many cases the common hepatic duct will not be clipped but will instead be divided by scissors or cautery. (Reproduced, with permission, from Davidoff AM, Pappas TN, Murray EA, et al. Mechanisms of major biliary injury during laparoscopic cholecystectomy. *Ann Surg*. 1992;215:196.)

end, viewing a two-dimensional picture of the operative field. The classic laparoscopic injury occurs when the cystic duct and the common bile duct are aligned in the same plane, leading to clipping and dividing the common bile duct. Retraction of the gallbladder infundibulum excessively cephalad aligns the cystic and common bile duct, leading to misidentification and injury. As the operative dissection is carried cephalad, the common hepatic duct may also be transected, often without recognition, resulting in a postoperative bile leak. The right hepatic artery may also be injured, creating excessive bleeding. This classic injury is estimated to occur in over 75% of major bile duct injuries referred to major centers. The classic laparoscopic injury is usually also associated with excision of a segment of bile duct, making the proximal extent of the injury high, usually at or near the hepatic duct bifurcation.

There is also a growing understanding of surgeon cognitive factors associated with bile duct injury during laparoscopic cholecystectomy. A report examined 252 laparoscopic cholecystectomy bile duct injuries using the human error factor and cognitive science techniques and found that 97% of injuries were due to a visual perceptual illusion or inadequate visualization.[51] In a subsequent study from the same group, one of the main explanations for the surgeon's frequent inability to recognize a bile duct injury associated with laparoscopic cholecystectomy appears to be confirmation bias, which is the propensity to seek clues to confirm a belief and to discount clues that might discount that belief.[52] While cognitive factors are important for understanding the psychological issues associated with bile duct injuries, surgeons must continue to have appropriate corrective mechanisms in place to minimize the chance of these injuries, including knowledge of anatomy, typical mechanisms of injury, appropriate level of suspicion, and logic.[53]

The role of intraoperative cholangiography in preventing bile duct injury remains controversial, with mixed results from reported series. A large series in Australia demonstrated a protective effect,[47] whereas a review from the Veteran's Administration Hospitals demonstrated that bile duct injury occurred more commonly in patients undergoing cholangiography (0.7 vs 0.2%).[45] Clinical information from patients in the Medicare claims database and surgeon data from the American Medical Association Physician Masterfile were recently used to examine the influence of intraoperative cholangiography on the rate of major bile duct injury, finding the rate of injury to be significantly higher when intraoperative cholangiography was not used.[54] In this study, surgeons who routinely performed intraoperative cholangiography had a lower rate of injuries than those who did not, and this lower rate disappeared when intraoperative cholangiography was not used by these surgeons. Whether or not intraoperative cholangiography actually prevents bile duct injury, the procedure can often lead to early recognition of the injury, and therefore potentially minimize the injury and its associated morbidity (Fig. 50-8). The best

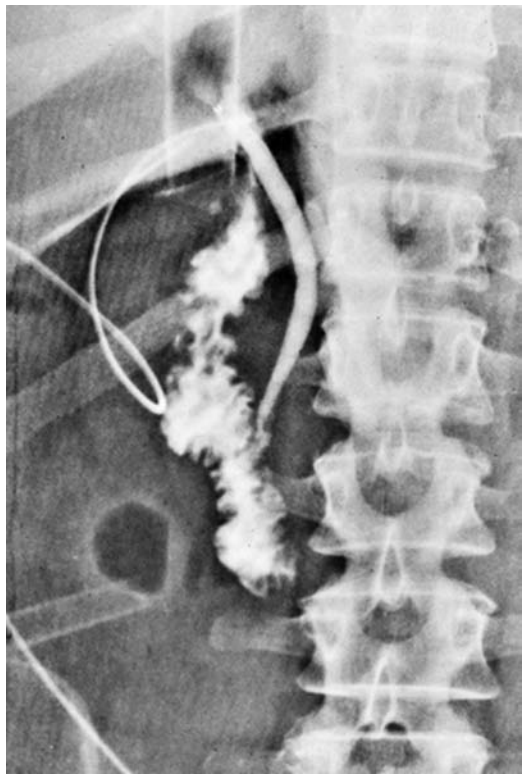

FIGURE 50-8 Intraoperative cholangiogram obtained during laparoscopic cholecystectomy. Cholangiogram demonstrates an injury to the common bile duct (which is clipped such that contrast does not fill the proximal biliary tree). Contrast fills the normal distal bile duct and duodenum.

technical approach in preventing and limiting bile duct injuries, regardless of the use of cholangiography, includes methodical dissection with careful exposure and identification of the structures of the triangle of Calot.[44]

The operative technique for laparoscopic cholecystectomy, which defines the "critical view of safety," is a corrective mechanism that helps prevent misidentification and injury to the major bile ducts.[55] In this method, the triangle of Calot is cleared of fat and fibrous tissue. Only two structures are connected to the lower end of the gallbladder once this is done; the cystic duct and cystic artery and the lowest part of the gallbladder attachment to the liver have been exposed. Once the critical view is attained, the cystic duct and artery may be clipped and divided, as they have been conclusively identified. Failure to achieve the critical view is an indication for conversion or possible cholangiography.

Physiologic Factors. Several physiologic processes have been implicated in the formation of bile duct strictures. Ischemia of the bile duct from excessive periductal dissection may have an important role in the formation of postoperative anastomotic strictures. Studies show that the blood supply to the ducts can be thought of having three elements: afferent arteries, marginal arteries, and the epicholedochal plexus. The afferent arteries are branches of the hepatic arteries or less commonly of the superior mesenteric artery or other upper abdominal arteries. The marginal arteries lie on and run parallel to the long axis of the bile ducts. Anatomically, these are the major arteries of the common bile duct located at the 3- and 9-o'clock positions that can be injured or divided by unnecessary dissection during cholecystectomy, or more commonly the bile duct can be excessively "skeletonized" while performing a bile duct anastomosis.

Fibrosis and scarring can be intense following a bile duct injury. In canine models, bile duct ligation results in an elevation of bile duct pressure that is immediate and sustained and is accompanied by an increased bile duct diameter and formation of high local concentrations of bile salts at the canalicular membrane.[56] A month after bile duct ligation, the bile duct wall is thickened, will have reduced mucosal folds, and have loss of surface microvilli with epithelial degeneration. On pathologic staining 2 weeks after ligation, there is evidence of increased synthesis of collagen and proline hydroxylase activation. Recently, an animal model of bile duct injury demonstrated healing in traumatized bile duct tissue to occur in a mode of overhealing, implicating myofibroblasts as the main cause of contracture of scar and stricture of the bile duct.[57] Inflammation in the surrounding tissues compounds the problem by encouraging fibrosis, especially when associated with bile leakage.

Injuries and strictures of bile ducts occur less commonly in association with other operative procedures. After cholecystectomy, common bile duct exploration is the next most frequently associated procedure with stricture, typically occurring at the site of choledochotomy or an impacted stone. Procedures requiring biliary-enteric anastomoses may be complicated by postoperative stricture. Typically, these procedures involve choledochoenteric or hepaticoenetric anastomosis in such cases as reconstruction after pancreaticoduodenectomy, bile duct resection for mid–bile duct tumors, and after excision of choledochal cysts. Gastrectomy and hepatic resection are the most common nonbiliary operations associated with postoperative strictures. Injuries associated with gastrectomy typically occur during pyloric and proximal duodenal dissection associated with closure of the duodenal stump or with creating a Billroth I gastroduodenostomy. Injuries during hepatic resection often take place during dissection of the hepatic hilum. Bile duct injury and stricture is also associated with hepatic transplantation, pancreatic procedures, and penetrating or blunt trauma. Finally, the recurrence of stricture after an initial attempt at repair is not uncommon and may occur over a decade following initial repair (Fig. 50-9).[58]

CLASSIFICATION

Strictures and injuries to the bile duct vary widely in their complexity and nature. The ease of management, operative risk, and outcome of biliary injuries vary considerably depending on the location and the type of injury. Injuries associated with laparoscopic cholecystectomy are often complex, located at or

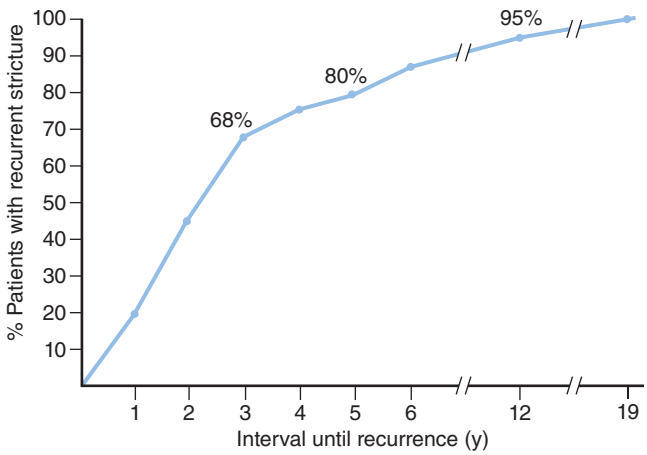

FIGURE 50-9 The cumulative percentage of recurrent strictures is shown with respect to the time interval from the initial repair to the next repair. (Adapted, with permission, from Pitt HA, Miyamoto T, Parapatis SK et al. Factors influencing outcome in patients with postoperative biliary strictures. *Am J Surg* 1982;144:14–21.)

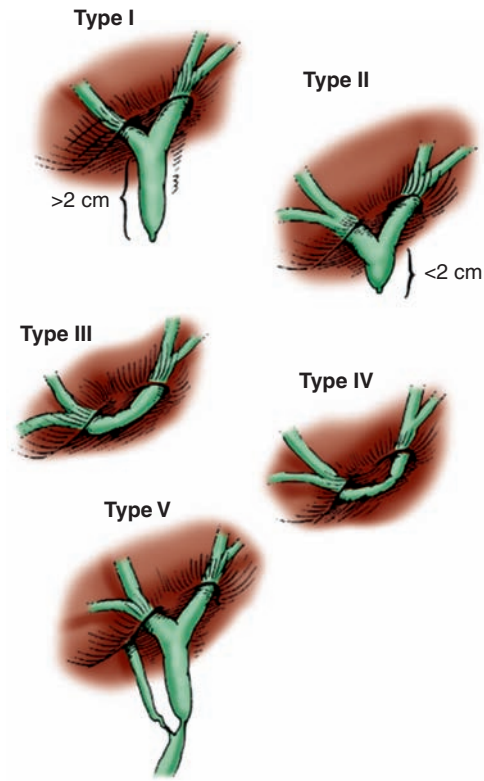

FIGURE 50-10 Bismuth classification system. Classification of bile duct strictures based on the level of the stricture in relation to the confluence of the hepatic ducts. Types III–V are usually considered complex injuries. (Reproduced, with permission, from Bismuth H. Postoperative strictures of the biliary tract. In: Blumgart LH, ed. *The Biliary Tract. Clinical Surgery International Series*, Vol. 5. Edinburgh, Scotland: Churchill Livingstone; 1983:209–218.)

near the level of the hepatic duct bifurcation, and potentially include one or more hepatic duct branches. Minor injuries to the bile duct include lacerations of the bile duct, clip placement on an intact bile duct, injury via electrocautery, or avulsion of the cystic duct.

A number of classification systems or major bile duct strictures have been presented, with the traditional classification being that described by Bismuth (Fig. 50-10), which classifies major injuries based on the level of obstruction of the biliary tree regarding the hepatic duct confluence or the involvement of an aberrant right sectoral hepatic duct with or without a concomitant hepatic duct stricture.[59] A drawback of the Bismuth classification system is that patients with limited strictures, isolated right hepatic duct strictures, or cystic duct leaks cannot be classified. The Strasberg classification system has been developed to classify all types of injury and is used extensively in describing bile duct injuries associated with laparoscopic cholecystectomy (Table 50-3).[55]

PRESENTATION

Most patients with bile duct injuries unfortunately are not recognized at the time of laparoscopic cholecystectomy. After open cholecystectomy, only 10% of injuries are suspected after the first week, but nearly 70% are diagnosed within the first 6 months after operation.[58] However, injuries after laparoscopic cholecystectomy are recognized earlier more likely because of heightened awareness and suspicion.

Large series reviews have demonstrated that less than one-third of major bile duct injuries are detected at the time of injury during laparoscopic cholecystectomy.[60,61] Possible indications that a bile duct injury had occurred intraoperatively include a persistent and unexpected bile leak, atypical anatomy, or a second bile duct discovered during dissection. Injuries may also be discovered if the removed gallbladder specimen and cystic duct are carefully examined to ensure normal duct anatomy. Intraoperative cholangiography will also diagnose bile duct injuries at the time of cholecystectomy and may minimize injury, allowing early repair (see Fig. 50-8).

TABLE 50-3: STRASBERG CLASSIFICATION OF BILIARY INJURY AND STRICTURE

Class A	Injury to small ducts in continuity with the biliary system, with cystic duct leak
Class B	Injury to sectoral duct with consequent obstruction
Class C	Injury to sectoral duct with consequent bile leak
Class D	Lateral injury to extrahepatic ducts
Class E_1	Stricture >2 cm distal to bifurcation
Class E_2	Stricture <2 cm distal to bifurcation
Class E_3	Stricture at bifurcation
Class E_4	Stricture involving right and left bile ducts; ducts are not in continuity
Class E_5	Complete occlusion of all bile ducts

The clinical presentation of patients with a bile duct injury in the early postoperative period depends on the type of injury. In most cases the injury is associated with uncontrolled bile leakage into the peritoneal cavity, while in others the duct is completely ligated by clip placement leading to obstructive jaundice usually without cholangitis. Patients with significant bile leaks generally present within the first week after operation with abdominal pain, distention, nausea, vomiting coupled with fever, or other signs of sepsis. Prompt investigation is required if patients have bilious drainage from incision sites or from intraoperatively placed drains. Bile leaks result in either biliary ascites with associated chemical peritonitis if allowed to drain freely into the abdominal cavity or, alternatively, bile can become loculated resulting in biloma (Fig. 50-11) or, if infected, a subhepatic or subdiaphragmatic abscess. In the latter scenario, presentation is more subtle with low-grade fever and localized abdominal pain. Because significant abdominal complaints are uncommon after uncomplicated laparoscopic cholecystectomy, all patients with such symptoms should be appropriately evaluated without delay for possible bile leak to prevent progression to frank sepsis. Failure to recognize a major bile leak or to institute appropriate treatment can result in life-threatening sepsis and the development of multisystem organ failure. In a recent series of 200 major bile duct injuries treated at The Johns Hopkins Hospital, three patients were transferred to this tertiary care center and died of complications of sepsis secondary to delayed or inadequate treatment.[62]

Bile duct strictures may also present months to years after the original operation. Patients with a slowly evolving stricture may have nonspecific abdominal complaints, jaundice, pruritus, cholangitis, or derangements in liver function tests. In addition, patients with an isolated right sectoral hepatic duct injury may present with a history of unexplained fevers, pain, or generalized malaise. Episodes of cholangitis are typically mild and respond effectively to antibiotics. Less often, patients can present with painless jaundice, which can be confused with a malignant stricture.

The findings on physical examination are usually not specific. Abdominal distention and pain may be seen in patients with bile peritonitis or focal tenderness if the patient presents with a collection or abscess. If the patient has jaundice, there may be multiple excoriations from pruritus. Hepatomegaly may be present in patients with chronic biliary obstruction or possible splenomegaly if there is any portal hypertension from portal venous injury or severe underlying hepatocellular damage.

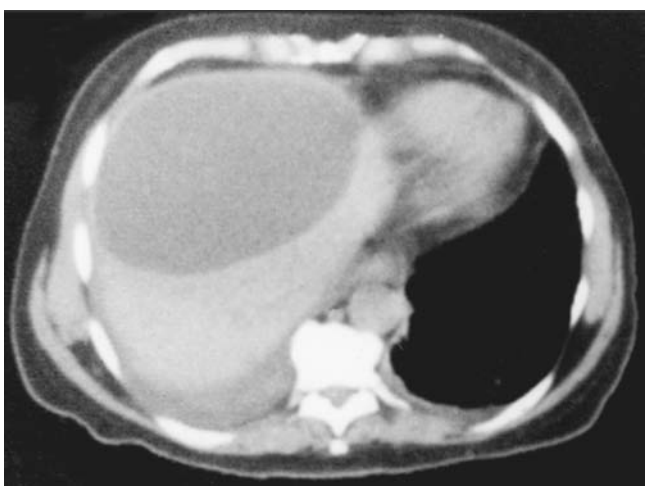

FIGURE 50-11 CT scan demonstrating biloma associated with biliary leak after bile duct injury. (Reprinted, with permission, from Lillemoe KD, Pitt HA, Cameron JL. Postoperative bile duct strictures. *Surg Clin North Am*. 1990;70:1362.)

DIAGNOSIS

Patients presenting with a biliary leak from injury usually present without evidence of biliary obstruction, and bilirubin levels are normal or slightly elevated due to absorption of bile from the peritoneal cavity. Patients with postoperative bile leak or cholangitis will also have an elevated white blood cell count, pyrexia, or occasionally frank sepsis. Patients with postoperative bile duct strictures typically reveal a stereotypical biochemical profile of cholestasis. In particular, liver function tests typically consist of an elevated alkaline phosphatase and normal or slightly elevated liver transaminases (alanine and aspartate aminotransferases). Serum bilirubin levels are usually elevated in the range of 2–6 mg/dL. In rare cases, patients with long-term obstruction will present late in the course of disease with cirrhosis, diminished serum albumin, and abnormal coagulation studies from altered hepatic synthetic function.

Definitive diagnosis for bile duct strictures and injuries requires radiographic imaging. Ultrasound and abdominal CT scan are both helpful in patients who present in the early postoperative period for the detection of bilomas and biliary ascites, as well as bile duct dilation from obstruction. Ultrasound has little value in assessing the extent of a stricture and is unhelpful if the biliary tree is decompressed. Abdominal CT scan is usually the best first-line study often showing a dilated biliary tree or intra-abdominal collections or ascites, which can direct further investigations. The CT should be performed with arterial-phase contrast to evaluate for concomitant vascular injury. Nuclear medicine imaging with technetium-HIDA (hepatobiliary iminodiacetic acid) scanning can demonstrate bile leakage noninvasively but typically does not have the sensitivity to define the specific anatomic site of injury. MRCP has been demonstrated to be an effective noninvasive method for demonstrating biliary leakage or obstruction, as well as precisely defining biliary anatomy and the nature of the injury (Fig. 50-12). Last, sinography, typically performed by injecting water-soluble contrast via operatively placed drains, can define the biliary anatomy and the source of bile leakage.

Cholangiography currently remains the gold standard for evaluating the biliary tree. Endoscopic retrograde

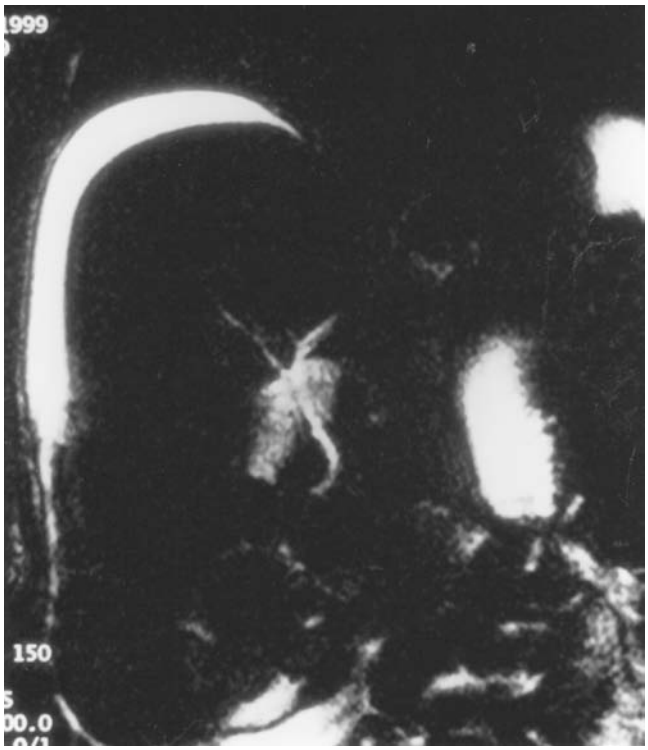

FIGURE 50-12 Diagnostic magnetic resonance cholangiopancreatography (MRCP) demonstrating biliary anatomy associated with a cystic duct leak after laparoscopic cholecystectomy. There is an intact biliary system with extravasation of contrast in the subhepatic space.

cholangiography (ERC) is performed via a distal approach to the biliary tree and is useful only in patients if the native bile duct is intact, such as with partial injuries or after end-to-end repair. ERC is the procedure of choice for patients suspected of cystic duct leaks (Fig. 50-13A) or leaks from peripheral hepatic radicals (ducts of Luschka). In these cases, the biliary leak may be effectively controlled with the use of an endoprosthesis. Most cases of major bile duct injury, however, are associated with complete duct transection, and the cholangiogram via the retrograde endoscopic route will demonstrate a normal distal bile duct terminating in misapplied clip(s) devices (Fig. 50-13B). Therefore, ERC will neither define the site of bile leakage nor the proximal anatomy necessary for reconstruction. In such cases, PTC is necessary to define the proximal biliary anatomy and the site of injury (Fig. 50-14). In addition to delineating the anatomy, a percutaneous biliary drainage catheter should be placed at the time of PTC to decompress the biliary tree, and treat cholangitis and control the biliary leak. Percutaneous biliary drainage catheters will also be useful at the time of operative repair as a guide for dissection and identification of the transected bile duct, which is often retracted high into the liver hilum. Finally, in those cases in which biliary-enteric continuity exists, percutaneous catheters allow access for balloon dilation.

FIGURE 50-14 Percutaneous transhepatic cholangiogram in a patient with complete transection of the common hepatic bile duct. Note the surgical clips near the cutoff point.

Significant arterial injury associated with major bile duct injury has been increasingly reported in recent years. The "classic" biliary injury during laparoscopic cholecystectomy in which the common bile duct is mistaken for the cystic duct often includes injury to the right hepatic artery as it enters either above or below the hepatic duct. While this injury may cause bleeding at the time of operation, the arterial injury often is unnoticed, usually resulting in arterial occlusion or less commonly a hepatic artery pseudoaneurysm. In a large study by Stewart et al[63] on combined right hepatic artery and bile duct injury, there were 7 pseudoaneurysms compared to 77 right hepatic artery occlusions. The incidence of disruption of the right branch of the hepatic artery during major bile duct injury ranges between 12 and 39%.[64] However, the presence of an arterial injury does not appear to affect either early or late outcomes.[63,65] Because of the recognized association of vascular injuries during laparoscopic bile duct injuries especially if there is a history of excessive bleeding at the time of cholecystectomy, a CT scan with arterial and venous phase contrast or arteriography should be obtained. Some authors believe if arterial injury has occurred, biliary reconstruction should be delayed to decrease the risk of late stricture recurrence.[55] In patients presenting in a delayed manner after cholecystectomy, the combination of biliary and vascular injuries often leads to segmental or lobar atrophy, which may suggest a role for hepatic resection rather than reconstruction.

PREOPERATIVE MANAGEMENT

The timing of presentation is often a primary determinant of the preoperative management of a patient with a postoperative bile duct stricture or injury. In the early postoperative period, patients with a bile leak associated with a bile duct injury are often either septic due to intra-abdominal infections or otherwise manifesting a systematic inflammatory response from chemical peritonitis associated with the bile leak. Treatment and control of sepsis may require broad-spectrum parenteral antibiotics, percutaneous biliary drainage, and percutaneous or, rarely, operative drainage of bilomas. Once sepsis is controlled, there is no hurry in proceeding with surgical reconstruction of the bile duct injury. Most biliary fistulae can be controlled with the combination of proximal biliary decompression and external drainage. After early control and clinical improvement, the patient may be discharged home for several weeks to permit return of overall health and for the resolution of inflammation in the periportal region.

It should be stressed that despite the belief of many surgeons that a suspected bile leak warrants urgent reoperation, exploration with an attempt at repair should be avoided early after presentation with a bile leak. In this situation exploration often reveals marked inflammation associated with bile spillage and small, decompressed bile ducts retracted high into the porta hepatis, making recognition of the injury and repair virtually impossible. Instead of proceeding to urgent exploration, a more prudent approach is to define biliary anatomy via preoperative cholangiography and to control the bile leak with percutaneous stents. Early operative intervention to deal with bile collections or ascites is not usually required because the intraperitoneal bile either can be drained percutaneously or is simply absorbed by the peritoneal cavity. Delayed reconstruction, with facilitation by percutaneous biliary catheters, allows for the most favorable operative results especially when concurrent hepatic artery injury is suspected.

Patients who present with a biliary stricture remote from the initial operation usually experience symptoms of cholangitis that necessitate urgent cholangiography and biliary decompression. The choice of technique depends on the nature of any prior repair. If the native bile duct is intact, endoscopic drainage with stent placement can sometimes be achieved. If a prior hepaticojejunostomy has been performed, transhepatic biliary drainage will be necessary for diagnosis. Both parenteral antibiotics and biliary drainage are central to controlling sepsis. Patients who present with jaundice without cholangitis should undergo either ERC or PTC to define the anatomy. As with patients presenting early in the postoperative period, ERC may not completely define the proximal biliary anatomy, making PTC the more favorable procedure. Preoperative biliary decompression in patients presenting

with jaundice without cholangitis has not been demonstrated to improve outcome.

OPERATIVE MANAGEMENT

Operative repair for postoperative bile duct strictures is aimed at reestablishing a reliable, long-term conduit for bile flow from the biliary tree to the gastrointestinal tract. Complications of an unsuccessful operative procedure include bile leak resulting in fluid collection or abscess, recurrent stricture with stones or sludge and potentially cholangitis, or biliary cirrhosis. To this end, the ideal technical procedure results in a tension-free, mucosa-to-mucosa repair to a segment of uninjured bile duct. Ideally, surgeons should also seek to maintain ductal length by not sacrificing tissue. Options for operative repair may include end-to-end repair, Roux-en-Y hepaticojejunostomy, or choledochoduodenostomy. The optimal operative procedure is contingent upon the timing of presentation, overall clinical status of the patient, and level and type of injury.

Injury Recognized at Initial Operation. If injury to the bile duct is recognized at the time of initial cholecystectomy, the surgeon should consider his or her ability to technically perform immediate reconstruction and should consider seeking the counsel and assistance of a more experienced surgeon. Studies show that immediate open repair by an experienced surgeon is associated with reduced morbidity, shorter duration of illness, and lower cost.[62] Each failed attempt at repair is associated with loss of bile duct length and exacerbation of a difficult situation. If the surgeon is unable to repair the injury and competent help is unavailable, drains should be placed to control any bile leak and the patient referred immediately to a tertiary specialty center.

When the surgeon suspects an injury or variant anatomy, biliary anatomy must be clearly defined using intraoperative cholangiography and/or careful dissection, being cautious to avoid additional injury or devascularizing the bile duct. Conversion from laparoscopic to open cholecystectomy is often necessary to properly identify anatomy and the injury. Segmental or accessory duct injuries where the diameter of the bile duct is less than 3 mm and where the bile duct does not communicate with the major duct system or drain a large segment of hepatic parenchyma on cholangiography may be ligated. Bile ducts that are 4 mm or larger in diameter or when the cholangiogram shows sectoral or lobar drainage, then the ducts must be operatively repaired, as they likely drain multiple hepatic segments or an entire liver lobe.

Immediate intraoperative repair is indicated in most cases for a major injury to the common hepatic or common bile duct. The nature of that repair is determined by the length of separation between opposed residual, viable ends of the injured duct. Partial common duct transections, involving less than 180-degree circumference of the biliary tree, may be closed primarily over a T-tube using interrupted absorbable sutures (Fig. 50-15). Transection of the common duct involving more than 180-degree circumference or complete

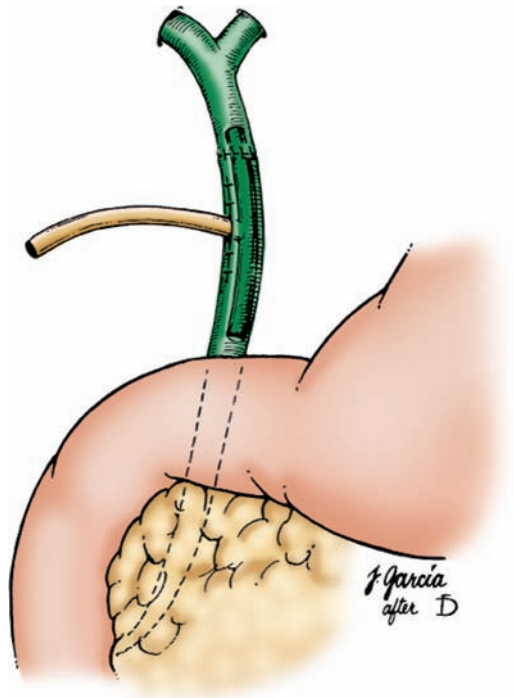

FIGURE 50-15 Primary end-to-end repair of the biliary tree over a T-tube. In general, this technique is used for partial transections of the bile duct, when there has been no associated loss of duct length. Note that the T-tube does not exit at the site of injury.

transactions with an injury less than 1 cm in length can usually be repaired with an end-to-end anastomosis with a T-tube that exits either above or below the anastomosis via a separate choledochotomy. Primary reconstruction of the bile duct, however, should be used very selectively and be avoided when the injury is near the bifurcation or when duct approximation cannot be accomplished without tension. A generous Kocher maneuver should be done to mobilize the duodenum out of the retroperitoneum and should be used to alleviate tension at the repair. In at least one series, a 100% restricture rate following primary end-to-end repair has been reported.[66] Other series have shown better results and suggest an advantage that, if a stricture occurs, endoscopic access for balloon dilation remains an option.[67]

Transections of the bile duct high in the biliary tree or with significant loss of bile duct length cannot be repaired with a primary biliary anastomosis that remains tension-free. These injuries require reconstruction using a biliary-enteric anastomosis typically using Roux-en-Y hepaticojejunostomy to ensure a tension-free repair. In this situation, the distal bile duct should be oversewn, the injured tissue in the proximal end debrided, and then a biliary-enteric end-to-side anastomosis to the Roux-en-Y jejunal limb. Transhepatic Silastic biliary stents should be placed to control potential anastomotic leaks and for postoperative cholangiography. A perianastomotic drain should also be placed in all cases so that any potential postoperative leak is well-controlled.

Injury Recognized in the Immediate Postoperative Period. Biliary injuries that are not appreciated in the intraoperative period may present in the first few days. The presentation may include bile drainage from the wound, bile peritonitis, or progressive jaundice. The initial management of a patient who presents in the delayed fashion following laparoscopic cholecystectomy depends on the nature of the injury and the mode and timing of presentation. Any elective repair should generally occur only after preoperative clinical optimization of the patient, and exact anatomy of the biliary system has been identified. Those presenting with biliary leak should have the bile leak and sepsis controlled prior to having definitive repair. In this situation, the result of reconstruction is almost always better if the definitive repair is made well after the leak and the consequent intra-abdominal inflammation and sepsis are controlled with percutaneous biliary drainage. Biliary spillage and marked inflammation can obscure fields and can make identification of ducts difficult making urgent early laparotomy prior to biliary decompression problematic. Finally, the patient should be clinically stabilized prior to elective repair to correct fluid and electrolyte balances, anemia, and malnutrition. The repair is ideally performed 6–8 weeks after adequate control of the leak has been attained.

In patients who present with biliary stricture weeks to months after cholecystectomy, identification of the biliary system is also essential. Patients with a stricture and symptoms of cholangitis should be treated with broad-spectrum antibiotics until sepsis is controlled, followed by biliary decompression with transhepatic percutaneous catheter placement.

Definitive Management of Bile Duct Stricture. The goal of operative management of a bile duct stricture is the establishment of bile flow into the proximal gastrointestinal tract in a manner that prevents sludge, stone formation, cholangitis, restructure, and cirrhosis. The type of repair should be determined by several factors: previous history of attempted repair, location of stricture or injury, surgeon experience, and surgeon preference. Intraoperatively, biliary anatomy must be carefully defined followed by exposure of healthy proximal bile ducts. Care must be taken to avoid excessive dissection and devascularization of tissue. A biliary-enteric anastomosis is performed using a mucosa-to-mucosa technique in a tension-free manner.

The preferred technique, with few exceptions, is a hepatico- or choledochojejunostomy to a Roux-en-Y limb of jejunum. End-to-end anastomosis after excision of the stricture or area of injury is not prudent because of the loss of bile duct length and associated fibrosis. Significant loss of bile duct length is also a strict contraindication to performing choledochoduodenostomy, which is unlikely to be performed in a tension-free fashion and is also associated with duodenal fistula if leak occurs.

The exact details of the reconstruction depend on the particular anatomic features of the stricture. For strictures where there is more than 2 cm of healthy common hepatic duct present (Bismuth I), a simple end-to-side biliary-enteric anastomosis will suffice. For strictures in where there is less than 2 cm of healthy common hepatic duct (Bismuth II) or the stricture involves the bifurcation of the hepatic duct but the left and right still communicate (Bismuth III), it may be necessary to lower the hilar plate and extend the dichotomy along a short length of the left hepatic duct to allow a common biliary-enteric anastomosis. Strictures that completely separate the right and left biliary system (Bismuth IV and V) require separate right and left biliary-enteric anastomosis. When duct length cannot be found outside of the hepatic parenchyma, an intraoperative ultrasound is essential to locate the segments II and III ducts. Often, a wedge of liver may need to be resected until an adequate duct can be found to do a biliary-enteric anastomosis.

The use of percutaneous biliary stents with elective reconstruction of the biliary tree remains a topic of debate for hepatobiliary surgeons. Preoperatively placed stents act as intraoperative aids for defining anatomy, especially if the stricture is located proximally. Stents left in place after reconstruction also allow postoperative cholangiography and control early anastomotic leaks in the immediate postoperative period. Many surgeons also advocate extended postoperative transanastomotic stenting, with the purpose of minimizing fibrosis and risk of late anastomotic stricture. In this setting, follow-up cholangiography will reveal early evidence of anastomotic stricture and provide access for balloon dilation if necessary.

Biliary reconstruction with the technique of hepaticojejunostomy with a Roux-en-Y limb with transhepatic biliary stents is depicted in Fig. 50-16. Dissection of the porta hepatis is performed to clear any adhesions between the duodenum or colonic hepatic flexure to the gallbladder fossa, subhepatic space, or Glisson's capsule. Preoperatively placed percutaneous stents are essential in assisting in dissection and bile duct identification in patients with a high bile duct transection. In patients with an intact but strictured bile duct, the duct is divided at the most distal portion of the stricture, and a segment of the strictured duct should be resected and sent to pathology for frozen section. The distal end of the stricture is then oversewn. The proximal extent of the duct should be debrided for a length not to exceed 5 mm to obtain healthy bile duct circumferentially for use in the anastomosis. Careful limited dissection is important to avoid vascular compromise to the bile duct. Preoperatively placed percutaneous transhepatic catheters, which now protrude from the proximal end, are usually exchanged for soft Silastic stents. Silastic stents range from 12 to 22F in size, with multiple side holes that are generally interspersed along 40% of the length of the catheter. A radiologic guidewire is placed through the percutaneous transhepatic catheter; using the Seldinger technique, a series of progressively larger coudé catheters are passed over the guidewire in order to dilate the system for Silastic stent placement. The Silastic stent is arranged with the side holes extending beyond the anastomosis distally and within the liver parenchyma proximally. The end of the Silastic stent without holes is brought through the hepatic parenchyma

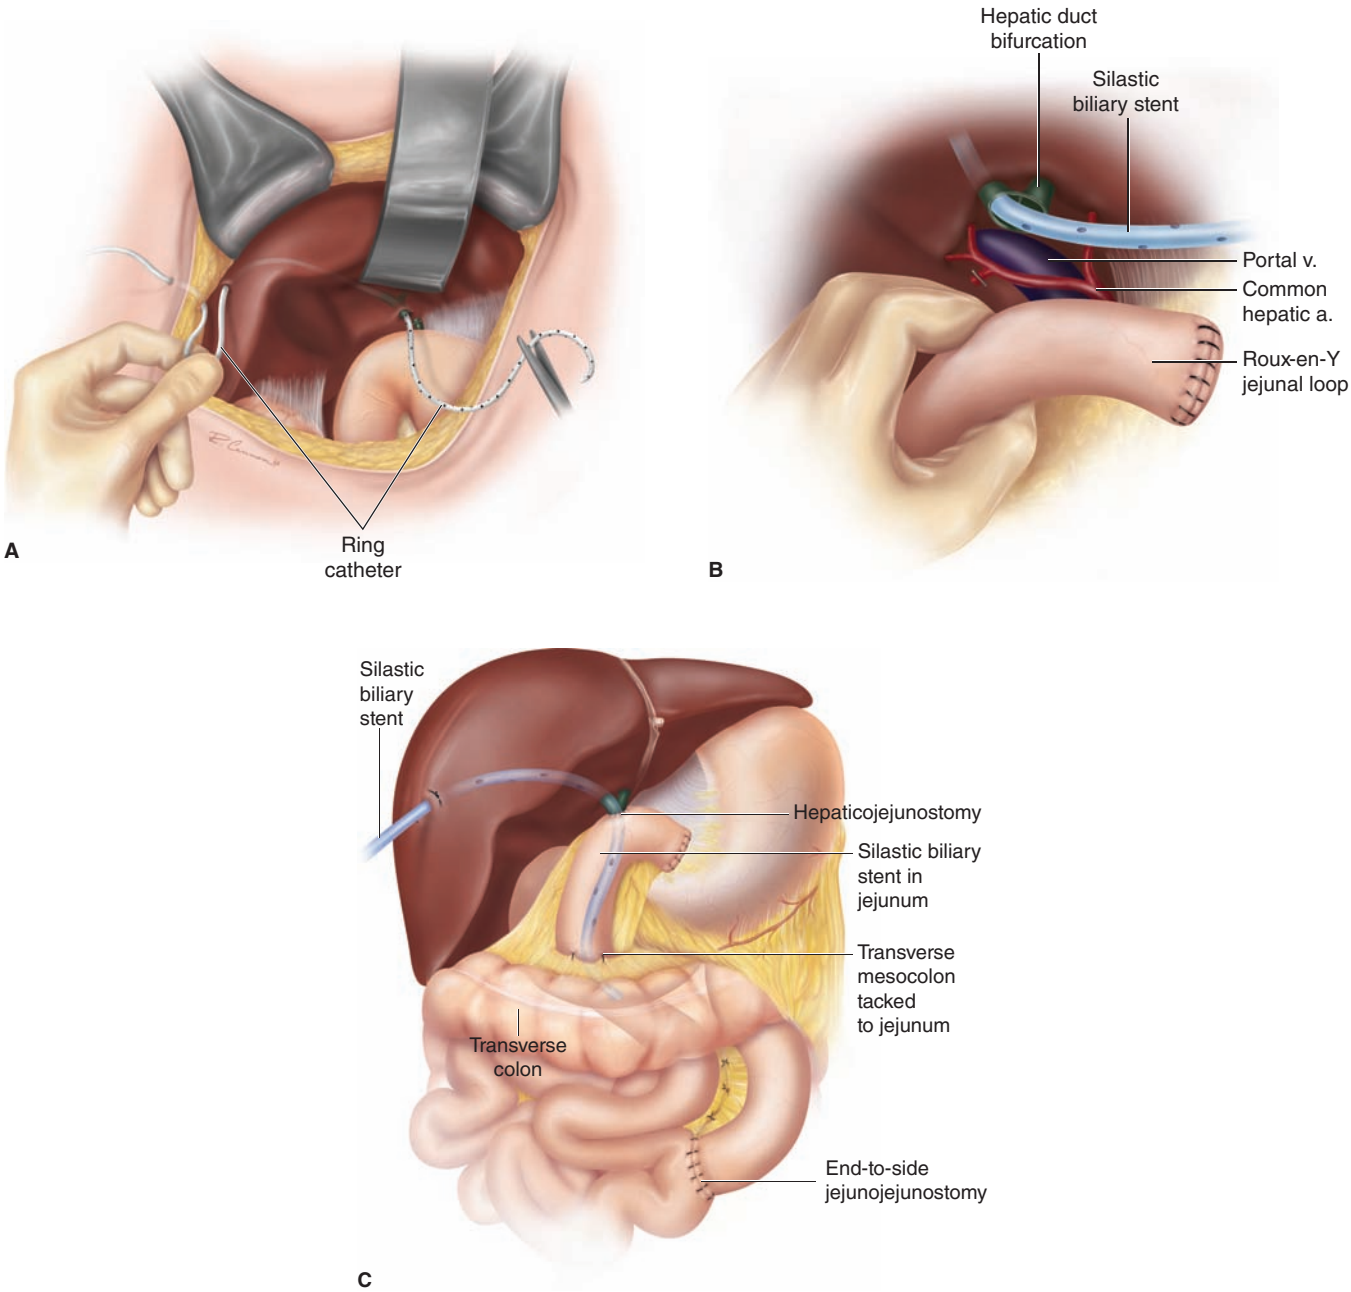

FIGURE 50-16 Roux-en-Y hepaticojejunostomy reconstruction of biliary tree. **A.** Repair of common hepatic duct stricture with transhepatic ring catheter exiting at the bifurcation. The stricture has been resected, and the distal biliary tree is oversewn. The hepaticojejunal anastomosis can then be performed over the ring catheter, or the ring catheter can be exchanged for a Silastic transhepatic stent. **B**. The Silastic transhepatic stent is shown exiting the biliary tree, with the Roux-en-Y jejunal limb prepared for the hepaticojejunostomy. **C.** Completed repair showing the Silastic biliary stent traversing the liver and the hepaticojejunostomy. The Roux-en-Y jejunal limb has been brought to the hepatic hilum in retrocolic position. (Reproduced, with permission, from Cameron JL, ed. *Atlas of Surgery*, Vol. I. Hamilton, Ontario, Canada: BC Decker; 1990:43, 53, 57.)

and out through the upper anterior abdominal wall. A Roux-en-Y jejunal limb is then created by mobilizing a suitable segment of intestine of approximately 60 cm in length. The anastomosis is then constructed with a standard end-to-side Roux-en-Y hepatico- or choledochojejunostomy, typically using a single layer of 4-0 or 5-0 absorbable sutures.

In the postoperative period, Silastic stents are left to external gravity drainage. A cholangiogram is then performed on postoperative day 4 or 5 (Fig. 50-17). If the biliary tree is adequately decompressed and no leakage is seen, the stents can be internalized and the perianastomotic drain is removed.

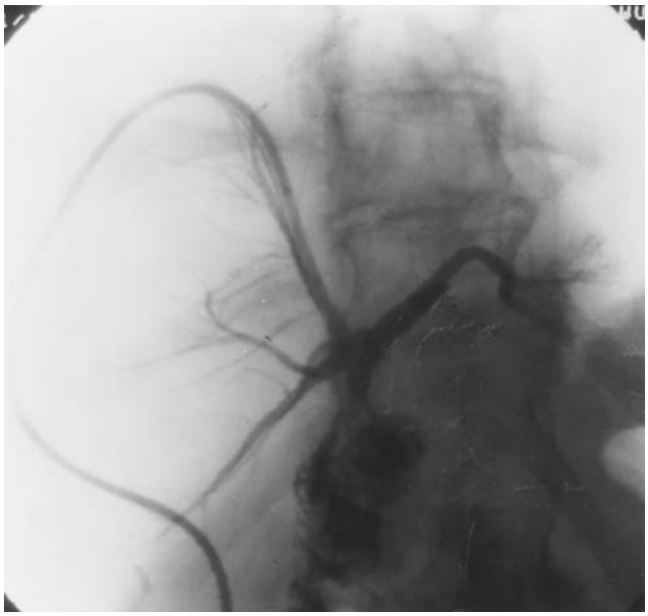

FIGURE 50-17 Postoperative cholangiography after hepaticojejunostomy via percutaneous Silastic biliary stents; the image shows no evidence of anastomotic leak.

The length of postoperative transanastomotic stenting is dependent on the individual patient, the clinical setting, and surgeon preference. Long-term stenting involves fluoroscopic exchange of stents at regular 2- to 3-month intervals. Timing of stent removal can be aided by biliary manometric flow studies that give objective data about the adequacy of the anastomosis, or by passing a clinical trial with the stent placed above the anastomosis.[68]

An alternative described approach of doing a hepaticojejunostomy involves an anterior longitudinal opening created in the bile duct and a long side-to-side anastomosis performed. Often, this is done to the extrahepatic portion of the left hepatic duct after it is lowered by dividing the hepatic plate (Hepp-Couinaud approach). This approach is particularly suitable for injuries at or just below the bifurcation. Right ducts do not lend themselves to this approach as well, because they have a short extrahepatic length. Sometimes the end of the right duct is used. However, dissection of the left duct provides a guide to the coronal plane in which the intrahepatic right hepatic ducts will be found and may further be exposed by removing liver tissue. During these procedures, exposure can be improved by dividing the bridge of tissue between segments 3 and 4 and opening the gallbladder fossa. Finally, if still more exposure is needed, resecting part of segments 4b and 5 will open the upper porta hepatis. The technique can avoid the need for postoperative stenting.

Nonoperative Therapy. Nonoperative interventional radiology and endoscopic techniques have also been developed for the management of select patients with bile duct strictures and injuries. The most common nonoperative technique in these patients is interventional radiologic percutaneous stenting and balloon dilation, which may be possible in patients with intact biliary-enteric continuity. With the administration of conscious sedation, the proximal biliary tree is accessed so that the stricture can be traversed using a guidewire under fluoroscopic guidance (Fig. 50-18). Angioplasty-type balloon catheters are used to perform dilation of the stricture to a goal diameter based on the stricture location and the normal bile duct diameter. Following dilation, a transhepatic biliary stent is left in place across the stricture. The stent allows for future cholangiography, repeat dilation, and maintenance of the lumen while the bile duct heals. Complications of balloon dilation occur in up to 20% of patients and include cholangitis, hemobilia, and bile leaks. Percutaneous management will usually require numerous dilations.

Results for the treatment of bile duct strictures using percutaneous balloon dilation are limited. In a retrospective comparison, percutaneous balloon dilation was compared to surgical repair in 43 patients with postoperative bile duct strictures treated between 1979 and 1987.[69] Twenty-five patients underwent surgical repair with postoperative stenting and 20 patients had percutaneous balloon dilation with transhepatic stenting (mean: four dilations). Three patients underwent both surgical management and balloon dilation. Successful outcome was achieved in 89 and 52% of surgical

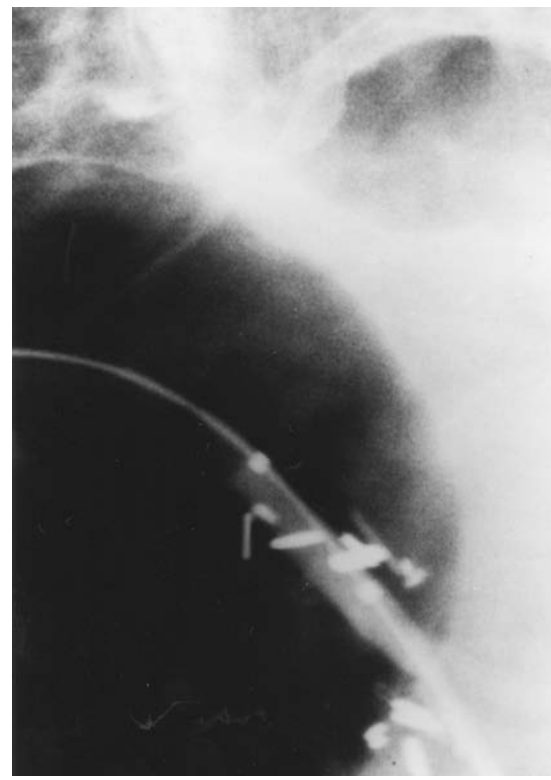

FIGURE 50-18 Percutaneous balloon dilation of postoperative bile duct stricture using an angioplasty-type balloon catheter. Cholangiogram showing mid–bile duct stricture.

and balloon dilation patients, respectively. These results would appear comparable to other series in the prelaparoscopic cholecystectomy era.[70–73] However, the follow-up in most studies was less than 3 years, which is insufficient to make a definitive comment regarding long-term efficacy.

A series of 51 patients undergoing percutaneous balloon dilation therapy for bile duct strictures following laparoscopic cholecystectomy was reported by Misra and associates.[74] At a median 76-month follow-up, overall success with balloon dilation, defined as stent-free without the need for further intervention, was 58%. With additional stenting and balloon dilation for two patients and surgical reconstruction for the remaining patients, all but one patient (98%) had a successful long-term outcome. These results suggest that in highly selected patients, percutaneous balloon dilation can provide long-term successful results.

Endoscopic balloon dilation has a more limited application, because it is technically possible only in patients with primary bile duct stricture repair or with choledochoduodenal anastomosis. ERC is performed, followed by endoscopic sphincterotomy. Sequential balloon dilation is performed after the stricture is traversed by a guide wire, often with one or more endoprostheses left in place after dilation. Complications associated with stent placement include cholangitis, pancreatitis, stent occlusion, migration, dislodgment, and ductal perforation, and have a reported incidence between 9 and 70%.[75–77]

Repeat cholangiography, often with repeat dilations, may be performed at regular intervals of every 3–6 months. While most endoscopists advocate regular follow-up and reevaluation of the stricture, the risks of stent occlusion and replacement need to be weighed against the risks and costs of the repeat procedures, and there is still some debate about timing of stent change to avoid occlusion. Bergman and associates demonstrated a 70% reobstruction rate with resultant jaundice or cholangitis when stents were not exchanged at 3-month intervals.[77] In contrast, De Masi and colleagues describe and advocate leaving the stents in place until patients were symptomatic.[78]

In addition, the rate of stent occlusion appears to vary with the type of stent used. While metallic stents provide a longer period of patency than plastic stents for patients with malignant obstruction, the indications for their use in patients with benign strictures are limited. Metallic stents cannot be routinely exchanged or removed, and several studies have demonstrated high reocclusion rates at long-term follow-up.[79–81] Newer covered metallic stents may provide a suitable alternative as they can be changed or removed after completion of treatment.[82]

While there have been no determinative studies for the length of time that stents should remain in place, most studies having excellent results have used larger-bore stents (≥10F) left in place for 2–6 months.[76,77,83] Long-term studies reporting the endoscopic treatment of benign bile duct strictures are few. One of the few studies that directly compare endoscopic therapy to surgical reconstruction was done by Davids and colleagues from the Netherlands.[75] In 66 patients, endoscopic therapy consisted of dilation and placement of an endoprosthesis, which was exchanged every 3 months. Surgical repair in 35 patients consisted of Roux-en-Y hepaticojejunostomy. Surgery was associated with excellent or good results in 29 patients (82%), with 6 patients (17%) developing a recurrent stricture at mean 40 months from initial surgery. In contrast, endoscopic stenting resulted in 81% with excellent or good outcome and 18% developing restricture at a mean of 3 months after stent removal. Recurrent strictures after stent removal in several other series have been reported to occur at a rate varying from 0 to 20% at median follow-up of 29–108 months.[76,77,83]

OPERATIVE RESULTS

Biliary injury and stricture repair are associated with significant morbidity and mortality. With improved medical technology and experience, the incidence of operative mortality has decreased markedly. A recent series of 200 consecutive patients repaired at The Johns Hopkins Hospital reported a perioperative mortality of only 1.7%.[62] Advanced age, comorbid disease, and a history of major biliary tract infection are factors associated with operative mortality. Underlying liver disease is the most important correlated factor for operative mortality and morbidity, with advanced biliary cirrhosis and portal hypertension having mortality rates approaching 30%. Fortunately, in the modern era such advanced disease is uncommon.

A recent analysis of Medicare claims, patients' examined mortality associated with major bile duct injuries over an 8-year period in 791 elderly patients demonstrated a perioperative mortality of 2.7% associated with repair.[84] In addition, the study demonstrated an adjusted hazard ratio for death during the follow-up period was significantly higher for patients with a bile duct injury than in patients without a bile duct injury. The hazard increased with advancing age and comorbidities and decreased with experience of the repairing surgeon. The adjusted hazard for death during follow-up was 11% greater if the repairing surgeon was the same as the injuring surgeon. This study gives supportive evidence for improved survival in patients with major bile duct injuries treated by experienced hepatobiliary surgeons at tertiary referral centers.

In most series, postoperative morbidity rates are in the range of 20–40%. Morbidity nonspecific to biliary surgery includes hemorrhage, infection, and risks associated with general anesthesia. Complications specific to biliary repairs include anastomotic leak, cholangitis, and hepatic insufficiency associated with preexisting liver disease. Anastomotic leaks can typically be managed via nonoperative means, especially when transanastomotic stenting has been utilized. Percutaneous transhepatic stenting may also have specific morbidity, including bile leaks from hepatotomy sites, hemobilia, and cholangitis from stent occlusion.

The series reporting the outcomes in 200 patients undergoing surgical reconstruction demonstrated a 43% overall postoperative complication rate.[62] The most common complications were wound infection (8%), cholangitis (6%), minor stent-related complications (6%), and intra-abdominal abscess/biloma

(3%). Postoperative cholangiography revealed an anastomotic leak in 4.6% of patients and extravasation at the liver dome–stent exit site in 10.3%. These complications were all managed conservatively with either new biliary stent placement or biliary stent exchanges required in 2.3%. Postoperative percutaneous abscess/biloma drainage was required in nine patients (5.1%). No patients required reoperation in the postoperative period. Despite the relatively high morbidity rate, median length of stay was similar to that in other reports (8 ± 4.6 days).

There are mixed results regarding perioperative complications when vascular injury has occurred in association with a bile duct injury.[65,85,86] A report from Schmidt and associates[87] reported that a repair in the presence of uncontrolled infection, a concurrent hepatic artery injury, and injury level (at or above the bifurcation) were independent predictors of the development of major biliary complications.

The ultimate goal of the repair of a bile duct stricture is a successful repair with no further symptoms, including jaundice, cholangitis, and preserved liver function. Excellent long-term results following operative repair of postoperative bile duct injuries after open cholecystectomy have been reported with approximately 80–90% having a successful outcome (Table 50-4).[69,75,88–94] Early reports and observations from the laparoscopic era were less favorable than those previously reported with open cholecystectomy repairs. Stewart and Way[66] reviewed 85 patients who had undergone 112 biliary repairs and defined four factors that influenced success or failure of operative repairs after laparoscopic cholecystectomy bile duct injury: (1) performance of preoperative cholangiography, (2) choice of surgical repair, (3) details of surgical repair, and (4) experience of the repairing surgeon. Procedures without preoperative cholangiography were unsuccessful 96% of the time, and those with incomplete cholangiography data had a success rate of only 31%. With complete cholangiography data, the success rate was 84%. All patients with complete transection of the bile duct who underwent primary end-to-end repair over a T-tube had a failed result. In contrast, 63% of Roux-en-Y hepaticojejunostomy repairs were successful. Initial repair by the original laparoscopic surgeon was successful in only 17% of cases. Repeat attempts at repair by the same surgeon were never successful. Finally, those patients whose first repair was by a tertiary care biliary surgeon achieved a 94% success rate.

A series providing long-term results after repair of bile duct injuries and strictures in the 1990s was reported by Lillemoe and associates.[94] A total of 156 consecutive patients underwent surgical reconstruction with a mean follow-up period of 57.5 months (range 11–119 months; median 54.7 months). The original operation consisted of laparoscopic cholecystectomy in 118 patients (76%), open cholecystectomy in 27 patients (17%), open cholecystectomy with bile duct exploration in 4 patients (3%), or other abdominal surgery or trauma in 7 patients (4%). Sixty patients (41%) had a previous attempt at repair prior to referral with eight patients (5.5%) having more than one attempt at repair prior to referral. Of the 156 operatively repaired patients, 142 patients had completed treatment at the time of final evaluation with an overall success rate of 91%. Even though they were more likely to have had repair prior to referral and higher and more complex injuries, patients with repair of a stricture or injury associated with laparoscopic cholecystectomy had a better success rate than repair after other operations (94 vs 80%; $p < .05$). There were 13 failures following surgical reconstruction. Ten had successful results following either surgical revision (one patient) or percutaneous balloon dilation (nine patients), resulting in an overall success rate of 98% including secondary intervention. Only three patients continued to require long-term biliary stents to prevent biliary obstruction symptoms and/or cholangitis. Comparable results have been reported from other high-volume hepatobiliary centers with similar volume of patients in the series.[96–99] Outcomes after surgical repair for laparoscopic cholecystectomy injury from other series are outlined in Table 50-5.[94,97–100]

TABLE 50-4: RESULTS OF SURGICAL REPAIR OF POSTOPERATIVE BILE DUCT STRICTURES

there is an impression that patients may have an impaired quality of life even after a successful repair of their bile duct injury. Quality of life after laparoscopic cholecystectomy bile duct injury has been addressed in several recent reports, with differing results.[101–104] Two studies using the Short Form 36 (SF-36) Health Survey quality-of-life instrument in patients with laparoscopic cholecystectomy injury found both the physical and mental quality-of-life aspects to be reduced compared to controls at approximately 5-year follow-up.[101,104] A study with SF-36 found that patients with laparoscopic bile duct injury and subsequent biliary reconstruction had quality of life similar to matched controls and national norms in all eight quality-of-life areas.[103] Melton and associates[102] assessed quality of life in 54 patients having undergone successful surgical repair of laparoscopic cholecystectomy bile duct injuries and compared these results to quality-of-life measures in patients after uncomplicated laparoscopic cholecystectomy and in healthy controls using a standard quality-of-life instrument, which was used to assess the physical, psychological, and social domains of health-related quality of life. Patients after surgical repair had overall quality-of-life scores comparable to those of controls. Only in the psychological dimension were patients post–bile duct injury repair found to have significantly worse scores compared to controls. Patients who reported pursuing a lawsuit following their injury (31%) had significantly worse quality-of-life scores in all domains when compared to those who did not entertain legal action ($p < .01$).

Summary

Postoperative bile duct strictures and major injuries remain a considerable surgical challenge. With proper diagnostic workup, clinical optimization, and definitive treatment, the vast majority of patients can achieve satisfactory outcomes. With success rates of over 90% at long-term follow-up, the gold standard for managing patients with major bile duct injuries and strictures in the current era remains surgical reconstruction. In select patients with biliary-enteric continuity, percutaneous or endoscopic management with balloon dilation may be an appropriate alternative, with success rates of approximately 50% at long-term follow-up.

INFLAMMATORY CAUSES OF BILIARY STRICTURE

Biliary strictures may occur in association with a wide range of processes causing fibrosis of the bile ducts. While inflammatory causes of bile duct strictures account only for a minority of biliary strictures in the United States, biliary strictures from these causes are important diagnostic and therapeutic challenges. Strictures from chronic pancreatitis, biliary calculous disease, sphincter of Oddi stenosis, and peptic ulcer disease can usually be managed with choledochoduodenostomy or Roux-en-Y hepaticojejunostomy without long-term stenting. The management of other infrequent causes of benign biliary strictures depends on the etiology, natural history, and severity of disease.

Chronic Pancreatitis

Chronic pancreatitis is an infrequent cause of bile duct stenosis and stricture, accounting for fewer than 10% of benign biliary strictures. While acute pancreatitis is frequently associated with transient partial obstruction of the distal common bile duct from inflammation and edema, chronic pancreatitis can result in distal bile duct obstruction from inflammation and parenchymal fibrosis of the pancreatic gland. Strictures from chronic pancreatitis typically involve the entire intrapancreatic segment of the common bile duct, resulting in proximal dilation of the biliary tree.

Chronic pancreatitis resulting in bile duct stricture is most commonly caused by alcoholism. Strictures more commonly present in patients who have advanced disease with pancreatic calcification, diabetes, or malabsorption at the time of presentation. The exact incidence of common bile duct strictures is not known because cholangiography is not routinely performed in patients with chronic pancreatitis. With a review of several clinical series, common bile duct strictures associated with chronic pancreatitis occur in approximately 5% of patients with estimated ranges varying from 3 to 29% of patients.[105,106]

Common bile duct strictures due to chronic pancreatitis may have a wide range of clinical presentations. On one end of the spectrum, patients can be asymptomatic with only abnormal liver function tests. Serum alkaline phosphatase, the most sensitive liver function test, is elevated in over 80% of cases. Patients can also present with abdominal pain with or without jaundice. Importantly, abdominal pain from biliary strictures can be difficult to distinguish from pain caused by chronic pancreatitis. Patients with pain from biliary stricture who are not properly diagnosed and treated for their stricture may undergo inappropriate and unsuccessful operative procedures to address pain presumed to be from chronic pancreatitis. Finally, patients who develop jaundice in the setting of chronic pancreatitis may present a diagnostic dilemma, as an underlying periampullary malignancy must also be considered.[107]

Evaluation of bile duct strictures from chronic pancreatitis is most effectively accomplished with cholangiography. MRCP is the preferred route for noninvasive assessment, with ERCP and PTC both effective at delineating anatomy and allowing decompression of the biliary tree in the setting of cholangitis or severe jaundice. ERCP is the preferred diagnostic procedure because it has the advantage of demonstrating pancreatic ductal anatomy, including possible abnormalities, which are especially useful in surgical management. The most common cholangiographic image in chronic pancreatitis–associated bile duct strictures is a long (usually 2–4 cm), smooth, gradual tapering of the distal common bile duct (Fig. 50-19).

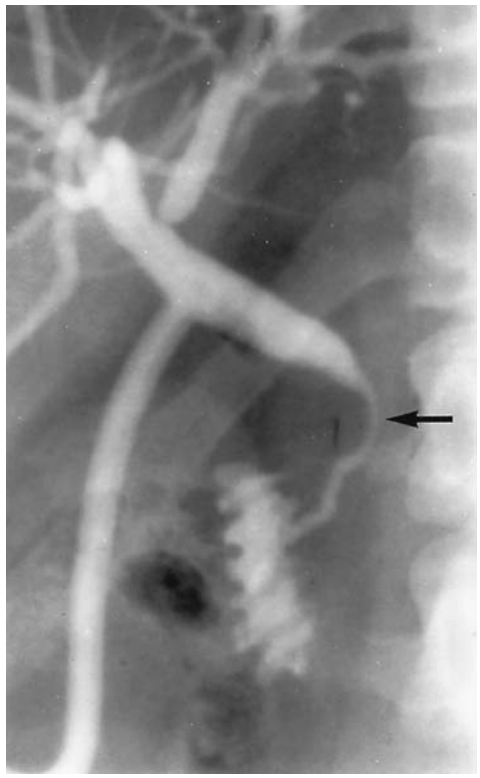

FIGURE 50-19 Stricture from chronic pancreatitis involving the entire intrapancreatic segment of the common bile duct, resulting in proximal dilation of the biliary tree. (Reprinted, with permission, from Lillemoe KD. Biliary injuries and strictures and sclerosing cholangitis. In: Mul-holland MW, Lillemoe KD, Doherty GM, Maier RV, Upchurch GR, Jr, eds. *Greenfield's Surgery: Scientific Principles and Practice*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:1013.)

The most common accepted indications for operative management in common bile duct strictures from chronic pancreatitis are cholangitis, jaundice, or significant pain. It remains unclear, however, if biliary decompression in asymptomatic patients with elevated serum alkaline phosphatase is indicated. Many surgeons do advocate biliary bypass in this situation, as early biliary cirrhosis changes may be observed in liver biopsy specimens in patients with long-standing, significant biliary obstruction from chronic pancreatitis.[108,109]

Biliary bypass with choledochoduodenostomy or Roux-en-Y choledochojejunostomy represents the optimal form of management for bile duct strictures associated with chronic pancreatitis. Potential advantages of choledochoduodenostomy over Roux-en-Y choledochojejunostomy include maintenance of bile flow into the duodenum that may be more physiologic, increased technical ease, and no loss of small bowel length for formation of a Roux-en-Y limb. Operative management with pancreaticoduodenectomy is appropriate in those patients in whom periampullary malignancy cannot be ruled out by imaging studies or clinical course or in those patients with significant pain attributed to proximal pancreatic duct disease. Both long- and short-term outcomes of surgically managed distal bile duct strictures from pancreatitis are usually excellent.[100,110]

The management of common bile duct strictures from chronic pancreatitis with either transduodenal sphincterotomy or endoscopic sphincterotomy is not recommended owing to the stricture's long length. While long-term follow-up is lacking, several series have reported success in 60% of patients with follow-up at approximately 2 years after endoscopic balloon dilation of distal bile strictures from chronic pancreatitis.[111,112] It would appear that in most cases when a benign process can be expected to require years of follow-up, that surgery would be the best form of management.

Gallstone Disease

Long-standing cholelithiasis with recurrent bouts of cholecystitis results in a progressively fibrosed, shrunken gallbladder. Eventually, the gallbladder lumen can lie alongside the common hepatic duct, resulting in inflammation and resultant bile duct stricture. Often referred to as *Mirizzi's syndrome*, this process is typically subdivided into two categories. Type I Mirizzi's syndrome occurs when the process results in either mechanical compression of the duct or an inflammatory stricture of the common hepatic duct. In contrast, type II consists of erosion of the stone in the duct, resulting in cholecystocholedochal fistula.

Mirizzi's syndrome usually presents as jaundice or recurrent cholangitis. In some long-standing cases, these findings exist in the face of chronic gallbladder symptoms. In cases of Mirizzi's syndrome associated with acute cholecystitis, care must be taken at the time of cholecystectomy to avoid bile duct injury during initial dissection. The presence of Mirizzi's syndrome obliterates the triangle of Calot and makes laparoscopic cholecystectomy particularly difficult and will often require conversion to an open procedure. If Mirizzi's syndrome is considered, intraoperative cholangiography should be performed.

If urgent cholecystectomy is not indicated, ERC or PTC can help to delineate the anatomy. Importantly, Mirizzi's syndrome can be difficult to distinguish from strictures that result from gallbladder cancer or cholangiocarcinoma.[113] ERC can also be helpful for obtaining brush biopsies in these patients.

Formal management of strictures from biliary stones varies according to the extent of disease. Patients in whom the bile duct is inflamed and no fistula is present (type I) can often be managed with cholecystectomy. The common hepatic duct almost always returns to normal after the offending stone has been removed by cholecystectomy and the inflammatory process has resolved. Care must be taken, however, during the dissection to avoid creating a defect in the common hepatic duct. Rarely, after the acute episode has resolved, a well-established stricture presents months to years after the acute episode. In such cases, management by Roux-en-Y hepaticojejunostomy is appropriate. If cholecystocholedochal fistula (type II) is present, partial cholecystectomy is recommended and the cuff of remaining gallbladder is used to repair the bile duct over a T-tube.

In addition to Mirizzi's syndrome, calculous disease also rarely results in strictures due to choledocholithiasis. The pathogenesis of strictures from choledocholithiasis is thought to be from epithelial erosion of the distal bile duct from calculous disease, resulting in inflammation with subsequent fibrosis and stricture.

Nearly all stones remain entrapped in the intrapancreatic portion of the common bile duct because of the anatomic tapering of the common bile duct. These trapped stones are often difficult to remove via endoscopic means or via a supraduodenal approach during common bile duct exploration. In fact, common bile duct exploration to retrieve stones with forceps, scoops, and catheters can often result in additional trauma to the friable distal duct from excessive intraoperative manipulation. After stone removal, the distal bile duct should be gently sized with a soft rubber catheter to check for the presence of a stricture. Strictures often may not be recognized until the postoperative period when T-tube cholangiography is performed. When strictures are found postoperatively, stricture repair should be performed after inflammation has resolved, typically after 4–6 weeks. Stricture repair of the distal bile duct is indicated for persistent strictures using either Roux-en-Y choledochojejunostomy or choledochoduodenostomy biliary-enteric anastomosis. A choledochoduodenal anastomosis is preferable in patients with a large, dilated (>2 cm in diameter) proximal duct because of its technical ease and excellent results.

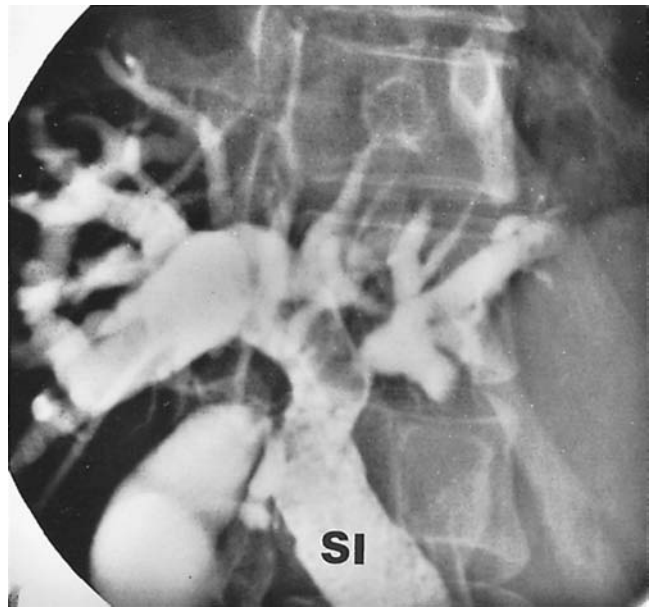

FIGURE 50-20 Cholangiogram in a patient with cholangiohepatitis with diffuse bile duct dilation. The biliary tree is filled with sludge (*SI*) and stones. (Reprinted, with permission, from Lillemoe KD. Biliary injuries and strictures and sclerosing cholangitis. In: Mulholland MW, Lillemoe KD, Doherty GM, Maier RV, Upchurch GR, Jr, eds. *Greenfield's Surgery: Scientific Principles and Practice*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:1014.)

Recurrent Pyogenic Cholangitis and Other Parasitic Disease

Recurrent pyogenic cholangitis, also known as oriental cholangiohepatitis, is endemic is Southeast Asia. Recurrent pyogenic cholangitis occurs infrequently in Western countries but with immigration from Asia is now increasingly encountered. Most cases are due to parasitic infection (*Ascaris lumbricoides* or *Clonorchis sinensis*) of the biliary tree. The infection results in biliary stasis, bacterial overgrowth and inflammation, biliary sludge, and brown (calcium bilirubinate) stone formation. Patients will typically have multiple intra- and extrahepatic stones and strictures, as well as recurrent cholangitis. Although strictures can occur throughout the biliary tree, they are most common in the main hepatic ducts, with disease in the left hepatic duct typically more frequent and more severe than the right. Classically, patients are young, thin, of Asian descent, and present with recurrent bouts of cholangitis. Cholangitis can range in severity from subclinical chronic illness to life-threatening acute suppurative cholangitis.

Diagnostic imaging modalities for oriental cholangiohepatitis include ultrasonography, CT scan, MRCP, ERC, and PTC. While ultrasound is poor at showing biliary strictures reliably, ultrasound is effective at demonstrating biliary obstruction, biliary tract stones, pneumobilia from gas-forming organism infection, and liver abscesses. Intrahepatic stones on ultrasound have a characteristic posterior acoustic shadowing. CT scan is useful for delineating hepatic anatomy and parenchymal involvement in more advanced disease, which is helpful for guiding potential liver resection. MRCP should be the first step to noninvasively define the biliary anatomy for the presence of strictures and stones. In addition, ERCP and PTC provide therapeutic biliary decompression in the setting of acute cholangitis (Fig. 50-20).

Long-term management of recurrent pyogenic cholangitis is aimed at treating biliary strictures using improved biliary drainage via biliary reconstruction. Following temporary decompression of the biliary tree with ERCP or PTC for acute cholangitis, patients are allowed a period of several weeks for clinical optimization prior to further management. Attempts at percutaneous or endoscopic manipulations of the biliary tree for stone extraction and biliary stricture dilation may be entertained. These interventions, however, have only temporary short-term benefit, and operative management will eventually need to be considered.

Standard operative management consists of Roux-en-Y hepaticojejunostomy, usually with a transhepatic stent. An attempt at complete clearance of stones from the intrahepatic ducts should be made, including the use of choledochoscopy. The stent is useful for follow-up cholangiography and further stone clearance after the initial procedure. Another option for follow-up management is for the blind end of the Roux-en-Y limb to be sutured to the peritoneal surface of the abdominal wall, along with a radiopaque marker. This creates an enteric

portal for future access to the biliary tree and anastomosis. In cases in which disease is confined to one portion of the liver with extensive fibrosis or hepatic abscess, hepatic resection may be considered.

Other causes of biliary strictures from parasites include various forms of echinococcal disease. Biliary strictures from echinococcal infection are primarily related to the compression of bile ducts by a thick-walled cyst. Because of its low rate of morbidity, long-term endoscopic stent therapy has become the initial therapy of choice in patients with biliary stricture from hydatid disease.[114,115] Operative therapy should be considered only in cases of failed previous repairs or failed endoscopic therapy. Surgical treatment of echinococcal liver and biliary disease is associated with a high rate of postoperative bile duct stricture, necessitating long-term clinical surveillance.

Sphincter of Oddi Stenosis

Also referred to as *papillitis*, stenosis of the sphincter of Oddi is a benign intrinsic obstruction of the common bile duct outlet. Papillitis is typically associated with inflammation, fibrosis, or muscular hypertrophy of the sphincter of Oddi. Patients with sphincter of Oddi stenosis are prone to (1) common bile duct obstruction from fibrosis and stenosis of the papilla, (2) recurrent pancreatitis, and (3) recurrent right upper quadrant abdominal pain in the absence of jaundice or pancreatitis. Initial presentation is most often jaundice or cholangitis. Patients can also sometimes present with an impacted stone at the ampulla.

The etiology of papillitis is unknown. Many cases are thought to be caused by trauma from the passage of multiple small stones or sludge from the common bile duct through the ampulla, resulting in inflammation, fibrosis, and stricture formation. There are other patients, however, that have papillary stenosis without gallstones. The cause in these cases is less clear; potential triggers include primary sphincter motility disorders and congenital anomalies.

Management consists of proper diagnostic imaging and therapeutic sphincterotomy. Cholangiography with either MRCP, PTC, or ERCP is the mainstay of diagnostic imaging. Therapeutic sphincterotomy can be performed either endoscopically or operatively in conjunction with cholecystectomy. The procedure of choice in patients with previous cholecystectomy is endoscopic sphincterotomy.

PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis (PSC) is an idiopathic condition characterized by a progressive, chronic cholestatic process, resulting in diffuse inflammation, sclerosis, and obliteration of the intra- and extrahepatic biliary duct systems and subsequently leading to biliary cirrhosis. The diagnosis of PSC is confirmed by cholangiography, with findings of multiple areas of stricture and dilation.

PSC has a variable course but can progress to biliary obstruction with secondary cirrhosis, portal hypertension with bleeding varices, or hepatic failure. Finally, PSC is a strong risk factor for the development of cholangiocarcinoma. Surgical management for symptomatic disease in patients with primarily extrahepatic and/or hilar disease and with no evidence of cirrhosis includes resection of the hepatic bifurcation with long-term transhepatic stenting. Finally, liver transplantation is the treatment of choice in patients with primarily intrahepatic strictures or advanced cirrhosis.

Pathogenesis

The etiology of PSC remains unknown, and a variety of causal theories have been proposed. Inflammatory bowel disease, particularly ulcerative colitis, is present in 30–90% of patients with PSC in several large population-based studies.[116,117] This tight association with inflammatory bowel disease suggests an autoimmune process. However, other mechanisms likely have a role in pathogenesis because only a minority with ulcerative colitis have PSC.[116] Although both ulcerative colitis and PSC may occur in the same individual, the two disorders may occur at different times. PSC, for example, may occur years after colectomy for ulcerative colitis. In addition to commonly occurring in patients with ulcerative colitis, PSC can occur with multifocal fibrosclerosis syndromes, including retroperitoneal, mediastinal, and/or periureteral fibrosis, Riedel's thyroiditis, or pseudotumor of the orbit.

Because there is the association between PSC and inflammatory bowel disease, several investigators have speculated that increased bacterial spread into the portal circulation from inflamed large or small intestine may lead to chronic or recurrent cholangitis. In support of this, an animal model of small intestinal bacterial overgrowth has biliary findings similar to PSC.[118] Although some studies have documented increased portal bacteremia in patients with PSC, other studies have not confirmed this finding.[119,120]

Correlating evidence for an immunological cause of PSC includes its association with hypergammaglobulinemia (30%) and an increase in IgM (50%). Patients with PSC can also have autoantibodies, with titers in the range associated with autoimmune hepatitis. In particular, anti–smooth muscle antibodies and antinuclear antibodies are present in approximately 75%.[121] Other autoantibodies commonly associated with the disease include cytoplasmic and nuclear antigens to neutrophils (pANCA). The autoantibody pANCA is often found in patients with PSC and no ulcerative colitis but is uncommon in patients with ulcerative colitis alone.[122]

Several genetic factors appear to give individuals a predisposition to PSC, including increased prevalence of HLA-B8, -DR3, and -Drw52a. The HLA-B8 and HLA-DR3 haplotypes are associated with other autoimmune diseases, including celiac disease, myasthenia gravis, and diabetes mellitus. A specific mutation of MICA (an MHC class I-related molecule) is also strongly associated with PSC patients (58 compared to 22% in controls).[123]

In contrast to PSC, secondary sclerosing cholangitis has similar clinical characteristics but has identifiable causes. The inciting factors for secondary sclerosing cholangitis include infectious cholangiopathy associated with acquired immunodeficiency syndrome, congenital biliary abnormalities, ischemic cholangiopathy secondary to intrahepatic arterial infusion of 5-fluorouracil, hepatic allograft rejection, graft-versus-host disease in bone marrow transplantation, collagen vascular diseases, histiocytosis X, sarcoidosis, and mast cell cholangiopathy. Patients with diffuse stricturing from 5-fluorouracil are managed by simple discontinuation of infusion, and in some cases percutaneous transhepatic drainage. Surgery should be reserved for patients with persistent evidence of biliary obstruction. The pathogenesis of acquired immunodeficiency syndrome cholangiopathy is believed to be viral and related to cytomegalovirus infection. No experience in the surgical management of this condition has been reported.

Presentation

Primary sclerosing cholangitis is predominantly a disease of young men. Approximately 70% of patients are male, and the average age at the time of diagnosis is 40 years. The typical presentation includes either an asymptomatic individual with abnormal liver function tests or an individual with intermittent jaundice. Other common symptoms may include right upper quadrant pain, weight loss, fever, pruritus, and fatigue. Despite its name, a minority have acute cholangitis, and blood cultures are rarely positive, approximately 10% are very symptomatic at the time of diagnosis; however, asymptomatic patients can have deceptively advanced disease.

Diagnosis

Laboratory tests with PSC typically reveal a cholestatic picture. Patients will have an elevated alkaline phosphatase, and during exacerbations may have elevated bilirubin. Early in the disease course, patients will have a normal albumin. The diagnosis is usually made through cholangiography, usually MRCP or ERCP. The typical study reveals multifocal strictures and dilations, referred to as "beading," of the intra- and extrahepatic ducts (Fig 50-21). The therapeutic modality of choice for cases requiring intervention is via the endoscopic route. PTC may be difficult because cannulation of nondilated and fibrotic ducts associated with PSC can be technically challenging via this approach. At the time of diagnostic cholangiography, brushings for cytology should be obtained to help distinguish between benign and malignant strictures.

Management

Management of PSC has several important treatment goals, including halting or reversing the disease process, managing disease progression, and symptom control. Unfortunately, there are no effective medical treatments that slow the progression of PSC. Patients should be monitored closely with cholangiography, liver biopsy, and cytologic brushings, to detect disease progression and development of malignancy or biliary cirrhosis.

FIGURE 50-21 Cholangiographic appearance in primary sclerosing cholangitis. Multiple irregular strictures and dilation (beading) of intrahepatic ducts. (Reprinted, with permission, from Lillemoe KD. Biliary injuries and strictures and sclerosing cholangitis. In: Mulholland MW, Lillemoe KD, Doherty GM, Maier RV, Upchurch GR, Jr, eds. *Greenfield's Surgery: Scientific Principles and Practice*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:1011.)

Most medical therapies are aimed at symptomatic relief or antibiotic treatment in the setting of cholangitis. Immunosuppression with glucocorticoids, methotrexate, azathioprine, 6-mercaptopurine, tacrolimus, or cyclosporine have not demonstrated efficacy for disease progression or survival. The use of ursodeoxycholic acid (UDCA) has demonstrated improvement of liver function tests and symptoms. A prospective, randomized, placebo-controlled trial of UDCA, however, did not demonstrate long-term clinical benefit with UDCA.[124] High-dose UDCA in several small pilot studies has demonstrated decreased disease progression and improved survival[125,126]; larger-scale prospective trials with high-dose UDCA are still ongoing.

A dominant extrahepatic biliary stricture (a high-grade, localized area of narrowing) occurs in approximately 20% of patients with PSC. These patients can be managed potentially with endoscopic therapy using dilation with or without stenting. Cytologic brushings at the time of endoscopy should also be obtained to investigate for cholangiocarcinoma. Several retrospective reports have demonstrated benefit in relieving

symptoms and improving liver function tests from endoscopic therapy,[127] and possible delay in disease progression.[128] The durability, however, of endoscopic therapy appears to be poor, with most patients requiring repeat dilations at regular intervals. Whether patients should undergo stenting at the time of dilation is not clear, with short-term results of stenting similar to those of dilation treatment alone,[129] and with no long-term outcomes at present comparing the two techniques.

Operative biliary reconstruction with transhepatic stenting for primarily extrahepatic and/or hilar disease in noncirrhotic patients has been demonstrated to have excellent long-term outcomes.[130,131] Ahrendt and associates[131] reported 146 patients with PSC managed with either biliary reconstruction or nonoperative biliary dilation. Survival was significantly longer in noncirrhotic patients with PSC managed surgically compared to those managed nonoperatively, and time before requiring liver transplant was significantly longer in the surgically-managed patients (Fig 50-22).

The natural history of PSC is typically progressive. Regardless of therapy, median survival is typically 12 years following diagnosis.[132,133] Survival is significantly worse in patients symptomatic at the time of diagnosis.[133] The incidence of cholangiocarcinoma of PSC patients at 5 years is 10–15% and at 10 years increases to 30%.

Hepatic transplantation provides excellent results in patients with PSC and end-stage liver disease, with 5-year actuarial survival and graft functioning of 85 and 72%, respectively.[134] Liver transplant should be considered in patients with sclerosing cholangitis before the disease is too advanced. Primary indicators for referral for liver transplant include persistently elevated bilirubin or decreased quality of life from disabling fatigue, severe pruritus, muscle wasting, or bacterial cholangitis. Biliary tract surgery before transplant does not affect either short-term outcomes or survival after transplant.

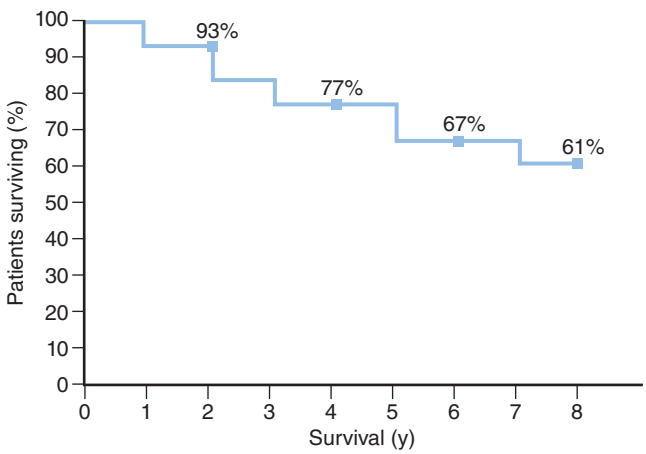

FIGURE 50-22 Actuarial survival rates among 31 noncirrhotic patients with primary sclerosing cholangitis who underwent resection of the hepatic bifurcation and long-term transhepatic stenting. (Reprinted, with permission, from Lillemoe KD, Pitt HA, Cameron JL. Primary sclerosing cholangitis. *Surg Clin North Am.* 1990;70:1397.)

Patients with preoperatively recognized cholangiocarcinoma have a poor prognosis. These patients are not appropriate candidates for transplantation. On the other hand, the presence of a small (<1 cm) cholangiocarcinoma discovered incidentally on pathology at transplant does not appear to portend a poor prognosis.

Patients transplanted for PSC are also at increased risk of postoperative biliary stricture compared to those transplanted for other primary disease processes. Recurrent PSC occurs in approximately 10% of patients following transplant, but with typically a less aggressive course.[134]

Summary

PSC currently has no proven effective medical treatment. Resection of the hepatic duct bifurcation in conjunction with long-term transhepatic stenting in noncirrhotic patients with primarily extrahepatic and/or hilar disease can delay or even prevent the need for hepatic transplantation. This operation does not influence the outcomes associated with hepatic transplantation. Transplant is recommended in patients with primarily intrahepatic strictures or advanced cirrhosis.

CANCER OF THE GALLBLADDER AND BILE DUCTS

Edward E. Whang • Mark Duxbury • Flavio G. Rocha • Michael J. Zinner

INTRODUCTION

This chapter focuses on biliary tract cancers, including those of the gallbladder and intrahepatic and extrahepatic bile ducts. Because the epidemiology, clinical presentation, and surgical approach associated with gallbladder cancer and bile duct cancer are distinct, these two cancers are discussed separately.

GALLBLADDER CANCER

Epidemiology

With an incidence of 6500 cases annually in the United States, gallbladder cancer is the fifth most common gastrointestinal tract malignancy in this country.[1] Incidence increases with age and is two to six times higher in women than in men. Worldwide, the highest incidence rates (up to 7.5 per 100,000 in men and 23 per 100,000 in women) occur among populations in the Western part of South America (eg, Chile and Peru), in North American Indians, in Mexican Americans, and in northern India.[2] The best characterized risk factor for the development of gallbladder cancer is chronic inflammation associated with gallstones (Table 51-1). Although only 0.5–3% of patients with cholelithiasis will develop gallbladder cancer, gallstones are present in 70–90% of patients diagnosed with gallbladder cancer.[2–4] Further, the geographic pattern of gallbladder cancer incidence correlates with that of cholelithiasis.

Other factors implicated to increase the risk of developing gallbladder cancer include porcelain gallbladder (the incidence of gallbladder cancer is reported to range from 12.5 to 60% in patients with this condition),[2–4] adenomatous polyps of the gallbladder (in contrast, cholesterol and inflammatory polyps and adenomyomas are not believed to be the risk factors), chronic infection with *Salmonella typhi*, carcinogen exposure (eg, increased risk has been reported for miners exposed to radon), and abnormal pancreaticobiliary duct junction (APBDJ). In this latter condition, a long common channel, formed by an abnormally proximal junction between the pancreatic and common bile ducts (CBDs), and elevated sphincter of Oddi pressures create a predisposition to reflux pancreatic exocrine secretions into the bile ducts. APBDJ is most prevalent in Asian countries and appears to increase the risk of development of biliary cancers, especially gallbladder cancer.[5] Gallbladder cancers arising in patients with APBDJ tends to occur at a younger age, to have a lesser degree of female predominance, and to be less often associated with cholelithiasis than those arising in patients without APBDJ.

Pathogenesis and Pathology

Chronic inflammation of the gallbladder mucosa related to gallstones is hypothesized to be the major factor leading to malignant transformation in most cases of gallbladder cancer. The progression from dysplasia, to carcinoma in situ (CIS), then to invasive cancer has been described for gallbladder cancer. The molecular changes associated with this progression are under investigation: *K-ras* mutations appear to be relatively uncommon, whereas *p53* mutations are prevalent and tend to arise early during this progression.[2]

Gallbladder cancers arising in patients with APBDJ may be associated with a distinct pathogenetic mechanism. These cancers are associated with a high prevalence of K-*ras* mutations and a late onset of *p53* mutations.[2] In addition, there is a high prevalence of premalignant epithelial hyperplasia with a papillary or villous histology in the gallbladder mucosa of patients with APBDJ.

TABLE 51-1: RISK FACTORS FOR DEVELOPING GALLBLADDER CANCER

Cholelithiasis
Porcelain gallbladder
Adenomatous polyps of the gallbladder
Chronic *Salmonella typhi* infection
Carcinogens (eg, radon)
Abnormal pancreaticobiliary duct junction (APBDJ)

Eighty percent of primary gallbladder cancers are adenocarcinomas. Other histological types include small cell cancer, squamous cell carcinoma, lymphoma, and sarcoma. Gallbladder cancers are also classified according to morphology as infiltrative, nodular, papillary, or a combination of these types. Papillary cancers tend to grow within the gallbladder lumen and are less likely to invade the liver or to metastasize to lymph nodes; it is associated with the best prognosis. Infiltrative or nodular cancers have a more diffuse pattern of growth that is difficult to recognize on imaging studies. These lesions are more likely to have invaded the liver and to have metastasized to lymph nodes by the time of diagnosis.

Several staging systems for gallbladder cancer have been described. The Nevin staging system, originally put forth in 1976, is of historical interest; the tumor, node, metastasis (TNM) system is used today (Table 51-2). The seventh edition of the American Joint Committee on Cancer (AJCC) staging system, published in 2010, contains important modifications to the staging of gallbladder cancer contained in the sixth edition.[6] N stage now includes N1 (metastasis to cystic duct, CBD, hepatic artery, and/or portal vein lymph nodes) and N2 (metastasis to periaortic, pericaval, superior mesenteric artery, and/or celiac artery lymph nodes) designations. Stage classifications have been revised to better reflect patient outcomes. For example, locally unresectable T4 cancers are now classified as stage IV, whereas T4N0 cancers were classified as stage III in the sixth edition. M0 cancers associated with lymph node metastasis are now classified as stage IIIB (with N1 disease) or stage IVB (with N2 disease), whereas these cancers were classified as stage IIB or III (depending on T stage) in the sixth edition.

TABLE 51-2: TNM STAGING OF GALLBLADDER CANCER: AMERICAN JOINT COMMITTEE ON CANCER, 7TH EDITION

Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage IIIA	T3	N0	M0
Stage IIIB	T1–3	N1	M0
Stage IVA	T4	N0–1	M0
Stage IVB	Any T	N2	M0
	Any T	Any N	M1

Tis, carcinoma in situ; T1, cancer invades lamina propria and/or muscularis;T1a, cancer invades lamina propria; T1b, cancer invades muscularis; T2, cancer invades perimuscular connective tissue but not beyond serosa or into liver; T3, cancer perforates serosa and/or directly invades the liver and/or one other adjacent organ or structure; T4, cancer invades main portal vein or hepatic artery or invades two or more extrahepatic organs or structures; N0, no regional lymph node metastasis; N1, metastasis to nodes along cystic duct, CBD, hepatic artery, and/or portal vein; N2, metastasis to periaortic, pericaval, superior mesenteric artery, and/or celiac artery lymph nodes; M0, no distant metastasis; M1, distant metastasis.

Clinical Presentation and Diagnosis

In the absence of advanced disease, patients with gallbladder cancer are asymptomatic or have symptoms, such as abdominal pain, anorexia, nausea, and vomiting, that may be indistinguishable from those of cholelithiasis or cholecystitis. With advanced disease, patients can present with weight loss, obstructive jaundice (due to tumor invasion into the biliary tree or to liver metastases), and duodenal obstruction. Signs associated with advanced disease include palpable abdominal masses, hepatomegaly, and ascites.

Laboratory tests may suggest obstructive jaundice if this condition is present; otherwise, they are not helpful in the diagnosis of gallbladder cancer. Tumor markers carcinoembryonic antigen (CEA) or CA 19-9 may be elevated; however, they lack sufficient sensitivity or specificity to be useful in clinical decision making for individual patients.

Patients with suspected gallstone- or gallbladder-related conditions typically undergo transabdominal ultrasonography (US). Findings suggestive of gallbladder cancer on ultrasonography include mural thickening or calcification, a gallbladder mass greater than 1 cm in diameter, and loss of the normal gallbladder wall–liver interface (Fig. 51-1). Relative to transabdominal ultrasonography, endoscopic ultrasonography (EUS) offers greater accuracy in assessing depth of gallbladder wall penetration by masses and regional lymph node enlargement. Selective application of EUS in patients with a gallbladder mass can help in the determination of whether the mass is non-neoplastic (eg, cholesterol pseudopolyp) or neoplastic. In addition, EUS-guided biopsy is an effective technique in cases in which a tissue diagnosis is required.

Computed tomography (CT) scanning should be performed on patients suspected of having gallbladder cancer. Findings of gallbladder cancer include a mass protruding into the gallbladder lumen or completely replacing the gallbladder and focal or diffuse thickening of the gallbladder wall (Fig. 51-2). CT scanning also offers information on the presence or absence of distant metastases, regional lymph node involvement, and local invasion into the liver and porta hepatis.

Magnetic resonance imaging (MRI) and magnetic resonance cholangiopancreatography (MRCP) can offer additional information on local invasion, particularly into the porta hepatis. These tests are used selectively, if CT findings

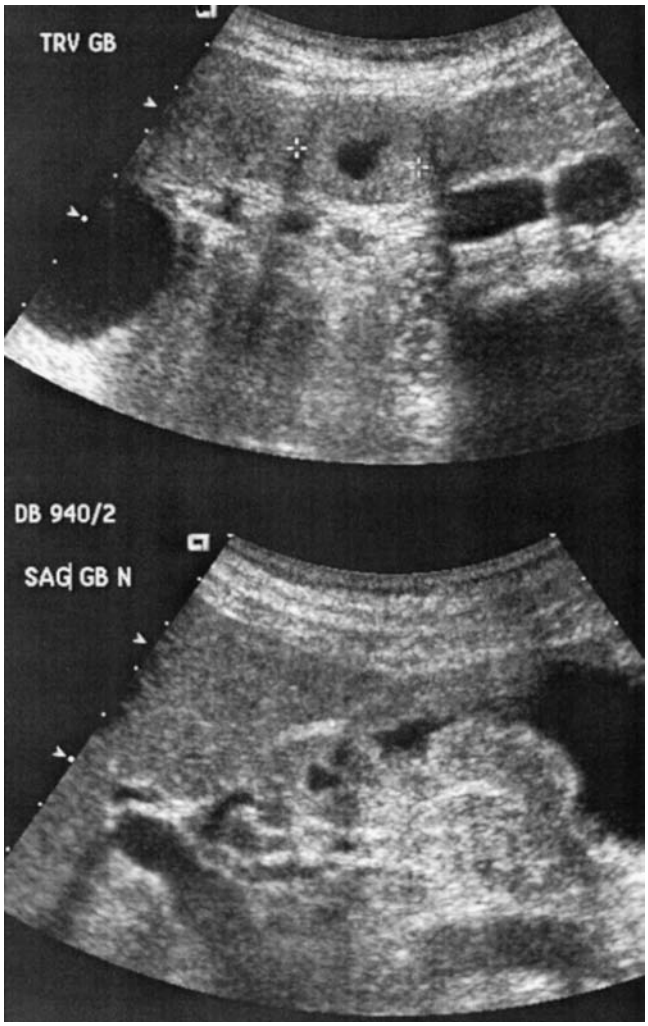

FIGURE 51-1 Ultrasound of gallbladder cancer. The images demonstrate asymmetric wall thickening of the body and neck of the gallbladder. (Used with permission from Dr. Steven E. Seltzer, Department of Radiology, Brigham & Women's Hospital; www.brighamrad.harvard.edu)

are equivocal. Similarly, endoscopic or percutaneous cholangiography is not routinely indicated; they are used primarily for palliation or preoperative management of obstructive jaundice.

Surgical Therapy

Surgical resection is the only known curative form of therapy for gallbladder cancer. For patients in whom surgical exploration is contraindicated because of medical comorbidities or evidence of unresectable disease on imaging studies (eg, metastatic disease), a percutaneous or endoscopic needle biopsy can be obtained to confirm the diagnosis. For patients in whom surgery is planned, a preoperative biopsy is contraindicated, as gallbladder cancer has a propensity for dissemination along needle tracts.

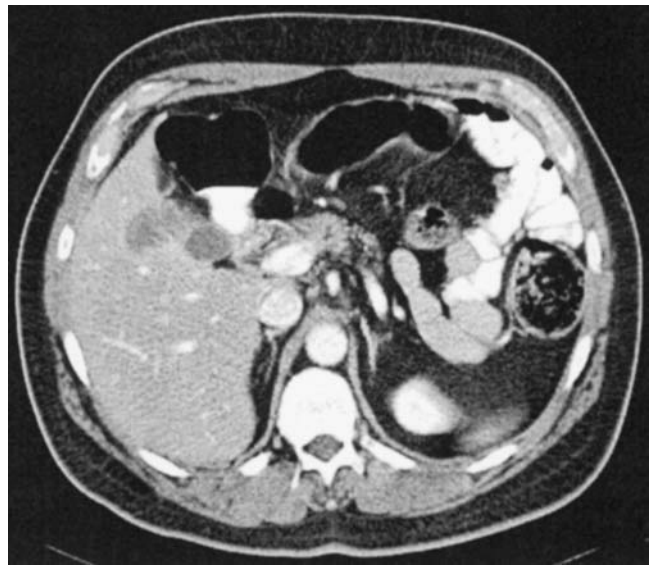

FIGURE 51-2 CT scan of gallbladder cancer. The image shows a 3.5 × 4 cm lesion arising from the gallbladder fundus and extending into segment 5 of the liver.

Recommendations for extent of surgical resection according to disease stage are given below. Specific technical issues are discussed subsequently.

STAGES 0 AND I

For Tis (carcinoma in situ) and T1a (cancer that invades the lamina propria but does not extend into the muscularis) lesions, the available retrospective data suggest that simple cholecystectomy is sufficient therapy in most cases. These lesions are most frequently detected on pathological examination of gallbladders removed for presumed benign disease. Patients diagnosed with gallbladder cancer in this manner should undergo formal imaging-based staging, and the cholecystectomy specimen should be carefully examined to ensure that all margins are negative for cancer. Patients with imaging studies that reveal no evidence of residual or metastatic gallbladder cancer and are found to have a cystic duct margin that is positive for cancer should undergo re-exploration with common duct excision, regional lymphadenectomy, and hepaticojejunostomy. In contrast, patients with negative margins and negative imaging studies who undergo no additional treatment for their gallbladder cancer have excellent outcomes that are unlikely to be improved by radical surgery.[7]

The management of T1b (cancer that invades the muscularis but does not extend into the perimuscular connective tissues) lesions has been controversial. In published series, the 5-year survival rate for patients with T1b gallbladder cancer having undergone radical resection averages 87.5%, whereas it averages only 61.3% in patients having undergone simple cholecystectomy alone.[8] Further, a recently published decision analysis suggests that radical surgery (described later for stage II cancers) is associated with improved survival compared to

that associated with simple cholecystectomy alone in most patients with T1b gallbladder cancer.[8] Therefore we treat patients with T1b gallbladder cancer in the same way we treat patients with T2 gallbladder cancer.

STAGE II

Patients found to have a T2 (cancer invasion into the perimuscular connective tissues of the gallbladder) lesion in their cholecystectomy specimen following surgery for presumed benign disease should undergo staging (as described earlier), and in the absence of contraindications, radical resection. Simple cholecystectomy is usually performed using a subserosal dissection plane, and, hence, may leave positive margins in the gallbladder fossa. Indeed, re-exploration reveals residual tumor in 40–76 % of these cases.[9–12] In addition, the probability of regional lymph node metastasis in patients with T2 gallbladder cancer has been reported to range from 28 to 63%.[9–12] These findings provide rationale for performing re-exploration with liver resection and regional lymphadenectomy of the hepatoduodenal ligament. There is convincing, albeit retrospective, evidence that such radical surgery is associated with improved survival for patients with T2 gallbladder cancer.[9–12] Given the propensity of gallbladder cancer to seed wound sites, re-excision of all surgical wounds, including laparoscopic port sites, during re-exploration has traditionally been recommended. However, re-excising port sites can be difficult (the trajectory through which ports had traversed the abdominal wall during the initial operation may be impossible to determine at the time of definitive surgery), and the value of this practice is unproven.

Patients suspected of having a T2 gallbladder cancer preoperatively (prior to cholecystectomy) should undergo staging, and in the absence of contraindications, exploration with en bloc resection of the gallbladder and adjacent liver to a depth of at least 2 cm, in addition to regional lymphadenectomy of the hepatoduodenal ligament. Although a nonanatomic liver resection encompassing the gallbladder fossa can be applied at the time of re-exploration or en bloc with the gallbladder during the initial procedure, anatomical resection of liver segments 4b and 5 may be associated with less intraoperative bleeding.

STAGE III

A role for aggressive surgical resection for some stage III gallbladder cancers has been receiving increasing recognition. This stage includes T3 lesions (locally advanced cancers that perforate the gallbladder serosa or directly invade the liver and/or one adjacent organ) and T1–3 lesions associated with regional lymph node metastasis.

Surgery for patients with T3 lesions requires careful planning and must be tailored to individual patients. For some patients with liver invasion, hepatic resections encompassing segments 4b and 5 may be sufficient. However, because the gallbladder fossa bridges both right and left hepatic lobes, trisegmentectomy is often required. Adjacent involved structures, such as the hepatic flexure of the colon, should be resected en bloc. Long-term survival rates ranging from 15 to 63% have been reported from some centers to be associated with these extended procedures for T3 lesions.[9–12]

STAGE IV

Stage IVA (invasion of the main portal vein, common hepatic artery, multiple extrahepatic organs) and stage IVB (N2 and/or distant metastasis) disease meet criteria for unresectability. Anecdotal reports of super-radical procedures involving resection of the main portal vein and/or common hepatic artery exist, but these procedures are associated with substantial morbidity and mortality rates and are unlikely to confer any survival benefits.

There is no evidence to support the application of debulking cholecystectomy to prevent subsequent episodes of cholecystitis; we do not recommend it.

Surgical Technique

For patients suspected of having resectable gallbladder cancer, we begin surgical exploration with laparoscopy. In the absence of disseminated disease, we proceed with open laparotomy. Because of the risk for gallbladder perforation and tumor spillage, we recommend against laparoscopic cholecystectomy in patients suspected of having gallbladder cancer. We also recommend early conversion to open laparotomy in patients undergoing laparoscopic cholecystectomy for presumed benign disease in whom the suspicion of gallbladder cancer arises intraoperatively.

We use a right subcostal incision, as it easily can be extended to a chevron incision if necessary. We then conduct a thorough examination for metastases, especially in the liver and on the peritoneal surfaces. For patients in whom the suspicion of gallbladder cancer is low at this point a simple cholecystectomy is done, and the gallbladder is examined using frozen-section analysis. Confirmation of T1b, T2, or T3 disease should prompt radical resection, as described later. If the diagnosis based on frozen-section analysis is ambiguous (ie, the presence of gallbladder cancer cannot be confirmed), radical surgery should be deferred. For patients in whom the suspicion of gallbladder cancer is high because of the presence of a firm mass, we obtain a small biopsy of the lesion. If the diagnosis of gallbladder cancer is confirmed on frozen-section analysis, the gallbladder is resected en bloc with the adjacent liver, as described later. Although determining depth of cancer invasion can be difficult on frozen sections, these grossly apparent cancers are likely to be T2 or more advanced lesions.

If radical resection is indicated, we then perform a Kocher maneuver to mobilize the duodenum and the head of the pancreas. Enlarged retropancreatic, celiac, superior mesenteric, or para-aortic lymph nodes are sampled and subjected to frozen-section analysis. If these lymph nodes are positive for metastases, N2 disease is present, and radical resection is aborted.

In the absence of N2 disease, we then perform regional lymphadenectomy. We skeletonize CBD and common hepatic duct, hepatic artery, and portal vein from the superior border of the duodenum to the liver hilum. During this dissection, lymph node–bearing fibrofatty tissues are swept toward the gallbladder and removed as a specimen. Tumor invasion of the portal vasculature is assessed during this dissection. We do not perform major vascular resection for advanced gallbladder cancer at our institution.

In contrast, we do perform common duct resection if the gallbladder cancer has invaded this structure. Common duct resection may also facilitate resection of bulky nodal disease in the hepatoduodenal ligament. The CBD is clamped and transected at the superior border of the duodenum, and its stump is oversewn with a nonabsorbable monofilament suture. Similarly, the common hepatic duct is transected near its bifurcation. We take care to minimize spillage of bile that may contain cancer cells.

We then perform en bloc resection of the gallbladder and the adjacent liver (or the liver resection alone if the patient has already undergone cholecystectomy). If the CBD has not been transected, the cystic duct is divided near its junction with the CBD. Similarly, the cystic artery is ligated and divided near its origin. For T2 cancers, either a nonanatomic wedge resection of the liver that encompasses the gallbladder fossa to a depth of 2 cm or anatomical resection of liver segments 4b and 5 is acceptable (Fig. 51-3). The capsule of the liver is scored with electrocautery to mark the resection plane. Overlapping chromic liver sutures are then placed around the periphery of the resection plane for hemostasis and retraction. The liver parenchyma is then transected using one of the standard methods (we usually use a combination of electrocautery and argon-beam coagulation). Care should be taken near the base of the liver resection margins to avoid injuring the right hepatic artery as it traverses inferiorly in the gallbladder fossa.

If the common duct has been resected, a 60-cm Roux-en-Y limb of jejunum is used to create a hepaticojejunostomy. The anastomosis is constructed using a single layer of 5-0 absorbable sutures.

Adjuvant Therapies

Adjuvant chemoradiotherapy is commonly administered after resection of gallbladder cancers. External beam or intraoperative radiation therapy alone or in combination with 5-flourouracil (5-FU) is associated with diminished rates of local recurrence. The impact of these regimens on survival is unclear; no data derived from prospective randomized clinical trials on the efficacy of these regimens exist.

Palliation

The goals of palliative therapy are relief of pain, manifestation of biliary obstruction (eg, pruritis and cholangitis) and bowel obstruction. Given the limited expected survival duration of patients diagnosed with unresectable gallbladder

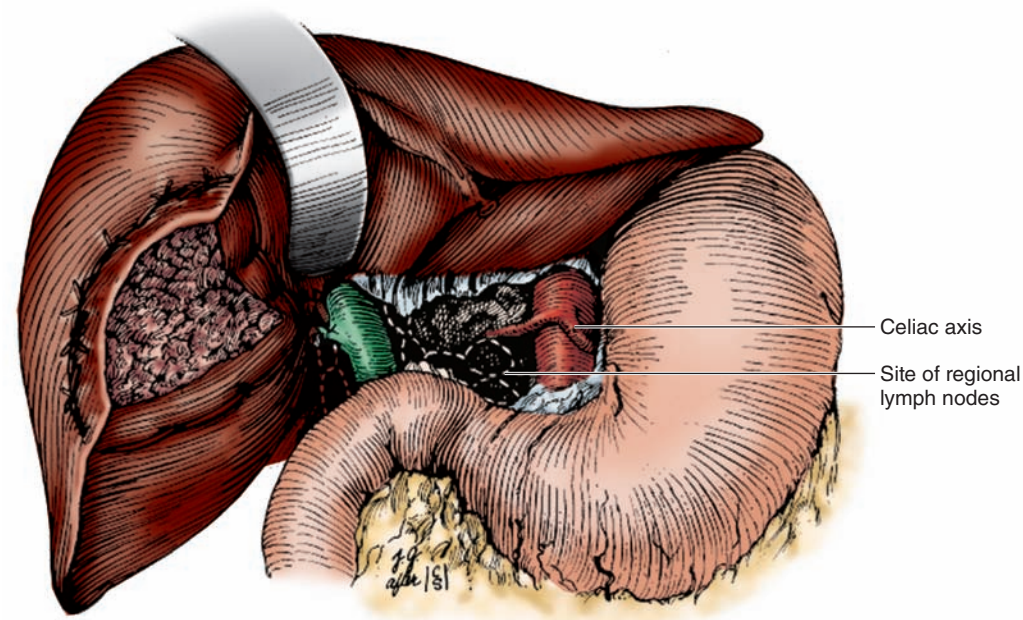

FIGURE 51-3 Radical resection of gallbladder cancer. This illustration depicts the operative field after radical cholecystectomy has been performed. The hatched line denotes the regions included in the lymphadenectomy.

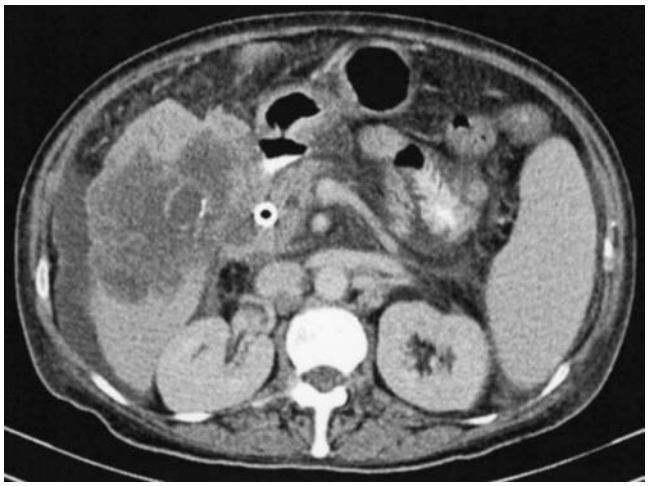

FIGURE 51-4 CT scan of advanced gallbladder cancer. The image demonstrates an advanced gallbladder cancer with extensive liver invasion. A stent has been placed for palliation of obstructive jaundice.

cancer (weeks to months), endoscopic or percutaneous stenting, rather than surgical bypass, is generally recommended for relief of symptomatic biliary obstruction (Figs.51-4 and 51-5). Biliary stents are discussed in greater detail later in the section on palliation of bile duct cancers.

Palliative radiation therapy, regional intra-arterial chemotherapy, systemic chemotherapy, and chemoradiotherapy all have been applied in patients with advanced gallbladder cancer. Results of the **ABC-02 trial** were recently published.[13] Data from this multicenter phase III trial of patients with locally advanced or metastatic biliary tract cancer (of whom ~36% had gallbladder cancer) demonstrated that the combination of gemcitabine plus cisplatin is associated with improved overall and progression-free survival than gemcitabine alone. As such, this gemcitabine-cisplatin combination represents the current standard treatment option for patients with advanced biliary tract cancers, including gallbladder cancer.[14]

FIGURE 51-5 Palliation of gallbladder cancer. This radiograph depicts a Wallstent that has been placed for palliation of obstructive jaundice in a patient with advanced gallbladder cancer.

Outcomes

Data derived from the National Cancer Database support the nihilistic view traditionally associated with gallbladder cancer.[15] In these population-based data, 5-year survival rates for patients with T1N0, T2N0, and T3N0 (or node-positive) disease are 39, 15, and 5%, respectively.

However, contemporary surgical series suggest that substantially improved outcomes can be achieved by the application of surgical resection of gallbladder cancers.[16] In these reports, 5-year survival rates following resection of T1 lesions ranges from 85 to 100%. With radical resection of T2, T3, and T4 lesions, reported 5-year postoperative survival rates range from 80 to 90%, 15 to 63%, and 2 to 25%, respectively. Radical resection of node-positive disease has been reported to be associated with 5-year survival in as high as 60% of patients, although some reported series contained no patients who survived 2 or more years among those with lymph node metastasis.[9–12]

Reported morbidity and mortality rates associated with resection of gallbladder cancers range from 5 to 54% and from 0 to 21%, respectively. In general the highest morbidity and mortality rates are associated with series describing more extensive resections.

The best reported outcomes among patients with unresectable biliary tract cancers are those from the **ABC-02 trial**.[13] The median overall survival among patients treated with the combination of gemcitabine and cisplatin was 11.7 months, whereas it was 8.1 months in those treated with gemcitabine alone.[13]

BILE DUCT CANCER

Epidemiology

In this discussion, the term *cholangiocarcinoma* is used interchangeably with *bile duct cancer* and is used to denote cancers arising in the intrahepatic or extrahepatic biliary tree, exclusive of the ampulla of Vater and gallbladder.

Approximately 6000 new cases of cholangiocarcinoma are diagnosed annually in the United States.[1] Most patients are diagnosed in the fifth through the seventh decades of life. Unlike gallbladder cancer, for which there is a clear female predominance, the incidence of bile duct cancer is slightly higher in males than in females.

TABLE 51-3: RISK FACTORS FOR BILE DUCT CANCER

Primary sclerosing cholangitis
Liver flukes infestation (*Opisthorchis viverrini* and *Clonorchis sinensis*)
Choledochal cysts
Caroli's disease
Hepatolithiasis
Chemicals (eg, Thorotrast and dioxin)
Hepatitis C
Lynch syndrome II
Bile duct adenoma and multiple biliary papillomatosis

Although most patients diagnosed with cholangiocarcinoma have no identifiable predisposing factors, several conditions clearly increase the risk of developing this cancer (Table 51-3). In Western countries, primary sclerosing cholangitis (PSC) is the most important risk factor; indeed, approximately 30% of cases of cholangiocarcinoma in the West are diagnosed in patients with PSC. Among patients with PSC, the estimated lifetime incidence of cholangiocarcinoma ranges from 10 to 15%, with an annual incidence of 0.6–1.5%.[17] In addition, cholangiocarcinoma tends to be diagnosed at an earlier age (third through fifth decades of life) in patients with PSC than in the general population.

In Asian countries, infestation with the liver flukes *Opisthorchis viverrini* or *Clonorchis sinensis* and hepatolithiasis are important factors for cholangiocarcinoma. Other risk factors include choledochal cysts, Caroli's disease, and exposure to the radiological contrast agent Thorotrast. Increased risk has been reported for workers in the auto, rubber, chemical, and wood-finishing industries and among patients with hepatitis C viral infection. Two genetic conditions (Lynch syndrome II and multiple biliary papillomatosis) have been identified as increasing the risk of developing bile duct cancer.

Pathogenesis and Pathology

Malignant transformation in the bile duct epithelium, as in other regions of the gastrointestinal tract, is hypothesized to arise in association with a step-wise accumulation of genetic abnormalities. A range of mutations and other abnormalities involving oncogenes (eg, K-*ras*, c-*myc*, c-*neu*, c-*erbB*-2, and c-*met*) and tumor suppressor genes (eg, *p53*) have been reported to be prevalent in bile duct cancers; the biological and clinical significance of these abnormalities remains to be characterized.[17]

Greater than 90% of bile duct cancers are adenocarcinomas. Other cancer types include squamous cell carcinoma, small cell carcinoma, and sarcomas. Adenocarcinomas of the bile duct are classified as sclerosing, nodular, or papillary (analogous to the classification scheme for gallbladder adenocarcinomas). Sclerosing (scirrous) tumors, which comprise over 80% of cholangiocarcinomas, are associated with an intense desmoplastic reaction, tend to be highly invasive, and are associated with low resectability rates. Nodular tumors have the appearance of constricting annular lesions and are also associated with low resectability rates. Papillary tumors are rare and present as bulky masses that project into the bile duct lumen. Because these lesions tend to cause symptomatic obstructive jaundice relatively early in their progression, they are associated with higher resectability rates than sclerosing or nodular tumors.

Cholangiocarcinomas are also classified into three groups according to their anatomical location: (1) intrahepatic or peripheral (10% of cases), (2) perihilar (65% of cases), and (3) distal (25% of cases). The transition between perihilar and distal locations occurs where the CBD becomes a retroduodenal structure. Bile duct tumors involving the hepatic duct bifurcation are known as *Klatskin tumors*. An additional anatomical classification system for perihilar cholangiocarcinomas, originally proposed by Bismuth,[18] is useful in surgical planning (Table 51-4).

The seventh edition of the AJCC staging system, published in 2010, contains separate staging systems for intrahepatic (Table 51-5), perihilar (Table 51-6), and distal bile duct cancers (Table 51-7).[6] These systems represent a significant departure from the AJCC sixth edition, in which intrahepatic cholangiocarcinomas were staged in the same manner as hepatocellular carcinomas, and all extrahepatic cholangiocarcinomas were grouped together in a single staging system.

Clinical Presentation and Diagnosis

Intrahepatic cholangiocarcinomas typically present with nonspecific symptoms, such as abdominal pain, anorexia, weight loss, and malaise. Another mode of presentation for these cancers is the incidental detection of an intrahepatic mass on imaging studies. The most common presentation of extrahepatic cholangiocarcinomas is painless jaundice. Other manifestations of biliary obstruction, such as acholic stools, dark urine, and pruritis, are also prevalent. Abdominal pain, fatigue, malaise, and weight loss can occur with advanced disease. Signs of advanced bile duct cancer include right upper quadrant abdominal tenderness, hepatomegaly,

TABLE 51-4: CLASSIFICATION OF PERIHILAR BILE DUCT CANCERS ACCORDING TO ANATOMIC LOCATION

Type I: tumors below the confluence of the left and right hepatic ducts
Type II: tumors reaching the confluence
Types IIIa/IIIb: tumors involving common hepatic duct and either the right or the left hepatic duct, respectively
Type IV: tumors that are multicentric or involve the confluence and both the right and left hepatic ducts

Stage IIA	T3	N0	M0
Stage IIB	T1–3	N1	M0
Stage III	T4	Any N	M0
Stage IV	Any T	Any N	M1

Tis, carcinoma in situ; T1, cancer confined to bile duct; T2, cancer invades beyond the wall of bile duct; T3, cancer invades gallbladder, pancreas, duodenum, or other adjacent organs without involvement of the celiac axis or the superior mesenteric artery; T4, cancer involves celiac axis or superior mesenteric artery; N0, no regional lymph node metastasis; N1, regional lymph node metastasis (regional lymph nodes are those along the CBD, hepatic artery, posterior and anterior pancreaticoduodenal nodes, and nodes along superior mesenteric vein and right lateral wall of superior mesenteric artery); M0, no distant metastasis; M1, distant metastasis.

and a palpable gallbladder. Cholangitis is unusual in the absence of prior biliary tract instrumentation.

The differential diagnosis for patients with these presentations includes primary and metastatic hepatobiliary and pancreatic neoplasms, and benign biliary strictures due to conditions such as PSC, choledocholithiasis, Mirizzi's syndrome, and postoperative strictures.

In patients with intrahepatic cholangiocarcinoma, laboratory studies usually reveal an increased alkaline phosphatase level in the setting of normal bilirubin levels. In patients with extrahepatic cholangiocarcinoma, laboratory tests are usually consistent with the presence of obstructive jaundice. Tumor markers (eg, CEA, CA 19-9, and CEA in combination with CA 19-9) may have utility in surveillance of patients with PSC; however, their sensitivities and specificities are too low for them to be applicable to screening or diagnosis in the general population.

Transabdominal ultrasonography may reveal dilation of the biliary tree, which, in the absence of choledocholithiasis, suggests a possible biliary or pancreatic malignancy and should prompt contrast-enhanced spiral CT scanning. CT scan findings of intrahepatic cholangiocarcinomas include a liver mass with or without peripherally dilated ducts (Fig. 51-6). With perihilar cholangiocarcinomas, the primary tumor may not be

Tis, carcinoma in situ; T1, cancer confined to bile duct, with extension up to the muscle layer or fibrous tissue; T2a, cancer invades beyond the wall of bile duct to surrounding adipose tissue; T2b, cancer invades adjacent hepatic parenchyma; T3, cancer invades unilateral branches of the portal vein or hepatic artery; T4, cancer invades main portal vein or its branches bilaterally, or the common hepatic artery, or the second-order biliary radicals bilaterally, or unilateral second-order biliary radicals with contralateral portal vein or hepatic artery invasion; N0, no regional lymph node metastasis; N1, regional lymph node metastasis (including nodes along cystic duct, CBD, hepatic artery, and portal vein); N2, metastasis to periaortic, pericaval, superior mesenteric artery, and/or celiac artery lymph nodes; M0, no distant metastasis; M1, distant metastasis

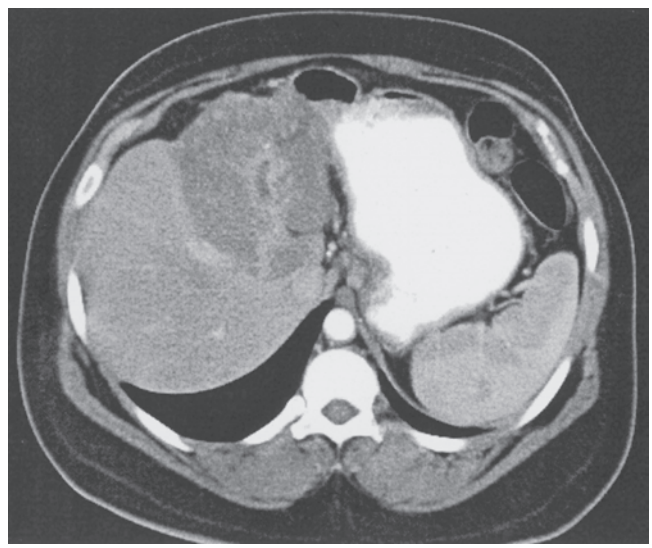

FIGURE 51-6 CT scan of intrahepatic cholangiocarcinoma. The image shows an intrahepatic cholangiocarcinoma primarily involving the left lobe of the liver.

visualized; their presence is suggested by the detection of dilated intrahepatic bile ducts (often bilateral), a normal or collapsed gallbladder (if the site of biliary obstruction of proximal to the cystic duct–bile duct confluence), a normal caliber distal CBD, and a normal pancreas. Findings of distal cholangiocarcionomas include dilation of intra- and extrahepatic bile ducts and the gallbladder, with or without a mass in the head of the pancreas. In addition to offering information on the site of the primary lesion, the CT scan offers valuable information necessary for staging and planning of therapies, including the presence or absence of local vascular invasion, regional lymphadenopathy, distant metastasis, and liver atrophy. Unilobar bile duct obstruction typically results in atrophy of the affected liver lobe together with hypertrophy of the unaffected lobe (atrophy-hypertrophy complex). Absence of the atrophy-hypertrophy complex can suggest vascular encasement by tumor.

For patients who are surgical candidates, an important goal of the preoperative evaluation is determining the proximal and distal tumor extent. If CT scanning fails to demonstrate the tumor itself (as is usually the case for resectable perihilar cholangiocarcinomas), additional imaging is helpful in surgical planning. In most centers, distal tumors are assessed by endoscopic retrograde cholangiopancreatography (ERCP, Fig. 51-7), whereas intrahepatic and perihilar tumors are best assessed by percutaneous transhepatic cholangiography (PTC). Recently, there has been increasing application of MRCP in this setting. Unlike conventional cholangiography, MRCP is noninvasive and does not require contrast material to be injected in the biliary ductal system. It also allows for visualization of the bile ducts both proximal and distal to a stricture. Some reports suggest that MRCP when applied to patients with cholangiocarcinoma offers information equivalent to that offered by CT scanning and traditional cholangiography combined.[19] For these reasons, MRCP has been supplanting traditional cholangiography in the evaluation of patients with suspected cholangiocarcinoma in some centers.

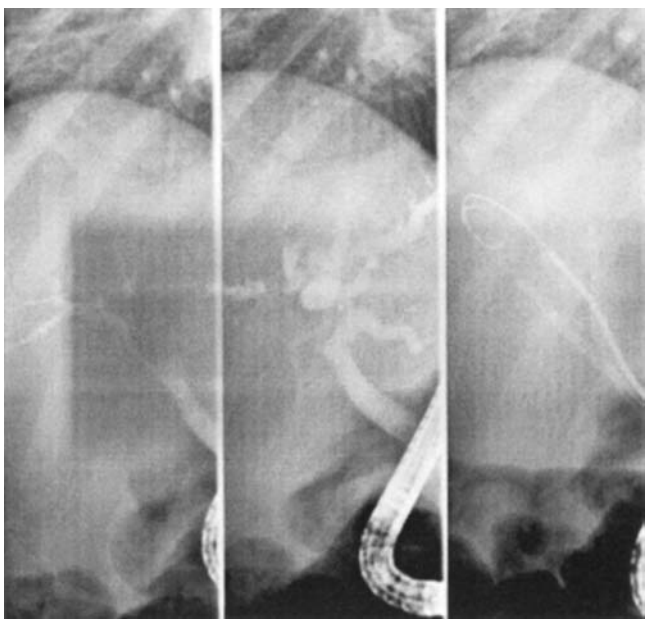

FIGURE 51-7 ERCP of hilar cholangiocarcinoma. The images depict a stricture at the confluence of the hepatic ducts in a patient with a Klatskin tumor.

Additional studies are not routinely indicated. The role of positron emission tomography (PET) scanning in the evaluation of patients with cholangiocarcinoma continues to be studied but is not yet established. If surgery is not planned, tissue diagnosis can be obtained through endoscopic or percutaneous biopsy. If surgical exploration is planned, a preoperative biopsy is not indicated.

A particularly challenging situation can arise in patients with PSC, 20–50% of whom will develop a benign dominant biliary stricture. These dominant strictures can be morphologically indistinguishable from cholangiocarcinomas on cholangiography. Cytological examination of brushings obtained during ERCP is the most common modality used for the diagnosis of cholangiocarcinoma in this setting; however, the sensitivity of this modality (40–80%) can be poor.[20] The most accurate modality for diagnosing cholangiocarcinoma in patients with PSC who present with a dominant biliary stricture is endoscopic ultrasonography with fine-needle aspiration (EUS-FNA, sensitivity and specificity approaching 80 and 100%, respecively).[21] EUS-FNA should be applied in patients with equivocal or negative brush cytological findings if clinical suspicion of cholangiocarcinoma being present in a dominant stricture is high.

Surgical Therapy

As is the case for gallbladder cancer, complete surgical resection is the only potentially curative therapy for patients with cholangiocarcinoma. Therefore, all patients suspected of having cholangiocarcinoma should be offered exploration unless contraindications to surgical resection exist. These contraindications include (1) major comorbidities precluding safe surgery, including cirrhosis, (2) metastatic disease, (3) invasion of the main portal vein or hepatic artery proximal to their bifurcations, (4) bilateral invasion of portal vein and/or hepatic artery branches, (5) bilateral hepatic duct involvement (up to secondary radicles bilaterally), and (6) unilateral duct and/or vessel involvement with contralateral liver lobe atrophy.

The utility of preoperative biliary stenting in patients with cholangiocarcinoma is controversial. Available retrospective data and one recently reported multicenter randomized controlled trial[22] suggest that among patients undergoing pancreaticoduodenectomy for periampullary cancers, routine preoperative biliary stenting is associated with increased perioperative morbidity rates, especially with respect to infectious complications. Therefore, we do not recommend routine preoperative stenting for patients with distal bile duct cancers. Instead, selective application of stenting in patients with obstructive jaundice who experience significant delay until surgery is performed (eg, those

undergoing neoadjuvant therapy) is appropriate. However, this experience should not be extrapolated to patients with perihilar cholangiocarcinomas, for whom the relationship between preoperative stenting and operative outcomes is less clear. Some authors believe stents placed preoperatively make intraoperative assessment of tumor extent more difficult. In our experience, bilateral Ring catheters, placed percutaneously into the left and right biliary systems shortly before the time of surgery, greatly facilitates the resection of perihilar cholangiocarcinomas. Our approach is described in detail later.

Surgical Technique

Resectable intrahepatic cholangiocarcinomas are treated using standard liver resections, and distal cholangiocarcinomas are treated by pancreaticoduodenectomy. These procedures are discussed elsewhere in this textbook. The following discussion focuses on our surgical approach to resectable perihilar cholangiocarcinomas.

We begin with exploratory laparoscopy to rule out the presence of disseminated disease that may have escaped detection on preoperative imaging. Reports suggest that 25–30% of patients undergoing laparoscopic exploration for cholangiocarcinoma are found to have unresectable disease during laparoscopy.[23] If laparoscopic examination fails to reveal metastasis, we proceed with laparotomy through either an upper midline or a right subcostal incision (that can be extended to the left as necessary). We then conduct a thorough examination for the presence of distant metastases. Enlarged lymph nodes are biopsied and subject to frozen-section analysis. The presence of metastasis in N2 (periaortic, pericaval, superior mesenteric artery, and/or celiac artery) lymph nodes is a contraindication to radical resection.

Next, we lower the hilar plate by incising the liver capsule at the base of the quadrate lobe (segment 4) between the gallbladder fossa and the umbilical fissure (Fig. 51-8). This maneuver facilitates inspection of the porta hepatis. At this point we palpate the tumor in an attempt to assess its proximal and distal extent.

We then begin mobilization of the extrahepatic biliary tree from its surrounding structures. The gallbladder is mobilized, and the CBD is circumferentially dissected just proximal to where it assumes a retroduodenal location. We transect the CBD at this level and oversew the stump of the distal CBD with a nonabsorbable monofilament suture. We then dissect the extrahepatic biliary tree off of the underlying vascular structures, starting distally and working proximally (Fig. 51-9). During this step, cephalad and anterior traction is applied to the gallbladder, distal CBD, and the distal ends of the preoperatively placed Ring catheters (which in combination form a convenient handle that can be grasped). The bile duct and surrounding lymph node–bearing soft tissues

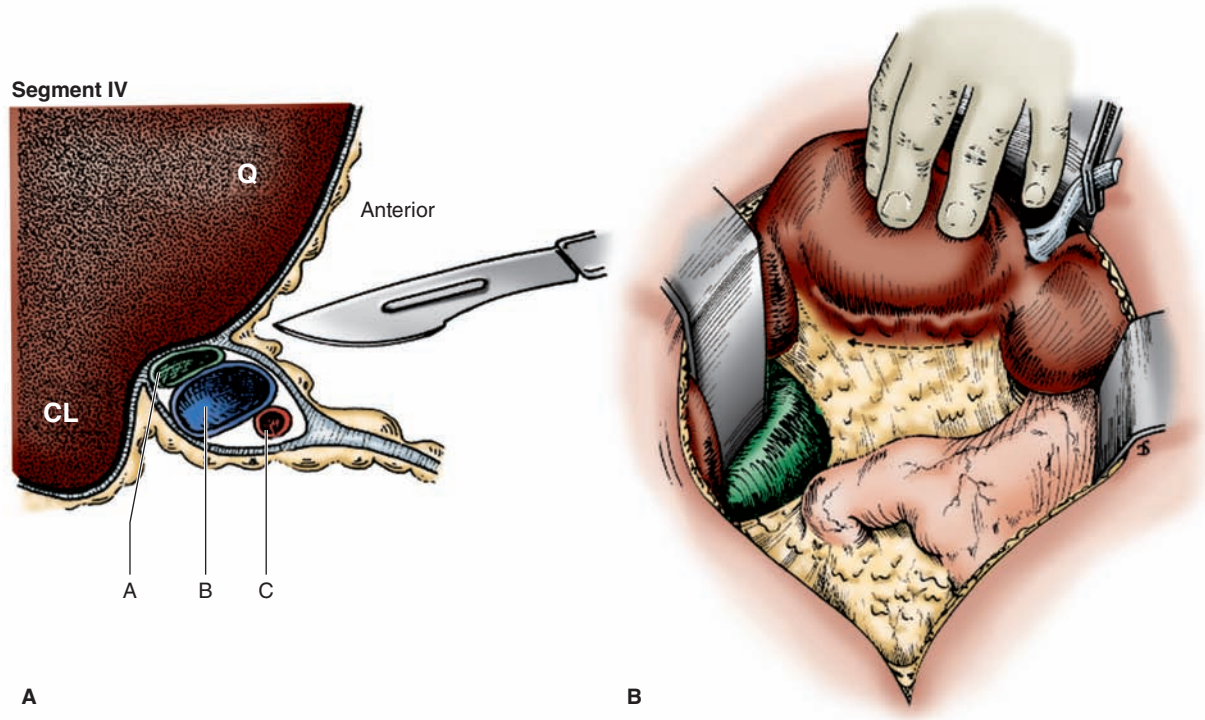

FIGURE 51-8 Lowering of hilar plate. This illustration showing the quadrate (*Q*) and caudate (*CL*) lobes and the portal trial (bile duct [*A*], portal vein [*B*], and hepatic artery [*C*] depicts a sagittal section through the region of the hilar plate. The knife indicates the point of incision used when lowering the hilar plate.

should be cleared en bloc from the portal vein and the hepatic artery. Only after this step is accomplished the possibility of tumor vascular invasion is definitely eliminated.

The most difficult step in this dissection is usually encountered at the hepatic duct bifurcation, the site of Klatskin tumors. Dissection here is facilitated by placing vessel loops around the left and right hepatic ducts and placing them on traction as necessary. Because the left duct typically runs along the undersurface of the liver (segment 4) for a longer distance than the right duct, it is usually easier to dissect the left duct first and encircle it with a vessel loop prior to dissecting the right duct. We find that the Ring catheters are particularly helpful in the identification of the right and left hepatic ducts during this stage of the procedure. The resection is completed by transecting the biliary duct(s) proximal to the tumor (Fig. 51-10). Figure 51-11 shows the operative field following resection of a Klatskin tumor. The skeletonized hepatoduodenal ligament structures are visible. Frozen sections of the proximal and distal margins should be checked intraoperatively, with the goal of achieving negative microscopic margins (R0 resection).

Reconstruction following resection of Klatskin tumors consists of bilateral hepaticojejunostomies to a 60-cm retrocolic Roux-en-Y limb of jejunum. Small secondary or tertiary biliary branches should be incorporated into the anastomoses or ligated. Prior to performing the anastomoses, the Ring catheters are replaced with soft Silastic catheters (usually 14–18F) (Fig. 51-12). Catheter exchange is performed as follows: The Silastic catheters are placed over the distal ends of the cut Ring catheters (the portions protruding from the transected bile

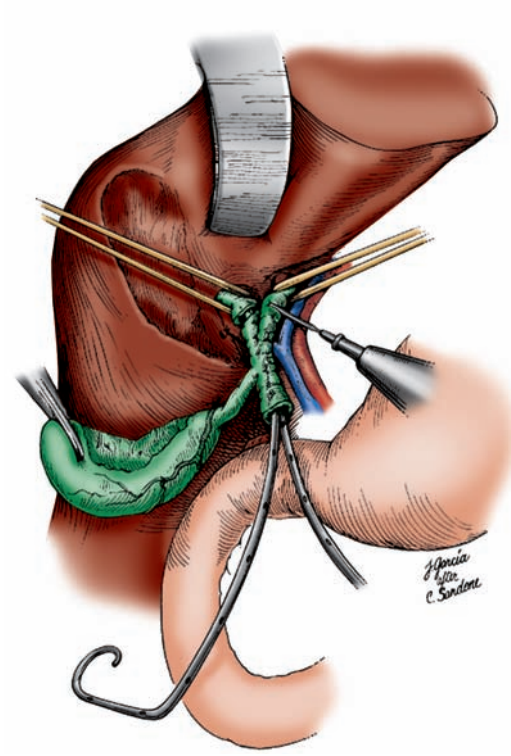

FIGURE 51-10 Transection of proximal bile ducts. This illustration depicts the transection of the left and right hepatic ducts proximal to the hilar cholangiocarcinoma. Note the vessel loops around each of the hepatic ducts and the Ring catheters.

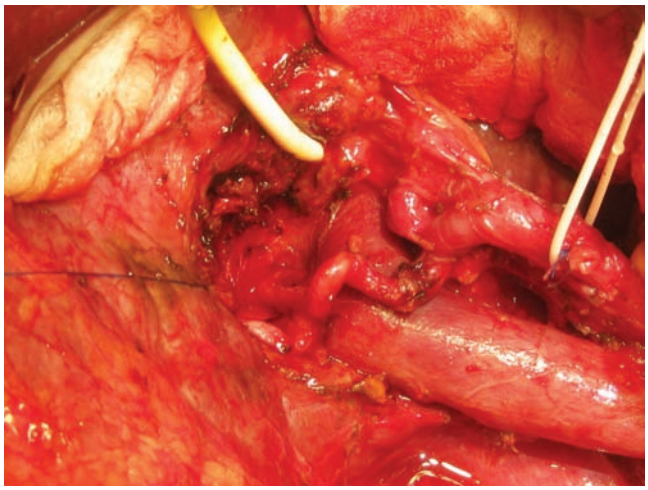

FIGURE 51-11 Intraoperative photograph showing skeletonized hepatoduodenal ligament structures following resection of Klatskin tumor. A vessel loop has been placed around the common hepatic artery.

ducts), and the Ring and Silastic catheters are sewn together with cross sutures. The Ring catheters are then pulled proximally through the intrahepatic biliary tree and out the surface of the liver with the Silastic catheters attached. Finally, the Ring catheter is removed. If Ring catheters have not been placed preoperatively, the Silastic catheters can be placed as follows: Randall stone forceps are inserted into the intrahepatic biliary tree through the transected bile ducts and out the liver surface. The Silastic catheters are then sewn to the "eyelet" at the end of the forceps and pulled back down the duct. This maneuver is repeated so that a Silastic catheter is present in each of the right and left biliary systems.

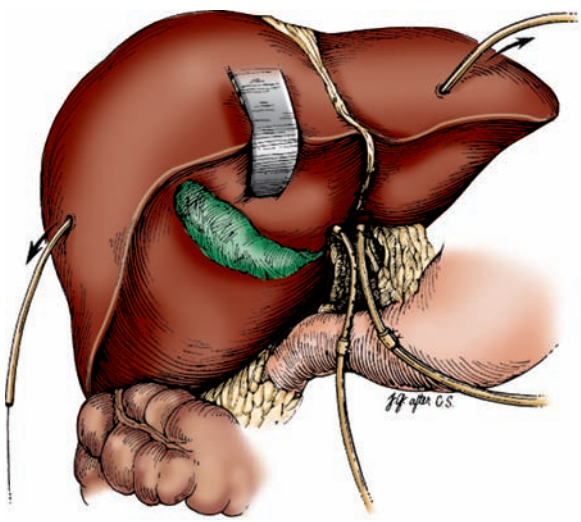

FIGURE 51-12 Replacement of biliary stents. Following completion of resection, the Ring catheters are exchanged for Silastic catheters, as described in the text.

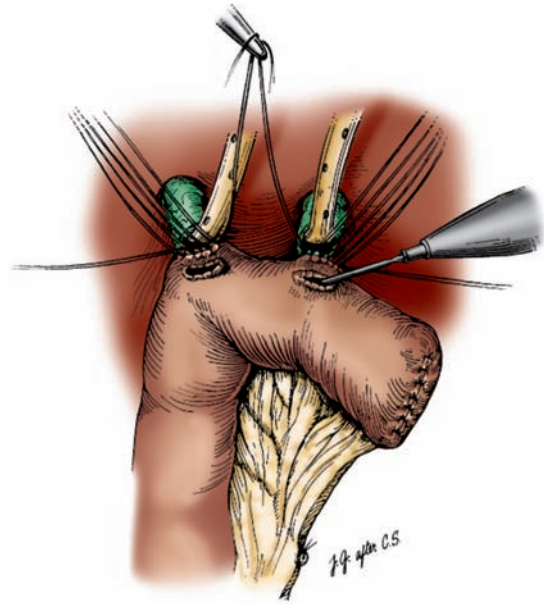

FIGURE 51-13 Bilateral hepaticojejunostomies. The biliary–enteric anastomoses are created, starting with the posterior row of sutures.

The hepaticojejunostomies are created using a single layer of interrupted 5-0 absorbable monofilament sutures (Fig. 51-13). The posterior row of sutures are placed but not tied until the entire row can be "parachuted" closed. Using cautery, two small openings in the distal portion of the Roux limb are made, through which the distal ends of the Silastic catheters are placed. The anterior row of sutures are then placed and tied to complete the anastomosis (Fig. 51-14).

We then suture the Roux limb to the undersurface of the liver and to the mesocolon. We suture two large radiopaque clips to the surface of the liver at the sites where each of the Silastic tubes exit. These clips serve as permanent markers of the exit sites and allow for radiological visualization of the relationship between the liver surface and the last radiopaque marker on the Silastic catheters.

Recently, more aggressive approaches that include the routine application of liver resection, and portal vein resection in select cases, are being reported with increasing frequency. Addition of hepatic resection can extend the possibility of R0 resection to patients with Bismuth type III lesions (Fig. 51-15). Because Bismuth types II and III tumors may involve the caudate lobe ducts, some authors recommend routine caudate lobectomy when resecting these lesions. Although the highest 5-year postoperative survival rates have been reported from centers using such aggressive surgical approaches, these extended procedures should be done only if they can be performed with low perioperative morbidity and mortality rates. In addition, some centers have reported the application of preoperative portal vein embolization, to induce lobar hypertrophy and thereby extend the limits of liver resection in patients at risk of developing hepatic insufficiency postoperatively.

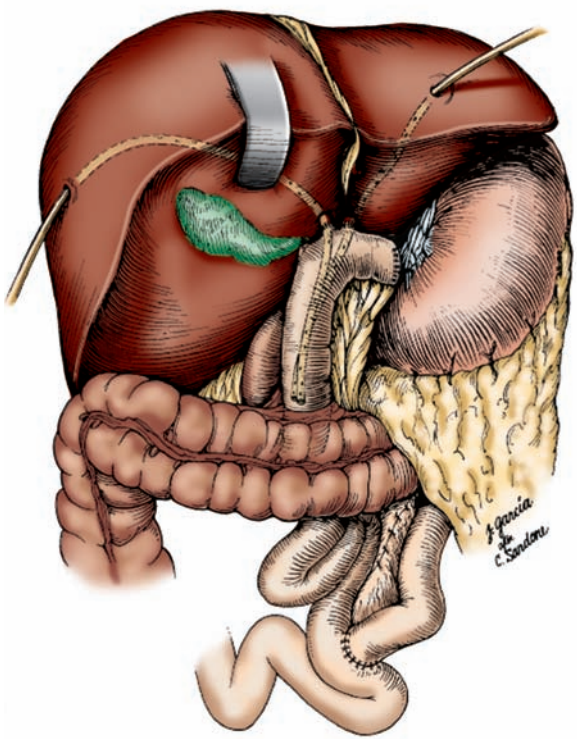

FIGURE 51-14 Completed reconstruction. This illustration depicts the operative field following completion of the bilateral hepaticojejunostomies.

Finally, orthotopic liver transplantation has been applied to patients with intrahepatic and perihilar cholangiocarcinomas. However, cancer recurrence occurs in over 50% of cases, and 5-year survival rates average only 22%. Long-term survivors have been reported; most of these patients had small, peripheral cholangiocarcinomas discovered incidentally. For patients with known cholangiocarcinoma, liver transplantation following neoadjuvant therapy in carefully selected and staged patients is being studied, with some promising initial results.[24] This form of therapy should not be offered outside the context of a study protocol.

Adjuvant Therapies

Adjuvant chemotherapy, radiotherapy, or chemoradiotherapy is commonly offered, based on results of retrospective series. However, clear efficacy data derived from prospective randomized clinical trials are lacking. Similarly, neoadjuvant therapy, associated with anecdotal reports of tumor response sufficient to permit margin-negative resection in patients with advanced cholangiocarcinoma, needs to be studied further.

Palliation

The major goal of palliation is relief of symptoms of biliary obstruction. Endoscopic or percutaneous biliary stenting is associated with less morbidity than surgical biliary bypass and is therefore recommended except in patients who are found to have unresectable disease at the time of surgical

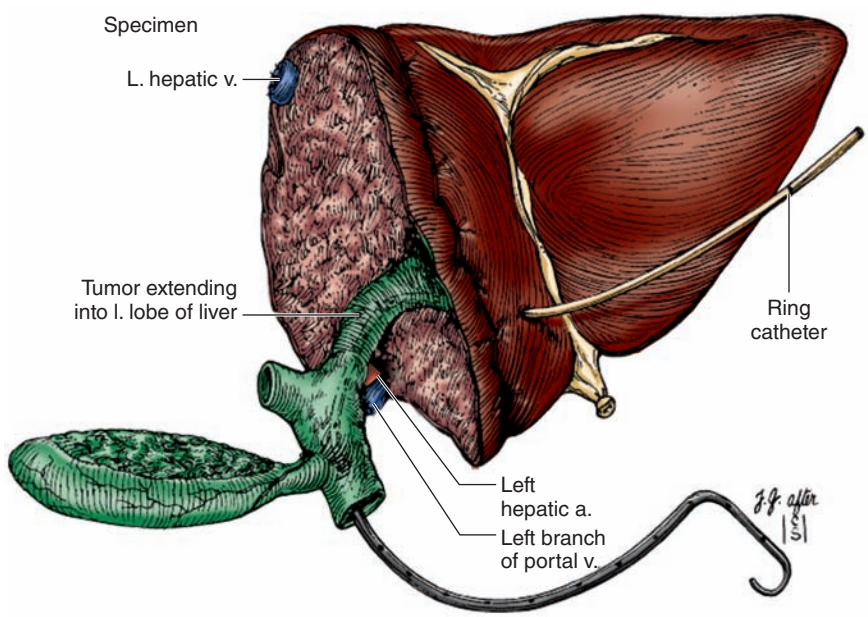

FIGURE 51-15 Extended resection of hilar cholangiocarcinoma. This illustration depicts of the resection specimen following removal of the extrahepatic bile duct en bloc with the left lobe of the liver.

exploration or those in whom nonsurgical stenting cannot be accomplished. Endoscopic stenting is the preferred approach for distal bile duct cancers; proximal cancers are more difficult to stent endoscopically and usually require a percutaneous approach.

Patients with a Bismuth type I hilar cholangiocarcinoma are usually palliated effectively with a single biliary stent. Patients with Bismuth types II, III, and IV hilar cholangiocarcinomas may require two or more separate stents to decompress the entire biliary tree and prevent obstruction-related cholangitis. However, in a prospective, randomized controlled trial of patients with hilar cholangiocarcinoma, unilateral biliary drainage was found to provide adequate palliation of obstructive jaundice; patients randomized to receive bilateral biliary stents had higher complication rates (cholangitis) but no detectable benefits.[25] The approach therefore needs to be individualized.

Metal stents tend to provide more durable palliation than plastic (polyethylene) stents (median stent patency of 8–12 vs 4.8 months) and are generally preferable in patients with malignant biliary obstruction. Plastic stents should be changed every 3–6 months to prevent episodes of cholangitis related to stent occlusion; these stents may be appropriate for patients with estimated survival durations of less than 3 months (eg, patients with diffuse metastases).

For patients who are found to have carcinomatosis at the time of exploratory laparoscopy, laparoscopic cholecystectomy traditionally has been recommended, to prevent subsequent development of acute cholecystitis related to biliary stent–induced cystic duct obstruction. The value of prophylactic cholecystectomy in this setting is unproven and should be performed only if it can be done safely. Stenting should be performed using percutaneous or endoscopic techniques postoperatively.

For patients who are found to have unresectable disease at the time of open exploration, available retrospective evidence suggests that surgical biliary bypass offers more durable palliation than percutaneous or endoscopic stenting. Patients with unresectable distal cholangiocarcinoma should undergo choledocho- or hepaticojejunostomy. The palliative options for patients with unresectable perihilar cholangiocarcinoma include (1) tumor debulking with Roux-en-Y hepaticojejunostomy and intraoperative placement of Silastic transhepatic catheters (as described earlier) and (2) Roux-en-Y hepaticojejunostomy using the segment 4 or 5 duct. Segment 3 or 5 bypass is used in patients with advanced perihilar cholangiocarcinoma with predominantly right- or left-sided disease, respectively. The segment 3 hepatic duct is approached by following the falciform ligament into the recess of the left lobe in the umbilical fissure (Fig. 51-16). Localization of the segment 5 duct is difficult, as no external anatomic landmarks exist and considerable parenchymal dissection if often necessary. Intraoperative ultrasonography (IOUS) considerably facilitates this procedure. These unilateral bypasses should be avoided in the presence of ipsilateral liver lobe atrophy, a finding that indicates limited functional hepatic parenchyma.

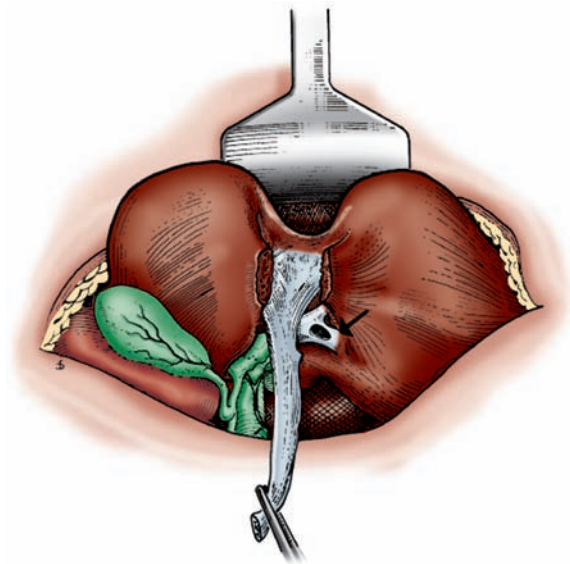

FIGURE 51-16 Segment 3 bypass. This illustration depicts the approach to the segment 3 duct (arrow) to which a Roux-en Y limb of jejunum can be anastomosed for palliation of obstructive jaundice in patients with advanced perihilar cholangiocarcinoma primarily affecting the right biliary system.

External beam radiation and transcatheter brachytherapy may contribute to pain relief and biliary decompression; however the data on the effects of radiation on survival duration are conflicting.

Recently published results of the ABC-02 trial (discussed earlier in the section on palliation of patients with advanced gallbladder cancer) indicate that the combination of gemcitabine plus cisplatin should be offered to patients with advanced bile duct cancer.[13] Nearly 60% of patients who were enrolled in this multicenter phase III trial had locally advanced or metastatic bile duct cancer. Administration of the gemcitabine-cisplatin combination was associated with prolongation of overall and progression-free survival compared to administration of gemcitabine alone.

Finally, photodynamic therapy (PDT), in which endoscopic application of light activates a photosensitizer, leading to local cell death, has been associated with promising results. One prospective randomized trial, in which 19 patients with advanced cholangiocarcinoma were randomized to stenting alone or stenting followed by PDT, was terminated prematurely because patients randomized to the PDT arm were found to have a significantly longer survival (493 vs 98 days, median survival) in addition to improved biliary drainage and quality of life.[26] PDT-associated prolongation of survival was observed in another small prospective randomized trial.[27] Additional study of this modality is warranted.

Outcomes

Less than 50% of patients diagnosed with perihilar cholangiocarcinoma are able to undergo curative resection. Reported 5-year postoperative survival rates for patients with these cancers are highly variable; they range from 8 to more than 50%.[19] In general, the highest survival rates are associated with series containing a high proportion of cases in which R0 resection was achieved. Series containing the highest R0 resection rates (>75% of cases in some published experiences) tend to be reported by institutions where liver resection is applied liberally to patients with cholangiocarcinoma.[19] A caveat that should be remembered is that these same series also tend to be associated with the highest perioperative mortality rates (up to 10% in some cases).

For patients with intrahepatic cholangiocarcinoma, reported 3-year survival rates following curative resection with negative margins range from 22 to 66%. For patients with distal cholangiocarcinoma, 5-year survival rates following pancreaticoduodenectomy range from 15 to 25% in most reported series. Among patients with node-negative disease, 5-year postoperative survival rates as high as 54% have been reported.

The best reported outcomes among patients with unresectable biliary tract cancers are those from the ABC-02 trial.[13] The median overall survival among patients treated with the combination of gemcitabine and cisplatin was 11.7 months, whereas it was 8.1 months in those treated with gemcitabine alone.[13]

INTRODUCTION

The most common biliary tract procedure currently performed is the laparoscopic cholecystectomy. This has yielded interest in management of common bile duct (CBD) stones encountered during the procedure. Successful management of such stones during a laparoscopic cholecystectomy is beneficial to the patient by preventing a secondary or more invasive procedure to clear the duct, such as endoscopic retrograde cholangiopancreatography (ERCP) or laparoscopic CBD exploration, respectively. Furthermore, an all-inclusive operation may be more cost-effective. Other operations on the biliary tract, including bile duct resections and reconstructions can be the most technically demanding procedures that a general surgeon performs. The advancement of technology and surgical skills in the field of minimally invasive surgery has allowed for traditionally open complex biliary procedures to be attempted and successfully performed laparoscopically. This chapter focuses on minimally invasive techniques in the management of biliary tract disease. Identification and management of CBD stones and performing biliary bypass procedures are discussed in detail. Highly advanced laparoscopic biliary tract procedures that are performed in selected patients are briefly mentioned as well. These procedures have not gained widespread use and are generally performed by specialized laparoscopic surgeons due to the inherent technical difficulties and there are viable endoscopic therapies that are just as effective as the surgical therapies. Nevertheless, the knowledge and utility of these techniques will be important in practices where advanced endoscopic procedures are not available and at centers specialized in hepatobiliary surgery.

LAPAROSCOPIC COMMON BILE DUCT EVALUATION

Common bile duct stones are present in as much as 10% of patients with cholelithiasis. The large majority of these stones are less than 4 mm and generally pass into the duodenum without any clinical consequence.[1] Nevertheless, stones greater than 3–4 mm should be removed since they may cause severe complications such as pancreatitis and/or cholangitis. Cholangiography and ERCP are the standards by which the CBD is evaluated for the presence of stones. Cystic duct cholangiography can be accomplished in 90% of patients and, overall, the intraoperative cholangiogram (IOC) has a sensitivity of 87% and specificity of more than 95% for the detection of stones.[2] As it was in the era of open cholecystectomy, the use of IOC during laparoscopic cholecystectomy remains somewhat controversial. Those that support the routine use of IOC cite this practice (1) to clarify anatomy and therefore reduce bile duct injuries during laparoscopic cholecystectomies; and (2) to detect asymptomatic bile duct stones, which may be present in 5–10% of patients undergoing laparoscopic cholecystectomies. The disadvantages of routine IOC are (1) that it prolongs operative time and (2) false-positive results may lead to unnecessary procedures (~50% of patients with incidental CBD stones found at time of surgery will not need any intervention).[3,4] Presently, the literature suggests that there is no difference in major and minor bile duct injuries whether routine or selective IOC are performed.[2,5–7] Additionally, a large number of routine IOCs have to be performed, compared to a selective approach, to detect missed CBD injuries or retained CBD stones significant in size. Given this, the financial cost to diagnose a clinically significant bile duct stone that was not suspected intra-operatively has been calculated at half a million dollars.[7] Therefore, we recommend that surgeons should individually weigh the pros and cons of routine versus selective use of IOC and tailor their practice in that manner. For those who perform IOC in all of their cholecystectomies, they must attempt to do it in all of their cases in order to get the benefits of their approach. And for those who selectively perform IOC should have a predetermined set of criteria to follow in which they feel IOC is indicated in a case-by-case manner (Table 52-1).

TABLE 52-1: INDICATIONS FOR LAPAROSCOPIC CHOLANGIOGRAM

Preoperative factors

- Clinical presentation with biliary pancreatitis, cholangitis, or jaundice
- Radiographic findings increasing the risk of having CBD stones (multiple small gallstones)
- Radiographic findings suggestive of having CBD stones:
  - Dilated cystic duct
  - Common bile duct diameter >8 mm
- Radiographic evidence of CBD stones
- Elevated alkaline phosphatase (>2 times the upper normal limit) and total bilirubin (>3 mg/dL)

Intraoperative factors

- Uncertain anatomy
- Multiple small gallstones in the gallbladder
- Dilated cystic duct
- Routine use of intraoperative cholangiography to prevent or for early recognition of CBD injury

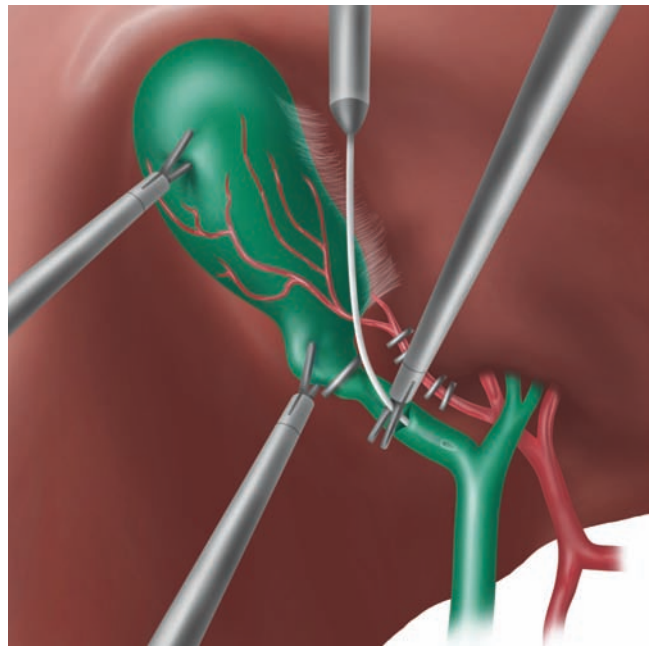

FIGURE 52-1 The catheter is guided into the partially transected cystic duct. When not using the cholangiogram clamp, the grasper may be used in maneuvering the catheter and secured with a single metal clip.

LAPAROSCOPIC CHOLANGIOGRAPHY

There are multiple commercially made cholangiogram catheters and instruments to facilitate IOC. Any type can be used for the procedure described below:

1. Once the cystic duct is identified, the proximal side is clipped as close to the gallbladder as possible. A transverse ductotomy is made just distal to the clip using laparoscopic scissors.
2. A cholangiogram catheter is then inserted via an introducer sheath or fed through a cholangiogram clamp via one of the right upper quadrant ports of a standard laparoscopic cholecystectomy port placement. The catheter is maneuvered into the cystic duct and then is secured with a single clip or held in place with a cholangiogram clamp (Fig. 52-1).
3. Once the catheter is in place, the instruments that may interfere with the cholangiogram imaging are removed. A three-way stopcock is placed on the cholangiogram catheter in order to secure one syringe filled only with sterile normal saline (NS) and another with only the contrast media. The catheter is flushed with NS only to make sure the tip of the catheter is in the correct position in the CBD and all the air bubbles are evacuated from the syringe (since air bubbles in the CBD may look like stones during a cholangiogram).
4. Isotonic contrast media is used for the cholangiogram. We mix it with 1:1 with sterile NS to prepare a 50% solution of contrast media to minimize contrast exposure for the patient and to have an adequate study.
5. The patient is positioned in a slight Trendelenberg position in order to have the contrast opacify the hepatic ducts as well as the distal CBD.
6. Fluoroscopy is used if dynamic imaging is desired. If not, regular static x-ray machine may be used for imaging.
7. Once the setup is complete, contrast is injected while obtaining radiographic imaging. A proper study should document (1) contrast filling of both the right and left hepatic ducts, (2) contrast filling the distal CBD and emptying into the duodenum, and (3) careful evaluation of the CBD for filling defects suggestive of CBD stone(s). If the pancreatic duct is opacified (and visualized) during the injection of contrast, care should be taken to avoid excessive intraductal pressure to minimize the risk of pancreatitis.

LAPAROSCOPIC ULTRASOUND

Intraoperative ultrasound (IOUS) is commonly used during liver resections to locate liver lesions and its vicinity to nearby hepatic or portal vein. There are laparoscopic ultrasound probes that have also been used for laparoscopic partial liver resections with success.[8,9] Its use in CBD evaluation has been more limited, however, prospective trials have shown that IOUS is comparable in terms of sensitivity and specificity to IOC in its ability to diagnose CBD stones.[10] This technique involves the use of linear-array transducer with frequency of 7.5–10 MHz. The image is obtained by moving the transducer first along the cystic duct and the hepatoduodenal ligament to the terminal CBD.[11,12] Potential advantages of IOUS are that it is inexpensive, noninvasive, and requires a

shorter examination time than the more invasive methods. The disadvantages are equipment availability, difficulty in visualizing the distal CBD, and operator dependency. IOUS can be an alternative to IOC for evaluation of CBD stones during a laparoscopic cholecystectomy in experienced hands (see also Chap. 49).

LAPAROSCOPIC MANAGEMENT OF CHOLEDOCHOLITHIASIS

Choledocholithiasis is defined as the presence of stones in the CBD. The most common location of obstruction is at the papilla, which is the most narrow portion of the duct. There are several preoperative findings on laboratory tests and radiographic imaging as well as intra-operative findings that can predict the presence of CBD stones (Table 52-2). The management of CBD stones differs depending on (1) whether they were found preoperatively or intra-operatively, (2) the experience of the surgeon performing laparoscopic or open CBD exploration, and (3) the availability of ERCP in your practice (Fig. 52-2).

In general, patients who are diagnosed with CBD stones prior to their cholecystectomy are usually symptomatic from their CBD stones—they may present with jaundice, cholangitis, and/or pancreatitis. The management differs significantly depending on the surgeon's ability to perform laparoscopic CBD exploration and the availability of ERCP in the institution. For instance, if the surgeon cannot perform a laparoscopic CBD exploration and ERCP is not available, the options are to (1) perform an open cholecystectomy and CBD exploration, especially if the patient is unstable for transfer, or (2) transfer the patient to a facility where at least ERCP is available. Conversely, if the surgeon can perform a laparoscopic CBD exploration and ERCP is available at that institution, any treatment strategy will suffice (Fig. 52-2A).

The reported success rate of ERCP for clearing the CBD of stones approaches 90–95%, although this varies with the local expertise and experience of the endoscopist. Stone size is the limiting factor with stones greater than or equal to 2 cm will require fragmentation prior to removal. A sphincterotomy is usually performed because relying on spontaneous stone passage increases the risk of pancreatitis, stone impaction, and/or cholangitis. The laparoscopic success rate of clearing the duct is 70–90%. The choice of clearance method should be based on several factors: (1) the availability of expert endoscopists with high success rate with ERCP and stone extraction, (2) the availability of laparoscopic and choledochoscopic equipment, (3) the surgical expertise in laparoscopic CBD surgery, and

TABLE 52-2: INDICATION FOR PREOPERATIVE ERCP IN PATIENTS WITH CHOLEDOCHOLITHIASIS

Clinical suspicion of CBD stones and:

- Small cystic duct and/or CBD (making laparoscopic transcystic exploration difficult)
- Elderly patient
- High operative risk
- Endoscopist with limited experience (if ERCP fails, surgical CBD exploration will be needed)
- Surgeon with limited experience in laparoscopic treatment of CBD stones
- Strong desire of the patient to avoid open procedure

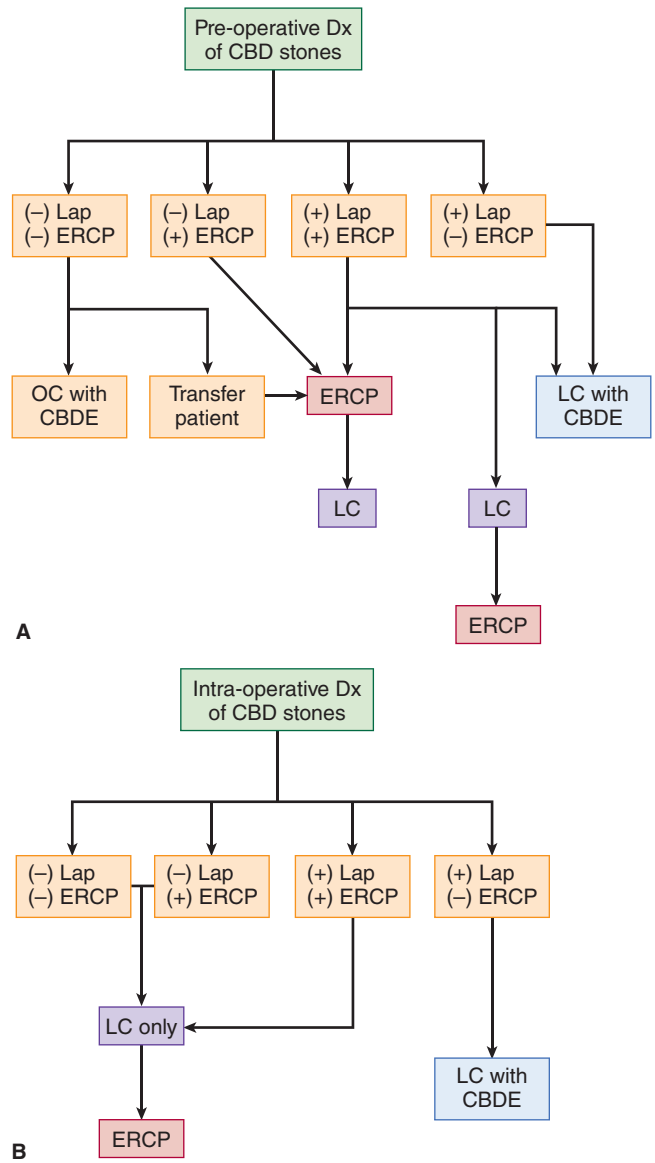

FIGURE 52-2 Algorithms for the management of common bile duct (CBD) stone diagnosed (**A**) preoperatively and (**B**) intraoperatively during a laparoscopic cholecystectomy. (+) Lap, the surgeon can perform a laparoscopic CBD exploration; (−) Lap, the surgeon cannot perform a laparoscopic CBD exploration; (+) ERCP, ERCP available at the institution; (−) ERCP, ERCP not available at the institution; LC, laparoscopic cholecystectomy; OC, open cholecystectomy; CBDE, CBD exploration.

(4) the general condition of the patient. Table 52-2 suggests a strategy for selective use of preoperative ERCP.

In contrast to those who are diagnosed with choledocholithiasis preoperatively, CBD stones found at the time of surgery are usually incidental findings after an IOC. These patients have normal preoperative radiographic imaging and liver function tests. The algorithm in this setting is relatively straightforward (Fig. 52-2B). In one study, only half of the patients with a positive IOC finding required postoperative ERCP.[3] There is a significant false-positive rate with IOCs and in cases where there really is a CBD stone, there is a good chance that it will pass spontaneously if it is smaller than 5 mm in size. However, patients should have a postoperative ERCP to remove the CBD stones if the stones are larger than 5 mm in size. If one chooses to observe the small CBD stones, ERCP may be performed at a later time if the patient develops symptoms and/or elevated liver function tests.[4,13–15]

LAPAROSCOPIC TRANSCYSTIC DUCT EXPLORATION (WITHOUT A CHOLEDOCHOSCOPE)

When a CBD stone is found during an IOC, several treatment options are available. If the duct is small and a single, less than 5 mm stone is found, a simple maneuver may be attempted with just the cholangiogram catheter still in the CBD. Intravenous (IV) administration of 1–2 mg of glucagon followed by the flushing of the CBD with saline is sometimes successful in clearing the duct (Fig. 52-3). Larger stones or the presence of multiple stones will require other methods of clearance. Laparoscopic transcystic duct exploration without a choledochoscope will be described first. This can be accomplished with a balloon or a basket technique.

Balloon Techniques

Low-pressure balloon catheters may be introduced through a percutaneous cholangiogram sleeve into the cystic duct and then into the CBD. A 4 French (4F) Fogarty-type balloon catheter is most effective and can fit through a 12–14F introducer sheath placed in the abdominal wall.[16] Once the catheter tip is in the duodenum, correct position of the catheter tip should be confirmed with radiography to avoid disruption of the ampulla by direct dilation. The balloon is then inflated and gently pulled back typically causing the duodenum to move with movement of the catheter. Traction is stopped and the balloon deflated. The catheter is withdrawn approximately 1 cm and the balloon is reinflated. Traction is then resumed until the balloon is seen at the cystic duct cannulation site. Occasionally small stones or debris can be delivered by this method (Fig. 52-4).

Another option is to use balloon dilation of the ampulla/sphincter of Oddi. Results from a few series have shown it to be a useful complementary tool for clearing CBD debris at

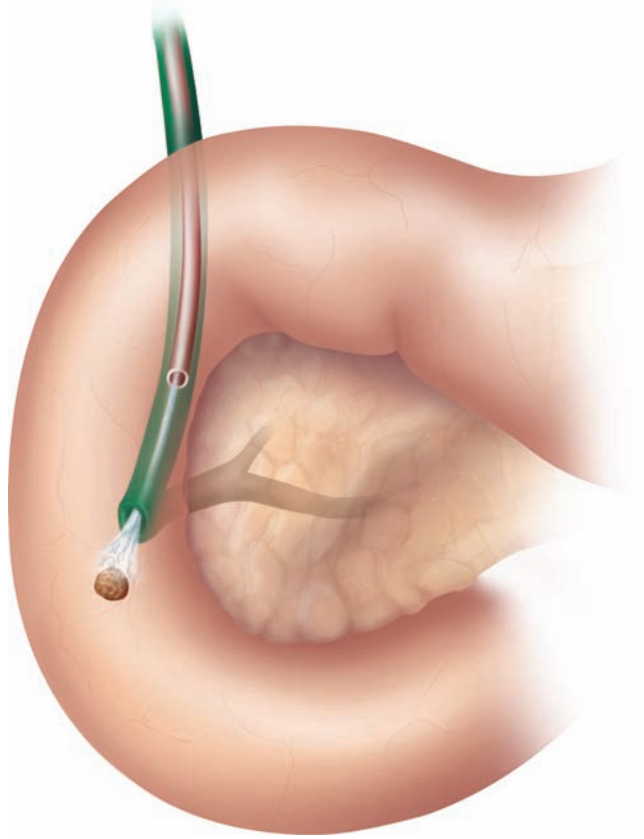

FIGURE 52-3 Stone forced through ampulla with saline flush. IV glucagon administration may also be used as an adjunct to flushing. Flushing may be accomplished with the cholangiocatheter or a red rubber catheter inserted via the cystic duct or CBD (if a choledochotomy has been made).

the initial operation without embarking on the more complex CBD exploration via a formal choledochotomy. The technique employs a 6-mm diameter balloon dilating catheter over a guide wire. This is most easily accomplished using the right subcostal port site in the standard laparoscopic cholecystectomy or, alternatively, using an additional trocar in the right subcostal space. Fluoroscopy is used throughout the procedure. The wire is confirmed to be in the CBD and the distal tip in the lumen of the duodenum. The balloon catheter is advanced over the wire and passed through the ampulla and into the duodenum. The balloon is then inflated using a dilute contrast media. The location of the ampulla is demonstrated by the point at which the inflated balloon catheter cannot be withdrawn out of the duodenum and into the biliary system. Radiopaque markers on the balloon catheter help guide the deflated catheter so that it traverses the sphincter of Oddi. The balloon is then slowly inflated. The balloon should never be inflated larger than the diameter of the CBD. Dilation is held for a few minutes and then deflated. This is followed by irrigation of warm saline through the cystic duct and a complete cholangiogram. Placement of a drain is usually not necessary. Instrumentation of the ampulla may result in pancreatitis and this should be kept in mind in the

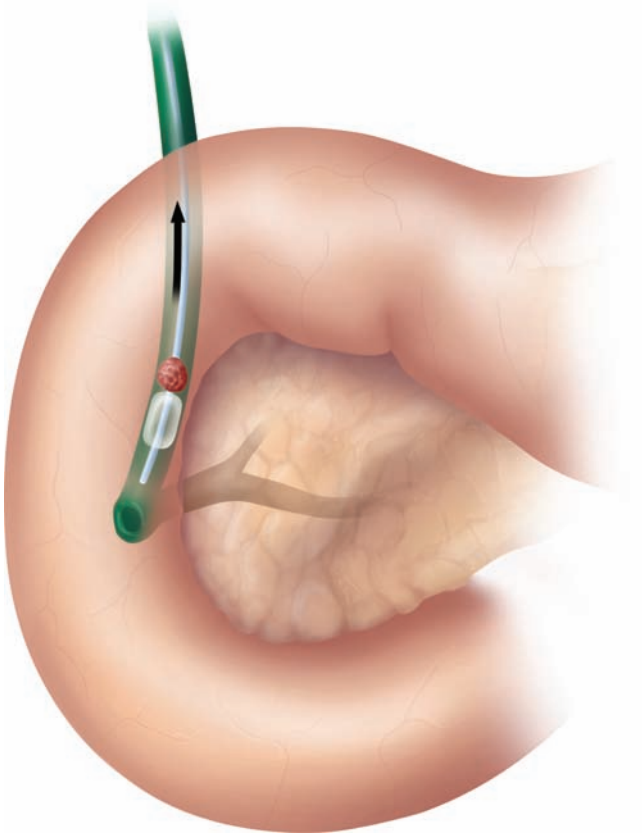

FIGURE 52-4 Stone retrieval using a balloon catheter inserted via the cystic or common bile duct. The diameter of the inflated balloon should not be larger than the diameter of the CBD.

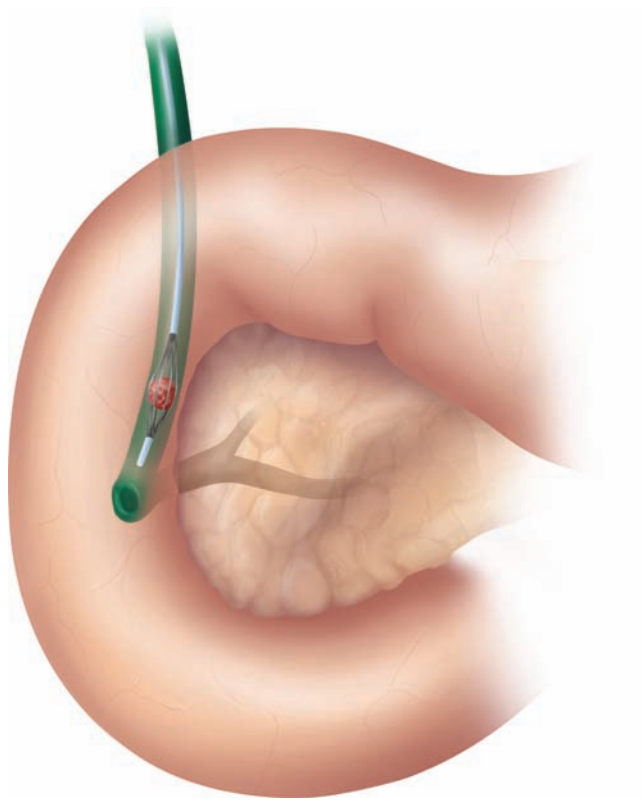

FIGURE 52-5 Stone retrieval using wire basket. Occasionally the basket will crush the stone. In these instances flushing and balloon sweeps may result in ductal clearance.

postoperative period. The incidence of pancreatitis is less than 10% unless the sphincter is forcefully disrupted. Operative time is usually less than 2 hours when accompanied with a cholecystectomy with successful clearance of stones reported 85–93% of the time.[17,18]

Basket Techniques

Stone retrieval baskets may also be introduced through a 12–14F introducer sheath. Either a helical (Dormia-type) or straight (Segura-type) basket may be employed. While some authors advocate using baskets with soft filiform tips in order to avoid damage to the duct, there appears to be no difference in ductal injuries as compared to nonfiliform-type baskets.[19] However, it is important to use these baskets with extreme care. These baskets can be employed with or without fluoroscopy. When using the basket with fluoroscopy, the duct is filled with contrast media though the cholangiogram catheter that is already in place and the location of the stone is determined. The basket is then inserted through the introducer sheath into the duct and manipulated with the forceps. The position of the basket and the stones are monitored with fluoroscopy (Fig. 52-5). There are two disadvantages with this technique: (1) the radiation exposure to the operating team and (2) the difficulty in manipulating the basket with the fluoroscopic C-arm in position over the patient. Because of these disadvantages, many have described using a nonfluoroscopic technique.[20] In order to accomplish this, several factors must be established. First, the surgeon must know the approximate length and course of the cystic duct as determined by the cholangiography. Second, the basket needs to be calibrated lengthwise in order to know the location of the tip of the catheter. Lastly, the surgeon must control the handle of the basket to know when the basket is open, closed, or partially closed suggesting the capture of a stone. When the basket is placed in the distal duct, the basket is gradually closed as it is withdrawn. This maneuver may have to be repeated several times. A major complication is capture of the papilla if the basket is advanced too far into the duct. This requires careful manipulation as pancreatitis or duct perforation may easily occur.

LAPAROSCOPIC TRANSCYSTIC EXPLORATION (WITH A CHOLEDOCHOSCOPE)

The CBD can be explored under direct visualization if a choledochoscope is available. Before the CBD is cannulated with the choledochoscope, the cystic duct must be prepared.

The procedure is performed at the time of laparoscopy after the cholangiogram. In order to pass the scope easily and safely, the cystic duct must be large enough for this approach.[16,20,21] When the cystic duct is small, attempts to dilate it may be useful. Cystic duct dilation may be safely done up to 4 mm but not beyond 8 mm because of the increased risk of disruption.[20] Dilation may be performed by mechanical tapered dilators or balloon dilation. Although the most expensive way is pneumatic dilation, this is felt to be safer since radial dilatational forces exerted on the duct are safer than the shearing force of gradual mechanical dilation. The balloon-tipped catheter is passed over a 0.035-in hydrophilic wire and dilated to approximately 6 mm (Cook, Bloomington, IN). In the situation that the cystic is very short and large enough to accept a choledochoscope, curved-tipped forceps may be inserted to expand the duct. If the cystic duct–CBD junction is disrupted by forceful dilation, an open repair may be required. Once the cystic duct is dilated, the scope is inserted using the hydrophilic guide wire already in place through a sheath placed as close to the cystic duct as possible. Alternatively, the scope may be introduced without a guide wire as well (Fig. 52-6). Careful manipulation of the scope with atraumatic forceps is extremely important as these scopes can easily be damaged. The scope can be advanced over a guide wire or freely into the cystic duct with manipulation using grasping atraumatic forceps. The most difficult part of accessing the CBD is negotiating the scope through the cystic duct. In this situation, the gallbladder should be retracted as to straighten the cystic duct as much as possible and the choledochoscope angle should be straightened as much as possible. The scope is then advanced via the cystic duct into the CBD under direct vision. The scope is first directed into the distal CBD and stone(s) visualized may be removed with a basket passed via the working channel of the scope. Once the stone is negotiated into the basket, both the scope and the basket are removed together through the cystic duct.

A complete cholangiogram should be performed to document clearance of both the common and hepatic ducts. Because the cystic duct has been dilated, it is best secured with a suture ligature rather than placing metal clips. Inspecting the proximal ductal system is rarely possible since it requires a short cystic duct entering at a 90-degree angle; however, proximal exploration is rarely needed. In this case, the laparoscopic surgeon can attempt to clear the duct via a direct choledochotomy approach.

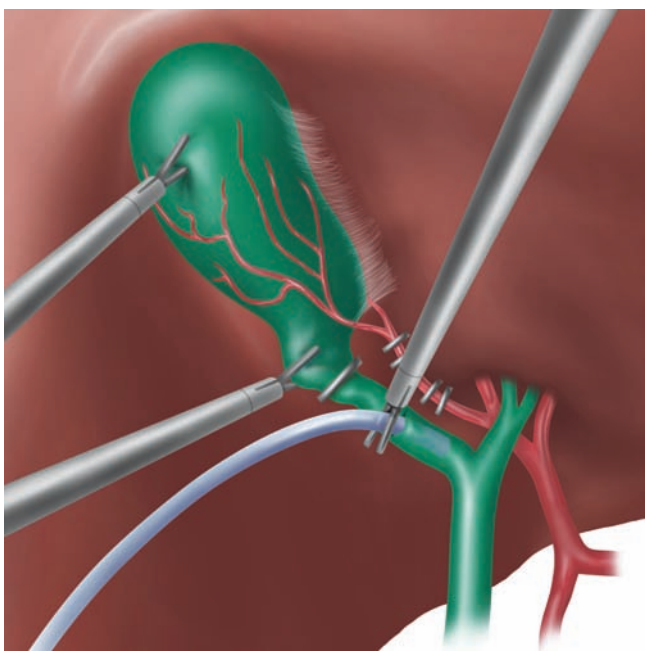

FIGURE 52-6 A flexible choledochoscope is passed through an introduced sheath placed in the right upper quadrant as close to the cystic duct as possible. The scope can be introduced free hand or with the use of a 0.035-in guide wire. Care should be taken to manipulate the scope using atraumatic forceps. Using a working channel, wire baskets or balloon-tipped catheters can be passed under direct visualization for stone retrieval. To facilitate visualization, pressurized saline irrigation is used throughout the procedure to distend the common duct and clear free-floating debris.

LAPAROSCOPIC CHOLEDOCHOTOMY

While a transcystic approach clears the duct in the majority of cases, in certain instances it will not be feasible or successful. The lumen of the duct may not dilate enough to accommodate a scope or the duct may follow a long tortuous course before joining the CBD. In this situation, the surgeon has the option of performing a postoperative ERCP or transductal exploration either via open or laparoscopic approaches. We will describe the laparoscopic approach. We do not recommend this approach in patients with small CBDs (<6 mm). A transductal exploration allows the surgeon to easily explore the proximal and distal ductal system, use a larger scope, and evacuate the stones directly. A choledochotomy will require the placement of a T-tube, which has the advantage of potentially retrieving stones in the postoperative period.

The gallbladder is left in place to facilitate upward and cephalad retraction to straighten and provide tension to the common duct. Just distal to the cystic duct–CBD junction, a short, anterior longitudinal ductotomy is created sharply. It is important to avoid vigorous circumferential dissection around the duct and use a longitudinal incision along the axis of the duct to prevent subsequent development of ischemic strictures by inadvertent injury to the CBD blood supply. The choledochoscope is introduced at a right angle to the common duct and advanced under pressure saline irrigation, allowing the CBD to nicely distend and visualize any stones or strictures. The scope can also be advanced proximally to remove stones with baskets or balloon as previously described.

Upon completion of the laparoscopic CBD exploration via the choledochotomy, T-tube closure of the common duct is recommended. An appropriate size T-tube is selected based on the size of the duct, usually a 12–14 Fr T-tube is sufficient. The tube is fashioned to the surgeon's preference.

Filleted tubes are easier to insert. A long and short segment allow for orientation when inserted into the peritoneum and then again when inserted in the bile duct. Also, the point of entry in the abdomen to the point of entry into the duct should follow a smooth curvilinear route. The standard trocar sites do not usually allow for this and as such a separate stab incision should be used when the tube is brought out. The T-tube is fully inserted into the abdomen, the horizontal limbs are compressed with a grasper and inserted into the CBD. The choledochotomy is then closed over the long end of the T-tube, beginning at the neck and working caudally using interrupted 4-0 absorbable suture. Intracorporeal suturing is used to accomplish this (Fig. 52-7). The tube is then brought out lateral to the CBD and out of the abdomen at a suitable location keeping to the principles highlighted above. A complete cholangiogram is recommended to ensure correct tube placement. A subhepatic closed suction drainage is then inserted and removed if there is no bile leakage around the T-tube.

LAPAROSCOPIC BILIARY TRACT RESECTION AND RECONSTRUCTION

Laparoscopic biliary tract resection and reconstruction is not currently widely applied because it is technically challenging even in an open setting. In addition, there are alternatives to surgery such as endoscopic placement of biliary stents or percutaneous placements of transhepatic biliary drains for biliary obstruction. Nonetheless, laparoscopic cholecystojejunostomy, choledochoduodenostomy, hepaticojejunostomy, and choledochal cyst excision have been successfully performed in the hands of experienced laparoscopic surgeons.[22–27] Surgical biliary bypass to relieve malignant obstructive jaundice requires the morbidity of an operation whether it is minimally invasive or open. While minimally invasive surgery allows for less postoperative pain and more expedient recovery, the inherent risks of general anesthesia and surgical stress remain. In light of this, endoscopic stenting has gained utility especially in the palliative setting. The success of endoscopic techniques, such as stenting and sphincterotomy, in the management of malignant biliary obstruction is well documented.[28] However, recurrent jaundice and cholangitis from stent obstruction or migration necessitate changing of the stents and add to the overall morbidity and cost. Newer, self-expanding metallic wall stents have had less frequent rates of occlusion.[29] Nonetheless, patients who are younger, healthier, who might have increased survival (>6 months) or for those whom endoscopic biliary stenting is not technically possible, will be better served by a surgical biliary bypass. For benign disease, endoscopic management is not indicated as it does not achieve the long-term patency that is desirable for the treatment of benign disease. Thus, surgical biliary bypass will continue to be a valid treatment option.

While the enthusiasm for laparoscopy has extended to complex biliary procedures, it is important to keep in mind that indications and patient selection for biliary bypass do not change with the laparoscopic modality. In fact, the technical considerations often limit rather than broaden the patient selection. Furthermore, fundamental laparoscopic principles that contraindicate its use or require discontinuation and

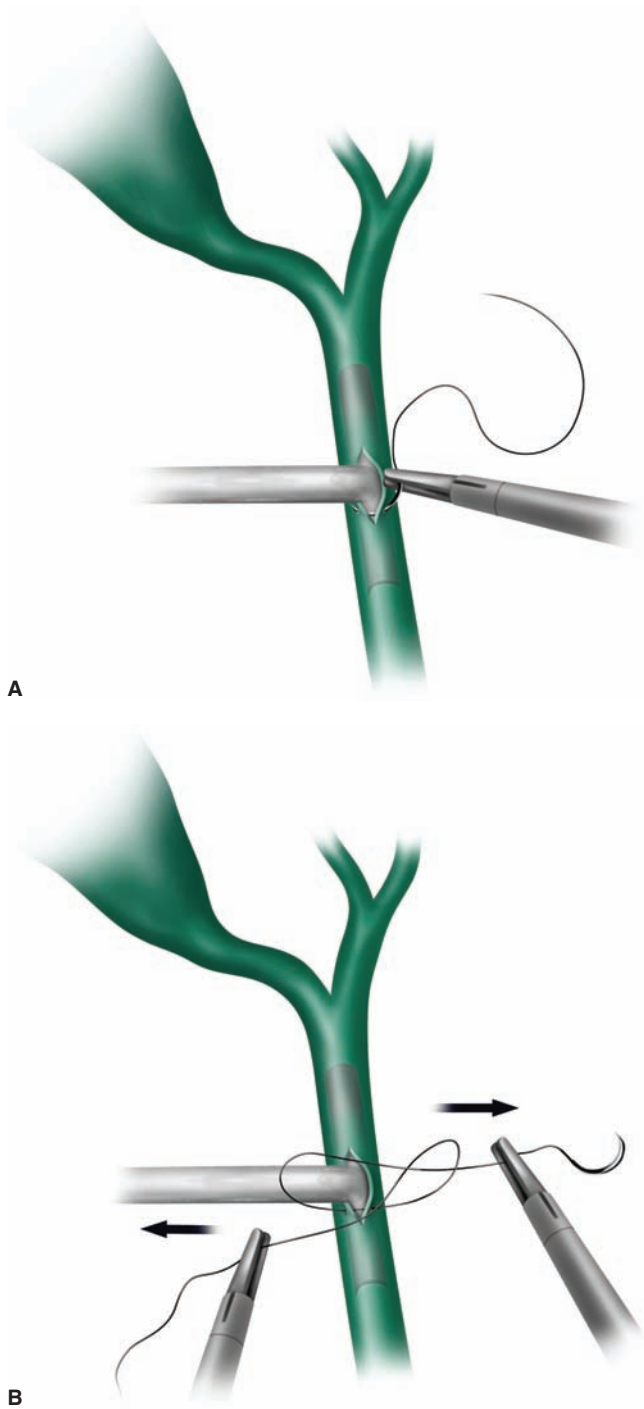

FIGURE 52-7 T-tube being secured in place following CBD exploration via a choledochotomy. A Vicryl/Polysorb or Maxon/polydioxanone (PDS) suture may be used to secure the T-tube. Vicryl/Polysorb may be a better option if the T-tube is to be removed within 3 weeks.

conversion to an open procedure should always be kept in mind. It should also be emphasized that standard, accepted procedures should not have to be significantly modified to make them easier to perform in the laparoscopic setting. Conversion to an open procedure should be utilized if the goals of the operation cannot be accomplished safely through the laparoscopic technique.

Laparoscopic Cholecystojejunostomy

Laparoscopic cholecystojejunostomy is a safe, effective method of palliation for biliary obstruction.[1] It is relatively easy to perform when keeping with standard laparoscopic principles and can be accomplished in 45–60 minutes.[1,30] In patients with prior surgery and small bowel adhesions, adhesiolysis may be required to ensure that there is no tension or twisting of the bowel loop that will be utilized in the anastomosis. It should also be noted that postoperative episodes of cholangitis are more frequent with cholecystoenteric bypass when compared to other biliary-enteric bypasses.[31] Despite the limitations, it continues to be worthwhile in select patients.

In all instances, cholangiography, either intraoperatively or preoperatively via ERCP, should be performed to confirm the patency of the cystic duct and hepatocystic junction. This step is imperative since obstruction of either the cystic duct or hepatocystic junction will result in failure of the operation with recurrent biliary obstruction. Tumor encroachment within 1 cm of the hepatocystic junction is also a contraindication for cholecystojejunostomy. Table 52-3 lists the relative and absolute contraindications for a laparoscopic cholecystojejunostomy. A retrospective review of 218 patients from our institution revealed that only about 20% of patients that are candidates for a laparoscopic cholecystojejunostomy actually remain eligible after further testing.[22,32] Thus, this procedure is indicated for only a minority of patients. The relative ease with which it can be performed and the palliative function that is provided without the associated morbidities of an open operation make it a valuable option in carefully selected patients.

TABLE 52-3: CONTRAINDICATIONS FOR LAPAROSCOPIC CHOLECYSTOJEJUNOSTOMY

Absolute
Prior cholecystectomy
Occluded cystic duct
Occluded hepatocystic junction
Hilar malignancy
Tumor encroachment within 1 cm of hepatocystic junction
Relative
Prior biliary surgery
Tumor encroachment within 2 cm of hepatocystic junction
Chronic inflammation or cholecystitis
Tumor involvement of the small bowel
Multiple small bowel adhesions

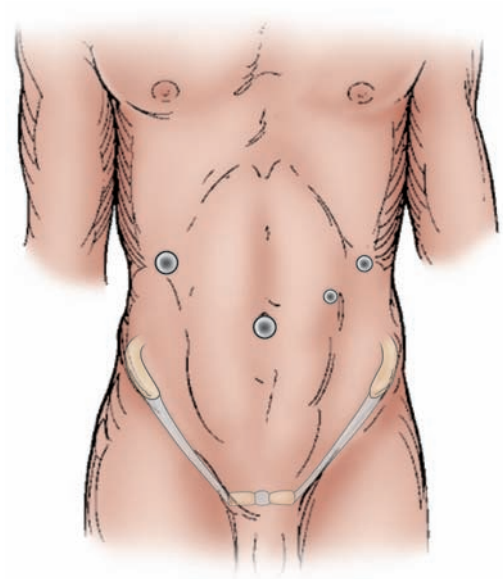

FIGURE 52-8 Port placement for laparoscopic cholecystojejunostomy. A Hasson technique (through the umbilicus) or a Veress needle technique (through the left upper quadrant) can be employed for entry. Two 5-mm ports are placed on the left hemiabdomen and an 11-mm port placed in the right upper quadrant.

The patient is placed supine and general endotracheal anesthesia is induced. See Fig. 52-8 for the location of the port placement.

1. Confirm the patency of the cystic duct if it has not been done by ERCP preoperatively. This can be accomplished by grasping the gallbladder and needle decompressing until it is at least half-emptied. The gallbladder is then cannulated and contrast injected under fluoroscopy. The procedure should not commence if the cystic duct is occluded or if the hepatocystic duct junction is strictured from tumor involvement.
2. Next, a suitable loop of small bowel is grasped using atraumatic graspers and the small bowel is run 30–40 cm distal to the ligament of Treitz. This segment of small bowel is transposed to the right upper quadrant (antecolic) and placed adjacent to the fundus of the gallbladder in a parallel orientation (Fig. 52-9A). Sometimes the body habitus or positioning makes alignment of the bowel and gallbladder difficult. In these circumstances, the setup for this anastomosis may be facilitated by passing a 3-0 nylon suture on a Keith needle through a separate stab incision in the right upper quadrant. The needle is expeditiously grasped once inside the peritoneal cavity to prevent inadvertent visceral injury. The needle is then passed through the gallbladder and then the anti-mesenteric side of the jejunum. The needle is then passed back out of the peritoneal cavity and secured extracorporeally. This suture will help manipulate the bowel and gallbladder during stapling.

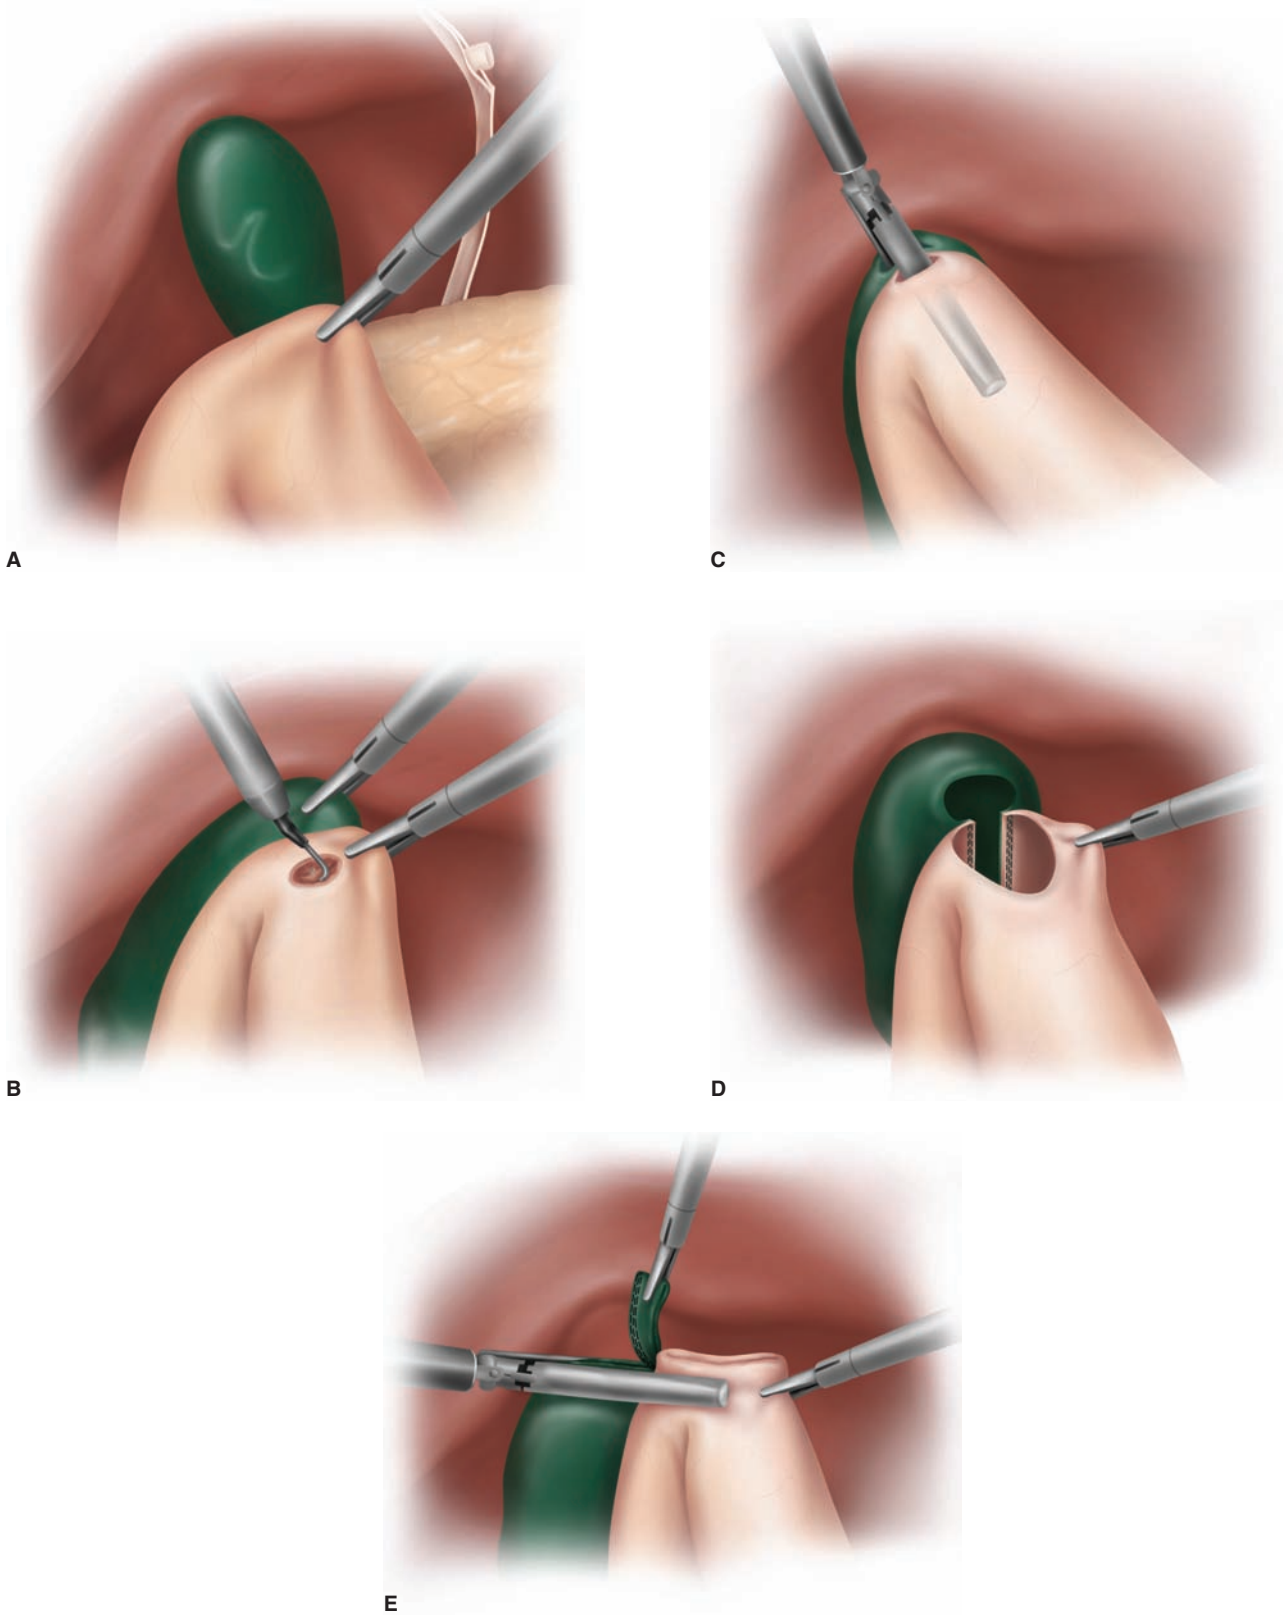

FIGURE 52-9 **A.** A portion of small bowel at 30–40 cm beyond the ligament of Treitz is grasped and brought up antecolic to the gallbladder fundus. **B.** A 5-mm hook-type cautery device placed through the 11-mm right upper quadrant port is used to create a 5-mm opening in the antimesenteric portion of the small bowel. **C.** An endoscopic stapler is placed through the 11-mm right upper quadrant port. Each blade of the stapler is carefully inserted into the enterotomy and cholecystotomy, respectively. The stapler is closed and fired after proper position and freedom from surrounding structures is assured. **D.** Careful inspection of the anastomosis for integrity and hemostasis. **E.** The remaining defect is closed by transverse stapling of the anastomotic site taking care not to narrow the anastomosis.

3. An enterotomy and cholecystotomy are then made in the bowel and the gallbladder, respectively, using the hook-cautery device passed through the right upper quadrant 11-mm port (Fig. 52-9B). The opening should be as small as possible and a grasper can then be used to enlarge the track to permit the end of the laparoscopic stapling device to be placed through without difficulty. Confirmation of intraluminal penetrance is confirmed by placing a grasper through the enterotomy and visualizing mucosa.
4. The enterotomies are then held in apposition using the left-sided ports. Once these left-sided graspers have been placed, they should not be moved until the stapler is fired. We use a Endo GIA-30 2.5 mm laparoscopic stapler (Covidien, Norwalk, CT) for our anastomosis. The stapler is placed through the right upper quadrant 12-mm port. One blade of the stapler is inserted in the cholecystotomy. The enterotomy is then pulled over the second (lower) blade. The stapler is carefully closed making sure that no small bowel mesentery or adjacent structures have been caught. The stapler is fired and removed (Fig. 52-9C).
5. The graspers are then used to open the anastomosis to permit inspection of the staple line for integrity and hemostasis (Fig. 52-9D). Clips may be utilized for hemostasis.
6. The enterocholecystostomy is closed by transverse stapling of the anastomotic site taking care not to narrow the cholecystojejunostomy. This usually requires sequential firing of at least two Endo GIA staplers.
7. Finally, the stay suture is removed and the anastomosis is inspected. Placement of a drain is not necessary.

A completely hand-sewn anastomosis can also be performed. The operative time for this is usually significantly greater and the patency and complication rates are not significantly different.[26,32] Hence, our bias is to perform the faster stapled anastomosis. Another variant is to staple the anastomosis between the bowel and gallbladder and then close the enterocholecystostomy with a running intracorporeal stitch using 3-0 absorbable suture. This may be useful in instances in which the stapler cannot be configured to prevent narrowing of the newly created anastomosis during closure of the defect. Another variant is to a use a Roux-en-Y reconstruction rather than a loop reconstruction.

Laparoscopic Choledochoduodenostomy and Hepaticojejunostomy

The gold standard for open biliary bypass is choledochoduodenostomy or the more commonly utilized Roux-en-Y hepaticojejunostomy. As stated previously, many patients are ineligible for the cholecystojejunostomy. In an effort to increase the number of patients qualifying for laparoscopic biliary bypass, laparoscopic choledochoduodenostomy and hepaticojejunostomy have been investigated and successfully performed. Furthermore, these two procedures are preferred over cholecystojejunostomy in patients with benign diseases such as choledocholithiasis, inflammatory strictures, or iatrogenic bile duct injuries since they have a better long-term patency rate. These procedures are considered highly advanced laparoscopic procedures and take a significant amount of time to perform. Median operative time in the hands of a skilled minimally invasive surgeon is 300 minutes compared to the open median time of 180 minutes.[26,33–35] Advancements in surgical technology have aided surgeons to reduce the operative time. Lapra-TY (Ethicon), Surgitie (Covidien), and Endo-Stitch (Covidien) facilitate intracorporeal suturing. The temporarily endoluminally stented anastomosis (TESA) technology has been used in animal models to assist in anastomosis creation.[27,35] The basic principles remain the same, but certain variances have been adopted for successful laparoscopic performance. For instance, a transverse choledochotomy rather than the traditional longitudinal has been used for a laparoscopic choledochoduodenostomy. If a transverse choledochotomy is made, care must be taken to avoid devascularizing the bile duct as the blood supply runs parallel to the duct at the lateral and medial aspects of the duct. For a choledochoduodenostomy, the duodenum is longitudinally incised following a Kocher maneuver and a side-to-side anastomosis is created using a 4-0 polyglycolic acid suture (Fig. 52-10). Roux-en-Y hepaticojejunostomy are beginning to be performed at a few centers with a moderate amount of success being reported.[33–35] In one series of 14 patients who underwent laparoscopic hepaticojejunostomy, the median operative time was 129

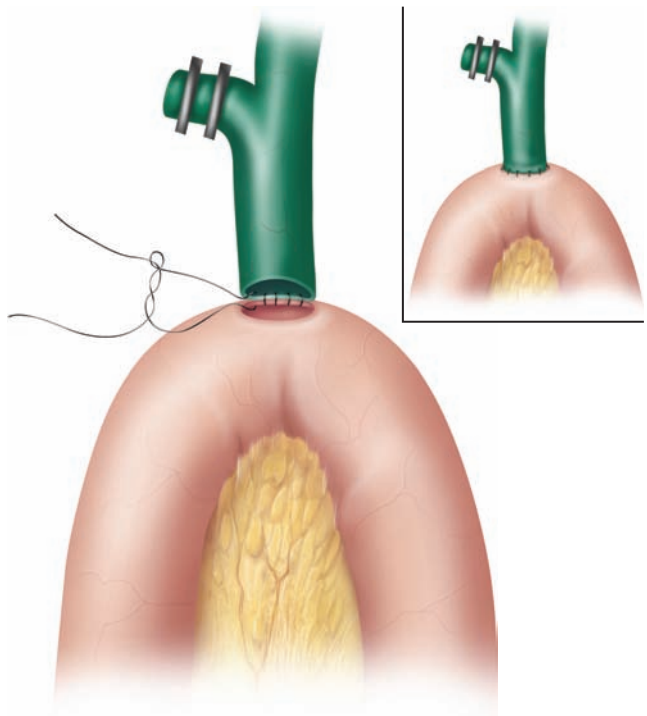

FIGURE 52-10 Laparoscopic choledochoduodenostomy created by placement of interrupted 4-0 absorbable sutures with intracorporeal knot tying technique.

minutes. However, the median hospital stay was 9 days.[36] Further studies are needed to determine the value of these more complex biliary bypasses.

Laparoscopic Choledochal Cyst Excision

Choledochal cyst is a congenital disease which results in dilatation of the intra- and/or extrahepatic biliary tract. This condition is rare in the United States (incidence 1:100,000–2,000,000 live birth), but is more prevalent in Asia. The etiology of the disease is unknown. Most patients are diagnosed during their first year of life, but the diagnosis may be delayed into their adulthood since it may not cause any symptoms until then. Common signs or symptoms are right upper quadrant pain or mass, jaundice, and/or cholangitis. Even if they are asymptomatic, treatment is indicated because it carries a 9–28% lifetime risk of malignant degeneration into cholangiocarcinoma and the cyst may be harboring cancer at the time of diagnosis. There are five types of choledochal cysts and their surgical treatment differs based on their anatomic differences (Table 52-4). Type I is the most common type and these can be treated with a CBD excision of the involved segment. Reconstruction is performed with a Roux-en-Y hepaticojejunostomy and excellent long-term results can be achieved. Excision of the CBD does not eliminate the risk of malignant degeneration since the entire biliary tree is at risk. Thus, some hepatobiliary surgeons leave a small cuff of dilated bile duct on the proximal (liver) side so it would be easier to sew the hepaticojejunostomy anastomosis. Minimally invasive approach is an interest in this particular field since a majority of these patients are children. Decreased postoperative pain and faster recovery time may translate into limiting their absence from school and other activities important to their development. It is also more cosmetically appealing.

To date, laparoscopic excision of choledochal cysts and subsequent reconstruction have only been described in case reports or series in the pediatric population.[37–40] The largest pediatric series reported nine patients, however, the hepaticojejunostomy anastomosis was performed extracorporeally.[39] In a series of 12 adult patients, the mean operative time for excision and a Roux-en-Y reconstruction was 228 minutes with an average length of hospital stay of 5.8 days. In addition, they reported no mortalities nor anastomotic complications.[41] Under laparoscopic guidance, the enlarged bile duct and gallbladder (if present) are excised. End-to-side biliary-enteric anastomosis is created with a continuous suture and the jejunojejunostomy can be accomplished with a circular or linear stapler.

The advantages of the laparoscopic approach for the management of choledochal cysts are the magnified view afforded by the laparoscope and the potential advantage of less pain and faster recovery. However, the lengthy operative time, the cost of advanced laparoscopic instruments to facilitate laparoscopic performance, and the absence of long-term outcome data are considerable disadvantages. Currently, the laparoscopic management of choledochal cysts will be practiced in centers specialized in minimally invasive hepatobiliary surgery. More studies and refinements in the instruments available are needed to address the disadvantages of this approach.

CONCLUSION

The application of minimally invasive surgery continues to evolve and is developing at a rapid pace. The success rate for removing stones among accomplished minimally invasive surgeons exceeds 90%. Unfortunately, most surgeons do not currently use a laparoscopic approach to the treatment of CBD stones. This presents significant costs (nearly double) to the patient and the health care system. However, as

TABLE 52-4: CLASSIFICATION AND THE SURGICAL TREATMENT OF CHOLEDOCHAL CYSTS

Type	Description	Surgical Treatment
I	Dilation of the extrahepatic biliary tree (choledochal cyst); the most common type (50–85% of cases)	Excision of the extrahepatic bile duct and Roux-en-Y hepaticojejunostomy
II	Simple diverticulum of extrahepatic biliary tree (supraduodenal CBD diverticulum)	Resection of the diverticulum and the resultant defect closed over a T-tube
III	Dilation of the intraduodenal extrahepatic biliary tree (choledochocele)	Transduodenal excision with sphincterotomy
IVa	Dilation of intra- and extrahepatic biliary tree; the second most common type	Excision of the extrahepatic bile duct and Roux-en-Y hepaticojejunostomy; the intrahepatic segment is left alone unless it becomes symptomatic (can be managed with partial liver resection if it only involves the right or left hemiliver)
IVb	Multiple dilations of the extrahepatic biliary tree	
V	Intrahepatic biliary cyst (Caroli's disease)	Right or left hepatectomy (if it only involves the right or left hemiliver); liver transplantation (if it involves both sides)

laparoscopy becomes a more commonplace in surgical practice, the increased cost will be mitigated and the immediate benefits of earlier recovery from laparoscopic surgery will be emphasized. Currently, institutions with hepatobiliary surgeons usually have gastroenterologists who perform ERCPs, thus, it is not mandatory for hepatobiliary surgeons to have the skill sets to laparoscopically treat benign biliary tract pathology in one setting. Nevertheless, laparoscopic management of choledocholithiasis will be a valuable armentarium for the surgeon to have and can be used as a stepping stone for more advanced laparoscopic biliary tract procedures.

Laparoscopic biliary reconstruction is feasible, but it demands long operative times and requires advanced laparoscopic skills as well as significant experience in hepatobiliary surgery. Nevertheless, with careful patient selection as well as a low threshold for conversion to an open approach, certain biliary reconstruction and resection procedures can be completed laparoscopically. The cholecystojejunostomy provides satisfactory biliary bypass in carefully selected patients and is readily accomplished through the minimally invasive technique. Further studies are necessary to accurately determine the long-term patency rates and the utility of more complex laparoscopic biliary-enteric reconstructions.

53A

PERSPECTIVE ON BILIARY SURGERY

Douglas W. Hanto

LAPAROSCOPIC CHOLECYSTECTOMY AND BILE DUCT INJURIES

There is little question that laparoscopic surgery in general surgery has had the greatest impact in the treatment of cholelithiasis and cholecystitis with over 80% of cholecystectomies being performed laparoscopically and laparoscopic cholecystectomy being one of the most common general surgical procedures performed. Although laparoscopic cholecystectomy has led to more frequent surgical treatment of gallbladder disease and a reduction in postoperative pain and hospital stay, as well as earlier return of bowel function and full activity, and decreased cost, it has not led to a reduction in the incidence of common bile duct (CBD) injuries. The most recent data cite an estimated incidence of 0.4–1.3% bile duct injuries after laparoscopic cholecystectomy compared to 0.2% after open cholecystectomy with significant patient morbidity and a high risk of litigation.[1,2] It has always seemed odd that, faced with a bile duct injury, no more than 15% of surgeons refer these patients to subspecialty hepatobiliary surgeons for repair.[3] The risk of bile duct injury had been thought to be greater earlier in a surgeon's experience with a 1.7% incidence of bile duct injury in the first case and a 0.17% chance of bile duct injury in the 50th case.[4] However, other studies have shown that there is no reduction in risk as surgeons do more cases.[2,5]

Anatomic variability is common in the biliary tree and methods to reduce the incidence of bile duct injury have included routine cholangiography, identifying the boundaries of Calot's triangle, and identifying the "critical view,"[6] all appropriately emphasized by Auyang and Soper.[1] However, it has been my practice to emphasize to the residents to "stay on the gallbladder, stay on the gall bladder, and stay on the gosh darn gallbladder" as the most effective way to avoid injury to either the CBD or right hepatic artery. This prevents transection of the CBD and, if adhered to as the gallbladder is dissected free of the gallbladder fossa adjacent to the porta hepatis medially, will prevent injury to a low-lying right or right posterior hepatic duct. If this is not easily accomplished due to acute cholecystitis or other abnormalities, consideration should be given to converting to an open procedure. This principle still holds true for an open cholecystectomy as well. Late conversion is often associated with bile duct injuries. Although cystic duct leaks, transection or clipping (partial or complete) of the CBD or common hepatic duct have been the most commonly described injuries; increasingly we are seeing injuries to the right hepatic duct or right posterior hepatic duct which may be difficult to characterize as they are not in communication with the common duct and may be missed on endoscopic retrograde cholangiopancreatography (ERCP).[7] Only with percutaneous transhepatic cholangiography (PTC) or injection of a subhepatic drain, along with a high index of suspicion, will they be identified.

Choledocholithiasis

Because most patients with suspected choledocholithiasis undergo preoperative ERCP, there are fewer laparoscopic surgeons who have extensive experience or are comfortable with laparoscopic CBD exploration and stone extraction. In addition, as Yoo and Pappas[8] point out, the success rate of ERCP in clearing CBD stones is 90–95% compared to a laparoscopic success rate of 70–90%. di Carlo and McFadden[9] point out there are many adjunctive procedures that can be used to extract and break up stones endoscopically including the use of a Dormia basket, mechanical lithotripsy, and intraductal shock wave lithotripsy using a cholangioscope. The method of choice will depend on the expertise available and the specific patient circumstances.

However, because of the known complications of ERCP, particularly pancreatitis and cholangitis, and a relatively high incidence of negative ERCPs, it is important to try preoperatively to identify the presence of choledocholithiasis noninvasively which can best be done with magnetic resonance cholangiopancreatography (MRCP) or endoscopic ultrasound (EUS) with a high degree of specificity and sensitivity.[9] Patients with a positive MRCP or EUS can then be treated appropriately with laparoscopic CBD exploration or ERCP, and the

number of negative ERCPs reduced. ERCP or intraoperative cholangiography remain, however, the diagnostic gold standards and are still indicated in clinical situations where the suspicion for choledocholithiasis is high and the MRCP or EUS is negative. PTC can be used in patients in whom anatomic considerations preclude the performance of an ERCP.

Patients who are found to have stones following cholecystectomy are usually treated with ERCP; PTC or operative exploration may be indicated if the CBD cannot be accessed endoscopically. The need for surgical drainage procedures such as Roux-en-Y hepaticojejunostomy for recurrent CBD stones has been almost eliminated by the other noninvasive techniques for stone removal. Choledochoduodenostomy should be avoided if possible because of a higher incidence of obstruction, cholangitis, and anastomotic strictures. Patients with intrahepatic stones and strictures are best managed with surgical resection in order to rule out malignancy and because of a lower incidence of recurrent stones.[10]

Choledochal Cysts

Parikh and Lillemoe[2] have emphasized the association between type I and type IV choledochal cysts and cholangiocarcinoma and the importance of complete cyst excision and reconstruction with a Roux-en-Y hepaticojejunostomy. The association with type II and type III (choledochoceles) is less clear, but adult patients still often present with jaundice, cholangitis, or pancreatitis and these cysts should also be resected. An important diagnostic tool in patients with choledochal cysts is biliary cytology, but the authors do not describe the potential screening value of the tumor-associated antigen CA19-9,[11] that has also been shown to be useful in patients with primary sclerosing cholangitis who are at risk for developing cholangiocarcinoma. The fluorescence in situ hybridization (FISH) cytological test is a new screening tool that holds additional promise for early identification of cholangiocarcinoma.[12] The authors note that unilobar Caroli's disease (type V) should be managed with hepatic resection because of the risk of cholangiocarcinoma and this has been pointed out to be true in children as well where they are often seen in association with type I or type IV choledochal cysts and concomitant cyst excision and lobectomy should be performed.

In the authors' discussion of bile leaks after laparoscopic cholecystectomy, they note that hepatobiliary iminodiacetic acid (HIDA) scans are not sensitive enough to identify the source of the leak. However, in a patient with a suspected bile duct injury, the HIDA scan can help in determining whether the patient should undergo an ERCP or PTC. If the HIDA scan shows the radionuclide passing into the duodenum, then an ERCP would be the appropriate initial diagnostic test, whereas if no radionuclide passes into the duodenum the most appropriate initial study would be a PTC since the ERCP would likely only show an obstructed, clipped, or transected duct. The role of injecting a subhepatic drain, placed to drain a biloma, in diagnosing the source of leak cannot be overemphasized if the PTC or ERCP do not show the source of the leak. Drain injection can demonstrate a transected right posterior duct that is not in communication with the CBD. Finally, the authors suggest for waiting 6–8 weeks after drainage to proceed with repair. My practice has been to wait about 2 weeks after drainage from above (PTC) and below (CT or ultrasound-guided drainage) before proceeding with Roux-en-Y hepaticojejunostomy which provides more than adequate time for the inflammatory process to abate and permits safe repair. I also leave the transhepatic catheter in place for 3 months, obtaining a cholangiogram at 5 days, 1 month, and 3 months.

The authors argue that the management of recurrent pyogenic cholangitis involves primarily treating biliary strictures with biliary drainage utilizing a Roux-en-Y hepaticojejunostomy. However, just as with percutaneous or endoscopic management, drainage procedures are associated with a high risk of recurrence and hepatic resection of unilobar disease is curative and is the treatment of choice.[10]

Gallbladder Carcinoma and Cholangiocarcinoma

Whang et al[13] point out the important changes in the tumor, node, metastasis (TNM) staging system for gallbladder carcinoma that reflect data showing differences in survival in patients with N1 (metastasis to cystic duct, CBD, hepatic artery, and/or portal vein lymph nodes) or N2 (metastasis to periaortic, pericaval, superior mesenteric, and/or celiac artery lymph node) nodal disease and in patients with locally unresectable T4 malignancies. Incidentally found gallbladder carcinoma with invasion into the muscularis is not uncommon and requires gallbladder fossa (segment V) resection, portal lymph node dissection, and possible CBD resection with Roux-en-Y hepaticojejunostomy if the cystic duct margin is positive.

In the discussion of tumor markers the authors indicate that CA19-9 is not sensitive or specific enough to be applicable for screening or diagnosis in the general population, which is to a degree true, but in patients with risk factors for the development of cholangiocarcinoma, for example primary sclerosing cholangitis (PSC), it can be useful, especially when combined with ERCP, EUS, and cytology or the newer FISH assay for detecting early malignancy.[12] In patients where CA19-9 has been elevated it can be followed as a useful marker for recurrence postresection. Sadly, imaging of cholangiocarcinoma is still not able to separate unresectable from resectable tumors reliably compared to imaging in pancreatic cancer and usually underestimates the degree of disease, which is why the resection rate is still so low. Preoperatively placed percutaneous transhepatic catheters can be helpful in determining the extent of involvement of the left and right hepatic ducts and guide the surgeon as to which liver lobe to resect to facilitate negative margins on the opposite side (>75% of hilar cholangiocarcinoma resections include a concomitant hepatic resection).[14]

Laparoscopic Procedures

Yoo and Pappas[15] discuss the controversy around the utility of routine versus selective intraoperative cholangiography and suggest that it is probably not cost-effective for the number of significant common duct stones identified that need removal (most small stones will pass spontaneously) and whether it prevents common duct injuries remains controversial. I use the selective approach and perform intraoperative cholangiography if the anatomy is unusual or confusing or if there is a clinical indication (eg, elevated liver function tests [LFTs] or preoperative imaging that suggests common duct stones). Their review of laparoscopic procedures illustrates the many options available to surgeons and patients for laparoscopy in biliary surgery, but also points out the difficulties of some of these procedures and the need for advanced training and acquisition of the necessary skills to optimize patient care. These advanced procedures (eg, Roux-en-Y hepaticojejunostomy) still take much longer than their open counterparts and provide marginal patient benefit at this time, but this may change over time as surgeons, techniques, and equipment all improve.

53B

PERSPECTIVE ON BILIARY DISEASES

Steven M. Strasberg

This is a perspective on biliary diseases to complement a number of excellent chapters on biliary tract disease in this text. It focuses on areas that I believe require emphasis and areas where we are lacking information. Understandably, the latter is often controversial.

CHOLECYSTECTOMY AND BILIARY INJURY

Biliary injury is still a serious problem and major injuries are most often caused by a misidentification, in which the common bile duct (CBD) is taken to be the cystic duct. Unfortunately, good updated epidemiological data are lacking, so the true incidence of biliary injury is unknown. Based on the referral data the problem still seems to be substantial.

The Rationale of the "Critical View of Safety"

The critical view of safety (CVS) technique was developed to mimic a technique of ductal identification used for open cholecystectomy.[1,2] In that method the cystic duct and the cystic artery are first putatively identified by dissection in the hepatocystic triangle. Identity is then confirmed by freeing the gallbladder from the cystic plate so that the gallbladder is pedunculated on the two cystic structures only. The rationale of CVS is to reproduce the principles of this method without removing the gallbladder completely from the liver bed since this leads to undesirable twisting of the organ. To attain the CVS the triangle of Calot must be cleared of fat and fibrous tissue revealing two and only two structures entering the gallbladder and the base of the gallbladder has to be freed from the lower one-third of cystic plate so that it is apparent that the dissection is clearly onto the cystic plate. If any doubt exists more of the gallbladder should be freed off the plate. The CVS technique is not a method of dissection. It is a method of identification. The moment of identification should preferably be treated like a "time out" with the surgeon pointing out the CVS to the operative team before going on. A number of publications have now supported this method of ductal identification but level 1 evidence will never be attained since comparing methods for an event that occurs with a frequency of 0.1–0.4% would require a randomized trial with 4000 patients per arm. Cholangiography should be used liberally and preferably always when a less sure method such as the infundibular technique is used. Cholangiography is effective in reducing the incidence and extent of major injuries but is less effective in preventing injuries to aberrant ducts.

Culture of Cholecystectomy

The author's conclusion, arrived at from reading a large number of operative notes, is that biliary injury is sometimes the result of persistence in performing cholecystectomy, usually in the face of severe acute and/or chronic inflammation. Although the Cochrane group arrived at the conclusion that one could not detect an increase in the incidence of biliary injury in patients who have cholecystectomy in the presence of acute cholecystitis, the number of patients available for study was so small that a significant difference could easily have been missed.[3] Cholelithiasis is a benign disease and cholecystectomies do not need to be completed in the face of operative difficulty. Some of the most serious injuries occur after conversion when the surgeon, unable to make headway in the triangle of Calot, takes the gallbladder down fundus first. Such difficult cholecystectomies may be safely terminated by cholecystostomy or partial cholecystectomy, which leave the gallbladder attached to the cystic plate. Teaching of this "culture of safety first" should be encouraged and it mimics safety strategies in aviation industry.[4]

Vasculobiliary Injuries

Many biliary injuries are accompanied by vascular injuries.[5] Therefore patients presenting with major biliary injuries

require some form of assessment of the vasculature. More than 90% of the time the right hepatic artery is the artery which is injured. This injury leads to biliary ischemia which extends the injury to a higher level in the biliary tree. Slow patchy infarction of the right hemiliver ensues to a minority of patients. Early repair of a biliary injury in the face of a vasculobiliary injury (VBI) risks making an anastomosis to an ischemic bile duct. Delaying the repair allows the duct to "die-back" to a vascularized level. "Extreme VBIs" involve a major portal vein and hepatic artery. They usually result in rapid infarction of the liver.

CHOLEDOCHOLITHIASIS

This was once a very common problem for community surgeons to treat at the time of cholecystectomy by bile duct exploration. Laparoscopic bile duct exploration is very well developed in minimally invasive surgery (MIS) centers and has as good results as endoscopic retrograde cholangiopancreatography (ERCP) in the treatment of the problem. However, residents graduating from residency programs have on average experience with fewer than five laparoscopic bile duct explorations and therefore in a practical sense ERCP has taken over as the main method of treatment of choledocholithiasis in community hospitals around the country.

CHOLEDOCHAL CYSTS

This is a rare problem in which there is a serious knowledge gap. While choledochal cysts are associated with the development of cancer, the true incidence of cancer in this disease is unknown. Part of the reason is that there have not been good population-based studies that have searched for persons with asymptomatic cysts to determine natural history. As a result the prevalence of asymptomatic cysts in the population is unknown. Currently patients who are diagnosed by chance are advised to have resection. This strategy, although the current standard of care, can be questioned since it implies that a screening program should be in place. Furthermore, the threshold diameter of the bile duct which should be diagnosed as a choledochal cyst has not been defined.

GALLBLADDER CANCER

This disease presents in two ways. In the early more readily curable stages (stages 1 and 2) it most often presents as biliary colic in a patient with stones. Presentations with classic manifestations of cancer such as palpable mass, weight loss, and jaundice are usually associated with more advanced usually inoperable stages 3 and 4. Surgeons need to be aware of signs associated with early gallbladder cancer in patients presenting with cholelithiasis so that preoperative suspicion of cancer will arise and an inappropriate operation may be avoided. These signs consist of gallbladder wall thickening out of keeping with history or clinical evidence of acute cholecystitis, eccentric wall thickening or eccentric displacement of a stone in the gallbladder.[6] Gallbladder polyps may be malignant or precursors of malignancy and the risk increases if the polyps are single and greater than 1 cm. Porcelain gallbladder has an increased risk of malignancy but not if the gallbladder wall is completely calcified. When malignancy is suspected, an open cholecystectomy is indicated since this operation can be done without placing a clamp on the gallbladder. The latter risks creation of small perforations, even microperforations perhaps, through which cancer cells might pass. Laparoscopic cholecystectomy is associated conservatively with a 20% gross perforation rate. Case reports or small case series which suggest that laparoscopic cholecystectomy is safe under these conditions are subject to selection bias since the probability that negative outcomes would be reported in the same manner is very small.

CHOLANGIOCARCINOMA

There is little doubt that intrahepatic cholangiocarcinomas (CCAs) are increasing in incidence in Western countries for unknown reasons. The Japanese classification of the gross types of cholangiocarcinomas is very useful and corresponds to the older American descriptions. The types are MF (mass forming—formerly nodular), PI (periductal infiltrating—formerly sclerosing), and IG (intraductal growth—formerly polypoid). Any of the three may appear in the three anatomic regions, that is, intrahepatic, hilar, or lower duct. The PI type is the classic type which infiltrates along the outer wall of the ducts for long distances beyond the palpable tumor and is associated with a higher likelihood of positive microscopic margins at resection. The uncommon IG type has the best prognosis. Diagnosis has been difficult because of inaccessibility of the ducts but recent advances in scope technology such as the Spyglass technique and use of fluorescence in situ hybridization (FISH) to evaluate specimens have increased the chance of obtaining a positive preoperative diagnosis. Nevertheless, malignant tumors may be hard to differentiate from inflammatory pseudotumors. The Japanese who have much experience in this disease have classically favored preoperative percutaneous intubation of bile ducts but are now shying away from this approach because of recently demonstrated higher incidence of recurrence in the tube tracts.[7] The author avoids preoperative percutaneous transhepatic cholangiography (PTC) for this reason. If diagnostic ERCP is performed for hilar CCA stenting of the side to be preserved is advantageous since this will result in hypertrophy of that side. In order for this to be possible, ERCP should be avoided as the primary investigation of jaundice. Instead axial imaging should be performed and if hilar CCA is suspected the patient should be referred to a hepatopancreaticobiliary (HPB) center at which a multidisciplinary team can evaluate and direct diagnosis and staging. If hemihepatectomy is required for hilar CCA, portal vein embolization to the side

to be resected is frequently practiced. Even when the side to be preserved has been decompressed one cannot count on normal liver function. Therefore remnant liver volumes should be increased from the 25% level associated with resection of normal livers to 40% or greater if possible.

MANAGEMENT OF ACUTE PANCREATITIS

Thomas E. Clancy • Stanley W. Ashley

INTRODUCTION

Acute pancreatitis includes a wide spectrum of disease, from mild self-limiting symptoms to a fulminant process with multiple organ failure and high mortality. Of the approximately 185,000 patients who develop acute pancreatitis each year in the United States, most experience relatively minor episodes of disease characterized by mild parenchymal edema without distant organ dysfunction and an uneventful recovery.[1] Severe episodes, however, may involve a progression to extensive pancreatic necrosis, development of the systemic inflammatory response syndrome (SIRS), multiorgan failure, rapid clinical deterioration, and even death.[2,3] Although the overall mortality rate with acute pancreatitis is 2–10%, this is primarily related to the 10–30% of patients with severe disease characterized by pancreatic and peripancreatic necrosis.

Given the wide spectrum of disease seen, the care of patients with pancreatitis must be highly individualized. Patients with mild acute pancreatitis can generally be managed with resuscitation and supportive care. Etiologic factors are sought and treated, if possible, but operative therapy has essentially no role in the care of these patients. In contrast, patients with severe and necrotizing pancreatitis may require maximal nonoperative care and nutritional support in an intensive care unit. On occasion, care of these patients may include wide operative debridement of the infected pancreas or surgical management of local complications of the disease. The precise indications for surgery in patients with pancreatitis have evolved in recent years. Whereas early aggressive debridement was commonly used for all patients with pancreatic necrosis in the past, now most pancreatic surgeons have adopted a more conservative algorithm of selective and delayed pancreatic debridement.[4,5] This chapter reviews current management strategies in acute pancreatitis, with particular attention to assessment of disease severity, the timing and routes of supplemental nutrition, the role of prophylactic antibiotics, the indications for and timing of surgery, the methods of pancreatic debridement for necrotizing pancreatitis, and the role of endoscopic and minimally invasive techniques.

ETIOLOGY

Acute pancreatitis has been attributed to a wide range of etiologic factors, some rare and rather obscure (Table 54-1). Intra-acinar activation of trypsinogen, with subsequent activation of other pancreatic enzymes, is thought to play a central role in the pathogenesis of the disease. Furthermore, ischemia-reperfusion injury is believed to be critical to disease progression. A local inflammatory response in the pancreas is associated with the liberation of oxygen-derived free radicals and cytokines including interleukin (IL)-1, IL-6, IL-8, tumor necrosis factor alpha (TNF-α), and platelet-activating factor; these mediators play an important role in the transformation from a local inflammatory response to a systemic illness.

Approximately 80% of cases are associated with cholelithiasis or sustained alcohol abuse; the relative frequency of these two factors depends on the prevalence of alcoholism in the population studied. Of the mechanical causes of pancreatitis, choledocholithiasis is certainly the most common. The majority of nonalcoholic patients with acute pancreatitis will have gallstones on examination, and between 36 and 63% will develop recurrent acute pancreatitis if stones persist. Approximately 1% of patients undergoing endoscopic retrograde cholangiopancreatography (ERCP) develop clinically detectable pancreatitis. Several metabolic processes are associated with pancreatitis, particularly alcohol abuse. Symptoms and signs of pancreatitis are recognized in between 1 and 10% of alcoholic patients, usually after 10 years or more of heavy ingestion. The precise mechanism of this association is not well established, but may be related to changes in pancreatic exocrine secretion and calculus formation in the pancreatic ducts. Several drugs are causally related to pancreatitis, particularly corticosteroids, thiazide diuretics, estrogens, azathioprine, and furosemide. Furthermore, in approximately 10% of cases, no underlying cause can be indentified. Some investigators have suggested that occult biliary microlithiasis may be the etiology in a majority of cases of idiopathic acute pancreatitis.[6]

TABLE 54-1: ETIOLOGIC FACTORS IN ACUTE PANCREATITIS

Metabolic
- Alcohol
- Hyperlipoproteinemia
- Hypercalcemia
- Drugs
- Genetic
- Scorpion venom

Mechanical
- Cholelithiasis
- Postoperative
- Pancreas divisum
- Post-traumatic
- Retrograde pancreatography
- Pancreatic duct obstruction: pancreatic tumor, ascaris infestation
- Pancreatic ductal bleeding
- Duodenal obstruction

Vascular
- Postoperative (cardiopulmonary bypass)
- Periarteritis nodosa
- Atheroembolism

Infection
- Mumps
- Coxsackie B
- Cytomegalovirus
- Cryptococcus

DIAGNOSIS, STAGING, AND SEVERITY

The early diagnosis and precise staging of disease severity are important goals in the initial evaluation and management of pancreatitis. Pancreatitis must not only be differentiated from a myriad of other potential diagnoses, but patients must also be stratified to identify those with severe disease and to guide appropriate therapy. Unfortunately, despite our increased understanding of the pathophysiology of pancreatitis, diagnostic tools for pancreatitis have not changed much in recent years. Clinical signs and symptoms of pancreatitis, such as upper abdominal pain, back pain, vomiting, fever, tachycardia, and leukocytosis are relatively nonspecific. Periumbilical and flank bruising may be seen with severe and hemorrhagic pancreatitis (Cullen's and Grey-Turner's signs), but these uncommon clinical signs are not pathognomonic of severe pancreatitis and are seen with any cause of retroperitoneal bleeding. Diagnosis therefore typically depends on a high level of clinical suspicion and the demonstration of elevated plasma concentrations of pancreatic enzymes. Levels of both amylase and lipase peak within the first 24 hours of symptoms, and amylase has a slightly shorter half-life in plasma. As a result, lipase levels may have a slightly greater sensitivity, particularly when measured late (>24 hours) after initial presentation.[7] Hyperamylasemia is neither specific for pancreatitis[8] nor perfectly sensitive, as normal amylase levels have been described in some cases of acute pancreatitis.[9] Other pancreatic enzymes have not been shown to have any advantage over amylase and lipase for diagnostic purposes. Of note, plasma levels of pancreatic enzymes serve a purely diagnostic and not prognostic role; absolute levels have no direct correlation with disease severity. A common misconception is that amylase and lipase levels only slightly elevated above normal are associated with mild disease; in fact, such low levels may also be associated with severe cases.

Identification of patients with severe pancreatitis is crucial early in the course of the disease, so that early goal-directed therapy may be instituted. However, an objective, reproducible, and universally accepted measure of disease severity is still lacking.[10] Early clinical evaluation is complicated by a relatively nonspecific presentation, and severe disease may present with a fulminant sepsis-like syndrome or in a manner that is deceptively innocuous. Initial signs and symptoms of necrotizing pancreatitis are only different in degree from edematous pancreatitis; likewise both severe and mild forms of disease share the same etiologies.[11] Despite considerable experimental effort to identify differences in the pathogenesis of edematous and necrotizing pancreatitis,[12] no available clinical model is successful at predicting which patients will progress to severe disease.

Clinical Scoring Systems

Clinical scoring system for pancreatitis such as the Ranson[13] (Table 54-2) and Glasgow[14] scores utilize multiple clinical variables to predict outcomes in groups of patients with acute pancreatitis. Patients are evaluated at admission and again during the subsequent 48 hours, utilizing demographic and laboratory parameters; the number of positive prognostic signs is then used to predict subsequent morbidity and mortality. In Ranson's report from the 1970s, for instance, the presence of five or six positive signs was associated with 40% mortality and prolonged intensive care unit (ICU) stay in 50% of patients, whereas the presence of seven or eight signs was associated with virtually 100% mortality. Although these scoring systems are relatively successful in predicting disease severity, they require 48 hours from admission for full assessment. Furthermore, while higher scores suggest poorer outcomes, these scoring systems have not been adequately reassessed to reflect the substantial improvements in critical care since their introduction over two decades ago.[15]

The acute physiology and chronic health evaluation II (APACHE II) score is another physiological scoring system that attempts to estimate disease severity based on quantifying the degree of abnormality of multiple physiological variables. Though not specific for pancreatitis and somewhat cumbersome to use, the APACHE II system is as accurate at 24 hours as other systems at 48 hours, and it is now regarded as perhaps the optimal scoring system to assess disease severity in pancreatits.[10] Twelve physiological variables are measured and

TABLE 54-2: THE RANSON SCORE—EARLY PROGNOSTIC SIGNS THAT CORRELATE WITH THE RISK OF MAJOR COMPLICATIONS OR DEATH IN ACUTE PANCREATITIS

At Admission or Diagnosis

1. Age over 55 years
2. White blood cell count over 16,000/mL
3. Blood glucose level over 200 mg/dL (100 mmol/L)
4. Serum lactic dehydrogenase concentration (LDH) >350 IU/L
5. Serum glutamic oxaloacetic transaminase (SGOT) >250 sigma-Frankel units/dL

During Initial 48 Hours

1. Hematocrit decrease >10%
2. Blood urea nitrogen (BUN) increase >5 mg/dL
3. Serum calcium level <8 mg/dL (2 mmol/L)
4. Arterial PO_2 <60 mm Hg (8 kPa)
5. Base deficit >4 mEq/L (4 mmol/L)
6. Estimated fluid sequestration >6000 mL

weighed based on their degree of abnormality: temperature, mean arterial pressure, heart rate, respiratory rate, arterial oxygen tension (Pao_2), arterial pH, serum sodium, serum potassium, serum creatinine, hematocrit, white blood cell (WBC) count, and the Glasgow coma scale. The score is determined from the most deranged physiological value measured, and further points are added for increased age and chronic organ dysfunction. Unlike other systems, the APACHE II score may be continuously recalculated through the course of the disease. APACHE II scores have also been identified as not only prognostically important at admission, but also after subsequent interventions such as pancreatic debridement.[16] The newer APACHE III system uses an additional five physiological variables to improve accuracy, although the newer system may be less useful than the APACHE II score in distinguishing mild from severe pancreatitis.[17] A recent modification of the APACHE II system, which includes a clinical assessment of obesity (APACHE-O score) has been suggested to further improve predictive accuracy, with a positive predictive value of 74%.[18] All versions of this scoring system are somewhat unwieldy for use with most patients, and are more appropriately applied to critically ill patients.

MARKERS OF SEVERITY

Numerous individual markers have been investigated as possible indicators of prognosis in pancreatitis, in both the laboratory and clinical settings. With few exceptions, these have not gained widespread clinical application. Banks[19] and others[20] have shown that hemoconcentration predicts parenchymal necrosis, as well as the presence of organ failure, in acute pancreatitis. C-reactive protein (CRP) assays are readily available, and levels rise with disease severity. Based on the trajectory of CRP levels, however, this marker is useful to identify severe disease only 48 hours after the onset of symptoms.[21] Other inflammatory mediators such as IL-8 and IL-6 have shown promise as early indicators of severe disease, but await general availability and further clinical validation.[22] Other inflammatory markers, including TNF soluble receptors, polymorphonuclear (PMN) elastase, serum procalcitonin, soluble IL-2 receptors, and soluble E-selectin, have shown potential in the investigative setting but await the availability of reproducible assays as well as clinical validation prior to their use as prognostic indicators.[23]

Trypsinogen activation peptide (TAP) is an additional marker that may be useful in determining prognosis in acute pancreatitis. TAP is released with the activation of trypsinogen to trypsin, and plasma and urine levels are known to correlate with the severity of pancreatitis. However, the molecule is present in low concentrations of urine and is cleared rapidly from plasma. Recent data suggest that clinically useful TAP assays may be soon to come. Some authors have reported high sensitivity and specificity for elevated urinary TAP levels in severe pancreatitis.[24,25] Similarly, a recent report suggested that severe acute pancreatitis could be recognized with sensitivity and specificity of 70 and 78%, respectively, using a plasma assay.[26]

It is increasingly recognized that organ failure is perhaps the most significant prognostic indicator in severe acute pancreatitis.[27] Plasma D-dimer has been suggested as a surrogate marker of future organ dysfunction with sensitivity and specificity of 90 and 89%, respectively.[28] While further validation is required, early recognition of patients who will subsequently develop organ failure in the course of pancreatitis could potentially allow early therapeutic interventions to limit the severity of disease.

Contrast-Enhanced Computed Tomography

Computed tomography (CT) scans have proven invaluable in determining disease severity in acute pancreatitis. CT findings in pancreatitis include enlargement of the pancreas with loss of peripancreatic fat planes, areas of decreased density, and occasionally the presence of fluid collections (Fig. 54-1). The Balthazar scoring system, and other similar grading systems have incorporated various CT findings such as pancreatic inflammation and peripancreatic fluid collections to correlate radiographic appearance with morbidity and mortality.[29,30] The contrast-enhanced CT scan is perhaps most useful in its ability to demonstrate pancreatic necrosis. From a baseline of 30–50 Hounsfield units (HU), viable pancreas will typically enhance by more than 50 HU with the administration of intravenous (IV) contrast. Nonviable pancreas, however, will show no such enhancement with IV contrast (Fig. 54-2). Various criteria used to diagnose necrosis include nonenhancement of more than 30% of the pancreatic parenchyma

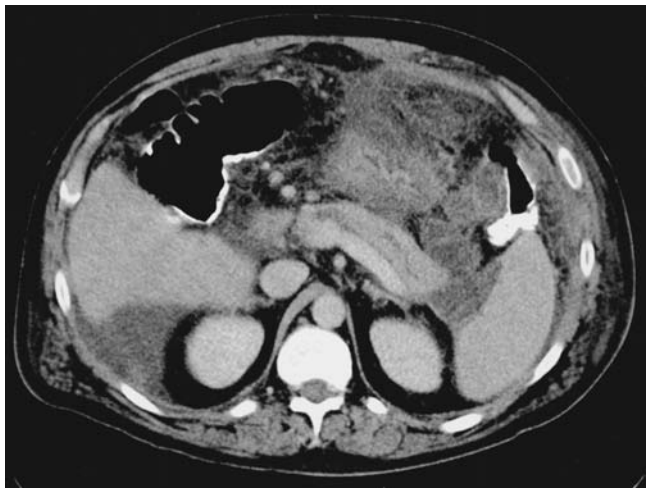

FIGURE 54-1 Contrast-enhanced abdominal CT scan in a 47-year-old man with acute pancreatitis. Relevant findings include significant fat stranding of the peripancreatic tissue, with a fluid collection at the tail of the pancreas measuring approximately 4 × 4 cm. Pancreatic parenchyma enhances with IV contrast, with no evidence of pancreatic necrosis. (Reproduced with permission from Clancy TE, Benoit EP, Ashley SW. Current management of acute pancreatitis. *J Gastrointest Surg.* 2005;Mar;9(3):440–452.)

or an area of greater than 3 cm of the pancreas that does not enhance.[31] The sensitivity and specificity for diagnosing pancreatic necrosis increase with greater degrees of pancreatic nonenhancement, and complications have also been shown to correlate with the degree of nonenhancement.[30] In the patient with moderate renal impairment or allergy to IV contrast, magnetic resonance imagining (MRI) may be used as an alternative. MRI has been shown to have comparable sensitivity and specificity to contrast-enhanced CT for detecting severe acute pancreatitis,[32] although MRI is currently less practical for the critically ill patient.

Clinical judgment rather than strict criteria often guides the timing of and indications for CT scans in acute pancreatitis, and precise recommendations are not universally accepted. Early CT scans often fail to identify developing necrosis until such areas are better demarcated, which may become evident only 2–3 days after the initial clinical onset of symptoms. The use of CT to diagnose necrosis or to predict severity within the first 24 hours of illness is therefore not recommended. Some authors have cautioned against the widespread use of CT scans in the setting of acute pancreatitis based on limited experimental evidence suggesting that IV contrast might exacerbate early pancreatic necrosis.[33] However, clinical evidence to support this phenomenon in humans is lacking. The sensitivity for identifying pancreatic necrosis using contrast-enhanced CT scan approaches 100% after 4 days from diagnosis.[10] It is therefore reasonable to recommend an abdominal CT scan with oral and IV contrast in patients with clinical and biochemical features of acute pancreatitis who do not improve after several days of conservative management. Follow-up scans may be obtained with any signs of clinical deterioration.

CT scans have also been instrumental in facilitating the early diagnosis of infected pancreatic necrosis. Despite an increasing trend toward nonoperative management of sterile pancreatic necrosis, as reviewed below, infection remains an absolute indication for intervention.[1] Unfortunately, the precise diagnosis of infected pancreatic necrosis can be difficult to make. It is not possible to differentiate infected from sterile pancreatic necrosis based only on clinical and laboratory data, as organ failure, significant leukocytosis, and fever are seen in both cases. Emphysematous pancreatitis, the demonstration of gas within the pancreatic parenchyma, is diagnostic of infection but is uncommonly seen (Fig. 54-3). Using

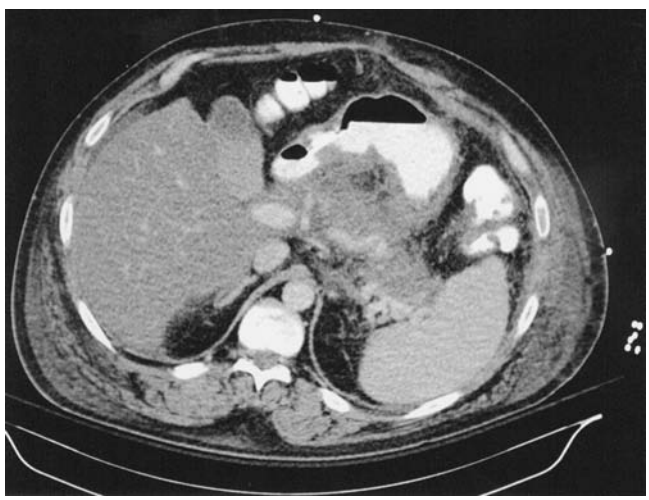

FIGURE 54-2 Contrast-enhanced abdominal CT scan in the same 47-year-old man with a second episode of acute pancreatitis. Scan shows stranding of peripancreatic fat, consistent with acute pancreatitis. Most notable is the near-complete absence of pancreatic enhancement, diagnostic of pancreatic necrosis. (Reproduced with permission from Clancy TE, Benoit EP, Ashley SW. Current management of acute pancreatitis. *J Gastrointest Surg.* 2005;Mar;9(3):440–452.)

FIGURE 54-3 CT scan demonstrating emphysematous pancreatitis, pathognomonic for infected pancreatic necrosis. Operative debridement is indicated without additional confirmation of pancreatic infection.

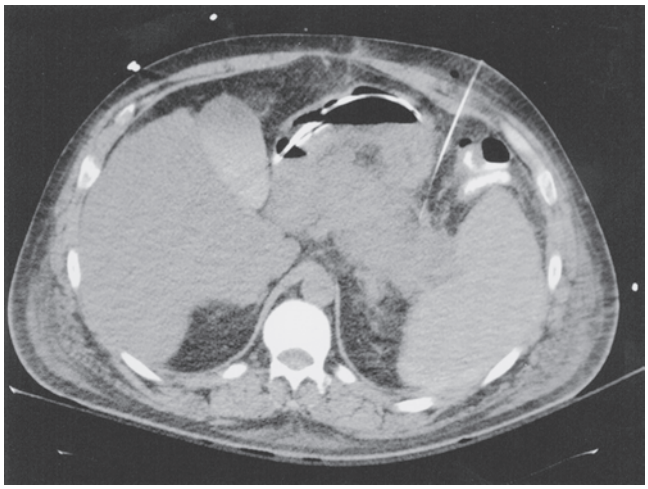

FIGURE 54-4 CT-guided percutaneous fine-needle aspiration (FNA) of the pancreatic tail. The aspiration area had previously been identified as necrotic in the contrast-enhanced CT shown in Fig. 54-2. Gram's stain and cultures were negative for organisms, consistent with sterile pancreatic necrosis. (Reproduced with permission from Clancy TE, Benoit EP, Ashley SW. Current management of acute pancreatitis. *J Gastrointest Surg.* 2005;Mar;9(3):440–452.)

image-guided precise aspiration of the necrotic pancreas, however, infected pancreatic necrosis can be diagnosed with a high degree of accuracy (Fig. 54-4). CT-guided pancreatic aspiration is usually reserved for patients with documented pancreatic necrosis who are not improving clinically or who experience clinical decline. All patients should receive oral contrast to opacify the gastrointestinal (GI) tract and avoid inoculating the pancreatic necrosum with GI flora from the inadvertently perforated viscus.

The sensitivity and specificity for detection of infection using this method are reported as 96.2 and 99.4%, respectively, with a positive predictive value of 99.5% and negative predictive value of 95.3%.[34] Areas of nonenhancing pancreas are aspirated under CT guidance, and samples are sent for aerobic, anaerobic, and fungal cultures. In most patients with infected necrosis, diagnosis may be made with a positive Gram's stain of the aspirate rather than waiting for confirmatory culture data. Gram's stains of the pancreatic aspirate are positive in most cases later documented to have infection, thus enabling rapid decision making.

Infection may occur at any point in the clinical course of a patient with pancreatic necrosis. The interval from presentation with necrosis to infection is variable, and the incidence of infection increases up to 3 weeks after presentation. In one study, infection was documented in 49% of patients in the first 14 days; less than 15% of patients had infection diagnosed after 35 days.[34] Infection may occur later in the course of the disease, even after a prior negative aspiration. Repeat CT-guided aspirations are therefore often necessary in patients in whom a conservative strategy is adopted for sterile pancreatic necrosis, until clinical improvement is documented. In a series at our institution with fine-needle aspirations (FNAs) demonstrating infection, the first aspirate was positive in 17 of 30 patients (57%); 7 patients (23%) required two procedures and 6 patients (20%) required three or more aspirations to demonstrate infection.[35]

Classification System for Acute Pancreatitis

The most commonly used classification system in acute pancreatitis emerged from an interdisciplinary symposium in 1992. The Atlanta Classification defined acute pancreatitis, its severity, organ failure, and local complications of the disease in an attempt to introduce uniformity in assessment of severity and complications (Table 54-3). This classification was an important step in achieving some descriptive consistency in acute pancreatitis, thus helping to standardize clinical care as well as aiding clinical research. However, improved understanding of the pathophysiology of pancreatitis, improved imaging techniques, and the development of new minimally invasive techniques have recently focused some attention on potential shortcomings of the classification. Recent literature review of all clinical papers published on acute pancreatitis

TABLE 54-3: DEFINITIONS PROPOSED BY THE INTERNATIONAL SYMPOSIUM ON ACUTE PANCREATITIS (THE "ATLANTA SYMPOSIUM"), 1992[31a]

Acute pancreatitis (AP)	Acute inflammatory process of the pancreas with variable involvement of other regional tissues or remote organ systems.
Severe AP	Association with organ failure and/or local complications, such as necrosis, abscess, or pseudocyst.
Acute fluid collection	Occurs early in the course of AP, located in or near the pancreas, always lacking a wall of granulation or fibrous tissue; bacteria variably present; occurs in 30–50% of severe AP; most acute fluid collections regress, but some progress to pseudocyst or abscess.
Pancreatic necrosis	Diffuse or focal area(s) of nonviable pancreatic parenchyma, typically associated with peripancreatic fat necrosis, diagnosed by CT scan with IV contrast enhancement.
Acute pseudocyst	Collection of pancreatic juice enclosed by a wall of fibrous or granulation tissue, which arises as a consequence of AP, pancreatic trauma, or chronic pancreatitis; formation requires 4 or more weeks from onset of AP.
Pancreatic abscess	Circumscribed intra-abdominal collection of pus usually in or near the pancreas, containing little or no pancreatic necrosis, arises as a consequence of AP or pancreatic trauma.

[a]The terms *phlegmon*, *infected pseudocyst*, *hemorrhagic pancreatitis*, and *persistent acute pancreatitis* are discouraged.

guidelines or review articles since 1993 found that alternate definition of severity and organ failure was used in more than half of the studies.[36] Continued revision of the classification scheme is therefore underway to establish a more accurate system for communication among clinicians and across multiple institutions, particularly pertaining to assessment of disease severity and description of fluid and solid peripancreatic collections.[37]

PRINCIPLES OF MANAGEMENT

Resuscitation and Monitoring

Although patients with acute pancreatitis require management strategies specifically tailored to disease severity, the nonoperative management of acute pancreatitis has become increasingly standardized.[3,38–40] Aggressive fluid resuscitation is important in order to replenish extravascular or "third-space" fluid losses, which may be considerable. Intravenous fluids at rates of greater than 200 mL/h are often necessary to restore and maintain intravascular volume. This degree of fluid resuscitation is important to avoid systemic complications, particularly acute renal insufficiency, that may occur with hypovolemia. Furthermore, inadequate resuscitation has recently been shown to pose a significant risk for further pancreatic injury. Banks and others have shown that while aggressive fluid resuscitation does not necessarily prevent the progression to pancreatic necrosis, patients with inadequate resuscitation have an increased risk of developing necrosis.[41] Close monitoring of respiratory, cardiovascular, and renal function is essential to detect and treat complications from hypovolemia. The degree and intensity of monitoring is tailored to disease severity. All patients require close assessment of fluid balance including a Foley catheter. Monitoring for respiratory compromise and electrolyte imbalance is important in all, and any patient with severe disease should be admitted to an ICU with the capacity for continuous blood pressure and oxygen saturation monitoring. Intravenous narcotics are often essential for pain control in these patients. The use of nasogastric tubes to avoid pancreatic stimulation had previously been commonplace, although no clinical data support this practice and the routine use of nasogastric suction should probably be abandoned. Paralytic ileus is not uncommon with acute pancreatitis, however, and nasogastric tubes should be used in this circumstance to prevent emesis and aspiration pneumonia.

Nutritional Support

Historically, enteral feeding was limited in acute pancreatitis for the purpose of providing "pancreatic rest." Enteral nutrition was believed to exacerbate the existing inflammatory process via stimulation of exocrine pancreatic function and release of proteolytic enzymes. In mild cases of pancreatitis, brief periods without oral intake may be expected and acceptable, as a full diet is often tolerated in several days with the resolution of pain. Limitation of nutritional intake, however, may have grave consequences in the subset of patients with critical illness. Inflammatory stress will increase basic metabolic rate, leading to enhanced catabolism and negative nitrogen balance.[42] In such cases of severe acute pancreatitis, the prolonged disease course, hypercatabolic state, and ileus, has led to a general use of parenteral nutrition as a principle means of nutritional support.[43]

Recent data, however, suggest that such strict limitations of enteral nutrition are unnecessary. Increasing evidence has accumulated to suggest that enteral nutrition may be feasible, safe, and even desirable in severe pancreatitis.[44] Enteral nutrition has the advantage of avoiding the high cost of total parenteral nutrition (TPN) as well as its associated catheter-related complications; furthermore, the use of enteral nutrition may support intestinal mucosal integrity and avoid the alterations to intestinal barrier function and altered intestinal permeability seen with TPN.[45] A small trial from 1997 randomized 38 patients with severe pancreatitis to TPN versus nasojejunal feeding.[46] In this cohort, enterally fed patients had significantly fewer septic and total complications. McClave et al[47] randomized 30 patients in a similar fashion, and demonstrated only a trend toward fewer complications in the enterally fed group. One significant advantage of enteral nutrition in this study was the lower cost; this was four times greater in the TPN group. Furthermore, Windsor et al[48] demonstrated that patients with pancreatitis randomized to enteral nutrition had significant improvement in CRP and APACHE II scores. Recently, a larger study from China[49] randomized 96 patients with severe pancreatitis to TPN versus nasojejunal feeding. Measures of inflammation including CRP and IL-6 decreased earlier with enteral nutrition, as did APACHE II scores. Furthermore, mucosal permeability was improved, as inferred by urine endotoxin levels. Others have suggested that the addition of *Lactobacillus* preparations to enteral nutrition formulas may have a role in decreasing infectious complications in pancreatitis.[50]

A recent systematic review of the literature has not concluded that there are sufficient data to definitively recommend preferential enteral nutrition in acute pancreatitis[51]; however studies continue to accumulate demonstrating its safety and feasibility. For instance, in a meta-analysis of prospective randomized studies comparing enteral and parenteral nutrition with acute pancreatitis, Marik and Zaloga conclude that enteral nutrition is preferred in acute pancreatitis, and is associated with significantly lower rates of infection and reduced hospital stay.[52] The use of TPN will continue to have a role in severe pancreatitis, particularly in cases with prolonged ileus. However, early enteral nutrition in the form of jejunal feeding should be considered preferable for patients who will not resume oral intake early in the course of their disease. Of note, no randomized studies have defined the best time to initiate nutritional support in severe acute pancreatitis.[53]

Most studies investigating the use of enteral nutrition in pancreatitis have used nasojejunal feeding, though others have investigated the role of nasogastric feedings in this setting. Eatock et al randomized 49 patients with severe acute pancreatitis to nasogastric or nasojejunal feeding.[54] There were no differences in pain, serum CRP levels or clinical outcome between the groups, leading to the conclusion that nasogastric feeding is simpler, cheaper, and easier than nasojejunal feeding. Similarly, Kumar et al[55] randomized 31 patients to nasogastric versus nasojejunal feeding, finding no difference in outcomes. These data were confirmed recently by Eckerwall et al [56] in a randomized study in which early nasogastric feeding was found to be feasible and blood glucose was better controlled. The delayed gastric emptying seen in many patients with acute pancreatitis may limit the nasogastric route for some patients. If tolerated, however, nasogastric feeding may be a reasonable alternative for patients with acute pancreatitis receiving nutritional support.

The Role of ERCP

As noted above, the presence of gallstones leading to choledocholithiasis is recognized as a major cause of acute pancreatitis, and the primary cause of acute pancreatitis in most populations. Endoscopic retrograde cholangiopancreatography (ERCP) has therefore been used as a diagnostic and potentially therapeutic modality in acute pancreatitis. The basis for selecting patients with pancreatitis who might benefit from ERCP lies predominantly in whether evidence exists for obstructive choledocholithiasis. The role of ERCP in cases of acute biliary pancreatitis with biliary obstruction or cholangitis is clear. Less obvious, however, is the role of early ERCP and papillotomy in acute biliary pancreatitis without evidence of obstruction. By randomizing patients with acute pancreatitis to early ERCP versus no ERCP, both Neoptolemos et al[57] and Fan et al[58]demonstrated a significant reduction on morbidity with nonsignificant trends to improved mortality with the routine use of ERCP. However, these studies were criticized for the inclusion of patients with known obstruction and cholangitis in the cohort, possibly accounting for the observed benefit from intervention. A more recent multicenter randomized study by Folsch et al[59] excluded patients with known biliary sepsis or obstruction, and demonstrated increased complications and mortality in the ERCP group. It was therefore suggested that early ERCP might be harmful in the absence of ongoing obstruction. Though diagnostic and management strategies continue to evolve, most surgeons and gastroenterologists would agree that it is generally not recommended to perform ERCP in acute pancreatitis in the absence of biliary obstruction or cholangitis.

Magnetic resonance cholangiopancreatography (MRCP) is an additional alternative to ERCP that avoids the risk of postprocedure pancreatitis. Although therapeutic maneuvers to clear identified stones cannot be performed with MRCP, its use as a diagnostic tool may allow ERCP to be used selectively for patients with known choledocholithiasis.[60] MRI poses unique challenges in the critically ill patient, including the need for prolonged scan times and compatible nonmetallic equipment for ventilators and IV fluid administration. Its use is therefore currently primarily restricted to patients outside the critical care setting. As technology evolves, it is expected that MRI and MRCP will play an increased role in diagnosis of pancreatitis and ductal obstruction.

Prophylactic Antibiotics

One management principle which has dramatically evolved in recent years concerns the use of prophylactic antibiotics in severe, necrotizing pancreatitis, with a new trend to avoid prophylaxis and treat for defined infection only. Of patients with severe pancreatitis who succumb to the disease, most do so from local and systemic infectious complications. Local infection is increasingly common with larger amounts of pancreatic necrosis, and this increases in incidence as time progresses for at least the first 3 weeks in the course of the disease.[61] In one study, 24% of patients operated on for pancreatic necrosis had infection at 1 week, whereas 71% of patients were infected when exploration was performed at 3 weeks.[62] Aerobic and anaerobic GI flora are the primary organisms involved, and infections may be monomicrobial or polymicrobial. In a collected series of over 1100 cases, the predominant microbes seen were *Escherichia coli* (35%), *Klebsiella pneumoniae* (24%), *Enterococcus* (24%), *Staphylococcus* (14%), and *Pseudomonas* (11%).[63] The association of pancreatic infection with mortality has been the rationale behind the widespread use of prophylactic systemic antibiotics targeted against enteric organisms for patients with pancreatic necrosis. The use of broad-spectrum antibiotics for this purpose is known to change the bacterial flora of pancreatic infections, and has been demonstrated to encourage the development of antibiotic-resistant bacterial infections and fungal infections.[64,65] Antibiotic use to forestall pancreatic infection with pancreatic necrosis has therefore been the subject of considerable debate and clinical investigation.[66,67]

Several animal studies have shown a benefit from early antibiotic administration with pancreatitis,[66] although this benefit has not been as consistently demonstrated in humans. Early clinical studies suggested no benefit of prophylactic antibiotics for necrotizing pancreatitis, possibly due to inclusion of patients at low risk for infection or to the use of antibiotics with poor pancreatic penetration. The precise relationship between antibiotic "penetration" into healthy pancreatic parenchyma and their efficacy in preventing or treating infection in necrotic pancreatic tissue is unclear. Still, considerable investigative effort has been made to characterize the penetration of various antibiotics into the pancreatic parenchyma[68] and these studies have influenced the commonly used prophylactic antibiotic regimens.

Several randomized controlled trials have been published examining the role of prophylactic systemic antibiotics in necrotizing pancreatitis, with conflicting recommendations. Pederzoli et al[69] randomized 74 patients with necrotizing

pancreatitis to systemic imipenem or no antibiotics. Pancreatic infection was decreased with imipenem (12 vs 30%), although there was no difference in the rate of multiorgan system failure, need for surgery, or overall mortality. Antibiotic therapy was particularly useful with lesser degrees of necrosis; no patient with less than 50% necrosis developed septic complications with imipenem, compared to 29% in the control group. Sainio et al,[70] however, showed a decrease in complications and mortality with prophylactic antibiotics, in the absence of any difference in local infection. Patients with necrotizing alcoholic pancreatitis given cefuroxime in a randomized fashion showed a decrease in infectious complications, operations, and mortality. However, this apparent mortality benefit was not associated with any difference in local pancreatic infections between treated patients and controls. This study was subject to some criticism for the high incidence of antibiotic use in the control arm. Another small randomized study[71] with 26 patients showed a nonsignificant trend to improved mortality with IV ofloxacin and metronidazole for CT-confirmed pancreatic necrosis.

Further disagreement about the role of antibiotics in acute pancreatitis was stimulated in 2004 by the publication of a prospective, randomized, double-blind trial by Isenmann et al[72] of 114 patients with severe acute pancreatitis which suggested no difference in mortality or the development of infected pancreatic necrosis with the use of ciprofloxacin and metronidazole. This was criticized for not limiting the study to patients with CT-confirmed pancreatic necrosis, and for large cross-over to antibiotics in the control group. In this setting of conflicting data, poor trial accrual, heterogenous studies, several meta-analyses were attempted to overcome the limited statistical power of available trials. In one such meta-analysis,[73] early antibiotic use was associated with decreased mortality from pancreatitis for patients with severe disease receiving broad-spectrum antibiotics. A second meta-analysis looked at randomized, controlled, nonblinded studies of prophylactic antibiotics in necrotizing pancreatitis. A nonsignificant trend toward decreased local infection was suggested with the use of imipenem, cefuroxime, or ofloxacin. Sepsis and overall mortality were significantly lower with antibiotic use, and the authors therefore supported prophylactic antibiotics for all patients with acute necrotizing pancreatitis.[74]

Despite some variations in institutional practices, a consensus had emerged in the past decade that broad-spectrum antibiotics should be used early in the course of necrotizing pancreatitis, particularly in patients with signs of organ failure or systemic sepsis.[75] The risks of superinfection with fungal or antibiotic-resistant organisms has been well recognized,[76] and is thought to be related to the length of treatment with prophylactic antibiotics. The optimal duration of antimicrobial therapy was not defined, although the incidence of pancreatic infection increases for approximately the first 3 weeks after diagnosis.[61] A treatment course of 1–4 weeks was therefore commonly recommended, with many authors limiting treatment to 14 days.[5] Mortality is considerable when fungal infection complicates pancreatic necrosis, and some authors therefore recommended the use of antifungal therapy for all patients receiving antibiotic therapy for necrotizing pancreatitis.[65] Prophylactic use of the antifungals garlicin or fluconazole has been shown to reduce fungal infection in a randomized study in severe acute pancreatitis.[77] As the incidence of toxic side effects from fluconazole is relatively low, prophylactic antifungal treatment may be a useful addition to an antibiotic regimen in patients with necrotizing pancreatitis.

As recently as 2007, the trend to use prophylactic antibiotics in severe acute pancreatitis may have shifted again. In one prospective, randomized study of patients with severe acute pancreatitis[78] the use of imipenem early in the course of acute pancreatitis was associated with a reduced rate of septic complications, though there was no effect on need for interventions or mortality. In perhaps the most definitive study to date, Dellinger et al[79] showed in a randomized, prospective, multi-institutional, double-blind, placebo controlled study of 100 patients with confirmed necrotizing pancreatitis, that the use of meropenem had no impact on the rates of pancreatic or peripancreatic infection, intervention rate, or mortality. A more recent meta-analysis limited to randomized controlled trials[80] has also suggested that antibiotic prophylaxis does not reduce mortality or protect against infected necrosis or frequency of surgical intervention. With these new data, consensus among surgeons and pancreatologists in recent years has therefore changed to a general agreement that antibiotics should not be used solely in the prophylactic setting in necrotizing pancreatitis. While the authors endorse this position, in practice many patients are still exposed to broad-spectrum antibiotics due to sepsis from another source or treatment initiated prior to transfer from another institution. In all settings, we attempt to discontinue antibiotics in the absence of documented infection.

Since infection in necrotizing pancreatitis arises primarily from commensal organisms from the GI tract, some investigators have suggested using gut decontamination to reduce intestinal bacterial load and thereby prevent pancreatic infection. Limited laboratory evidence does support the use of gut decontamination to decrease mortality in experimental pancreatitis,[81] although the use of selective gut decontamination has only been reported in one clinical study. Luiten et al[82] randomized patients with severe acute pancreatitis to oral and rectal administration of nonabsorbable antibiotics. Mortality was decreased in the treatment group, predominantly via a reduction in late mortality and decrease in gram-negative pancreatic infection. However, patients also received a short course of IV antibiotics in the study, potentially confounding the results. Definitive recommendations regarding the use of gut decontamination await further studies.

Surgical Management—Indications and Timing

In the majority of patients with acute pancreatitis, the process is limited to parenchymal edema without necrosis. These patients require surgical therapy for very limited indications;

specifically, intervention may be needed to address the etiology of pancreatitis or its complications. Interventions, either surgical or endoscopic, to prevent recurrent gallstone pancreatitis are recommended in any patient with suspected choledocholithiasis. Delayed surgery is also rarely needed for the delayed treatment of local complications such as pseudocysts. Patients with severe pancreatitis, however, may require surgical therapy as an integral part of their management. Between 10 and 30% of patients with pancreatitis develop severe illness, with pancreatic and peripancreatic necrosis and high associated morbidity and mortality.[2] The indications for surgical therapy with acute necrotizing pancreatitis have evolved in recent years. Prompt pancreatic debridement is the accepted standard of care for patients with infected pancreatic necrosis. As discussed later, an increasingly conservative surgical approach has been adopted in recent years toward the surgical management of patients with sterile pancreatic necrosis.

Occasionally, patients with severe disease may require urgent surgical intervention for reasons unrelated to their pancreatitis. For instance, at presentation, a surgical emergency such as perforated viscus may be suspected. Diagnostic laparotomy may be appropriate in such circumstances. A patient managed conservatively may also require exploration for subsequent development of other intra-abdominal pathology, such as abdominal compartment syndrome. In other patients with severe pancreatitis or pancreatic necrosis, three indications for surgical intervention remain (Table 54-4). The first, documented pancreatic infection, is not disputed. Whether (and when) to operate for severe sterile necrosis is controversial. Finally, delayed intervention with symptomatic organized necrosis is increasingly recognized as a valid indication for drainage or debridement.

INFECTED PANCREATIC NECROSIS

The majority of deaths from acute pancreatitis occur in patients with infected pancreatic necrosis. The mortality rate is virtually 100% without intervention, although with appropriate surgical therapy it should approach the less than 15% mortality seen with sterile necrosis.[4,35,83] A minority of patients with infected pancreatic necrosis may demonstrate radiographic evidence of such, emphysematous pancreatitis, or intraparenchymal gas (see Fig. 54-3). In most patients, CT-guided percutaneous FNA is needed to diagnose infection. As noted previously, both severe sterile necrosis and infected pancreatic necrosis are associated with significant leukocytosis and fever, making clinical distinction impossible. Patients with severe pancreatitis, organ failure, or those who fail to improve clinically in the first 2 weeks should be investigated for possible infected necrosis.

- Severe sterile necrosis
- Symptomatic organized pancreatic necrosis

FNA, fine-needle aspiration.

SEVERE STERILE PANCREATIC NECROSIS

The presence of pancreatic necrosis was historically considered sufficient justification for open surgical pancreatic debridement. This practice was called into question in 1991 when Bradley and Allen[62] published a small series of 11 patients with sterile pancreatic necrosis managed nonoperatively. This concept was introduced with some resistance, as some authors have argued that all patients with pancreatic necrosis would benefit from debridement. Shortly after Bradley and Allen's study was published, Rattner et al suggested that early pancreatic debridement was beneficial in pancreatic necrosis regardless of the status of infection.[84] With increased experience using nonoperative management and FNA of the pancreatic necrosum, clinicians have become increasingly comfortable with conservative therapy in stable patients. The indications for surgery in patients with sterile necrosis have continued to be refined since that time. Numerous criteria for pancreatic debridement other than infection have been considered in the literature.[85,86] CT evidence of necrosis of more than 50% of the pancreas has been examined, but is insufficiently specific for use in decision making.[86] Other indices are no more predictive.[87] Series utilizing aggressive surgery regardless of pancreatic infection continue to be reported,[83,88] although most centers have increasingly managed sterile necrosis in a conservative manner.

Two large series have demonstrated the validity and analyzed the results of this approach. A group from Bern[4] prospectively studied 86 patients with necrotizing pancreatitis followed with a strict conservative protocol. In this cohort, the mortality rate was 10%, with only one patient undergoing operation in the absence of documented infection. A retrospective review from the Brigham and Women's Hospital analyzed 99 patients with CT-documented pancreatic necrosis (Fig. 54-5).[35] Six patients who had other reasons for surgery or who had their care withdrawn for severe underlying medical conditions were excluded from the analysis. Of the remaining 93 patients, 59 patients without infection were managed conservatively with 7 deaths (11%). Thirty-four patients underwent open or percutaneous therapy for infected necrosis, with a mortality rate of 12%. Thirty-five patients did not have sufficient evidence of infection to warrant FNA. These 35 recovered relatively rapidly, despite admission APACHE II scores similar to those who required further intervention. Overall these studies suggest that conservative strategies can be applied in most patients with necrotizing pancreatitis with reasonable outcomes. Furthermore, it is very difficult to prospectively identify which persons might benefit from a more aggressive strategy. A randomized controlled trial may be the only way

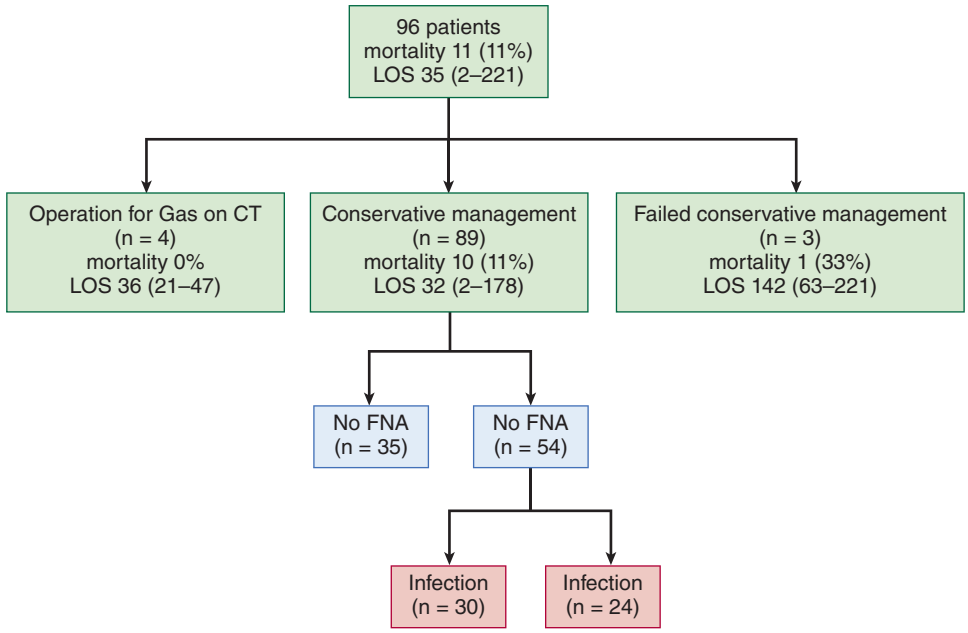

FIGURE 54-5 Management strategy in necrotizing pancreatitis utilized in Ashley et al.[35] (Reproduced from *Annals of Surgery* with permission.)

to definitively resolve this controversy, although the small number of patients with this condition may preclude meaningful conclusions. Whether surgical management is ever indicated in this patient population, and the precise timing of such intervention, continues to be a matter of debate.

While a conservative management strategy is widely accepted for stable patients, some debate continues regarding whether a subgroup of patients with presumed sterile pancreatic necrosis might be identified who would benefit from surgery. Of particular concern are the patients who appear increasingly ill and fail maximal medical management. Some clinical criteria have been suggested as possible markers to determine who might benefit from debridement in the absence of infection: extensive necrosis of over 50% of the gland, organ failure, and the systemic inflammatory response, response to therapy, and unresolving or new systemic inflammation. To date, however, while these are markers of prognosis and outcome, particularly the presence of organ failure, a reliable marker of which patients with severe sterile necrosis might benefit from surgical debridement remains elusive. Organ failure in particular is strongly linked to prognosis and in numerous studies is related to mortality rates of 30–60%. Rocha et al[89] recently demonstrated that organ failure in necrotizing pancreatitis is directly related to mortality, with increased mortality based on the number of organ systems that have failed. While organ failure is perhaps the most significant prognostic indicator with necrotizing pancreatitis, however, this has not proven useful in surgical decision making.

In regards to the early surgical debridement for patients with severe sterile necrosis and clinical deterioration, it is imperative to consider available data on the timing of surgical intervention in regards to perioperative mortality. Specifically, as outlined in a study by Mier and others[90] and confirmed in numerous other studies, early surgical debridement, compared to delayed intervention, has much higher perioperative mortality. For the deteriorating, critically ill patient with organ failure taken emergently to the operating room for pancreatic debridement early in the course of illness, perioperative mortality is extremely high.

A further consideration regarding debridement for sterile pancreatic necrosis concerns the time-dependent nature of pancreatic infection. CT-guided FNA to diagnose infected pancreatic necrosis has become a very useful and commonplace tool in diagnosing infected necrosis, and data suggest that sensitivity, specificity, as well as positive and negative predictive values are reported to be in the mid-90% range.[34] As pancreatic infection is a time-dependent process, repeat FNA may be required to rule out occult infection and ensure true sterility of the pancreatic necrosum.[35]

Pancreatic infection remains the primary indication for pancreatic debridement, and surgical intervention for the most severe cases of pancreatitis remains controversial. Settings in which pancreatic debridement might be considered for severe sterile necrosis include (1) persistent signs of sepsis or organ failure after a prolonged resuscitation, but preferably at least 2 weeks after the onset of disease; (2) clinical deterioration of a patient after an initial period of stability with conservative management; and (3) infection strongly suspected clinically but confirmatory FNA not available, not feasible to perform, or felt to be unreliable. In practice, these indications should apply to a small minority of patients.

ORGANIZED PANCREATIC NECROSIS

Despite increased acceptance among most authors of initial nonoperative management for sterile pancreatic necrosis, some

have emphasized the eventual need to operate on patients who do not clinically improve. Among patients managed nonoperatively for pancreatic necrosis, some experience persistent pain, malaise, and inability to eat. Warshaw[91] has described this phenomenon as "persistent unwellness." The pathological correlate of the pancreas later in the course of the disease is what Baron et al[92] described as "organized pancreatic necrosis"; a process of maturation of the inflammatory tissue with improved demarcation from healthy pancreatic and peripancreatic tissue. As is the case with sterile necrosis in the acute setting, the indications for and timing of surgery for this group of patients has not been precisely defined.

Several nonrandomized studies have demonstrated significantly better outcomes in patients undergoing late versus early debridement,[83,90] and surgical debridement is considerably facilitated by the demarcation that occurs later in the course of pancreatic necrosis. In the above-mentioned series of 99 patients with pancreatic necrosis at the Brigham and Women's Hospital, five patients underwent an operation for this indication at a mean of 29 days (23–34) after presentation. This group accounted for approximately one-fifth of the patients who had undergone a negative CT-guided FNA.[35] All patients were debrided, and two were found to have an inflammatory process sufficiently mature to add cystogastrostomy after the debridement. All patients recovered well and were discharged at a mean of 27 (8–146) days after surgery. The optimal timing for surgery in this group is unclear; Fernandez-del Castillo et al[83] suggest that there is no added benefit in delaying longer than 4 weeks from the onset of illness. Such delayed procedures are an important part of a conservative management strategy that emphasizes nonoperative management for most cases of sterile necrosis and late operations if necessary.

An algorithm for management strategies in acute pancreatitis summarizing the principles discussed above is outlined in Fig. 54-6. For those patients requiring operative intervention, percutaneous drainage is increasingly employed as an adjunct to or in lieu of open surgical management.

SURGICAL MANAGEMENT—PROCEDURES

Surgical therapy for acute pancreatitis may address either the etiology of pancreatitis or its complications. Operations addressing etiology are generally limited to interventions to eliminate cholelithiasis and thus eliminate gallstone pancreatitis. For patients with known gallstone pancreatitis, cholecystectomy is recommended after the resolution of pancreatic inflammation. Preoperative endoscopic examination of the common bile duct (CBD) is common in some institutions; if choledocholithiasis is detected on ERCP, endoscopic duct clearance is often attempted, with or without endoscopic papillotomy. In the absence of endoscopic interrogation and clearance of the biliary system, cholecystectomy should be combined with intraoperative cholangiogram, with or without CBD exploration.

The surgical management of the long-term complications of pancreatitis, such as pseudocysts and strictures, is addressed elsewhere. The primary surgical dilemma presenting in an acute or subacute fashion is surgical management of necrotizing pancreatitis. Surgical strategies for approaching the necrotic pancreas are addressed below, with particular attention to strategies for pancreatic debridement and postdebridement management, and the use of minimally invasive techniques.

Resection

Pancreatic resection for acute pancreatitis is primarily of historical interest only and is not currently recommended. Several authors in the 1960s and 1970s recommended partial or total pancreatectomy for pancreatitis based on the possibility that the remaining pancreas could be a source of persistent inflammation.[93–95] Operative mortality was as high as 60% in one series.[95] Although others have reported more acceptable mortality, conventional imaging and staging systems were not universally applied. In addition to the hazards posed by the dissection of a highly vascularized organ amidst an acute

inflammatory process, resection risks overtreatment of many patients if performed for necrotizing pancreatitis. Viable tissue typically exists adjacent to necrotic tissue, and intraoperative differentiation between healthy pancreatic parenchyma and necrotic tissue can prove difficult. For instance, even with apparent total necrosis, the central pancreas surrounding the main pancreatic duct is often viable and is important for endocrine and exocrine function after resolution of the acute disease.[96] Resection would therefore inevitably risk the loss of viable, functioning parenchyma. Anatomic resection for pancreatitis, with or without associated pancreatic necrosis, is therefore thought to serve little utility and potentially may confer significant risk.

Pancreatic Debridement

All techniques of pancreatic debridement and postdebridement care are based on two principles: first, wide removal of devitalized and necrotic tissue with thorough exploration and unroofing of all collections of solid and liquid debris; second, the assurance of postoperative removal of the products of ongoing local inflammation and infection which persist after debridement. Various techniques of open pancreatic debridement for necrotizing pancreatitis have been advocated in the literature.[83,88,97,98] While different approaches are fundamentally equal in terms of the method of debridement, postdebridement strategies differ considerably. Debridement with closure over drains, debridement with open packing, or debridement with closure over irrigation drains and postoperative lavage are the three methods commonly reported. Mortality and complication rates for several published series, representing each postoperative strategy, are shown in Table 54-5. Reported morbidity and mortality across these studies varies widely; however, comparisons between different studies are difficult given a lack of standardization in disease severity or criteria used for operative management.

Further complicating any comparison between studies is the relative lack of standard definitions in the earlier literature; many cases of pancreatic necrosis were likely incorrectly considered "pancreatic abscess." Over the past decade there has been increased precision in the definitions used to describe local complications of acute pancreatitis. As noted earlier, the definitions proposed at the 1992 International Symposium on Acute Pancreatitis in Atlanta (see Table 54-3) have proven useful for comparing data between studies and for standardizing treatment indications. However, these standards have only recently been applied and are not universally utilized. As a result of this lack of standardization and other difficulties listed earlier, recommendations for techniques of debridement and postdebridement management have not been uniform in the literature. No method is universally accepted, and the techniques have not been adequately compared in a randomized prospective fashion. The method of postdebridement management used may be tailored to individual patients, and each method may have a role under specific circumstances.

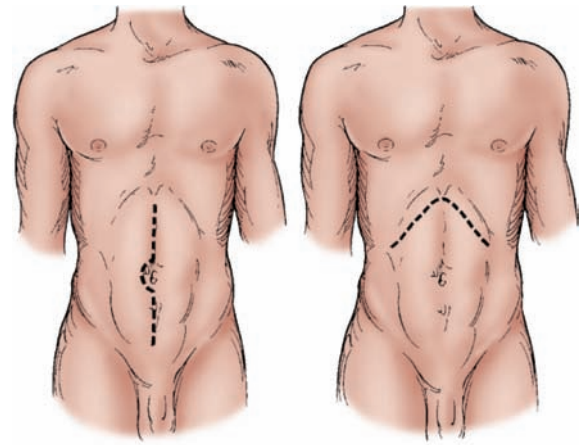

FIGURE 54-7 Operative approaches to open pancreatic debridement. Either a midline or bilateral subcostal approach is acceptable.

Technique of Debridement

Prior to surgical debridement, accurate preoperative imaging is essential. It is of paramount importance to identify all areas of necrosis or fluid collections to properly guide surgical exploration. To achieve this, a high-quality CT scan with IV contrast enhancement is essential to identify areas of pancreatic or peripancreatic tissue requiring drainage. Exploration of the pancreatic bed may be initiated via either a bilateral subcostal or midline incision (Fig. 54-7). The pancreatic bed and lesser sac may be approached either through the gastrocolic ligament or through the transverse mesocolon. Some authors[83] have strongly advocated an approach to the lesser sac via the left side of the transverse mesocolon to avoid the dense inflammatory process that can obscure tissue planes between the stomach and transverse colon (Fig. 54-8). If the anatomic plane between the stomach and colon is obliterated by inflammation, the transmesocolic approach avoids inadvertent injury to these structures. The middle colic vessels present a potential anatomic barrier to the transmesocolic approach, although these vessels are often thrombosed in the setting of necrotizing pancreatitis. If patent, these vessels may often be interrupted without consequence as the colon is supplied with collateral vasculature. An additional advantage of the transmesocolic approach is that drains may be placed in a dependent position after debridement. Other investigators have advocated an approach to the lesser sac via the gastrocolic ligament (Fig. 54-9), for the primary reason that the inframesocolic space is typically uninvolved with peripancreatic inflammation and infection, and transmesocolic exposure renders the remainder of the abdomen to this inflammatory process.[88]

Pancreatic debridement is accomplished bluntly, primarily using finger dissection. The differentiation between necrotic tissue, which has a looser consistency, and viable tissue, which is firm, is often best made by palpation. Necrotic tissue should separate easily from the surrounding tissue, without extensive dissection. While complete

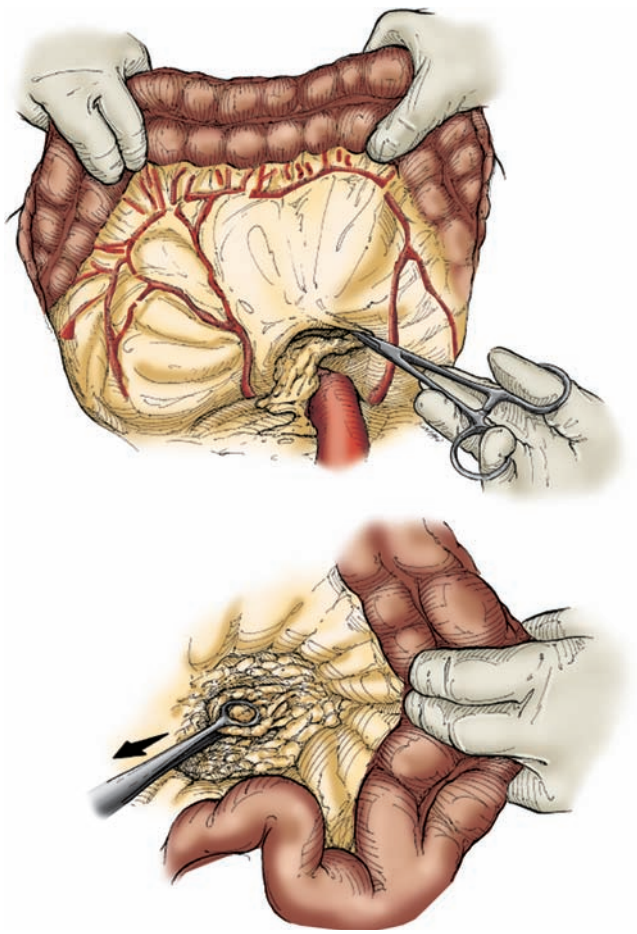

FIGURE 54-8 Transmesocolic approach to the lesser sac. The necrotic pancreas is approached through the transverse mesocolon, to the left of the middle colic artery.

debridement is essential, efforts should be made to avoid overzealous handling of inflamed tissue, which encourages bleeding. Debridement should therefore be limited to all clearly necrotic tissue that is easily separable from surrounding structures. All fluid as well as necrotic tissue is sent for aerobic and anaerobic culture. Hemorrhage from diffuse oozing from inflamed retroperitoneal tissues is not uncommon; hemostasis may require packing of the cavity. Rapid hemorrhage from the intraoperative rupture of a major blood vessel, such as the splenic artery or vein, may require suture ligature. Precise vascular control in an inflamed tissue field can prove difficult if not impossible. If such is the case, hemostasis may require prolonged manual compression and possibly multiple sutures.

As the inflammatory mass is exposed during the course of the debridement, it may become necessary to extend the intra-abdominal dissection to fully expose all necrotic tissue. A complete search for and identification of all necrotic foci must take place. For necrosis of the head, improved exposure may be achieved either through the right side of the mesocolon or via an approach posterior to the second and third portions of the duodenum. Additional exposure may also entail a release of the hepatic and splenic flexures of the colon. Thorough exposure of all necrotic tissue may involve opening both paracolic gutters, the pararenal spaces, the retroperitoneum into the pelvis, or the gastrohepatic omentum.

DEBRIDEMENT AND CLOSED DRAINAGE

Several authors have demonstrated very favorable results with debridement and closed drainage.[83,99] Proponents of this technique stress that the presence of residual necrotic pancreatic tissue is the most important factor dictating the need for subsequent re-explorations, each of which is associated with some morbidity and mortality. For this reason, the completeness of the initial debridement is the most crucial factor in avoiding subsequent re-explorations. In contrast to the open packing technique, a concerted effort is made to perform a complete debridement and drainage of fluid collections at the first surgical procedure. All necrotic tissue is debrided unless it is densely adherent to vital structures, and all spaces involved on preoperative imaging are opened and debrided.

Debridement is followed with gentle irrigation (Fig. 54-10). The cavities left after debridement are drained with either closed-suction drains or Penrose drains stuffed with gauze. All drains are brought out through separate stab wounds in the abdomen. The placement of enteral feeding or drainage tubes (gastrostomy, jejunostomy) is optional. Drains are removed one at a time beginning 6–10 days after surgery in an effort to allow the cavity to collapse. If Penrose and closed-suction drains are used together, closed-suction drains are removed last, and only when their output is minimal.

In some cases, complete debridement is not possible during the first exploration. If hemodynamic instability or coagulopathy prohibit further debridement, temporary closure is achieved after packing the necrotic cavity with Mikulicz's pads and placing drains; repeat procedures may occur in 24–48 hours, along with additional procedures such as gastrostomy or jejunostomy.

Reported mortality for debridement and closure over drains has been as high as 40%. Recurrent pancreatic infection is an acknowledged complication of this technique, with early series reporting a recurrence rate of 30–40%.[100] However, a more recent series has reported significantly better results, with mortality of 6.2%.[83] In this series, an additional operation was required in 17% of patients, most of whom had persistent infected pancreatic necrosis. In addition, 20% required postoperative image-guided drainage of residual or recurrent fluid collections. Overall, 69% required only one operation without further procedures.[83] The reported success of this procedure, and rate of recurrence, is attributed to thorough surgical debridement, with maximal removal of necrotic tissue at the first operation.

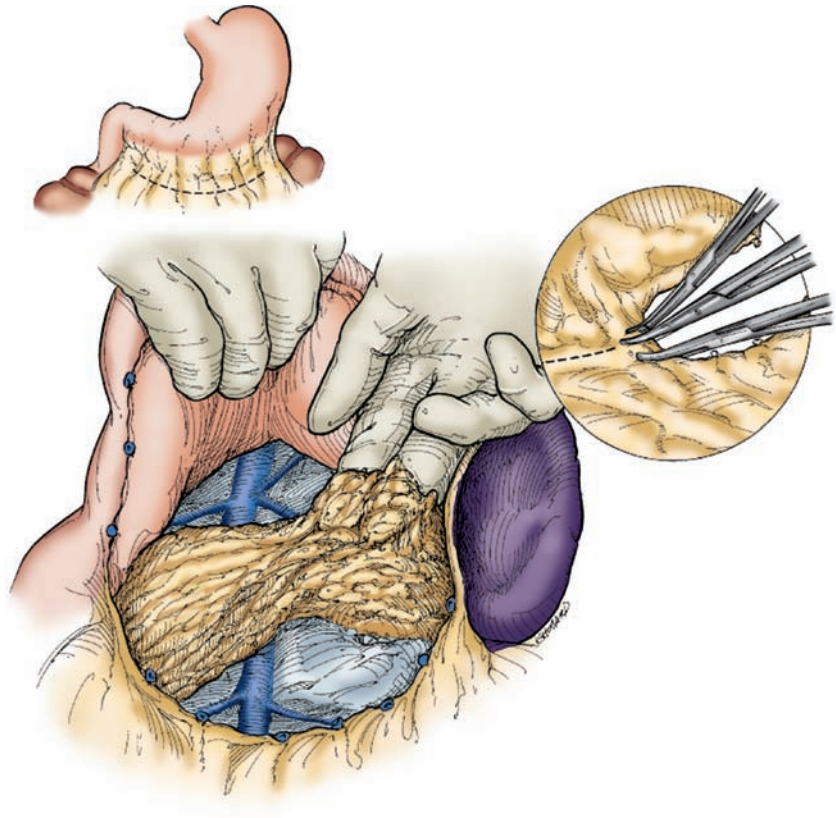

FIGURE 54-9 Approach to lesser sac via gastrocolic ligament.

OPEN DRAINAGE (MARSUPIALIZATION) FOR PANCREATIC NECROSIS

As mentioned earlier, a recognized complication after an apparently adequate pancreatic debridement is recurrent pancreatic sepsis. While most necrotic debris is easily separated from surrounding structures, some borderline tissue may not be so easily debrided. Presumably, pancreatic necrosis is an ongoing process, and further demarcation of necrotic tissue after an initial debridement can result in a mass of particulate matter that is inadequately removed by sump drainage. Furthermore, the persistence of necrotic tissue is combined with the persistent postoperative leakage of activated pancreatic enzymes from the necrotic and inflamed tissue into the retroperitoneum. This combination of necrotic material and chemical inflammation may be responsible for the occasional failure of simple debridement and drainage. For this reason, some authors have advocated a process of open packing, or "marsupialization," by which recurrent pancreatic debridement is facilitated.[101]

The surgical approach is typically a left subcostal incision, which is easily extended to a bilateral subcostal incision should additional exposure be necessary. This transverse incision is optimally situated above a transverse opening in the gastrocolic omentum to facilitate open packing. Advocates of open packing have preferred to access the lesser sac via the gastrocolic ligament, which may provide a more direct access to the entire pancreatic bed for future packing. Pancreatic debridement using blunt finger dissection is employed, with wide exposure of all areas of retroperitoneal necrosis. However, unlike procedures with planned closed packing, no effort should be made to remove every identifiable piece of necrotic tissue at the first procedure; rather, only tissues that are easily separated by blunt dissection should be dissected. Complete removal of all necrotic tissue is accomplished by multiple re-explorations and blunt debridements, limiting blood loss.

After debridement, the stomach and colon may be covered with a nonadherent gauze to prevent debridement of healthy tissue during dressing changes. This constructs a cone or cylinder with the pancreas at the base. Laparotomy pads or other gauze may be placed directly within this area, and some authors have recommended presoaking these packs in iodinated solutions. Some surgeons will suture the gastrocolic ligament to the skin, creating an inverted cone with the base consisting of the divided gastrocolic ligament at the skin level and the point at the pancreatic bed. However, in the setting of acute inflammation this cavity may be ill-defined, and suturing to the skin is generally not necessary. No attempts are usually made to close the fascia or skin, although occasionally

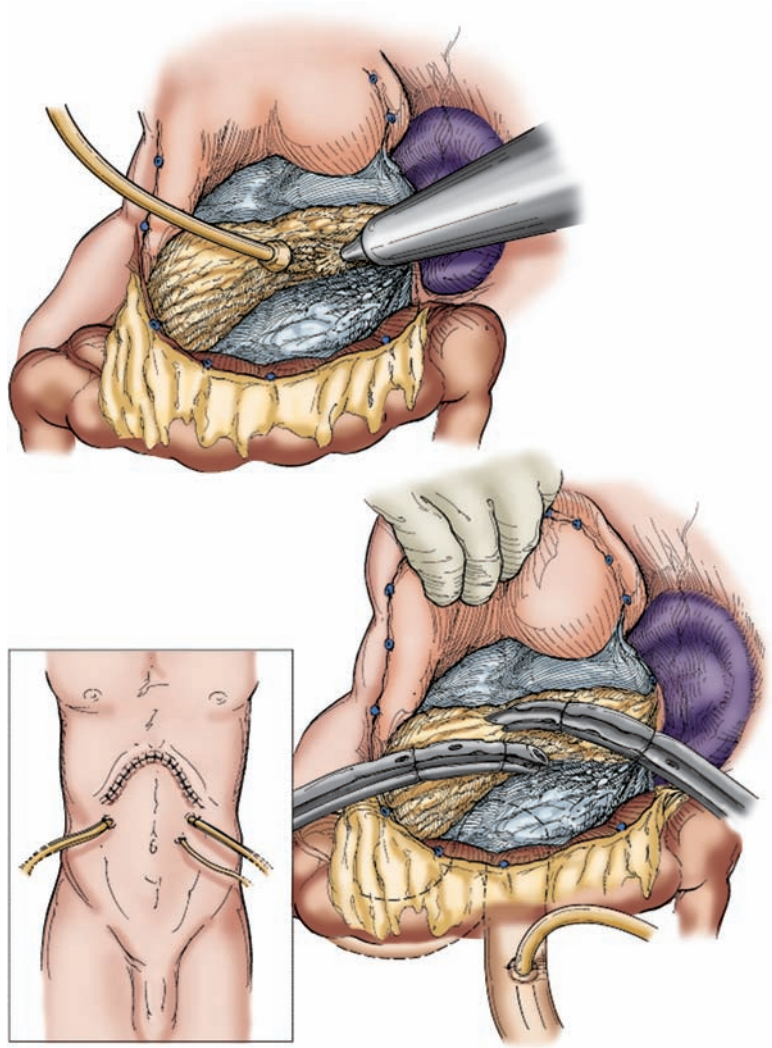

FIGURE 54-10 Irrigation and drainage of pancreatic bed. Drainage tubes are used for technique of closed drainage or postoperative saline lavage; for open packing technique, pancreatic bed is packed with sterile bandages.

a small number of extraperitoneal stay sutures of nylon may be loosely tied to discourage evisceration. This results in an open communicating defect for packing. Alternatively, some have used a separate retroperitoneal incision through which to bring packs, closing the abdominal incision. This method likely provides inferior access for future debridements.

Planned re-explorations are performed in the operating room at 2–3 day intervals for additional debridement. When retroperitoneal granulation tissue begins to form, daily dressing changes may be performed in the ICU utilizing mild sedation and/or pain control. Although the majority of necrotic tissue is debrided with the first effort, significant amounts of tissue may be removed at the fourth or even fifth debridement procedure.[102]

After debridement has been achieved by open packing, the abdominal wound may either be left to heal entirely by secondary intention, or may undergo delayed primary closure. In some cases, the open packing procedure may be combined with delayed closure over lavage catheters and continuous closed lavage of the lesser sac and abscess cavity. Catheters are gradually withdrawn over weeks after it is demonstrated that there is no pancreatic fistula.

Debridement and Continuous Closed Postoperative Lavage of the Lesser Sac

After an initial pancreatic debridement, small amounts of residual necrotic tissue are inevitably present. Furthermore, the persistent soilage of the retroperitoneum with pancreatic enzymes and inflammatory mediators may also contribute to persistent systemic inflammation and sepsis. Removal of residual necrotic tissue, bacteria, and biologically active substances is therefore proposed to decrease persistent inflammation.

While some have advocated open packing and planned repeated operations to accomplish this goal, others report success with continuous postoperative high-volume lavage of the lesser sac.[96] Even an aggressive initial debridement is therefore not considered an end in itself, but rather the first step of a thorough washout of the pancreatic bed.

Beger et al have written extensively on the procedure of debridement and continuous closed postoperative lavage.[97] With this technique, pancreatic debridement is performed in the standard fashion. Postoperative lavage is facilitated by the insertion of two to five large double-lumen tubes**.** After drain placement, the gastrocolic ligament may be sutured to form a closed compartment in the lesser sac. Continuous lavage is undertaken with hyperosmolar, potassium-free dialysate at approximately 2 L/h, although irrigation with normal saline is also employed.[96] Branum et al[88] describe the completion of one or more debridements, followed by the placement of multilumen sump drains for postoperative irrigation. Irrigation continues until the effluent is free of particulate matter. These drains are gradually downsized and eventually withdrawn.

Beger et al have published an overall operative mortality of 10.6% with this procedure, and a mortality of 15% when the procedure is performed for infected pancreatic necrosis. These authors and others have argued that using postoperative continuous lavage results in decreased rates of postoperative pancreatic sepsis compared to closed drainage techniques, and the incidence of postoperative complications such as incisional hernia and GI fistulas is said to be less than that with open packing and repeated debridement.

Comparison of Techniques Used in Pancreatic Debridement

As noted earlier, the benefits of various techniques of pancreatic debridement and postdebridement care have been debated in the literature. No strict criteria have been proposed to adequately select patients for different procedures, and the optimal method of debridement has not been examined in a prospective fashion. A number of case series have been reported in which patients with either pancreatic necrosis or severe acute pancreatitis have undergone pancreatic debridement followed by either closure over drains, open packing and redebridement, or closure over lavage catheters with postoperative continuous lavage (see Table 54-5). As seen in this table, reports of postoperative complications and mortality vary widely across different studies. Comparisons between these different studies can prove difficult for several reasons. Preoperative disease severity is difficult to standardize across different reports, as are the criteria for operative management employed. Earlier studies did not employ currently accepted criteria of disease severity, and the presence of pancreatic infection is not universally documented via preoperative studies. The various methods of pancreatic debridement have not been compared in a prospective, randomized fashion.

One small single-institution retrospective study compared surgical outcomes in 86 patients with acute pancreatitis after debridement and closed drainage, debridement with open packing, or debridement with continuous closed postoperative lavage. Patients were noted to have similar preoperative Ranson's scores. Mortality was significantly higher after closed drainage (48.4%), compared to 15% following open packing, and complications were not significantly different between the groups. However, as pancreatic necrosis and the time of operation are not documented, it is not clear that these results are applicable to current practice.

Several series in the literature have quoted a high rate of recurrent pancreatic sepsis and high rate of reoperation when the technique of debridement and closure over drains is used.[88] Bradley has quoted a rate of re-exploration for recurrent sepsis in 30–40% of patients,[102] and a review of large series suggests that the majority of postoperative deaths after closed drainage are due to persistent or recurrent infection.[55] These figures have been used to argue for either repeated pancreatic debridement via open packing or for continuous postoperative pancreatic lavage. However, the Massachusetts General Hospital experience with the closed drainage technique reports a mortality of 6.2%, the lowest reported mortality rate in any series of pancreatic debridement for pancreatic necrosis.[83]

Bradley reports a favorable mortality rate of 14% for the technique of open packing.[102] Given a need for reoperation in up to 30–40% of patients after closed drainage or high-volume lavage, an argument is then made for controlled, planned re-exploration to achieve thorough debridement. Others have suggested that the open packing technique might be particularly useful in patients with a larger mass of necrotic tissue.[103] However, postoperative morbidity can be considerable with the open packing technique. Bradley has reported a rate of incisional hernia of 23% after open packing.[102] Though this complication is not widely reported in other series, one other has reported a hernia rate of 80%.[104] An increased rate of GI fistulas has been reported in some series of open packing, although a brief review of published series shows that this complication is not universal. As with other complications, however, the precise definition of GI fistula is not clarified in different series. Length of hospital stay, which is not commonly reported in different series, has been suggested to be prolonged after open packing.[105]

The recent trend toward delayed surgical therapy for pancreatic necrosis may facilitate atraumatic debridement, as necrosis becomes increasingly organized and demarcated from viable tissue over time.[92] Some investigators have suggested that a policy of delayed exploration and debridement may therefore facilitate closed drainage without packing or postoperative lavage. In the previously mentioned 2001 series of 99 patients with pancreatic necrosis managed conservatively at the Brigham and Women's Hospital, operation was offered only for documented infection or for sterile pancreatic necrosis with persistent systemic illness. In this series, Ashley et al demonstrated that most patients were managed with closed drainage.[35] The mean interval from presentation to surgery

was 27 days. Of these patients, 31 (86%) were managed with debridement and closure over drains, 1 received postoperative irrigation, and 4 required open packing and planned re-exploration. Nineteen patients (34%) developed complications, including 9% each with pancreatic or enteric fistulas, and 15% with endocrine or exocrine insufficiency. Of patients managed with closure over drains, only four (13%) needed re-exploration due to inadequate persistent illness and presumed inadequate debridement. We continue to believe that each technique has its place. When early operation is mandated, open packing or lavage may be necessary to deal with the consequences of ongoing necrosis. If operation can be delayed, debridement with closed drainage and sometimes even internal drainage may be adequate.

Minimally Invasive Approaches

Although mortality after open pancreatic debridement has decreased in recent years, many series still demonstrate a mortality rate of approximately 15%; in addition, the mortality in patients with established organ failure may exceed 75%.[106] Open approaches are often associated with initial postoperative deterioration, requiring intensive physiological support. Given the considerable morbidity, organ failure, and mortality associated with traditional open pancreatic debridement, some investigators have suggested that minimally invasive surgical procedures may be used successfully with pancreatic necrosis. Avoiding open debridement has the theoretical advantage of minimizing activation of systemic inflammatory processes and reducing respiratory and wound complications.

In recent years there has been a proliferation of reports describing minimally invasive approaches in necrotizing pancreatitis.[107] Percutaneous, endoscopic, and laparoscopic techniques have all been described. Solid pancreatic debris has traditionally been thought to be too thick for adequate evacuation with percutaneous drains; still, small studies have demonstrated success with percutaneous catheter drainage as a primary treatment for infected pancreatic necrosis. Several series of successful percutaneous management in infected pancreatic necrosis have been reported in the literature.[108–110] For instance, Freeny et al[108] successfully managed 16 of 34 such patients with an aggressive protocol of percutaneous drainage. This required a mean of four catheter insertions and lavage for a mean of 85 days. In nine other patients, percutaneous intervention was not the sole means of therapy but allowed eventual open surgical intervention to be delayed. Thus, combined with the 52% of patients requiring elective or emergency surgery, approximately 75% of patients subsequently needed surgical intervention.[106] It is possible that percutaneous drainage in this case functioned just to delay an operation and prevent the need for laparotomy during the most acute phase of the illness. The concept that percutaneous drainage of infected necrosis may delay the need for early intervention, permitting surgery once the process has become more organized, is appealing but needs further validation. A recent study by Rocha et al[89] in which 28 patients with necrotizing pancreatitis were managed using percutaneous drainage found no clear improvement in overall mortality with catheter drainage. The overall role of percutaneous catheter drainage in the management of necrotizing pancreatitis remains undefined.

An often-unstated principle of therapy for pancreatic necrosis in the past has been the need to externally drain the pancreatic bed. Necrotic tissue, pancreatic enzymes, bacteria, and inflammatory mediators in the infected milieu of the necrotic pancreas were all thought to be best drained outside the body. The concept of internal drainage, whereby inflammatory tissue and fluid is drained to the GI tract directly, has only recently been considered to be feasible. In this regard, some investigators have suggested endoscopic therapy for pancreatic necrosis, and have recently summarized the results.[111] Forty-four patients with pancreatic necrosis were treated for suspected or documented infection, or for intractable symptoms from organized necrosis including nausea, pain, or early satiety. Endoscopic transmural drainage was successful in 31 (72%) patients with pancreatic necrosis, although 9 (29%) experienced recurrence and 16 (37%) experienced complications. Transmural drainage was more successful with central rather than peripheral necrosis due to close proximity of the necrotic area to the gastric wall. Subsequent analysis has suggested that collections with solid debris of more than 1 cm are not suitable for endoscopic drainage.[112] In addition, up to 60% of patients successfully drained developed more collections over a 2-year period.

Seifert et al[113] have described a method of retroperitoneal endoscopy via transgastric fenestration. Direct visual access to retroperitoneal collections is thereby obtained to allow optimal drainage. Few patients have been described using this method, and larger studies are necessary to validate this approach. These techniques were also not always performed for infected pancreatic necrosis. Of concern is the certainty that if sterile retroperitoneal collections are accessed via the GI tract, these collections soon become contaminated with commensal GI flora.[114] Inadequate drainage after endoscopic intervention clearly has the ability to complicate a troublesome but not life-threatening collection.

Various techniques of minimally invasive surgery have been adopted to treat pancreatic necrosis. One method employed with several variations can be considered the "video-assisted retroperitoneal debridement" method. Gambiez et al[115] have suggested using a retroperitoneal approach via dorsal lumbotomy and a 23 cm endoscope to explore and drain the peripancreatic area; necrotic peripancreatic tissue could be removed by blunt dissection and drains may be left for irrigation. These authors have employed this technique, repeating debridements at regular 5-day intervals until the resolution of necrotic debris, with a mean of five procedures. Purported advantages of this technique include an avoidance of peritoneal contamination, though extraction of the pancreatic necrosum is limited by the diameter of the retroperitoneal instrumentation. Furthermore, in the series reported by Gambiez et al,[115] subsequent laparotomy was required in just two patients for persistent collections. Overall mortality in

20 patients with infected pancreatic necrosis was 10%, which compares favorably with historical controls.

Percutaneous necrosectomy and sinus tract endoscopy are techniques described by Carter et al[116] for minimally invasive debridement of the necrotic pancreas. Briefly, methods borrowed from percutaneous nephroscopy are utilized to directly visualize the retroperitoneum. Under CT guidance an 8F pigtail catheter is advanced into the pancreatic cavity, either between the lower pole of the spleen and the splenic flexure, or, for right-sided necrosis, through the gastrocolic omentum anterior to the duodenum. The cavity is accessed in the operating room under fluoroscopic guidance; the catheter tract is serially dilated, first manually then with a balloon dilator, until a 34F sheath is accepted. An operating nephroscope may then be passed to the cavity, allowing irrigation, suction, and piecemeal removal of necrotic debris. Devitalized tissue is easily identified and may be removed by gentle traction in a piecemeal fashion. Large drains may be placed through the same access sites to allow postoperative drainage and/or lavage. Planned second-look procedures may be performed every 7–10 days, until the cavity is clean. The technique of sinus tract endoscopy employs similar methods to inspect, debride, and drain residual collections after an initial open debridement. These techniques may achieve adequate debridement and drainage and/or lavage of the pancreatic bed. Carter et al,[116] in an initial report with only 10 patients, report a mortality that was 20%. However, postoperative organ dysfunction was minimized, and the majority of patients were managed outside of the ICU postoperatively.

The use of minimally invasive techniques can undoubtedly reduce the severity of systemic sepsis and organ dysfunction associated with open pancreatic debridement. The primary risk of these procedures is an inadequate debridement of solid necrosum and inadequate drainage of the pancreatic bed. No randomized studies exist to compare these techniques to traditional open debridement. Furthermore, studies are difficult to compare given small sample size, the retrospective nature of reports, and varying comorbidities and selection criteria. For the current time, open surgical debridement continues to be the "gold standard" treatment for surgical management of pancreatic necrosis. However, as management strategies become more nonoperative, it is likely that minimally invasive and percutaneous techniques will play an increasing role in the treatment of pancreatic necrosis in the future.

SUMMARY

While the treatment of mild pancreatitis has changed little in recent years, advances in the management of severe pancreatitis have been associated with significantly reduced morbidity and mortality. Improvements in the recognition of severe disease with scoring systems and serial CT scanning has allowed early goal-directed therapy in appropriate patients. Timely resuscitation and invasive monitoring are standard, and there is an increased recognition of the role of prophylactic antibiotics for pancreatic necrosis and image-guided FNA to diagnose infection. While the need for aggressive intervention in infected pancreatic necrosis remains unchanged, initial conservative management of most patients with sterile pancreatic necrosis has gained widespread acceptance. Some patients with sterile necrosis may eventually require delayed debridement either for persistent systemic illness or failure to thrive, although accurate prospective identification of these patients has not been possible. For patients needing debridement, open surgical techniques remain the "gold standard" of management. Advances in minimally invasive technology hold promise as adjuncts to open procedures in the future, particularly as a means of delaying surgery to facilitate debridement when the necrotic pancreas becomes more organized.

COMPLICATIONS OF ACUTE PANCREATITIS (INCLUDING PSEUDOCYSTS)

John A. Windsor • Benjamin P. T. Loveday

INTRODUCTION

Recovery from acute pancreatitis is now expected, with mortality less than 10%, which reflects improvements in the treatment of complications and intensive care management.[1] A third of patients with acute pancreatitis develop complications and a quarter of these will die of them. These complications can be local, regional, or systemic. Most regional and systemic complications occur in association with severe acute pancreatitis. The most important determinants of severity in acute pancreatitis are infected local complications and multiple organ dysfunction.[2] These regional and systemic complications provide the basis for defining four categories of severity (Table 55-1).[3] This chapter will focus on the diagnosis and management of the important complications of acute pancreatitis.

LOCAL COMPLICATIONS

Severe acute pancreatitis is associated with fluid collections and tissue necrosis in and around the pancreas.[4] These local complications of acute pancreatitis were defined by the Atlanta Symposium in 1992 as pancreatic necrosis, pseudocyst, and abscess. These terms, however, have proven to be confusing and new terminology has been introduced in an attempt to reflect current understanding of the pathophysiology and morphology of the disease.[5,6] In the revised Atlanta Classification, fluid collections less than 4 weeks after disease onset are termed either an acute fluid collection or a postnecrotic pancreatic or peripancreatic fluid collection.[7] Over time changes in the morphology of the lesion occur, in particular the reaction of the surrounding tissue to the enzyme-rich fluid produces a wall, and this is usually well defined on CT scan after 4 weeks. A pancreatic pseudocyst is the term that has traditionally been applied to this lesion, but it is now appreciated that the contents may be anywhere on a continuum from entirely solid to entirely fluid.[8] When a fluid collection has developed in association with pancreatic necrosis, the revised Atlanta Classification has suggested that this is termed "walled off necrosis" (WON). In addition to this variation in content (solid to fluid) local complications can also be sterile or infected, with the latter having significant prognostic significance.

Acute Fluid Collections

DESCRIPTION

Acute fluid collections have no solid component or wall, and typically exist adjacent to the pancreas confined by anatomical fascial planes (eg, anterior pararenal fascia).[7] These collections occur in 30–50% of cases[9,10] and contain a mixture of inflammatory exudates and/or enzyme-rich pancreatic secretions that are a consequence of breakdown of small peripheral ductal side branches. While they may be associated with parenchymal necrosis, their presence does not necessarily indicate necrosis or significant duct disruption. The pancreatic fluid can track widely and may take the form of peripancreatic fluid collections in the retroperitoneum and mediastinum, pancreatic ascites, and/or pleural effusions. The most common routes of extension are into the lesser sac, behind the pancreatic head, behind the left and right colons on the psoas muscle, and into the small bowel mesentery and bulging through the transverse mesocolon.

DIAGNOSIS

Acute fluid collections are a common feature of acute pancreatitis, usually developing in the first 48–72 hours of the disease. Contrast-enhanced CT (CECT), magnetic resonance imaging (MRI) or endoscopic ultrasound (EUS) may be used to confirm the diagnosis and to differentiate acute fluid collections from other local complications (Fig. 55-1).

TABLE 55-1: CLASSIFICATION AND DEFINITIONS OF FOUR CATEGORIES FOR THE SEVERITY OF ACUTE PANCREATITIS

Severity Category	Local Complications		Systemic Complications
Mild	No (peri)pancreatic complication	And	No organ failure
Moderate[a]	Sterile (peri)pancreatic complication	Or	Transient organ failure
Severe[a]	Infectious (peri) pancreatic complication	Or	Persistent organ failure
Critical	Infectious (peri) pancreatic complication	And	Persistent organ failure

[a]Severity is graded on the basis of more severe local or systemic complication, for example, sterile pancreatic necrosis without organ failure must be graded as "moderate," sterile pancreatic necrosis with persistent organ failure must be graded as "severe."
Reproduced from Petrov MS, Windsor JA. Classification of the severity of acute pancreatitis: how many categories make sense? *Am J Gastroenterol.* 2010; 105:74–76.

MANAGEMENT

Acute fluid collections usually remain sterile and resolve spontaneously.[9,10] They are only important in and of themselves because they may be the precursor of pancreatic pseudocysts. If spherical or ovoid with sharp margins, suggesting that under some pressure from ongoing leakage, they are more likely to persist. Massive collections of fluid around or within the pancreas are more likely to be due to disruption of the main pancreatic duct and are more likely to persist for a number of weeks or continue to increase in size.

Acute fluid collections are rarely symptomatic and do not require active treatment. Intervention, by surgical or radiological drainage, risks introducing infection into a usually sterile collection. An asymptomatic fluid collection is managed by observation alone, and only in the presence of infection drainage is usually necessary. Medical therapy, such as with diuretics, is not indicated. Continuous peritoneal lavage does not alter the course of the disease and should not be a routine practice.[11]

Rarely, leakage from injury to the main pancreatic duct can be treated by endoscopic or surgical intervention. Endoscopic treatment uses a trans-sphincteric pancreatic duct stent, which can be placed across the sphincter of Oddi (to decrease ductal pressure and facilitate drainage), into the fluid collection through the disrupted duct (to drain the collection directly) or across the damaged duct (to redirect drainage from the collection to the duodenum and to stent the duct to reduce the risk of stricture formation). The operative approach is either a distal resection of the pancreas or internal drainage of the collection into a Roux-en-Y limb of jejunum. The latter can only be considered once the wall of the collection has matured (see later).

The drainage of pleural effusions in patients with acute pancreatitis should be considered if there is compromised respiratory function or inadequate oxygenation. Chronic pleural effusions as a result of an internal pancreatic fistula often are treated with a chest tube, nasojejunal tube feeding, and somatostatin. Persistence or recurrence will require identification of a pancreatic leak and either drainage into a Roux-en-Y limb of jejunum or distal resection of the pancreas.

Postnecrotic Pancreatic and Peripancreatic Fluid Collection

DESCRIPTION

Postnecrotic collections contain both solid and fluid components, and are not surrounded by a fibrous capsule during the first few weeks. These lesions arise from liquefaction of solid necrosis, but may also contain pancreatic secretions due to an associated pancreatic duct disruption. Over time necrotic tissue undergoes liquefaction and forms part of this fluid collection. As the lesion matures, a wall without an epithelial lining develops around the collection, and is termed WON. Postnecrotic collections are usually sterile but infection may ensue. The term pancreatic abscess is best abandoned as it might represent an infected fluid collection or an infected area of solid necrosis with little associated fluid. This differs from the original definition of a pancreatic abscess, which was defined as a collection of pus, usually in close proximity to the pancreas, containing little or no pancreatic necrosis.[4]

DIAGNOSIS

Postnecrotic fluid collections are diagnosed with CECT, MRI, or EUS after the first week from disease onset. Infection may be identified on CT as extraluminal gas (Fig. 55-2), although definitive diagnosis requires image-guided fine-needle aspiration (FNA) for Gram's stain and culture. Endoscopic retrograde cholangiopancreatography (ERCP) can be used to determine whether there is any ductal communication associated with the lesion, but is rarely required and risks the introduction of infection.

MANAGEMENT

Management of postnecrotic collections is the same as that for pancreatic necrosis, which is described in detail later in this chapter.

Pseudocyst

A pseudocyst is a well-circumscribed fluid collection with no associated tissue necrosis that is present for 4 or more weeks after disease onset.[7] In the original Atlanta Classification a pseudocyst was defined as a collection of pancreatic juice enclosed by a wall of fibrous tissue, and there was no mention

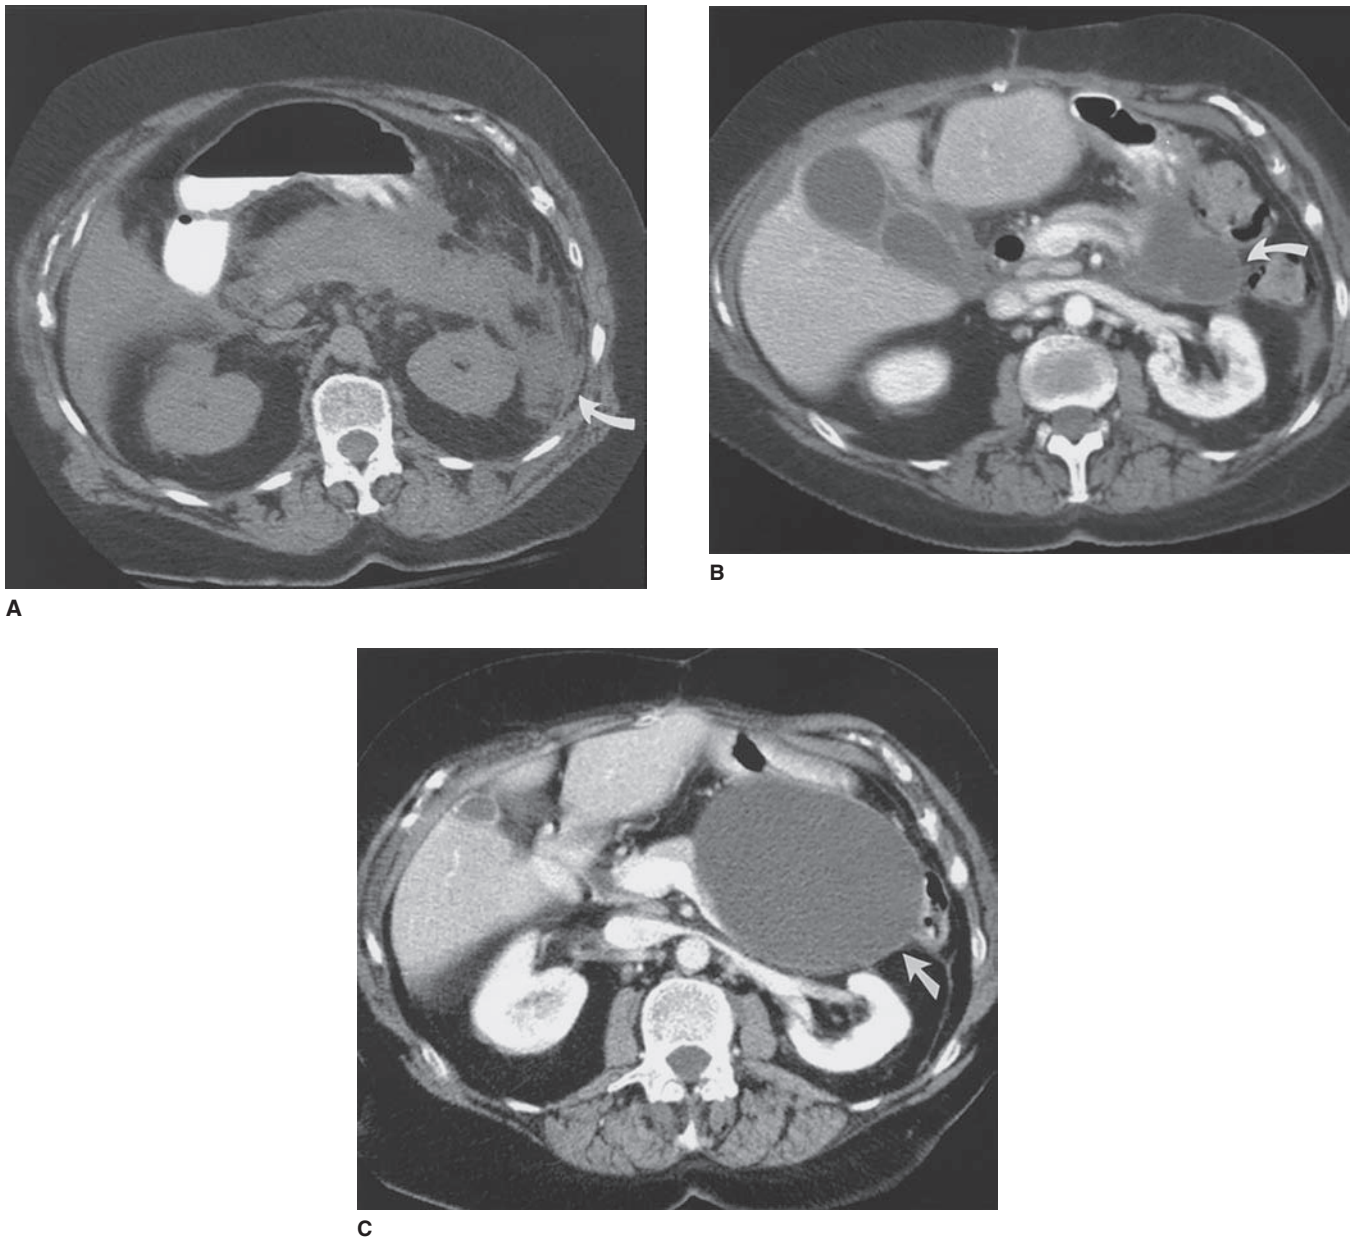

FIGURE 55-1 Progression from an acute fluid collection to a pseudocyst. **A.** Unenhanced CT scan shows an edematous pancreas and an ill-defined, acute fluid collection surrounding the tail of the pancreas (*arrow*) with peripancreatic inflammatory changes, an appearance compatible with acute pancreatitis. **B.** On a follow-up contrast-enhanced CT scan obtained 1 month later, the lesion appears as a bilobed cystic mass with a septum in the pancreatic body and tail (*arrow*). The peripancreatic inflammatory changes are markedly decreased. **C.** On a follow-up CT scan obtained 2 years later, the lesion appears as a unilocular, low-attenuation fluid collection with a well-defined thin wall (*arrow*). This is the typical appearance of a postinflammatory pseudocyst. (Reproduced from Kim Y H et al. Imaging diagnosis of cystic pancreatic lesions: pseudocyst versus nonpseudocyst. *Radiographics*. 2005; May-Jun;25(3):671–685.)

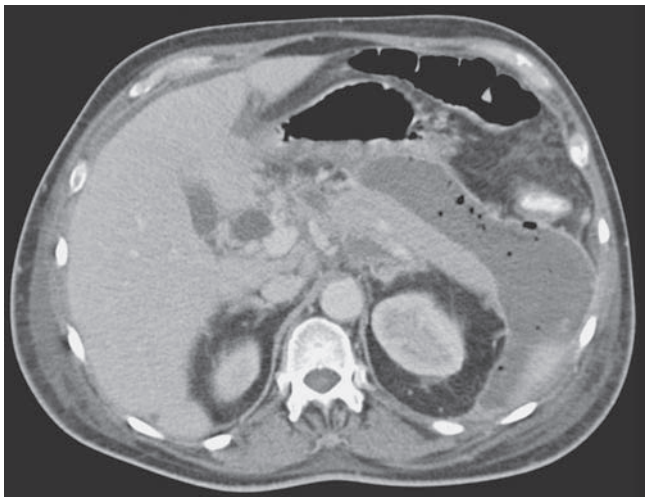
of whether it could also contain a solid component. In practice the lesion is either a fluid collection that does not contain necrosum, which when mature (>4 weeks) is best termed a pseudocyst, or a postnecrotic collection that contains necrosum, which when mature (>4 weeks) is best termed WON.

Thus the pseudocyst precursor is the acute fluid collection, and it is differentiated from the former by the presence of a well-defined wall (capsule) without an epithelial lining (Fig. 55-3). This is in contrast to cystic neoplasms of the pancreas, which are characterised by an epithelial lining. However, this is not an absolute distinction as there may be discontinuous epithelium within cystic neoplasms (probably due to pressure atrophy) and partial epithelialization within chronic pseudocysts (facilitated by communication with the main pancreatic duct). In fewer than 20% of cases, more than one pseudocyst is present. Acute pseudocysts are



A

B

FIGURE 55-2 CT scan showing infected pancreatic necrosis with gas within the collection on cross-sectional (**A**) and coronal (**B**) views.

located most often in close proximity to the pancreas, especially in the lesser sac (see Fig. 55-3) but also may be found in the pelvis, scrotum, mediastinum, or thorax. The extent and number of fluid collections are included in the Balthazar grading of the severity of acute pancreatitis CT scanning.[12]

PATHOGENESIS AND CLASSIFICATION

The development of a pseudocyst requires pancreatic duct disruption, and this occurs in the context of acute pancreatitis (10–15% of cases), trauma, or duct obstruction in chronic pancreatitis (20–40% of cases).[13,14] The leakage of enzyme-rich

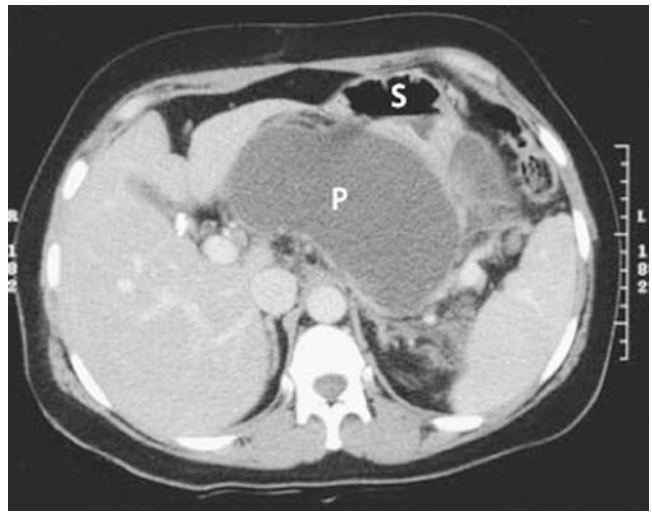


FIGURE 55-3 A CT scan of a pancreatic pseudocyst located in the lesser sac. P, pseudocyst; S, stomach.

secretion incites a marked inflammatory reaction in the peritoneum, retroperitoneal tissue, and serosa of adjacent viscera. As a result, the fluid is contained by a developing layer of granulation tissue and fibrosis that matures over time. If the communication between pancreatic duct and pseudocyst persists, the pseudocyst can continue to enlarge, sometimes reaching 20–30 cm in diameter. The contents of the pseudocyst usually consist of a relatively clear watery fluid. However, with hemorrhage, it may contain clot and become xanthochromic. In the presence of infection, a pseudocyst will contain pus. If a collection of fluid develops following pancreatic necrosis, and it contains solid tissue, it should not be termed a pseudocyst but rather walled off necrosis (WON).

Pseudocysts secondary to blunt trauma tend to develop anterior to the neck and body of the gland because the duct is injured where it crosses the vertebral column. In chronic pancreatitis, pseudocysts are thought to develop secondary to obstuction of the pancreatic duct. The pseudocysts are usually located within the fibrotic gland, can be multiple and sometimes are difficult to distinguish from pancreatic retention cysts. The latter are formed by progressive dilatation of the pancreatic duct and tend to retain the epithelial lining of the duct.

A useful classification of pseudocysts was proposed by D'Egidio in 1991, which incorporates the key features discussed earlier (Table 55-2).[15] Type I pseudocysts occur after an episode of acute pancreatitis and are associated with normal duct anatomy and rarely communicate with the pancreatic duct. Type II pseudocysts occur after an episode of acute or chronic pancreatitis and have a diseased but not strictured pancreatic duct, and there is often a communication between the duct and the pseudocyst. Type III pseudocysts occur in chronic pancreatitis, and are uniformly associated with a duct stricture and a communication between the duct and the pseudocyst.

TABLE 55-2: THE D'EGIDIO CLASSIFICATION OF PANCREATIC PSEUDOCYSTS AND THE PRIMARY TREATMENT OPTIONS

	Context	Pancreatic Duct	Duct-Pseudocyst Communication	Primary Treatment
Type I	Acute postnecrotic pancreatitis	Normal	No	Percutaneous drainage
Type II	Acute-on-chronic pancreatitis	Abnormal (no stricture)	50:50	Internal drainage or resection
Type III	Chronic pancreatitis	Abnormal (stricture)	Yes	Internal drainage with duct decompression

COMPLICATIONS

With modern imaging practice, a higher proportion of asymptomatic pseudocysts are diagnosed. As a result the risk of pseudocyst complications is probably less than previously considered when pseudocysts were diagnosed on the basis of symptoms. Complications occur in about 10% of cases and the four main complications of pseudocysts are infection, rupture or internal fistulation, bleeding, and mass effect.[16]

Pseudocysts are initially sterile, but infection can occur in up to 25% of cases.[16,17] The presence of sepsis due to an infected pseudocyst is an indication for drainage of the infected contents. This can be done by percutaneous drainage, with the risk of a persisting external pancreatic fistula, or by internal drainage to the stomach or small bowel.

The rupture of a pseudocyst can occur by erosion into the adjacent gastrointestinal tract, which may allow the pseudocyst to resolve or it may leave a cystoenteric fistula or pancreaticopleural/bronchial fistula. The term fistula is not strictly accurate in this setting as the communication is not between two epithelial-lined structures. Rupture into the gastrointestinal tract may be associated with significant haemorrhage, that is a sentinel bleed. Rupture into the peritoneum leads to pancreatic ascites and can be a dramatic presentation with acute abdominal pain and rigidity from chemical peritonitis.

Bleeding associated with a pancreatic pseudocyst can be a life-threatening complication. There are several causes of bleeding. Bleeding may occur secondary to erosion of the gut mucosa with the impending development of a cystoenteric fistula. This may produce hematemesis and melena. More ominous is the direct erosion of a significant visceral vessel, including the splenic, gastroduodenal, and middle colic vessels. The action of pancreatic enzymes (especially elastase) on the vessel wall can lead to thinning of the vessel wall with aneurysm and pseudoaneursym formation (Fig. 55-4). This situation carries a high mortality (~20%).[18] The risk of bleeding is increased in the presence of local infection. If time and patient stability permit, emergency selective splanchnic angiography is performed to delineate the site of bleeding, and embolization is attempted (Fig. 55-5A, B). Otherwise, emergency surgery is required, consisting of oversewing of the bleeding vessels and internal or external drainage of the pseudocyst. Occasionally it is possible to resect the pseudocyst, which is effective in preventing recurrent hemorrhage.

A large pseudocyst may exert a mass effect, and thereby produce early satiety (stomach), partial or complete intestinal obstruction (duodenum, gastric outlet, esophagogastric junction, and rarely small or large bowel), cholestasis (bile duct), and venous thrombosis (portal, superior mesenteric, and splenic veins) leading to portal or segmental hypertension and varices. Mass effect is more likely when a pseudocysts is greater than 6 cm in diameter.[16]

DIAGNOSIS

A pseudocyst should be suspected when a patient with acute pancreatitis fails to recover after a week of treatment or when, after initial improvement, symptoms return. Most patients

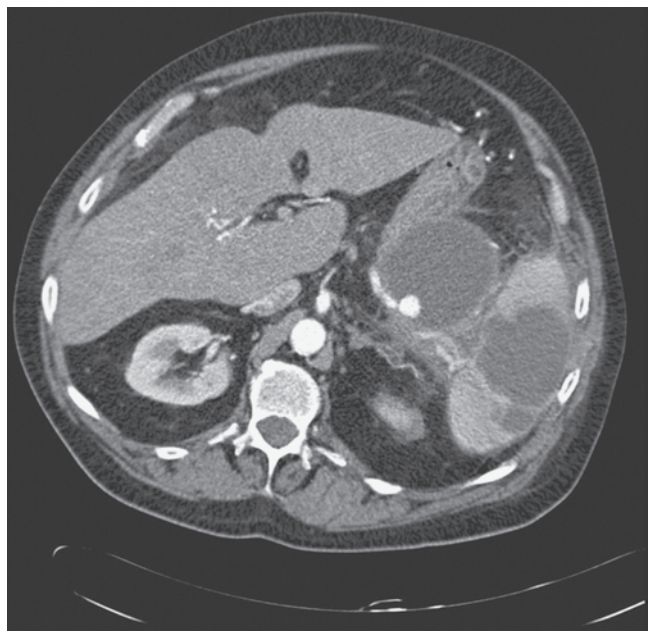

FIGURE 55-4 A contrast CT scan showing the pseudocysts, the medial one complicated by a pseudoaneurysm related to the splenic artery.

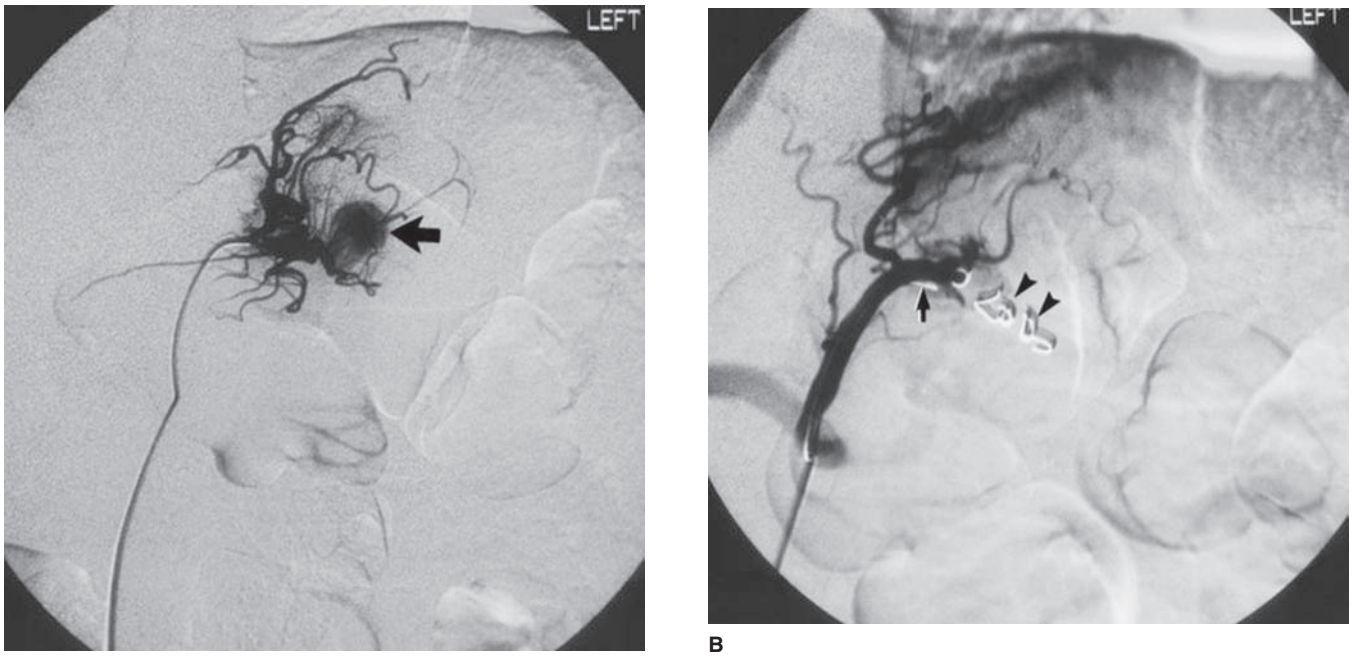

FIGURE 55-5 Selective mesenteric angiogram showing a pseudoanuerysm related to the left gastric artery (**A**) and successful embolization (**B**).

with symptomatic pseudocysts have epigastric discomfort or pain. There may be anorexia, early satiety, nausea, mild fever, back pain, and a palpable mass. Signs of sepsis are not usually overt. In about half the patients there is failure of the serum amylase level to return to normal or a mild (2–4 times normal) secondary rise. However, often the early stages of pseudocyst formation are observed radiologically before symptoms develop, and this provides some forewarning.

The clinical suspicion of a pseudocyst may be investigated by CECT or MRI scan, where it appears as a rounded, low attenuation, fluid-filled structure within or adjacent to the pancreas (for diagnostic and treatment algorithm, see Fig. 55-6). While ultrasonography (US) is excellent for the detection of a pseudocyst, it is limited by operator skill, the patient's habitus, and overlying bowel gas. The advantage of ultrasonography is that it is better able to determine the extent of solid tissue within a fluid collection, and it is used often to guide FNA. EUS can be useful in distinguishing a pseudocyst from a cystic neoplasm because it often delineates internal septation better than CT scan.[19] Compared with ultrasonography, CT scanning has an accuracy approaching 100% for the diagnosis of a pseudocyst, is not operator-dependent, and is more useful in planning therapy. It will demonstrate the key features of a pseudocyst (ie, size, shape, wall thickness, and contents), the nature of the pancreas (ie, presence and extent of necrosis, diameter of pancreatic duct, and features of chronic pancreatitis, including atrophy and calcification), and the relationship of these to the surrounding organs (see Fig. 55-3), which can be critical in planning internal surgical drainage. Triphasic helical CT scanning will delineate the regional arteries (to look for pseudoanuerysm formation) and veins (to look for thrombosis, cavernous transformation, and formation of varices). More recently, MRI is excellent at characterising the morphological features of the lesion and in particular outlining the solid component of the lesion.[7]

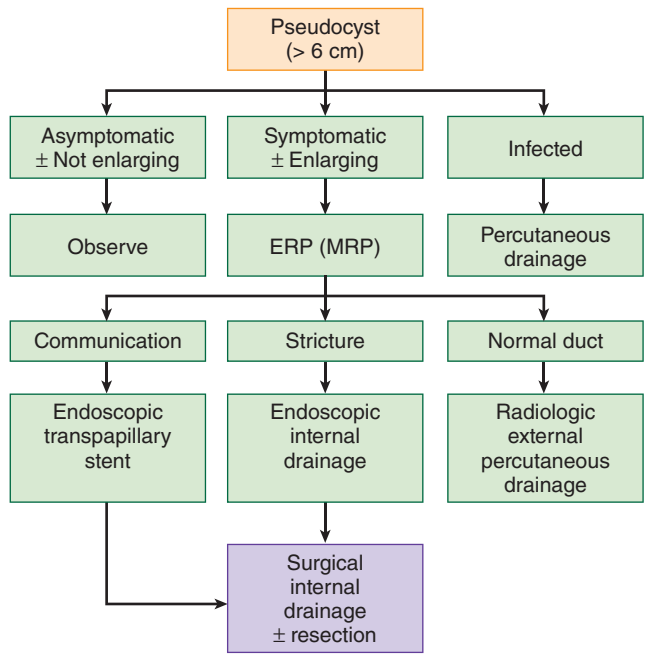

FIGURE 55-6 Algorithm for investigation and treatment of pancreatic pseudocysts. ERP, endoscopic retrograde pancreatogram; MRP, magnetic resonance pancreatogram.

ERCP is not routinely required as part of the diagnostic workup for pseudocysts. In symptomatic cases where treatment is likely, it may be useful to plan further management. The advantage of ERCP is that it has both diagnostic and therapeutic roles. Because of the risks of exacerbating pancreatitis, perforation, bleeding, and introducing infection, it is preferably done within 48 hours of any planned drainage procedure. Over 90% of patients with a pseudocyst have some abnormality of the pancreatic duct. The unique diagnostic contribution of ERCP is to accurately delineate a communication between the main pancreatic duct and the pseudocyst, which occurs in over 60% of patients. A communication of this type is a relative contraindication to external drainage of a pseudocyst.[20] The classification of the main pancreatic duct by ERCP has been shown to assist in selecting the type of treatment, where the presence or absence of a stricture, communication, and obstruction is an important feature to note.[21] Magnetic resonance cholangiopancreatography (MRCP) may be used to assess pancreatic and biliary duct morphology instead of ERCP and in some centers has replaced ERCP in its diagnostic role and has the advantage of being noninvasive with similar diagnostic accuracy to ERCP, but has no therapeutic role.[22]

The clinical diagnosis of a complication of a known pseudocyst is usually straightforward. The rupture of a pseudocyst into the peritoneal cavity is associated with the onset of acute abdominal pain and signs of peritonitis. This is in contrast to the spontaneous decompression of a pseudocyst into an adjacent organ, which usually results in the relief of symptoms. Infection of a pseudocyst is accompanied by signs of sepsis. Infection can be confirmed with image-guided FNA for Gram's stain and bacterial culture. Bleeding usually results in an increase in abdominal pain and possible syncope, tachycardia, and hypotension. A drop in hemoglobin concentration is expected.

Although cystic neoplasms are rare, they can be mistaken for pseudocysts. Absence of an antecedent history of acute pancreatitis, elevation of carcinoembryonic antigen (CEA) or carbohydrate antigen (CA) 19-9, and/or the presence of internal septation should suggest this diagnosis. If EUS is available, it will enable the identification of septations (microscopic characteristics of serous lesions or macrocystic characteristic of mucinous lesions), mural nodules, echogenic debris, and calcification, and it may also allow aspiration of fluid content for analysis. Pseudocysts usually contain fluid with elevated amylase (>5000 U/mL) and an absence of tumor markers, but this should not be relied on for a definitive diagnosis.[23]

MANAGEMENT

The natural history of a pseudocyst is not easy to predict. Spontaneous resolution occurs frequently and usually within 6 weeks. When larger than 6 cm in diameter, and when it continues to enlarge during the first month, a pseudocyst is more likely to persist and develop complications. Size alone is a poor predictor because resolution can occur even with very large pseudocysts. Persistence is also more likely if there is a distal stricture of the main pancreatic duct and a proximal communication between the main pancreatic duct and the pseudocyst. Although not directly correlated, a large pseudocyst is more likely to cause discomfort and pain.

The two principal indications for treating pancreatic pseudocysts are to relieve symptoms and to treat complications. In the absence of symptoms or evidence of enlargement, conservative management is usually reasonable. A traditional approach that dictated treatment of all pseudocysts that have been present for more than 4–6 weeks is no longer justified.[24] The decision as to whether a pseudocyst in a particular patient requires active intervention can be difficult. The desire to allow time for spontaneous resolution to occur must be balanced against the risk of complications while waiting for cyst wall maturity. The traditional indications for treatment were the complications of a pseudocyst. Now the focus is on preventing complications. In many centers it has become less common to treat a pseudocyst solely on the grounds of a failure to resolve. An enlarging asymptomatic pseudocyst that has been present for 6 weeks is usually treated. A natural-history study from India indicates that asymptomatic pseudocysts less than 7.5 cm in diameter and without internal debris will resolve spontaneously at an average of 5 months.[25] In modern series, the mean diameter of pseudocysts requiring treatment is approximately 9 cm.[26,27] At the same time as this trend toward conservatism, there has been an increase in the number of treatment modalities, including open surgical, laparoscopic, endoscopic, and radiological.

There are two important rules in the treatment of pseudocysts. The first is that a cystic neoplasm must not be treated as a pseudocyst. The second is that elective external drainage of a pseudocyst must not be done if there is downstream and unrelieved pancreatic ductal obstruction because of the high risk of an external pancreatic fistula. The approach to treatment (Table 55-3) depends on the nature of the pseudocyst, the pancreatic duct, and the fitness of the patient. Also important is the level of available expertise and experience with the various treatment modalities.

The following general features of a pseudocyst are important in considering the most appropriate treatment:

- The thickness of the pseudocyst wall, which is usually a function of the duration of the pseudocyst. This is important because the operative drainage of a pseudocyst requires that it safely accept sutures or staples. After 6 weeks the fluid collection is fully walled off in a fibrous capsule.[28]
- The location of the pseudocyst. If adherent to the stomach or duodenum, the options are different than if the pseudocyst is deep within the retroperitoneum and covered by bowel loops.
- The contents of the pseudocyst. The presence of blood may indicate the need for prior embolization of a pseudoaneurysm. Pus will require drainage, either internally or externally. The presence of solid necrosum suggests the lesion is in fact WON and may require some form of necrosectomy.

TABLE 55-3: THE TREATMENT APPROACHES FOR PANCREATIC PSEUDOCYST

Approaches	Examples
Open surgical	Cystogastrostomy
	Cystoduodenostomy
	Roux-en-Y cystojejunostomy
	Distal pancreatectomy ± splenectomy
	External drainage
Laparoscopic	Cystogastrostomy
	Cystoduodenostomy
	Roux-en-Y cystojejunostomy
	Distal pancreatectomy ± splenectomy
	External drainage
Radiologic	Percutaneous drainage
	Percutaneous transgastric drainage
Endoscopic	Transpapillary pancreatic duct stent
	Transgastric stent
	Transduodenal stent

- The number of pseudocysts. If multiple pseudocysts are present, then minimally invasive approaches may not be feasible. Conservative management is not recommended with symptomatic multiple pseudocysts.
- The etiology of the pseudocyst. Lesions arising from acute-on-chronic pancreatitis may require different treatment to those arising from the first episode of acute pancreatitis.
- The main pancreatic duct anatomy and degree of disruption. The pancreas and the pancreatic duct need separate consideration in planning the treatment of a pseudocyst. The pancreas may warrant treatment in its own right, especially if there is a ductal stricture, a dilated duct, or regional disease warranting resection.

Open Surgical Treatment. There is no single surgical procedure that is appropriate for all pseudocysts. The most important factor dictating the mode of treatment is local expertise.[29] In principle, drainage procedures are preferred to resection because they preserve pancreatic function, are technically easier, and have a lower mortality rate. Despite the many alternatives and less invasive approaches, it is important to emphasize that the most effective and reliable means of treating a pseudocyst is internal drainage by an open surgical approach (see Table 55-3). The complication and mortality rates of internal drainage are half those of external drainage.

A D'Egidio type II pseudocyst is best treated by internal drainage or resection, particularly when ductal disruption or stricture is present. When there is a mature wall, internal drainage is the best surgical option. Recurrence rates should be less than 5%, and mortality should be less than 2%. The pseudocyst can be drained into the stomach, the duodenum, or the jejunum. The choice of surgical procedure depends on the location of the pseudocyst and its relationship to these organs.

A cystogastrostomy is ideal when the pseudocyst is adherent to the posterior stomach and indenting it (Fig. 55-7). A longtitudinal anterior gastrostomy is followed by the stepwise excision of a disk (>2 cm diameter) of stomach with subjacent pseudocyst wall. The tissue is sent for frozen section in all cases to exclude cystic neoplasia. Sutures are placed in stages to reduce the risk of edge bleeding as the disk is excised. Prior confirmation of the location of the pseudocyst may be required by needle aspiration, although it is usually obvious. The stoma should be large enough to allow transgastric débridement of any necrotic tissue within the pseudocyst cavity. A laparoscope can be used after open débridement to confirm that the cavity it clear of debris. The disadvantage of the cystogastrostomy is that it is not a dependent stoma, may act as a sump, and when the pseudocyst is large can accumulate gastric debris. Where access permits, a Roux-en-Y cystojejunostomy is ideal for internal drainage (Fig. 55-8) and is particularly suited to drainage of pseudocysts arising from the body and tail of the pancreas, or not adherent to the stomach or bulging through the left transverse mesocolon.

Combining internal drainage of a pseudocyst with a lateral pancreaticojejunostomy should be considered in patients with chronic pancreatitis and a dilated pancreatic duct because it will improve outcome without increasing the risk of the procedure. The blind end of the Roux limb should be placed toward the tail of the pancreas because this allows the head of the pancreas to be drained and the bile duct to be bypassed using the same limb.

Distal pancreatic resection has a role, particulary when the head of the pancreas is relatively preserved. An endoscopic retrograde pancreatogram will help to define the extent of resection. Provided that there is no pancreatic duct obstruction, the recurrence and fistula rates are very low. Specific ligation of the pancreatic duct will decrease the fistula rate.

External drainage of a pseudocyst has a limited role but is useful in the critically ill patient and where a controlled external fistula is an acceptable goal. Other rare indications for external drainage at the time of laparotomy include the control of an immature ruptured pseudocyst and for some bleeding pseudocysts where there has been under-running of the bleeding point. An external fistula may resolve more rapidly with placement of a transpapillary stent and with the use of a long-acting somatostatin analogue.

Radiological Treatment. The first description of direct percutaneous aspiration and external drainage using radiologic guidance was in the early 1980s.[30–33] This technique has become widely practiced with a reported morbidity of between 10 and 30%. It can be used with an immature pseudocyst wall, although the risk of complications is higher in this setting. Percutaneous drainage is best suited to D'Egidio type I pseudocysts in which there is no significant underlying duct abnormality or communication between the duct and pseudocyst. In the setting of acute pancreatitis, catheter drainage may not be helpful because of small catheter size and the inability to allow the drainage of necrotic and viscous material. In the setting of chronic pancreatitis, the downstream obstruction of

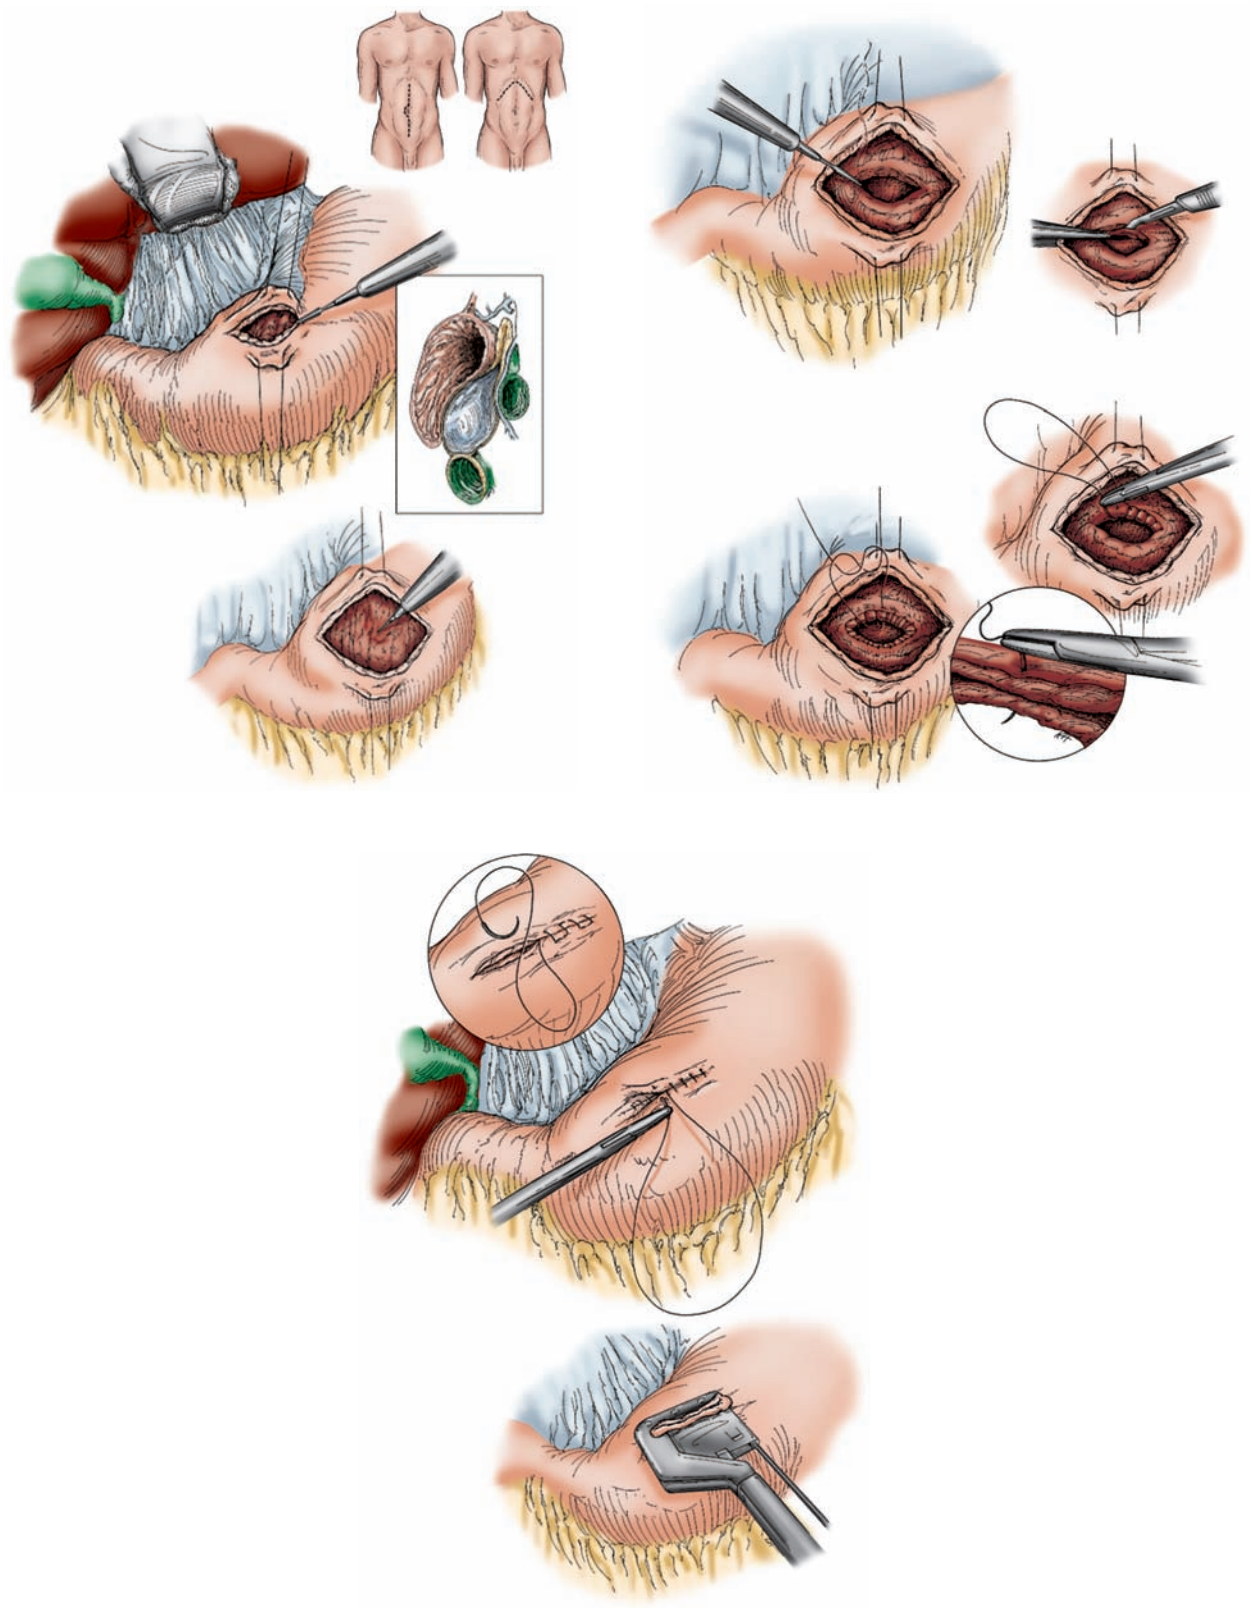

FIGURE 55-7 Internal drainage of a pseudocyst through the posterior wall of the stomach (cystogastrostomy).

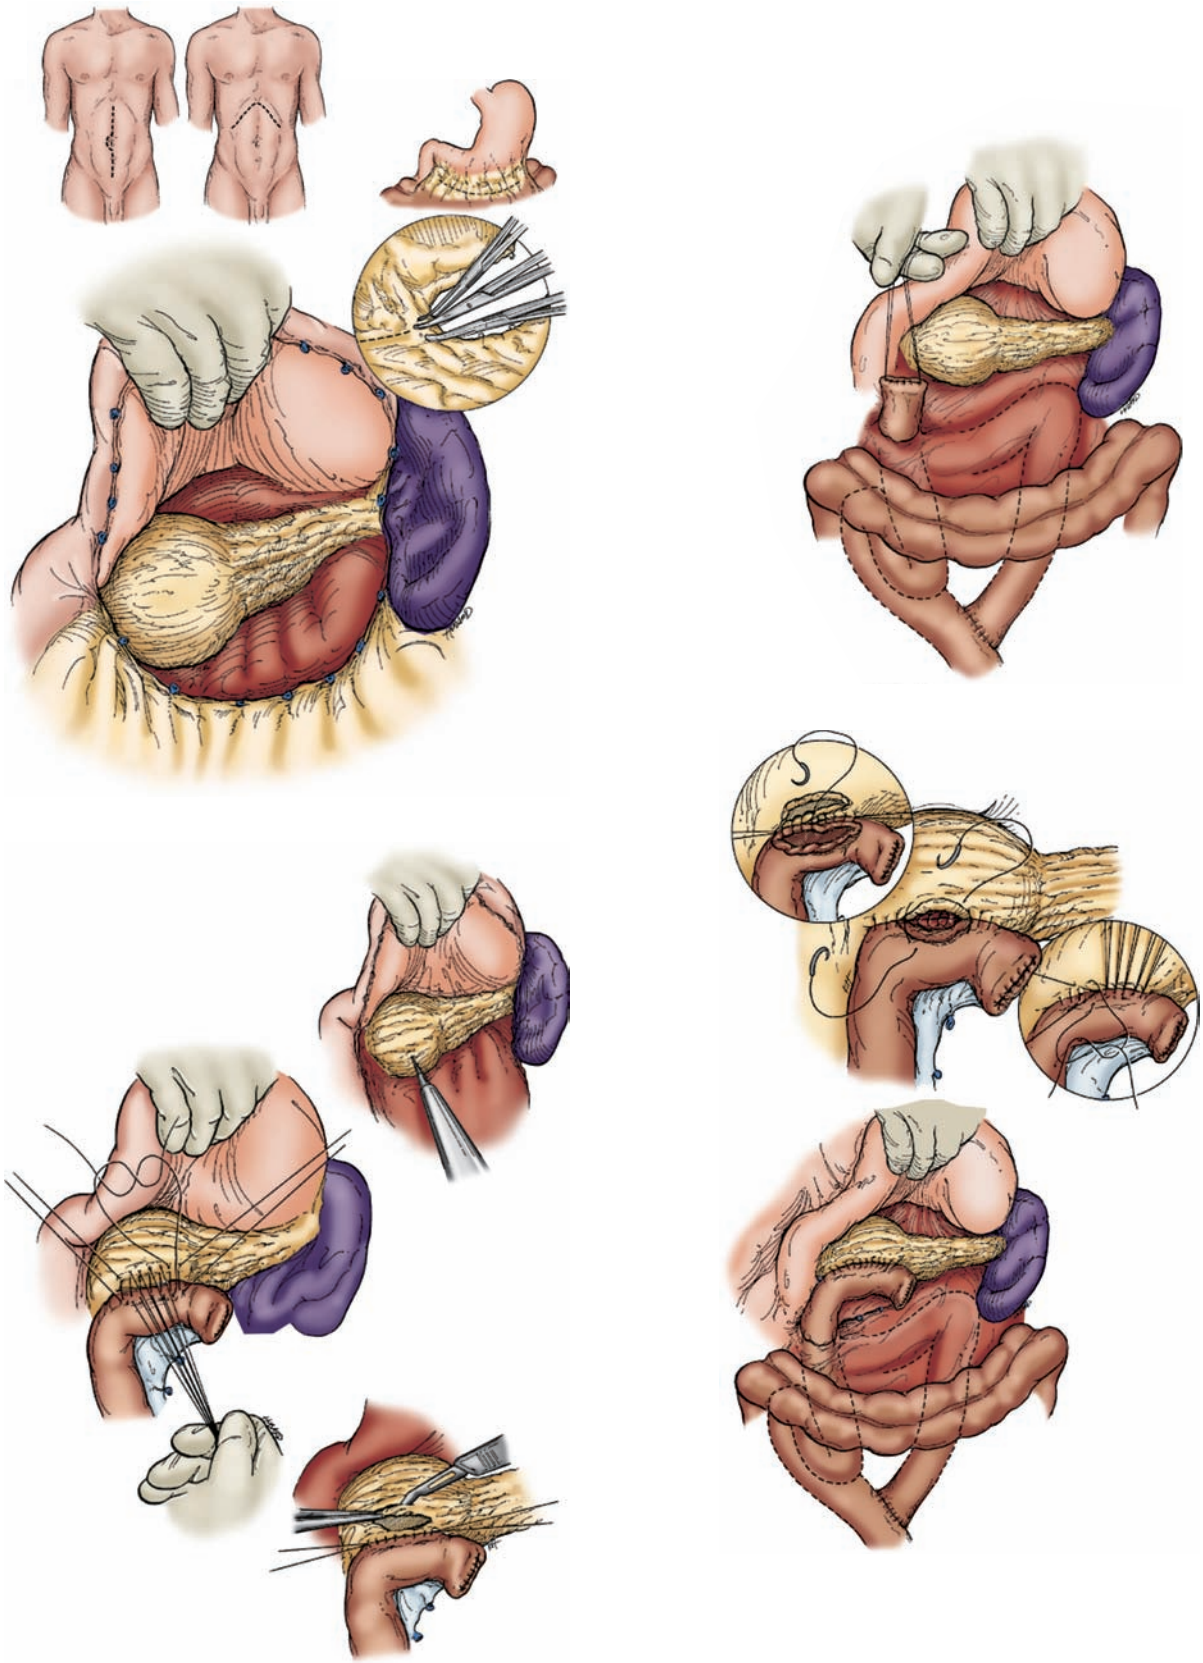

FIGURE 55-8 Internal drainage of a pseudocyst to the jejunum (Roux-en-Y cystojejunostomy).

the duct gives rise to a high recurrence rate and/or an external fistula along the catheter tract. In simple, uncomplicated pseudocysts, percutaneous drainage is usually successful, but not necessary since this is the group with the fewest symptoms, the lowest complication rate, and the best chance of spontaneous resolution.

The introduction of a transgastric approach to percutaneous drainage has almost abolished the problem of external pancreatic fistulas (Fig. 55-9A, B).[34] This produces a percutaneous cystogastrostomy but requires an initial period of external transgastric drainage, clamping at 3 days, and then internalization at 2 weeks. Internalization can be helped with a concurrent endoscopic view, especially using double pigtail catheters. The endoscopic approach is also used for the subsequent removal of the catheters. A well-matched population-based study comparing percutaneous (n = 8121) with open surgical drainage (n = 6409) in 14,914 patients with pancreatic pseudocysts revealed a longer length of hospital stay and twice the mortality (5.9 vs 2.8%) for the former[35] (ie, percutaneous). Currently there is limited use of percutaneous pseudocyst drainage, unless there is an underlying medical problem or cyst complication.

Endoscopic Treatment. There has been significant activity in the endoscopic treatment of pseudocysts over the last decade. Endoscopic transpapillary techniques include stenting the sphincter of Oddi to lower ductal pressures. The stent also can be advanced via the pancreatic duct into the pseudocyst when there is a demonstrable communication. Endoscopic transmural drainage is also possible and involves identifying the bulge into stomach or duodenum caused by the pseudocyst. The cyst generally is entered using a diathermy needle knife. Prior endoscopic ultrasonography allows greater accuracy and safety by confirming the anatomic route, and Doppler can be used to help avoid larger blood vessels. A number of pigtail stents can be inserted. The tract also can be dilated with a balloon catheter and the endoscope itself inserted into the cavity of the pseudocyst for direct visualization and retrieval of the cyst contents and wall biopsy (to rule out a cystic neoplasm).

These endoscopic methods are still evolving but have a reported success rate of up to 90% with experienced practitioners. But it must be remembered that the reports generally are in carefully selected patients. Caution needs to be exercised because of the risks of perforation, peritonitis, and infection through inadequate internal drainage. This is also a less reliable means of obtaining a large tissue sample to exclude cystic neoplasia and there is also an increased risk of bleeding. The risk of bleeding is significantly reduced when the initial puncture is guided by EUS. The real complication rate probably is higher than the reported 20%, many related to catheter plugging or being dislodged and subsequent sepsis.

Minimally Invasive Surgery. All the open surgical techniques have been undertaken using a laparoscopic approach.[36] Intraluminal laparoscopic surgery, where the trocars are placed through the abdominal and stomach walls, has been successful. The cystogastrostomy can be performed with a stapler or by suture. A more recent modification of this approach is the minilaparoscopic cystogastrostomy using a 2-mm intraluminal laparoscope. The view is augmented by the insertion of a flexible endoscope per os, which also can be used to explore the cyst cavity.

The balloon dilatation of a percutaneous catheter track using a similar approach to that used for percutaneous nephrolithotomy is feasible in many cases. It is worth considering this when the initial radiologic attempts have failed to bring

resolution. The placement of a sheath then allows the insertion of an operating nephroscope to enable débridement of the pseudocyst and removal of organized pancreatic necrosis and infected necrosum. This procedure can be repeated and allows the placement of a soft large-bore external drain.

Summary of Treatment for Pseudocysts. The treatment of choice for pancreatic pseudocysts depends on a number of factors, including size, number, and location of pseudocysts; whether the main pancreatic duct is obstructed or communicates with the pseudocyst; and whether there are complications of the pseudocyst. The clinical context is important (see Table 55-2). With the range of approaches to treatment and the variation in the availability of equipment and expertise, it is necessary to develop a rational treatment algorithm that is appropriate for the clinical setting and the patient (see Fig. 55-6). In practice, type I pseudocysts can usually be managed conservatively. Percutaneous drainage should be considered if the pseudocyst becomes symptomatic or infected. Type II pseudocysts are best managed by internal drainage, especially when there is communication between duct and pseudocyst. Endoscopic, laparoscopic, and radiologic approaches have an emerging role in expert hands.[37] With type III pseudocysts, consideration needs to be given to decompression of the pancreatic duct and relieving the stricture at the same time as drainage of the pseudocyst.

Pancreatic Necrosis

Necrosis may involve the pancreatic parenchyma and/or the peripancreatic tissue, and involvement of either of these tissues differentiates necrotizing pancreatitis from edematous pancreatitis.[7] Over time the solid necrosis gradually liquefies and becomes surrounded by a capsule, such that after 4 weeks it is termed WON. This partially solid and partially fluid, encapsulated lesion has been described in the literature by a range of terms, including organised necrosis, necroma, and pancreatic sequestrum. The extent of tissue necrosis is not fixed and may progress as the disease evolves during the first 2 weeks of the disease. The necrotizing process can extend widely to involve retroperitoneal fat, small and large bowel mesentery, and the retrocolic and perinephric compartments. The presence of necrosis usually determines a more protracted course lasting weeks to months. From a clinical viewpoint, the development of necrosis is the most important event in the course of acute pancreatitis because subsequent complications, both local and systemic, are associated with it.

EPIDEMIOLOGY

The incidence of acute pancreatitis exhibits marked regional differences, and has been reported to from 5 to 80/100,000.[38,39] The proportion of patients with acute pancreatitis that develop pancreatic necrosis is approximately 20%, and of these 25–70% will develop infected necrosis.[40,41] The risk of infection is higher when necrosis is more extensive (ie, >30% of the gland).[42] In addition, the risk of infection increases with time, from 24% by the end of the first week of illness, to 36% at the end of the second week, and to 71% by the end of the third week.[43] The overall mortality of edematous pancreatitis is 1% or less, that of sterile necrosis is 5%, and that of infected necrosis is 10–25% in the best published series.[44]

PATHOGENESIS

Of the patients who develop pancreatic necrosis, 70% have evidence of it by 48 hours of the onset of abdominal pain, and all of them by 96 hours.[43] The premature activation of proteolytic enzymes within the acinar cells and interstitium of the lobule results in extensive necrosis of pancreatic tissue and the substantial accumulation and activation of leukocytes. There are a number of factors that contribute to the failure of the pancreatic microcirculation, which is evident histologically as stasis and/or thrombosis of intrapancreatic vessels. The failure of the pancreatic microcirculation leads to ischemia, which compounds the enzymatic and inflammatory injury and leads to the full syndrome of necrotizing pancreatitis. During this first week or so, in the so-called early or vasoactive phase, there is the release of proinflammatory mediators that contribute to the pathogenesis of pulmonary, cardiovascular, and renal insufficiency. This early systemic inflammatory response and multiorgan dysfunction are frequently present with evidence of pancreatic infection. In the septic or late phase, which occurs in most patients after 3–4 weeks, these systemic events usually occur as a consequence of infected pancreatic necrosis.

During mild edematous pancreatitis, the surface of the pancreas may show spotty fat necrosis and be larger and firm due to edema,[45] usually without hemorrhage or parenchymal necrosis. Early during necrotizing pancreatitis, there is obvious necrosis of the peripancreatic fatty tissue while the parenchyma of the gland may appear less affected. The surface of the pancreas typically demonstrates considerable heterogeneity, with areas of mineralised fat necrosis (saponification) mixed with areas of superficial hemorrhage. There may also be disseminated areas of necrosis in the omentum, mesentery, retroperiotoneum, or other regions of the abdomen. Within the parenchyma of the pancreas there may be only a few foci of hemorrhage associated with fat necrosis between lobules, although in more severe cases lobules are also affected, transforming large areas into necrosis. In severe cases, necrosis of the pancreatic duct or its tributaries may be present, resulting in significant extravasation of pancreatic enzymes. The distribution of parenchymal necrosis is extremely variable, with some patients having necrosis affecting only a portion of the gland (eg, head or tail) and others having confluent necrosis affecting most of the gland.

On histopathological examination there are large areas of peripancreatic fat necrosis and within the pancreas there is evidence of interstitial edema along with necrosis of the parenchyma. This necrosis is initially present in the interlobular fatty tissue, and may be more severe when there is more

fatty tissue present. Islets are usually only affected in lobules that are mostly or entirely necrotic. Granulocytes and macrophages are present at the periphery of necrotic areas.

Mild edematous pancreatitis does not usually progress to necrotizing pancreatitis, implying that pathophysiological events soon after the onset of the disease are decisive in determing the course of the disease.[45] While edema usually resolves within a few days, the resolution of fat necroses is more variable, depending on the size and location of the lesions. Foci of necrosis less than 1 cm in diameter on the surface of the pancreas usually resolve entirely. This occurs by phagocytosis of necrotic material by macrophages, and these areas may later be replaced by fibrotic scar tissue. Larger foci of necrosis, 2–4 cm in diameter, are demarcated by macrophages that slowly phagocytose the necrotic material. The inner contents of the foci become liquefied. Large foci of necrosis, greater than 5 cm in diameter, do not resolve spontaneously. Macrophages rich in hemosiderin, along other immune cells, form a thin layer of granulation tissue around the lesion by 10–20 days after disease onset. After 20–30 days this becomes a fibrous capsule which gradually increases in thickness.[46] As with the smaller lesions, the contents slowly liquefy or organize over time. The contents may also contain high levels of pancreatic enzymes, suggesting the presence of communications with pancreatic ducts. Necrotic lesions are most likely to permit entry of bacteria when they are demarcated by only a thin rim of granulation tissue (4–20 days). Over time necrotic areas slowly resolve and are replaced by fibrotic scar tissue (necrosis-fibrosis sequence).[47–49]

MICROBIOLOGY OF INFECTED NECROSIS

There are five routes by which bacteria are thought to be able to infect pancreatic necrosis: (1) hematogenous, (2) transpapillary reflux of duodenal content into the pancreatic duct, (3) translocation of intestinal bacteria and toxins via the mesenteric lymphatics to the systemic circulation via the thoracic duct, and possibly directly to the pancreas via lymphatic connections between the intestine and pancreas, (4) reflux of bacteriobilia via a disrupted pancreatic duct into the necrotic parenchyma, and (5) transperitoneal spread.

Cultures of infected pancreatic necrosis are polymicrobial in approximately one-third of patients and monomicrobial in two-thirds of patients.[50] Gram-negative aerobic bacteria are the most common organisms identified (eg, *Escherichia coli*, *Pseudomonas*, *Proteus*, and *Klebsiella*), followed by gram-positive bacteria (eg, *Enterococcus*, *Staphylococcus aureus*). Anaerobic bacteria are identified in only around 5% of positive cultures, although this may reflect inadequate culture techniques. Fungi may also be cultured, and are more common after use of prophylactic antibiotics.[51,52] The spectrum of bacteria cultured from infected necrosis demonstrates that enteric bacteria dominate, suggesting bacterial translocation is an important event in the pathogenesis of infected pancreatic necrosis.[41] Pancreatic necrosis is most likely to become infected during the late phase of acute pancreatitis, with a median time from hospital admission to infection of 26 days.[42]

PREDICTION AND DIAGNOSIS

There are no specific symptoms or signs that are indicative of pancreatic necrosis. The presentation is usually nonspecific with abdominal pain, distension, guarding and associated low-grade fever, and tachycardia. The severity of pain and the extent of hyperamylasemia do not correspond with the severity of acute pancreatitis. Patients presenting late with severe disease will often have established multiorgan dysfunction. The classic skin signs of retroperitoneal necrosis, including discoloration of the navel (Cullen's sign), the flanks (Grey-Turner's sign), and the inguinal region (Fox's sign), are rare and often not seen until the second or third week after disease onset. The diagnosis of pancreatic necrosis requires more than just clinical acumen.

Predicting the severity of acute pancreatitis and the presence of pancreatic necrosis remains an imprecise science. Scoring systems, such as Ranson, Glascow, APACHE II, or "bedside index for severity in acute pancreatitis" (BISAP), are often used for severity stratification, but the derived scores are not accurate with high false-positive and negative rates.[53] Patients with predicted severe disease and high likelihood of pancreatic necrosis require radiological confirmation of the presence and extent of necrosis, which is conventionally categorized as less than 30%, 30–50%, and greater than 50% of the pancreas.[54] Dynamic contrast-enhanced CT (CECT) is the gold standard for diagnosing pancreatic necrosis and other local complications (see Fig. 55-2), but is not usually indicated within the first 48–72 hours after the onset of acute pancreatitis.[55–57] Pancreatic hypoperfusion is usually established by about 72 hours and imaging before then probably underestimates the extent of necrosis and the ultimate disease severity.[57] CECT can also be used to score the severity by the CT severity index as proposed by Balthazar.[12,55]

Current guidelines recommend that CECT is indicated for patients with persisting organ failure, signs of sepsis, or clinical deterioration 6–10 days after admission.[55] There has been concern that contrast used for the CT might worsen the necrosis and/or exacerbate existing renal failure.[55,56,58–60] A range of alternative modalities have been developed to diagnose the extent of pancreatic necrosis, including MRI and echo-enhanced ultrasound (EEU), which are at least as accurate as CECT in diagnosing and determining the extent of pancreatic necrosis.[61,62] In practice, the indications to diagnose and determine the extent of pancreatic necrosis by CECT are predicted severe acute pancreatitis (usually during the second week), when a patient fails to improve with initial resuscitation and/or when the CRP has crossed the diagnostic threshold (see later). The CECT scan can also be used to grade the severity of acute pancreatitis (CT severity index [CTSI]) based on the extent of extrapancreatic changes and pancreatic necrosis.[12] It is important to recognize the limitations of CECT, where a pseudocyst and WON can be difficult to distinguish. Imaging by MR or EUS, which better delineate the solid components within a lesion, may be employed when the diagnosis of necrosis is uncertain.

In the absence of a specific marker of pancreatic necrosis, many serum predictors have been proposed. An ideal predictor or prognostic indicator should be simple, cheap, reproducible, valid, available on admission, and specific for necrosis. While a full discussion of markers is beyond the scope of this chapter, there are several that fulfill most of these criteria, compare favorably with CT scanning, and have an established role in routine clinical practice.

C-reactive protein (CRP) is the most widely used predictor of pancreatic necrosis and is useful as a daily monitor of disease progress. The accuracy in detecting necrosis is about 85%, but it requires 3–4 days after the onset of the disease to reach a diagnostic level. The threshold values depend on the assay and the study used. A commonly used threshold is greater than 120 mg/L.[63] Other prognostic markers, none of which has been shown to outperform CRP, include interleukin-6 (IL-6) (threshold >14 pg/mL) which peaks a day earlier than CRP; polymorphonuclear elastase (threshold >120 μg/L), which peaks early and reflects neutrophil activation and degranulation; and phospholipase A_2 type II (threshold >15 U/L). Urinary trypsinogen-activating peptide has also been proposed as a predictor of necrosis, but is not the major advance that was first anticipated.[64] Procalcitonin has been proposed as a sensitive and specific marker for infected necrosis but it has not become part of routine management.[41–43]

The importance of determining the severity of acute pancreatitis is the need to initiate early intensive care management, and this may necessitate transfer of the patient to a tertiary unit. The initiation of prophylactic antibiotics has been the subject of considerable debate.[65–67]. The concerns with this approach relate to the increased risk of invasive fungemia, which increases mortality, and of the development of multiresistant organisms.[68,69] The current consensus is that there is not a routine role for prophylactic antibiotics.[56]

The diagnosis of infected necrosis is very important because it is generally considered an indication for intervention. Rarely, the early invasion of gas-forming organisms, such as *Clostridium perfringens*, makes the diagnosis of infection on CT scanning straightforward.[70] It is more usual to suspect pancreatic infection with rapidly progressive disease or a secondary deterioration after 2 or 3 weeks of admission. This is often heralded by a significant rise in CRP. A CT scan will usually confirm the presence of a tense collection with rim enhancement arising from the region(s) of pancreatic necrosis. The presence of gas within the tissues confirms infection, with an "air bubble" appearance (see Fig. 55-2), but this is present in the minority of cases.

Infected necrosis is best diagnosed by image-guided (CT or ultrasound) fine-needle aspiration (FNA) for Gram staining and/or bacterial culture.[55,56] The UK guidelines recommended all patients with greater than 30% necrosis and persistent symptoms, and those with smaller areas of necrosis and clinical suspicion of infected necrosis, should undergo image-guided FNA.[1] There is now considerable debate over this recommendation, with some authorities suggesting that in addition to significant and secondary clinical deterioration, patients should have a rise in serum markers (eg, CRP, procalcitonin) to increase the index of suspicion for infected necrosis.[71] The decision to intervene is one of the most difficult decisions in clinical practice.

There has been some concern that FNA is associated with a potential risk of secondary infection.[72] However, clinical practice guidelines are consistent in their recommendation to use FNA as the gold standard test to diagnose infected necrosis.[1,4,8,15,46,56,73–79] The rationale for early diagnosis of infected necrosis with FNA is to allow prompt treatment with antibiotics and invasive intervention. Over the last 20 years this has been the prevailing approach to reduce the morbidity and mortality associated with infected necrosis.[80] More recently the debate surrounding FNA has been reopened, with the understanding that surgical intervention should be delayed as long as possible or even avoided completely with the judicious use of radiological drainage. When surgical intervention is clinically indicated (by nonresponse to antibiotics and intensive care management) the results of the FNA will not alter patient management because surgery might be undertaken even in the absence of FNA-confirmed infection.[71] In summary it is better to view FNA of pancreatic necrosis as an adjunctive measure and one that is only undertaken in a patient in whom there is already a strong clinical suspicion of infection and in whom confirmation of infection will result in intervention.

INDICATIONS FOR INTERVENTION

The indications for intervention in patients with pancreatic necrosis are evolving such that infected pancreatic necrosis, of itself, is no longer considered an absolute indication for surgery in many centres. However, infected necrosis, confirmed by culture-positive FNA, is the strongest indication for intervention, particularly in a deteriorating patient receiving maximum intensive care. Where radiological drainage has been attempted, failure of drainage and/or persistent sepsis from infected necrosis are also clear indications for intervention. Any necrotizing process, regardless of the infectious status, that causes massive hemorrhage or bowel perforation (eg, duodenum or transverse colon) is an indication, albeit rare, for surgical intervention. The indications for surgery in the absence of infection are very limited. Amongst patients with sterile necrosis, only those who are clinically deteriorating despite maximal supportive care and who have a clear target lesion to drain or debride should be considered for surgery.[81,82] Surgery is rarely indicated in some patients who "fail to thrive," but this remains controversial.[82] These patients may have documented sterile necrosis, abdominal symptoms, and intolerance to oral feeding more than 4 weeks after disease onset, although the vast majority of patients with sterile necrosis can and should be managed without surgery.

TIMING OF INTERVENTION

Historically, surgical intervention for pancreatic necrosis was during the first week after disease onset. Early surgery

was advocated in order to remove the dead tissue, the focus of infection, and terminate the inflammatory process. We now know that the inflammatory cascades are not easily switched off and are exacerbated by the surgical procedure. Early surgery is more difficult and dangerous because the necrotic tissue is immature, poorly demarcated and not easily separated from viable tissue, resulting in a significant risk of bleeding. Additionally, early surgery may cause infection of sterile necrosis. With mortality rates of up to 65%, the trend for early intervention was called into question.[73] In recent years the timing of surgical intervention has become progressively later, such that the current concept for timing of intervention is that it should be undertaken as late as possible after disease onset (preferably >4 weeks), when the necrotic process has stopped extending, there is clear demarcation between viable and nonviable tissues, and infected necrotic tissues have become organized and "walled off."[1,56,73] Such a delay allows time for stabilization of the patient, and decreases the risk of bleeding and pancreatic insufficiency through the unnecessary removal of viable tissue.

Once a diagnosis of infected necrosis has been established, it is now quite common practice to undertake percutaneous catheter drainage of infected fluid.[83] This often results in some improvement in the patient's overall clinical status, or an arrested decline. The type and timing of further intervention is dictated by a number of factors, including the patient's condition and comorbidities, local expertise, and the anatomical location and complexity of the lesion. There are two main approaches in regards to repeated surgical intervention. With "programmed intervention," surgery is repeated according to a set schedule (eg, every second day). With "on demand intervention," surgery is repeated only if and when it is clinically indicated, by a failure to improve or with secondary deterioration.[82]

TYPE OF INTERVENTION

There are many different interventions and the challenge is to select the intervention that is appropriate for the particular local complication, taking into account the anatomical location, infection status and complexity of the target lesion(s), the physiological status, comorbidity of an individual patient, and the availability of expertise with the type of intervention. A review of current guidelines highlights the absence of level 1 evidence to guide decision making regarding the types of intervention.[84] There are two broad philosophies regarding the type of intervention used. Some experts state that open surgical drainage and necrosectomy remains the gold standard in the management of infected pancreatic necrosis, and reserve less invasive interventions for subsequent complications. These include percutaneous and endoscopic drainage of residual fluid complications. Such a step-down approach contrasts with the step-up approach, which advocates the use of less invasive interventions initially (eg, percutaneous or endoscopic drainage) and only employing open surgical techniques later in the disease course in those who fail to respond. These two approaches have been subjected to a randomized controlled trial in the PANTER trial.[85] This demonstrated that a minimally invasive approach, as compared with open necrosectomy, reduced the rate of the composite end point of major complications or death. Mortality itself was not decreased, but new onset multiple organ failure occurred less often in patients assigned to the step-up approach. Another important finding was that a third of patients who would have previously undergone an open necrosectomy were managed by radiological percutaneous drainage alone.

There is a need to standardize the description of invasive interventions to facilitate communication between clinicians, comparison of techniques, and controlled clinical trials. Interventions can be classified based on the method of visualization of the lesion, the anatomical route taken to reach the lesion, and the purpose of the intervention.[86]

The possible *visualization* modalities include open procedures where the operative site is exposed through the skin incision, endoscopic procedures where the operative site is visualized with an endoscope (eg, gastroscope, laparoscope, or nephroscope), radiological procedures where CT, ultrasound, or fluoroscopy are used to visualize the lesion during the procedure, and hybrid procedures that combine endoscopic and radiological techniques.

The *routes* taken by these interventions are defined by the external route into the body (skin or external orifice) and the internal route into the lesion. The internal routes used to reach the target lesion might pass through the gastrointestinal wall, peritoneum, or retroperitoneum.

The overall purpose of treatment is to eliminate areas of necrotic and infected tissue and/or fluid, as well as inflammatory and enzyme-rich exudates. However, the way in which this is achieved varies considerably, with some procedures being considerably more aggressive than others. Therefore, the *purpose* of individual interventions may be to effect simple drainage alone, lavage of the necrotic cavity to assist drainage of necrotic debris, fragmentation of necrotic tissue to facilitate its drainage, débridement of necrotic tissue, and excision or resection of the pancreas. The overall purpose of intervention is to control the focus of sepsis combined with preservation of vital tissue. Drainage procedures involve allowing fluid and solid necrotic to drain externally out of the body or internally into the gastrointestinal tract. Lavage describes flushing away solid necrotic matter with fluid to facilitate external or internal drainage. Fragmentation is a method used to break down solid necrotic matter by instrumental or mechanical disruption to facilitate drainage. Débridement, which is often termed "necrosectomy," involves taking or cutting out solid necrotic matter (typically with blunt dissection), and may or may not include postoperative lavage. Débridement may involve removal of all or only some of the necrotic tissue, although normal tissue is never intentionally removed. Only during excision or resection of the pancreas is normal tissue intentionally removed along with devitalised tissue. Such an approach is no longer recommended.

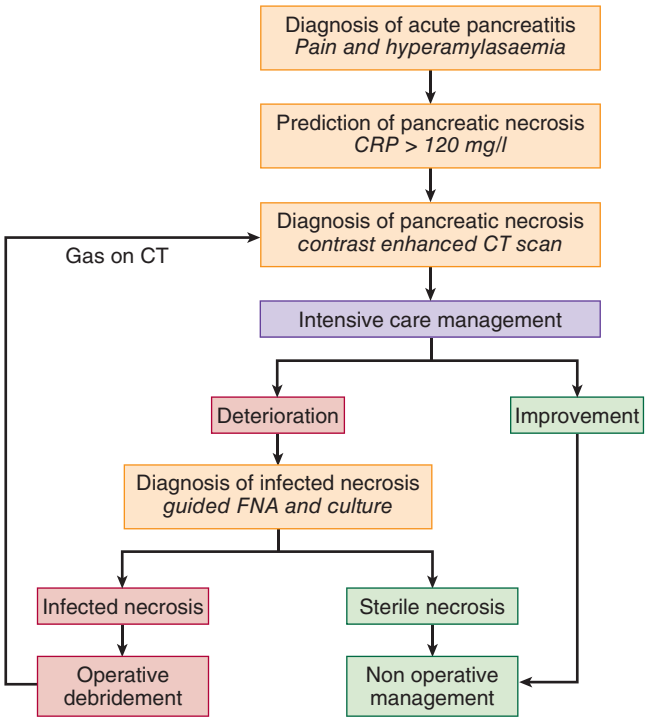

FIGURE 55-10 Algorithm for management of infected necrosis.

GENERAL PRINCIPLES FOR INTERVENTION

Figure 55-10 is an algorithm for clinicians who are faced with the management of patients with infected necrosis. The general principles for intervention are the removal of all infected and necrotic tissue and fluid, preservation of vital tissues, and avoidance of intraoperative hemorrhage. Infected necrotic tissue and fluid should be sent for bacterial culture, in order to confirm the causative organisms and rationalize antibiotic therapy. All fluid collections identified on the preoperative CECT must be identified, opened, and evacuated. Débridement of necrotic tissue is performed bluntly, usually with digital dissection, careful use of instruments, and lavage. Only loosely adherent necrotic tissue should be removed and this is easier if there has been a significant delay between onset of disease and surgery. Use of a systematic approach, such as examining in turn the retroperitoneum behind the transverse, ascending, and descending colon, helps to ensure all areas of necrotic tissue are identified and removed. If multiple procedures are planned, the first necrosectomy provides the best exposure and therefore the most complete débridement that is safe should be accomplished at this time. The thoroughness of the initial débridement is the most important factor in determining the need for subsequent reoperation.[87] The need for complete débridement has been questioned and it has been suggested that incomplete débridement may be sufficient if adequate drainage and lavage is established.[88]

A key point is to avoid sharp dissection in order to prevent major hemorrhage. Adherent necrotic tissue should be left in situ, as this will subsequently demarcate and become loose.

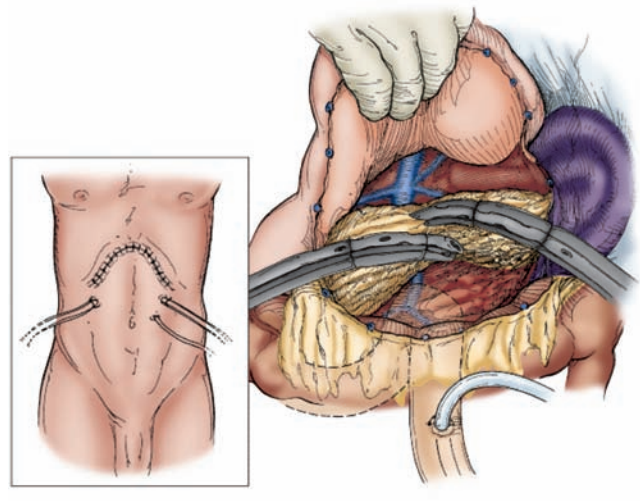

FIGURE 55-11 Large peripancreatic drains and placement of a tube feeding jejunostomy following necrosectomy.

Strands of tissue forming bridges across the cavity may be vessels and should not be avulsed. This is important, because bleeding from inflamed vessels within the retroperitoneum is difficult to control and may require formal packing.

Following débridement, extensive irrigation is used to flush away necrotic debris, inflammatory exudates, and residual bacteria. A gentle hydrodissection device can be used for this purpose. Postoperative lavage may be employed, and this can be either intermittent or continuous (Fig. 55-11).[89,90] The fluids most commonly used for this purpose are normal saline and peritoneal dialysis fluid, although there is no evidence to support any specific fluid type or flow rate in this setting.

The choice of operation is determined by the location, extent, and maturity of the necrotic material; status of the infection; the patient's condition; the degree of organ dysfunction; and the preference and experience of the surgeon.[41] A number of different approaches have been described (Table 55-4), some of which are only of historical interest. Interventions are complex, fraught with potentially life-threatening complications, and should only be performed by experienced surgeons in referral centers.

OPEN SURGICAL PROCEDURES

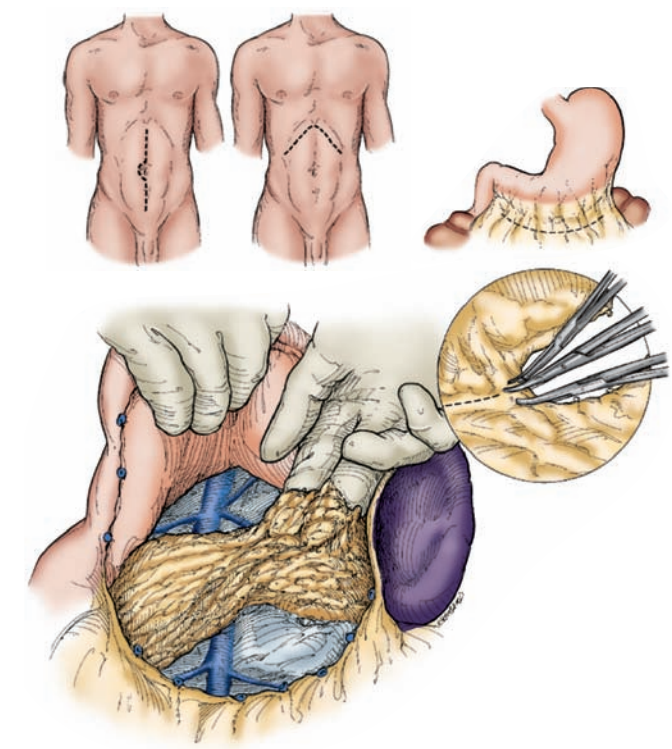
The role of open surgical treatment of infected pancreatic necrosis is diminishing with the accumulating evidence for the less invasive approaches.[85] There are three broad approaches to open necrosectomy: (1) open necrosectomy with open or closed packing; (2) open necrosectomy with continuous closed postoperative lavage; and (3) programmed open necrosectomy. While the débridement technique for all the approaches is similar, they differ in terms of how they provide exit routes for infected fluid, debris, and tissue. The abdomen is best entered though a bilateral subcostal incision since this allows better access to the extremities of the gland and less contamination of the greater peritoneal sac if there

TABLE 55-4: OPEN AND MINIMALLY INVASIVE APPROACHES TO THE TREATMENT OF PANCREATIC NECROSIS

Open surgery approaches
Pancreatic resection
Necrosectomy + wide tube drainage
Necrosectomy + relaparotomy (staged re-exploration)
Necrosectomy + drainage + relaparotomy
Necrosectomy + laparostomy ± open packing
Necrosectomy + drainage + closed continuous lavage
Minimally invasive approaches
Laparoscopic necrosectomy
Laparoscopic intracavity necrosectomy
Laparoscopic-assisted percutaneous drainage
Laparoscopic transgastric necrosectomy
Percutaneous necrosectomy and sinus tract endoscopy
MRI–radiologically assisted necrosectomy
Translumbar extraperitoneal retroperitoneoscopy
Video-assisted retroperitoneal débridement

are subsequent procedures. The pancreas is exposed by dividing the gastrocolic omentum (Fig. 55-12) or gastrohepatic omentum to access the pancreas through the lesser sac. The body and tail of the pancreas can be exposed by elevating the transverse colon and gaining access to the lesser sac via the transverse mesocolon (Fig. 55-13). Inflammatory adhesions may exist between the pancreas and stomach or transverse mesocolon, and great care is required during exposure. It is generally useful to take down both the hepatic and splenic flexures, if possible, as this will facilitate exposure and reduce the risk of colonic fistula secondary to drain erosion. When the process involves the head of the pancreas, access might require medial mobilization of the duodenum.

Open Necrosectomy With Closed Packing. The goal of necrosectomy with closed packing is to perform a single operation, with thorough débridement and removal of necrotic and infected tissue, and to avoid or minimize the need for reoperation or subsequent drainage.[82] Once the necrotic cavity is opened, fluid collections are evacuated and all areas of necrosis debrided. Some units use gauze stuffed Penrose drains placed via separate stab incisions, but there are many variations in practice with regards to the type and number of drains. With the Penrose drain technique, the intention is to fill the cavity and provide compression rather than facilitate external drainage per se, and between two and twelve drains are usually placed. Additional silicon drains (eg, Jackson-Pratt) are placed in the pancreatic bed and lesser sac to drain fluid from the area. Primary closure of the abdomen is routine with this approach. The stuffed Penrose drains are removed once every other day, starting 5–7 days postoperatively. The silicon drains are removed last. Packing techniques are probably best reserved to control hemorrhage as it is associated with an increased risk of enteric fistulae.



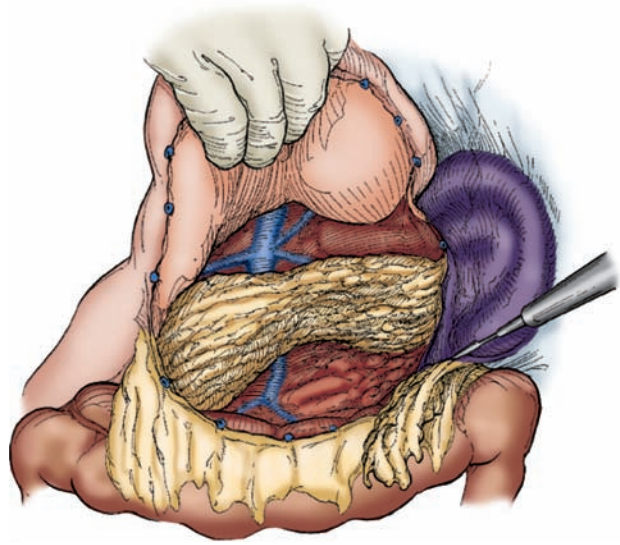


FIGURE 55-12 Necrosectomy via lesser sac.

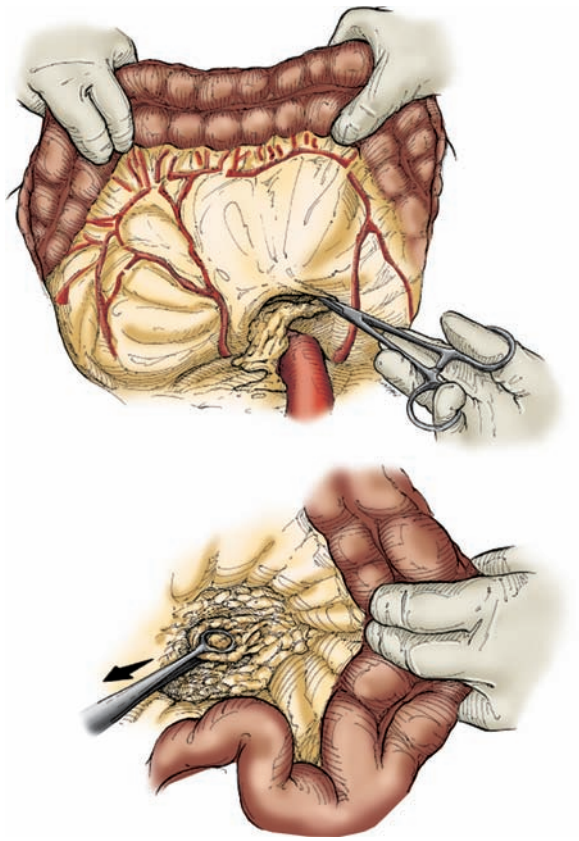

FIGURE 55-13 Necrosectomy via transverse mesocolon.

Open Necrosectomy With Open Packing. The difference with this approach to closed packing is that the abdomen is left open after débridement and packing of the abdomen.[91] An alternative form of open packing uses a 20-cm flank incision instead of an anterior laparotomy.[92] Open packing techniques have been reported to have higher incidences of fistulae, bleeding, and incisional hernias, as well as a slightly higher mortality rate.[93] However, it should be noted there are no prospective trials comparing open packing with any other techniques.

Open Necrosectomy With Continuous Closed Post-Operative Lavage. In this technique débridement is followed by continuous peripancreatic lavage to remove infected necrotic debris, peripancreatic exudates, and extravasated pancreatic exocrine fluid.[82,86] Drainage catheters, usually two on each side, are placed with their tips at the head and tail of the pancreas behind the ascending and descending colon. Placement of sump drains (20–24F) with two lumens allows inflow of lavage fluid and outflow of drainage fluid. Larger silicon drains (28–32F) allow evacuation of larger necrotic debris. During closure, a closed peripancreatic compartment is attempted by resuturing the gastrocolic and duodenocolic ligaments. Postoperative continuous lavage is instituted at 1–10 L per day, and is usually continued until the effluent is clear and the patient shows improvement in clinical and laboratory parameters.[82,94] There is no evidence as to the best irrigation fluid, the optimal number or calibre of drains, or the duration of irrigation.

Programmed Open Necrosectomy. The principle of this approach is to be more conservative with débridement, particularly if the necrosis has not fully demarcated, with the intention of performing repeat procedures until débridement is no longer required.[82] Following necrosectomy, the pancreatic bed is packed and drains are placed on top of the packing. The abdominal wall is closed with a zipper or mesh sewn to the fascia. This allows easy repeated access to the abdomen and helps to prevent wound retraction. Reoperation is repeated every 48 hours until there is no further necrotic tissue to remove. In a proportion of patients primary closure is not possible and healing by secondary intention is allowed to occur. This procedure may be modified with the addition of intra-abdominal vacuum sealing (negative pressure 50–75 mm Hg) in order to encourage granulation of the pancreatic bed.[95]

Endoscopic Techniques. In 1996 Gagner described the first true endoscopic treatment of necrotizing pancreatitis, where the pancreas was debrided using a laparoscopic approach.[96] Over the last decade a wide range of endoscopic approaches for pancreatic necrosectomy have been described, including infracolic laparoscopy, transgastric laparoscopy, hand-assisted laparoscopy, retroperitoneal laparoscopy, transgastric flexible endoscopy, flexible endoscopy via a percutaneous endoscopic gastrostomy, and retroperitoneal nephroscopy.[97–103] This array of endoscopic techniques may be classified by the type of scope that is used: laparoscope, nephroscope, or flexible endoscope.[104] While some endoscopic procedures do not utilize radiological modalities, many are hybrid procedures using fluoroscopy or EUS.

Laparoscopic Techniques. Most laparoscopic techniques are minimally invasive versions of open surgical techniques, and use an anterior or lateral approach. In Gagner's original description of laparoscopic necrosectomy, two anterior routes (retrogastric retrocolic and transgastric) and one lateral route were described.[96] In the retrogastric retrocolic route, a 30-degree laparoscope is introduced through the umbilical port following CO_2 insufflation. Placement of additional ports depends on the position of the necrosis. Large drains are placed in the necrotic beds and continuous lavage may be established. In the transgastric route, the stomach is opened anteriorly and posteriorly. Endoluminal ports are used, which maintain the tip of the port inside the stomach. Débridement is performed internally through the posterior stomach wall. It is also possible to use a transduodenal route for necrosis of the pancreatic head. No drains are left in the stomach, although a drain might be placed over the incision in the anterior gastric wall. With the retroperitoneal route, the patient is placed in the left (or right) lateral position and a small flank incision made. The three muscle layers of the abdominal wall are split and a trocar is inserted. Using a 0-degree laparoscope and

CO_2 insufflation, a tract is made to access the pancreas. Once the necrotic areas have been identified, necrosectomy proceeds as when approached via a retrogastric retrocolic route.

These techniques have subsequently been modified. Of the lateral approaches, one of the most widely used laparoscopic techniques is "videoscopic-assisted retroperitoneal débridement" (VARD).[101,105] The purpose of this procedure differs from those of open necrosectomy. Rather than performing complete removal of all infected and necrotic tissue, its goal is to facilitate percutaneous drainage. In this technique radiological drainage of the lesion is first instituted. Following this, a 4–5 cm incision is made in the left flank at the site of the drain. A finger is used to probe and confirm entry into the necrotic cavity. Fluid and loose necrotic debris are removed by suction, and two ports (10–12 mm) are inserted through the incision. The incision is sealed with wet sponges and towel clips to allow insufflation with CO_2. Débridement of necrotic tissue is performed with hydrodissection and 10 mm forceps. Drains are placed for postoperative continuous lavage. A 10F red rubber drain is brought through a separate anterolateral incision, and two Penrose drains are placed in the original skin incision. An ostomy bag is then positioned over the flank incision and Penrose drains, and continuous lavage is performed through the red rubber drain at 200 mL/h for 5 days or until the effluent is clear.

Variations on the anterior laparoscopic approaches are well described. In addition to the retrogastric, recolic, and transgastric routes, a transmesocolic route may be used. The transverse colon is elevated to expose the pancreatic lesion in the lesser sac.[98] Laparoscopic ultrasound may be used to confirm the position of the lesion, and transverse mesocolon is usually opened to the left of the middle colic vessels. Two or more drains are placed in the pancreatic bed for postoperative lavage. Anterior approaches may also incorporate a hand-assist device (hand-assisted laparoscopic surgery—HALS).[100]

Nephroscopic Techniques. Nephroscopic techniques utilize warmed fluid to expand the necrotic cavity and maintain a clear visual field. Use of a nephroscope for necrosectomy was termed "percutaneous necrosectomy" in the unit that pioneered this approach.[106] Its principle is the same as for open necrosectomy—debridement of devitalized tissue and establishment of a system for continuous postoperative lavage—although with reduced physiological stress on the patient. Percutaneous necrosectomy may only be used when the area of necrosis is accessible to percutaneous puncture, and is contraindicated in the presence of bowel ischemia, perforated viscus, or significant preoperative hemorrhage.[82] The first step is to insert a drainage catheter under CT guidance into the pancreatic lesion. The preferred path for drainage is between the lower pole of the spleen and the splenic flexure, although in right-sided necrosis a path through the gastrocolic omentum (anterior to the duodenum) may occasionally be used. The patient is then transferred to the operating room and positioned in the left (or right for right-sided necrosis) lateral position. The drain tract is then dilated to allow insertion of a 34F Amplatz sheath. A nephroscope is inserted through the sheath into the cavity, and lavage is used to clear away debris and suppurative fluid (Fig. 55-14). Following necrosectomy, a 32F soft drainage tube is left in the cavity. An additional catheter may be used to allow continuous postoperative lavage. Repeat procedures are often required after 2–10 days.[82,107]

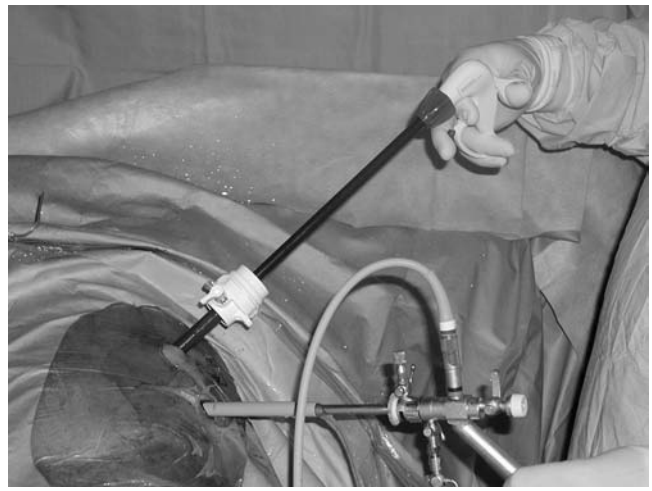

FIGURE 55-14 Percutaneous necrosectomy using operating nephroscope and supplemental laparoscopic port.

Flexible Endoscopic Techniques. Peroral flexible endoscopic techniques follow an internal route through either the gastric or duodenal wall or duodenal papilla, and some authors consider this to be a form of natural orifice transluminal endoscopic surgery (NOTES).[108] Initial descriptions of flexible endoscopic treatment of pancreatic necrosis used lavage and drainage without instrumental débridement.[109] A more aggressive approach was subsequently introduced, which demonstrated necrotic tissue could be debrided with baskets, snares, forceps, and suction.[110,111] Endoscopic retrograde cholangiopancreatography (ERCP) may be used to diagnose any communication between the duct and cavity or duct stenosis or disruption, and transpapillary stenting might be employed to decompress the duct. Puncture of the posterior gastric wall into the pancreatic lesion is performed at the point of maximal bulging, although confirmation of the location with EUS helps achieve correct placement of the perforation and avoid injury to vessels. The injection of contrast with fluoroscopy can be used to determine the extent of the cavity. The gastric perforation is dilated with balloons up to 20 mm. For lavage and drainage, a 7F nasocystic (lavage) and a 10F pigtail drain (drainage) are placed in the cavity. Necrosectomy may be performed with endoscopic instruments (eg, Dormia basket or polypectomy snare), and introduction of a forward-viewing endoscope into the necrotic cavity can be used for better visualization during the necrosectomy. Multiple necrosectomy procedures are usually required to clear the cavity of necrotic tissue.

Other techniques using flexible endoscopy through skin incisions have been described. Following percutaneous necrosectomy with a nephroscope, subsequent débridement may be undertaken using a flexible endoscope (sinus tract endoscopy).[106] A similar technique has been described following open necrosectomy via a translumbar incision, where a flexible endoscope is inserted into the cavity for débridement of ongoing necrosis.[112] Usually multiple débridement procedures are required, typically 8–10 sessions. The wide range of endoscopic approaches to necrosectomy and the absence of formal comparison make a recommendation for the optimal approach difficult. The selection of an endoscopic technique will be influenced by training, experience, and the availability of equipment, but it will also be determined by the location and complexity of the target lesion and the clinical status of the patient.

The first randomized controlled trial comparing two different minimally invasive approaches to the treatment of infected pancreatic necrosis has now been published (PENGUIN).[112] In this study endoscopic transgastric necrosectomy was found to be superior compared with VARD. There was a reduction in the incidence of the predefined composite endpoint (new onset multiple organ failure, intra-abdominal bleeding, enterocutaneous fistula, and/or pancreatic fistula) or death. There was a decrease in the incidence of new onset of multiple organ failure, supported by the finding that there was a significantly lower proinflammatory response after the procedure, and a reduction in the incidence of pancreatic fistulation.

Radiological Techniques. Since solid pancreatic necrosis is commonly associated with a fluid component (postnecrotic pancreatic or peripancreatic fluid collection or walled-off pancreatic necrosis), interventional radiological techniques are assuming greater importance, particularly for initial sepsis control to allow a delay in definitive necrosectomy.[113] Ultrasound, fluoroscopy, or CT are used to guide the interventional radiologist into the pancreatic lesion. These radiological modalities are then used to define the extent and composition of the lesion, visualize the position of instruments used, and determine the efficacy of the treatment procedure. The purpose of radiological techniques may be to achieve either drainage (with or without lavage) or débridement.

Radiological Drainage Techniques. Image-guided percutaneous catheter drainage may be used as a primary treatment for pancreatic necrosis, as a secondary treatment to manage postsurgical accumulation of fluid and residual necrosis, or to delay more definitive treatment until the patient has stabilized clinically or to allow the target lesion to mature.[83] Most collections are located in the lesser sac, anterior pararenal space, and other parts of the retroperitoneum.[114] The available internal routes into the target lesion are multiple but are most commonly retroperitoneal or transperitoneal. Transmural (transgastric or transduodenal) and transhepatic routes have been described, although these are less common.[83] While transgressing the stomach poses little infection risk, gastric peristalsis may dislodge the catheter over time. Transgressing the liver carries increased theoretical risk of bleeding, but in practice this is generally safe. Routes should avoid colon, small bowel, spleen, and kidney to minimize the risk of hemorrhage and bacterial contamination. A retroperitoneal approach that avoids the peritoneal cavity is the preferred route, as this prevents contamination of the peritoneal cavity and possible peritonitis.[114]

Appropriate catheter selection is required to ensure adequate drainage and to maximize catheter patency. Typically catheters should have multiple side holes and a minimum diameter of 12–14F (4.0–4.7 mm).[83] Often multiple catheters are required, especially for large or complex lesions. Lavage can be employed to reduce the concentration of digestive enzymes and proinflammatory mediators in the lesion, and to remove solid necrotic debris from the cavity.[115] Lavage may also help ensure catheters remain patent. There have been theoretical concerns that lavage may spread infection, either from infected fluid spilling over into previously sterile cavities, or from the increased intracavity pressure resulting in translocation of bacteria into surrounding tissues. However, this is not been demonstrated as a major concern clinically, most likely because the pancreatic lesion is walled off in a fibrous capsule 4 to 6 weeks after the onset of acute pancreatitis.[28]

The efficacy of drainage procedures is limited by the contents of the target lesion, with purely solid lesions less likely to be amenable to radiological drainage. In patients with pancreatic necrosis treated with percutaneous catheter drainage, approximately half will be successful and not require surgical intervention.[116,117] Indications for surgical intervention in patients who have undergone percutaneous catheter drainage include persistent systemic or local manifestation of infected necrosis, physiological deterioration despite drain patency, persistent abdominal pain, and intolerance of oral intake after the systemic inflammatory response syndrome has resolved.[116]

Radiological Débridement Techniques. In some specialized centers, radiological techniques have been used to debride pancreatic necrosis. These procedures are similar to percutaneous catheter drainage as described earlier, but also include removal of necrotic material with snares, baskets, or by applying suction to a catheter during its removal.[89,118,119] Necrotic tissue may be fragmented with wires before attempting its extraction.[89] Use of lavage is essential to flush away the loosened necrotic debris.

PROGNOSIS

The prognosis of patients with necrotizing pancreatitis depends on the extent of necrosis and the onset of infection. The overall mortality associated with infected pancreatic necrosis is around 25%,[44] while that associated with sterile necrosis is much lower (<5%).[120] Most deaths are in the context of multiorgan failure.[121]

Pancreatic Abscess

The term *pancreatic abscess* was defined by the Atlanta Symposium as a circumscribed intra-abdominal collection of purulent material containing little or no pancreatic necrosis.[4] This term has been used in very different ways including infected acute fluid collection or pancreatic pseudocyst, and a collection of infected fluid arising from infected necrosis. Due to the confusion surrounding this term, it has been abandoned by the revised Atlanta Classification. In units or publications where use of this term persists, the principles guiding management of the lesion are the same as those for infected WON: elimination of infected tissue and/or fluid.

REGIONAL COMPLICATIONS

Vascular Complications

VENOUS THROMBOSIS

Venous thrombosis is a rare complication of acute pancreatitis and one that usually develops a few weeks after the onset. The etiology is multifactorial, but extrinsic compression of the vein by the swollen pancreas and/or fluid collection is important. Other factors include hypercoagulability and hemoconcentration. The consequences of splenic vein thrombosis are splenomegaly with discomfort and possible hypersplenism. Segmental venous hypertension may result in upper gastrointestinal bleeding from gastric varices. Because the risk of gastric variceal bleeding from pancreatitis-induced splenic vein thrombosis is low (5% for CT-identified varices and 18% for endoscopically identified varices) routine splenectomy is no longer recommended.[122] Portal vein thrombosis occurs insidiously and often is discovered after gastrointestinal hemorrhage has occurred. The consequences of acute superior mesenteric vein thrombosis are venous ischemia and infarction of the intestine. CT scanning with contrast material is helpful in the diagnosis of venous thrombosis and may show features of impaired mucosal enhancement, edematous swelling of the vessel wall, and most commonly filling defects within the vein. The goal of the initial treatment of venous thrombosis is to reduce extrinsic compression of the vein by drainage and/or débridement. The role of acute anticoagulation is controversial because of the risk of bleeding. If thrombosis occurs later in the disease course, anticoagulation can be prescribed with less trepidation. Thrombolytic therapy and surgical thrombectomy have no established role in the context of acute pancreatitis. Acute venous thrombosis is associated with a 25% recurrence rate without anticoagulant therapy and a 30% mortality. Anticoagulant therapy combined with surgery is associated with the lowest recurrence rate (3–5%).

BLEEDING

Bleeding associated with severe acute pancreatitis is usually, but not always, due to a pseudoaneursym related to a pancreatic pseudocyst. The splenic artery is the most commonly affected artery (30–50%) because of its proximity to the pancreas, followed by the gastroduodenal artery (10–15%), the inferior and superior pancreaticoduodenal arteries (10%), and all others to a lesser extent.

Pathogenesis. The disruption of the pancreas by necrosis and the damage to pancreatic ducts leads to the accumulation of activated proteolytic enzymes (eg, elastase), weakens the vessel wall, and promotes aneurysmal dilatation. This process is accelerated in the presence of infection. The contained rupture of the aneurysm is a pseudoaneurysm, an extravascular hematoma communicating with the intravascular space.

Diagnosis. Patients usually present with hypovolemic shock or with an unexplained drop in hemoglobin concentration. Bleeding may occur into a pseudocyst and tamponade, preventing any overt evidence of bleeding. Very rarely the diagnosis will be made in a patient with a known pseudocyst who develops an abdominal bruit.

Selective mesenteric angiography is the best way to make the diagnosis of pseudoanuerysm (see Fig. 55-5A, B), although it can often be detected on the arterial phase of CT scan. Angiography identifies the location of the pseudoanuerysm and its relationship to named vessels. The majority of patients will require surgical management, and the angiogram provides a useful guide.

Treatment. Pancreatic or peripancreatic bleeding is one of the most formidable and life-threatening complications of pancreatitis. The standard of care in dealing with pseudoaneurysms has been surgical intervention; however, many interventional radiologists have reported excellent outcomes after angioembolization. The approach to treatment depends on the hemodynamic stability of the patient. If the patient is anemic but stable, then transarterial catheter angioembolization of the pseudoaneurysm (see Fig. 55-5A, B) will be considered. If subsequent surgery is required, it can be performed under better conditions, with less risk of torrential hemorrhage. Success with embolization is operator-dependent but success approaches 90% in leading centers. Failure results from an inability to selectively cannulate the bleeding vessel or the poor placement of embolization material. This approach is less likely to succeed with diffuse bleeding, bleeding from the pancreatic head, and bleeding after necrosectomy. Recurrent bleeding occurs in fewer than 40% of patients, and the overall mortality is under 20%.

If emergency laparotomy is required for bleeding, it may not be possible to arrange prior angioembolization. The lifesaving surgery may involve under-running the bleeding vessel (inside or outside the pseudocyst) and/or pancreatic resection. The mortality rate following surgical treatment of arterial hemorrhage during the acute phase of pancreatitis ranges from 28 to 56% and is higher when bleeding from the head of the pancreas. The mortality rate following surgical treatment of massive hemorrhage is usually over 50%.

Intestinal Complications

PARALYTIC ILEUS

The proximity of the inflamed pancreas to the intestine commonly results in regional self-limiting paralytic ileus affecting the duodenum, proximal jejunum, or transverse colon. Another factor which may contribute to the ileus is the relative splanchnic ischemia secondary to the reflex vasoconstriction in reponse to systemic hypotension. An ileus gives rise to the classic "sentinel loop" and "colon cutoff" signs on plain radiographs.

INTESTINAL ISCHEMIA AND NECROSIS

Subclinical mucosal ischemia is common in acute pancreatitis, particularly during the early phase, and occurs in response to the hypovolemia and reflex splanchnic vasoconstriction. Intestinal ischemia might be compounded by abdominal compartment syndrome, nonselective inotropes, and the demands of early and continuous enteral feeding. Full-thickness necrosis is rare and probably involves venous and/or arterial thrombosis at sites proximal to the inflammatory process. The middle mesocolic vessels and the transverse colon are mostly at risk.

INTESTINAL OBSTRUCTION

Mechanical obstruction rarely complicates acute pancreatitis. The mechanism is usually inflammatory stenosis which presents very late. It is unusual to require surgery.

CHOLESTASIS

Biochemical and clinical jaundice occur in approximately 20% of patients with acute pancreatitis, often during their hospital course. Mild cholestasis is more common and has been attributed to periductal edema and cholangitis. Long-term total parenteral nutrition will contribute to abnormal liver tests. Extrahepatic bile duct obstruction most often is due to choledocholithiasis or compression by a pseudocyst or pancreatic abscess.

SYSTEMIC COMPLICATIONS

Systemic Inflammatory Response Syndrome

The systemic inflammatory response syndrome (SIRS) is common with acute pancreatitis and encompasses the hallmarks of a proinflammatory state (ie, tachycardia, tachypnea or hyperpnea, hypotension, hypoperfusion, oliguria, leukocytosis or leukopenia, pyrexia or hypothermia, and the need for volume infusion) but without end-organ damage, identifiable bacteremia, or the need for pharmacologic support. SIRS is distinct from sepsis (where there is an identified pathogen) and septic shock (where there is associated hypotension). SIRS is best regarded as an exuberant host inflammatory response and the consequence of hypoperfusion.

There is no single trigger for SIRS. Instead, it represents a whole-organism response to a variety of quite different challenges. Theories on the drivers for SIRS include the immunologic dissonance theory (where there is imbalance between the pro- and anti-inflammatory responses)[123] and the gut motor theory (where decreased intestinal perfusion and subsequent damage to the mucosal and immunologic barriers may allow the translocation of endogenous bacteria or their products into the systemic circulation).[124] More recently, the intestinal mucosa has been considered another source of inflammatory mediators activated by hypoperfused mucosa. Measurement of intramucosal pH (tonometry) can stratify mortality risk in acute pancreatitis.[125]

The mediation of SIRS is due to a number of well-described cytokines responsible for the proinflammatory state, a full description of which is beyond the scope of this chapter. In many patients with acute pancreatitis, SIRS progresses to multiple organ dysfunction syndrome (MODS) and possible end-organ damage. Occasionally, patients will be admitted with fulminant or early severe acute pancreatitis, often with respiratory and renal impairment from the outset, and these patients are responsible for early deaths. Organ failure on admission, which occurs in 30–40% of patients with necrotizing pancreatitis, is a very poor prognostic sign, doubling intensive care stay and increasing the mortality rate to fourfold.[43] Early aggressive volume resuscitation has an important role in attenuating the systemic inflammatory response.[125]

Multiple Organ Dysfunction Syndrome

The development of MODS is common in severe acute pancreatitis. It has been defined as the presence of altered organ function in a severely ill patient such that homeostasis cannot be maintained without intervention.[126] Many patients with early organ failure respond rapidly to supportive treatment and appear to have an otherwise uncomplicated outcome. These patients are said to have transient organ dysfunction, if it resolves within 48 hours. Recently, it has been shown that organ failure in the first week of admission is a dynamic process and that the progression of early organ failure was attended by a mortality rate in excess of 50%. The response to the initial intensive care is an important determinant of outcome (Fig. 55-15).[127]

The sequence of organ dysfunction in acute pancreatitis has not been defined. Initial pulmonary insufficiency and renal impairment are often followed by circulatory failure and then metabolic dysfunction and liver failure.

Many potential predictors of organ failure early in the course of admission have been studied. MODS can be predicted with reasonably high accuracy at the time of hospital admission using a combination of the anti-inflammatory cytokine IL-10 (an early marker of systemic inflammation) and serum calcium (an early marker of organ dysfunction).[128]

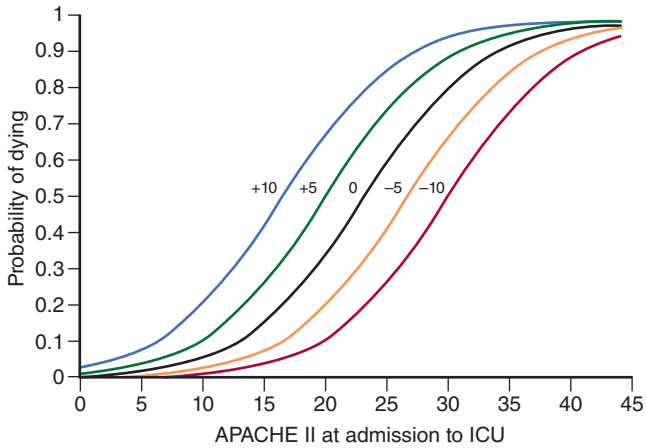

FIGURE 55-15 The relationship between the change in the severity of acute pancreatitis (APACHE II score) over the initial 48 hours of intensive care management and the change in predicted mortality. (Reproduced from Flint R, Windsor JA. The physiological response to intensive care: a clinically relevant predictor in severe acute pancreatitis. *Arch Surg*. 2004;139:438–443, copyright © 2004 American Medical Association. All rights reserved.)

MODS scoring systems can be classified using general physiologic critical care scores, that is, the Acute Physiologic and Chronic Health Evaluation (APACHE) score, the Simplified Acute Physiology Score (SAPS), the Mortality Probability Model (MPM), a specific organ score to describe dysfunction (Multiple Organ Dysfunction Score [MODS])], developed by Bernard and colleagues as a descriptor of clinical outcome in MODS, the Sepsis-related Organ Failure Assessment (SOFA), and the Logistic Organ Dysfunction System (LODS). The specific organ dysfunction scores classify organs as failed (yes or no) or dysfunctional using an ordinal scale (graded score). The aggregate score quantitates severity in any one organ and the overall severity of organ dysfunction. The aggregate score then can be interpreted as the likelihood of predicted mortality based on the observed mortality in those study patients used to construct the original scoring system.

There exists no rationale to favor one scoring system over another. The scoring systems do not tell the clinician when specific organ dysfunction is reversible or irreversible. Practically, a simple count of organs affected and the duration of the dysfunction will stratify mortality within broad ranges between 60 and 98% depending on age, with dysfunction in three or more organs for at least a week.

Respiratory Complications

Respiratory impairment can result from several causes, including atelectasis, pleural effusion, pneumonia, mediastinal pseudocyst or abscess, and/or adult respiratory distress syndrome (ARDS). Tachypnea, mild respiratory alkalosis, and mild hypoxemia are common within 2 days of the onset of acute pancreatitis. These clinical features usually can be corrected with analgesia, supplemental oxygen, and chest physiotherapy. A pleural effusion may require a chest drain. Impending respiratory failure is suggested when the arterial PO_2 remains less than 60 mm Hg despite high-flow oxygen by mask. These patients should be considered for mechanical ventilation. Lung-protection ventilation strategies, with low tidal volumes for patients with ARDS, are recommended.[129] ARDS may occur within a few days of admission or after the development of infected necrosis and septicemia. ARDS results from the release of activated pancreatic enzymes, vasoactive lysosomal enzymes, and especially phospholipase A_2 (which destroys surfactant). Parenchymal injury appears to be due primarily to oxidative damage from the activated neutrophils in the lung.

Renal Complications

Renal impairment is usually due to both hypovolemia (prerenal failure) and direct nephrotoxicity from the mediators of acute pancreatitis. Activation of the renin-angiotensin system may contribute to reduced renal perfusion. This manifests as oliguria (<30 mL/h) or anuria and as an increased serum concentration of creatinine and urea. The initial approach is aggressive intravenous crystalloid administration (of up to 10 L/24 h). Then diuretics (furosemide 20–200 mg/24 h) and dopamine infusion (4 μg/kg/min) should be considered. Further deterioration will necessitate continuous hemofiltration and/or hemodialysis.

Cardiovascular Complications

These include arrhythmias, pericardial effusion, impaired myocardial contractility, reduced peripheral vascular resistance, and increased permeability. Hypovolemia, from third-space fluid loss, is common during the first 12 hours and may be up to 30% in severe acute pancreatitis. This problem should be anticipated with aggressive intravenous fluid therapy in the first 24–48 hours. Circulatory failure (mean arterial pressure [MAP] <70 mm Hg) requires prompt, aggressive fluid resuscitation plus or minus inotropic support. SIRS is characterized by decreased peripheral vascular resistance and is the reason for the preferred use of norepinephrine to increase vascular tone and blood pressure (dose 0.05–0.2 μg/kg/min). Epinephrine (dose 0.05–0.2 μg/kg/min) also may be used to support cardiac output. Unfortunately, these inotropes will compound splanchnic vasoconstriction.

If the patient with infected necrosis meets the criteria for severe sepsis, he or she should be managed by current sepsis guidelines.[130] Although not widely adopted, there is the evidence for the use of recombinant human activated protein C and low-dose corticosteroids for vasopressor-dependent shock.[131,132] There is evidence that glycemic control is important in patients with severe sepsis, although

very tight control is associated with hypoglycemia and possibly increased mortality.[133,134]

Metabolic Complications

Hypocalcemia is the most frequent metabolic disturbance, and it usually occurs during the first week. Low serum albumin will make the hypocalcemia appear worse, and therefore, replacement should be based on ionized calcium. There are several factors likely to be responsible for low calcium. Primarily, calcium is sequestered in areas of fat necrosis by the process of saponification. In addition, there is probably a contribution from altered calcium-regulating hormones (eg, calcitonin, parathyroid hormone, and glucagon). Hypomagnesemia may inhibit parathyroid hormone and contribute to the hypocalcemia.

Hyperglycemia is a frequent finding and usually corrects without the need for treatment. It is an adverse prognostic sign in itself. There are three contributing factors to hyperglycemia, including a stress-induced increase in cortisol and catecholamines, hyperglucagonemia, and probably most important, an insulin deficiency that may reflect necrosis of the islet cells. Glucose intolerance, if not insulin-dependent diabetes, occurs in up to half of patients who have had severe necrotizing pancreatitis.

Disseminated intravascular coagulopathy is not common, but there is a well recognized tendency toward hypercoagulability in acute pancreatitis. Other rare complications include subcutaneous fat necrosis and polyarthritis, which are also seen in patients with acinar cell carcinoma of the pancreas and thought to be due to increased serum lipase. There have also been reports of osteolysis and rhabdomyolysis in severe acute pancreatitis.

Protein-calorie malnutrition is a complication of acute pancreatitis, especially when it is severe and associated with infected necrosis. These patients have a significantly elevated resting energy expenditure, and it has been shown that total parenteral nutrition is unable to reverse this hypercatabolic insult on body protein (Fig. 55-16).[135] The importance of and the approaches to nutritional support in patients with severe acute pancreatitis are discussed in Chap. 54.

Encephalopathy

Pancreatic encephalopathy is a rare complication of acute pancreatitis. Clinical features include focal neurologic signs and acute onset of dementia. This picture can fluctuate over time; cyclic progression with remission and relapses has been described. Although the exact mechanisms are unclear, postmortem examination reveals amylase in the cerebrospinal fluid. MRI of the brain may be helpful. Patchy white matter signal abnormalities resembling the plaques seen in multiple sclerosis may reflect the lesions that are found in the cerebral white matter of postmortem-confirmed cases. Treatment is supportive. Any patient with suspicious or unusual neurologic symptoms and signs associated with possible malnutrition, hyperemesis, or malabsorption should be given intravenous thiamine to avoid the potential morbidity and mortality associated with undiagnosed Wernicke's encephalopathy.

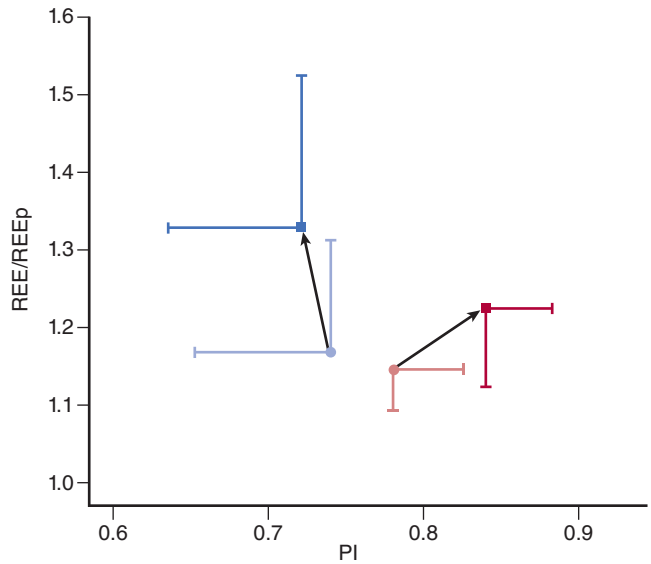

FIGURE 55-16 The changes in protein index (measured/predicted total body protein, expressed as mean ± SEM) on day 0 (*circles*) and day 14 (*squares*) of total parenteral nutrition in acute pancreatitis patients with (*open symbols*) and without (*closed symbols*) sepsis and/or recent surgery. (Reproduced from Chandrasegaram MD, Plank LD, Windsor JA. The impact of total parenteral nutrition on the body composition of patients with acute pancreatitis. *JPEN J Parenter Enter Nutr*. 2005;29:65–73. Reprinted by permission of SAGE Publications.)

CONCLUSION

The many and varied complications of acute pancreatitis present a considerable clinical challenge and highlight the need for the treatment of patients with severe disease in centers able to offer expertise in a wide range of disciplines including intensive care, surgery, endoscopy, radiology, infectious disease, and nutrition. The two primary goals of research in the field of acute pancreatitis should be aimed at preventing infected pancreatic necrosis and reducing the frequency and severity of multiple organ dysfunction. In the meantime the clinician caring for patients with acute pancreatitis must remain vigilant to detect the development of local, regional, and systemic complications of this protean disease, and be well versed in the considerable recent progress in the treatment of local complications. Of note is the more conservative approach to the simple pseudocyst, the judicious primary use of percutaneous drainage for infected local complications, and the evolution of minimally invasive techniques, which if required should result in improved outcomes in these patients with limited physiological reserve.

CHRONIC PANCREATITIS

Marshall S. Baker • Jeffrey B. Matthews

INTRODUCTION

Chronic pancreatitis is an inflammatory and fibrosing disease of the exocrine pancreas characterized by irreversible morphological changes and permanent loss of function. The apparent incidence of chronic pancreatitis has increased approximately fourfold over the past several decades, likely due a broadening of its definition and the inclusion of patients with earlier-stage disease. The natural history of chronic pancreatitis is unpredictable. Affected individuals typically suffer a pattern of persistent or recurrent attacks of pain along with progressive pancreatic exocrine insufficiency. Symptoms may also result from extension of the disease process to adjacent organs and vascular structures. In later stages, pancreatic endocrine insufficiency may develop. Decision making in the management of chronic pancreatitis must be individualized to the specific anatomic and pathological circumstances, taking into account the extent of local expertise in various diagnostic and therapeutic modalities as well as the fact that there is a relative paucity of high-quality data on the clinical effectiveness of surgical and medical interventions. Optimal management is facilitated by a multidisciplinary approach that includes surgical, endoscopic, and radiological expertise in addition to nutrition, endocrinology, pain management, and psychosocial support.

DEFINITION AND RISK FACTORS

Pancreatitis is thought to have its origin as an autodigestive disease initiated by inappropriate activation of pancreatic zymogens. The terms *acute pancreatitis* and *chronic pancreatitis* are often used to draw the temporal distinction between an isolated episode and a more persistent illness associated with progressive loss of pancreatic function. In fact, pancreatitis represents a far more heterogeneous clinical entity than can be captured by these two simple descriptors. A number of international conferences have been held in order to develop uniform terminology to characterize the spectrum of morphology seen in acute and chronic pancreatitis.

According to the Marseille-Rome classification of 1988, the term *acute pancreatitis* is used to refer to single or repeated episodes of abdominal pain associated with a range of potentially reversible pancreatic lesions including pancreatic edema, necrosis, and hemorrhage, as well as peripancreatic fluid collections, necrosis, and pseudocysts. *Chronic pancreatitis* is used to refer to recurrent or persistent abdominal pain that is associated with irreversible and ongoing inflammatory destruction of exocrine parenchyma and, eventually, islets. In practice, however, the distinction between acute and chronic pancreatitis is rarely made based on tissue sampling, and there is no consensus on the definition of irreversible morphological change.[1] It is also acknowledged that certain forms of chronic pancreatitis can occur in the absence of pain.

The Marseille-Rome classification further divides chronic pancreatitis into several morphological subtypes that may coexist in the same patient. *Chronic obstructive pancreatitis* is characterized by exocrine atrophy and is associated with duct stenosis caused by tumors, pseudocyst, or scarring from prior acute pancreatitis. *Chronic calcifying pancreatitis* is characterized by intraductal calcifications and protein plugs, and is often associated with atrophy, stenotic ducts, and areas of acute inflammation or pseudocyst. *Chronic inflammatory pancreatitis* consists of dense infiltration of mononuclear inflammatory cells. *Retention cysts and pseudocysts,* seen in both calcifying and obstructive forms, may also become infected. *Fibrosis* may develop in the absence of symptoms.

Chronic pancreatitis lacks a simple unifying theory of disease pathogenesis. The precise mechanism by which any specific agent or circumstance induces pancreatitis remains obscure. Excessive alcohol ingestion has been associated with chronic pancreatitis ever since the term was introduced by Comfort in 1946.[2] However, the precise relationship between alcohol and chronic pancreatitis remains poorly understood. Alcohol ingestion in and of itself does not lead to pancreatitis in experimental animals. Chronic pancreatitis in humans occurs in the absence of significant alcohol usage, and, in fact, it is only a small percentage (fewer than 5%) of alcoholics that develop pancreatic disease.[3,4] Acute and chronic forms of pancreatitis have been found to share common risk

factors including exposure to toxic agents other than alcohol, and acute pancreatitis clearly has the potential to evolve into chronic disease. However, repeated episodes of acute pancreatitis do not invariably lead to chronic pancreatitis, and chronic pancreatitis may present without prior acute attacks. As with alcohol, most individuals exposed to the other toxic substances associated with pancreatitis do not develop the chronic form of the disease.

For these reasons, the concept of identifying risk modifiers rather than etiologies or causes of chronic pancreatitis may be more appropriate in classifying the disease particularly when making decisions regarding patient management. Far from being merely a "drunkard's disease," chronic pancreatitis should be attributed to a variety of genetic, environmental, anatomic, immunologic, and other poorly understood susceptibility factors that interact to initiate and perpetuate the pathology. The TIGAR-O system (Table 56-1) proposed by Whitcomb[4] is a framework that allows various risk factors associated with the disease to be logically organized into categories: *T*oxic or metabolic, *I*diopathic, *G*enetic, *A*utoimmune, *R*ecurrent acute, and *O*bstructive. The TIGAR-O system implies that chronic pancreatitis is not a uniform disease with one etiology and a single common pattern of presentation. Instead, there is a diversity of etiologic risk factors that contributes to a spectrum of pathological and functional derangements, clinical features, and natural history.

Modified and updated from Etemad B, Whitcomb DC. Chronic pancreatitis: diagnosis, classification, and new genetic developments. *Gastroenterology*. 2001;120(3):682–707.

Toxic or Metabolic

The majority of patients with chronic pancreatitis (55–80%) will report significant alcohol intake over the years prior to diagnosis. A relationship between dose and duration of alcohol use has been repeatedly documented, and there appears to be a threshold level for the risk of pancreatitis at approximately 50 gm (four drinks) per day.[5] Several mechanisms have been proposed to account for pancreatic injury including alterations in pancreaticobiliary secretory flow, ductal plugging, and direct toxic action on acinar cells. Chronic pancreatitis in the setting of alcohol use is associated with pancreatic calcification and ductal stone formation, but none of the proposed mechanisms is convincingly supported experimentally, and the hypotheses are not mutually exclusive. Several other toxic agents have been identified as risk factors for pancreatitis. Included among these is tobacco, which has been shown to confer increased risk of chronic pancreatitis independent of alcohol use.[6] Several medications have been implicated in acute pancreatitis but probably do not play a role in the chronic form of the disease. Similarly, hypercalcemia (eg, associated with hyperparathyroidism) and various forms of hyperlipidemia (eg, hypertriglyceridemia) are linked to acute but not chronic pancreatitis. So-called tropical chronic pancreatitis, described in children living in developing parts of the world, is thought to be either due to a dietary toxin or to an unidentified micronutrient deficiency.

Idiopathic

About 20% of patients with chronic pancreatitis have no clinically obvious risk factor. It is suspected that a great many of these idiopathic cases will ultimately prove to harbor yet unidentified genetic or molecular derangements that explain the process. In recent years, many patients previously considered to be idiopathic recurrent acute and chronic pancreatitis have been found to carry mutations, polymorphisms, or splice variants of the gene associated with cystic fibrosis. Recent evidence also suggests that polymorphisms in genes associated with oxidative stress and xenobiotic metabolism may be more prevalent in patients with what is now characterized as idiopathic disease.[7] Thus, as new genetic associations that predispose to the development of chronic pancreatitis become recognized, the percentage of patients with truly idiopathic disease will decrease.

Genetic

Hereditary pancreatitis was first characterized in 1952 as early onset of chronic pancreatitis clustering in family members without other risk factors.[8] At least half of

hereditary pancreatitis kindreds have been found to carry germline mutations in the cationic trypsinogen (*PRSS1*) gene.[3,4,9] The arginine-to-histidine (R122H) substitution is the most common defect. Hereditary pancreatitis has an autosomal dominant pattern of inheritance, with a high degree of penetrance. Cationic trypsinogen is produced in the pancreatic acinar cells and, upon cleavage by duodenal enteropeptidase, forms trypsin. Trypsin is a protease that acts to hydrolyze dietary proteins and plays the key role in both initial activation of other pancreatic zymogens (including trypsinogen itself) and in their subsequent proteolytic inactivation. Trypsin encoded by pancreatitis-associated *PRSS1* mutations is unusually stable and resists autolytic inactivation, predisposing to premature and extended activation of trypsin within the pancreatic parenchyma.[10] Mutations in other genes such as anionic trypsinogen (*PRSS2*) or the calcium-sensing receptor (CASR) have also been reported in some cases of hereditary pancreatitis, although in many other kindreds, the responsible gene has not yet been identified.[11] Other gene associations with hereditary or otherwise idiopathic chronic pancreatitis will undoubtedly emerge over the next several years. Recently, for example, inactivating mutations in the gene encoding for the trypsin-degrading enzyme chymotrypsin C have been identified in a German cohort.[12]

Another genetic disorder associated with pancreatic pathology is cystic fibrosis (CF), a disease linked to mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene.[9,13–15] CFTR is a chloride ion channel involved in water, chloride, and bicarbonate secretion by epithelial cells such as those lining the gastrointestinal tract and respiratory system. In the pancreas, CFTR is localized to centroacinar and proximal lobular duct cells.[16] Over 90% of CF patients are pancreatic insufficient, and, while severe pancreatic fibrosis is common, acute pancreatitis is rare.[17] However, a subset of patients with otherwise idiopathic recurrent acute and chronic pancreatitis has been noted to have borderline abnormalities in functional tests for cystic fibrosis such as sweat chloride content. These patients harbor at least an eightfold increase in CF-associated CFTR mutations on a single allele. Various other CFTR mutations, polymorphisms, and splice variants not associated with classical pulmonary manifestations of CF are also frequently identified in patients with recurrent acute and chronic pancreatitis. The CFTR gene shows autosomal recessive inheritance with incomplete penetrance, and thus a family history of CF or pancreatic disease is usually absent in CFTR-associated pancreatitis. The mechanism of CFTR-associated pancreatitis is thought to involve the viscous, low-volume, low-bicarbonate containing pancreatic fluid secretion leading to duct sludge and enzyme hyperconcentration, enhancing the potential for intraglandular enzyme activation.

Mutations and polymorphisms in other genes may also modify susceptibility to chronic pancreatitis. Pancreatic serine protease inhibitor Kazal type 1 (SPINK1) is a natural protease inhibitor that localizes with trypsinogen within zymogen granules. SPINK1 binds to and inhibits activated trypsin, thus serving as a "buffer" of sorts against inappropriate early trypsinogen activation. Mutations of the SPINK1 gene (notably N34S) appear to increase the risk of recurrent acute and chronic pancreatitis, particularly in patients who harbor two mutated alleles.[3,4,9] A single mutated SPINK1 allele appears to increase the risk of alcohol-associated pancreatitis and tropical pancreatitis.

Autoimmune

Autoimmune chronic pancreatitis (AIP), also known as lymphoplasmocytic sclerosing pancreatitis, is characterized by diffuse glandular enlargement and infiltration with CD4 or CD8-positive lymphocytes and IgG4-positive plasma cells.[3,4,18,19] The exact immunologic etiology is unknown, although circulating antibodies with homology both to a peptide sequence associated with a protein from *Helicobacter pylori* (infection with which is associated with various autoimmune disorders including AIP) and to a protein highly expressed in pancreatic acinar cells have recently been found in over 90% of patients.[20] Inflammatory infiltrates are particularly concentrated in duct rather than acinar zones, however, and thus a duct-origin autoantigen has been postulated. Notably, diffused ductal narrowing rather than dilation is usually observed. Initially described predominately in young men, AIP has been increasingly recognized as a cause of biliary obstruction and pseudotumor in older individuals.[21] Most patients report little in the way of pain, and prior attacks of acute pancreatitis are unusual. It has been associated with serologic elevation of IgG4 levels in about two-thirds of patients and with other autoimmune conditions in approximately 20%, including Crohn's disease, ulcerative colitis, Sjögren's syndrome, primary biliary cirrhosis or primary sclerosing cholangitis.[18,21]

Recurrent and Severe Acute Pancreatitis

Recurrent episodes, or even a single severe episode of, acute pancreatitis may lead to chronic pancreatitis, but the basis for progression is poorly understood. Patients with prior episodes of necrosis appear to be at particular risk for developing chronic disease. In many cases, progression may be due to postpancreatic ductal scarring, persistent activation of pancreatic stellate cells, and neuroplasticity leading to hyperalgesia.

Obstructive

Post-traumatic duct strictures, or obstruction associated with tumors including cystic neoplasms, neuroendocrine lesions, and pancreatic adenocarcinoma have been associated with pancreatic pathology consistent with chronic pancreatitis, although these patients are often asymptomatic. Chronic pancreatitis has also been associated with anomalous anatomic variations in the pancreatic ductal system, most notably *pancreas divisum*, and it has been postulated that relative

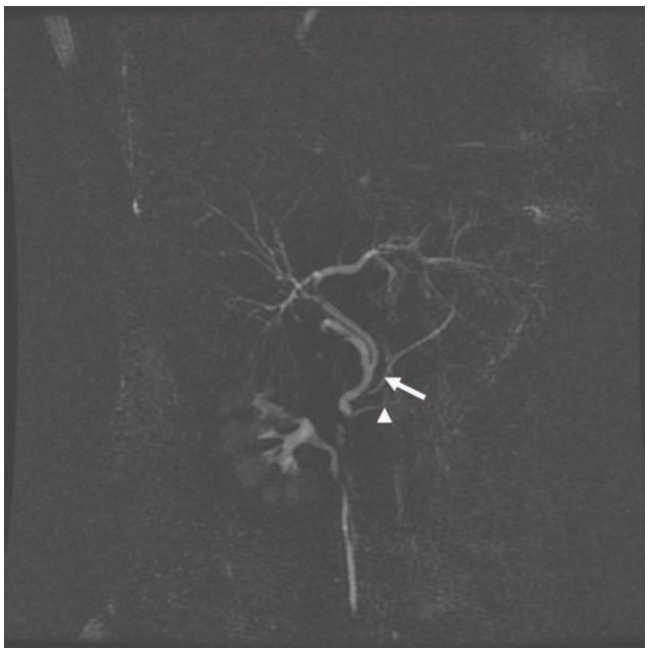

FIGURE 56-1 Recurrent acute and chronic pancreatitis in a 41-year-old woman with pancreas divisum and a pancreatitis-associated mutation in the cystic fibrosis (CF) gene. Magnetic resonance cholangiopancreatography (MRCP) demonstrates noncommunicating dorsal (*arrow*) and ventral (*arrowhead*) pancreatic ducts.

obstruction to pancreatic flow through the dorsal duct and minor papilla predisposes to recurrent acute and chronic pancreatitis. The evidence supporting the association to chronic pancreatitis in particular is largely circumstantial and may reflect referral bias[22] but pancreas divisum may be a contributing factor in the presence of certain genetic risk factors (Fig. 56-1). Some cases of chronic pancreatitis are attributed to sphincter of Oddi dysfunction, although rigorous evidence to support this association is also lacking.

PATHOPHYSIOLOGY AND MECHANISM OF PAIN

Progress in elucidation of the pathogenesis of chronic pancreatitis has been hampered by the lack of a suitable experimental model that adequately recapitulates the features of the disease seen in humans.[23] However, existing evidence suggests a number of useful conceptual frameworks that may help guide efforts to treat patients with chronic pancreatitis. Traditional theories of the pathogenesis of acute pancreatitis include the toxic-metabolic or oxidative stress hypotheses, in which normal acinar cell processing and release of zymogens are disrupted by a toxic or oxidative stressor, and the ductal obstruction hypothesis that proposes a mechanical role for ductal plugs and stones causing disruption of the integrity of the acinar cell (common in alcoholic and tropical disease). In certain situations, notably autoimmune disease, pancreatitis may begin not in the acinar cell but in the duct cell, triggered by the development of an as-yet-unidentified autoantigen on the duct epithelium. Recently, attention has focused on understanding the mechanism of pancreatic fibrosis, the central histological feature that characterizes the evolution from acute disease to chronic pancreatitis. One attractive hypothesis is that a sentinel acute pancreatitis event (SAPE) primes the pancreas for fibrogenesis.[23] According to the SAPE concept, local inflammatory cytokines released during acute pancreatitis activate circulating macrophages that infiltrate the gland as well as resident pancreatic stellate cells, myofibroblast-like cells that are normally quiescent. During the subsequent healing phase, anti-inflammatory mediators (particularly anti-inflammatory cytokines such as tumor growth factor beta [TGF-β]) drive stellate cells and tissue macrophages to synthesize and deposit fibrogenic matrix proteins. The pancreatic parenchyma may return to normal after a mild self-limited episode. However, the damage may not completely resolve after a severe attack, particularly if there has been significant tissue necrosis. Thus, following the SAPE, the local pancreatic environment may be permanently altered by the persistent presence of anti-inflammatory and profibrogenic cell populations that are perpetually activated by ongoing toxic-metabolic, oxidative, or mechanical stress. The pancreas then becomes subject to repeated cycles of inflammation and progressive fibrosis.

A comprehensive mechanistic explanation for pain, often the most debilitating symptom of chronic pancreatitis, also remains elusive.[23] One hypothesis is that pain results from capsular stretch associated with ductal or organ hypertension. This hypothesis is supported by the favorable results of surgical or endoscopic ductal drainage in patients with chronic pancreatitis associated with dilated pancreatic ducts, and the success of surgical resection in other selected patient populations. An alternative, and possibly complementary, hypothesis is that the pain represents a neuropathy caused by repeated inflammatory insults and damage to retroperitoneal sensory nerves.[23–25] Recent evidence demonstrating neuroplasticity in nociceptive dorsal root ganglia in chronic inflammatory states, with evidence of upregulation of nociceptors such as TRPV1 by proteolytic enzymes such as trypsin[26] supports this theory.

CLINICAL PRESENTATION

As in acute pancreatitis, pain in chronic pancreatitis typically localizes to the left upper quadrant or epigastric region, often radiating around or into the back. The pattern of pain is variable. Some patients experience recurrent attacks of moderate to severe pain interspersed with periods of relative or complete quiescence. In others, the pain may be persistent and lead to significant incapacitation and chronic disability. During acute exacerbations, the pain may be increased by food intake and is frequently associated with nausea and vomiting.

Weight loss and malnutrition are common, due to both decreased intake as well as exocrine insufficiency with consequent malabsorption of protein and fat. Exocrine insufficiency

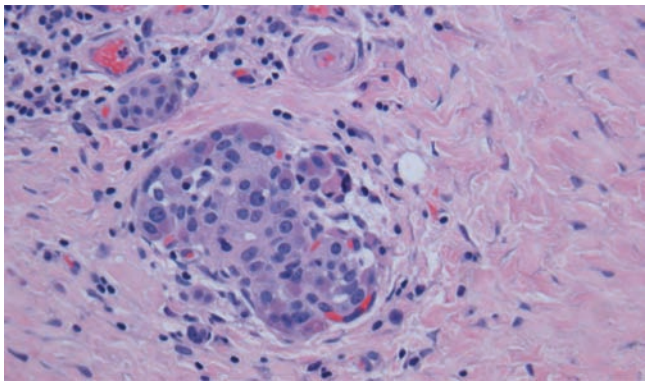

FIGURE 56-2 Histopathology of chronic pancreatitis showing islet entrapment within exocrine parenchymal fibrosis. (Used with permission from Dr. Jerrold Turner)

is usually obvious in patients with classical steatorrhea (loose, bulky bowel movements that may be greasy, sticky, oily, or foul-smelling), but these symptoms are obscured by narcotic-associated constipation.

Endocrine insufficiency typically occurs late in the course of disease, often after exocrine insufficiency has appeared, and usually not before about 90% of the pancreatic parenchyma has been replaced by fibrosis. Diabetes is more common in patients with alcohol-associated chronic calcifying pancreatitis with 80% of these individuals demonstrating endocrine insufficiency within 10 years of the development of severe exocrine insufficiency.[27] For unclear reasons, there is a relative sparing of islet cells until late in the course of the disease. Histologically, pancreatic islets are seen to persist within areas of extensive fibrotic replacement of exocrine tissue (Fig. 56-2). Because diabetes of chronic pancreatitis is associated with indiscriminate destruction of all cell types within the islets of Langerhans, counter-regulatory glucose control may be considerably more labile than in either type I or type II diabetes. Less is known regarding the natural history of nonalcohol-associated chronic pancreatitis but the risk of diabetes appears to be lower.[27] Both endocrine and exocrine insufficiency occur later and less frequently in patients with chronic pancreatitis associated with gene mutations than those without gene mutations.[28]

On occasion, the initial manifestation of chronic pancreatitis will be related to extrapancreatic complications such as intestinal or biliary obstruction due to compression by a pseudocyst, and gastrointestinal hemorrhage due to blood lost into the pancreatic duct (*hemosuccus pancreaticus*) or due to rupture of pseudoaneurysm into a pseudocyst or to splenomesenteric vein thrombosis.

DIAGNOSIS

The diagnosis is usually suspected based on an appropriate clinical history and is confirmed by imaging studies. Laboratory investigation is of limited value. Acute exacerbation of abdominal pain may be paralleled by a transient increase in serum amylase or lipase, but these may be normal with progressive destruction of acinar cell mass. Elevation of liver function tests, particularly serum bilirubin and alkaline phosphatase, may indicate the presence of bile duct obstruction.

The diagnosis of chronic pancreatitis is usually confirmed by imaging studies, most commonly computed tomography (CT). CT findings depend on the morphologic type of chronic pancreatitis, the duration of disease, and the presence of complications. In the early phases of chronic pancreatitis, ductal or parenchymal changes may be rather subtle, but as the disease advances, progressive and irreversible changes in organ architecture are readily apparent. Chronic pancreatitis associated with toxic-metabolic or genetic risk factors, and idiopathic chronic pancreatitis may demonstrate calcifications either focally or scattered throughout the organ. There may be evidence of acute inflammatory changes or focal areas of enlargement associated with areas of dense calcifications, particularly in the pancreatic head (Fig. 56-3); this so-called "inflammatory head mass" appears to be more common in European than American cohorts.[29] There may be evidence of segmental or diffuse pancreatic ductal dilation related to stricture formation, and pseudocyst formation and evidence of extrapancreatic complications such as duodenal or biliary obstruction, or splenomesenteric vein thrombosis (Fig. 56-4). In autoimmune pancreatitis, calcifications are almost uniformly absent and the pancreas is usually diffusely enlarged although a focal mass-forming variant is occasionally encountered.[18] In obstructive forms of chronic pancreatitis, the pancreatic duct is dilated upstream of the area of stenosis and the acinar parenchyma appears atrophic. Although CT can readily confirm the clinical suspicion of chronic pancreatitis, it rarely provides sufficient information for therapeutic decision making.

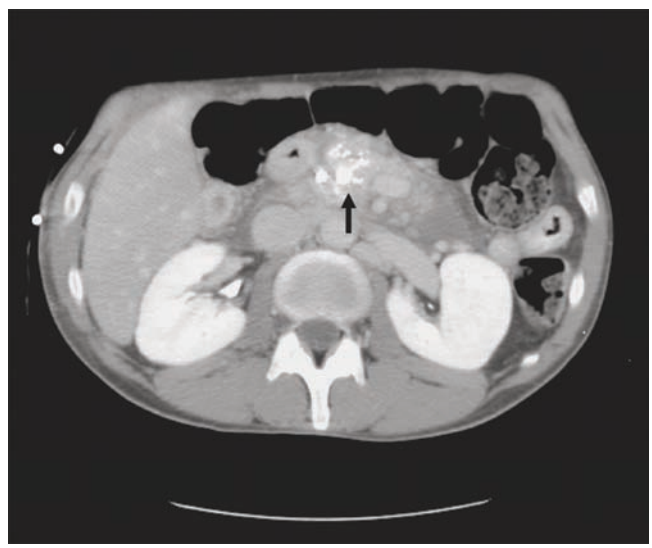

FIGURE 56-3 Axial cross-sectional abdominal CT demonstrating enlargement and dense calcifications (*arrow*) in the pancreatic head in alcohol-associated chronic pancreatitis.

FIGURE 56-4 Axial cross-sectional abdominal CT demonstrating pseudocyst involving the splenic hilum with splenic vein compression (*arrow*) in alcohol-associated chronic pancreatitis.

Pancreatic ductography complements CT imaging and is generally considered essential in planning intervention. Endoscopic retrograde cholangiopancreatography (ERCP) has long served as a gold standard of sorts in mapping duct pathology and offers endotherapeutic options including sphincterotomy and stent placement (Fig. 56-5). Magnetic resonance cholangiopancreatography (MRCP) is less invasive and provides image quality that rivals ERCP; the addition of secretin stimulation further enhances duct visualization and allows some assessment of pancreatic exocrine function (Fig. 56-6).[30] Anatomic ductal anomalies such as pancreas divisum are readily defined by ERCP or MRCP, as are dominant focal duct strictures that might be amenable to endoscopic stenting or surgical drainage procedures. MR imaging integrates information regarding parenchymal and ductal involvement and may be particularly helpful when the disease is regionally heterogeneous and architecturally complex.

FIGURE 56-5 ERCP image showing classic diagnostic features of chronic pancreatitis including marked main duct dilation, intraluminal filling defects (stones), clubbing of side-branches, and areas of duct stricture.

FIGURE 56-6 Secretin-stimulated MRCP shows a diffusely dilated main pancreatic duct with obstruction to pancreatic flow associated with a dorsal duct stricture in the setting of pancreas divisum and chronic pancreatitis.

It is not difficult to establish the diagnosis of chronic pancreatitis in its advanced stages, when classical clinical symptoms are present or when imaging studies demonstrate obvious abnormalities such as strictures, ductal dilation, or pancreatic calcifications. Recognition of disease in its earlier stages presents more of a challenge. A 1983 conference held in Cambridge categorized chronic pancreatitis as equivocal, mild, moderate, or marked and established criteria (Table 56-2) according to combinations of features seen in the main and side branch pancreatic ducts on CT and ductograms.[1,31,32] Although this consensus approach has proven useful over the years, there continues to be a subset of patients with symptoms suspicious for chronic pancreatitis but in whom imaging studies are negative. Some of these patients may suffer from functional abdominal pain disorders rather than pancreatic disease.[33] Others may have early forms of chronic pancreatitis. Consensus workshops

TABLE 56-2: CAMBRIDGE CLASSIFICATION OF CHRONIC PANCREATITIS BASED ON ENDOSCOPIC RETROGRADE PANCREATOGRAPHY

Grade of Pancreatitis	Main Pancreatic Duct Appearance	Side Branch Pancreatic Duct Appearance
Normal	Normal	Normal
Equivocal	Normal	<3 abnormal branches
Mild	Normal	>3 abnormal branches
Moderate	Abnormal	>3 abnormal branches
Marked	Abnormal plus any of the following: Cavity >10 mm Stricture Intraductal filling defects Pancreatic calcification Contiguous organ involvement on CT Severe duct dilation or irregularity	>3 abnormal branches

Modified from Sarner M, Cotton PB. Classification of pancreatitis. *Gut*. 1984;25(7):756–759.

TABLE 56-3: ENDOSONOGRAPHIC CRITERIA FOR CHRONIC PANCREATITIS

Parenchymal Criteria	Ductal Criteria
Hyperechoic foci	Main pancreatic duct dilation
Hyperechoic strands	Duct irregularity
Lobularity of the gland	Hyperechoic duct margins
Cysts	Dilated side branches
	Stones

Modified from Pungpapong S, Wallace MB, Woodward TA, Noh KW, Raimondo M. Accuracy of endoscopic ultrasonography and magnetic resonance cholangiopancreatography for the diagnosis of chronic pancreatitis: a prospective comparison study. *J Clin Gastroenterol*. 2007;41(1):88–93.

by the Japan Pancreas Society (1995 and 2001) continue to address the ongoing challenge of so-called "minimal change" disease in the context of evolving imaging and diagnostic modalities.

Endoscopic ultrasound (EUS) appears to be valuable in evaluation of the suspicious pancreatic mass and in characterizing cystic lesions of the pancreas.[34] EUS generally adds little to the evaluation of chronic pancreatitis in its advanced stages but has potential applicability in early stage, minimal change disease where other imaging modalities fail to establish the diagnosis.[3,35–37] EUS appears to be more sensitive than ERCP or MRCP in detecting early parenchymal fibrosis and subtle ductal changes occurring in early forms of chronic pancreatitis. Various systems using up to 11 different parenchymal and ductal endosonographic criteria (Table 56-3) to diagnose chronic pancreatitis have been proposed.[38] There is however, no gold standard grading system or agreement on the threshold number of abnormalities that must be present for the diagnosis of chronic pancreatitis. Because of this, the value of EUS in making an early diagnosis of chronic pancreatitis, remains uncertain. EUS may have more practical utility in cases of suspected autoimmune pancreatitis. Surgical interventions may be avoided in some of these patients that present with a mass-forming variant by EUS-directed core needle biopsy demonstrating the pathognomonic lymphoplasmacytic infiltrate[39] and thus ruling out malignancy.

Functional testing to demonstrate pancreatic exocrine insufficiency is occasionally helpful, although from a practical standpoint, the condition is usually clinically obvious. Symptoms of steatorrhea, postprandial gaseous distension, or progressive weight loss despite adequate caloric intake are all suggestive of exocrine insufficiency. Quantification of fecal fat content or measurement of fecal human elastase (FE-1) levels can confirm the diagnosis and can be used to monitor efficacy of enzyme supplementation and surgical intervention.[40] Unfortunately, these studies are most reliable in those patients in whom the diagnosis is clinically obvious. They are of questionable accuracy in the setting of patients with more subtle symptoms where objective documentation of exocrine insufficiency might be most needed.

Elevation in fasting serum glucose or glycosylated hemoglobin (HgA_{1c}) suggests pancreatic diabetes. Functional evaluation (eg, formal oral glucose or arginine-tolerance testing) for pancreatic endocrine insufficiency may be helpful in patients prior to pancreatic resection, particularly if autologous islet transplantation is under consideration.

In patients with suspected autoimmune pancreatitis, measurement of serum immunoglobulin G levels, particularly IgG4, is indicated. Other markers of autoimmune disease include rheumatoid factor, antinuclear antibody, C-reactive protein (CRP), or erythrocyte sedimentation rate, although these are less specific.[19]

The role of genetic testing in patients with idiopathic or suspected hereditary pancreatitis is controversial.[41] It may be most reasonable to screen for *PRSS1* mutations in patients with a strong family history of pancreatitis because of the autosomal dominant inheritance and the high risk of development of pancreatic cancer; a risk that is further dramatically elevated by tobacco use. However, hereditary pancreatitis patients without *PRSS1* mutations may have the same elevated risk of cancer, and there is no evidence that screening by serial imaging studies leads to earlier diagnosis or improved prognosis of pancreatic cancer. Identification of CFTR or SPINK1 gene mutations may be useful in selected circumstances; for example, patients with idiopathic pancreatitis may feel reassured by having an "explanation" for their disease. However, in the absence of therapy directed at the

specific functional defects associated with these mutations, the clinical value of gene testing is debatable.

MEDICAL MANAGEMENT

Cessation of potential inciting agents such as alcohol may reduce the intensity or frequency of attacks. Avoidance of high-fat foods and tobacco use may also be of value. Occasionally, patients are unable to tolerate oral food intake for extended periods of time, in which case nutritional support by an enteral route that minimizes pancreatic stimulation (eg, via nasojejunal or gastrojejunal tube) or by a parenteral approach may be required. Pancreatic enzyme replacement is used to treat steatorrhea and other symptoms of exocrine insufficiency. Enteric-coated preparations are most useful in this setting.[42] Various formulations differ in lipase, protease, and amylase content and enzyme replacement therapy should be titrated to effect.[42,43] Patients must be carefully instructed to time enzyme ingestion appropriately in relation to meals to optimize mixing.

In certain circumstances, medical therapy may alter the intensity or frequency of exacerbations of chronic pancreatitis. For example, some patients with early, small duct, or minimal change disease appear to benefit from high doses of noncoated enzyme preparations.[42] The presence of activated enzymes within the duodenum has been shown to decrease cholecystokinin-mediated stimulation of the pancreas. Noncoated enzyme preparations must be protected from destruction by gastric acid suppression therapy; trials that instead utilize enteric-coated delayed release enzyme formulations showed no benefit.[42,43] Several randomized trials suggest that a five-component antioxidant regimen reduces the frequency and intensity of painful episodes.[44] Patients with autoimmune pancreatitis confirmed by elevated IgG4 levels or tissue biopsy may be treated with an 8-week tapering course of corticosteroids.[21]

The major reason patients with chronic pancreatitis seek medical attention is unrelenting or frequently relapsing pain. Pain, more than any other feature, accounts for intractability and overall loss of quality of life. While in some patients, the intensity of pain may burnout as the disease reaches its end stage, this natural history is highly variable and may take years, if it occurs at all. Thus, a conservative, watch-and-wait approach is rarely acceptable. Pharmacotherapy for pain should begin with nonsteroidal anti-inflammatory medications, but if more powerful agents are needed, propoxyphene or tramadol may be used prior to escalating to more aggressive pharmacotherapy. Long-acting narcotics supplemented by short-acting narcotic formulations for breakthrough pain may be more effective than short-acting agents alone. Unfortunately, narcotic dependency is a common consequence of the use of these agents. Psychosocial supports such as counseling are essential to successful longitudinal management of chronic pain. Variable results have been reported with the use of long-acting somatostatin analogues. Occasionally, tricyclic antidepressants or gabapentin may be useful. Alternatives such as placement of infusion pumps for intrathecal delivery of narcotics have been anecdotally successful.[45]

Neurolysis may be considered in patients who have failed medical management and who do not appear to have favorable anatomic circumstances amenable to endoscopic or surgical intervention. The most common neurolytic procedure is celiac plexus block, which can be performed under radiological or endoscopic guidance. The initial approach involves injection of a combination of steroids and a local anesthetic into the celiac ganglion. If temporary relief if obtained, this is followed by permanent neurolysis with 100% alcohol injection. Results of celiac plexus block in chronic pancreatitis have been mixed, but transient improvement (typically no more than 6 months) may be of benefit in selected patients.[36,46] Splanchnicectomy, usually performed by a thoracoscopic approach, has also been used, but similar to other forms of neurolysis, permanent resolution of pain is unusual.[47]

Therapeutic endoscopic intervention may be considered in patients with obstructive and inflammatory disease. Lithotripsy of pancreatic duct stones and pancreatic duct stent placement has been reported in several small retrospective series. Technical success can be reliably achieved in appropriately selected patients (eg, manageable stone size and local density sufficiently close to the working end of the scope and without intervening duct stricture). However, the effectiveness of endotherapy over time is often less than 50% with respect to improvement in pain or reduction in frequency of attacks. Multiple procedures are often necessary, recurrence of strictures and stones is frequent, and the substantial fraction of patients that fail generally require surgical intervention (Fig. 56-7).[48,49]

FIGURE 56-7 Coronal CT image of a biliary endoprosthesis in a patient with chronic calcifying pancreatitis. Attempts at endoscopic pancreatic duct stone removal were unsuccessful, and the patient underwent pancreaticoduodenectomy.

TABLE 56-4: RANDOMIZED COMPARISONS OF ENDOSCOPIC STENTING TO SURGICAL MANAGEMENT FOR MAIN DUCT DILATION

			Number of Patients			% With Durable Pain Relief		
Author	Year	Surgical Procedures	Endo Stenting	Surgery	Median Follow-Up	Endo Stenting	Surgery	p Value
Dite[50]	2003	Resection and drainage	36	36	5 y	61.4	85.9	0.002
Cahen[51]	2007	Lateral pancreaticojejunostomy	19	20	2 y	32.0	75.0	0.007

Long-term presence of stents within the pancreatic duct may worsen inflammatory ductal strictures, although most series find a few patients who achieve durable pain relief following removal of stents. Patients who are suitable for endotherapy are usually also candidates for surgical intervention, provided there are no medical contraindications to operation. The two randomized trials (Table 56-4) to date that directly compared surgical therapy to endoscopic stenting reported long-lasting superiority of the surgical approach with respect to pain relief, quality of life, over time, and other endpoints.[50,51]

SURGICAL MANAGEMENT OF CHRONIC PANCREATITIS

Surgical therapy for chronic pancreatitis is usually reserved for patients with symptoms that are otherwise intractable to pharmacotherapy and other therapeutic approaches. In over 90% of patients, the main indication for operation is pain. Occasionally, an operation is performed to relieve biliary or gastrointestinal obstruction, to internally drain a symptomatic pseudocyst, or for vascular complications of chronic pancreatitis such as gastric variceal hemorrhage secondary to splenic vein thrombosis.

A number of pancreatic operations have been developed over several decades of international effort. These operations generally involve either ductal drainage, parenchymal resection, or some combination of resection and ductal drainage. The choice of operation depends on anatomic morphology. In many patients, the disease appears to be driven predominantly by pathology within the pancreatic head, sometimes considered the "pacemaker" of chronic pancreatitis, particularly in those with a sizable inflammatory mass in this region of the organ. Others present more diffuse disease involving extensive areas of stricture and dilation of the main pancreatic duct or its ductal tributaries. Occasionally, disease appears limited to the body or tail. Operations on the pancreas may be technically demanding and carry significant risks of postoperative morbidity and mortality. Although in appropriately selected patients, the immediate results may be excellent, long-term success (durable pain relief) is achieved in at most 85% of patients at 5 years of follow-up. Alternatives for surgical intervention are best individualized and considered in the context of the most frequently encountered clinical and anatomic scenarios.

Large-Duct Disease

Large-duct chronic pancreatitis is characterized by enlargement of the main pancreatic duct lumen to a diameter exceeding 7–8 mm. Ductal dilation is often diffuse along the length of the organ, but there may be one or more intervening areas of ductal stricture. In many patients, calcific deposits (stones) may be evident on imaging studies within the main or secondary ducts.

Puestow described a procedure to provide enteric drainage to a diffusely dilated main pancreatic duct, with the goal of achieving pain relief by duct decompression. In its initial description, the Puestow procedure consisted of a longitudinal unroofing of the dilated pancreatic duct in the body and neck of the gland, and also involved resection of the pancreatic tail.[52] A long segment longitudinal pancreaticojejunostomy was then constructed to establish enteric drainage. A modification reported by Partington and Rochelle in 1960 eliminated the distal pancreatectomy. Lateral pancreaticojejunostomy is now thus referred to as either a (modified) Puestow or Partington-Rochelle procedure[53] and continues to be commonly used for disease characterized by a diffusely dilated main pancreatic duct with no significant biliary obstruction and no mass in the pancreatic head.

LATERAL PANCREATICOJEJUNOSTOMY—TECHNIQUE

Midline or transverse upper abdominal incisions provide acceptable exposure for this procedure. The dissection is begun by incising the peritoneal lining adjacent to the lateral border of the second portion of the duodenum, extending laterally to release the hepatic flexure of the right colon. Using electrocautery, the retroperitoneal attachments lateral and posterior to the duodenum are divided to widely mobilize the duodenum and posterior aspect of the head of the pancreas (Kocher's maneuver). This dissection is carried inferiorly to free the third portion of the duodenum from the base of the transverse mesocolon, effectively exposing the head of the

pancreas and anterior surface of the duodenum from the pylorus to the level of the superior mesenteric vessels. Exposure of the anterior surface of the pancreatic body and tail requires access to the lesser sac, which is entered by dividing the gastrocolic omentum or by separating the avascular plane of attachment from the transverse colon and mesocolon. Next, the gastroduodenal artery (GDA) is identified at its supraduodenal origin from the common hepatic artery and traced across the head of the pancreas. The GDA is then suture ligated at both the superior and inferior border of the head of the pancreas in an effort to prevent intraoperative hemorrhage during incision of the pancreatic head and main pancreatic duct during the dissection as well as postoperative bleeding at the site of the pancreaticojejunostomy. The anterior surface of the pancreas is then carefully examined to confirm the presence of main duct dilation and the absence of suspicious mass lesions or unanticipated inflammatory changes in the head of the gland. The dilated pancreatic duct is usually visible by direct inspection or palpation of the anterior surface of the pancreas but can also be accessed by means of a fine needle and low-volume syringe. The duct can also be localized using intraoperative ultrasound, but this is usually not necessary. The pancreatic duct is then incised longitudinally along its full length using electrocautery. This ductotomy should extend across the neck into the head of the organ where the GDA traverses the pancreas, and should extend laterally as far as possible along the length of the tail so that the entire segment of dilated duct is unroofed. The pancreaticojejunal anastomosis is performed in Roux-en-Y fashion using a 40–50 cm defunctionalized jejunal limb. Using a linear gastrointestinal stapler, the proximal jejunum is divided at the apex of a mesojejunal vascular arcade of suitable mobility, typically at least 20–30 cm distal to the ligament of Treitz, although the precise distance is probably unimportant. The distal staple line is inverted using a series of 3-0 silk sutures placed in a Lembert fashion which are tied (but not cut) and then held by a fine clamp that facilitates later positioning of the pancreatic anastomosis. Intestinal continuity is then re-established by a handsewn or stapled enteroenterostomy such that the intestinal conduit is approximately 60 cm in length. The Roux limb is then advanced through the transverse mesocolon either to the right or left of the middle colic vessels. A longitudinal jejunostomy is made to correspond to the pancreatic ductotomy. The pancreaticojejunostomy is handsewn with a running absorbable suture (eg, 4-0 double-armed polyglyconate or polydioxanone suture), which, according to surgeon preference, may be additionally reinforced by an outer later of interrupted nonabsorbable suture (Fig. 56-8). After completion of the anastomosis, the distance between the pancreaticojejunostomy and the enteroenterostomy should measure at least 40 cm to prevent reflux of enteric contents up to the anastomosis.

LATERAL PANCREATICOJEJUNOSTOMY—OUTCOMES

Results of the Partington-Rochelle procedure in appropriately selected patients are generally favorable. In most series,

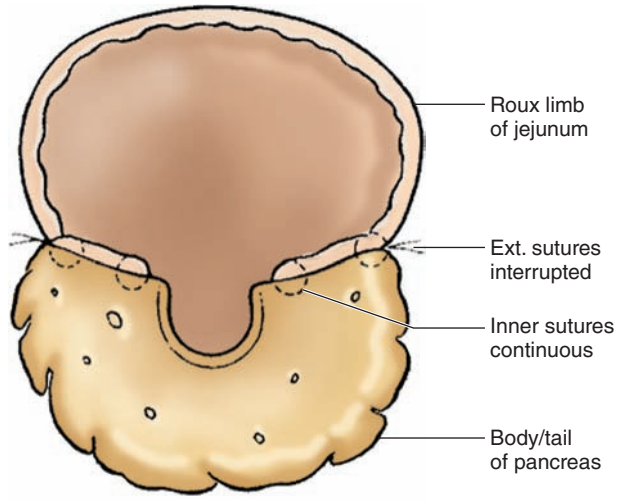

FIGURE 56-8 Cross-section of the anastomosis for a lateral pancreaticojejunostomy (applies to Puestow, Frey, or Izbicki procedures).

75–80% of patients with diffusely dilated main pancreatic ducts (>7 mm) and no dominant inflammatory mass, have achieved durable pain relief over 5–10 years of follow-up.[52,54–57] Compared to other major pancreatic operations, perioperative morbidity is low, and because no pancreatic parenchyma is removed, endocrine and exocrine functions are generally preserved relative to preoperative levels. Failure of lateral pancreaticojejunostomy is usually due to inappropriate patient selection (underappreciated extent of disease with the presence of significant fibrosis in the pancreatic head), or ongoing fibrosis with the progressive development of neuropathic pain.

Chronic Pancreatitis With a Dominant Pancreatic Head Mass

Lateral pancreaticojejunostomy has limited applicability in patients without diffuse main duct dilation. Multiple groups have reported that an isolated drainage procedure in patients with complex inflammatory changes in the pancreatic head, body, or tail results in poor clinical outcome with quick recurrence of symptoms of pain and progression to exocrine insufficiency. For patients with an inflammatory mass, extensive calcifications or duct stones in the pancreatic head, results appear to be better either with pure resectional or with hybrid resection and drainage procedures. There are four procedures being used in a great frequency today. These include pancreaticoduodenectomy (Whipple procedure, with or without pyloric preservation) and three forms of duodenum-preserving pancreatic head resection (DPPHR): the Beger procedure, the Berne procedure, and the Frey procedure.

The outcomes associated with these procedures have been compared in several randomized trials enrolling small numbers of patients with head predominant morphology. None of these studies has demonstrated any one of the techniques to be clearly superior to others (Table 56-5). There are no measurable differences in outcomes compared, the numbers in the trials are small and the metrics used to evaluate the outcomes are variable and imperfect.[58–61] As a result, no consensus opinion among pancreatic experts about which procedure is the best in any given clinical situation has emerged. In recent years, European surgeons have tended to favor a duodenum-preserving approach and American surgeons have tended to favor pancreaticoduodenectomy. One recent survey of American surgeons who were members of the Pancreas Club found that of 59 surgeons surveyed, only 34 had ever performed DPPHR and that only 23 US surgeons continue to perform these procedures on a regular basis.[62]

In spite of the lack of data supporting the relative superiority of any given procedure, we do believe that each has specific applicability to certain subtypes of head predominant morphology. A reasonable approach is to tailor the procedure to the anatomic morphology seen on the preoperative axial imaging and ductography. Patients with a dominant head mass and a dilated main pancreatic duct but no biliary dilation, may be best served by a Frey procedure (limited duodenum-preserving resection of the pancreatic head with extended lateral pancreaticojejunostomy). Patients with a dominant head mass without main duct dilation and no biliary obstruction may be better suited for the Berne modification of the Beger procedure (limited duodenum-preserving resection of the pancreatic head without extension of the lateral pancreaticojejunostomy toward the tail). Patients with biliary obstruction or imaging characteristics more suspicious for the presence of malignancy should probably undergo pancreaticoduodenectomy rather than any form of DPPHR.

PANCREATICODUODENECTOMY—TECHNIQUE

The early primary objective in the pancreaticoduodenectomy is making an efficient determination of whether or not the pathology allows safe resection. This typically involves a thorough manual examination of the abdomen to rule out metastatic cancer and then a rapid exposure of the pancreatic neck superiorly and inferiorly in an effort to assess the operator's ability to free the hepatic artery, superior mesenteric vein, and superior mesenteric artery from the pathology in the pancreatic head safely. Pancreaticoduodenectomy may be performed through a midline laparotomy or bilateral subcostal incision. Careful inspection and palpation of the peritoneal surfaces and liver is performed first, with frozen-section biopsy obtained of any suspicious lesions. Small areas of fat necrosis or fibrosis from prior attacks of pancreatitis are easily mistaken for metastatic deposits. The base of the transverse mesocolon should be inspected for evidence of foreshortening or inflammatory involvement that may herald a difficult or dangerous dissection in the vicinity of the superior mesenteric vessels, and to confirm the absence of otherwise unsuspected tumor extension. The hepatic flexure of the colon is mobilized by freeing the lateral retroperitoneal attachments using the electrocautery, an extended Kocher maneuver is performed, and the lesser sac is then entered by separation or division of the gastrocolic omentum, as described in the previous section. The mass in the head of the gland is palpated and determined to be safely free from the superior mesenteric vein (SMV) at the inferior border of the neck of the pancreas by preliminary dissection of the plane anterior to the SMV posterior to the neck of the pancreas. Attention is

then turned to the supraduodenal region. A cholecystectomy is performed, and the portal dissection is initiated by isolating the common bile duct (CBD) at the level of the cystic duct stump. The bile duct is carefully freed from the anterolateral surface of the portal vein and secured temporarily with a vessel loop. The common hepatic artery is usually found anteromedially to the portal vein, and it should be carefully isolated with a vessel loop and preserved. The lateral, free edge of the gastrohepatic ligament at the foramen of Winslow should be carefully inspected and palpated for an accessory or replaced right hepatic artery, which, if present, should also be isolated and protected during the subsequent resection. The GDA is isolated at its origin from the common hepatic artery and secured temporarily with a vessel loop. The continued presence of pulsatile flow in the proper hepatic artery after temporary occlusion of the GDA should be assured, both to confirm the vascular anatomy and to ensure that there is no stenosis in the proximal common hepatic artery or celiac trunk due to atherosclerotic plaque. Preliminary dissection of the plane anterior to the portal vein is begun. These measures demonstrate that there is no evidence of unresectable cancer and that the pancreatic head can be removed without concern for undue injury to the blood supply of the small intestine and liver.

At this point, technical resectability of the pancreatic head has been assured (Fig. 56-9). The GDA is divided between clamps and is doubly tied or suture ligated. The common hepatic duct is divided just proximal to the cystic duct entry, and bile flow is controlled with a small bulldog clamp. The right gastric artery is divided between suture ligatures. For a standard pancreaticoduodenectomy, the greater omentum is divided to a point on the greater curvature of the stomach in the vicinity of the junction of the right and left gastroepiploic arteries. The lesser omentum is divided at the level of the incisura of the lesser curvature of the stomach, and the descending branch of the left gastric artery is carefully secured. The stomach is then divided with two firings of a linear gastrointestinal stapler. The lesser curve staple line is inverted with silk Lembert sutures. For pyloric-preserving pancreaticoduodenectomy, the duodenum is divided using a stapler approximately 2 cm distal to the pyloric ring. The ligament of Treitz is taken down with electrocautery, being certain to avoid injury to the inferior mesenteric vein. The proximal jejunum is divided approximately 15 cm distal to the ligament of Trietz with a linear gastrointestinal stapler. The distal staple line is oversewn with interrupted Lembert sutures, initially left long to use for traction and positioning of the limb during the reconstruction. The short mesojejunal vessels of the proximal segment are carefully isolated and secured close to the mesenteric border of the jejunum using fine nonabsorbable ligatures, surgical clips, or an electrosurgical vessel-sealing device. This dissection is continued proximally to the duodenojejunal junction, and then the proximal jejunum is advanced into the supracolic compartment by passing it under the superior mesenteric vessels. At this point blunt dissection is used to complete development of a tunnel between the neck of the pancreas and the SMV or portal vein. The superior and inferior pancreatic vascular arcades are then ligated on either side of the planned transection site at the neck of the pancreas using nonabsorbable suture. The neck is then divided with electrocautery. Gentle retraction of the pancreatic head, distracting it from the right lateral wall of the SMV or portal vein, helps to expose small venous tributaries from the uncinate process, which should then be carefully controlled with fine ties or suture ligatures. The first jejunal venous tributary may be quite large and is easily injured during this dissection. The uncinate branches from the superior mesenteric artery (SMA) are then divided sequentially between clamps with great care to preserve the integrity of the SMA. The specimen is then oriented and submitted for pathological examination.

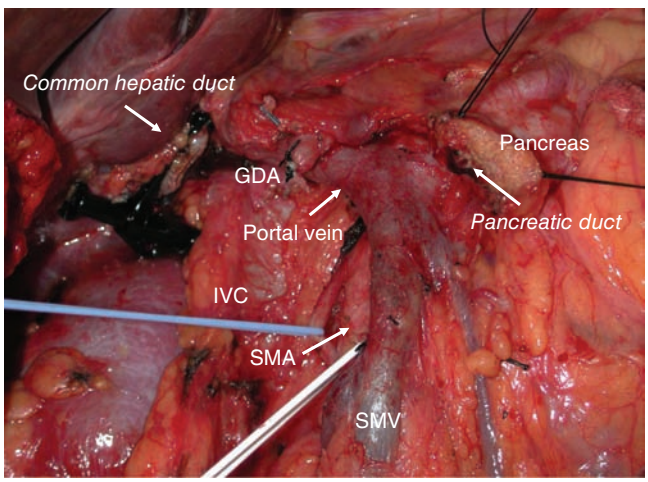

FIGURE 56-9 Retroperitoneal dissection for pancreaticoduodenectomy. Note the ligated gastroduodenal artery (GDA), portal vein, inferior vena cava (IVC), superior mesenteric artery and vein (SMA, SMV), and the main pancreatic duct at the edge the transected pancreas. (Reproduced from, Ahmad SA, Wray C, Rilo HL, et al. Chronic pancreatitis: recent advances and ongoing challenges. *Curr Probl Surg.* 2006;43(3):127–238.)

The reconstruction begins with the pancreaticojejunostomy (Fig. 56-10). The jejunum is advanced through the transverse mesocolon either to the right or left of the middle colic vessels according to surgeon's preference. Several techniques of pancreaticojejunostomy have been described. One commonly used approach is a two-layer method that is begun by placing a posterior row of interrupted nonabsorbable sutures between the pancreatic capsule and the seromuscular layer at the antimesenteric aspect of the jejunum. A small enterotomy is then made with bovie cautery across from the site of the main pancreatic duct at the pancreatic neck. An inner layer of four to eight interrupted fine absorbable monofilament sutures is used to secure the pancreatic duct to the intestinal wall at the enterotomy in a duct-to-mucosa fashion. An anterior row of interrupted nonabsorbable suture is then used to secure the anterior pancreatic capsule to the anterior serosa at the antimesenteric border of the jejunal limb. The duct-to-mucosa anastomosis may also be performed over a

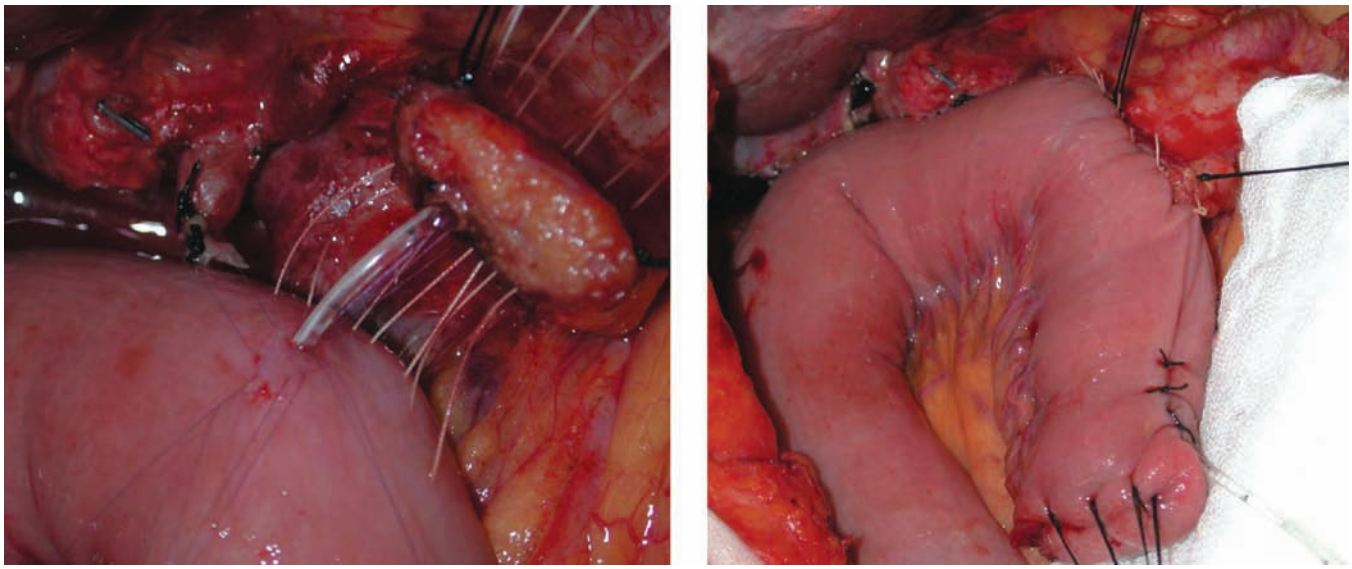

FIGURE 56-10 Pancreaticojejunostomy. At left, a duct-to-mucosa anastomosis is constructed using fine absorbable mattress sutures over a small (5F) pediatric feeding tube. At right, the completed anastomosis, with transanastomotic stent exteriorized through the jejunum and abdominal wall to divert pancreatic secretions. (Reproduced from Ahmad SA, Wray C, Rilo HL, et al. Chronic pancreatitis: recent advances and ongoing challenges. *Curr Probl Surg*. 2006;43(3):127–238.)

5F pediatric feeding tube, which can then be exteriorized through the jejunal limb using a Witzel-type closure. The choledochojejunostomy is then constructed at a site approximately 15 cm distal to the pancreaticojejunostomy. A small enterotomy is made at the antimesenteric border of the jejunal limb at this location. The choledochojejunostomy is also performed in a duct-to-mucosa fashion, either with a single layer of interrupted absorbable monofilament suture or, if the bile duct is dilated, using absorbable continuous suture. The pancreaticobiliary limb is then secured to the transverse mesocolon using interrupted sutures and any potential gap through which herniation may occur is closed. The retroperitoneal space at the level of the ligament of Treitz is also closed. Gastric continuity is reestablished by means of an antecolic loop gastrojejunotomy performed at a site sufficiently distal to the transverse mesocolon closure to prevent angulation of the afferent limb. A Hofmeister-type configuration is typically used, wherein the lesser curvature half of the gastric transection line is oversewn and the anastomosis is performed to the greater curvature half. The jejunal limb is oriented with the afferent limb toward the lesser curvature, efferent limb to the greater curvature. A two-layered anastomosis is preferred, with an outer layer of nonabsorbable interrupted seromuscular Lembert sutures and an inner continuous absorbable Connell-style layer. The abdomen is then irrigated with saline or dilute antibiotic solution and the abdominal wall closed. No closed suction peritoneal drains are necessary.

BEGER PROCEDURE—TECHNIQUE

Duodenum-preserving pancreatic head resection was first described by Beger in 1972. The operation evolved from the premise that a pancreaticoduodenectomy was unnecessarily radical for benign pathology and that a more limited resection preserving the duodenum would avoid some of the adverse sequelae associated with pancreaticoduodenectomy such as delayed gastric emptying and insulin-dependent diabetes.[63] The procedure is performed through a midline laparotomy or bilateral subcostal incision. As at the start of the pancreaticoduodenctomy, the gastrocolic ligament is separated or divided, the transverse mesocolon is mobilized off the head of the pancreas and duodenum, and a wide Kocher maneuver is performed. A cholecystectomy is performed. The GDA is isolated and divided. A tunnel is then created between the pancreatic neck and superior mesenteric vein or portal vein. The pancreatic neck is divided at this location and the pancreatic head manually rotated out of the retroperitoneum so that the cut edge faces up into the midline wound. The cystic duct is cannulated with a Bakes dilator and the CBD manually palpated in the head of the pancreas. Electrocautery is then used to core out the head of the gland with care taken to leave a rim of pancreas attached to the duodenum and to leave the bile duct intact within that rim (Fig. 56-11). The specimen is submitted to pathology for frozen-section examination to confirm the absence of malignancy. Pancreaticoenteric drainage is then reestablished by means of a two-sided Roux-en-Y pancreaticojejunostomy (Fig. 56-12). A Roux limb of jejunum is fashioned and advanced into the supracolic compartment through the transverse mesocolon as described for the lateral pancreaticojejunostomy. A two-layered handsewn duct to mucosa pancreaticojejunostomy is constructed at the neck margin as done for a typical pancreaticoduodenectomy with the exception that the anastomosis is sited closer to the mesenteric margin of the jejunum. The jejunal limb is then

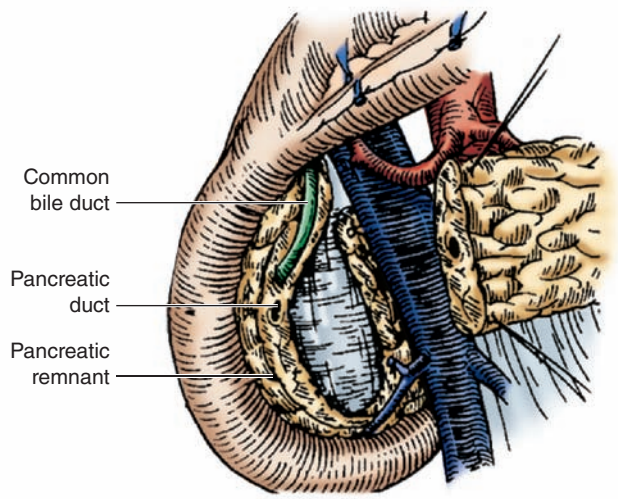

FIGURE 56-11 The anatomy following transection of the neck of the pancreas and removal of the head during the Beger procedure.

laid such that the antimesenteric border of the limb faces the midline wound. A second long pancreaticojejunostomy is constructed here by opening the border of the jejunal limb contralateral to the first pancreaticojejunostomy at the neck for a distance appropriate to include the entire length of the proximal pancreatic rim. This pancreatic margin is then secured to the long longitudinal enterotomy by means of a single layer of interrupted nonabsorbable suture. Intestinal continuity is then reestablished by means of a jejunojejunostomy performed as described earlier for the lateral pancreaticojejunostomy. The abdomen is irrigated and closed. No closed suction drains are necessary.

BEGER PROCEDURE VERSUS PANCREATICODUODENCTOMY—OUTCOMES

Beger has recently reviewed his three-decade experience with DPPHR for chronic pancreatitis presenting with an inflammatory mass in the pancreatic head. His perioperative results demonstrate very reasonable rates of morbidity and mortality and an impressive improvement in pancreatic pain. His pancreatic fistula rate is reported as 3.3%, the rate of delayed emptying reported is 1.5%, and perioperative mortality rate is 0.7% in 603 consecutive patients. Late outcomes reported in this series demonstrated 91.3% of patients are free of pain at a median follow-up of 5.7 years.[64] There have been two randomized trials that have attempted to compare outcomes from DPPHR to those achieved with pylorus-preserving pancreatoduodenectomy (PPPD). The most widely cited is by Buchler and colleagues and has been recently represented with long-term results. In this study 40 patients with chronic pancreatitis and a dominant focus in the pancreatic head were randomized to PPPD or DPPHR. The initial paper reported 6-month outcomes. This demonstrated a statistical advantage to DPPHR with regard to pain (75% of patients undergoing DPPHR were pain free at 6 months vs 40% of patients undergoing PPPD) and weight gain (average weight gain for those undergoing DPPHR was 4.1 kg whereas that for those undergoing PPPD was 1.9 kg).[65] Length of hospital stay, perioperative morbidity and perioperative mortality rates were statistically identical. The authors of this study have recently presented their long-term results. At median follow-up of 7 years, the early advantages of the DPPHR were no longer evident with patients in each group having identical health-related quality of life scores, identical pain scores, and identical rates of exocrine and endocrine insufficiency. The other randomized comparison again studied only 40 patients

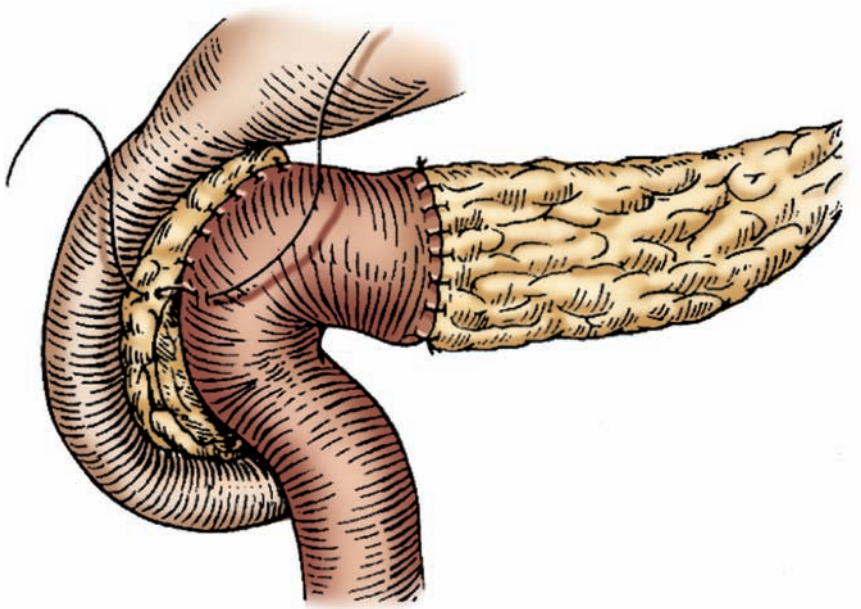

FIGURE 56-12 Final anatomy of the reconstruction following a Beger procedure.

for 12 months. This study demonstrated statistically identical rates of pain relief but a slight statistical advantage in terms of scores seen on a general assessment of health-related quality of life for patients undergoing DPPHR relative to those undergoing PPPD.[58]

FREY PROCEDURE—TECHNIQUE

The disadvantage of the DPPHR as described by Beger is that it does not address disease (either diffuse parenchymal fibrosis with side branch disruption or stricturing with upstream dilation of the main pancreatic duct) that may coexist in the pancreatic body and tail. Late failures of the Beger procedure have been attributed to poor drainage of the pancreatic body and tail. In an effort to overcome this, and in large part to avoid the certain exocrine and endocrine insufficiency that comes with the near-total pancreatectomy pioneered by one of his early mentors, Frey and colleagues developed a procedure that combines a duodenum-preserving pancreatic head resection with a hybrid resection or drainage procedure at the pancreatic body and tail (referred to as a local resection of the pancreatic head with longitudinal pancreaticojejunostomy or LR-LPJ) (Fig. 56-13). In this procedure, no tunnel is created behind the pancreatic neck. Instead the entire length of the pancreas is exposed anteriorly. The GDA is ligated. The gallbladder is removed. The cystic duct is cannulated using a Bakes dilator and the bile duct is identified in its course through the head of the pancreas by palpating the dilator. The pancreatic head is then excavated down to the level of the portal vein with care taken to leave a rim of tissue surrounding the bile duct at the duodenal margin. From this cavity an extensive longitudinal unroofing of the pancreatic duct through the body and tail is made using electrocautery. If the duct is not dilated in the tail, then the body and tail may simply be excavated as done at the pancreatic head (Fig. 56-14). Pancreaticoenteric drainage is then accomplished by means of a lateral pancreaticojejunostomy covering the entire excavation cavity, typically constructed using a Roux-en-Y jejunal limb sewn to the pancreatic capsule in one or two layers.

FREY PROCEDURE VERSUS BEGER PROCEDURE—OUTCOMES

In various reports including small randomized trials, the results of LR-LPJ appear similar to those reported for the Beger DPPHR, with postoperative mortality less than 1% and morbidity reported as 19–32%.[60,66] Excellent pain relief is obtained in about 75% of patients and the change in postoperative pain scores and rates of postoperative exocrine and endocrine insufficiency are identical over follow-up as long as 9 years. A small prospective randomized trial compared LR-LPJ to PPPD with an average length of follow-up of 2 years. Postoperative morbidity was significantly higher in the PPPD group (53 vs 17% for the LR-LPJ group). Although there was similar improvement in pain symptoms, the LR-LPJ group demonstrated a statistically better overall quality of life as assessed by a general assessment of health-related quality of life.[67] The long-term results of the study were published in 2008 with a median follow-up of 7 years. At that length of follow-up, there were no statistical differences with regard to the improvement in pain, health-related quality of life or the incidence of exocrine or endocrine insufficiency.[68]

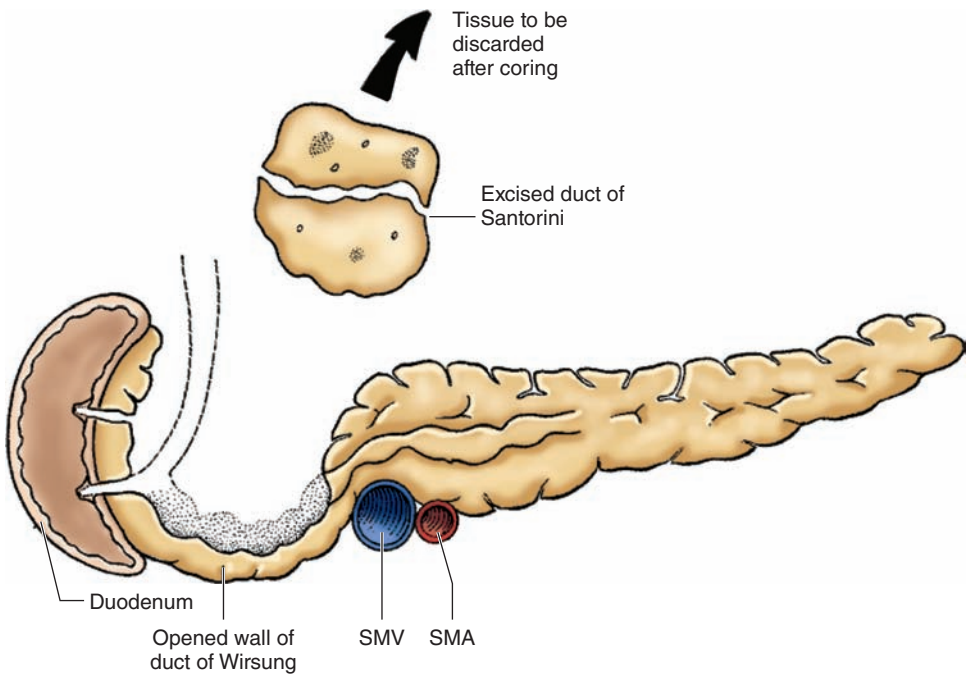

FIGURE 56-13 Cross-sectional drawing of the pancreas following coring of the pancreatic head during a Frey procedure.

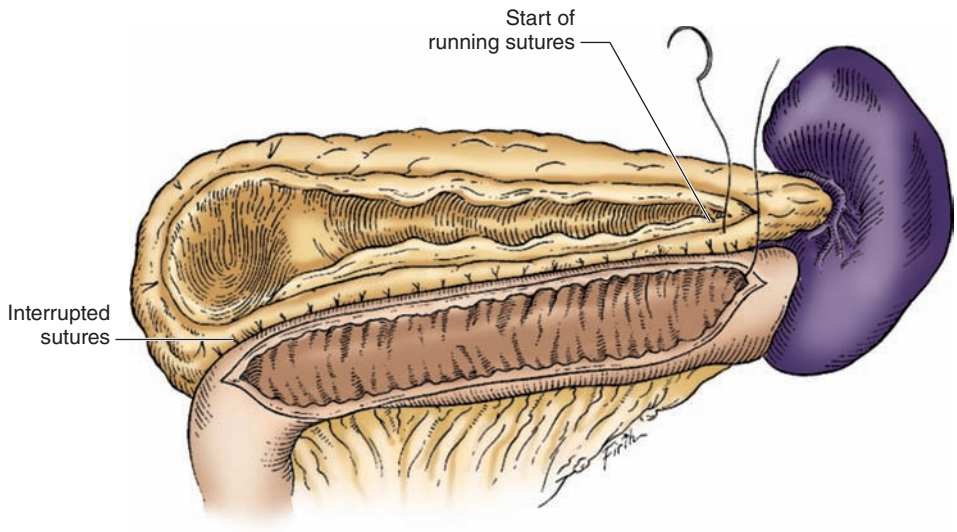

FIGURE 56-14 Pancreaticojejunostomy (Frey procedure).

BERNE PROCEDURE—TECHNIQUE AND OUTCOMES

There has been one further modification of the Beger DPPHR made in recent years. The Berne procedure adopts the technical safety advantage of the Frey LR-LPJ that comes by avoiding transaction of the neck of the pancreas off the portal vein. In this modification as in the Beger DPPHR, no lateral pancreaticojejunostomy is performed. The anterior surface of the mass in the head is palpated and then cored out by electrocautery. A Roux limb is then sewn to the residual pancreatic rim at this location. One randomized trial comparing the Berne modification to the standard Beger DPPHR showed rough equivalence of outcomes with these procedures.[59]

Small Duct Disease or Diffuse Sclerosis

In many instances, as the disease progresses there will be no dominant focus of ductal obstruction and no dominant mass. Instead the morphology of the disease is characterized by diffuse calcification and/or diffuse fibrosis with atrophy of the pancreatic parenchyma. In these cases the pancreatic remnant may be quite small and will have a uniform firm consistency. Patients with this morphology of disease present a particular challenge, as there is no discrete target for either endoscopic or surgical intervention. Those manifesting intractable pain syndromes have had, until very recently, few and imperfect options for surgical management. These have included total or near-total pancreatectomy procedures that have traditionally been avoided due to the significant morbidity associated with profound postoperative exocrine and endocrine insufficiency. Autologous islet transplantation may mitigate the diabetic consequences of total pancreatectomy. Another alternative for small duct disease is the V-shaped or wedge pancreatectomy described by Izbicki.[69]

TOTAL PANCREATECTOMY WITH AUTOLOGUS ISLET TRANSPLANTATION—TECHNIQUE

Total pancreatectomy is performed as either an en bloc resection of the pancreatic head, body, and tail or, more commonly, in a staged fashion with a left pancreatectomy followed by a head resection (pancreaticoduodenectomy) allowing initial islet processing on the body and tail specimen. The isolation process relies on enzymatic and mechanical mechanisms to dissociate the islets from surrounding acinar tissue and fibrosis. Depending on the proximity of the islet isolation facilities and the efficiency of the process, infusion of the islet preparation into the portal circulation may be performed during the same anesthetic or postoperatively (usually the same day) under radiological guidance.[70] Briefly, the resected pancreas is cooled to 4°C in an organ-preserving solution (eg, University of Wisconsin Solution). The pancreas is then transected at the neck of the gland and the pancreatic duct cannulated. The ductal system is then perfused with a cold solution of the purified digestive enzyme collagenase. The gland is sectioned, and then physically shaken in a small digestion chamber at 37°C until the acinar tissue is separated from the endocrine tissue. The islets are then partially purified from the acinar debris by gradient density centrifugation on a cold dextrose gradient. The islets are washed and resuspended in an albumin-rich transplant medium or cultured. The islets are transplanted by direct injection into portal circulation with access to the portal circulation being achieved under ultrasound-guided percutaneous placement of a transhepatic portovenous catheter in interventional radiology or by direct operative cannulation of the portal vein.

AUTOLOGUS ISLET TRANSPLANTATION—OUTCOMES

The first human autologous islet transplant was performed at the University of Minnesota in 1977 and since that time several hundred procedures have been reported from Minnesota, Miami, Cincinnati, Leicester, and other emerging centers.[71] Taken together, the results from these institutions suggest that in a highly selected group of patients, complete pain relief (without the use of narcotics) can be achieved in approximately 50–60% of patients but that there is a significant rate of recidivism of pain after 1 year of follow-up. Insulin-independence is initially achieved in 40–50% of patients but there is a steady decline in islet function that continues even at 10 years of follow-up. Although reports of assessment of quality of life after total pancreatectomy with autologous islet transplantation suggests that the procedure compares favorably to either total pancreatectomy without islet transplantation or to continue nonoperative management of pain, direct evidence supporting this approach over alternatives in appropriately matched controls is lacking. Total pancreatectomy with autologous islet transplantation is costly and requires a high degree of technical expertise that is difficult to replicate. The indications for islet autotransplantation are controversial and the overall safety and efficacy of the procedure have not been fully validated outside a handful of centers. Questions regarding the long-term viability of the islets and adverse impact on the surrounding liver parenchyma have been raised. Pathologic analysis of liver tissue that has been explanted following islet transplant has demonstrated that the transplanted islets typically migrate across the liver sinusoids and reside in the liver parenchyma. It has also been noted that the transplanted islets exhibit some degree of peri-islet fibrosis in the liver. There have been no reports of chronic hepatic fibrosis or cirrhosis in patients receiving autologous islets but the concern exists. It must be emphasized that complete long-term insulin independence is achieved only in a relatively small minority of patients after islet autotransplantation and that pain is persistent or recurrent in about half of patients even after total pancreatectomy.[72] Currently, the strongest arguments in favor of total pancreatectomy and islet autotransplantation can perhaps be made in the setting of a limited subset of patients with hereditary pancreatitis, who otherwise carry a significant long-term risk of developing pancreatic cancer. When a more traditional surgical operation (resection or drainage) is also possible in this setting, decision making must be highly individualized (Fig. 56-15).

IZBICKI PROCEDURE—TECHNIQUE AND OUTCOMES

An alternative to total pancreatectomy (with or without islet autotransplantation) that may yield similar rates of pain relief yet preserve islet function is the V-shaped longitudinal pancreatic resection introduced by Izbicki and colleagues for patients with small duct disease and diffuse fibrosis. In this procedure the entire pancreas is excavated along the trajectory of the main pancreatic duct from the pancreatic head (as with the Frey procedure) across the body and tail of the organ. Pancreaticoenteric drainage is established by Roux-en-Y lateral pancreaticojejunostomy similar to the Puestow and Frey procedures. The short-term results of the Izbicki procedure compare favorably to those reported in the Minnesota and Cincinnati series of autologous islet transplantation, although the patient populations are not matched.[61]

FIGURE 56-15 Hereditary chronic pancreatitis associated with *PRSS1* gene mutation. A single calcification is evident in the pancreatic head, and the main pancreatic duct shows diffuse dilation. Lateral pancreaticoduodenectomy is an appropriate surgical option; total pancreatectomy with islet autotransplantation to eliminate cancer risk associated with hereditary pancreatitis is controversial.

CONCLUSIONS

Chronic pancreatitis is a relapsing inflammatory process that results in a variable degree of parenchymal destruction and fibrotic change in the pancreas with consequent clinical manifestations typically including characteristic abdominal pain, exocrine and endocrine insufficiency. A single unifying model for the pathogenesis of chronic pancreatitis remains elusive, although recent basic and clinical research has identified a number of gene mutations, immunologic conditions, environmental toxins, and anatomic anomalies that alone and together confer risk of developing chronic pancreatitis. The morphology of pathological change seen in the gland at the time that patients present for treatment varies significantly from one patient to the next. A myriad of endointerventional and surgical procedures have been developed over time and are now applied in the treatment of the disease. Both the endoscopic and surgical procedures used are technically demanding and carry substantial risk of morbidity.

While there is substantial retrospective, case-series evidence demonstrating the utility of these approaches in well-selected patients, high-level evidence comparing the efficacy of the interventions in large series is lacking. For all of these reasons, chronic pancreatitis is often best managed in experienced centers in which multidisciplinary teams collaborate to individualize treatment in the context of established local expertise with various medical, endoscopic, and surgical therapies.

PERSPECTIVE ON MANAGEMENT OF PATIENTS WITH SEVERE ACUTE PANCREATITIS

Timothy R. Donahue • Howard A. Reber

INTRODUCTION

In the foregoing chapters, the authors have comprehensively reviewed the pathophysiology of patients with severe acute pancreatitis and the different approaches to the diagnosis and management of the disease. The reviews are extensive, particularly in regard to various medical and surgical interventional techniques. In an effort to simplify the management of these complex patients, we present here our own high-yield approach using the experience gathered over a 25-year period at a single center. This management strategy has resulted in excellent results with morbidity and mortality rates amongst the lowest reported.[1]

PRESENTATION AND INITIAL ASSESSMENT

There is general agreement that patients with severe acute pancreatitis should be referred *early* in the course of their disease to a tertiary high-volume medical center where an experienced multidisciplinary team can provide coordinated care. In practice, however, the referral is often delayed for several weeks or more while the patient continues to deteriorate or the physicians in charge are frustrated because there is no improvement in the patient's condition. There may be a question as to whether surgery is indicated. Thus, the patients we see are often at least several weeks into their illness, and may have failure of one or more organ systems when they arrive at our center. Some may require ventilatory support; some have developed renal failure. They usually have been placed on antibiotics and may have one or more abdominal drains that were inserted by an interventional radiologist at the referring institution. Their management is outlined in the subsequent discussion (Fig. 57-1).

First 24–48 hours

Upon admission, patients are placed in the intensive care unit (ICU). Appropriate intravenous (IV) fluid resuscitation is continued and central monitoring is established. After the medical records from the referring hospital are reviewed, consults from indicated disciplines (eg, cardiology, pulmonary, nephrology, gastroenterology, etc) are requested. The outside imaging is assessed with the radiologists. At this point, we usually repeat the abdominal imaging to provide up-to-date information about the patient's condition.

At that time, the pancreatic parenchyma and surrounding tissues are evaluated for evidence of inflammation, necrosis, fluid collections, and/or infection. These findings are best displayed by a high-resolution pancreatic protocol CT scan. The pancreatic protocol calls for a precisely timed IV contrast infusion to enhance the pancreatic parenchyma, and surrounding tissue and vessels. Following the injection of the contrast, successive 2- to 3-mm images of the pancreas are obtained during the "pancreatic arterial phase" followed by 5-mm images during the "venous phase." Oral contrast is not administered. During the pancreatic phase the pancreatic parenchyma and the distribution of the celiac axis and superior mesenteric arteries are enhanced with contrast; the venous phase demonstrates the areas drained or supplied by the superior mesenteric, portal, and splenic veins. The parts of the pancreatic parenchyma that do not enhance with IV contrast during the pancreatic arterial phase are presumed to be necrotic. Furthermore, infection is highly suspected if there are gas bubbles present, so long as the pancreas and peripancreatic tissues have not been instrumented recently (eg, percutaneous drain, etc). The gas is produced by bacterial growth and fermentation. The presence of a significant amount of pancreatic necrosis and/or infection raises the general level of concern

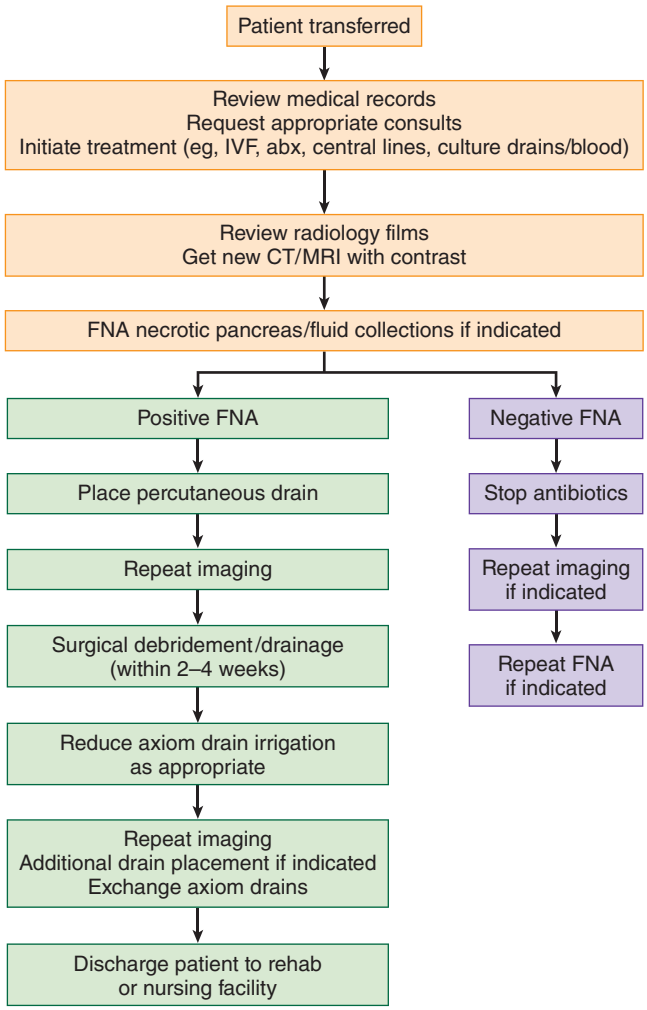

FIGURE 57-1 An overview of the management of patients with severe acute pancreatitis.

about the severity of the patient's course and influences future management decisions. If patients have an iodinated contrast allergy, a magnetic resonance imaging (MRI) or magnetic resonance cholangiopancreatography (MRCP) with precisely timed IV gadolinium contrast to reveal the pancreas and surrounding tissues is also satisfactory.

The large amount of cytokines often released in patients with severe acute pancreatitis may result in leaky capillaries and fluid extravasation to the interstitium. Thus, many of them have a depleted intravascular space, and a component of prerenal insufficiency. However, we still perform an IV contrast computed tomography (CT) scan as long as the serum creatinine is less than 1.5 mg/dL. All patients are kept well hydrated to minimize the chance of contrast-induced nephropathy. *N*-acetylcysteine (Mucomyst) is also administered as an adjunct. If the degree of renal failure is more severe, an MRI with IV gadolinium is done instead. However, if the patient's glomerular filtration rate (GFR) is lower than 30 mL/min/1.73 m^2, neither iodinated nor gadolinium contrast can be administered. Gadolinium can cause toxic skin necrosis in patients with severe renal failure. Then, we would perform a high-resolution CT scan without any contrast. Of course this limits the ability to detect necrosis of the pancreatic parenchyma as well as peripancreatic inflammation.

We try to avoid prophylactic antibiotics, since they can lead to bacterial resistance and fungal superinfection, and also can confound the results of a fine-needle aspiration (FNA). In patients who arrive with a percutaneous drain in place and are already on antibiotics, we will continue the drugs but may change them based on the culture results (blood, abdominal fluid, FNA) from the referring institution as well as new cultures drawn on arrival. If there is no evidence of infection on high-resolution imaging and/or FNA, then the antibiotics are stopped. We limit the use of antifungals to patients with culture-proven fungal infections and/or unexplained elevations in their white blood cell count despite being on an effectively tailored antibiotic regimen.

After the patient is adequately resuscitated and stabilized, and all pertinent tests have been reviewed, an FNA of the pancreatic parenchyma and/or fluid collections is performed for almost all patients. All transferred patients with percutaneous drains in place undergo a fresh FNA. An FNA is also performed on those patients who have suspicious features on imaging (eg, nonenhancing pancreas), and have clinical signs of infection (eg, fever, elevated white blood cell count). At the time of FNA, in patients without a drain in place, we specifically ask the radiologist to *not* leave a percutaneous drain following the aspiration. Such a drain often infects a sterile fluid collection and/or necrosis. The FNA fluid should be sent for a Gram stain, anaerobic and aerobic bacterial culture, and a fungal culture. If the Gram stain and/or culture results suggest infected pancreatic necrosis or fluid collections, then percutaneous drains are placed where appropriate. Patients who have clear evidence of infection on high-resolution imaging as previously discussed (eg, gas bubbles) have a percutaneous drain placed during the first procedure within the day 1 or 2 of hospitalization. The drain fluid is cultured.

The percutaneous drain definitively addresses the infection only rarely (see later). Rather, its primary roles are to delay the timing of surgery until the patient's overall condition has improved, and/or to provide a landmark, a route to follow, for laparoscopic drainage. The patient's sepsis may improve dramatically with adequate percutaneous drainage. Also, additional time allows for the necrosis and fluid collections to organize and become better defined, minimizing the debridement and drainage that will be required later. In patients who are transferred with percutaneous drains in place, we often change the drains to larger ones (eg, 28–30F diameter red rubber catheters), as the pigtail drains that are usually in place are often too small for effective drainage. We also may ask the interventional radiologist to percutaneously drain other areas that were not adequately addressed.

Sometime during the first week or so of management, a detailed discussion should be held with the patient and family about the seriousness of the problem, the potential for recovery, and the likely long course of hospitalization and rehabilitation (1 year or more in some cases). Some patients

have become severely depressed and required psychiatric treatment as part of the overall treatment program. They need to know early on what is in store.

DEFINITIVE DRAINAGE

Who and When?

Despite the percutaneous drainage techniques previously discussed, most patients with infected pancreatic necrosis eventually benefit from definitive surgical drainage during their hospital course. This includes patients who have infected pancreatic necrosis and/or fluid collections that initially responded to drain placement, but whose septic course continues. Surgery is usually performed 2–4 weeks after transfer to our center. Definitive surgery should not be delayed for weeks or more hoping that an operation can be avoided in this group of patients. A minority of patients with radiographic or culture evidence of infection and clinical sepsis who are not responding to percutaneous drainage and resuscitative measures, may need to be taken to surgery sooner, however.

Although they are not critically ill, another group of patients who eventually requires surgery are those who present a few weeks to months after their episode of acute pancreatitis and fail to improve. On CT scan they may have evidence of sterile walled-off pancreatic necrosis. These patients often present with obstructive symptoms (eg, inability to tolerate oral intake) or generalized abdominal pain. Some physicians prefer that these patients (with fluid collections, no infection, ongoing symptoms) be managed by percutaneous or endoscopic-guided drainage without surgery. If the fluid is clear and without particulate matter, this may be effective. However, patients with debris within the fluid should generally not be managed with endoscopic or percutaneous drainage techniques. The particulate matter clogs the drain(s), infection supervenes, and the overall condition deteriorates. Despite the lack of an infection, open surgical debridement and drainage is preferred in this group.

How?

We have experience with closed laparoscopic and open transabdominal techniques, and prefer the latter for most patients. The general principles of both techniques are the same and include (1) complete drainage of fluid and debridement of infected or necrotic pancreatic and peripancreatic debris, and (2) placement of large-bore Silastic sump drains with closed continuous postoperative lavage.

For the open approach, a midline or bilateral subcostal incision is used. The midline incision is usually reserved for thin patients and/or those who have peripancreatic fluid collections that may extend to the lower abdomen. This incision is associated with less postoperative pain than a subcostal incision. However, the subcostal approach allows better exposure to the lateral aspects of the lesser sac. The posterior and anterior fascial layers are reapproximated separately with running or interrupted 0 or #1 polydioxanone (PDS) absorbable sutures, which makes a hernia unlikely. With either incision, the skin edges are loosely approximated with staples and Kerlix Packing is tucked between them to reduce the chance of a wound infection.

After entering the peritoneal cavity, the lesser sac is entered either through the gastrocolic ligament or the transverse mesocolon. If the ligament is fused to the inflammatory mass behind it then the transverse colon is elevated and the location of the mass is identified through the tented mesentery. The site for entry through the mesentery can be identified by aspiration via a 16- or 18-gauge needle, or the space can be entered directly with electrocautery if it is otherwise apparent. The mesocolon is opened widely with an effort to avoid injury to the colon and vessels. After a window is created and the cavity is entered, the infected pancreatic necrosis is debrided with ringed forceps. If significant bleeding is encountered, it means that particular area is still viable and does not need additional debridement. Oozing in one area should be packed while another area is debrided. Once the oozing stops, that area is addressed again. Occasional suture ligatures may be needed to stop brisk arterial or venous bleeding. Bleeding is usually not a significant problem if one debrides only the necrotic material; many of the vessels are thrombosed. We use monofilament (eg, Prolene) sutures rather than silk which can serve as a nidus for infection. Copious irrigation helps to clean out the debris from the cavity. All of the areas of infected necrotic pancreas and peripancreatic tissues should be debrided. The radiographic images should be available in the operating room to be certain that this is accomplished.

After the debridement is complete, we place one or more closed suction continuous irrigation drains (Axiom) into the areas that have been debrided. An effort should be made to place the drains so they do not lie on top of the colon, to avoid erosion into the bowel lumen. Approaching the lesser sac through the transverse mesocolon rather than the gastrocolic ligament facilitates this. Axiom drains contain three separate lumens. The largest lumen in the middle is hooked to low continuous wall suction. The two smaller lumens on the sides are used for (1) continuous irrigation with saline and (2) left open to air as a sump. We do not close the gastrocolic ligament and/or transverse mesocolon around the drains, which has been suggested by others in an effort to contain the infection within the lesser sac.

If a laparosopic drainage is planned, we place a percutaneous drain prior to surgery. The drain can then be followed into the lesser sac to the fluid collection and necrotic pancreas. Debridement of infected necrotic pancreas can be performed with platypus-like instruments. The axiom drains are placed using the same technique as previously discussed with the open approach, and they are brought out through anterior abdominal wall via the trocar sites.

If a diagnosis of gallstone pancreatitis has been made, we also prefer to remove the gallbladder at the initial operation, if it can be done safely. This decision is made by inspecting

the porta hepatis for inflammation. Some bleeding is usually encountered in the gallbladder fossa of the liver, and this is controlled with Argon beam coagulation. The surgical approach that is selected (eg, laparoscopic vs open) does not influence our decision to remove the gallbladder.

This strategy is associated with excellent morbidity and mortality rates that are consistent with some of the best series that have been reported.[1] The overall 30-day perioperative mortality is less than 10% and is due to recurrent sepsis with multidrug-resistant bacteria and/or other existing comorbidities in most cases. Furthermore, the reoperation rate is less than 5%. Recurrent fluid collections occur in 25–30% of the patients, but these can almost always be managed by percutaneous drainage placed by the interventional radiologist. Almost all patients are discharged from the hospital to rehabilitation or skilled nursing facilities for an additional period of recovery.

Postoperative Management

All patients should be placed into the ICU even if they did not require intensive care preoperatively because many of them experience a transient period of bacteremia and sepsis as a result of the operation. As previously discussed, these patients require aggressive fluid resuscitation and adequate central monitoring (eg, central venous catheter, etc).

Each Axiom drain should be irrigated at 100 mL/h continuously with 0.9 normal saline, and the suction port aspirated with the vacuum set at low continuous suction. This irrigation rate is continued for at least 24 hours, and until the effluent becomes less particulate, the white blood cell count normalizes and the patient's septic physiology resolves. The rate of irrigation is then cut in half until the drains are left to gravity (eg, 100, 50, 25). This process usually takes 1–2 weeks to complete. During this time, we usually get a contrast-enhanced CT scan on a weekly basis or as it is clinically indicated (eg, rising white blood cell count, etc). After the drains are put to gravity, they are exchanged in radiology after at least 2 weeks from the time they were placed at operation, for large-bore red rubber catheters (28–30F diameter). Once continuous irrigation of the drains is stopped, the drains should still be irrigated 3–4 times per day with 20–30 mL of sterile saline to maintain their patency. The effluent drains into a plastic bag.

In parallel, we enterically feed these patients as early as possible. This usually occurs by the end of the first postoperative week, once bowel function has returned. They are most often nutritionally depleted due to their acute episode with less than 10 mg/dL serum prealbumin levels. They are often on total parenteral nutrition prior to surgery, and this should be continued until they are nutritionally replete (albumin >3 mg/dL) which is often at the time of discharge or later.

We do not routinely place feeding tubes (eg, gastrostomy or jejunostomy) at the time of surgical debridement. Rather, a nasogastric tube is placed with its position confirmed in the body of the stomach. If necessary, a Dobhoff tube is also placed postoperatively. We have found that transnasal feeding tubes are sufficient. Surgical tubes have a number of potential risks that should be avoided. They can leak, and jejunostomy tubes can cause a bowel obstruction, particularly if the balloon is overinflated. Furthermore, the peritoneal irrigation that is continued for the first few postoperative weeks can leak around the feeding tube site, complicating management. In addition, many patients can eat on their own within a few days of the surgery.

After discharge, we see these patients in the office every 1–2 weeks until their stability is assured. In patients who still have drains in place, daily irrigations are continued. If there is no evidence of a pancreatic fistula, the drains are withdrawn several inches at each office visit, through the tracks that have developed. Over 4–6 weeks, the drains have usually been removed. If a pancreatic fistula is present, the drain must be left in place until the fistula closes or the patient is operated upon to close the fistula. Operative fistula repair in most of these patients should not be done for a minimum of 9–12 months after the surgical debridement.

CONCLUSION

Patients with acute necrotizing pancreatitis are often difficult to manage, both in the acute setting and after discharge from the hospital. They are often hospitalized for a long time (months), are in the intensive care unit, and require multiple interventional procedures. There are many points in their care where important management decisions need to be made. During this process, it is important for the clinician to remember that most of these patients will in fact completely recover and will have an excellent quality of life after the episode resolves.[2,3] The patient and family also need to be continually reminded and reassured.

CYSTIC NEOPLASMS OF THE PANCREAS

Warren R. Maley • Charles J. Yeo

INTRODUCTION

Cystic neoplasms of the pancreas and other cystic lesions, many of which cause "cyst-like" dilatations of the main or branch pancreatic ducts are collectively referred to as cystic lesions of the pancreas on cross-sectional imaging of the abdomen. The incidence of these cystic lesions increases with age. One autopsy study has demonstrated that up to a quarter of elderly individuals harbor cystic lesions of the pancreas at their demise.[1] With the ever increasing use of computed tomography (CT) and magnetic resonance imaging (MRI), cystic lesions of the pancreas are being defined with progressively greater frequency, and an ever increasing number are asymptomatic at discovery.[2,3] Some of these lesions will be malignant or have malignant potential at diagnosis, while others are clearly benign and may not warrant further surveillance. Resection of benign cystic pancreas lesions or those containing only carcinoma in situ leads to nearly universal survival, while surgery for invasive carcinoma associated with cystic neoplasms generally has a more favorable prognosis than the results for pancreatic ductal adenocarcinoma.[4,5] Thus careful consideration must be given to the diagnosis and prognostic implications of these lesions.

An ideal diagnostic approach would allow for the resection of only those lesions with present or near-future risk of malignancy, while excluding from surgery those individuals with either benign lesions or a prohibitive operative risk, thus minimizing the potential occurrence of mortality and morbidity associated with the surgical treatment of these cystic lesions. Recent advancements in imaging by CT, MRI, and endoscopic ultrasonography (EUS), linked with refinements in the pathological understanding of cystic neoplasms of the pancreas have furthered this effort. History and clinical criteria, such as age, gender, presence of symptoms, location of the neoplasm within the pancreas, as well as, morphology by cross-sectional imaging and cyst fluid analysis by EUS with fine-needle aspiration (EUS-FNA), all may play a role in the diagnosis of pancreatic cystic neoplasms and assessment of the need for resection. A recent analysis using decision analysis with Markov modeling has indicated that for patients focused on overall survival, regardless of quality of life, surgery is optimal for branch duct lesions greater than 2 cm in size.[6] For patients more focused on quality-adjusted survival, a 3-cm threshold is more appropriate for surgical intervention, except for the very elderly patients.

Pancreatic pseudocysts (or early postpancreatitis acute fluid collections) have been considered as the most common non-neoplastic cysts of the pancreas. Their diagnosis is aided by a history of acute or chronic pancreatitis.[7] Congenital cysts are rare and include those associated with genetic diseases such as autosomal dominant polycystic disease,[8] cystic fibrosis,[9] and von Hippel-Lindau (VHL) disease.[10,11] Lymphoepithelial cysts are rare benign lesions of the pancreas lined with squamous epithelium.[12]

Three cystic lesions make up 90% of the cystic neoplasms seen in the pancreas: serous cystic neoplasms (SCNs), mucinous cystic neoplasms (MCNs), and intraductal papillary mucinous neoplasms (IPMNs). SCNs rarely demonstrate a progression to malignancy. Unequivocal definition of an SCN may permit nonoperative management of these lesions, provided symptoms do not mandate resection. Mucin-producing lesions of the pancreas can be segregated into two types which may differ significantly in natural history. Restriction of the definition of MCNs, to include only those lesions with subendothelial ovarian-type stroma, has permitted an improved distinction between MCN and IPMN.[13] Recent consensus guidelines developed by the International Association of Pancreatology[14] may assist in the management of cystic neoplasms of the pancreas. The premalignant nature of MCN prompts resection in patients who are acceptable operative risks, while observation of some branch duct IPMNs, may be tenable with an eventual risk of malignancy less than the operative mortality of pancreatic resection.[6] Finally, solid pseudopapillary neoplasms (which may have cystic components) are rare lesions occurring predominantly in young women, for which, resection of the primary tumor results in an excellent opportunity for cure.

PATHOLOGICAL CLASSIFICATION

The accurate pathological description of pancreatic cystic neoplasms has evolved significantly in the past two decades, influenced largely by an improved understanding of the malignant potential of MCNs, in comparison to the largely benign SCNs, and the emergence of an understanding of the pathogenesis and behavior of IPMNs. Current classification of these tumors follows the World Health Organization (WHO) International Classification of Tumors as published in 2000 (Table 58-1).[15] While the diagnostic criteria and organizational schema for these tumors are likely to be adapted further in future editions, the current classification system provides a means to stratify these tumors in terms of prognosis and management. In this review, particular attention will be paid to the three most common lesions: SCNs, MCNs, and IPMNs.

SEROUS CYSTIC NEOPLASMS

SCNs, previously referred to either as serous cystadenomas, glycogen-rich adenomas, or microcystic adenomas, are almost always benign. Careful delineation of the radiological and clinical features that distinguish these lesions may support and facilitate nonoperative management (ie, observation) of these lesions.

Pathological Features

The majority of SCNs are polycystic or so-called microcystic adenomas, characterized by a well-circumscribed, soft mass which includes numerous small cysts filled with clear serous fluid arranged in a characteristic honeycomb-like pattern. Larger cysts may line the periphery of the lesion. The multiple small cystic loculations are well defined and often focus on a central stellate scar with or without calcifications. These features may be highly suggestive of an SCN when seen on CT or magnetic resonance imaging (MRI) (Fig. 58-1). A small number of SCNs (≤10%) are oligocystic adenomas, and present with one or more dominant cysts, rather than multiple conjoined microcysts. These unusual SCN lesions may be more difficult to distinguish radiographically from MCNs, IPMNs, pseudocysts, and other cystic lesions.

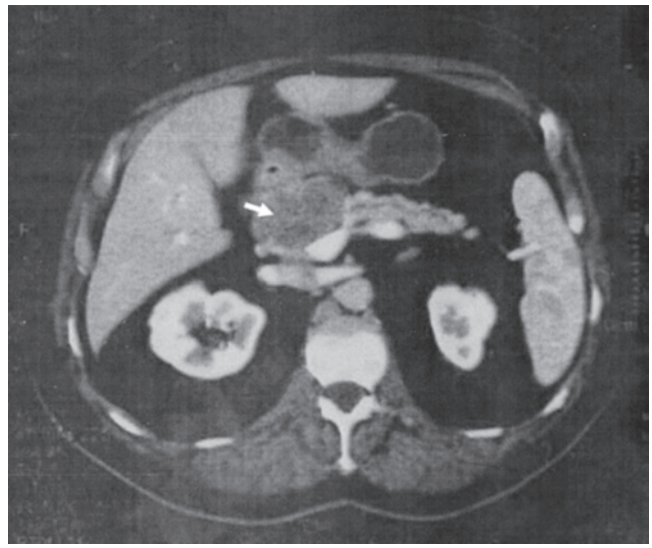

FIGURE 58-1 This CT image depicts a cystic neoplasm in the head and neck of the pancreas (*small arrow*) detected incidentally in a 75-year-old man undergoing evaluation for nephrolithiasis. The patient underwent a pylorus-preserving pancreaticoduodenectomy without complications. Final pathology revealed a 6-cm serous cystic neoplasm without evidence of malignancy.

Beyond these gross distinctions, both microcystic and oligocystic adenomas are composed of a single layer of simple cuboidal epithelium with rounded nuclei and clear cytoplasm which is glycogen rich and stains periodic acid-Schiff-positive (Fig. 58-2). The cystic fluid is serous and typically has no mucin content, with a low carcinoembryonic antigen (CEA) level (<5 ng/mL), factors that may provide diagnostic information upon cyst aspiration. Cytology diagnostic for SCN is present in less than 50% of cases; however, when positive the sensitivity is high.

The malignant potential of SCN is so low that most experienced centers recommend management of these lesions as benign entities. Certainly the argument can be made that a clearly documented classic-appearing SCN need not be resected, unless symptomatic or enlarging. The incidence of serous cystadenocarcinoma is extremely low, as fewer than 25 cases have been definitively documented in the literature.[16] In the largest single institution experience to date, Galanis and colleagues from Johns Hopkins reported on 158 patients with SCN, only one of whom had serous

Characteristic features include the single layer of cuboidal epithelial cells lining the microcysts within the lesion, uniform round nuclear architecture, and clear cytoplasm. The cyst cavities contain serous fluid and little cellular debris.

cystadenocarcinoma on presentation, while another patient, who had a "locally aggressive neoplasm," returned 13 years postresection with metastatic disease.[17] Thus, two cases of aggressive tumor were observed, out of 158 resected SCNs. Evidence of distant metastatic disease is typically necessary to confirm the rare diagnosis of serous cystadenocarcinoma, as both the primary and extrapancreatic disease may appear histologically indistinguishable from benign SCN.[18] Vascular and perineural invasion, or local invasion of the stomach and duodenum, are not sufficient criteria for the diagnosis of malignancy of SCN.[17,19]

Clinical Presentation

SCNs occur predominately in women in the sixth decade of life, while men tend to present at a later age. Bassi and colleagues described 100 patients with SCN, 87 of whom were female, with a mean age at presentation of 52 years.[20] The average age of the 13 male patients was 54 years. In another study from the Massachusetts General Hospital, 75% patients were women, and the female patients were significantly younger at presentation than were the men (60 vs 67 years, $p = .018$).[21] In the Galanis study from Johns Hopkins a similar number of patients were women (75%), though no age difference was noted between the genders.[17]

In 25–75% of the patients with SCN, abdominal pain is the presenting complaint.[17,20,21] Weight loss is seen in 14–22%,[17,20] and fewer patients (10%)[20] present with a mass or fullness. Symptoms typically associated with invasive disease, such as jaundice (6%) or pancreatitis, are uncommon.[17] Nausea and vomiting related to compression of the upper gastrointestinal tract may occur in 7–10% of patients.[20]

Traditionally, SCNs have been described as having a predilection for the pancreatic body and tail, though Le Borgne and coworkers described a relatively even distribution throughout the gland in 170 lesions (38% head, 41% body, 20% tail).[22] Large SCNs located in the head are surprisingly unlikely to cause biliary or duodenal obstruction, reflecting their slow pattern of growth, soft texture, and lack of invasive behavior. Rarely, extremely large tumors have been seen in elderly patients, with considerable symptoms of abdominal fullness, and occasionally gastroduodenal obstruction or jaundice.

One clinical condition that has been clearly associated with SCNs of the pancreas is the von Hippel–Lindau (VHL) syndrome. Simple pancreatic cysts or SCNs occur in 17–56% of patients with this heritable multisystem neoplastic syndrome.[23] The VHL tumor suppressor gene is located on chromosome 3p25. Vortmeyer et al demonstrated deletion of 3p25 in 7 of 10 sporadic SCN cases studied, suggesting a role for the VHL gene in SCN tumorigenesis, even in the absence of the VHL syndrome.[24]

Diagnosis

As mentioned earlier, SCNs often have a characteristic imaging phenotype (see Figs. 58-1 and 58-3). Most are well-demarcated solitary multicystic masses composed of innumerable small cysts. Up to one-third have a central, calcified starburst scar.[22,25] SCN may also present as oligocystic or unilocular cystic lesions, making differentiation from other cystic lesions of the pancreas difficult. Lee and colleagues reported on the preoperative diagnostic accuracy of CT in pathologically confirmed SCN.[26] Radiological features

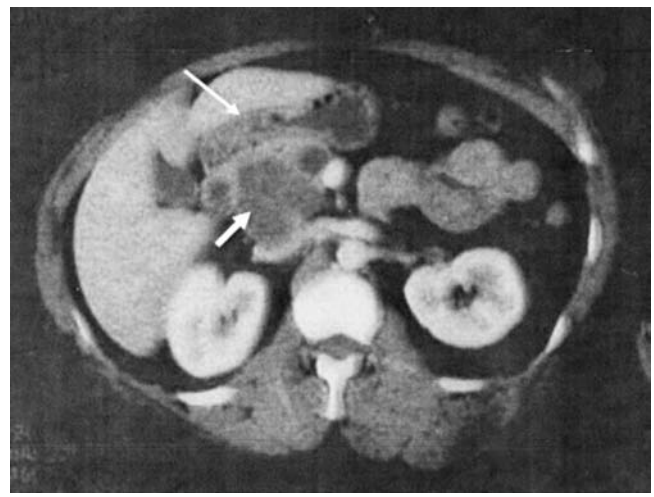

FIGURE 58-3 Abdominal CT of a 47-year-old woman who presented with abdominal pain and was found to have a cystic lesion in the head of the pancreas (*wide short arrow*). This mass closely abutted the proximal duodenum and pylorus (*narrow long arrow*), necessitating a classic pancreaticoduodenectomy for complete resection. Final pathology revealed a benign serous cystic neoplasm.

led to a correct diagnosis in only 36% of unilocular SCNs, while honeycombed microcystic and multilocular macrocystic SCNs were appropriately defined in 81 and 88%, respectively ($p = .005$). Overall in their series, CT diagnosis was accurate in 71% of SCN lesions. In 164 patients with surgically verified pancreatic cystic lesions, 28 of whom had SCN, Shah et al suggested that the CT features predictive of the diagnosis of SCN are microcystic appearance (22/28, 78%), surface lobulations (25/28, 89%), and central scar (9/28, 32%).[27] Stepwise logistic regression analysis showed that only a microcystic appearance was predictive for the CT diagnosis of SCN ($p = .0001$). MRI correctly predicted the pathological diagnosis of SCN with greater frequency than did CT in the study by Bassi and coworkers.[20] CT allowed for the correct diagnosis in 54%, incorrect diagnosis in 34%, and was nondiagnostic in 12%. The results with MRI were 74, 26 and 0%, respectively.

The limitations of the radiological diagnosis of SCN may call for additional analysis, which is frequently sought by EUS-FNA with cyst fluid cytology and biochemical study. The risk of complications with EUS-FNA is relatively low, with significant bleed occurring in less than 1% of studies, though intracystic hemorrhage may be as high as 6%.[28] The risk of cyst bacterial inoculation with subsequent infection is less than 1%[29] and the rate of pancreatitis is 1–2%.[30] Cyst fluid aspirates from SCN are frequently sparsely cellular and may be contaminated with columnar enterocytes and mucin from the scope and needle traversing the gastric or bowel mucosa, potentially clouding the diagnostic accuracy of cytology. Cytology alone was found to be diagnostic of SCN in only 7 of 21 cases studied by Huang and others from M. D. Anderson.[31] Detection of intracytoplasmic glycogen was noted to enhance the diagnostic confidence for the diagnosis of SCN. A recent 10-year review of 317 patients evaluated by EUS for pancreatic cysts by Pausawasdi and colleagues revealed that those followed for asymptomatic incidental cysts less than 3 cm in size almost uniformly had stable disease over a relatively short mean follow-up of 28 months.[32] While these results are confirmed by other EUS studies, others prefer serial imaging (typically MRI to avoid radiation exposure) over EUS surveillance.

Cyst fluid analysis is an additional adjunct (beyond cytology) to improve the diagnostic accuracy of EUS-FNA. Fluid from within an SCN is typically low in viscosity and amylase, due to a consistent lack of connection to the pancreatic ductal system.[33] CEA levels less than 5 ng/mL have a sensitivity of 54–100%, and specificity of 77–86% in the differentiation of SCN from other pancreatic cystic lesions.[34,35] The finding of a cyst fluid carbohydrate antigen (CA) 19-9 level less than 37 U/L and a CEA less than 5 ng/mL virtually excludes an MCN or IPMN.

Allen et al recently reported on the analysis of cyst fluid using a biomarker panel developed for pancreatic cancer.[35] Assessment of protein expression within the cyst fluid led to an error in classification of lesions of 27%, when all three types of cystic neoplasms were evaluated (SCN, MCN, and IPMN). When limiting the analysis to separating SCN from IPMN, this method had an error rate of only 8%, compared with a 14% error rate for use of CEA levels alone. The greatest utility of protein expression analysis might be in the differentiation of cystic lesions of the head of the pancreas, as the vast majority of MCN occur in the body and tail of the pancreas. However, the cost of this method may not be justified by the relatively small improvement in diagnostic accuracy. When cross-sectional imaging is sufficiently compelling, EUS alone is often unnecessary, but EUS-FNA may further clarify the diagnosis, particularly with oligocystic and unilocular SCNs.

Treatment

Observation of patients with SCN may be appropriate in asymptomatic patients. When a secure diagnosis of SCN is made, modern series demonstrate that a growing number of SCN are being followed by serial imaging (Table 58-2). Typically a pathological diagnosis is not required. Bassi and colleagues followed 32 patients with the diagnosis of SCN for a median time of 69 months, without any observed development of malignancy or significant increase in diameter of the lesion.[20] Rapid rate of growth of a lesion may heighten suspicion for the development of malignancy or increase the likelihood of developing symptoms. In a report from the Massachusetts General Hospital, Tseng and coworkers found a more rapid rate of growth in SCN greater than or equal to 4 cm in size at presentation compared with smaller tumors (1.98 cm/y vs 0.12 cm/y, $p = .0002$).[21] Tumors less than 4 cm were less likely to be symptomatic than were those greater than or equal to 4 cm (22 vs 72%, $p < .001$). Resection was thus suggested by these authors, even for asymptomatic SCNs which were greater than or equal to 4 cm.

When the diagnosis of SCN is uncertain, pancreatic resection is most often performed according to oncological principles, as if the lesion was malignant or had malignant potential (Fig. 58-4). Standard procedures include distal pancreatectomy for lesions of the body or tail, or pancreaticoduodenectomy for right-sided lesions. This practice avoids performance of an inadequate cancer operation in cases in which a malignancy is found on final pathological analysis. However, if the diagnosis of SCN is confirmed either preoperatively or with intraoperative biopsy (which is not routinely performed), a less radical approach may be considered. Enucleation of SCNs has been shown to be technically feasible, although it can be associated with a significant risk of pancreatic fistula.[36,37] A central pancreatectomy, with distal pancreatic reconstruction via pancreaticogastrostomy or Roux-en-Y pancreaticojejunostomy may be considered in selected patients with lesions of the pancreatic neck.[38] Distal pancreatectomy with splenic preservation may also be considered, particularly for small lesions in the tail, where the splenic hilum is more easily dissected. Lesions in the head of the pancreas that are not amenable to enucleation are best treated with pylorus-preserving pancreaticoduodenectomy. In patients who have an otherwise normal pancreas, meticulous attention must be paid to the technique of pancreaticojejunostomy, since

TABLE 58-2: FEATURES AND TREATMENT OF SCN, MCN, AND IPMN

Types of Neoplasm	Classic Features	Treatment[a]
Serous cystic neoplasm (SCN)	• Women > men • Solitary and polycystic • Single-layer cuboidal epithelium • Cyst fluid CEA and amylase low • Rarely malignant	• If symptomatic—resect • Stable size and asymptomatic—surveillance • Size increase—consider resection
Mucinous cystic neoplasm (MCN)	• Women >> men • Solitary and unilocular • Tall columnar epithelium • Subendothelial ovarian-type stroma • Cyst fluid CEA high and amylase low • Potentially malignant (exhibit spectrum from adenoma to carcinoma)	• If symptomatic—resect • Asymptomatic and size ≥3 cm—resect • Asymptomatic and size <3 cm—surveillance or resection, after patient education
Intraductal papillary mucinous neoplasm (IPMN)	• Gender distribution equal • Older than SCN and MCN • Pancreatitis seen with main duct > branch duct variant • Tall columnar epithelium with variable degrees of dysplasia • Cyst fluid CEA and amylase high • Potentially malignant (exhibit spectrum from adenoma to carcinoma)	• Main duct IPMN—resect, with intraoperative pancreatoscopy and careful inspection of remnant pancreas for synchronous neoplastic lesions • Branch duct IPMN a. Resect, if symptomatic, tumor ≥3 cm, mural nodules, positive cytology, rapid growth, main duct dilatation or young and healthy (age <55 years) b. Observe, if asymptomatic, tumor <3 cm, no mural nodules, negative cytology, stable size, normal main pancreatic duct and advanced age (>75 years)

[a]Treatment decisions are not easily tabulated, and must take into consideration patient health status, age at presentation, comorbid conditions, tumor location in the pancreas, and many other factors. We have attempted to briefly summarize our current approach at the Jefferson Pancreas, Biliary and Related Cancer Center.

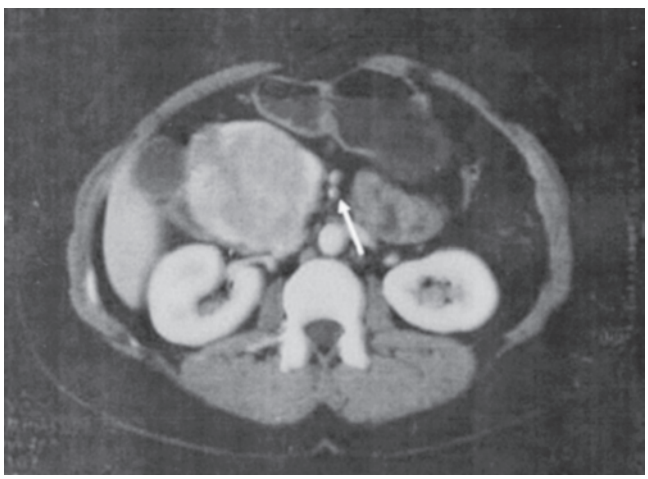

FIGURE 58-4 Abdominal CT of a large cystic mass with solid components arising from the head of the pancreas and extending into the root of the mesentery along the mesenteric vessels (*arrow*). The partially solid nature of the tumor raised concern of a malignant pancreatic tumor; however, at exploration the mass was found to be well localized and easily separable from surrounding structures. A pylorus-preserving pancreaticoduodenectomy was performed; final pathology showed a 7-cm serous cystic neoplasm.

such patients have a significantly higher risk for developing a pancreatic fistula. There has been some enthusiasm recently for duodenum-preserving pancreatic head resection as well, although this procedure has not had widespread application.[39] Patients with pathologically proven, completely resected SCN do not require serial imaging in follow-up. Recommendations for appropriate monitoring of unresected SCN vary, but serial imaging with either CT or MRI every 6 months for 2 years, and then annually thereafter seems reasonable.[40]

MUCINOUS CYSTIC NEOPLASMS

Progress in the diagnosis and management of pancreatic cystic neoplasms has been aided in large part by the recognition of distinct pathological features that distinguish MCNs from other cystic lesions.[41,42] The distinction between MCN and SCN is critical, as the premalignant and malignant behavior of MCNs stand in stark contrast to the nearly universally benign SCNs. Many of the same diagnostic challenges that exist for SCN are true for MCN, but the management decisions may be quite different, due to the differing clinical phenotype of these lesions.

MCNs account for approximately 15–30% of cystic neoplasms of the pancreas, at least as recorded in recent series in which the distinction of these lesions from IPMN has

been clarified.[2,40,43] Clinical series published prior to the establishment of diagnostic criteria for IPMN in 1996 likely overestimated the relative prevalence of MCNs in comparison to other cystic lesions, since they included what are now categorized as IPMNs as various "mucinous tumors."

Pathological Features

MCNs are typically spherical, thick-walled, septated or unilocular cysts with a tall columnar mucin-producing epithelium accompanied by a subendothelial ovarian-type stroma that appears as a dense layer of spindle cells with sparse cytoplasm and uniform, elongated nuclei (Figs. 58-5). This stroma regularly expresses progesterone receptors, and less frequently estrogen receptors, and over 60% stain for human chorionic gonadotropin.[44] Both the WHO and the Armed Forces Institute of Pathology (AFIP) have defined the presence of this ovarian-like stroma as a requirement for the diagnosis of an MCN.[41,42] The Sendai consensus guidelines have also required the presence of ovarian-type stroma as a necessary criterion for the diagnosis of MCN, so as to prevent the misclassification of IPMN as MCN.[14] Given the similarity of the histology and immunohistochemistry between MCN and ovarian mucinous cystadenomas, MCNs have been postulated to arise from ovarian rests (or ovarian-like stem cells) within the pancreas.[45]

MCNs exhibit characteristics of an adenoma-carcinoma sequence. Dependent on the degree of atypia, they are classified as mucinous cystadenomas, borderline lesions, in situ lesions or invasive cystadenocarcinoma. Atypical changes within the lining epithelium may be patchy and sparse, with abrupt transitions to normal mucosa. Classification of MCN should be based upon the highest degree of atypia present, and the entire lesion should be examined pathologically.[46,47] Invasive carcinomas arising within MCNs are usually tubular or ductal type, though some may be undifferentiated carcinoma with osteoclast-like giant cells,[48] adenosquamous carcinoma,[49] choriocarcinoma or even high-grade sarcomas.[50] Colloid carcinomas are extremely rare in MCN, but they occur commonly in IPMN.[47]

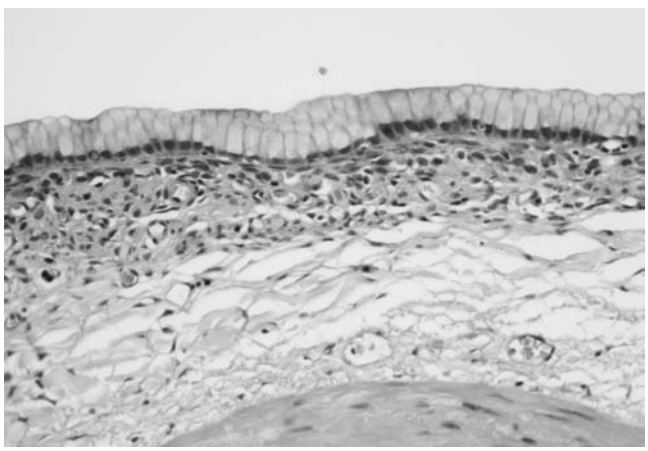

FIGURE 58-5 MCNs of the pancreas are distinguished by a uniform columnar epithelium (*top*) associated with a dense underlying ovarian-like stroma (*bottom*).

Clinical Presentation

In light of the mandatory presence of ovarian-type stroma, not surprisingly, MCNs are now diagnosed almost entirely in women.[44,45,51–56] This requirement, combined with the usual lack of communication with the pancreatic duct, defines a unique phenotype separate from IPMN. In a combined report from the University of Verona and the Massachusetts General Hospital, Crippa and colleagues reviewed their experience with 163 MCNs that met the WHO criteria for diagnosis.[55] Of the 163 patients, 95% (155 patients) were perimenopausal females. Only 8 males were identified, and they were significantly older than the female patients (63 vs 44 years, $p = .011$). The location of MCN within the gland was almost entirely confined to the body and tail of the pancreas (97%), and only five lesions were found in the pancreatic head. In reviewing the literature regarding MCN, these researchers noted the importance of segregating studies according to whether or not the presence of ovarian-type stroma was required for inclusion of pathological specimens within collected reports. Goh et al reviewed those studies where the presence of ovarian-type stroma was a mandatory criterion for the diagnosis of MCN: 99.7% of the patients were women, the mean age at presentation was 47 (range, 18–95) years, and 95% of MCNs occurred to the left of the pancreatic neck.[57] By comparison, when this criterion was previously not a prerequisite to diagnose MCN, patients were older, more often male and the lesions were located in the head with a frequency exceeding 30%.

Abdominal pain or discomfort is the most common presenting symptom, occurring in over 70% of patients.[52–54] A history of acute pancreatitis may also be elicited in 9–13% of patients, although less commonly than in patients with IPMN.[4,52,55] Patients with MCN with an associated invasive carcinoma present 11 years later than those with noninvasive neoplasms, likely representing the longer time required to progress to overt malignancy within these neoplasms.[55]

Diagnosis

Macroscopically, MCNs have some characteristic features that may be evident during imaging or operative evaluation. Classically, MCNs contain large septated cysts with thick irregular walls that may be well visualized on CT, MRI, or ultrasound evaluation. Papillary projections from the epithelium often extend into the cystic cavities and may be visible, particularly on high quality axial or endoscopic ultrasound imaging. In a minority of cases, the wall of the MCN may contain calcifications, a characteristic associated with a higher

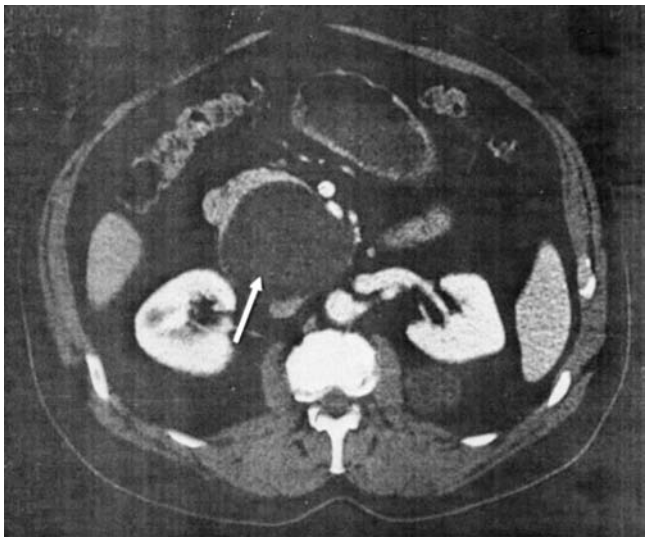

FIGURE 58-6 Abdominal CT performed on a 69-year-old healthy man who had a palpable abdominal mass detected on routine physical examination. The mass (*arrow*) was homogeneous in character and was initially presumed to be a pseudocyst. Pylorus-preserving pancreaticoduodenectomy was performed, revealing an 8.5-cm mucinous cystic neoplasm without malignancy.

likelihood of malignancy.[58] MCNs may also present as large unilocular cysts that may appear similar on cross-sectional imaging to long-standing pseudocysts (Fig. 58-6). Two distinguishing characteristics in this scenario are the lack of surrounding inflammatory changes beyond the wall of the neoplasm in MCN, and the absence of pancreatitis, two features common in evolving pseudocysts related to pancreatitis.[7] Demonstration of ductal communication with the cyst by MRI or magnetic resonance cholangiopancreatography (MRCP) may distinguish pseudocyst or IPMN from MCN, though MCN can in rare instances exhibit connection with the pancreatic duct.[57]

Similar to SCN, determination of a treatment plan for MCN is predicated upon whether or not a given lesion is mucinous. Analysis of cyst fluid aspirated from MCNs typically show elevated levels of CEA and low amylase concentrations. The Cooperative Pancreatic Cyst Study demonstrated that a CEA value greater than 192 ng/mL achieved the greatest efficiency for differentiating mucinous from nonmucinous lesions.[25] The accuracy of CEA (88/111, 79%) was greater than the accuracy of EUS morphology or cytology ($p < .05$). No combination of tests further improved diagnostic accuracy. A CEA level greater than 800 ng/mL has a specificity of 98% for predicting MCN, but a sensitivity of only 48%.[59] Khalid and his coinvestigators tested the utility of DNA analysis of cyst fluid to diagnose mucinous and malignant cysts.[60] The presence of a *K-ras* mutation was highly specific for a mucinous cyst (96%), but had a low sensitivity of 45%. A considerable selection bias was introduced by the study design which may have overestimated the ability of DNA analysis to define a mucinous cyst.[61] Presence of a *K-ras* mutation in cyst fluid may provide additional information when CEA levels are not discriminative, particularly in lesions that appear to not have clear imaging patterns which allow separation of SCN versus MCN.

Treatment

In their pooled review of the literature, including 10 studies of MCN defined by ovarian-type stroma, Goh and coworkers noted that, in the 40 invasive carcinomas found in 344 patients, only one of the malignant MCNs was less than 4.5 cm at the time of resection.[57] Crippa and colleagues noted that lesions containing either in situ or invasive carcinoma were larger (median size 80 vs 45 mm, $p = .0001$), and intracystic nodules or papillae were more frequently present (64.3 vs 4.4%, $p = .0001$), when compared with benign neoplasms.[55] All lesions demonstrating cancer on pathology were either greater than 4 cm in diameter or contained nodules by preoperative imaging. Careful observation of asymptomatic lesions less than 3 cm in size, without the presence of nodules, appears to be a reasonable approach for MCN (see Table 58-2). However, a recent post-hoc analysis by Sawhney and associates has questioned whether size alone, based on the Sendai Consensus criteria,[14] is a sufficient predictor of malignancy in pancreatic cysts.[62] Their data indicated that the original consensus guidelines should be applied with caution, and that more accurate diagnoses might be generated by the combination of cyst size and main pancreatic duct dilation greater than 3 mm.

Biopsy of MCN should not be utilized to determine the presence of carcinoma, because the presence of invasion within a lesion may be patchy and a negative biopsy may be obtained based on sampling error. Due to the significant rate of malignancy and the risk of progression to malignancy associated with MCN, symptomatic neoplasms, lesions greater than 3 cm or those containing nodules or papillae should undergo resection. As with SCN, enucleation has been documented to be an effective strategy for resection in selected MCN cases.[36,37,63] However, there is some risk of performing an inadequate oncologic resection for an MCN should it harbor an invasive component, while there is virtually no risk for SCN. Therefore enucleation should only be applied to highly selected cases of small, peripherally located MCNs with confirmation by extensive frozen-section analysis. Likewise, segmental pancreatic resections for lesions in the pancreatic neck and body (central pancreatectomy) or tail (spleen-preserving distal pancreatectomy) should be performed cautiously in selected patients without any indication of invasive disease. Larger tumors in older patients (ie, patients fitting the characteristics of MCN with an associated invasive cancer) should be treated with formal pancreatic resection to include specimen-associated lymph node harvest. Lesions in the pancreatic head are best treated with pancreaticoduodenectomy, while

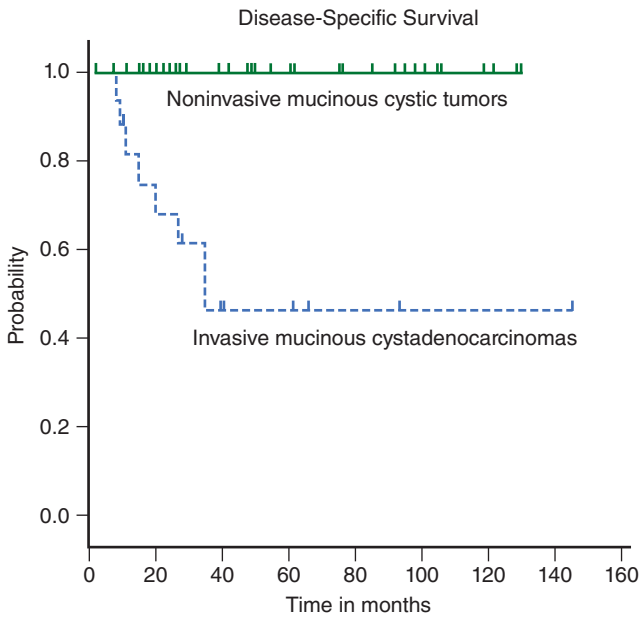

FIGURE 58-7 Kaplan-Meier disease-specific actuarial survival curves for invasive MCN and noninvasive MCN among 61 patients treated at the Johns Hopkins Hospital. The difference in survival between the two curves was statistically significant ($p < .005$, log-rank test). Five-year survival for patients with invasive MCN is approximately 50%. (Reproduced, with permission, from Wilentz RE, et al. Pathologic examination accurately predicts prognosis in mucinous cystic neoplasms of the pancreas. *Am J Surg Pathol.* 1999;23:1320–1327.)

left-sided lesions are treated via distal pancreatectomy with en bloc splenectomy. Extended lymphadenectomy, which has not been shown to definitively improve locoregional control or survival in patients with pancreatic ductal adenocarcinoma, has no role in the treatment of patients with cystic neoplasms.[64,65]

The 5-year disease-specific survival for benign or noninvasive MCN is 100%, but falls to 50–60% for patients with invasive mucinous cystadenocarcinoma[55] (Fig. 58-7). Failure to completely resect a noninvasive MCN may result in a later recurrence (persistence), and a missed opportunity for cure.

Adjuvant therapy for mucinous cystadenocarcinoma has been poorly investigated and has no proven benefit. A single case report describes the use of neoadjuvant chemoradiation and treatment monitoring by serum CEA level, but no prospective clinical trials have been performed.[66] Some high-volume centers would likely offer adjuvant chemotherapy to patients with invasive cystadenocarcinoma, extrapolating from the experience with ductal adenocarcinoma.[67] There are no data to support the utility of adjuvant radiotherapy. Follow-up with serial MR imaging every 6 months for 2 years and annually thereafter appears reasonable for patients with resected MCN with an associated invasive cancer.[36] Patients with resected noninvasive MCNs receive no postoperative adjuvant therapy and are not typically followed with serial imaging.

INTRADUCTAL PAPILLARY MUCINOUS NEOPLASMS

In the past, these lesions were variably referred to as mucinous ductal ectasia, intraductal papillomatosis, intraductal adenoma or adenomatosis, intraductal mucin-secreting tumor, and intraductal papillary mucinous tumor. However, the earliest report of this "new" lesion is attributed to Ohashi and Maruyama and was published in the Japanese literature in 1982.[68] This report described four malignant lesions associated with the main pancreatic duct and characterized the now well-described copious amounts of mucus that distend and emanate from the ductal system. The authors noted the comparatively better survival of these patients compared to those with classic invasive ductal adenocarcinoma of the pancreas. While many subsequent authors have helped to further characterize the subtleties of IPMN, these initial observations accurately depict typical cases.

In 1996, the WHO first formally recognized IPMN as a distinct entity, establishing criteria for the pathological diagnosis of these lesions.[41] Characteristic features include a tall, columnar epithelium with marked mucin production, and cystic transformation of either the main pancreatic duct or one of its side branches (Fig. 58-8). More recent versions of these diagnostic criteria have allowed the stratification of noninvasive IPMNs based on their degree of dysplastic change, and the clear separation of noninvasive IPMN from IPMN with an associated invasive carcinoma.

Pathological Features

Histologically, IPMNs are characterized by intraductal proliferation of mucinous cells which form papillae. Secretion of mucin leads to dilatation of the pancreatic ducts (Fig. 58-9). Lesions may be localized, multicentric, or rarely involve the entire ductal system. The proliferation of mucinous cells may involve the main pancreatic duct (main duct type), or be confined to the branch ducts (branch duct type) or show a pattern spanning both areas in a combined type. Three different morphologic patterns of IPMN can be seen.[69] Most branch duct type IPMN demonstrate papillae lined by tall columnar cells with basally oriented nuclei and abundant pale mucin. This pattern is also prevalent in the nonpapillary areas of main duct type IPMN and appears similar to the gastric mucosa. Scattered goblet cells are present and stain for MUC2. This pattern is called the gastric-foveolar type. Most main duct type IPMN closely resemble colonic villous adenomas and show molecular characteristics of intestinal differentiation, such that the cells express CDX2 and MUC2.[70] These are classified as *villous-intestinal type*. Their papillae are also positive for MUC5AC. Cancers arising in these IPMN are typically colloid carcinomas (Fig. 58-10). Colloid carcinomas also express CDX2 and MUC2, but not MUC1. A small proportion of IPMN is more complex and lined by cuboidal cells which do not express MUC2 or CDX2. This form is referred to as the *pancreatobiliary type*. Invasive cancers associated

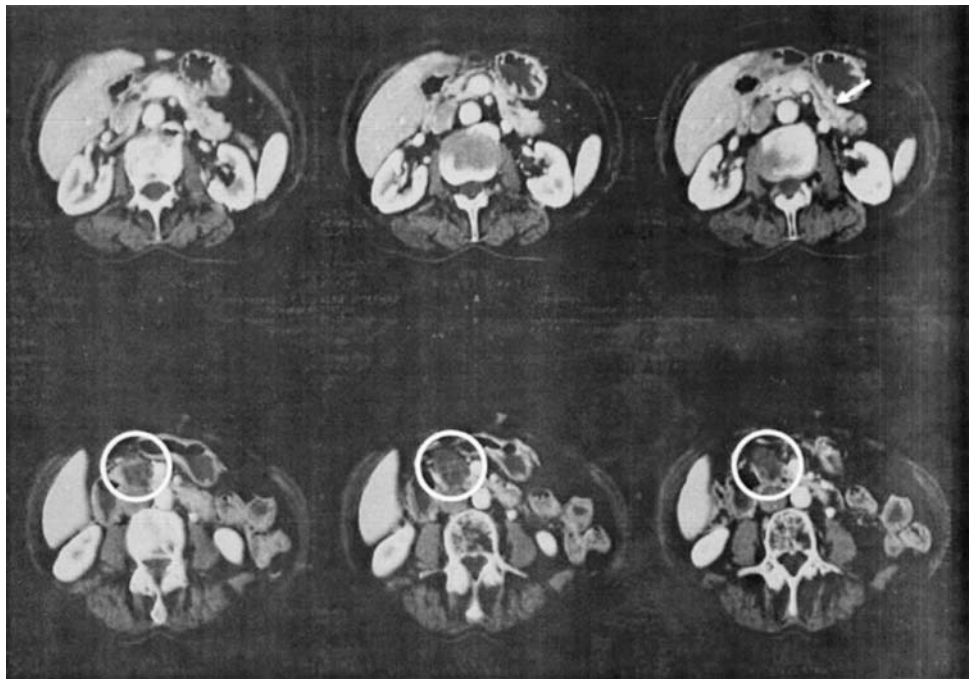

FIGURE 58-8 Abdominal CT of an 80-year-old woman who presented with abdominal pain. The patient underwent a pylorus-preserving pancreaticoduodenectomy; final pathology revealed a 3.5-cm IPMN with a small focus of carcinoma in situ located in the head of the pancreas. Notable findings on this series of images that are characteristic of IPMN include the multiloculated cystic mass in the right side of the pancreas (*circle*) associated with mild to moderate pancreatic ductal dilatation (*arrow*).

with the pancreatobiliary morphology are usually tubular, with structure similar to ductal adenocarcinoma. The invasive component expresses MUC1, but not MUC2. While both the villous-intestinal and the pancreatobiliary types may be found alongside the gastric-foveolar type, it is however, uncommon to identify both the villous-intestinal and pancreatobiliary type of papillae in the same IPMN.[69]

IPMNs demonstrate a progressive precursor model of carcinogenesis similar to that seen in colon cancer.[71] Tall mucin-producing columnar epithelial cells that remain well differentiated characterize IPMN adenoma (low-grade dysplasia). Little or no dysplasia is present in these lesions. IPMN borderline lesions (moderate grade dysplasia) are described as lesions with moderate epithelial dysplasia,

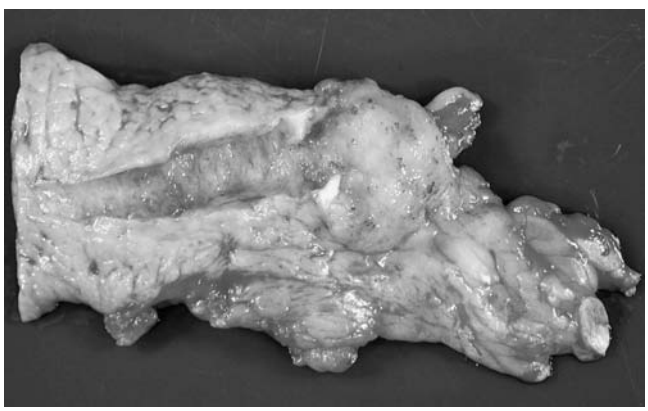

FIGURE 58-9 Gross photograph of a distal pancreatectomy specimen from a patient with an IPMN with carcinoma in situ. Characteristic features include the mass in direct communication with a markedly dilated main pancreatic duct.

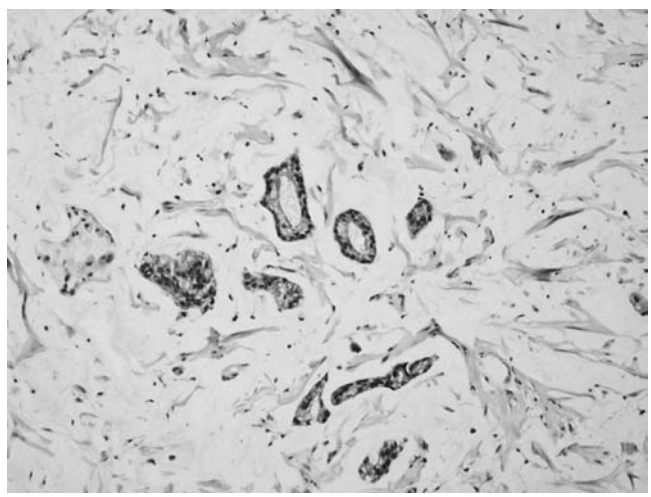

FIGURE 58-10 Photomicrograph of a colloid carcinoma within an IPMN. Note the largely acellular nature of these cancers and their abundant mucus production.

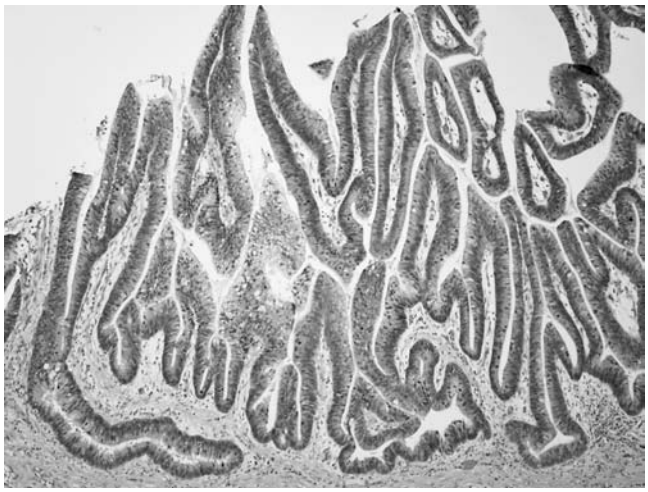

FIGURE 58-11 Photomicrograph of an IPMN with borderline features. Characteristic features include the tall columnar cells lining the papillary projections of the tumor, moderate dysplastic changes of the epithelium, and varied nuclear morphology.

characterized by moderate loss of polarity, changes in nuclear morphology, and pseudopapillary formation (Fig. 58-11). IPMNs with carcinoma-in situ have severe dysplastic changes. These lesions may be papillary or micropapillary, and severely dysplastic lesions may lose the ability to secrete mucin. IPMNs are pathologically similar to pancreatic intraepithelial neoplasia (PanIN). IPMNs, like PanIN, are intraductal lesions that may demonstrate a range of cellular atypia and malignant transformation. However, IPMNs may be distinguished based on their gross visibility and involvement of large ducts. PanIN should be considered a microscopic finding involving ducts less than 5 mm in diameter, while IPMNs are macroscopic findings.[72] In addition, IPMNs often express the mucin MUC2, while PanINs usually express MUC1.

IPMNs appear also to have distinct molecular events contributing to the clinical and pathological behavior that further distinguish them from lesions in the PanIN–ductal adenocarcinoma sequence. Iacobuzio-Donahue and associates described the intact (normal) expression of the tumor-suppressor gene *Dpc4* in the intraductal components of 79 IPMN.[73] In contrast, *Dpc4* inactivation has been shown to be relatively specific for pancreatic adenocarcinoma, and its persistence in both noninvasive and invasive IPMNs argues that these lesions may arise through a pathway that is distinct from the PanIN–ductal adenocarcinoma. IPMNs also appear to have a significantly lower rate of *K-ras* and *p53* mutations, lesions that are common in ductal adenocarcinoma.[74] Fritz and coworkers recently demonstrated that loss of chromosome 5q, 6q, and 11q was significantly higher in IPMN with high-grade dysplasia or invasion compared with ductal adenocarcinoma.[75] These data and others suggest that IPMNs are unique pancreatic neoplasms, with a pathogenesis that is distinct from that of the PanIN–ductal adenocarcinoma sequence.

Clinical Presentation

The biologic behavior of IPMNs parallels their classification according to their distribution within the pancreatic ductal system. Main duct type and combined main duct and branch duct type lesions are more likely to present with symptoms, while strictly branch duct type IPMNs are more frequently detected as asymptomatic cystic neoplasms on cross-sectional imaging.[76] Pancreatitis is seen more commonly in main duct type IPMN, possibly related to mucous plugging of the ampulla. In a combined experience of the Massachusetts General Hospital and the University of Verona reported by Salvia and colleagues, acute pancreatitis occurred in 23% of 140 patients with main duct variant IPMN.[77]

Both genders are affected by IPMNs, with a moderate male predominance in some series. Patients with IPMN tend to be older, with a mean age of 65 years, as compared with those having MCN who are predominantly perimenopausal. Similar to the situation with MCN, IPMN patients demonstrated to have a malignancy, a trend toward being older, again suggestive of an adenoma-to-carcinoma sequence of progression and the time necessary to undergo this transformation. Main duct type IPMNs are more likely to demonstrate the development of malignancy. Of note, malignant IPMNs are more likely to present with symptoms typically attributed to ductal adenocarcinoma, such as obstructive jaundice and weight loss.[5,77]

The development of symptoms more commonly attributed to ductal adenocarcinoma in patients with IPMN may herald the occurrence of carcinoma either synchronously or metachronously in the gland. Several studies have demonstrated the presence of an invasive ductal adenocarcinoma elsewhere in the pancreas, distinct from the location of the cystic neoplasm in up to 10% of IPMN patients.[40,78,79] Ingkakul and colleagues recently showed that, in a multivariate analysis, worsening diabetes (odds ratio 15.73 [95% CI: 4.40–56.25]; $p < .001$), and an abnormal CA 19-9 (odds ratio 3.70 [95% CI: 1.19–11.48]; $p = .024$) are independent factors predictive of synchronous or metachronous separate ductal adenocarcinoma in patients with IPMN.[79] In a report from Memorial Sloan-Kettering, Allen et al sought to characterize those cystic lesions which should be initially resected.[40] Asymptomatic cystic neoplasms, less than 2.5 cm in size, without septations or a solid component were followed over time. Eventually, 28 of 369 patients, initially managed conservatively, were operated upon primarily for cyst growth. Malignancy was found in 11 of these 28 patients (38%): three were cystic neuroendocrine tumors, while 8 of 11 were ductal adenocarcinomas. Further review of these eight ductal adenocarcinomas demonstrated that the cancer arose adjacent to the initially discovered cyst. This study demonstrates the need to thoroughly investigate the entire pancreas when electing to observe a cystic neoplasm. In addition, the incidence of extrapancreatic malignancies appears to be higher in patients with IPMN.[80,81] The development of colorectal adenomas and carcinomas, Barrett's mucosa and gastric carcinomas appear to be important entities seen in IPMN patients.

Diagnosis

CT scanning (with all of its advances up to multidetector imaging) has been the primary method for imaging the pancreas in the past. However, the use of MRI, particularly in combination with MRCP imaging has allowed for more thorough identification of IPMN. IPMNs characteristically appear as cystic masses resulting from dilatation of the main pancreatic duct or side branch ducts. Polypoid projections (mural nodules) into the cystic spaces may be present. Approximately half of IPMNs occur in the pancreatic head, though they may be present anywhere within the pancreas and can diffusely involve the entire gland. Currently MRCP is the modality of choice for defining mural nodules, demonstration of the communication of the cystic neoplasm with the pancreatic ductal system, and evaluating the extent of the pancreatic ductal dilatation.[82] Use of MRCP has largely supplanted endoscopic retrograde cholangiopancreatography (ERCP) in the diagnosis of IPMN, since MRCP is noninvasive, does not require sedation, and does not carry the risks of pancreatitis and perforation which accompany ERCP.

With the increasing emphasis on managing asymptomatic branch duct type IPMN by observation, imaging studies have sought to define features associated with invasive carcinoma by correlating preoperative imaging with pathology obtained by resection. Several imaging features suggestive of the presence of malignancy have been demonstrated, including tumor size (cyst diameter ≥30, 40, or 50 mm), main duct type IPMN, main duct dilatation greater than or equal to 10 or 15 mm, patulous papilla, mural nodules (≥3, 5, or 10 mm in size), presence of biliary ductal dilatation greater than or equal to 15 mm, a solid mass, or occurrence of an area of abnormal attenuation in the surrounding pancreas.[82–90] Importantly, a recent report from Verona, Italy by Salvia and colleagues notes that they followed 121 patients with multifocal branch duct IPMN (median diameter of the largest lesion being 1.7 cm) over a 40-month observation period.[91] All of the 121 patients remained alive, without surgery, and all remained asymptomatic. Thus, there is clearly a role for conservatism in the management of patients with branch duct IPMNs and no additional worrisome features.

Endoscopic ultrasound (EUS) may provide additional information which may prompt resection or promote a more conservative approach. Ohno et al demonstrated that the finding of a papillary mural nodule or a nodule exhibiting an invasive component on EUS was predictive of malignancy with a sensitivity of 60%, specificity of 93%, and an accuracy of 76%.[92] EUS-FNA may also be useful in reinforcing a decision not to resect a branch duct type IPMN, if it is otherwise without features predictive of malignancy. Marie and colleagues found that the combination of a CEA level less than 200 ng/mL and a CA 72.4 level greater than 40 U/mL retrieved from the cystic material of an IPMN together had a 96% negative predictive value for the diagnosis of malignancy.[93]

Treatment

The Japan Pancreas Society performed a multi-institutional, retrospective study of 1379 cases of IPMN drawn from 98 of their member programs. The clinicopathologic features of benign IPMN (see Table 58-2) (adenoma [low-grade dysplasia] and borderline lesions [moderate dysplasia]; n = 564) were strikingly different when compared with tumors containing frank adenocarcinoma (n = 445).[85] Patients with adenocarcinoma were significantly older (67 vs 65 years, $p = .0002$) and more frequently symptomatic (49 vs 35%, $p < .0001$), as compared to the noncarcinoma group. Cancer occurred more commonly in either main duct type or combined-type tumors, as compared to branch duct type neoplasms (60, 65, and 30%, $p < .001$), respectively. The preoperative imaging of patients who were subsequently found to have adenocarcinoma on pathology, demonstrated a higher incidence (63 vs 28%) and size of mural nodules (12 vs 5 mm) when compared with those who had benign lesions (both $p < .0001$). Branch duct type tumors with cancer were larger (35 vs 28 mm, $p < .0001$) than those without cancer.

Based on the data generated in the earlier report, the International Association of Pancreatology convened a consensus conference in Sendai, Japan in 2004. The subsequent guidelines published in 2006, have become a new benchmark for the management of IPMN.[14] These guidelines recommend the resection of all IPMN of a main duct type and mixed variants, those showing main pancreatic duct dilatation greater than or equal to 10 mm, as well as those with the presence of mural nodules, or a positive cytology, provided the patients are reasonable candidates for surgery with an acceptable life expectancy. All symptomatic IPMNs were deemed to warrant resection. These recommendations were predicated upon the risk of carcinoma in symptomatic or main duct type lesions. Branch duct IPMNs less than 30 mm in diameter, without evidence of mural nodules or main duct dilatation, were felt to be of low malignant potential and were candidates for careful observation. At follow-up examinations, appearance of symptoms, cyst expansion to greater than 30 mm, detection of positive cytology on FNA, development or identification of mural nodules or main pancreatic duct dilatation (≥6 mm) were deemed indications for resection.

Since the development of the Sendai guidelines, much of the subsequent literature has sought to examine the accuracy of the recommendations, particularly with regard to the observation of asymptomatic branch duct type IPMN. Pelaez-Luna and colleagues identified 147 patients with branch duct type IPMN, of whom 66 underwent resection at diagnosis and 81 were followed over time (of which 11 were resected during the follow-up period).[94] Of the patients undergoing resection who demonstrated Sendai consensus guideline indications for surgical therapy, 9/61 (15%) had carcinoma on pathology, whereas none of the 16 patients without consensus indications for resection had malignancy ($p = .1$). A single guideline indication for resection taken as an indicator of carcinoma had a sensitivity,

specificity, positive predictive value, and negative predictive value of 100, 23, 14, and 100%, respectively.

Several studies have suggested that the development of mural nodules is predictive of the risk of developing malignancy, while a progressive dilatation of duct size remains controversial. Schmidt and colleagues identified 103 patients with branch duct type IPMN.[95] The mean size of the 20 malignant lesions was 2.0 ± 0.1 cm, while the mean size of the nonmalignant neoplasms was 2.2 ± 0.1 cm, suggesting that size alone is an insufficient indicator of malignancy. In multivariate analysis, only the presence of mural nodules and atypical cytopathology were predictive of the presence of carcinoma. Tanno et al prospectively followed 82 patients with flat lesions within branch duct type IPMN diagnosed by CT or MR and EUS.[96] During a median follow-up of 59 months, 9/82 patients (11%) exhibited progressive dilatation of the cystic lesion. Six elected to continue regular screening, while three underwent resection; the IPMNs resected were staged as IPMN-adenoma in two and IPMN-borderline in one. Four patients (5%) developed mural nodules during a median follow-up of 105 months. All four of these individuals were resected, demonstrating IPMN-adenoma in three and carcinoma in situ in the fourth. Sixty-nine of the 82 patients (84%) showed no changes in their dilated branch duct lesions over a median follow-up of 57 months.

A recent study from Kyushu University attempted to determine whether cyst size is predictive of the malignant potential in flat branch duct type IPMN.[97] One hundred seventy patients with branch duct type IPMNs without mural nodules were retrospectively identified from their previous 10-year experience. Seventy-three patients underwent resection of their IPMN: 26 patients had lesions less than 30 mm in size, while 47 patients had neoplasms greater than 30 mm in diameter. All of the noninvasive (n = 5) and invasive (n = 1) malignancies were seen in the IPMN of greater than or equal to 30 mm. In a similar report, Salvia and coworkers followed 89 patients with flat branch duct type IPMN less than or equal to 3.5 cm in size for a median time period of 32 months.[98] Five patients (5.6%) exhibited an increase in diameter of the cystic lesion, none of which demonstrated carcinoma in the resection specimen pathologically. Clearly, longer follow-up will be needed to determine whether or not clear evidence of carcinoma develops in patients without Sendai consensus guidelines for surgical therapy. As might be anticipated, increasing knowledge and follow-up has raised questions about the universal accuracy of the consensus guidelines.

The majority of studies, particularly those following IPMNs conservatively in a prospective fashion, would suggest that the development of invasive carcinoma in flat branch duct IPMN less than 30 mm in size is unusual. The occurrence of high-risk stigmata (mural nodules, dilated main duct, or positive cytology) clearly have great predictive value for the ultimate finding of malignancy. EUS appears to be an important adjuvant to fully evaluate IPMN patients for the presence of mural nodules, as well as for aspiration of cytologic specimens. Some authorities insist that any lesion which is to be followed conservatively should be examined by EUS at regular intervals. We have tended to use MRI or MRCP for serial surveillance of small (<3 cm) branch duct IPMNs, as this is a noninvasive procedure (as compared to EUS) which avoids radiation exposure (as compared to CT).

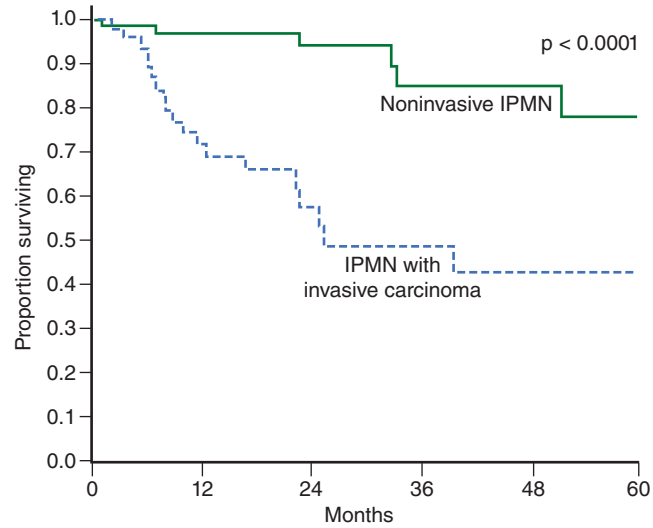

FIGURE 58-12 Kaplan-Meier actuarial survival curves comparing 84 patients with noninvasive IPMN to 52 patients with invasive IPMN following pancreatic resection at the Johns Hopkins Hospital (1987–2003). Patients with noninvasive IPMN have a significantly greater survival than those with invasive carcinoma ($p < .0001$). (Reproduced, with permission, from Sohn TA, et al. Intraductal papillary mucinous neoplasms of the pancreas: an updated experience. *Ann Surg.* 2004;239:788–797.)

Given the excellent survival following resection of IPMN free of an invasive component, every effort must be made to define lesions at risk for the development of carcinoma at the earliest point possible (Fig. 58-12). Schnelldorfer and coworkers have demonstrated that the survival after pancreatectomy of patients with IPMN with invasive adenocarcinoma is equivalent to that of a matched cohort of patients following resection of ductal adenocarcinoma (median survival, 32 vs 21 months; 5-year survival rate, 31 vs 24%; $p = .26$).[99] Other studies have revealed that survival of patients without lymph node involvement and invasive IPMN is quite good, while patients with lymph node involvement and invasive IPMN have equivalent outcomes to patients with lymph node–positive pancreatic ductal adenocarcinoma.[5] Despite the poor survival in patients with invasive disease, surgery remains the best opportunity for cure. Swartz et al have recently shown that adjuvant chemoradiotherapy confers a 57% decrease in the relative risk of mortality after pancreaticoduodenectomy for invasive IPMN after adjusting for major confounders.[100] This effect was most significant in patients with lymph node metastases or positive surgical margins.

Use of the Sendai consensus guidelines means that the preponderance of resections for IPMN will be performed with at least a suspicion of the presence of carcinoma. Targeted pancreatectomies, either pancreaticoduodenectomy

or distal pancreatectomy with en bloc splenectomy, have been advocated so as to adhere to oncologic principles of resection. Most centers have advocated the use of frozen-section examination of the pancreatic margin, with attempted clearance of microscopically malignant margins by re-resection and occasional conversion to total pancreatectomy when needed to achieve negative margins. Skip lesions clearly occur, such that a normal resection margin may not be indicative of a lack of neoplasia in the pancreatic remnant. A recent report by Nara et al from Tokyo analyzed 130 consecutive patients undergoing resection for IPMN with frozen-section analysis of the pancreatic margin[101]. While most initial frozen-section results showed no neoplasia at the margin, 29 patients had additional pancreas resected for "positive" frozen-section results (12 for low or moderate dysplasia, 10 for high-grade dysplasia, 1 for floating cancer cells, and 6 for invasive cancer). Most patients who recurred following re-resection had their recurrence at a distance from the pancreatic margin (peritoneum, liver, and lymph nodes), raising doubt about the true value of re-resection for margins determined to be positive at frozen section. The role of total pancreatectomy to achieve clearance of all dysplastic epithelium, even prophylactic total pancreatectomy, is controversial. Notably, of the 84 patients with noninvasive IPMN described by Sohn and colleagues,[5] 7 patients developed recurrent disease in the pancreatic remnant. Negative margins at resection do not eliminate the need for chronic surveillance of the pancreatic remnant, perhaps best done by annual MRI/MRCP.

UNUSUAL PANCREATIC CYSTIC NEOPLASMS

Solid Pseudopapillary Neoplasm (Solid and Papillary Neoplasm)

These rare tumors are notable for several characteristic clinical and pathological features. The ratio of women to men is roughly 10:1, with lesions typically appearing in the second or third decade of life (mean age 22 years, range 2–85 years). Patients often present either with abdominal pain or a palpable abdominal mass. The lesions may be large, presenting in one review at a mean size of 6.1 cm (range 0.5–34.5 cm).[102] On CT, these tumors often appear well circumscribed, with hypodense areas representing hemorrhage or necrosis (Fig. 58-13). Lesions tend to be evenly distributed throughout the pancreas. Most of these lesions harbor β-catenin mutations, express the beta subtype of estrogen receptors and stain for galectin-3.[103] Though most of these tumors are benign, some may be considered low-grade malignancies, with local invasion into contiguous structures and occasional distant metastases (roughly 15–20% of cases). An aggressive surgical approach is warranted for both the primary and metastatic disease, as 5-year survival in completely resected patients exceeds 95%.[104,105]

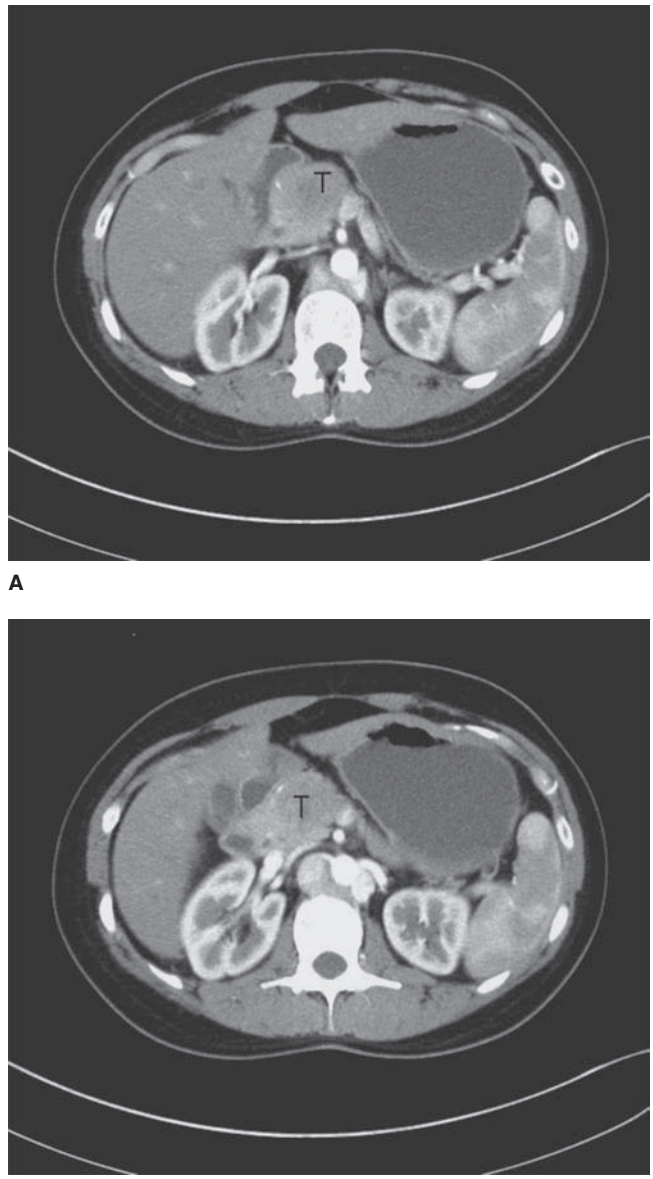

FIGURE 58-13 Abdominal CT scan of a 29-year-old woman with a right-sided solid and papillary neoplasm. **A.** The tumor (T) resides within the duodenal C loop, and there is some deformation of the portal vein. **B.** On this more inferior image the tumor (T) is seen to further deform the superior mesenteric vein (SMV), but not touch the superior mesenteric artery (SMA). The tumor was resected via a pylorus-preserving pancreaticoduodenectomy which was extended to include the proximal body of the pancreas. The tumor was dissected free from the SMV, portal vein, and no venous resection was needed.

Cystic Neuroendocrine Neoplasms

Neuroendocrine tumors showing partial or complete cystic components are uncommon. The Cooperative Pancreatic Cyst Study demonstrated only 5 of these lesions out of 341 cystic neoplasms. Immunohistochemical staining of cytological

specimens obtained by EUS-FNA demonstrating endocrine markers confirms the diagnosis.[106] In a retrospective review of 170 patients undergoing resection for a pancreatic neuroendocrine tumor at the Massachusetts General Hospital over a 30-year period, 29 cystic neuroendocrine tumors were identified.[107] Ten (34%) of the cystic lesions were purely cystic, while 19 (66%) were partially cystic. Cystic neuroendocrine neoplasms were larger (49 vs 23.5 mm, $p < .05$), more likely to be symptomatic (73 vs 45%, $p < .05$), and most likely to be nonfunctional (80 vs 50%, $p < .05$), when compared with solid pancreatic neuroendocrine lesions. The propensity for metastases, invasion, and survival (87 vs 77% at 5 years, $p = .38$) in patients with cystic lesions was the same as in those with solid pancreatic endocrine neoplasms. Thus, these lesions have a favorable prognosis if completely resected and should be treated aggressively and with similar technique as for a solid neuroendocrine tumor in appropriate surgical candidates.

Cystic Acinar Cell Neoplasms

Acinar cell carcinoma of the pancreas is a rare neoplasm, however, several recent registry reviews and multi-institutional series have better defined this entity.[108,109] This lesion has a 2:1 male predominance and although many individuals will present with advanced disease, stage-specific survival is statistically better than that seen in ductal pancreatic adenocarcinoma.[108] Occasionally, acinar cell carcinoma may display an intraductal, papillary or papillocystic growth pattern and may appear to mimic IPMN with a cystic component. A significant proportion of these tumors (up to 40%) may demonstrate a concomitant endocrine neoplasm.[109] Acinar cell neoplasms with intraductal growth patterns tend to present somewhat earlier than typical acinar cell carcinoma, secondary to the pancreatitis resulting from duct obstruction. Characteristic immunohistochemical staining for trypsin and chymotrypsin, as well as presence of eosinophilic granular cytoplasm in acinar cell carcinoma are helpful in establishing the correct diagnosis.[109]

Cystic Degeneration of Pancreatic Ductal Adenocarcinoma

While not truly a distinct lesion, it is important to realize that pancreatic ductal adenocarcinoma may present with cystic features. Thus all cystic lesions should at least be considered as potential pancreatic ductal adenocarcinomas until an alternative diagnosis is established. In a comparative review of symptomatic and incidental pancreatic cysts by Fernandez-del Castillo and colleagues, 9% of symptomatic lesions and 2% of incidental cysts proved to harbor pancreatic ductal adenocarcinoma.[43] Adenocarcinomas that obstruct the pancreatic duct may be associated with retention cysts in up to 8% of patients.[110]

CANCERS OF THE PERIAMPULLARY REGION AND THE PANCREAS

Christopher L. Wolfgang • Richard D. Schulick • John L. Cameron

Periampullary cancers are composed of a group of malignant neoplasms arising in the region of the ampulla of Vater. These include mainly adenocarcinomas of the head of the pancreas, ampulla of Vater, distal bile duct (cholangiocarcinoma), and duodenum. Less commonly, acinar cell carcinomas or pancreatic endocrine neoplasms occur in the periampullary region of the pancreas. Periampullary cancers are often discussed as a group based on their similar presentation, workup, and surgical management. In addition, pancreas cancer is also discussed with this group since the natural history for both proximal and distal pancreatic lesions is similar—differing mainly in the type of resection performed.

The first successful resection of a periampullary tumor was performed by Halsted in 1898. He described a local ampullary resection with reanastomosis of the pancreatic and bile ducts to the duodenum in a patient who presented with obstructive jaundice.[1] In the early part of the 20th century, most periampullary cancers were managed by a transduodenal approach similar to that first reported by Halsted. Codivilla is often credited with performing the first en bloc resection of the head of the pancreas and duodenum for periampullary carcinoma, but this patient did not survive beyond the early postoperative period.[2] The first successful two-stage pancreaticoduodenectomy was performed in Germany by Kausch in 1909.[3] In 1914, Hirschel reported the first successful one-stage pancreaticoduodenectomy.[4] Pancreaticoduodenectomy was not popularized until Whipple and colleagues reported three successful, two-stage, en bloc resections of the head of the pancreas and the duodenum in 1935.[5] Over the next decade, a number of modifications and technical refinements were made in the procedure, including the first one-stage pancreaticoduodenectomy, reported in the United States by Trimble in 1941. The procedure was infrequently performed despite technical advances, until the 1980s because of the formidable operative morbidity, mortality, and the poor prognosis associated with periampullary cancers.

Currently, the resection of periampullary cancer with a pancreaticoduodenectomy is performed routinely at many referral centers and carries a mortality of approximately 2%. Moreover, significant advances have been made in understanding of the pathogenesis, biology, and staging of periampullary carcinoma in the past two decades.

INCIDENCE

Periampullary carcinomas are a major public health concern throughout the world. Pancreatic cancer is the fourth leading cause of cancer death in the United States. In 2009, there were an estimated 35,240 deaths in the United States compared to 159,390 deaths for lung cancer, 49,920 for colorectal cancer, and 40,610 for breast cancer.[6] The incidence of pancreatic carcinoma rose dramatically from the 1930s until the mid-1970s, nearly doubling during this time period. Since 1973, the incidence in the United States has remained stable at about 8–9 per 100,000 of population. The incidence in Western Europe is similar to that in the United States and has also remained stable during the past three decades. In Europe, pancreatic cancer is the sixth leading cause of cancer death. In Japan, however, a dramatic increase has been observed during the last three decades, although the overall incidence is still less than that observed in the West. The lowest incidence worldwide is seen in parts of the Middle East and in India. Worldwide, over 200,000 people die annually of cancer of the pancreas.[7]

The incidence of periampullary carcinoma increases with age, and the majority of patients present in or beyond their sixth decade of life. There is a slight male preponderance, and African American males have the highest overall incidence in the United States.

PATHOLOGY

The most common cancer types of the periampullary region and pancreas are the adenocarcinomas. These neoplasms are

thought to arise from their respective epithelial layer and histologically are characterized by unorganized gland forming structures within a stromal background. Review of pancreaticoduodenectomy specimens from high-volume centers reveals that 40–60% are adenocarcinomas of the head of the pancreas, 10–20% are adenocarcinomas of the ampulla of Vater, 10% are distal bile duct adenocarcinomas, and 5–10% are duodenal adenocarcinomas. Because these data represent resected specimens and because the resectability rate of the nonpancreatic periampullary cancers is much higher, it is likely that pancreas cancer is the site of origin in up to 90% of cases.[8,9] Given the close proximity of the pancreatic duct, the distal bile duct, the ampulla of Vater, and the periampullary duodenum, the site of origin of a periampullary malignancy can at times be difficult to determine. Various sarcomas including gastrointestinal (GI) stromal tumors, fibrosarcomas, leiomyosarcomas, hemangiopericytomas, and histiocytomas may also arise in the periampullary region. Similarly, lymphomas can occur in these regions and present with less well-defined margins than the typical adenocarcinomas. Finally, the periampullary region can be the site of metastases from other primaries, including kidney, breast, lung, melanoma, stomach, colon, and germ cell primaries. Pancreatic ductal adenocarcinoma is by far the most common malignant histologic type of pancreatic carcinoma regardless of location within the pancreas. However, more than two-thirds of these tumors arise in the pancreatic head, neck, or uncinate process. Other rare histologies include acinar, squamous, pancreatic endocrine neoplasms (islet cell tumors), or tumors of nonepithelial origin. Pancreatic endocrine neoplasms may be either benign or malignant and may be functional with hormone production, resulting in clinical manifestations. Cystic neoplasms of the pancreas can also arise from the exocrine pancreas and are classified as benign serous cystadenomas, potentially malignant mucinous cystadenomas, and intraductal papillary mucinous neoplasms (IPMNs).

ENVIRONMENTAL RISK FACTORS

There are few established risk factors for cancer of the pancreas. They include tobacco smoking and inherited susceptibility, which account for only 5–10% of cases. Chronic pancreatitis, type 2 diabetes mellitus, and obesity have been consistently associated with pancreatic cancer and are weak risk factors. Other possible risk factors include physical inactivity, certain pesticides, and high carbohydrate/sugar intake. Cholecystectomy, cholelithiasis, coffee consumption, and alcohol have all been sporadically associated with the development of pancreatic cancer, but they are unlikely true risk factors.

There is a significant amount of evidence that links cigarette smoking to pancreas cancer. Multiple animal studies have demonstrated the carcinogenic effects of tobacco smoke and nitrosamines on the pancreas. Human autopsy studies have revealed increases in hyperplastic changes with atypical nuclear patterns in pancreatic ductal cells of cigarette smokers. Several prospective studies have demonstrated an increased risk ratio of death from pancreatic cancer in smokers ranging from two- to 16-fold.[10] Many of the studies have demonstrated a dose-response relationship with either the number of cigarettes smoked or the duration of smoking.

There are numerous conflicting data in reviews examining the relationship of dietary factors and cancer of the pancreas.[10–12] Pancreas cancer seems to be associated with increased total calorie intake, as well as increased intake of carbohydrate, cholesterol, meat, salt, dehydrated food, fried food, refined sugar, and nitrosamines. Fat, beta carotene, and coffee are of unproven risk. Consumption of dietary fiber, vitamin C, fruits, vegetables, and unprepared food may have a protective effect, as may pressure and microwave cooking.

Alcohol, coffee, and radiation do not appear to be significant risk factors for development of pancreas cancer. When age, gender, smoking, amount of alcohol consumed, and socioeconomic class were controlled, three case-control studies from Europe did not demonstrate an increased risk of pancreatic cancer with coffee.[10] This is in disagreement with earlier reports of the association between pancreas cancer and coffee consumption.[13,14] Ionizing radiation does not seem to have a propensity to cause pancreas cancer when compared to other tissues. The survivors of the bombings of Hiroshima and Nagasaki have not shown an increased risk.[15,16]

Chronic pancreatitis has been associated with cancer of the pancreas.[10,17–19] It is hard, however, to determine whether this is a causative condition or whether chronic pancreatitis may represent an indolent presentation of pancreatic cancer. The association of type 2 diabetes and pancreatic cancer is similarly implicated in multiple studies.[20,21] Again, it is difficult to distinguish whether diabetes is an early symptom of pancreas cancer or whether it is truly a causative factor.

Distal common bile duct, ampullary, and duodenal cancers are less common than pancreatic cancer and are less well characterized in terms of their risk factors. All are more common in the elderly with peak incidences in the 60- to 80-year range. Distal common bile duct cancers are associated with several known host factors in addition to advanced age, including inflammatory bowel disease, sclerosing cholangitis, choledochal cysts, and intrahepatic or common bile duct stones.

HEREDITARY RISK FACTORS

The hereditary risk factors for pancreatic cancer have been the most studied among the periampullary cancers. It is estimated that approximately 10% of all pancreatic cancers are hereditary. Most of these are associated with well-known, but relatively rare, hereditary syndromes that have been previously described for other cancer types. These include hereditary nonpolyposis colorectal cancer (HNPCC), familial breast cancer associated with the BRCA2 mutation, Peutz-Jeghers syndrome, ataxia-telangiectasia syndrome, familial atypical multiple mole-melanoma syndrome (FAMMM), and hereditary pancreatitis. It is also becoming clear that pancreatic

cancer also runs in some families and is not associated with any of the known genetic syndromes. So-called familial pancreatic cancer is being studied by the Johns Hopkins Hospital group who have amassed data on a large number of families with this condition. Members of families with two or more first-degree relatives affected by pancreatic cancer in the National Familial Pancreas Tumor Registry (NFPTR) have a 16-fold increased risk of developing pancreas cancer. This increased risk could be attributable to either a genetic basis or environmental exposure, but there is strong evidence that the familial aggregation has some genetic basis.[22]

Duodenal and ampullary cancers occur with increased frequency in patients with hereditary polyposis syndromes, including HNPCC, Peutz-Jeghers syndrome, familial adenomatous polyposis, and Gardner's syndrome.

GENETIC ALTERATIONS

As with all cancers, periampullary cancers are diseases of genetic alterations. Over the past decade our understanding of the genetics behind cancer has burgeoned. The development of high-throughput DNA sequencing, gene expression, and the field of genomics have been the driving force behind this expansion of knowledge. The entire sequence of the human genome has recently been made publically available (International Human Genome Sequencing Consortium, 2004),[23,24] and through additional efforts we now have an understanding of the normal genetic variation among individuals and populations of people (International HapMap Consortium, 2007).[25] This information has set the stage for the global assessment of genetic alterations associated with the development of specific cancers.

The best example of the application of this knowledge to the study of periampullary cancers is that of pancreatic cancer.[26] Using the genetic material from approximately 100 patients with pancreatic cancer, a team of researchers at Johns Hopkins Hospital sequenced the "pancreatic cancer genome." Interestingly, pancreatic cancers contain an average of 48 genetic alterations. These alterations, consisting of mutations, deletions and amplifications cluster in 12 cell signaling pathways that are known to be important for cellular growth and differentiation. Most of these mutations were already identified as being involved with pancreatic cancer while several novel mutations were discovered. The frequency with which each one of these mutations occurs within the population of pancreatic cancer patients in this study is supported by previous work involving individual genes. For example, the most commonly altered genes in the pancreatic cancer genome project include *K-ras*, p53, p16, and DPC4. This is consistent with the results of Rozenblum and associates who analyzed pancreas cancers from 42 patients and found that all of them (100%) had mutations in the proto-oncogene *K-ras*, and 82%, 76%, and 53% had mutations in the tumor suppressor genes *p16*, *p53*, and *DPC4*, respectively.[27]

The genetics behind the other periampullary cancers is less well characterized. This is likely due to their less common incidence in comparison to pancreatic cancer. It is interesting that what limited information is known of the genetic alterations associated with certain other periampullary adenocarcinoma shows similarities and striking differences to that of pancreatic adenocarcinoma. For example, 40–60% of patients with ampullary adenocarcinoma have alterations of either p53 or p16 similar to pancreatic adenocarcinoma.[28] In contrast, at most 50% of ampullary adenocarcinomas carry an activating *K-ras* mutation and the *APC* gene, which plays a minimal role in pancreatic cancer, is frequently altered in ampullary cancer.

DIAGNOSIS AND PREOPERATIVE EVALUATION

The diagnosis of periampullary cancer is made on the basis of clinical presentation, laboratory data, and radiologic workup. The key determination in the workup of a periampullary cancer is that of resectability. Those patients with a resectable lesion based on overall patient health, absence of distant spread, and local tumor relationships should proceed to a potentially curative resection. Although in some situations a preoperative tissue diagnosis is available, treatment should not be delayed by attempts to obtain histologic confirmation of malignancy. In patients, who are deemed to be unresectable, a tissue diagnosis is often required before the commencement of palliative therapy.

Clinical Presentation

Patients with periampullary cancer often have only vague symptoms early in the course of their disease. Often, it is not until the later stages that patients will develop more definitive symptoms. The symptoms at presentation are related to the location of the tumor. Lesions occurring in or near the bile duct are much more likely to present with obstructive jaundice, whereas those presenting in the body or tail are more likely to present with pain. Two-thirds to three-fourths of patients with pancreas cancer present with the classic constellation of symptoms indicative of obstructive jaundice: jaundice, pruritus, acholic stools, and tea-colored urine. Contrary to popular teaching, patients with pancreas cancer often experience pain as a part of their symptoms. Albeit early in the course of the disease, the pain is often vague and involving the upper abdomen, epigastrium, or back. Later in the course of the disease, this pain can progress to severe pain often radiating to the back. Patients may also present with other general symptoms, including anorexia, fatigue, malaise, and weight loss. Nausea and vomiting may herald gastric outlet obstruction from duodenal involvement and is an ominous sign of locally advanced disease.

Patients may also present with very subtle signs such as the presence of elevated liver function tests performed on routine

laboratory screening, new-onset diabetes mellitus, or anemia from gastrointestinal blood loss, usually from tumor erosion into the duodenum. Patients may also present with acute pancreatitis from obstruction of the pancreatic duct. Therefore, elderly patients who present with acute pancreatitis in the absence of a history of alcohol use or gallbladder stones should be screened for a pancreatic or periampullary cancer.

Patients with a distal common bile duct cancer are even more likely to present with obstructive jaundice than those with pancreas cancer because the tumor does not have be very large to obstruct the duct. Patients with pancreas cancers involving the body or tail of the gland are more likely to have weight loss and abdominal pain rather than jaundice as their presenting complaints. Because tumors can grow to a larger size before producing noticeable symptoms, pancreas cancers in the body and tail are often diagnosed at a later stage and have a poorer prognosis.

Physical findings on examination include scleral icterus, jaundice, hepatomegaly, a palpable gallbladder (Courvoisier's sign), and skin excoriation from pruritus and scratching. Signs of advanced disease include cachexia, palpable nodules in the liver, palpable metastatic disease in the left supraclavicular fossa (Virchow's node), palpable metastatic disease in the periumbilical area (Sister Mary Joseph's node), and pelvic metastatic disease palpable anteriorly on rectal examination (Blumer's shelf).

Patients who present with obstructive jaundice have elevated serum levels of bilirubin and alkaline phosphatase, usually associated with only mild to moderate elevations in liver transaminases. Long-term obstruction of the biliary tree may also lead to coagulopathy and prolongation of protime because of decreased absorption of vitamin K and the effect on the clotting factors of the intrinsic pathway. There are no great serum markers for pancreas cancer to facilitate early diagnosis. A marker commonly used is carbohydrate antigen 19–9 (CA 19–9) that is elevated in 75% of patients with pancreas cancer. Unfortunately, CA 19–9 levels are also elevated in benign conditions of the pancreas, liver, and bile ducts. CA 19–9 is neither sensitive nor specific enough to be used in population screening. It is sometimes of use in trying to measure response to therapy or for screening for recurrence in a patient who originally had an elevation of the marker.

Because approximately 90% of pancreatic cancers contain mutations in the *K-ras* protooncogene, several groups have tried to detect these mutations from duodenal aspirates, pancreatic duct aspirates, and stool.[29–31] These tests have not become clinically useful, but this type of strategy will be necessary to detect disease at an earlier stage.

Imaging Studies

The main imaging modalities used for patients with suspected periampullary neoplasms include right upper quadrant (RUQ) ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI) with or without magnetic resonance cholangiopancreatography (MRCP), endoscopic ultrasound (EUS), endoscopic retrograde cholangiopancreatography (ERCP), and percutaneous transhepatic cholangiography (PTC). The role of positron emission tomography (PET) has not been clearly established for pancreatic and the other periampullary cancers. Over the last 10 years, there has been a trend away from the invasive imaging studies (ERCP and PTC), toward the noninvasive imaging studies. This is especially true as surgeons have become more willing to operate on jaundiced patients based on clinical presentation and imaging studies.

RUQ ultrasonography is a commonly used initial test and is very sensitive for the detection of gallstones, the presence of a dilated biliary tree, and whether acute cholecystitis is causing a patient's RUQ pain. This study is commonly available around the clock and heavily used in emergency departments. In addition to gallstones, dilation of the biliary tree, and pericholecystic fluid, this imaging modality can also pick up hepatic metastases, pancreatic masses, peripancreatic and hilar lymphadenopathy, and ascites. The sensitivity for demonstrating pancreatic masses is not high, and the absence of a pancreatic mass by RUQ ultrasonography does not rule out the presence of one in the patient.

The "workhorse" in the workup of patients suspected of a pancreatic cancer or a periampullary neoplasm is a multidetector spiral CT and is probably the single most useful diagnostic and staging modality (Fig. 59-1).[32] If a pancreatic mass is identified by another modality, spiral CT is often indicated, because CT provides more complete and accurate imaging of the pancreatic head and surrounding structures. It has largely supplanted ultrasound as the initial diagnostic procedure of choice. Pancreatic cancer is much more likely to be visible on a spiral CT than a distal common bile duct, ampullary, or duodenal cancer. It gives very important information about the immediately adjacent vascular structures such as the portal, superior mesenteric, and splenic veins, as well as the superior mesenteric artery (SMA) and celiac axis. Three-dimensional (3D) reconstruction of these vessels from thin cut multidetector spiral CT scans performed in both arterial and venous phase may also help in visualizing the anatomic relationships between the vessels and the mass (Fig. 59-2). The involvement of periampullary lymph nodes and retroperitoneal structures may be demonstrated. Additionally, information about distant metastatic disease can be gleaned if metastatic deposits are seen in the liver or in the peritoneal cavity. The presence of ascites is usually an ominous sign.

When both intra- and extrahepatic ductal dilations are found on imaging studies but no discrete mass lesion is seen on CT, cholangiography may be useful. Advances in MRI technology allow this modality to play an increasing role in hepatobiliary imaging (Fig. 59-3). Ultrafast spin-echo MRI can also be quite sensitive, but it can be limited by motion artifact, lack of bowel opacification, compromised resolution, and patient discomfort from the longer scanning times.[32] MRCP is now being used to image the biliary tree and the pancreatic duct. It has the advantage of being completely noninvasive (Fig. 59-4). This is also

its main disadvantage secondary to the lack of immediate access to perform a therapeutic intervention such as removal of a stone, stenting of a lesion causing proximal biliary or distal pancreatic stasis and infection. The vascular structures can also be visualized with the use of the contrast agent gadolinium and the performance of a magnetic

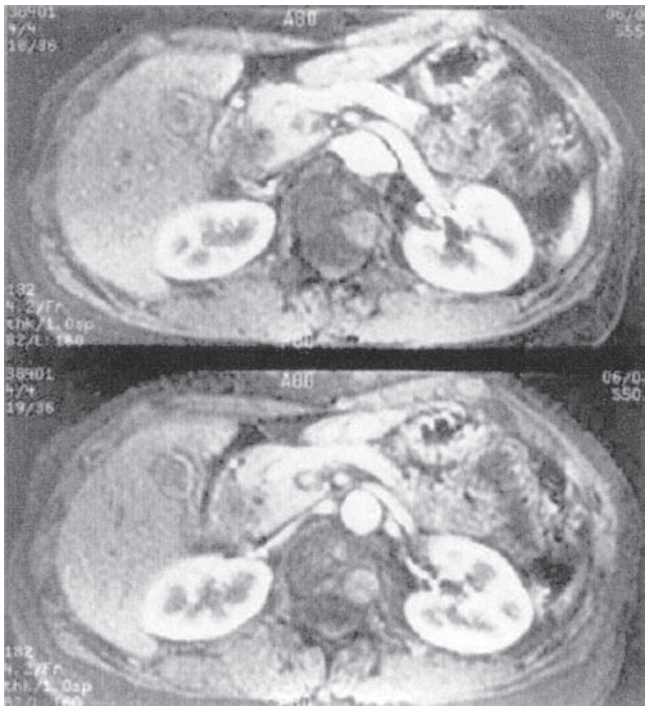

FIGURE 59-3 T1-weighted MR images with gadolinium contrast. A mass in the head of the pancreas appears hypodense. (Reproduced with permission from Yeo CJ, et al. Pancreatic cancer. *Curr Probl Surg*. 1999;Feb;36(2):59–152.)

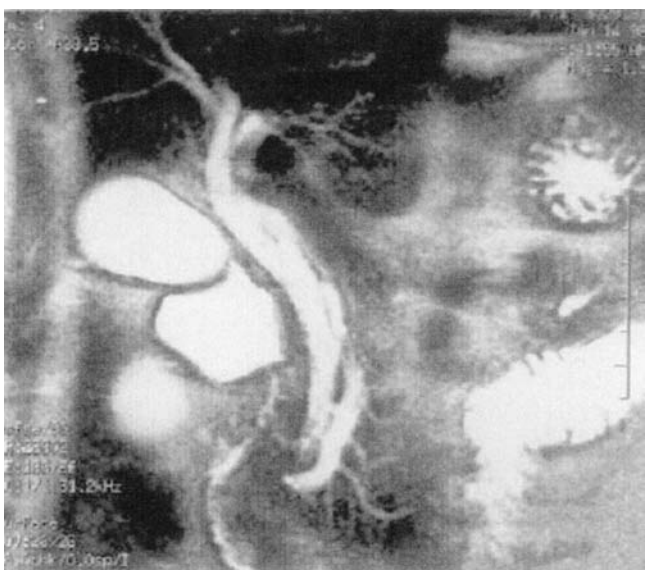

FIGURE 59-4 Single-shot spin-echo MR cholangiopancreatogram of patient with obstructive jaundice. Both the common bile duct and the pancreatic duct are dilated. The hypointense tumor is apparent in the periampullary region. (Reproduced with permission from Yeo CJ, et al. Pancreatic cancer. *Curr Probl Surg*. 1999;Feb;36(2):59–152.)

resonance angiogram (MRA). Thus a single (long) session in a scanner can provide information about tumor size and extent (MRI), the intraductal anatomy of the biliary and pancreatic system (MRCP), and the status of the nearby vasculature (MRA). The resulting scan has the potential to provide information about tumor size and extent, biliary and pancreatic ductal anatomy, and vascular involvement through a single, noninvasive procedure.

ERCP sometimes is required to solidify the diagnosis of pancreatic cancer. The classic findings of a long, irregular stricture in a pancreatic duct with distal dilation or a "double duct sign" in which there is cutoff of both the pancreatic duct and distal bile duct at the level of the genu of the pancreatic duct are pathognomonic (Fig. 59-5). With the current imaging capabilities of CT and MRI, diagnostic ERCP is rarely necessary to guide treatment. However, many patients still show up in surgery clinic already having had an ERCP performed. ERCP may be of benefit in patients with biliary obstruction and cholangitis whereupon an endoscopic stent can be placed for decompression. ERCP is most useful when there is pancreatic duct obstruction, but no mass is evident on either CT or MRI. In this situation, it is necessary to try to distinguish chronic pancreatitis from pancreatic cancer. A history of heavy alcohol consumption in the setting of abdominal pain and multiple focal stenoses of the main pancreatic duct as well as radicals is more compatible with pancreatitis, whereas an abrupt cutoff of the pancreatic duct at a single location in an elderly patient without significant pain is more compatible with pancreas cancer.

PTC is another invasive means of defining the biliary anatomy and better defines the proximal biliary anatomy above the level of obstruction (Fig. 59-6). During this procedure a percutaneous biliary drain (PBD) can also be left in place for the relief of cholangitis. The disadvantages of PTC are a result of the more invasive nature of this technique and include bleeding, hemobilia, and patient discomfort, as well as the inability to visualize the pancreatic duct. For periampullary cancer, ERCP is more commonly used than PTC or PBD.

The role of PET in the preoperative staging periampullary cancers is evolving. One theoretical advantage is the ability to differentiate between benign and malignant lesions, and there are reports of PET scans identifying CT-occult *primary* pancreatic cancers in patients with unclear etiology of painless jaundice.[33,34] Its application for this use, however, is limited, because most of these patients will be offered resection based on clinical suspicion for malignancy regardless of PET results. The main application of PET in the evaluation of patients with pancreatic cancer has been for the clarification of the presence of metastases. Several studies have reported PET to be more sensitive than CT alone in identifying metastatic disease.[33,34] Although PET is able to identify metastatic disease in sites other than liver, its efficacy in relation to other modalities has not been established in this regard.

Upper endoscopy is useful in the diagnosis of ampullary and duodenal cancers as these lesions can be directly viewed

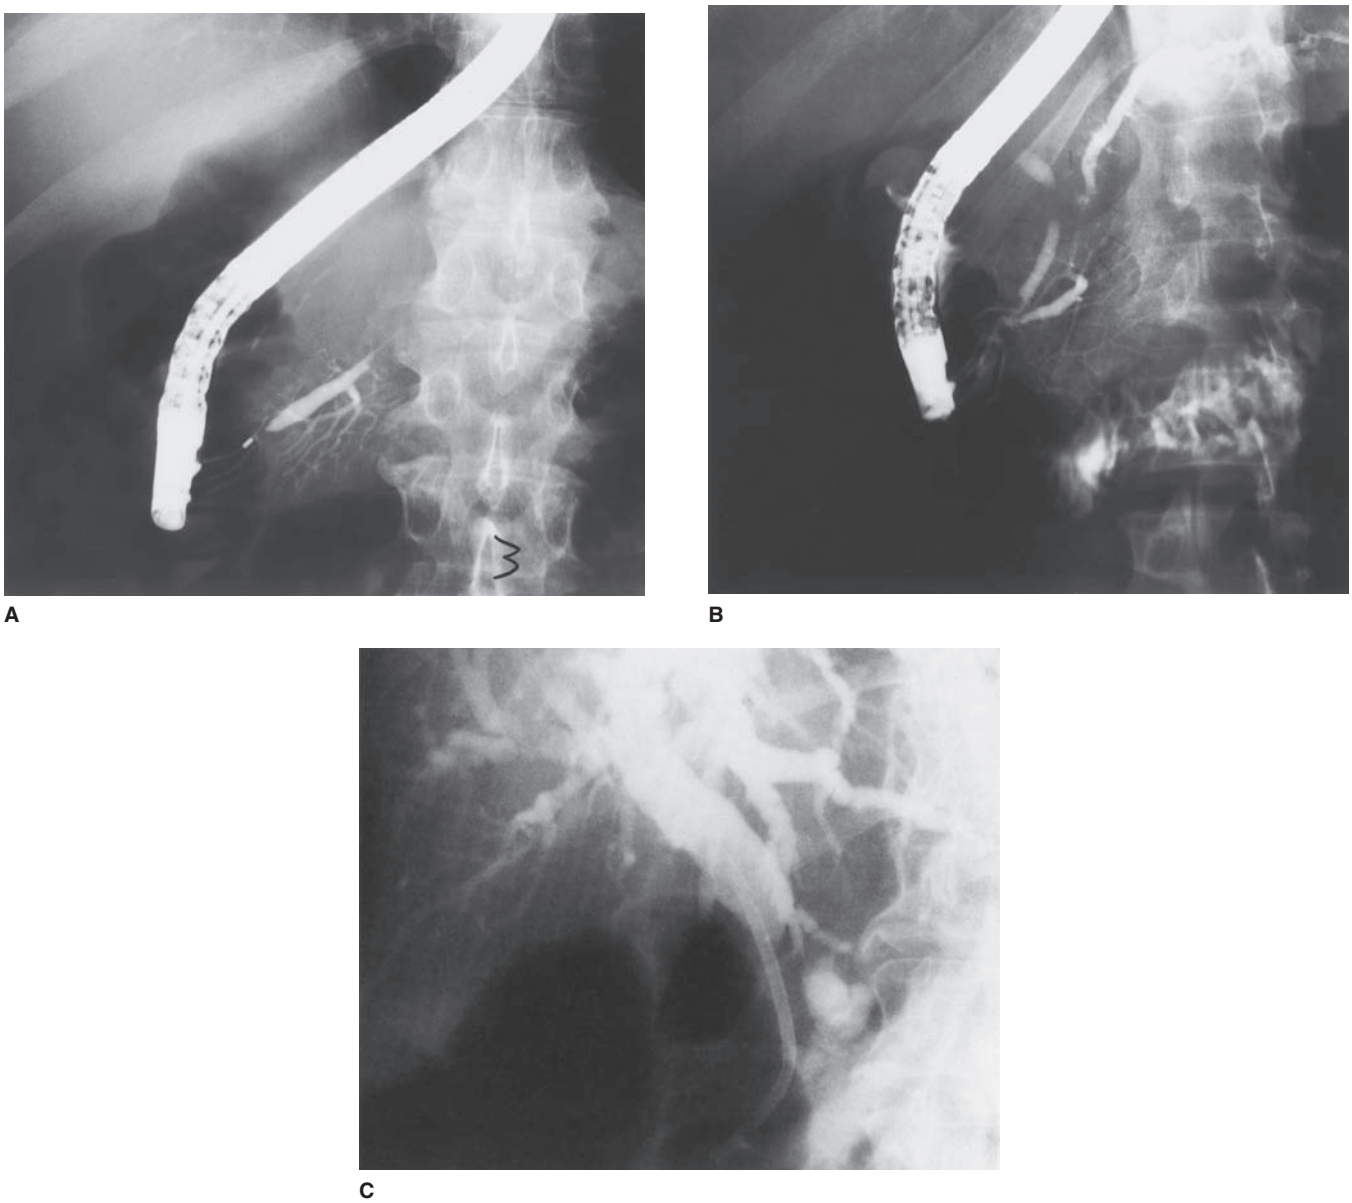

FIGURE 59-5 **A.** Endoscopic retrograde cholangiopancreatogram (ERCP) of patient with pancreas cancer with abrupt cutoff of main pancreatic duct secondary to tumor. **B.** ERCP of patient with pancreas cancer with obstruction of both main pancreatic duct and common bile duct. **C.** Completion cholangiogram after endoscopic placement of endoprosthesis. through the endoscope. If visualized, it is relatively straightforward to obtain a biopsy and tissue diagnosis. Additionally, EUS may be performed during upper endoscopy. The duodenum, ampulla, head of the pancreas, and uncinate process of the pancreas are accessible with an ultrasound probe positioned in the duodenum. The body and tail of the pancreas are accessible with an ultrasound probe positioned in the stomach. Fine-needle aspiration (FNA) of any suspected lesions can be performed at the same time as EUS if tissue diagnosis is of benefit.

Tissue Diagnosis

A tissue diagnosis of adenocarcinoma is not required prior to an attempt at a curative resection in most cases. The presentation of jaundice and weight loss along with a pancreatic mass or stricture of the distal bile duct should be considered carcinoma until proven otherwise in a patient with appropriate risk factors. Biopsies by EUS, or less commonly by percutaneous means, can easily be performed, but malignancy cannot be ruled out with certainty when no malignant cells

FIGURE 59-6 Percutaneous transhepatic cholangiogram (PTC) of patient demonstrating a dilated intrahepatic biliary tree with complete obstruction at the genu of the common bile duct. (Reproduced with permission from Lillemoe KD. Current management of pancreatic carcinoma. *Ann Surg.* 1995;Feb;221(2):133–148.)

are found in the FNA aspirate. Thus, a negative biopsy in a patient suspected of having pancreas cancer with a low operative risk and apparently resectable disease will not alter the decision to explore the patient. Several exceptions to this paradigm exist. Patients undergoing neoadjuvant therapy require a tissue diagnosis prior to the institution of therapy. In addition, the diagnosis of adenocarcinoma may be uncertain in the workup of a pancreatic mass. Neuroendocrine cancers, lymphomas, cystic lesions, and even nonneoplastic condition may not appear distinct on CT imaging. In these cases EUS-guided FNA may yield a tissue diagnosis and alter the therapeutic management.

As discussed in the previous section, FNA may be performed at the same time as EUS and may be a more attractive means of obtaining a tissue diagnosis. EUS can be performed safely with rare complications that include fistula, pancreatitis, hemorrhage, abscess, tumor seeding, and death.

Tissue diagnoses of ampullary and duodenal cancers are relatively straightforward and can easily be performed through the endoscope. Because of their locations, the ability to obtain large and deep biopsies allows better sampling. However, the histologic finding of a benign villous adenoma with or without dysplasia cannot reliably rule out malignancy. Distal common bile duct lesions are sometimes scraped with brushes or biopsied via ERCP or PTC in order to obtain a tissue diagnosis. It is often difficult to preoperatively establish the histologic diagnosis of a distal bile duct cancer with false-negative rates nearing 50%.

Preoperative Biliary Decompression

A common clinical feature of periampullary cancers is the presence of jaundice. This condition is often associated with severe pruritus, coagulopathy resulting from the impaired absorption of the fat-soluble vitamin K and less commonly cholangitis. These conditions are often managed preoperatively by biliary decompression through PTC/BD or ERCP. However, unlike hepatectomy in which preoperative jaundice has clearly been associated with an increased risk of morbidity and mortality, the same has not been shown for the resection of periampullary cancer. As a result, biliary decompression is not an absolute requirement prior to resecting a periampullary cancer in jaundiced patients. However, many factors make the use of preoperative biliary decompression both common and acceptable. These include treatment of patients with neoadjuvant therapy, organization of referral to specialist, and limited operating room availability at high-volume centers.

Most studies have demonstrated that only wound infections are increased in patients with periampullary cancers undergoing preoperative biliary decompression.[35,36] The largest series on this topic comes from the Johns Hopkins Hospital.[36] In their analysis of 567 patients, only the risk of wound infection was increased in patients undergoing preoperative biliary decompression. Mortality was equivalent in both the stented and unstented groups. Similar results were found in another large series of 300 patients from M.D. Anderson Cancer Center.[35]

Preoperative Staging

The goal of preoperative staging of pancreas and other periampullary cancers is to determine the optimal treatment for each individual patient. Substantial overlap exists between diagnosis and staging. Multidetector thin slice spiral CT with intravenous contrast is useful in both diagnosis and staging. It can detect liver metastases with high sensitivity if they are over 1 cm, but it often misses those that are less than 1 cm in size. CT scans are not highly accurate in assessing retroperitoneal lymphadenopathy or carcinomatosis in the absence of ascites or large pockets of metastases.[32] Generally, a CT scan of the chest (with or without intravenous contrast) is often performed during the preoperative staging CT. The cost-effectiveness of this approach is often questioned, and some surgeons prefer a simple chest radiograph. However, when the patient is referred postoperatively for adjuvant or palliative therapy, a staging CT including the chest is usually required. It is rare for pancreas or the other periampullary cancers to metastasize exclusively to the lungs without any signs of dissemination in the abdominal cavity.

Three-dimensional reconstruction of CT scans has also increased the ability to predict resectable disease because of the capability to focus on the vasculature at risk. In a study of 140 patients who were thought to have resectable periampullary tumors after preoperative 3D-CT, 115 (82%) were subsequently determined to have periampullary cancer.[37] The remaining 25 patients had benign disease. Among the patients with periampullary cancer, the extent of local tumor burden involving the pancreas and peripancreatic tissues was accurately depicted by 3D-CT in 93% of the patients. Three-dimensional CT was 95% accurate in determining cancer invasion of the superior mesenteric vessels. Preoperative 3D-CT accurately predicted periampullary cancer resectability and a margin-negative resection in 98 and 86% of patients, respectively. For patients with pancreatic adenocarcinoma (n = 85), preoperative 3D-CT resulted in a resectability rate and a margin-negative resection rate of 79 and 73%, respectively. The ability of 3D-CT to predict a margin-negative resection for periampullary cancer, including pancreatic adenocarcinoma, relies on its enhanced assessment of the extent of local tumor burden and involvement of the mesenteric vascular anatomy. Encasement of the portal or superior mesenteric vein over a distance not amenable to vascular reconstruction after resection, and/or encasement of the superior mesenteric, celiac, or hepatic arteries with or without occlusion are ominous signs and portend unresectability.

EUS is sometimes used to stage patients with periampullary lesions, especially if an FNA diagnosis is important in the decision to operate (Fig. 59-7). It is highly accurate in assessing the size of the primary lesion. More information is needed to adequately assess its accuracy in predicting vascular involvement. It is very operator dependent and in borderline cases may lead to the overcall of vessel involvement. EUS is poor at predicting lymph node involvement or liver metastases unless they are quite sizable.

The use of staging laparoscopy prior to an attempt at resection of a periampullary cancer varies widely among institutions. The variance in its application is related to the confidence with which the preoperative diagnosis of carcinomatosis or small hepatic metastases can be made. Proponents of routine use of laparoscopy feel that its use will save significant numbers of patients from the morbidity and mortality of exploratory laparotomy only to find metastatic unresectable disease. They feel that if a patient cannot be resected for potential cure, they are best palliated by nonoperative means.[38] The general argument made against routine laparoscopy are that current cross-sectional imaging studies are sensitive enough to identify patients who have abdominal metastases and thus does not justify the added expense of laparoscopy. They further argue that as many as 20% of the unresectable patients will go on to develop gastric outlet obstruction requiring surgical intervention.[39] Additionally they feel that operative chemical splanchnicectomy will be of benefit. Most high-volume hepatobiliary and pancreatic surgeons will selectively use staging laparoscopy.[40] The likelihood of finding disease that is unresectable is highest in those with pancreas cancers involving the body or tail or uncinate process. These lesions usually are larger and more advanced at the time of diagnosis because they do not tend to cause obstructive jaundice. The likelihood of finding disease that is unresectable is lower for duodenal, ampullary, and distal common bile duct cancer compared to pancreas cancer.

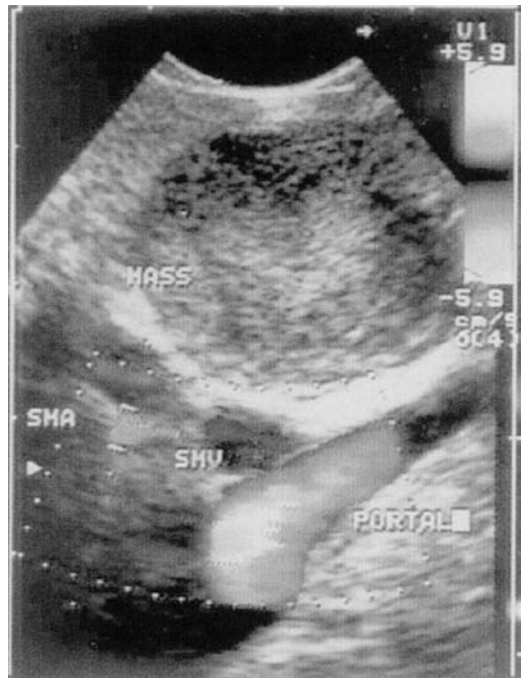

FIGURE 59-7 Endoscopic ultrasound (EUS) image with linear array echoendoscope demonstrating a mass in the head of the pancreas with no vascular invasion of the superior mesenteric artery (SMA), superior mesenteric vein (SMV), or portal vein (PORTAL). CLINICOPATHOLOGIC STAGING

Patients with exocrine pancreatic, distal bile duct, ampullary, and duodenal carcinomas are staged according to the American Joint Committee on Cancer (AJCC) staging system. These staging criteria are based on the size and extent of the primary tumor (T stage), lymph node involvement (N stage), and the presence of distant metastases (M stage). Based on these criteria, patients are stratified to the different stage groupings that guide prognosis and treatment. Pancreatic adenocarcinomas are staged using the AJCC exocrine pancreas guidelines. Distal common bile duct cancers are staged using the AJCC extrahepatic bile duct guidelines. Ampullary cancers are staged using the AJCC ampulla of Vater guidelines. Duodenal cancers are staged using the AJCC small intestine guidelines.

RESECTION OF PERIAMPULLARY CANCERS

Operative Technique of Pancreaticoduodenectomy (Whipple Procedure)

Exposure for a pancreaticoduodenectomy can be performed through a vertical midline incision from the xiphoid process to several centimeters below the umbilicus. Alternatively, a bilateral subcostal incision can be used. Exposure is greatly enhanced with the use of a mechanical retracting device.

The first portion of a pancreaticoduodenectomy is devoted to assessing the extent of disease and resectability. The benefits and disadvantages of staging laparoscopy were discussed in the previous section. At open exploration, the entire liver is assessed for the presence of metastases not seen by preoperative imaging studies. The celiac axis is inspected for lymph node involvement. Tumor-bearing nodes within the resection zone do not contraindicate resection because long-term survival is sometimes achieved with peripancreatic nodal involvement. The parietal and visceral peritoneal surfaces, the omentum, the ligament of Treitz, and the entire small and intra-abdominal large intestine are carefully examined for the presence of metastatic disease. An extensive Kocher maneuver is performed by elevating the duodenum and head of the pancreas out of the retroperitoneum and into the midline, allowing the visualization of the SMA at its origin at the aorta (Fig. 59-8). The porta hepatis is assessed by mobilizing the gallbladder and dissecting the cystic duct down to the junction of the common hepatic and common bile duct. The common hepatic artery and proper hepatic artery should also be assessed to determine that they are free of tumor involvement.

If the intraoperative assessment reveals localized disease without tumor encroachment upon resection margins, the resection is performed in relatively standard fashion. If assessment reveals evidence of local tumor extension giving the early impression of possible unresectability, the normal sequence for performing the pancreaticoduodenectomy should be modified. The easiest and safest portions of the resection should be performed first and the more difficult portions later. Tumors that initially appear unresectable can be successfully resected by patiently working where it is easiest first and finishing the harder portions later.

The distal common hepatic duct is divided close to the level of the cystic duct entry site early during the operation. For distal common bile duct cancers or pancreatic cancers near this area, more margin on the bile duct into the hilus of the liver may be required. The bile duct is retracted caudally, and a dissection plane is opened on the anterior surface of the portal vein (PV) and developed posterior to the second portion of the duodenum and the neck of the pancreas. During these maneuvers, the portal structures should be assessed for a replaced right hepatic artery originating from the SMA. If found, this vessel should be dissected and protected from injury. If the patient appears to have an accessory right hepatic artery and a significant native right hepatic artery, the accessory vessel can often be taken if involved with tumor without consequence. The gastroduodenal artery is next identified and clamped atraumatically. This maneuver confirms that the hepatic artery is not being supplied solely retrograde through the SMA collaterals (in the setting of celiac axis stenosis or occlusion). For a classic Whipple procedure, a 30–40% distal gastrectomy is performed by dividing the right gastric and right gastroepiploic arteries. The antrectomy is then completed using a linear stapling device. For a pylorus-preserving pancreaticoduodenectomy, the proximal GI tract is divided 2–3 cm distal to the pylorus with a linear stapling device. The right gastric artery can often be spared, but it may be taken if it allows better mobilization of the duodenum for reconstruction. The gastrointestinal tract

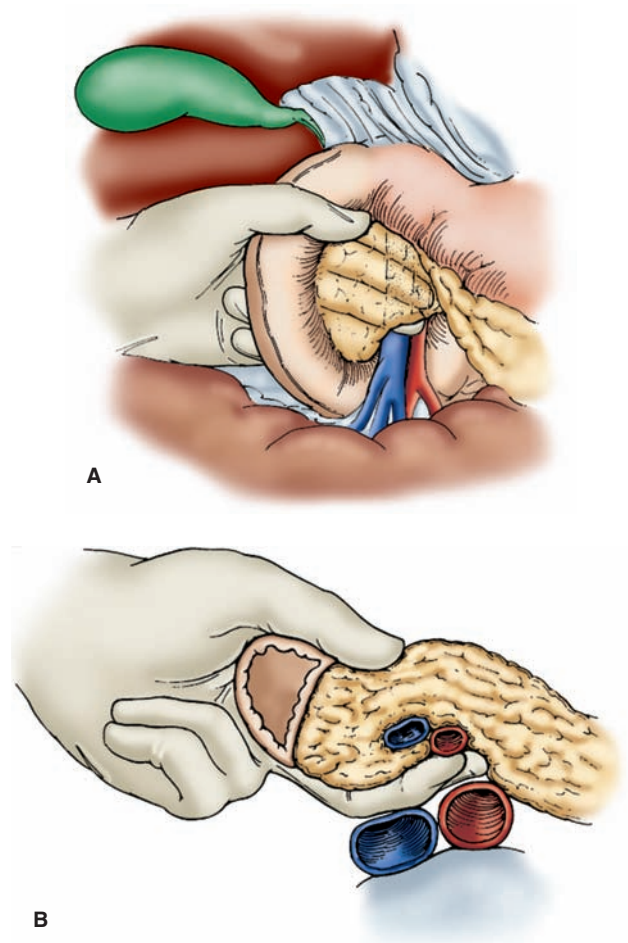

FIGURE 59-8 The uncinate process, head of the pancreas, and superior mesenteric artery (SMA) are palpated between the thumb and index finger. This maneuver enables the surgeon to determine whether the tumor has extended into the uncinate process to involve the SMA. (From Crist DW, Cameron JL. The current status of the Whipple operation for periampullary carcinoma. *Adv Surg*. 1992;25:21.)

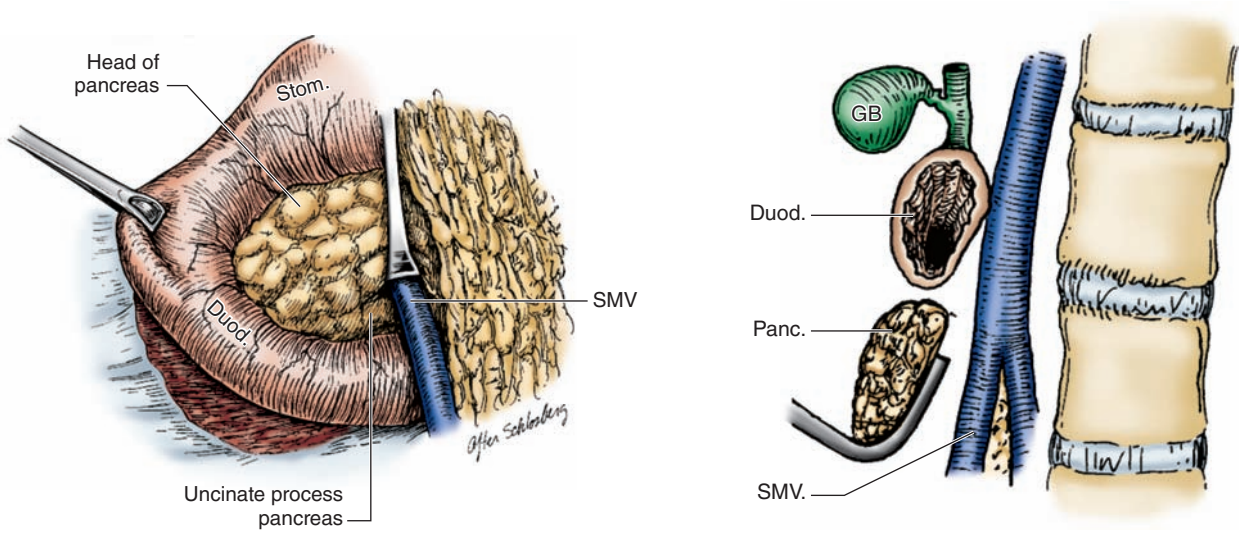

FIGURE 59-9 If one extends the Kocher maneuver of the duodenum along the third portion, the first structure one encounters anterior to the duodenum is the superior mesenteric vein (SMV). It can be cleaned quickly and visualized under direct vision from the posterior aspect of the pancreas (insert), and the dissection can be connected to that of the portal vein (PV) from above. Duod., duodenum; GB, gallbladder; Panc., pancreas; Stom., stomach.

is divided distally at a point of mobile jejunum, typically 20 cm distal to the ligament of Treitz. The mesenteric vessels to this initial portion of the jejunum are carefully divided over clamps and tied to avoid bleeding. Once the proximal jejunum is separated from its mesentery, it can be delivered dorsal to the superior mesenteric vessels from the left to the right side.

The superior mesenteric vein (SMV) caudal to the neck of the pancreas can be identified by performing an extensive Kocher maneuver of the third of the duodenum. The SMV is identified running anterior to the third portion of the duodenum. In this location, the SMV is identified by dissecting the fatty areolar tissue surrounding the veins. Division of the gastroepiploic vein emptying into the anterior surface of the SMV allows continued cephalad dissection. Often, a vein retractor lifting the inferior edge of the neck of the pancreas is useful for visualization (Fig. 59-9). The plane anterior to the SMV is developed under direct vision. With the exception of the gastroepiploic vein, there are usually no veins entering the anterior surface of the SMV in this location (Fig. 59-10). Care should be taken to avoid inadvertent injury to the splenic vein as it joins the SMV posterior to the neck of the pancreas. After the plane anterior to the PV and SMV is developed both from above and below, a Penrose drain is looped under the neck of the pancreas.

Stay sutures are placed superiorly and inferiorly on the pancreatic remnant to reduce bleeding from the segmental pancreatic arteries running in those locations. The pancreatic neck is then divided after confirming a free plane anterior to the portal and superior mesenteric veins. The Penrose drain previously placed behind the neck of the pancreas is used to elevate the pancreatic tissue to be divided and protect the underlying major veins. Some attention has been paid to identifying the blood supply of the resection margin of the pancreatic remnant and to not using electrocautery to divide the pancreas.[41] The site of the main pancreatic duct should be noted so it can be incorporated into the subsequent reconstruction.

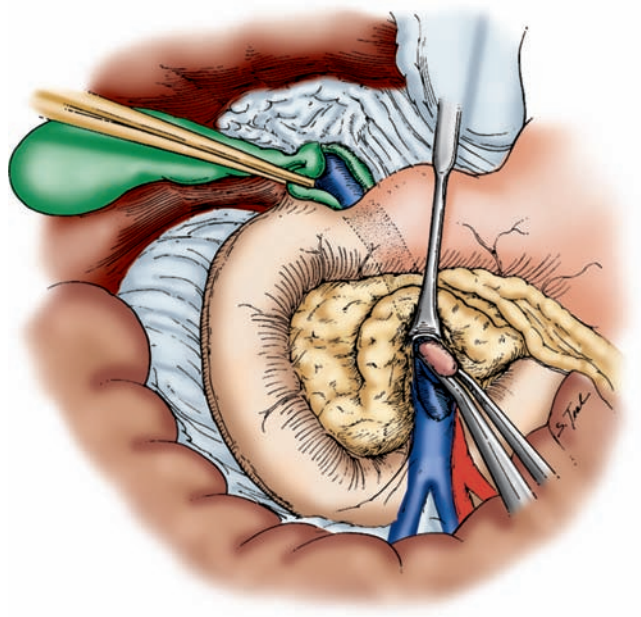

FIGURE 59-10 The superior mesenteric and portal veins are separated from the neck of the pancreas by dissection above and below the pancreas. The dissection should be limited to the anterior surface of these vessels, since there are usually no venous branches in this plane. (From Crist DW, Cameron JL. The current status of the Whipple operation for periampullary carcinoma. *Adv Surg*. 1992;25:21.)

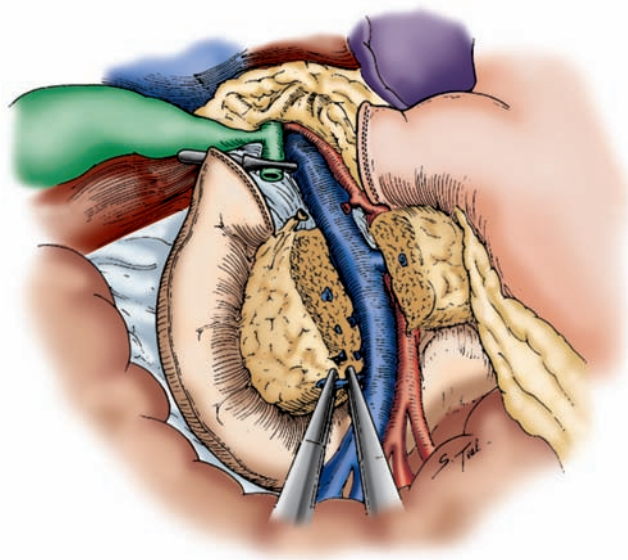

FIGURE 59-11 The portal and superior mesenteric veins are dissected from the uncinate process of the pancreas and the small venous branches between the veins and the uncinate process are ligated and divided carefully. (From Crist DW, Cameron JL. The current status of the Whipple operation for periampullary carcinoma. *Adv Surg*. 1992;25:21.)

The specimen now remains connected by the uncinate process of the pancreas. This structure is separated from the PV, SMV, and SMA. This is performed by serially clamping, dividing, and tying the smaller branches off the portal and superior mesenteric vessels (Fig. 59-11). Dissection should be performed flush with these structures to remove all pancreatic and nodal tissue in these areas. Great care is taken not to injure the superior mesenteric artery and vein at this level, but to remove completely the pancreatic tissue and lymph nodes near the vascular structures. With these areas dissected, the specimen is removed and the pancreatic neck margin, uncinate margin, and common hepatic duct margins are marked for the pathologists. To speed up analysis of these frozen section margins, the common hepatic duct margin and the pancreatic neck margin may be sampled earlier and sent to pathology while the main specimen is still being removed.

There are multiple options for reconstruction after pancreaticoduodenectomy. Most commonly the reconstruction first involves the pancreas, followed by the bile duct and then the duodenum or stomach. The issues and controversies surrounding the pancreatic and biliary reconstructions are outlined by multiple papers specifically addressing them.

The most common reconstruction involves the end of the divided jejunum brought up in a retrocolic position with creation of a pancreaticojejunostomy, followed by hepaticojejunostomy and then a duodenojejunostomy (Fig. 59-12B, C). The pancreatic reconnection is the most problematic anastomosis of the three and responsible for much of the morbidity associated with the procedure.

If the jejunum is used for reconstruction, some groups favor a separate Roux-en-Y reconstruction for the pancreas. Controversy continues regarding the best type of

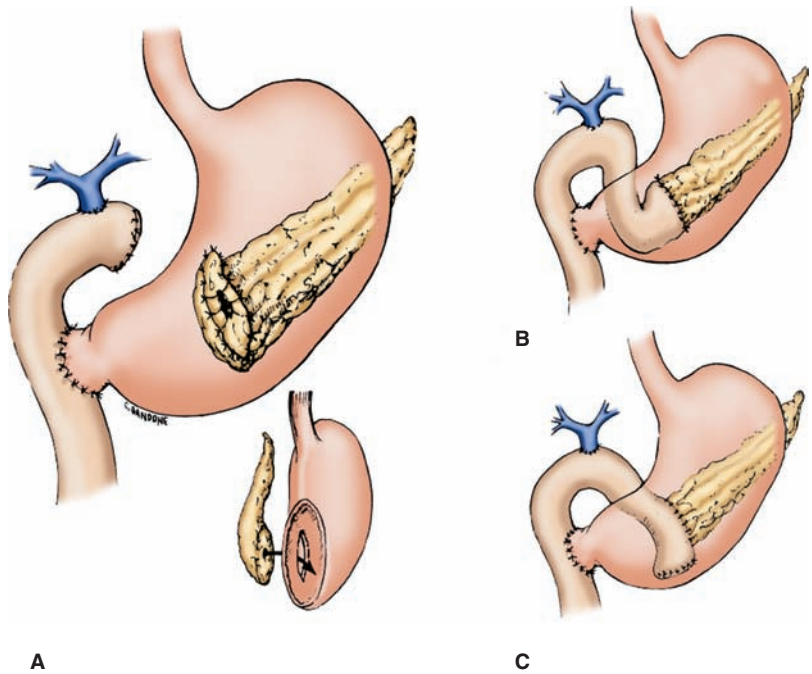

FIGURE 59-12 Schematic illustration of **A.** pancreaticogastrostomy; **B.** end-to-end pancreaticojejunostomy; and **C.** end-to-side pancreaticojejunostomy. Insert: detailed pancreaticogastrostomy, indicating the location of the posterior gastrostomy. (From Yeo CJ, Cameron JL, Maher MM, et al. A prospective randomized trial of pancreaticogastrostomy versus pancreaticojejunostomy after pancreaticoduodenectomy. *Ann Surg*. 1995;222:580.)

pancreaticojejunostomy, the importance of duct-to-mucosa sutures, and the use of pancreatic duct stents. The pancreatic reconstruction is typically performed with either a duct-to-mucosal anastomosis or with an invagination technique. With either technique, the proximal jejunal stump is brought through a defect in the mesocolon to the right of the middle colic artery. The duct-to-mucosal anastomosis is constructed in an end-to-side fashion in which the outer row consists of interrupted 3-0 silk sutures incorporating the capsule of the transected pancreas and seromuscular bites of the jejunum. A small defect is made in the jejunum to which a duct-to-mucosa anastomosis is performed incorporating the pancreatic duct and the full thickness of the jejunum using interrupted 5-0 or 4-0 Maxon (SatureDirect, Mettawa, IL). Some surgeons prefer to stent this anastomosis with a 6-cm stent cut from a 5 or 8F (French) pediatric feeding tube. Three centimeters of the stent are placed into the pancreatic duct and the other half is placed into the jejunum. The stent is held in place with an absorbable stitch such as 4-0 Vicryl (Ethicon, Somerville, NJ). This stent typically passes through the rest of the intestinal tract within several of weeks.

The invagination technique is typically performed with an end-to-end or end-to-side pancreaticojejunostomy. The pancreatic remnant should be circumferentially cleared and mobilized for 2–3 cm, to allow for an optimal anastomosis. The pancreaticojejunostomy is typically performed in two layers. The outer layer consists of interrupted silk sutures that incorporate the capsule of the pancreas and the seromuscular layers of the jejunum. The inner layer consists of a running 3-0 absorbable suture (or interrupted absorbable sutures) that incorporates the capsule and a portion of the cut edge of the pancreas and the full thickness of the jejunum. If possible, the inner layer should incorporate the pancreatic duct for several bites, to splay it open. When completed, this anastomosis nicely invaginates the cut surface of the pancreatic neck into the jejunal lumen.

If the stomach is used to reconnect the pancreas, it is invaginated into the back wall of the stomach as described previously for the jejunum (Fig. 59-12A). In a prospective randomized trial comparing pancreaticogastrostomy to pancreaticojejunostomy, there was no difference in the leak or fistula rate between the two types of anastomoses.[42]

The biliary anastomosis is typically performed with an end-to-side hepaticojejunostomy distal to the pancreaticojejunostomy. This anastomosis is performed with a single layer of interrupted absorbable sutures. If the patient has a percutaneous biliary stent, this is left in place, traversing the anastomosis. Preoperative biliary stenting remains controversial. Stenting should be used selectively in patients with obstructive jaundice who will have a substantial delay between initial presentation and definitive surgery, and in rare patients with primary suppurative cholangitis. The method of stenting, endoscopic versus percutaneous, should be chosen based on local expertise.

The third anastomosis performed is the duodenojejunostomy in cases of pylorus preservation, or the gastrojejunostomy in patients who have undergone classic pancreaticoduodenectomy with distal gastrectomy. This anastomosis is performed 10–15 cm downstream from the hepaticojejunostomy, proximal to the jejunum traversing the defect in the mesocolon.

After the reconstruction is completed, closed-suction drains are left in place to drain the biliary and pancreatic anastomoses. Some groups prefer not to place closed-suction drains, accepting that, if a fluid collection becomes clinically evident postoperatively, percutaneous drainage by interventional radiology may be required.

The postoperative management following pancreaticoduodenectomy consists of keeping the patient with nothing by mouth for 1 or 2 days and advancing the diet with liquids and then solids as tolerated. The stomach is decompressed overnight after the day of surgery with a nasogastric tube that is usually removed the next morning unless there is an extraordinarily high output. The drains around the pancreatic anastomosis are removed once the patient has been on a regular diet. Drain amylase is typically checked before pulling the drains to check for leak or fistula.

DISTAL PANCREATECTOMY FOR PANCREAS CANCER IN THE BODY OR TAIL

Staging with laparoscopy is often of benefit in patients with distal pancreatic cancers. If metastatic disease is found, distal pancreatectomy is unlikely to help in the palliation of the patient. The advantages of performing splenectomy with distal pancreatectomy include the ability to gain wider margins, removal of lymph nodes and lymphatic tissues at the tip of the pancreas and the hilum of the spleen, and avoidance of the tedious dissection of the splenic artery and vein away from the pancreatic parenchyma. The main disadvantage is the perceived increased incidence of postsplenectomy sepsis. For this reason, vaccines are given either preoperatively or after recovery postoperatively for pneumococcus, *Haemophilus meningitides*, and *Haemophilus influenzae*.

Exposure for a distal pancreatectomy and splenectomy can be obtained through a vertical midline incision from the xiphoid process to several centimeters below the umbilicus. Alternatively, a bilateral subcostal incision can be used. Exposure is greatly enhanced with the use of a mechanical retracting device. Folded sheets placed behind the patient underlying the spleen can also enhance exposure, especially in patients with a deep body habitus.

After exploration, the lesser sac is entered by removing the gastrocolic ligament from the transverse colon through the avascular plane using electrocautery. This line of dissection is carried to the descending colon, and the proximal white line of Toldt is divided. The stomach is further mobilized by dividing the omentum anterior to the hilum of the spleen as well as the short gastric vessels (vasa brevia).

This dissection is carried to the superior pole of the spleen. Once the stomach is fully mobilized, it is retracted superiorly along with the omentum to provide wide exposure of the anterior surface of the pancreas. The general location of the tumor should be noted at this point. The peritoneum is divided along the inferior edge of the pancreas using electrocautery. Care is taken to identify and avoid injury of the inferior mesenteric vein (IMV) that joins the splenic vein posterior to the body of the pancreas or less commonly directly joining the SMV.

The splenic artery that sends multiple branches to the superior edge of the pancreas before terminating in the spleen is identified and encircled near its origin at the celiac. Once a test clamp is performed and preservation of flow to the hepatic artery is confirmed, the splenic artery is divided. The splenic artery stump should be further secured with a nonabsorbable suture ligature. After the spleen toward the spine is retracted medially, the electrocautery is used to incise the peritoneal reflection starting at the previously made incision at the inferior edge of the pancreas and extending this incision laterally and superiorly. The spleen and tail of the pancreas are mobilized out of the retroperitoneum using electrocautery or sharp dissection. Care must be taken to remain anterior to the left adrenal gland and Gerota's fascia of the left kidney. Once the junction of the IMV is reached, the splenic vein can usually be separated from the pancreatic parenchyma and divided lateral to this junction. If the lesion is in the body of the pancreas, it may be necessary to divide the splenic vein near its junction with the SMV-PV confluence. Transection of the pancreas can be accomplished with a knife, electrocautery, linear stapler, or harmonic scalpel. The development of a postoperative pancreatic fistula may occur in up to 25% of patients. Only direct ligation of the pancreatic duct and the perioperative use of octreotide have been shown to reduce the rate of postoperative pancreatic fistulas. If a stapler is not used to transect the pancreas, the remnant is oversewn in two layers with absorbable suture. A surgical drain is placed in order to identify and control a pancreatic fistula.

Cancer of the body of the pancreas can be the most difficult lesion to manage surgically. By virtue of this location, extension superiorly beyond the pancreas often results in involvement of the celiac trunk, common hepatic artery, and base of the splenic artery at its takeoff from the celiac trunk. Growth slightly to the right and posterior will involve the medial wall of the PV or SMV and may also infiltrate the junction of the splenic vein with the PV-SMV confluence. In these patients, considerable complexity is added to a distal pancreatectomy. The determination of resectability in these patients is based on the extent of involvement of the celiac axis. Therefore dissection should begin at the common hepatic artery and carried toward the celiac axis. If a clear margin is achievable, then the tumor is resectable. Involvement of the PV-SMV may require en bloc resection and PV reconstruction to achieve a negative margin.

OPERATIVE PALLIATION

With accurate preoperative staging, the resectability rate for periampullary cancers is approximately 80%.[37,43–46] When a patient undergoes exploratory laparotomy (and sometimes exploratory laparoscopy) and is found to be unresectable, a decision must be made as to whether to operatively palliate the patient. Operative palliation is indicated in a patient without widespread metastatic disease and with a relatively long life expectancy. The added potential morbidity and mortality of operative palliation must be weighed against the more durable palliation achieved with hepaticojejunostomy and/or gastrojejunostomy (Fig. 59-13). Additionally, chemical splanchnicectomy can be performed at the same time for relief of pain (Fig. 59-14).

Operative Palliation of Obstructive Jaundice

The most commonly performed operative procedure for the relief of obstructive jaundice is hepaticojejunostomy. Cholecystojejunostomy should no longer be performed.

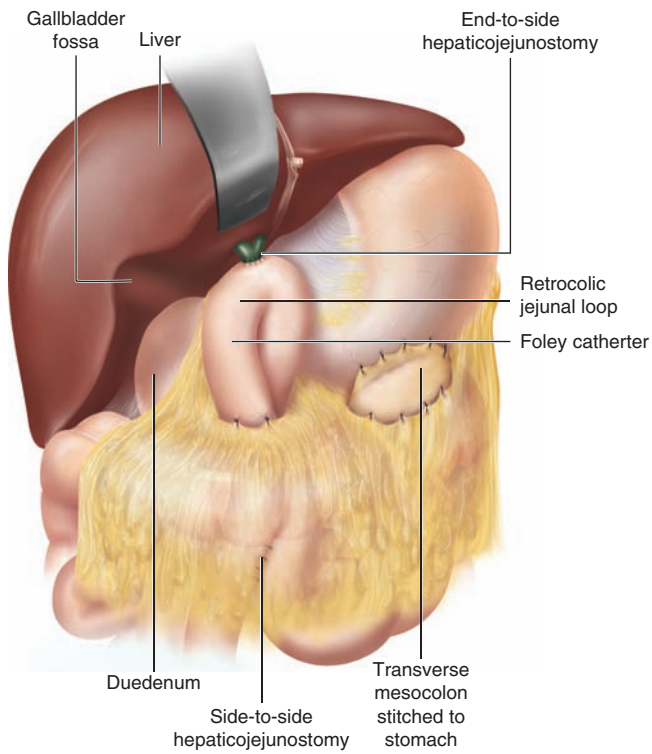

FIGURE 59-13 Anatomy after one method of palliative intervention. The biliary-enteric anastomosis is shown as a retrocolic end-to-side hepaticojejunostomy with a jejunal loop. A jejunojejunostomy is performed below the transverse mesocolon, to divert the enteric stream away from the biliary tree. Also shown is a retrocolic gastrojejunostomy. (From Cameron JL. *Atlas of Surgery*, Vol 1. Toronto, Canada: B.C. Decker; 1990:427, Image V.)

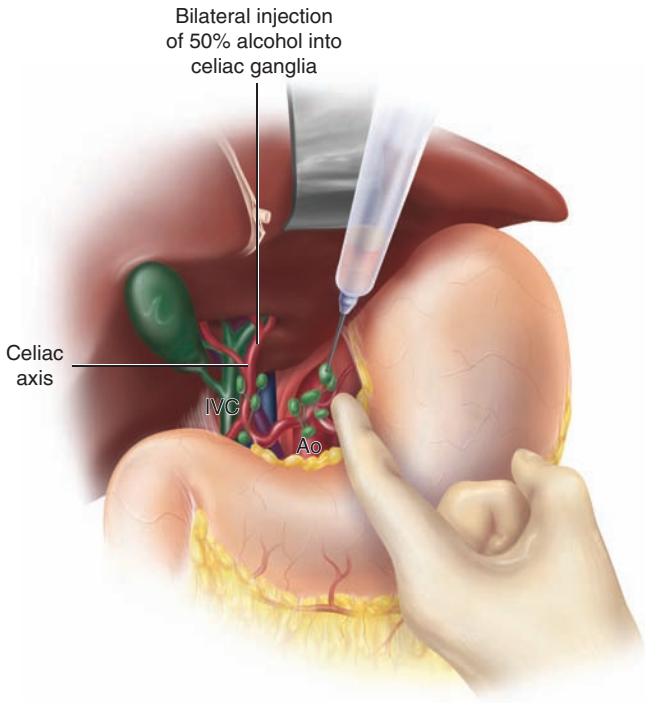

FIGURE 59-14 Technique of alcohol celiac nerve block. Twenty milliliters of 50% alcohol are injected on each side of the aorta (Ao) at the level of the celiac axis. IVC, inferior vena cava. (Redrawn with permission from Lillemoe KD, et al. Chemical splanchnicectomy in patients with unresectable pancreatic cancer. A prospective randomized trial. *Ann Surg*. 1993;May;217(5):447–455.)

Simple drainage through a T tube inserted above the biliary obstruction should be avoided as this causes a high-output biliary fistula and results in major electrolyte abnormalities. Hepaticojejunostomy provides more durable relief of obstructive jaundice than does cholecystojejunostomy because of the proximity of the cystic duct to most periampullary cancers.[47,48] The hepaticojejunostomy is performed after cholecystectomy in an end-to-side fashion to either a Roux limb or a loop of jejunum with a Braun jejunojejunostomy between the afferent and efferent limbs. Only 4% of patients with unresectable periampullary cancers palliated with hepaticojejunostomies develop recurrent jaundice prior to their deaths.[44] As operative palliation is attempted more with minimally invasive techniques, perhaps laparoscopic cholecystojejunostomies or hepaticojejunostomies will be performed more often secondary to the relative ease with which they can be done and to avoid a major incision.

Operative Palliation of Duodenal Obstruction

Periampullary cancers may cause gastric outlet obstruction by compromising the duodenal lumen. Most patients with gastric outlet obstruction from a periampullary cancer that is not widely disseminated benefit from palliation, whether operative or with endoscopic stenting techniques. There remains controversy, however, regarding the role of prophylactic gastrojejunostomy in a patient who is being explored but without symptoms of gastric outlet obstruction. Much of this controversy rests on the exact proportion of patients who actually develop gastric outlet obstruction requiring surgical intervention in the course of their disease. This number is surprisingly low in some series (3%)[49] and approaches 20% in other series.[50] In a prospective, randomized trial from the Johns Hopkins Hospital, 87 patients with unresectable periampullary cancers without signs of gastric outlet obstruction were randomized to either a retrocolic gastrojejunostomy or no gastric bypass.[51] None of the patients who underwent prophylactic gastrojejunostomy subsequently developed gastric outlet obstruction, whereas 19% of them who did not have a gastric bypass subsequently developed gastric outlet obstruction requiring intervention. In this study, performance of the gastrojejunostomy did increase operative time, but it did not increase morbidity, mortality, or length of stay. The gastrojejunostomies were performed typically in a retrocolic (to the left of the middle colic vessels) and isoperistaltic fashion, using a loop of jejunum just beyond the ligament of Treitz. The gastrotomy is placed on the back wall of the stomach in the most dependent portion. Vagotomy is not performed because of its contribution to delayed gastric emptying, the limited life expectancy of the patients, and the ability to control acid secretion medically.

Operative Chemical Splanchnicectomy for Pain

Operative chemical splanchnicectomy was first introduced in the 1960s to alleviate the pain associated with unresectable pancreas cancer.[52] A prospective, randomized trial compared intraoperative chemical splanchnicectomy to placebo in 137 patients with unresectable pancreatic cancer.[51] The procedure was performed by injecting 20 mL of 50% ethanol or saline through a spinal needle on either side of the aorta at the level of the celiac plexus. There were no differences in hospital morbidity, mortality, or length of stay. The group receiving the alcohol had significantly lower pain scores at 2, 4, and 6 months postoperatively. Even those patients who did not report pain preoperatively derived benefit from the splanchnicectomy as they appeared to have a delay in the onset of their pain and had lower pain scores as their disease progressed when compared to control patients.

NONOPERATIVE PALLIATION

Only 15–20% of patients with pancreas cancer are found to be resectable for cure at the time of presentation because of disseminated disease or locally advanced disease. Patients with distal common bile duct, ampullary, and duodenal cancers are more likely to be resectable. For the majority of patients,

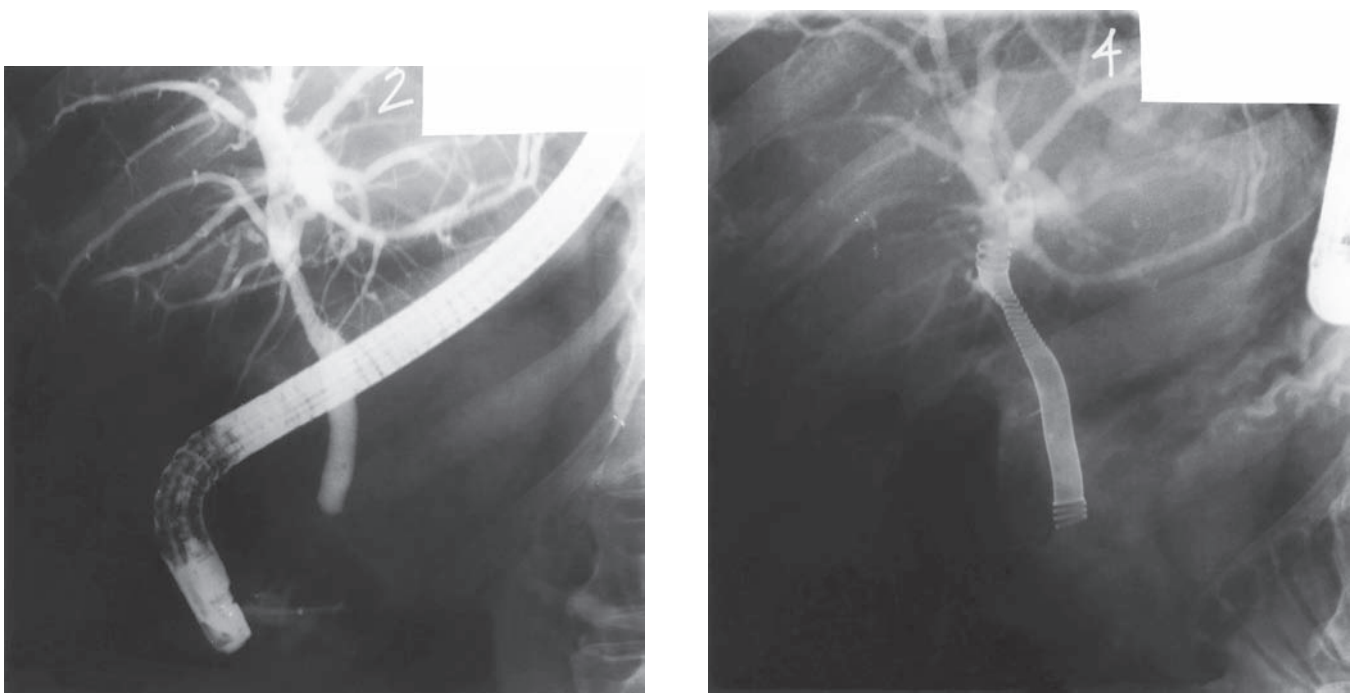
palliation of symptoms is the primary goal of any invasive intervention. As discussed in the previous section, the three main problems that need to be palliated include obstructive jaundice, gastric outlet obstruction, and pain.

Nonoperative Palliation of Obstructive Jaundice

Nonoperative biliary drainage can be achieved either through a percutaneous or an endoscopic approach (Fig. 59-15). Percutaneous transhepatic approaches are aided by the fact that the intrahepatic ducts are usually dilated in patients presenting with obstructive jaundice. Endoscopic drainage has the advantage of not having any external catheters. In a randomized trial comparing endoscopic versus percutaneous stent placement in 70 patients, the success rate, overall complication rate, and procedure-related mortality rate was significantly lower in the endoscopic group.[53] Endoscopic biliary stents may be either plastic or metal. Plastic stents are generally temporary and are available in different diameters and lengths. Because the diameter of the accessory channel of endoscopes is limited, usually the largest plastic stent that can be placed is 12F. This relatively small diameter results in frequent occlusion and the necessity of periodically changing these stents. In an effort to improve on the rate of stent occlusion, self-expanding metallic stents have been developed and, when deployed, they can reach a diameter of 30F. Randomized controlled clinical trials comparing 10 or 11.5F plastic stents to 30F metallic stents have shown metallic stents to have a longer patency rate (6.2–9.1 months compared to 4.2–4.6 months) and to be associated with lower rates of cholangitis, stent replacement, and hospital days.[54,55] Metallic stents eventually fail because of tumor ingrowth at the ends and through the interstices. Polyurethane-covered stents are currently being developed and used, and they probably have better patency and results. The disadvantage of metallic stents is that they cost more and should be used in patients who are expected to live longer than 6 months. It should be noted that the placement of a metallic stent does not preclude the ability to perform a subsequent cancer resection. Division of the bile duct and removal of the stent can easily be performed at the time of operation.

Nonoperative Palliation of Duodenal Obstruction

Until recently, duodenal obstruction in patients found to be unfit for surgical bypass was treated with placement of gastrostomy tubes. The development of expandable metallic bowel stents has provided an additional way of controlling gastric outlet obstruction in this group of patients. Gastroduodenal stenting is successful in 80–90% of patients and provides adequate relief of obstruction in most patients.[56,57]



A B

FIGURE 59-15 **A.** Endoscopic retrograde cholangiopancreatogram (ERCP) showing distal bile duct obstruction owing to pancreatic cancer. **B.** ERCP showing a metallic expandable stent in place.

Nonoperative Palliation of Pain

In addition to opioids and nonsteroidal anti-inflammatory agents, several nonoperative palliative treatment modalities for pain with periampullary cancers have been developed, including ultrasound or CT-guided celiac plexus nerve blocks and even external beam radiotherapy. Several randomized controlled clinical trials comparing percutaneous celiac plexus nerve blocks to standard oral analgesics have demonstrated significant diminution in pain and narcotic use in the majority of the patients.[58,59]

COMPLICATIONS FOLLOWING PANCREATICODUODENECTOMY AND DISTAL PANCREATECTOMY

The mortality rate after pancreaticoduodenectomy at centers specializing in pancreatic surgery is in the range of 2–3%. Despite low mortality rates, the incidence of postoperative complication remains high. In a series of 650 consecutive pancreaticoduodenectomies, the mortality rate was 1.4% with a complication rate of 41%.[60] The three most common complications were delayed gastric emptying in 19%, pancreatic fistula in 14%, and wound infection in 10%. Delayed gastric emptying is not life-threatening and is usually self-limited. The condition, however, can significantly increase lengths of stay for the patient, as well as hospital costs. Patients are usually treated with parenteral nutritional support and nasogastric decompression until the condition resolves. Erythromycin, a motilin agonist, has been shown to improve gastric emptying after pancreaticoduodenectomy and is sometimes used.[61] Pancreatic fistulae are not uncommon after pancreaticoduodenectomy. The reported rates of pancreatic fistula vary and, to some degree, depend on how they are defined. In general, a pancreatic fistula exists if, at 7 days postoperatively, there is amylase-rich fluid in excess of 50 mL/d. In the great majority of patients, the pancreatic leak will seal with conservative management. Most centers place intraoperative closed-suction drains near the pancreatic anastomosis to control potential leaks. Some centers do not place drains intraoperatively and prefer to have them placed postoperatively and by interventional radiological techniques should the patient become symptomatic with a pancreatic leak. If the patient is relatively asymptomatic and the output is less than 200 mL/d while on a diet, consideration toward sending the patient home with outpatient drain management should be given. In most cases, the fistula will improve and cease within a couple of weeks. If the patient is symptomatic or the fistula is high output (>200 mL/d), consideration to making the patient NPO and using parenteral nutrition should be given.

Distal pancreatectomy is required for the resection of pancreatic cancers of the body and tail of the pancreas. Although, this operation is less involved than a pancreaticoduodenectomy, the potential for significant morbidity exists. In a series of 704 patients who underwent a distal pancreatectomy for any indication, the operative mortality was less than 1%.[62] However, the morbidity rate rivals that of the pancreaticoduodenectomy at 33%. Twelve percent of patients had a clinically significant postoperative pancreatic fistula. Other complications included intra-abdominal abscess (5%), small bowel obstruction (5%) and new-onset diabetes (7%). A postoperative pancreatic fistula following distal pancreatectomy is managed in the same manner as that following a pancreaticoduodenectomy.

Long-Term Survival After Resection of Periampullary Cancers

The periampullary adenocarcinomas share a common location of origin but vary greatly in their long-term survival. In an analysis of actual 5-year survivors from 242 consecutive patients with resected periampullary adenocarcinoma, of which 149 (62%) were pancreatic primaries, 46 (19%) arose in the ampulla, 30 (12%) were distal bile duct cancers, and 17 (7%) were duodenal cancers, there were 58 actual survivors.[63] The tumor-specific 5-year survival rates were only 15% for pancreatic, while ampullary, distal bile duct, and duodenal had much better survival of 39, 27, and 59%, respectively (see Figs. 59-16, 59-17, and 59-18). When compared with patients who did not survive 5 years, the 5-year survivors had a significantly higher percentage of well-differentiated tumors, negative resection margins, and negative lymph nodes.

Several series have reported survival and prognostic features for some of the individual periampullary adenocarcinomas. The most lethal of the periampullary cancers is pancreatic adenocarcinoma. In a series of 1423 pancreaticoduodenectomies for pancreatic adenocarcinoma, the median survival

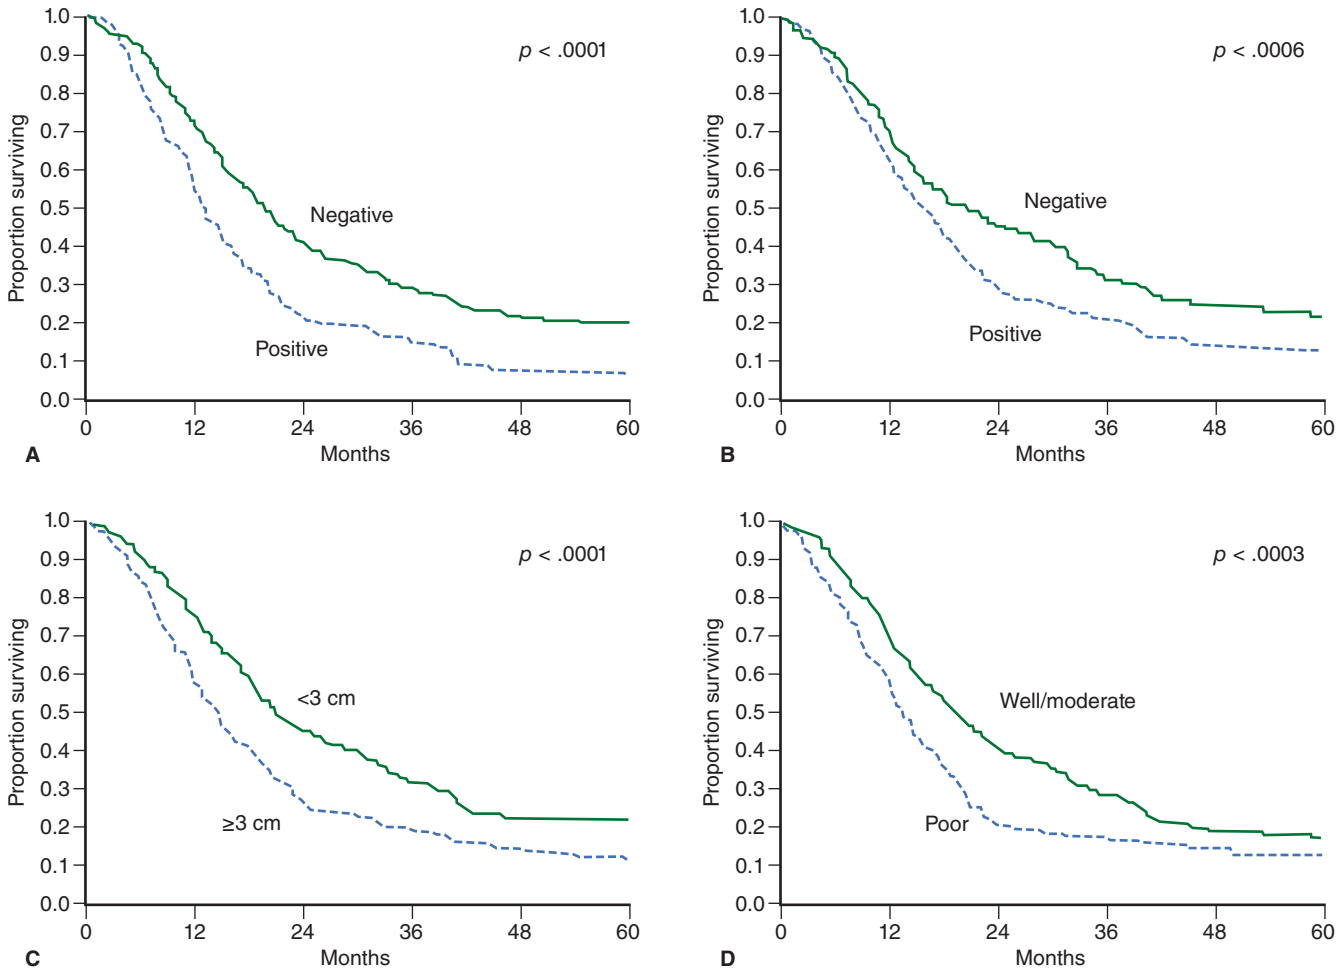

FIGURE 59-17 Survival curves comparing patients with **A.** negative resection margins (n = 442) to those with positive resection margins (n = 184); **B.** negative lymph nodes (n = 166) to those with positive lymph nodes (n = 441); **C.** tumor diameter <3 cm (n = 268) to those with tumor diameter >3 cm (n = 325); and **D.** well/moderate tumor differentiation (n = 380) to those with poor tumor differentiation (n = 216). (Reproduced with permission from Sohn TA, et al. Resected adenocarcinoma of the pancreas-616 patients: results, outcomes, and prognostic indicators. *J Gastrointest Surg*. 2000; Nov-Dec; 4(6):567–579.)

was 18 months with a 5-year survival of 18%.[64] Factors that affected survival in this cohort included tumor size of greater than 3 cm (hazard ratio [HR] 1.6; $p < .001$), positive resection margin (HR 1.6; $p < .001$), histological grade (HR 1.6; $p < .001$), and regional lymph node metastases (HR 1.3; $p = .05$), among others. In a series of 127 resected patients with ampullary adenocarcinoma, a 5-year survival rate of 36% was reported.[65] On multivariate analysis, only depth of invasion and lymph node status were predictors of survival.

There is accumulating evidence suggesting that mutations in tumor suppressor genes, oncogenes, and DNA mismatch repair genes also influence prognosis in pancreas cancer. Patients who have pancreas cancers with p53 mutations have been shown to have a worse prognosis.[66] Additionally, the number of tumor suppressor gene mutations found in a pancreatic cancer correlates with the risk of death in patients.[27] In contrast to this and in line with improved prognosis in patients with HNPCC, patients with pancreas cancers with DNA mismatch repair mutations seem to have a better prognosis.[67]

There is also evidence that hospital volume is related to perioperative mortality, length of hospital stay, hospital cost, and long-term outcome in patients undergoing pancreatic resection.[68–71] These studies seem to suggest that regionalization of care of patients requiring pancreaticoduodenectomy and complex pancreatic procedures will affect both the cost and outcome.

ADJUVANT THERAPY

There are numerous adjuvant regimens for periampullary cancer and these vary with the cancer type and often for a particular cancer. The diversity in treatments is in large part because no one regimen has been shown to carry a significant advantage over another. In fact, at best adjuvant therapy

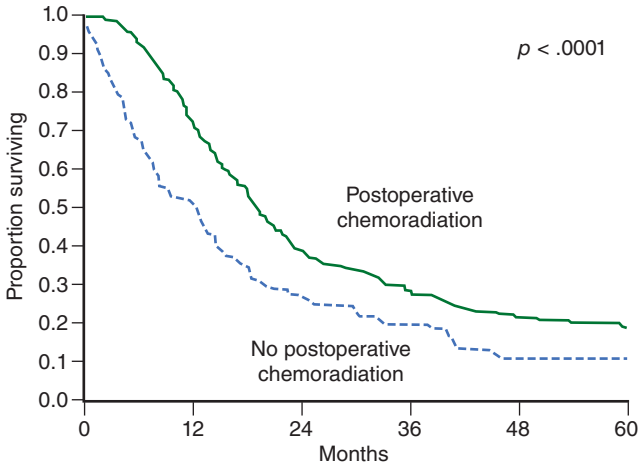

FIGURE 59-18 Survival curves comparing patients receiving postoperative chemoradiation (n = 333) to those not receiving postoperative chemoradiation (n = 119). (Reproduced with permission from Sohn TA, et al. Resected adenocarcinoma of the pancreas-616 patients: results, outcomes, and prognostic indicators. *J Gastrointest Surg.* 2000; Nov-Dec;4(6):567–579.)

adds only a modest benefit over surgery alone. Unanswered questions in this field include the relative effectiveness of chemoradiation versus chemotherapy alone, radiation fractionation and dosing, and optimal systemic therapy. Because current chemotherapy is relatively ineffective, the next leap-forward in improving outcomes for these patients will be the development of more effective systemic therapy.

Adjuvant therapy for periampullary cancer is best studied in pancreatic adenocarcinoma for which several prospective trials were conducted. In 1985, the Gastrointestinal Tumor Study Group (GITSG) trial was published.[72] This was a prospective randomized trial comparing observation (control) to split-course radiotherapy (4000 cGy, 20 fractions, over 6 weeks) with bolus 5-flourouracil (5-FU) 500 mg/m^2 intravenous daily on each of the first 3 days of radiotherapy of each 200-cGy sequence in patients with pancreas cancer. Additionally, patients receiving adjuvant therapy received bolus 5-FU every week for 2 years. The patients on this trial who received adjuvant therapy had better median and overall survival rates.

It has also been demonstrated that multiagent 5-FU chemotherapy regimens can be combined with radiotherapy. The group at the Virginia Mason Clinic have combined 5-FU, cisplatinum, α-interferon, and radiotherapy, and have shown significant activity in the adjuvant setting.[73] The effectiveness of delivering 5-FU as a continuous infusion, a manner of delivery associated with improved efficacy in rectal and colon cancer, is also being explored.[74] Gemcitabine has been compared to 5-FU for the nonradiotherapeutic components by the Radiation Therapy Oncology Group (RTOG) 97–04 (now closed with completion of accrual). This comparison was based on the observation that, in patients with metastatic pancreatic cancer, gemcitabine produced statistically superior survival results to 5-FU. We are likely to see more trials in the future combining gemcitabine with radiotherapy. A randomized controlled trial was performed by the European Study Group for Pancreatic Cancer (ESPAC-1) in which 541 eligible patients with pancreas cancer were randomized to adjuvant chemoradiotherapy (20 Gy in 10 daily fractions over 2 weeks with IV 5-FU on days 1–3 and 15–17), chemotherapy (IV 5-FU and folinic acid for 5 days every month for 6 months), both, or observation. The study demonstrated no survival benefit for adjuvant chemoradiotherapy but revealed a potential benefit for adjuvant chemotherapy over observation (median survival of 19.7 vs 14.0 months).[75]

The most recent prospective randomized trial for adjuvant therapy for pancreas cancer also comes from Europe.[76] The CONKO-001 trial did not evaluate the effect of chemoradiotherapy based on the results of the ESPAC-1 trial and compared chemotherapy alone versus observation. Gemcitabine was chosen as the single agent in this study based on its benefit when used as palliative therapy. This trial demonstrated that gemcitabine increased the median disease-free survival from 6.9 to 13.4 months in a cohort of 368 patients. Despite this difference, there was no improvement of overall median survival that was 22.1 months in the treatment group and 20.2 months in the observation group.

The role of adjuvant chemoradiation in the treatment of distal bile duct, ampullary, and duodenal cancers is less well understood than for pancreas cancer. This is because of the relative rarity of these diseases, especially in relation to pancreas cancer. As a group, these patients tend to be treated with 5-FU–based chemotherapy or chemoradiotherapy. No large prospective trials have been conducted solely for any of these periampullary cancers. Several retrospective studies have suggested a benefit for chemoradiotherapy in some instances. For example, Krishnan et al[77] conducted a retrospective analysis of 96 patients with resected ampullary cancer and demonstrated a trend toward improved survival in those who receive chemoradiotherapy in comparison to observation. This study, as with most retrospective studies on this topic, is confounded by the potential for selection bias in that "healthier" patients tend to undergo adjuvant therapy.

NEOADJUVANT THERAPY

Neoadjuvant therapy has several theoretical advantages. It allows more timely administration of chemo- or chemoradiotherapy to patients who are at a high risk of failure after surgical resection. It has the potential to shrink the tumor and theoretically can decrease the extent of local disease. Patients who develop disseminated disease during neoadjuvant treatment are unlikely to have benefited from initial resection and are spared the time commitment, morbidity, and potential mortality of resection. It may allow better selection of patients who are most likely to benefit from surgical resection.

A recent series was reported from Duke University of 193 patients with biopsy-proven pancreatic adenocarcinoma

who completed neoadjuvant chemoradiotherapy and 70 patients who underwent resection.[78] Exact treatment regimens varied, but 183 patients (95%) received 5-FU–based chemotherapy delivered concurrently with daily external beam radiotherapy for a planned total dose of 4500 cGy at 180 cGy per fraction over 5 weeks plus a 540-cGy boost to the tumor. Ten patients (5%) received gemcitabine chemotherapy with twice-daily external beam radiotherapy with a planned total dose of 3000 cGy at 150 cGy per fraction over 3 weeks. Complete histologic responses occurred in 6% of patients. Patients who underwent resection with minimal residual disease, and those whose tumor specimens had significant tumor necrosis, enjoyed significantly better survival.

The M.D. Anderson Cancer Center experience with neoadjuvant chemoradiation for resectable pancreatic cancer was recently summarized.[79] Since 1988, four prospective neoadjuvant trials have been completed at that institution with identical eligibility criteria using a CT-based definition of resectable disease, a uniform surgical technique for the performance of pancreaticoduodenectomy, and a standardized system for pathologic evaluation of the surgical specimens. All eligible patients were required to have biopsy-proven adenocarcinoma of the pancreatic head. The trials have evolved with the first two using 5-FU as the chemotherapy component, the third using paclitaxel, and the fourth using gemcitabine. All four trials combined chemotherapy with radiotherapy in the neoadjuvant setting (Table 59-1).

NOVEL AGENTS IN PANCREATIC CANCER

In the recent past new agents have emerged that have been targeted toward some of the known molecular or genetic defects found in pancreatic cancer. Countless agents, both classic chemotherapy and biological, are in various stages of investigation. In this section several of the biological agents that have been studied in early-phase clinical trials will be reviewed. These include immunotherapy, angiogenesis inhibitors, *K-ras* inhibitors, and inhibitors of the epidermal growth factor receptor (EGFR) family.

Immunotherapy

Immune-based therapies can exploit both the cellular and humoral components of the immune system. Strategies aimed at the cellular components recruit and activate T cells that recognize tumor-specific antigens. Strategies using monoclonal antibodies are being designed to target tumor-specific antigens that can kill tumor cells by direct lysis or through delivery of a conjugated cytotoxic agent. Both approaches are attractive for several reasons. First, immune-based therapies act through a mechanism different from chemotherapy or radiation therapy and would not be prone to cross-resistance in previously treated patients. Second, through the genetic recombination of their respective receptors, the B cells and T cells of the immune system are capable of recognizing a diverse array of potential tumor antigens. New knowledge into the mechanisms by which T cells are successfully activated and by which tumors evade immune recognition is driving the development of new combinatorial approaches. Also, recent advances in gene-expression analysis have allowed for the identification of new pancreatic targets, including candidate tumor antigens that might serve as T-cell and antibody targets. These advances now make it possible to exploit the immune system to recognize and destroy pancreas cancer.

In a phase I trial of patients with surgically resected adenocarcinoma of the pancreas, 14 patients were treated with an allogeneic tumor cell vaccine transduced to secrete granulocyte-macrophage colony-stimulating factor. No dose-limiting toxicities were encountered.[80] This vaccine approach induced dose-dependent systemic antitumor immunity as measured by increased postvaccination delayed-type hypersensitivity responses against autologous tumors. Moreover, the three long-term survivors had the strongest postvaccination responses. This strategy is currently being evaluated in a phase II trial at Johns Hopkins Hospital.

Angiogenesis Inhibitors

Bevacizumab is a recombinant humanized monoclonal antibody directed against the vascular endothelial growth factor (VEGF). Bevacizumab has been studied in combination

with gemcitabine in a phase II study.[81] A total of 52 patients with advanced or locally advanced pancreatic cancer received gemcitabine and bevacizumab. Eleven patients (21%) had confirmed partial responses and 77% of the patients were alive at 6 months. Median survival was 8.8 months. These results prompted the initiation of a definitive phase III study under the auspices of the Cancer and Leukemia Group B (CALGB 80303). The final results of this trial are pending.

K-ras Inhibitors

An activating mutation of the *K-ras* is present in nearly 100% of pancreatic cancers. *K-ras* requires farnesylation to be active. This reaction is mediated by the enzyme farnesyltransferase, and inhibitors of this enzyme have been developed as potential anticancer therapies. One of these, tipifarnib, has been studied in pancreatic cancer. Tipifarnib was tested in a single-agent phase II study in 20 patients with advanced pancreatic cancer with no objective responses and a median survival of less than 5 months.[82] A larger randomized phase III study compared the combination of tipifarnib with gemcitabine against gemcitabine plus placebo in 680 patients with advanced pancreatic cancer.[83] No improvement in outcome was found.

Epidermal Growth Factor Receptor Family

The epidermal growth factor receptor (EGFR) family of receptors are frequently dysregulated in cancer and have been associated with the process of tumor growth, invasion, and metastasis. The inhibitors of the EGFR belong to two broad classes of drugs, including monoclonal antibodies against the extracellular domain of the receptor and small molecules inhibitors of the intracellular TK domain. The studies conducted in pancreatic cancer have mainly tested the combination of these drugs with gemcitabine.

Approximately 20% of pancreatic cancers are Her-2 positive, and preclinical studies have shown that inhibition of Her-2 signaling with Herceptin (trastuzumab) is associated with antitumor effects in pancreatic cancer models. As a result, a phase II study evaluated the effect of trastuzumab, a monoclonal antibody that targets the Her-2 receptor, in combination with gemcitabine in patients with pancreatic cancer.[84] Thirty-four patients with Her-2–positive pancreatic cancer received gemcitabine and trastuzumab. Sixteen percent of patients screened tested positive for Her-2. Two patients (6%) had a partial response, and the median survival and one-year survival were 7 months and 19%.

Two small-molecule EGFR inhibitors, EKB-569 and erlotinib, have been specifically developed in pancreatic cancer models. Erlotinib has been tested in combination with gemcitabine in a phase III study in patients with locally advanced and advanced pancreatic cancer.[85] The study, conducted by the National Cancer Institute of Canada, randomized 569 patients with unresectable pancreatic cancer not preselected for EGFR expression status to receive gemcitabine in combination with either erlotinib or placebo. The addition of erlotinib to gemcitabine resulted in a statistically significant improvement in survival (HR, 0.81; 95% confidence interval, 0.67–0.97; $p = 0.025$), with improvement in the median survival from 5.9 to 6.4 months. The 1-year survival rate improved from 17 to 24% with the addition of erlotinib. The progression-free survival also improved significantly in the gemcitabine/erlotinib group (HR, 0.76; $p = 0.003$). As seen with other EGFR inhibitors, the development of drug-induced rash was associated with a better survival. This study resulted in the approval of erlotinib for treatment of patients with unresectable pancreatic cancer in combination with gemcitabine.

CONCLUSION

Pancreas and other periampullary cancers represent significant clinical challenges. Although traditionally patients with these diseases had a dismal prognosis, proper staging and patient selection have led to improved results. When possible, surgical resection for cure should be attempted as this gives the only chance of long-term survival. Surgical resection should be performed by surgeons experienced in the management of these diseases and at centers that can aptly care for these patients to minimize morbidity and mortality. There are many developments on the horizon that have the potential to improve the survival and well-being of patients with these diseases.

ENDOCRINE TUMORS OF THE PANCREAS

Taylor S. Riall • B. Mark Evers

INTRODUCTION

Pancreatic endocrine tumors are rare and occur with an annual incidence of approximately 5 cases per 1,000,000 population.[1] They are classified as "functioning" if they produce symptoms related to hormone overproduction, or as "nonfunctioning." The morbidity from pancreatic endocrine tumors arises from the secretion of active gastrointestinal hormones leading to the characteristic syndromes and physiologic derangements associated with pancreatic endocrine tumors. These tumors can occur sporadically or can be associated with inherited disorders. The diagnosis of pancreatic endocrine tumors is usually established by biochemical assay of abnormally high blood hormone levels consistent with the observed clinical syndrome. Even with the diagnosis, management can be difficult because localization is the key to the treatment. Benign and malignant neuroendocrine tumors appear histologically similar, as clustered nests of normal islet cells. Malignancy is defined by the presence of local invasion or metastasis to distant sites, and the functional status is determined by tissue staining for the specific hormone product.

Surgical resection is the mainstay of treatment and only curative option for pancreatic endocrine tumors. Unlike patients with tumors arising from the exocrine pancreas, surgical resection offers a high chance for cure in patients with localized disease. Surgical resection even has a role in metastatic disease, serving to debulk the disease and limit the associated debilitating symptoms arising from hormone overproduction. This chapter reviews the clinical syndromes, diagnostic tools, and therapeutic approach to pancreatic endocrine tumors.

PANCREATIC ENDOCRINE PATHOLOGY, ANATOMY AND PHYSIOLGY

Pancreatic islets are of part of the family of amine precursor uptake and decarboxylation (APUD) cells and constitute less than 2% of the pancreatic mass. Each pancreatic islet contains an average of over 3000 cells and is composed of four cell types (Table 60-1): Alpha (A) cells that secrete glucagon, beta (B) cells that secrete insulin and amylin, delta (D) cells that secrete somatostatin, D_2 cells that secrete vasoactive intestinal peptide (VIP), and F cells that secrete pancreatic polypeptide (PP). B cells are located centrally within the islets and constitute approximately 70% of the islet cell mass. F cells and A cells are located along the islet periphery and constitute 15 and 10% of the islet mass, respectively. D cells are evenly distributed throughout the islets and constitute the remaining 5% of the islet cell mass (Fig. 60-1).[2] Cells secreting gastrin (G cells) are not present in the pancreas in the nondisease state.

The distribution of pancreatic endocrine cell types is not uniform throughout the gland. Alpha cells are concentrated in the body and tail of the pancreas, and F cells are concentrated in the uncinate process, whereas B and D cells are evenly distributed throughout the pancreas. This distribution is of clinical relevance, because resection of different parts of the pancreas will have different endocrine consequences. Pancreatic islets have a rich blood supply into which the hormone products are secreted.

HISTOLOGY

Pancreatic neuroendocrine tumors are thought to arise from pluripotent cells in the ductal epithelium.[3] A normal pancreatic islet is shown in Fig. 60-2A. Benign and malignant neuroendocrine tumors appear histologically similar as uniform, clustered nests of normal islet cells (Fig. 60-2B). Differentiation from neuroendocrine lineage is suggested by positive cytoplasmic staining with silver stains. In addition, many neuroendocrine tumors stain positive for chromogranin an synaptophysin (Fig. 60-2C).[4] Cellular patterns can be either solid, acinar, or trabecular, but the specific pattern is not correlated with biological behavior. Malignancy is defined by the presence of local invasion or metastasis to distant sites. Functional status is determined by tissue staining for the specific hormone product (Fig. 60-2D).[4]

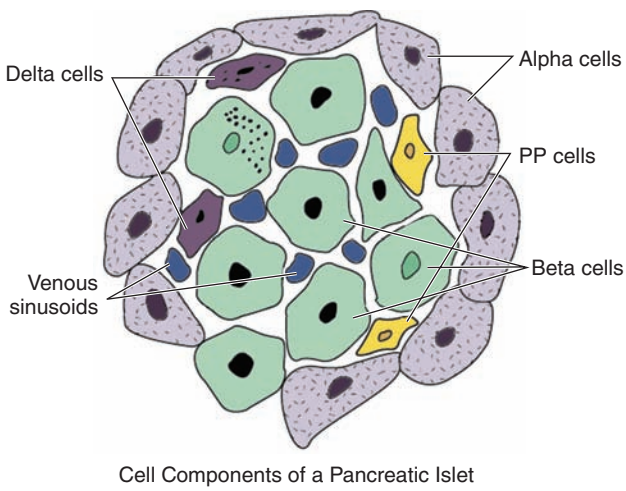
TABLE 60-1: PANCREATIC ENDOCRINE TUMORS: ENDOCRINE CELL TYPE, HORMONES PRODUCED, CLINICAL SYNDROMES, AND DISTRIBUTION OF CELLS WITHIN THE PANCREAS

Cell Type	Hormone Produced	Endocrine Tumor/ Syndrome	Distribution of Cells throughout the Pancreas
Alpha (A)	Glucagon	Glucagonoma	Uniform throughout
Beta (B)	Insulin	Insulinoma	Body/tail
Delta (D)	Somatostatin	Somatostatinoma	Uniform throughout
F	PP	PPoma	Uncinate process
D_2	VIP	VIPoma/WDHA	Uniform throughout
G	Gastrin	Gastrinoma/ZES	Not present/secreted in normal state

PP, pancreatic polypeptide; VIP, vasoactive intestinal peptide; WDHA, watery diarrhea, hypokalemia, and achlorhydria; ZES, Zollinger-Ellison syndrome.

HISTORY

In 1908, Nichols reported the first description of a pancreatic adenoma composed of islet tissue. Several years later, Mayo recognized the relationship between hyperinsulinemia and a pancreatic islet cell tumor. Subsequently, Whipple's triad (symptoms of hypoglycemia, low blood glucose, and relief of symptoms by administration of glucose, Table 60-2) was described in 1935 by Whipple and Frantz.[5] Over the next 25 years, additional syndromes associated with islet cell tumors were identified and reported. In 1942, Becker et al described a patient with severe dermatitis, anemia, and diabetes who also had an islet cell tumor.[6] Over two decades later in 1966, McGarvan et al identified the cause of the syndrome described by Becker, a glucagon-secreting islet cell carcinoma of the pancreas.[7] Zollinger and Ellison described a syndrome of severe peptic ulcer disease, acid hypersecretion, and a non–beta islet cell tumor of the pancreas in 1955.[8] It was later found that the overproduction of gastrin by the islet cell tumor was the cause of the syndrome, now known as *Zollinger-Ellison syndrome* (ZES). The first description of watery diarrhea and hypokalemia related to an islet cell tumor was by Priest and Alexander in 1957.[9] In 1958, Verner and Morrison described two patients who died from refractory watery diarrhea and hypokalemia and an associated islet cell tumor.[10] Later, this syndrome was clearly defined when patients with this constellation of symptoms and an islet cell tumor were found to have high circulating levels of VIP.[11] Initially, the lack of sensitive radioimmunoassay techniques limited the understanding and diagnosis of these syndromes. Yalow and Berson developed and refined these techniques in 1956 allowing for detection of micromolar concentrations of circulating peptides.[12] The distribution of islet cell tumors by functional syndrome is shown in Fig. 60-3.



Cell Components of a Pancreatic Islet

FIGURE 60-1 This diagram depicts the cells that compose a pancreatic islet and their typical location within the islet (ie, alpha cells on the periphery and beta cells localized to the central region). The dots within the beta cell cytoplasm depict the strong staining often seen from insulin-containing granules. Delta and PP cells constitute only a minority of the pancreatic islets endocrine cells. The rich blood supply is demonstrated by the abundance of venous sinusoids within the islet.

GENETICS

While the majority of pancreatic endocrine tumors occur sporadically, others can be associated with genetic syndromes. The tumorigenesis pathway in neuroendocrine tumors differs from that of pancreatic adenocarcinoma. Mutations in the *k-ras*, *p53*, *myc*, *fos*, *jun*, *src*, and the *retinoblastoma* genes are not seen. Transcriptional silencing is thought to play a role in neuroendocrine tumorigenesis. More than 90% of gastrinomas and nonfunctioning neuroendocrine tumors had homozygous deletions or silencing 5'CpG island methylation.[13] Loss of heterozygosity (LOH) at chromosome 11q is common in functional pancreatic endocrine tumors, while LOH at chromosome 6q is associated with the development of nonfunctional tumors.[14] One-third of patients with sporadic pancreatic endocrine tumors have been shown to have allelic loss on chromosome 3p. This allelic loss is associated with malignant clinical disease.[15]

The most common genetic syndrome associated with pancreatic endocrine tumors is multiple endocrine neopasia type 1 (MEN1 Werner syndrome). Pancreatic endocrine tumors occur in 30–80% of patients with MEN1. The syndrome is also characterized by parathyroid hyperplasia and pituitary adenomas, but tumor-related death in MEN1 patients is most often related to metastatic pancreatic endocrine cancers. It is caused by mutations/allelic deletions in the tumor suppressor gene, *MENIN*, on chromosome 11q13 and is inherited in an autosomal dominant fashion. Mutation or

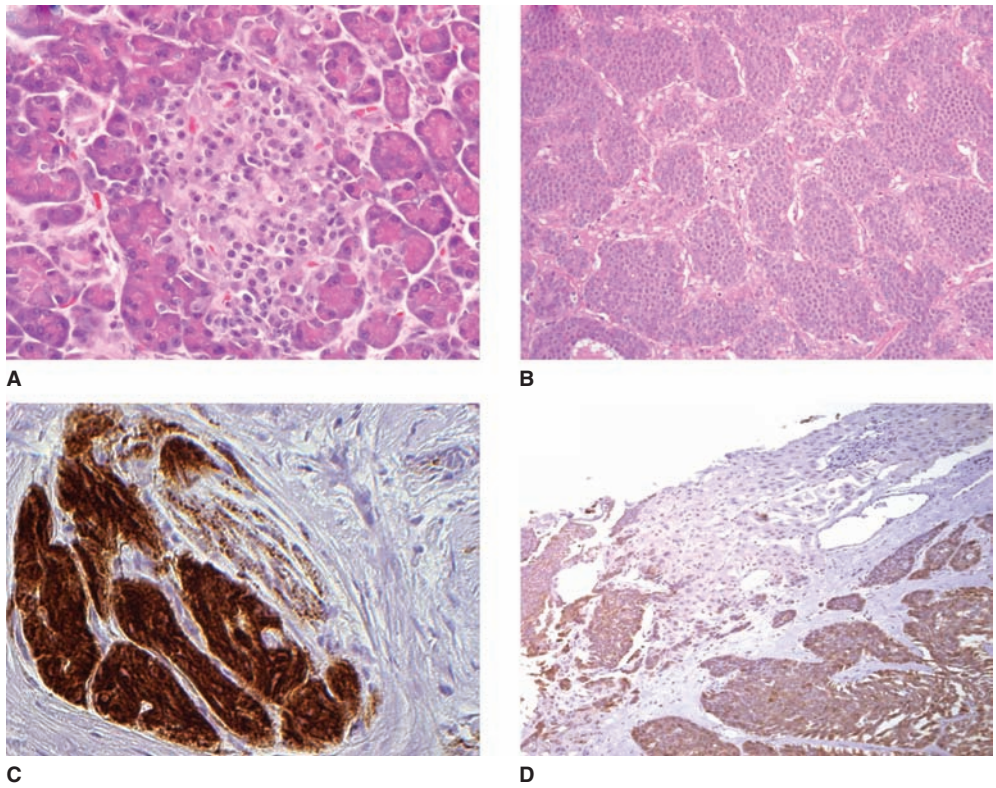


FIGURE 60-2 **A.** High-power view of a normal pancreatic islet on H and E staining. The endocrine cells are arranged as irregular cords around abundant capillaries into which the hormone products are secreted. The islets are surrounded by clusters of acinar cells. No pancreatic ductal cells are seen in this image. **B.** H and E stain of a pancreatic endocrine tumor. Note the uniform, clustered nests of normal-appearing islet cells with scant mitosis. **C.** Pathology of a pancreatic endocrine tumor stained positive for chromogranin, a neuroendocrine tumor marker. The chromogranin is cytoplasmic and stains brown. **D.** Pancreatic endocrine tumor staining positive for gastrin, diagnostic of gastrinoma. Again, the staining is cytoplasmic. Goodgame, MD, University of Texas Medical Branch, Galveston, TX.)

allelic deletion causes loss of tumor suppressor function and predisposes patients to neoplastic growth in the parathyroid, pituitary, and pancreatic endocrine tissue. Patients with MEN1-associated pancreatic endocrine tumors are usually younger (30–40 years old), have malignant disease, and have multicentric disease than those with sporadic tumors. Approximately 50% of patients with MEN1-associated neuroendocrine tumors will present with metastatic disease.[16] Gastrinomas are the most common functional pancreatic endocrine tumors occurring in MEN1 patients (54% of functional MEN1-associated tumors).

PPomas (which are not associated with a functional syndrome) are the most commonly observed islet cell tumor in patients with MEN1, observed in more than 80% of MEN1 cases.

Management of patients with MEN1 and pancreatic endocrine tumors requires recognition and staged treatment of associated tumors. Patients suspected of having MEN1 should undergo biochemical screening for gastrin, insulin/proinsulin, PP, glucagons, and chromogranin A (a tumor

marker elaborated by most pancreatic endocrine tumors). Hyperparathyroidism, if present, should be treated first as correction of hypercalcemia will improve the outcome of treatment for gastrinomas.[17] Gastrinomas in MEN1 patients are more likely to occur in the duodenum and are more likely to be multiple, complicating their management.[16,18–20] Conversely, treatment of insulinomas or VIPomas associated with MEN1 is essentially identical to those seen in sporadic disease.

DIAGNOSIS

Insulinoma

Insulinomas occur at an annual incidence of 1 per 1,000,000 patients per year and account for 60% of all pancreatic islet cell tumors (see Fig. 60-3).[1] There is no gender or race predilection, and the average age of patients at the time of diagnosis is 45 years old. Despite the predominance of beta cells in the body and tail of the pancreas, 97% insulinomas are located in the pancreas with equal distribution in the head, body, and tail. The remaining 3% of insulinomas are located in the duodenum, splenic hilum, or gastrocolic ligament. Insulinomas are typically small with an average size of 1.0–1.5 cm. Grossly, they are encapsulated, firm, hypervascular, yellow-brown nodules. Because of their rich vascular supply, pancreatic endocrine tumors are hyperattenuating when compared to surrounding pancreatic tissue on contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI).[21] About 90% of insulinomas are benign. Histologically, they appear as clustered nests of normal islet cells, without typical islet anatomy, which stain positive for insulin. Most occur as solitary lesions; however, multicentricity does occur in 10% of cases and should alert the physician to the possibility of MEN1 that occurs in 4–7% of all patients with insulinoma.

Proinsulin, the precursor peptide to insulin, is secreted by insulinomas. Similar to their normal beta-cell counterparts, the proinsulin is cleaved into C-peptide in the Golgi complex and released into the blood stream as functional insulin and the associated C-peptide cleavage product. However, insulinoma cells do not respond to the normal regulatory pathways, leading to tumor overproduction of proinsulin, high circulating levels of insulin causing profound, and potentially dangerous hypoglycemia. This may lead to neuroglycopenic symptoms, including headache, lethargy, dizziness, diplopia, diaphoresis, palpitations, anxiety, hunger, amnesia, and even seizures. Symptoms tend to occur early in the morning before eating or after exercise and are the result of sympathetic nervous system response to profound hypoglycemia, with release of catecholamines and glucagon. These symptoms may partially resolve if glycogenolysis is also stimulated, thus increasing glucose levels and reducing the catecholamine surge by feedback inhibition. Patients with insulinoma are often overweight, as they will typically attempt to control their symptoms by eating frequent meals. Chronic hypoglycemia may have profound, even permanent neurologic consequences, including apathy, clouded sensorium, behavioral changes, seizures, and coma.

Laboratory studies will usually confirm the diagnosis of insulinoma. Classically, patients will present with Whipple's triad: a low glucose level (<50 mg/dL) while having symptoms of hypoglycemia, which resolve with administration of glucose (Whipple's triad) (see Table 60-2). The diagnosis of insulinoma is usually made with a monitored 72-hour fast. The fast is monitored for two reasons: the first is to prevent life-threatening hypoglycemia and the second is to rule out the possibility of factitious hypoglycemia as a result of exogenous insulin administration. C-peptide levels should be measured to confirm an endogenous source of insulin if there is any suspicion of hypoglycemia from surreptitious insulin injections.[22] Also, urine should be checked for elevated sulfonylurea levels, suggesting surreptitious administration of oral hypoglycemia agents.

Hypoglycemia (<50 mg/dL in men or <40 mg/dL in women) after a 72-hour fast occurs in 95% of patients; 75% of patients will achieve this degree of hypoglycemia within the first 24 hours (Fig. 60-4). Insulin levels greater than 7 μU/mL in the presence of hypoglycemia are highly suggestive of an insulinoma; however, these levels can also be found in patients with hyperinsulinemia from other causes. Evaluating the insulin/glucose ratio is also useful. A ratio greater than 0.3 occurs with insulinoma. An insulin to glucose ratio of 0.3 can also occur with obesity as a result of insulin resistance, but these patients should not be hypoglycemic.[23] Levels of circulating proinsulin can be measured and compared to the total insulin present. Proinsulin may account for 40% of total insulin if the tumors are malignant and a proinsulin level greater than 24% of total insulin is suggestive of insulinoma. C-peptide levels of greater than 1.2 μg/mL with a glucose level less than 40 mg/dL are also highly suggestive of an insulinoma.[23]

Two other rare clinical syndromes may be difficult to distinguish from insulinoma: nesidioblastosis and noninsulinoma pancreatogenous hypoglycemia (NIPH). Nesidioblastosis will produce neuroglycopenic symptoms due to hyperplasia of pancreatic islets, but no pancreatic tumor is noted.[24] Patients with NIPH have high insulin levels and hypoglycemia; however, symptoms are rare even after a 72-hour fast. Islet cell hypertrophy may be seen with NIPH, but no focal tumor is involved.[25] While less common than in other neuroendocrine tumors, insulinoma can be associated with MEN1 syndrome. This should be considered in the diagnosis, especially because it mandates a different approach to the surgical management.[26]

Provocative testing to confirm the diagnosis of insulinoma is rarely required. When necessary, stimulation of insulin release with calcium gluconate or tolbutamide and serial measurements of insulin and glucose levels should be performed in a carefully monitored setting. Because cerebrocytes use glucose as their sole source of energy, this must be done with extreme caution; profound hypoglycemia and subsequent permanent neurologic injury can occur.

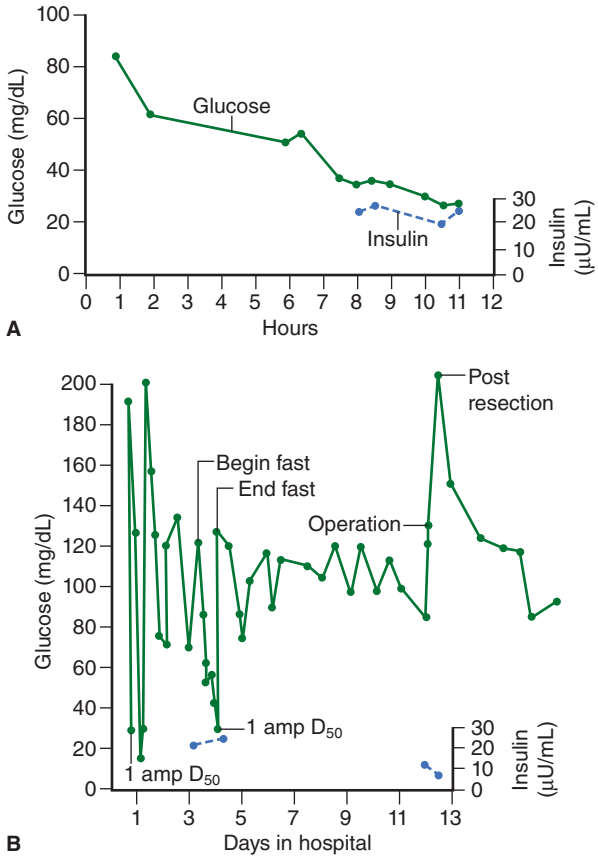

FIGURE 60-4 **A.** Simultaneous circulating glucose and insulin levels in a fasting patient with insulinoma. Although glucose levels fall, insulin levels remain constant, demonstrating a relative hyperinsulinemia. **B.** Periodic glucose determinations in a patient with insulinoma. The first major fall was spontaneous and the patient became comatose but was resuscitated with an ampule of 50% glucose. On the second occasion, the patient was fasted on purpose. Postoperatively, glucose increased to 200 and then decreased gradually and remained between 90 and 120.

Gastrinoma

Gastrinomas are the second most common functional pancreatic endocrine tumor with an incidence of 1 per 2.5 million.[27] The mean age of patients at diagnosis is 50, and there is a slight male predominance (60%). Gastrinomas produce ZES (severe peptic ulceration, hypergastrinemia) as the result of overproduction of gastrin that is normally synthesized by G cells located in the antral mucosa of the stomach. Gastrinomas do not secrete gastrin in response to normal stimuli, such as amino acids and peptides in the stomach or gastric distension, and are not subject to normal feedback mechanisms. Specifically, gastrinomas are not suppressed by low luminal pH and can be stimulated (instead of inhibited) by secretin.[28]

Over 60% of gastrinomas are malignant. Similar to other pancreatic endocrine tumors, malignancy is defined by the presence of lymph node or distant metastases. The liver is

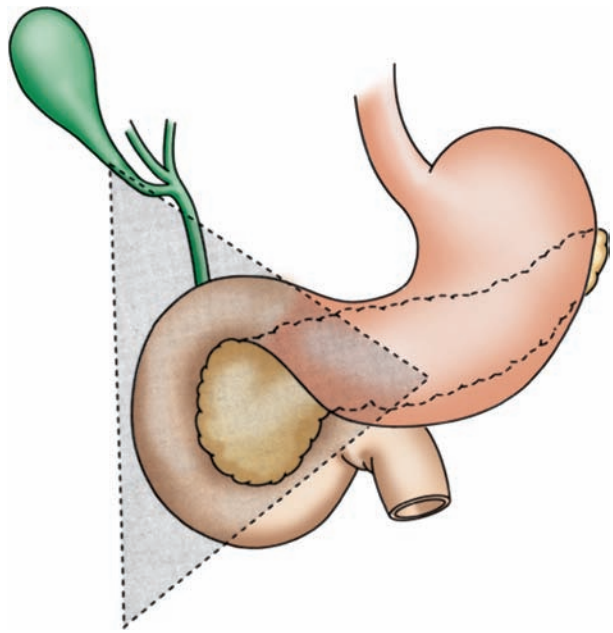

FIGURE 60-5 The gastrinoma triangle—the anatomic triangle in which approximately 90% of gastrinomas are found. (From Stabile BE, Morrow DJ, Passaro E. The gastrinoma triangle: operative implications. *Am J Surg.* 1984;147:26, with permission from Elsevier.)

the most common site of spread, but peripancreatic lymph nodes are also commonly involved. Between 70 and 80% of patients with malignant gastrinoma have metastases to the liver or lymph nodes at the time of diagnosis. Metastases may also involve the lungs or bone. Ninety percent of gastrinomas are located within the gastrinoma triangle, bounded by the lines connecting the cystic duct, the junction between the second and third portions of the duodenum, and the junction between the neck and body of the pancreas (Fig. 60-5).

It is important to consider the diagnosis of MEN1 in patients with ZES, as 20% of patients with ZES have MEN-associated disease.[16] These patients should be tested for hyperparathyroidism that, if present, should be treated first because it can complicate the management of their gastrinoma.

The diagnosis of ZES is classically made after patients present with severe forms of peptic ulcer disease that are either refractory to standard treatment or are atypical in location. Ninety percent of patients with ZES have peptic ulcers, most in the duodenal bulb with synchronous ulcers found in more distant portions of the duodenum or proximal jejunum. Jejunal ulcer perforations occur in 7% of patients. Patients may complain of upper abdominal pain and/or gastrointestinal bleeding (melena or hematochezia), weight loss, or nausea and vomiting. Symptoms of gastroesophageal reflux are also common. High acid production can lower the normal pH of the duodenum and inactivate pancreatic enzymes, leading to diarrhea, which is relieved by nasogastric suction. Endoscopy performed in patients with ZES may show multiple ulcers, large gastric rugal folds, edema of the mucosa lining the duodenum

TABLE 60-3: CAUSES OF HYPERGASTRINEMIA

High Gastric Acid Output	Low Gastric Acid Output

G-cell hyperplasia	Prior acid-reducing procedure
Retained gastric antrum	Atrophic gastritis
	Pernicious anemia
	Achlorhydria
	Renal failure

or proximal jejunum, or jejunal hypermotility. ZES should be suspected in patients with ulcer disease and diarrhea, a strong family history of peptic ulcer disease, atypical or multiple ulcers, or recurrence of ulcers after acid-reducing operations or H_2 blocker or proton pump inhibitor (PPI) therapy.

The diagnosis of ZES is usually made by laboratory testing for gastrin levels. Other conditions can also cause hypergastrinemia (Table 60-3) and fall into two categories: hypergastrinemia associated with high and low gastric acid output. The other diagnoses should be excluded before making the diagnosis of ZES. It is important to document acid secretion (low gastric pH), because conditions causing low acid secretion or achlorhydria can also lead to elevated gastrin levels. A gastric pH greater than 3 without acid-suppressing medications or prior acid-reducing operations virtually excludes ZES as the potential cause of hypergastrinemia. H_2 blockers should be stopped 1 week or PPIs 3 weeks before testing for gastrin levels. If achlorhydria is suspected, gastric acid production can be measured. Basal acid output in patients with ZES is usually greater than 15 mEq/h, which is not seen with achlorhydria.

Three normal fasting serum gastrin determinations should be done to exclude ZES. The fasting serum gastrin level is typically 200–1000 pg/mL in patients with a gastrinoma, compared to 100–150 pg/mL in normal patients. A gastrin level of greater than 1000 pg/mL in a patient without gastric outlet obstruction or suppression of acid production is virtually diagnostic of ZES. In equivocal cases, a secretin stimulation test can also be used to confirm the diagnosis: 2 IU/kg of secretin is given intravenously and serum obtained for gastrin levels before injection and every 3–5 minutes thereafter for 30 minutes. The diagnosis is made when gastrin levels rise above 200 pg/mL or greater than 50% above baseline levels following administration of secretin.

VIPomas

VIP is a small peptide normally found in the brain, G cells of the antrum, adrenal medulla, gut mucosa, pancreatic neurons, and the D_2 cells of pancreas. VIPomas in the pancreas are believed to originate from neoplastic D_2 cells that release high levels of VIP producing the Verner-Morrison syndrome. This syndrome is also known as *WDHA syndrome* (an acronym for its most prominent symptoms—Watery Diarrhea, Hypokalemia, and Achlorhydria) or pancreatic cholera. Overall, these tumors are exceedingly rare with an incidence 1 per 10,000,000 population.[29,30] Over two-thirds are malignant and at the time of presentation over 70% of patients have metastatic disease.[31] Ninety percent of lesions are found in the pancreas, while 10% have been described in the colon, bronchus, liver, adrenal gland, and sympathetic ganglia. Pancreatic lesions are usually solitary, and 75% are found in the pancreatic body or tail. Lesions tend to be large and are usually diagnosed at greater than 3 cm in size. There is a bimodal age distribution with most patients diagnosed at middle age but a small percentage (~10%) diagnosed before the age of 10. Elevated VIP levels in these young patients are most commonly from ganglioneuromas, ganglioblastomas, or neuroblastomas, instead of pancreatic tumors. Approximately 10% of patients with VIPomas have MEN1.

Superphysiologic levels of VIP cause the symptoms associated with Verner-Morrison syndrome. VIP is a 28-amino acid polypeptide with close structural homology to secretin. VIP normally functions as a neurotransmitter. It has a half-life of less than 1 minute, and levels are low and unresponsive to meals in individuals without VIPomas. VIP acts on intestinal epithelial cells to activate adenylate cyclase, thus increasing cyclic adenosine monophosphate (cAMP) levels within colonocytes, which stimulates hypersecretion of fluid into the lumen, resulting in watery diarrhea. The diarrhea is further exacerbated as cAMP inhibits sodium reabsorption and stimulates chloride secretion causing increased fluid and electrolyte shifts into the intestinal lumen. Profuse, watery, iso-osmotic secretory diarrhea is the most common presenting symptom and may exceed a volume of 3 L/d.

The differential diagnosis for watery diarrhea is shown in Table 60-4. Stool volume less than 700 g/d is unlikely a result of VIPoma. This secretory diarrhea is independent of food intake and does not resolve with nasogastric suction, distinguishing it from the diarrhea associated with ZES. The liquid stool has the appearance of "weak tea" and is devoid of blood, fat, or inflammatory cells, which further distinguishes VIP-associated diarrhea from infectious, inflammatory, and malabsorptive conditions. Weight loss, crampy abdominal pain, dehydration, electrolyte abnormalities, and metabolic acidosis (from fluid and bicarbonate loss) are common. Hypokalemia may be profound as patients can lose more than 400 mEq of potassium/d, which may lead to disturbances of cardiac rhythm and even sudden death in extreme cases. Nearly 75% of patients have hypochlorhydria or achlorhydria and decreased levels of magnesium and phosphorus are often present. The profound electrolyte abnormalities and associated dehydration associated with Verner-Morrison syndrome need to be corrected prior to definitive surgical management.

Diagnosis of a VIPoma can be established by measuring serum levels of VIP, which are usually greater than 150 pg/mL, in association with secretory diarrhea. Levels of VIP should be measured after an overnight fast. VIPomas commonly

produce additional GI peptides, including PP, calcitonin, neurotensin, gastrin, gastric inhibitory peptide, serotonin, glucagons, insulin, somatostatin, growth hormone–releasing hormone, and peptide histidine-methionine.[32]

Glucagonomas

Glucagonomas are exceedingly rare with an estimated incidence of 1 per 20,000,000 population.[33] They are two to three times more common in women than men and tend to be larger than most other pancreatic endocrine tumors, averaging 5–10 cm in size at the time of diagnosis. Glucagonomas are believed to arise from neoplastic alpha cells that normally produce glucagon to maintain glucose homeostasis. These tumors nearly always arise in the pancreas; 65–75% of these are found in the body or tail, which corresponds to the normal distribution of alpha-cells in the pancreas. Malignancy occurs in over 50% of patients with a glucagonoma,[34] as defined by metastases to regional lymph nodes or the liver. Eighty percent of patients with malignant glucagonomas have liver metastases at the time of diagnosis. Most glucagonomas are sporadic; however, 5–17% are associated with MEN1. As with other neuroendocrine tumor, patients with MEN1 associated glucagonomas tend to be younger and have more advanced disease at the time of diagnosis.

The glucagonoma syndrome is a rare syndrome with a classic presentation of the "four Ds": diabetes, dermatitis, deep vein thrombosis, and depression. It is also characterized by a severe catabolic state with weight loss, depletion of fat and protein stores, and associated vitamin deficiencies.[34,35] Glucagon acts on the liver to stimulate glucose release, glycogenolysis, gluconeogenesis, and ketogenesis. It also acts to inhibit glycolysis and lipogenesis. This catabolic state causes hyperglycemia, depletion of the circulating pool of amino acids, and depletion of fast stores. Diabetes develops in 76–94% of patients with glucagonoma at some point during their illness, and 38% of patients will demonstrate an elevated glucose level at initial presentation. Hypoaminoacidemia and normochromic normocytic anemia are also common.

The classic rash associated with glucagonoma is necrolytic migratory erythema (Fig. 60-6).[36] It is noted in approximately two-thirds of patients and often appears before other symptoms of the syndromes. The etiology is thought to be due to severe amino acid deficiency, although trace element deficiency and general malnutrition probably contribute. Necrolytic migratory erythema begins as erythematous patches in intertriginous areas that spread radially to form a serpiginous pattern on the trunk, extremities, or face. Bullae develop and then slough, leaving crusty necrotic areas that may become superinfected with bacteria or fungi from the skin. Healing begins from the center of these lesions and takes between 2 and 3 weeks, leaving the healed skin hyperpigmented. With successful treatment of the underlying glucagonoma, this rash usually resolves spontaneously. The diagnosis of glucagonoma is established by measuring glucagon levels; a fasting glucagon level greater than 50 pmol/L is considered diagnostic.

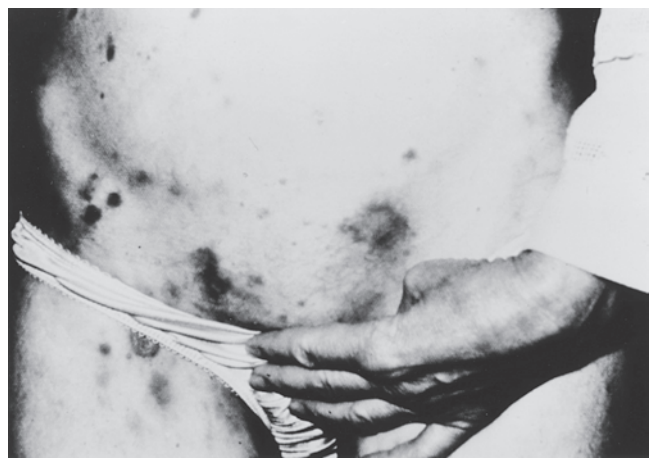

FIGURE 60-6 Characteristic skin rash associated with glucagonoma. This figure shows the migratory necrolytic dermatitis in a woman, 42 years of age, who has been symptomatic for 16 years. The rash had spread to involve the entire body. Note the central clearing. (Used, with permission, from Hugo Villar, from Beauchamp RD, Thompson JC, Endocrine tumors of the pancreas. In: Zinner MJ, Schwartz SI, Ellis H, eds. *Maingot's Abdominal Operations.* 10th ed. Appleton & Lange/McGraw-Hill; 1997:1961–1976.)

Somatostatinomas

Somatostatinomas are exceedingly rare with fewer than 100 cases reported in the literature. These tumors are usually large (85% are >2 cm) and solitary. Patients are typically in their fifth or sixth decade of life at the time of diagnosis. Over 60% are found in the pancreas (usually the head) with the remainder in the duodenum or elsewhere in the small intestine. The majority are malignant with metastases to the liver or lymph nodes commonly noted at the time of diagnosis.[37] Somatostatinomas are rarely associated with MEN1 but are associated with von Recklinghausen's disease[38] and pheochromocytomas.

Somatostatin, normally produced by the delta cells of the pancreas, function in a paracrine fashion to inhibit the secretion of glucagon, insulin, VIP, gastrin, secretin, motilin, and PP from pancreatic islets and cholecystokinin (CCK)–mediated release of pancreatic enzymes. Inhibition of pancreatic enzyme and hormone secretion causes steatorrhea, diabetes, malabsorption, and cholelithiasis due to reduced gallbladder emptying.[39]

Because the symptoms are nonspecific, the diagnosis of somatostatinoma is rarely made preoperatively. When suspected, the diagnosis can be confirmed by documenting an elevated fasting somatostatin level of greater than 14 mol/L.[40]

Nonfunctional Neuroendocrine Tumors

Twenty percent of pancreatic endocrine tumors are nonfunctional, defined as a pancreatic tumor arising from endocrine origin with no definable hormonal syndrome. PP, neurotensin, and calcitonin-secreting tumors are also classified as nonfunctional: The hormone products have little biological consequence and rarely cause symptoms.[41] Nonfunctional tumors are usually diagnosed by histologic findings after a suspected pancreatic exocrine tumor has been resected, or less commonly discovered during the workup for nonspecific gastrointestinal complaints. On microscopic examination, nonfunctional tumors do not appear different than their functional counterparts; the endocrine origin of these tumors is usually identified by positive immunostaining for chromogranin or synaptophysin.

Two-thirds of nonfunctional pancreatic endocrine tumors are malignant, and 60–80% of malignant tumors have metastasized to distant sites at the time of diagnosis. These tumors are typically larger than their functional counterparts (4–5 vs 1–2 cm, respectively) when initially discovered. Patients may present with abdominal pain and jaundice secondary to compression of adjacent structures. This is particularly common with PPomas that occur predominately within the head of the pancreas.[41]

Other Pancreatic Endocrine Tumors

Pancreatic endocrine tumors that produce other hormones have been described, but they are extremely rare. Case reports of pancreatic endocrine tumors that secrete gastrin-releasing factor (GRF), calcitonin, enteroglucagon, CCK, gastric inhibitory peptide, luteinizing hormone, neurotensin, or ghrelin have also been described.

IMAGING AND LOCALIZATION

Modalities

Once the diagnosis of a functional pancreatic endocrine tumor is made, cross-sectional imaging with CT or MRI is the first step in localization. In a large single-institution study, 50% of functioning islet cell tumors were less than 1.3 cm in size.[42] The sensitivity of dual-phase CT in the localization of functioning islet cell tumors is 71–82%.[43] The sensitivity is directly related to the size of the tumor, so insulinomas and gastrinomas that present at a smaller size are more difficult to localize. As a result, the CT technique including thinner collimation (1-mm cuts) and multiple-phase imaging is critical to improving sensitivity of CT for these small lesions.[21,43] Capturing the vascular blush in the arterial phase is critical in identification and differentiation from other types of pancreatic tumors (Fig. 60-7A).[21] The enhancement is less pronounced in the venous phase (Fig. 60-7B). In addition, the use of water as oral contrast may assist in identifying small duodenal gastrinomas.[21]

The ability of MRI to demonstrate contrast between normal pancreatic parenchyma and small pancreatic endocrine tumors makes this modality a useful primary modality for localization. Pancreatic endocrine tumors demonstrate low-signal intensity on T1-weighted images and high-signal intensity on T2-weighted images. As with CT, size is directly related to sensitivity. In one large series of insulinomas, contrast-enhanced MRI identified all lesions of greater than 3 cm, 50% of lesions 1–2 cm, and no lesions less than 1 cm.[44] The overall sensitivity of MRI for detecting pancreatic endocrine tumors is 85%.[45] The vast majority of noninsulinoma or nongastrinoma pancreatic endocrine tumors will be indentified on cross-sectional imaging.

Many pancreatic endocrine tumors overexpress the somatostatin receptor subtype 2. Somatostatin receptors are present in 100% of gastrinomas, 67% of insulinomas, and no pancreatic adenocarcinomas.[46] They are also present in a significant portion of glucagonomas and nonfunctioning endocrine tumors. Somatostatin-receptor scintigraphy (SRS) involves administering a somatostatin analogue (^{111}In-DTPA-D-Phe1 octreotide). The abundance of somatostatin receptors on certain types of pancreatic endocrine tumors makes SRS a useful adjunct in localization, if tumors are not evident on CT/MRI. The sensitivity for SRS is 80% for all pancreatic endocrine tumors excluding insulinomas. The radioisotope scan has an overall sensitivity of 80–100% and specificity of greater than 90% for gastrinomas. This technique is also useful in detecting hepatic metastases from noninsulinoma endocrine tumors (Fig. 60-8). Although sensitive, SRS may not show the exact location of a tumor, only its general vicinity within a few

centimeters. More precise localization may be obtained by CT scanning, MRI, or other techniques.

If unable to localize a pancreatic endocrine tumor on CT or MRI, endoscopic ultrasound (EUS) can be performed. When compared to CT or MRI, EUS has a greater sensitivity for detecting tumors less than 3 cm and an overall sensitivity of 93% for tumors of all sizes.[47,48] EUS has significantly improved the ability to localize even small insulinomas preoperatively within the pancreas and GI tract, with a sensitivity and diagnostic accuracy of 81 and 78%, respectively (Fig. 60-9).[49] EUS may be useful to localize pancreatic gastrinomas not seen with other modalities (sensitivity approaches 90%), but detection of duodenal tumors with EUS is still poor (<50%). EUS also

allows for fine-needle aspiration (FNA) of tumors for a pathologic diagnosis (Fig. 60-10). This is especially useful in the case of nonfunctional tumors without a classic CT appearance of pancreatic endocrine tumors. Given the good prognosis of advanced pancreatic endocrine tumors relative to pancreatic adenocarcinoma, an FNA confirming the former may mandate a more aggressive surgical approach.

Angiography is useful for small insulinomas and gastrinomas that have not been identified with CT, MRI, SRS, or EUS. Angiography will detect approximately 70% of insulinomas greater than 5 mm (Fig. 60-11), showing a characteristic "blush" that corresponds to the highly vascular nature of insulinomas. If standard radiographic techniques are unsuccessful, selective portal venous sampling for insulin or gastrin levels may allow localization to a region of the pancreas (head, body, or tail) to aid in operative planning (see Fig. 60-11). Provocative testing, known as *arterial stimulation venous sampling* (ASVS), can further increase the likelihood of localization by injecting calcium or secretin into the celiac and superior mesenteric arteries with simultaneous portal

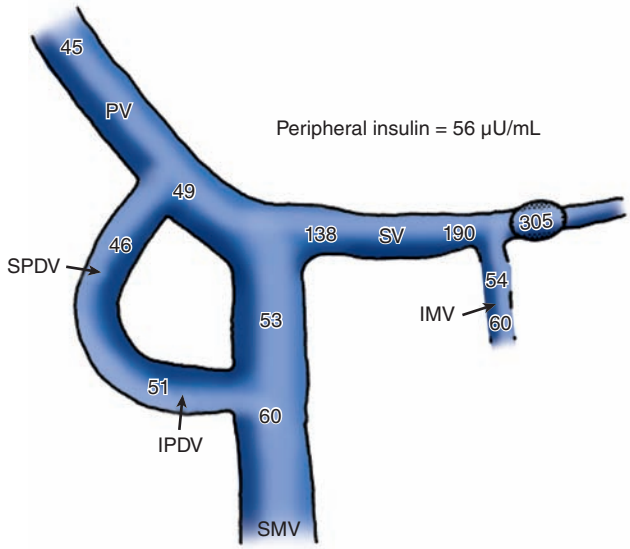

FIGURE 60-12 Schematic of transhepatic selective venous sampling of the portal vein and its tributaries for insulin. Venous insulin levels are greatly elevated in the distal splenic vein *(shaded circle)*. Intraoperative ultrasound and palpation of the pancreas failed to reveal an insulinoma. A distal pancreatectomy was performed on the basis of the portovenous sampling gradient shown here, and the pathologists confirmed the presence of a 1-cm insulinoma. IMV, inferior mesenteric vein; IPDV, inferior pancreatic duodenal vein; PV, portal vein; SMV, superior mesenteric vein; SPDV, superior pancreatic duodenal vein; SV, splenic vein. Insulin concentrations are given in microunits per milliliter. (From Norton JA, Shawker TH, Doppman JL, et al. Localization and surgical treatment of occult insulinomas. *Ann Surg.* 1990;212(5):615–620.)

venous sampling for appropriate hormone levels. ASVS has a sensitivity of over 90% (Fig. 60-12).[50,51]

In the unlikely event that preoperative studies cannot localize the tumor; blind exploration with intraoperative ultrasound combined with careful palpation and exploration of the entire pancreas and duodenum will identify most tumors. Performance of effective intraoperative pancreatic ultrasound requires complete mobilization of the pancreas. Duodenal gastrinomas are usually difficult to localize preoperatively by any technique owing to their small size.

Algorithms for Localization

The algorithm for localization of insulinomas is shown in Fig. 60-13. After the biochemical diagnosis of insulinoma is made, CT or MRI should be performed. If the tumor is localized, the surgeon proceeds to resection. If not, EUS should be performed. If the tumor remains unlocalized, angiography with or without stimulation should be performed. Only in the event of all of the above being negative should blind exploration and intraoperative ultrasound be performed.

For patients with biochemically confirmed ZES (Fig. 60-14), the first step of the algorithm should include both

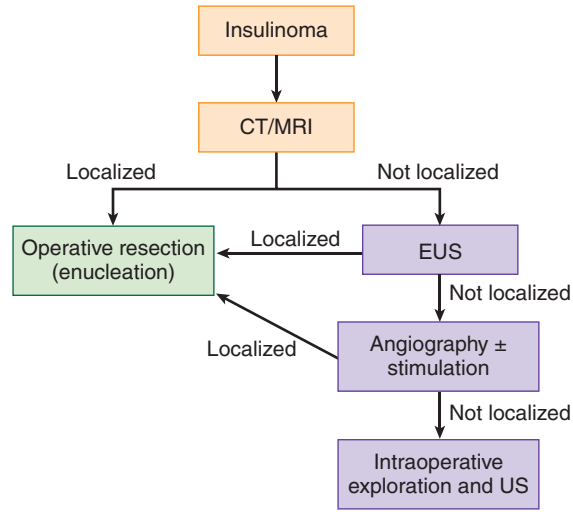

FIGURE 60-13 Localization of insulinomas. EUS, endoscopic ultrasound.

CT and SRS, because nearly all gastrinomas express somatostatin receptors. If not localized, EUS and/or MRI should be used to evaluate for small pancreatic lesions. If localization has still not been achieved, angiography with or without stimulation should be performed next. If not found by other techniques, it may be reasonable to proceed with operative exploration to definitively localize and treat the tumor at the same operation. Intraoperative ultrasound and endoscopic transillumination of the duodenum will aid in the localization of small gastrinomas within the duodenal wall. Routine duodenotomy should also

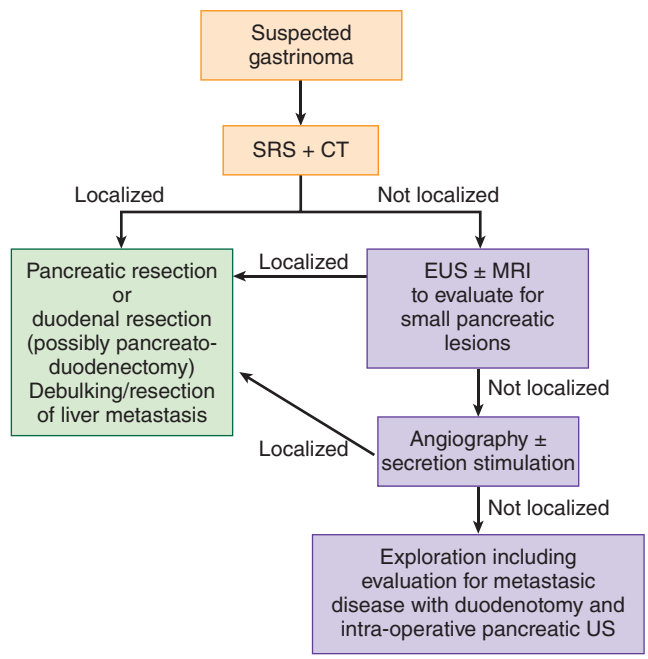

FIGURE 60-14 Localization of gastrinomas.

FIGURE 60-15 CT image of a nonfunctional pancreatic endocrine tumor in a 41-year-old woman. Note the 3.5-cm hyperattenuating mass in the head of the pancreas (*gray arrow*). The mass abuts the superior mesenteric vein (*white arrow*), but there is a good tissue plane between the superior mesenteric vein and the mass. This patient underwent an uncomplicated pancreaticoduodenectomy. (Used, with permission, from Christopher L. Wolfgang, MD, PhD, Johns Hopkins Medical Institutions, Baltimore, MD.)

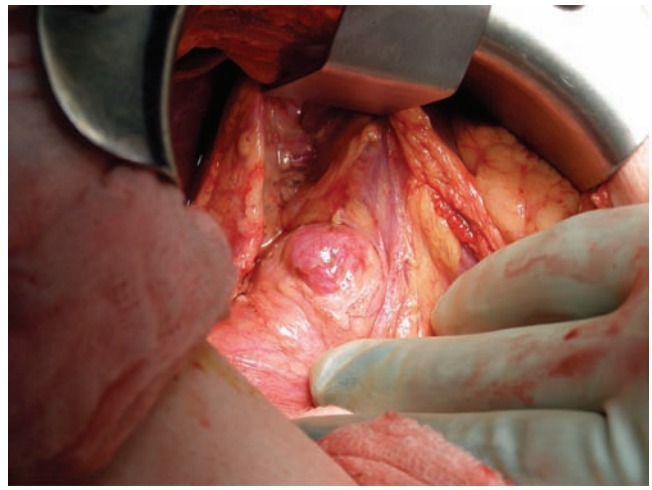

FIGURE 60-16 An intraoperative photograph showing a solitary insulinoma in the tail of the pancreas. The tumor appears as solitary, encapsulated, reddish-brown mass. (Used, with permission, from Sharon Weber, MD, University of Wisconsin, Madison, WI.)

be used especially if the location of the tumor is at all in doubt or if multifocal disease is suspected as is common in MEN1. Duodenotomy will detect 25–30% of tumors not seen on preoperative imaging; therefore endoscopic transillumination of the duodenum and duodenotomy should be routinely performed.[52]

VIPomas, glucagonomas, and somatostatinomas are usually larger and easier to localize. Localization of these tumors is usually performed by CT scanning or SRS if CT is not informative. Most nonfunctional neuroendocrine tumors are diagnosed initially on CT based on symptoms of abdominal pain or jaundice. They are differentiated from pancreatic adenocarcinoma by their hyperdense, enhancing nature on arterial phase imaging (Fig. 60-15). Standard CT or MRI has nearly 100% sensitivity for locating nonfunctional pancreatic endocrine tumors because of their size.

MANAGEMENT

Insulinoma

Surgical resection is the mainstay of treatment and only curative option for pancreatic endocrine tumors. After localization, surgical resection of insulinoma is usually curative as most tumors tend to be small, benign, and solitary. Preoperatively, it is important to prevent severe hypoglycemic attacks by administration of diazoxide that decreases beta-cell release of insulin (usually 3 mg/kg/d divided in two or three doses daily). Rarely, other agents such as verapamil, glucocorticoids, and growth hormone may be required to maintain normoglycemia. Glucose infusions must be used in the perioperative period especially when patients are taking nothing by mouth.

Surgical technique includes careful inspection of the liver and regional lymph nodes for evidence of metastatic disease. The pancreas is exposed through the lesser sac by traversing the gastrocolic omentum. A generous Kocher maneuver and mobilization of the pancreatic tail are usually required to adequately inspect the entire pancreas. After complete mobilization, the pancreas should be visually inspected, palpated, and intraoperative ultrasound should be applied. These tumors usually appear as solitary, encapsulated, reddish-brown tumors (Fig. 60-16) and, once identified, should correlate with preoperative localization studies (Fig. 60-17). Because over 90% of insulinomas are benign, enucleation is usually preferred when possible to preserve functional pancreatic mass.[53] The mass shown in Fig. 60-16 is superficial and easily seen and was successfully enucleated. Enucleation should not be performed if the tumor is within 2 mm of the main pancreatic duct. In all enucleations, careful dissection is necessary to avoid entry into the main pancreatic duct. Resection via distal pancreatectomy, central pancreatectomy, or pancreaticoduodenectomy may be necessary for tumors abutting the main pancreatic duct, or large tumors. Many surgeons advocate placement of a silastic drain adjacent to the enucleation site to control any leak of pancreatic secretions postoperatively.

Laparoscopic resection of pancreatic endocrine tumors is becoming more common, especially for insulinomas where simple enucleation is adequate treatment.[54,55] Distal pancreatectomy may also be performed laparoscopically, allowing

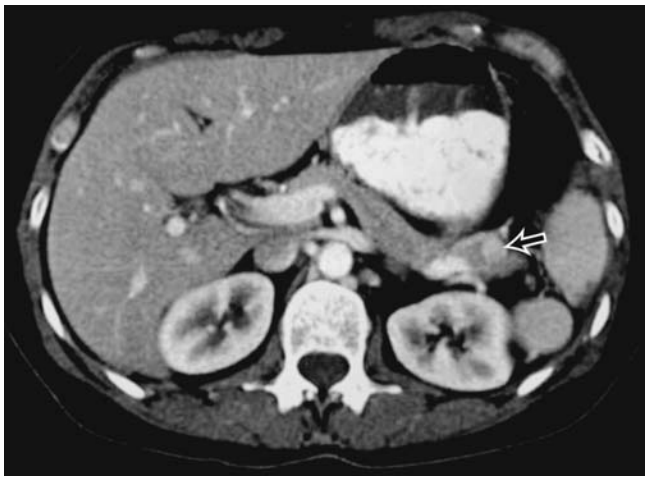

FIGURE 60-17 Once identified, this mass was correlated with preoperative CT findings. The CT demonstrates a hyperattenuated mass in the tail of the pancreas corresponding to the lesion identified intraoperatively (*arrow*). This mass was successfully enucleated. (Used, with permission, from Sharon Weber, MD, University of Wisconsin, Madison, WI.)

for adequate resection of even small malignant tumors in the pancreatic body or tail.[56] Expanding the patient population in which laparoscopic resection is possible will depend on improvements in preoperative localization. More extensive pancreatic resections for malignant tumors are best resected through an open approach.

In the rare instance that the tumor cannot be localized with pre- or intraoperative techniques, blind resection of any part of the pancreas is not recommended. When no tumor can be identified, biopsies should be taken from the pancreatic tail to evaluate for nesidioblastosis.

Normal life expectancy is achieved by complete excision of a benign insulinoma. More extensive resections are required for complete excision of malignant insulinomas, which are typically much larger (~6 cm), and in patients with MEN1 or multifocal disease. These patients may require a combination of partial pancreatic resection (distal pancreatectomy or pancreaticoduodenectomy) and enucleation for multiple lesions in the pancreas.[20,26] In general, total pancreatectomy is not indicated for insulinoma. While complete resection insulinomas is usually associated with resolution of hypoglycemia, tumor debulking results in a 95% biochemical cure rate because some residual disease may not be functional.[57]

For patients with metastatic insulinoma, resection of gross disease, along with octreotide for symptom control and systemic chemotherapy, is the appropriate treatment. For patients with unresectable disease, a new somatostatin analogue (lanreotide) that has recently developed remains biologically active for up to 2 weeks following a single injection and controls symptoms as well as octreotide that must be given three times daily.[58] Even with metastatic disease, the median survival following resection is approximately 5 years. Streptozotocin (with or without 5-fluorouracil) is associated with improved survival in metastatic pancreatic endocrine tumors.

Gastrinoma

Operative treatment of gastrinomas is indicated when curative resection appears possible based on preoperative imaging or for palliative cytoreduction for symptom control. The goals of surgery are twofold: potentially curative resection of the primary tumor and prevention of malignant progression. The presence or absence of malignant disease is the prime determinant of survival.

As with insulinomas, the entire pancreas should be mobilized to allow for thorough palpation and intraoperative ultrasound. The surgical approach begins with careful inspection of the gastrinoma triangle (see Fig. 60-5) to confirm the location of the tumor. After extensive kocherization, intraoperative ultrasound should be routinely applied to identify small pancreatic lesions or liver metastases. After transillumination of the duodenum with intraoperative endoscopy, the duodenal wall can be gently palpated between the surgeon's fingers through a 3-cm duodenotomy on the anterior/lateral surface of the second portion of the duodenum allowing the detection of gastrinomas less than 1 cm in size.[52]

Small, well-encapsulated tumors in the pancreas can be removed by enucleation. Large, unencapsulated lesions deep within the gland may require segmental resection, including distal pancreatectomy or pancreaticoduodenectomy. Pancreaticoduodenectomy may increase disease-free survival in patients with MEN1 because, following local excision, recurrent tumors are most commonly found within the duodenum.[16,27,58] In 5–8% of cases, the surgeon is unable to localize a gastrinoma intraoperatively.[59] In this case, blind pancreatic resection is not indicated. Detailed inspection of peripancreatic, periduodenal, and portohepatic lymph nodes should be performed as resection of grossly positive lymphatic spread may increase disease-free survival.

Unfortunately, more than half of patients with gastrinomas have metastatic disease at the time of diagnosis. For these patients, treatment should focus on symptom control (ie, reduction in acid production). The development of PPIs has reduced the need for surgical intervention for control of acid-related symptoms in patients with ZES. PPIs are so effective at reducing acid secretion that surgical procedures, which had previously been superior to medications, are now rarely performed. Symptoms are controlled in more than 90% of patients starting with doses of 40–80 mg daily, although higher doses may be required. Efficacy can be demonstrated by measuring basal acid output (BAO); PPI dosage should be titrated to keep BAO less than 10 mEq/h (or <5 mEq/h if the patient had a prior acid-reducing procedure). Octreotide can be used to decrease gastrin release and control acid secretion but is rarely effective without concurrent PPI use.

Historically the treatment for ZES, one of the few remaining indications for total gastrectomy in patients with ZES, is

the presence of gastric carcinoid tumors that may arise from prolonged hypergastrinemia. Gastric carcinoids probably occur in fewer than 10% of patients with MEN1 and ZES; thus gastrectomy is rarely required. Gastrectomy may also be indicated for patients who are unable to tolerate PPIs and cannot achieve acid secretion control through other means. Total gastrectomy cures all symptoms produced by excessive acid but has no effect on survival for metastatic disease.

The best predictor of survival for patients with gastrinoma is the presence of liver metastases, while lymph node metastases are not predictive. Patients with bulky metastatic disease have a 5-year survival less than 50%, while 90% of patients without metastases are alive after 5 years. Resection of all gross disease and metastases may provide palliation of symptoms and may prolong survival. Norton and colleagues showed that 58% of patients with gastrinomas had normalized gastrin levels following resection; the 5-year survival was nearly 100% for patient without liver metastases. Patients who had no synchronous liver lesions but developed them metachronously had a 5-year survival of nearly 100% and a 10-year survival rate of 80%. Patients presenting with synchronous liver metastases had a 5-year survival rate of approximately 45% (Fig. 60-18). Aggressive surgical therapy is indicated, as patients have been known to live more than 20 years with residual disease. Chemoembolization or radiofrequency ablation of hepatic metastases may be effective in reducing tumor burden within the liver. Cytotoxic chemotherapy has been used in patients with metastatic disease but does not provide a demonstrated survival benefit.

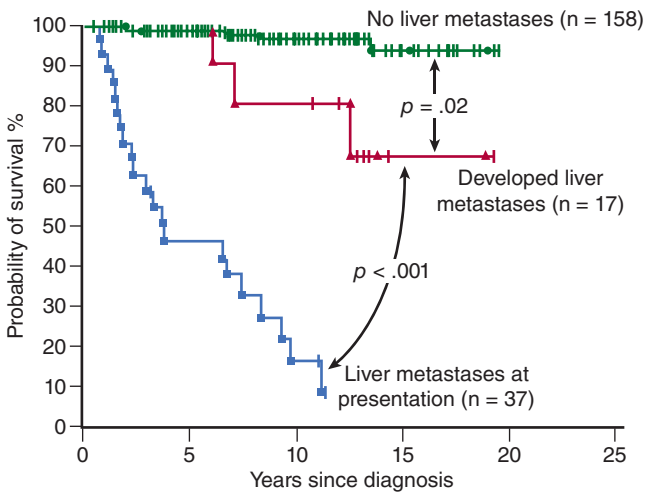

FIGURE 60-18 Effect of the presence of liver metastases at the initial evaluation or the development of liver metastases on survival in patients with gastrinomas. Disease-specific survival rates are shown. Of the 158 patients with no liver metastases, 6 died during follow-up, whereas 4/17 patients who developed liver metastases died and 23/37 patients who initially had liver metastases at first evaluation died during the follow-up period since diagnosis. (Modified from Yu F, Venzon DJ, Serrano J, et al. Prospective study of the clinical course, prognostic factors and survival in patients with long-standing Zollinger-Ellison syndrome. *J Clin Oncol.* 1999;17:615–30, with permission.)

VIPomas, Glucagonomas, Somatostatinomas, and Nonfunctional Endocrine Tumors

Surgical treatment of VIPomas and glucagonomas requires special preoperative preparation. Treatment of VIPomas begins with aggressive preoperative hydration and correction of electrolyte abnormalities and acid-base disturbances. Octreotide is commonly used preoperatively to reduce diarrhea volume and facilitate fluid and electrolyte replacement. If diarrhea persists despite octreotide therapy, addition of a glucocorticoid may be helpful.

For patients with glucagonomas, treatment begins with medical therapy to improve the nutritional condition of these patients who have typically lost a significant amount of weight and lean body mass. Supplemental enteral nutrition in excess of basic caloric needs is often required in conjunction with high doses of octreotide (up to 1000 μg/d) to reverse the catabolic state. Prophylaxis against thromboembolism should be instituted early in the hospitalization to prevent perioperative deep vein thrombosis and pulmonary embolism that are the leading causes of death in these patients. Intravenous infusions of amino acids may be required to reverse symptoms and improve dermatitis.

Resection of the VIPoma, glucagonoma, somatostatinoma, nonfunctioning pancreatic endocrine tumors is the treatment of choice as complete excision offers the only chance of cure. Because these tumors tend to be invasive, simple enucleation is often inadequate and partial pancreatic resection is usually recommended. Unfortunately, the frequent presence of synchronous metastases may make complete excision impossible. Palliative resection of recurrences and metastatic foci may be helpful in controlling symptoms; however, improvement in overall survival is unlikely. In a review of the literature, 86% of VIPomas were resected and 23% of patients died of disease from 12 to 52 months after diagnosis/surgery.[29] Other forms of therapy for metastatic disease have been used anecdotally, including hepatic artery embolization, radiofrequency ablation, liver transplantation, radioactive octreotide, chemotherapy, and cryotherapy. Adjuvant chemotherapy has not been shown to be beneficial.

Following resection, 5-year survival for patients with glucagonoma is nearly 85% if no metastases are present. Five-year survival is approximately 60% in patients with metastatic disease.[34] Dacarbazine is uniquely effective against glucagonoma as compared to other pancreatic endocrine tumors, and complete remission has been reported in several cases.[60]

For patients with somatostatinomas and nonfunctional islet cell tumors, surgical resection remains the mainstay of treatment. There is little necessity in the way of specific preoperative preparation. The high frequency of malignancy mandates pancreaticoduodenectomy or distal pancreatectomy (not enucleation) if the intent of the pancreatic resection is curative. Even in patients with liver metastases, pancreatic resection may eliminate symptoms related to the size of the mass and improve survival. Overall 5-year

survival for nonfunctional pancreatic endocrine tumors is approximately 50%.[42]

CONCLUSIONS

The management of pancreatic endocrine tumors requires a thorough understanding of the biological behavior of these tumors and the essential role of surgical intervention in providing both potential cure and symptom relief. Challenges remain in the localization of these tumors although modern imaging technology identifies the tumor in most cases preoperatively. Patients with MEN1-associated neuroendocrine tumors often have more aggressive and multifocal tumors, thus mandating a different surgical approach and preoperative evaluation. Tumor resection provides an excellent chance for cure, especially for insulinomas. Debulking of even widespread metastatic disease can lead to control of debilitating hormonal symptoms and allow for favorable long-term survival. Surgeons are uniquely qualified to care for patients with pancreatic endocrine tumors because resection of tumor burden, including recurrences, remains the most effective method to control the debilitating symptoms caused by hormone overproduction.

PERSPECTIVE ON PANCREATIC NEOPLASMS

Douglas B. Evans

Dr Wolfgang, Dr Schulick, and Dr Cameron provide an extremely comprehensive chapter on the evaluation and treatment of patients with cancer of the periampullary region and specifically the pancreatic head. The multidisciplinary working group from Johns Hopkins Hospital has made numerous contributions to the field of pancreatic cancer biology as well as the clinical management of patients with this disease. As all of you know, over the past two to three decades, Dr Cameron has demonstrated how to surgically manage patients with pancreatic cancer to achieve optimal outcome. Importantly, there has been a tremendous advance in both the understanding of the molecular biology of pancreatic cancer as well as our ability to accurately image the pancreas and periampullary region prior to surgery. Advances in both computed tomography (CT) and magnetic resonance imaging (MRI) have allowed for accurate assessment of critically important tumor-vessel relationships. Such accurate assessment of the relevant anatomy is important for both pretreatment staging and for planning the technical steps in performing pancreaticoduodenectomy, especially if vascular resection and reconstruction may be indicated. Although very experienced surgeons such as the authors can accurately assess resectability at the time of laparotomy, the ability to preoperatively classify patients as resectable, borderline resectable or locally advanced allows for the appropriate triage of patients for optimal treatment sequencing (surgery first or after neoadjuvant therapy), the evaluation of patients for investigator-initiated and cooperative group clinical trials, and for the referral of patients to higher volume centers. Indeed, to the extent that outcome is improved for patients with localized disease at high-volume centers (by high-volume surgeons), patients will need to be accurately staged (CT imaging) and, when necessary, have biliary stents placed safely in order to facilitate referral to a specialty center. The ability to perform endoscopic ultrasound (EUS)–guided fine-needle aspiration (FNA) biopsy will prevent diagnostic uncertainty and allow for medical oncology consultation and multidisciplinary care.

Fortunately, the last decade has witnessed the development of consensus for the CT staging of pancreatic cancer. In an attempt to clarify the anatomy of resectable, borderline resectable, and locally advanced disease, Varadhachary and colleagues from the University of Texas M.D. Anderson Cancer Center proposed an objectively defined, CT-based classification that distinguished borderline resectable from both resectable and locally advanced pancreatic cancer.[1] The Varadhachary definitions considered venous abutment and encasement (without occlusion) to be resectable, in the absence of tumor extension to the celiac or superior mesenteric (SMA) arteries. However, this definition was developed for the conduct of clinical trials of neoadjuvant treatment sequencing and was not intended to support a surgery-first strategy for patients who may require vascular resection and reconstruction. The Varadhachary definitions also assumed the technical capability to resect and reconstruct the superior mesenteric-portal vein (SMPV) confluence when necessary and that the major determinant of margin status (R status) was the tumor-artery (celiac, hepatic, SMA) relationship (Table 61A-1). Katz and colleagues in 2008 reported 160 patients with borderline resectable disease (using the Varadhachary definition) and introduced three subtypes of the borderline category, often referred to as Katz types A, B, and C.[2] Type A patients were those with borderline resectable tumor anatomy as defined in the Varadhachary manuscript. Type B patients were borderline resectable because of a concern for possible extrapancreatic metastatic disease and included those with CT findings suspicious for, but not diagnostic of, metastatic disease. One could also add to this group those patients with very high cancer antigen 19-19 (CA19-9) levels (important that the CA19-9 be measured when the serum bilirubin is normal). Type C patients were borderline resectable due to a marginal performance status or significant preexisting medical comorbidity thought to require protracted evaluation that precluded immediate surgery. By definition, type C patients were thought to have reversible causes of their current symptoms such as hyperbilirubinemia-induced anorexia and fatigue. Katz and colleagues provided compelling data in support of induction chemotherapy (followed by chemoradiation) for patients with borderline resectable disease. Of equal importance, they defined borderline resectable disease in all three forms that we see clinically: anatomic (local tumor

TABLE 61A-1: THE VARADHACHARY/KATZ CT STAGING SYSTEM FOR ADENOCARCINOMA OF THE PANCREATIC HEAD AND UNCINATE PROCESS

		Tumor-Vessel Relationship on CT			
Clinical Stage of Disease	**AJCC Stage**	**SMA**	**Celiac Axis**	**CHA**	**SMV-PV**
Resectable[a] (all 4 required to be resectable)	I/II	Normal tissue plane between tumor and vessel	Normal tissue plane between tumor and vessel	Normal tissue plane between tumor and vessel	Patent (may include tumor abutment or encasement)
Borderline resectable (only 1 of the 4 required)	III	abutment	abutment	Abutment or short-segment encasement	May have short-segment occlusion if reconstruction possible
Locally advanced (only 1 of the 4 required)	III	encasement	encasement	Extensive encasement with no technical option for reconstruction	Occluded with no technical option for reconstruction

AJCC, American Joint Committee on Cancer; CHA, common hepatic artery; CT, computed tomography; SMV-PV, superior mesenteric vein-portal vein confluence.
Definitions: abutment, ≤180° or ≤50% of the vessel circumference; encasement, >180° or >50% of the vessel circumference.
[a] Assumes the technical ability to resect and reconstruct the SMV, PV, or SMV-PV confluence when necessary.

anatomy), oncologic/biologic (possible advanced disease not fully apparent on imaging), and physiologic (marginal performance status).

For those surgeons who recommend a surgery-first strategy to patients with localized, potentially resectable pancreatic cancer, the CT definition of what should be considered "resectable" for which immediate surgery may be considered is often more limited than the M.D. Anderson definitions above. The AHPBA-SSO-SSAT consensus panel definition of resectable (as distinct from borderline resectable) included only those tumors with no evidence (on CT) of even abutment or distortion of any aspect of the SMPV confluence as well as no extension to the adjacent mesenteric arteries.[3] At present, there appears to be growing consensus for a fairly narrow definition of "resectable" when a surgery-first strategy is planned. In the absence of neoadjuvant therapy, resectable disease is defined as the absence of tumor extension to the adjacent visceral arteries (SMA, celiac, hepatic) and the absence of tumor-induced unilateral shift, distortion, or narrowing of any aspect of the SMPV confluence; such patients may be taken directly to surgery if a suitable clinical trial is not available.[3] In contrast, patients with borderline resectable pancreatic cancer, as defined by the AHPBA-SSO-SSAT consensus panel, should be treated with induction therapy before surgery.

What is not clear at present is how best to treat patients with borderline resectable pancreatic cancer before consideration of surgery. Many incorporate a period of induction systemic therapy, especially in those with arterial abutment, to include at least 2 months of chemotherapy before chemoradiation.[2] Emerging clinical trials, as well as off-protocol therapy, will likely include what may prove successful in metastatic disease. For example, gemcitabine plus nab-paclitaxel (Abraxane) or FOLFIRINOX (5-flouro-uracil [5-FU], leucovorin, irinotecan, and oxaliplatin).[4,5] The length of induction systemic therapy, the timing and dose of radiation therapy, and the optimal postoperative systemic therapy remain undefined. The published experience to date with neoadjuvant treatment sequencing for resectable and borderline resectable pancreatic cancer has largely used chemoradiation as a component of the treatment program. Experience using chemotherapy alone is relatively untested, the obvious concern being the risk for local tumor recurrence. The first national trial of neoadjuvant therapy for resectable pancreatic cancer (the American College of Surgeons Clinical Oncology Group Z5041 [ACOSOG Z5041]) does not incorporate radiation therapy; the local recurrence rate will be an important endpoint with major therapeutic implications.

Probably the most important technical aspect of pancreaticoduodenectomy is the dissection of superior mesenteric artery.[6] In general, exposure of the SMA is facilitated by complete mobilization of the SMPV confluence to the patient's left. This allows for careful separation of the uncinate process from the jejunal branch of the SMV and, ultimately, exposure of the SMA. Our current understanding of the pathophysiology of local recurrence following pancreaticoduodenectomy (with or without multimodality therapy) is microscopic infiltration of the autonomic neural sheath that surrounds the SMA. Adenocarcinoma of the pancreas has a predisposition to spread along neural tissue, and this is likely responsible for the high frequency of local recurrence. As our systemic therapies become more effective, local recurrence may become a more dominant pattern of failure. It is impossible to argue with the technique described by Dr Wolfgang as the operation of pancreaticoduodenectomy is arguably done better at Johns Hopkins Hospital than any other institution in the

world. Students, residents, and even experienced surgeons will benefit greatly by careful review of this chapter.

Chapter 58 by Dr Maley and Dr Yeo is equally comprehensive in their superb discussion of cystic neoplasms of the pancreas. They focus predominantly on serous cystadenoma, mucinous cystic neoplasm (MCN), and intraductal papillary mucinous neoplasm (IPMN). Regarding serous cystadenoma, this histology demonstrates fascinating tumor biology. As mentioned by the authors, it is generally felt that serous cystadenomas do not have the biologic ability to metastasize to distant organs or regional lymph nodes. However, they can be locally invasive and erode into adjacent bowel (duodenum, transverse colon, stomach) and occasionally can obstruct the splenic vein (resulting in sinistral portal hypertension) or the superior mesenteric and/or portal veins (resulting in extrahepatic portal hypertension). Importantly, the diagnosis of (microcystic) serous cystadenoma can usually be made on high-quality CT imaging with or without the additional benefit of EUS because of its characteristic imaging appearance (unless the serous cystadenoma is macrocystic). When referring a patient for EUS to confirm a diagnosis of serous cystadenoma, we would recommend an FNA biopsy if the EUS is not consistent with this diagnosis or there appears to be discrepancy between CT or MRI imaging and the EUS appearance. As noted by the authors, serous cystadenomas are characterized by a cyst fluid CEA level that is usually undetectable or very low (<5 ng/mL). In 2011, the diagnosis of a serous cystadenoma is usually not difficult; however, knowing when to intervene with surgery is often challenging. As patient age and operative risk (medical comorbidities) increase, the benefit to surgery in an otherwise asymptomatic patient may be low. For example, it is relatively easy to understand a recommendation for surgery in an otherwise completely healthy 60-year-old patient with a 5- to 6-cm serous cystadenoma.[7] However, the same pancreatic tumor in a 75-year-old patient with one or two coronary stents and a relatively sedentary lifestyle may not be the correct approach. In our practice, we try to carefully weigh risk versus benefit in asymptomatic patients.[8] In addition, for serous cystadenomas that are less than 4–5 cm in size, we usually require that they demonstrate growth, over a period of observation, before proceeding with surgery. Our underlying philosophy is to avoid surgery-related mortality and major morbidity, especially in patients who are asymptomatic with a tumor histology such as serous cystadenoma that poses no risk for distant metastases.

The discussion on MCN is particularly well done and as emphasized my Dr Maley and Dr Yeo, ovarian stroma is now required to secure a diagnosis of MCN. While the relationship between size of the MCN and malignant potential is not perhaps as well worked out as with IPMN, it is reasonable to utilize the same 3-cm rule. For example, in the absence of a solid component or mural nodule, mucinous neoplasms less than 3 cm in diameter, that are radiographically consistent with MCN, can usually be safely observed. A recommendation for observation is all the more compelling in patients of advanced stage and with medical comorbidities. Obviously, it is sometimes difficult to differentiate an MCN from a unifocal branch duct IPMN in a woman. Importantly, as mentioned by the authors, MCNs occur in the pancreatic body and tail and are exceedingly rare in the pancreatic head or uncinate process. In our practice we would consider an MCN in the pancreatic head or uncinate process to represent an IPMN. What remains controversial is the surgical approach to MCNs of presumed low malignant potential. For example, consider an otherwise healthy 50-year-old woman with a 3-cm presumed MCN in the pancreatic body who has undergone EUS-guided FNA biopsy and the mucinous nature of the cyst fluid has been confirmed. In this patient with no evidence of a solid component or mural nodule on CT or EUS, surgery is recommended because of the patient's young age as well as the size of the MCN. Because this is a premalignant neoplasm, it would be very difficult to support a recommendation of observation in a patient of this age. If her serum level of CA19-9 was also normal, this finding adds further support to there being no invasive component to the tumor at this time. The compelling question then is whether she should undergo middle segment pancreatectomy, distal pancreatectomy (with or without splenic preservation), or enucleation. In patients without cancer, we do need to pay more attention to preservation of islet cell mass in an effort to avoid the intermediate and long-term complications of insulin-dependent diabetes (in addition to the lifestyle changes introduced with insulin dependence). Our choice for operation in this patient would be a middle segment pancreatectomy with pancreaticojejunostomy for the distal pancreas and creation of a serosal patch sewn to the proximal pancreatic transection site. This would hopefully minimize the risk for anastomotic leak, preserve islet cell mass, and ensure that the lesion is completely excised with negative margins. We have not yet adopted enucleation as a routine part of our practice when dealing with mucinous (premalignant) neoplasms.

When dealing with a patient who has presumed IPMN, especially those with branch duct disease, the Sendai guidelines have now been widely incorporated into clinical practice.[9] As noted by the authors, use of these guidelines will result in a slightly higher-risk (for invasive adenocarcinoma) population being considered for surgery. By definition, the low-risk patients would be treated with at least a period of observation until the size of the cyst or the CT characteristics (suggestion of a solid component) prompt surgical intervention. Such a strategy is designed to avoid surgery, and its associated risk for mortality and morbidity, in patients with small cystic neoplasms who have no chance of harboring an invasive cancer. In our practice, enucleation would rarely be considered as we do not operate on the cystic neoplasms that would be considered most appropriate for enucleation (those of very low risk). However, the increasing use of cross-sectional imaging has resulted in many more patients being diagnosed with cystic neoplasms of the pancreas. Would it be reasonable to consider a lesser procedure (enucleation or endoscopic alcohol ablation) in smaller branch duct IPMNs that may be diagnosed in younger patients? Is there a role for enucleation or ablative therapies in patients where the risk for invasive carcinoma is approaching zero? This is now a subject of debate

at national meetings, and I suspect represents a fruitful area for cooperative group clinical trials.

Fortunately, when dealing with a patient who has IPMN and requires surgery, the need for total pancreatectomy is uncommon. If the right or left side of the pancreas requires resection, we commonly send the pancreatic transection margin for frozen-section analysis. Work from our group and others has demonstrated that it is probably unnecessary to chase a margin with low-grade dysplasia (PanIN-1) as this can result in the unnecessary resection of additional pancreas.[10] Importantly, at many institutions, there is only modest expertise in the interpretation of frozen-section evaluation of pancreatic transection margins. Surgeons should be cautioned to avoid overaggressive resection of grossly normal pancreatic parenchyma based on frozen-section evaluation of pancreatic transection margins especially when dealing with IPMN. Another area of operative/technical challenge includes IPMN involving the neck of the pancreas; should one resect the right or the left side of the gland? In this situation we would typically divide the pancreas to the right of the neoplasm at the junction of the head and neck of the pancreas. We would then send this margin for frozen-section evaluation before committing the patient to an extended distal pancreatectomy (in those cases where middle segment pancreatectomy is not preferred). When performing an extended distal pancreatectomy, one needs to be certain that the proximal pancreatic transection margin will be negative, especially if the patient could also be treated with an extended pancreaticoduodenectomy and thereby preserve some islet cell mass. In general, the preservation of some islet cell mass does facilitate improved blood sugar control even if not obviating the need for insulin. Last, it is important to note that patients who undergo surgery for IPMN (in contrast to those who undergo pancreatectomy for MCN) do require long-term follow-up. We typically obtain an MRI of the abdomen 2–4 months following surgery and our next scan would typically occur 1 year later. If there is no evidence of an abnormality in the remaining pancreas, our MRI imaging interval is in the range of 12–24 months depending on the histology of the previous resection, patient age, and the general health (performance status) of the patient.

As described by Dr Riall and Dr Evers, pancreatic neuroendocrine tumors (pNETs) are usually low- to intermediate-grade tumors arising from the pancreatic islets. They are also known as pancreatic endocrine tumors, islet cell carcinoma, and pancreatic carcinoid tumors. The current preferred nomenclature is pancreatic neuroendocrine tumors or pNETs.[11] The biology of this class of tumors is both unique and fascinating. For example, why should sporadic, nonmetastatic insulinomas virtually never develop distant recurrence and only very rarely recur locally (virtually all local recurrences are secondary to incomplete enucleation)? Metastatic insulinoma is very rare and, when seen, it is always synchronous at the time of diagnosis; we have not seen a case of metachronous metastases. In contrast, patients with multiple endocrine neoplasia type I (MEN1) who have nonfunctioning pNETs have a risk of metastatic spread that appears related to the size of the primary tumor in the pancreas. Patients with primary tumors less than 2.5 cm in size rarely have associated liver metastases.[12] When weighing the risk of long-term insulin-dependent diabetes with the risk for distant metastases, we often observe small (<1–1.5 cm) nonfunctioning pNETs in young MEN1 patients. Further, why should the biology of patients with Zollinger-Ellison syndrome differ based on whether the primary tumor is in the pancreas or the duodenum and what determines where the tumor arises? Equally mystifying is why duodenal gastrinomas are so small, often less than 1 cm in diameter and rarely associated with liver metastases. Gastrinomas, when located in the pancreas, are usually found within the pancreatic head or uncinate process (gastrinoma triangle) and those 3 cm in size and larger are frequently associated with liver metastases. Consistent with the biology of duodenal gastrinoma, patients with carcinoid tumors of the duodenum also rarely have synchronous or metachronous liver metastases even though lymph nodes metastases are very common.[13] Indeed, the biologic explanation for the varied metastatic potential of functioning and nonfunctioning pNETs is an area of active investigation. Recent studies suggest that pancreatic, but not duodenal, gastrinomas express pancreatic-duodenal homeobox1 (Pdx1) and that only duodenal gastrinomas express sonic hedgehog signifying a different molecular origin for the two tumors.[14]

When evaluating a patient with hypergastrinemia, it is important to remember that the major cause of hypergastrinemia is parietal cell dysfunction, resulting in achlorhydria and pernicious anemia. Such patients can be differentiated from those with Zollinger-Ellison syndrome by the absence of gastric acid production. In the outpatient center, placement of a nasogastric tube with aspiration of gastric juice for pH testing will easily make this diagnosis. We frequently see patients who have elevated serum gastrin levels from either concomitant administration of a proton pump inhibitor or because of parietal cell dysfunction. A pancreatic or duodenal producing tumor is a much less frequent cause of hypergastrinemia. Importantly, consistent with the optimal operative management of virtually all pNETs, regional lymphadenectomy is an important part of the operative procedure for patients with gastrinoma. Patients with functioning or nonfunctioning pNETs can have persistent or recurrent disease in regional lymph nodes in the absence of liver, bone, or lung metastases. Careful attention to regional lymphadenectomy is an underemphasized and very important component of their surgical management.

As noted by the authors, patients with insulinoma virtually always have an insulin level greater than 3 μIU/mL (usually >6 μIU/mL) when the blood glucose is less than 40–45 mg/dL and an insulin to glucose ratio of 0.3 or less reflects the inappropriate secretion of insulin at the time of hypoglycemia. The conclusion of any carefully done observed fast, performed to confirm the diagnosis of hyperinsulinism, includes the administration of 1 mg of glucagon given intravenously. It is critically important to confirm the diagnosis of insulinoma by allowing the glucose to decline to a level of less than 45 mg/dL (at which point the patient is usually symptomatic) and observing the relief of symptoms with the

administration of glucagon. Intravenous glucagon is associated with an elevation of serum glucose of approximately 20 mg/dL. The reversal of hypoglycemia with glucagon confirms that hypoglycemia is insulin mediated. In contrast to gastrinomas that usually occur in the duodenum and pancreatic head/uncinate, insulinomas may develop anywhere throughout the pancreas and do not arise in the duodenum. In the absence of MEN1, the overwhelming majority of insulinomas are unifocal. As previously mentioned, if metastatic disease is not seen at the time of diagnosis, metachronous distant metastases from a presumed benign insulinoma does not occur. However, if the insulinoma is incompletely enucleated, a local recurrence can develop; such local recurrences may not occur for years after the primary operation. When we perform an enucleation of a benign insulinoma, we typically use bipolar forceps and are extremely careful to avoid violation of the tumor capsule. The advantage of bipolar cautery is that the operative field remains dry and that one can appreciate the junction of the tumor capsule and the normal pancreatic parenchyma. Because the pancreas is highly vascular, it is critically important to keep the operative field as dry as possible. Proper technique for enucleation is much more important than whether the operation is done laparoscopically or open. In the event of a pancreatic fistula, the presence or absence of an abdominal incision becomes insignificant. When an enucleation is performed, the anatomy of the primary tumor in relation to the pancreatic duct should be appreciated on preoperative imaging, and, if needed, this important anatomic relationship can be confirmed with intraoperative ultrasound. If one performs a very large enucleation or injures the pancreatic duct, a Roux-en-Y limb of jejunum can be used to create a pancreaticojejunostomy. For large defects in the pancreas, we have made liberal use of Roux-limbs for internal drainage.

Regarding MEN1, all at-risk patients should undergo genetic testing. In addition to MEN1, pNETs can occur in association with tuberous sclerosis, neurofibromatosis, and von Hippel-Lindau (vHL) syndrome. As previously mentioned, there is a defined association between tumor size and risk for liver metastases in MEN1 patients with nonfunctioning pNETs. Balancing the risk for insulin-dependent diabetes with the risk for metachronous liver metastases is indeed a difficult challenge. In our practice, the timing of pancreatic surgery in MEN1-associated nonfunctional pNETs is based on the tumor biology seen within the family (frequency of metastases and death secondary to metastatic pNET), the age of the patient, and the size of the pancreatic tumors. For patients who have a family history of metastatic neuroendocrine carcinoma, we begin to discuss surgery when the pNET becomes greater than 1 cm in size and argue against continued observation when the largest pNET reaches 1.5–2 cm in size. Dr Norman Thompson was the first to recommend a partial pancreatectomy for patients with MEN1.[15] He described the combination of distal subtotal pancreatectomy with enucleation of identified lesions in the pancreatic head and uncinate process. This operation also included regional lymphadenectomy. The "Thompson procedure" aimed to decrease the risk of metachronous liver metastases while preserving some islet cell function, hopefully enough to avoid insulin dependent diabetes. Patients with aggressive MEN1-associated pNETs will often eventually require completion of total pancreatectomy, as one would expect metachronous recurrence within the remaining pancreas after the first operation. However, one would hope that the second operation to complete the total pancreatectomy would not occur until many years after the first operation, thereby avoiding insulin dependence until later in life at which time the long-term complications of type 1 diabetes are less unlikely. Because the natural history of MEN1-associated pNETs becomes clear only after decades of follow-up, we still have much to learn in the management of these patients.

Importantly, the last decade has witnessed an explosion in the understanding of the biology of pNETs and their potential response to targeted therapies. Tyrosine kinase inhibitors such as sunitinib and the mammalian target of rapamycin (mTOR) inhibitor everolimus have shown activity in patients with metastatic pNETs and have stimulated renewed interest in translational research and novel therapies for this disease.[16,17] Importantly, many patients who develop metachronous recurrence years after pancreatectomy for a nonfunctioning pNET will have somewhat indolent disease. The majority of these patients will be treated with octreotide, and disease stabilization is frequently seen.[18] The optimal management of patients with low-volume metastatic pancreatic neuroendocrine carcinoma requires thoughtful multidisciplinary input from oncologists, interventional radiologists, and frequently surgeons. Liver resection, systemic therapy (to include octreotide), and ablative therapies both intra-arterial and percutaneous can all add to improved length and quality of life for affected patients.

Last, in our practice we rarely proceed with surgery in a patient with a nonfunctioning pNET if a gross, complete resection cannot be performed. However, in the setting of known metastatic disease or a large, borderline resectable primary tumor, we frequently use neoadjuvant therapy (cytotoxic and/or biologic). In the setting of synchronous liver metastases, a one- or two-stage surgical approach can be used with or without neoadjuvant therapy. In contrast to exocrine pancreatic cancer, we frequently resect neuroendocrine liver metastases. When dealing with a resectable primary tumor and resectable liver metastases, we usually remove the pancreatic tumor first; if the pancreatectomy goes well, some or all of the liver disease can be addressed at the same operation. If the magnitude of surgery required for the pancreatic primary is too large, the liver surgery should be performed at a second stage. As one can imagine, there are various degrees of complexity regarding combined pancreas-liver resections. For patients with more advanced liver metastases, in whom a future liver remnant can be cleared at the time of the initial pancreatectomy, one can even consider portal vein embolization and second-stage extended hepatectomy. This of course assumes excellent health of the patient, a reasonable age category, and the absence of medical comorbidities. Indeed, future options to combine novel systemic therapies with advanced surgical techniques hold great promise for patients with pNETs, even those with disease that may have been considered nonoperable in the past.

PERSPECTIVE ON SURGERY FOR EXOCRINE NEOPLASMS OF THE PANCREAS

Andrew L. Warshaw

The last 40 years have seen remarkable advances in what we know about pancreatic neoplasms, their biology, how we approach their management, and the quality and safety of surgical treatment. Some can be attributed to better surgical technique, but most are due to developments in imaging, along with nonsurgical interventions such as endoscopic retrograde cholangiopancreatography (ERCP), stenting, and percutaneous or endoscopic needle biopsies. In most cases the diagnosis can be made preoperatively; the extent of the tumor can be determined; and the timing as well as the nature of the probable surgical procedure can all be planned before or even instead of a laparotomy. Pancreaticoduodenectomy has become sufficiently safe (2–5% mortality, median postoperative length of stay 8 days in high-volume centers) that the operation can be offered to most patients without biopsy proof of malignancy because the risk of missing a cancer now exceeds the risk of mistakenly operating for a benign condition. This radical approach to resection applies as well to ampullary neoplasms, which contain cancer in up to 50% of villous adenomas in spite negative biopsies. The conclusion is that a negative biopsy should not deter resection of a lesion with significant malignant potential.

Yet there are still important shortcomings to the methods we have. There is no reliable screening test for pancreatic cancer and, even if one were invented that had a remarkable 99% accuracy, we would probably be unable to find the lesion at the desired very early stage of growth because current imaging with the best computed tomography (CT) or endoscopic ultrasound (EUS) still cannot "see" masses much smaller than 1 cm (at which size many pancreatic adenocarcinomas have already spread).

For purposes of staging pancreatic cancers, multidetector contrast-enhanced angio-CT is as good as we have for evaluating the mesenteric, celiac, and hepatic blood vessels, but it still misses small liver or peritoneal metastases in at least 10% of cases of apparently resectable cancers.[1] In addition, the use of preoperative laparoscopy will in another 10% demonstrate peritoneal dissemination of cancer cells that indicate a significantly diminished prognosis.[2]

There is a consensus that preoperative biliary stenting is unnecessary if the operation can be expeditiously performed, but it is useful when the patient is uncomfortable with pruritus and relief by biliary decompression will not be immediate or when neoadjuvant treatment is planned. The fear of increased postoperative surgical site infections has not been substantiated in a recent randomized controlled trial.[3] Whether neoadjuvant therapy confers a benefit is debatable, either for downstaging borderline resectable cancers involving the mesenteric vessels or for increasing long-term survival.[4] The M.D. Anderson group has argued that neoadjuvant chemoradiation helps to define the 25% of patients in whom metastases are predestined to blossom immediately, ensures delivery of the treatment to some patients who would not tolerate or receive postoperative adjuvant treatment, and may improve survival, perhaps by reducing positive resection margins. However, with the relatively ineffective chemotherapy drugs available, the end results of a neoadjuvant approach have not been convincingly superior. In contrast to the prevailing European studies, adjuvant radiation added to chemotherapy for resected pancreatic cancer was associated with a significant survival advantage demonstrated in a large American database.[5]

Many studies have demonstrated that higher volumes, whether of the surgeon or the hospital, are related not only to lower postoperative mortality but also to higher long-term survival. New data show that both better technique, manifested by a higher percentage of negative margins,[6] and better hospital infrastructure for perioperative support play a part. Ensuring an adequate retroperitoneal margin by skeletonizing the superior mesenteric artery of its nerve plexuses (pancreatic cancer spreads along perineural channels) may help to reduce the positive margin rate that otherwise may be as high as 75% when there is assiduous pathological examination.[7] Intraoperative radiation, which in theory

might be useful for potentially positive margins, has been disappointing in achieving better survival.[8]

The technique for pancreaticoduodenectomy described in Chap. 60 is acceptably generic. It does not address the growing utilization of laparoscopic techniques for resection, now common for distal pancreatectomy but perhaps in the future for pancreaticoduodenectomy as well.[9] It also does not take sides in the debate about whether to perform a "classic Whipple operation" with pyloroantrectomy and gastrojejunostomy or a pylorus-preserving version with a duodenal-jejunostomy. Unless the proximal duodenum or antrum is directly involved by the cancer, there seems to be no demonstrable difference in survival or cure rates, despite that there may be some difference in extent of lymphadenectomy (even extended lymph node dissections have proven to make no difference).[10]

A recent meta-analysis of pylorus-preserving versus standard pancreaticoduodenectomy with antrectomy has found no significant difference in various perioperative indices except for 275 cc of greater blood loss and 72 minutes longer operation with the antrectomy version.[11] They noted no difference in the occurrence of delayed gastric emptying with the pylorus-preserving version. Our experience at the Massachusetts General Hospital differs in that the antrectomy portion adds less than 15 minutes for mobilization and the Hofmeister turn-in of part of the gastric staple line, and we, along with some others, have found that one-third of patients have 5–7 extra days of gastroparesis after the pylorus-preserving operation (erythromycin did not help). In our practice we avoid pylorus preservation. From my perspective, you can take it or leave it.

While extended retroperitoneal lymph node dissection has not fulfilled its theoretical promise, vascular resection, at least portal and mesentery vein resection, is establishing acceptance.[12] Involvement of the superior mesenteric or celiac arteries probably signals that the cancer has spread far enough along retroperitoneal lymphatic and neural channels that control of margins and metastases is out of reach, but vein resection when the cancer is adherent or invasive—it is difficult to differentiate between these without resecting the vein—can be accomplished safely with consequent negative margins and a 5-year survival comparable to patients not requiring a vein resection. The extent of vein involvement that still allows resection and reconstruction, whether with a graft or with mobilization of the mesentery and end-to-end anastomosis, will vary with the skill and aggression of the surgeon.

Postoperative leak at the pancreatic anastomosis leading to a pancreatic fistula or intra-abdominal collection is one of the most common complications of a pancreaticoduodenectomy, and the one most likely to be lethal. Breakdown of the pancreaticojejunostomy is more common with a soft, nonfibrotic pancreas, which does not hold sutures as well. It occurs more frequently, therefore, after resections for cystic neoplasms, neuroendocrine tumors, bile duct cancers, and duodenal cancers than in pancreatic cancers, which obstruct the pancreatic duct and cause induration of the gland. Fistulas occurred in 13% of our Whipple operations (75/581) over 5 years.[13] While 39% of these fistulas healed with closed-suction drainage, allowing the drains (which we routinely use) to be removed, 61% were high impact and were complicated by an abscess or bleeding requiring intervention. Seven patients died (9% of those with fistulas), 6/7 from vascular erosion and pseudoaneurysm. A sentinel bleed from a drain must be taken very seriously and it warrants immediate angiographic evaluation for purposes of embolization or stenting of the culprit vessel.

Probably all high-volume pancreatic surgery practices are seeing increasing numbers of pancreatic cystic tumors, in large measure the product of cross-sectional imaging for other purposes. Thirty years ago, pseudocysts were said to be the most common cystic lesions of the pancreas; now cystic neoplasms are far more prevalent, the majority being asymptomatic and found by serendipity. Cystic neoplasms comprised about one-fourth of our pancreaticoduodenectomies in 2009 and are now the most common pancreatic neoplasm entering our practice. The challenge for pancreatic surgeons and their colleagues is how to estimate the relative risk of watchful waiting versus intervention.

Much attention is paid to the differential diagnosis of serous cystadenomas (SCA), mucinous cystic neoplasms (MCN), intraductal papillary mucinous neoplasms (main-duct and branch-duct IPMN), cystic neuroendocrine tumors, and other uncommon entities by the use of CT, magnetic resonance imaging (MRI), EUS, and fine-needle aspiration, the latter in part for cytology but especially for carcinogenic embryonic antigen (CEA) levels in the fluid. An elevated CEA tends to indicate one of the mucinous family of tumors but gives no indication of malignancy at any level.[14] However, the level of sensitivity and specificity of these diagnostic tests generally does not exceed 70% across the board, with the exception that an elevated CEA essentially excludes serous cystic neoplasms, which are almost always benign.

From a pragmatic standpoint, therefore, it may be more useful to develop guidelines that can be applied to an undetermined cystic lesion that does not fit the clinical or morphologic criteria for a pseudocyst. Some are easy: if the cyst is producing symptoms (pain, jaundice, and pancreatitis) or is bulky and demonstrably growing over time, it probably should be resected. If the main pancreatic duct is dilated, main-duct IPMN, with its 60% likelihood of containing at least in situ cancer, must be considered and resected. If there is a mural nodule or solid component, the risk of malignancy is too great to ignore. The Sendai consensus,[15] which provides reliable guidelines that have been repeatedly validated, adds the element of cyst size. While there are uncommon exceptions, generally there is minimal risk of malignancy, even carcinoma-in-situ, in mucinous cysts (MCN or branch-duct IPMN) smaller than 3 cm. Consequently smaller, asymptomatic cysts without mural nodules or other solid components can be watched for growth or change, preferably by MRI/magnetic resonance cholangiopancreatography (MRCP), perhaps every year

or two. Most will turn out to be branch-duct IPMNs, at least 30% of which will be multiple. Those individual cysts that fit a guideline for potential malignancy need segmental resection—metachronous small cysts can be left behind and watched for future growth and change.

There is growing appreciation that many small, incidentally discovered pancreatic cystic lesions do not grow or develop cancerous change over a period of many years while many, perhaps 5% (8/159 in our experience[16]), turn out to be indeterminate nonneoplastic cysts upon resection. On the other hand, because the mucinous cystic neoplasms—MCN or IPMN—may eventually degenerate into aggressive incurable adenocarcinomas, there is a premium on timely determination of the need for resection, erring on the side of taking out many benign lesions to prevent one cancer from getting beyond cure. Cystic carcinomas are highly curable if removed before invasion or metastases, and the majority of those that are invasive can still be cured. Lymph node metastases are less common in IPMN carcinomas and unheard of in MCN carcinomas, at least in our experience.[17] For this reason segmental and other atypical resections that focus on the locale of the lesion suffice. Local excision of the tumor, including duodenum-preserving head resection (which is essentially a wide enucleation), is also acceptable as long as the tumor can be removed with adequate surrounding pancreas to ensure negative margins. Evaluation of the pancreatic duct margin, of special importance for main-duct IPMN, requires an experienced pathologist to differentiate mucinous hyperplasia (acceptable) from neoplasia (unacceptable) on frozen section.

Surveillance, generally with MRI/MRCP, is indicated for residual cysts, perhaps no more often than at intervals of 1 or 2 years. We have not seen the appearance of a new serous or mucinous cystic neoplasm after resection of the propositus lesion and do not recommend surveillance imaging for these patients. Surveillance is, of course, appropriate after removing a cancer or any main-duct IPMN because of the possibility of metastasis, recurrence, or development of a new main-duct lesion in the residual pancreas. In addition, patients with IPMN are at somewhat greater risk of developing other gastrointestinal cancers, especially in the colon and stomach.

THE SPLEEN

62

Ali Tavakkoli

BACKGROUND

The spleen was regarded by Galen as "an organ of mystery," by Aristotle as unnecessary, and by Pliny as an organ that might hinder the speed of runners.[1] In many societies, spleen was also thought to be affiliated with mood. The word *spleen* comes from a Greek word that has idiomatic equivalent of the heart in English, that is, to be good-spleened means to be good-hearted or compassionate. In contrast, spleen has been typically associated with melancholy, and in 19th-century England women in bad humor were said to be afflicted by the spleen or the vapors of the spleen. Although over the last century the functions of spleen have become clearer, an element of mystery remains around the organ.

Surgeons often have a love–hate relationship with the spleen. A surgeon's experience with the spleen is often tainted as most of his or her experience with the organ comes from emergent settings, when the patient is often unstable and the spleen is the source of significant bleeding. Even when dealing with elective cases, the increased complexity of medical indications for splenectomy has made the role of surgery often confusing. Despite these drawbacks, surgery on the spleen remains an enticing procedure for most surgeons, one that is wonderfully challenging and often memorable.

In this chapter we review the anatomy, physiology, and pathology of splenic diseases, before focusing on techniques of splenectomy, focusing on the laparoscopic approach.

RELEVANT ANATOMY

Gross Anatomy

The spleen arises by mesenchymal differentiation along the left side of the dorsal mesogastrium in juxtaposition to the anlage of the left gonad in the 8-mm embryo. The organ ultimately migrates to the left upper quadrant.

In the healthy adult, the spleen weights 150 g (range 75–250 g), although there are variations based on sex, age, and racial background.[2] It resides in the posterior portion of the left upper quadrant lying deep to the 9th, 10th, and 11th ribs, with its long axis corresponding to that of the 10th rib, and measures about 11 cm. On ultrasound imaging, 13 cm is regarded as the upper limit of normal size for spleen. It's convex superior, and lateral surfaces are immediately adjacent to the undersurface of the left leaf of the diaphragm. The configuration of the concave medial surface of the spleen is a consequence of impressions made by the stomach, pancreas, kidneys, and splenic flexure of the colon (Fig. 62-1).

The position of the spleen is maintained by several suspensory ligaments, which need to be divided during a splenectomy to allow full mobilization of the organ. These are the gastrosplenic, splenophrenic, splenocolic, and splenorenal ligaments (Figs. 62-2 and 62-3). The gastrosplenic ligament contains the short gastric vessels that course to the splenic hilum from the greater curvature while the remaining ligaments are generally avascular, except in patients with portal hypertension or myeloproliferative disorders. The splenorenal ligament contains the pancreas and the splenic vessels. The tail of the pancreas is thus in close proximity to the splenic hilum. Recent computed tomographic (CT) image analysis has shown that the average distance between the tail of the pancreas and the splenic hilum is 3.4 ± 1.5 cm, and at least 1 cm in all cases. To minimize the risk of injury to the pancreatic tail during surgery, it is therefore important that the surgeon stay close (within 1 cm) to the splenic hilum during a splenectomy to avoid injury to the pancreas.[3]

Accessory spleens, which are often distinct and separate masses of splenic tissue, have been reported in 14–30% of patients, with a higher incidence in patients with hematologic disorders. They are present in decreasing order of frequency in the hilus of the spleen and the tail of the pancreas, the greater omentum, the gastrosplenic ligament, and splenocolic ligament (Fig. 62-4A). Accessory spleens may also occur in the pelvis of the female, either in the presacral region or adjacent to the left ovary, and in the scrotum in juxtaposition to the left testicle (Fig. 62-4B). The accessory spleens can vary in size and may be small lesions that can be easily missed unless a careful examination is performed (Fig. 62-5).

Splenoptosis (wandering spleen) refers to a rare condition in which the spleen hangs by a long pedicle from the mesentery and may present itself as an asymptomatic mass or with

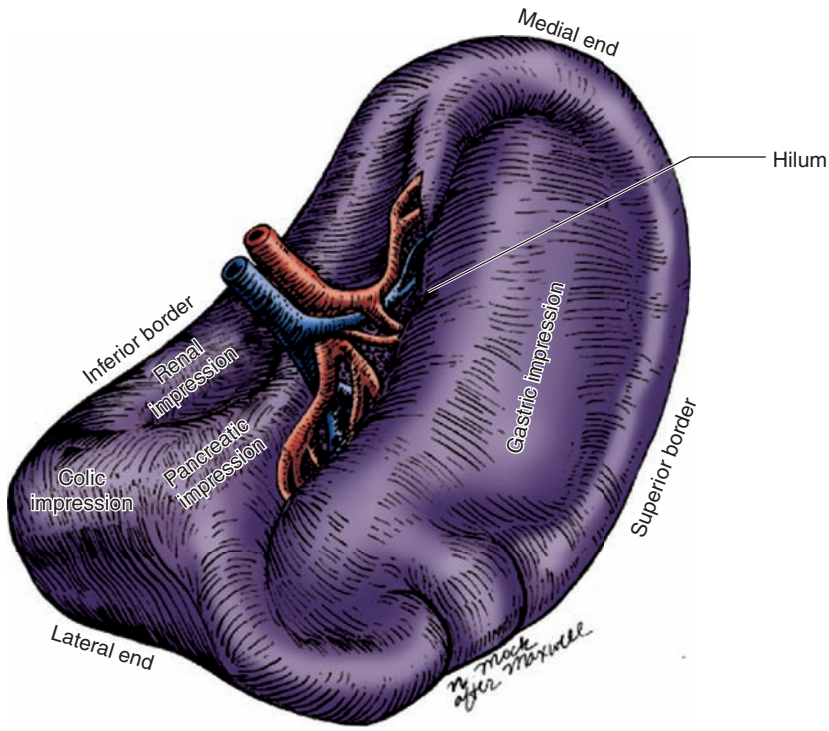

FIGURE 62-1 Gross anatomy of the spleen.

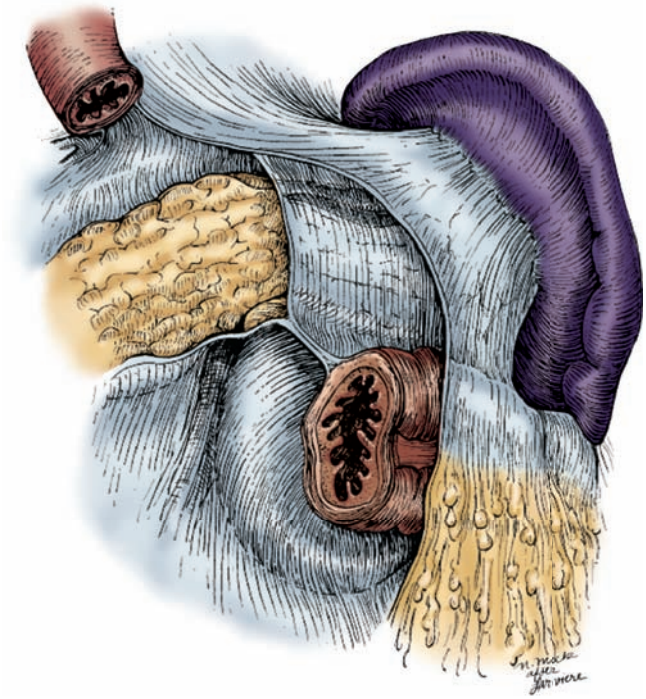

FIGURE 62-2 Anatomy of the spleen showing complicated peritoneal reflections in the region of the hilus.

symptoms of intermittent or acute abdominal pain due to torsion. Treatment involves splenectomy in cases of ischemia, but splenopexy should be considered in other cases.[4]

Splenic Blood Supply

The splenic artery commonly arises from the celiac plexus and is the longest of its three branches. Most of the splenic arterial supply is derived through this vessel although short gastric vessels, arising from the gastroepiploic artery, also provide some supply. The splenic artery has a very tortuous course and a unique pattern of distribution in every individual. Following the work of Michels, the splenic arterial supply has been divided into two general types:

Distributed type: The most common variation seen in 70% of cases. Here the main splenic artery is short, dividing into several long brunches that enter the spleen on the medial aspect, involving 75% of the medial border (Fig. 62-6A).
Magistral type: The less common variation seen in 30% of cases. Here a long main trunk, divides near the hilum to a few branches that enter the spleen medially but only involve 30% of the spleen's medial surface (Fig. 62-6B).

Each of these anatomical variations can raise their own surgical challenges, and identification of the arterial supply type can help the surgeon plan their approach. The splenic artery also has a pancreatic branch (pancreatica magna) that is worthy of note. Occlusion of this branch, most often seen

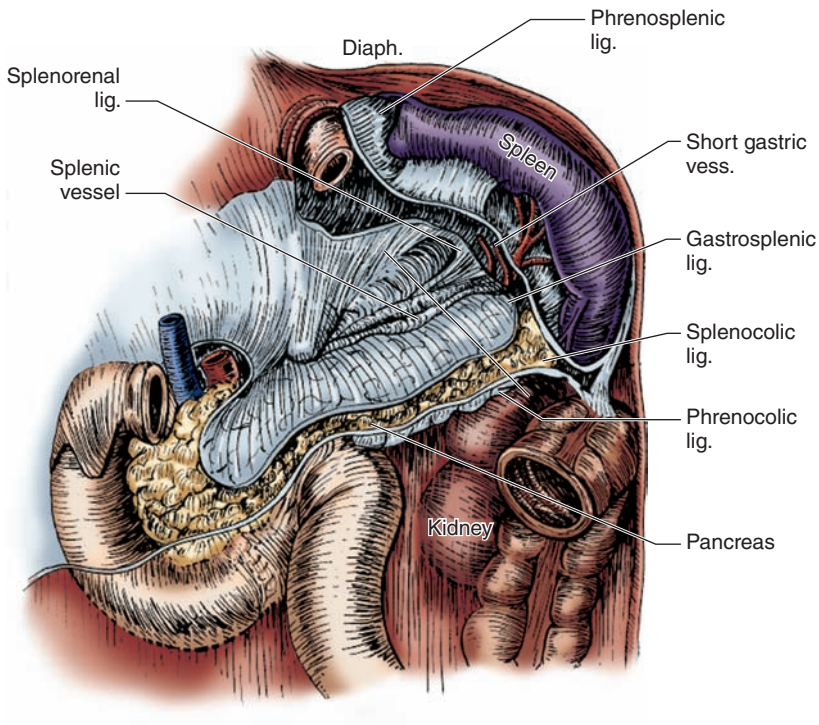

FIGURE 62-3 The multiple ligaments of the spleen.

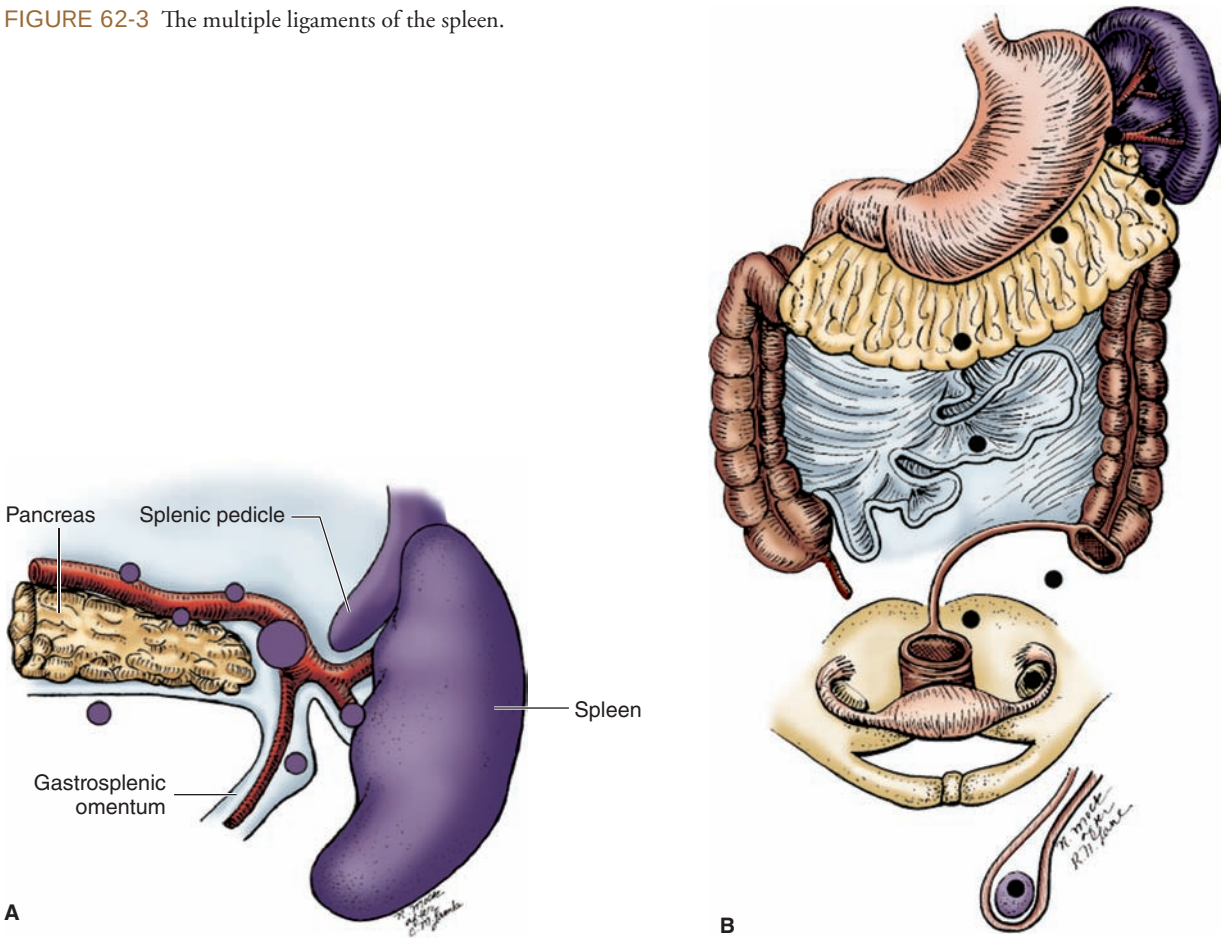

FIGURE 62-4 **A.** The more common locations of accessory spleens. Accessory spleens are also found in the left ovary, in the left testicle along the course of the left ureter, and in the lesser sac and greater omentum. **B.** Locations of accessory spleens. Note position of presacral and paraureteric splenuli.

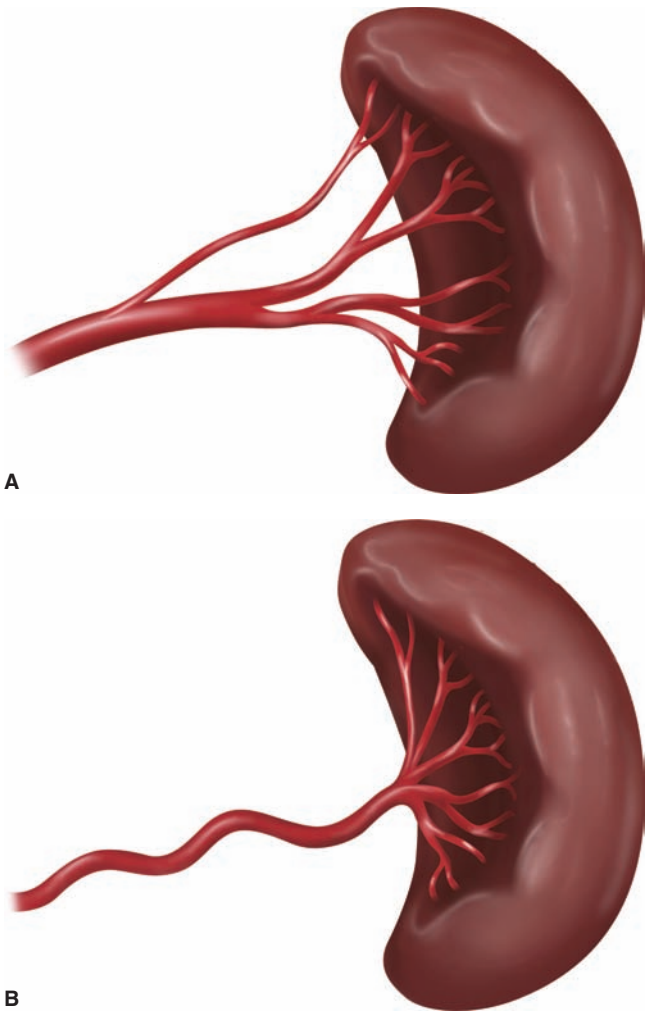

FIGURE 62-6 Different types of splenic artery distribution: **A.** Distributed type: short splenic artery that divides into long brunches that enter the spleen medially, involving 75% of the medial border. **B.** Magistral type: here the splenic artery is long with few hilar brunches.

after splenic artery embolization, can lead to pancreatitis. This topic is discussed in more detail later.

The major venous drainage flows through the splenic vein, which usually receives the inferior mesenteric vein centrally, and then joins the superior mesenteric vein to form the portal vein.

Histology

The spleen is made up of a capsule that is normally 1–2 mm thick, and trabeculae that surround and invaginate the pulp. Approximately 25% of the parenchyma (Fig. 62-7) is made up of "white pulp" that functions as an immunologic organ, with the remaining 75% made up of the "red pulp" that phagocytizes particulate matter from the blood. The two zones are separated by a narrow marginal zone.

The white pulp, which is central and surrounds a central artery, is made of lymphatic nodules with germinal centers and periarterial lymphatic sheaths that constitute a reticular network filled with lymphocytes and macrophages. Peripheral to the white pulp is the marginal zone that contains end arteries arising from the central artery and from peripheral penicilliary arteries. The marginal zone contains lymphocytes and macrophages and red blood cells (RBCs) that have exited from terminal arteries. The marginal zone also contains the marginal sinus that filters material from the centrally located white pulp. Locally produced immunoglobulins enter the marginal zone, eventually coursing to the blood stream.

Physiology

Spleen receives 250–300 mL of blood per minute, which corresponds to 5% of the cardiac output. At any given time, however, it contains only 30–40 mL of blood. Although the spleen is not necessary for human life, it performs important functions that are generally attributed to its unique blood flow pattern. As the blood enters the spleen, it can take two paths of flow. A fast (closed) circulation that takes the blood directly from the arterioles to venules or a slower (open) circulation that takes the blood through the pulp. The majority (90%) of flow is of the slow (open) type that exposes the circulating cells and erythrocytes to splenic macrophages in the red pulp (see Fig. 62-7).

Functions of the spleen can be generally divided into the following:

Erythrocyte quality control and removal of defective red cells: This is achieved through pitting and culling. *Pitting* refers to the removal of rigid structures such as Heinz bodies (denatured intracellular hemoglobulin), Howell-Jolly bodies, and hemosiderin granules from red cells. The process involves the removal of nondeformable intracellular substances from deformable cells. The rigid body is phagocytized while the deformable cytoplasmic mass passes into the sinus and returns to the general circulation. The postsplenectomy

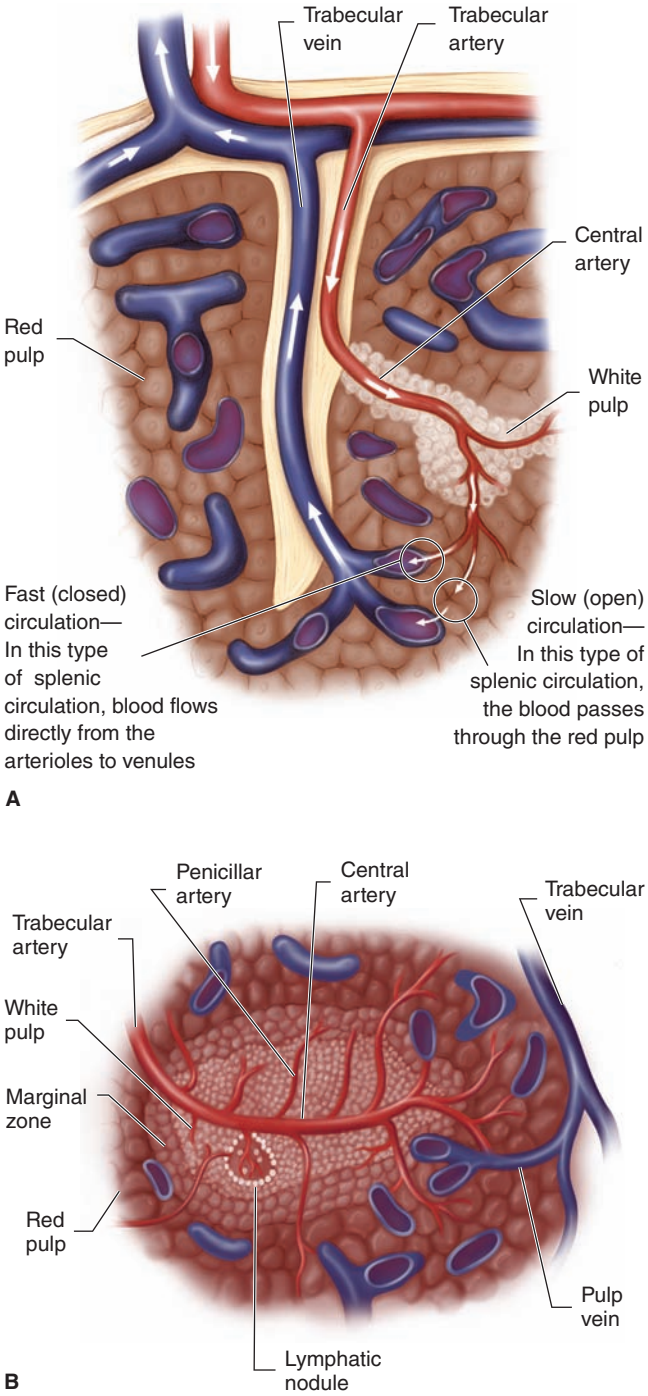

FIGURE 62-7 Diagram illustrating splenic compartments and the two different types of circulation.

blood smear is thus characterized by the presence of circulating erythrocytes with Howell-Jolly and Pappenheimer bodies (siderotic granules).

Culling is the term applied to the spleen's ability to remove red cells that are aged or abnormal. During its 120-day life cycle, the red cell spends an estimated minimum of 2 days within the spleen. Normally, as the red cell ages after a life span of approximately 120 days, it loses osmotic balance and membrane integrity, and therefore deformability. When these cells lose their deformability, they are phagocytized by native macrophages. The spleen does not represent the only site for red cell destruction, and there is no difference in red cell survival following splenectomy. About 20 mL of RBCs are removed daily from the blood.

Pooling: In health, the spleen does not serve as an important reservoir for blood cells but does so for platelets. Normally, about one-third of the platelet mass is pooled in the spleen, and this pool exchanges freely with the circulating platelets that have a life span of about 10 days. With splenomegaly, a large proportion of platelets are sequestered in the spleen (up to 80%) and this, coupled with accelerated platelet destruction in the spleen, accounts for thrombocytopenia. The role of spleen in platelet storage also explains the elevation in platelet count that is seen after splenectomy.

The neutrophil has a half-life of about 6 hours; hence 85% of neutrophils either migrate at random into tissues or are destroyed within 24 hours. Although the role of the spleen in the destruction of neutrophils under normal conditions is not well quantified, this role is amplified in some hypersplenic states, with resulting neutropenia. This augmented removal can occur because of splenic enlargement and accelerated sequestration of granulocytes or because of enhanced splenic removal of altered granulocytes, as seen in immune neutropenias.

Hematopoiesis: The spleen has an important hematopoietic function in fetal life that ceases by the seventh intrauterine month, and does not occur in healthy adults with exception in certain pathological conditions where bone marrow is unable to meet the needs (ie, extramedullary hematopoiesis).

Filtration: Macrophages residing in the splenic parenchyma capture cellular and noncellular material from blood, including encapsulated bacteria such as pneumococci, and destroy them. This function explains the increased risk of infections caused by encapsulated organisms that is seen after splenectomy.

Antibody synthesis in the white pulp: In addition to the phagocytosis of antibody-coated cells, the immunologic functions of the spleen include antibody synthesis (especially immunoglobulin M [IgM]); generation of lymphocytes; and production of tuftsin, opsonins, properdin, and interferon. Foreign antigens that are filtered in the white pulp are presented to lymphoid cells. Here the immunoglobulin response is mounted, leading to release of antibodies.

SPLENIC TRAUMA AND RUPTURE

Etiology

The causes of splenic rupture, in which the organ's parenchyma or capsule is disrupted, include penetrating trauma,

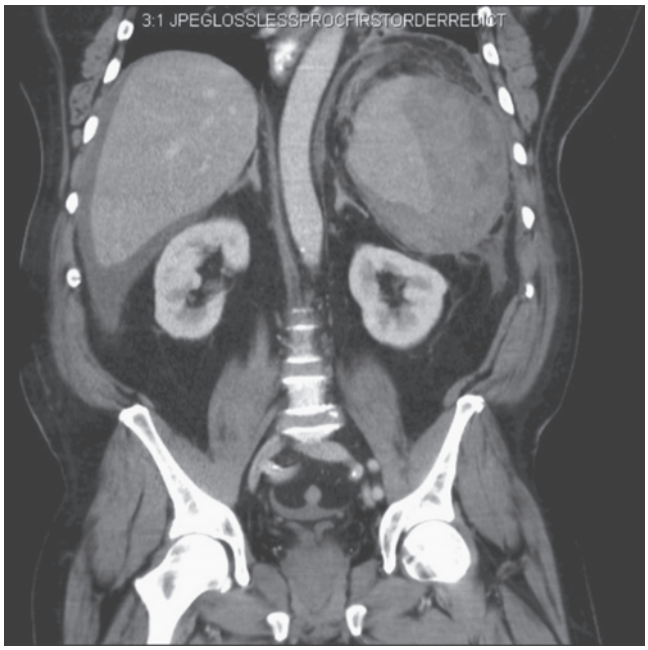

FIGURE 62-8 A large splenic hematoma that developed following intraoperative injury to the spleen during gastric bypass surgery. The patient was hemodynamically stable and the hematoma resolved without any further intervention.

nonpenetrating or blunt trauma, operative (iatrogenic) trauma, and, rarely, spontaneous rupture.

Spontaneous rupture of the spleen is rare but serious complication of a few diseases. In a review of over 800 spontaneous ruptures, six major etiological groups were defined: neoplastic (30.3%), infectious (27.3%), inflammatory (20.0%), drug- and treatment-related (9.2%), mechanical (6.8%), and normal spleen (6.4%). Majority of patients were treated with splenectomy with an overall mortality rate of 12%.[5]

Iatrogenic splenic injuries during abdominal procedures, especially colectomy, are well documented (Fig. 62-8). In a 16-year review of nearly 14,000 colectomies performed at Mayo clinic, the risk of splenic injury requiring a splenectomy or repair was 0.4%. The majority of these injuries occurred following mobilization of the splenic flexure, although in 10% of cases no splenic flexure mobilization was performed and the injury likely reflected tension on the colon. Although repair was attempted in 50% of cases, the majority of these patients ultimately require splenectomy. Those with an incidental splenectomy also had a high 30-day morbidity (34%) and mortality (15%).[6] Other contemporary studies have shown that patients who undergo an incidental splenectomy during colorectal surgery for cancer have a poorer prognosis compared to the nonsplenectomized group, highlighting also the negative long-term impact of splenic injury in these patients.[7] Iatrogenic splenic rupture has also been reported after endoscopic examination of the colon, although the rate of this adverse event is extremely low at 0.001%.[8]

Traumatic injury to the spleen remains the most common cause of splenic rupture and its management is discussed in the following text. The injury may be caused by puncture wounds due to stabbing or missiles. The trajectory of the penetrating wound may pass through the anterior abdominal wall, the posterior abdominal wall, the flank, or, transthoracically, piercing the pleural space and diaphragm. Isolated splenic injury may be present, or organs in juxtaposition may be involved; this would include the stomach, left kidney, left adrenal gland, colon, pancreas, and root of the mesentery. Nonpenetrating or blunt trauma represents an increasing etiologic factor in splenic rupture.

Diagnostic Studies

A decrease in serial hematocrit measurements may suggest continued intraperitoneal hemorrhage. Increases in the white blood cell (WBC) count to levels frequently greater than 15,000/mm^3 are often seen. Findings on routine abdominal films such as fractured ribs, elevated left hemidiaphragm, enlarged splenic shadow, medial gastric displacement, and widening of the space between the splenic flexure and the preperitoneal fat pad may be helpful. However, abdominal ultrasound and CT scan offer more specific information to diagnose the extent of disease or injury, with CT as the gold standard. Radiologic classification of splenic injury are now well established and can help the clinician identify patients who can be managed nonoperatively (Table 62-1).

TABLE 62-1: SPLENIC ORGAN INJURY SCALE

Class I	Nonexpanding subcapsular hematoma <10% surface area.
	Nonbleeding capsular laceration with <1-cm-deep parenchymal involvement.
Class II	Nonexpanding subcapsular hematoma 10–50% surface area.
	Nonexpanding intraparenchymal hematoma <5 cm in diameter.
	Bleeding capsular tear or parenchymal laceration 1–3 cm deep without trabecular vessel involvement.
Class III	Expanding subcapsular or intraparenchymal hematoma.
	Bleeding subcapsular hematoma or subcapsular hematoma >50% surface area
	Intraparenchymal hematoma >5 cm in diameter.
	Parenchymal laceration >3 cm deep or involving trabecular vessels.
Class IV	Ruptured intraparenchymal hematoma with active bleeding.
	Laceration involving segmental or hilar vessels producing major (>25% splenic volume) devascularization.
Class V	Completely shattered or avulsed spleen.
	Hilar laceration that devascularizes entire spleen.

Data from Cogbill TH, Moore EE, et al. Nonoperative management of blunt splenic trauma: a multicenter experience. *J Trauma*. 1989;29:1312.

Management

Penetrating injury patients and hemodynamically unstable blunt trauma patients with hemoperitoneum or peritonitis are treated with laparotomy and likely splenectomy.

The first total splenectomy for trauma was performed by Nicolaus Matthias in 1678 in Capetown, South Africa, on a patient whose spleen protruded through a flank wound. However, partial splenectomy for trauma antedated this procedure with the first successful partial splenectomy for trauma reported by Franciscus Rosetti in 1590. Increasing understanding of the functions of the spleen and increased risk of infection in splenectomized patients have rejuvenated interest in splenic salvage in trauma. The first successful partial splenectomy for trauma in modern times was reported by Campos Christo in 1962.[9] Splenic salvage may be attempted if hemostasis is achieved, greater than one-third of the splenic mass can be preserved, and if other intraabdominal injuries, such as pancreatic trauma, do not warrant splenectomy.

Observation that splenic injury may heal itself has also promoted conservative management of splenic injuries, and avoidance of surgery. While this practice was largely accepted in the treatment of injured pediatric patients to salvage the spleen and its immunologic function, it is only recently that nonoperative management has become established in the management of hemodynamically stable adults with blunt splenic injuries. With advances in imaging including spiral CT scan, more accurate and immediate grading of splenic injuries has been possible to guide therapy (see Table 62-1).

Increasingly, splenic injuries are managed with close observation and serial hematocrits. The success rate in such management strategy depends on severity of injury, and is reported greater than 95% for grade I injuries, greater than 90% for grade II, and greater than 80% for grade III injuries. Although grades IV and V are typically treated surgically, increasing numbers of trauma centers are adopting a nonoperative approach to some grade IV injuries. In a recent review of nonoperative management of splenic injuries in New England, the success rate of nonoperative management was only 40% for grade IV and 26% for grade V injuries.[10]

Identification of factors that increase the risk of delayed hemorrhage and failure of nonoperative management after splenic trauma has been attempted in an effort to reduce nonoperative failures. Such factors include presence of contrast extravasation or "blush" on CT scan, pseudoaneurysm, and arteriovenous fistulas.[11] Admission angiography with embolization is used increasingly to manage hemodynamically stable patients with such CT findings to help improve the success of splenic conservation.

Splenic salvage rates with angiographic embolization have been in the order of 90–95%, which likely explains the increasing pattern of its utilization.[12] Splenic embolization, however, has its own risks and may be complicated by splenic abscess, infarction, and significant pain.

Although there were concerns that such nonoperative approach would lead to increased need for blood transfusions, this has not been borne out in recent literature, even in the nonoperative management of higher grade injuries. Pachter and associates reported that 85% of 102 patients with splenic injuries managed nonoperatively did not require blood transfusion and, in fact, required less blood than the splenectomy cohort.[13]

LOCAL SPLENIC DISORDERS

Splenic Artery Aneurysm

Splenic artery aneurysm was first described by Baussier in 1770, and St. Leger Brockman described one of the first surgical cases in 1930. Although mycotic aneurysm can be seen in the splenic artery, the majority are idiopathic. The splenic artery is the most common visceral artery aneurysm and the second most common site of intra-abdominal aneurysms, second to the abdominal aorta. The incidence in autopsy series ranges between 0.02 and 0.16%, with a female predominance (4:1). The incidence of splenic aneurysm can increase in certain patient groups, including those with cirrhosis and portal hypertension. In fact, splenic artery aneurysms have been reported in 14% of patients awaiting liver transplant, which can lead to major hemorrhage after transplant.[14] Splenic artery aneurysm may also develop in patients with history of pancreatitis and should be suspected in a patient with pancreatitis who develops gastrointestinal (GI) bleeding without an obvious source.

In a contemporary review of 217 splenic aneurysms seen at the Mayo clinic, the mean age at presentation was 62 years, with 79% of the patients being female. Over 90% of the patients were asymptomatic, with only 5% of patients presenting with a rupture, with a mean size of 3.1 cm. While over 10% of men presented with a rupture, this rate was less than 3% in women, in large part due to larger aneurysm sizes in men. The mean size for nonruptured cases was 2.2 cm, and the smallest-diameter aneurysm to rupture was 2.2 cm.[15]

Risk of rupture of splenic aneurysms is believed to be higher in pregnant women, where rupture of aneurysms less than 2 cm has been reported. Such ruptures have been associated with maternal and fetal death rates of 22 and 15%, respectively.[16] Ruptures occur in the third-trimester of pregnancy in 69% of cases.[17]

Diagnosis in asymptomatic patients is often made as an incidental finding on a CT scan, although occasionally a calcified lesion is noted on plain film of the abdomen (Fig. 62-9).

Rupture of the aneurysm is manifested by sudden abdominal pain. In 12.5% a warning hemorrhage occurs, with temporary cessation of bleeding. Rupture into the colon, stomach, and intestine may take place, but intraperitoneal rupture is by far the most common presentation. When rupture occurs in the nonpregnant woman, it is usually contained in the lesser sac, resulting in a patient mortality rate of less than 5%.

Surgical resection in all symptomatic aneurysms is recommended; however, criteria for elective repair of asymptomatic aneurysms are not firm. In general, asymptomatic aneurysms greater than 2 cm should be removed if the patient is a

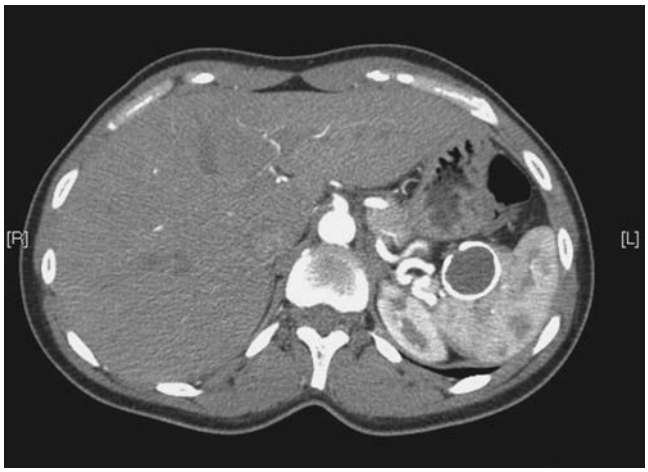

FIGURE 62-9 A CT scan of a large splenic artery aneurysm with calcified wall. This calcified wall can also be seen on plain abdominal roentgenogram.

reasonable operative risk.[15] Aneurysms of any size detected in pregnancy should be considered for resection as many of the ruptured aneurysms during pregnancy are less than 2 cm in size.[16] These resections should be done before the third trimester, when the risk of rupture is at its peak.

Lesions proximal to the hilus of the spleen can be managed by resection and primary end-to-end anastomosis or proximal and distal ligation with resection of the involved segment.[18] Proximal ligation is reasonable because the spleen will not become ischemic following central ligation of the main splenic artery.

Distal lesions generally require laparoscopic splenectomy with resection of the involved splenic artery (Fig. 62-10).

Although there has been significant recent progress in treating such aneurysms by endovascular means, with a less than 90% success rate the disadvantages of the endovascular procedures include treatment failures, postprocedural pain, and abscess formation, as well as pancreatitis due to occlusion of the pancreatica magna vessel.[19]

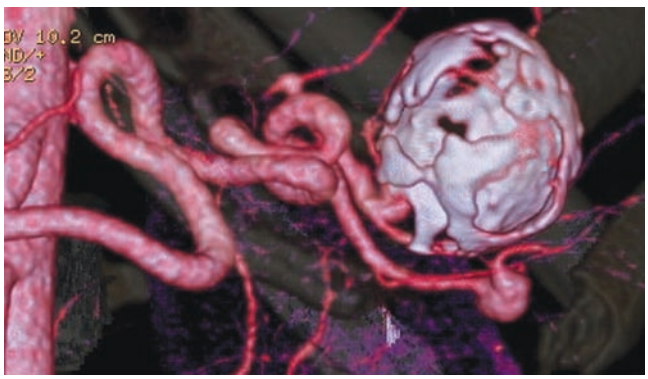

FIGURE 62-10 A 3D CT reconstruction of a partially thrombosed large splenic artery aneurysm with a smaller aneurysm more distal. Both aneurysms were treated by a laparoscopic splenectomy.

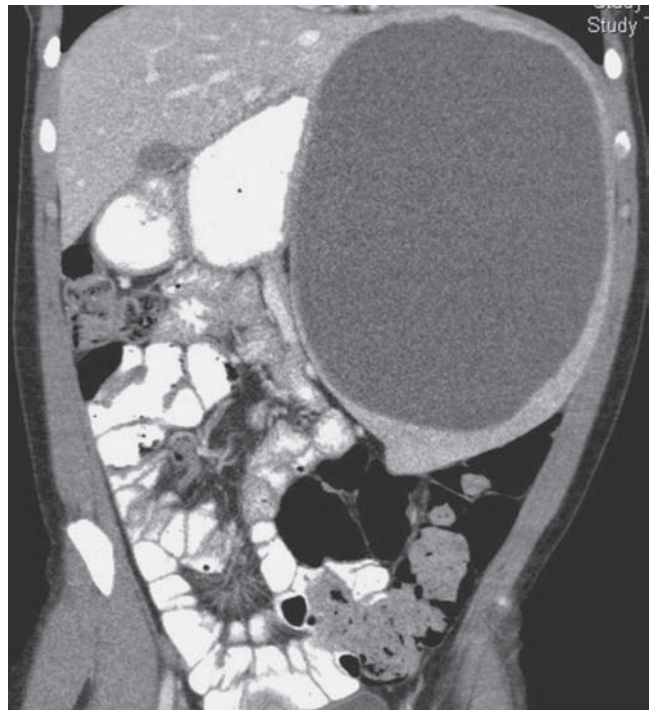
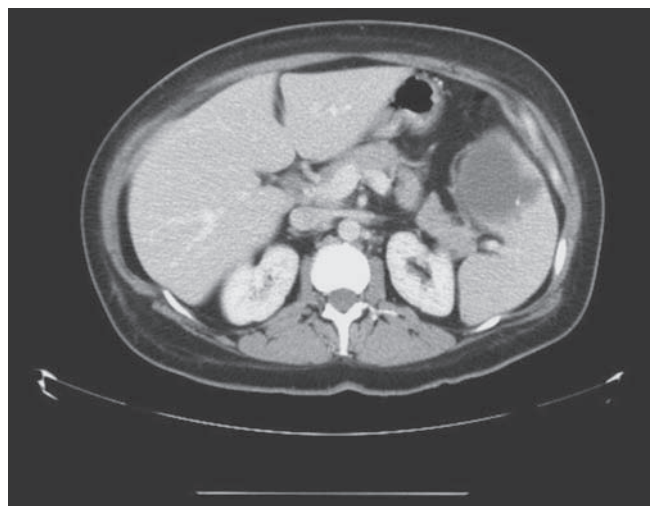
Cysts

Splenic cysts are generally classified as primary or secondary (pseudocysts). Some of the splenic tumors may also have a large cystic component to them and are discussed separately in the following text (Fig. 62-11). Primary cysts have an epithelial lining and can be nonparasitic or parasitic (echinococcal).



A



B

FIGURE 62-11 **A.** A large splenic cyst seen on CT. **B.** A large splenic cyst that, on careful review, had septations and calcifications. Patient underwent a splenectomy, and pathology confirmed an 8-cm lymphangioma.

PARASITIC PRIMARY CYSTS

Worldwide, *Echinococcus* infection (hydatid disease) is the most common cause of a splenic cyst. *Echinococcus granulosis*, the most commonly implicated species, usually results in a unilocular cyst composed of an inner germinal layer (endocyst) and an outer laminated layer (ectocyst) surrounded by a fibrous capsule. Unlike the nonparasitic cysts, these are filled with fluid under positive pressure, and also contain daughter cysts and infective scolices. Echinococcal cysts are usually asymptomatic unless they reach a size causing pressure symptoms or become secondarily infected or rupture.

For diagnostic purposes, the older Casoni skin test is now replaced with serologic testing, which provides reliable diagnostic specificity and sensitivity. Ultrasound, CT, and MRI studies demonstrate a cystic mass that is septated and contains daughter cysts.

Splenectomy is the treatment of choice because there is no effective medical therapy. Care should be taken to avoid spilling the contents of the cyst. Intraoperatively, the lesions can be sterilized by instilling a 3% sodium chloride solution. If intraperitoneal spillage occurs during the dissection, anaphylactic hypotension may occur and require epinephrine to treat the shock. Laparoscopic and percutaneous treatment has not been widely accepted in treating hydatid cysts because of a traditional fear of spillage and anaphylaxis.[20]

NONPARASITIC PRIMARY CYSTS

This group of cysts includes simple cysts, epidermoid cysts, and dermoid cysts. Various classifications have been proposed based on whether they are lined with mesothelial, transitional, or epidermoid linings and also whether they are neoplastic, traumatic, or degenerative.[21] Simple congenital cysts are lined by flattened or cuboidal cells originating from infolding of peritoneal mesothelioma during splenic development. These lesions are usually small and asymptomatic and do not require excision. When these cysts are large and symptomatic, they can be removed by laparoscopic or open total or partial splenectomy.

About 10% of cysts are lined by squamous epithelium and are rare. These cysts are usually round and unilocular and may be very large. They are filled with yellow or brown turbid fluid. The cyst is dense, and the diagnosis is established by microscopic definition of the stratified squamous lining. Examination of multiple cuts may be required to demonstrate the pathology.

Epidermoid cysts of the spleen occur in children and in young adults in 75% of the cases. About two-thirds of the patients have been female. The clinical manifestations are dependent on the size and are similar to those of the pseudocysts, as are the imaging findings. Laparoscopic or open splenectomy or partial splenectomy is recommended for large or symptomatic cysts.

True dermoid cysts of the spleen are exceedingly rare; fewer than 10 cases have met the pathologic criteria of a squamous epithelium with dermal appendages such as hair follicles and sweat glands. Splenectomy is indicated.

It can be difficult to differentiate these cysts from one another based on imaging only, and usually the differential diagnosis is made when symptomatic cysts, usually greater than 5 cm, are excised and analyzed histologically.[22] Asymptomatic cysts, which are often smaller, are observed with no need for surgical resection.

SECONDARY PSEUDOCYSTS

These cysts do not have an epithelial lining and comprise 70–80% of splenic cysts in the Western countries. They are usually a result of trauma and represent resolution of a subcapsular or intraparenchymal hematoma. In over 80% of the cases the lesion is unilocular, and the cyst wall is dense and smooth. Microscopically, the wall consists of fibrous tissue without an internal epithelial lining.

Pseudocysts occur more frequently in women, children, and young adults. One-third of the patients are asymptomatic, and in others the most frequent complaint is left upper quadrant pain radiating to the left shoulder or chest. Symptoms related to pressure on the stomach occur less frequently. Ultrasonography, CT, MRI, and magnetic resonance arteriography will define the cystic nature of the lesion. Although splenectomy is the definitive therapy, these cysts are increasingly managed by laparoscopic unroofing and drainage. Such simple approach is, however, associated with a recurrence rate of 20–40%, and recommendations would be to marsupialize the cyst or decapsulate the cyst when possible, which has been associated with very low recurrence rates.[23,24]

Splenic Abscess

Splenic abscesses tend to be rare, due to the spleen's ability at fighting infections and bacteria. They are more frequently seen in the tropics, where there is a higher incidence of sickle cell anemia, with associated thrombosis of parenchymal vessels and subsequent superimposed infarction.

The major risk factors for such abscesses in the Western world are intravenous drug use, human immunodeficiency virus disease, other hematogenous spread (endocarditis), splenic trauma, and contiguous spread. Endocarditis can be complicated with splenic abscesses in 5% of cases. They are often multiple splenic abscesses associated with similar findings in other organs; spleen is just a part of overwhelming sepsis.[25]

Most infections are polymicrobial and include such organisms as *Staphylococcus*, *Salmonella*, and *Escherichia coli*, *Proteus mirabilis*, *Streptococcus* group D, *Klebsiella pneumoniae*, *Peptostreptococcus* species, *Bacteroides* species, *Fusobacterium* species, *Clostridium* species, *Candida albicans*, and *Mycobacterium*.

The symptoms are usually nonspecific such as malaise, weight loss, left upper quadrant pain, and fever. Most patients have a leucocytosis and an ultrasound, CT or magnetic resonance study establishes the diagnosis of a splenic

abscess. Treatment consists of broad-spectrum antibiotics and percutaneous drainage, which, if fails, will require laparoscopic or open splenectomy. Many patients have multiple other abscesses, and the spleen is just a part of overwhelming sepsis. Antibiotic treatment should continue until the drains or percutaneous catheters have been removed. If the spleen has multiple abscesses, splenectomy may be required.

Splenic Tumors

Splenic masses may be identified during workup of symptoms, or often incidentally during other imaging (Fig. 62-12). Some of these masses, can have a large cystic component (see Fig. 62-11B). Management of such lesions can be difficult as imaging alone does not always help with a definitive diagnosis. Often, these lesions may need to be followed serially or, if concerning, splenectomy should be considered. In a series of 44 such cases, half of whom were symptomatic and treated surgically, 75% of lesions were benign while the remainder were malignant.[26] In a similar study of 28 patients, the risk of a malignant diagnosis was significantly higher at 72%, although 25% of these patients had had a previous history of lymphoproliferative disorder.[27] There are increasing data on the use of fine-needle aspiration of the spleen in differentiating such masses, with low complication rates.[28] Sensitivity and specificity of such aspiration have been reported as 94 and 79%, respectively.[29]

BENIGN NEOPLASMS

Benign splenic neoplasms generally arise from the lymphoid or vascular elements of the spleen. The most common primary neoplasm of the spleen is hemangioma.[30] The lesion can be single or multiple.

FIGURE 62-12 Multiple splenic masses were seen during a right upper quadrant ultrasound for symptomatic gallstones and were further evaluated by a CT scan as shown. The lesions were negative on PET scan. Patient did not wish to have a splenectomy or percutaneous biopsy and is therefore followed by regular imaging. Lesions have remained unchanged, and patient is asymptomatic.

Hemangiomas vary from well-circumscribed to irregular vascular proliferations. The majority are cavernous in nature. The potential for malignant transformation to angiosarcoma is not known but appears to be low and associated with large hemangiomas. Many splenic hemangiomas are now diagnosed incidentally during the course of imaging for other pathology. On CT scan, hemangiomas appear as homogeneous, hypodense, or multicystic lesions with variable calcification, and peripheral enhancement. Angiography may also be employed to confirm the diagnosis, although this is much more invasive. On angiography, the splenic hemangioma resembles a hepatic hemangioma with fine vascularity and "laking" effect in the capillary phase, which may be accompanied by early filling of the splenic vein.

The majority of splenic hemangiomas do not require surgical intervention. Splenectomy is reserved for large and symptomatic lesions. Most splenic hemangiomas are asymptomatic, with symptoms being associated with enlargement of the tumor and mass effect or rupture. Although there has traditionally been concern about risk of spontaneous rupture of these hemangiomas, a contemporary series from the Mayo Clinic reported no spontaneous rupture among 32 patients with splenic hemangioma, 80% of whom were entirely asymptomatic.[30]

Littoral cell angioma has been recently described as an endothelial cell neoplasm arising from the cells lining the sinus channels of the splenic red pulp. These rare lesions express vascular and histiocyte-associated antigens. Patients often present with splenomegaly and multiple hypoattenuating masses seen on CT.[31] While littoral cell angioma has been described as a benign neoplasm cured with splenectomy, there have been reports of associated malignant lymphomas, other visceral organ cancers, and recurrent disease identified as malignant littoral cell hemangioendothelioma. Splenectomy and close observation are thus warranted.[32]

Lymphangioma of the spleen is composed of a malformation of lymphatics (see Fig. 62-11B). Microscopically, these endothelium-lined spaces are filled with lymph and blood elements. The lesion may be focal or multiple, a small or large cystic mass, or may diffusely involve the spleen and account for splenomegaly. The diagnosis is made by ultrasound, CT scan, or MR imaging, which reveals water-density cystic lesion(s) of the spleen. The lymphangioma may be isolated to the spleen or occur as a generalized lymphangiomatosis with multivisceral involvement and a poor prognosis. Symptoms, when present, are related to the size and mass effect of the lesion. Splenectomy is indicated for symptomatic lesions. Partial splenectomy is reserved for small, focal symptomatic lesions.

Other benign lesions of the spleen are uncommon. Inflammatory pseudotumor of the spleen is a reactive lesion characterized by a mixture of inflammatory cells and disorganized spindle cells.[33] This tumor is typically found incidentally and is generally asymptomatic but may present with systemic symptoms such as fever, malaise, and weight loss. Inflammatory pseudotumor is infiltrative in nature and may mimic malignant lymphoproliferative disease. Splenic

hamartomas are composed of irregular vascular channels lined by splenic sinus endothelium with a disorganized reticulin stroma. Splenic hamartomas are uncommon with autopsy series noting an incidence of 0.024–0.13%. Peliosis is not a true neoplastic lesion but a blood-filled cystic lesion without an endothelial lining that may be associated with focal, patchy, or diffuse involvement of the spleen. This lesion is likely reactive as it has been associated with steroids, oral contraceptives, immunosuppression medications, tuberculosis, renal disease, and malignancy. Other benign splenic tumors, such as angiomyolipoma, lipoma, hemangiopericytoma, and fibroma are rare.

PRIMARY MALIGNANT TUMORS

Primary, nonlymphoid, malignant tumors of the spleen are exceedingly rare. These include angiosarcomas, malignant fibrous histiocytomas, and plasmacytomas. Angiosarcoma is the most common nonlymphoid primary malignant neoplasm of the spleen. The clinical presentation may include abdominal pain, left upper quadrant abdominal mass, and constitutional symptoms. Metastasis is frequent and often involves the liver. Spontaneous rupture has been reported and is associated with a dismal outcome. Normocytic anemia is present in the majority of cases. Splenomegaly with hypersplenism is also seen. CT imaging often identifies a splenic lesion with central necrosis. The primary treatment is splenectomy. Cisplatin-based chemotherapy has also been used. However, even without rupture, splenic angiosarcoma holds a poor prognosis. Recent studies have reported respective 1-, 3- and 5-year survival rates of 60, 40, and 40%.[34]

METASTATIC TUMORS

Splenic metastasis of nonhematologic malignancies is rarely seen clinically and usually represents widespread dissemination of disease. In a review of a German oncological database, only 0.002% of those with a malignancy developed reported splenic metastasis, with isolated splenic metastasis being extremely rare.[35] Despite lack of clinically evident splenic metastasis, postmortem evidence of splenic metastasis is reported to be higher, although the exact prevalence of this is debated, with older literature reporting rates as high as 34%, while contemporary reports put this rate at approximately 3%.[36]

The diagnosis of malignancy can be confirmed by positron emission tomography (PET) scanning, although percutaneous biopsies for isolated lesions can also be performed (Fig. 62-13).[28]

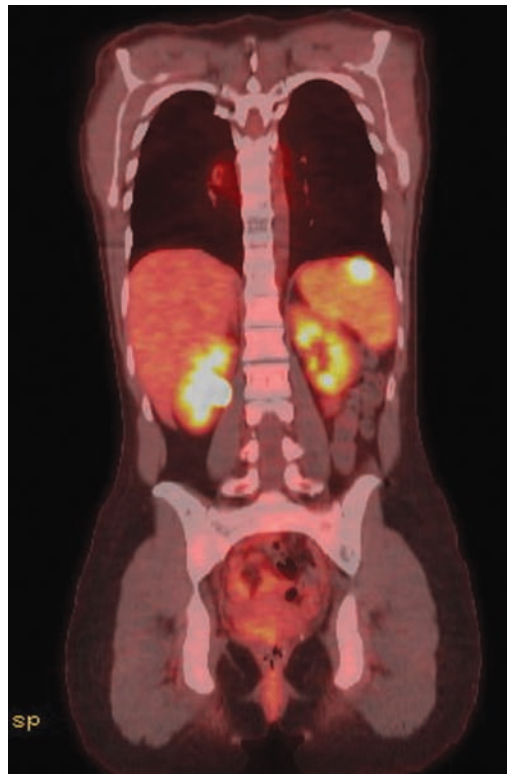


FIGURE 62-13 The patient was found to have a splenic lesion on CT which was active on PET scan. She subsequently underwent a splenectomy to obtain a tissue diagnosis.

HEMATOLOGIC DISORDERS

In 1887, Sir Thomas Spencer Wells, the renowned gynecologist, performed a therapeutic splenectomy for what proved to be hereditary spherocytosis. The first splenectomy for autoimmune hemolytic anemia (AIHA) was performed in 1911 by Micheli. Six years later, Schloffer, at the suggestion of a medical student, Kaznelson, performed a splenectomy for idiopathic thrombocytopenic purpura.[9] Today, the role of splenectomy in the management of hematologic disease has grown in parallel with the rise in laparoscopic splenectomy and its decreased morbidity compared to open splenectomy.

ANEMIAS

Splenectomy is indicated for specific cases of anemia. The major categories of anemia that benefit from splenectomy are those caused by the following:

- Membrane abnormalities: Hereditary elliptocytosis and spherocytosis
- Enzyme defects: Pyruvate kinase deficiency
- Hemoglobinopathy: Thalassemias and sickle cell
- AIHA

Hereditary Spherocytosis

This hemolytic disorder results from a genetic defect or deficiency in one of the components of the red cell cytoskeleton. It is transmitted as an autosomal dominant trait but occurs sporadically in rare instances. Hereditary spherocytosis is the

most common cause of familial chronic hemolytic anemia in North America and Northern Europe, with an incidence of 1–5 in 10,000 births or even higher if mild cases of osmotic fragility are included.[37]

The defect in red cell membrane components (spectrin, ankyrin, band 3, and/or protein 4–2) weakens the structure of the red cell and changes the morphology, making it more susceptible to destruction. Spleen plays a critical role in pathophysiology of hereditary spherocytosis, as it is the main site of hemolysis. The red cell membrane change results in excessive red cell trapping within the splenic pulp and hemolysis. Cells that escape the spleen on first passage are more susceptible to trapping and destruction during each successive passage. The red cells also exhibit increased osmotic fragility.

The salient clinical features include anemia, jaundice, and splenomegaly. The severity of disease varies from asymptomatic "carrier" with normal hemoglobulin level, to severe spherocytosis with baseline hemoglobulin level less than 6 g/dL. The disease severity is related to the degree of red cell cytoskeleton protein deficiency, particularly spectrin shortage. The jaundice usually parallels the severity of anemia and generally is not intense. It is related to the increased red cell destruction, resulting in abundant bile pigment that cannot be cleared by the liver. Approximately 30% of cases are mild, maintain a near-normal hemoglobin and bilirubin levels, and compensate with a reticulocytosis. Up to 63% of patients with hereditary spherocytosis have cholelithiasis, but this is unusual in children younger than 10 years. The gallstones are generally pigmented and a major indication for surgery in this patient group. Most have mild to moderate spleen enlargement, but splenomegaly alone is not an indication for surgery. Increases in splenic size in patients with hereditary spherocytosis may be seen in the presence of acute infection. Periodic worsening of the associated anemia and jaundice may be seen, often following infection, emotional stress, fatigue, or prolonged exposure to cold.

Splenectomy is effective in reducing the hemolysis associated with hereditary spherocytosis and recommended in those with anemia. Failures are uncommon and often reflect missed accessory spleens, which can be identified using radiocolloid liver-spleen scans.[38] The preferred approach is the laparoscopic approach that has been shown to be associated with less postoperative morbidity and pain. Because of the increased risk of serious postsplenectomy sepsis among young children, splenectomy is reserved preferably for patients older than 5 years. Splenectomy for hereditary spherocytosis before this age should be performed only in cases of severe transfusion-dependent disease and only after the age of 3.[39] There are institutional reports of partial splenectomy in such children with the objective of leaving some functional spleen behind for immunologic purposes.[40,41] In children without cholelithiasis, cholecystectomy is not indicated at the time of splenectomy. A limited review of patients younger than 18 years by Sandler and colleagues demonstrated that none of them developed cholelithiasis postsplenectomy over a mean follow-up of 15 years.[42]

The indication for a splenectomy in mild cases is more controversial. Using decision analysis, it has been suggested that patients with asymptomatic gallstones who are younger than 39 years gain benefit from a prophylactic cholecystectomy and splenectomy. In patients with symptomatic cholelithiasis, the patients gained quality-of-life advantage if they underwent the combined procedure versus cholecystectomy alone up to the age of 52.[43]

Hereditary Elliptocytosis

Hereditary elliptocytosis is a heterogenous group of erythrocyte disorders that have in common the presence of elongated, oval, or elliptically shaped RBCs on the peripheral blood film. Most are transmitted as an autosomal dominant trait. The majority of patients are asymptomatic or have mild form of the disease with compensated hemolytic anemia, as the defects often do not significantly shorten the red cell life span despite striking abnormalities seen on blood film. The presence of hemolysis often is a familial characteristic, and it has been suggested that excessive hemolysis occurs only when the gene for elliptocytosis is present in the homozygous form or is modified in some other way.

The majority of patients with hereditary elliptocytosis are Caucasian and the signs and symptoms are related directly to the severity of the hemolysis. Occasionally an acute hemolytic episode may be precipitated by infection. The clinical syndrome is indistinguishable from that described for hereditary spherocytosis. Gallstones and chronic leg ulcers have been reported in symptomatic patients. The spleen is usually palpably enlarged in symptomatic cases. Diagnosis is established by the smear.

Laparoscopic splenectomy is indicated in the few symptomatic patients because removal of the organ is almost always followed by lasting effects of decreased hemolysis and corrected anemia, although the morphologic abnormality of the RBC remains unchanged. Associated cholelithiasis should be managed as in hereditary spherocytosis.

Pyruvate Kinase Deficiency

Pyruvate kinase deficiency is the most common RBC enzyme deficiency to cause chronic hemolytic anemia. It is an autosomal recessive condition that has a much lower frequency than glucose-6-phosphatase deficiency (G6PD); however, it a more common cause of anemia because G6PD patients rarely suffer hemolysis.

Clinical manifestation varies from transfusion dependent anemia to compensated chronic hemolysis. Splenomegaly is common. Splenectomy has a role in transfusion-dependent individuals and can reduce or even abolish the need for transfusion. As with other children being evaluated for splenectomy, the procedure should be delayed until after age 3 owing to immunosuppressive effect of the surgery.

Thalassemia

Thalassemia (Mediterranean anemia) is a congenital disorder transmitted as a dominant trait in which the anemia is primarily the result of a defect in hemoglobin synthesis. Thalassemias are the most common monogenetic disease in man and have been referred to as *Cooley's anemia*, *erythroblastic anemia*, and *target-cell anemia*. The disease is classified as alpha, beta, and gamma types, determined by the specific defect in the synthesis of the relevant globulin chain of the adult hemoglobulin. As a consequence of the defect, there is imbalance production of globulin chains with resultant formation of atypical hemoglobulin proteins that can lead to intracellular precipitates (Heinz bodies) that contribute to premature red cell destruction. The hemoglobin-deficient red cells are small, thin, misshapen, and have a characteristic resistance to osmotic lysis.[44]

In the United States most patients suffer from beta thalassemia, and there is a quantitative reduction in the rate of beta-chain synthesis, resulting in a decrease in the hemoglobin A. Over 200 genetic mutations having been identified leading to beta thalassemia.[45] The characteristic feature is the persistence of Hb-F and a reduction in Hb-A. Gradations of the disease range from heterozygous thalassemia minor to severe homozygous thalassemia major. The latter is manifested by chronic anemia, jaundice, and splenomegaly.

Patients with homozygous thalassemia major usually present with clinical manifestations in the first year of life. In addition to the anemia and consequent pallor, there is usually retarded body growth and enlargement of the head. Intractable leg ulcers may be noted, and intercurrent infections are particularly common. Some patients present with repeated episodes of left upper quadrant pain related to splenic infarction. Cardiac dilatation occurs, and in advance stages there is subcutaneous edema and effusion into serous cavities. Intercurrent infections occur frequently, often leading to death in the more severe cases. These infections may be associated with aplastic crises. Gallstones have been reported in up to 24% of cases.

Therapy is directed only at symptomatic patients, those having thalassemia major, or intermedia. In these patients, transfusions are usually required at regular intervals. Because most children with thalassemia major accommodate to low hemoglobin levels, transfusions are given when the hemoglobin level is less than 10 g/dL. Owing to the high rate of hemolysis, these patients are also at high risk of iron overload and are treated with iron chelators. In select cases stem cell transplant may be considered.[44]

Although splenectomy does not influence the basic hematologic disorder, it may eliminate or reduce the hemolytic process responsible for accelerated destruction of normal donor red cells within the patient's circulation and this reduces transfusion requirements. In one study of 49 patients, blood transfusion requirement declined from 12 units of packed red cells per year to 4 units after surgery.[46] In general, the best results associated with splenectomy have been obtained in older children and in young adults with large spleens in whom excessive splenic sequestration of red cells has been demonstrated. Splenectomy should be avoided in children younger than 5 years.[44] Occasionally, splenectomy may be indicated because of mass effect symptoms associated with marked splenomegaly or repeated episodes of abdominal pain due to splenic infarction.

Sickle Cell Disease

Sickle cell anemia, first reported in 1910, is a hereditary hemolytic anemia seen predominantly in blacks, and characterized by the presence of crescent-shaped erythrocytes that, because of a lack of deformability, are trapped in the splenic cords. In this disorder, the normal hemoglobin A is replaced by hemoglobin S. Under conditions of reduced oxygen tension, hemoglobin S molecules undergo crystallization within the cell, which elongates and distorts the cell. The sickle cells increase the blood viscosity and circulatory stasis, thus establishing a vicious cycle. Although the sickle cell trait occurs in approximately 9% of the black population, the majority of patients are asymptomatic. Sickle cell anemia is observed in 0.3–1.3% of blacks. Many body systems can be affected by sickle cell disease. Depending on the vessels affected by vascular occlusion, the patients may have bone or joint pain, osteomyelitis, priapism, neurologic manifestations, or skin ulcers. Abdominal pain and cramps due to visceral stasis are frequent.

Spleen is commonly affected in these patients. Sickling occurs so rapidly that blood flow through both the fast and slow compartments of the spleen is obstructed; as a consequence, a series of microinfarcts develop and eventually lead to "autosplenectomy." In most adult patients only a fibrous area of the spleen remains, but autosplenectomy is preceded by splenomegaly in about 75% of patients. Calcification may occur with autoinfarction (Fig. 62-14). Such functional asplenia is defined and detected by the presence of Howell-Jolly bodies in the blood film and can be confirmed by absence of technetium-99m (^{99m}Tc) splenic uptake. Patients are subsequently at risk of developing infection by encapsulated organisms such as *Streptococcus pneumoniae*, due to impaired filtration and antibody production of the spleen. Rarely thrombosis of the splenic vessels may result in the complication of splenic abscess manifested by splenomegaly, splenic pain, and spiking fever. Percutaneous drainage of such abscesses may be attempted, but it may require a splenectomy.

For most patients with sickle cell anemia, only palliative therapy is available. Adequate hydration and partial exchange transfusion may help the crisis. Randomized multicentered studies have shown a role for hydroxyurea in treatment of adults with sickle cell disease. Such treatment leads to reduction in frequency of painful crisis, hospitalization, and transfusion.[47] The beneficial effects are in part due to an

FIGURE 62-14 Calcified spleen in a patient with sickle cell disease causing persistent pain. Splenectomy relieved the patient's pain.

increase in hemoglobulin F levels, although the mechanism underlying this process is not known. Hydroxyurea is therefore recommended in patients with three or more crises per year and its use if being evaluated in younger patient.[48] Other hemoglobulin F–inducing agents and stem cell transplant are also currently under investigation.

There are two situations in sickle cell anemia where the spleen is a pathologic red cell reservoir, and splenectomy may have a role. The first is a form of chronic hypersplenism that usually occurs in childhood or adolescence and is manifested by reduced red cell survival, leukopenia, and thrombocytopenia. In these patients, for some unknown reason, there is a failure to undergo autosplenectomy. In this rare circumstance, splenectomy will correct the leukopenia and thrombocytopenia and will also increase the rate of red cell survival and can lead to reduced transfusion requirement.[49] The second abnormality has been termed *acute splenic sequestration* and is marked by sudden splenic enlargement associated with worsening anemia and profound hypotension. It usually occurs in the first 5 years of life in a homozygous child; streptococcal pneumonia infection may act as a precipitating event in these patients. The acute splenic sequestration is usually effectively treated with packed red cell transfusion. If there is a propensity for recurrence, splenectomy may be indicated.

Immune Hemolytic Anemia

The first description of the disease is credited to Chauffard and Troisier who, in 1908, demonstrated autohemolysins in the serum of several patients with acute hemolytic anemia. Three years later Micheli performed the first planned, successful splenectomy, thus stimulating the application of splenectomy for hematologic disease.

Immune hemolytic anemia (IHA) is a disorder in which immunoglobulin G (IgG) and/or IgM antibodies bind to erythrocyte surface antigens and stimulate erythrocyte destruction. This occurs through the complement and reticuloendothelial systems. IHA is classified as *autoimmune*, *alloimmune*, or *drug-induced*. Alloimmune hemolytic anemia occurs only after exposure to allogeneic erythrocytes, such as through blood transfusion, pregnancy, or transplant. There is no antibody reactivity against autologous red cells. Acute hemolysis after transfusion is estimated to occur in 0.0003–0.0008%, and a delayed response is seen in 0.05–0.07%.[50] Drug-induced IHA occurs as drug-induced antibodies recognize intrinsic red cell antigens or erythrocyte-bound drug. Alpha-methyldopa, high-dose penicillin, second- and third-generation cephalosporins have been implicated. Drug-induced IHA should resolve with cessation of the medication in question but may require corticosteroids and may involve a protracted recovery.

Autoimmune hemolytic anemia (AIHA) is estimated to occur in 1 per 100,000 per year, with a prevalence of 17/100,000.[51] It is an antibody-mediated process that involves IgG or IgM antibodies. For cases if IgG-mediated disease, antibodies bind to the erythrocyte and are recognized by Fc receptors of macrophages and other phagocytic cells of the reticuloendothelial system for phagocytosis. In contrast to IgG antibodies, IgM antibodies readily activate the classical complement pathway and may lead to intravascular hemolysis. Additionally, IgM-bound erythrocytes may undergo extravascular hemolysis, particularly in the liver.

Both warm and cold antibodies have been reported. Warm antibodies react best at 98.6°F (37°C) and account for the majority of cases. Secondary causes of warm AIHA have been reported, most notably, lymphoproliferative disorders such as chronic lymphocytic leukemia (CLL). The presentation of warm AIHA is variable and includes vague constitutional symptoms consistent with anemia, such as weakness and dizziness. Additionally, fever, abdominal pain, cough, and bleeding may be seen. Symptoms vary with the severity of the hemolysis. Mild jaundice is often present. Splenomegaly is seen in approximately half of cases, and 25% may have associated cholelithiasis. While reticulocytopenia may occur early in the disease prior to adequate marrow response, reticulocytosis, and elevated mean cell volume (MCV) is generally seen. Mild to moderate indirect hyperbilirubinemia and elevated LDH are often seen. Platelets are usually normal, but occasionally AIHA and idiopathic thrombocytopenic purpura occur together (Evan's syndrome). Over 95% of warm AIHA have a positive Coombs test (direct antiglobulin test), which indicates that antibodies or complement system are bound to the red cell surface antigens in vivo.

The therapy is guided by the severity of the hemolysis, with first-line treatment being corticosteroids. Prednisone therapy is maintained for 3 weeks with rapid response being the norm. If a satisfactory response is achieved, the steroid is gradually and slowly tapered to avoid relapse. Approximately 80% of patients have a partial or complete response

to steroids, but 15–20% will require high dose (>15 mg/d) of maintenance prednisone for months. In nonresponders, or those requiring high dose of maintenance steroids, second-line therapy should be considered. These options include splenectomy or rituximab. Splenectomy can lead to good short-term results, with complete remission in 40–60% of cases, although remission is well documented. It is believed, however, that the patients who relapse often require less steroids for further therapy. In general, the decision for splenectomy in patients should be individualized and based on detailed discussions with the patient and the hematologist.[51]

In contrast, cold agglutinin syndrome treatment is often inadequate. Primary cold agglutinin syndrome patients may only present with mild anemia and may respond favorably to cold exposure avoidance. Folic acid supplementation may be beneficial. Corticosteroids are less effective than in warm AIHA. Other immunosuppressive drugs such as chlorambucil and cyclophosphamide have demonstrated favorable results. Plasmapheresis offers a temporary response but requires concomitant immunosuppression to address cold agglutinin production. Splenectomy is ineffective in cold agglutinin syndrome.

Paroxysmal cold hemoglobinuria is an uncommon form of AIHA and is generally self-limited and treated with supportive care. Most cases occur in children, usually after a viral illness. Corticosteroids are often given to children with severe anemia but are not routinely effective.

PURPURAS

Immune (Idiopathic) Thrombocytopenic Purpura

Immune thrombocytopenic purpura (ITP) is the most common hematologic indication for splenectomy. It is an acquired disorder in which platelets are destroyed by circulating antiplatelet antibodies, often IgG. The antibodies are often targeted against GPIIb/IIIa proteins. Antibody-coated platelets bind to antigen-presenting cells via Fc receptor primarily in the spleen, leading to platelet destruction. Demonstration of such antibodies is not always possible and bears no effect on treatment strategy. The diagnostic criteria are a platelet count less than 100,000/mm^3 without an obvious initiating or underlying cause including medications.

The spleen is the source of antiplatelet antibody production as well as the major site of platelet-antiplatelet antibody complex destruction by macrophage-induced phagocytosis.

Female patients outnumber males 3:1. Although up to one-third of patients may be diagnosed incidentally, with no bleeding complications and platelet counts above 30,000/mm^3, most present with petechiae or ecchymosis. Bleeding complications such as gum bleeding, vaginal bleeding, mild GI bleeding, and hematuria may be seen. Central nervous system (CNS) bleeding occurs in 2–4% of patients and typically when platelet count in below 10,000/mm^3. Risk of hemorrhagic death is very low and estimated to be 0.02–0.04 cases per adult patient-year at risk.[52] The spleen is typically normal size. The platelet count may approach zero, and marked thrombocytopenia is associated with a prolonged bleeding time. Generally, there is no significant anemia or leukopenia unless the ITP occurs in conjunction with AIHA. ITP is often associated with other immune disorders as well, such as systemic lupus erythematosus. The workup should include a blood film, as well as human immunodeficiency virus (HIV), hepatitis C virus (HCV), and *Helicobacter pylori* testing in adults.[53] If any of these infectious etiologies are identified, therapy should be aimed at treating the underlying process rather than platelet count per se. *H. pylori* eradication has been shown to result in rapid improvement in platelet count that is long lasting.[54,55] To confirm the diagnosis of ITP, a bone marrow aspirate can be obtained and this will demonstrate normal to high megakaryocytes.

ITP in children is typically self-limited and rarely requires surgical therapy. The disease in adults is usually more persistent with a low spontaneous remission rate (9%) and requires medical and possibly surgical treatment.[56] Treatment is generally not indicated in those with platelet counts above 30,000/mm^3 and no bleeding complications.[57] The goal of all medical therapies is to simply increase platelet count to a safe level, and not to cure. Corticosteroids are the first line of therapy and are generally given for a maximum of 4 weeks to avoid adverse effects associated with chronic use. Around 40% of patients have a clinical response to steroids, but more than 50% have a remission once the steroids are tapered or stopped. Improved results have been noted with high-dose steroid regimens as a first-line therapy. For those not responding to steroids, intravenous (IV) immunoglobulin (Ig) and anti-Rh(D) (anti-D, WinRho) administration can provide temporary and rapid rise in platelet and can be used in those with critically low platelet count or when the patient is being prepped for surgery.[57]

Second-line therapy is often indicated for those with persistent low platelet counts (>30,000/mm^3) or bleeding. The objective of second-line therapy is to provide long-term and durable results. Second-line therapy now includes rituximab or splenectomy. Although studies have shown superiority of splenectomy in terms of long-term remission (40% for rituximab vs 80–90% for splenectomy), rituximab may be preferred second-line therapy in patients who are high-risk surgical candidates or who may wish to avoid surgery.

Splenectomy provides the best long-term results for ITP with 80% of patients responding to it, and around 70% achieving complete remission.[58] In most patients, the platelet count rises to greater than 100,000/mm^3 within 7 days. Rarely, platelet normalization is more gradual over a period of months. Splenectomy should be performed in patients who fail to respond to steroid treatment within 6 weeks, who recur after steroid taper, who respond to medical therapy but cannot tolerate the side effects, or who develop intracranial bleeding or profound GI bleeding and do not respond to intensive medical treatment.

About 15% of patients fail to respond to splenectomy, and predicting the outcome in this group is of great interest to clinicians. Although some have reported response to IVIg or steroids as a predictor of response to surgery, the predictive value is low.[53]

Indium-labeled autologous platelet scanning may be the most sensitive predictor but is only available presently as a research tool. When the scan demonstrates splenic platelet destruction, the response rate is 90%, thus improving on the current clinical pattern, but only modestly.

The laparoscopic approach to splenectomy is well suited for ITP, because of the normal size of the spleen. Retrospective studies in patients with ITP have demonstrated reduced postoperative pain, less analgesic use, and shorter hospital stay in those undergoing laparoscopic splenectomy compared to open.[59] Assessment of the abdominal cavity for accessory spleens and excision of any such identified masses are critical to success of splenectomy in management of ITP.

Thrombotic Thrombocytopenic Purpura-Hemolytic Uremic Syndrome

Although thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) were originally thought to be different diseases, they represent the same pathophysiology. In those classified as TTP, neurologic symptoms predominate, while in those with HUS, renal complications are the dominant symptom. TTP-HUS is recognized as the pentad of microangiopathic hemolytic anemia, thrombocytopenia, fever, neurologic disturbance, and renal dysfunction. Largely an idiopathic disorder, TTP-HUS also has been seen in association with bone marrow transplant, mitomycin, cyclosporine, penicillin, and other therapeutic agents. TTP-HUS is a microvascular disorder affecting arterioles and capillaries with venule sparing. Platelet microthrombi cause partial vessel occlusion with overlying endothelial proliferation and subintimal hyalinization. Subsequent erythrocyte damage occurs during passage through the narrowed vascular channels with abnormal forms (helmet cells, schistocytes, etc) seen on peripheral blood smear. Marked platelet trapping occurs, namely in the spleen, with resultant thrombocytopenia (<20,000/mm^3). This may be seen as a profound decrease in platelets within hours of onset. Petechial hemorrhage and, more rarely, epistaxis, retinal hemorrhage, GI and genitourinary bleeding, and hemorrhagic stroke may be seen. However, it is more usual to see no bleeding even with severe thrombocytopenia partly because of the thrombotic nature of the disease. Other clinical manifestations include fever, general malaise and flu-like symptoms, headache, altered mental status, focal neurologic deficits, hematuria, and renal failure. The neurologic changes may be severe, such as coma, prompting emergent therapy.

Since the advent of plasmapheresis for TTP, the survival associated with the once uniformly fatal disease has improved markedly to over 90%. Daily therapy is conducted until the hemolytic process is stabilized, and the thrombocytopenic and neurologic complications subside. Plasma exchange is then tapered. For those with refractory disease (10–20%), the next line of therapy should be immunosuppressive agents, including steroids, rituximab, or cyclosporine. Splenectomy is generally not recommended and reserved for refractory cases or those with recurrent disease after multiple plasma exchanges.[60] In such select patient population, splenectomy can lead to a 70% remission rate.[61]

HEMATOPOIETIC NEOPLASMS AND LYMPHOMAS

The early classification of such malignancies, simplified to lymphomas and leukemias, has evolved extensively over the past decade with the introduction of immunophenotyping and cytogenetics. Many tumor subtypes that were initially thought to be the same have been subdivided into groups with different management and prognosis. The 2008 World Health Organization (WHO) classification of hematopoietic and lymphoid malignancies has provided a framework for classification of these diseases, which encompasses over 65 different types of tumor. A detailed description of this classification falls beyond the scope of this chapter. In general, however, these neoplasms fall into three categories[62]:

Myeloid neoplasms: Derived from bone marrow progenitors that form erythrocytes, granulocytes (neutrophils, basophils, eosinophils), and megakaryocytes. An example of such tumor is chronic myeloid leukemia, a tumor always associated with *BCR-ABL* fusion gene.

Lymphoid neoplasms: Derived from cells that form T and B lymphocytes. When such neoplasms presented with predominantly bone marrow and blood involvement, they were referred to as *leukemia*, while those presenting with a mass were referred to as *lymphoma*. In the new classification, however, using our new knowledge about tumorigenesis and the fact that lymphomas can present or evolve to a leukemia picture, and any leukemia can present as a mass, more emphasis has been placed on cell of origin. This classification method based on cell type only, however, provides no information on clinical behavior of tumors. Some have therefore added a clinical classification to further group lymphomasto: indolent (survival without treatment in years), aggressive (survival without treatment in months), highly aggressive (survival of untreated tumor in weeks), and Hodgkin's lymphomas that is generally regarded as a distinct entity with excellent prognosis.

Histocytic/dendritic neoplasms: Derived from cells that develop into antigen-presenting cells such as dendritic cells and macrophages.

Indications for surgical intervention have evolved over the years as our knowledge and therapeutic options have expanded. Below is a brief overview, concentrating on situations where a splenectomy may be indicated.

Myeloid Neoplasms

These tumors are generally subdivided into three categories, including *acute myeloid leukemias* for which there is little surgical role, as well as *myelodysplastic syndrome* and *myeloproliferative disorders*.

Myelodysplastic syndrome is a group of disorders that is associated with ineffective blood production, and risk of transformation to acute leukemia. Again, there is little indication for splenectomy or surgery in this group of patients.

In *myeloproliferative disorders*, there is proliferation of one or more of the myeloid lineage cells, with increases in the numbers of one or more of the peripheral blood elements. There is usually an associated mutation that causes increase in tyrosine kinase and growth factor–dependent proliferation of bone marrow elements. Examples of such mutations include the *BCR-ABL* fusion gene seen in chronic myeloid leukemia. Other diseases in this category include polycythemia vera, idiopathic thrombocytosis, and chronic leukemias. The presenting symptoms include symptomatic splenomegaly and anemia.

The laboratory hallmark is a peripheral smear that demonstrates red cell fragmentation and shows many immature forms of numerous teardrop and elongated shapes. The white blood count is in the range of 50,000/mm^3 and may reach extremely high levels. Immature myeloid cells are found in the peripheral smear. Thrombocytopenia is present in about one-third of the patients and thrombocytosis, with white blood counts of fewer than 1 million, is observed in about one-fourth of the patients.

Although splenectomy does not alter the course of the disease, the procedure is indicated for increasing transfusion requirements and control of anemia, leukopenia, or thrombocytopenia, or symptomatic splenomegaly. There may be massive splenic enlargement with myeloproliferative disorders. The morbidity associated with splenectomy is historically higher than that reported for other hematologic disorders with normal spleen size, although recent series are challenging that assessment. Hand-assisted laparoscopic techniques have been successfully applied for management of massive splenomegaly.

Lymphoid Neoplasms

Staging laparotomy in cases of Hodgkin's lymphoma was once considered the main means of determining the extent of abdominal involvement with stage I to II supradiaphragmatic disease, and critical in determining the best therapy for patients. Those with disease limited to above the diaphragm were treated with radiation, while others received radiation and chemotherapy. Advances in imaging technology, including spiral CT scan, and 18-fluorodeoxyglucose PET have improved the detection of splenic and abdominal lymph node involvement without need for surgical sampling. With further change in treatment paradigm, favoring combined modality treatment over extended field radiation, surgical staging, and splenectomy for Hodgkin's lymphoma are now infrequently performed. When surgical staging is needed, the laparoscopic approach to splenectomy and staging has been shown to be feasible and associated with decreased morbidity compared to laparotomy without compromising adequate pathologic staging.[63] Laparoscopic staging for Hodgkin's lymphoma generally begins with splenectomy from the lateral approach. The patient is then moved to a supine position to complete the wedge liver biopsy, performed with ultrasonic dissection or vascular stapling devices, percutaneous core-needle liver biopsies, and biopsies of portal, para-aortic, and parailiac lymph nodes. The para-aortic sampling may also be performed from the lateral approach. Metallic clips are placed at each lymph node sampling site.

Non-Hodgkin's lymphomas are the most common malignant neoplasm of the spleen and the most common indications for splenectomy in more recent times. The spleen is involved in approximately 30–40% of patients, usually as a result of spread from other sites.[63] Primary splenic lymphoma, that confined to the spleen, is an uncommon presentation seen in fewer than 2% of patients with non-Hodgkin's lymphoma.[64]

Indications for Splenectomy in Lymphoproliferative Disorders

With new classifications of these disorders and variability in clinical presentation and treatment, the decision for splenectomy often requires close collaboration and discussion with the hematologists and oncologists. In general, however, splenectomy is indicated for the following:

- Treatment of symptomatic splenomegaly: abdominal fullness, pain, early satiety, and constitutional symptoms
- Treatment of hypersplenism, which is defined as blood cytopenias in the setting of splenomegaly
- Treatment or tissue diagnosis when the spleen is the only or main site of disease

Splenectomy may be indicated in cases of secondary hypersplenism where mass effect symptoms or cytopenias become disabling. The hematologic response is favorable in the majority of patients with improvement in the neutropenia and thrombocytopenia.

In patients with advanced CLL with hemoglobulin of less than 10 or platelet count less than 50,000/mm^3, splenectomy not only improves hematologic parameters, it may also offer survival advantage compared to those who received only chemotherapy.[65]

The beneficial effect of splenectomy in chronic myelogenous leukemia (CML) is less clear. Surgery does not alter the natural process of the disease, but in carefully selected patients it may improve thrombocytopenia. The operative mortality in this patient population can be as high as 9%, emphasizing the importance of patient selection.[66]

Splenic marginal zone lymphoma is a rare type of marginal zone lymphoma that presents with splenomegaly, no lymphadenopathy (except splenic hilum), and a variable degree of bone marrow involvement. The disease is often associated with hepatitis C infection, which is thought to have a tumorigenesis role in some cases. Splenectomy can have a therapeutic role in this disease and is the treatment of choice. In those not suitable for surgery, rituximab is the therapy of choice.

Hairy cell leukemia is an indolent B-cell lymphoproliferative disorder that was initially recognized by Ewald in 1923. It accounts for only 2–3% of adult leukemias. The typical presentation includes cytopenia, circulating hairy cells, and splenomegaly. Chemotherapy with purine analogues or interferon-α is used. Splenectomy is indicated for symptomatic splenomegaly, severe thrombocytopenia, ruptured spleen, or failure to respond to chemotherapy. Approximately 50% of patients will have normal hematologic parameters postsplenectomy and 90% will improve in at least one parameter.[67]

OTHER DISEASES AND SPLENECTOMY

Splenectomy may significantly improve the neutropenia in patients with Felty's syndrome characterized by splenomegaly, neutropenia, and arthralgia. Splenectomy is reserved for patients with significant neutropenia and serious or recurrent infections, increased transfusion requirements, or marked thrombocytopenia. While splenectomy does not reduce the arthralgia, leg ulcers, when present, generally heal.

In patients with portal hypertension secondary to splenic vein thrombosis, splenectomy usually resolves the portal hypertension and its complications.

Splenectomy may also be indicated for symptomatic splenomegaly or severe secondary hypersplenism in patients with Gaucher's disease or sarcoidosis, although splenectomy will not alter the course of the disease (Fig. 62-15).

FIGURE 62-15 Patient with a remote history of ovarian cancer was found to have a splenic mass (shown in white square). CT-guided biopsy was inconclusive, and she therefore underwent a splenectomy. Pathology confirmed the diagnosis of sarcoidosis. She had no evidence of pulmonary involvement.

SPLENECTOMY

The first recorded splenectomy was performed for splenomegaly on a 24-year-old Neapolitan woman in 1549 by Adrian Zacarelli. Over the next several centuries, however, only a few other splenectomies were attempted, most proving fatal. In a 1908 literature review of all published cases, totaling fewer than 50 splenectomies, surgery had a mortality rate close to 90%. Over the last 100 years, and in particular the first few decades of the 20th century, improvement in surgical techniques and a better understanding of the splenic anatomy have led to a significant reduction in surgical mortality and morbidity. By the 1970s, the mortality had been reduced to around 10%, and now most elective series report a mortality rates of less than 1%.

Open splenectomy remains the standard therapy for splenic injury in trauma and emergencies, as it allows quick control of bleeding and easy assessment of other organs for injury. Although some trauma centers have reported successful management of splenic injuries laparoscopically, the laparoscopic approach is typically used for elective procedures.[68]

The many advantages of the laparoscopic approach can explain this increased utilization. These benefits include less postoperative pain, decreased length of stay, faster return to full activity, a better cosmetic result, and reduced costs, when compared with the open technique.[69] Our own institutional experience echoes this finding. In a review of over 262 cases (184 open splenectomy and 78 laparoscopic splenectomy), laparoscopic approach resulted in shorter hospital stay and less complications, as well as less intraoperative blood loss. These data have placed laparoscopic splenectomy as the gold standard approach for elective splenectomy. This has been reflected in many institutions' rates of utilization of laparoscopic splenectomy, including a report from The Cleveland Clinic where they reported an increase in the number of splenectomies attempted laparoscopically from 17% in 1994 to 75% in 1998.[70] There is, however, significant variation in the rate of uptake of this technique, with room for improvement.

Preoperative Preparation and Vaccination

The spleen contributes to the immune system by cell filtration, antibody and opsonin production, and phagocytic clearance of bacteria. Asplenic or hyposplenic patients are particularly susceptible to encapsulated bacteria, such as pneumococcus, and malaria. The liver may compensate for

the loss of the immunologic function of the spleen, but this requires an intact complement system and higher antibody production.

Overwhelming postsplenectomy sepsis (OPSS) is a rare phenomenon among adult patients after splenectomy for trauma and nonhematologic disease, but more common among children. Young children, particularly younger than 2 years, are at increased risk because of the immaturity of the immune system. OPSS occurs in 0.9% of adults and 4.4% of children younger than 16 years with an attendant mortality risk of 0.8 and 2.2%, respectfully.[71] Others have, however, have reported mortality rates as high as 50–70%. Reticuloendothelial dysfunction, such as that caused by hematologic disease or immunosuppression, increases the likelihood of sepsis. The risk persists over the patient's lifetime, with approximately 42% of cases occurring more than 5 years after splenectomy.

Several strategies have been developed to reduce the risk of OPSS, and these include vaccination programs, prophylactic antibiotic use, patient education, antibiotic use, and, importantly for the surgeon, splenic salvage whenever possible.[72]

VACCINATION

Patients should be vaccinated against encapsulated organisms with recombinant polyvalent *S. pneumonia* (most common cause of OPSS), *Haemophilus influenzae* type B, and *Neisseria meningitides* vaccines. Although such vaccination routine is recommended by most, there is significant international variation between recommendation regarding exact vaccine type and boosters.[73] Some of the recommendations are summarized in Table 62-2. We follow the US Centers for Disease Control and Prevention (CDC) recommendations and immunize with all three vaccines preoperatively.

These vaccines should be administered at least 2 weeks before planned splenectomy. Guidelines for postsplenectomy vaccinations for patients who have undergone an emergency procedure are less clear. In a prospective study, it was shown that polyvalent pneumococcal vaccine results in the highest antibody titers, for the most common serotypes, when administered 14 days postsplenectomy.[74] Other data have, however, questioned this finding, and therefore some centers recommend vaccination before hospital discharge to ensure that patients receive their vaccination and improve the postsplenectomy vaccination rates, which have been reported as low at 26%, even in recent literature.[75]

DAILY PROPHYLACTIC ANTIBIOTIC

Lack of compliance and concern for breeding of resistant organisms has made this option less attractive. Again an area of some debate, there is some evidence for efficacy of this policy in reducing OPSS in children. It therefore appears reasonable to consider daily prophylactic antibiotic in children until the age of 5, or for 2–3 years after the splenectomy in teenagers. British guidelines recommend prophylaxis for longer, however, with daily usage until the age of 16. Prophylactic daily use is not recommended in adults, due to lower rate of OPSS.

PATIENT EDUCATION AND RESCUE ANTIBIOTICS

Early recognition of postsplenectomy infection is key. This is particularly important as vaccination does not imply immunity and the pneumococcal vaccine is only 70% protective even in the immunocompetent host.[72] Additionally, other pneumococcal, *Haemophilus* non–type B, and meningococcus strains as well as other bacteria may cause overwhelming infection. Meningitis, particularly among children, and pneumonia are often seen. However, the initial prodrome of fever, myalgia, emesis, headache, and abdominal pain may go unrecognized without an astute awareness of the possibility of postsplenectomy sepsis. These early symptoms can quickly escalate into profound septic shock, accompanied by disseminated intravascular coagulation, and organ failure. Asplenic or hyposplenic patients should be instructed to seek immediate medical

TABLE 62-2: US AND UK IMMUNIZATION RECOMMENDATIONS AFTER SPLENECTOMY

	Pneumococcal Immunization Recommendations	Meningococcal Immunization Recommendations	*Haemophilus influenzae* Type B Immunization Recommendations
Advisory Committee on Immunization Practices for CDC	23-valent pneumococcal polysaccharide vaccine Revaccination only once after 5 y	Age 11–55: tetravalent meningococcal vaccine; meningococcal polysaccharide vaccine an acceptable alternative Age >55: meningococcal polysaccharide vaccine	Hib not contraindicated
British Committee for Standards in Haematology	23-valent pneumococcal polysaccharide vaccine Revaccination every 5 years	Meningococcal C vaccine No revaccination	Recommends vaccination if not previously vaccinated

attention at the first sign of illness, with some physicians advocating a personal supply of prescribed antibiotics to have on hand. With the onset of fever, the patients should take the first dose of antibiotics and then seek immediate medical evaluation. Amoxicillin-clavulanate or levofloxacin are appropriate choices for this purpose.

LAPAROSCOPIC SPLENECTOMY

Delartie and Maiguier first introduced laparoscopic splenectomy in 1991. At that time, conversion rates were high and some surgeons argued against the routine use of laparoscopic splenectomy. As experience with laparoscopic procedures has evolved in general and laparoscopic instruments and equipment have improved, laparoscopy has become the preferred technique for elective splenectomy.[76] The laparoscopic approach necessitates destruction of the splenic anatomy as the spleen is removed piecemeal through the small-port incision. Although many clinicians are concerned that this morcellation can influence the pathologic assessment of the spleen, often the spleen can be removed in large enough pieces not to interfere with the pathologist's assessment. Most patients requiring elective splenectomy are therefore candidates for a laparoscopic procedure, although splenic size can be a limit. Increasing difficulty is reported with increasing degree of splenomegaly, which is often assessed by measuring the maximal craniocaudal length of the spleen. Although normal splenic size varies depending on sex, age, and racial background, Table 62-3 provides a general classification that can be used for preoperative patient evaluation. Postoperatively, the splenic weight can be used as a measure of the degree of splenic enlargement.

Although splenic length measured with the patient in supine position has a good correlation with overall splenic volume and the degree of splenomegaly, it is in fact not the best surrogate with the splenic length measured with the patient in the right lateral decubitus position providing the strongest correlation with splenic volume.[77] Some believe that preoperative splenic volume (rather than length alone) can provide a more reliable assessment of the degree of splenic enlargement and predict difficulty of the laparoscopic approach. With improved CT technology, such volumetric assessment is increasingly easy to perform. However until wider spread and use of these measurements, and validation, the splenic length remains the more common measurement of the degree of splenomegaly.

TABLE 62-3: DEGREES OF SPLENOMEGALY BASED ON CRANIOCAUDAL LENGTH ON CT OR POSTRESECTION WEIGHT

	Splenic Length (cm)	Splenic Weight (g)
Normal spleen	Up to 13	<300
Mild splenomegaly	>13–15	300–500
Moderate splenomegaly	16–20	500–1000
Massive splenomegaly	>20	>1000

Patient Selection for Laparoscopic Approach

The cutoff above which laparoscopic splenectomy is associated with prohibiting difficulty is not clear. Some have proposed using clinical examination criteria, excluding those with spleens that extend below and to the right of the umbilicus.[78] Most surgeons, however, use splenic length as a measure of anticipated difficulty and consider splenic size greater than 20 cm to be a contraindication to laparoscopy. Increasing number of studies have, however, demonstrated the feasibility of the laparoscopic approach in this subgroup of patients recognizing limitations.[79] Several studies have, however, documented the increased risks associated with laparoscopy in the setting of massive splenomegaly (>1000 g) when compared to spleens of normal size. These include longer operative time (203 vs 156 minutes and 170 vs 102 minutes), increased blood loss (600 vs 125 cc), higher conversion rates (41 vs 3% and 18 vs 5%), increased postoperative length of stay (4 vs 2 days and 5 vs 3 days), and postoperative morbidity (56 vs 6%).[80] The conclusion from these studies is not that massive splenomegaly is a contraindication for laparoscopic splenomegaly, but rather it emphasizes the need for vigilance and a low threshold for conversion to an open procedure. Besides a more challenging dissection, placement of the spleen in the removal bag following resection can be difficult. The risk of intra-abdominal rupture with subsequent splenosis also contributes to the reluctance of some surgeons to perform laparoscopic splenectomy in patients with splenomegaly. Placement of the spleens up to 27 cm in large specimen bags has, however, been achieved by the author and his team, accomplishing a completely laparoscopic approach in these cases. In general, our group has been successful in performing laparoscopic splenectomy, without preoperative embolization, in spleens less than 25 cm with low conversion rates and outcomes. Laparoscopic approach for larger spleens is undoubtedly associated with increased operative time and complication, and many advocate the use of hand-assisted laparoscopic surgery (HALS) in cases of massive splenomegaly. The technique is described later in the chapter.

Preoperative Splenic Artery Embolization

Although initial experience with total splenic artery embolization was discouraging and associated with significant complications, partial splenic artery embolization (SAE) has been used to manage select cases of splenic trauma (see the

TABLE 62-4: RISKS OF SPLENIC ARTERY EMBOLIZATION (SAE)

Catheter site hematoma and pseudoaneurysm
Postembolization syndrome: pain, fever, ileus, pleural effusion
Pancreatitis
Splenic abscess or rupture
Peritonitis

previous text). SAE has also been used by some as a preoperative intervention to reduce vascularity and size of massive spleens in preparation for a laparoscopic approach. Embolization is achieved using microcoils and/ or Gelfoam.

It is generally agreed that SAE is not helpful in laparoscopic cases where the spleen measures less than 20 cm in length.[81] The benefit of SAE in preoperative management of larger spleens remains controversial. Although some studies have shown that preoperative SAE can lead to reduced intraoperative blood loss in cases of large spleens, they reported no significant differences in conversion rates, incidence of postoperative complications, or length of hospital stay.[82] The potential for a modest reduction in blood loss, however, needs to be balanced against the potential risks and additive nature of this procedure. Risks are summarized in Table 62-4 and have been reported in up to 20% of cases. Some have also expressed concerns about staple malfunction during subsequent splenectomy, as the staple comes across coils that are often used to achieve embolization. In general, preoperative SAE is now infrequently used.

Approaches to Laparoscopic Splenectomy

The first attempts at laparoscopic splenectomy were performed through an anterior approach. This was performed with the patient in the lithotomy position, by five laparoscopic ports. This approach was later abandoned in favor of the lateral approach (described in detail in the following text), which is currently the preferred technique. The lateral approach, initially developed for adrenalectomy, uses the weight of the spleen and gravity to gain exposure during various steps of the procedure. In addition, it facilitates dissection of the superior short gastrics and superior pole when compared to the traditional anterior approach.

Details of the Operative Procedure: Lateral Approach

PATIENT POSITIONING AND ROOM SETUP

Figure 62-16 illustrates the optimal room setup and patient positioning for this procedure. A monitor should be placed on each side of the patient toward the head of the operating room table. The patient is initially supine for the induction of general anesthesia and placement of the Foley catheter as well as a nasogastric tube for gastric decompression. The patient is then placed in a modified right lateral decubitus position. The optimal angle is 60° between the patient's back and the operating room table. This advantage of this angle over the full lateral decubitus position relates to ease of positioning should conversion to an open procedure be necessary. A roll is placed behind the patient for support. The patient should

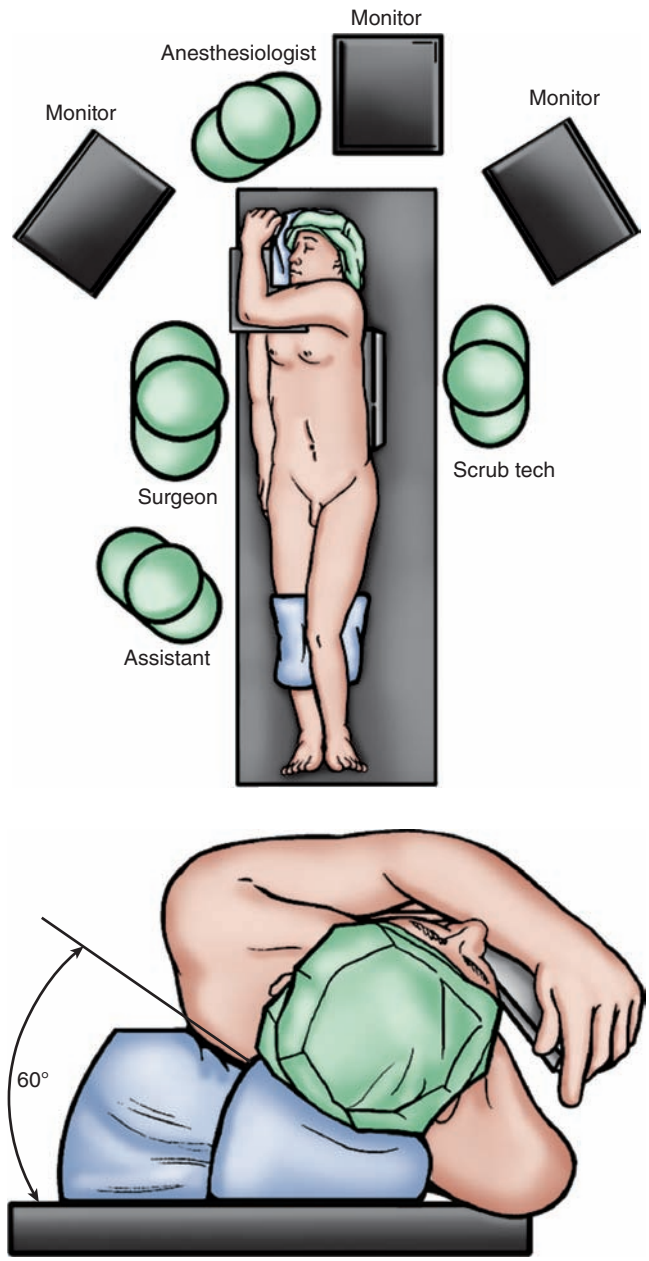

FIGURE 62-16 Room setup and optimal patient positioning for laparoscopic splenectomy.

be taped in this position to prevent movement when the table is manipulated during the case. An axillary roll is required in the dependent axilla, and the left arm should be placed on an elevated armrest and secured in place. The legs should be padded with the left leg straight and the right leg bent to 60°. The table should be broken at the level of the umbilicus to maximize the distance between the rib cage and the superior iliac spine. The sterile field should extend from the nipples to the pubic bone in the cranial-caudal position and from the right anterior axillary line to the left scapular tip. The table can be rolled to the left to flatten the abdomen for trocar placement. For the remainder of the procedure, reverse Trendelenburg position will facilitate visualization of the spleen in the left upper quadrant.

Energy sources such as ultrasonic dissecting shears (Harmonic, Ethicon Endosurgery, Cincinnati, OH) are useful and used by the author. A formal open laparotomy set should be readily available in case emergent conversion to an open procedure is necessary.

TROCAR PLACEMENT

We have traditionally used a four-port technique; however, more recently we have adopted a three-port technique in cases where spleen is of normal size and adequate exposure to the splenic vessels can be obtained without an additional assistant's instrument. There are a number of possible trocar placements for laparoscopic splenectomy, and placement will need to be individualized to the patient anatomy. Figure 62-17 illustrates our usual placement for either the three- or four-port technique. The most lateral port can be omitted if the patient's anatomy permits. Figure 62-17B offers an example of an alternative approach for the three-port technique. The abdomen is entered using the Veress needle just inferior to the left costal margin in the midclavicular line. In cases where the spleen is large and occupies most of the left upper quadrant, we revert to the open technique for placement of the camera port. Pneumoperitoneum is attained, using carbon dioxide gas to a pressure of 15 mm Hg. The camera port is placed to the left of the midline through the rectus muscle taking care to avoid the epigastric vessels. A 10-mm 30-degree laparoscope is introduced into the peritoneal cavity. The remaining ports should be placed under direct visualization once the camera has been placed and the spleen has been visualized. Port placement will need to be individualized to the patient's anatomy. The camera port and two working ports should be triangulated to allow adequate manipulation. A fourth port can always be added in the lateral position near the anterior axillary line if necessary as the case progresses. We use a 12-mm camera port and two 5-mm ports initially. The 12-mm port can be used for the camera, as well as the stapling device.

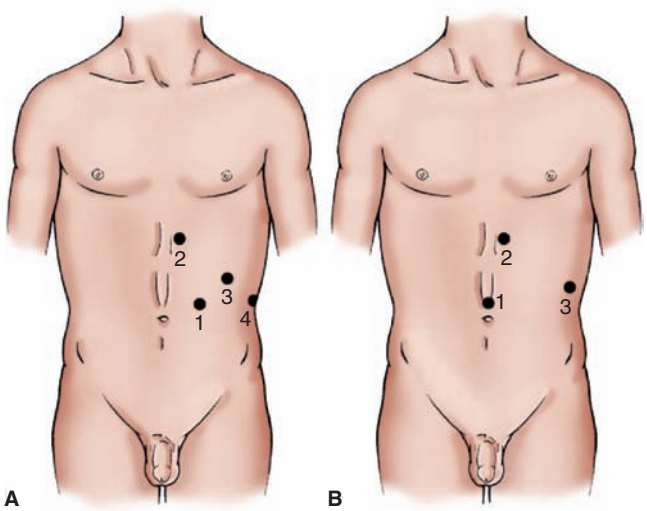

FIGURE 62-17 Trocar placement for laparoscopic splenectomy. **A.** Recommended trocar placement. Port 1 is 12 mm to allow introduction of laparoscopic stapler. The remaining ports are 5 mm. Port 4 is omitted for the three-port technique. **B.** Alternative trocar placement technique.

DISSECTION

The procedure begins by exploring the abdomen to identify any accessory spleens. They are present in approximately 12–20% of patients and may be the source for inadequate response to splenectomy in the treatment of hematologic disease, such as ITP. The splenic hilum, gastrosplenic ligament, gastrocolic ligament, greater omentum, mesentery, and presacral space are potential sites for accessory spleens, with the splenic hilum being the most common (see Fig. 62-4). Each of these sites should be considered as the dissection continues. The dissection begins by mobilizing the splenic flexure of the colon, including the renocolic ligament, as needed to provide adequate exposure to the inferior pole of the spleen and the gastrocolic and splenocolic ligaments (Fig. 62-18A). The lower pole of the spleen can be elevated with a blunt dissector. The splenocolic and phrenocolic ligaments are divided. Once the inferior pole of the spleen has been freed, attention is turned to the lower lateral splenic attachments. These are divided moving superiorly from the inferior pole using the ultrasonic shears until the dissection becomes difficult (Fig. 62-18B). Only the lower half of these attachments should be divided at this point in the operation. It is important to avoid full lateral mobilization at this point as this would result in the spleen falling medially and hindering dissection of the short gastric vessels.

Next, attention is turned to ligating the short gastric vessels (Fig. 62-18C). The first step is to enter the gastrocolic ligament through the avascular plane. Once the lesser sac has been entered, the short gastric vessels are identified and divided. Dissection should continue in a caudal to cranial direction ligating the short gastrics as they are encountered. The ultrasonic dissecting shears will facilitate quicker dissection in this area, and the short gastrics can be coagulated with confidence using this technique. As the surgeon mobilizes the gastrosplenic ligament, traction and countertraction should be provided by the surgeon's nondominant hand and one hand of the assistant. In the four-port technique, the

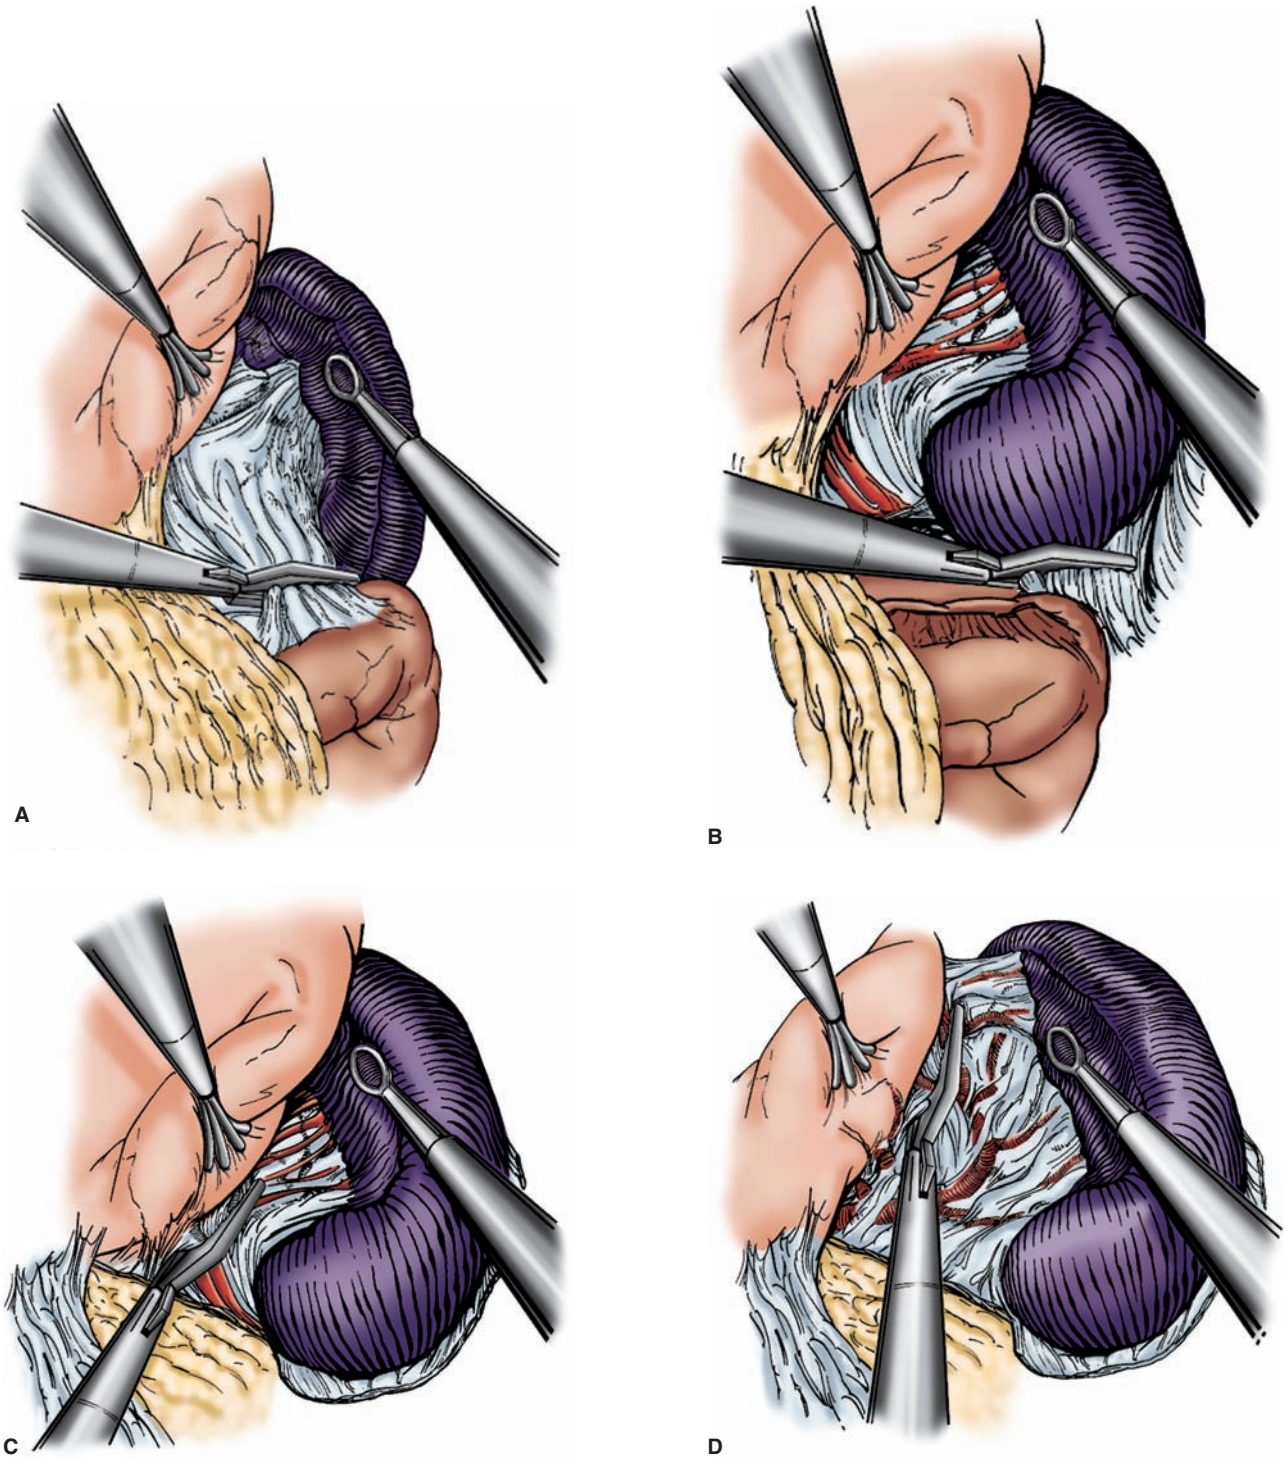

FIGURE 62-18 Steps of laparoscopic splenectomy. **A.** Mobilize the splenic flexure of the colon using ultrasonic dissecting shears to free the lower pole of the spleen. **B.** Free the lateral attachment of the spleen, leaving the superior attachments to the diaphragm intact for later division. This way premature medialization of the spleen is prevented. **C.** Divide the short gastric vessels using ultrasonic dissecting shears. **D.** Medial rotation of the stomach can help visualize the superior most vessels. Special care and attention should be given to these vessels that are often very short in length. **E.** Divide the splenic hilum using endoscopic staplers.

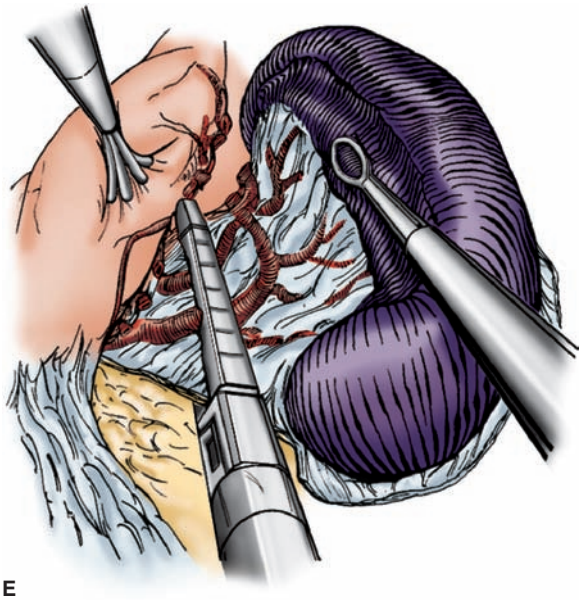

E

FIGURE 62-18 (*Continued*)

assistant's other hand should be providing blunt retraction on the spleen toward the left shoulder. It is crucial that the all of the short gastric vessels be divided before proceeding to avoid bleeding that can be difficult to control at a later stage. The most cranial vessels can be difficult to identify and may be immediately adjacent to the left crus of the diaphragm. Medial rotation of the stomach can help expose these vessels and ensure complete ligation (Fig. 62-18D). Once all of the short gastric vessels have been ligated, the assistant and the surgeon elevate the spleen using blunt dissectors while the surgeon divides the entire splenic hilum using an endoscopic stapling device (Fig. 62-18E). The hilum should be divided close to the spleen to avoid injury to the pancreatic tail, which can be as close as 1 cm to the splenic hilum. It is imperative that the stapler includes the entire hilum to avoid partial division of one of the vessels. If this is not possible, the hilum should be dissected further until the stapler fits comfortably across the hilum. We typically use a 60- × 2.5-mm stapler. If the hilar vessels are closely related, we prefer to use a 45- × 2.0-mm stapler. The smaller staples (2.0 mm) provide better hemostatic control of the vessels, but they are only supplied in the short length (45 mm) and thus not suitable for all occasions. To minimize port size, we typically change to a 5-mm laparoscope at this point. The new camera is then inserted through one of the 5-mm ports, freeing the 12-mm port for the introduction of the stapler. An alternative approach is to utilize two 12-mm ports: one for the camera and a separate one for the stapler.

REMOVAL OF THE SPECIMEN

We continue to use the 5-mm laparoscope for the remainder of the procedure. The 12-mm port should be removed, extended, and a 15-mm endoscopic bag should be placed directly through the skin incision without a port. The spleen is placed in the endoscopic bag, and the bag is brought up through the skin. This maneuver provides a good seal at the port site and allows for reinflation of the pneumoperitoneum. The splenic bed is now inspected for hemostasis. Particular attention should be given to the splenic hilum and short gastric vessels. Iatrogenic injury to other organs, particularly the pancreatic tail, should be ruled out. The spleen is then morselized using digital disruption and removed using ring forceps until the entire bag can be removed from the abdominal cavity. Care should be taken during this part of the procedure to ensure that the ring forceps do not tear the retrieval bag and inadvertently grasp intra-abdominal contents through the bottom of the bag. This can lead to unrecognized complications, such as a small bowel enterotomy or colonic injury. As discussed before, pieces large enough to allow adequate histologic analysis can often be obtained even with morcellation.

In cases of massive splenomegaly, placement of the spleen inside the specimen bags can be challenging. For spleens over 20 cm or so, we use the larger specimen retrieval bags (Lahey bag) and use the "trousers" technique (where the spleen is positioned in the left upper quadrant and the bag is pulled up the spleen, similar to when one is putting on pants/trousers), or "jumper" technique (where the spleen is positioned in midabdomen, the bag is placed at the superior pole and then pulled down over the spleen, similar to when one puts on a pullover/jumper).

After removal of the specimen, the ports are reinserted and the abdomen is examined and irrigated if necessary. If an open technique is used for the camera port, closure of this fascia may be necessary. All lateral port sites for ports 12 mm or less do not require fascial closure. The incision site through which the morcellated spleen is removed, however, should be closed with absorbable sutures as the incision is often enlarged for placement of the endoscopic bag and extraction of the spleen. The skin is approximated with absorbable sutures. A closed suction may be placed at this point, although there has been concerns for an increased risk of postoperative infection in cases were drains were placed. We generally avoid such a drain unless the spleen was very large or there was some concern about injury to the pancreatic tail. If a drain is placed, the drain fluid amylase and lipase is assessed after patient starts on an oral diet and, if normal, the drain is removed. If the patient has evidence of a pancreatic leak, the drain is left in place until output is less than 10 cc for 2 days.

Hand-Assisted Laparoscopic Surgery

Hand-assisted laparoscopic splenectomy offers an alternative to conventional laparoscopic splenectomy. The hand-assisted technique allows the surgeon to regain the sense of depth and tactile feel that is lost in the conventional laparoscopic technique. In addition, it facilitates exposure when that is limited and will allow greater manipulation of the specimen. This can be especially important in difficult cases, such as those with

splenomegaly. Another advantage is that the retrieval of the specimen, which in cases of spleens of greater than 25 cm, can be difficult to morcellate. The hand-port incision can be placed in a variety of positions, such as the supraumbilical midline or a Pfannenstiel incision. The hand port is important in maintaining the pneumoperitoneum when the operator withdraws their hand from the peritoneal cavity. A number of such ports have been developed and are commercially available. Typically, the nondominant hand is placed in the abdominal cavity and used to assist with the surgery.[83]

The role of HALS in splenic surgery is widely debated. Several case series suggest possible advantages for HALS in cases of splenomegaly compared to open splenectomy, including less postoperative pain and a shorter hospital stay.[84] This technique allows for gentler retraction of the spleen during dissection, as well as palpation and precise location of the splenic artery. No advantage is seen for hand assistance over conventional laparoscopy when the spleen is of normal size.

Single-Incision Splenectomy

In the recent years, efforts have been directed toward making laparoscopic surgeries even less invasive, culminating in the recent interest in single-site surgery. This approach, referred to as LESS (laparoendoscopic single site) surgery, involves placement of several trocars, or a single multichanneled trocar, through a single small incision (typically ≤2.5 cm) usually at the umbilicus. Several reports of LESS splenectomy have now been published with success rates of 75%, and conversion to standard laparoscopy in the remaining patients.[85] These early reports clearly demonstrate the feasibility of this approach for splenectomy although benefits, other than cosmetic, are unclear and will likely be answered in years to come as further studies are undertaken.

Postoperative Management

Some surgeons advocate postoperative decompression of the stomach with a nasogastric tube to prevent hemorrhage from the short gastrics. We have not found this necessary and allow sips of clear liquids on the night of surgery, advancing the diet over the course of the first postoperative day. We feel that a single dose of preoperative antibiotics is sufficient and do not use postoperative antibiotics. The patients are provided a patient-controlled analgesia (PCA) for their first postoperative night and switched to oral analgesia in the morning. Unless the patient has an ongoing coagulation problem or low platelet counts, we use nonsteroidal anti-inflammatories in management of their postoperative pain. The patient's complete blood count is typically checked on the morning after surgery. Patients are typically discharged on postoperative day 1 or 2.

The manipulation of the stomach may lead to some early satiety in the immediate postoperative period. This will resolve in 6–8 weeks. Patients are also instructed to refrain from high impact or jarring-type exercises for 2 weeks so that raw surfaces within the splenic fossa are allowed to heal without disturbance.

Complications

Generally, the complication rate of laparoscopic splenectomy is 10–15%, with a mortality rate of less than 1% for elective cases. Splenectomy for hematological malignancy and splenomegaly, however, can have a high complication rate with reports of a 9% mortality rate. An intraoperative complication that may occur during laparoscopic splenectomy but is rarely seen with open splenectomy is diaphragmatic perforation, usually related to thermal injury during mobilization of the superior pole, emphasizing the importance of a good technique and visualization during the procedure.[86]

Early postoperative bleeding must be closely monitored, particularly in patients with thrombocytopenia or myeloproliferative disorders. In these patients it is an error to indict hematologic abnormalities as the cause of bleeding, and it is generally safer to reexplore the patients early and to evacuate a hematoma to reduce the incidence of subphrenic abscess. Alternative therapy would be angiography with embolization, but this may be difficult as the most common site of bleeding is a short gastric vessel.

Left lower lobe atelectasis and effusion is another complication; it occurs more frequently following splenectomy, but most large series have not yet substantiated this finding.

In unusual cases, the platelet count may rise to very high levels, at times greater than 2 million/mm^3. In cases where the platelet count rises to above 1 million, a drug that inhibits platelet aggregation, such as acetylsalicylic acid, can be used.

Thrombosis of the splenic vein, with extension into the portal vein and superior mesenteric vein, is a complication that appears more frequently after laparoscopic approach (Fig. 62-19). The etiology is poorly understood, but it may relate to decrease portal blood flow during laparoscopic surgery or a hypercoagulable state following pneumoperitoneum. In a recent literature review of splenoportal vein thrombosis (SPVT), the overall incidence of symptomatic thrombosis was 3.3%, and similar between open and laparoscopic approach.[87] When the authors, however, focused on prospective studies that included asymptomatic SPVT, the overall incidence increased to 12.3%, with a large difference based on surgical approach. After open splenectomy, SPVT rate was 8.3%, but it increased to 23% after laparoscopic splenectomy. Increased rate of SPVT after laparoscopic approach has been documented by others with several risk factors for this complication, which are summarized in Table 62-5. Interestingly, traumatic splenectomies are not associated with a significant risk for SPVT.

This has generated much debate on whether patients should have surveillance imaging (US or CT) after laparoscopic splenectomy to look for SPVT, since two-thirds will have asymptomatic thrombosis. If imaging is to be undertaken, CT is more sensitive than US; however, CT exposes the patient to additional radiation. It has been suggested that a postoperative surveillance US on postoperative day 7 may be

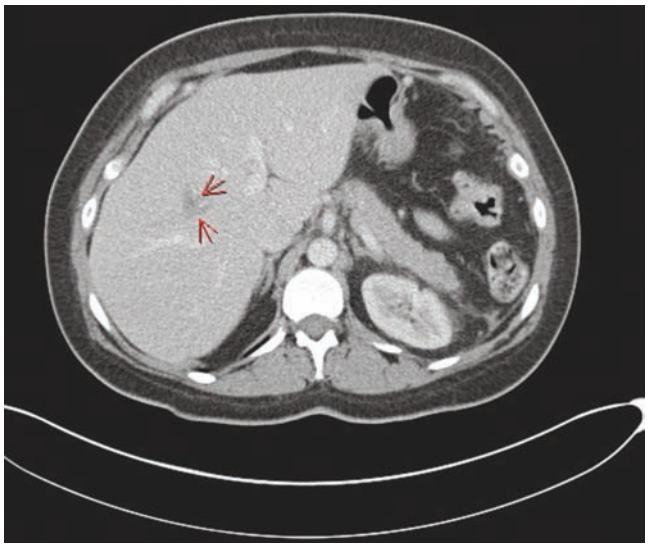

FIGURE 62-19 Splenic-portal vein thrombosis (SPVT) after a laparoscopic splenectomy. The thrombosis may be small and involve intrahepatic branches of the portal vein only, as is the case here where the patient had thrombus in the anterior branch of the right portal vein. The patient was asymptomatic and was initially observed. Follow-up imaging after 3 weeks, however, showed persistent thrombosis, and she was therefore anticoagulated for 3 months.

best at detecting a developing thrombosis.[88] Such surveillance imaging is not, however, standard practice and not routinely performed by the author.

Full anticoagulation is generally recommended for symptomatic cases. Management of asymptomatic cases is less clear. Involvement of superior mesenteric vein with thrombosis often indicates need for prompt anticoagulation. Isolated thrombosis in the splenic vein may, however, be observed with serial imaging to confirm resolution and without full anticoagulation.[89]

Injury to the tail of the pancreas with a symptomatic complication can occur in up to 10% of cases.[90] The majority of these injuries is self-limited with hyperamylasemia and pain but may be more severe with development of a pancreatic collection requiring drainage.

The increased incidence of fulminant sepsis related to pneumococcus or to *H. influenzae* following splenectomy is an established fact, but it occurs more commonly in patients who are immunosuppressed or have myeloproliferative diseases with a propensity for infection. The risk may be reduced with appropriate vaccination and early recognition as previously noted.

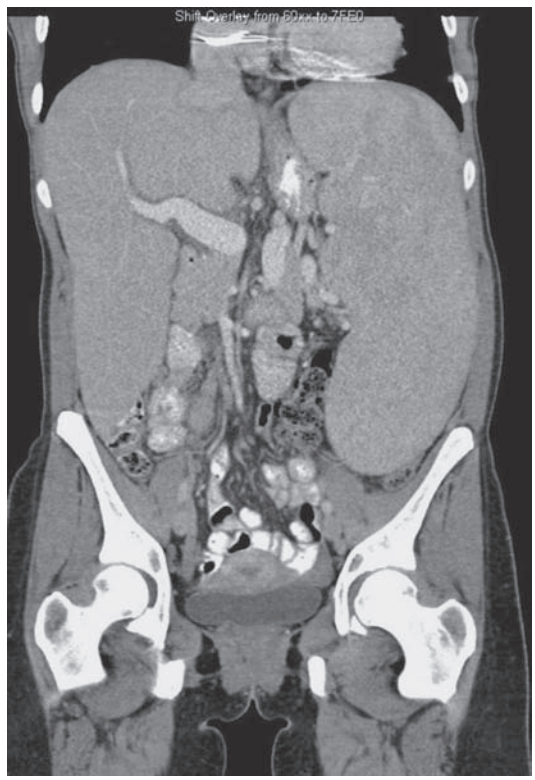
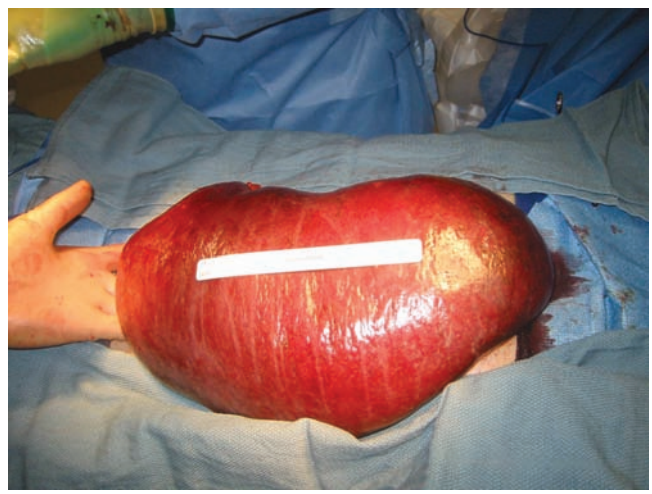
OPEN SPLENECTOMY

Open approach is most commonly used in cases of trauma and splenic injury, but it also has a role for elective management of massive spleens (Fig. 62-20).



A



B

FIGURE 62-20 **A.** This spleen measured 27 cm and was successfully removed laparoscopically. **B.** This spleen measured over 30 cm, and in view of this we proceeded directly to open surgery.

A variety of incisions may be used, depending on the nature of the disease and the personal preference of the surgeon. A midline incision is generally applied to cases of traumatic injury because of the speed of access as well as exposure of the spleen and other possibly injured viscera. A left subcostal incision also has been employed, as well as thoracoabdominal approach, which has been largely abandoned because of its associated morbidity.

Open splenectomy is usually performed by a technique of media mobilization of the spleen and dissection down to an ultimate pedicle of splenic artery and vein which is then finally divided. The procedure begins with mobilization of the spleen to the midline by division of the lateral and superior pole attachments. This includes division of the splenophrenic ligament superiorly, and the splenocolic and splenorenal ligaments at the lower pole (Fig. 62-21). The short gastric vessels are then divided between ligatures or clips, taking care to avoid injury to the gastric wall (Fig. 62-22). Alternatively, an ultrasonic dissector may be used to divide these vessels.

The spleen is medialized and hilar dissection performed carefully with isolation of the splenic vessels and gentle medial displacement of the tail of the pancreas to avoid pancreatic injury. The splenic hilum may be clamped en bloc with three clamps in the manner of Federoff (Fig. 62-23) and divided and doubly ligated proximally and once distally. Some advocate individual ligation of the splenic artery and splenic vein. Alternatively, the vessels may be divided with a vascular linear stapler. Drainage is not necessary unless the pancreas has been injured.

In elective cases for splenomegaly, some start the procedure by entering the lesser sac, identifying the splenic vessels, which is often above the pancreas, tying and dividing them at this point, before proceeding with the splenectomy (Fig. 62-24). This helps to reduce excessive splenic bleeding during the surgery should there be injury to the capsule.

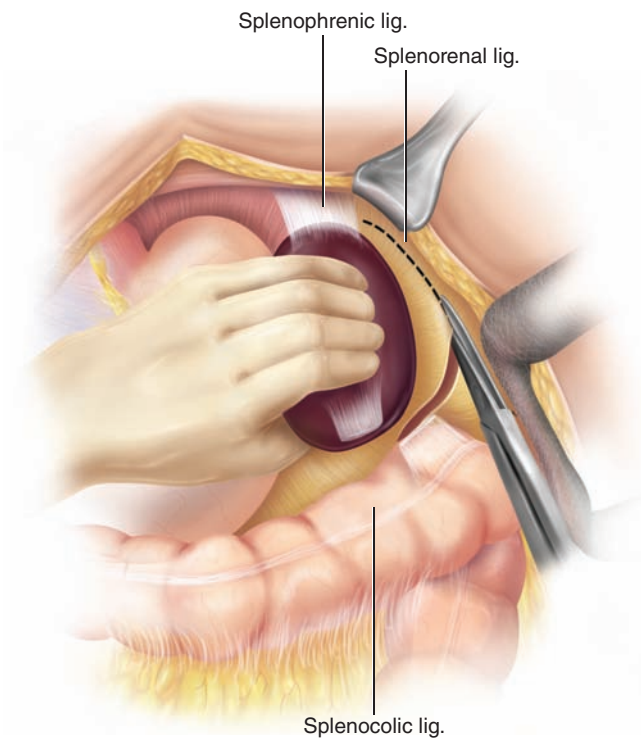


FIGURE 62-21 Division of the ligamentous attachments of the spleen during open splenectomy.

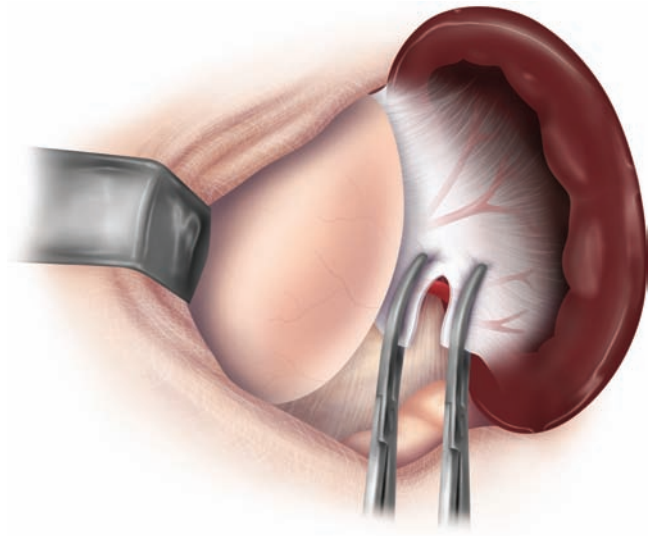

FIGURE 62-22 Ligation of the short gastric vessels and the gastrosplenic omentum.

SPLEEN-PRESERVING APPROACHES

The techniques to preserve splenic tissue and function are dictated by the extent of planned resection, or in case of trauma, splenic damage. These approaches have gathered increased popularity because of the critical role of spleen in fighting encapsulated organisms and the small, but real, risk of OPSS.

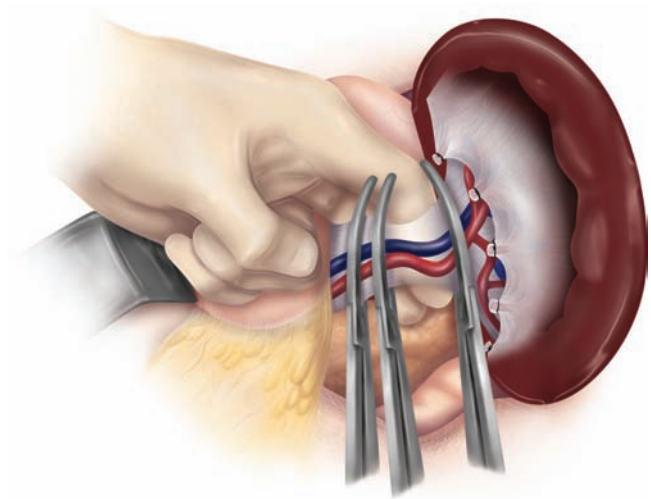

FIGURE 62-23 Division of the splenic hilum using the three-clamp method of Federoff.

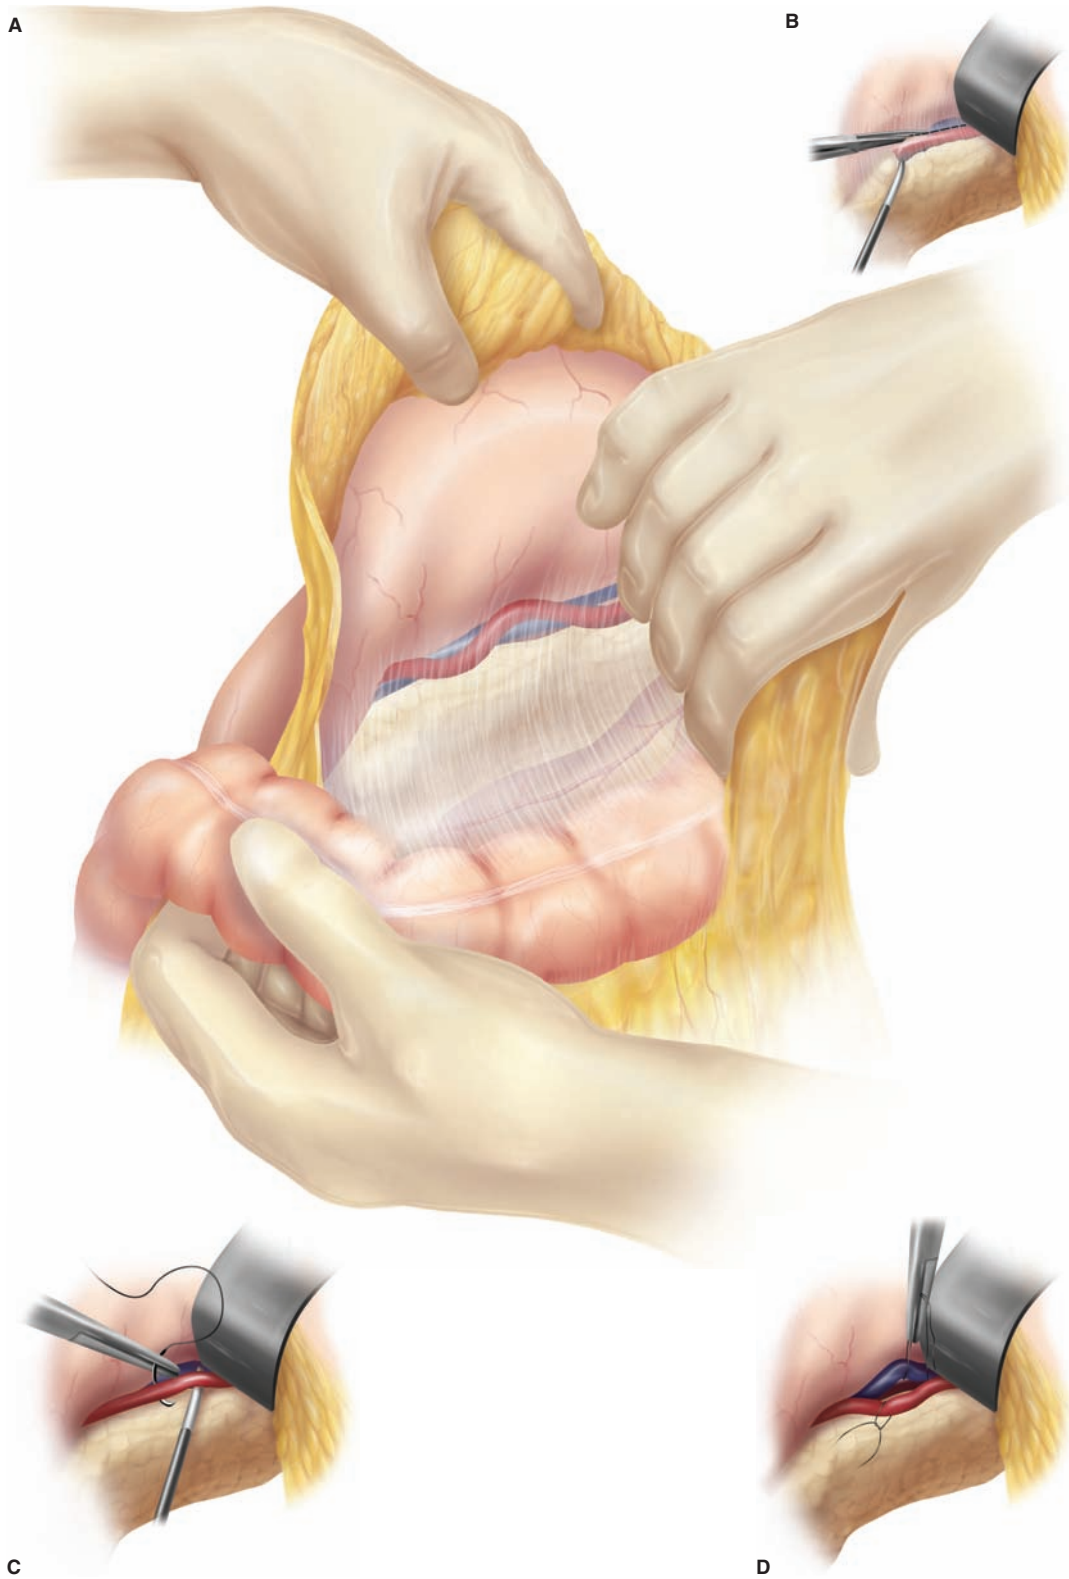

FIGURE 62-24 In cases of massive splenomegaly, access is obtained to the lesser sac and the splenic vessels identified. The artery is often seen above the pancreas. The vessels are carefully dissected and ligated twice proximally and once distally before being divided. The splenic dissection and mobilization is then performed.

Splenorrhaphy

The spleen must be mobilized carefully to allow thorough inspection of the organ. The ligamentous attachments must be divided as in splenectomy. Small lacerations can be managed by compression and the application of a hemostatic agent, such as oxidized cellulose, micronized collagen, thrombin, or fibrin glue. Significant disruptions of the splenic capsule and parenchyma can be managed generally with absorbable sutures that traverse the capsule and incorporate the parenchyma. In this circumstance, horizontal mattress sutures are advantageous because cutting through the tissue is minimized; some use pledget for these sutures. If trauma is localized to one pole of the spleen, this area should be resected and the edges approximated with a series of mattress sutures (Fig. 62-25). The omentum may be used to fill large defects or to cover the injury site to provide tamponade. Splenorrhaphy has largely been supplanted by the nonoperative management of relatively hemodynamically stable injured patients, with the addition of angiographic embolization when indicated.

Partial Splenectomy

Partial elective splenectomy has been described for management of localized lesions of the spleen, as well as management of more systemic disease, in select cases such as Gaucher's disease or spherocytosis. The technique is similar to standard

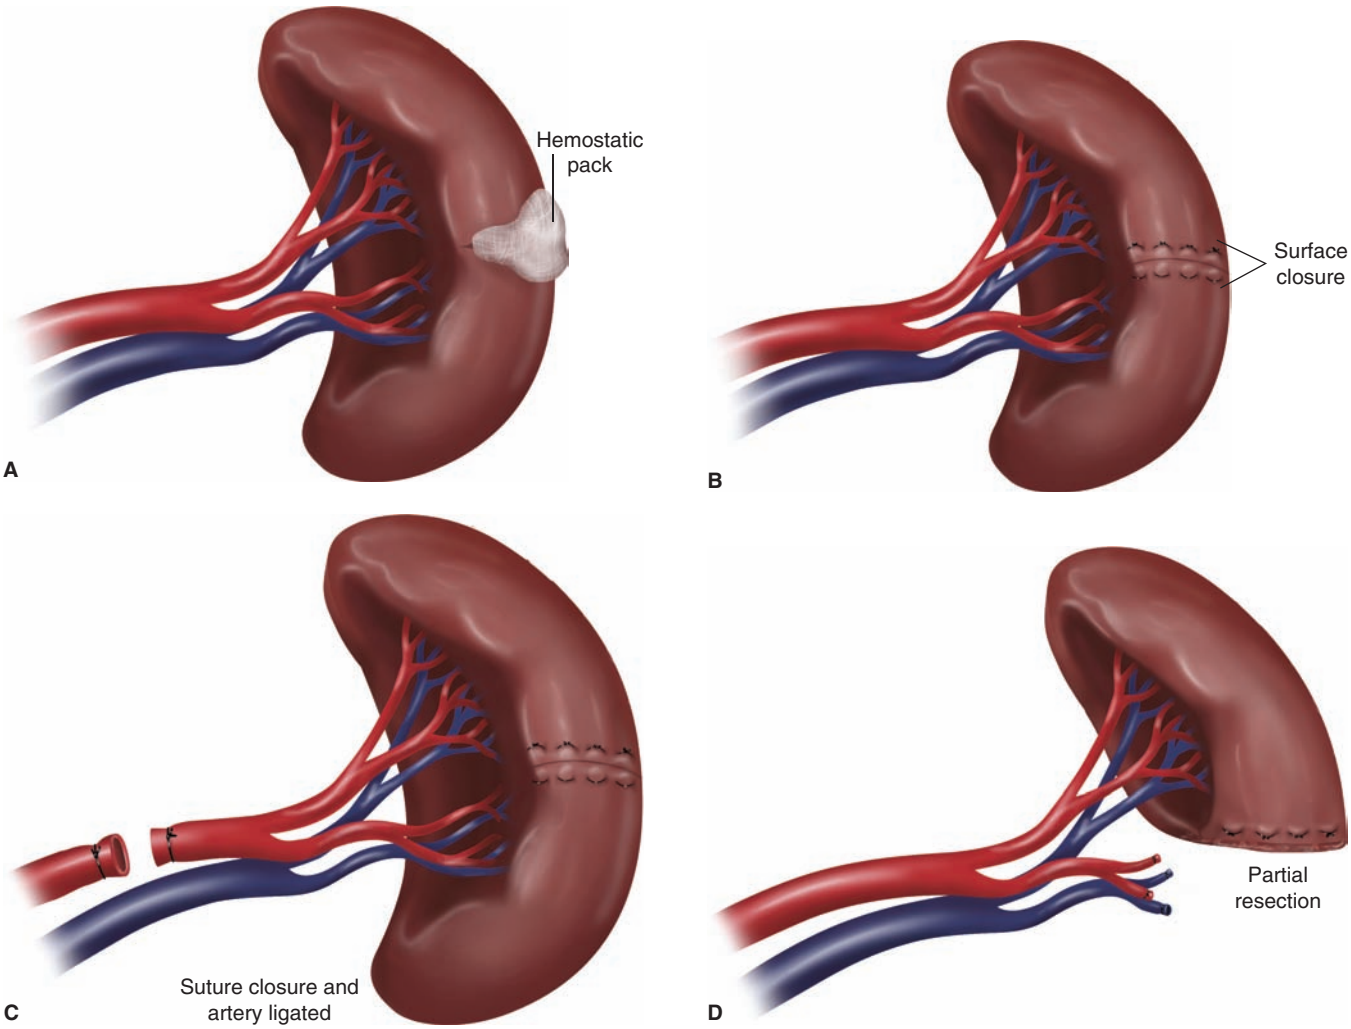

FIGURE 62-25 Approaches to preserving a traumatized spleen. Depending on the degree of splenic injury, on of these techniques can be used.

laparoscopic splenectomy. For partial resection of the lower pole, branches of the gastroepiploic vessel supplying the lower pole are divided and spleen is allowed to demarcate. Once appropriate segments have become ischemic, the splenic capsule is divided using electrocautery. The dissection is then continued to the splenic parenchyma until the desired segment is fully divided. A new technique has been described using radiofrequency-generated heat to perform a partial splenectomy in a patient with a tumor in the lower pole of the spleen.[91]

ADRENALECTOMY

Matthew A. Nehs • Atul A. Gawande • Francis D. Moore, Jr • Daniel T Ruan

INTRODUCTION: ADRENAL ANATOMY AND PHYSIOLOGY

The adrenal, or suprarenal, glands are paired retroperitoneal organs positioned superomedial to the kidneys at the level of the 12th rib. Each gland is divided into an outer cortex and an inner medulla, which are histologically and functionally distinct layers derived from separate embryologic tissues. The cortex originates from ectoderm and is composed of three zones that produce steroid hormones: the *zona fasciculata*, which produces mineralocorticoids; the *zona glomerulosa*, which produces glucocorticoids; and the *zona reticularis*, which produces sex hormones. The medulla is derived from neural crest cells and is composed of modified postganglionic neurons that connect with the sympathetic nervous system in order to produce epinephrine, norepinephrine, and dopamine in response to sympathetic stimuli.

The arterial supply to the adrenals originates from the inferior phrenic arteries, aorta, and renal arteries. Although the anatomy is quite variable, the majority of the arterial supply approaches from the medial and inferior borders of the adrenal glands with few substantial arteries from the superior, posterior, or lateral sides. The adrenal arteries are generally small and amenable to electrocautery. Conversely, the venous anatomy to the adrenal gland is more consistent; usually there is a single large draining vein of substantial size that requires ligation. The right adrenal vein length tends to be short and it drains directly into the inferior vena cava (IVC). In contrast, the left adrenal vein is usually of generous length and drains into either the left renal vein or the inferior phrenic vein. Ligation of the left inferior phrenic vein is of no significant physiologic consequence. The adrenal gland is surrounded by variable amounts of fat, which is loosely attached posteriorly to diaphragmatic muscle. This surrounding fat can obscure the visualization and identification of adrenal tumors. Left-sided adrenal tumors can be adjacent to the spleen, pancreas tail, liver, kidney, or renal hilum. Right-sided adrenal tumors can be adjacent to the liver or IVC. Invasive adrenal tumors can extend into these surrounding structures.

INDICATIONS FOR ADRENALECTOMY

Aldosteronoma

Aldosteronomas are cortical adrenal tumors that autonomously secrete aldosterone. Hyperaldosteronism was first described by Jerome Conn in 1955 and is characterized by hypertension and hypokalemia.[1] These symptoms should be controlled preoperatively with an aldosterone antagonist and potassium supplements. Biochemical confirmation of autonomous hypersecretion of aldosterone should be confirmed prior to adrenalectomy. This is best achieved by salt loading followed by a 24-hour urine collection of aldosterone, sodium, and creatinine. Aldosterone antagonists should be held prior to testing for at least a few weeks. While there are several forms of primary hyperaldosteronism, surgery is indicated only in the setting of unilateral adrenal adenoma or hyperplasia. Because aldosteronomas are almost always benign tumors, a cortex-sparing nodulectomy can be performed when the tumor is peripheral; however, this approach has a higher risk of persistent hyperaldosteronism.

Since benign, nonfunctional adrenal tumors are common relative to the incidence of hyperaldosteronism, selective venous sampling should be used to confirm laterality of disease in patients who are older than 40 years. Although many surgeons believe that computerized tomography (CT)[2] or magnetic resonance imaging (MRI) is sufficient when unilateral disease is identified in younger patients, it is our practice to perform selective venous sampling for all patients who are considered candidates for adrenalectomy. This is supported by a recent study that found that 50% of patients in their primary hyperaldosteronoma cohort would have been inappropriately managed based on preoperative CT findings alone.[3]

Postoperatively, normalization of aldosterone levels confirms surgical cure and is typically associated with correction of hypokalemia. Infrequently, hyperkalemia can result from chronic suppression of the contralateral adrenal gland. With complete resection of the aldosteronoma, nearly all patients have normal serum potassium levels and hypertension is improved in most. Persistent hypertension after curative adrenalectomy is usually due to underlying essential hypertension.

Pheochromocytoma

Pheochromocytomas are rare neuroendocrine tumors that are derived from chromaffin cells and usually arise from the adrenal medulla. Although most pheochromocytomas are sporadic and unilateral, genetic syndromes, such as multiple endocrine neoplasia 2 and von Hippel-Lindau disease, increase the risk of bilateral disease. Pheochromocytomas can produce catecholamines such as epinephrine, norepinephrine, and dopamine that can cause the classic clinical symptomatology of this disease: episodic headaches, palpitations, and diaphoresis. Rarely, pheochromocytomas are nonfunctional. Preoperative preparation with alpha-blockade (eg, phenoxybenzamine, doxazosin) and salt loading should be undertaken. Ideally, this can be done in the outpatient setting. The alpha-blocker is titrated up to the maximal tolerated dose, which is typically limited by orthostatic hypotension. In addition, beta-blockade can be added to the regimen if the patient has persistent tachyarrhythmias. Although the optimal preparation time before pheochromocytoma resection is controversial, we generally alpha-block and salt-load our patients for 1–2 weeks before elective adrenalectomy.

The first successful resection of a pheochromocytoma was performed by César Roux in Switzerland in 1926 and shortly thereafter by Charles Mayo in the United States. Delicate tissue handling and avoidance of tumor compression should be emphasized to minimize catecholamine release. Because tumor manipulation and adrenal vein clipping can result in significant hemodynamic changes, coordination and communication between the adrenal surgeon and anesthesiologist are critical to the success of this operation. Because of the risk of catecholamine surges during tumor manipulation, many propose early identification and clipping of the adrenal vein. After dividing the adrenal vein, we grab the tumor side of the divided vessel to use as a handle for retraction. However, some caution that adrenal vein ligation increases intratumoral venous pressure, which can increase bleeding.[4] Regardless, if the vein is ligated early or late in the dissection, communication between the surgical and anesthesia teams is necessary, because hypotension is often recognized after vein ligation.

Endoscopic adrenalectomy is the favored procedure when there is no evidence of malignant disease.[5] A randomized controlled trial of laparoscopic versus open adrenalectomy for pheochromocytoma found no significant differences in hemodynamic instability between the two groups, but operative time and blood loss were favored in the laparoscopic group.[6] Although laparoscopic or retroperitoneoscopic resection is favored for small and noninvasive tumors, conversion to the open approach should be considered whenever there is difficulty achieving gross tumor clearance. Conversion to open surgery is appropriate if capsular disruption seems imminent during endoscopic dissection.

Cortisol-Producing Adrenal Adenoma

Adrenal adenomas that produce cortisol can be incidentally discovered during abdominal imaging or when the patient develops the signs and symptoms of Cushing's syndrome. In the early 1930s, Harvey Cushing was among the first to describe the clinical entity of hypercortisolism, which is characterized by truncal obesity, round face, fragile skin, depression, and abdominal striae. These tumors autonomously secrete cortisol without the usual dependence on adrenocorticotrophic hormone (ACTH) and can increase the risk of cardiovascular complications and mortality.

Because adrenocortical carcinomas (ACCs) also frequently secrete cortisol, a careful preoperative evaluation should be performed to look for signs of malignancy, such as radiographic evidence of local invasion, regional lymphadenopathy, distal metastases, and rapid growth. Small tumor size and well-defined borders are predictive of benign cortisol-producing adenomas. Because the risk of ACC increases with larger tumor size, patients should be considered for open resection if the tumor size exceeds 6 cm.[7–9]

Postoperatively, adrenal function may be suppressed in the contralateral gland, and patients should be given a prophylactic hydrocortisone taper to avoid potential postoperative adrenal insufficiency. The steroid taper can progress according to patient symptoms and can be monitored with serum cortisol and ACTH levels drawn in the morning. Because patients with these tumors can have obesity resulting from Cushing's syndrome, they can present an additional technical challenge for laparoscopy. Often, port sites at the skin can dilate during the procedure, resulting gas leakage during the operation. Therefore, it is ideal to make the port site incisions as small as technically possible to avoid gas leakage and loss of operative domain during peritoneal insufflation. Cushing's patients also have a higher risk of postoperative infection, so preoperative prophylactic antibiotics should be used.

Adrenal Cyst

Simple cystic lesions are usually incidental, and surgery is not indicated unless there is a solid component to the cyst wall. Complex cysts with evidence of local invasion should undergo open resection. Large cysts that cause symptoms or that are at high risk of spontaneous rupture can be excised by laparoscopic nodulectomy or subjected to fenestration of the cyst wall into the peritoneal cavity.

Myelolipoma

These lesions are also typically discovered in an incidental manner. Their appearance can cause confusion with liposarcoma, a situation easily resolved with needle biopsy showing typical bone marrow elements. Patients with these benign adrenal lesions are often referred to surgery because of compressive symptoms.

Adrenal Cortical Cancer

Adrenal cortical carcinoma is a rare and aggressive tumor derived from the adrenal cortex. As many as 60% of ACCs in adults autonomously hypersecrete cortisol or sex steroids.

Although complete surgical resection is the mainstay of therapy, ACC is often locally invasive, which typically precludes complete extirpation. Local tumor invasion precludes endoscopic resection. Initial reports of laparoscopic adrenalectomy for ACC suggested that the recurrence rates were higher than open resection.[8] This was the reason for many to recommend that malignancy was an absolute contraindication for laparoscopic resection of primary adrenal cancers. Recently, several groups have challenged this paradigm and have reported success with laparoscopic resection of malignant adrenal disease.[9,10]

While this topic remains controversial, we do not attempt minimally invasive adrenalectomy when local invasion is determined on preoperative imaging. Intraoperative difficulty with establishing tissue planes between the adrenal gland and neighboring structures due to tumor extension portends malignancy and should prompt immediate conversion to open adrenalectomy.

Incidentaloma

Incidentalomas are tumors that come to clinical attention through abdominal imaging for some other indication. The clinical relevance of these masses pertains to the concern for malignancy. Small, nonfunctional incidental tumors (<4 cm) do not require resection and are typically benign.[11] Biochemical exclusion of pheochromocytoma, aldosteronoma, and hypercortisolism is necessary. Larger lesions (>4 cm) are at higher risk for carcinoma, and open resection should be considered. Although controversial, laparoscopic resection of incidental tumors greater than 4 cm in size can be safely achieved for tumors without gross extension.[2] Formal decision analysis of the management of incidentalomas has determined that laparoscopic resection is ideal if the morbidity of surgery is less than 3% and the probability of hypersecretion, tumor growth, or malignancy exceeds 7.5%.[12] The former can often be achieved in the hands of an experienced adrenal surgeon and the later is seen in tumors larger than 5 cm.

Paraganglioma

Paragangliomas are neuroendocrine tumors histologically similar to pheochromocytomas but occur in extra-adrenal sites throughout the abdomen, chest, and head. Most of these tumors are sporadic and can present as a painless mass or with the symptomatology of a pheochromocytoma resulting from catecholamine production. There are a several case reports of successful laparoscopic resection of these tumors.[13–15] The decision to use this approach should depend on the location and size of the paraganglioma, as well as the surgeon's experience.

Metastasis

Resection of adrenal metastases is controversial and the role for surgical treatment is changing, now that safe minimally invasive resection can be achieved with minimal morbidity. Although no prospective trials have proven that adrenalectomy improves survival, many groups have reported safe laparoscopic resection of various secondary tumors, such as lung, renal cell,[16] colon, and melanoma.[17,18] For the laparoscopic approach specifically, it is equivalent to open adrenalectomy regarding recurrence and survival and provides the additional benefit of reduced postoperative morbidity.[19] Furthermore, there is a role for palliative laparoscopic resection for patients with symptomatic secondary tumors. Attempts at laparoscopic metastasectomy should be avoided in any patient with radiographic evidence of local invasion, as complete resection without capsular disruption is unlikely.

ENDOSCOPIC ADRENALECTOMY

Since the initial report of laparoscopic adrenalectomy in 1992,[20] surgical experience has grown along with significant progress in endoscopic technologies. As such, the laparoscopic approach has become the procedure of choice for most adrenal tumors less than 6 cm in size. Retroperitoneoscopic adrenalectomy uses laparoscopic instruments but avoids entrance and insufflation of the peritoneal cavity. This technique involves direct entrance into the retroperitoneal space from the posterior side. Retroperitoneoscopic adrenalectomy is superior to laparoscopic adrenalectomy in selected patients, and there are numerous considerations when considering which surgical approach to use for the resection of adrenal tumors.

Advantages of the Laparoscopic Approach

For most patients who undergo laparoscopic adrenalectomy, the smaller incisions, lower blood loss, and lessened abdominal wall/flank trauma from divided muscles translate into a less painful and more rapid recovery when compared to open adrenalectomy. Median hospital stay is under 3 days for laparoscopic adrenalectomy, versus 7 days or more for the open procedure.[21] In addition, one can anticipate a reduction in general morbidity, such as catheter-associated urinary tract infections, pneumonias, and deep venous thrombosis.

One can counter that modern large-incision surgery has improved dramatically with the use of continuous epidural anesthesia, more rapid mobilization, and improvements in operative technique. Nonetheless, incisions for open adrenalectomy are large and morbid: subcostal incisions produce long-term limitation of rectus abdominis function; midline celiotomies result in ileus and a frequent incidence of ventral hernia; and thoracoabdominal incisions can produce pain and muscle denervation syndromes. These long-term issues are avoided almost entirely with the laparoscopic approach.

The laparoscopic approach is particularly advantageous for the patient who is disabled with Cushing's syndrome from an

autonomous adrenal adenoma. Patients with this diagnosis have such reduced muscle mass and reduced defense against infection that they become essentially immobilized with an open adrenalectomy. Adrenalectomy in patients with hypercortisolism carries a higher risk of general complications, including wound disruption and infection.

Laparoscopy is also especially advantageous for the patient with Conn's syndrome and a small unilateral peripheral adrenal adenoma. These patients can undergo nodulectomy for their tumors, be discharged from the hospital within 24 hours, and be back to work within days.

It is also technically feasible to perform laparoscopic adrenalectomy through a single laparoscopic port site. This new approach provides the incremental benefit of using a single 2-cm incision, rather than three or four separate laparoscopic ports, for access to the adrenal gland through the peritoneal cavity.[22] Because the current experience with single-incision laparoscopy is limited, future studies are needed to determine patient selection criteria.

Disadvantages of the Laparoscopic Approach

Laparoscopy is not appropriate for every patient, and some general contraindications to laparoscopy and transperitoneal resection include severe chronic obstructive pulmonary disease (COPD) (related to the inability to tolerate CO_2 insufflation), uncorrectable coagulopathy, dense intra-abdominal adhesions, and widely metastatic disease. There are, however, circumstances in which the adrenal gland must remain unseen—in other words, it must be removed as a radical adrenalectomy with an intact capsule of surrounding perinephric and suprarenal fat. The most common circumstance is that of suspected malignancy, in which breach of the tumor capsule and spillage of cancer cells can compromise postsurgical outcome.

The other circumstance in which a laparoscopic approach might be problematic is in patients who require bilateral adrenalectomy for ACTH-dependent Cushing's syndrome. In these patients, spillage of adrenal cortical cells in the presence of increased levels of their trophic factor, ACTH, risks reimplantation and the adrenal equivalent of splenosis. The authors are aware of such an unfortunate case. This risk is compounded by the absolute necessity to remove all adrenal tissue, a maneuver that is difficult to accomplish with certainty without laparoscopic manipulation and retraction of the adrenal itself. The adrenal gland is so friable in these cases that manipulation usually results in breach of the adrenal.

Another limiting circumstance is morbid obesity. The adrenal can frequently be obscured by surrounding fat. A CT scan will provide an estimate of the amount of fat around the adrenal. Large amounts should dissuade the surgeon from choosing laparoscopy, as there already will be substantial difficulty encountered even with effective patient positioning and longer instruments. Although ultrasound can demonstrate the exact location of the adrenal in these cases, it does not readily allow the safe dissection of the adrenal vein within a field of fat that should not be retracted.

The use of the hand-assisting ports might attenuate some of these issues, but this is unproven. It could also be the case that use of an incision large enough to admit a hand or forearm could abrogate some of the advantage of laparoscopy regarding long-term wound complications and short-term wound pain.

Last, one must keep the 5% conversion rate to open surgery in mind. Thus any advantage to the 19 nonconverted cases must be weighed against the possible disadvantage of urgent conversion to the 20th patient. Furthermore, there is such a breadth of patient response to equivalent injuries that this technique will present no advantage to some. Published series consistently show a subset of patients who tolerate open surgery with little morbidity and another subset of patients who do not tolerate even laparoscopic surgery without substantial morbidity and prolonged hospital stays.[23] We are presently unable to reliably predict which patients will not benefit from a less invasive technique.

EXPOSURES AND OPERATIVE TECHNIQUE

General Considerations

There are a few general recommendations that reduce the difficulty of laparoscopic adrenalectomy. First, any bleeding substantially impairs visualization. Dissection should be gentle and every act of tissue division accompanied by a hemostatic maneuver. Second, irrigation to remove obscuring blood cannot be reliably evacuated. Irrigation generally should not be used, as it tends to accumulate and obscure the bed of dissection. Third, removal of blood by suction tends to collapse the operative field and lead to tedious adjustment of retraction. For these reasons, small neurosurgical patties or rolled Kitner sponges are the best way to remove blood and to control minor bleeding. The use of instruments with hemostatic capability, such as ultrasonic shears or bipolar vessel sealing devices, should be used. Fourth, manipulation of instruments through the most lateral port is impaired by patients with wide hips. Port sites should be placed at least 7 cm apart to avoid limitations from instrument crowding. Thus the details of the patient's position and the placement of the ports are not routine and should not be delegated. Finally, the adrenal itself cannot be gripped and retracted directly without rupture and bleeding. Retraction should be performed by leaving periadrenal fat strategically attached to the adrenal and gripping the fat or by elevation of the adrenal from beneath. The specimen side of the adrenal vein after ligation can also be used as a handle for retraction. Otherwise, a rolled Kitner sponge held with a grasper can provide gentle and effective traction.

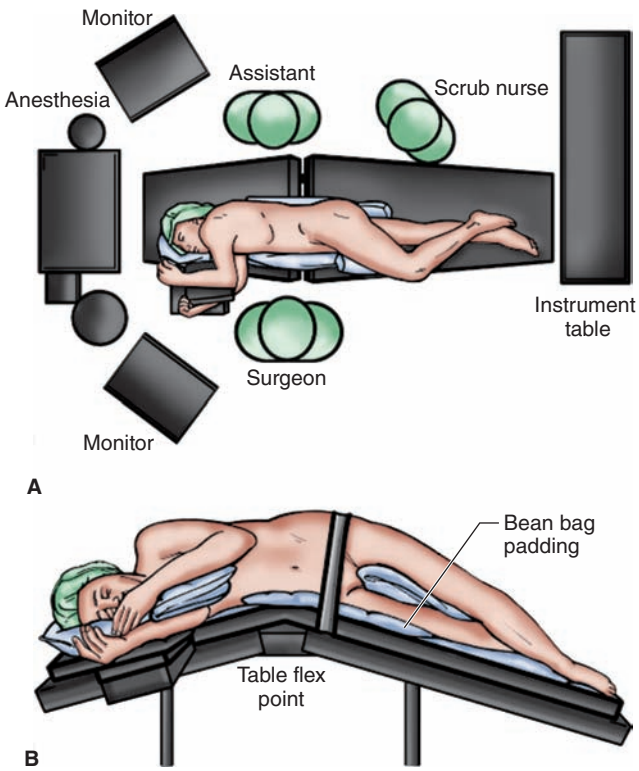

FIGURE 63-1 Optimal positioning of patient for a left laparoscopic adrenalectomy in the lateral decubitus position. The midabdomen is placed over the break in the table to optimize trunk extension and reduce interference with instrument movement by the iliac crest. The anterior abdominal wall should not be compressed.

Positioning

As in all operations, patient positioning and exposure are critical to the success of the laparoscopic adrenalectomy. For the lateral transperitoneal approach, the lateral decubitus position favors retraction of the abdominal viscera by gravity and facilitates exposure of the adrenal gland (Fig. 63-1). In obese patients, it may be a useful position for the anterior border of the patient's body near the edge of the bed and may allow the abdominal pannus to hang over the edge. The surgical table should be flexed with the center of the break in the table located approximately at the midpoint between the costal margin and the iliac crest to facilitate the greatest exposure. Exposure can be improved by raising a kidney rest. Care should be taken during flexion in the elderly and in patients with spine disease. The patient should be secured to the table, an axillary roll placed, and all pressure points should be adequately protected.

Instrumentation

Selection of the appropriate instruments can greatly facilitate visualization, exposure, and dissection. A high-definition video camera and monitors in conjunction with a 30-degree laparoscope provides the best visualization of the operative field. Fan retractors provide excellent exposure with the least risk of injury to the liver and spleen. Other essential equipment includes blunt dissectors, an endoscopic clip device, a laparoscopic bag, Kitner sponges, and a hook electrocautery. Laparoscopic devices, such as the Harmonic scalpel (Ethicon, Cincinnati, OH) or LigaSure (Valleylab, Boulder, CO), are useful and likely decrease operation times.

Right Laparoscopic Adrenalectomy

The patient is placed in the left lateral decubitus position, and the surgeon marks four-port sites along the right costal margin from the xiphoid to the midaxillary line (Fig. 63-2). Either a Veress needle entry or a muscle splitting open entry can be used to gain access to the peritoneal cavity. After insufflation of the peritoneal cavity and placement of additional ports under direct vision, the fan retractor is placed in the most medial port and the camera is placed in the second most

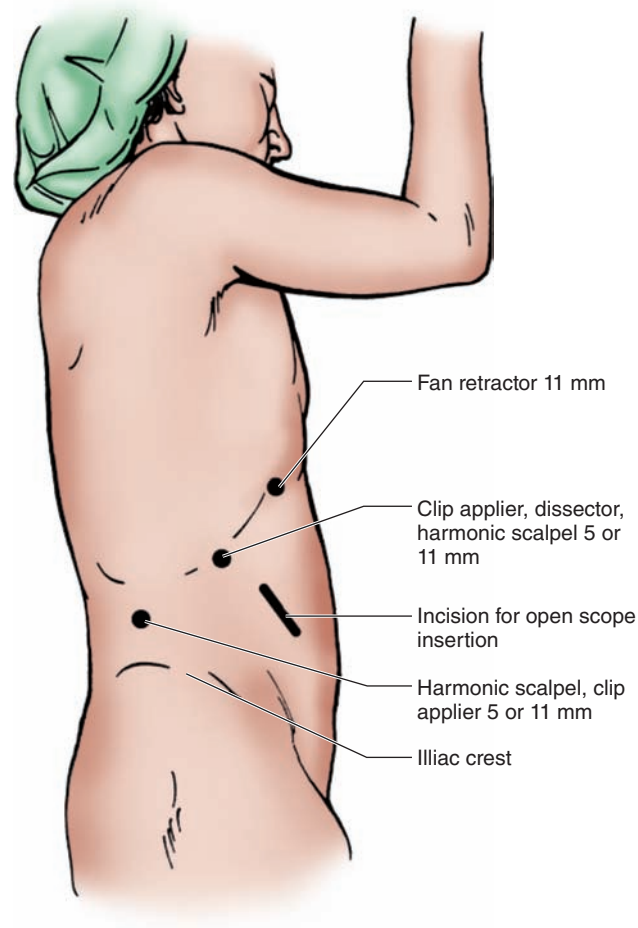

FIGURE 63-2 Port placement for a right laparoscopic adrenalectomy. In this example, abdominal entry is gained under direct visualization through the most medial site.

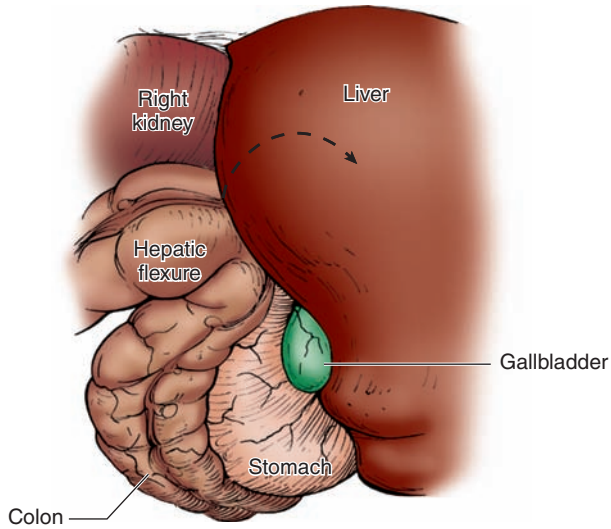

FIGURE 63-3 Initial view of right upper quadrant in a right laparoscopic adrenalectomy. The *arrow* indicates the direction of liver retraction from the epigastric port.

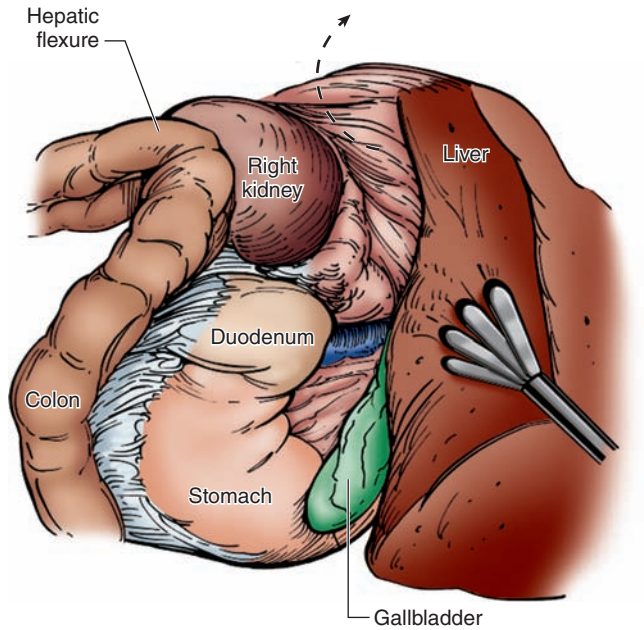

FIGURE 63-4 View during right laparoscopic adrenalectomy with the liver retracted from the epigastric port. Some attachments of the right lobe of the liver to the diaphragm have been divided. The *dotted line* indicates the line of further peritoneal incision to mobilize the right lobe of the liver from the diaphragm.

medial port. Figure 63-3 shows the initial view of the right upper quadrant after entry is achieved. The hepatic flexure of the colon is freed from its attachments and allowed to retract inferomedially from gravity. The fan retractor initially retracts the right lobe of the liver in the medial direction, and the right triangular ligament is taken down with a hook electrocautery. This mobilization enables superior and anterior retraction of the right lobe of the liver, which uncovers the retroperitoneum near the adrenal gland (Fig. 63-4). In most cases, the kidney, periadrenal fat, and IVC are visible after this maneuver.

We begin the dissection in the superolateral border of the periadrenal fat with a hook electrocautery. This exposes the diaphragm posteriorly, and the dissection is carried out in the medial direction along the superior border of the periadrenal fat (Fig. 63-5). A few small arteries are typically located in this area, which can be controlled with electrocautery, clips, or a hemostatic device. Careful dissection with blunt graspers should be used while approaching the IVC, near the superomedial border of the periadrenal fat. After establishing the superomedial corner of the periadrenal fat, the dissection is carried down in the caudal direction between the IVC and periadrenal fat (Fig. 63-6). The adrenal vein typically resides near the top third of this medial border and approaches the IVC at approximately a right angle. After clip or stapler ligation of the adrenal vein, this medial plane of dissection opens significantly (Fig. 63-7). Some surgeons routinely divide the adrenal vein with the LigaSure device without the use of a clips or staples (Fig. 63-8).

At this point, the specimen side of the adrenal vein can be grasped for retraction. The inferomedial border of the dissection also requires careful blunt dissection, with special attention to avoid injuring the renal hilar vessels. The dissection is then carried laterally along the superior surface of the kidney.

Special care must be taken to avoid accidental ligation of any arterial branches to the superior pole of the kidney. Once the plane of dissection is established between the inferior border of the periadrenal fat and the kidney, the only remaining attachments are posterior and lateral to the adrenal gland. A blunt

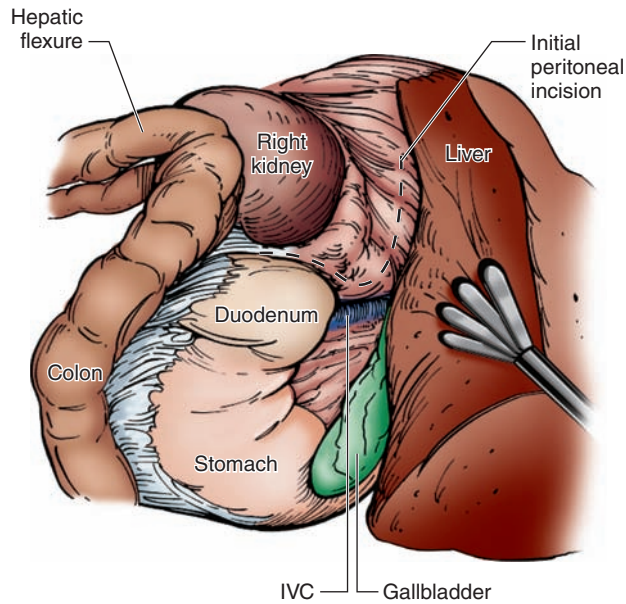

FIGURE 63-5 View during right laparoscopic adrenalectomy after initial dissection to mobilize the right adrenal. The *dotted line* shows the peritoneal incision under the retracted liver that exposes the adrenal.

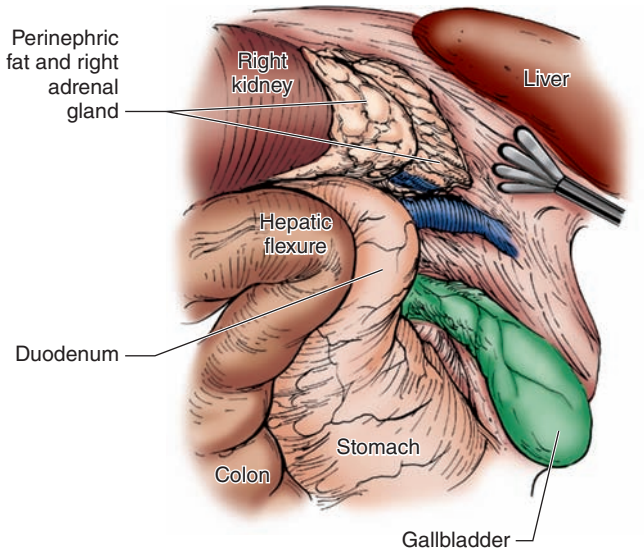

FIGURE 63-6 Dissection to expose the adrenal gland during right laparoscopic adrenalectomy.

grasper can be used to elevate the adrenal gland in the anterior direction, with special care to avoid disruption of the adrenal capsule. The remaining posterior and lateral attachments can be divided with a LigaSure or Harmonic scalpel device. The dissection should clear all fibrofatty and lymphatic tissue from the diaphragmatic surface. Once all attachments are divided, the gland is placed into an endoscopic bag for removal. If appropriate, the mouth of the bag can be exteriorized and the specimen can be morcellated and removed through a port incision. Otherwise, dilation of the fascia and skin are often required to remove the specimen en bloc.

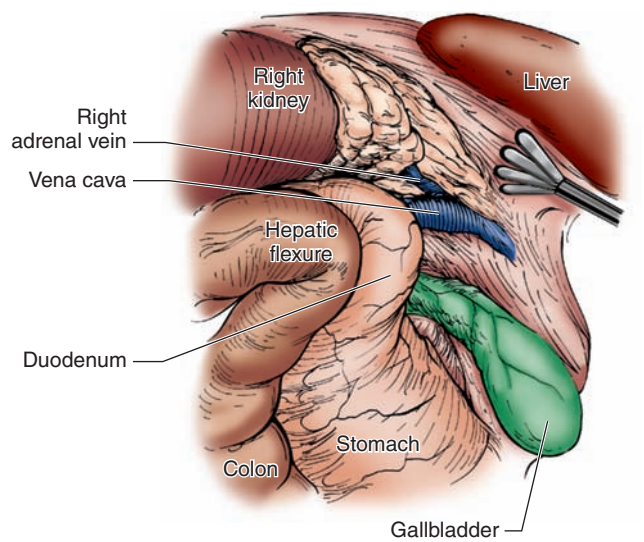

FIGURE 63-7 Dissection to expose the adrenal vein during right laparoscopic adrenalectomy. The length of the right adrenal vein is exaggerated in this schematic.

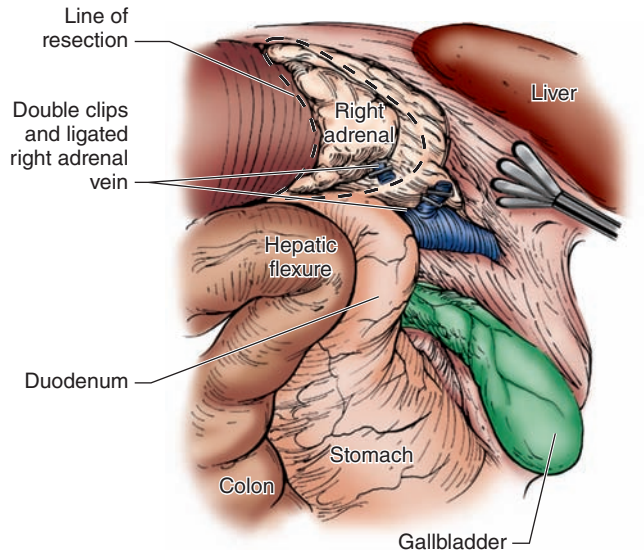

FIGURE 63-8 View during right laparoscopic adrenalectomy after division of the right adrenal vein with clips. The *dotted line* indicates the line of resection to complete the adrenalectomy. Retraction underneath the adrenal at the site of the severed adrenal vein is often advantageous. The length of the right adrenal vein is exaggerated in this schematic.

Left Laparoscopic Adrenalectomy

The steps are the same as the right adrenalectomy, with a few differences that will be delineated. The patient is placed in the right lateral decubitus position and the surgeon marks three- or four-port sites along the costal margin from the xiphoid to the posterior axillary line (Fig. 63-9). Sometimes the fourth port is not needed, as the spleen retracts medially with gravity. After access and insufflation of the peritoneal cavity, the splenic flexure of the colon is taken down (Fig. 63-10). The left liver and spleen are mobilized from the diaphragm using hook electrocautery. With medial mobilization of the spleen, the retroperitoneum is exposed. The left kidney, periadrenal fat, and tail of the pancreas are often visualized at this point. The dissection begins in the superolateral corner and proceeds in the medial direction between the spleen and the superior border of the adrenal gland (Fig. 63-11). The splenic vessels are often in close proximity to this plane of dissection. Once the superomedial corner is reached, the tail of the pancreas and the inferior phrenic vein can often be seen. The appearance of the pancreas tail can be similar to the adrenal gland. The dissection continues in the inferior direction along the medial border. The left adrenal vein is often located in the inferomedial portion of the dissection. After adrenal vein ligation, the dissection continues along the inferior border between the adrenal gland and the kidney (Fig. 63-12). In a similar fashion to the right adrenalectomy, the remaining posterior and lateral attachments are divided flush to the surface of the kidney and diaphragm, and the adrenal tumor is removed in bloc with the surrounding periadrenal fat.

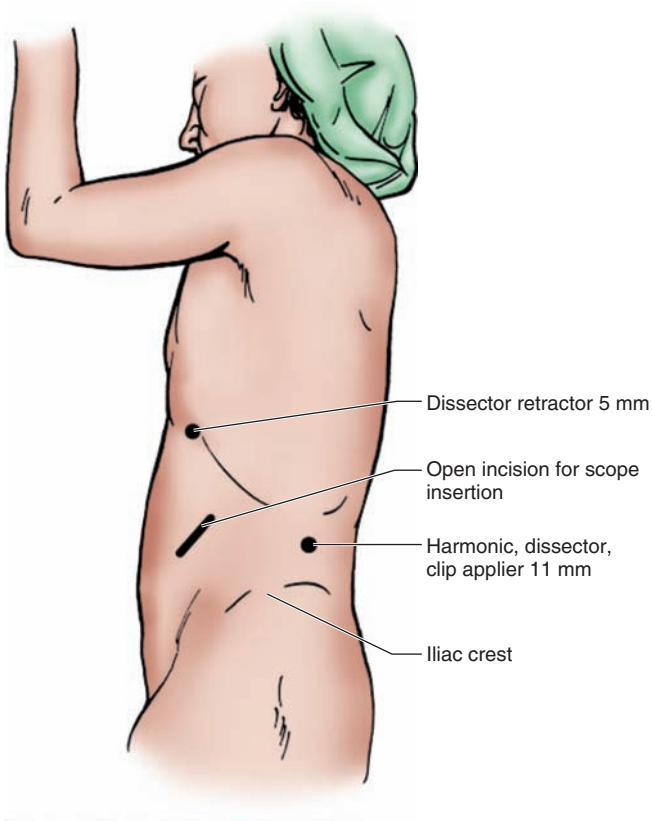

FIGURE 63-9 Port placement for left laparoscopic adrenalectomy in the right lateral decubitus position. In this example, initial abdominal entry is gained through a medial incision. A fourth port is often not required on the left.

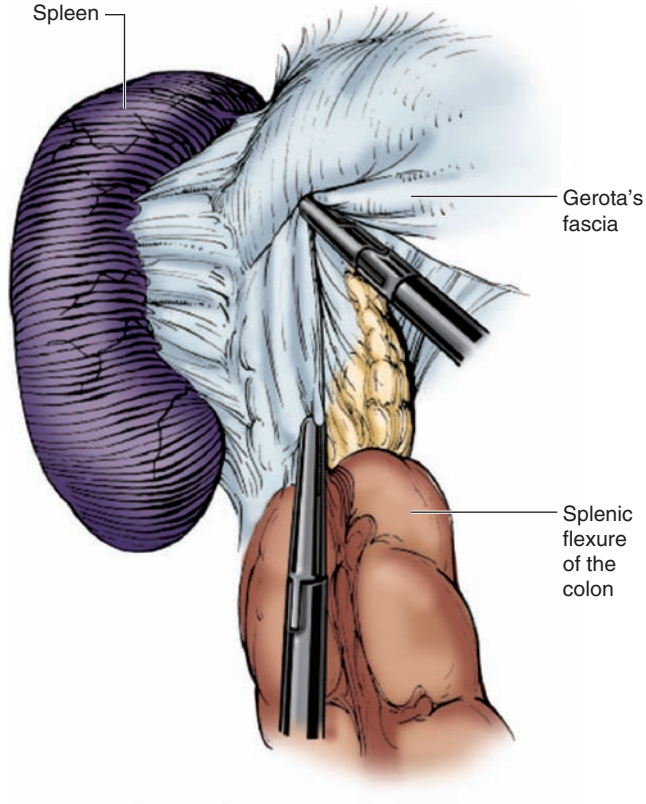

FIGURE 63-10 View during left laparoscopic adrenalectomy, showing division of the peritoneum over the kidney and progressive detachment of the spleen from the left diaphragm.

Retroperitoneoscopic Adrenalectomy

Retroperitoneoscopic adrenalectomy involves directly accessing the retroperitoneal space from the posterior approach. This does not entail entrance into the peritoneal cavity, and therefore it is not laparoscopic surgery. Unlike laparoscopic adrenalectomy, the retroperitoneoscopic approach does not require mobilization of peritoneal organs (e.g., liver, spleen, colon). Furthermore, the surgeon can access both adrenal glands from the same position, which minimizes operative time during bilateral adrenalectomy. Retroperitoneoscopic adrenalectomy is particularly useful for patients with intraperitoneal adhesions from previous laparotomy and is most suitable for small lesions positioned well above the renal hilum that do not have radiographic evidence of local invasion.

First, the patient is intubated, and all tubes and lines are placed in the supine position. Then the patient is flipped into the prone position, with the hips and knees flexed. This positioning requires the use of bolsters across the chest and hips, as well as sufficient padding for the face, arms, and knees. The abdomen should hang down between the two transversely positioned bolsters.

A small transverse incision is made just caudal to the tip of the 12th rib, and sharp dissection is used to dissect through

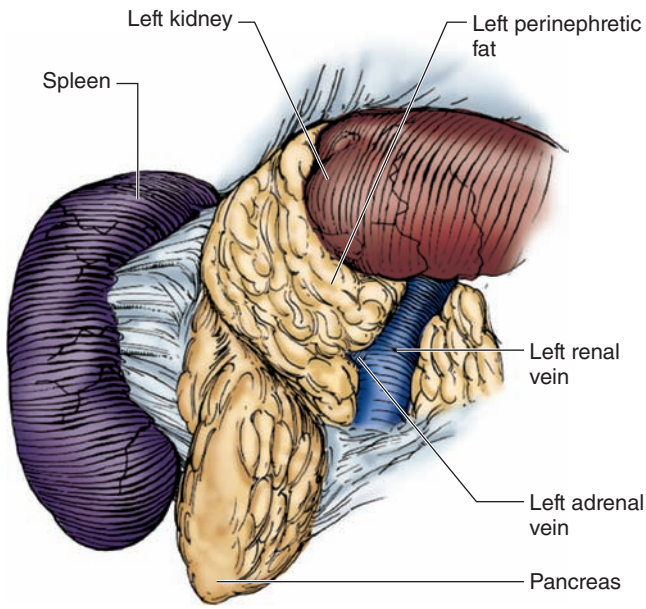

FIGURE 63-11 View during left laparoscopic adrenalectomy. The spleen had been partially mobilized and is retracting to the right by gravity. The separation between the posterior pancreas and the anterior surface of the left adrenal had been developed. The left renal vein is exposed, as well as the takeoff of the left adrenal vein.

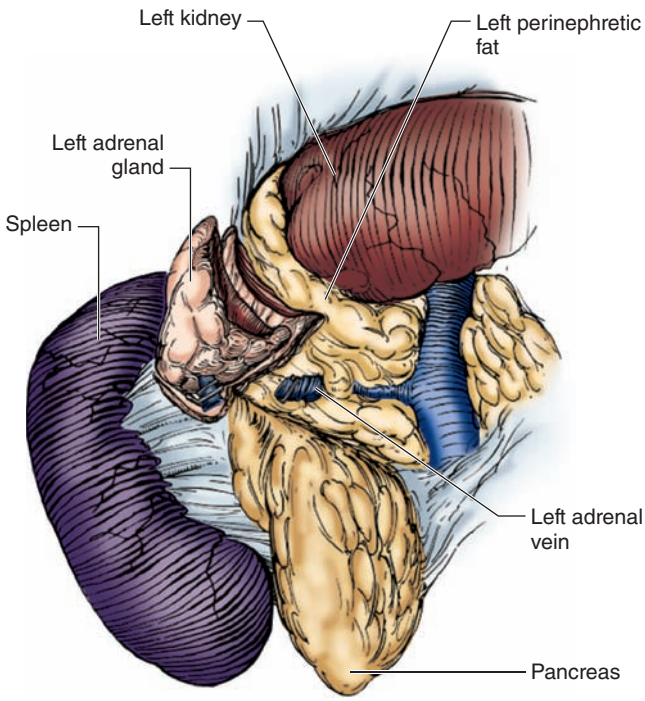

FIGURE 63-12 View during left laparoscopic adrenalectomy. The spleen is fully mobilized. The adrenal vein has been divided between endoclips. The *dotted line* indicates the line of resection.

the subcutaneous tissues and deep fascia. The length of this incision should be around 1.5 cm, which should be enough to accommodate the surgeon's index finger. Digital examination with the index finger can be used to confirm that the dissection is through the deep fascia, and it allows palpation of the smooth underside of the ribs. A second lateral 5-mm port is placed at near the midaxillary line at the same craniocaudal level under direct palpation using the index finger as a guide through the first incision. Then a third 5-mm port is placed similarly under digital palpation, just lateral to the paraspinous muscles at the same craniocaudal level. This medial port should be approximately 3 or 4 cm caudal to the lowest rib.

Then a 12-mm balloon port is placed in the middle incision to ensure that an airtight seal and the space are insufflated to a pressure of 20–30 mm Hg. A 30-degree 10-mm scope is placed in the middle trocar with the angle toward the ceiling. A blunt grasper is used though the lateral port to dissect through Gerota's fascia. Using blunt dissection, the tissues around the medial and lateral ports are cleared and space is created posterior to kidney and adrenal gland. Usually, the paraspinous muscles can be seen medially. With some blunt dissection, the peritoneal lining can be visualized laterally. At the floor of the dissection (anterior), careful blunt dissection can be used to visualize the kidney.

Dissection is carried along the superior border of the kidney, from lateral to medial to separate the top of the kidney from periadrenal fat. Usually during this portion of the dissection, the adrenal gland itself becomes evident through the periadrenal fat. On the right side, the IVC is found anterior and medial to the inferomedial border of the periadrenal fat. The adrenal vein is usually anterior and thus can be difficult to visualize. Division of the adrenal vein can be done with a LigaSure device with or without clips. The specimen side of the adrenal vein can be used to retract the adrenal gland in the cephalad and posterior dissection. The remaining attachments between the periadrenal fat anteriorly and superiorly can be divided with a LigaSure device or electrocautery. As with laparoscopic adrenalectomy, the small adrenal arteries can be controlled with either hook electrocautery or a hemostatic device; clips are usually not required. Small holes in the peritoneum are of no significant consequence and do not require repair. Removal of the specimen can usually be achieved without morcellation or extension of the incision. Closure of the deep fascia in the middle incision usually requires only a single simple nonabsorbable suture. Hernia through these posterior incisions is uncommon.

COMPLICATIONS

Endoscopic adrenalectomy is both safe and effective in experienced hands; however, there are many potential complications with this operation. The most common complications include bleeding (5.9%), wound infection (1.5%), cardiac complications (0.8%), solid-organ injury (0.7%), and pulmonary complications (0.6%).[24]

The specific risks of the procedure are related to the fact that the adrenal glands are deeply situated in the retroperitoneum and in close proximity to large vascular structures and other organs. Consequently, minimally invasive adrenalectomy poses the same anatomic risks as open adrenalectomy: major vascular injury (IVC, splenic vessels, renal vessels) and injury to the spleen, liver, and colon. Although rare, transection of the porta hepatis, hepatic artery, ureter, and renal artery has been reported.[25]

Pneumoperitoneum poses several risks for this operation aside from traumatic injury relating to port placement. The dissection of the adrenal gland is in close proximity to the posterior aspect of the diaphragm, so ipsilateral pneumothorax is a potential complication. A small pneumothorax can be followed without intervention, and larger defects can be treated with a tube thoracostomy. The pneumoperitoneum can also impair venous return that can be particularly dangerous in the setting of catecholamine surges during resection of pheochromocytoma. This risk can be minimized with pre- and intraoperative hydration. The spleen and liver are also at risk for injury during laparoscopic adrenalectomy; these organs can sustain trocar injuries, capsular tears from grasping or retraction, or vascular injury.

The most life-threatening complication of laparoscopic adrenalectomy is a vascular injury, which results from the limitations of visualization and lack of tactile confirmation. On the right, the renal vein can have an oblique course and course through the inferior portion of the dissection, causing confusion with the adrenal vein. The right adrenal vein is often well visualized with laparoscopic technique but is also

of variable location in a superior-inferior plane and anterior-posterior plane. A vein with a diameter significantly smaller than the length of a standard endoscopic clip should be viewed with skepticism if thought to be the adrenal vein. A vein with a diameter significantly larger than an endoclip or that does not clearly connect to the variegated dark yellow adrenal gland is a suspect for the renal vein and should not be divided without certain identification.

On the left, the tail of the pancreas is encountered, and it can often appear similar to the adrenal with its lobular consistency. However, the pancreas is a distinct grayish-white color in contrast to the characteristic bright coloration of the dark yellow adrenal. The granularity of the adrenal is also much finer than the lobules of the pancreas. In addition, there can be a segmental upper pole renal artery that lies just deep to the lower portion of the adrenal. The named arteries of the adrenal are all quite narrow, in the 0.5-mm range, and are often not seen during dissection. Division of an identifiable artery should therefore be very carefully considered. Any major vascular injury should prompt immediate conversion to an open technique. Regarding retroperitoneoscopic adrenalectomy, higher insufflation pressures are tolerated better with less hemodynamic compromise, in comparison to the laparoscopic technique. Intraoperative hypercarbia can be relieved by releasing insufflation and hyperventilating the patient. Subcutaneous emphysema and subcostal nerve dysfunction can be observed after retroperitoneoscopic adrenalectomy, and both are transient in nature.

OPEN ADRENALECTOMY

Open adrenalectomy can be performed via multiple approaches, depending on tumor characteristics, patient body habitus, and surgeon experience with each technique. As mentioned previously, the laparoscopic approach is not appropriate for large tumors or those with local extension; the open approach is the procedure of choice in these cases. The open approach should also be performed in cases where laparoscopy is unsuccessful or when a major vascular or visceral injury occurs. The main open approaches to the adrenal glands are addressed as follows.

Anterior Approach

The anterior approach provides excellent exposure and allows access to both adrenal glands as well as extra-adrenal foci as in the case of pheochromocytoma. The patient is placed in the supine position on the operating table, and either a midline laparotomy or bilateral subcostal incision can be used for this approach with excellent exposure. For right-side access, the hepatic flexure of the colon is taken down inferiorly, the liver is retracted superiorly, and a Kocher maneuver is performed to expose the retroperitoneal space. Gerota's fascia is identified and incised. Once the adrenal gland is exposed, the lateral and superior aspects of the gland are mobilized and the adrenal vein is ligated and divided. Given the proximity of the right adrenal gland to the IVC, the surgeon must use care when dissecting and ligating the right adrenal vein. The left adrenal gland can be exposed from an anterior approach by a medial visceral rotation of the stomach, spleen, splenic flexure of the colon, and pancreas toward the midline. The left adrenal vein can drain either into the left renal vein or the left inferior phrenic vein. The remainder of the dissection is similar to the right side.

Posterior Approach

The posterior approach is particularly useful for patients with adrenal disease who have undergone prior abdominal surgery. These patients might have dense adhesions that make an intra-abdominal exposure formidable. In this operation, the patient is placed in the prone position on the operating table, and a curvilinear incision is made starting in a paramedian line and extending laterally. After the skin and subcutaneous tissues are incised, the latissimus dorsi muscle is divided with electrocautery near its origin and the serratus posterior is divided in a similar way. The 12th rib is removed to facilitate the exposure, and the 11th rib and the pleura are retracted superiorly, which exposes the underlying Gerota fascia. The fascia is incised, and the adrenal gland and the kidney are exposed. The superior vessels are ligated and divided, and the superior aspect of the gland is dissected free. After the gland is mobilized, the adrenal vein is isolated, ligated, and divided. When the gland has been removed, closure is performed in layers.

Thoracoabdominal Approach

The thoracoabdominal incision, though morbid, has great utility for the exposure and removal of large tumors. The patient is placed in the anterolateral position, and the table is rotated to facilitate the exposure. The dissection is carried down between the eighth and ninth ribs, which allows the full exposure of the adrenal gland, renal fossa, and surrounding tissues. The remainder of the dissection is carried out as mentioned previously. If the pleural space is entered, a tube thoracostomy should be placed, and a postoperative chest x-ray obtained to exclude pneumothorax.

CONCLUSIONS

Safe and effective resection of adrenal tumors presents both anatomic and physiological challenges for the surgical team. Preoperative planning is critical with particular consideration of the size, radiographic consistency, and specific hormonal products for each tumor. For resection of benign adrenal tumors, minimally invasive adrenalectomy has been shown to be safe, effective, and offers the patient decreased surgical morbidity and decreased length of stay. With improved

technologies and further study, the role of minimally invasive surgery for adrenal disease may expand to include malignant disease both for palliative and curative intent. Open adrenalectomy, however, remains an important operation for large and malignant lesions.
