Fortunately, significant airway injuries in our experience have been exceedingly rare, occurring in only two patients. One of these injuries occurred postoperatively during reintubation for respiratory distress and one was believed to result from injury to the posterior membranous trachea from unintentional contact of the autosonic shears. In other series, tracheal injury has been associated with the resection of bulky, midthoracic tumors. This is usually either due to traction or cautery injury during esophageal mobilization. In these cases of bulky tumors, we would therefore recommend a thoracotomy, particularly if the patient has received neoadjuvant radiation.

With a median follow-up of 19 months, overall survival was similar to that after open esophagectomy. Of importance in assessing outcomes is not only overall survival but also the quality of life following esophagectomy. We have documented this by administering a validated quality-of-life instrument (Short Form-36 [SF-36]) and a disease-specific questionnaire (the Gastroesophageal Reflux Disease Health-Related Quality of Life [GERD-HR-QOL] index[44]) to patients before and after MIE. The GERD-HR-QOL instrument noted that dysphagia and heartburn scores following esophagectomy were excellent, and that only 4% of patients had severe, poorly controlled reflux. In addition, the overall quality of life as measured by the SF-36 was no different than that of age-matched controls.

In our experience, perhaps the most significant technical concern with the minimally invasive McKeown approach is the cervical dissection. Recurrent laryngeal nerve injuries, perturbations in pharyngeal transit, and swallowing dysfunction even in the absence of recurrent nerve injury are not infrequent. Moreover, as described in open series using a cervical anastomosis, anastomotic stricture and leak have been shown to occur with increased frequency.[45] Out of these concerns emerged our more recent experience with completely thoracoscopic-laparoscopic Ivor Lewis esophagectomy. However, we did first evolve through a transition phase whereby a minithoracotomy (hybrid approach) was performed for creation of the intrathoracic anastomosis.

Outside of case reports, there are currently few series reporting experience with laparoscopic-thoracoscopic Ivor Lewis esophagectomy.[46,47] Kunisaki et al described a small series of laparoscopic-thoracoscopic Ivor Lewis esophagectomies (n = 15), but the anastomotic leak rate was somewhat high (13.3%) and length of stay was prolonged (30 days).[48] We recently reported the largest series of minimally invasive Ivor Lewis esophagectomies (n = 50) published to date.[49] Of these, the first 35 included hybrid approach with a planned minithoracotomy. The last 15 patients in this series were performed with a completely laparoscopic-thoracoscopic method without need for minithoracotomy. The median length of stay was 9 days for the entire group, with the completely minimally invasive group having a significantly shorter hospitalization (7 vs 9 days). The median ICU stay was 1 day for both groups.

The anastomotic leak rate was 6%. All pneumonias (10%) occurred in the hybrid minithoracotomy group. Importantly, there were no recurrent nerve injuries.

We believe that the experience with totally thoracoscopic-laparoscopic Ivor Lewis esophagectomy will ultimately reproduce the low morbidity and mortality we have previously published with our established MIE technique. The omission of a cervical dissection has reduced our recurrent nerve injury rate to near zero. From a theoretical standpoint, one would presume that pharyngeal transit problems and oropharyngeal swallowing dysfunction should be reduced as well with a chest anastomosis. It should be emphasized that there is a steep operator learning curve associated with this approach. Both blood and lung can obscure visualization of the esophagus, which lies at the dependent aspect of the operative field. Prone positioning has been described as an alternative approach that may facilitate operative exposure and address such technical concerns.[50]

BENIGN ESOPHAGEAL DISEASE

Resection of Esophageal Leiomyoma

Leiomyomas represent the most common benign tumor of the esophagus, accounting for approximately two-thirds of all cases.[51] These tumors occur in the middle (33%) and lower (56%) esophagus, a distribution that parallels the degree of smooth muscle in the esophageal wall.[51] Consequently, leiomyoma are rarely found in the cervical esophagus, which is composed predominantly of skeletal muscle. The majority of these tumors arise from the muscularis propria and extend into the lumen of the esophagus. On occasion, however, they may arise from the muscularis mucosa, in which case they tend to pedunculate because of peristalsis.[52]

Over 85% of patients with small leiomyoma are asymptomatic. When present, symptoms are often nonspecific, such as chest pain, regurgitation, and dysphagia. On rare occasion, these tumors may ulcerate and present with gastrointestinal bleeding. Interestingly, there does not appear to be a clear correlation between the size of the tumor and either the frequency or severity of symptoms.[53,54]

The natural history of these uncommon tumors is not well understood, and therefore the guidelines for resection of asymptomatic tumors are unclear. Certainly, resection of either symptomatic tumors or those in which a malignant histology is suspected is appropriate. In most series, the criterion for resection of asymptomatic lesions has been a size greater than 3–5 cm. However, it has been well-documented that the size of these tumors can remain stable over several years.[55] Furthermore, unlike smooth muscle tumors of the stomach, the propensity of these tumors to degenerate into leiomyosarcoma is extremely rare, and in fact only two cases have ever been documented.[56,57] What is clear is that the decision to recommend surgery will depend on the morbidity associated with the procedure.

Technique of Resection

The approach to resection depends on the location of the tumor. Including our own experience, in most published series, benign esophageal tumors (ie, leiomyoma) of the thoracic esophagus are approached through a right VATS or right thoracotomy, whereas a laparoscopic transhiatal approach is employed for most distal tumors at or near the GE junction.[58–60] Although there are published case series that report resection of GE junction leiomyoma with left-sided thoracoscopy,[61] we are not in favor of this approach. Similarly, although a distal intrathoracic, benign esophageal tumor could be enucleated through a laparoscopic transhiatal approach, we believe the best exposure is achieved through the right chest. Our preference is to resect tumors through a minimally invasive approach, reserving thoracotomy or laparotomy for tumors larger than 7 cm. For the purposes of this chapter, we focus on the right VATS approach.

1. The patient is intubated with a double-lumen endotracheal tube for single-lung ventilation.
2. Esophagoscopy is performed prior to draping to confirm location of the tumor. The scope is frequently left in place to assist the surgeon in determining where to begin the myotomy. In some cases, a 54F bougie may be left in place to facilitate dissection and accentuate tumor location.
3. The patient is positioned in the left lateral decubitus position. The surgeon stands at the patient's back.
4. The thoracoscopic ports are essentially the same as those used for MIE as depicted in Fig. 19-2.
5. Exposure of the tumor is obtained by placing the diaphragm stitch, as previously described, above for tumors in the distal thoracic esophagus. Removal of benign midesophageal lesions does not always require this maneuver. Subsequently, the inferior pulmonary ligament is divided with the ultrasonic shears. The mediastinal pleura overlying the esophagus is opened sharply. Care must be exercised at this point to preserve the vagus nerve trunk and its branches. The esophagus may need to be dissected circumferentially for exposure, particularly if the tumor appears to arise from the left side of the esophagus. A Penrose drain can be placed around the esophagus and manipulated to help expose left-sided tumors (Fig. 19-17).
6. A myotomy is performed on the esophageal wall overlying the tumor (Fig. 19-18). The longitudinal muscular layer is then opened sharply and the leiomyoma is exposed. The vagal trunks should be identified and preserved during this maneuver. Because of the firm, rubbery nature of the tumor, it is often difficult to grasp and we frequently place a stitch into the tumor for traction. The plane between the tumor, muscularis propria, and submucosa is developed.
7. The tumor is then enucleated with the ultrasonic dissector, hook electrocautery, and the Endo Peanut (Covidien, Mansfield, MA).

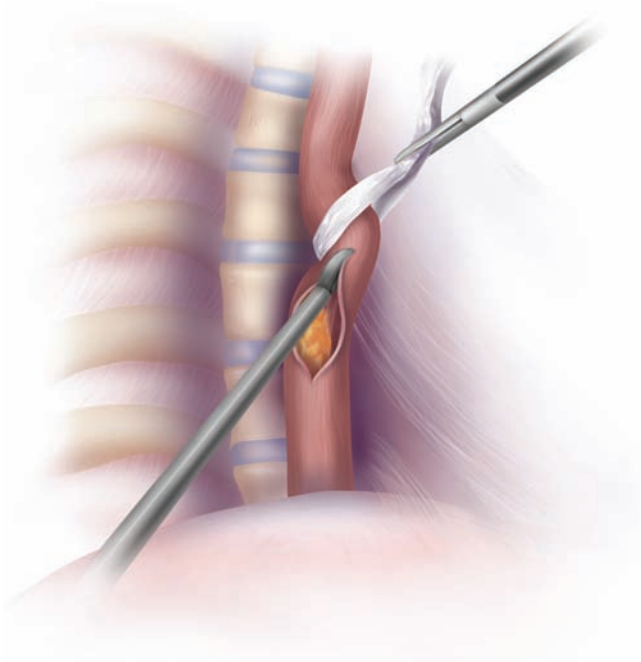

FIGURE 19-17 Resection of an esophageal leiomyoma is facilitated by use of a Penrose drain.

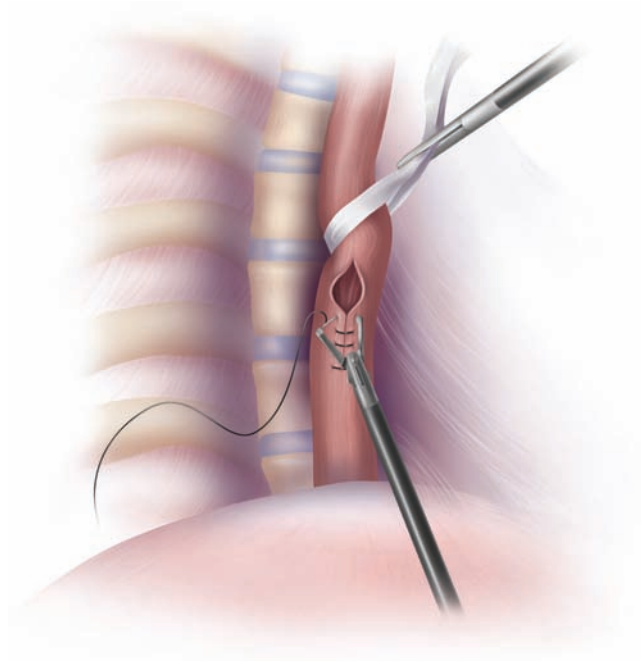

FIGURE 19-19 Closure of myotomy.

8. The tumor is removed with an endoscopic specimen bag.
9. After the tumor is removed, the esophagus is submerged under water and insufflated with air from the esophagoscope to determine mucosal integrity.
10. The myotomy is then closed using interrupted 2-0 Surgidac Endo Stitch (Fig. 19-19). Although not all surgeons feel that this step is necessary,[62] several studies have documented the occurrence of postoperative dysphagia due to the formation of a mucosal pseudodiverticulum at the myotomy site. In these cases, symptoms resolved after approximation of the myotomy.

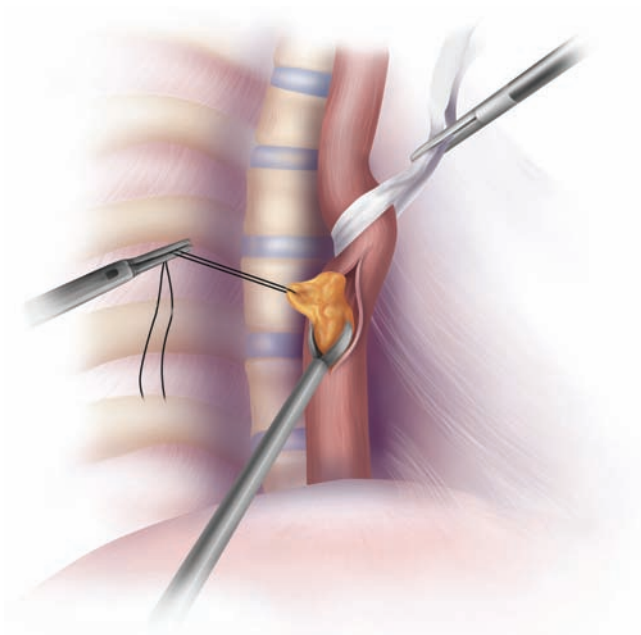

FIGURE 19-18 Thoracoscopic myotomy.

Outcomes of Minimally Invasive Thoracoscopic Resection for Leiomyoma

Between 1990 and 2005, we resected 15 patients with esophageal leiomyoma.[63] In this series, the tumor location was midesophageal in eight patients and distal third of the esophagus in six patients. All the patients with a tumor less than 7 cm in the thoracic esophagus were approached with a right VATS. Four patients with midesophageal tumors went on to require an additional antireflux procedure for either new-onset or worsening reflux. Among all patients, there were no perioperative complications and the median hospital stay was 2.3 days. One patient was noted to have a mucosal injury at time of surgery; this was repaired using an endo-GIA stapler over a bougie without complication. The mean tumor size was 2.7 cm; however, we have safely resected tumors up to 8 cm in size using minimally invasive techniques. Larger tumors do pose a greater technical challenge. As such, we recommend reserving thoracoscopic resection for tumors less than 7 cm. On the basis of this limited data set, the size of the tumor does not correlate with the development of postoperative reflux. Patients require close follow-up because of the potential for delayed postoperative reflux.

Treatment of Achalasia

The introduction of minimally invasive techniques has revolutionized the treatment paradigm of patients with achalasia. The long-term benefits of surgery over medical management have been clearly documented for many years.[64,65] However, in the past, patients were often not referred for surgery because of the morbidity of the thoracotomy necessary for an esophagomyotomy. The advent of minimally invasive techniques has led to a resurgence in surgery as the primary treatment modality for this disease.[4]

Most surgeons experienced in the treatment of achalasia have adopted laparoscopy as their preferred approach (refer to Chap. 14). Indeed in our own series of minimally invasive esophagomyotomy, 92% of patients underwent laparoscopy as opposed to thoracoscopy.[66,67] Similarly, the initial group to describe VATS myotomy has now come to favor laparoscopy.[68] However, there are reasons to consider thoracoscopy as an acceptable alternative. During thoracoscopy, the distal esophagus and GE junction are visualized without the necessity of dividing the phrenoesophageal ligament. Proponents of thoracoscopy claim, consequently, that the preservation of this ligament will prevent postoperative reflux and obviate the need for an antireflux procedure, which is usually added after a laparoscopic esophagomyotomy.[69]

However, there are some inherent disadvantages to thoracoscopic myotomy. First, anesthesia is complicated by the need for single-lung ventilation. In addition, thoracoscopy is more uncomfortable for the patient, particularly because a "minithoracotomy" access incision[70,71] and a chest tube are often required for the procedure. More important is the concern that the myotomy may be incomplete when performed thoracoscopically. Critics of the operation cite the difficulty of working in a plane perpendicular to the esophagus and extending the myotomy adequately onto the stomach when working through the chest.[72] Additionally, the addition of a partial fundoplication to myotomy for the treatment of achalasia has become standard practice and is readily performed and with reproducible results using laparoscopy.

Overall, thoracoscopic myotomy has been shown to provide symptomatic improvement in 76% of patients with achalasia. These results do not compare favorably to laparoscopy, in which 94% of the nearly 500 patients reported in the literature have had relief of their dysphagia.[72] In addition, a 35% rate of postoperative reflux is associated with thoracoscopy, compared with a rate of only 9% following laparoscopic myotomy and fundoplication.[73]

Most recent reports of thoracoscopic myotomy describe a "hybrid operation," which utilizes a minithoracotomy through which standard instruments are used.[74,75] Additional port sites are placed to provide illumination and counter-retraction. This approach likely reflects the preferences of thoracic surgeons who may not be as familiar with techniques of laparoscopy. We favor laparoscopy, as do the vast majority of surgeons performing myotomy. In our opinion, only the rare patient with a hostile abdomen from multiple prior abdominal procedures would be a potential candidate for VATS myotomy. Even in this setting, a laparoscopic approach would still be considered preferable.

Other Indications

A variety of other thoracoscopic esophageal procedures have been described, though their merit is difficult to determine due to the rarity of the diseases and the small number of patients studied. Aside from esophageal tumors (benign and malignant) and achalasia, thoracoscopic management of esophageal diverticulum has also been reported in the literature. Similar to the literature on leiomyoma, many authors report utilizing a laparoscopic transhiatal approach for epiphrenic diverticula at or near the GE junction. Palanivelu et al reported one of the larger more recent experiences with a minimally invasive approach.[76] In their series, eight epiphrenic (defined as within 10 cm of the GE junction) and four thoracic ("midesophageal") diverticula were resected. Laparoscopy (with or without myotomy and fundoplication) was employed for the epiphrenic diverticula whereas prone position right-sided thoracoscopy was used for the thoracic diverticula. Myotomy was included only when an underlying motility disorder was present. The only anastomotic leak occurred with a midthoracic diverticulum resected by VATS. In a few, very small series (fewer than five patients), results were described as "excellent."[77,78] However, in a larger series of 11 patients from France, three developed an esophageal fistula and two required reoperation.[79] The authors of that study concluded, "Minimally invasive surgery does not confer significant benefit compared with open surgery in the treatment of diverticula of the thoracic esophagus." We have reviewed our experience with this disease.[80] Of 20 patients who underwent minimally invasive surgery for esophageal diverticula (either laparoscopy or VATS) at UPMC, four patients developed an esophageal leak and one death occurred as a result. Overall, the results from these small case series of thoracoscopic resection of midesophageal diverticula suggest the potential for considerable morbidity with a 20–30% leak rate. Management of epiphrenic diverticula with a minimally invasive laparoscopic approach (resection with or without myotomy and fundoplication depending on underlying pathology) seems to yield better results with low morbidity.

Thoracoscopic treatment of Boerhaave's syndrome[81,82] and repair of an anastomotic leak following esophagectomy[83] have also been described in case reports. A minimally invasive approach certainly merits consideration in these cases only if the surgeon feels he/she can make safe and expeditious progress in these semiurgent cases. In general, we approach the majority of these cases through an open approach.

PERSPECTIVE ON MALIGNANT ESOPHAGEAL DISEASE

Thomas R. DeMeester

It was a pleasure to receive a letter from Dr Michael Zinner inviting me to write a perspective on the chapters of Dr Simon Law's group from Hong Kong on the diagnosis and treatment of esophageal cancer, Dr David Sugarbaker's group from Boston on the techniques used to resect the esophagus and reconstruct the foregut, and Dr James Luketich's group from Pittsburgh on minimally invasive esophagectomy. Of truth, I have rarely read such well-written and thoroughly thought-out reviews. While reading, I identified areas where I was motivated to comment on the discussion from my personal experience. These usually took the form of helpful thoughts or alternatives. Occasionally, they raised a note of caution or took a controversial point of view.

The reason for the dramatic rise in adenocarcinoma of the esophagus continues to remain a mystery even though it represents the largest epidemiologic change ever recorded for a solid cancer. The rise is largely confined to the Caucasian population and is widely attributed to gastroesophageal reflux disease and its complication, Barrett's esophagus. Some have also evoked the rise in obesity as the cause. Based on sound logic, I still support the hypothesis that potent acid suppression therapy played a role in the epidemiologic change. The incidence of adenocarcinoma began to rise in 1975; the same time acid suppression with H_2 blockers became widely available. Over time the H_2 blockers were largely replaced by proton pump inhibitors that had a greater capacity to suppress acid. Although this hypothesis has been difficult to prove short of a large and long prospective randomized study, an unbiased review of the small nonrandomized studies published in the surgical and medical literature to date will convince the practitioner of the truth of this hypothesis. A recent study[1] showed that medically treated patients who had relief or mildly persistent reflux symptoms while on proton pump inhibitors have significantly higher odds of developing esophageal adenocarcinoma than medically treated patients who have persistent severe reflux symptoms. My explanation for this observation is that acid suppression therapy decreases reflux symptoms by decreasing the acid content of gastric juice and causing the pH to rise from less than 2 to 4 or greater, that is, in the range of a weak acid. On the stealth side, this increase in pH also increases the solubility of bile acids in the refluxed neutralized gastric juice. Bile acids at the pH of 4–6 have ready access into the Barrett's epithelial cell. When in the cell, bile acids are known stimulants of CDX2, the most powerful genetic stimulus for the development of intestinal metaplasia. They also stimulate the expression of genes involved in the carcinogenesis of intestinalized Barrett's epithelium to adenocarcinoma. In contrast, the persistence of severe reflux symptoms while on medication indicates incomplete acid suppression. The persistent acidic gastric juice causes bile acids to precipitate out of solution. This nullifies their effect, hence less or no intestinal metaplasia or adenocarcinoma.

I take exception, as does Dr Law, with the current dogma that there is no evidence proving that surveillance will result in a better survival of patients with Barrett's esophagus who progress to adenocarcinoma. Rather, I believe that all individuals who are identified as having Barrett's esophagus should enter a surveillance program. In our experience surveillance of patients with Barrett's esophagus does detect tumors at an earlier stage. Indeed, the percentage of patients presenting with an early T1 N0 adenocarcinoma has increased over time and, in the more recent years, account for nearly 50% of all resected tumors. Looked at from a different perspective, 86% of esophageal adenocarcinomas identified by Barrett's surveillance have stage I disease.

In the new staging system cancers of the gastric cardia that extend into the gastroesophageal junction are classified as adenocarcinomas of the esophagus rather than the stomach. This is an improvement but still is imprecise due to the inability to consistently define the location of the gastroesophageal junction. In 2000, the Association of Directors of Anatomic and Surgical Pathology defined the *gastroesophageal junction* as a horizontal line drawn across the end of the tubular esophagus at the point where it begins to flare into the stomach. Using this definition, there is evidence that adenocarcinomas of the gastric cardia commonly

arise in areas of intestinal metaplasia within the gastric cardia that have strong similarities to adenocarcinomas of the distal esophagus. We have suggested that the location of the gastroesophageal junction is defined more accurately by histology as the proximal limit of gastric oxyntic mucosa. The area cephalad to this limit is histologically the esophagus and in normal people is lined by squamous epithelium and in patients with reflux is lined, to a variable extent, with different types of metaplastic columnar epithelium (cardiac, oxyntocardiac, and intestinal). Important to understanding disease at this location is to obtain an accurate estimate of the incidence of Barrett's adenocarcinoma. With greater precision it is likely that the number of Barrett's adenocarcinomas would be more than double. This would give us a greater appreciation for the exponential rise of adenocarcinoma in this area and could well make the screening of patients with Barrett's more cost-effective.

Endoscopic surveillance of patients with Barrett's esophagus has identified a rather large number with high-grade dysplasia in the Barrett's segment. Most regard this finding as a threshold for intervention. The new technique of endoscopic mucosal ablation has allowed the treatment of high-grade dysplasia with preservation of the esophagus and a morbidity and mortality lower than an esophagectomy. The survival following either treatment is similar. This has reduced the use of surgical resection to treat these patients. Many, however, have visible lesions within the flat Barrett's segment such as a nodule or ulcer. Such lesions must be removed by endoscopic mucosal resection to determine the nature of the lesion and, if a cancer, its depth of penetration into the esophageal wall. If a cancerous lesion is limited to the lamina propria, ablation of the Barrett's segment can proceed. If a cancerous lesion extends beyond the muscularis mucosa, there is a significant increase in the probability of lymph node metastasis and an esophagectomy is required. Despite flawed statements to the contrary, there is no "safe" level of invasion into the submucosa that would extend the use of endoscopic resection. To manage these patients correctly requires that surgeons become adept at endoscopy and endoscopic mucosal resection. The opportunity for this training is limited and is an issue that must get the attention of the Residency Review Committee for Surgery and the American Board of Surgery. The new therapy is extremely work intensive and is associated with the risk of developing cancer during the treatment. Consequently a vigilant support staff is necessary to handle the patients. In our experience patients who have high-grade dysplasia in a long segment of Barrett's esophagus, or in an anatomically short esophagus with a large hiatal hernia, or in an esophagus with a severe motility problem, or have multifocal high-grade dysplasia or multiple failures of ablation therapy are not candidates for esophageal preservation therapy and are better off having a vagal sparing esophagectomy. This form of esophagectomy is associated with less perioperative morbidity and a shorter hospital stay than a standard transthoracic or transhiatal esophagectomy. Further, its late morbidity, including weight loss, dumping, and diarrhea, is significantly less.[2]

Surgical resection remains the mainstay of treatment for fit patients with localized esophageal carcinoma that has invaded into the submucosa or beyond. In my mind, the only exception to this rule is a cervical esophageal cancer that is located sufficiently close to the cricopharyngeal muscle to prevent a clear resection margin. These patients are better off receiving definitive radiochemotherapy. If a recurrence occurs, a pharyngolaryngoesophagectomy is performed as a salvage procedure. It is critical that these patients understand this approach prior to treatment and are willing to submit to yearly surveillance after the definitive radiochemotherapy. Fit patients with tumors in the lower cervical or upper thoracic esophagus are treated with cytoreduction of the tumor by radiochemotherapy followed by resection and reconstruction with a free jejuno-interposition. Fit patients with tumors in the mid or lower thoracic esophagus, gastroesophageal junction, or gastric cardia are treated with an en bloc esophagectomy and complete lymphadenectomy. The superiority of this approach has become gradually apparent over the years with the greatest benefit seen in patients with fewer than eight lymph nodes involved in specimens that contain more than 30 resected nodes. The historical development of this position is nicely documented in the 10 publications.[3–13]

Critical in performing an en bloc esophagectomy is that the proximal, distal, and radial margins are free of tumor. I agree with Dr Law's comment that the proximal esophageal margin is most critical and a good guide is to obtain 10 cm of grossly normal esophagus above the superior margin of the tumor. After removal, the fresh specimen contracts to approximately 50% of its length or down to 5 cm of grossly normal appearing esophagus. With this length of margin, there is less than a 5% chance of an anastomotic recurrence. Similarly, it is important to have a greater than l-mm free circumferential radial margin on the specimen after a curative resection. This has been shown to be an important independent prognostic variable.[13] Simply put, patients with less than a 1-cm free circumferential radial margin in what would otherwise have been a curative resection doubles their risk of dying from cancer. As would be expected, the effect of a clear circumferential radial margin is most important in patients who have limited or no lymph node involvement.

An en bloc resection includes a complete lymphadenectomy. The number of lymph nodes removed is an independent predictor of survival. To maximize this survival benefit, a minimum of 23–29 nodes need to be removed. Taking additional nodes is of benefit, but the effect begins to drop off. When analyzed by Cox regression, the number of lymph nodes removed modeled as a continuous variable was the third most important prognostic factor behind the number of involved nodes and the depth of tumor invasion. Of the three factors, the number of nodes removed is the only predictor of survival that can be influenced by the surgeon. The operation most likely to maximize the number of nodes removed is the two-field en bloc esophagectomy.

I am not convinced that adding a third field, that is a cervical node dissection, improves the survival sufficiently to overcome the increased morbidity. Rather, we have taken

the approach of obtaining a positron emission tomography (PET) scan and ultrasound examination 1 year after the initial resection and performing a modified radical neck dissection if involved neck nodes are detected or suspected. An exception to this policy is when unsuspected involved recurrent laryngeal nodes are discovered while performing the neck dissection during the initial operation in preparation for a neck anastomosis. In this situation a cervical node dissection is added to the initial operation to remove recurrent laryngeal and deep cervical nodes on the left.

In a unique study, the en bloc and transhiatal resections were compared using a retrospective case-control study of nonrandomized patients with similar-size transmural tumors (T3) and lymph node metastasis selected at random from our registry. The result showed that the survival benefit of an en bloc resection was limited to patients with eight or fewer involved nodes. There was no difference in outcome when nine or more lymph nodes were involved. When this information was applied to the 5-year outcome of the only randomized studies done to compare the two resections, only those patients with one to eight involved lymph nodes significantly benefited from an en bloc resection. This finding fits with the results of a multi-institutional international study showing that the probability of systemic disease is 50% when three nodes are involved and approaches 100% when more than eight nodes are involved. Based on these studies, the en bloc resection is most likely to benefit patients with eight or fewer lymph nodes involved. Beyond this number the likelihood of systemic disease approaches 100%, and neither an en bloc nor a transhiatal resection provides a long-term benefit.

The most dreaded complication of esophagectomy is ischemic injury to the conduit used for reconstruction. This is often the cause for an anastomotic leak and a cascade of sepsis, multiorgan failure, and death. Factors known to contribute to this complication are diabetes, hypertension, cardiac arrhythmia, chronic obstructive pulmonary disease, and neoadjuvant therapy. Indeed, I believe that conduit ischemia is the "Achilles heel" of a successful esophageal resection and reconstruction. When faced with a worrisome ischemic conduit, we pull the conduit up and anchor it in the neck without performing the anastomosis. A Prolene stitch is placed into the conduit and brought out to the subcutaneous tissue for a guide to find the conduit at the time of delayed reconstruction. The proximal esophageal remnant is brought out to the neck as an esophagostomy and a feeding jejunostomy constructed in the abdomen. Ninety days after the esophagectomy, a cervical esophagogastrostomy is performed through the original neck incision. Over the years we have used this strategy in 35 patients. At the time of reconstruction, all had well-perfused gastric conduits and the delayed anastomosis healed without a leak, wound infection, or sepsis.[14]

As Dr Law pointed out, the past two decades have witnessed a proliferation in chemotherapy and chemoradiotherapy trials in esophageal cancer. The basis for this explosion is the suboptimal surgical cure rate for advanced cancer. True, distant failure remains a major problem in patients with advanced cancer, and a search for more effective systemic drugs as well as a method to select the right drugs for the right patient needs to be supported and encouraged. I agree with Dr Law that currently the results of neoadjuvant chemoradiation therapy are conflicting, and that published meta-analysis show minimal to no benefit. Despite this, neoadjuvant chemoradiation is widely practiced in the United States. A limitation of the current randomized trials is the lack of accurate staging prior to randomization. If randomization is done correctly, major known factors that affect survival, such as stage of disease, need to be evenly distributed in the study groups prior to randomization as the concept of randomization is used only to manage unknown factors that affect survival. I have concluded that the studies done to date have shown neoadjuvant therapy to be only effective in causing cytoreduction of the primary tumor. The lack of a similar response in the secondary lesions is an indication that their sensitivity to chemotherapy is different than the primary tumor, perhaps through tumor cell interaction with host tissues cells and their cellular immune response. I would recommend that future neoadjuvant studies be done only on patients of similar stage based on carefully done pretreatment minimally invasive surgical staging. I would also suggest an adjuvant chemotherapy trial where the chemotherapy given is based on chemosensitivity studies done on the involved lymph nodes removed at the time of surgery or on biopsies of solid-organ metastasis done at the time they are discovered after surgery. Clearly, a new approach is needed. The movement toward definitive chemotherapy is based on its known cytoreduction effect on the primary tumor. The concept is designed to eliminate surgical therapy because surgery as currently performed has failed to control local disease. This is largely due to the resistance and inability of surgeons to perform an en bloc resection. After an appropriately done en bloc resection the local recurrence rate is less than 2% whereas after transhiatal resection it is 25% or greater. My concern is that our failure to centralize esophageal surgery in the United States, as is currently being done in England, will relegate surgical therapy from a primary position in esophageal cancer to an adjuvant role.

Dr Wee and Dr Sugarbaker provide an excellent description of the en bloc esophagogastrectomy done through what is known as the *tri-incision* or *McKeown technique*. We perform the operation similar to their description with a few exceptions. We begin in the right chest by dividing the intercostal veins as they join the azygos vein from the arch down to the diaphragmatic hiatus. We then dissect out the intercostal arteries and follow them to where they join the aorta. The aorta is then easily skeletonized from the right and over into the left chest as the left intercostal arteries pass directly posterior to the costospinous junctions and have never interfered with this dissection. The mobilized azygos vein is divided at its junction with the superior vena cava. Both the azygos vein and the thoracic duct are taken with the specimen. The distal azygos vein and thoracic duct are ligated adjacent to the spine deep within the esophageal diaphragmatic hiatus, using a laparoscopic endo-loop. The proximal thoracic duct is divided later in the dissection and does not leak because of proximal valves. Both the right and left sides of the chest are drained

using ½-in Jackson-Pratt (J-P) drains positioned adjacent to the spine on the right and aorta on the left and both resting on the posterior chest wall. The drains are placed through the esophageal diaphragmatic hiatus during the abdominal portion of the procedure after the specimen has been removed and before the gastric conduit has been pulled up. The drains are brought out through stab wounds in the right and left upper quadrant. This allows the right and only chest tube to be removed on the first or second postoperative day. We also skeletonize the superior and anterior wall of the common and right hepatic artery, the superior and inferior wall of the portal vein, and the superior and anterior wall of the splenic artery out to the splenic hilum. Skeletonizing the inferior wall of the portal vein is done by using a vein retractor to displace the vein caudally and using the cautery along the superior border of the pancreatic head. The width of our gastric conduit is 3–4 cm, and a pyloroplasty is performed using an end-to-end stapler (EEA, US Surgical, Norwalk, CT) inserted through the conduit staple line near the antrum and taking a cookie bite out of the anterior portion of the pyloric ring.

Dr Luketich's group deserves the credit for being on the frontier of adapting esophagectomy into a laparoscopic and thoracoscopic procedure. Their work is commendable and has shown that there is some reduction in procedural morbidity, postoperative discomfort, and length of hospital stay, but not as much as one would suspect. To their credit they appear not to have limited the extent of the resection to accommodate the new approach but rather creatively altered their approach to maintain the extent of the dissection. There is a point when the benefits of minimally invasive surgery are overcome by the extensiveness of the internal surgical dissection and manipulation. When that point is reached, the advantages of a minimally invasive procedure will diminish and the world of surgery will continue to do such a procedure openly until further technological developments occur that will allow us to go further in our quest for "user-friendly" surgery. I believe minimally invasive esophagectomy is near that point.

PERSPECTIVE ON MALIGNANT ESOPHAGEAL DISEASE

Lee L. Swanstrom

Descriptions of the techniques and reasons for esophageal resections are presented by three leaders in esophageal surgery, working at major, high-volume esophageal centers. A thorough review of the epidemiology (such as is known) and international differences in approaches and outcomes for esophageal cancer treatments is made by Dr Law who points out the ever-increasing differences between the Western and Eastern hemispheres. In the East and Middle East, mid and proximal squamous cell cancers are by far the most prevalent, related to the persistence of carcinogenic environmental exposures. The rapid growth of adenocarcinoma in the West is a more complex issue; at our center, Barrett's esophagus–related cancers now represent 92% of esophageal cancers presenting for treatment. Unfortunately this is not totally related to the decrease in squamous cancers secondary to the decreasing incidence of smoking and other environmental factors. It is more related to the incredibly rapid growth in the incidence adenocarcinoma—now the most rapidly increasing cancer in North America. As Dr Law points out, this is probably related to the increasing incidence of both morbid obesity and gastroesophageal reflux (GER). An additional factor in either the development or, more likely, the progression to cancer may be the widespread use of proton pump inhibitors (PPIs) as a symptomatic treatment of GER. Avissar et al have shown that, at the biologic level, genetic damage that is related to dysplasia progression is facilitated by the pH environment created by usual doses of PPIs.[1] Certainly the fact that many patients with Barrett's esophagus have no or minimal GER symptoms complicates the possibility of screening to turn the tide of this cancer. Dr Law presents the arguments against screening very well—basically, too rare a cancer in too large an "at-risk" population. There remains a movement, however, that argues strongly for screening of high-risk individuals.[2] Their argument includes the ease of screening, the high percentage of Barrett's esophagus in the gastroesophageal reflux disease (GERD) population (8–17%), and the 0.5–1% per annum dysplasia progression, which screening advocates describe as the equivalent risk profile of colon polyps. Colon polyps occur in 15% of colonoscopies, have a cancer progression risk of 0.5–1% per year, and yet claim a high priority for endoscopic screening. Finally, the argument that Barrett's screening is irrelevant because nothing would be done for anything but high-grade dysplasia (HGD) Barrett's esophagus is falling by the way as technologies like radiofrequency ablation (RFA) or cryotherapy show good efficacy at eradicating Barrett's esophagus[3,4] and laparoscopic antireflux surgery induces regression in 30–40% of cases.[5] Therefore, we may still see a future where routine screening for Barrett's esophagus makes sense, particularly as cancer rates continue to increase and better risk factor stratification is developed.[6]

All three chapters cover the never-ending controversy over the transhiatal/transthoracic approaches. Save the obvious holdout,[7] there seems to be a gradual move to a more aggressive node-removing approach with a very gradual shift in outcomes data to support better cancer outcomes with en bloc resection at the cost of markedly increased operative morbidity.[8] The introduction of laparoscopic/thoracoscopic surgical approaches has further muddied these waters. This confusion arises from the conflict between the aspects of minimally invasive esophagectomy (MIE) that emphasizes less patient morbidity (with perhaps the implication of poorer oncologic outcomes) versus the absolute push for curative resection (for those that survive the surgery). This movement toward "less invasiveness" is not unexpectedly resisted by many established programs who have worked hard to optimize surgical outcomes for esophageal cancers and who are sought out by patients familiar with their well-publicized expertise. The majority of institutions, however, are faced with the referral dilemma engendered by the perception of esophagectomy being a highly morbid procedure, with poor long-term quality of life and having no survival advantage over chemoradiation. An actual quote from a leading medical periodical states "Recent trials fail to identify any significant advantage associated with the routine use of surgery for most patients."[9] In my opinion, the migration to endoscopic techniques is inevitable—not only because it offers a new paradigm of a better (or equivalent) oncologic outcomes

due to better imaging, better access, and less patient morbidity, but also because most surgeons will never see patients with esophageal cancer in referral if all they offer is "traditional" esophagectomy. Arguments for minimally invasive approaches to GI cancers have intrinsic appeal: applying the "minimally invasive philosophy" to evidenced-based colorectal cancer treatments has resulted in recommendations that all colorectal cancers be approached laparoscopically whenever possible. In 2009, the National Health Service (NHS) in the United Kingdom, recognizing the preponderance of data in support of an MIS approach, mandated its use to all HMS participants.[10] I would propose that esophageal cancer treatments will eventually follow the same path.

As both Dr Sugarbaker and Dr Luketich have emphasized, esophagectomy is all about the details. This is true both for intraoperative technique and for postoperative care. Increasingly, it is obvious that to achieve a lower mortality and morbidity rate, the institutional system may be more important than a particular surgical approach or even to the experience of the surgeon.[11] Ideally though, esophagectomy is done both by a skilled experienced surgeon and in a high-volume system-oriented institution. Nonetheless, it is eternally interesting for surgeons to discuss the operative details of a surgical procedure and esophagectomy is a fertile field for controversy and differing opinions.

To date, most MI esophagectomy techniques have sought to replicate their open equivalents, but the focus is on the minimally invasive approach; this has led to an implication that minimally invasive approaches would be a patient-pleasing compromise to oncologic outcomes. Perhaps a better mindset would be to address the question: Can the potential advantages of an MI approach (magnification, precision, shorter hospital stay, fewer wound complications, quicker return to presurgical activity levels, less immunosuppression) be hybridized onto current established techniques? Our group has explored the possibility of using laparoscopy or thoracoscopy to replicate en bloc esophagectomy in a less morbid way—either by transhiatal laparoscopic en bloc esophagectomy for distal tumors or thoracoscopic formal en bloc resections.[12] Replicating the "gold standard" open procedure with no compromise and with expected patient benefit has been demonstrated feasible by the aggressive program at the University of Pittsburgh.[13] Unfortunately it remains a consistent concern that MI approaches take more time and demand extraordinary (unobtainable?) skills. While the latter is perhaps irrefutably true, but not insurmountable, the time element may require innovative thinking to overcome.

STAGED ESOPHAGECTOMY

There has been some interest in performing MIE in a two-stage manner—primarily to provide an ischemic preconditioning of the gastric conduit in order to minimize the chance of ischemic complications at the anastomosis but also to compensate for the increased operative times of MIE and the increased mental workload of an endoscopic approach.[14] No randomized comparisons have yet been published that would document any advantages with this approach, but it has appeal for MIE as it can be conceived as an initial staging laparoscopy followed by the definitive resection 7 days later. Our current protocol calls for laparoscopic staging, celiac/hepatic node dissection, left gastric division, and placement of a feeding jejunostomy.

Changes in the thoracic portion of the procedure are an interesting change from a standard approach. Cadier has popularized the performance of the thoracic mobilization in the prone position. This has the advantage of having gravity as a retractor for the lung, which permits the surgeon to have fewer ports and superb visualization.[15] We have also adopted the use of positive-pressure capnothorax to perform thoracic mobilization. This involves the use of standard laparoscopic trocars rather than thoracoports without valves. The ports are connected to a standard laparoscopic insufflator set to a low pressure (10 mm Hg) that effectively collapses the lung without the need for a double-lumen endotracheal tube. This has the additional advantage of displacing the mediastinum, creating more operative space. Having used this technique for the past 20 years, we have found that the vast majority of patients will tolerate it and that the exposure and simplicity of the approach are superior to standard VATS techniques.

A final comment is made regarding the width of the gastric conduit or "neoesophagus." Narrow tubes versus wide tubes versus full gastric pull-up remain a controversial topic. We have favored a narrow conduit as per Akiyama, all be it at a cost of a higher leak rate due to elevated intraluminal pressures during the period of mucosal edema.[16] We feel that the benefits of long-term esophageal clearance and better swallowing outweigh the troublesome but self-limited risk of anastomotic leaks. Once again, however, there is no prospective comparative data that confirm this personal bias.

CONCLUSION

Esophageal cancer and cancer surgery are rapidly changing—epidemiologically and from the "consumer's" (ie, patient's and referring physician's) viewpoint. Surgery has been slow to react to this change and is in danger of becoming increasingly irrelevant in the face of improvements in noninvasive early cancer treatments (mainly endoscopic), definitive chemoradiation, and, in the future, highly targeted novel therapies. It is good that leaders in the field are exploring improvements in standard surgery outcomes as well as novel minimally invasive approaches—providing patient-friendly alternatives will help ensure the continued relevancy of surgeons in esophageal cancer treatments.

BENIGN GASTRIC DISORDERS

21

Ian S. Soriano • Daniel T. Dempsey

INTRODUCTION

The surgical management of benign gastric disorders has evolved significantly over the past 30 years. Elective surgery for ulcer disease has largely been abandoned in favor of medical management with surgery being utilized mainly for complications after failed medical treatment. Most elective (and some emergent) gastric procedures can now be performed with laparoscopy if local expertise is available, augmented by either radiologic (mainly via intra-operative ultrasound) or endoscopic guidance for more accurate localization. These techniques can help the surgeon perform a more targeted resection because wide margins are not necessary.

HELICOBACTER PYLORI INFECTION

When Marshall and Warren elucidated the relationship between *Helicobacter pylori* and peptic ulcer disease, a discovery for which they were later awarded the Nobel Prize in Medicine, they rekindled the hypothesis that this common clinical malady was an infectious disease.[1] *H. pylori* is a gram-negative spiral flagellated organism that currently infects more than half of the people in the world. The prevalence of *H. pylori* infection varies among populations and is strongly correlated with socioeconomic conditions. In a number of developing countries, *H. pylori* infection affects more than 80% of middle-aged adults. Infection rates are lower in industrialized countries. Epidemiological data indicate that the prevalence of infection in the United States has been declining since the second half of the 19th century, with the decreases corresponding to improvements in sanitation. Nonetheless, *H. pylori* infection is predicted to remain endemic in the United States for the next century.

Human beings are the only reservoir for *H. pylori*. Infection is presumed to occur by oral ingestion of the bacterium. Direct transmission from person to person occurs via saliva and feces, and infection also occurs through contact with contaminated water. In developing countries, most individuals are infected during childhood. Family members are at increased risk of infection. A number of occupations also show increased rates of *H. pylori* infestation, notably health care workers. Infection with *H. pylori* is a chronic disease and does not resolve spontaneously without specific treatment.

H. pylori has evidently adapted to the hostile gastric environment and displays a number of features that permit its entry into the surface mucus layer, attachment to gastric epithelial cells, evasion of immune responses, and persistent colonization despite luminal acidity. Up to 15% of the protein in a helicobacter organism is composed of cytoplasmic urease that converts periplasmic urea into CO_2 and ammonia, the latter buffering the surrounding acid.[2]

Host Response to *H. Pylori*

H. pylori infestation is followed by continuous gastric inflammation in virtually all individuals. Because spontaneous cure is unusual for most infected individuals, this means that *H. pylori* gastritis is a lifelong affliction. Worldwide, *H. pylori*–induced gastritis accounts for 80–90% of all gastritis.

H. pylori infection is not invasive of the gastric mucosa, and the host immune response is triggered by the attachment of bacteria to surface epithelial cells. The initial inflammatory response is characterized by recruitment of neutrophils, followed sequentially by T and B lymphocytes, plasma cells, and macrophages. The resultant chronic gastric inflammation in affected individuals is characterized by enhanced expression of multiple cytokines.

The relationship between *H. pylori* infection and ulceration is overwhelmingly strong; multiple observations establish *H. pylori* as a factor in the pathogenesis of duodenal ulceration.[3–7] Most of the evidence is inferential. An effective vaccine has not yet been developed.

Observations that support *H. pylori* as a factor in the pathogenesis of human duodenal ulceration include the following:

1. *H. pylori* infection is invariably followed by the development of chronic gastritis, and the organism is the primary cause of chronic active gastritis worldwide. The infectious response to *H. pylori* is characterized by nonerosive inflammation of the gastric mucosa. Antral gastritis is present histologically in patients with duodenal ulcer, and *H. pylori* can be isolated from gastric mucosa of ulcer patients.
2. *H. pylori* binds only to gastric-type epithelium. Gastric metaplasia of the duodenal bulb is a nonspecific response to damage, which develops after infestation of the gastric mucosa. Antral gastritis with *H. pylori* is preceded by active chronic duodenitis. Metaplastic gastric epithelium is colonized by *H. pylori* from gastric sources. Gastric metaplasia is extremely common in duodenal epithelium surrounding areas of ulceration.
3. Eradication of *H. pylori* with antibiotics that have no effect on acid secretion leads to ulcer healing.
4. Therapy of peptic ulceration with bismuth compounds, which eradicate *H. pylori*, is associated with reduced rates of ulcer relapse relative to acid suppression therapy.
5. Relapse of duodenal ulcer after eradication of *H. pylori* is preceded by reinfection of the gastric mucosa by the organism.

However, infection by *H. pylori* alone does not cause peptic ulceration in most individuals, suggesting the existence of other pathogenetic factors. Half of patients evaluated for dyspepsia have histologic evidence of bacterial infection. In developed countries, one-fifth of healthy volunteers harbor the bacteria, and the incidence of bacterial infestation increases with age in the healthy, asymptomatic population. The occurrence of peptic ulcers in only a fraction of individuals who harbor the organism suggests that other factors must also act to induce ulceration.

H. pylori infection can be diagnosed by both invasive and noninvasive means. Noninvasive methods include the urea breath test, serology, and detection of antigen in stool samples. The urea breath test is based on production of urease by *H. pylori* in the gastric mucosa. C^{14}-labeled urea is ingested and C^{14}-labeled CO_2 is produced and excreted in the breath. This test has a sensitivity and specificity of greater than 90% and indicates ongoing infection. The urea breath test is useful for initial diagnosis of infection and for follow-up after eradication therapy.

The stool antigen test is another noninvasive test to detect both initial *H. pylori* infection as well as response to treatment. Both polyclonal and monoclonal kits have been developed. Likewise, different kits are available for both out- and inpatient settings. Overall results have been comparable to those obtained using the urea breath test method.[8]

Because *H. pylori* induces a strong immunologic response, serological testing is useful but may not be as accurate as the urea breath test or the stool antigen test. Validation with either of the two tests is recommended. It may be used for epidemiologic studies. Because *H. pylori*–induced serology does not return to normal after bacterial eradication, this test is not reliable in monitoring therapy.

H. pylori infection can also be diagnosed on the basis of biopsies in patients undergoing upper endoscopic examination. Individuals older than 50 years, or those with significant symptoms including gastrointestinal (GI) bleeding, anemia, and weight loss, should undergo endoscopic diagnosis. During endoscopy, antral biopsies can be obtained and the organism cultured in agar containing both urea and a pH-sensitive colorimetric agent. *H. pylori* hydrolysis of urea causes a diagnostic change in color. The sensitivity of this test varies from 80 to 100% and specificity exceeds 90%. The test is associated with false-negative results in patients with active or recurrent bleeding and in those taking antibiotics or antisecretory compounds. Biopsy also permits histologic examination with visualization of the organism. Culture of *H. pylori* is not routine and is usually reserved for recurrent infection and for antibiotic sensitivity testing when second-line therapy has failed.

Complete eradication of *H. pylori* infection is the goal of treatment, and recurrence of disease signifies reinfection in most circumstances. An enormous worldwide experience has developed relating to *H. pylori* eradication. More than 2000 articles report the results of antibiotic trials, and a large number of summary articles and meta-analyses are available. It is important to note that none of the therapeutic regimens reported to date cure *H. pylori* infection in 100% of patients. To be effective, antimicrobial drugs must be combined with gastric acid secretion inhibitors or bismuth salts.

In the absence of treatment, eradication of *H. pylori* infection is very rare. Three consensus conference meetings as well as numerous clinical guidelines in various regions have been published in the past decade to further define the approach to diagnosis and treatment of *H. pylori*. The Maastricht III Consensus Report brought together a multidisciplinary group in 2007 from around the world to publish an update on the initial guidelines published in 1996 (known then as the European *Helicobacter* Study Group) and subsequently revised in 2000 after including a review of published guidelines from North America, Europe, China, and Japan (Table 21-1).[9]

Current evidence indicates that eradication therapy with a proton pump inhibitor, metronidazole, and amoxicillin

TABLE 21-1: FIRST CHOICE TREATMENT FOR *H. PYLORI* INFECTION

1. For PPI (standard dose BID) clarithromycin (500 mg BID), amoxicillin (1000 mg BID), or metronidazole (400 or 500 mg BID), 14-d treatment is more effective than that of 7-d by 12% (95% confidence interval 7–17%). A 7-d treatment may be acceptable where local studies show that it is effective.
2. PPI-clarithromycin-amoxicillin or metronidazole treatment is the recommended first-choice treatment in populations with < 15–20% clarithromycin resistance. In populations with < 40% metronidazole resistance, PPI-clarithromycin-metronidazole is preferable. Quadruple treatments are alternative first-choice treatments.
3. The same first-choice *H. pylori* treatments are recommended worldwide, although different doses may be appropriate.

Malfertheiner P, Megraud F, Bazzoli F, et al. Current concepts in the management of *Helicobacter pylori* infection: the Maastricht III Consensus Report. *Gut.* 2007;56:772–781.

decreases the prevalence of metronidazole-resistant *H. pylori* strains. The prevalence of clarithromycin-resistant strains varies greatly from country to country, with the highest rates reported in southern Europe. In this region, clarithromycin resistance now approximates 15%. This rate is predicted to rise over the next several years with increasing use of macrolide antibiotics. In patients failing therapy, culture of *H. pylori* from gastric mucosa is possible for resistance testing. Also, a recent multicenter trial in Spain demonstrated that a 10-day regimen of levofloxacin (500 mg BID), amoxicillin (1 g BID), and omeprazole (20 mg BID) had 97% compliance and 77% eradication based on a negative ^{13}C urea breath test done 4–8 weeks after completion of therapy.[10]

NONULCERATIVE DYSPEPSIA

Dyspepsia is a very common symptom complex that is characterized by pain and discomfort centered in the upper abdomen. Dyspepsia is among the most common disorders encountered by primary care physicians and gastroenterologists in the United States and Western countries. It is estimated that approximately 25% of the population will experience dyspepsia and that this problem accounts for 5% of visits to primary care providers.

Dyspepsia is characterized by symptoms that are focused in the upper abdomen. Symptoms may include heartburn, but a symptom complex limited to this complaint suggests gastroesophageal reflux disease and excludes the diagnosis of dyspepsia. Nonulcerative dyspepsia is considered when no anatomic or biochemical abnormality is discovered that explains the patient's symptoms. This common disorder is not associated with increased morbidity or mortality. However, it is generally long lasting and responsible for impaired quality of life. Investigation of nonulcerative dyspepsia and its treatment represent a large economic burden. Optimal treatment is controversial.

Since the description of *H. pylori* as a cause of gastritis, its association with nonulcerative dyspepsia has been disputed. *H. pylori* infestation is always associated with histologic gastritis, but may be absent in cases of nonulcerative dyspepsia. A large number of studies have reported the efficacy of therapy for *H. pylori* infection on symptoms of nonulcerative dyspepsia.[11–13] A recent Cochrane review of the literature showed a small but statistically significant effect of *H. pylori* treatment in nonulcer dyspepsia but recommended further research before making any definitive recommendations.[14]

For surgeons, the importance of nonulcerative dyspepsia relates to its place in the differential diagnosis of epigastric pain. There is no role for surgery in the treatment of this disorder.

PEPTIC ULCER DISEASE

Epidemiology

Peptic ulcer disease is a major public health problem in the United States and a source of substantial health care expenditure.[15] Overall, peptic ulcer mortality and hospitalization rates have declined for the past two decades from over 200,000 admissions in 1993 down to a little over 150,000 in 2006. Hemorrhage continues to be the most frequent presentation at admission, followed by perforation and obstruction. A significant shift was also seen in the management of ulcer hemorrhage from surgery (21% decrease) to endoscopy (59% increase). Although overall mortality rates decreased slightly (2.7%, down from 3.8%), no change was seen in the determinants of mortality, with perforation still being associated with the highest mortality, followed by obstruction and then bleeding. The mortality from surgical intervention decreased over the time period but remains high compared to endoscopy and embolization.[16]

In parallel with the discovery of *H. pylori* and the subsequent development of improved therapies for its eradication, surgical treatment of peptic ulcer has changed dramatically, with the virtual elimination of elective operations for ulcer disease. Operative therapy is now used mostly for emergent treatment of complicated disease. Antibiotics have become primary antiulcer therapy with the realization that, in most cases, peptic ulceration is an infectious disease. A wide variety of antisecretory drugs are available for clinical practice. Endoscopic and surgical therapies are frequently integrated in the care of individual patients.

Pathophysiology

The pathogenesis of peptic ulceration is multifactorial but increasingly understood to be a consequence of *H. pylori* infection. Before the recognition of the role of *H. pylori*, ulcer disease was conceived as an imbalance between acid and pepsin secretion and mucosal defense, with the balance shifted toward peptic injury and disease. In groups of patients, increases in acid secretion are well-documented, and, although gastric acid is crucial in the development of ulcers, an acquired defect in mucosal defense exists to tip the balance away from health. Mucosal infestation with *H. pylori* is the factor that contributes to ulceration in most patients; nonsteroidal anti-inflammatory drug (NSAID) use is the second most important factor in ulcer pathogenesis.

OTHER FACTORS

Substantial evidence implicates cigarette smoking as an additive risk factor in the development of duodenal ulcers. Smokers appear to have an increased risk of developing *H. pylori* infection relative to nonsmokers. Cigarette smoking impairs ulcer healing and increases the risk of recurrent ulceration. Continued smoking blunts the effectiveness of active ulcer therapy. Cigarette smoking increases both the probability that surgery will be required and the risks of operative therapy. When *H. pylori* is eradicated in smokers, they appear to have no greater risk of peptic ulceration than nonsmokers.[17,18] This observation suggests that smoking is probably not an independent risk factor for ulcer disease but acts by increasing the harmful effects of

bacterial infection. Cessation of smoking is a key goal of antiulcer therapy.

Abnormalities of gastric acid secretion in patients with peptic ulceration have been recognized for more than 50 years. The formation of duodenal ulcers clearly depends on gastric secretion of acid and pepsin. This association is emphasized by the dictum "no acid-no ulcer." *H. pylori* infection is now known to secondarily induce alterations in gastric acid secretion as a prerequisite for ulcer development, and a more complete and accurate statement might be "no acid and no *H. pylori*–no ulcer."

Abnormalities of mucosal function have been invoked as contributing factors to peptic injury. In support of this concept, several agents that are used to treat peptic ulceration are cytoprotective. Cytoprotective agents inhibit mucosal injury at concentrations lower than threshold doses that suppress acid secretion.[19] The ability of such agents to heal ulcers suggests that abnormalities in mucosal defense, in addition to abnormalities in acid secretion, cause ulceration. Most cytoprotective agents act via mucosally secreted bicarbonate or on mucosal prostaglandin production.

NSAIDs are a major risk factor for the development of acute ulceration and for hemorrhagic complications of ulceration. NSAIDs produce a variety of lesions, ranging from superficial mucosal erosions to deeper ulcerations. While the mucosal injury caused by NSAIDs is more common in the stomach than in the duodenum, ulcer complications occur with equal frequency in these two sites. *H. pylori* and NSAID use independently increase the risk of peptic ulcer and ulcer bleeding. These agents also act synergistically. In the duodenum, it appears likely that invasive *H. pylori*–associated ulcers are compounded by the direct injurious effects of NSAIDs.

The injurious actions of NSAIDs are secondary to systemic suppression of prostaglandin production. Numerous experimental models have demonstrated that NSAIDs injure the gastroduodenal mucosa. Ulcers resembling those occurring in humans can be produced by administration of NSAIDs to animals, and NSAID-associated gastric ulcers can be prevented by the coadministration of prostaglandin analogues. Ulcers associated with NSAIDs heal rapidly when the drug is withdrawn, corresponding temporally to reversal of antiprostaglandin effects.

None of the currently available NSAIDs are free of the hazard of gastroduodenal ulceration.[19] Clinically significant ulceration of the stomach and duodenum is estimated to occur at a rate of 2–4% per patient-year. The risks of long-term NSAID use are increased by *H. pylori* infection and cigarette smoking. The incidence of NSAID-related ulcer complications is highest in older patients, as is attendant mortality rate. Peptic ulcer disease is rare in individuals who are *H. pylori*–negative and who do not receive NSAID medications.[20]

Diagnosis

Duodenal ulceration is characterized by epigastric pain. The pain is usually localized to the upper abdomen without radiation and is described as burning, stabbing, or gnawing. In the absence of complications such as perforation or penetration into the head of the pancreas, referral of pain to extra-abdominal sites is not common. Many patients report that pain is worsened by fasting. Ingestion of antacids usually provides prompt relief. In uncomplicated cases, physical examination is usually normal.

The differential diagnosis includes a variety of diseases originating in the epigastrium and upper GI tract. Common disorders to be distinguished include nonulcer dyspepsia, gastritis, gastric neoplasia, cholelithiasis and related diseases of the biliary system, neoplastic lesions of the liver, and both inflammatory and neoplastic disorders of the pancreas. In dyspeptic patients, especially those older than 50 years of age, the most important differential diagnoses are peptic ulceration and gastric cancer.

The evaluation of patients with suspected peptic ulceration usually involves endoscopic examination of the esophagus, stomach, and duodenum. In most circumstances, contrast radiography is not the preferred initial diagnostic method; endoscopy has become the standard to which other modalities are compared. Endoscopy eliminates the need for radiation, is safe, is tolerated by elderly patients, and permits both visual inspection and biopsy of the esophagus, stomach, and duodenum. In controlled trials, endoscopy was both more sensitive (92 vs 54%) and more specific (100 vs 91%) than radiographic examination.[21] Endoscopy must be utilized with discretion because of the potential for perforation (approximately 1 per 5000 cases) and cost.

Endoscopically, duodenal ulceration is characterized by lesions that are erosive to the intestinal wall. When viewed endoscopically, peptic ulcers have a typical appearance, with edges that are usually sharply demarcated. The ulcer consists of the exposed underlying submucosa. With chronic ulcers, the base is usually clean and smooth. Acute ulcers and ulcers with recent hemorrhage may demonstrate clot, eschar, or adherent exudate. The surrounding duodenal mucosa may be friable, but marked inflammation is uncommon. The most frequent site for peptic ulceration is the first portion of the duodenum, with the second portion less frequently involved. Peptic ulceration of the third or fourth portions of the duodenum is distinctly unusual; occurrence of ulcers in these locations raises the possibility of gastrinoma. Peptic ulcers in the pyloric channel or the prepyloric area are similar in appearance to duodenal ulcers. Endoscopic demonstration of a duodenal ulcer does not require duodenal biopsy but should prompt mucosal biopsy of the gastric antrum to demonstrate the presence of *H. pylori* and guide subsequent therapy.

Contrast radiographs demonstrate retention of contrast within the ulcer. When viewed tangentially, the ulcer projects beyond the level of the duodenal mucosa. Distortion of the duodenal bulb by spasm or scarring is a secondary sign of current or previous ulceration.

OPERATIVE TREATMENT OF ULCER DISEASE

The realization that peptic ulceration is an infectious disease has fundamentally altered the role of surgery in ulcer treatment.[22,23] Indications for operative intervention have changed over the past 20 years as a consequence, with the virtual elimination of

elective operations.[24] Operative intervention is now reserved for the treatment of complicated ulcer disease. Three complications are most common and constitute contemporary indications for peptic ulcer surgery: hemorrhage, perforation, and obstruction. Evolving indications are also reflected in the forms of operative therapy and in surgical training experience.[25,26]

The first goal of current surgical therapy is treatment of anatomic complications, such as pyloric stenosis or perforation. The second major goal should be patient safety in the acute setting, combined with freedom from undesirable chronic side effects. The third goal in contemporary surgical treatment of complicated ulcer disease should be alteration of the ulcer diathesis so that ulcer healing is achieved and recurrence is minimized. To achieve these goals, the gastric surgeon can combine therapy through endoscopic, radiologic, or operative means, the appropriate choice depending on the clinical circumstances.

Operative Procedures

There is currently no indication for surgical treatment of uncomplicated ulcer disease. A number of operative procedures have been developed to treat peptic ulcer but have been used with decreasing frequency in the past decade. Operative treatment of gastric outlet obstruction has decreased by approximately 50%. The majority of surgical patients are currently treated emergently for the complications of bleeding or perforation.

Truncal vagotomy and drainage, truncal vagotomy and antrectomy, and proximal gastric vagotomy are the most widely utilized procedures in the operative treatment of peptic ulcer disease. However, surgical therapy of complicated peptic ulcer disease is directed increasingly at correction of the immediate problem without gastric denervation. The underlying cause of the ulcer diathesis may then be addressed after recovery from surgery by antibiotic therapy directed at *H. pylori* and by long-term acid suppression therapy. This approach is applicable to most patients with peptic ulcer undergoing emergent operation and is also reflected by the fact that the use of gastrectomy and vagotomy has decreased significantly from 4.4 to 2.1% (gastrectomy) and 5.7 to 1.7% (vagotomy) over the last two decades.[16]

Transection of both vagal trunks at the esophageal hiatus, termed *truncal vagotomy*, denervates the acid-producing fundus of the stomach. The procedure also denervates the remainder of the supplied viscera, including the liver and biliary tree, pancreas, small bowel, and colon to the midtransverse portion. Because denervation impedes normal pyloric coordination and impairs gastric emptying, truncal vagotomy is usually combined with a procedure to eliminate or bypass pyloric sphincter function. A pyloroplasty or gastrojejunostomy is performed for gastric drainage.

Several methods of pyloroplasty have been developed. The Heineke-Mikulicz pyloroplasty (Fig. 21-1) consists of a longitudinal incision of the pyloric sphincter extending into the antrum and the duodenum. The incision is closed transversely, eliminating sphincteric closure and increasing the lumen of the pyloric channel.

The Finney pyloroplasty (Fig. 21-2) extends the pyloric incision 5 cm onto the duodenal wall forming an inverted

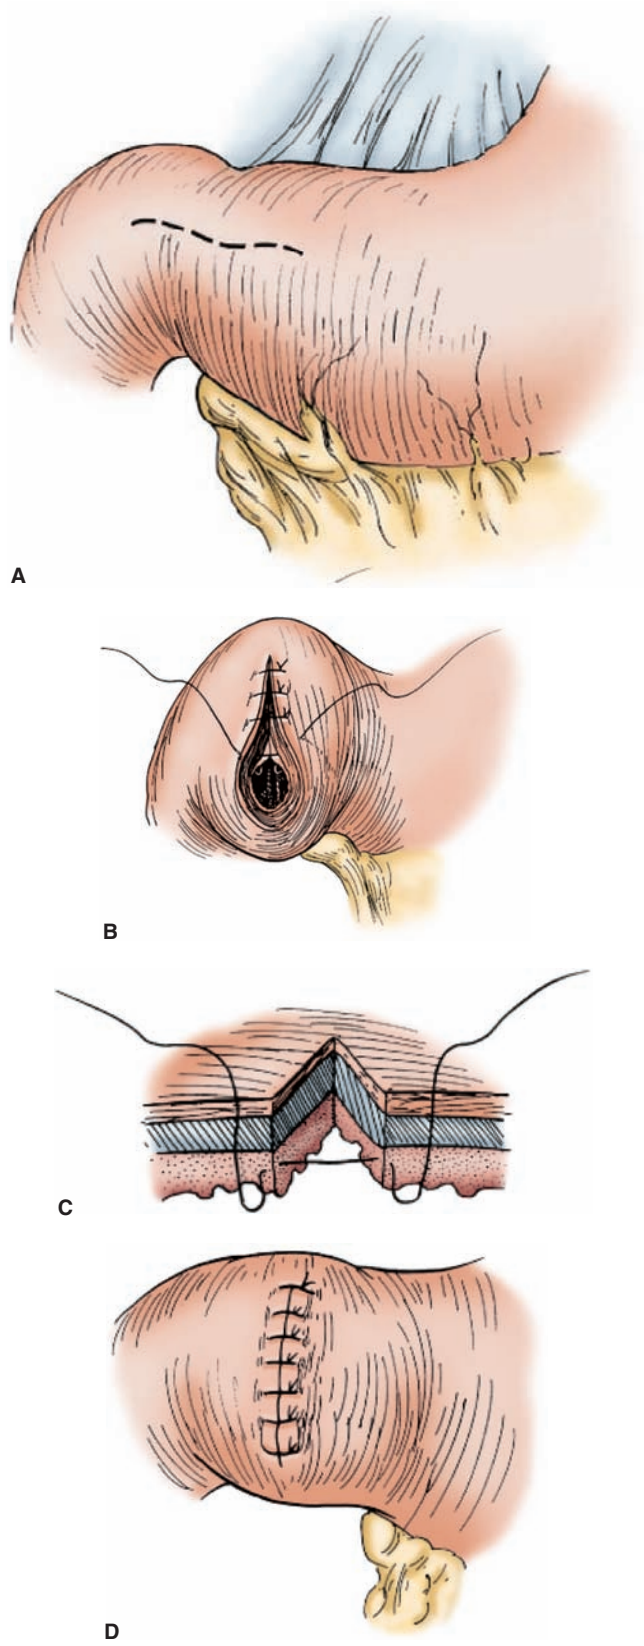

FIGURE 21-1 Heinecke-Mikulicz pyloroplasty. (Redrawn with permission from Zinner MJ. *Atlas of Gastric Surgery*. New York, NY: Churchill Livingstone; 1992. Illustrated after Gwynne Gloege.)

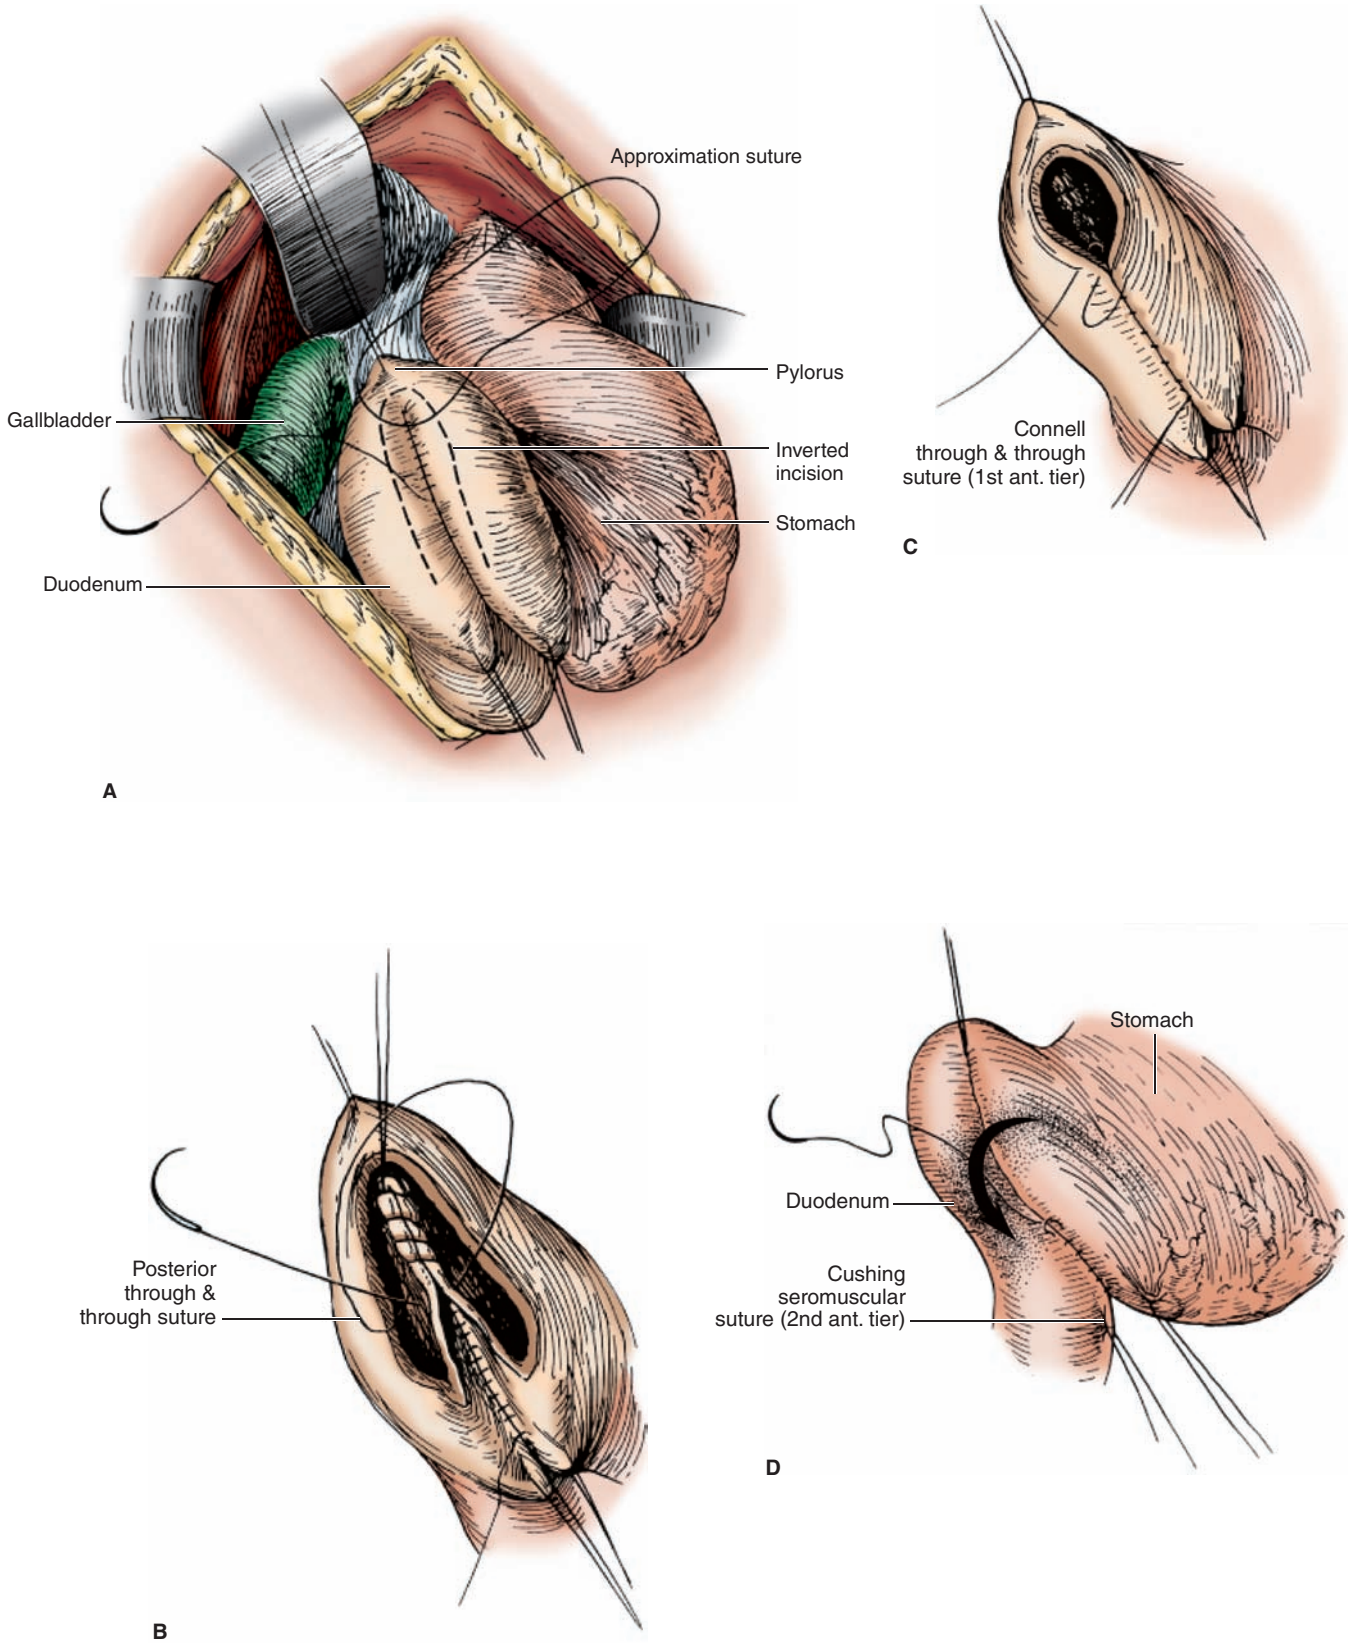

FIGURE 21-2 Finney pyloroplasty (From Soybel DI, Zinner MJ. Stomach and duodenum: operative procedures. In: Zinner MJ, Schwartz SI, Ellis H, eds. *Maingot's Abdominal Operations*. 10th ed. London, UK: Prentice Hall Inc.; 1997:Chap. 13.)

U-shaped incision after the placement of superior and inferior traction sutures. Once traction is applied, the two limbs of the inverted U-shaped incision are lined up and sutured to each other to complete the procedure, with the inferior suture line forming the posterior wall and the superior suture line forming the anterior wall of the pyloroplasty.

A Jaboulay gastroduodenostomy (Fig. 21-3) requires more extensive dissection beginning with a Kocher maneuver followed by corresponding incisions on the stomach and the duodenum proximal and distal to the pylorus respectively. Traction sutures are then placed between the stomach and duodenum to approximate the two incisions, and the anastomosis is then performed.

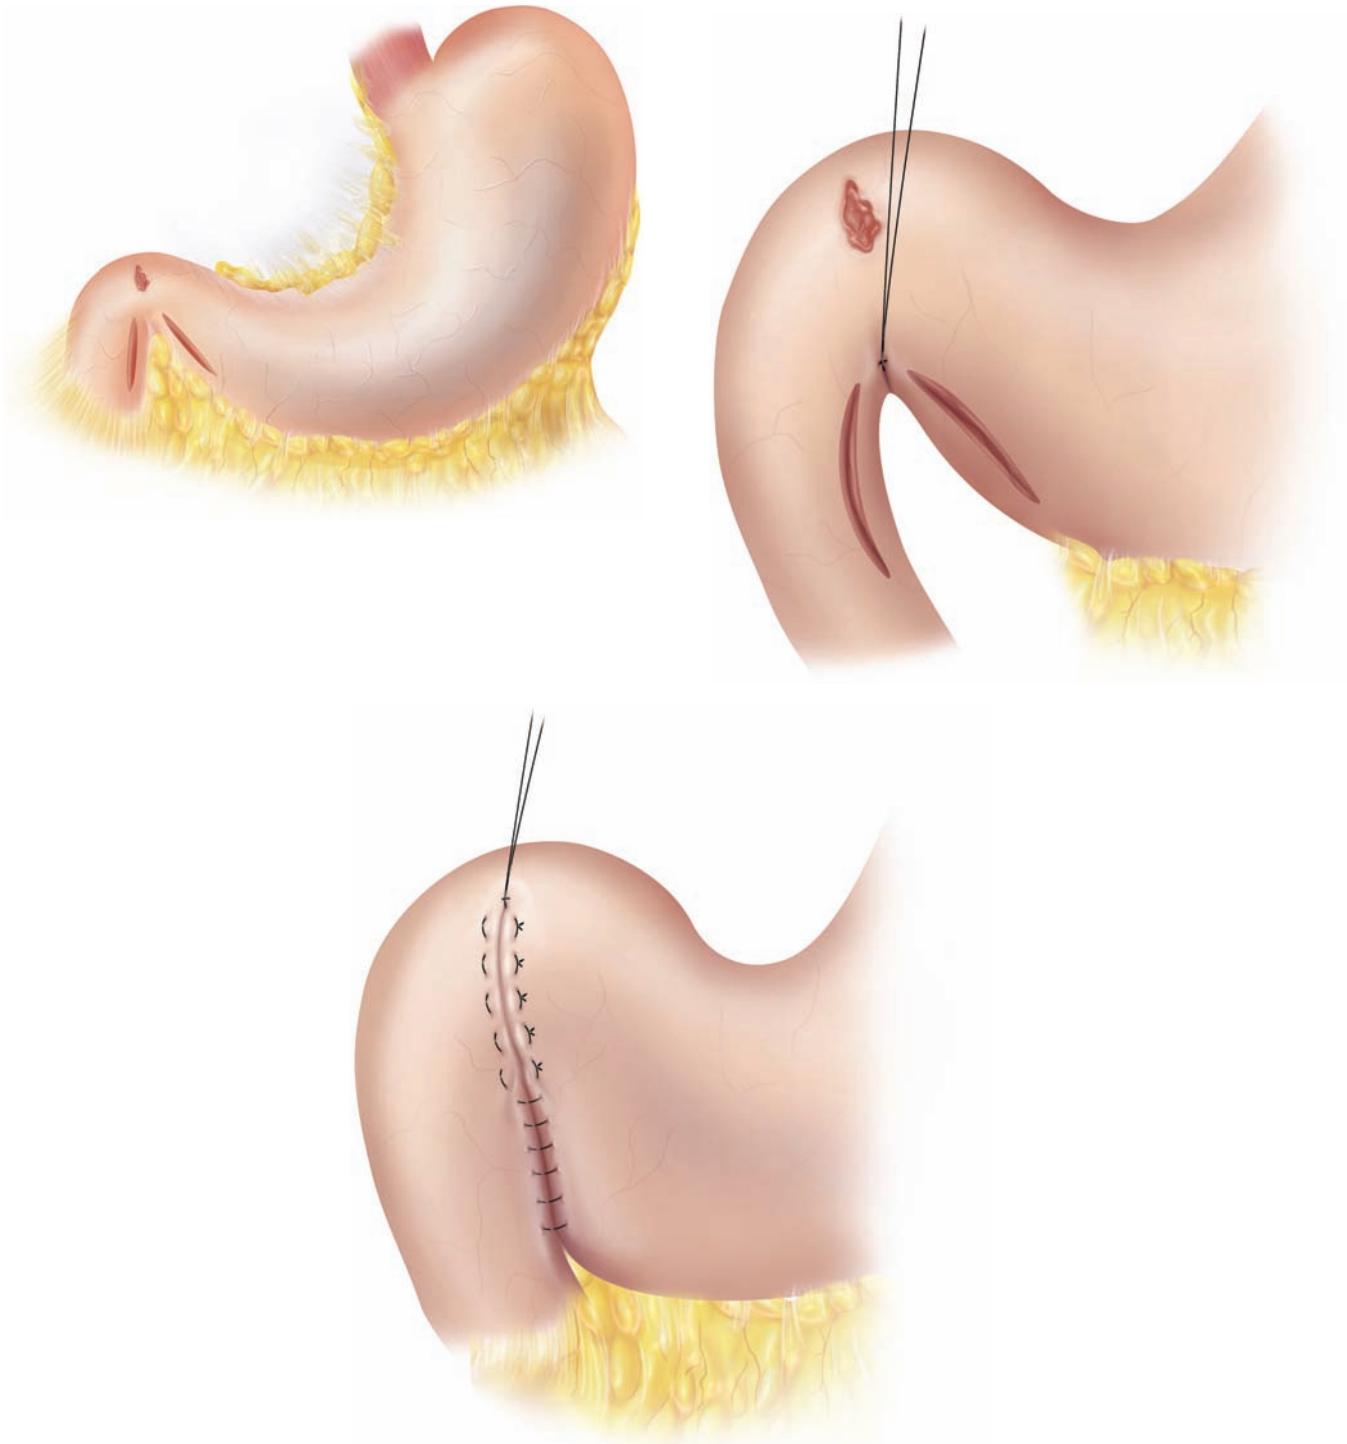

FIGURE 21-3 Jaboulay gastroduodenostomy.

Truncal vagotomy can be combined with resection of the gastric antrum to further reduce acid secretion by removing antral sources of gastrin. The limits of antral resection are defined by external landmarks. The stomach is divided proximally along a line from a point above the incisura angularis to a point along the greater curvature midway from the pylorus to the gastroesophageal junction. Reconstruction via a gastroduodenostomy is called a *Billroth I procedure*. A *Billroth II procedure* uses a gastrojejunostomy to restore GI continuity.

Proximal gastric vagotomy, also termed *highly selective vagotomy* (HSV), differs from truncal vagotomy in that only the nerve fibers to the acid-secreting fundic mucosa are transected (Fig. 21-4). The hepatic and celiac divisions are not divided, and vagal nerve fibers to the antrum and pylorus remain intact. The operation has also been called parietal cell vagotomy to emphasize the intended functional consequence.

Proximal gastric vagotomy is a safe operation. The procedure has a reported operative mortality rate of less than 0.05%, lower than the reported mortality for any other gastric procedure for peptic ulcer. Truncal vagotomy and pyloroplasty has an accepted mortality rate of 0.5–0.8%, whereas mortality after truncal vagotomy and antrectomy approximates 1.5%. These statistics require an important caveat; almost all large series report the results of elective operations on patients with peptic ulceration and may not accurately reflect expected results when similar procedures are performed emergently.

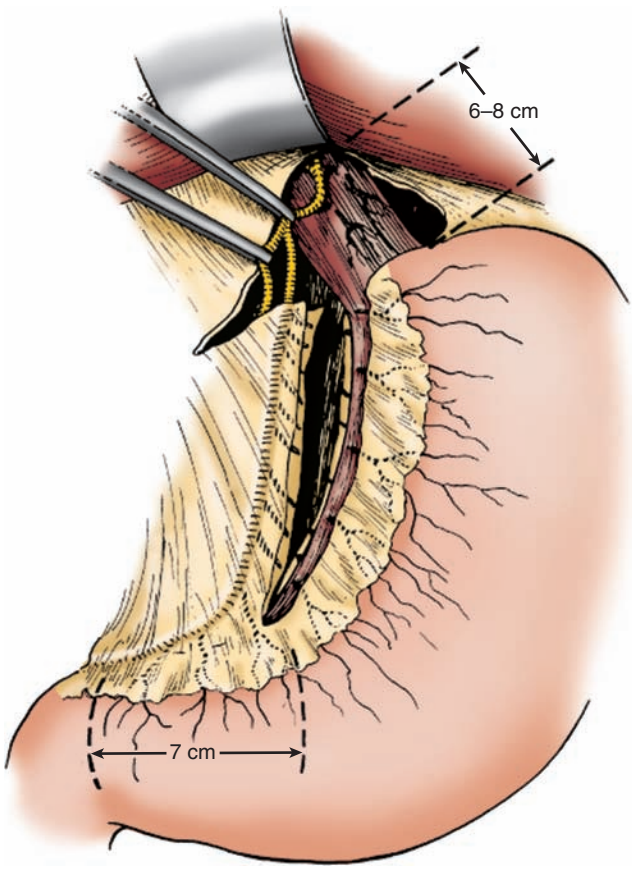

FIGURE 21-4 Technique of proximal gastric vagotomy. The distal 6 cm of the esophagus is skeletonized. Denervation spares the antrum and pylorus by stopping 7 cm proximal to the pylorus. (Reproduced with permission from Holle F, Anderson S. *Vagotomy: Latest Advances.* New York: Springer; 1994.)

Postoperative Alterations

Division of vagal nerve fibers alters gastric acid secretion by reducing cholinergic stimulation of parietal cells. Vagal denervation also decreases parietal cell responsiveness to gastrin and histamine. Basal acid secretion is diminished by approximately 80% in the immediate postoperative period and is maintained over time. The maximal acid output in response to secretagogues such as pentagastrin is reduced by approximately 70%. After 1 year, pentagastrin-stimulated maximal acid output increases to 50% of prevagotomy values but remains at this level on subsequent testing. Acid secretion due to meal stimulation is reduced by 60–70% relative to normal subjects. The inclusion of antrectomy to truncal vagotomy further reduces acid secretion. Maximal acid output is reduced by 85% relative to values recorded before antrectomy.

Both forms of vagotomy cause postoperative hypergastrinemia. Fasting gastrin values are increased to approximately twice preoperative levels. Postprandial gastrin response is exaggerated. Hypergastrinemia is due to decreased luminal acid, with loss of feedback inhibition of gastrin release. Chronic hypergastrinemia is caused by mucosal gastrin cell hyperplasia in addition to loss of inhibitory feedback. When antrectomy is performed, circulating gastrin levels are decreased. Basal gastrin values are reduced by approximately half and postprandial gastrin levels by two-thirds.

Operations that involve vagotomy affect gastric emptying. Both truncal vagotomy and proximal gastric denervation abolish vagally mediated receptive relaxation that normally allows the ingestion of a meal with no increase in intragastric pressure. After vagotomy, the intragastric pressure rise is greater for any given volume ingested, and the gastroduodenal pressure gradient higher than in normal subjects. As a result, emptying of liquids, which depends on the gastroduodenal pressure gradient, is accelerated. Because nerve fibers to the antrum and pylorus are preserved with proximal gastric vagotomy, the function of the distal stomach to mix solid food is preserved and emptying of solids is nearly normal. Truncal vagotomy affects the motor activity of the distal stomach, and solid and liquid emptying rates are usually increased when truncal vagotomy is accompanied by pyloroplasty.

Dumping is defined by a postprandial symptom complex of abdominal discomfort, weakness, and vasomotor symptoms of sweating and dizziness. Dumping occurs transiently in 10–15% of patients after truncal vagotomy and antrectomy and is persistent in 1–2%. Dumping is present initially in 10% of patients undergoing truncal vagotomy and pyloroplasty, and remains in approximately 1%. Permanent symptoms of dumping are unusual after proximal gastric vagotomy. The incidence of diarrhea, presumably caused by denervation of the pylorus

and small bowel and by elimination of pyloric function, parallels the incidence of dumping when truncal vagotomy is performed. Persistent and disabling diarrhea is present in fewer than 1% of patients after proximal gastric vagotomy.

The largest surgical series examining ulcer recurrence rates were reported at a time before the pathogenic role of *H. pylori* was appreciated. With appropriate use of antibiotics directed against *H. pylori*, ulcer recurrence rates as low as 0.22% have been reported.[27] Although recurrence rates (without *H. pylori* treatment) as low as 5% have been reported, a more generally representative figure is 10%. This rate is similar to that of reinfection with *H. pylori* after successful eradication. Ulcer recurrence rates after proximal gastric vagotomy can be adversely affected by the inclusion of prepyloric and pyloric channel ulcers. Proximal gastric vagotomy is significantly less effective when used to treat ulcers in this position than when used for duodenal ulceration.

Ulcer Hemorrhage

Hemorrhage continues to be a major source of morbidity in patients with peptic ulceration. Bleeding is the leading cause of death associated with peptic ulcer. The incidence of hemorrhage has not changed since the introduction of H_2-receptor antagonists.[23] The lifetime risk of hemorrhage for patients with duodenal ulcer who do not undergo specific therapy approximates 35%. Hemorrhage usually occurs during the initial episode of ulceration or during relapse; patients who have bled previously have a higher risk of bleeding again. Patients with recurrent bleeding and elderly patients are at greatest risk of death.[25,28]

The risk of mortality from bleeding peptic ulcer is surprisingly high at 10–20%. When surgery is necessary, operative risk is increased in patients who have shock at admission, recurrent bleeding, delay in operative intervention, or comorbid illnesses. Surgical delay leads to recurrent hypovolemia and subsequently multisystem organ failure.

Upper GI endoscopy is the appropriate initial diagnostic test, following resuscitation, when hemorrhage from ulceration is suspected. Endoscopy identifies the site and source of bleeding in over 90% of patients. An ulcer should be accepted as the bleeding source only if it exhibits stigmata of active or recent hemorrhage (Table 21-2). Active hemorrhage is defined by an arterial jet, active oozing, or oozing beneath an adherent clot. Signs of recent hemorrhage include adherent clot without oozing, adherent slough in the ulcer base, or visible vessel in the ulcer. Up to 30% of patients who have stigmata of recent hemorrhage experience rebleeding, and most of the patients who bleed recurrently require emergency treatment. The signs are not sufficiently accurate, nor are rebleeding rates high enough, to be indications for surgery. Endoscopic stigmata indicate that aggressive therapy is needed and close follow-up mandatory. The occurrence of hypovolemic shock, rebleeding during hospitalization, and a posteroinferior location of the ulcer are clinical features that are associated with increased risk of recurrent bleeding. Acute

reduction of acid secretion by H_2-receptor antagonists or proton pump inhibitors is not sufficient to prevent recurrent hemorrhage. However, the continuous infusion of proton pump inhibitors has been shown to decrease rebleeding.[26]

The ability to visualize bleeding duodenal ulcers endoscopically permits endoscopic treatment. Methods of endoscopic therapy include thermal coagulation by bipolar electrocoagulation or direct application of heat through a heater probe.[29] Injection of epinephrine into the base of the bleeding ulcer is also an established method to control ulcer hemorrhage.

Both reduced rebleeding rates and avoidance of operation have been demonstrated for endoscopic hemostasis.[29,30] Proof of efficacy for endoscopic treatment of hemorrhage is complicated by the 70% rate of spontaneous, sometimes temporary, cessation of bleeding without intervention (Table 21-3). In addition to endoscopic stigmata, hemodynamic instability, continuing transfusion requirements, red stool or hematemesis, age older than 60 years, and medical comorbidity are clinical features that mandate endoscopic therapy. Rebleeding during hospitalization and the endoscopic findings of visible vessel, oozing, or bleeding associated with an adherent clot are also indications for endoscopic hemostasis. Ulcers with clean bases and no stigmata of recent hemorrhage require no treatment.

Failure of endoscopic treatment is usually due to inaccessibility of the ulcer that is caused by pyloric scarring, rapid active bleeding, or an obscuring clot. Patients treated endoscopically should be observed closely for further hemorrhage. Those who rebleed within 72 hours of initial endoscopic control may be successfully retreated without increased risk of mortality.[30]

Data from Sharma VK, Sahai AV, Corder FA, et al. *Helicobacter pylori* eradication is superior to ulcer healing with or without maintenance therapy to prevent further ulcer hemorrhage. *Aliment Pharmacol Ther*. 2001;15:1939–1947.

The efficacy of endoscopy diagnosis and therapy depends on timing. Early endoscopy correctly classifies patients as low risk for recurrent hemorrhage and permits safe avoidance of hospitalization. Early endoscopy also benefits high-risk patients by directing specific, active hemostatic therapy. Patients with early endoscopy have been demonstrated to have fewer episodes of rebleeding, lower rates of operation, less resource consumption, and shorter hospitalizations.[31]

Operative intervention is indicated for the following:

Massive hemorrhage leading to shock or cardiovascular instability
Prolonged blood loss requiring continuing transfusion
Recurrent bleeding during medical therapy or after endoscopic therapy
Recurrent hemorrhage requiring hospitalization

The need for emergency intervention significantly increases surgical risks, and not surprisingly, mortality is increased 10-fold. Emergent operative therapy should consist of duodenotomy with direct suture ligation of the bleeding vessel in the ulcer base (Table 21-4). Postoperatively, patients should receive proton pump inhibitors and antibiotics directed against *H. pylori*. This treatment approach is based on the observation, in medically treated patients, that peptic ulcer hemorrhage recurs in 20% of patients when *H. pylori* is not eradicated, while rebleeding is reduced to 3% in patients who receive *H. pylori* antibiotic therapy.[31–34] This recommendation is an extrapolation; the studies that support this practice were not designed to evaluate postoperative hemorrhage (Table 21-5).

PERFORATION

The lifetime risk for perforation in patients with duodenal ulceration not receiving therapy approximates 10%, while ulcer perforation is unusual if initial ulcer healing has been achieved. Duodenal ulcer perforation is followed by sudden and severe epigastric pain. The pain is caused by contact of the peritoneum with highly caustic gastric secretions. Pain is often instantaneous and remains constant. Peritoneal irritation is usually intense and causes most patients to avoid movement.

Physical examination reveals fever, diminished bowel sounds, rigidity of the abdominal musculature, and guarding. Upright abdominal radiographs demonstrate pneumoperitoneum in 80% of cases. If free air is not present, computed tomography of the abdomen is very sensitive for demonstrating perforation.

Occasional reports have described nonoperative treatment of this complication, but this approach is not appropriate for the large majority of patients with perforated peptic ulcer. Perforation is a strong indication for surgery in most circumstances. Laparotomy or laparoscopy affords the opportunity to relieve intraperitoneal contamination and to close the perforation.

The results of surgical treatment of duodenal perforation in the era preceding the recognition of *H. pylori* are instructive. Signs of preexisting duodenal ulceration, in terms of history of prior symptoms and anatomic evidence of duodenal scarring, should be sought, but a lack of antecedent symptoms is not protective. Patients without antecedent symptoms are at substantial risk for recurrent ulceration. By 5–6 years, symptomatic ulcer recurrence in patients with acute ulcer perforation is similar to that for patients with chronic disease. Before the role of *H. pylori* was appreciated, simple omental closure of duodenal perforation had not provided satisfactory long-term results; up to 80% of patients so treated had recurrent ulceration and 10% experienced reperforation. It is now known that four-fifths of all patients with perforation have *H. pylori* infestation and therefore are at risk of recurrent disease.

The mortality of emergency operation for ulcer perforation is most clearly correlated with the existence of preoperative shock, coexisting medical illness, and the presence of perforation beyond 48 hours.[35] For stable patients who receive prompt surgical attention, the operation can be performed with safety.[36] Proximal gastric vagotomy with omental patch closure of the perforation is one option in this circumstance. This procedure has been shown to be both safe and effective in preventing ulcer relapse. Incorporation of the site of perforation as part of a pyloroplasty or resection of the perforation during antrectomy can also be combined with truncal vagotomy. The performance of these operations has declined significantly, however, with the focus on *H. pylori* as the cause of most ulcer recurrences.

Several investigators advocate omental patch closure alone with postoperative anti–*H. pylori* therapy.[37–41] Omental patching can also be accomplished laparoscopically in select patients.[42] This approach rests upon three assumptions: (1) that most perforated duodenal ulcers are caused by *H. pylori*; (2) that the duodenal perforation is small enough that secure closure can be obtained; and (3) that further surgical therapy will be obviated by the effects of postoperative antibiotic therapy and acid suppression. Minimally invasive approaches are becoming frequently performed.

OBSTRUCTION

Gastric outlet obstruction can develop either acutely or chronically in patients with duodenal ulcer disease. Surprisingly, the incidence of *H. pylori* infection in this subgroup of patients may not be as high as that seen in patients presenting with hemorrhage or perforation.[43] Acute obstruction, due to edema and inflammation, is associated with ulcers in the pyloric channel and the first portion of the duodenum. Pyloric obstruction causes recurrent vomiting and dehydration. Hypochloremic alkalosis, due to loss of hydrochloric acid in gastric secretions, is distinctive of gastric obstruction. Hypokalemia may develop as a secondary renal compensation for alkalosis. Acute gastric outlet obstruction is treated by nasogastric suction, rehydration, and intravenous administration of antisecretory agents. Acute obstruction due to pyloric inflammation resolves with supportive measures within a few days.

Repeated episodes of ulceration can lead to pyloric scarring and a fixed stenosis with chronic gastric outlet obstruction. In cases of recurrent duodenal ulceration, the lifetime risk of chronic pyloric stenosis approximates 10%.

Initial investigation begins with upper GI endoscopy to confirm the site of obstruction and to exclude intrinsic or extrinsic obstruction due to malignancy, the most common cause of gastric outlet obstruction in the modern era. Endoscopic balloon dilation of the area of peptic ulcer obstruction can also be attempted; with success obtained in up to 85% of patients.[44] Most treated patients note immediate symptomatic improvement, but only 40% have sustained improvement by 3 months after balloon dilation. Recurrent symptoms are presumed due to residual scarring in the pyloric channel. In most cases, operative correction is required. This should include treatment of the underlying ulcer disease and relief of the anatomic abnormality. Truncal vagotomy with antrectomy and parietal cell vagotomy with gastrojejunostomy have both been used with success in this circumstance.

GASTRIC ULCER DISEASE

Diagnosis

In the United States, benign gastric ulcers are found in approximately 90,000 new patients a year, about one-fifth that of duodenal ulceration. The opposite is found in Japan where gastric ulcers are 5–10 times more common. Gastric ulcer is more common in men than women and occurs in a patient cohort approximately 10 years older than that of duodenal ulceration. In symptomatic patients, upper GI endoscopy is the preferred method for diagnosing gastric ulceration. The visual appearance of benign and malignant gastric ulcers may be identical, and differentiation may be made only by biopsy. Benign gastric ulcers appear smooth and flat and are often covered by a gray, fibrous exudate. The margin is often raised and erythematous. The ulcer margin is friable and may bleed with manipulation. All gastric ulcers should undergo multiple biopsies, obtained from the perimeter of the lesion. The addition of endoscopic brushings to multiple biopsies increases diagnostic accuracy to approximately 95%.

Although benign gastric ulcers may occur in any location in the stomach, more than half are located along the lesser curvature proximal to the incisura angularis. Fewer than 10% of benign ulcers are located on the greater curvature. Most benign gastric ulcers lay within 2 cm of the histologic transition between fundic and antral mucosa.

Similar to duodenal ulceration, *H. pylori* infection is the key to the pathogenesis of benign gastric ulcers. Antibiotic treatment regimens useful for duodenal ulcer have also been used for benign gastric ulceration. The response of gastric ulcers to antibiotic therapy is equivalent to that of duodenal ulcers. Recurrence of gastric ulcers after *H. pylori* eradication is equal to the rate of reinfection.

In addition to *H. pylori* infection, alterations in gastric motility have been demonstrated in some patients with benign gastric ulcers. Motility defects include delayed gastric emptying, abnormal pyloric sphincter function, prolonged high-amplitude gastric contractions, duodenogastric reflux, and alterations in the gastric migrating motor complex. These alterations have not been definitively demonstrated to be pathogenic, and their relevance to gastric ulceration is unsettled. A definite association between chronic NSAID use and benign gastric ulceration has been recognized. As with duodenal ulceration, cigarette smoking is associated with development of gastric ulceration, and continued smoking impairs medical therapy. Gastric and duodenal ulcers may occur in patients who receive hepatic artery chemotherapy if improper placement of the catheter permits perfusion of gastric and duodenal mucosa. A variety of agents, including 5-fluorouracil, cisplatin, doxorubicin, and mitomycin C, have been implicated.

Therapy

The primary therapy for benign gastric ulceration is antibiotic treatment of *H. pylori* infection using treatment protocols similar to those for duodenal ulceration. Antibiotic response rates are similar. Cessation of NSAID therapy is required to improve results. Operative treatment is reserved for complications of gastric ulcer, including hemorrhage and perforation. Unlike duodenal ulcer, failure of a recurrent

ulcer to respond to medical therapy may be an indication for operation, usually because nonhealing raises concerns about malignant disease.

For benign gastric ulcers, the elective operation of choice is usually a distal gastrectomy with either gastroduodenal (Billroth I) or gastrojejunal (Billroth II) anastomosis. The ulcer should be excised with the gastrectomy specimen (Fig. 21-5). Performed electively, operative mortality approximates 2–3%, and ulcer recurrence rates are less than 5%. Inclusion of vagotomy does not improve recurrence rates, which is not surprising given the variability of acid secretion in patients with gastric ulcers. The occurrence of a benign ulcer near the gastroesophageal junction (type IV ulcer) represents a difficult surgical problem. The ulcer may be excised via a distal gastrectomy with an extension along the lesser curvature and reconstruction with gastrojejunostomy. Emergency treatment of hemorrhage or perforation requires ulcer excision. Distal gastrectomy, including the site of perforation or bleeding, is usually the procedure of choice. Operative mortality rates average 10–20% in the presence of hemorrhage or perforation.

Intractability or Nonhealing Ulcers

This should indeed be a rare indication for surgery performed today. Arguably, the patient referred for surgical evaluation of intractable peptic ulcer disease should raise red flags for the surgeon. Acid secretion can be totally blocked and *H. pylori* eradicated with modern medication; therefore, the question remains: "Why does the patient have a persistent ulcer diathesis?" The surgeon should review the differential diagnosis of nonhealing ulcer prior to any consideration of operative treatment (Table 21-6).

Brunicardi FC, Anderson DK, Billiar TR, et al. *Schwartz's Principles of Surgery*. 8th ed. New York, NY: McGraw-Hill; 2005:969.

Surgical treatment should be considered in patients with nonhealing or intractable peptic ulcer disease who have multiple recurrences, large ulcers (>2 cm), complications (obstruction, perforation, or hemorrhage), or suspected gastric cancer. Surgery should be approached most cautiously in the thin or marginally nourished individual.

It is important that the surgeon not fall into the trap of performing a large, irreversible operation on these patients, based on the unproven theory that if all other methods have failed, a larger operation is required. Today's patients are different than those of three or four decades ago. One might argue that modern medical care has healed the minor ulcer, and that patients presenting with true intractability or nonhealing will be more difficult to treat and are likely to have chronic problems after a major ulcer operation. If surgery is necessary, less is often better. It is the practice of the authors never to perform a gastrectomy as the initial elective operation for intractable duodenal ulcer in the thin or asthenic patient. Instead, the preferred operation for this group of patients is HSV. In patients with nonhealing gastric ulcer, wedge resection with HSV should be considered in thin or frail patients. Otherwise distal gastrectomy (to include the ulcer) is recommended. It is unnecessary to add a vagotomy in patients with type I gastric ulcer.

Juxtaesophageal gastric ulcers (type IV) are pathophysiologically akin to type I gastric ulcers (ie, associated with gastric acid hyposecretion) but are often difficult to resect as part of a distal gastrectomy. A variety of techniques have been used to treat these ulcers surgically, including the Csendes operation, the Pauchet gastrectomy, and the Kelling-Madlener procedure (Fig. 21-6).

POSTGASTRECTOMY SYNDROMES

A number of syndromes have been described after gastric operations performed for peptic ulceration as well as gastric neoplasm. The occurrence of permanent disabling postoperative symptoms is uncommon, occurring only in about 1–3% of cases, and unpredictable. The two most common postgastrectomy syndromes are dumping and alkaline reflux gastritis.

Dumping

Dumping is defined as a postoperative clinical syndrome with gastrointestinal and vasomotor symptoms. The cause of dumping is uncertain but is likely related to unregulated entry of ingested food into the proximal small bowel following resection, bypass, or division of the pyloric sphincter. Early dumping symptoms occur within 1 hour of ingestion of a meal and include nausea, epigastric discomfort, tremulousness, and sometimes dizziness or syncope. Late dumping symptoms follow a meal by 1–3 hours. Late symptoms are usually due to reactive hypoglycemia.

Most patients who undergo vagotomy or gastrectomy do not experience dumping symptoms postoperatively. For patients who experience mild dumping symptoms in the early postoperative period, dietary alterations, and time bring improvement in all but approximately 1–2%. For those who remain persistently symptomatic, the long-acting somatostatin analogue, octreotide, improves dumping symptoms when administered subcutaneously before a meal.[45] The effects of somatostatin on the vasomotor symptoms of dumping are summarized below (Table 21-7).

TABLE 21-7: MECHANISMS OF ACTION OF OCTREOTIDE IN DUMPING SYNDROME

Delay in the accelerated gastric emptying

Alkaline Reflux Gastritis

Alkaline reflux gastritis is a postoperative syndrome characterized by postprandial epigastric pain associated with nausea and bilious vomiting. Endoscopic examination reveals reflux of bile into the stomach, and biopsy demonstrates histologic evidence of gastritis.

Alkaline reflux gastritis is a diagnosis of exclusion. The differential diagnosis of postoperative epigastric pain includes recurrent ulceration, calculous biliary disease, pancreatic inflammation, afferent loop obstruction, and esophagitis. Upper endoscopic examination is essential to exclude recurrent ulcer. The gastric mucosa appears inflamed, friable, and edematous. Gastric inflammation is often uneven and nonulcerative. Histologic examination shows glandular atrophy, mucosal and submucosal edema, and the presence of acute and chronic inflammatory cells in the lamina propria. Intestinal metaplasia may be present.

Postoperative alkaline reflux gastritis is resistant to medical treatment. Antacids, proton pump inhibitors, and dietary manipulations have not been definitively demonstrated to be beneficial. The most effective treatment for persistent alkaline reflux gastritis is operative diversion of intestinal contents from contact with the gastric mucosa. This solution usually requires conversion of a Billroth I or II gastrectomy to a Roux-en-Y gastrojejunostomy with an intestinal limb of 50–60 cm (Fig. 21-7). The length of the Roux limb prevents reflux of intestinal contents. This procedure is very effective in eliminating bilious vomiting. However, persistent pain is reported in up to 30% of patients, and 20% of patients develop postoperative delayed gastric emptying.

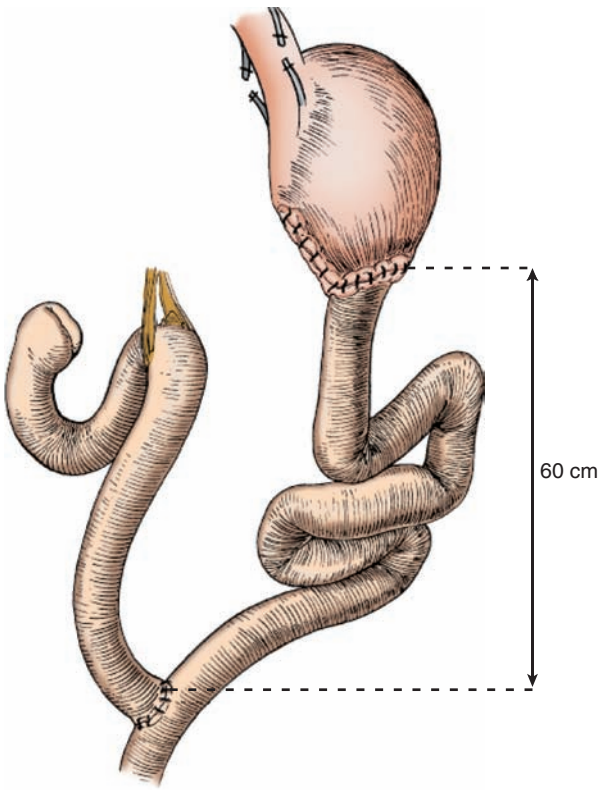

FIGURE 21-7 Roux-en-Y gastrojejunostomy used to treat alkaline reflux gastritis. (Redrawn from Schwartz SI, Ellis H. *Maingot's Abdominal Operations*. 9th ed. Stamford, CT: Appleton & Lange; 1989:716.)

STRESS ULCER DISEASE

Gastritis and gastric ulceration can be induced by physiologic stress. Usually occurring in hospitalized patients with critical illness, stress gastritis can be demonstrated endoscopically in the majority of patients recovering from shock. While occult bleeding in this population is common, clinically significant hemorrhage defined by the need for blood transfusion, hypotension, or alteration in other vital signs occurs in only 0.5–5% of patients. In four recent surgical series comprising more than 28,000 patients, the incidence of clinically significant stress ulceration was 0.4%.[46] In another series of 16,612 hospitalized patients, the incidence of overt stress bleeding was only 0.1%.[47] In a review of patients admitted to both surgical and medical intensive care units (ICUs), the incidence of clinically significant and endoscopically proven stress ulceration was 0.17%.[48]

Major trauma, especially if accompanied by hypotension, sepsis, respiratory failure, hemorrhage, or multiple injuries, predisposes to acute stress gastritis (Table 21-8). Acute stress gastritis is also common after thermal injury with greater than 35% total body surface area burned. A form of gastritis similar to that following trauma may complicate central nervous system injury or intracranial hypertension. When viewed endoscopically, multiple ulcerations are observed in the proximal, acid-secreting portion of the stomach. Fewer lesions are found in the antrum, and only rare ulcerations in the duodenum.

The major complication of stress gastritis is hemorrhage. Patients with coagulopathy and those requiring mechanical ventilation are at increased risk of hemorrhage. Patients without these two risk factors have been reported to have an overall risk of hemorrhage of only 0.1%, while those with both demonstrate clinically significant bleeding in 3.7% of

TABLE 21-8: RISK FACTORS FOR STRESS ULCER BLEEDING

Respiratory failure
Coagulopathy
Hypotension
Sepsis
Hepatic failure
Renal failure
Steroids
Injury Severity Score > 16
Spinal cord injury
Age >55 y

cases. Respiratory failure is defined as greater than 48 hours on a mechanical ventilator. Coagulopathy is defined as a platelet count less than 50,000/mm^3, an international normalized ratio greater than 1.5, or a partial thromboplastin time greater than two times control.

Admission to an ICU by itself does not place patients at risk for hemorrhage, and patients undergoing major GI surgery do not have an increased risk of stress-related bleeding in the absence of complications. Increased patient age, emergency surgery, need for reoperation, and the occurrence of hypotension are risk factors for postoperative gastric bleeding. The occurrence of sepsis and respiratory failure are also risk factors. Multiple regression analysis has shown that mechanical ventilation and coagulopathy impart the greatest risk.

The diagnosis of stress ulceration requires endoscopic examination. Acute mucosal ulcerations may be observed as early as 12 hours postinsult; lesions appear as multiple shallow areas of erythema and friability, accompanied by focal hemorrhage. Histologically, the lesions consist of coagulation necrosis of the superficial endothelium with infiltration of leukocytes into the lamina propria. Signs of chronicity, such as fibrosis and scarring, are absent. With resolution of injury or sepsis, healing is accomplished by mucosal restitution and regeneration.

A survey of Society of Critical Care Medicine members showed that ranitidine, famotidine, sucralfate, and cimetidine were the drugs used most commonly for prophylaxis. The presence of bright red blood in the nasogastric tube was considered by most to define prophylaxis failure, and the addition of a second drug from a different therapeutic class was the preferred mode of treatment.[49]

Because hemorrhage does not occur in all patients, studies that use bloody nasogastric discharge as a sign of stress gastritis underestimate the true incidence in critically ill patients. In one endoscopically controlled study, 100% of patients with life-threatening injuries had evidence of gastric erosions by 24 hours. A high prevalence of gastric erosions is also noted in burn patients, while GI hemorrhage occurs in only 25–50% of patients with burn wound infection. Barium contrast examinations have no role in the diagnosis of stress gastritis and interfere with endoscopic examination.

It is important to distinguish stress ulceration from other causes of postoperative hemorrhage. Several recent studies have demonstrated that duodenal ulceration and gastric ulcers are common in postoperative patients. In one series, sources of clinically significant bleeding included duodenal ulcer in 26%, gastric ulcer in 13%, esophagitis in 18%, and esophageal varices in 7%. Similar results have been reported in other series, emphasizing the need for specific diagnosis.

UPPER GASTROINTESTINAL BLEEDING

Acute upper gastrointestinal (GI) hemorrhages are frequent medical events occurring at a rate of approximately 50 cases per 100,000 persons per year. Acute GI hemorrhage still has a significant associated mortality, approximating 10%. Although urgent endoscopy has been used for the past 20 years for the diagnosis and management of acute upper GI hemorrhage, the mortality rate has not substantially declined even with the introduction of endoscopic intervention. Patients with acute upper GI hemorrhage are increasingly of advanced age and have preexisting medical comorbidities.

Endoscopy has become the preferred method for diagnosis in patients with acute upper GI bleeding. This method is informative in most patients, correctly identifying the site and source of bleeding in 90% of cases. While the efficacy of upper endoscopy has been established for diagnosing acute upper GI tract hemorrhage, optimal timing has been controversial. The majority of existing studies support the claim that early endoscopy is both safe and effective for all risk groups.

For low-risk patients, the current evidence demonstrates that early endoscopy promotes safe patient disposition. In many instances, these patients can avoid hospitalization with a very low risk of recurrent bleeding. For high-risk patients, there is benefit of early endoscopy for outcomes, including transfusion requirements, rebleeding rate, and the need for emergency surgery. Early endoscopy directs therapy and significantly reduces length of hospitalization relative to delayed endoscopy without evidence of cost shifting to the outpatient setting. In this sense, early endoscopy provides prompt diagnosis and assists in decision making regarding clinical triage and subsequent management. Current evidence does not demonstrate, however, that early endoscopy decreases overall mortality. There is no evidence that the practice of early endoscopic intervention results in patient harm.

Based on current information, gastroduodenal ulceration accounts for approximately 40% of cases of acute upper GI hemorrhage. Other diagnoses, in decreasing frequency, include acute gastritis, esophageal variceal bleeding, esophagitis, duodenitis, Mallory-Weiss tears, and upper GI tract malignancies.

Initial treatment of upper GI tract hemorrhage begins with restoring intravascular volume. Hemodynamic monitoring is crucial. Unstable patients should be initially treated in an ICU setting. Interestingly, although numerous trials have examined the efficacy of H_2-receptor antagonists in patients with bleeding peptic ulcers, none of these have demonstrated consistent therapeutic benefit either individually or when examined by meta-analysis. Sixteen prospective trials have also examined the use of proton pump inhibitors in the setting of acute ulcer bleeding. Only 7 of these 16 trials have demonstrated a statistically significant benefit in terms of rebleeding or need for urgent surgical intervention. None of the trials showed a reduction in mortality. Over half (9 of 16) of the studies did not demonstrate reduction in any of the primary outcomes that included rebleeding, surgery, or mortality.

In addition to providing diagnostic information, aggressive endoscopy also presents an opportunity for therapeutic intervention. Relative to medical therapy alone, patients with stigmata of active bleeding, visible vessels, and nonbleeding adherent clots benefit from endoscopic ulcer hemostasis.

The major modalities used include bipolar electrocautery probes, heater probes, and epinephrine injection.

Mechanisms by which epinephrine injections cause ulcer hemostasis have been examined experimentally. Epinephrine causes intense vasoconstriction, platelet aggregation, and vessel sclerosis. These combined effects permit permanent control of arterial hemorrhage in most patients. Absolute alcohol has also been used for injection therapy with good results.

Potential complications of endoscopic therapy include bowel perforation and incitement of active bleeding from a nonbleeding vessel. The rate of perforation is low and has been reported to approximate 0.7%. New bleeding is induced by therapy in fewer than 1% of patients.

Under selective circumstances, repeated attempts at endoscopic therapy may also be used. In a prospective randomized trial, investigators evaluated whether emergency surgery or repeated endoscopic therapy resulted in better outcomes for patients with severe ulcer hemorrhage. Endoscopic therapy consisted of a combination of epinephrine injection and heater probe application. Definitive hemostasis was significantly higher in surgically treated patients (93 vs 73%), but the complication rate was significantly higher in the surgery group (36%) relative to the endoscopy group (15%).

Acute therapy of variceal bleeding may also be directed endoscopically. Major approaches have included variceal injection with sclerosants and band ligation. Because of efficacy and safety, endoscopic variceal ligation has largely replaced sclerotherapy as the endoscopic method of choice for acute variceal hemorrhage.[50] This method has also been used for secondary prevention of esophageal variceal hemorrhage. Prospective randomized trials indicate that prophylactic variceal ligation decreases the risk of first variceal bleeding relative to no treatment or to treatment with propranolol. In addition, ligation decreases the risk of recurrent bleeding and associated mortality relative to no treatment. In this circumstance, however, relative to propranolol therapy, ligation does not improve mortality.

In patients with acute peptic ulcer as a cause for upper GI hemorrhage, *H. pylori* is a common etiology. After initial control of hemorrhage, eradication of infection should be a treatment imperative. Because eradication of *H. pylori* eliminates ulcer recurrence, it is logical to assume that it would also decrease the rate of recurrent ulcer bleeding. Randomized trials demonstrate that recurrent hemorrhage usually occurs in patients who have persistent or recurrent *H. pylori* infection. Without antibiotic treatment, recurrent hemorrhage occurs in as many as 20% of patients. The risk of recurrent hemorrhage can be reduced to approximately 3% in individuals treated with an effective antibiotic regimen after hemorrhage.

POLYPS

Gastric epithelial polyps are the most common benign tumor of the stomach. There are essentially five types of benign epithelial polyps: adenomatous, hyperplastic (regenerative), hamartomatous, inflammatory, and heterotopic (eg, ectopic pancreas). The most common gastric polyp (~75% in most series) is the hyperplastic or regenerative polyp, which frequently occurs in the setting of gastritis and has a low but real malignant potential. Adenomatous polyps may undergo malignant transformation, similarly to adenomas in the colon. They constitute about 10–15% of gastric polyps. Hamartomatous, inflammatory, and heterotopic polyps have negligible malignant potential. Polyps that are symptomatic, larger than 2 cm, or adenomatous should be removed, usually by endoscopic snare polypectomy. Consideration should also be given to removing hyperplastic polyps, especially if large. Repeat esophagogastroduodenoscopy (EGD) for surveillance should be done following removal of adenomatous polyps.

A fourfold rise in the incidence of nonfamilial fundic gland polyps has been noted due to the increased use of proton pump inhibitors. However, no increased risk of dysplasia has been noted.[51]

LIPOMA

Lipomas are benign submucosal fatty tumors that are usually asymptomatic, found incidentally on upper GI series or EGD. Endoscopically they have a characteristic appearance; there also is a characteristic appearance on endoscopic ultrasound. Excision is unnecessary unless the patient is symptomatic.

BEZOARS

Bezoars are collections of undigestible matter that accumulate in the stomach and small bowel. They are the most common foreign body found in the stomach and may be seen in patients who have undergone prior gastric surgery, including after bariatric surgery.[52–54] The most common bezoar is composed of hair (trichobezoars). It occurs most commonly in young women. Phytobezoars are composed of vegetable matter and are usually seen in association with gastroparesis or gastric outlet obstruction. Other types of bezoars include lactobezoars (concentrated milk formula), mixed medication bezoars, and food bolus bezoars.[55] Bezoars may present with obstruction, ulceration or bleeding, and rarely as intussusception.[56] Diagnosis is suggested by upper GI series and confirmed by endoscopy. Enzyme therapy with papain, cellulase, or acetylcysteine may be used, but most patients will need endoscopic or surgical disruption and extraction.

DIEULAFOY'S LESION

Dieulafoy's lesion is a congenital arteriovenous malformation of the proximal stomach, typically on the lesser curve where it derives its supply from branches of either the left or right gastric artery. It is seen in middle-aged or elderly men and characterized by an unusually large tortuous submucosal artery. Prior to widespread endoscopy, Dieulafoy's lesions were

diagnosed postoperatively but are now becoming diagnosed and treated routinely via endoscopy.[57] It clinically presents as an upper GI bleed if eroded and on endoscopy appears as a stream of arterial blood emanating from what appears grossly to be a normal gastric mucosa. Patients may also present with intermittent episodes of mild upper GI bleeding, and endoscopy can miss the lesion if it is not actively bleeding. Most lesions are now treated via endoscopic therapy (injection of epinephrine or other sclerosants, electrocoagulation, hemoclipping, rubber band ligation, and photocoagulation) or via angiographic embolization. Surgery is sometimes necessary, at which time the lesion may be oversewn or resected.

Dieulafoy's lesions may occasionally be seen in the duodenum and jejunum, as well as in the colon.[58–60] These lesions have also been successfully managed via endoscopy or surgery.[61]

DIVERTICULA

Gastric diverticula are typically solitary and may either be congenital or acquired. Congenital diverticula are rare, true diverticula that typically occur near the gastroesophageal junction and are found on the lesser curve or in the posterior area. They will demonstrate all three layers of the gastric wall on endoscopic ultrasound.[62] Acquired or pseudodiverticula usually have a negligible outer muscle layer and are due to either pulsion or traction and most are found in the antrum. Symptoms are due to inflammation and may produce pain or bleeding but perforation is rare. Symptomatic lesions should be removed and can be done laparoscopically.

Foreign Bodies

Ingested foreign bodies are usually asymptomatic, but removal of sharp or large objects should be considered to avoid bleeding, perforation or obstruction. This can usually be done endoscopically. Aspiration of the foreign body during removal may occur, as well as potential rupture of drug-containing bags in "body packers." Both complications can be fatal. In body packers as well as in patients with large jagged objects, surgical removal is recommended.

Mallory-Weiss Tear

The Mallory-Weiss lesion is a longitudinal tear in the mucosa of the GE junction, usually due to forceful vomiting and/or retching, and is commonly seen in alcoholics. It typically presents with impressive upper GI bleeding. Endoscopy confirms the diagnosis and may be useful in controlling the bleeding, but 90% of patients stop bleeding spontaneously. In patients who continue to bleed, balloon tamponade; angiographic embolization; or selective infusion of vasopressin, systemic vasopressin, and surgery are other treatment options. At surgery, the bleeding lesion is oversewn via a long gastrotomy.

VOLVULUS

Gastric volvulus occurs when the stomach twists around one of its axes, usually seen with a large hiatal hernia. It can also occur in the unusually mobile stomach without a hiatal hernia. Typically, the stomach twists along its long axis (organoaxial volvulus), and the greater curvature flips up. Less frequently, it occurs around the transverse axis, called mesoaxial volvulus. It is usually a chronic condition that can be surprisingly asymptomatic and expectant nonoperative management is usually advised, especially in the elderly. The risk of strangulation and infarction has been overestimated in asymptomatic patients.

Surgery is recommended for symptomatic patients, especially if these are severe and/or progressive. These patients complain of pain and pressure related to the intermittently distending and poorly emptying twisted stomach. Dyspnea, palpitations, and dysphagia may be seen due to compressive effects of the distended stomach on the surrounding organs. Symptoms are often relieved with vomiting or, if possible, passage of a nasogastric tube. The patient who presents moribund most likely has an infarcted stomach and is a case of surgical emergency requiring resection. Elective operation may often be done laparoscopically and usually involves reduction of the stomach and repair of hiatal hernia, with or without gastropexy. Gastropexy alone may be considered for high-risk patients.

GASTROPARESIS

Gastroparesis is a chronic gastric motility disorder defined by delayed gastric emptying of solids without evidence of mechanical obstruction.[63] Primary gastroparesis affects mostly young and middle-aged women who present with nausea, abdominal pain, early satiety, vomiting, fullness, bloating, anorexia, and weight loss, with nausea and vomiting being the most disquieting of all the symptoms. The condition is diagnosed by symptom assessment and delayed gastric emptying of a solid meal. Gastric retention of more than 10% of the standard low-fat meal at 4 hours is indicative of delayed emptying.

Severe gastroparesis might result in recurrent hospitalizations, malnutrition, and significant mortality. Patients failing medical therapy are often considered for a variety of surgical interventions, the efficacy of which is not well studied. These procedures include gastrostomy, jejunostomy, gastric pacing/stimulation, and gastrectomy or surgical drainage procedures. Completion gastrectomy seems to provide symptom relief in postsurgical gastroparesis.[64]

LAPAROSCOPIC GASTRIC OPERATIONS

Perhaps the most common laparoscopic gastric operations performed today are for gastroesophageal reflux disease and obesity. Most of the procedures described in this chapter can be performed with minimally invasive techniques.

Some (eg, partial or total gastric resection) are technically difficult or are of debatable merit (eg, laparoscopic resection for cancer).

The operations, described previously, that lend themselves most readily to minimally invasive techniques are highly selective vagotomy, vagotomy and gastrojejunostomy, and gastrostomy. Laparoscopic wedge resection, combined with either intra-operative endoscopic or radiologic localization, often is possible for most localized, benign lesions such as lipomas, or gastric diverticula, although the incision required to retrieve the specimen may be larger than the initial port incisions.[65,66] Combined endoscopic and laparoscopic techniques have also been described.[67] Diagnostic laparoscopy may prevent a futile laparotomy in some patients with gastric cancer. The number as well as the location of ports is determined by triangulating around the target organ, and most procedures can be performed using four to five ports. The benefits of laparoscopic surgery (less post-op pain, quicker recovery, and decreased hospital stay) are all realized without compromising surgical principles of adequate resection and tension-free anastomosis.

GASTRIC ADENOCARCINOMA AND OTHER GASTRIC NEOPLASMS (EXCEPT GASTROINTESTINAL STROMAL TUMORS)

John T. Langell • Sean J. Mulvihill

EPIDEMIOLOGY OF GASTRIC CANCER

Gastric cancer describes a broad mix of malignant neoplasms derived from the different histological components that make up the stomach. These include adenocarcinoma, lymphoma, carcinoid, and sarcoma. Gastric adenocarcinoma accounts for over 90% of all cases of gastric cancers globally.[1,2] The incidence of gastric cancer decreased dramatically in the latter half of the 20th century; however, a recent rise in proximal gastric cancer incidence has been noted. Gastric cancer remains the second leading cause of cancer-related deaths worldwide (Fig. 22-1).[1–4] As is the case for many cancers, the epidemiological distribution of gastric cancer demonstrates a marked variation in regional incidence—with as much as a 10-fold difference between the highest- and lowest-risk populations.[5] An estimated 900,000–950,000 newly diagnosed gastric cancer cases per year occurred worldwide at the beginning of the 21st century, with the great majority of these cases found in developing countries and China.[2,3,5–7] Industrialized nations continue to see a marked decline in the incidence of gastric cancer, particularly in the body and antrum. In the United States, the estimated number of new cases diagnosed in 2009 was 21,130 with the number of gastric cancer–associated deaths estimated to be 10,620.[7] These numbers highlight the continued decreasing trend in both gastric cancer incidence and mortality (Table 22-1). In fact, death rates attributed to gastric cancer in the Unites States fell by over 40% for males and 32% for females between the years 1990 and 2005.[7]

The diagnosis of gastric cancer portends a poor prognosis with reported overall 5-year survival rates between 20 and 25% in most industrialized nations.[1,6,8] Stage of disease at time of diagnosis is clearly one of the most important correlates of cancer survival. Patients diagnosed with earlier stages of gastric cancer have a distinct advantage in 5-year survival compared to those with more advanced-stage disease (Fig. 22-2). Although the 5-year survival rate for all cases of gastric cancer in the United States between the years 1996 and 2004 was 25%, it was as little as 3% for patients with distant disease and as high as 61% for those who had only localized disease at time of diagnosis.[7] The survival advantage of early diagnosis is best exemplified by Japan's overall 5-year gastric cancer survival rate of 52%. This has been attributed to a high percentage of early-stage diagnosis due to mass photofluoroscopic screening of their population.[2,6] In the United States where the relatively low incidence of gastric cancer does not support routine population screening, only about one-quarter of all patients are found to have localized disease at the time of diagnosis.[6]

ASSOCIATED RISK FACTORS

The risk of developing gastric cancer is associated with a complex interrelationship between environmental factors and their influence on an individual's genetic and epigenetic make up.[1,2,6,9,10] Aside from *Helicobacter pylori* infection, smoking, and possibly a high dietary salt intake, very few proposed environmental risk factors have been validated through scientific analysis.[1–3] The effect of regional environmental influences seems apparent given the marked

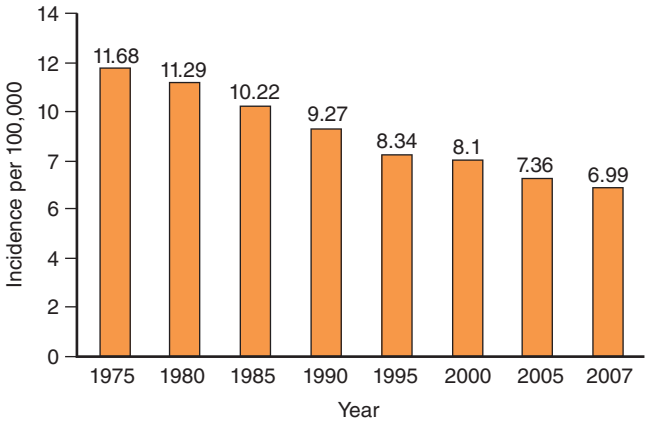

FIGURE 22-1 Incidence of invasive gastric cancer in the United States. (From the SEER Cancer Database, 1975–2007.)

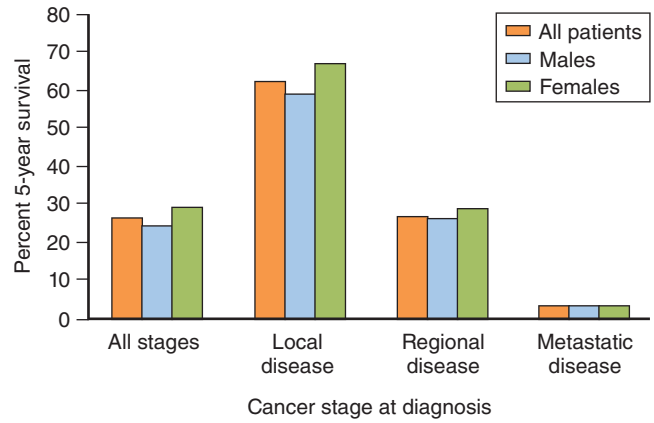

FIGURE 22-2 Gastric cancer 5-year survival rate in the United States. (From the SEER Cancer Database, 1999–2006.)

variation in the incidence of gastric cancer between different geographical regions of the world.[6] Although regional and racial genetic variation could account for a portion of this effect, mass global migration of the population and immigrant cancer susceptibility studies indicate a large environmental effect.[11–15] Epidemiological studies have shown that immigrants who travel from high- to low-prevalence regions still maintain an overall gastric cancer risk about equal to the region they emigrated from.[3] The progenies of these immigrants who are born in the low-prevalence regions, on the other hand, exhibit a prevalence similar to local peoples of comparable ethnic origin.[11–15] This effect points to likely environmental factors that impact an individual's risk of gastric cancer development at an early age of exposure.

In addition to environmental factors, a clear impact of genetic susceptibility on the risk of developing gastric cancer has been identified.[9] This includes not only familial associated genetic cancer syndromes but the effects of similar common genomic composition in individuals sharing ethnic origins. This may account for the notable ethnic variations in gastric cancer observed among members of a population in the same geographic region.[1,7,10] Not only does a geographic subpopulation's ethnicity seem to impact their risk of developing gastric cancer, it also affects their average age of presentation and response to therapy.[10] What is not clear is what proportion of these observed affects are secondary to a subpopulations' shared genetic background and what may be due to shared local cultural differences within their geographic regions.

TABLE 22-1: U.S. GASTRIC CANCER INCIDENCE AND MORTALITY PER 100,000 POPULATION, 2001-2005

	White	African American	Asian American Pacific Islander	American Indian	Hispanic
Incidence	14.7	26.3	29.1	24.5	25
Mortality	7.5	17	16	15.1	13.6

Data from Jemal A, Siegel R, Ward E, et al. Cancer statistics 2009. CA *Cancer J Clin.* 2009;59:225-249.

Helicobacter pylori

H. pylori infection has been demonstrated to be linked to the development of distal gastric cancers but not cancer of the gastric cardia.[16,17] The clear association between *H. pylori* infection and the development of gastric cancer led the International Agency for Research on Cancer (IARC) to classify *H. pylori* infection as a type I human carcinogen in 1994.[18] This has been supported by numerous prospective trials that have estimated that *H. pylori* infection confers an increased relative risk for the development of gastric cancer of 2.1–20 fold.[1,2,19,20] Further, a prospective Japanese study of patients tested for *H. pylori* by serology found that gastric cancer developed in 2.9% of patients who were *H. pylori* seropositive, but in none of the patients in the *H. pylori*–seronegative group.[21] Based on early data, Correa proposed a model of gastric carcinogenesis whereby *H. pylori* initiated an inflammatory cascade leading to the sequential development of chronic gastritis, gastric atrophy, intestinal metaplasia, and dysplasia followed by carcinoma.[22] This concept is supported by the linkage between chronic inflammation and cancer development in many other organs.

Smoking

Convincing evidence has been derived from the European Prospective Investigation into Cancer and Nutrition (EPIC) trial showing cigarette smoking as a causal factor in

the development of gastric cancer. In this study, there was a marked increased risk for developing gastric cancer in patients who had a history of smoking tobacco products with a hazard ratio (HR) of 1.45. The HR increased to 1.73–1.87 for current smokers with an increased risk of gastric cancer proportional to the duration and intensity of the smoking history. Further, cigarette smoking had a more profound effect on the development of gastric cardia cancer (HR 4.10) than of antral cancer (HR 1.94). Overall, the large population-based EPIC trial found that 17.6% of gastric cancer cases may be attributable to smoking tobacco products.[23]

Obesity

Obesity has also emerged as a possible significant risk factor for the development of several cancer types, including cancer of the gastroesophageal junction and gastric cardia.[1,2,24–27] A Swedish population-based study completed by Lagergren et al demonstrated a 2.3-fold increased risk of gastric cancer in the heaviest-weight quartile of the population compared to the lightest-weight quartile and a 4.3-fold increased risk for patients classified as obese.[26] These findings were supported by the results of a large case-control study performed in the United Kingdom that demonstrated a strong association between an increased body mass index and the development of gastric cardia cancer (odds ratio [OR] 1.46), but not noncardia gastric cancer.[25] Furthermore, this effect was dose-dependent and seemed independent of the presence of gastroesophageal reflux disease. The mechanism of increased cancer risk in the obese population has not been elucidated but has been hypothesized to be linked to altered metabolism and/or increased gastroesophageal reflux disease.[24–26]

Diet

Numerous studies have examined the possible association between dietary intake and either the development or prevention of gastric cancer.[1,2] Specifically, a diet rich in fruits and vegetables has been proposed to be protective against the development of gastric cancer. Although evidence from several retrospective studies support an association between a high dietary intake of fruits and vegetables and a decreased gastric cancer risk, this association proved not to be statistically significant in prospective trial analyses.[2]

Another dietary association that has been extensively studied is the possible increased risk of gastric cancer in patients who consume a high intake of salts and nitrates.[28,29] The evidence for this association is still heavily debated, though most published cohort and case-control studies have found a strong association between a high dietary salt intake and gastric cancer.[28,29] These findings, however, have not been uniform. In fact a well-publicized population-based study out of Norway evaluating a cohort of over 73,000 patients found no association between dietary salt intake and cancer.[30] Despite these findings, the majority of studies support a possible association between a high dietary salt intake and the development of gastric cancer in higher-risk populations.

Hereditary Forms of Gastric Cancer

One of the first documented cases of hereditary gastric cancer dates back to the 17th century and was described for the family of the French emperor Napoleon Bonaparte.[31] We now know that up to 3% of gastric cancers are the result of hereditary syndromes.[4] Although many more are likely to be characterized, several well-studied hereditary syndromes include hereditary diffuse gastric cancer (HDGC), Li-Fraumeni syndrome, hereditary nonpolyposis colon cancer, and BRCA2.[9]

The majority of known hereditary gastric cancers are due to HDGC that carries a high penetrance and incidence of gastric cancer in the studied kindreds.[4,9] These patients usually present at an early age with a diffuse multifocal form of gastric cancer. Between 30 and 40% of kindreds with HDGC demonstrate a germline mutation of a single *CDH1* allele, the gene encoding for the structural glycoprotein *E-cadherin*.[32] A complete understanding of the sequence of events that lead to gastric cancer through this single allelic mutation is still unfolding, but there is evidence for loss of heterozygosity though somatic cell epigenetic dysregulation of the normal *CDH1* allele via promoter site methylation in several well-studied cases. Because these patients have a 60–90% lifetime risk of developing a diffuse-type gastric cancer, they present an unusual therapeutic challenge.[9,33] Some have advocated curative early prophylactic gastrectomy in patients who carry the *CDH1* mutation, while others advocate early and routine surveillance endoscopy reserving surgery for patients found to have cancer on surveillance biopsy.[33,34]

CLINICAL PRESENTATION

Signs and Symptoms of Gastric Cancer

The signs and symptoms of gastric cancer are nonspecific and commonly found in unaffected individuals in the general population. They include dyspepsia, fatigue, and malaise among others. Other, more concerning symptoms that are often referred to as alarm symptoms, include weight loss, dysphagia, persistent vomiting, gastrointestinal bleeding, anemia, and a palpable abdominal mass.[35]

Dyspepsia is a very common complaint among patients presenting to primary care physicians.[36] Dyspepsia is also a frequent complaint in patients with gastric cancer; however, peptic ulcer disease, gastroesophageal reflux disease, and functional dyspepsia are far more common causes of dyspepsia.[35] The presence of alarm symptoms presents a more concerning clinical picture in patients with a history of dyspepsia and should alert the evaluating physician that a more extensive

workup to rule out malignancy may be indicated. The presence of alarm symptoms is not specific for malignancy; in fact the incidence of alarm symptoms in dyspeptic patients is high, whereas the incidence of gastric cancer is low.[35] Despite this, prospective and retrospective studies have shown that 56–90% of patients with gastric cancer had alarm symptoms at the time of endoscopy.[37–40] A meta-analysis of seven prospective endoscopic studies involving over 13,000 patients reported the presence of alarm symptoms in 30% of all patients and in 62% of patients found to have gastrointestinal cancer.[41] Of these, no single alarm symptom was present in more than 30% of patients with malignancy.

Another study analyzing patients who underwent urgent endoscopy for the presence of alarm symptoms or dyspepsia unresponsive to empiric therapy found that 3.8% had a gastrointestinal malignancy.[42] In this study, the only alarm symptoms that were predictive of cancer were dysphagia and weight loss with ORs of 3.1 and 2.6, respectively. The presence of uncomplicated dyspepsia, on the other hand, was found to be a negative predictor for cancer with an OR of 0.1.

Although the presence of alarm symptoms is poorly predictive for the presence of cancer, when they are present in gastric cancer patients, the presence and number of alarm symptoms has been shown to correlate with an advanced stage of disease.[43,44] Therefore, the presence of specific alarm symptoms may be of prognostic value in gastric cancer patients. This notion is supported by a recent study completed by Stephens et al where the presence or absence of alarm symptoms correlated with patient survival time. Here, patients were followed from their initial diagnosis of gastric cancer to their date of death. Those patients who presented with alarm symptoms had a survival range of only 7–11 months, whereas patients without alarm symptoms survived between 24 and 39 months.[44]

Physical examination abnormalities in early gastric cancer are generally not present. In patients with advanced disease, a palpable supraclavicular mass, generally on the left side, can be a sign of distant nodal metastasis (the Virchow node). A bulky antral tumor or extensive nodal metastases will occasionally lead to jaundice from bile duct obstruction in the hepatoduodenal ligament. A palpable abdominal mass may be found, sometimes from a bulky primary tumor, but more commonly from omental caking with metastases. Abdominal distension and ascites is a finding concerning for peritoneal carcinomatosis, as is the finding of a palpable nodule at the umbilicus (the Sister Mary Joseph node). Rectal examination may identify an anterior mass in the pouch of Douglas related to peritoneal carcinomatosis and drop metastasis to the pelvis (the Blumer shelf). In advanced disease, pallor related to anemia and evidence of weight loss may be present.

DIAGNOSIS AND STAGING

In symptomatic patients or those with a history of familial gastric cancer undergoing screening evaluation, the diagnosis of cancer is most commonly made by the finding of a mass lesion or concerning ulceration during upper endoscopy. Other patients presenting with more advanced disease may have the diagnosis of malignancy made by CT scan and biopsy of metastatic lesions. Although commonly used in the past, upper gastrointestinal contrast studies with barium or water-soluble contrast agents have largely been replaced by the complementary nature of the combination of endoscopy and CT. Once the diagnosis of gastric cancer has been made, the patient must undergo a staging workup to determine the extent of the disease and potential for curative resection.

Preoperative Staging and Selection of Patients for Surgery

Accurate preoperative staging is essential for appropriate treatment planning. The workup should include upper endoscopy with or without endoscopic ultrasonographic (EUS) evaluation to assess the extent of local and regional disease. The addition of EUS to the preoperative evaluation may improve the accuracy of preoperative staging because it has been shown to be slightly superior to computed tomography (CT) imaging in assessing tumor depth of invasion and locoregional lymph node involvement.[45,46] Because EUS may provide only limited additional information to CT scan in most cases, the recent 2010 Practice Guidelines of the National Comprehensive Cancer Network consider it an optional adjunctive study.[4]

A CT scan of the abdomen with contrast should be performed on all patients along with pelvic CT or ultrasound in females and thoracic imaging in all patients to evaluate the tumor (T) stage, nodal (N) stage, and distant metastatic disease (M) stage, for the purpose of treatment planning. Though CT scan is a recommended and routine part of the preoperative evaluation, it has a relatively low sensitivity for evaluating tumor depth and the presence of metastatic lymph nodes.[4] Newer modalities such as multidetector CT, helical CT, and positron emission tomography CT (PET-CT) have been shown to provide better preoperative staging data; however, their routine use has not yet been advocated as an essential or necessary part of the preoperative staging workup.[4]

In addition to radiographic staging, a complete history and physical examination, an assessment of exercise tolerance, relevant laboratory testing, and indicated physiological evaluations must be performed. These studies help provide evidence of advanced disease as well as the presence and extent of comorbid conditions that may need to be considered prior to treatment. In some patients, the presence of significant comorbid illness or limited performance status may preclude certain treatment options.

Preoperative laboratory testing should include a comprehensive metabolic panel to assess the patient's nutritional status, renal and hepatic function. Patients with a poor nutritional status may benefit from preoperative nutritional supplementation before considering surgical resection. Those with evidence of reduced renal function or poor hepatic synthetic function may not tolerate radical surgical resection or

may be demonstrating signs of advanced disease that will need more extensive staging studies. A complete blood (cell) count (CBC) and basic coagulation studies should be performed to assess the status of known or possible bleeding disorders. Anemia is common in gastric cancer and may represent bleeding from the primary tumor or a vitamin B_{12} deficiency from associated atrophic gastritis

Patients who have signs and symptoms suggestive of cardiopulmonary disease should have at minimum an electrocardiogram (ECG) and chest x-ray (CXR) performed. Additional more extensive testing will be guided by the extent of the patient's symptoms and the findings of the ECG and CXR.

NCCN guidelines recommend that all patients with a diagnosis of gastric cancer, and particularly those with gastroesophageal junction lesions, should undergo comprehensive review of their staging, findings, and treatment planning options by a multidisciplinary cancer treatment team. Unless the patient is to be enrolled in a treatment study protocol approved by an institutional review board, treatment should be based on the current NCCN Practice Guideline recommendations.[4]

Staging

In the United States and the majority of the Western world, staging is based on the TNM (tumor-node-metastasis) system jointly developed by the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer.[47] Table 22-2 summarizes the TNM-based staging system for gastric cancer. This system stratifies patients to a stage of disease that correlates strongly with patient survival. This staging system is based on tumor depth relative to the gastric wall histological layers, presence and number of involved regional lymph nodes, and the presence or absence of distant metastatic disease.

NCCN Practice Guidelines for treatment recommendations for initial therapy are based on the preoperative TNM stage of the disease.[4] To be considered a candidate for curative resection, a patient must be found medically fit to withstand a major abdominal surgery, have limited locoregional disease amenable to resection with negative margins, and be free of evidence of distant metastatic disease. Those who have local disease but are found medically unfit to undergo a major surgical procedure may be candidates to undergo endoscopic mucosal resection (EMR) as discussed below. Those with advanced disease who are otherwise good surgical candidates may be candidates for palliative procedures if indicated. Patients with unresectable disease and those with extensive locoregional disease who are medically unfit to safely withstand radical surgery should be treated in a nonsurgical treatment arm based on current treatment guidelines.

Patients with advanced locoregional disease who are medically fit and have a marked response to a neoadjuvant treatment protocol should undergo complete preoperative restaging once treatment has been completed to determine whether their response to therapy renders them a potential candidate for curative surgical resection.

TABLE 22-2: AJCC TNM CLASSIFICATION OF GASTRIC CANCER

Stage	Primary Tumor	Regional Lymph Node	Distant Metastasis
Stage 0	Tis	N0	M0
Stage IA	T1	N0	M0
Stage IB	T1	N1	M0
	T2a/b	N0	M0
Stage II	T1	N2	M0
	T2a/b	N1	M0
	T3	No	M0
Stage IIIA	T2a/b	N2	M0
	T3	N1	M0
	T4	N0	M0
Stage IIIB	T3	N2	M0
Stage IV	T4	N1–3	M0
	T1–3	N3	M0
	Any T	Any N	M1
	Primary Tumor Definition	**Regional Lymph Node Definition**	**Distant Metastasis Definition**
	Tis: Carcinoma in situ	**N0:** No nodes involved	**M0:** No distant metastasis
	T1: Invades lamina propria or submucosa	**N1:** 1–6 regional nodes involved	**M1:** Distant metastasis
	T2a: Invades muscularis propria	**N2:** 7–15 regional nodes involved	
	T2b: Invades subserosa	**N3:** >15 regional nodes involved	
	T3: Penetrates serosa		
	T4: Invades adjacent structures

ADJUNCTIVE THERAPIES

The 5-year survival rate for gastric cancer remains dismally low even for resectable disease. Surgical resection with curative intent remains the mainstay of therapy; however, the addition of neoadjuvant and/or adjuvant therapy has been shown to improve both disease-free survival and overall survival rates in patients with select stages of disease.[4,48–50] The literature is replete with case series, retrospective studies, and a few prospective randomized control trials (RCTs) that sought to investigate the efficacy of various adjunctive therapeutic regimens in patients who have undergone a curative surgical resection for gastric cancer. In general, these studies have been plagued with inconsistent results and complicated by

the use of diverse therapeutic regimens, many of which are thought to be suboptimal. Fortunately, a handful of well-designed studies and more recent meta-analysis of these data have demonstrated their therapeutic efficacy.

Neoadjuvant therapy consists of a combination of chemotherapeutic agents or chemotherapy plus radiation therapy instituted in the preoperative setting. The theoretical advantages of preoperative treatment include assessing tumor chemosensitivity preoperatively to help tailor postoperative therapy, potential early treatment of micrometastatic disease, better tolerance of therapeutic side effects, and disease down-staging to improve the number of potentially curative resections.[48,49] Preoperative radiation therapy alone or in combination with chemotherapy has been demonstrated to provide a significant increase in down-staging, tumor resectability, and overall 5-year survival rates. Unfortunately, these data were obtained from RCTs of patients with predominantly gastroesophageal junction tumors and therefore may not have similar efficacy with cancers of the gastric body or antrum.[48]

The MAGIC (Medical Research Council Adjuvant Gastric Infusional Chemotherapy) trial[51] demonstrated that the addition of combined preoperative and postoperative chemotherapy consisting of epirubicin, cisplatin, and 5-fluorouricil leads to a significant increase in overall survival and reduced disease progression when compared to patients who received surgery alone, establishing the benefit of neoadjuvant chemotherapy without radiation. Currently, the NCCN guidelines recommend the addition of neoadjuvant chemotherapy or combined chemoradiation therapy for any patient without metastatic disease who is either node positive or staged as T2 or greater in the preoperative setting.[4]

The role of combined modality chemoradiation adjuvant therapy in the postoperative period has been established to significantly increase patient overall survival rates.[4] Until recently, the benefit of adjuvant chemotherapy in the absence of radiation has been more controversial. A recent meta-analysis published in the Journal of the American Medical Association by the Global Advanced/Adjuvant Stomach Tumor Research International Collaboration (Gastric) Group provided the first level I evidence to support the benefits of fluorouracil-based adjuvant chemotherapy.[50] They reported a statistically significant increase in both overall survival and disease-free survival, when compared to surgery alone. The current NCCN guidelines recommend adjuvant therapy for patients without distant disease based on their pathological disease stage and resection margin status. The addition of adjuvant therapy is optional for those who undergo an R0 resection with stage T2/N0/M0 or lesser disease. For those who underwent an R1 resection or an R0 resection with greater than T2 or node-positive disease, an adjuvant fluoropyrimidine-based chemoradiation regimen (preferred) or alternative chemotherapy alone is recommended. Patients who undergo an R2 resection, regardless of T or N stage, have the option of undergoing therapy as noted previously for an R1 section or alternatively may be treated with best supportive care in the absence of adjuvant therapy. Unless patients are enrolled in an approved study protocol, we recommend adherence to the most current published treatment guidelines outlined by the NCCN.[4]

SURGICAL APPROACH TO GASTRIC CANCER

The principles of surgical resection are to obtain resection margins that are grossly at least 5 cm from the visible or palpable mass.[52] The specimen should be sent for frozen-section pathological analysis to access margin status. Ideally, margins should be microscopically free from cancer, often referred to as an R0 resection.[53] If the surgical margins are not initially free of microscopic disease, an additional resection should be performed if anatomically feasible. Obtaining an R0 resection is the guiding principle in determining whether to perform a distal gastrectomy, a total gastrectomy, or an esophagogastrectomy. The long-term survival rates for patients undergoing a total gastrectomy and a distal gastrectomy are similar provided that negative surgical margins are obtained.[54] However, a more limited surgical resection may provide a lower rate of postoperative complications and a higher quality of life.[55] Although some authors advocate performing a proximal gastrectomy for limited proximal gastric cancers, the authors of this chapter have not found consistent convincing evidence for its benefit over total gastrectomy. In proximal gastrectomy, the antrum can be preserved; however, it is not highly distensible and provides little capacity advantage compared to total gastrectomy. We have therefore decided not to include the technique for proximal gastrectomy in this chapter but recognize that it is a reasonable surgical option practiced at some centers.

It is important to acknowledge that preoperative staging is not always correct and that some patients will be found to be unable to undergo curative resection at the time of surgery. These include patients found to have previously undiagnosed distant metastatic disease, carcinomatosis, or advanced locoregional disease. It is for this reason that many authors advocate laparoscopic staging prior to advancing to a full laparotomy.[4] Relatively asymptomatic patients found to have unresectable disease on laparoscopic evaluation can be referred for nonsurgical treatment options without suffering the attendant risks of a full laparotomy or radical surgical resection. Functional, but symptomatic, patients presenting with marked anemia or obstructive symptoms may benefit from a limited surgical approach to include intestinal bypass or partial gastric resection as a palliative measure. These patients do not necessarily need to undergo laparoscopic staging because they will need a palliative procedure if they are found to be unresectable for cure.

In experienced centers, patients with limited disease may be candidates for laparoscopic gastrectomy for cancer. Recent published case series and one randomized control study have shown patients undergoing laparoscopic gastric resections to have similar oncological outcomes to patients undergoing

open gastrectomy techniques.[56–58] The data from these studies are limited, and the selection criteria defining patients appropriate for laparoscopic resection have not yet been well defined. Sufficient randomized data have not convincingly demonstrated equivalent or superior survival following laparoscopic resection compared to laparotomy and resection. If applied, the laparoscopic approach should follow the same surgical principles as for open gastric resection. The major differences will lie in the unique requirements of the laparoscopic approach. Because it has not been studied sufficiently to regard it as the standard of care, we have elected not to include a detailed description of nuances of the laparoscopic approach in this chapter.

Extent of Lymph Node Dissection

The importance of the presence and extent of lymph node metastasis is reflected in the system used to stage the disease and provide prognosis for the patient's extent of disease. What is less clear, however, is the impact of surgical resection of regional lymph nodes on survival. The locoregional gastric nodes have been characterized based on their anatomical location relative to the stomach and are described according to their stations 1–11.[59] As demonstrated in Fig. 22-3, stations 1, 3, and 5 lymph nodes are located along the lesser curvature of the stomach. Stations 2, 4, and 6 nodes lie along the greater curvature of the stomach. Station 7 nodes are found in the tissue along the left gastric artery, station 8 nodes along the common hepatic artery, station 9 nodes along the celiac artery, and stations 10 and 11 nodes along the splenic artery.

The perigastric lymphatics located at nodal stations 1–6 make up a subset of lymph nodes referred to as N1 nodes.[5] Lymph nodes located at nodal stations 7–11 are referred to as N2 nodes. All other nodes encountered in the surgical dissection are considered distant nodes and are thought to preclude a curative resection when positive for metastasis. The extent of surgical lymph node dissection has traditionally been categorized as a D1 resection when care is taken to completely dissect and remove all of the N1 nodes with the surgical specimen, a D2 resection when all N1 and N2 nodes are completely dissected and removed, or a D0 resection when stations 1–6 are not completely removed.[4] The extent of resection is important when the Japanese gastric cancer staging system is used; however, it is not used as a prognostic factor in the TNM staging system adopted by Western nations. When the TNM staging system is used, the most important principles of lymph node dissection that have emerged are to remove all grossly involved nodes and to obtain at least 15 perigastric lymph nodes for pathological sampling.[47]

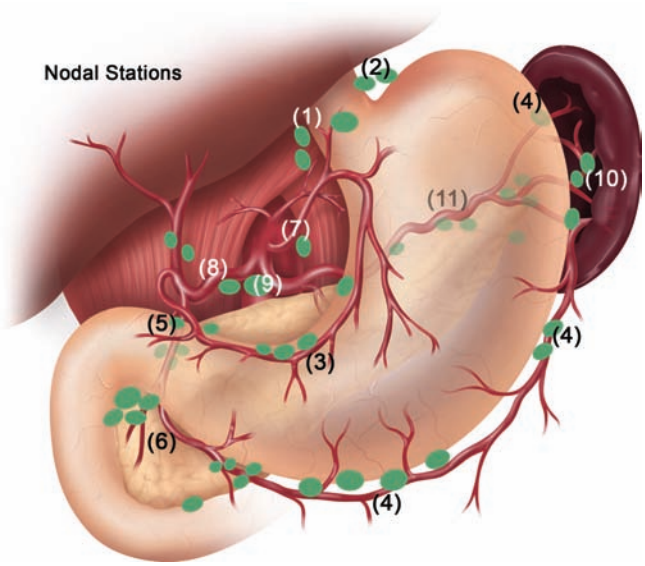

FIGURE 22-3 Gastric lymph node stations.

The extent of lymph node dissection to be performed and its impact on postoperative survival is perhaps the most debated topic in surgery for gastric cancer. The Japanese and, more recently, several European centers have published studies advocating more extensive D2 and D3 lymph node dissections for patients undergoing surgery with curative intent.[60–62] The literature on this topic contains a large number of small case series, retrospective studies, and uncontrolled noncomparative studies on the impact of various degrees of lymph node dissection concurrent with both partial and total gastrectomy for gastric cancer. Only two RCTs from Western centers that had adequate study designs and appropriate statistical analysis of outcomes measures have been published comparing D1 and D2 lymph node dissections in gastric cancer patients.[63–67] Both studies evaluated similar primary outcomes measures looking at 5-year survival rates, postoperative morbidity, and postoperative mortality. Both studies concluded that a more extensive D2 dissection provided no significant benefit to 5-year survival, while those patients undergoing D2 lymph node dissections had significantly more postoperative complications and a higher in-hospital mortality rate. Other, nonrandomized single-arm trials evaluating outcomes after D2 dissections completed at specialized centers noted much lower postoperative morbidity and mortality rates, similar to rates reported for D1 dissections. These authors have criticized the data from the previously described RCT, stating that they suffered from lack of surgeon experience and operative standardization.[62,68]

In 2004 the Cochrane collaboration attempted to determine the superiority of D1 versus D2 lymph node dissections for gastric cancer through a meta-analysis and systematic review of the literature.[68] Here they critically analyzed the literature, then evaluated properly conducted studies from both randomized control trials and nonrandomized trials with similar outcomes measures. Based on a meta-analysis of RCT, they concluded there was no survival benefit to patients undergoing a D2 dissection, with the possible exception of patients with T3-positive disease. They also concluded that there was a markedly higher operative mortality rate specifically associated with D2 dissection and concurrent spleen and pancreas resection. They also noted that both RCTs were

confounded by a lack of surgeon compliance and inexperience. Based on published nonrandomized comparative studies, they concluded that D2 dissections may provide a survival benefit to patients with intermediate-stage gastric cancer. In addition, based on their analysis of published observational studies, they found that patients undergoing D2 dissections may have an overall survival advantage without a markedly increased operative mortality rate when performed at experienced centers. Overall, they noted the available published data comparing D1 and D2 lymph node dissections to be limited and seriously flawed.[68]

Since the publication of the Cochrane review, numerous nonrandomized comparative studies and single-armed observational studies have continued to argue the case for the benefit of a D2 dissection over a D1 dissection. The majority of these studies have shown that patients undergoing D2 dissections have superior 5-year survival rates with equivalent or better rates of operative-associated morbidity and mortality. Most authors attribute these findings to improved surgical skill and experience along with performance of D2 dissections without performing concurrent spleen and pancreas resections, as was standard for both of the published RCTs.[60–62,69–71] In support of this, the Dutch RCT study group recently published a 15-year follow-up of their trial and noted an increased trend in the overall 15-year survival rate of patients undergoing D2 resections (29%) compared to patients undergoing D1 resections (21%), though the difference proved not to be statistically significant (p = .34). They did, however, find a significantly lower gastric cancer–related death rate and lower rate of locoregional recurrence in the D2 population. Based on these data, and contrary to previous recommendations from this group, they now advocate D2 lymphadenectomy for patients undergoing curative resection when performed at experienced high-volume centers using safer spleen-preserving techniques.[71] Despite the increasing trend in the literature advocating D2 lymph node dissections, it is clear that further multicenter RCTs are needed to determine the risks and benefits of more extensive lymph node dissection techniques. Currently, the question of whether to perform a D1 versus a D2 dissection for patients undergoing surgery with curative intent remains to be determined by individual surgeons and their associated multidisciplinary cancer treatment teams (Table 22-3).

The system of lymph node staging in gastric cancer also continues to be a topic of debate. In a recent study of over 700 gastric cancer patients, four lymph node staging systems, including the Japanese and TMN systems were compared for their ability to predict patient outcomes. In this study the system found to be easiest to use and most predictive of postoperative outcomes was a method based on the ratio of nodes positive for metastatic disease to the total number of nodes collected, independent of the total number of nodes sampled.[72] In light of data from this and other recent studies and the ongoing intense debate regarding the optimal staging of lymph nodes in gastric cancer, we are likely to see modifications to the current systems in the future.

TABLE 22-3: RANDOMIZED CONTROLLED TRIAL RESULTS COMPARING D1 VERSUS D2 LYMPH NODE DISSECTION IN PATIENTS UNDERGOING GASTRECTOMY WITH CURATIVE INTENT

Authors	Study Groups	Number of Patients	Outcomes Measure	Findings
Bonenkamp et al[63]	Dutch	711	Perioperative mortality	D2 dissection had significantly higher mortality rate
Bonenkamp et al[64]	Dutch	711	Mean 5-y survival rate	No difference in 5-y survival rate between groups
Hartgrink et al[67]	Dutch	711	Mean 11-y survival rate	No difference in 11-y survival rate between groups
Songun et al[71]	Dutch	711	Mean 15-y survival rate	No difference in overall survival rate between groups Statistically higher local recurrence rate in D1 group Statistically higher cancer-specific death rate in D1 group
Cuschieri et al[65]	British	400	Perioperative mortality	D2 dissection had significantly higher mortality rate
Cuschieri et al[66]	British	400	Mean 5-y survival rate	No difference in 5-y survival rate between groups

Endoscopic Submucosal Resection

Endoscopic submucosal resection (ESR) is a minimally invasive resection technique usually performed by gastroenterologists, primarily in Japan and a few specialized centers worldwide.[4,73] This procedure is reserved for relatively small (<2 cm) mucosal lesions that have a very low risk of lymph node metastasis and no findings consistent with metastatic disease.[74] Recently this technique was extended to include lesions at high risk for lymph node metastasis in patients with a poor performance status or in higher-risk lesions when ESR is accompanied by a laparoscopic lymph node dissection. The results of ESR case series on patients meeting these later criteria are published in the literature, but appropriate controlled studies and scientific analysis of this technique for higher-risk lesions are absent.[75,76]

SURGICAL TECHNIQUES FOR GASTRIC CANCER

Distal Gastrectomy

Laparoscopic exploration of the peritoneal cavity should be considered prior to initiation of a formal laparotomy to ensure absence of carcinomatosis or distant disease that would preclude a curative resection. Patients in whom the yield of laparoscopy may be higher include those with a prolonged duration of symptoms, those with weight loss, and those with equivocal CT findings of metastatic disease. NCCN guidelines suggest that the use of laparoscopy may be helpful in complete clinical staging prior to resection, but the level of evidence supporting its use is not high enough to make it the standard of care for all patients.[4] Next, an upper midline or bilateral subcostal incision is made of adequate length to allow placement of a fixed surgical retractor and facilitate adequate operative exposure. The operative sequence that follows may vary depending on the extent of lymph node dissection and the reconstructive technique chosen.

Step 1 is to identify the location of the tumor through manual palpation, or for smaller lesions, visualization of an endoscopically placed tattoo. This first step is essential in order to determine the extent of resection necessary to obtain an adequate resection margin. It is critically important in proximal lesions to ensure that a negative esophageal margin can be obtained before transaction of the duodenum. Next, if there is a high concern for metastatic disease, the duodenum and pancreatic head are mobilized in order to expose the para-aortic lymph nodes that may demonstrate signs of distant nodal spread and help establish whether there is potential for a curative resection. The retroperitoneum is then incised along the lateral border of the second portion of the duodenum. Medial visceral rotation of the duodenum and pancreatic head is performed, exposing the inferior vena cava (IVC) and aorta. The exposed para-aortic lymph nodes located in the aortocaval space are dissected and sampled. If pathologic-appearing nodes are encountered, frozen-section analysis should be performed to exclude distal nodal spread, as this would preclude a curative resection. Once the absence of distal nodal spread is confirmed, we commence with the inferior portion of the dissection.

The gastrocolic ligament is detached from the transverse colon along the avascular plane using electrocautery (Fig. 22-4). The anterior layer of the transverse mesocolon is sharply dissected to the level of the inferior border of the pancreas. This step separates the anterior mesocolonic peritoneum from the underlying vessels and posterior layer, thus skeletonizing the mesocolonic vessels (Fig. 22-5). The exposed right gastroepiploic vessels are ligated and transected. Dissection of the anterior layer of the mesocolon is typically continued to its confluence with the anterior capsule of the pancreas. The dissection will expose the left gastroepiploic vessels, which must be ligated and transected. Continued dissection of the anterior pancreatic capsule is continued to the superior margin of the pancreas, allowing

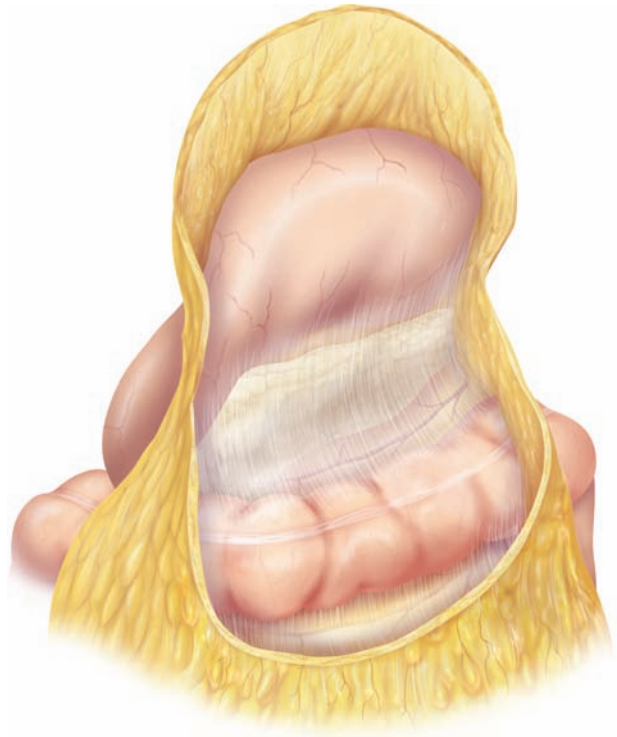

FIGURE 22-4 Detachment of the greater omentum from the colon through the avascular plane.

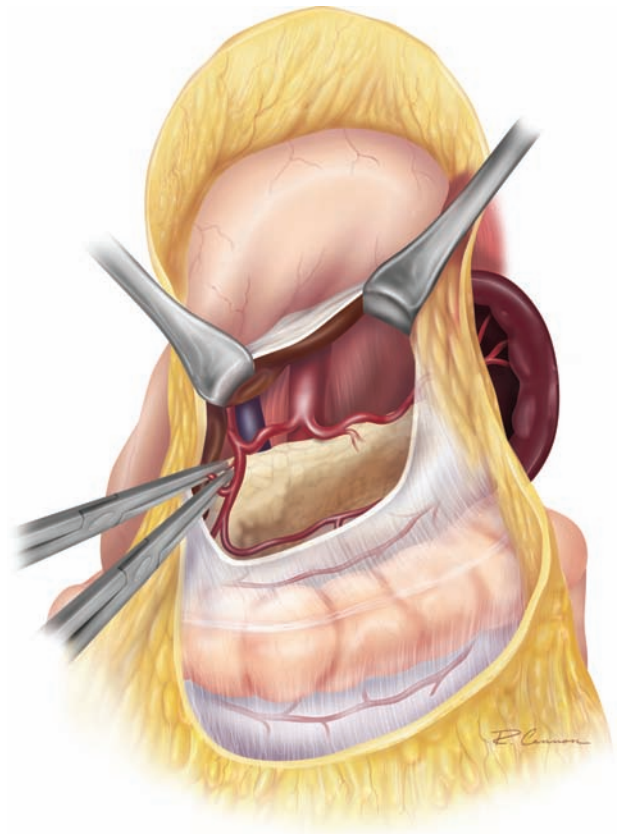

FIGURE 22-5 The anterior mesocolon is separated from the underlying vessels and posterior layer.

exposure of the celiac, splenic, and hepatic arteries and their associated nodal beds. When a D2 node dissection is to be performed, these nodal beds are cleared of lymphatic tissue. Ideally, dissection of these nodes is delayed until the duodenum has been divided in order to facilitate exposure.

The gastroduodenal junction is palpated and evaluated for distal tumor involvement. If the area appears free of malignancy, the duodenum is divided 1–2 cm distal to the pylorus (Fig. 22-6). If tumor is palpable at the pylorus or proximal duodenal bulb, the duodenum is divided 1–2 cm distal to that point to obtain a microscopically negative resection margin. In this situation, however, care must be taken not to injure the retroduodenal portion of the common bile duct, the minor papilla, or the ampulla of Vater. The gastroduodenal artery serves as a useful landmark as it passes behind the duodenal bulb. The retroduodenal common bile duct usually lies within 1 cm to the right of this vessel. We generally complete the division of the duodenum with a GIA stapler. Others prefer to transect the duodenum between bowel clamps and close the duodenal stump with a running 3-0 absorbable monofilament suture such as PDS. There are no data to support the superiority of one method over the other. Some surgeons invaginate the duodenal staple/suture line with interrupted sutures in a standard Lembert fashion (Fig. 22-7).

If a D2 node dissection is performed, division of the duodenum provides improved exposure to the nodal bearing tissue adjacent to the hepatic, celiac, and splenic arteries located along the superior border of the pancreas. This tissue should be dissected and cleared from the region of the gastroduodenal artery to the basin adjacent to the proximal splenic artery. Care must be taken not to injure the pancreatic parenchyma or the celiac plexus.

Dissection of the lesser omentum is completed along the lesser curvature of the stomach from the inferior edge of the hepatoduodenal ligament to the right crus of the diaphragm. The retroperitoneal incision created along the lateral border of the second portion of the duodenum is extended superiorly to the confluence with the hepatoduodenal ligament at the inferior aspect of the foramen of Winslow. Next, the left lobe of the liver is retracted superiorly and to the right to expose the region of the diaphragmatic hiatus. The hepatogastric ligament is then incised from the diaphragmatic crus anterior to the gastroesophageal junction and along the hepatic border to the level of the porta hepatis at its confluence with the hepatoduodenal ligament (Fig. 22-8). The incision is then carried

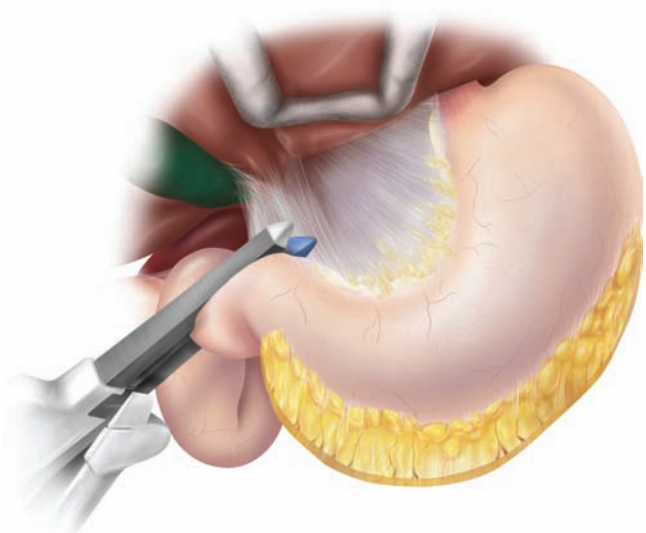

FIGURE 22-6 The duodenum is divided 1–2 cm distal to the pylorus.

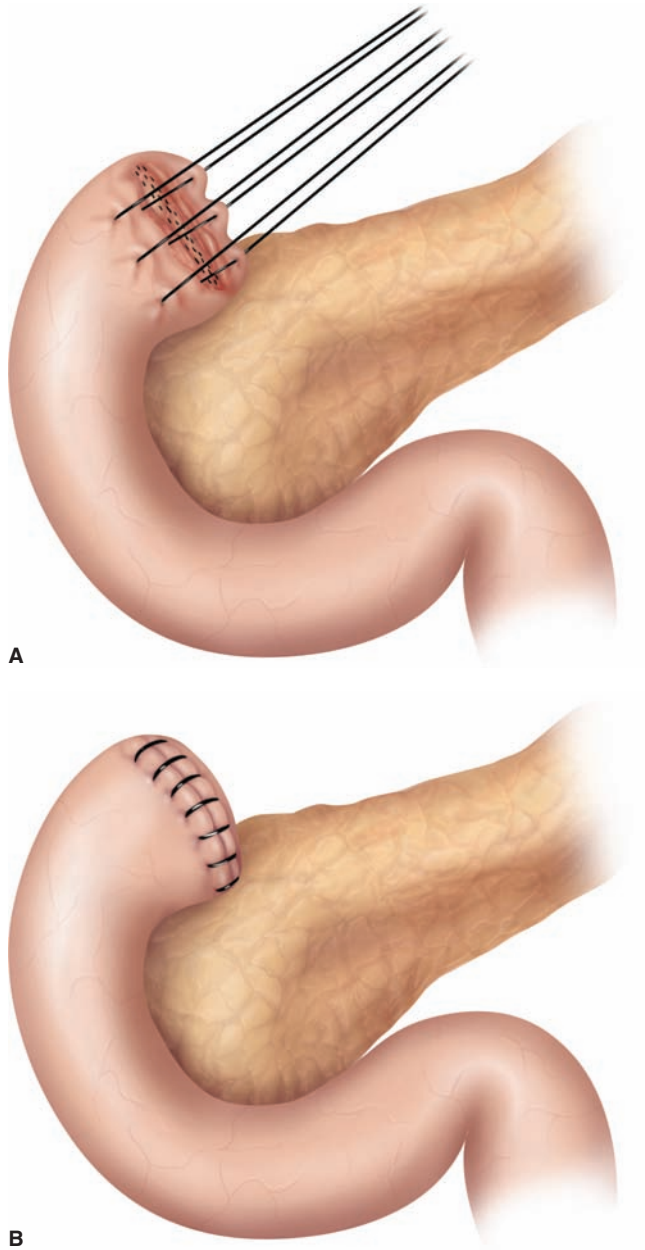

FIGURE 22-7 **A.** and **B.** The duodenal staple/suture line is invaginated with interrupted Lembert sutures.

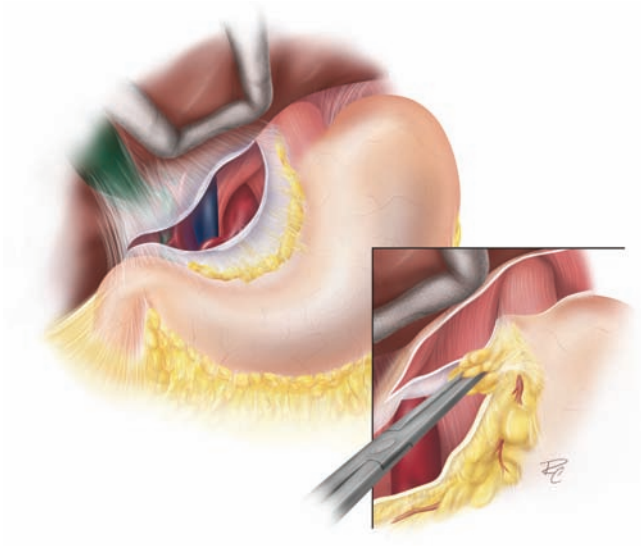

FIGURE 22-8 The hepatogastric ligament is incised from the diaphragmatic crus anterior to the gastroesophageal junction and along the hepatic border from the porta hepatis to the hepatoduodenal ligament.

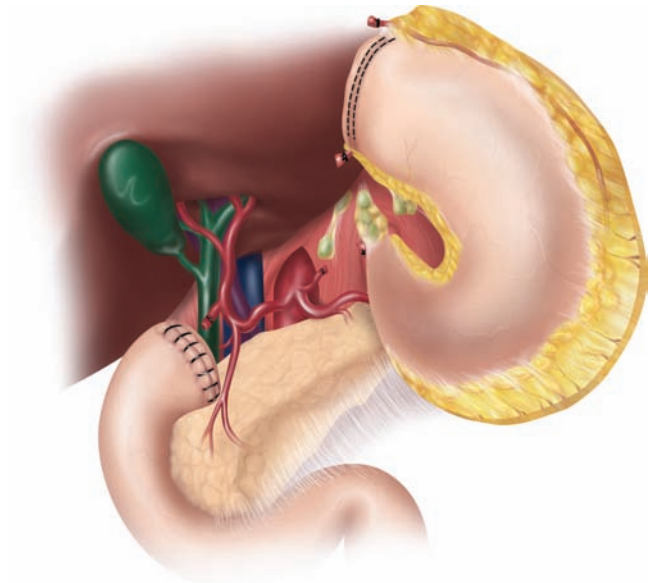

FIGURE 22-9 The left gastric artery and vein are exposed and ligated. The retroperitoneal dissection is carried to the left and inferiorly to join the retroperitoneal resection margin along the superior border of the pancreas.

inferiorly along the left border of the left hepatic artery to just above the junction with the duodenum, then medically to join with the retroperitoneal incision created previously. The hepatoduodenal ligament is then incised superiorly at the level of the cystic duct, and then reflected medially, exposing the structures of the porta hepatis inferiorly. The superior and inferior resection margins of the hepatoduodenal ligament are carried posteriorly behind the portal vein. The right gastric artery and vein are identified, ligated, and transected. The hepatoduodenal ligament that had been freed circumferentially from the porta hepatis can now be taken along with the nodal bearing connective tissue medial to the portal triad. The retroperitoneal dissection is then continued to the right of the aorta superiorly to the median arcuate ligament. The left gastric artery and vein are then exposed and ligated at their origins. If a D2 dissection is to be completed, dissection and clearance of the nodal bearing tissue around the left gastric artery should be performed at this point. The retroperitoneal dissection is then carried to the left and inferiorly to join the retroperitoneal resection margin along the superior border of the pancreas (Fig. 22-9).

The point of proximal gastric resection must be determined based on the location of the lesion. This requires resection of the entire lesion with a minimum 5-cm margin free of cancer. For a distal gastrectomy, the proximal resection plane is created from approximately 2 cm distal to the esophagogastric junction along the lesser curvature to a point along the greater curvature that will allow for a 5-cm resection margin. Division of the remaining greater omentum is performed to the level of the greater curvature resection point either by dividing between clamps and suture ligating the short gastric vessels or with an appropriate surgical energy source. Care should be exercised to avoid injury to the short gastric vessels located in the unresected greater omentum. With the proximal resection line delineated, the stomach is transected either between clamps or with a surgical stapler (Fig. 22-10). The en bloc specimen should be marked to orient the pathologist to the appropriate margins and sent for frozen pathological analysis to ensure an adequate resection margin free of cancer has been obtained. Failure to obtain a cancer-free resection margin necessitates one or more attempted proximal gastric resections until appropriate margins are obtained if anatomically feasible.

Once the resection is complete, the decision as to which reconstructive technique will be used must be made. We

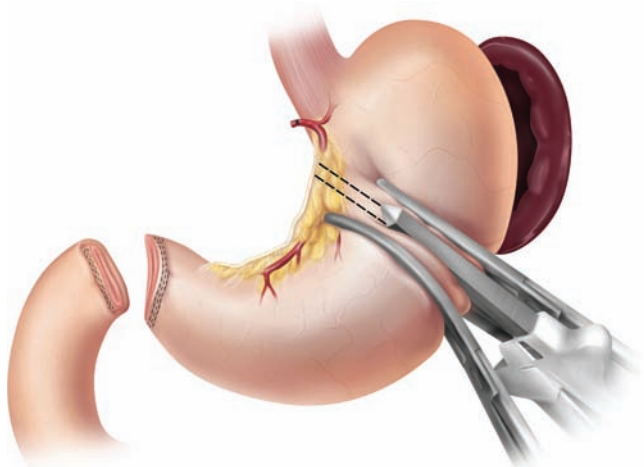

FIGURE 22-10 With the proximal resection line delineated, the stomach is transected either between clamps or with a surgical stapler.

generally perform a Billroth II reconstruction. For details on reconstructive options and surgical techniques, please review the section on operative reconstruction options below.

Total Gastrectomy

The surgical approach for a proximal gastric lesion is very similar to that outlined previously for a distal gastric lesion. The only major variation is completion of the proximal dissection at the gastroesophageal junction and diaphragmatic crura with en bloc removal of the gastric pericardial and paraesophageal lymph nodes (Fig. 22-11). The dissection of the omentum along the greater curvature must also be completed, taking care to divide the remaining short gastric vessels close to the spleen. Once the preceding dissection is completed, the proximal transaction margin is identified on the esophagus, just proximal to the gastroesophageal junction. Esophageal division can be completed with an intestinal stapling device or an angled bowel clamp can be placed proximal to the planned transaction margin using a scalpel to divide the esophagus (Fig. 22-12). As with the distal gastrectomy, frozen-section analysis of the proximal margin must be completed in order to ensure a curative resection. If a cancer-free margin cannot be obtained, the surgeon must determine whether the patient is a candidate for a curative esophagogastrectomy. Once the en bloc resection is complete and frozen-section pathological analysis has confirmed adequate operative margins, the intestinal reconstruction must be completed through the use of a Roux-en-Y esophagojejunostomy. The surgical approach to this reconstructive method is described in detail in the following text.

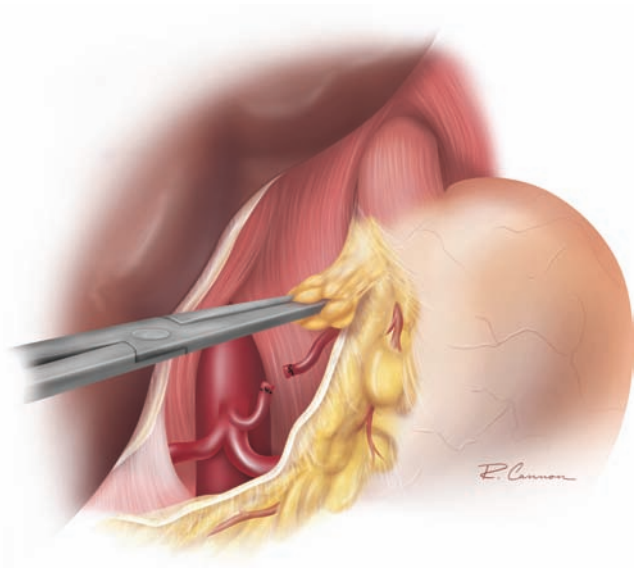

FIGURE 22-11 Proximal dissection at the gastroesophageal junction and diaphragmatic crura with en bloc removal of the gastric pericardial and paraesophageal lymph nodes.

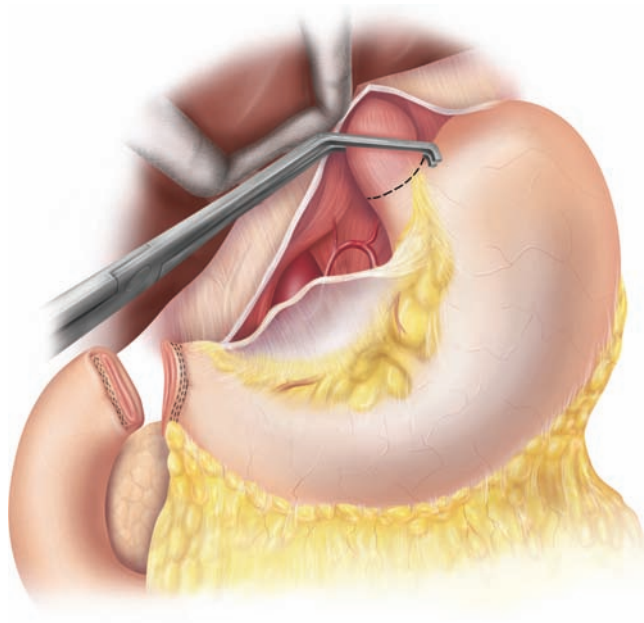

FIGURE 22-12 Esophageal division is completed with an intestinal stapling device or an angled bowel clamp.

GASTROINTESTINAL RECONSTRUCTIVE TECHNIQUES

When determining the appropriate reconstructive method to restore intestinal continuity after gastric resection, it is important to choose a technique that will minimize long-term postoperative nutritional deficiencies.[77,78] The most common of these complications include marked weight loss and dumping syndrome.[77–79] Some authors have asserted that this is best accomplished by restoring gastroduodenal integrity through construction of a jejunal interposition graft after total or subtotal gastrectomy.[80–82] Although numerous case reports and case series have been published on various jejunal interposition techniques, there is currently no convincing evidence to support their use or a consensus on a standardized or optimal technique. Given the lack of adequate scientific evidence to support the merits of jejunal interposition grafts, we do not currently recommend their use. What does seem clear from published studies is that the most important concepts of reconstruction are to choose a technique that restores gastrointestinal continuity while reducing the incidence of bile reflux and anastomotic strictures.

Intestinal Reconstruction After Distal Gastrectomy

BILLROTH II RECONSTRUCTION

Given its technical ease, reasonable long-term patency rate, and good functional outcome, we generally recommend the

use of a Billroth II reconstruction after distal gastrectomy. This is achieved by identifying the jejunal origin at the ligament of Treitz, by tracing the Billroth II reconstruction distally to identify the shortest amount of jejunum necessary to create a tension-free anastomosis, roughly 15 cm from the ligament of Treitz. A shorter limb is thought to reduce the incidence of afferent limb syndrome. Once this point has been identified, it is marked with a suture to facilitate ease of future identification. Next, it must be decided whether to bring the jejunal limb to the proximal gastric remnant through a retrocolic or antecolic approach. Although there are advocates of both approaches, neither has been shown to have a true functional advantage over the other. We prefer the antecolic approach when the jejunal limb can easily reach in this manner, as it does not carry the attendant risk of retrocolic internal herniation. If limb length is an issue, the retrocolic approach may shorten the distance involved for a tension-free anastomosis. In this setting, we prefer to bring the gastric remnant down through the mesocolic defect so that the anastomosis is completely inframesocolic. This may reduce the incidence of afferent limb obstruction.

The gastrojejunal anastomosis is then created by placing the segment of the jejunal limb previously marked with suture adjacent to and in parallel with the proximal gastric remnant along its posterior-inferior margin. Once the location of the gastrojejunal anastomosis has been determined, a posterior row of Lembert-type sutures is placed to join the jejunum to the gastric wall. This is accomplished using either 3-0 Vicryl or silk-interrupted sutures along the entire posterior aspect of the anastomosis. Electrocautery is then used to create a full-thickness defect in the gastric wall anterior to the row of the posterior Lembert sutures that is long enough to facilitate a 5-cm anastomotic opening. A similar full-thickness defect is made in the adjacent segment of jejunum. An anastomosis is created using 3-0 or 4-0 PDS beginning at the posterior-middle segment. Two 3-0 PDS sutures are placed immediately next to each other and run in opposite directions until they meet in the anterior aspect of the anastomosis. The two PDS sutures are then tied together to complete the anastomosis. Next, an anterior row of Lembert-type sutures are placed using either 3-0 Vicryl or silk suture (Fig. 22-13). If a retrocolic approach was used, the defect in the transverse mesocolon must be closed by sutures between the mesocolon and the stomach to avoid internal herniation.

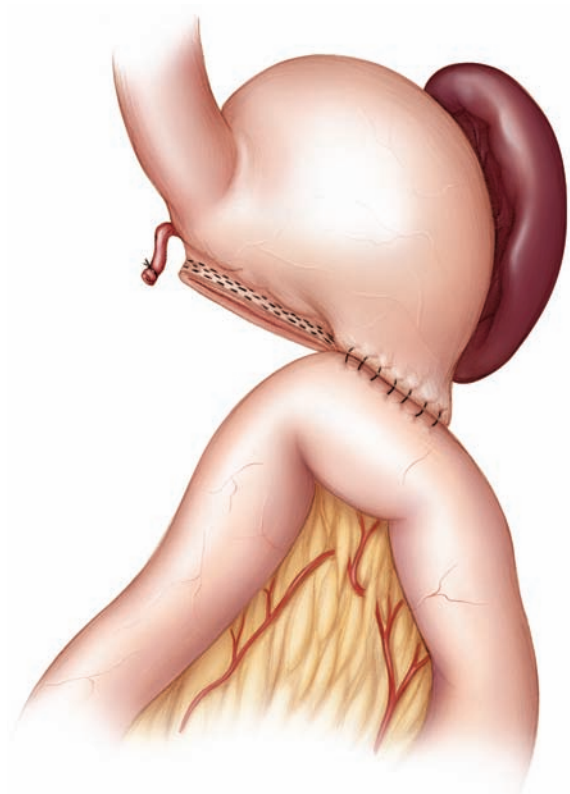

FIGURE 22-13 For a Billroth II anastomosis, a gastrojejunal anastomosis is performed with a running absorbable monofilament sutures.

ROUX-EN-Y RECONSTRUCTION

An acceptable alternative reconstruction method is Roux-en-Y gastrojejunostomy. The Roux technique has the advantage of eliminating bile reflux into the gastric remnant but has the disadvantages of two anastomoses and the possibility of Roux-stasis syndrome. The Roux technique is approached by identifying the origin of the jejunum at the ligament of Treitz. The jejunum is traced distally to approximately 10–15 cm. A defect is created in the jejunal mesentery just below the mesenteric border of the jejunum. The jejunum is then divided either between bowel clamps, or, as we prefer, with a gastrointestinal stapler (Fig. 22-14). The mesentery is divided enough to

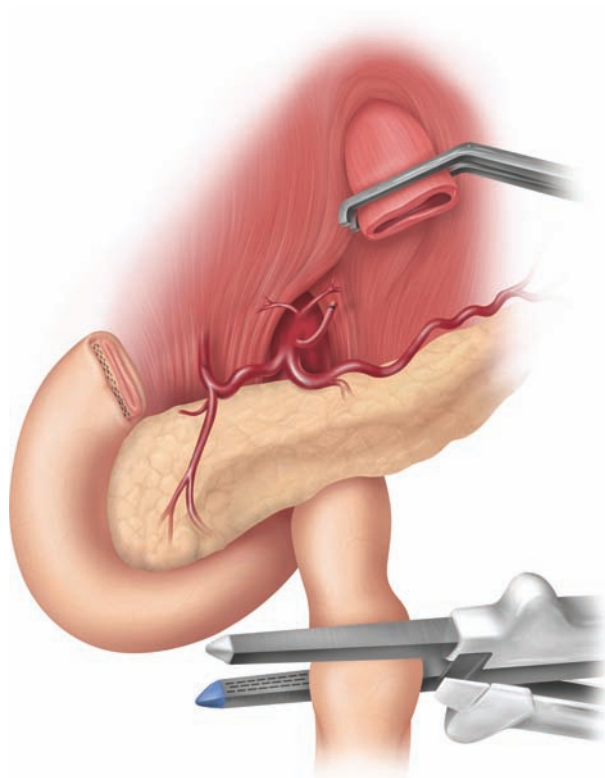

FIGURE 22-14 For Roux-en-Y reconstruction, the jejunum is divided 10–15 cm distal to the ligament of Treitz.

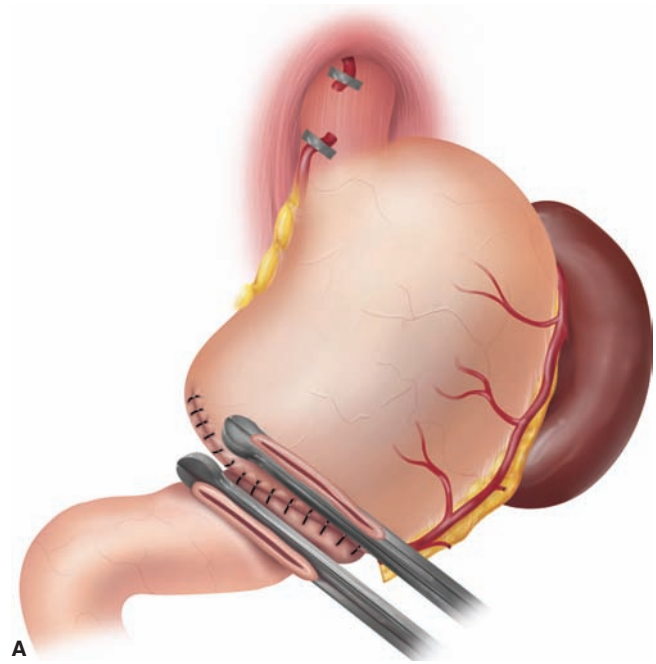
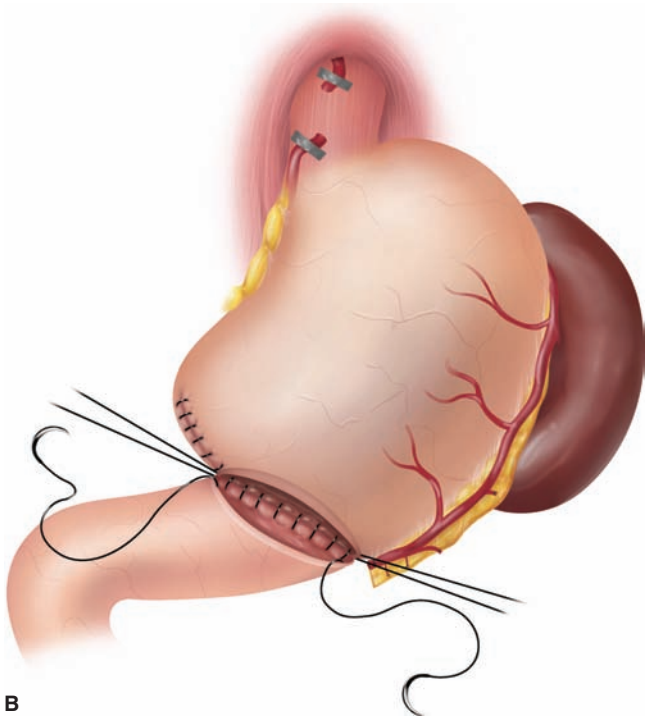
permit the limb to reach to the gastric remnant while avoiding bowel devascularization. This usually includes division of the first anastomotic arcade of the jejunum. Care should be taken with transillumination of the mesentery to understand the vascular anatomy and preserve blood supply to both limbs of the jejunum. The distal segment of the transected jejunum is brought to lie along the posterior-inferior aspect of the gastric margin as with the Billroth II reconstruction above. A posterior row of Lembert-type sutures is place to attach the jejunum to the gastric wall. This is accomplished using either 3-0 Vicryl or silk-interrupted sutures along the entire posterior aspect of the anastomosis. Electrocautery is then used to create a full-thickness defect in the gastric wall anterior to the row of the posterior Lembert sutures that is long enough to facilitate a 5-cm anastomotic opening. A similar full-thickness defect is made in the adjacent segment of jejunum. An anastomosis is created using 3-0 or 4-0 PDS beginning at the posterior-middle segment. Two 3-0 PDS sutures are placed immediately next to each other and run in opposite directions until they meet in the anterior aspect of the anastomosis. The two PDS sutures are then tied together to complete the anastomosis. Next, an anterior row of Lembert-type sutures are placed using either 3-0 Vicryl or silk suture (Fig. 22-15).

Attention is then turned to creation of the jejunojejunostomy. The proximal jejunal staple line is anastomosed to the distal jejunal segment approximately 45–50 cm distal to the gastrojejunostomy. This distance has previously been shown to be the optimal length of the Roux limb needed to reduce the incidence of bile reflux, while also reducing excessive limb length, which may contribute to stasis and malnutrition. The two segments of jejunum to be anastomosed are aligned parallel to each other in order to create a 5-cm antimesenteric anastomosis. The anastomosis may be





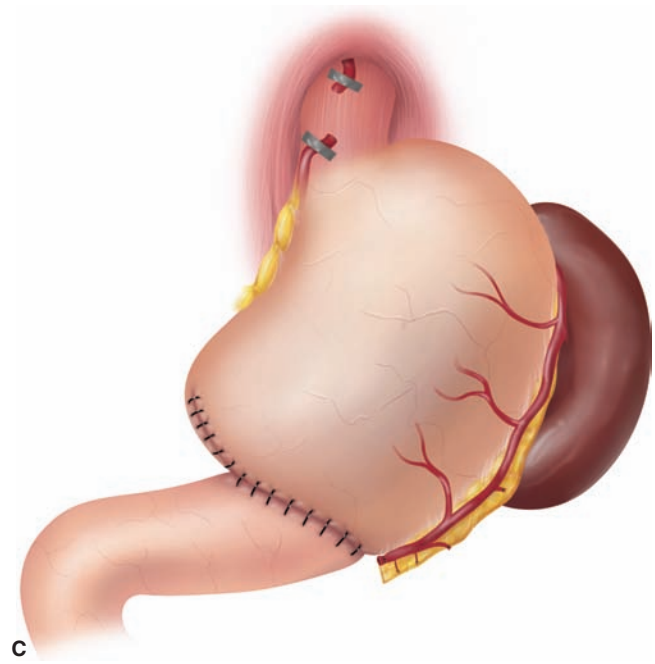


FIGURE 22-15 **A.** The distal segment of the transected jejunum is brought to lie along the posterior-inferior aspect of the gastric margin, and a posterior row of Lembert type sutures is place to attach the jejunum to the gastric wall. **B.** Two 3-0 PDS sutures are placed immediately next to each other and run in opposite directions until they meet in the anterior aspect of the anastomosis. **C.** An anterior row of interrupted reinforcing Lembert suture is placed to complete the superior anastomosis.

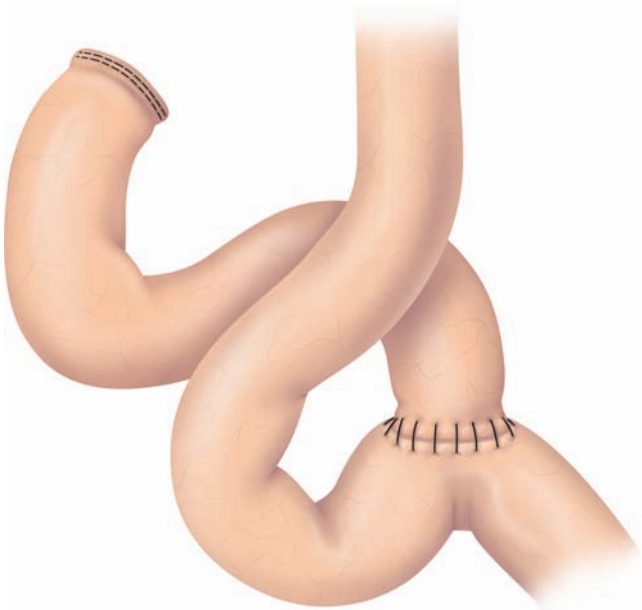

FIGURE 22-16 The two segments of jejunum to be anastomosed are aligned parallel to each other, and a 5-cm antimesenteric anastomosis is created.

created with the use of a gastrointestinal stapler or may be hand-sewn in the same manner a described for the gastrojejunostomy above (Fig. 22-16). Care must be taken to close all mesenteric defects with either 3-0 Vicryl or silk to prevent the development of an internal hernia.

Intestinal Reconstruction After Total Gastrectomy

Total gastrectomy is associated with worse postoperative weight loss and increased dumping symptoms when compared to distal gastrectomy. This is thought to be due to lack of a gastric reservoir. This has resulted in an ongoing debate of whether to create a jejunal pouch either with or without a jejunal interposition technique in order to simulate the gastric reservoir function. The literature in this area has generally been inconclusive due to the lack of appropriate controls, standardized outcomes measures, and poor study design.[80–82] A recent meta-analysis and systematic review of the literature has provided level IA evidence to support the use of an inverted J pouch or S pouch in conjunction with a Roux-en-Y reconstruction as a means of improving postgastrectomy-associated dumping, long-term weight loss, loss, and patient quality of life.[78] This study did not find evidence to support the benefit of a pouch with a jejunal interposition in order to maintain duodenal passage of enteric contents.

In most patients, a standard Roux-en-Y reconstruction will be the preferred technique to restore intestinal continuity. The procedure will be conducted as described previously for reconstruction after distal gastrectomy with one notable variation. Instead of creating a proximal gastrojejunostomy, the proximal anastomosis will be an end-to-end or end-to-side esophagojejunostomy. This may be performed as a hand-sewn anastomosis as described previously for a gastrojejunostomy or may be performed as a stapled technique using an appropriately sized EEA stapler.

As described previously, the hand-sewn technique entails performing a circumferential reinforcing row of Lembert-type sutures using 3-0 Vicryl or silk. The posterior row is placed after aligning the anastomotic segments, ensuring the jejunal limb is not twisted. The anastomosis is then performed with two full-thickness 3-0 or 4-0 PDS sutures placed immediately next to each other in the posterior segment of the anastomosis. The two sutures are then run circumferentially in opposite directions until they meet in the anterior midline. The sutures are then tied, completing the anastomosis. When feasible, an anterior row of interrupted reinforcing Lembert sutures are placed in the same manner as was completed in the posterior row (Fig. 22-17).

If a stapled technique is used, the anastomosis is created between the transected end of the esophagus and the antimesenteric border of the proximal Roux limb near the staple line. The anastomosis is performed in and end-to-side fashion. The EEA sizers are placed in the esophageal lumen, choosing an anvil size that will allow the largest possible diameter anastomotic lumen without causing undue tension on the esophageal or jejunal wall, preferably a 25- to 28-mm stapler. A purse-string suture is placed circumferentially at the distal end of the esophagus, just superior to the transection border using a 3-0 monofilament suture. The anvil is placed in to the esophageal lumen, and the purse-string suture is tightened and tied snugly around the anvil rod. The stapled end of the Roux limb is opened, and the EEA stapler is placed through the lumen in such a manner as to allow the staple pin to be punctured through the antimesenteric jejunal border several centimeters distally. The EEA anvil is then mated to the stapling device and closed, ensuring that the Roux limb is not twisted and no extraneous tissue is present between the anvil and stapler surface. Once stapling is completed, the device and anvil are removed through the jejunum and the stapler is inspected to ensure that the presence of two completed donuts of tissue are present (Fig. 22-18). The esophageal donut should be marked as "proximal esophageal margin" and sent to pathology for permanent section. The proximal end of the Roux limb must then be closed either with a surgical stapler or hand-sewn technique.

Once the esophagojejunostomy has been performed, attention is turned to creation of the jejunojejunostomy as described for the Roux-en-Y technique for distal gastrectomy previously (Fig. 22-19).

For select patients who are thought to have a good long-term prognosis, use of a jejunal pouch should be considered in an attempt to reduce postoperative weight loss and dumping syndrome. The jejunal S pouch or inverted J pouch are both reasonable choices, although no data exit to prove the benefits of one over the other. The reconstruction

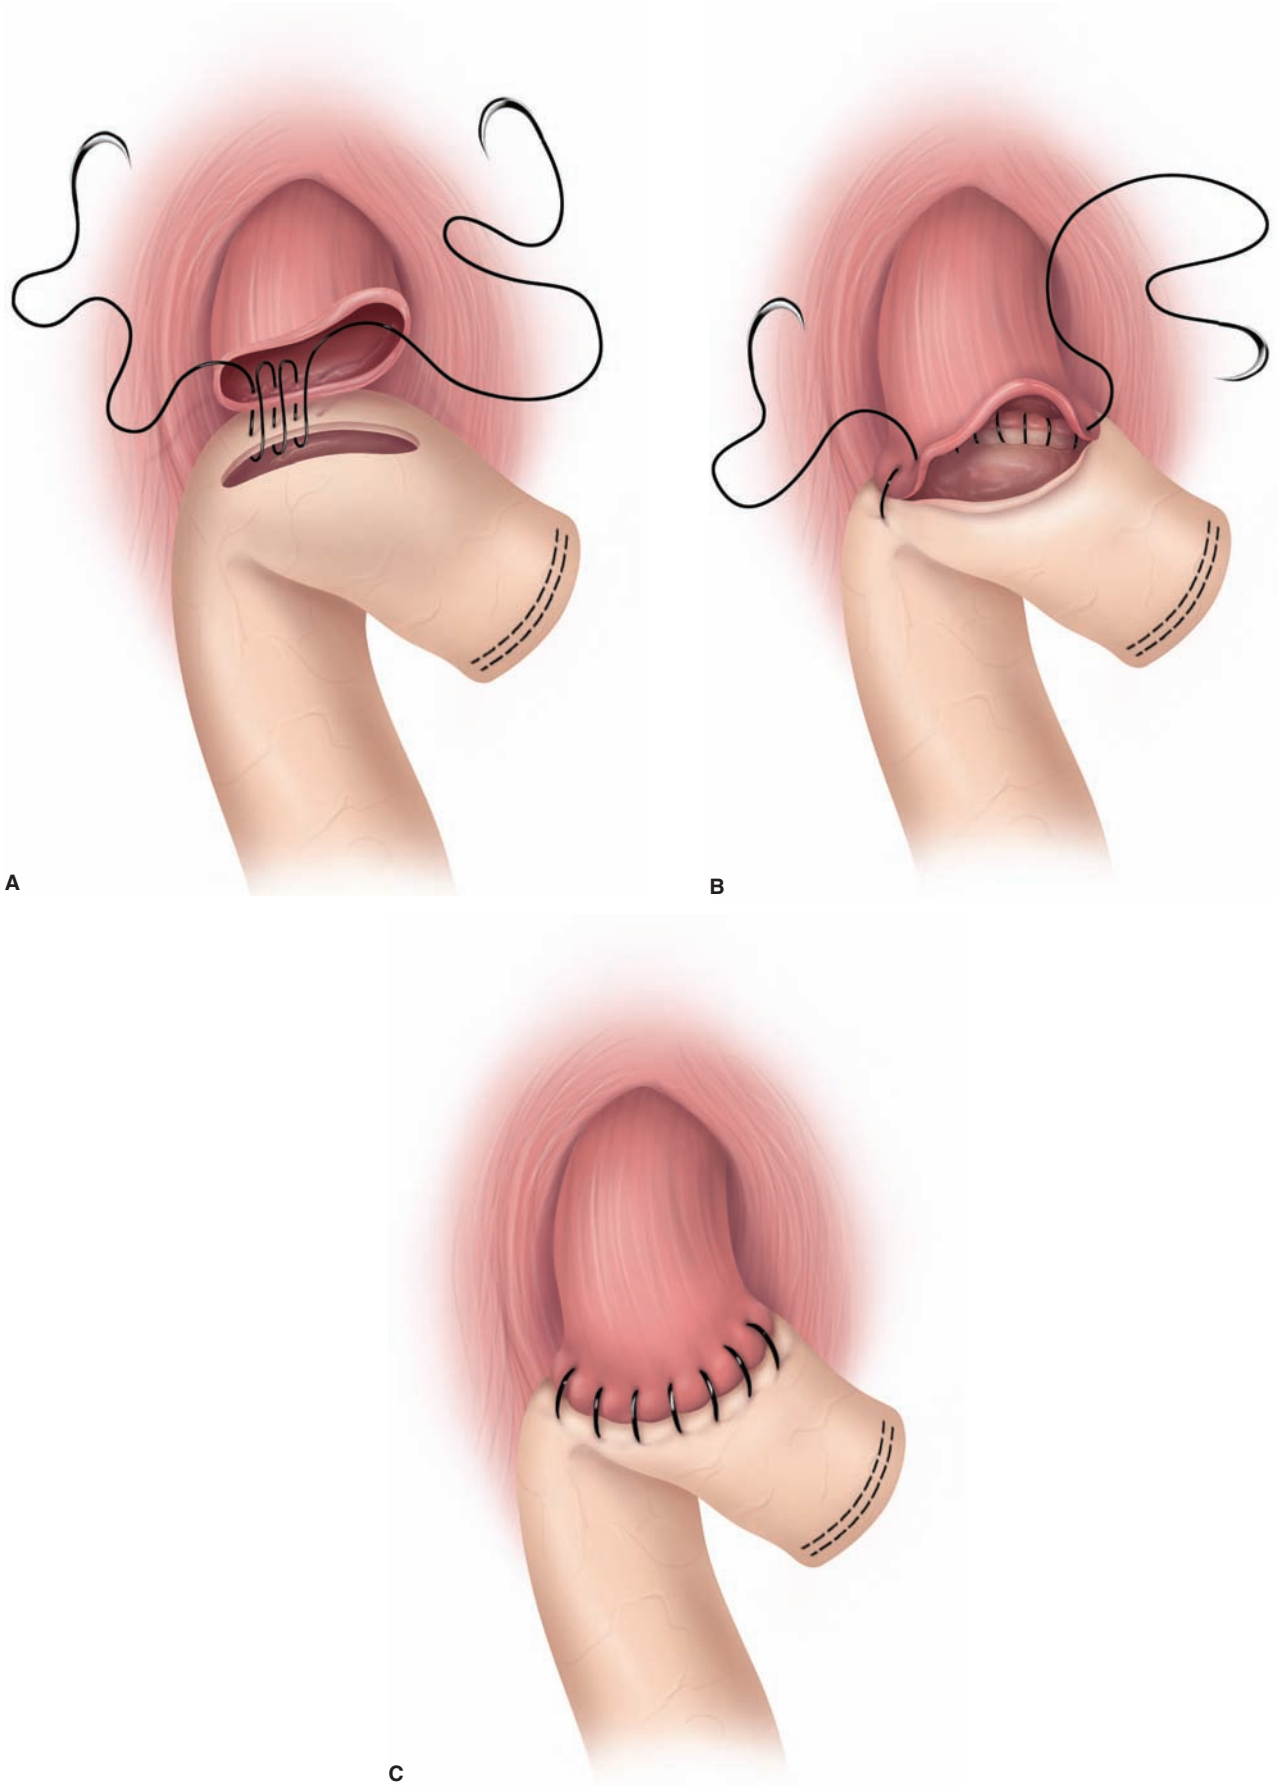

FIGURE 22-17 **A–C.** Roux-en-Y reconstruction with hand-sewn anastomosis after total gastrectomy.

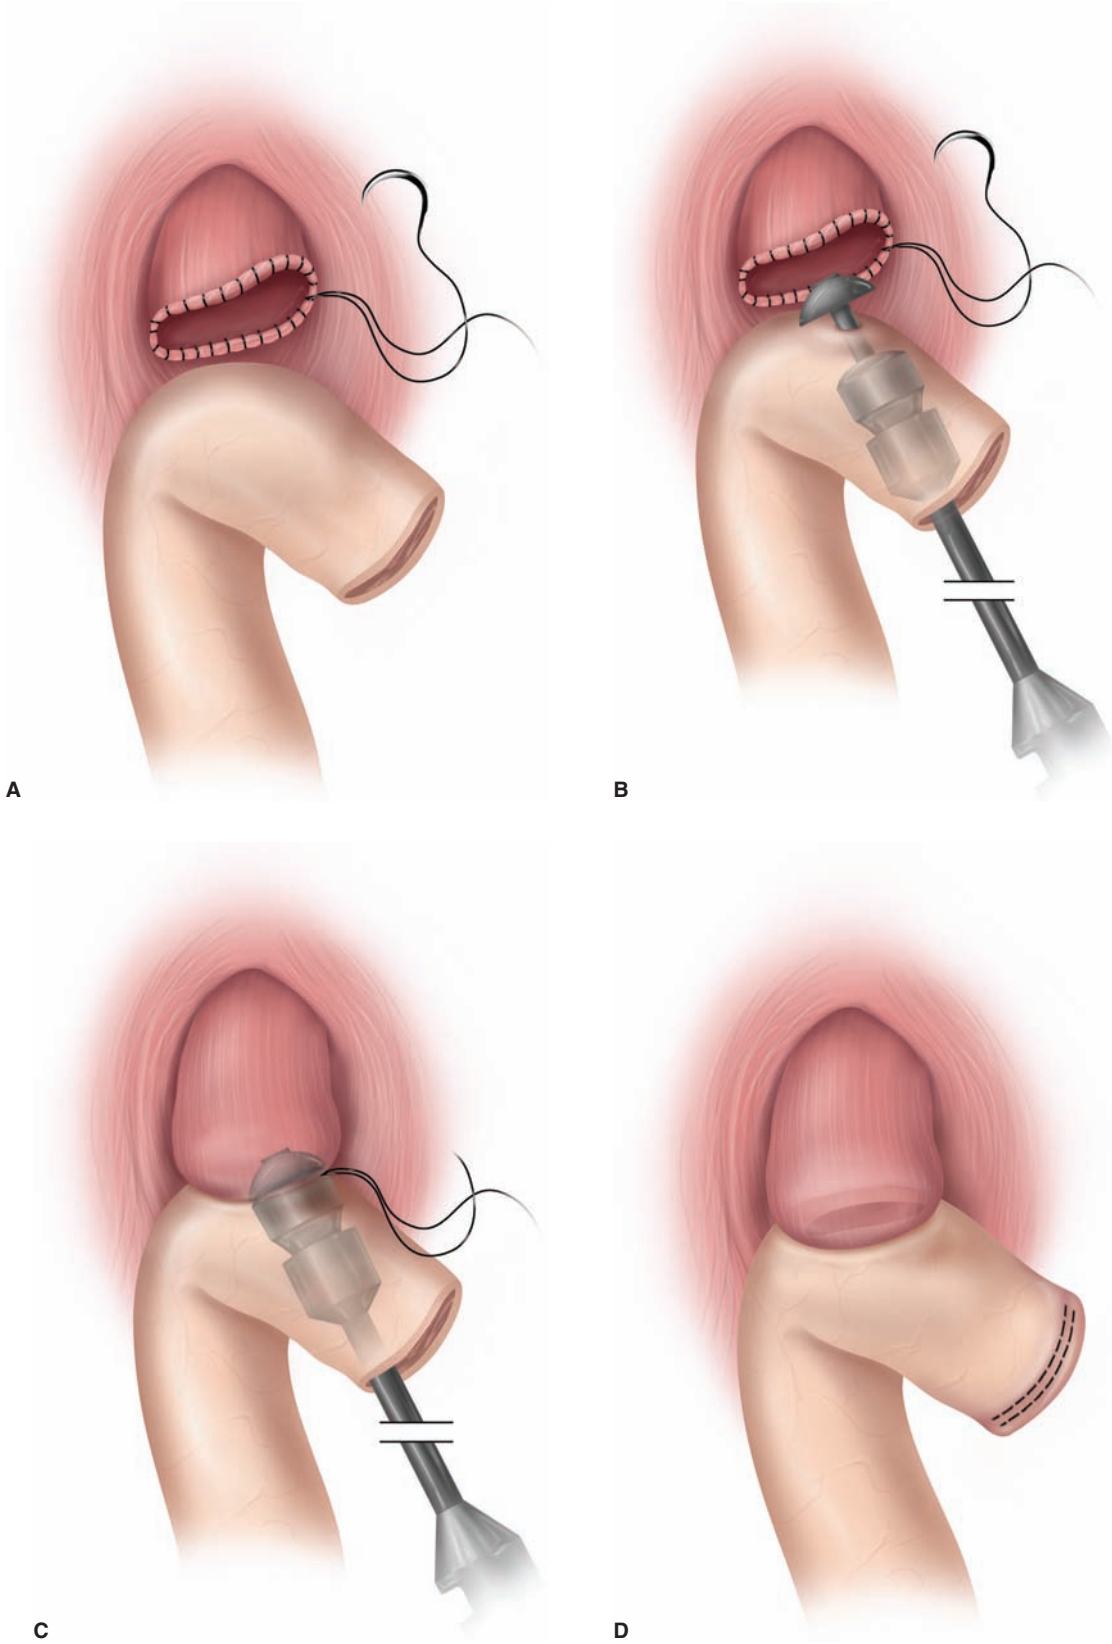

FIGURE 22-18 **A–D.** Roux-en-Y reconstruction with stapled anastomosis after total gastrectomy.

FIGURE 22-19 Completed Roux-en-Y reconstruction after total gastrectomy.

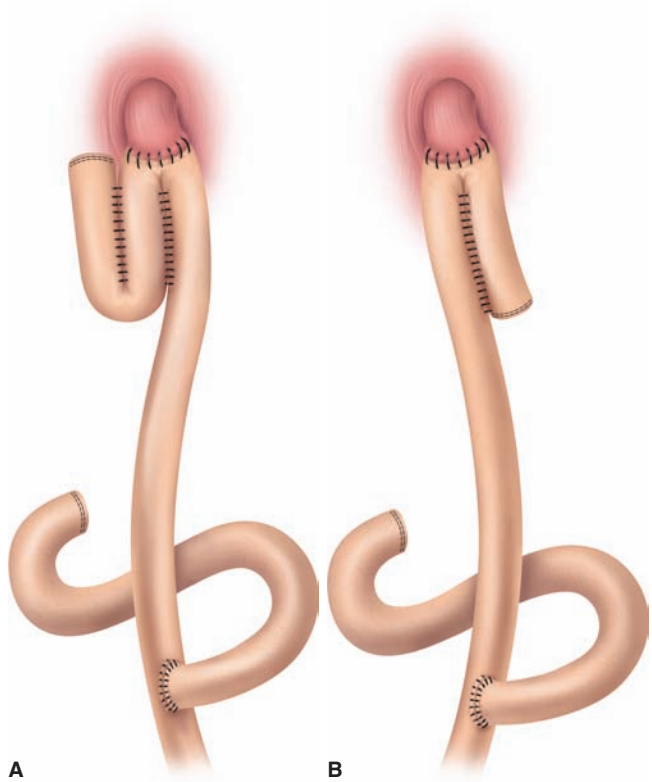

FIGURE 22-20 **A.** Creation of a jejunal S pouch. **B.** Creation of a jejunal J pouch.

is performed just as a standard Roux-en-Y technique with the exception that the pouch is created at the proximal Roux limb prior to creating the esophagojejunostomy. The pouch is created by aligning the proximal jejunum in an inverted J or an S configuration, then by creating a common channel between the overlapping jejunal segments with a GIA stapler (Fig. 22-20). Once the pouch has been formed, a standard Roux-en-Y with esophagojejunostomy is performed as was described previously.

PRIMARY GASTRIC LYMPHOMA

Epidemiology

Gastric lymphoma is the second most common primary malignancy of the stomach, accounting for approximately 5% of gastric cancers.[83] Over the past four decades, there has been a nearly 80% increase in the incidence of lymphoma in the United States.[84] This marked increase in lymphoma incidence has been especially notable for extranodal lymphomas, where up to 40% of cases present as primary gastrointestinal tract lesions.[85–87] Gastric lymphoma accounts for the majority of these cases, representing approximately 50–75 % of primary gastrointestinal lymphomas.[83,88,89] Primary gastric lymphoma is typically an extranodal form of a non-Hodgkin's lymphoma (NHL), whereas, Hodgkin's lymphomas, are rarely found to involve the stomach.[83,90]

Lymphomas represent a diverse and heterogeneous group of neoplasms and, as a result, have been very difficult to classify. Currently, the World Health Organization (WHO) lymphoma classification system is the accepted standard used by most medical professionals worldwide.[91] This classification system categorizes lymphomas based on their cell of origin and specific molecular, phenotypic, and genetic characteristics. Its most recent revision also takes into account clinical features such as patient age, site of involvement, and associated etiologic conditions.[92] Although the WHO classification system has facilitated treatment approaches and standardization of research protocols, it remains a very complex diagnostic schematic due to the intrinsic heterogeneity of lymphoproliferative disorders. The revised 2008 WHO lymphoma classification system recognizes more than 25 main categories of lymphoma derived from a mature B-cell origin and more than 20 derived from a T cell or NK cell of origin.[92,93]

Histology

Histologically, up to 98% of primary gastric lymphomas are derived from a B-cell origin.[93] Nearly 60% of these are classified as diffuse large B-cell lymphomas (DLBCL) and approximately 38% are marginal zone B-cell lymphomas of the mucosa-associated lymphoid tissue (MALT) (Table 22-4).[94] Both DLBCL and MALT-associated B-cell lymphomas are thought to be associated with chronic *H. Pylori* infection. This linkage is better established for MALT-associated B-cell lymphomas, where as many as 90% of cases are thought to be the result of *H. pylori* infection and where *H. pylori* eradication therapy usually leads to a durable remission.[95–98] The association between *H. pylori* infection and DLBCL is more controversial. Approximately 35% of patients with DLBCL are found to be *H. pylori* positive, with the majority of these patients showing concurrent MALT areas on endoscopic evaluation. Despite these data, up to 63% of patients with DLBCL have a durable treatment response to *H. Pylori* eradication therapy alone.[98]

Diffuse large B-cell lymphomas are aggressive high-grade lymphomas that may be derived from MALT-associated B-cell lymphomas.[87,88] Diffuse large B-cell lymphomas frequently express high levels of Bcl-6, an oncogene found on chromosome 3.[83] There are two recognized subcategories of DLBCL that can be immunohistochemically differentiated: those that resemble germinal center (GC)–type B cells (CD10+, Bcl-6–, and BCL2+/–) and those that are not GC-like (CD10–, Bcl-6+, and BCL2–).[83] GC-type B cells are thought to be derived de novo from mature B lymphocytes, while non–GC-type DLBCL is thought to arise from MALT-associated B-cell lymphomas.

MALT-associated B-cell lymphomas are typically multifocal lesions. They arise from gastric mucosal lymphatic tissue, which is thought to occur as a result of chronic *H. pylori* infection, in most cases. MALT-associated B-cell lymphomas express the CD20 cell surface antigen, generally produce IgG light-chain antibodies, and may express CD43. Three genetic translocations have been identified for MALT-associated B-cell lymphomas that, when combined, may be present in up to 65% of cases. These characteristic translocations include t(11;18)(q21;q21), t(1;14)(p22;q32), and t(14;18)(q32;q21).[83,98] Although each of these translocations produces a different direct upstream impact on cellular regulation, they all result in activation of the nuclear factor-kB cell activation pathway.[99]

TABLE 22-4: DISTRIBUTION OF LYMPHOMA HISTOLOGICAL SUBTYPE IN 398 PATIENTS WITH PRIMARY GASTRIC LYMPHOMA (REAL CLASSIFICATION)[94]

Lymphoma Histological Distribution	Frequency (%)
Diffuse large B-cell lymphoma	59
Without MALT component	14
With MALT component	45
Malt lymphoma of the marginal zone	38
Peripheral T-cell lymphoma	1.5
Mantle lymphoma	1
Follicular lymphoma	0.5

MALT, mucosa-associated lymphoid; REAL, Revised European-American Lymphoma.

Sings and Symptoms

The clinical presentation of patients with primary gastric lymphoma is similar to patients with gastric adenocarcinoma. The signs and symptoms tend to be nonspecific, with dyspepsia, abdominal pain, nausea, vomiting, anorexia, and change in bowel habits being the most common.[83,91,98,100] Gastrointestinal bleeding may also occur and is the initial presentation in up to 30% of patients.[88] With the exception of weight loss, B symptoms (weight loss, fevers, and night sweats) are rarely present in primary gastric lymphomas.[83] A complete history and physical examination must be performed with particular emphasis paid to examination of all accessible nodal beds, including Waldeyer's ring. A detailed abdominal examination should be performed to evaluate for an abdominal masses or organomegaly. The patient's presenting history provides the most important diagnostic clues, as the physical examination will fail to reveal any diagnostic findings up to 60% of the time.[83]

Diagnostic Workup and Staging

Patients with presenting histories or objective findings on clinical examination concerning for gastric malignancy must be undergo immediate upper endoscopic evaluation. Comprehensive upper endoscopy with biopsy of concerning lesions will make the diagnosis of gastric lymphoma in more than 95% of cases.[91] Once the diagnosis of gastric lymphoma has been pathologically confirmed, the patient must undergo staging of their disease to ensure initiation of the appropriate treatment algorithm and provide the patient with prognostic information. Although nearly universal acceptance of the 2008 WHO lymphoma classification system has helped to standardize the lymphoma staging workup, some variations still exist depending on the histological subtype.

All patients should undergo laboratory testing to include *H. Pylori* serology, a CBC with differential, liver function tests, serum chemistry panel with lactate dehydrogenase (LDH) and B_2 microglobulin, and serum electrophoresis to evaluate for M proteins. Additionally, although the bone marrow is rarely involved in primary gastric lymphoma, a bone marrow aspirate and biopsy should be completed. A spiral CT scan of the neck, chest, abdomen, and pelvis is performed to evaluate for addition lesions.[91,99] When DLBCL has been conformed by pathological analysis, a PET scan has been demonstrated to increase staging accuracy above that of CT scan alone with a sensitivity of more than 80% and a specificity of more than

90%.[101–103] When MALT-associated B-cell lymphoma has been confirmed, additional staging should include a second, more extensive, endoscopy with mapping. Twenty to thirty biopsy specimens should be obtained from both normal- and abnormal-appearing gastric and duodenal mucosa.[104,105] This is an important step because MALT-associated B-cell lymphoma is frequently multifocal and MALT-lymphoma containing mucosa may look normal on endoscopy. Repeat endoscopy with extensive biopsy has been shown to diagnose a previously unrecognized DLBCL component in as many as 10% of patients (Table 22-5).[91] The addition of colonoscopy and magnetic resonance imaging (MRI) of the salivary and lacrimal glands, in addition to the standard staging practices above, may lead to the finding of multiorgan involvement in as many as 25% of patients.[93] As discussed previously for adenocarcinoma, endoscopic ultrasound (EUS) may be of increased value in the locoregional N and T staging.[26,106]

The data obtained from the staging protocols described previously may then be used to stratify patients into a staging system to facilitate standardized treatment planning and obtain prognostic information. Several staging systems have been developed for primary gastrointestinal lymphomas and include the modified Ann Arbor staging system, the Lugano classification system, and the Paris staging system.[91] Although the modified Ann Arbor staging system is the oldest of the three, it is still the most frequently used system in the United States (Table 22-6).[107]

Treatment

Historically, surgical resection was the primary treatment for gastric lymphoma but is now generally reserved to treat complications of the disease, including perforated viscus, bleeding, and gastrointestinal obstruction. Recent data from RCTs demonstrated comparable durable treatment outcomes for chemotherapy, radiation therapy, or surgery.[83,108,109] Furthermore, chemotherapeutic treatment approaches yielded far lower treatment-associated complication rates.[99] The evolution of the treatment of primary gastric lymphoma continued into the 21st century as our understanding of lymphoma histological types continued to progress. The current treatment recommendations are radically different for MALT-associated B-cell lymphomas, than for the high-grade DLBCL.[83,91,99]

Malt-associated B-cell lymphoma treatment arms are generally based on *H. pylori* status and stage of disease. Early-stage *H. pylori*–positive disease has a high rate of complete remission with use of antibiotics to eradicate the *H. pylori* infection.[83,96,97] The treatment of early-stage *H. pylori*–negative MALT-lymphoma and *H. pylori*–positive antibiotic unresponsive disease remains unclear.[99] Although some *H. pylori*–negative patients will respond to antibiotic therapy, it is generally recommended that these patients be treated with either radiation therapy alone, rituximab, or chemotherapy.[83,99,110] Asymptomatic advanced-stage MALT-associated lymphoma is usually observed without treatment, given its indolent nature. Treatment, including chemotherapy and radiation therapy, is usually reserved for the relief of symptomatic disease to include bleeding, organ dysfunction, or gastrointestinal obstruction.[83,99]

Diffuse large B-cell lymphomas are a much more aggressive lesion than MALT lymphomas. The standard treatment regimen for DLBCL should include rituximab in addition to an anthracycline-based chemotherapy regimen.[83,99] Although early studies have suggested that either complete or partial gastrectomy in patients with early-stage DLBCL may have better survival outcomes and a reduced incidence of perforated viscus, obstruction, and bleeding, when compared to chemotherapy alone, more recent data contest these findings.[83]

TABLE 22-6: ANN ARBOR STAGING SYSTEM (MUSHOFF MODIFICATION)[107]

Stage	Extent of Disease
I_1	Confined to stomach. Involves submucosa or mucosa only. No lymph node involvement.
I_2	Confined to stomach. Extends beyond submucosa. No lymph node involvement.
II_1	Any depth of gastric wall involvement with regional lymph node involvement confined to the same side of the diaphragm.
II_2	Any depth of gastric wall involvement with distant lymph node involvement confined to the same side of the diaphragm.
III	Any depth of gastric wall involvement with lymph node involvement on both sides of the diaphragm or splenic involvement.
IV	Lymphoma disseminated beyond gastrointestinal tract to other extranodal organs.

Modified for extranodal primary gastric lymphoma.

Currently, the role for surgical intervention for any stage or histological type of gastric lymphoma is generally reserved for complications of the primary disease or the chemotherapy used to treat it.[83,99]

GASTRIC CARCINOIDS

Introduction

Carcinoids are an unusual group of neoplasms that arise from cells of neuroendocrine origin.[111] These tumors were first characterized as "carcinoids" by Siegfried Orbendorfer in 1907 based on their microscopic similarity to carcinomas, but generally indolent clinical course.[112] Carcinoids can occur in nearly any location, with approximately 55% arising from the gastrointestinal tract and 30% from the bronchopulmonary tree.[113] Gastric carcinoids represent only 11.7% of all gastrointestinal carcinoids, but their reported incidence has more than tripled over the past 50 years.[114,115] Although some of the observed increase may be due to more frequent use of upper endoscopic procedures over the past few decades, the increase in gastric carcinoid incidence is up relative to that of other gastric neoplasms. Overall, gastric carcinoids represent only a small fraction of gastric tumors accounting for about 1.8% of primary gastric neoplasms.[116]

Unlike carcinoids derived from the embryologic midgut and hindgut, gastric carcinomas do not typically secrete serotonin, characteristic of carcinoids derived from enterochromaffin cells. Gastric carcinoids generally arise from enterochromaffin-like (ECL) cells found in the acid-producing mucosa of the gastric body and fundus. These ECL cells account for approximately a third of all gastric endocrine–type cells and typically produce histamine as a means of regulating gastric acid production.[117,118]

Classification

Three main types of gastric carcinoids are generally recognized, although a fourth type has recently been reported. Each of the three main types of carcinoids has distinct pathological and physiologically associated conditions, different potentials for metastasis and treatment algorithms.

Type I gastric carcinoids are the most benign and by far the most common gastric carcinoid, accounting for up to 85% of cases.[111,119] These lesions develop in the setting of chronic atrophic gastritis with concomitant achlorhydria, occurring in more than 1% of these patients.[120] Chronic atrophic gastritis creates a hypoacidic state with development of hypergastrinemia as a result of unabated G-cell stimulation. Chronic hypergastrinemia stimulates ECL-cell upregulation and may lead to ECL-cell hyperplasia that can progress to dysplasia and the development of carcinoid.[121] Type I gastric carcinoids tend to be multicentric and are limited to the body and the fundus of the stomach. They are almost always small, benign, polypoid lesions limited to the gastric mucosa and submucosa.[111,122] They are generally asymptomatic lesions and have a low metastatic potential, with greater than 90% of lesions found to be confined to the gastric wall at the time of diagnosis.[123,124]

Type II gastric carcinoids are the rarest of gastric carcinoids accounting for only 5–10% of cases.[111] They also occur as a result of ECL-cell stimulation in response to hypergastrinemia; however, in these cases the hypergastrinemic state is the result of unchecked gastrin section from a gastrinoma rather than from chronic atrophic gastritis. The majority of type II gastric carcinoids are found in patients with Zollinger-Ellison syndrome (ZES) secondary to multiple endocrine neoplasia type I (MEN1) and a small minority in patients with sporadic ZES. There is undoubtedly more to the linkage between type II gastric carcinoids and ZES hypergastrinemia because the incidence of type II carcinoids in patients with ZES/MEN1 is up to 37%, whereas it is typically found in fewer than 2% of patients with sporadic ZES.[125] Like type I gastric carcinoids, type II gastric carcinoids are frequently multicentric, small tumors (<2 cm) with a relatively indolent clinical course. They occur in the gastric body and fundus and are confined to the gastric mucosa and submucosa in the majority of cases. Despite their relatively low metastatic potential, about 30% of patients have local lymph node involvement and as many as 12% will have metastatic disease at the time of diagnosis.[123,126]

Unlike types I and II gastric carcinoids, type III gastric carcinoids occur in the absence of hypergastrinemia or other notable pathological conditions and are therefore often described as "sporadic." Although type III gastric carcinoids are usually found in the gastric body and fundus, they may occur in any portion of the stomach. They are the second most frequent type of gastric carcinoid, accounting for 15–25% of cases.[111,119] Type III carcinoids are typically larger (>2cm) lesions that demonstrate a high mitotic rate and nuclear atypia under light microscopy.[119] They are aggressive lesions that are found to be metastatic or involve locoregional lymph nodes in over 75% of patients at the time of diagnosis.[125] Type III gastric carcinoids carry a poorer long-term prognosis than types I and II gastric carcinoids, with a 5-year survival rate of less than 50%.[127] In addition, unlike types I and II carcinoids, type III carcinoids may be functional tumors, productive of histamine. When histamine is actively secreted by these lesions, patients may develop atypical carcinoid syndrome characterized by pruritus, cutaneous flushing, and bronchospasm.[126]

Presentation and Diagnostic Workup

The diagnosis of gastric carcinoid is typically made in symptomatic patients undergoing diagnostic gastroscopy.[128,129] The most common presenting signs and symptoms in patients with gastric carcinoid are abdominal pain, gastrointestinal bleeding, and anemia. Other, less common symptoms include weight loss, reflux, obstruction, pruritus, wheezing, and skin flushing (Table 22-7).[111,128,129] Upper

Prognosis	Good	Moderate	Poor

MEN1, multiple endocrine neoplasia type I; ZES, Zollinger-Ellison syndrome.

endoscopy with biopsy is generally sufficient to make the pathological diagnosis of gastric carcinoid. Lesion(s) must be biopsied and removed, if possible. In addition, multiple biopsies should be obtained from the gastric antrum, body, and fundus along both the greater and lesser curvatures in order to improve diagnostic accuracy and assess for atrophic gastritis.[111,130] EUS-guided fine-needle aspiration may be useful for submucosal lesions not amenable to standard endoscopic biopsy techniques.

A full history and physical examination should be performed with careful attention to a history of gastritis, abdominal pain, anemia, flushing, or wheezing. Additionally, a detailed personal and family history must be obtained looking for signs, symptoms, or a history of MEN1 syndrome. As with gastric lymphoma, the physical examination will rarely provide diagnostic clues suggestive of gastric carcinoid. Laboratory analysis can be helpful in establishing the diagnosis and type of carcinoid. All patients should have a CBC, chromogranin A, serum gastrin, serum calcium, and parathyroid hormone (PTH) level. Patients with anemia present on CBC should also have a serum B_{12} and anti-intrinsic factor level evaluated. Gastric pH testing will be helpful in establishing the type of gastric carcinoid present, as it is expected to be high in type I, low in type II, and normal in type III gastric carcinoids.[111] Data combined from the CBC, B_{12}, and anti-intrinsic factor studies in anemic patients help to determine whether pernicious anemia is present, indicative of type I carcinoids. A serum gastrin level will help differentiate between patients with type I/II carcinoids that typically have hypergastrinemia from those with type III carcinoid who will typically have normal gastrin levels. An elevated serum calcium and PTH level may be diagnostic of hyperparathyroidism and should alert the clinician to the potential diagnosis of MEN1 syndrome (Table 22-8). Elevation of chromogranin A is a relatively sensitive and specific marker for neuroendocrine cell tumors. An elevated chromogranin A level may be helpful in narrowing the prebiopsy differential diagnosis of carcinoid, but, more importantly, if elevated, it serves as a marker to follow the therapeutic response or disease progression and recurrence.[131]

For small (<1 cm) types I and II gastric carcinoids, staging workup beyond endoscopy and biopsy is generally not necessary, given the low potential for spread beyond the submucosa. Tumors larger than 1 cm, however, should undergo EUS to evaluate tumor depth of invasion and characterize possible local lymph node involvement.[132] All patients with type III carcinoids and those with large types I and II tumors found to invade the muscularis propria or involve local lymph nodes on EUS should undergo more extensive workup to rule out advanced locoregional or metastatic disease.[132] These patients should have a CT scan of the chest, abdomen, and pelvis at minimum with consideration for a somatostatin receptor scintigraphic study. The former is especially useful in detecting small diffuse disease that may be missed by CT.[133,134]

Treatment

Treatment of gastric carcinoid is based on the type and the extent of disease. Treatment algorithms are similar for both types I and II gastric carcinoids with a few notable exceptions. Type III lesions, on the other hand, are treated far more aggressively because of their relatively high metastatic potential.

Both types I and II carcinoids have a generally indolent course and develop as a result of hypergastrinemia. The treatment for these lesions remains somewhat controversial, but, until appropriate clinical studies have been completed to support less invasive approaches, a more conservative treatment regimen should be pursued. If the lesion(s) are smaller than 1 cm, confined to the mucosa or submucosa and there are fewer than six total lesions in the stomach, endoscopic resection and close endoscopic follow-up is an appropriate treatment approach.[111,135] Somewhat more controversial are the recent recommendations of the European Neuroendocrine Tumor Society (ENETS) that is now advocating endoscopic surveillance only for type I gastric

carcinoids less than 1 cm.[123] These guidelines do not apply to type II carcinoids.

If more than six gastric lesions are present, partial gastrectomy is recommended. Because type I lesions develop as a result of G-cell–induced hypergastrinemia, a surgical antrectomy is also recommended.[111] Antrectomy is not indicated for type II carcinoids because the hypergastrinemia is the result gastrinoma. In these cases, surgical resection of the gastrinoma should be completed when feasible. In all cases, if these lesions recur, clear margins are not obtained, or surveillance demonstrates progression of the disease, surgical reexcision or gastrectomy should be performed. For patients undergoing surveillance endoscopy for small type I gastric carcinoids per ENETS guidelines and showing progression of disease, surgical resection of the lesion(s) with antrectomy versus total gastrectomy is indicated, depending on the extent of involvement.

When distant metastatic disease is present, traditionally treatment has involved medical therapy including, chemotherapeutic agents, radionuclides, and/or somatostatin analogues with minor benefit but no notable impact on long-term survival. Surgical therapy for these patients, on the other hand, has generally been reserved to treat limited metastatic lesions or complications of the disease, including gastrointestinal obstruction and bleeding. Recently, a small case series of patients undergoing aggressive surgical resection for metastatic gastric carcinoid had a mean 5-year survival rate of 82% with a reported increase in quality of life.[136] These data are intriguing; however, more substantial studies must be completed before this can be recommended as standard of care. Limited metastatic recurrences after gastrectomy may also be treated through surgical resection for favorable lesions or with radiofrequency ablation or chemoembolization if patients are not appropriate surgical candidates.[137]

Type III gastric carcinoids are far more aggressive lesions and should be approached similar to gastric adenocarcinoma.[111] Once extensive metastatic disease has been ruled out, all patients should undergo partial or total radical gastrectomy, depending on the extent of the disease at the time of diagnosis. An extended lymph node dissection has been advocated by some, but data showing any benefit of a D1 versus D2 node dissection for gastric carcinoid are absent.[117] Chemotherapy either as an adjunct to surgery or as the sole therapeutic modality in patients with a poor performance status or with widely metastatic disease is recommended, although it has been shown to be of limited benefit.[117]

PERSPECTIVE ON GASTRIC CANCER

Mitsuru Sasako • Hisashi Shinohara

CURATIVE SURGERY FOR GASTRIC CANCER

Theoretical Background

Dissection of regional lymph nodes had been controversial until recently, but an accumulation of evidence has led us to conclude that D2 dissection should be the standard surgery for potentially curable advanced gastric cancer in most of the world, including Europe. Details of these studies are included in the Chap. 22. It is worth emphasizing the importance of the quality of surgical treatment in clinical trials. The initial three trials—the South African, the Hong Kong, and the Medical Research Council (MRC) trials[1–3]—had problems with the quality of the surgery. The first two trials were single institutional studies and, although hospital mortality was not high, survival data were poor. In the MRC study, there was no serious quality control for D2 surgery, and both hospital mortality and survival results for the D2 arm were poor. In the Dutch study, their quality effort made the results better than in the MRC study, but hospital mortality was nearly 10% after D2 dissection.[4] Regarding overall long-term survival, D2 dissection was better than D1, although not systematically significantly. In 15-year follow-up, they demonstrated significantly better local control and disease-specific overall survival (OS).[5] These results are not clear evidence but strongly suggest the benefit of D2 dissection in a Western population. Even in the Dutch study, most of participating surgeons had a quite limited experience with D2 surgery before the study and had quite low hospital volumes throughout the study. We would suggest that the quality of the surgery and postoperative care was not sufficient. All the meta-analyses comparing D1 and D2 resection are therefore unreliable. The Taiwanese study, a single institutional study comparing D1 versus D2, demonstrated significantly better OS after D2 dissection in Asian patients.[6] Later, Hundahl et al, both in the INT-0116 and the Dutch studies, reported that insufficient nodal dissection reduces the OS of gastric cancer patients.[7,8].

Safe Surgical Margin

According to the recent Japanese gastric cancer treatment guidelines of the Japan Gastric Cancer Association (JGCA),[9] a proximal margin of at least 3 cm is recommended for T2 or deeper tumors with an expansive growth pattern, and 5 cm is recommended for those with infiltrating growth pattern. When these rules cannot be applied, a frozen-section examination of the resection margin (in such cases as those invading the esophagus) is recommended. For T1 tumors, a gross resection margin of 2 cm should be obtained. However, tumor borders of T1 tumors are often unclear; stepwise biopsies are often appropriate preoperatively.

Laparoscope-Assisted Gastrectomy for Gastric Cancer

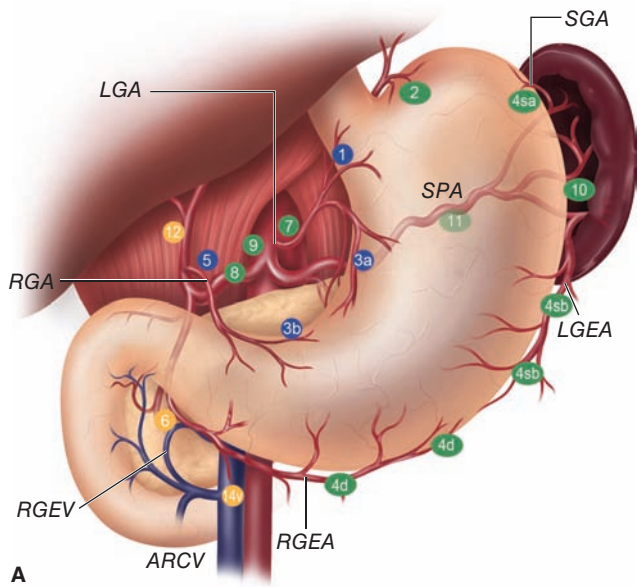
In Japan, many surgeons are performing laparoscope-assisted gastrectomy (LAG) for stage I tumors, although LAG is regarded as an experimental treatment even for stage I lesions in the guidelines. At the moment, there is no evidence demonstrating equivalence of long-term survival with this procedure. There are two large randomized controlled trials (RCTs) comparing LAG versus open gastrectomy for stage I tumors. The Korean RCT (KLASS study) is expected to enroll 1400 patients and the Japan Clinical Oncology Group (JCOG 0912) study will enroll 920 patients. In many respects, LAG has limitations: lack of tactile sensation; difficulty or impossibility of widely spreading the membranes, which is essential for proper D2 dissection; a compromised reconstruction technique; and a much larger variation in surgical skill. Gastric cancer has a high incidence of peritoneal recurrence, and with the frequent appearance of tumor deposits in fatty tissue surrounding the organ and the preservation of vessels during lymphadenectomy, the risk of increasing recurrence using laparoscopic approaches seems higher than is the case for colorectal cancer surgery.

SURGICAL TECHNIQUE

The basic technique of lymph node dissection is common for all gastrointestinal cancers, but, because of the high incidence of tumor deposits in the adipose tissue and significant tendency of developing peritoneal metastasis in gastric cancer, dissection without destroying the thin membranes surrounding the fatty tissue where all nodes and tumor deposits are imbedded is of paramount importance. To perform a proper lymph node dissection of the stomach, an understanding of the unique anatomical structure is essential. The stomach has two mesenteries: the dorsal mesogastrium and the ventral mesogastrium. Moreover, the distal part of the organ is fed by the ventral and dorsal mesoduodenum. During the rotation of the intestinal system, the ventral mesogastrium becomes the lesser omentum and the dorsal mesogastrium becomes the greater omentum. Arteries originating in the ventral mesogastrium include the right gastric artery from the proper hepatic artery and the gastric branch of the left gastric artery, which becomes quite short during the rotation of the intestinal tract, although the origin of the left gastric artery is located in the dorsal mesogastrium. The location of regional lymph node stations and vessels to the stomach[10] is shown in Fig 23-1A. The last part of the antrum (4–6 cm) and the first portion the duodenum (duodenal bulb) are fed by the inferior pyloric vessels in the dorsal mesoduodenum and by the supraduodenal vessels in the ventral mesoduodenum. To treat an antral cancer, proper dissection of both the mesogastrium and also the mesoduodenum is essential. The incidence of metastasis to the infrapyloric node station is nearly 50% for distal cancers that are T2 or more, and more than 40% of those having such metastasis will survive more than 5 years. The greater omentum originally hangs between the dorsal pancreas and the stomach and gradually fuses with the mesocolon. Then it elongates toward and over the ventral pancreas and the duodenum (see Fig. 23-1B, Fig. 23-2A). To carry out complete omentectomy, dissection from the anterior pancreatic fascia is essential. The omentobursectomy is the best way to safely access the root of the right gastroepiploic vein (see Fig 23-2A).

A. About 26% of metastatic nodes are 4 mm or less in largest dimension and they look normal.[11] However, they are sometimes swollen and adhere to the membranes wrapping the fatty tissue and perinodal deposits, or directly invade the neural sheath surrounding the major branches of the celiac artery. In the latter case, nodal dissection should extend along the adventitial layer of the major arteries (common or proper hepatic, splenic and celiac arteries), and, in the former case, the nerves should be preserved as well.

To carry out a D2 dissection without splenectomy, meticulous dissection along the splenic vessels and the splenic hilum is needed. For safe dissection of this area, accurate knowledge of the basic anatomy and its variations is essential. The branch-off point of the posterior gastric artery varies widely; it is sometimes at 3–4 cm from the root of the splenic artery and sometimes close to the splenic hilum. There are three or four short gastric



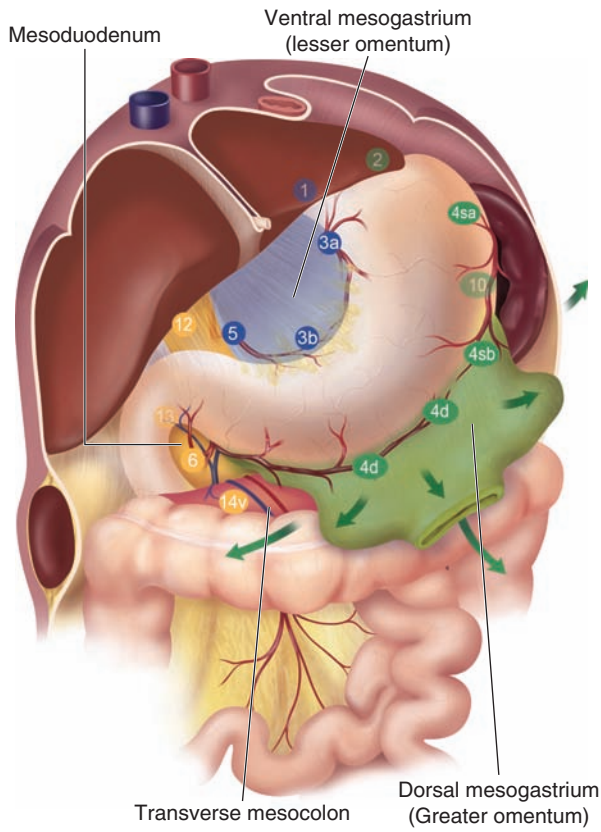


FIGURE 23-1 **A.** Numbers in circles indicate lymph node stations according to the Japanese classification of gastric carcinoma (3rd English edition). Blue ones belong to the ventral mesogastrium, green ones to dorsal mesogastrium, and yellow ones to mesoduodenum. ARCV, accessory right colic vein; IPA, inferior pyloric artery; LGA, left gastric artery; LGEA, left gastroepiploic artery; RGA: right gastric artery; RGEA, right gastroepiploic artery; RGEV, right gastroepiploic vein; SDA, supraduodenal artery; SGA, short gastric artery; SPA, splenic artery. **B.** Development of omentum, mesogastrium, and mesoduodenum. Numbers in circles indicate lymph node stations according to the Japanese classification of gastric carcinoma.

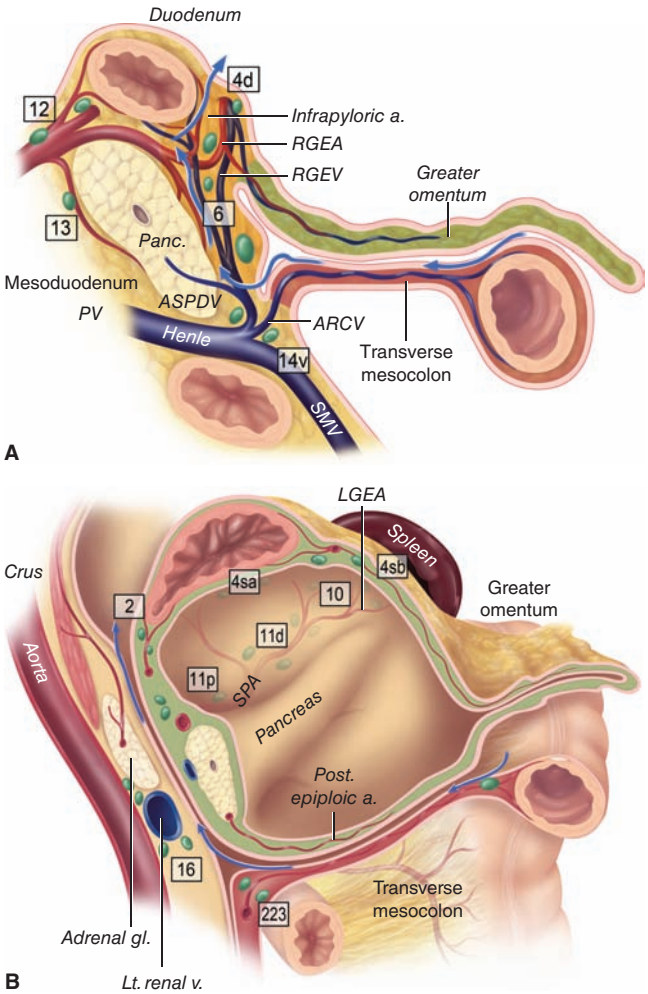

FIGURE 23-2 **A.** Sagittal transactional scheme near the origin of the right gastroepiploic vessels. Anatomical structures of the greater omentum, transverse colon and mesocolon, pancreas head, and duodenum are shown with vessels surrounding the organs. The ventral mesoduodenum includes the supraduodenal vessels, and the dorsal mesoduodenum includes infrapyloric vessels. The origins of the dorsal mesoduodenum and mesogastrium share the common root that joins with the anterosuperior pancreatoduodenal vein and the accessory right colic vein, making Henle's common trunk. ARCV, accessory right colic vein; ASPDV, anterosuperior pancreatoduodenal vein; GDA, gastroduodenal artery; IPA, infrapyloric artery; Pnac, pancreas; PV, portal vein; RGEA, right gastroepiploic artery; RGEV, right gastroepiploic vein; SDA, supraduodenal artery; SMV, superior mesenteric vein. **B.** Sagittal transaction near the root of the splenic artery and 3D scheme of the structures left lateral to the transection. All lymph nodes along the splenic vessels and posterior gastric vessels and in the splenic hilum are located between the posterior pancreatic fascia of Toldt and the posterior floor of the Bursa omentalis. Numbers in rectangles indicates lymph node stations according to the Japanese classification. LRV, left renal vein; PEA, posterior epiploic artery; PGA, posterior gastric artery; SPA, splenic artery.

arteries, each of which comes ventrally from the final branches of the splenic artery going into the splenic parenchyma. The left gastroepiploic artery is usually the most caudal branch of the splenic artery coming caudad along the splenic hilum. Often, it has a common trunk with the inferior pole branch to the spleen. As demonstrated in the Fig 23-2B, all nodes are included in the layer between the posterior pancreatic fascia of Toldt and the posterior floor of the Bursa omentalis. In the past, when the majority of gastric cancers were large and accompanied by large nodal metastasis surrounding the left gastric, splenic, and celiac arteries, en bloc resection of the entire tumor required the combined resection of the pancreatic tail with the spleen. This procedure that had been carried out for prophylactic dissection of the splenic artery and hilar lymph nodes was abandoned because of the higher mortality and morbidity with limited survival benefit compared with pancreas-preserving total gastrectomy. Now, this extended surgery is utilized only for T4b tumors invading the pancreas.

B. Our preferred method of reconstruction after a distal gastrectomy is a Roux-en-Y (RY), via a retrocolic route. There are a few reasons. First, anastomotic leak is much less common after gastrojejunostomy (including Billroth type II) than gastroduodenostomy (Billroth type I). Second, there is much less risk of reflux esophagitis caused by bile reflux, which is often seen after gastroduodenostomy. Third, severe gastritis of the remnant stomach is rare, which is often seen after Billroth type I. On the other hand, some authors claim a high incidence of so-called RY stasis and the uncut RY has been proposed to avoid it. As we personally seldom have patients who develop RY syndrome, this is not caused by interruption of the peristaltic signal but by hampered movement of the anastomosed intestine due to kinking or bending that is caused by adhesions to the dissected area above the mesocolon. We construct the gastrojejunostomy using a retrocolic route and fix the distal part of the stomach to the orifice of the hole in the mesocolon, so that the entire jejunum is located below the mesocolon and has less chance to kink or bend.

GASTROINTESTINAL STROMAL TUMORS

Chandrajit P. Raut

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are rare neoplasms. Although they represent only 0.1–3% of all gastrointestinal (GI) malignancies,[1–4] they account for 80% of gastrointestinal mesenchymal neoplasms.[5] Approximately 5000–6000 new cases are diagnosed per year in the United States, for an annual incidence of 14.5 per million and prevalence of 129 per million.[6] In the last 12 years, the understanding and treatment of GIST has witnessed remarkable advances due to two key developments: (1) the identification of constitutively active signals (oncogenic mutation of the *c–kit* and platelet–derived growth factor receptor alpha[*PDGFRA*] gene–encoding receptor tyrosine kinases) and (2) the development of therapeutic agents that suppress tumor growth by specifically targeting and inhibiting this signal (imatinib mesylate, sunitinib malate). These developments in the management of GIST represent a proof of the principle of translational therapeutics in oncology, confirming that specific inhibition of tumor–associated receptor tyrosine kinase activity may be an effective cancer treatment. The advent of effective therapy for GIST has not diminished but rather redefined the role of surgery for this disease. This chapter reviews the biology, treatment, and emerging clinical challenges of these mesenchymal neoplasms.

PATHOLOGIC FEATURES

Historical Background

The term "GIST" was initially coined in 1983 by Mazur and Clark to describe intra–abdominal nonepithelial neoplasms that lacked the ultrastructural features of smooth muscle cells and the immunohistochemical characteristics of Schwann cells.[7] GISTs typically exhibit heterogeneous histologic features. They are most commonly composed of long fascicles of spindle cells with pale to eosinophilic cytoplasm and rare nuclear pleomorphism, but may occasionally exhibit epithelioid characteristics, including sheets of round– to oval–shaped cells with abundant eosinophilic cytoplasm and nuclear atypia (Fig. 24-1). Based on their histologic and immunohistochemical features, GISTs are believed to arise from the interstitial cells of Cajal, components of the intestinal autonomic nervous system that serve as intestinal pacemakers.[8] Nonetheless, until the late 1990s, there were no objective criteria to classify GISTs. They were frequently misclassified as leiomyomas, leiomyoblastomas, leiomyosarcomas, Schwannomas, gastrointestinal autonomic nerve tumors, or other similar soft tissue histologies.[9] Consequently, interpreting clinical results for reports on "GISTs" published before 2000 can be challenging.

Receptor Tyrosine Kinase Mutations

In a landmark publication in 1998, Hirota and colleagues reported two critical findings: (1) near–universal expression of the transmembrane receptor tyrosine kinase KIT in GIST, and (2) presence of gain–of–function mutations in the corresponding *c–kit* proto–oncogene.[10] The KIT receptor is activated by binding its cytokine ligand known as *steel factor* or *stem cell factor*.[11] KIT plays a critical role in the development and maintenance of components of hematopoiesis, gametogenesis, and intestinal pacemaker cells.[12–14] Oncogenic *KIT* mutations have been identified in neoplasms corresponding to these functions, including mast cell tumors, myelofibrosis, chronic myelogenous leukemia, germ cell tumors, and GIST.[12] Mutated KIT remains constitutively active even in the absence of ligand binding and results in both unregulated cell growth and malignant transformation.[10]

GISTs are now identified by immunohistochemical staining for the CD117 antigen, part of the KIT receptor, in the appropriate histopathologic context (Fig. 24-2). CD117 expression is characteristic of most GISTs but not of other gastrointestinal smooth muscle tumors such as leiomyosarcoma, which are more likely to express high levels of desmin and smooth muscle actin.[12–15] Application of CD117 staining as a diagnostic criterion for GIST has altered understanding of the prevalence of this disease (see the following section Epidemiology).

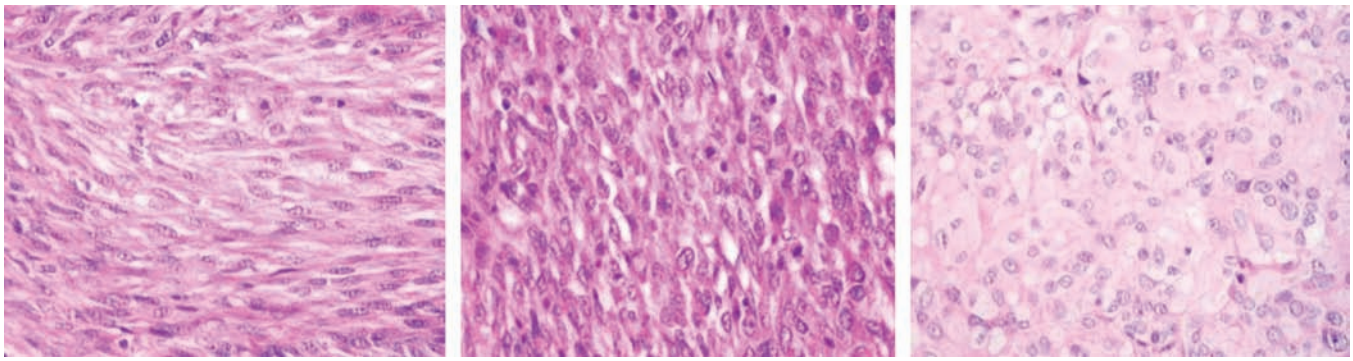

FIGURE 24-1 Gastrointestinal stromal tumor (GIST) histology. Staining of tumor paraffin sections with hematoxylin and eosin (H&E) reveals three patterns of GIST histology: **(A)** spindle cell, **(B)** mixed cell, and **(C)** epithelioid cell type.

Over 85% of GISTs have activating *KIT* mutations (Fig. 24-3).[12] These mutations commonly occur in exon 11 (in 57–71% of cases), exon 9 (10–18%), exon 13 (1–4%), and exon 17 (1–4%).[16–19] Some GISTs may stain strongly for KIT (CD117) by immunohistochemistry (KIT–positive) yet lack *KIT* mutations,[12] while others that do not stain for KIT (KIT–negative) may nevertheless harbor *KIT* mutations.[20] Approximately 35% of neoplasms lacking *KIT* mutations have activating mutations in a gene encoding a related receptor tyrosine kinase, the PDGFRA.[21–23] *PDGFRA* mutations have been identified in exon 12 (1–2% of GISTs), exon 18 (2–6%), and exon 14 (<1%).[21,24] Finally, a few GISTs, the so–called wild–type (WT) GISTs, exhibit no detectable *KIT* or *PDGFRA* mutations and presumably have alternative pathways for pathogenesis. Recently, additional putative mutations have been identified. A *BRAF* exon 15 mutation was identified in a small percentage of WT tumors.[25] Insulin–like growth factor 1 receptor (IGF–1R) overexpression was documented in some WT GISTs as well.[26]

EPIDEMIOLOGY

Age

The median age at diagnosis of GIST is 60 years (range 40–80 years).[2,6] They are equally common in men and women, and there is no racial or ethnic predilection. GIST does occur rarely in children, often as a familial syndrome or as part of Carney's triad (see the following text).[27,28] The clinical presentation is typically different in children, who

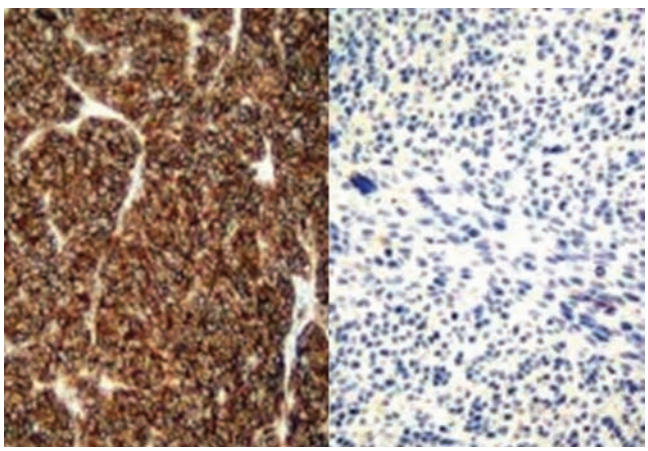

FIGURE 24-2 Immunohistochemistry to detect *c–kit* expression. Immunohistochemistry to detect expression of KIT (CD117) is present in approximately 95% of gastrointestinal stromal tumor (GIST) and varies among tumors from predominantly cytoplasmic (*left*), to perinuclear and dot–like (*right*). Variable expression within a given tumor also occurs (*right*).

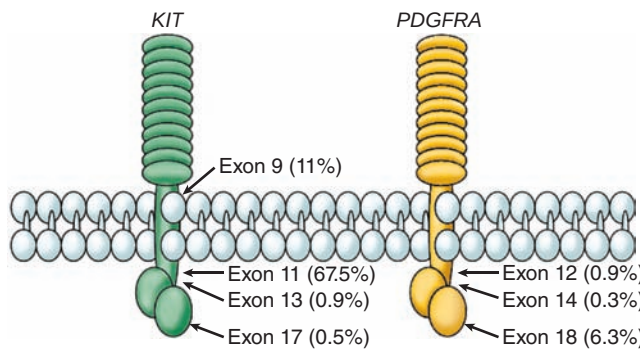

FIGURE 24-3 *KIT* and platelet–derived growth factor receptor alpha (*PDGFRA*) mutations in gastrointestinal stromal tumor (GIST). *KIT* and *PDGFRA* mutations in GIST produce constitutive ligand–independent receptor activation. Response to tyrosine kinase inhibitors correlates with the location of the activating mutation, with best response in patients whose tumors contain mutations in *KIT* exon 11.[35]

tend to present with multifocal gastric GISTs, harbor WT *KIT/PDGFRA* genes, and have a higher incidence of lymph node metastases.[25]

Hereditary GIST

The overwhelming majority of GISTs are sporadic. Nevertheless, 17 kindreds with germline *KIT* mutations and 3 with a *PDFGRA* mutation have been reported.[29–37] Individuals with GISTs secondary to germline *KIT* mutations are usually younger than those with sporadic GISTs, manifest multifocal disease at presentation, and only rarely develop metastatic disease.[36] The phenotype includes skin hyperpigmentation and diffuse hyperplasia of the intestinal myenteric plexus.[38]

Approximately 7% of individuals with von Recklinghausen's neurofibromatosis (NF1) have GIST, most commonly in the small intestine.[39–41] In addition to their *NF1* mutations, these individual express *KIT* and *PDGFRA* point mutations in 8 and 6% of GISTs, respectively.[42] Conversely, *NF1* mutations have not been identified in non–NF1 individuals with sporadic GISTs.[43]

Gastric GISTs are components of both Carney's triad and Carney–Stratakis syndrome. Fewer than 100 cases of Carney's triad, consisting of gastric GISTs, pulmonary chondromas, and paragangliomas, have been reported.[28,44] Approximately 85% occur in women and 80% are diagnosed before the age of 30. Patients with Carney's triad do not have somatic *KIT* or *PDGFRA* mutations. The similarly eponymous Carney–Stratakis syndrome describes familial cases expressing the dyad of gastric GIST and paraganglioma.[30] Recently, mutations in several succinate dehydrogenase subunits have been reported in Carney–Stratakis syndrome kindreds.[45]

Incidence

Investigators have attempted to determine the true incidence of GIST using the Surveillance, Epidemiology, and End Results (SEER) database from the National Cancer Institute. However, these data are difficult to interpret because many GISTs were previously misclassified as other GI mesenchymal neoplasms.[46] Although a near doubling of the incidence of all GI mesenchymal tumors (over 80% were GIST) has been reported (0.17/100,000 in 1992 to 0.31/100,000 in 2002), this may be due to increased recognition, increased screening, and/or true increased incidence.[46] The annual incidence in the United States is estimated to be approximately 5000 new cases per year.[47] European population–based studies identified annual incidence rates ranging from 11 to 14.5 cases per million population.[6,48]

CLINICAL PRESENTATION

GISTs commonly arise in the stomach (50–70%), small intestine (25–35%), colon and rectum (5–10%), mesentery or omentum (7%), and esophagus (<5%).[9,49] Occasionally, GIST may arise in the duodenal ampulla, appendix, gallbladder, and urinary bladder.[50–55]

GISTs are generally found due to symptoms. In one study, 69% of tumors were symptomatic, 21% were discovered incidentally at surgery, and 10% were discovered at autopsy.[6] GISTs are often highly vascular, soft, and friable, and bleeding is a common presenting symptom. They may cause life–threatening hemorrhage by erosion into the bowel lumen. Alternatively, tumor rupture may cause potentially catastrophic intraperitoneal bleeding and/or dissemination by peritoneal seeding. Intestinal obstruction may lead to perforation. Smaller tumors may remain asymptomatic, incidentally detected on radiographic studies, endoscopy, or laparotomy. Between 15 and 47% of patients with GIST have metastatic disease at diagnosis.[2,56] Common sites of metastasis include liver, peritoneum, and omentum; lymph node metastases are rare.[5] Extra–abdominal metastases (lung, bone, subcutaneous tissues, and brain) are rare, observed in approximately 5% of patients.[57]

DIAGNOSIS

Radiographic Studies

The initial imaging study for a suspected or confirmed GIST is a contrast–enhanced computed tomography (CT) of the abdomen and pelvis.[58] Primary GISTs are typically well–circumscribed masses within the walls of hollow viscera (Fig. 24-4). Magnetic resonance imaging (MRI) may help characterize metastatic liver or primary perirectal disease (Fig. 24-5). Although [^{18}F]fluoro–2–deoxy–D–glucose positron emission tomography (FDG–PET) may help characterize masses ambiguous on CT, monitor response to therapy, and detect emergence of drug–resistant clones, it

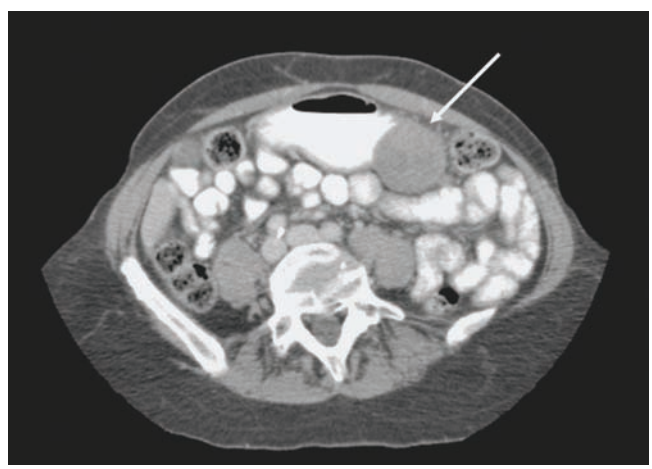

FIGURE 24-4 CT image of primary gastric gastrointestinal stromal tumor (GIST) presenting as an exophytic mass (*arrow*) off of the greater curvature of the stomach.

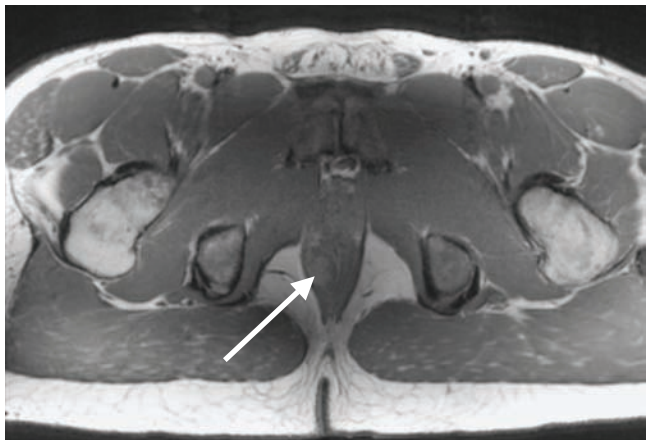

FIGURE 24-5 MRI image of gastrointestinal stromal tumor (GIST) along right posterolateral rectal wall (*arrow*).

FIGURE 24-6 Endoscopic image of incidentally identified primary gastric gastrointestinal stromal tumor (GIST), presenting as an asymptomatic submucosal mass in the proximal along the lesser curvature.

is not specific for GIST and thus is not recommended for most patients with suspected primary disease.[59–61]

Endoscopy, Fine–Needle Aspiration, and Biopsy

Endoscopically, a primary GIST may appear as a submucosal lesion, with or without ulceration, present in the upper or lower GI tract. They are often indistinguishable from other GI tumors of smooth muscle origin, such as leiomyomas (Fig. 24-6). Endoscopic ultrasound (EUS) is not necessary to evaluate a confirmed GIST. However, EUS–guided fine–needle aspiration (FNA) may be attempted to establish diagnosis. Nevertheless, EUS–FNA is not consistently diagnostic.[62] Additional cytologic morphology, immunohistochemistry, and reverse–transcriptase polymerase chain reaction analysis for *KIT* mutations may be required to confirm a diagnosis.[63]

A preoperative biopsy is not routinely necessary for a primary, resectable neoplasm suspicious for GIST. In fact, preoperative biopsy may rupture a suspected GIST and increase the risk of dissemination. However, if the differential diagnosis includes entities such as lymphoma that would be treated differently, if neoadjuvant therapy is under consideration, or if there is metastatic disease, biopsy is appropriate.

PROGNOSTIC FACTORS

While tumors under 1 cm likely have a low risk of recurrence, no tumors can be definitively called benign and most large tumors have malignant potential. The three established prognostic factors are tumor size, mitotic index, and tumor site of origin, with mitotic count the most important (Table 24-1).[15,64,65] Individuals with small bowel GISTs have a higher risk of progression than those with gastric GISTs of comparable size and mitotic count.

Additional adverse prognostic factors observed in some but not in all studies include high cellular proliferation index,[66] aneuploidy,[66,67] telomerase expression,[68,69] *KIT* exon 9 mutations,[65] and *KIT* exon 11 deletions involving amino acid W557 and/or K558.[70] Point mutations and insertions of *KIT* exon 11 appear to have a favorable prognosis.[65]

The ideal margin of resection is unknown. While a macroscopically complete resection with negative or positive microscopic margins (R0 or R1 resection, respectively) is associated with a better prognosis than a macroscopically incomplete resection (R2 resection), there are no data to confirm that a positive microscopic margin (R1 resection) impacts survival.[2]

THERAPY FOR PRIMARY DISEASE

Surgery

TECHNIQUE

Surgery remains the standard of care and only potentially curative therapy for patients with primary, resectable, localized GIST. The goal of the operation should be an R0 resection. Tumor rupture or violation of the tumor capsule during surgery is associated with an increased risk of recurrence.

At laparotomy, the abdomen is thoroughly explored to identify and remove any previously undetected peritoneal metastatic deposits. Although primary GISTs may demonstrate inflammatory adhesions to surrounding organs, they do not generally invade other organs beyond the site of origin despite CT appearance. The extent of surgery is usually a wedge or segmental resection of the involved stomach or bowel without the wide margins necessary for adenocarcinoma. In a series of 140 patients with gastric GISTs, wedge resections were performed in 68%, partial gastrectomies in

28%, and total gastrectomies in only 4%.[71] Occasionally, a more extensive resection (total gastrectomy for a large proximal gastric GIST, pancreaticoduodenectomy for a periampullary GIST, or abdominoperineal resection for a low rectal GIST) may be necessary. There are also no data indicating that patients who have an R1 resection require reexcision.[47] The value of wide surgical margins is unknown, particularly in the era of the targeted therapies described in the following text. Furthermore, margins may retract after resection, or the pathologist may trim away the staple line (converting a technically negative microscopic margin into a positive one). Therefore, all cases of positive microscopic margins should be carefully reviewed by a multidisciplinary team of surgical oncologists, pathologists, and medical oncologists to assess the need for reexcision. Lymphadenectomy is not required because lymph nodes are rarely involved (in adult patients).

All GISTs 2 cm in size or greater should be resected when possible, as none of these can be considered benign.[64] However, the natural history of GISTs under 2 cm in size is unknown, and thus their management is more debatable. Any small GISTs that are symptomatic (eg, hemorrhage from erosion through the mucosa) or increase in size on serial follow–up should be resected.

It is probable that most GISTs under 1 cm in size may be followed (especially gastric GISTs). Two studies have established that subcentimeter gastric GISTs are relatively common, detected in 22.5% of autopsies in adults older than 50 in Germany and in 35% of patients undergoing gastrectomy for gastric cancer in Japan.[72,73] Despite their relative frequency, few of these neoplasms appear to become clinically relevant. Until further data are available, the most appropriate management of such small tumors remains uncertain. Although endoscopic resection of small gastric GISTs has been reported, this cannot be recommended.[74] Unlike early gastric cancers (mucosal malignancies) amenable to endoscopic mucosal resection, GISTs involve the muscularis propria, so attempts at endoscopic resection risk leaving a positive margin and, due to the depth of the lesion, could result in perforation.

The management of gastric GISTs 1–2 cm in size is even more confusing. On the one hand, the very low risk of recurrence in conjunction with a low mitotic index supports a more conservative, nonoperative approach. On the other hand, an accurate mitotic index cannot be determined by biopsy or FNA. Therefore, observation cannot be recommended based on size alone. Resection (laparoscopic if possible) should be considered, and the risks and benefits of surgery versus observation should be reviewed with the patient.

Little data exist on the natural history of small nongastric GISTs. Given the higher risk of aggressive behavior of small bowel and colon GISTs, any tumor in such locations should be resected irrespective of size.

Laparoscopic or laparoscopy–assisted resection of primary GISTs may be performed following standard oncologic principles (Fig. 24-7). Two early studies confirmed both the safety and feasibility of a laparoscopic approach. Otani et al reported that in a series of 35 gastric GISTs (2–5 cm), resected laparoscopically, no local or distant recurrences were observed for tumors under 4 cm in size with a median follow–up of 53 months.[75] Novitsky et al reported a study of 50 patients with gastric GISTs (1.0–8.5 cm) resected laparoscopically or using laparoscopy–assistance, with 92% of patients disease–free with a mean follow–up of 3 years.[76]

OUTCOMES

Despite a macroscopically complete resection, as many as 50% of individuals may develop recurrent disease at a median of 24 months.[2,77] An R0 or R1 resection is associated with 5–year overall survival (OS) rates of 34–63% whereas R2 resection is associated with 5–year OS rates of as low as 8%.[1,2,78–82]

Neoadjuvant Therapy for Primary Disease

The identification of two effective, relatively well–tolerated orally available targeted tyrosine kinase inhibitors (TKI)—imatinib mesylate (STI571, Gleevec) and sunitinib malate (SU11248, Sutent)—has revolutionized the treatment of GIST (discussed in a later section). These agents were initially developed for the management of patients with metastatic disease. Imatinib selectively inhibits several tyrosine kinases, including KIT, PDGFRA, and BCR–ABL.[18,83–85] Several clinical trials have confirmed that up to 80% of patients with metastatic GIST achieve a complete or partial response or demonstrated stable disease on imatinib.[86,87]

As demonstrated previously, recurrence rates are high and survival rates are low after an R0/R1 resection. Therefore, the role of neoadjuvant therapy with imatinib combined with resection has been explored in one multi–institutional[88] and one single–institution[89] prospective trial. For the sake of brevity, only the former is discussed here. The Radiation Therapy Oncology Group (RTOG) 0312 phase II trial is the only multicenter study reported thus far evaluating the use of imatinib as a neoadjuvant agent. Patients with resectable primary or recurrent GIST were treated with 600 mg/d of imatinib for 8–12 weeks prior to surgery (Table 24-2). Nonprogressing patients underwent surgery and were then maintained on adjuvant imatinib for 2 years. An objective response was demonstrated in 90% of patients with primary GIST, and 92% underwent R0/R1 resections. Two–year recurrence–free survival (RFS) was 83%. Although this trial confirmed the safety of imatinib as a neoadjuvant therapy, it is still unclear what the optimal length of preoperative therapy is. Data from trials of advanced GIST have demonstrated that maximal radiographic response to imatinib generally required 6–9 months of treatment.[86,90,91] Thus, the optimal preoperative imatinib regimen may be 6 months or more as long as continued radiographic response is observed (Fig. 24-8).

Adjuvant Therapy for Primary Disease

The role of adjuvant therapy with imatinib combined with resection of primary disease was or is being explored in six prospective multi–institutional trials. The trials tested durations of adjuvant imatinib of 12 months (American College of Surgeons Oncology Group Z9000,[92] ASOSOG Z9001,[93] China Cooperative Group[94]), 24 months (European Organization for the Research and Treatment of Cancer [EORTC] 62024, Korean trial[95]), 12 versus 36 months (Scandinavian Sarcoma Group [SSG] XVIII), or 5 years (ongoing phase II multi–institutional trial, CSIT571BUS282) (see Table 24-2).[92–94] Data from the only published trial, ACOSOG Z9001, are discussed in detail. In this phase III trial, patients with completely resected primary GISTs at least 3 cm in size were randomized to receive either placebo or imatinib postoperatively for 1 year. The trial was halted early after a planned interim analysis of 644 evaluable patients confirmed that the 1–year RFS was significantly better in the imatinib arm (97 vs 83%, p = .0000014). However, the slopes of the Kaplan–Meier curves representing the two treatment arms, once recurrences were observed, were similar. Thus, adjuvant imatinib may delay recurrence but may not necessarily cure anyone over the short follow–up interval. Furthermore, there was no difference in OS between the two treatment arms. Additional follow–up is necessary to determine if a difference in OS will eventually be observed. Finally, the optimal length of adjuvant therapy is uncertain. The EORTC 62024 and SSG XVIII trials have completed accrual, but data are not yet available. Data from these two trials plus the ongoing CSIT-571BUS282 trial will help determine the comparative benefit of 2, 3, or 5 years of imatinib. Perhaps the most important question is whether administration of imatinib after resection of primary disease or after disease recurrence delays time to second–line therapy (imatinib dose escalation or changing to sunitinib). However, with the recent approval of imatinib for adjuvant use by both the Food and Drug Administration in the United States and the European Medicines Agency in Europe, it seems unlikely that any trial will ever be designed to answer this question.

THERAPY FOR ADVANCED DISEASE

Targeted Therapy

Historically, patients with recurrent GIST have been treated by a combination of the three traditional cancer therapeutic modalities: surgery, intravenous chemotherapy, and radiotherapy. Surgery is effective for patients with resectable disease, but disease may recur in as many as 50% of individuals. Traditional intravenous chemotherapy (including standard sarcoma regimens employing doxorubicin and/or ifosfamide) and radiotherapy have shown little efficacy.[1,2,91]

To date, two TKIs have been approved for the treatment of metastatic GIST: imatinib mesylate and sunitinib malate. Imatinib is the first–line therapy for advanced (unresectable primary or metastatic) GIST, based on data from international phases I, II, and III trials.[60,86,87,90,96] Partial responses (PRs) or stable disease (SD) were noted in nearly 85% of patients with advanced GIST treated with imatinib.[60] In the US phase III trial, the median progression–free survival (PFS) and OS with imatinib therapy were 18–20 months and 51–55 months, respectively.[86] The starting dose for imatinib is generally 400 mg once daily. In patients who develop progressive disease on 400 mg, dose escalation up to 400 mg twice daily is effective.[97–100] However, greater toxicity and more dose reductions are generally required at doses above 400 mg/d. In a meta–analysis of the two large phase III studies, a slight advantage in PFS was noted in patients initially treated with higher–dose imatinib, but that advantage was essentially limited to patients with *KIT* exon 9 mutations.[101]

Imatinib should be continued indefinitely. A French randomized imatinib discontinuation study demonstrated that patients with GIST on imatinib who stop imatinib therapy after 1 and 3 years had a much higher rate of disease progression than those who continued on therapy.[102,103]

If patients continue to progress on higher doses of imatinib or do not tolerate such doses, second–line sunitinib is started. Sunitinib is a multitargeted TKI whose targets include KIT, PDGFR, vascular endothelial growth factor receptor (VEGFR1, VEGFR2, VEGFR3), the ret proto–oncogene receptor (RET), and Fms–like tyrosine kinase–3 receptor (Flt3). A placebo–controlled phase III trial demonstrated significant improvement in time to progression in patients treated with sunitinib compared to those treated with placebo (27.3 vs 6.4 weeks, respectively), as well as PFS and OS.[104] Initially dosed as 50 mg daily in a 4–week–on–2–week–off cycle, many oncologists now favor a continuous dose regimen of 37.5 mg daily.[105]

When sunitinib resistance develops, protocol–based therapies should be considered. Additional TKIs under investigation include sorafenib,[106] nilotinib,[107] masitinib,[108] and vatalanib.[109] Novel and potentially attractive targets include heat shock protein–90 (HSP–90)[110] and IGF–1R.[26]

Surgery

Cytoreductive surgery for resectable advanced or metastatic disease is a relatively common practice for disseminated solid tumors originating in the colon, appendix, ovary, and testicle. With the advent of imatinib and sunitinib therapy, a number of investigators have pursued a similar strategy of aggressive cytoreductive surgery in patients with metastatic GIST on TKI therapy. Three observations support such an approach. First, the majority of patients experience durable periods of PR or SD on imatinib, lasting months to years. Second, pathologic complete responses are rare, noted in fewer than 5% of patients.[99,100] Third, response to imatinib is not maintained indefinitely; the median time to progression due to the development of secondary resistance to imatinib 18–24

months.[86,87] Once drug resistance develops, disease progression may be either limited (progression at one site of tumor, with other tumor deposits showing ongoing response to TKI) or generalized (progression at more than one site).[111,112]

Several single–institution retrospective studies have documented the PFS and OS rates following extensive cytoreductive surgery in patients with advanced GIST treated with TKI therapy (Table 24-3).[111–116]

In the experience at Brigham and Women's Hospital/Dana–Farber Cancer Institute (BWH/DFCI), the best results were generally seen in patients whose disease was still responsive to TKI therapy at the time of surgery. The ability to remove all macroscopic disease was greatest in patients demonstrating ongoing response to TKI therapy. After surgery, there was no evidence of any residual disease in 78, 25, and 7% of patients with responsive disease, limited progression, and generalized progression, respectively ($p < .0001$).[112] In contrast, bulky residual disease remained postoperatively in 4, 16, and 43% of patients with responsive disease, limited progression, and generalized progression, respectively.

The series from BWH/DFCI, Memorial Sloan–Kettering Cancer Center, and Istituto Nazionale Tumori each demonstrated that the highest rates of PFS and OS were observed when cytoreductive surgery occurred while the patients were still responding to TKI therapy. PFS rates for patients with ongoing response to TKI therapy (ie, PR or SD at the time of surgery) were 70–96% at 1 year after surgery and 72% at 4 years from the start of imatinib therapy, whereas the 1–year PFS for patients with generalized progression ranged from 0 to 14%.[111,112,115] OS rates approached 100% at 1 year after surgery in patients responding to TKI therapy and only 0–60% at 1 year in the setting of generalized progression. Although patients with limited progression had lower rates of PFS than those with responsive disease, the rates of OS were not significantly different; thus the benefits of surgery in this population are unclear.

In the BWH/DFCI series, approximately 40% of patients required liver resections, over 60% underwent peritonectomy and/or omentectomy, and over 60% needed multivisceral resections.[112] Radiofrequency ablation may be considered for liver disease. Complication rates ranged from 40 to 60% in the three large series, though the majority were minor.[111] Perioperative deaths were rare, usually occurring in the setting of emergency procedures, as reported in the French study.[114,116]

The goal of such operations is to perform a macroscopically complete (R0 or R1) resection when safely possible. However, the disease may frequently be too extensive to be removed completely, in which case progressing lesions are preferentially removed. Following surgery, these patients should remain on imatinib indefinitely, as failure to resume imatinib results in rapid disease recurrence.

Based on these data, from limited single–institution series, the patients who seemed to derive the most benefit from cytoreductive surgery were the ones still responding to TKI therapy at the time of surgery (PR or SD, Fig. 24-9). Such patients should be considered for surgery on an individual basis. Patients with generalized progression do not appear to derive any benefit from cytoreductive surgery and are best treated nonoperatively. Such patients may nevertheless need urgent surgery for palliative or emergency purposes such as obstruction or hemorrhage (Fig. 24-10). Although cytoreductive surgery is feasible in patients with responsive disease, there is still no evidence that outcomes are superior or even equal to those for patients who continue on TKI therapy without surgery. This question will hopefully be answered in randomized clinical trials under development in the United States and open in Europe and China. Figure 24-11 is a schema for the management of primary and advanced GIST.

B

FIGURE 24-10 Patient with unresectable metastatic gastrointestinal stromal tumor (GIST) (**A** and **B**). Therapy with imatinib failed to control growth of the disease. The patient underwent a palliative debulking to relieve proximal gastric obstruction, but the resection as anticipated was macroscopically incomplete.

SURVEILLANCE

The NCCN consensus panel recommended that patients who have had resection of a primary GIST should undergo a history, physical examination, and abdomen/pelvis CT scans with intravenous contrast every 3–6 months during the first 3–5 years and then annually thereafter.[47]

CONCLUSION

The principal and only potentially curative treatment for GIST is surgery. However, recurrences are common. In the era prior to the institution of TKI therapy, survival in the setting of recurrent or metastatic disease was poor. Because of its relatively low toxicity and significant efficacy in the treatment of GIST, TKI therapy has dramatically altered the natural history of this disease. The type and dose of TKI administered may soon be guided by mutational analysis. The role of imatinib has been expanded to patients with primary GIST, where it may be used safely as a neoadjuvant agent and improves RFS as an adjuvant agent following complete macroscopic resection. Ongoing studies will address the issues of optimal length and dose of adjuvant and neoadjuvant imatinib therapy, define the subset of candidates most likely to benefit from such therapy, and determine the long–term

impact on OS. Cytoreductive surgery may be considered in a subset of patients with advanced disease, but phase III trial data are necessary to determine if surgery adds any PFS or OS benefit over continuing imatinib therapy alone.

Future studies will focus on the integration of surgery with targeted therapy and the development of new agents for drug–resistant GIST.

PERSPECTIVE ON GASTROINTESTINAL STROMAL TUMORS

Ronald P. DeMatteo

INTRODUCTION

In the accompanying chapter, Dr Raut provides an overview of gastrointestinal stromal tumor (GIST). Clearly, the development of tyrosine kinase inhibitors for GIST is one of the most remarkable achievements to date for any solid tumor. Patients with metastatic GIST historically had a median survival of 12 months, but it is now 5 years.[1,2] The paradigm of targeted molecular therapy has been subsequently expanded to lung adenocarcinoma with epidermal growth factor receptor (EGFR) inhibitors, renal carcinoma with vascular endothelial growth factor receptor (VEGFR) inhibitors, and most recently melanoma with B-Raf inhibitors. Although GIST is an uncommon tumor, lessons from "the GIST story" will have relevance to the multimodality therapy of these more common tumors and other cancers for which targeted therapy is developed.

Despite the advances in molecular therapy, it is critical to realize that surgery remains the only potentially curative treatment for GISTs. There are no data to support chronic therapy with molecular agents instead of surgical removal in patients who are otherwise healthy and expected otherwise to have prolonged survival. Thus, a thorough understanding of the surgical principles for GIST is essential.

SPECIFIC SURGICAL ISSUES

There are a variety of surgical issues in GIST that deserve emphasis. First, it is important to handle GISTs gently, as they are often soft and prone to tumor rupture. They may become even more friable after response to neoadjuvant therapy. During laparoscopic resections, specimens should be placed into a plastic bag prior to removal from the abdominal cavity. Large GISTs tend to have extensive arterial and venous collaterals. Thus, careful dissection is necessary to minimize the chance of significant blood loss. While GISTs tend to push surrounding structures as opposed to invading them, if a GIST is adherent to a contiguous organ, it is necessary to remove the tumor en bloc with a portion of that organ.

The site and size of a primary GIST influence the surgical approach. For small- to medium-sized tumors, laparoscopic resection can be used. Some of these tumors will be cured by surgery alone as they generally tend to have low mitotic rates. Gastric GISTs are often easily identified at surgery because they tend to be exophytic. Tumors that grow more inward toward the gastric lumen may require intraoperative endoscopy to localize the exact site for partial gastrectomy. Intraoperative ultrasound may also be useful and is facilitated by instilling water into the stomach. Tumors arising from the posterior wall of the stomach are slightly more challenging to remove but still often can be removed laparoscopically after adequate stomach mobilization. It is often helpful during laparoscopy to retract the left lateral segment of the liver to the right to fully expose the stomach. Most gastric tumors can be removed using surgical staplers. Generally, a 1-cm margin of normal tissue is adequate. As Dr Raut mentions, it may not be possible or necessary to have a preoperative tissue diagnosis. Therefore, patients should be informed that their tumor may not prove to be a GIST. Other entities that can masquerade as GISTs include leiomyoma, Schwannoma, and even ectopic pancreas.

Occasionally, gastric GISTs arise near the gastroesophageal junction. In general, we prefer to remove these GISTs using laparotomy, especially if they arise from the posterior stomach. It may be necessary to open the stomach to facilitate adequate removal and proper reconstruction. If, instead, surgical staplers are used, it is advisable to use a bougie to avoid narrowing the entrance to the stomach.

Massive gastric tumors may be inseparable from the splenic hilum, distal pancreas, splenic flexure of the colon, or the fourth portion of the duodenum. In patients with large GISTs, neoadjuvant imatinib mesylate is highly recommended as it may reduce the extent of the operation required to remove the tumor. Generally, we perform a computed tomography (CT) 2–4 weeks after starting imatinib to check for tumor response, which can be detected by a decrease in tumor perfusion and density. Size is not a reliable indicator of response initially, because a responsive

tumor may not decrease in size and occasionally may even swell temporarily. Therefore, it is important that the surgeon personally review the radiologic films. In the absence of tumor progression, imatinib is then continued and scans are repeated 3 and 6 months later. Generally, resection is attempted between 6 and 9 months following the start of a tyrosine kinase inhibitor. Rarely, a total gastrectomy is required to remove adequately a proximal gastric GIST, especially if it is large. This possibility should be discussed with the patient preoperatively.

The small intestine is the next most common site of origin. The same basic surgical principles apply. GISTs of the duodenum are particularly complex to treat. A GIST in the second portion of the duodenum may require a pancreaticoduodenectomy, unless it is on the lateral wall and small in size. In that case, a lateral duodenal resection can be performed. Reconstruction can be performed with a Roux-en-Y jejunal limb. Sometimes, though, the defect can be closed primarily. GISTs in the fourth portion of the duodenum can be removed and reconstructed with a direct anastomosis between the duodenum and jejunum or closure of the distal duodenum with a Roux-en-Y jejunal limb that is sewn to the second portion of the duodenum. Neoadjuvant imatinib therapy is often useful in duodenal GISTs.

Although colonic GISTs are rare, GISTs arise from the rectum 5% of the time. Neoadjuvant therapy may reduce the extent of the operation and in particular preserve the anal sphincter and avoid an abdominoperineal resection. For distal tumors, local resection can be performed via the transanal route. The value of postoperative radiation following the local excision of a rectal GIST is uncertain.

PERIOPERATIVE CARE

Unlike many cytotoxic chemotherapeutic agents, imatinib and sunitinib (as well as sorafenib, dasatinib, and nilotinib) can just be stopped a day or two prior to surgery. For patients requiring postoperative therapy, the agent can be restarted when the patient is tolerating a regular diet well, usually within 2 weeks of surgery.

ADJUVANT THERAPY

As covered by Dr Raut, certain patients are considered for adjuvant therapy with imatinib following the resection of a primary, localized GIST. The results of a phase 3 trial demonstrated prolonged recurrence-free survival in patients assigned to 1 year of imatinib therapy compared with those assigned to placebo.[3] Overall survival is not different at this time. This trial included "all comers" with a tumor at least 3 cm in size. Subsequent analyses have shown that patients at low risk of recurrence (see Table 24-1) probably do not benefit from adjuvant imatinib because the chance of tumor recurrence is so low.

Recently, we have developed a nomogram based on tumor size, location, and mitotic rate to provide a numerical estimation of recurrence-free survival for any particular patient (http://www.mskcc.org/mskcc/html/98103.cfm).[4] The nomogram results can be used to guide the discussion of adjuvant therapy with a particular patient. As we accumulate more data on the impact of specific mutations in GIST, the nomogram will be further refined. The central question for patients who are at moderate to high risk of tumor recurrence and are receiving adjuvant imatinib is when the drug should be discontinued. It appears that 1 year of adjuvant imatinib may not be enough. As pointed out by Dr Raut, several ongoing trials are attempting to identify the optimal duration of adjuvant imatinib therapy.

SURGERY FOR METASTATIC GIST

The standard of care for metastatic GIST is treatment with tyrosine kinase inhibitors. However, in selected patients with resectable metastases, I and others have recommended surgical resection when all residual disease can be removed. Dr Raut references several retrospective series that have shown the safety of this approach. The results of course are confounded by selection bias. In addition, there is lead-time bias, because many of the patients underwent surgery early on after starting medical therapy. The true efficacy of surgery therefore remains unproven. The hypothesis is that the time to resistance to tyrosine kinase inhibition is proportional to the amount of residual tumor following the response to a tyrosine kinase inhibitor. There are two open trials in which patients are being randomized to a tyrosine kinase inhibitor with or without surgery. For obvious reasons, accrual may be problematic. As radiologic surveillance of patients who have undergone surgical removal of a primary GIST increases, it will become more commonplace to detect minimal amounts of metastatic disease that are amenable to surgical removal. In the absence of randomized data, it seems reasonable to perform surgery for metastatic GIST in well-informed patients when the disease has responded to tyrosine kinase inhibition and all the disease can be removed.

STOMACH AND DUODENUM: OPERATIVE PROCEDURES

David I. Soybel • Michael J. Zinner

HISTORICAL PERSPECTIVE

The earliest recorded operations on the stomach were performed for penetrating injuries.[1] In the late 1800s, experimental studies in the surgical laboratories of Billroth confirmed the feasibility of removing the pylorus, a concept developed by Michaelis in the early part of that century. In 1881, Rydygier performed the first successful pylorectomy, and in 1884 he performed the first gastroenterostomy. Both of these operations were performed for complications of benign peptic ulcer disease. In 1881, Billroth performed the first successful pylorectomy for malignancy. In this case, the duodenum was anastomosed to the lesser curvature of the stomach and the greater curvature was oversewn. The patient initially did well but died from disseminated abdominal carcinomatosis 4 months later. In 1885, Billroth performed a resection of a large pyloric carcinoma, using an anterior gastrojejunostomy for the reconstruction. In subsequent years, Billroth, his students, and others devised several approaches to gastroduodenal and gastrojejunal reconstruction.[1–3] Following popularization of gastrojejunostomy for reconstruction after gastric resection or palliation of unresectable gastric malignancy, surgeons were confronted with early complications such as bleeding, anastomotic leak, intestinal obstruction, and late complications such as stomal ulceration, bilious vomiting, afferent and efferent limb obstructions, and dumping.[4,5] At present, these problems remain only partially understood and controllable.

Pyloroplasty was initially devised by Heineke for treatment of congenital hypertrophic pyloric stenosis, and the results were poor. Jaboulay's side-to-side anastomosis of the distal greater curvature and duodenum in 1892, and the Faience extension of this anastomosis to include the pylorus itself were subsequently refined by Kocher. Kocher improved the technical ease of the operation by including a mobilization of the duodenum from its lateral peritoneal attachments. The first pyloromyotomy was performed for this lesion in 1912 by Ramstedt.

In the early part of the 20th century, a dramatic rise was observed in the incidence of duodenal ulceration. A period of intense clinical and laboratory investigation from 1920 through 1940 led to the recognition that surgically performed vagotomy could reduce gastric acidity under resting conditions and in response to luminal and humoral stimuli. The use of vagotomy for patients with complications of ulcer disease was pioneered by Latarjet, who reported 24 such cases in 1922. Latarjet himself recognized that vagotomy might lead to delayed gastric emptying and had added a drainage procedure, gastrojejunostomy. Confusion regarding the role of delayed gastric emptying in the pathogenesis of peptic ulcers, however, led many surgeons away from vagotomy and drainage as a treatment for recurrent peptic ulceration. It remained for Dragstedt and his colleagues at the University of Chicago to resurrect this concept in the 1940s.[5] Subsequently, Farmer, Smithwick, and others introduced the combination of truncal vagotomy (TV) and hemigastrectomy, an operation that also removed the gastrin-producing antral mucosa.[3] In the 1950s, Harkins' group in Seattle began to evaluate forms of vagotomy that left intact the celiac and hepatic branches (proximal selective vagotomy), along with or in combination with the preservation of vagal motor branches to the antrum (highly selective vagotomy [HSV] or parietal cell vagotomy). These modifications arose from an appreciation of the contributions of antral motility to proper digestion, as well as improved understanding of specific postvagotomy complications such as dumping and diarrhea. The popularization of HSV is largely attributable to the efforts of Johnston, Goligher, Amdrup, and others, who in the 1960s and 1970s demonstrated the feasibility of obtaining ulcer recurrence rates as low as those of conventional TV without the incidence of dumping and diarrhea that was associated with TV with drainage or gastrectomy.[6,7] It is worth noting that surgeons have done more than developing new and interesting operative approaches to acid peptic disease. They played a major role in advancing current concepts of pathophysiology in ulcer disease and recurrence, and in understanding the physiological consequences of ulcer treatments, both medical and surgical.[4,5]

VAGOTOMY

Even though the increasing use of medications that inhibit gastric acid secretion, such as proton pump inhibitors, has made elective antisecretory operations essentially nonexistent, these medications remain part of the surgeon's armamentarium in dealing with patients who remain refractory to maximal medical therapy for ulcer disease, and in some selected cases for patients with ulcer perforation and bleeding. To understand the importance of the technical details in the execution of antisecretory operations, it is necessary to fully appreciate the anatomy of the vagus nerve and the gastric microvasculature, as well as the physiology of acid secretion, mucosal barrier function, and gastric motility, which are expanded upon in the following text.

Tests of Vagal Control of Acid Secretion

Historically, vagal control of acid secretion has been assessed by measuring acid secretion in response to various stimuli. Acid secretion can be measured directly by the placement of a tube into the stomach, through which gastric juice is aspirated and the titratable acidity is measured by adding known quantities of 0.1 N NaOH. Gastric output is measured at baseline and after stimulation with pentagastrin or sham feeding. Measurements of gastric acid output pre– and post–vagotomy operations can be measured to assess the efficacy of vagotomy.[8,9] Acid secretion also can be assessed semiquantitatively, using pH-sensitive dyes, such as Congo red, that coat the mucosa and turn color when acid is being secreted from the gastric glands.[10,11] Although the former analytic methods permit accurate and quantitative assays of secretory capacity before and after the operation, the latter colorimetric methods can provide relatively rapid means of assessing secretory capacity of the stomach during the operation itself. These tests are rarely used today with the increasing use of medications that inhibit gastric acid secretion such as proton pump inhibitors and the consequent rarity of performing elective antiulcer gastric acid–reducing operations.

Vagal Regulation of Gastric Motility and Emptying

As stated by Professor David Johnson in a previous edition of this book, "… Only when one fully understands the physiologic rationale of highly selective vagotomy will be one sufficiently motivated to do it well." This statement was made not in reference to the innervation of parietal cells that secrete HCl, but to the neural regulation of gastric motor function and emptying. The vagus dominates the motor activity of the normally functioning stomach in three ways. First, it mediates receptive relaxation and gastric accommodation; that is, the relaxation of the gastric fundus when intraluminal pressures in the proximal esophagus and stomach are increased by the presence of chyme. Second, the vagus mediates increases in antral myoelectrical activity that result from distention of the proximal stomach by chyme. Third, the vagus appears to mediate coordination of pyloric emptying with antral myoelectrical activity, in response to changes in proximal gastric motor activity, and perhaps in response to changes in composition and pH of duodenal content.[12]

It should be recognized that while truncal or selective vagotomy interrupts the vagal pathways to the antrum and pylorus, all three forms of vagotomy (truncal, selective, and highly selective) abolish receptive relaxation and gastric accommodation. It has been claimed that in the absence of pyloric scarring or stenosis, vagotomy only temporarily impairs gastric emptying. This rationale has been used to justify combinations of selective and relatively nonselective approaches, such as a posterior truncal and anterior highly selective (or anterior seromyotomy) vagotomy. Such arguments become important in thinking about potential adverse consequences of laparoscopic approaches to the vagus and the need for, and choice of, drainage procedures. The assumptions that antral/pyloric coordination will return after truncal vagotomy or that gastric emptying after pyloromyotomy is as good as that after pyloroplasty now seems valid.[13–15] In addition, the spectrum of complications following such mixtures of approach has now been characterized and is not substantially different than those reported in symmetric operations.[15,16] Nevertheless, for open or laparoscopic procedures, it is advisable to use the same caution in utilizing mixtures of approach or dispensing with drainage procedures after truncal or selective vagotomy.

Open Approaches to the Vagus

PATIENT POSITION, INCISIONS, AND EXPOSURE

To perform a complete vagotomy, access to the upper part of the stomach and lower esophagus is crucial. It is helpful for the operating surgeon, standing on the patient's right, to wear a headlight. When access to the duodenum is required, as in a gastrectomy, excellent exposure is available through a chevron incision. However, in most patients, both thin and obese, a midline incision carried up along the xiphoid will be adequate. In the obese, extension of the incision below the umbilicus facilitates exposure. Placing the patient in reverse Trendelenburg position is helpful. A nasogastric (NG) tube is placed with its tip at the most dependent portion of the greater curvature. The NG tube helps to keep the position of the esophagus in mind. A self-retaining retractor is required. We use an upper abdominal self-retaining retractor that provides excellent accessories for securing wide exposure to the upper abdomen, and by means of well-placed Mikulicz's pads, for holding the small bowel and transverse colon in the lower abdomen (Fig. 26-1). Some surgeons advocate routine mobilization of the left lobe of the liver by dividing the left triangular ligament. This mobilization is not always necessary and, when the lobe is floppy, can impede exposure. If this maneuver is performed, the lateral segment of the left lobe is

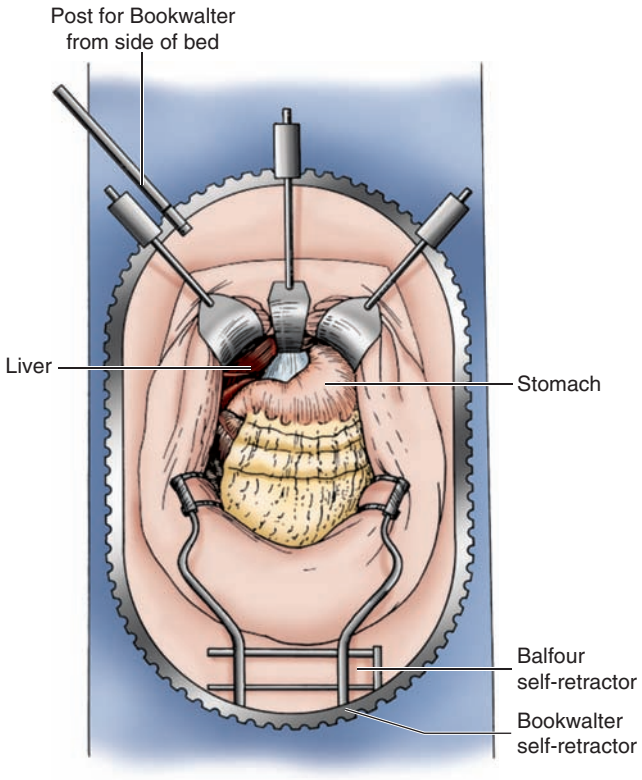

FIGURE 26-1 The use of the Bookwalter retractor for exposure of the upper abdomen.

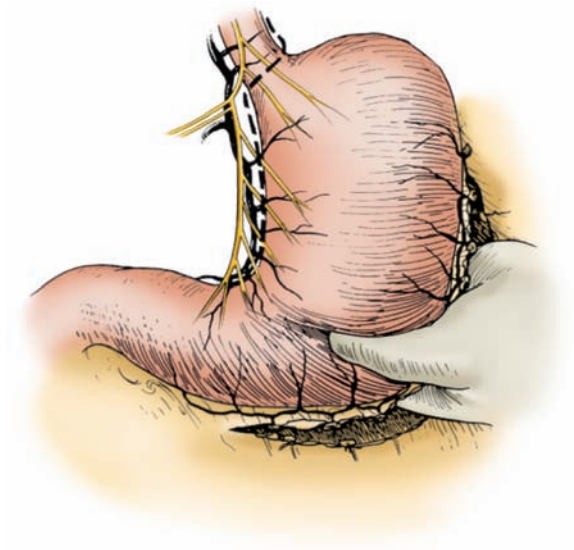

FIGURE 26-2 The distribution of the anterior vagus nerve is shown. The *dotted line* indicates the line of dissection. Note that it goes around the incisura to within about 6 cm of the pylorus. The gastrocolic omentum has been partially divided to permit access to the posterior nerve of Latarjet and to allow the stomach to be grasped and used as a retractor. Note that the gastroepiploic arteries are carefully preserved. (Redrawn, with permission, from Johnston D. Vagotomy. In: Schwartz SI, Ellis H, eds. *Maingot's Abdominal Operations*. 8th ed. Norwalk, CT: Appleton-Century-Crofts; 1985. After R.N. Lane.)

held upward and to the right by a Richardson or Herrington-type retractor accessory. Care must be taken to place sponges or a pack between the retractor attachment and liver, and not to put much tension on the liver. Otherwise, fracture of the liver parenchyma and bleeding will result.

TRUNCAL VAGOTOMY

Truncal vagotomy (TV) is performed in conjunction with some form of drainage procedure. In the elective setting, it is used in conjunction with antrectomy for definitive management of refractory symptoms of duodenal ulcer, pyloric channel ulcer (gastric ulcer type III), or gastric ulcers combined with duodenal (Dragstedt) ulcers. In the current era of highly effective antisecretory therapies such as omeprazole, and anti-*Helicobacter* antibiotics, the main indication for TV and antrectomy is in the setting of pyloric outlet obstruction with a long-standing history of ulcer symptoms or complications such as bleeding and perforation. TV and pyloroplasty are reserved for emergency operations for complications such as bleeding or perforation. Occasionally, TV plus gastroenterostomy will be an appropriate compromise when the duodenum is too scarred to permit safe antrectomy and duodenal closure. The anatomy of the vagal trunks and nerves of Latarjet has been reviewed[17] and is shown schematically in Figs. 26-2 and 26-3.

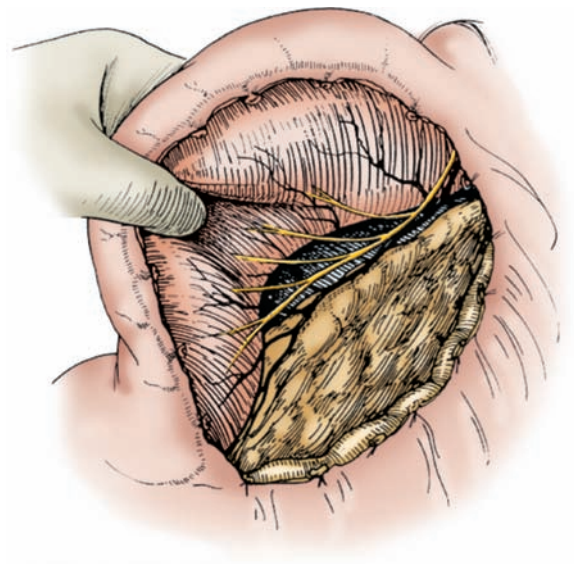

FIGURE 26-3 The posterior wall of the stomach and posterior nerve of the Latarjet are shown. The terminal Y fork of the nerve is preserved, and all of the branches to the stomach are divided, leaving about 5 cm of the distal portion of the stomach innervated. (Redrawn, with permission, from Johnston D. Vagotomy. In: Schwartz SI, Ellis H, eds. *Maingot's Abdominal Operations*. 8th ed. Norwalk, CT: Appleton-Century-Crofts; 1985. After R.N. Lane.)

Using a Mikulicz pad or carefully applied Babcock clamps, the assistant places downward traction on the greater curvature of the stomach, thereby placing traction on the gastroesophageal junction and lower esophagus. The first step is to incise the peritoneal covering of the gastroesophageal junction. The peritoneum is opened horizontally, from the angle at the lesser curvature to the cardiac notch at the greater curvature. The surgeon's thumb and right index finger are used in a blunt dissection to encircle the esophagus. When teaching this maneuver, it is not uncommon for the trainee to confuse the right crus of the diaphragm with the esophagus itself or even the posterior vagal trunk. Extra time spent at this juncture to correctly identify all structures is an essential aspect in teaching the operation. A Penrose drain can be passed around the junction in order to place more effective downward traction on the gastroesophageal junction. When encircling the esophagus, the surgeon stays wide of the esophagus in order to prevent inadvertent entry into the lumen and to include the vagal trunks. In the course of this maneuver, the posterior vagal trunk usually will be palpated as a taut cord.

A single anterior vagal trunk is usually identified in the anterior midportion of the esophagus, 2–4 cm above the gastroesophageal junction (Fig. 26-4). At this level, however, it is not uncommon for vagal fibers to be distributed between two or three smaller cords. These cords are palpable as much as they are visible and can be separated from surrounding esophageal muscle fibers using a nerve hook. These trunks are individually lifted up, and 2- to 4-cm segments of each are separated from surrounding tissues. A medium-sized clip is applied at the most superior end, and a clamp is applied inferiorly. The 2-cm length of nerve is resected and a clip is applied below the clamp; small bleeders are cauterized precisely. If it has not been done, the esophagus should be more widely mobilized for a distance of 4–5 cm above the gastroesophageal junction. Smaller, individual vagal fibers that ramify from the main trunks toward the lesser curvature and the cardiac notch then can be identified and cut or cauterized. The "criminal nerve" of Grassi, discussed in more detail in the section describing parietal cell vagotomy, also may be identified here, wrapping around the cardiac notch from its origin in the posterior trunk.

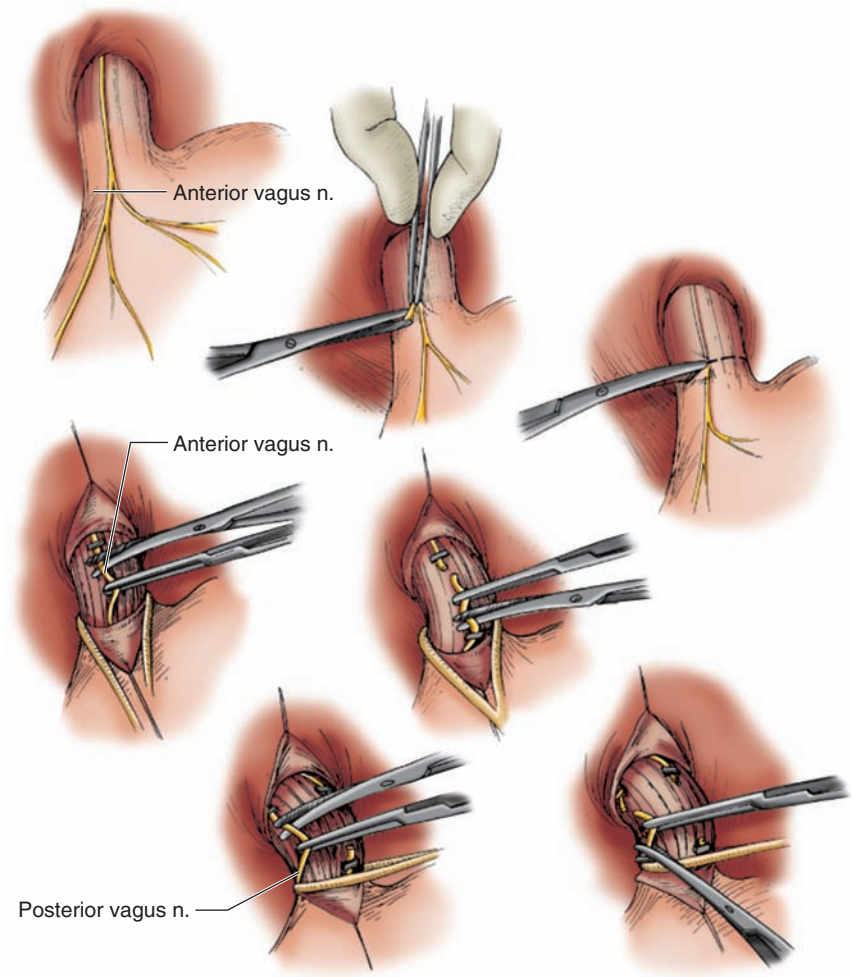

FIGURE 26-4 Division at both vagus nerves. (Redrawn, with permission, from Zinner MJ. *Atlas at Gastric Surgery.* New York, NY: Churchill Livingstone; 1992. After Gloege.)

The posterior vagal trunk itself usually will have been identified along the right edge of the esophagus. If the anterior vagus has already been divided, the esophagus is more mobile. This mobility allows the surgeon to place downward traction on the gastroesophageal junction, or along the most caudal portion of the greater curvature, thereby applying gentle tension on the EG junction, which causes the posterior vagus to "bowstring" and make it easier to identify. A 2- to 4-cm segment is separated from surrounding tissues, its margins marked with clips, and resected. Major branches of the anterior vagus and the posterior vagal trunk should be sent to pathology for examination in frozen section. Care should be taken to note the results of the pathologist's frozen section diagnosis in the dictated operative note.

SELECTIVE VAGOTOMY

Selective vagotomy (SV) is not commonly practiced in the United States, but it has found favor with European surgeons, who prefer not to cut the posteriorly derived vagal branch that innervates the small intestine and pancreas and anteriorly derived vagal branch that supplies the gallbladder and liver. There is evidence that preservation of such branches can avoid alterations in gallbladder motility that might lead to stasis and stone formation.[18] However, it is not clear whether preservation of the small intestinal and pancreatic nerves protects against some symptoms of the dumping syndrome.[19–22,] SV involves interruption of both nerves of Latarjet and therefore does not avoid the need for a drainage procedure.[22] Thus the main indication for SV may be in patients undergoing elective antrectomy with vagotomy for refractory ulcer symptoms or obstruction.

Exposure to the vagus, gastroesophageal junction, and esophagus is obtained in the same way that the surgeon would perform TV. Anteriorly, the nerve of Latarjet is identified by following the anterior vagal trunk as it descends from the esophagus to the lesser curvature of the stomach. Frequently, the descending branch of the left gastric artery is in close proximity to the site where the hepatic/gallbladder branches take off toward the liver in the gastrohepatic (lesser) omentum. A segment of the nerve of Latarjet is severed between clips and sent for examination on frozen section. The most expeditious way to perform this maneuver is to cross-clamp the portion of the lesser omentum that contains the artery and nerve, ligating and dividing these structures together (Fig. 26-5). The dissection continues upward along the lesser curvature, gastroesophageal junction, and esophagus. Division and ligation of blood vessels and nerves in this bundle avoids the hepatic/gallbladder branches and denervates the cardia, as was described for TV. This dissection opens up the plane for dissection and ligation of the posterior nerve of Latarjet.

HIGHLY SELECTIVE VAGOTOMY

Generally accepted indications for highly selective vagotomy (HSV) include elective management of intractable symptoms of duodenal ulcer disease, emergency treatment for perforated duodenal ulcer, and emergency treatment of perforated gastric ulcer when the ulcer is to be excised in a wedge rather than resected in continuity with the distal stomach. HSV also has been advocated for management of bleeding gastric or duodenal ulcers, but this has not been widely practiced. Finally, there is published experience in pyloric outlet obstruction using HSV in combination with finger or endoscopic balloon dilation,[19,23–25] but systematic audits of long-term persistence or recurrence rates of obstructing symptoms have yet to be reported.

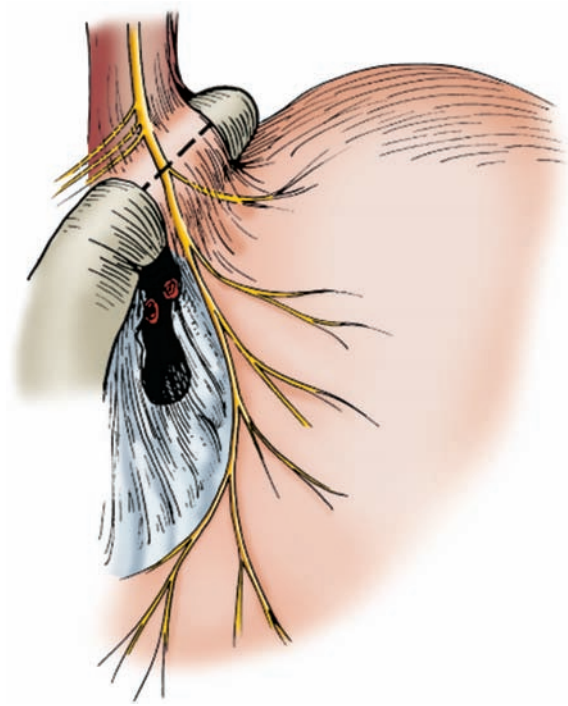

FIGURE 26-5 Selective vagotomy. The descending branch of the left gastric artery has been divided, and the anterior gastric branches of the anterior vagus are about to be divided.

A number of variations of the technique have been described and all are not reviewed here. However, it is worth cataloguing the decisions that the surgeon must make in preparing for and performing this operation. The first decision is whether to use Congo red dye for intraoperative testing of the completeness of vagotomy, in countries where it is approved for this application. It may be difficult, and sometimes contraindicated, to perform endoscopy in the setting of acute bleeding or perforation. If the test is to be used, the endoscopic equipment and reagents should be assembled in the operating room before the operation begins.[26] Conceptually then, the operation is divided into four phases: (1) exposure and gastric mobilization; (2) dissection of the anterior leaf of the lesser omentum; (3) dissection of the posterior leaf of the lesser omentum; and (4) dissection of vagal fibers traveling to the stomach along the distal esophagus.

Exposure and Gastric Mobilization. Exposure of the vagus nerves, esophagus, and gastroesophageal junction is obtained as described previously. A wide-bore (18F) NG tube should be placed by the anesthesia team. A number of authors have emphasized the importance of the stomach as a retractor in this operation. We recommend mobilization of the distal part of gastrocolic omentum. The dissection should be carried outside the gastroepiploic arcade, in order to avoid loss of any blood supply to the greater curvature. Congenital adhesions between the stomach and peritoneum overlying the pancreas are divided sharply. The goal of this dissection is to obtain sufficient mobility of the stomach so that it can be rotated upward and to the patient's right, thus permitting visualization of the posterior leaf of the lesser omentum and the posterior nerve of Latarjet through the lesser sac. The nerve can be seen running close to the descending branch of the left gastric artery. Vagal fibers can be seen running transversely toward the lesser curvature.

Dissection of the Anterior Leaf of the Lesser Omentum. The anterior leaf of the lesser omentum now is dissected. The next decision point is to define the distal margin of the dissection of the branches of the nerve of Latarjet (Fig. 26-6). An important landmark is the incisura angularis. The "crow's foot" is the neurovascular bundle that innervates the junction of the corpus and antrum, and has three characteristic branches from which its name derives. These nerves contain motor branches to the antrum and secretory branches to the oxyntic mucosa. Thus, leaving this bundle intact makes the antisecretory operation less complete, but fully severing it may lead to disturbances in gastric emptying. Two approaches for defining the distal margin of the dissection have been advocated. First, one may arbitrarily begin the dissection at a predetermined point 6–7 cm proximal to the pylorus, a distance that usually corresponds to the most proximal of the three branches of the crow's foot. Alternatively, one may identify this most proximal branch and begin the dissection there. It is helpful to begin the dissection a few centimeters proximal to the agreed-upon distal margin, because strong traction during subsequent parts of the operation may cause traction injury on the antral motor branches and vessels that accompany them. These last few centimeters are dealt with last.

The assistant provides downward and leftward traction on the greater curvature, thus placing tension on the anterior nerve of Latarjet as it runs along the lesser curvature. The hepatic fibers usually are visualized without difficulty in the upper part of the lesser omentum. It is helpful to "score" the serosa of the lesser curvature, from the incisura to the cardia, and then transversely across the gastroesophageal junction. The incision is performed with dissecting scissors or a no. 15 knife, not electrocautery. This maneuver widens the gap between the nerve and the gastric wall. Individual vessels run transversely from the lesser omentum onto the lesser curvature. These structures are ligated in continuity with 3-0 silk ligatures before division. (We avoid the use of hemostats in this dissection.) This part of the operation is performed gently and should not cause blood loss. The dissection proceeds along the lesser curvature until the gastroesophageal junction is reached. The left anterior aspect of the esophagus is now uncovered, and, for the moment, the dissection stops. Care should be taken not to continue up the right side to avoid interrupting the main anterior vagus.

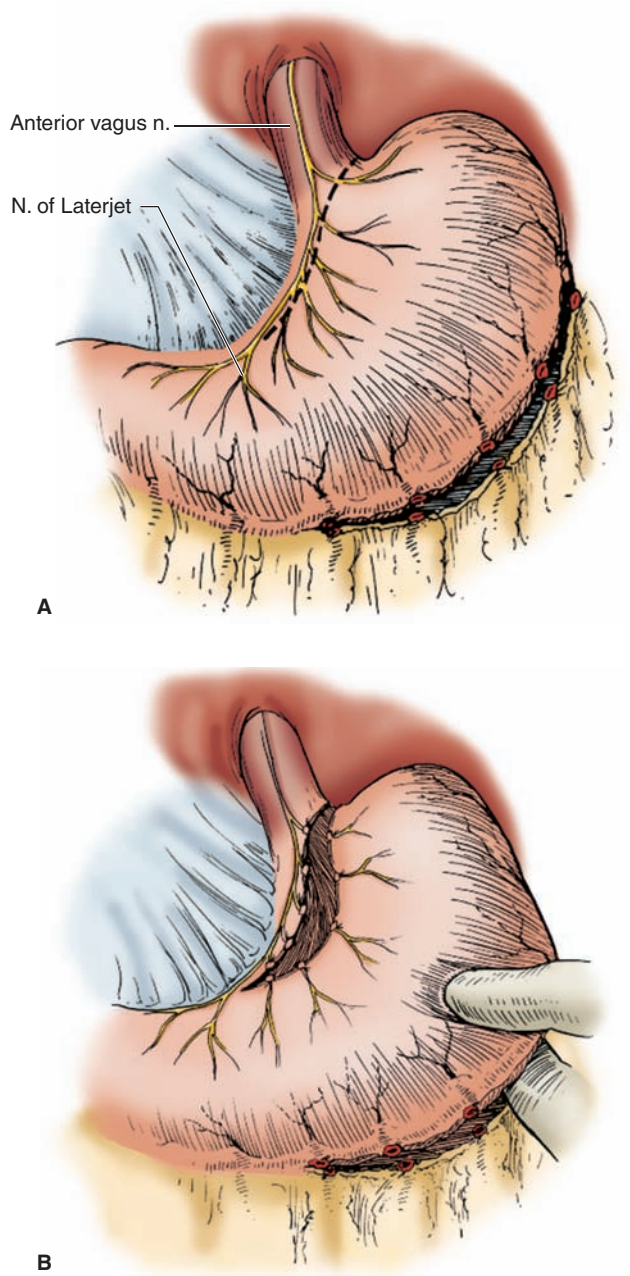

FIGURE 26-6 Highly selective vagotomy. **A.** Planned line of dissection of the anterior leaf of the gastrohepatic ligament. **B.** The dissection is carried out, beginning just proximal to the crow's foot and extending upward, to the left of the gastroesophageal junction. (Redrawn, with permission, from Zinner MJ. *Atlas of Gastric Surgery*. New York, NY: Churchill Livingstone; 1992. After Gloege.)

Dissection of the Posterior Leaf of the Lesser Omentum. The posterior leaf of the lesser omentum then is dissected. Care should be taken in setting up exposure for this part of the operation. In one approach, the stomach is rotated upward and to the patient's right. Alternatively, the posterior leaf can be reached by working through the anterior leaf as illustrated in Fig. 26-7. Using the thumbs and fingers, the gastroesophageal junction is "rolled" counter clockwise so that the posterior wall moves to the right and the anterior wall moves to the left. The nerve branches and their accompanying vessels then are ligated in continuity and divided. The dissection should not be carried to less than 6 cm from the pylorus. To avoid the main left gastric vessels, this approach to the dissection should be carried about two-thirds of the distance along the lesser curvature. After reaching the left gastric vessels, the surgeon returns to the anterior approach, ligating and dividing the remainder of the posterior leaf through the window in the anterior leaf.

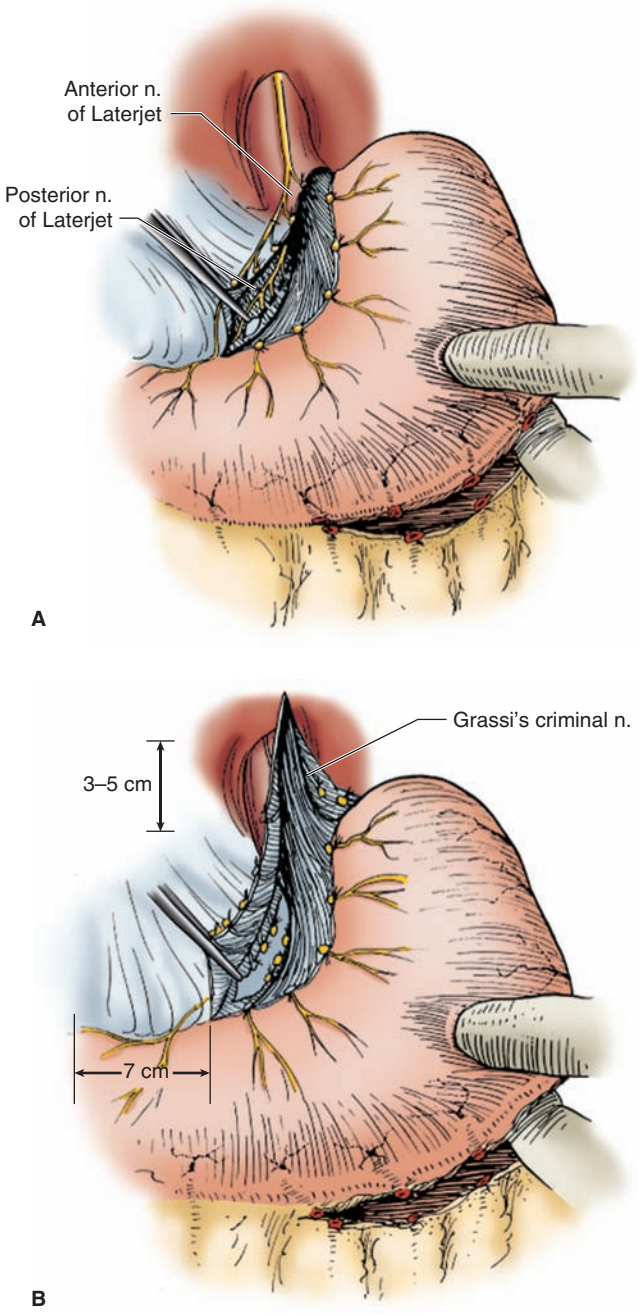

FIGURE 26-7 Parietal cell vagotomy. **A.** The line of dissection of the posterior leaf of the gastrohepatic ligament is illustrated. **B.** The dissection is carried out through the window created by prior dissection of the anterior leaf. (Redrawn, with permission, from Zinner MJ. *Atlas of Gastric Surgery.* New York, NY: Churchill Livingstone; 1992. After R.N. Lane.)

Dissection of the Distal Esophagus. The goal of this dissection is to clear the distal esophagus of all nerve fibers for a distance of approximately 5 cm above the gastroesophageal junction. The importance of this part of the dissection is well documented.[27] It should be noted that the prior dissection of the lesser omentum has allowed the main vagal trunks to move upward and to the patient's right, thereby minimizing the risk of damaging the main trunks in this part of the dissection. The operative technique requires that this dissection stay close to the lesser curvature and esophagus. Any dissection toward the tissues to the right (ie, toward the main vagal trunks) should be avoided.

This part of the procedure begins with the dissection of the left side of the esophagus (Fig. 26-8). Denuding the surface can be performed gently, using a finger or "peanut" dissector to isolate the adventitia that contains nerves, vessels,

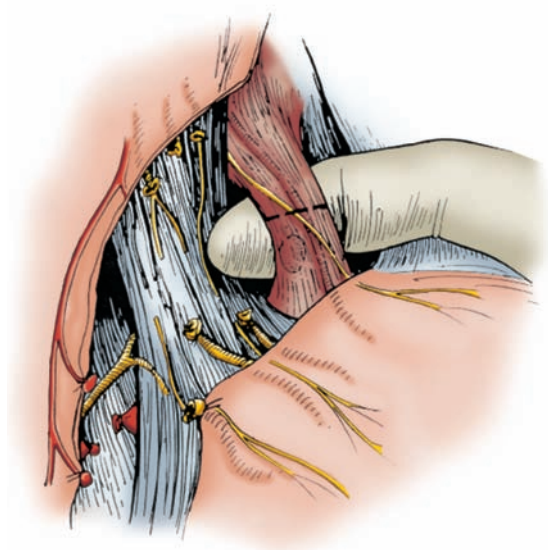

FIGURE 26-8 The serosa has been cut to the left of the esophagus, and fatty areolar tissue to the left of the esophagus, containing nerve fibers, blood vessels, and lymphatics, is hooked up by the right index finger. The angle of His and the adjacent esophagus with a 2- to 3-cm portion of the fundus of the stomach are thoroughly cleaned. In this way, small nerve fibers running to the proximal 3-cm portion of fundus ("criminal nerves of Grassi") are eliminated. (Redrawn, with permission, from Johnston D. Vagotomy. In: Schwartz SI, Ellis H, eds. *Maingot's Abdominal Operations.* Norwalk, CT: Appleton-Century-Crofts; 1985. After R.N. Lane.)

and lymphatics. This dissection is where the "criminal nerve" of Grassi is likely to be encountered. Tissues are ligated in continuity and divided. This dissection should also clear 2 or 3 cm of the cardia, just distal to the gastroesophageal junction, and small fibers running to the greater curvature will be divided here. It is usually not necessary to divide any of the short gastric arteries.

The anterior aspect of the esophagus is now cleared of vagal fibers (Fig. 26-9). Gentle traction and lifting of the fibers will isolate them for division between ligatures or by cautery. We prefer ligation in continuity with fine (4-0 or 5-0) silk to avoid injury to the esophageal muscle. The posterior aspect is now reexposed with downward traction of the gastroesophageal junction and a counter clockwise rotation of the distal esophagus. Working through the window of the anterior leaflet, the upward branches of the left gastric artery are visualized as they pass to the cardia and the gastroesophageal junction. They are ligated in continuity and divided. The dissection continues upward along the cardia and gastroesophageal junction, until it is possible to encircle the lower esophagus with a Penrose drain. Downward traction on the gastroesophageal junction is provided by this drain, and additional nerve fibers are seen in the adventitia. Smaller fibers are cauterized while held away from the esophageal muscularis, whereas larger ones are ligated with clips or fine silk and divided. Throughout this dissection, the positions of the nerves of Latarjet and the main trunks should be checked.

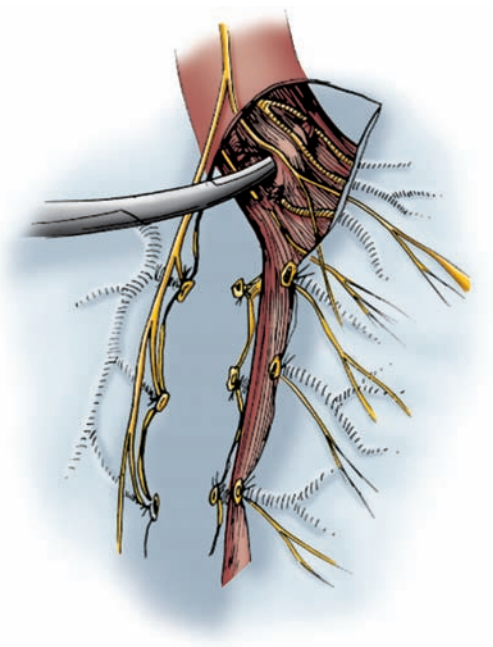

FIGURE 26-9 Anterior gastric branches of the anterior vagal trunk running downward on the anterior surface of the esophagus are gently lifted with a hemostat and either ligated or clipped before being divided or destroyed with diathermy. (Redrawn, with permission, from Johnston D. Vagotomy. In: Schwartz SI, Ellis H, eds. *Maingot's Abdominal Operations.* 8th ed. Norwalk, CT: Appleton-Century-Crofts; 1985. After R.N. Lane.)

The final part of the operation involves completion of the distal dissection to the crow's foot and checks for hemostasis. A number of authors have in the past suggested that reperitonealization of the lesser curvature be performed. Although we do not routinely do this, the rationale for this maneuver is that the devascularization that is part of HSV may lead to small areas of necrosis of the gastric wall and localized perforations. Such leaks have been reported in about 0.2% of patients.[28,29] Also, it has been argued that reperitonealization might impede reestablishment of vagal nerve connections to the gastric wall.[30] The reperitonealization would thus protect against such leaks. The reperitonealization can be performed by inversion of the serosa of the lesser curvature with running or continuous 3-0 long-acting absorbable suture. Alternatively, a vascularized pedicle of omentum can be used to cover the deserosalized lesser curvature. Bleeding complications have been reported with this latter method, but it minimizes tension within the gastric wall.

REOPERATIVE APPROACHES TO THE VAGUS NERVES

Approximately two-thirds of patients with duodenal or pyloric channel ulcer recurrence after an initial antisecretory operation (TV, SV, or HSV) have evidence of persistent (or possibly reestablished) vagal innervation.[9,31,32] Although many such recurrences are amenable to medical regimens, a small fraction ultimately may be considered for reoperation, especially if surgery is required to control an acute complication such as bleeding or perforation following a period of ulcer-related symptoms. Prior surgery will have made the standard approaches to the lesser curvature and gastroesophageal junction hazardous, which is often caused by dense adhesions to a previously mobilized left lobe of the liver. Thus, two approaches to the vagus, both nonselective, may be considered for completion of the failed vagotomy, especially if it was performed in conjunction with antrectomy. It should be stressed that when such a reoperation is contemplated, especially in a nonemergent setting, it is prudent to obtain some form of acid secretion profile to document the hypersecretory state. Also, because of the nonselective nature of the completion vagotomy, an antrectomy or drainage procedure must be performed.

In the setting in which standard access is difficult due to prior surgery, Barroso and associates have utilized a transabdominal suprahepatic approach to the vagi.[33] A high midline incision is used, with mechanical retraction to elevate the subcostal margin. An 18F NG tube is placed. The triangular, left coronary, and falciform ligaments and adhesions are divided, permitting downward retraction of the left lobe. Using the NG tube, the esophagus and hiatus are located. The esophagus and vagi are dissected at the level of the diaphragm at the hiatus and incised anteriorly for a distance of 3–5 cm, exposing the esophagus at the lower mediastinum. The trunks are easily identified and ligated in the untouched lower thoracic esophagus. The hiatus is closed with interrupted nonabsorbable sutures.

A transthoracic approach to this region has also been used,[34] and with the advent of thoracoscopy it may become increasingly attractive for this limited set of patients. Specific issues in anesthesia for this approach have been reviewed.[35] The operation is performed through the left chest, entered via the eighth intercostal space. An NG tube is positioned with its tip in the stomach. After division of the inferior pulmonary ligament, the base of the left lung is retracted upward and laterally. The mediastinal pleura overlying the esophagus is incised for a distance of 8 cm. The esophagus is then mobilized and encircled with a Penrose drain. Vessel loops are used to retract individual vagal trunks as they are identified. The supradiaphragmatic anterior vagus nerve may have multiple branches above the level of the diaphragm, but rarely are there multiple branches at a level 4 cm above the diaphragm.[30] In contrast, the posterior vagus has multiple branches above the level of the diaphragm, but is a single trunk at this level more than 90% of the time (Fig. 26-10). Thus, the best opportunity for a complete vagotomy lies 4 cm above the diaphragm for the posterior trunk. A circumferential dissection of the 6 cm of esophagus just above the diaphragm is carried out, with technique similar to that performed during the HSV. Tube thoracostomy is required for 2–3 days postoperatively.

DRAINAGE PROCEDURES

In the context of bilateral truncal or selective vagotomies, the purpose of a drainage procedure is to preserve the pylorus but bypass or render it ineffective. The options for drainage include (1) gastroenterostomy; (2) pyloric dilation; (3) pyloromyotomy; and (4) pyloroplasty. Generally, these techniques are used when TV or SV is performed, but they also may be used with HSV in order to treat obstruction resulting from peptic acid scarring. We discuss techniques for performing gastrojejunostomy in the subsequent discussion of gastric resection.

Pyloric Dilation

In open procedures, the simplest technique reported for performing pyloric dilation is to perform a small gastrotomy, approximately 3–4 cm in length, proximal to the pylorus. A finger is introduced through the pylorus, forcing it to widen. The gastrotomy then is used with a single layer of 3-0 silk interrupted sutures or staples. A second technique, advocated for use in laparoscopic cases, is to use a balloon. The balloon, 15 mm in length, may be positioned through a gastrotomy, endoscopically, or with radiologic control, and inflated to 45 psi (pounds per square inch) for 10 minutes.[25,36,37] Other dilators are available for positioning over a wire and inflation to higher pressures, which may prevent pyloric spasm. Advocates of pyloric dilation after laparoscopic TV or SV have suggested that a drainage procedure is not required as often as previously thought or may only be necessary in the early postoperative phase and not permanently.[25,36–38] Thus, it is argued that dilation can be repeated postoperatively and in the outpatient setting. Most surgeons, however, subscribe to the need for some form of formal drainage procedure after SV or TV.

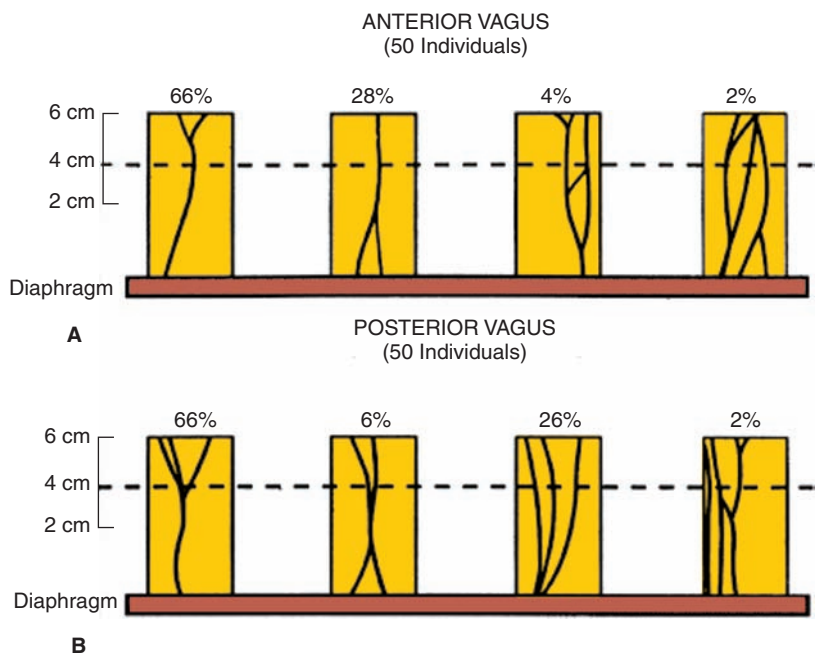

FIGURE 26-10 Anatomy of the anterior **(A)** and posterior **(B)** vagus nerves above the diaphragm in 50 cadavers. Incidence of each anatomic group is indicated by percentage. (Redrawn, with permission, from Jackson RG. Anatomy of the vagus nerve in the region of the lower esophagus and stomach. *Anat Rec*. 1949;103:1.)

Pyloromyotomy

Pyloromyotomy is performed using the same techniques as those described in the setting of hypertrophic pyloric stenosis in the infant (Fig. 26-11). An incision is made to score the anterior surface of the stomach from 1 to 2 cm proximal to 1 cm distal to the pyloric ring. The separation of pyloric muscles is accomplished mainly with a fine-tip hemostat and the knife. Cautery is avoided and only used in the muscularis, not the submucosa. When this procedure is performed in the setting of esophagogastrectomy, the pylorus is usually soft and unscarred. In the setting of chronic duodenal ulcer disease, the pylorus is often scarred, and it is difficult to perform the gentle, meticulous dissection of muscle layers, which is required, and at the same time to avoid entering the mucosa. Laparoscopic versions of this procedure also have been advocated in the setting of laparoscopic TV or SV.[39] Occasionally omentum is placed over the myotomy.

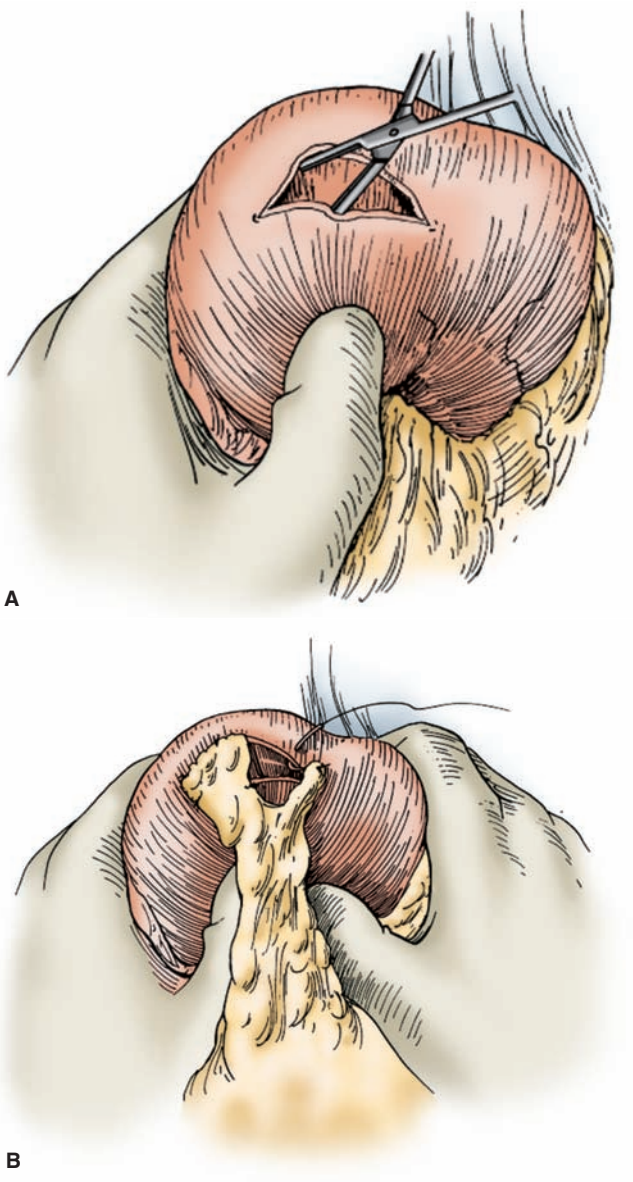

FIGURE 26-11 Pyloromyotomy. **A.** Dissection of seromuscular layers, avoiding entry into bowel. **B.** An omental patch is used to cover the dissected area. (Redrawn, with permission, from Welch CE. *Surgery of the Stomach and Duodenum.* Chicago, IL: Year Book Medical; 1973.)

Pyloroplasty

The most expeditiously performed pyloroplasty is the Heineke-Mikulicz procedure (Fig. 26-12).[40] This is difficult to perform if the pyloric region is very scarred. The operation usually is performed in the setting of emergency surgery for bleeding or perforation of a gastric or duodenal ulcer. A vagotomy is performed, usually after bleeding has been controlled. If the indication is a bleeding or perforated duodenal or pyloric channel ulcer, the incision for pyloroplasty may include the ulcer or be used to gain access to the ulcer. The incision is thus the planned pyloroplasty incision.

It is not always necessary to perform a Kocher maneuver; however, duodenal mobilization is usually helpful in relieving any tension on the intended suture line. Unless the duodenal bulb is unusually mobile, we recommend this as the initial step. In this maneuver, the peritoneum along the right border of the duodenum is incised from the lateral border of the common bile duct to the junction of the second and third portions of the duodenum. After duodenal mobilization, 3-0 silk stay sutures are placed untied, superior and inferior to the site of the intended incision, which then is made on the anterior surface in a longitudinal direction, using electrocautery, from 2 cm distal to the pyloric muscle to 3 cm proximal to the pylorus. The closure of the pyloroplasty is performed vertically, in order to minimize narrowing of the lumen. The Gambee stitch (see Fig. 26-12) is a single-layer inverting suture used in this setting. The suture, usually performed with 3-0 or 2-0 silk, begins on the outside and is (1) placed full thickness (serosa to mucosa) on the same side; (2) brought, on the same side, back through the mucosa to the submucosa; (3) carried through the submucosa to the mucosa on the opposite side; and (4) brought full thickness from mucosa to serosa on that side. When the pylorus is scarred and the tissues inflexible, it is often helpful to tie the sutures after they have been placed, rather than as they are being placed. The stay sutures then are removed, after completion of the pyloroplasty. A tongue of vascularized omentum (as shown for pyloromyotomy in Fig. 26-11) may be brought up to cover the closure and it is sutured to the gut wall with 3-0 absorbable (polyglactin 910) sutures.

The Finney pyloroplasty[1] can be used when scarring has involved the pylorus and duodenal bulb and would not permit a tension-free, patulous Heineke-Mikulicz pyloroplasty. The Finney pyloroplasty is in essence a side-to-side gastroduodenostomy (Fig. 26-13). When this operation begins, dense adhesions often are encountered surrounding the pylorus and duodenal bulb. These must be lysed systematically. The Kocher maneuver then is performed, carrying the

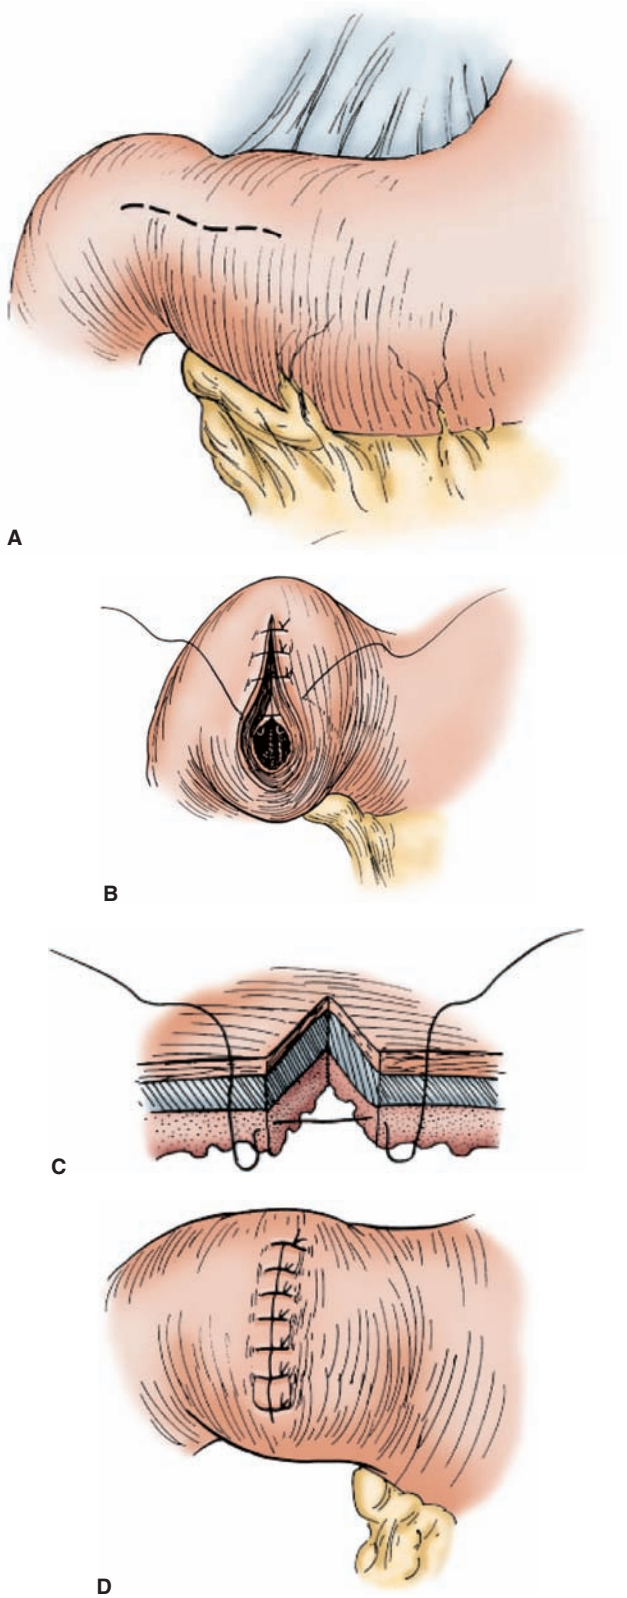

FIGURE 26-12 Heinecke-Mikulicz pyloroplasty. **A.** Full-thickness incision extends from 2 cm proximal to 1–2 cm distal to the pyloric ring. **B.** The incision is closed vertically. **C.** Illustration of Gambee stitch. **D.** Finished pyloroplasty. mobilization distally. Complete mobility of the duodenum and freedom from surrounding adhesions are essential to this operation.

A 2-0 silk stay suture is placed on the upper anterior surface of the pyloric ring. Another stay suture is placed on the greater curvature of the stomach approximately 10 cm proximal to the pylorus, and a third stay suture is placed approximately 10 cm distal to the pylorus. Traction cranially on the pyloric suture and caudally on the other two sutures brings the anterior surfaces on the stomach and duodenum into apposition. The apposed surfaces are sutured together using interrupted 3-0 silk Lembert seromuscular sutures. Using electrocautery, an inverted U-shaped incision is made beginning on the gastric side just distal to the traction suture, traveling longitudinally through the pylorus, then distally to a point just proximal to the traction suture. If the ulcer is present on the anterior surface of the duodenal bulb, it is excised. The posterior inner layer between the stomach and the duodenum then is sutured closed with a continuous over-and-over 3-0 Vicryl, chromic catgut suture, or DDS. This closure is begun at the superior edge, carried caudally, and then converted into a Connell inverting technique as the suture is brought around the inferior edge to begin closing the anterior portion of the inner layer. The anterior outer layer then is closed using interrupted 3-0 seromuscular inverting sutures (Lembert) sutures. Some surgeons use 3-0 Maxon or PDS suture material for single-layer continuous closure, as additional insurance against a suture line leak.

GASTRIC RESECTIONS

The common indications for gastric resections include peptic ulcer disease and tumors of the stomach. Safe performance of gastric resection requires an understanding of the following: (1) the physiology of vagal innervation and gastric emptying; (2) the surface and vascular anatomy of the stomach; (3) the principles of reconstruction following resection, specifically the Billroth I (B-I) gastroduodenostomy, the Billroth II (B-II) gastrojejunostomy, and the Roux-en-Y configuration; (4) the principles of surgical stapling techniques as well as hand-sewn suturing techniques; and (5) the specific early and late postoperative complications that arise from different gastric resections and different forms of reconstruction. Degrees of resection are correlated to the surface anatomy, as shown in Fig. 26-14. This discussion is divided into three sections. The first section describes techniques for performing wedge resections and closure of gastric wall for ulcers, polyps, or tumors derived from neuroendocrine elements or stromal tissue. Carcinomas are not amenable to wedge resection and should be removed, for cure or palliation, by formal regional resection. The second section describes techniques for distal gastric resection, focusing on antrectomy or hemigastrectomy (with or without vagotomy) for peptic ulcer disease and when the major decision involves the choice of B-I or B-II reconstruction. The third section describes techniques used

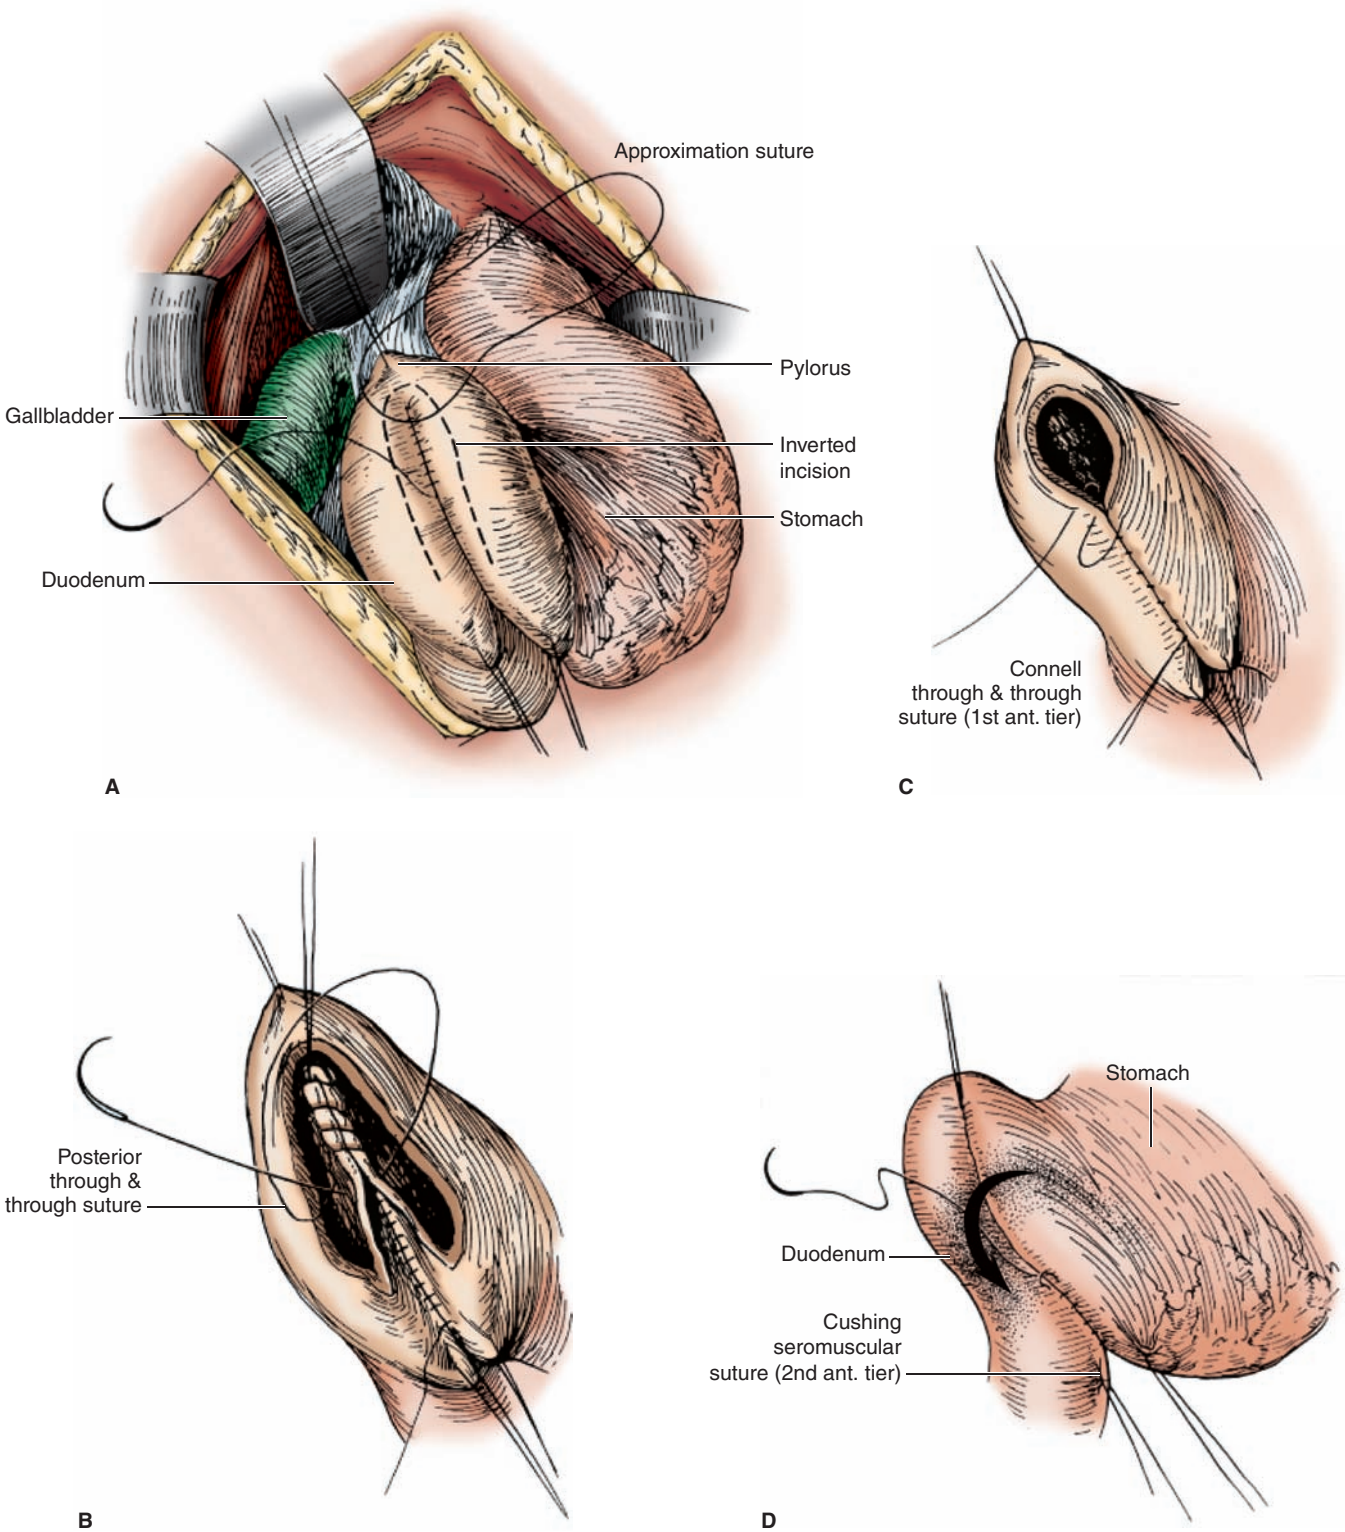

FIGURE 26-13 Finney U-shaped pyloroplasty. **A.** The distal stomach and proximal duodenum are aligned with traction strands and their adjacent walls approximated with a Cushing suture; the inverted U-shaped incision into the lumens of the stomach and duodenum is indicated. **B.** Suture of the posterior septum of the stomach and duodenum. **C.** The first anterior tier of sutures (Connell) is placed. **D.** The operation is completed with a reinforcing tier of Cushing sutures. FIGURE 26-14 Amount of stomach removed in antrectomy or hemigastrectomy: 60–75% for partial gastrectomy and 80% or over for subtotal gastrectomy. Note that most of the lesser curvature of the stomach is excised in all these resections.

in management of gastric carcinoma, focusing on proximal, subtotal, or total resection, and the techniques of regional node dissection.

Wedge Resection of the Stomach

Exposure is gained through an upper midline incision, carried from the xiphoid to the umbilicus. A Bookwalter or other self-retaining mechanical retractor is highly desirable, especially for lesions located on the lesser curvature or the proximal stomach. The technique of wedge resection depends on the location of the lesion. When a gastric tumor, such as a carcinoid or gastrointestinal stromal tumor (GIST), is located on the greater curvature of the stomach, it is important to note the proximity to the pylorus or gastroesophageal junction. Wedge resection may not be possible if the lesion lies too close (within 2 cm) to these borders, because the closure might narrow the lumen and cause partial obstruction to the flow of chyme. Formal resection may then be necessary. If proximity to these borders is not a problem, omental adhesions to the tumor are left in contact with the lesion. Farther away from the tumor, the portion of the omentum that is adherent is divided between clamps and will come with the specimen. Branches of the gastroepiploic arteries that supply the gastric wall adjacent to the tumor are ligated in continuity with 3-0 silk ligatures and divided. The gastroepiploic artery need not be divided, unless it is adherent to the surface of the tumor. At a distance of 2 cm from the base of the tumor, the serosa of the gastric wall is scored using cautery, inscribing a circle. The cautery then is used to deepen the incision through the muscularis. As the muscularis is divided, submucosal bleeders will pop through, requiring precise cauterization to secure hemostasis. When the tumor and the surrounding gastric wall have been excised, the gastrotomy is closed longitudinally in two layers. The inner layer is a full-thickness hemostatic layer sewn continuously using 3-0 chromic or Vicryl suture and the outer layer used interrupted seromuscular 3-0 silk Lembert sutures. An omental patch is not necessary, unless there are specific concerns about the blood supply to the closure. When situated favorably, such lesions are also amenable to laparoscopic resection[41–43] and to combined endoscopic-laparoscopic approaches involving intraluminal resections.[44,45] As long as the lumen is not compromised, stapled or open excision is possible.

When tumors are located on the lesser curvature, or it is necessary to perform a gastrotomy in order to stop ongoing bleeding from a gastric ulcer, the excision can be performed from the mucosal side of the lesion (Fig. 26-15). Once the inside borders of the lesion have been identified, it is important to obtain optimal exposure of the lesion from the serosal aspect. It may be necessary to sacrifice one or both nerves of Latarjet or the

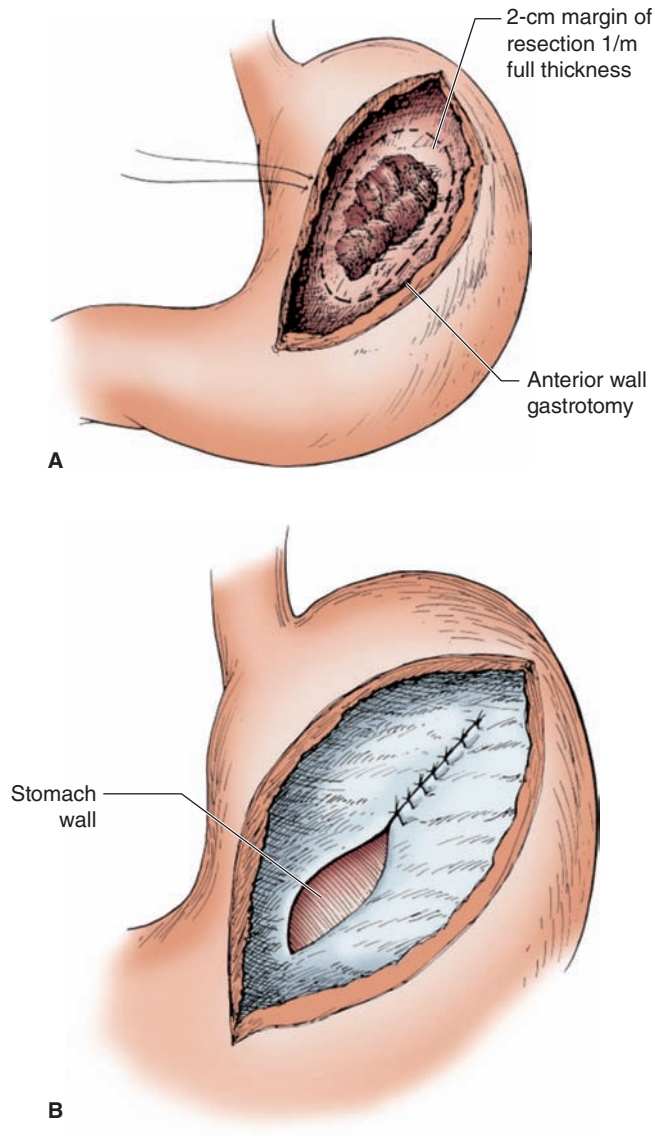

FIGURE 26-15 Small tumors or polyps not amenable to endoscopic polypectomy can be excised with surrounding wedge of normal gastric wall. **A.** A 2-cm margin is advisable. **B.** The gastrotomy can be closed in one or two layers, using 2-0 nonabsorbable sutures sewn in interrupted fashion.

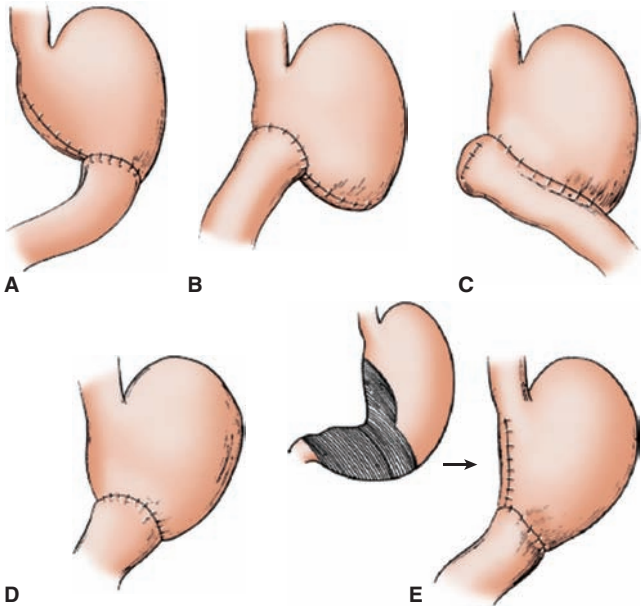

FIGURE 26-16 Billroth I operations. **A.** Billroth I. **B.** Horsley. **C.** von Haberer-Finney. **D.** von Haberer. **E.** Shoemaker.

left or right gastric arteries, and this determination can only be made from the outside of the stomach. A stapled option also exists if the lesion can be excised without narrowing the lumen. If the lesion is located on the lesser curvature and cannot be removed without sacrifice of both nerves of Latarjet, a pyloroplasty should be performed. In such cases, our preference is that the resection is extended to include the distal stomach and a B-I or B-II reconstruction (Fig. 26-16). One variation on this latter approach for high-lying bleeding or perforated gastric ulcers is Pauchet's operation, a modification of an operation described by Shoemaker. This procedure involves removal of the antrum and a tongue of the corpus that extends upward to include the ulcer (Fig. 26-16E).[46]

Distal Gastric Resections and Reconstruction

VAGOTOMY AND ANTRECTOMY

An antrectomy for duodenal or pyloric channel ulcer removes about 35% of the distal stomach and must include the entire non–acid-secreting portion. The incision is made in the upper midline and a Bookwalter or other self-retaining mechanical retractor is helpful. An NG tube is positioned under the surgeon's guidance, with its tip in the midportion of the stomach. TV is performed first, as described earlier. The incisura is a reasonable landmark for the proximal margin of resection on the lesser curvature, while the terminal portions of the right gastroepiploic artery indicate the margin on the greater curvature.

The distal stomach is mobilized in the following fashion: first, the lesser sac is entered by incising the gastrocolic ligament. These attachments are sometimes avascular but usually are divided between clamps and ligated with 3-0 silk ligatures. The stomach may thus be lifted upward, revealing the posterior gastric wall. Congenital adhesions from the posterior wall and pancreas capsule are divided sharply. The dissection is carried distally along the greater curvature (Fig. 26-17), dividing the small branches of the gastroepiploic artery to the gastric wall. The dissection reaches the main right gastroepiploic artery, which sometimes has to be divided between Kelly clamps and ligated with 2-0 silk ligatures. When possible, the dissection should be carried between the gastric wall and artery, thereby preserving the main gastroepiploic artery as additional collateral blood supply to the suture lines and coming anastomosis. When the dissection reaches the pylorus, small bleeders should be divided between fine hemostats and ligated with fine silk ligatures. The dissection should be meticulous and gentle, because pancreatic tissue lurks in this area and inflammation can be activated in this dissection. The dissection should be carried about 1 cm past the pylorus if a B-I reconstruction is anticipated. If B-II is anticipated, the dissection need only be carried far enough to comfortably place the transverse linear stapler past the pylorus or to oversew the duodenum by a hand-sewn technique.

The assistant's left hand is used to lift the distal stomach forward and inferiorly. The more flimsy tissues of the lesser omentum are divided along the lesser curvature, using electrocautery. Starting at the incisura and working toward the pylorus, the tissues of substance are divided between clamps and ligated with 3-0 silk ligatures. This dissection generally will include the descending branch of the left gastric artery. When the right gastric artery is reached, it is divided and ligated with 2-0 silk ligatures. At this point (Fig. 26-18), we prefer to divide the stomach. This is accomplished with a 90-mm GIA stapler or the gastric TA-90. If the latter stapler is used, the stomach distal to the staple line is occluded with a crushing intestinal clamp and the gastric wall is divided. The clamp is then used as a handle for manipulating the distal stomach. The final portion of the dissection involves gentle dissection of the posterior duodenal wall from the pancreas. Because this dissection may involve separation of pancreas elements from the posterior duodenal wall, cautery is used minimally or not at all and tissues are separated gently with fine hemostats and ligated with 4-0 silk. If a B-I anastomosis is anticipated, the duodenum is divided using the electrocautery, just distal to the pyloric ring. If a B-II anastomosis is anticipated, the transverse TA-30 stapler is placed flush with the pyloric ring. After firing the stapler, a knife is used to sever the pylorus from the staple line. The specimen then is removed to a sterile table. The staple line can be inverted with 3-0 silk Lambert sutures or covered with an omental patch, if there is a concern about vascular supply or tension in the staple line. The specimen then can be opened and turned inside out to reveal the gastric mucosa. The proximal border of the resection should contain transverse and obliquely oriented rugae characteristic of the acid-secreting gastric corpus and distinguishable from the longitudinally oriented antral folds. This maneuver verifies complete removal of the antrum.

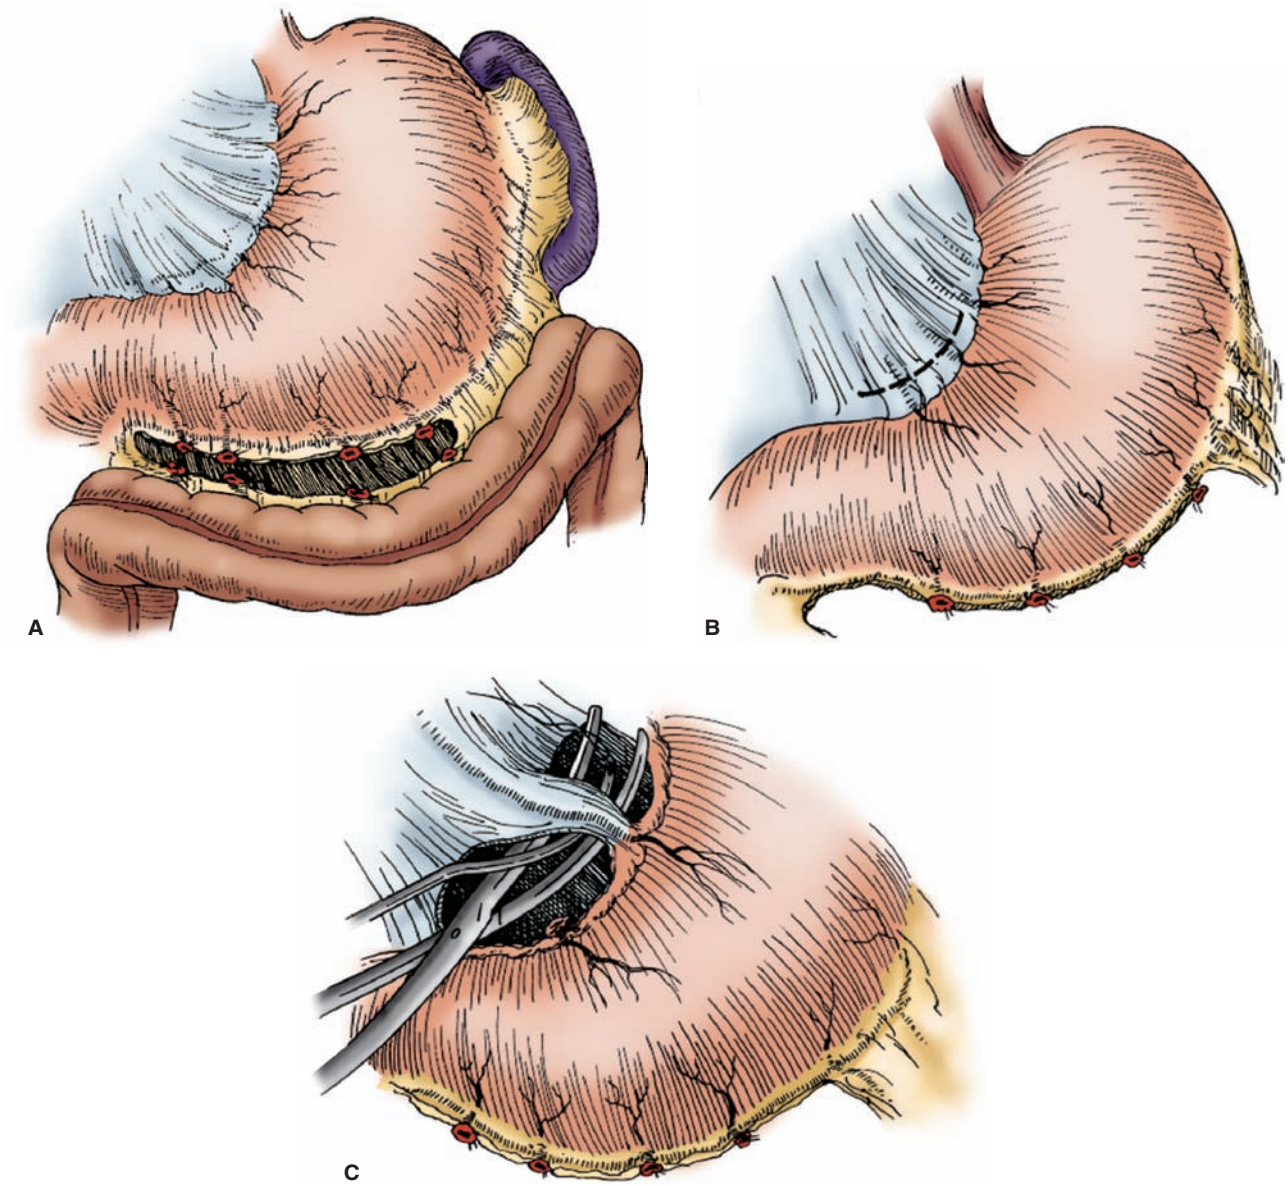

FIGURE 26-17 Billroth I operation. **A.** Use of the ligate-divide-stapler, LDS II. This instrument, employing a disposable cassette, applies two stainless steel clips and cuts between, thus reducing operating time and effort significantly. **B.** Extent of dissection of lesser curvature. **C.** Division of vessels entering the lesser curvature in much the same way as when performing proximal gastric vagotomy.

Billroth-I Reconstruction. When distal gastrectomy is performed for type I gastric ulcer, B-I anastomosis is preferable. A B-I anastomosis can be used safely for duodenal or pyloric channel ulcer, if scarring of the duodenal bulb and pylorus are minimal. If this form of reconstruction is planned, a Kocher maneuver should be performed prior to distal gastrectomy. This will help to minimize tension on the anastomosis. As shown in Fig. 26-19, the lower portion of the gastric staple line is removed by excision of gastric wall just posterior to the staple line. The length of the staple line to be removed is the width of the duodenal stump. The gastroduodenostomy is performed in two layers (Fig. 26-20). The posterior layer of interrupted 3-0 silk Lembert seromuscular sutures is placed first. The inner 3-0 Vicryl sutures are placed next to each other, sewn away from each other in an over-and-over fashion until the sutures are brought around the edges to the anterior aspect. Connell sutures are used to invert the inner anterior layer. The anterior outer layer is closed with interrupted 3-0 silk Lambert sutures. The junction of the sewn anastomosis and superior portion of the gastric staple line has been called the "angle of sorrow" because of the complication of leakage where these suture/staple lines meet. A number of authors recommend

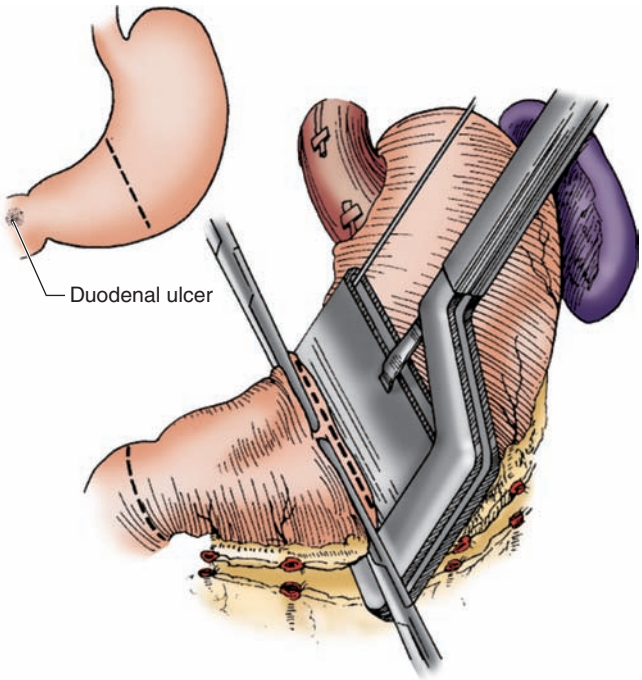

FIGURE 26-18 Billroth I operation. Division of stomach beyond the incisura. The gastric 90 stapler facilitates this maneuver. Note the truncal vagotomy has already been performed. (Redrawn, with permission, from Zinner MJ. *Atlas of Gastric Surgery.* New York, NY: Churchill Livingstone; 1992. After Gloege.)

inversion of the upper staple line by 3-0 silk Lembert sutures and a special covering suture for this junction. A second strategy is to cover this area with a tongue of omentum.

A B-I anastomosis also may be performed using mechanical stapling techniques. As shown in Fig. 26-21, the duodenum is transected just distal to the pylorus with the knife and a purse-string suture is positioned circumferentially around its edge. The anvil of the circular stapler, usually a size 25 mm, is secured in the duodenal stump by the purse string. The circular stapler is inserted through an anterior gastrotomy and fired through the posterior wall of the stomach (Fig. 26-22). It is important that the margin of the stapled suture line be placed 3 cm proximal to the stapled gastric closure, to provide maximum blood supply to both staple lines. The anterior gastrotomy then is closed with a TA-55 stapler or sutured closed in two layers.

Billroth-II Reconstruction. When scarring or undue tension precludes B-I anastomosis following distal gastrectomy, a B-II gastrojejunostomy is indicated. Before describing our technique, it is worth pointing out the decisions that one will make in performing this reconstruction.

Closure of the Duodenal Stump. The first set of decisions focus on the technique used for closure of the duodenal stump. Careful attention should be given to mobilizing the duodenal stump and obtaining a secure tension-free closure. If the duodenum is relatively free of scar or inflammation, this presents no problem and the TA-55 or TA-60 stapler may be used for closure as described previously. If heavily scarred, dissection of the duodenum and performance of the antrectomy may be abandoned in favor of a safer vagotomy and gastroenterostomy.

If one is committed to the antrectomy and scarring prevents mobilization of the pylorus and duodenal bulb, one may rarely find a need to perform a Bancroft procedure, in which the most distal portion of the pyloric channel and antrum are left in situ after resection of the more proximal antrum (Fig. 26-23). The mucosa of the retained segment is stripped,[47] removing all gastrin-secreting tissue that could

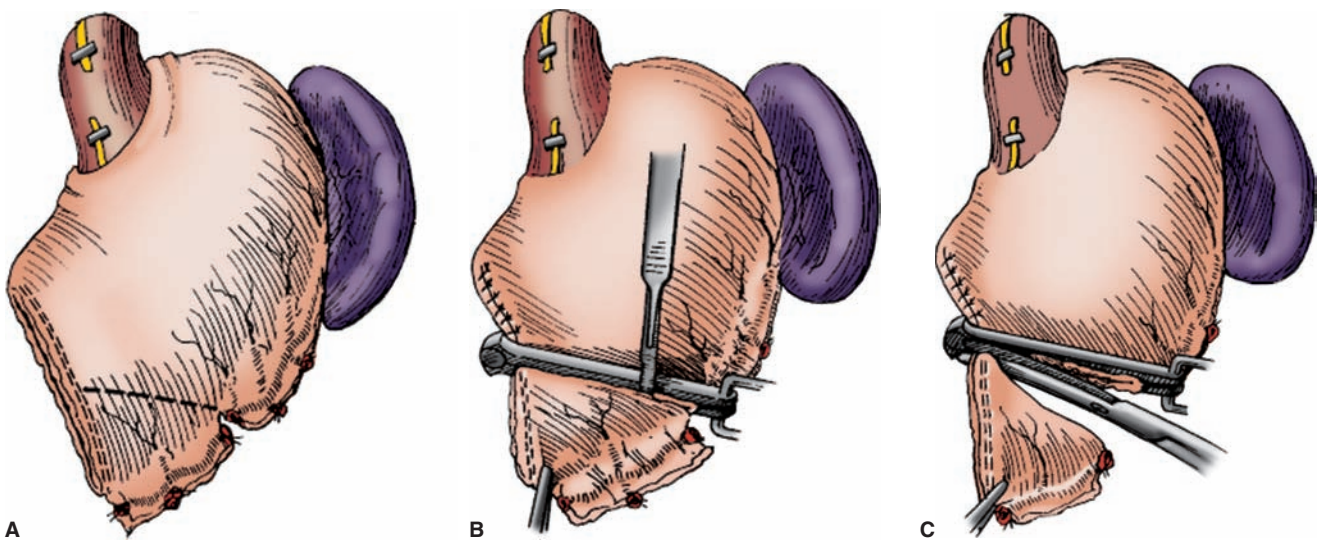

FIGURE 26-19 Billroth I operation. Division of the lower portion of the suture line. (Redrawn, with permission, from Zinner MJ. *Atlas of Gastric Surgery.* New York, NY: Churchill Livingstone; 1992. After Gloege.)

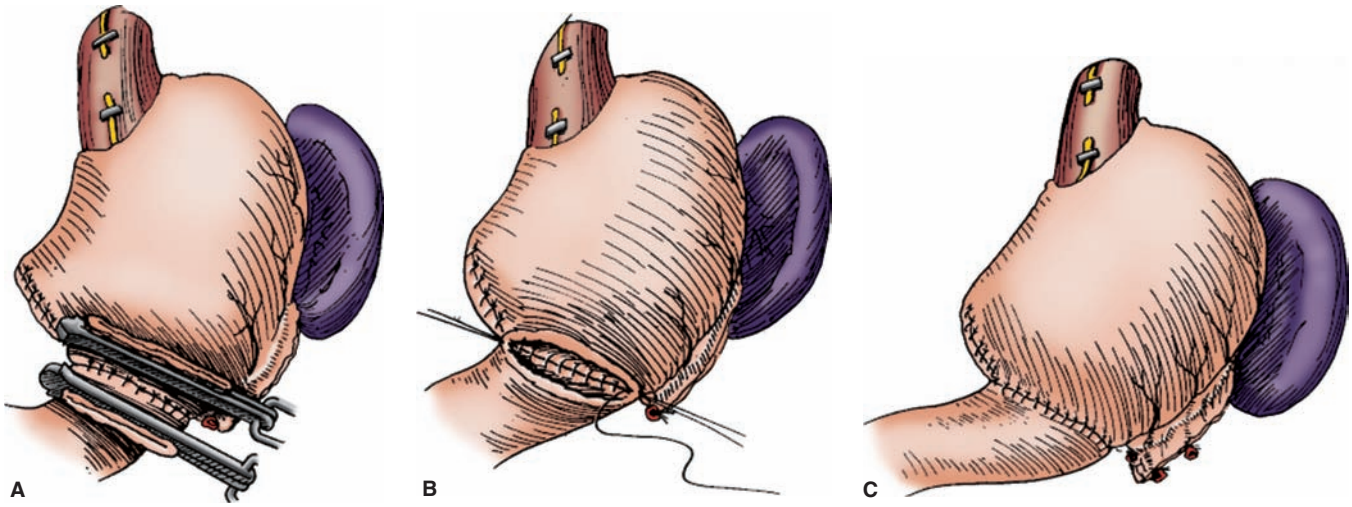

FIGURE 26-20 Billroth I operation. The construction of the gastroduodenostomy is performed end to end in two layers. (Redrawn, with permission, from Zinner MJ. *Atlas of Gastric Surgery.* New York, NY: Churchill Livingstone; 1992. After Gloege.)

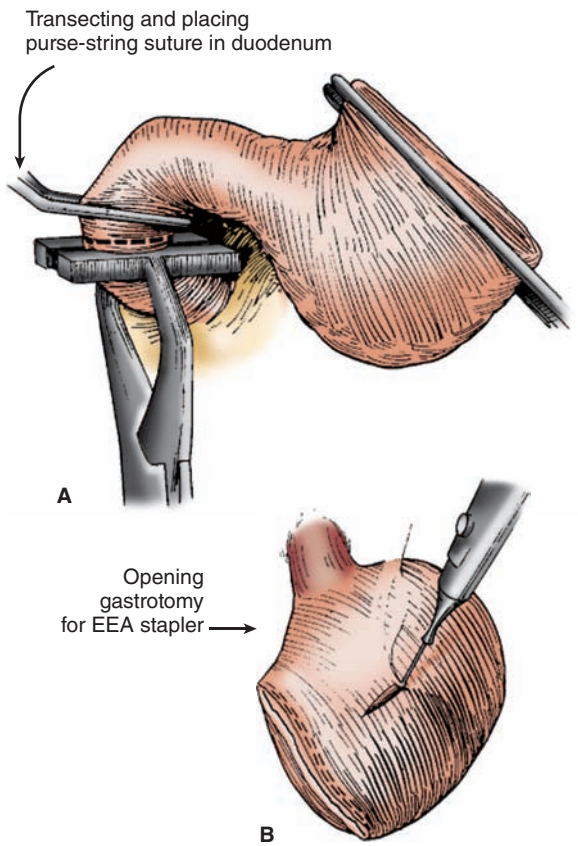

FIGURE 26-21 **A.** A Dennis clamp can be placed across the proximal duodenum, and the purse-string device can be placed at the selected site of duodenal division. **B.** A gastrotomy is made with the cautery on the anterior surface of the stomach, carefully avoiding large vascular arcades. This should be done at least 3 cm proximal to the row of staples. The gastrotomy should be large enough to accommodate the end-to-end stapling device easily. (Redrawn, with permission, from Siegler HF. Gastric resection: Billroth I. In: Sabiston DC, Jr, ed. *Atlas of General Surgery.* Philadelphia, PA: WB Saunders; 1994. After R. Gordon.)

cause a retained antrum syndrome. In the classic approach for this procedure, the greater and lesser curvatures are mobilized without dissecting too far into the tissues surrounding the pylorus. About 7–8 cm from the pylorus, the seromuscular coat of the antrum is incised circumferentially down to the level of the submucosa. Using sharp dissection, the muscle coat is separated from underlying mucosa. This dissection can be facilitated by submucosal injection of 1:100,000 epinephrine solution, as has been described for the mucosal proctectomy in ileal pouch–anal anastomosis procedures.[48] When the pyloric channel opening is reached, a fine purse-string absorbable suture (3-0 chromic catgut or Vicryl) picks up small bites of submucosa at the pyloric ring. Transfixion and ligation of the mucosa is tempting, but it should be avoided as this would lead to mucosal ischemia and subsequent perforation. A small margin of mucosa is left to be invaginated into the pylorus as the purse string is gently closed and tied. The proximal margins of the seromuscular cuff are excised, leaving just enough to close over the purse string. Omentum is used to cover this closure, if possible.

One other important circumstance to be prepared for is the closure of the duodenum distal to a posteriorly perforated or deeply penetrating ulcer. In this setting, the ulcer crater is left in situ (Fig. 26-24). In other settings, the anterior wall of the duodenum can be sutured to the ulcer base, with care being taken to suture-ligate any exposed vessels. The suture line can be protected by a vascularized tongue of omentum.

Position of the Jejunal Loop: Antecolic or Retrocolic. The second decision in performing a B-II reconstruction is whether to bring the loop of jejunum behind (retro) or in front of (ante) the transverse colon. In performing the gastrectomy for benign disease, there is no clear evidence that this makes any difference and we prefer the retrocolic position. For malignant disease, it has generally been held that the retrocolic position may be predisposed to

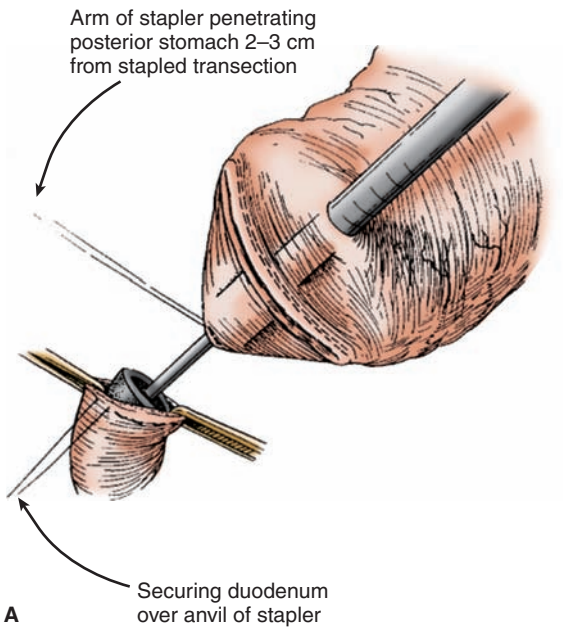

FIGURE 26-22 **A.** The gastrotomy edges should be grasped with two Babcock clamps, and the end-to-end stapling device, minus the anvil, should be passed into the lumen of the stomach. The center rod should be gently pressed against the posterior wall of the stomach approximately 4 cm from the gastric line, and cautery should be used to permit passage of the rod through the posterior wall of the stomach. A purse-string suture will ensure that the stomach does not tear at the site of center rod penetration. The selected anvil size should be applied, and the open end of the duodenum should be grasped with Allis clamps. The duodenal wall should be gently pulled over the anvil, and the purse-string suture should be snugly tied around the center rod. **B.** The cartridge and the anvil should then be approximated, being certain that no extraneous tissues are caught between the anvil and the circular cartridge. The instrument should be fired, and the anastomosis should then be carefully observed by direct visualization to ensure that hemostasis is adequate. The surgeon should then remove the anvil and check the circular tissue from both the duodenum and the stomach to be certain that the tissue doughnuts are intact. If the doughnuts are defective, external Lambert sutures will need to be applied to secure a complete anastomosis. The gastrotomy is closed by grasping each end with Allis clamps and incorporating the entire thickness of the stomach wall through the jaws of the 55-mm stapler. (Redrawn, with permission, from Siegler HF. Gastric resection: Billroth I. In: Sabiston DC, Jr, ed. *Atlas of General Surgery*. Philadelphia, PA: WB Saunders; 1994. After R. Gordon.)

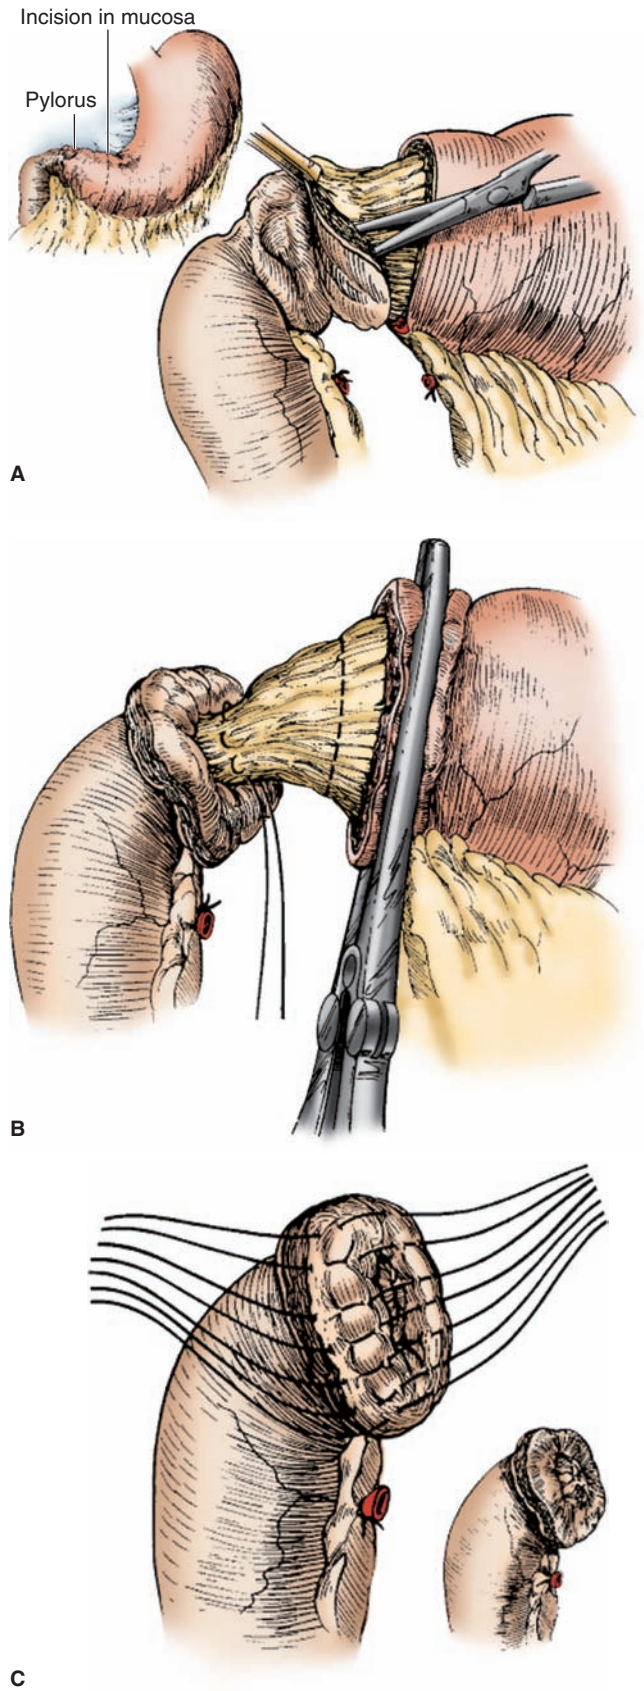

FIGURE 26-23 Bancroft procedure. (Redrawn, with permission, from Kirkham JS. Partial and total gastrectomy. In: Schwartz SI, Ellis H, eds. *Maingot's Abdominal Operations.* Norwalk, CT: Appleton Century-Crofts; 1985.)

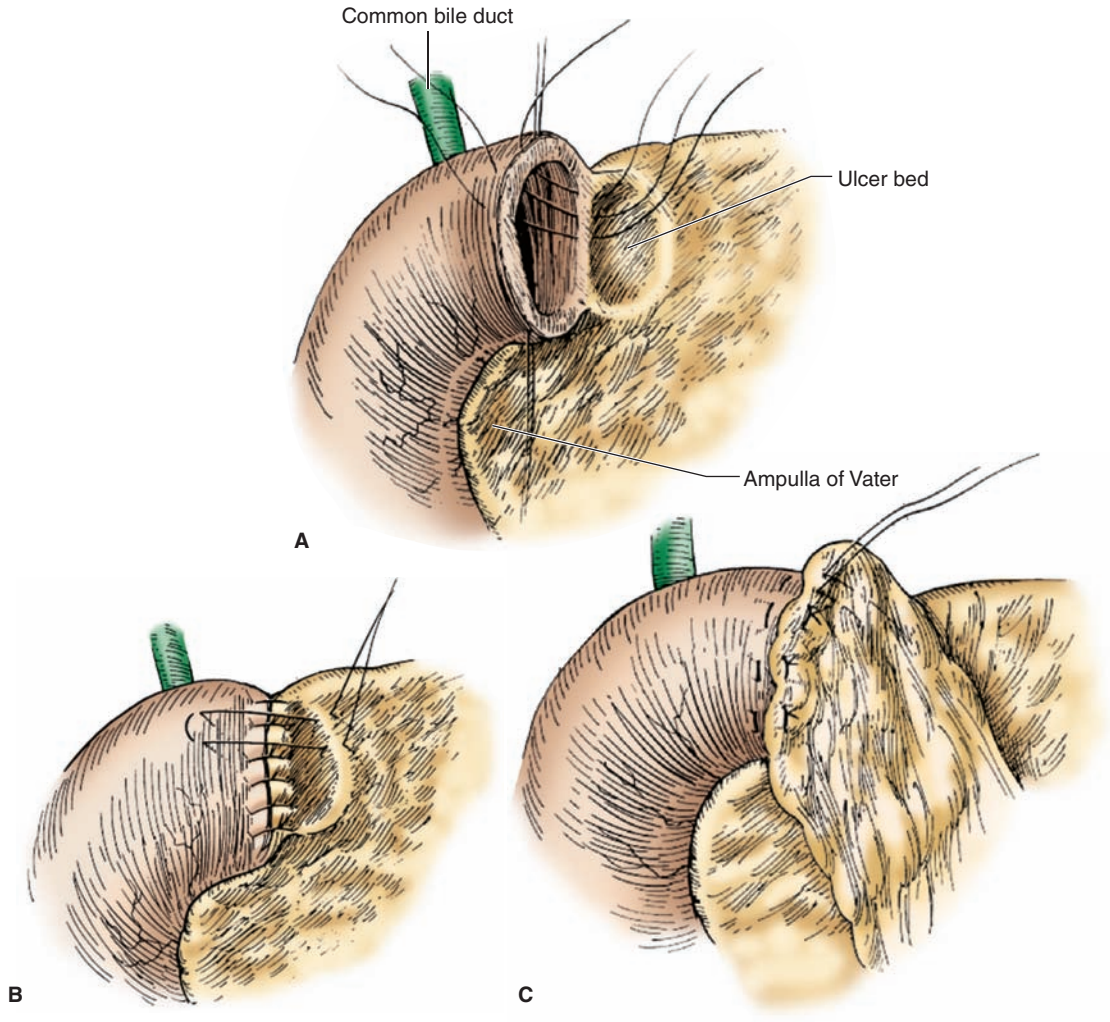

FIGURE 26-24 Closure of a chronic, ulcer-scarred duodenal stump. (Redrawn, with permission, from Zinner MJ. *Atlas of Gastric Surgery*. New York, NY: Churchill Livingstone; 1992. After Gloege.)

obstruction owing to enlargement of lymph nodes or serosal implants in the transverse mesocolon. Whether or not this predisposition exists, positioning the jejunal limb in front of the colon requires a somewhat longer mesentery. As long as the anastomosis will not be under tension, the antecolic position will permit emptying as effective as that through a retrocolic anastomosis. If a retrocolic position is chosen, the window in the transverse mesocolon should be wide enough to permit both the afferent and efferent limbs of the jejunum to slide comfortably through. When this window is closed following construction of the anastomosis, it is preferable to tack the mesentery above, on the gastric side, rather than on the jejunal side. This will prevent kinking and obstruction of the jejunal limbs and positions the anastomosis below the mesentery.

Length of the Afferent Limb. The third decision is the choice of the segment of jejunum used for the anastomosis. In general, the segment should be as close to the ligament of Treitz as possible and still reach the stomach without tension. This generally leaves 10–20 cm of the proximal jejunum as the afferent limb. The shorter this length, the less likely the possibility of an afferent limb syndrome developing. The incidence of other complications such as alkaline reflux gastritis, dumping, or postvagotomy diarrhea should not be influenced by the length of the afferent limb.

Anastomosis: Site on the Gastric Wall and Technique. Schematically illustrated in Fig. 26-25 are a number of described variations on the B-II reconstruction. We describe here one hand-sewn and one stapled technique for anastomosis. As shown in Fig. 26-26, a portion of the gastric staple line is excised with electrocautery, taking a small wedge of stomach behind the staple line. The superior portion of the staple line can be reinforced with 3-0 silk Lembert sutures at this time or can be reinforced later by tacking the afferent limb of jejunum, just beyond the anastomosis, to the gastric wall. The proximal jejunal limb is brought, untwisted, through a window in the transverse mesocolon (Fig. 26-27). Traction seromuscular

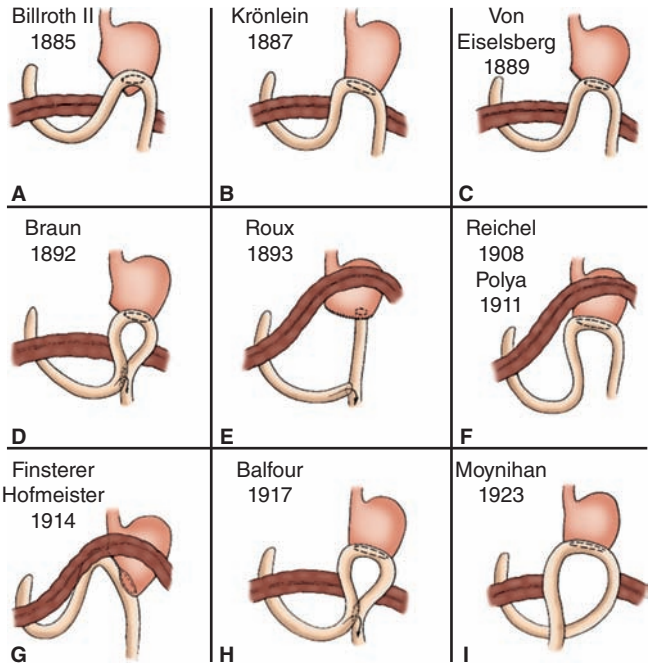

FIGURE 26-25 Billroth II operation and some of its modifications.

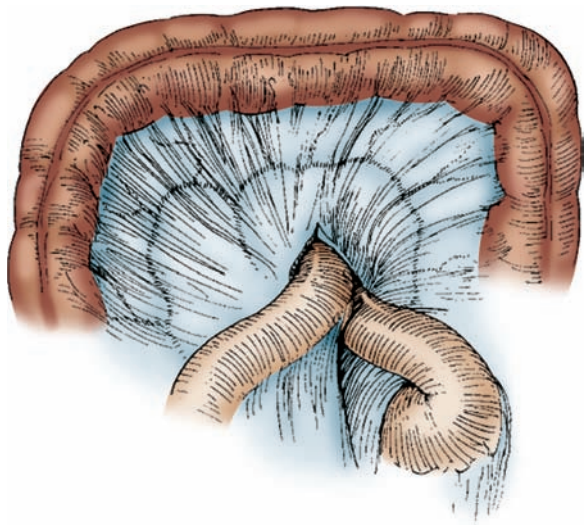

FIGURE 26-27 Billroth II operation. The jejunal segment, located 10–20 cm beyond the ligament of Treitz, is brought through a window in the retrocolic mesentery. (Redrawn, with permission, from Zinner MJ. *Atlas of Gastric Surgery*. New York, NY: Churchill Livingstone; 1992. After Gloege.)

sutures (2-0 or 3-0 silk) are placed at both corners of the anastomosis. The gastrojejunal anastomosis is performed in two layers (Fig. 26-28), between the most caudal part of the stomach and the jejunal limb. The outer layer is composed of 3-0 silk Lembert seromuscular sutures. The inner layer is performed in the posterior row by running two 3-0 Vicryl sutures in opposite directions around the corners and then in Connell fashion for the anterior row. Placement of the anastomosis on the posterior gastric wall, about 2–3 cm from the gastric staple line, also will provide a suitably dependent position for drainage of gastric contents. The window in the transverse mesocolon is closed, as illustrated in Fig. 26-29.

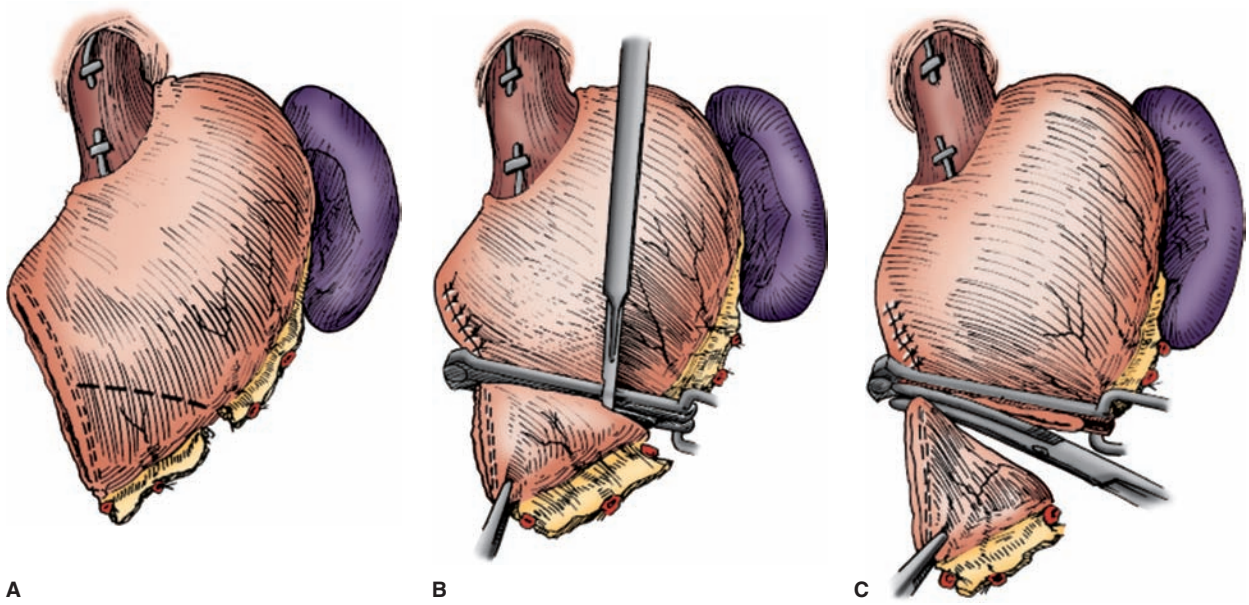

FIGURE 26-26 Billroth II operation. The antrum is resected as in a Billroth I operation. The distal portion of the resection line is excised. (Redrawn, with permission, from Zinner MJ. *Atlas of Gastric Surgery*. New York, NY: Churchill Livingstone; 1992. After Gloege.)

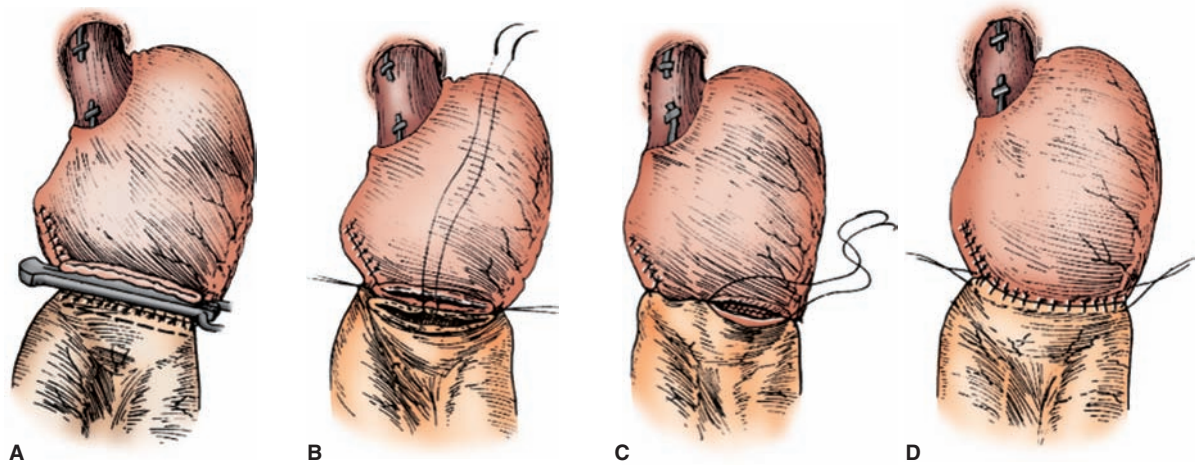

FIGURE 26-28 Billroth II operation. The gastrojejunal anastomosis is constructed in two layers, as described in the text. (Redrawn, with permission, from Zinner MJ. *Atlas of Gastric Surgery*. New York, NY: Churchill Livingstone; 1992. After Gloege.)

Illustrated in Figs. 26-30 and 26-31 is the technique for stapled gastroenterostomy. As before, the jejunal limb is placed in the retrocolic position. Traction sutures are placed on the gastric wall posterior to the anastomosis, bringing the jejunal limb into apposition. The 55-mm GIA stapler is fired after its two limbs are placed through a small gastrotomy and small enterotomy, respectively. The open end of the anastomosis is then closed with a TA-55 stapler. It should be noted that these staple lines, especially from the TA-55, are difficult to reinforce without undue tension. The blood supply of the gastric and intestinal walls is ample, and reinforcement with Lembert sutures generally is not necessary.

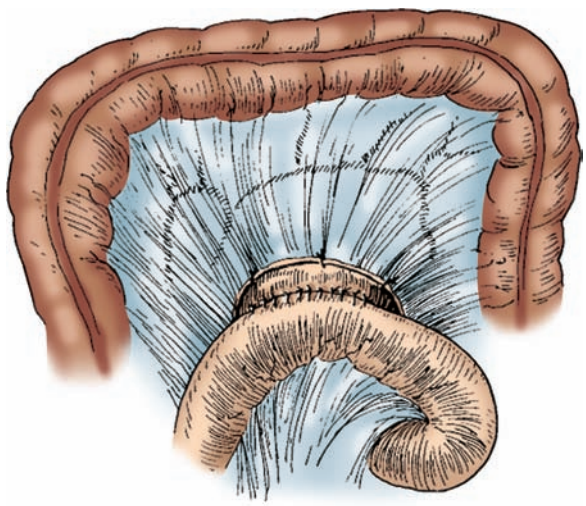

FIGURE 26-29 Billroth II operation. The retrocolic window in the mesentery is closed in order to avoid herniation of other viscera. The mesentery is linked to gastric wall, positioning the anastomosis below the closure. (Redrawn, with permission, from Zinner MJ. *Atlas of Gastric Surgery*. New York, NY: Churchill Livingstone; 1992. After Gloege.)

Subtotal and Total Gastric Resections

The main indications for subtotal (70–80%) gastric resection are carcinoma of the antrum or pylorus or primary gastric lymphoma. However, in cases of ulcers that lie very proximal on the lesser curvature, the proximity to the gastroesophageal junction prevents excision without significant narrowing of the gastric inlet. Similarly, the main indication for total gastric resection is a bulky carcinoma of the body or distal fundus, and rarely, otherwise unmanageable symptoms of an unresectable gastrinoma. Indications for near-total (>90%) gastric resection include the uncommon settings of the Roux stasis syndrome and gastroparesis unresponsive to medical management, as well as carcinoma or lymphoma of the body of the stomach. The approaches for subtotal and near-total gastrectomy are discussed here only briefly, focusing on issues of exposure and techniques for resection of the stomach itself and reconstruction. The principles of resection for gastric carcinoma will be presented subsequently in conjunction with the discussion of radical total gastrectomy for carcinoma.

SUBTOTAL AND NEAR-TOTAL GASTRIC RESECTIONS

In principle, a subtotal gastrectomy is simply an extended antrectomy or hemigastrectomy. A few technical issues are worth noting. First, the exposure provided by midline incision is usually not as adequate as that provided by a chevron incision. Second, the left gastric artery always is ligated and divided in this dissection, and, once the level of gastric transection has been determined, the branches of the left gastroepiploic artery and short gastric arteries are ligated in continuity and divided up to this predetermined level. Third, in opting for a near-total gastric resection, a 1- to

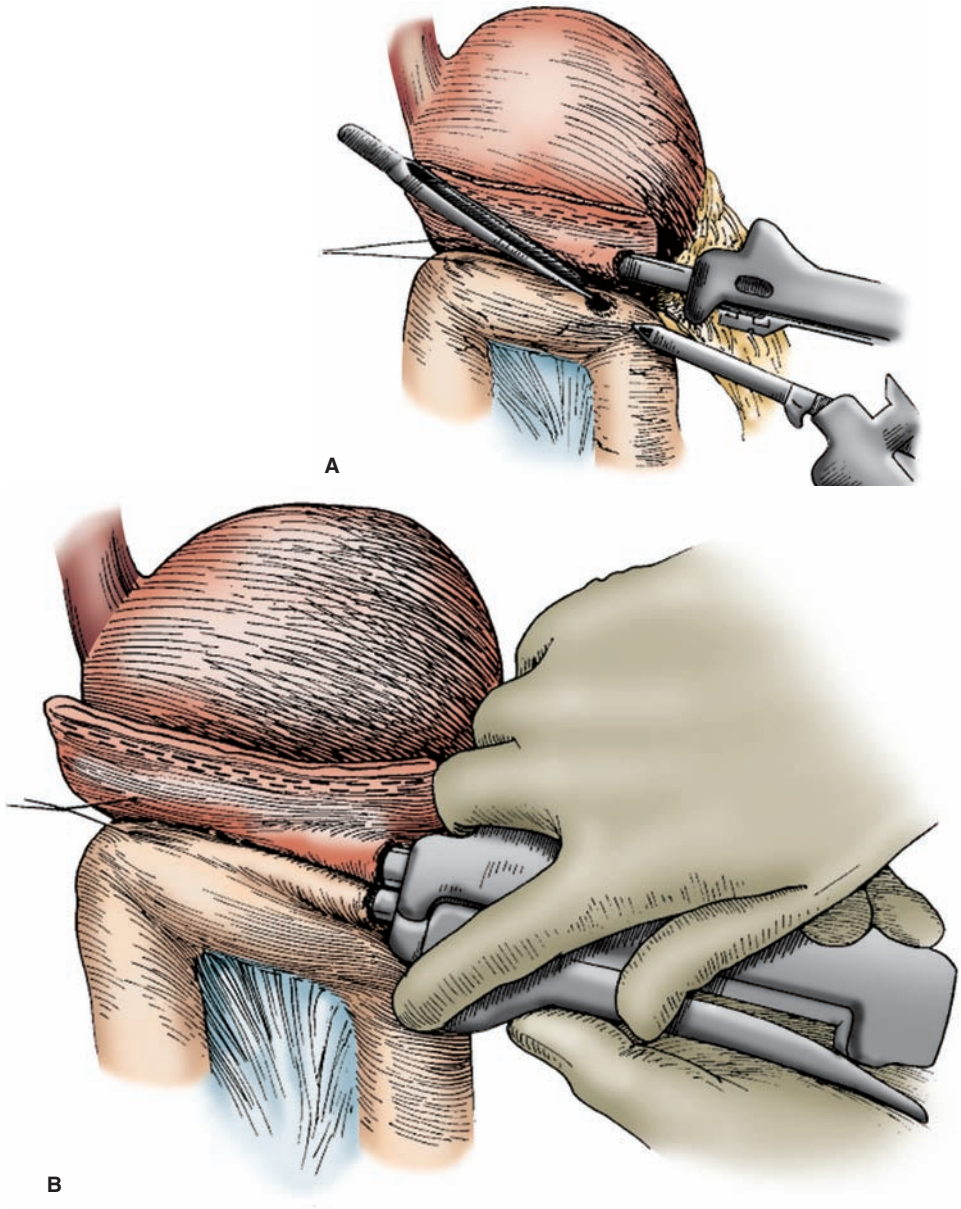

FIGURE 26-30 Stapling technique for Billroth II gastrojejunostomy.

2-cm cuff of gastric wall is left behind and is the margin for the anastomosis. For this operation, it is desirable to preserve the uppermost one or two short gastric vessels, in order to ensure the adequacy of the blood supply for the gastric side of the anastomosis.

One final issue is that a greater extent of lymph node dissection has shown in some series, both Japanese and Western series, improvement in survival for gastric cancer after resection[49,50] although with increased morbidity in some[51] but not necessarily in all[52] centers. Extended lymphadenectomy (D2 resection) involves dissection and removal of the perigastric lymph nodes, as well as those of the celiac axis, and the hepatoduodenal ligament.[53,54] Skeletonization of the celiac artery and its branches (left gastric artery, common hepatic artery, and splenic artery) is required to achieve adequate lymphadenectomy if it is desired. However, further studies are needed before it can be routinely recommended outside of highly specialized centers with surgeons who have specific expertise in this dissection.[52] Finally, although it is often possible to reconstruct with a standard gastrojejunostomy, we prefer a Roux-en-Y reconstruction because this minimizes tension on the suture line and theoretically reduces the risk of anastomotic obstruction by persistence or recurrence of tumor.

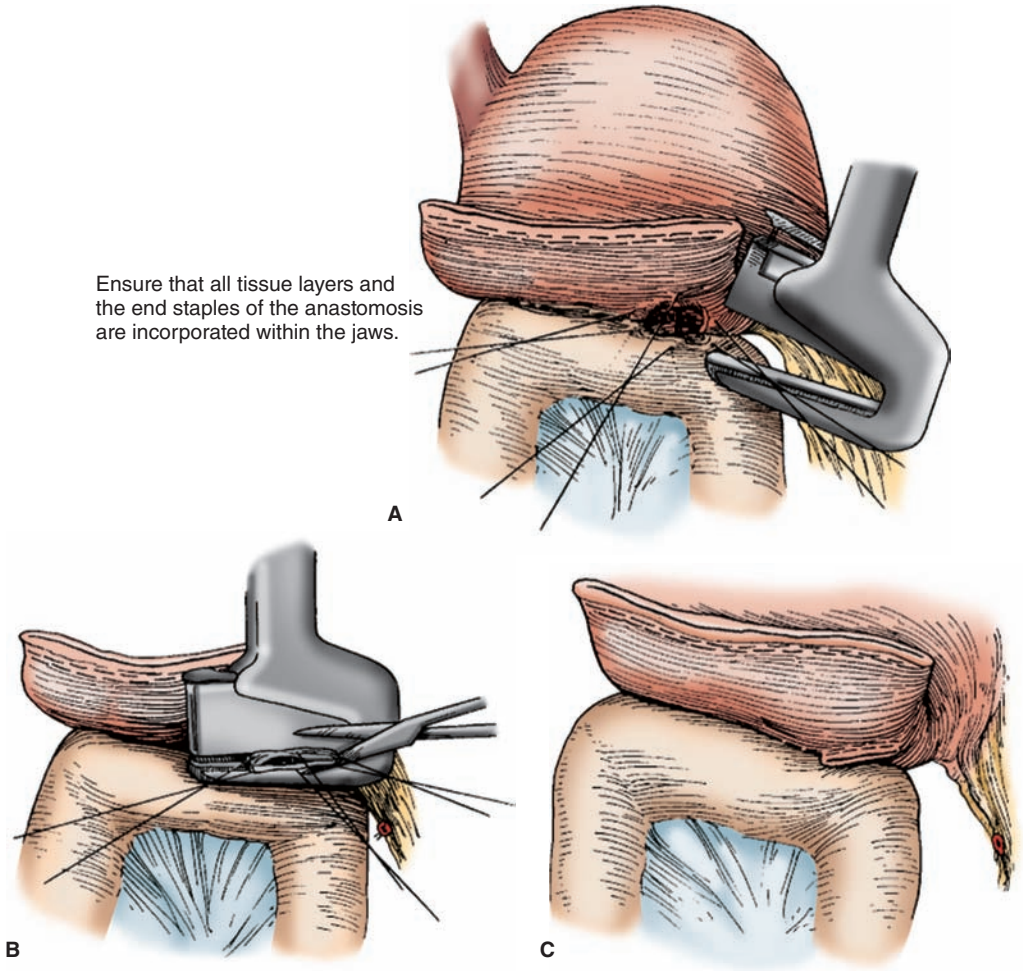

FIGURE 26-31 **A.** Billroth II operation. **B** and **C.** The transverse stapler is used to close the common opening over the gastrojejunal anastomosis.

TOTAL GASTRECTOMY FOR CARCINOMA

The goals of total gastrectomy for carcinoma are (1) clearing of margins on both esophageal and duodenal sides; (2) removal of local and regional lymph node–bearing tissues, including those surrounding the right and left gastric arteries, right gastroepiploic artery, and short gastric arteries; (3) removal of the omentum en bloc with the stomach; and (4) removal of the lymphatic tissues overlying the pancreatic capsule. Extended lymph node dissection (D2 resection) can be done here as described in the prior section.[40–43] However, as before, its potential survival benefit, as shown in some studies, must be weighed against its increased morbidity. After total gastric resection, we favor a Roux-en-Y reconstruction with a direct esophagoenterostomy rather than a jejunal pouch, although the techniques for both forms of reconstruction will be described.

Illustrated in Fig. 26-32 is the final specimen in an en bloc resection. Generally, an upper midline or chevron incision will provide good exposure. A thoracoabdominal incision (Fig. 26-33) is rarely necessary but can provide better exposure when the patient's habitus suggests a deep hiatus. This latter incision also should be considered when preoperative endoscopy suggests that the tumor is close enough to the cardia so that the distal thoracic portion of the esophagus might be included with the resection. If this latter approach is chosen, the abdominal portion of the incision is performed first, in order to assess resectability. The patient is placed in a left thoracotomy position. The incision is carried from the line of the eighth rib obliquely toward the umbilicus. If resection appears feasible, the incision is extended over the eighth rib to the posterior angle. Occasionally, the seventh rib will provide better exposure. A separate rib retractor for the chest and a self-retaining retractor without a ring for the abdominal portion provide the best retraction. The diaphragm is divided toward the hiatus, but the muscle does not always have to be divided completely. Thus it may be possible to spare the neurovascular bundle. Significant bleeding is encountered and it requires suture ligation with 2-0 or 0-0 Vicryl.

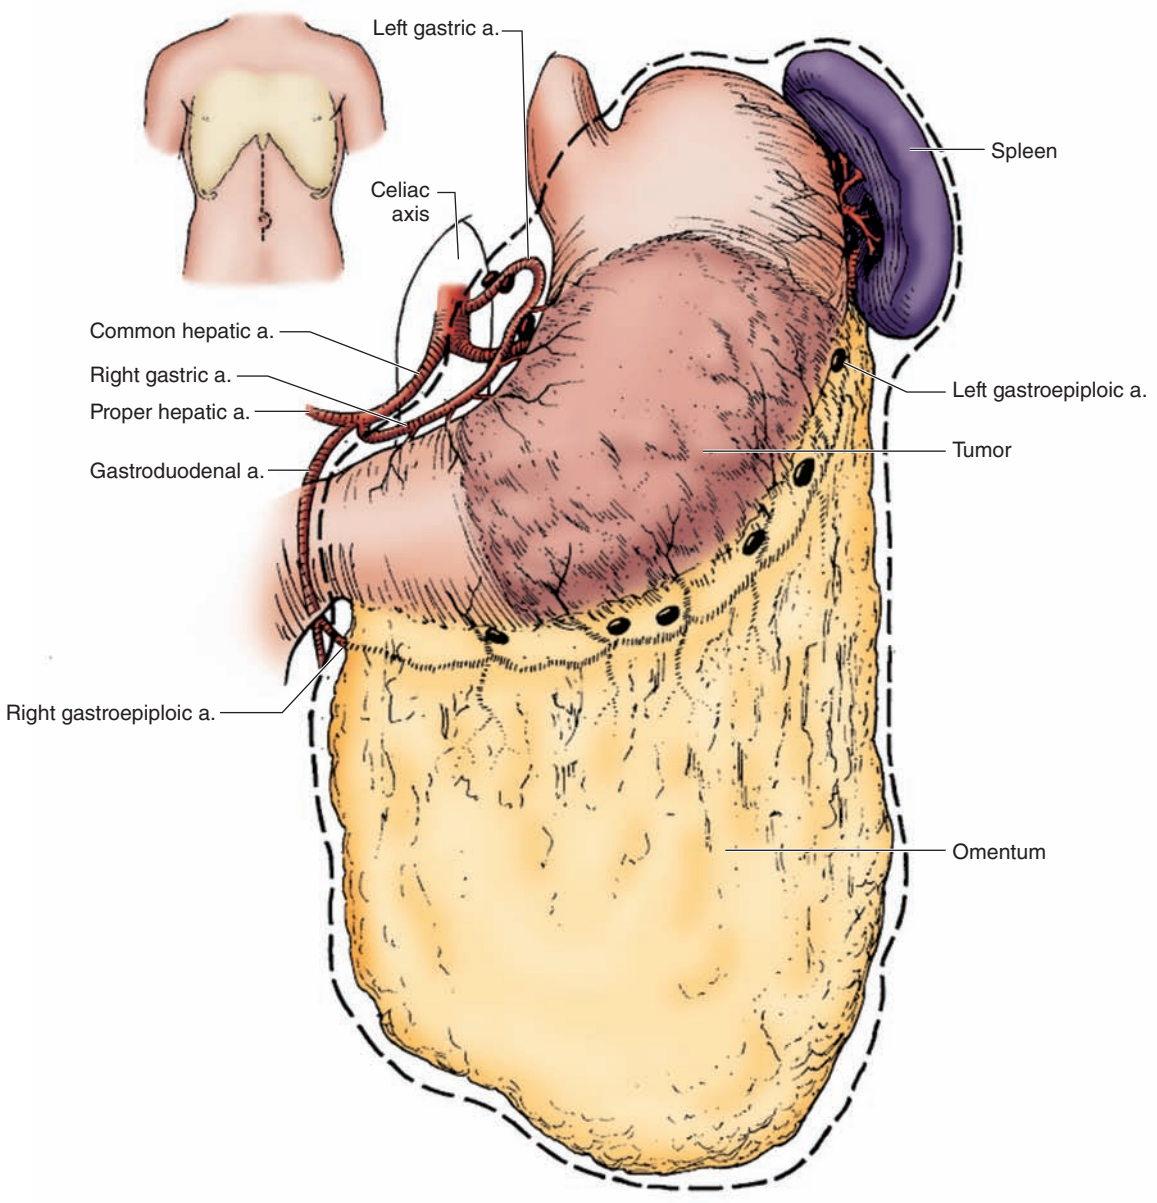

FIGURE 26-32 Anatomy relevant to resections for gastric carcinoma. (Redrawn from Zinner MJ. *Atlas of Gastric Surgery*. New York, NY: Churchill Livingstone; 1992. After Gloege.)

In the abdominal approach, the Bookwalter retractor is used. Extra care in positioning retractors on the left lobe of the liver, diaphragm, and small intestine, for optimal exposure of the hiatus is time well spent. The dissection is begun by dividing the omentum from the transverse colon (Fig. 26-34). This relatively avascular plane can be separated using the electrocautery. Deviation from this plane will injure the colon or require tedious ligation and division of omental blood vessels. The lesser sac is then entered, allowing assessment of the retroperitoneum, with regard to local tumor extension and lymph node involvement. The distal portion of the gastrectomy is then performed. The origin of the right gastric artery at the common hepatic artery is identified, ligated in continuity with 2-0 silk ligatures, and divided.

Lymphatic-bearing tissues are swept toward the gastric side. The right gastroepiploic artery is identified, usually by palpation, and traced as far to its base as possible. It is usually possible to trace the artery to its origin at the gastroduodenal artery, which is similarly ligated in continuity and divided. Using the electrocautery, the lesser omentum is incised near the liver and its tissues are swept toward the lesser curvature, from the duodenum to the esophagus. Any small vessels are ligated with 3-0 ligatures. The dissection is carried onto the peritoneal surface of the esophagus. The duodenum may then be divided using the GIA stapler or a TA-55 stapler that is

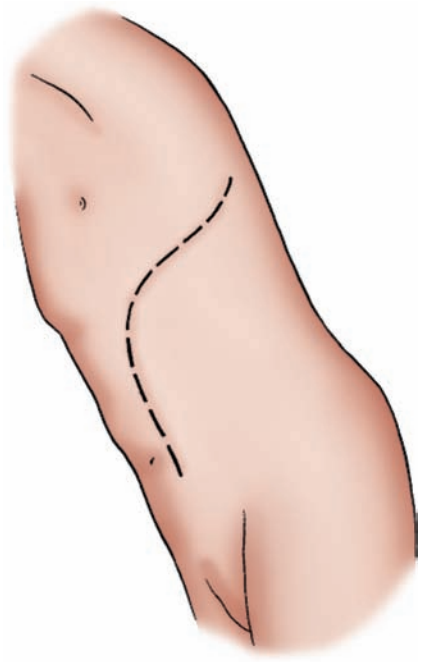

FIGURE 26-33 Thoracoabdominal incision for radical total gastrectomy for carcinoma of the stomach. The incision is carried along the seventh or the eighth interspace.

fired twice, once on the duodenum and once directly on the pylorus. The duodenum is divided just distal to the pyloric ring (Fig. 26-35).

With the distal portion of the stomach divided, full access to the left gastric artery is obtained posteriorly through

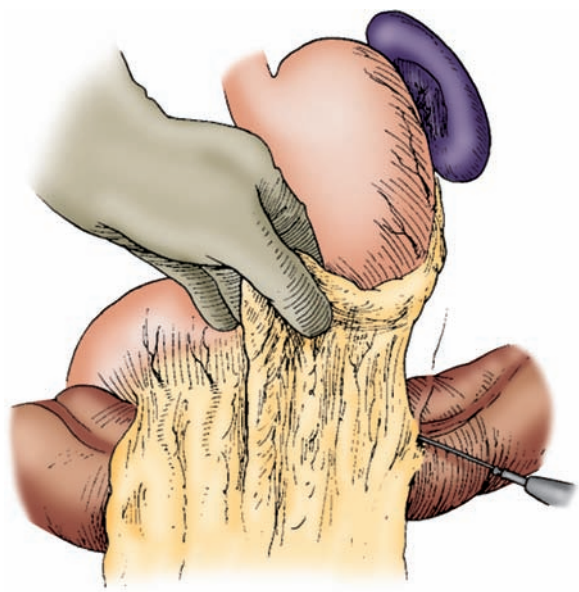

FIGURE 26-34 Resection for gastric carcinoma. The gastrocolic omentum is detached from the transverse colon using electrocautery. (Redrawn, with permission, from Zinner MJ. *Atlas of Gastric Surgery*. New York, NY: Churchill Livingstone; 1992. After Gloege.)

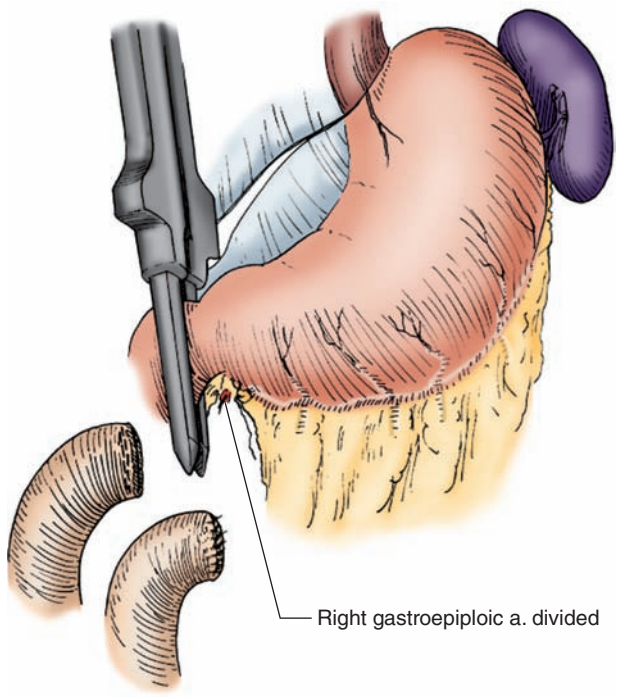

FIGURE 26-35 Resection for gastric carcinoma. The duodenum is divided beyond the pylorus. Either the linear cutter or transverse stapling instruments are appropriate. If feasible, the duodenal staple line is reinforced using 3-0 silk Lambert sutures. (Redrawn, with permission, from Zinner MJ. *Atlas of Gastric Surgery*. New York, NY: Churchill Livingstone; 1992. After Gloege.)

the lesser sac. This approach optimizes visualization of the celiac axis and its branches. With the assistant retracting the stomach upward and anteriorly, a number of congenital adhesions between the posterior gastric wall and the peritoneum overlying the pancreas are observed (Fig. 26-36). If tumor is invading this plane, a decision must be made regarding inclusion of the body and tail of the pancreas in the specimen. The plane made by the peritoneum overlying the pancreas is a natural plane, and there may be sense in taking this peritoneum with the en bloc specimen. This layer can be dissected off the anterior face of the pancreas and swept gently to the front toward the left gastric vessels and splenic hilum. If a curative resection appears to be feasible but would require removal of the body and/or tail of the pancreas, we do not see this as a contraindication to resection. The origin of the left gastric artery is then identified at the celiac axis, ligated in continuity using 2-0 silk, and divided (Fig. 26-37). The stump of the artery is suture-ligated as well. From the celiac axis side, the tissue surrounding the artery contains lymphatics and is swept toward the lesser curvature. When the tumor is located in the more proximal body and corpus, the case for inclusion of the spleen with the en bloc specimen has not been persuasive,[55,56] a recent meta-analysis suggesting no oncologic benefit[57] for removal of a spleen not apparently involved by direct extension. Inclusion of the spleen is indicated if there are obvious tumor-bearing nodes or if there is

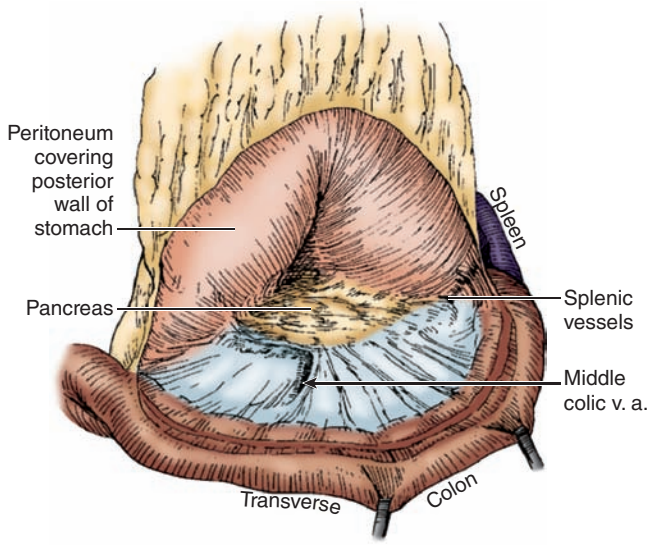

FIGURE 26-36 Resection for gastric carcinoma. With the lesser sac fully visualized, the thin layer of tissue overlying the pancreas is exposed and can be removed with the en bloc specimen. (Redrawn, with permission, from Zinner MJ. *Atlas of Gastric Surgery*. New York, NY: Churchill Livingstone; 1992. After Gloege.)

direct invasion of the splenic hilum. Through the lesser sac, the tail of the pancreas is identified. The splenic artery and vein are separated, suture-ligated, and divided individually. At this point, the short gastric vessels are then part of the en bloc specimen and are not dissected or divided.

The posterior aspect of the esophagus then comes into view as the stomach and spleen are lifted upward. Posteriorly, the front of peritoneal tissue can be dissected bluntly until the superior border of the pancreas is reached. The peritoneum is continuous with the peritoneum investing the gastric side of the gastroesophageal junction. If this layer has not been included with the dissection, the peritoneum must be divided here, exposing the gastroesophageal junction posteriorly. Figure 26-38 demonstrates the stomach completely mobilized except for its attachment to the esophagus. A noncrushing clamp is placed on the mobilized esophagus and the specimen is resected. To minimize spillage of luminal contents, a second clamp is placed on the gastric side or the TA-55 stapler may be fired below the line of resection and above the gastroesophageal junction.

Our preferred technique for reconstruction is a simple Roux-en-Y, with an end-to-side esophagojejunal anastomosis with the Roux limb. Using the GIA stapler, a section of jejunum is divided 10–15 cm beyond the ligament of Treitz (Fig. 26-39). The Roux limb is brought antecolic up to the esophagus. An enteroenterostomy is constructed between the jejunum on the duodenal side of the Y and the jejunum, 40–45 cm distal to the Roux limb staple line (Fig. 26-40). The enteroenteral anastomosis can be performed using hand-sewn two-layer technique or stapling technique. The esophagojejunal anastomosis is performed using interrupted 3-0 silk sutures for both the inner and outer layers, as shown in Fig. 26-41. The completed reconstruction is shown in Fig. 26-42. This figure emphasizes the antecolic position of the anastomosis when the operation is performed for malignant disease. Areas of potential internal

herniation in the mesentery are closed with absorbable 3-0 sutures.

A jejunal pouch (Hunt-Lawrence pouch) also may be constructed, with the idea of anastomosing the esophagus in end-to-side fashion with the antimesenteric border of the pouch.[58,59] The technique is illustrated in Figs. 26-43 through 26-45 and can be performed expeditiously using surgical staplers. The pouch is constructed with the goal of providing a reservoir function. Alternatively, a number of surgeons expressed a preference for leaving an island of undivided intestine at the bend in the pouch. This should theoretically optimize the blood supply to the anastomosis. The circular stapler can be passed through the open end of the Roux limb in order to perform the end-esophagus to side-jejunum anastomosis. The linear stapler then can be fired in such a way as to leave the island of undivided intestine. One important point is that the pouch can be made too long, giving rise to stasis and ineffective clearance of food from the pouch into the intestine. The pouch should not be more than 15 cm in length.

Laparoscopic Approaches

LAPAROSCOPIC APPROACHES TO THE VAGUS NERVE

As noted previously, the advent of laparoscopic approaches has led surgeons to reconsider traditional approaches to peptic ulcer disease. The advantages of minimally invasive approaches revolve largely around the minimal postoperative discomfort and rapid recovery, with a potential benefit in reduced cost of surgery versus the cost of long-term medication.[60] At the same time, rapid advances have occurred in our understanding of the role of *Helicobacter pylori* and mucosal growth, and angiogenic factors in ulcer healing and recurrence. In addition, limitations in access and suturing techniques have increased the difficulty of access to the lesser sac and of performing drainage procedures. These considerations have led surgeons to question the rationale for routine drainage whenever TV has been performed.[15,37] A number of approaches have evolved to address these difficulties and have been given credibility in the laparoscopic experience. One such approach has been to combine truncal vagotomy with pyloric dilation or seromyotomy.[26,16,21] Another has been to combine a posterior truncal vagotomy with an anterior highly selective vagotomy or with

an anterior seromyotomy.[16] The important elements of the laparoscopic approach to the vagi are discussed here.

PATIENT POSITION AND PORT PLACEMENT

The patient is placed on the operating room table with legs in stirrups and apart (Fig. 26-46). Video monitors are placed on either side at the head; often, the surgeon works best when standing between the legs, with the camera operator on the right and the first assistant on the patient's left. The scrub nurse/technician and instrument table are placed at the patient's right foot. A large esophageal tube or even a gastroscope is placed in the stomach to facilitate visualization of the distal esophagus. Frequent aspiration of the gastric contents is crucial to maintain total collapse of the stomach and the best visualization. We recommend an open technique to gain access to the peritoneum, insufflating to a pressure of 14 mm Hg. Five ports are placed in the following locations: (1) a 12-mm laparoscope port at the superior edge of the umbilicus or placed 5 cm above and lateral to the left of midline; (2) a 5-mm irrigation/suction and dissection port in the subxiphoid position, just to the right of midline; (3) a 10-mm port for retraction and grasping forceps midway between the umbilicus and xiphoid, to the right of the rectus, and possibly as far as the midclavicular line; (4) a 10-mm port for grasping forceps midway between the umbilicus and xiphoid, almost to the anterior axillary line on the left; and (5) a 12-mm operating port just lateral to the rectus 3 cm above the umbilicus. A number of surgeons prefer the angled 30-degree laparoscope for this operation.

LAPAROSCOPIC TRUNCAL VAGOTOMY

The left lobe of the liver is retracted using a probe placed via the subxiphoid port or the 10-mm fan retractor placed via the higher right-side port (Fig. 26-47). Visualization is improved when tissues from the hiatus are dissected away from the esophagus and lesser curvature (Figs. 26-48 and 26-49). One can encounter a coronary hepatic vein or accessory hepatic artery in this dissection. These do not always need to be sacrificed. The right crus of the diaphragm usually is seen here and can be retracted with one of the blades of the liver retractor (Fig. 26-50). A Babcock clamp or other atraumatic grasper is used to retract the anterior greater curvature (distal to the cardia) to the patient's left. A hook coagulator or dissecting forceps is used to incise the lesser omentum, entering the lesser sac just above the takeoff of the hepatic branch of the anterior vagus nerve. A plane is developed between the right crus and the esophagus and continued posteriorly. Continued dissection along the wall of the esophagus reveals the posterior trunk, which is ligated between clips and divided (Fig. 26-51). The excised nerve segment is sent for frozen-section examination. The next step is identification of the anterior vagal trunk(s). The phrenoesophageal membrane usually has been entered and incision is extended toward the left, first by scoring the membrane with scissors and then bluntly pushing away the membrane with a cotton dissector. The visualization of major anterior trunks is often easier in the laparoscopic approach, owing to magnification and excellent video optics. These branches also are ligated and divided between clips (Fig. 26-52), with frozen-section confirmation of the nerve segment. Smaller anterior branches are identified and cauterized after being held away from the esophageal wall.

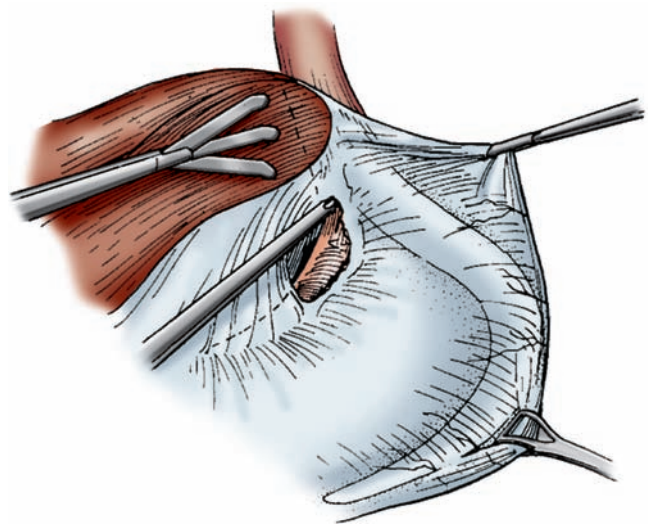

FIGURE 26-47 Laparoscopic view of the hiatus.

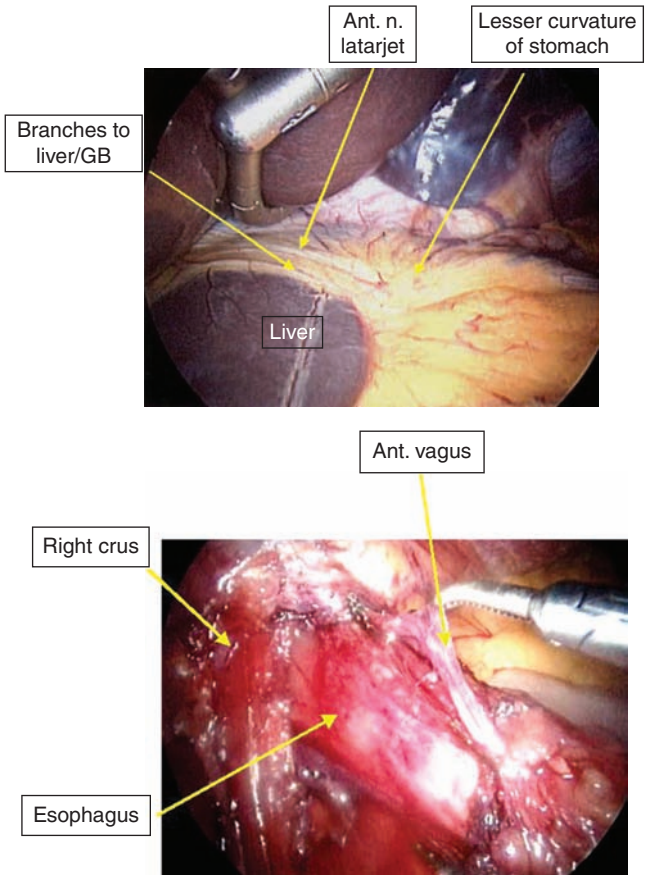

FIGURE 26-48 Laparoscopic view of the anterior vagus nerve. **A.** Before dissection. **B.** After dissection.

It is possible to dissect tissues on either side of the esophagus for a distance of 5–6 cm, thereby ensuring division of any nerve branches to the lesser curvature and cardia. The main difficulty can occur in visualizing the angle of His and possibly missing major vagal branches, including the "criminal nerve." With the use of a traction forceps placed through the subxiphoid port and a cotton dissector placed via the left grasping forceps, it is possible to expose the left edge of the gastroesophageal junction and cauterize or clip any branches.

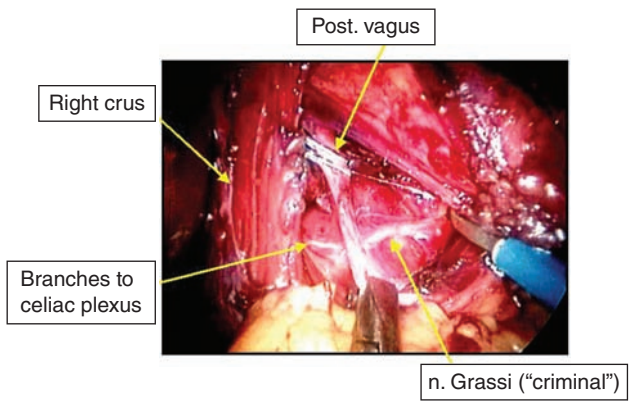

FIGURE 26-49 Laparoscopically assisted vagotomy. The gastrohepatic ligament is dissected anteriorly without injury to the vagus nerves.

ANTERIOR PROXIMAL VAGOTOMY OR SEROMYOTOMY

A laparoscopic dissection of the posterior leaf is feasible.[61,62] However, the combination of posterior TV and an anterior selective operation is appealing, because it avoids the difficult maneuver of working through the lesser sac in order to visualize the posterior lesser omentum and nerves accompanying the ascending left gastric artery branches. For HSV, dissection is begun at the crow's foot, approximately 6 cm from the pylorus. Retraction of the greater curvature is performed using a Babcock clamp (Fig. 26-53). With the magnification available through the scope, the proximal branch of the crow's foot is often, but not always, relatively easy to identify. The anterior leaf of the lesser omentum is approached by dividing and ligating the neurovascular bundle between clips. Electrocautery is used sparingly, and preferably not at all. The serosa overlying the gastroesophageal junction is scored as in the open procedure. Dissection of the distal 5 cm of esophagus and cardiac branches is carried out as described previously for TV.

The goal of an anterior seromyotomy, as described originally by Taylor et al[63] and then others,[13,26,64] is to sever the neurovascular bundles dividing the serosa and muscularis that transmit these nerves to the mucosa. The anterior surface of the stomach is retracted and placed on stretch using the right and left grasping ports. The outline of the seromyotomy is scored using a coagulator hook or spatula, on the anterior surface of the stomach, 1 cm from the visible border of the lesser curvature. Moving caudad and parallel to the lesser curvature, a line is traced from the gastroesophageal junction to the first branch of the crow's foot, or arbitrarily 6 cm from the pylorus. The hook coagulator is most suitable for performing the seromyotomy, using monopolar current for electrocoagulation. The hook cuts through successive layers of gastric wall, of the serosa, outer oblique muscle fibers, middle longitudinal fibers, and inner circular fibers. The two grasping ports then are used to place traction on the two edges of the gastric wall, exposing the deep circular fibers that may split as much from traction as from cautery. The darker submucosa/mucosa layer pops through the muscularis. This layer is inspected for any evidence of full-thickness cautery injury or perforation. With a complete seromyotomy, the gap between the cut edges should be about 6–8 mm. Alternatively, a laparoscopic surgical stapling device can be used for creation of a modified seromyotomy.[26]

A number of decent-sized vessels may be encountered in the dissection. Prolonged cauterization may provide hemostasis but risks a full-thickness burn and subsequent perforation. The hook can be used to isolate these vessels and lift them for clipping in continuity. Recent advances in the design of needle holders may make it possible to suture these vessels in continuity before division by scissors. Surgical stapling devices can be used for this purpose, as well as newer devices such as the harmonic scalpel, which utilizes ultrasonic energy for coagulating vessels, or electrothermal bipolar coagulator devices. After creation of the seromyotomy, the integrity of the mucosa should be verified by moderate expansion of the stomach using the NG tube for insufflation. Some authors use methylene blue solution (1 vial per 200 mL), placed intragastrically, for this maneuver. The seromyotomy then is closed using a continuous suturing technique. A tongue of omentum may be mobilized and secured over the seromyotomy as a patch, secured with sutures placed through either edge of the seromyotomy.

LAPAROSCOPIC APPROACHES TO THE GASTRIC RESECTION

The patient is positioned the same way as for laparoscopic antisecretory surgery, with the patient supine with legs in stirrups and apart as shown in Fig. 26-46. Port placement is similar with five ports placed in the following locations: (1) a 12-mm laparoscope port at the superior edge of the umbilicus or placed 5 cm above and lateral to the left of midline; (2) a 5-mm irrigation/suction and dissection port in the subxiphoid position, just to the right of midline; (3) a 10-mm port for retraction and grasping forceps midway between the umbilicus and xiphoid, to the right of the rectus and possibly as far as the midclavicular line; (4) a 10-mm port for grasping forceps midway between the umbilicus and xiphoid, almost to the anterior axillary line on the left; and (5) a 12-mm operating port just lateral to the rectus 3 cm above the umbilicus. A 30- or 45-degree angled laparoscope is useful for gastric resections, as it allows improved visualization of the stomach from multiple perspectives. If resections high in the lesser curvature are planned, retraction of the left lobe of the liver using a probe placed via the subxiphoid port or the 10-mm fan retractor placed via the higher right-side port (see Fig. 26-51) is useful as described for laparoscopic TV.

Wedge resections of benign but symptomatic masses on the greater curvature can be done by grasping the greater curvature with a Babcock or other atraumatic grasper and use of a laparoscopic stapling device to resect the involved portion of stomach. Occasionally intraoperative endoscopic confirmation of the position of intraluminal masses not readily apparent intraoperatively is useful. Wedge resections on the lesser curvature are more difficult due to the presence of the left lobe of the liver, which usually needs to be retracted, and the proximity of the esophagus and vagus nerves. However, with careful attention to the gastroesophageal junction, wedge resections of the lesser curvature can be done. Intraluminal approaches can also be utilized.[44,45] If the vagus nerve or its major branches are sacrificed in lesser curvature resections, a laparoscopic or endoscopic drainage procedure is recommended (endoscopic pyloric dilation or laparoscopic pyloric seromyotomy).

Distal, subtotal, and total gastrectomy procedures have all been adapted for laparoscopic approaches. With recent advances in equipment and concentrated experience, all approaches seem to be finding increasing application, with promising results in selected patients.[65–68] In laparoscopic subtotal or total gastrectomy, port placement is similar to that for wedge resections and antisecretory procedures (Fig. 26-54). Gastric mobilization, resection, and reconstruction are done in a similar fashion to that of the open procedures. After entry into the abdominal cavity and port placement, the left lobe of the liver is mobilized and retracted laterally with a fan retractor or probe through the subxiphoid port if the lesser curvature cannot be adequately visualized or if extensive dissection of the lesser curvature is required. The stomach is grasped with a laparoscopic Babcock clamp, and the distal stomach is mobilized by incising the gastrocolic ligament, which is taken bluntly if the plane is avascular and with the harmonic scalpel

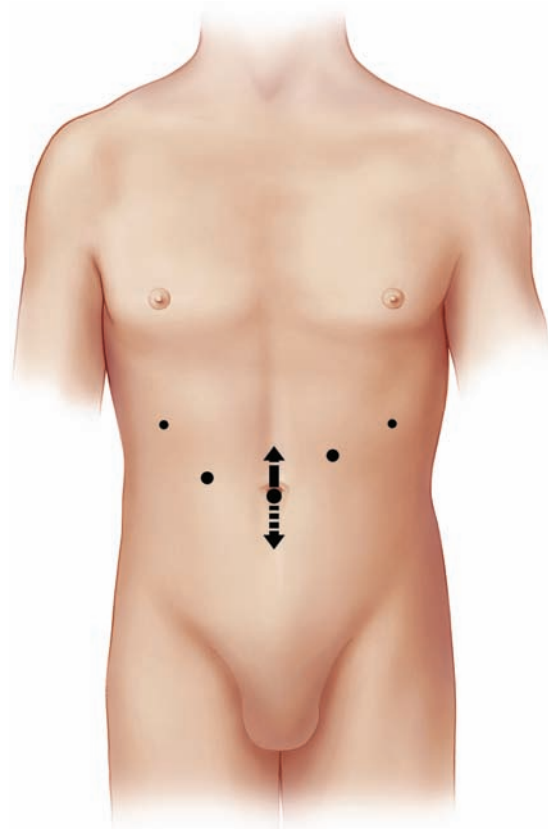

FIGURE 26-54 Port placement for laparoscopic subtotal or total gastrectomy.

or electrothermal bipolar coagulator device if small vessels are encountered. The dissection is carried distally along the greater curvature, dividing the small branches of the gastroepiploic artery to the gastric wall similarly with the harmonic scalpel or electrothermal bipolar coagulator device. Others have used endoscopic vascular staplers to take much of gastrocolic omentum and its vessels. Once the proximal portion of the gastric dissection is reached, the stomach is divided with laparoscopic staplers at our institution (2.5-mm stapler load on US Surgical, Norwalk, CT, or laparoscopic staplers on Ethicon, Somerville, NJ). The gastric resection is then completed by division of the distal stomach at or just past the pylorus with a laparoscopic stapler. Reconstruction is completed as a B-II gastrojejunal anastomosis. Babcock clamps are used to locate the jejunum at the ligament of Treitz and bring a freely mobile portion of jejunum typically 20–30 cm distal to the ligament of Treitz up to the proximal gastric remnant in an antecolic or retrocolic fashion through an avascular window in the transverse colon mesentery. The gastric remnant and jejunum are aligned together, being careful not to twist the jejunal mesentery, and then secured to each other at the proximal and distal suture lines by interrupted 3-0 Vicryl sutures placed either with an Endo Stitch (Auto Suture Company, Norwalk, CT) or with a laparoscopic needle driver. After the gastric and jejunal limbs are aligned, Bovie cautery is used to place

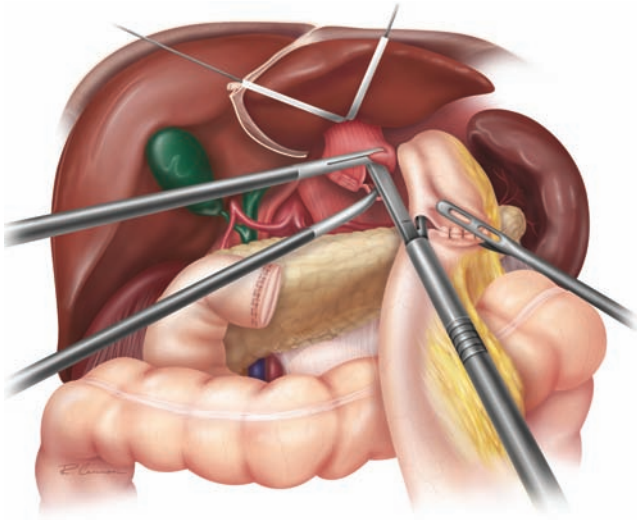

FIGURE 26-55 Schematic view of laparoscopic total gastrectomy. The esophagojejunal anastomosis is performed using the stapling device.

enterotomies in the proximal gastric remnant and jejunum. A laparoscopic stapler is placed into the gastric and jejunal limbs and then deployed to form the anastomotic staple line. The proximal portion of the anastomosis is then closed using a laparoscopic stapler or suture-closed using an Endo Stitch device or with a laparoscopic needle driver. For total gastrectomy, the esophagojejunal anastomosis is performed using the stapling device as illustrated in Fig. 26-55. The mesenteric defect in the transverse colon is then closed if a retrocolic anastomosis has been performed.

Laparoendoscopically Assisted Sentinel Node Navigation.

One of the concerns with laparoscopic gastrectomy procedures, done in patients with gastric cancer, is to determine whether a radical lymphadenectomy would be required. For early-stage gastric lesions (clinical and radiologic stage T1N0), sentinel node identification and so-called "sentinel node navigation" of the operation[69–71] have been advocated. Both single- and double-tracer methods have been described.[72] For complementary tracer injection, a method similar to that described recently by Orsenigo, et al would be utilized.[73,74] On the day prior to operation, endoscopy is performed to inject radioactive tracer (^{99}Tc-colloid, 2 mL total) at four equally spaced points in direct proximity to the tumor; at the beginning of the actual operation, blue dye (2% patent blue, 2 mL divided among four sites) is injected endoscopically. The accumulation of radioactive tracer in the nodal basin occurs over a period of 2–20 hours, while the transfer of blue dye to the sentinel node occurs very quickly. As a result, the sentinel node seems reliably identified when the blue node contains at least 10-fold higher radioactive counts than background.[73] It has been suggested that the radical lymphadenectomy may be limited to a D1 dissection if the sentinel node is clearly identified and clearly negative, but long-term outcomes in controlled trials are not yet fully known.[75]

MORBID OBESITY AND ITS SURGICAL TREATMENT

Bruce Schirmer • Peter Hallowell

INTRODUCTION

Obesity looms as the single largest threat to world health in the next few decades. In countries such as the United States, its consequences pose the very real likelihood that the next generation may not live longer or be more healthier than the previous one.[1] This would reverse a trend that has been present for centuries. The rate of obesity is rising worldwide, not just in countries that enjoy privileged economic status. The rise in obesity over the past 25 years in the United States has been dramatic. Currently nearly one-third of adults in the United States are obese, defined as having a body mass index (BMI, calculated as being weight in kg divided by height in meters squared) of 30 kg/m^2 or greater.[2] More concerning yet, the rate of obesity in young adolescents and teenagers is approaching or exceeding the adult rate in many geographic areas. Because obese adolescents have a very high likelihood of being obese adults, this predicts that the problem will continue to grow in terms of its consequences on the health of the population.

Obesity was not a major health problem in many areas of the world, such as Asia and Africa, until the past decade. Now even those countries, where the problem was previously rare, are experiencing a significant increase in its prevalence. It is likely that wider access to high-calorie fast-food meals and other higher-calorie foods from Western countries, combined with the decreased need for physical labor and activity with increasing mechanization present in these countries, are significant contributing factors. The flattening of the world has also led to its fattening.

Obesity also remains the only major characteristic or attribute for which discrimination is not illegal. Laws exist to prevent discrimination on the basis of gender, sexual preference, race, religion, or handicapped status. However, there are no laws to prevent the current and prevalent discrimination against obesity in the workplace, in travel, in accommodations, and in other areas of life that are often overlooked by nonobese individuals. Most damaging, however, is the persistent belief by the majority of the public that obesity stems from laziness and gluttony, rather than being a disease. Even more sadly, there are still medical care providers who hold such opinions. The Centers for Medicare and Medicaid Services (CMS) has officially recognized obesity as a disease and sanctioned its treatment as appropriate for recipients of federal insurance.[3] Unfortunately, the insurance industry overall, including those companies assigned to administer services to federally insured patients and the federal administrators as well in certain situations, has consistently raised barriers and made it difficult for patients with obesity, and particularly those with severe obesity, to obtain optimal treatment for their disease.[4] While such short-sighted behavior may save money for their balance sheets in the short term, it will not make the problem go away. The next generation worldwide will be required to pay the price of addressing the needs of the population with this disease.

One feasible reason for the aversion of insurance carriers toward funding surgical therapy for severe obesity is increased costs. The cost of obesity is now a huge part of the health care budget and rising more rapidly than the overall high rate of increasing health care costs. It is estimated that in 2007 the direct cost in dollars for treating obesity was $93 billion or over 9% of all direct health care costs.[5] That cost is likely higher today. In addition, such a number is based only on direct hospital or physician charges for diagnosis codes of obesity and related conditions. They do not include the increased cost that obesity confers to many other situations. An example would be a severely obese individual with a large incisional hernia. That person has a much higher risk of the recurrence of the hernia, the need for further operative care, and even for more severe complications such as bowel injury, fistula, or obstruction. Yet these costs are not at all calculated in to the cost of obesity, because incisional hernia is the problem. Similarly, the huge cost annually to the population of diets and other nonmedical-related costs of obesity are also not included in this figure.

This text focuses more on the surgical therapy of obesity than medical treatment options. As such, it also focuses largely on the individuals of the obese population that are surgical candidates. Table 27-1 defines the categories of obesity that we follow in this chapter. The term *severe obesity* will be used in preference to morbid obesity, as recommended by the National Institutes of Health (NIH) Consensus Conference

TABLE 27-1: DEFINITION OF TERMS FOR OBESITY

BMI 26–29.9	Overweight
BMI 30–34.9	Obese (class 1)
BMI 35–39.9	Obese (class 2)
BMI 40–49.9	Severely obese
BMI >50	Superobese

BMI, body mass index.

that also established the still adhered to guidelines for the indications for surgical therapy for obesity.[6] Arguments exist that, probably correctly, call for a reexamination of the data regarding bariatric surgery and revision of these quite old NIH guidelines, established long before laparoscopic surgery, and when vertical banded gastroplasty was still a commonly performed operation in the United States.[7]

Similarly, arguments have been voiced that BMI is not an adequately accurate predictor of health deficits related to obesity.[8] A highly muscular individual could have a high BMI but very little body fat, for example. Thus the risk to his or her health would not be nearly as great as the individual with the same BMI but high-body-fat content. While both such arguments have validity, and this is hereby recognized, barring the creation of newer NIH guidelines or the creation of a better and more easily calculated measure of obesity than BMI, this text accepts current use of current NIH guidelines and BMI as the gold standards for indications for bariatric surgery and measurement of obesity respectively.

PATHOPHYSIOLOGY OF OBESITY

Obesity is a poorly understood disease. Currently much investigation is ongoing to try and determine the aberrancies that occur both at a cellular level and at the level of the intact individual to determine its manifestations. It is hoped that such research will provide insights as to treatments for the metabolic consequences of obesity, as well as treatments for the metabolic causes of it. Until such time, however, individuals who develop obesity are highly susceptible to also developing one or more of the medical illnesses associated with obesity. These are listed in Table 27-2. It is these comorbid medical problems that jeopardize the length and quality of the lives of individuals with obesity and especially severe obesity. It is estimated that a male who is severely obese from childhood will live an average of 12 years less than his nonobese counterpart, while for a woman the difference is 9 years.[9] There is some variability by race and sex as to the consequences of obesity on health. The consequence of being a male patient with severe obesity and its limitation of lifespan is shown in Table 27-3, which gives the percentage of the population in the United States with severe obesity based on age and sex. Note that old males do not represent as high a

TABLE 27-2: MEDICAL DISEASES ASSOCIATED WITH OBESITY

General	Increased mortality risk
	Poor wound healing
Cardiovascular	Hypertension
	Hyperlipidemia
	Hypercholesterolemia
	Atherosclerosis
	Coronary artery disease
	Congestive heart failure
	Venous stasis disease
	Cardiomyopathy
	Left ventricular hypertrophy
Pulmonary	Obstructive sleep apnea
	Obesity hypoventilation syndrome
	Asthma
	Pulmonary hypertension
Gastrointestinal	Nonalcoholic fatty liver disease
	Gastroesophageal reflux disease (GERD)
	Cholelithiasis
Renal	Stress urinary incontinence
Musculoskeletal	Osteoarthritis
	Gout
	Back pain
Neurologic	Stroke
	Pseudotumor cerebri
	Carpal tunnel
Metabolic/endocrine	Type 2 diabetes
	Metabolic syndrome
	Infertility
	Polycystic ovarian syndrome
Neoplastic	Cancer of the esophagus, stomach, liver, pancreas, kidney, gallbladder, colon, rectum, uterus, cervix, ovaries, breast, prostate; multiple myeloma; non-Hodgkin's lymphoma
Other	Depression
	Hypercoagulable state
	Proinflammatory state
	Intertrigo
	Lymphedema

TABLE 27-3: INCIDENCE OF SEVERE OBESITY IN THE UNITED STATES BY AGE AND SEX

Age	20–39	40–59	60+
Male	3.3%	3.9%	1.7%
Female	6.4%	7.8%	5.6%

Data from Hedley, Ogden CL, Johnson CL, et al. Prevalence of overweight and obesity among US children, adolescents, and adults, 1999–2002. *JAMA*. 2004;291:2847–2850.

percentage of the population as females, largely because they are already dead of their comorbid medical diseases. Flum et al[10] showed that for males with Medicare insurance (and hence disabled if under age 65) undergoing bariatric surgery, the average mortality during the year after surgery was 6.4% for males age 18–65.

In addition to medical illnesses commonly associated with obesity, there is an increased incidence of certain types of malignancy in obese individuals. Cancers of the uterus, breast, prostate, and pancreas are all increased in this patient population.

Finally, among the major reasons for individuals to seek surgical therapy for severe obesity, lifestyle issues are often more important than medical problems. The loss of ability to perform common daily activities, the inability to participate fully as a parent, the lack of ability to perform on the job, and the social discrimination against obesity are all often cited by patients as the primary reason they seek surgical therapy for this condition.

Deciphering the likely multifactorial causes of the pathophysiology of obesity has given rise to several lines of investigation. Alterations of metabolism at the cellular level, genetic predispositions and patterns, and environmental influences all likely are active in contributing to the disease process etiology and mechanisms. The focus of this text is not on that subject, but a few observations from many years of clinical practice are offered. Certainly the alteration in satiety has to be forefront among the abnormalities in individuals with severe obesity. Appetite is often insatiable in these individuals, despite high-calorie intake daily. Body fat distribution is known to affect the incidence of comorbid problems. For example, the incidence of the metabolic syndrome is much higher in individuals with central obesity than those with pear-shaped body habitus. Higher amounts of organ fat and omentum are associated with conditions such as metabolic syndrome and diabetes. Genetic analysis of the different properties of adipose tissue is ongoing. Considerable investigation has been focused in the past 5 years on the mechanisms of rapid improvement of type 2 diabetes after Roux-en-Y gastric bypass. Such mechanisms almost certainly involve alterations in glucose metabolism by peripheral tissues based in turn on the altered pathway of food through the upper gastrointestinal tract. This gut influence on glucose metabolism is now under intense scrutiny. Hopefully one day the mechanisms of appetite regulation, satiety, and metabolism of adipose tissue will be better understood. When they are, perhaps we will have a better understanding of the complex disease process that is obesity.

MEDICAL THERAPY FOR OBESITY

All individuals with the problem of obesity need to make modifications in their eating habits, lifestyle, and exercise habits as a lifelong commitment to overcoming the disease. For individuals with class 1 obesity, such modifications have the possibility of altering weight and in turn altering the health risk of comorbid medical problems enough to make a difference in the toll that comorbid medical problems take on their life and health. However, as the amount of obesity increases, modest weight loss from medical therapy is less likely to make a profound difference in health. It is also less likely to be successfully sustained. The figure generally given for the likelihood of a severely obese individual successfully losing enough weight by dieting to become only obese or overweight is approximately 3%. In short, medical therapy is highly unlikely to be successful in reversing the problems of severe obesity. Nevertheless, because medical therapy has little risk involved (except the time lost from the benefit of potentially more effective therapy), it is uniformly agreed that a trial of medical therapy should occur first in any individual with morbid obesity prior to the use of surgical therapy. Unfortunately, this practice is not data-driven, but driven instead by the practicality of attempting the less risky and invasive therapy first prior to one that is more invasive. In reality, there are extraordinarily few patients who seek bariatric surgery who have not had multiple attempts at dieting during their lifetime. The motivation of those few individuals who have never dieted must be questioned, as they often perceive of surgery as a "magic bullet" which will eliminate obesity but not require any other changes in eating habits or lifestyle to produce or sustain these effects.

The role of medical therapy in the sense of dieting, exercising, and otherwise attempting to control weight by nonsurgical means is often not addressed further in texts on bariatric surgery beyond the simple statement that it is effective therapy in a minority of cases. However, it is our opinion that no surgical therapy can hope to have long-term effects without an accompanying change in eating and exercise habits by the recipient of the operation. Even the most effective bariatric operation can have its weight loss benefits mitigated over time by the patient who will not adapt better eating and exercise habits. Fortunately, the physical and mental metamorphosis that accompanies the postoperative period after bariatric surgery is usually profound enough in most patients to reinforce the need to make such changes to preserve this alteration in body habitus and health. The typical mindset of the long-term successful postbariatric surgery patient is that he or she will never allow themselves to go back to being severely obese again, now that they have been given the chance to be relatively normal in weight, had their medical diseases go into remission, and enjoy a lifestyle free of the burdens of obesity. Such a mindset is usually successful in maintaining the benefits of bariatric surgery. When patients do not have enough metamorphosis or if they regress to poor eating habits and stop exercising, erosion of the benefits of the operation is inevitable and they eventually join the estimated 30% of patients who regain weight and ultimately are considered to have failed bariatric surgery. The exact formula for bariatric surgery success is not well defined, but it includes selection of a motivated patient, success of the operation to produce significant physical, mental and medical changes, and the persistence of the patient in maintaining exercise and diet habits to preserve these changes. Thus surgical therapy

is truly only part, though the pivotal part, of the long-term success of therapy for the patient with severe obesity. Attention to the follow-up of patients, maintaining motivation to sustain appropriate exercise and diet habits, and any other such supportive measures that can be done postoperatively can all help ensure long-term success of bariatric surgery. In this sense, the "medical" treatment of obesity is quite important as an adjunct to maintaining the benefits achieved by surgical weight loss.

SELECTION OF PATIENTS FOR BARIATRIC SURGERY

The basic guidelines generally adhered to for performing bariatric surgery were defined by the NIH Consensus Conference in 1991.[6] Eligible patients must have a BMI of greater than or equal to 40 kg/m^2 or a BMI of greater than or equal to 35 kg/m^2 and the presence of a disease caused by or exacerbated by obesity such as diabetes, hypertension, or other comorbidities. Beyond these basic criteria, most centers advocate that the patient have the ability to understand the planned procedure and the major changes it will cause in eating and the required changes in diet and exercise to optimize results. The patient should be appropriately motivated. Areas less well defined, but which usually have some limitations from center to center, include age, upper limit of weight, substance abuse, psychiatric history and problems, compliance problems, ambulatory status, and severity of comorbid medical conditions.

While all patients should be given information on the types of available operations, some operations may be more appropriate or effective or feasible as the procedure of choice for a patient, depending on the individual circumstances. The expertise and ability of the bariatric surgeon is another factor that affects operative choice for many patients. The relative advantages and disadvantages of the various operative procedures are discussed within their following respective sections.

Unfortunately, often the operative procedure that a patient undergoes for weight reduction is governed by the procedures that his or her insurance company will cover. Access to surgery for patients is currently limited by numerous factors. Many insurance companies have set a variety of preoperative requirements for patients otherwise medically qualified for bariatric surgery. These include the need to follow a medically supervised diet for 3–12 months, the need for a psychological evaluation, and other measures. Available evidence suggests that these requirements add no benefit to operative outcomes, and if anything delay potentially helpful surgical intervention.[4,11] Their presence does serve as a deterrent for patients who may not be fully motivated or otherwise do not have the ability to meet these additional requirements. Some insurance companies will require a psychological evaluation, for example, but not cover the cost of such an evaluation.

Information about bariatric surgery and the availability of bariatric surgeons to the public as well as to the referring physician is now much more easily obtained than even a decade ago, and certainly much more available than two decades ago. Internet websites of bariatric societies, physician provider networks, hospital providers, and others all offer information on available surgeons. Use of search engines will usually produce surgeons in a prospective patient's geographic area.[12]

Access to care is still an issue for some patients with certain forms of insurance coverage. Some patients have policies that exclude bariatric surgery. Others have policies that include it only if the patient or their employer pays a significant fee for a rider to the policy. Even if a patient has coverage, some insurance policies, such as Medicare, reimburse the surgeon at such a low rate that only surgeons serving on the staff of public health care institutions will offer surgical care to such patients.

Once a patient is seen by a bariatric surgeon who will offer surgical services, the choice of operation is usually determined by a combination of any insurance restrictions, procedures offered by that surgeon, and patient interest. Medical comorbidities and conditions can affect operative choice as well. Limitations of indications of the various bariatric operations in terms of efficacy and overall outcomes and effectiveness are discussed with each individual operation in the following text.

PREOPERATIVE PREPARATION

Patients who are preparing for bariatric surgery need preparation for surgery in two major areas:

1. Specific knowledge about the planned bariatric operation and its expected outcomes, course, and potential complications and side effects
2. General preparation for a major surgical operation, including maximization of treatment of existing comorbid medical problems

Specific knowledge of the planned bariatric operation allows the patient to prepare for the changes in diet, lifestyle, daily activities, exercise patterns, and body image that will occur after the operation. *No bariatric operation will produce optimal long-term results without significant changes in diet, exercise, and lifestyle by the patient.* Hopefully, the combination of the power and durability of the operation to force an effective change in eating patterns, a decrease in appetite, an increase in satiety with eating, and a change in exercise patterns by the patient will serve to create an adequate metamorphosis of the patient and his or her lifestyle to promote a mindset that is strong enough to sustain these changes and resist any intrinsic genetic or behavioral tendency for recidivism to previous eating patterns that resulted in the preoperative morbidly obese condition. This alteration of the patient's physical and mental state of being is inherently necessary for the long-term success of bariatric surgery. Fortunately, such an alteration is achieved and sustained in the majority of patients who undergo bariatric operations. A frequently heard quotation from patients who are years out from bariatric surgery and who have successfully maintained weight loss and reversal of their comorbid

medical conditions associated with obesity is, "I will never go back to being the way I was before."

While not essential, personal interaction by prospective patients with other patients who have successfully undergone the same bariatric operation they are planning to undergo can be very helpful in terms of reassurance for likely success, as well as information exchange. The more the prospective bariatric patient is educated and familiar with the expected postoperative course of events, the more likely they will be to have less preoperative anxiety and more compliance with recommended postoperative treatment plans. Such interactions can be facilitated by support groups, Internet chat groups, and personal relationships. The surgeon and his or her staff should always inquire as to the support network available to the patient after surgery and their potential interaction with other individuals who have undergone the same operation. In our practice, we become concerned when a patient is pursuing bariatric surgery in opposition to the wishes of their family and/or spouse. While such patients may be strong-willed enough to do well postoperatively, if any complications result, there is often a significant adverse reaction by the family in these circumstances. Certainly the patient's wishes should always prevail, but a word of caution in such situations is in order.

LAPAROSCOPIC ADJUSTABLE GASTRIC BANDING

Procedure-specific preparation prior to surgery is always indicated. For patients planning to undergo Lap-Band (Allergan, Inc., Irvine, CA) procedures, we have found the following list of criteria tend to produce the optimal results after this operation:

1. Patient is able and willing to undergo the recommended schedule of band adjustments. This includes the coverage for such adjustments by their insurance carrier. Lack of such coverage inevitably leads to decreased compliance with suggested follow-up, and often less optimal results.
2. Patient is able and willing to undergo a regular exercise regimen. Our experience shows a strong correlation between exercise and postoperative weight loss for patients undergoing laparoscopic adjustable gastric banding (LAGB).
3. Patients expected and optimal weight loss is in the 100 lb or less range. We have found, and the literature supports, the fact that patients whose weight is over approximately 350 lb, and who have a BMI over 50–55, have a less optimal outcome after LAGB than those who have lower preoperative BMI and expected weight loss.
4. Patient can maintain a "dieter's mentality". This is usually documented by the fact that the patient has had at least one previous episode in their life of successful dieting, sustained over greater than 6 months. While the obvious fact is that such a diet did not have long-term effectiveness due to the patient now planning LAGB, the fact that LAGB is a relatively, but not overwhelmingly, powerful suppressant of appetite in patients makes this requirement important. The patient who can diet successfully without any appetite suppression is likely to be able to maintain an appropriate eating pattern after LAGB, which suppresses but does not eliminate appetite in most patients.
5. The Lap-Band is an excellent operation for the patient whose BMI is 50 or less, and who has no severe comorbid condition better treated by an alternative operation (such as severe diabetes better treated with a gastric bypass). Patients who have a BMI over 50 may do well with a Lap-Band, provided they do exercise and the band provides adequate suppression of appetite to alter eating habits. Most series in the literature reporting LAGB outcomes have either a limited number of patients with BMI over 50 or have a decreased success rate of the operation in that patient population.

LAPAROSCOPIC ROUX-EN-Y GASTRIC BYPASS

1. Patients who choose this as their bariatric operation of choice must be prepared to undergo a significant change in their eating pattern and ability. Laparoscopic Roux-en-Y gastric bypass (LRYGB) is a very powerful operation, usually eliminating appetite in most patients for a period of at least several months and altering the ability to intake food volume dramatically in most cases. Patients who rely on food as a significant psychological crutch may find the altered eating pattern forced on them to be a particular problem. However, most often the patient is delighted by the elimination of appetite and the rapidity of weight loss with concurrent resolution of comorbid medical conditions.
2. Patients planning LRYGB must understand that the operation will intrinsically limit their ability to absorb the critical nutrients of iron and calcium.
3. LRYGB is now the most commonly performed bariatric operation in the United States, and for good reason. The operation has the longest track record of continuous use, having first been performed in the late 1960s in slightly different form and of course using an open surgery approach in those days. Modifications to the operation have improved it, but not changed the basic essence of a largely restrictive operation with reduction in the gastric reservoir capacity to a minimal volume. In addition, the gastrojejunostomy of the proximal gastric pouch eliminates the pyloric sphincter's regulation of slowly delivering food to the small intestine, resulting in variably profound dumping syndrome in these patients. While the dumping is often ameliorated with time, its initial presence usually is instrumental in forcing a behavioral modification in eating habits by patients, which involves the avoidance of highly concentrated sweets in their diet.
4. Other benefits generated by the anatomic alteration of the gastric bypass include a profound improvement in insulin sensitivity in patients with type 2 diabetes due to elimination of food substances passing through the duodenum. Gastroesophageal reflux disease (GERD) is also resolved in over 90% of patients after gastric bypass, because the

volume of available gastric acid or secretions from the diminutive proximal gastric pouch is minimal. The operation thus is particularly indicated or effective for severely obese patients who suffer from GERD or type 2 diabetes.

5. It is an effective operation for the patient who needs to lose a significant amount of weight and is not a candidate for a malabsorptive operation. Overall, gastric bypass avoids the majority of the metabolic complications inherent in malabsorptive operations, yet is powerful and durable enough to provide good weight loss even in superobese individuals.
6. Gastric bypass has few contraindications. It does limit iron absorption, so it may not be a good choice for the patient with preexisting significant iron deficiency anemia. In populations where there is an appreciable incidence of gastric cancer, it may also not be a good choice as it eliminates the ability to monitor the majority of the stomach for potential development of that disease.
7. Performing gastric bypass using a laparoscopic approach has resulted in drastic reduction in the most common postoperative complication after open Roux-en-Y gastric bypass (RYGB)—that of incisional hernia. Wound infections are less severe. Benefits established for laparoscopic versus open operations of other types also apply to LRYGB, such as quicker return to normal activities, decreased pain, and so forth.

LAPAROSCOPIC SLEEVE GASTRECTOMY

1. The laparoscopic sleeve gastrectomy (LSG) is the most recent addition to the armamentarium of operations used by bariatric surgeons. Its adoption as a commonly performed operation is only evolving. Few centers had a large experience with the operation more than 3 years ago. The longest published follow-up data in the literature show only a small number of cases followed out to or beyond 5 years. The operation is, as with all primary bariatric operations, optimally performed laparoscopically, hence LSG.
2. LSG is a restrictive operation. It is technically easier to perform, in general, than LRYGB and avoids the risk of two anastomoses. It is more invasive than LAGB, as it involves resection of the majority of the stomach. Data to date show that the operation has a risk profile between that of LAGB (safest) and LRYGB for frequency of potentially severe complications.
3. Not all insurance companies currently cover LSG. Federal insurance and some other major private insurance companies still do not provide coverage for this operation.
4. The LSG originally had its birth as the first of a staged procedure to perform a laparoscopic duodenal switch (LDS) operation with less morbidity. Original experience with LDS showed a higher mortality rate than expected. LSG was then adopted as the first stage of the operation, to be followed by the malabsorptive component after initial weight loss.[13] The success of the LSG caused many patients to decline the second step and led to the adoption of LSG as a primary procedure.
5. Concerns still remain among experienced bariatric surgeons that this operation bears a strong resemblance anatomically and functionally to the vertical banded gastroplasty, which was a very popular bariatric operation two to three decades ago. It has been largely abandoned for poor long-term weight loss results.
6. Candidates for LSG would be patients appropriate for a restrictive operation of almost any weight class above or including class 2 obesity. Because its initial use was in higher-weight individuals felt to be candidates for the DS procedure, LSG is technically feasible on very large patients, a positive factor from the bariatric surgeon's viewpoint. Published data show LSG is also effective as a primary operation for patients with BMI less than 50.[14,15]

LAPAROSCOPIC DUODENAL SWITCH

1. This operation has been the least frequently performed of the commonly approved and accepted bariatric operations. It is technically the most challenging of the bariatric operations and is associated with both the highest durable weight loss as well as the highest frequency of complications, especially when metabolic complications are considered as well.
2. Laparoscopic duodenal switch (LDS) causes relative malabsorption of fats and proteins. Fat-soluble vitamins as well as the elements iron and calcium are not well absorbed. Supplements to replace these vitamins and minerals are indicated postoperatively. These supplements can be expensive.
3. Patients undergoing malabsorptive operations require close and long-term follow-up, due to the high potential for metabolic deficiencies and problems that may arise after such procedures.
4. Another malabsorptive operation, the biliopancreatic diversion (BPD), is now less frequently performed than the duodenal switch (DS), due to its higher incidence of marginal ulcers.[16] Both operations involve comparable rearrangement of the alimentary tract distal to the duodenum, with the gastric resection for BPD being distal, while for DS it involves the greater curvature.
5. Most patients who are felt to be candidates for LDS are those with higher weights initially, who are felt to likely not achieve adequate weight loss with a restrictive operation alone. Patients with preoperative BMI over 60 certainly should be considered for such procedures if the patient is able to be closely followed and is willing and able to take required nutritional supplements. Patients interested in the most effective operation for large amounts of weight loss who are willing to accept the increased risk profile are candidates for LDS.
6. The technical difficulty of this operation as well as the concern for follow-up requirements has limited its performance to only certain centers specializing in this procedure or centers where it is offered as a choice among other bariatric operations.

OPERATIVE DESCRIPTIONS AND OUTCOMES

Laparoscopic Adjustable Gastric Banding

Laparoscopic adjustable gastric banding (LAGB) for the treatment of morbid obesity was first described independently by Kuzmak in the United States and Halberg and Forsell in Sweden.[17,18] The band is an inflatable silicone balloon placed around the proximal stomach connected by thin tubing to a reservoir implanted subcutaneously usually on the abdomen. The reservoir is accessed via a noncoring needle to adjust the diameter of the balloon. In 2001 the Food and Drug Administration approved for use the one band currently marketed by Allergan called the Lap-Band, and subsequently the Swedish band was added in 2007, which is now marketed by Ethicon and called the Realize band. The bands can be placed either laparoscopically or open although most authors will argue for the laparoscopic route. Recently the FDA also approved the use of the Lap-Band for use in patients with a BMI 30–35 with comorbid medical problems or a BMI greater than 35 without comorbid medical problems.

OPERATIVE PROCEDURE

The preoperative evaluation and indications are similar for any bariatric operation and are described previously in the chapter. The patient should receive appropriate perioperative antibiotics as well as deep venous thrombosis prophylaxis. The patient will need to be positioned comfortably on the operating table with care taken to ensure the patient cannot slip when placed into steep reverse Trendelenburg's position.

Port number and position vary among surgeons. We describe what works in our practice. The pneumoperitoneum is established in the left upper quadrant, at the midclavicular line, one hand breath below the xiphoid. We prefer to use a Veress needle through an incision just large enough to admit a 15-mm trocar. We elevate the fascia with a tracheostomy hook that facilitates insertion of the needle into the appropriate space. Alternatively, access can be gained with an optical viewing trocar; this is again dependent on surgeon experience and preference. Once pneumoperitoneum is established, the abdomen is inspected for any evidence of injury. Additional trocars are placed. We place a 12-mm port for the camera in the midline approximately 15 cm from the xyphoid. A 5-mm port is placed in the right upper quadrant for the surgeon's left hand. A 5-mm port in the left upper quadrant is placed for the assistant and a port in the epigastrium is placed to assist in retracting the left lobe of the liver (Fig. 27-1).

The patient is placed in steep reverse Trendelenburg and dissection is begun with either the hook cautery or a harmonic scalpel at the angle of His. The peritoneum over the left crus and the gastrophrenic ligament is opened, and the dissection is carried down into the retrogastric fat. The gastrohepatic omentum is then opened in its avascular area, the *pars flaccida*. This allows exposure of the base of the right crus. If a hiatal hernia is appreciated, it should be repaired at this point and a standard posterior esophageal dissection is performed with suture closure of the crura. If no hernia is found, the peritoneum over the right crus is incised just wide enough to allow a grasper (Lap-Band) or the gold finger (Realize band) to pass (Fig. 27-2). It is important to note that these instruments should pass into the left upper quadrant in the previously dissected space with ease; any resistance indicates a wrong dissection plane. The grasper is passed just cephalad to the attachments of the proximal stomach to the retroperitoneum, thus remaining outside the lesser sac. Positioning the band in this space has decreased posterior slippage or prolapse of the gastric band. Once the instrument is visualized in the left upper quadrant, the band is placed into the abdomen through the 15-mm port. The tubing or suture is grasped and pulled through behind the stomach, pulling the band into place posteriorly (Fig. 27-3). The band is then buckled into its

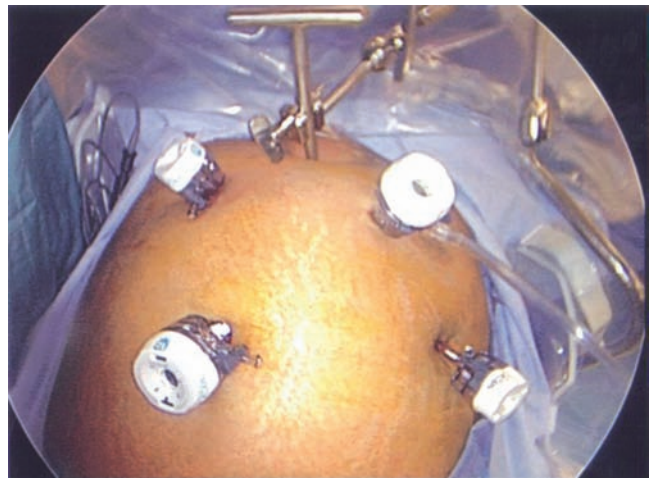

FIGURE 27-1 Port positions for laparoscopic adjustable gastric banding (LAGB).

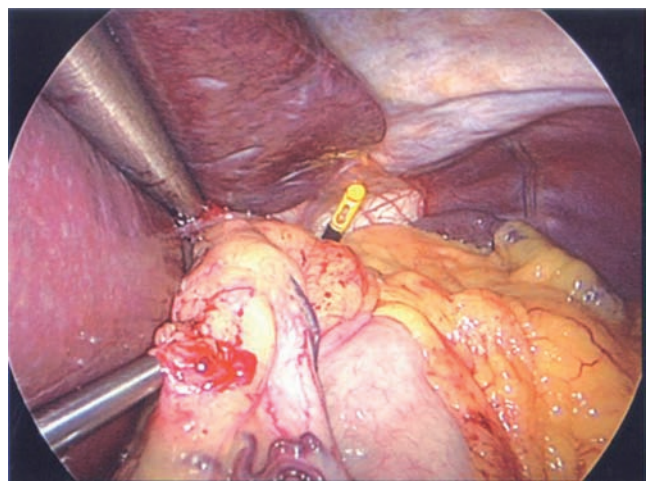

FIGURE 27-2 Passing grasper behind stomach.

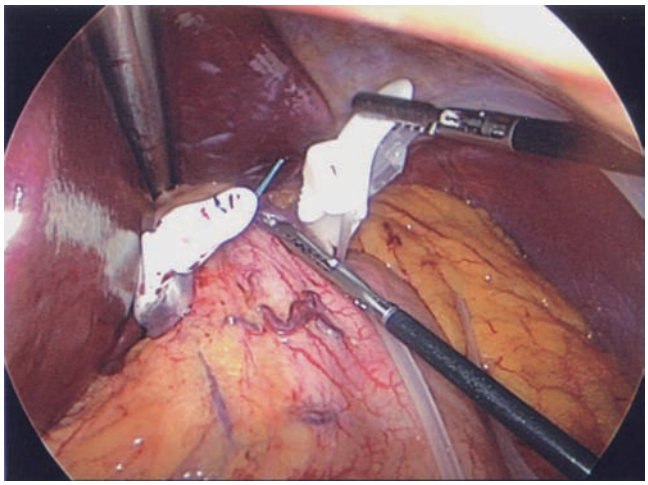

FIGURE 27-3 Pulling band into place.

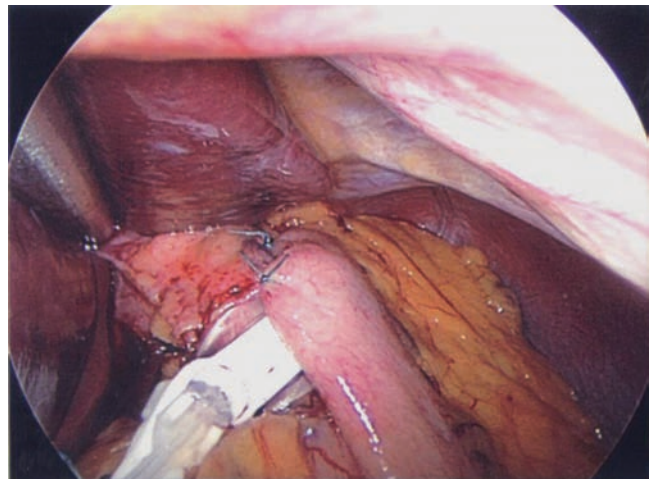

FIGURE 27-5 Suturing fundus imbrication sutures.

ring configuration (Fig. 27-4). Gastrogastric plication sutures secure the anterior fundus to the small portion of the stomach (optimally about 1–2 cm) above the band (Fig. 27-5). Usually two to three sutures are sufficient. It is important to not cover the buckle of the band as this may lead to band erosion. The tubing is removed from the abdomen through the epigastric or 15-mm port, depending on the surgeon's preference, and attached to the reservoir port. The reservoir port is secured to the abdominal wall fascia (Fig. 27-6). It is important to place the port in as thin a portion of the abdominal wall as possible to facilitate future access. The band system is accessed percutaneously with a Huber needle (Piwania Technologies Pvt. Ltd., New Delhi, India) to add and withdraw to confirm reservoir capacity and rule out leakage. All fluid is then removed from the reservoir at the end of the procedure, to be added later in adjustments postoperatively. It is recommended to begin with the band system empty so as not to have too much restriction initially for the patient.

POSTOPERATIVE CARE

The LAGB is now primarily performed as an outpatient procedure, unless medical or insurance issues require an overnight stay. Preoperatively and prior to discharge, the patient as well as family members should receive instructions on diet, activity, and pain medications. Instructions should be given on when and whom to call in case of emergencies. The patient is discharged on a liquid diet for 2–3 weeks. We usually see our patients back at this time to check the wounds and advance the diet. The diet is advanced to a soft diet and medications are checked as well as comorbidities. A multivitamin is recommended as sufficient supplementation as LAGB does not cause nutritional deficiencies seen in other bariatric procedures. Patients are often ready to return to work, if they have not done so already.

The success of LAGB depends on adjustments, adherence to dietary changes, and exercise. The timing of adjustments varies among surgeons; however, there is wide agreement that

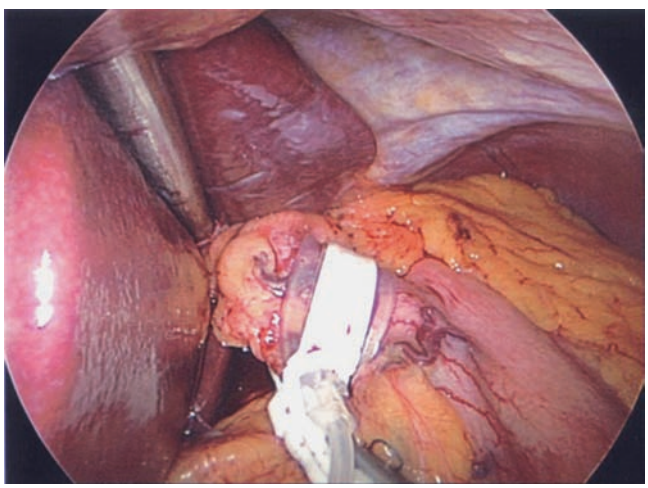

FIGURE 27-4 Buckling band.

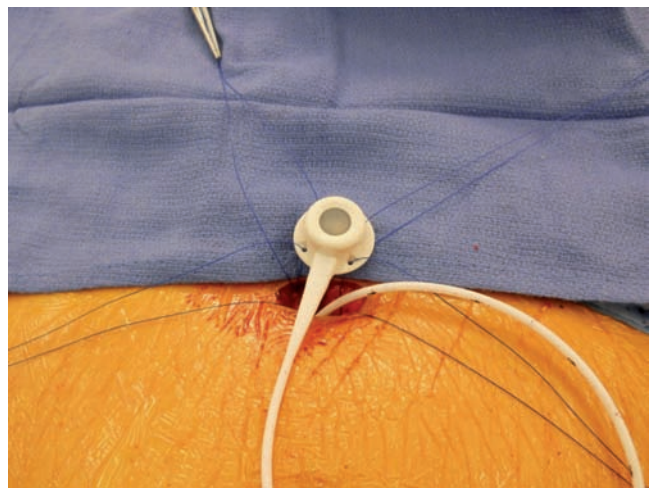

FIGURE 27-6 Securing reservoir to fascia.

the goal rate of weight loss is 1–2 lb/wk. Less weight loss, later satiety, or larger meal size are indications that an adjustment may be in order. This is done after careful evaluation of the patients' weight, dietary history, and exercise.

Band adjustments are typically office-based minor procedures. On occasion fluoroscopic assistance may be required to access the port or evaluate the restriction of the band. There are several adjustment algorithms, with the amount of fluid added based on hunger, weight loss, ability to eat bread, and type of band.[19] This is an area that is frequently more art than science.

OUTCOMES

Outcomes after LAGB are generally good in terms of weight loss and resolution of comorbidities versus significant adverse problems. The average weight loss for the larger series in the literature is usually reported for % excess weight loss (%EWL) at 1, 2, or multiple years after surgery. Generally speaking, patients undergoing LAGB will have a slower weight loss curve and take longer to achieve maximum weight loss than patients with either RYGB or LSG or DS. Figure 27-7 illustrates the weight loss curve for one such series.[20] The %EWL at two years after surgery has been reported in the 45–55% range from various authors.[21–23] Resolution of medical comorbidities is certainly seen after LAGB. Perhaps the most heralded study on this topic is the prospective randomized trial by Dixon et al[24] in which the group of patients with type 2 diabetes showed as 73% remission rate of their disease 2 years after undergoing LAGB, as opposed to the control group that had a very low resolution rate. Other comorbidities are improved as well after LAGB and generally correlate with successful weight loss.

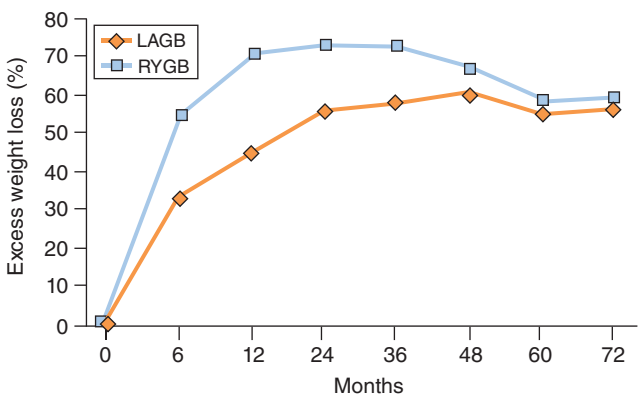

FIGURE 27-7 The percentage of excess weight loss after Lap-Band surgery and a comparison of Roux-en-Y gastric bypass (RYGB). Data include all published series with initial recruitment of at least 50 patients reporting data at least 3 years or more following surgery. There were eight RYGB studies and seven laparoscopic adjustable gastric banding (LAGB) studies. (From Dixon JB, O'Brien PE. Laparoscopic adjustable gastric banding: outcomes. In: Schauer PR, Schirmer BD, Brethauer SA, eds. *Minimally Invasive Bariatric Surgery.* New York, NY: Springer; 2007:190.)

Optimal outcomes for patients with LAGB seem to be correlated with frequent band adjustments, participation in support groups, and regular physical exercise.[25]

COMPLICATIONS

Complications following gastric banding include prolapse or slippage, erosion, port or tubing complications, over-filling of the band, esophageal dilation, and weight loss failure.

Prolapse or slippage is the most common complication requiring reoperation. The mechanics of the process are that too much gastric tissue from below the band lumen pushes up through the band circumference (prolapse) or, similarly, the band slips down on the stomach further than desired, resulting in too much stomach above the circumference of the band (slippage). The effect of both is similar: the excess tissue causes almost immediate complete food intolerance if severe, or heartburn and moderate food intolerance if not severe. New onset of GERD symptoms in an LAGB patient strongly suggests prolapse, which should be ruled out.

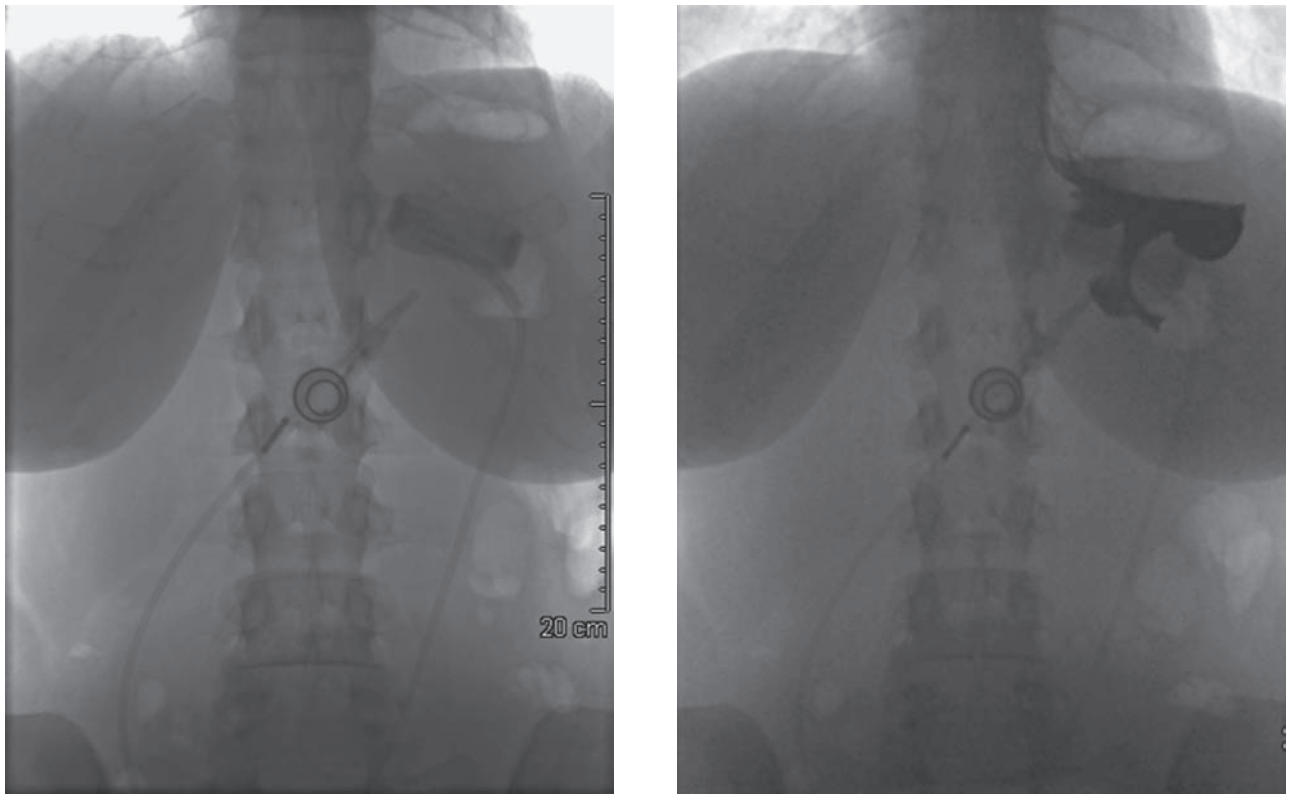
Diagnosis of prolapse begins with the above clinical picture. A plain radiograph will usually show the band in an abnormally horizontal position (Fig. 27-8A). Barium swallow will show a significantly greater amount of stomach above the band than would be expected, confirming the prolapse (Fig. 27-8B). The prolapse can be anterior or posterior.

Initial treatment of the prolapse is withdrawal of all fluid from the band. This will often allow the prolapse to spontaneously resolve. Radiographic confirmation of this can be performed. If symptoms persist and radiographic evidence shows persistence of the prolapse, operative intervention to reduce the prolapse is indicated. This can usually be done laparoscopically. Often, the band must be unbuckled to allow full reduction of the prolapse. Repositioning the band and resuturing the fundic plication to maintain its position complete the operation.

Band erosion is an uncommon problem, occurring in 1% or less of most large series.[26] Band removal and repair of the erosion, with appropriate antibiotic and supportive care, are indicated.

Esophageal dilation is perhaps one of the most severe complications that may result from LAGB. This complication arises when the band position is too high, restricting the distal esophagus instead of the proximal stomach. The incidence is in the 1–2% range in most series. Reflux, dysphagia, pain, and food intolerance may be presenting symptoms. Resultant dilation of the esophagus occurs. Esophageal motor dysfunction may occur if the condition becomes longstanding. Treatment for the problem, once discovered, is to immediately remove all fluid from the band, minimizing the restriction and obstruction. Hopefully this will reverse the dilation of the esophagus, and restore function. Band repositioning may be needed to prevent recurrence of the problem.

Port and tubing problems occur from 2–5% in most series.[26] These are usually issues that can be repaired with procedures under local anesthesia or limited intervention under general anesthesia. Repositioning the reservoir that tilts to a



A B

FIGURE 27-8 **A.** Picture of a plain film of a prolapsed band with the port flat. **B.** Picture of UGI showing band prolapse.

position that does not allow access is a not uncommon problem. Care in attaching the reservoir to the fascia at the index operation is the best prevention of this problem.

Band overfilling is usually an easily correctable problem. When the adjustment is done, the patient may not have immediate symptoms. However, dysphagia ensues within the next day, and persists. Removal of all or most of the fluid added from the last adjustment will usually promptly resolve the problem.

Poor weight loss is, unfortunately, a problem with all bariatric operations. However, some centers have experienced an unusually high incidence of poor weight loss in their LAGB patients. We have found that attention to the criteria listed previously for selection has decreased but not eliminated the incidence of individuals with poor weight loss. While our institutional band removal rate is well under 5%, there are well over 15% of our patients who have had poor weight loss (as defined by <25% EBW) after LAGB. Some centers in Europe, which have had over a 15-year experience in LAGB at this time, are reporting an increasing incidence of abandoning the use of LAGB because of poor long-term efficacy.[27] On the other hand, in Australia, LAGB is by far the main bariatric operation used, and the outcomes from that continent are generally the best published.[28]

Nutritional complications after LAGB are rare and are solely based on poor intake. LAGB does not alter the digestive process whatsoever, and hence there is no malabsorption of any nutrients. A standard multivitamin supplement is all that is necessary for patients following LAGB.

Laparoscopic Sleeve Gastrectomy

Laparoscopic sleeve gastrectomy (LSG) is the most recently recognized standard bariatric operation performed. The American Society for Metabolic and Bariatric Surgery recognized the procedure as being an appropriate standard operation for the surgical production of weight loss in 2009.[29] The operation is now rapidly increasing in popularity in the United States and is currently the third most common procedure performed (after LRYGB and LAGB). Insurance reimbursement is still not uniform for all carriers, which has likely limited its rise in popularity to some extent. It is predicted that recognition and reimbursement by all major insurers in the near future will lead to its increasing performance over the next several years. Midterm data are available in a few instances, but most of the reported results thus far for the procedure are short-term results. As with all bariatric operations, long-term data will solidify or nullify this operation's position as a standard bariatric operation in the years ahead.

Patient selection for LSG, described previously, varies widely based on surgeon experience and alternative operations available to the patient by the treating surgeon, as well as patient preference and insurance reimbursement capacity.

OPERATIVE PROCEDURE

The patient is positioned supine, with adequate support of the feet and legs such that reverse Trendelenburg's position is safely possible. The operating table must have capacity to safely maneuver with the largest of patients on it; hence hydraulic control is essential. The surgeon stands on the patient's right side, the assistant on the patient's left side, and the camera operator adjacent to the surgeon, on his or her right. A suggested port configuration is given in Fig. 27-9. Port placement can be varied, however. There are reports now in the literature of single-port performance of this procedure, with three instruments being placed through an enlarged single umbilical port.[30]

The LSG begins by dividing the blood supply along the greater curvature of the stomach, beginning at a point approximately 5 cm proximal to the pylorus on the greater curvature of the stomach. The gastroepiploic vessels are divided as they come off the greater curvature of the stomach, proceeding from distal to proximal along the greater curvature. An ultrasonic scalpel or other specialized energy device is used; electrocautery is insufficient to secure hemostasis of these vessels (Fig. 27-10). The division of vessels continues with the short gastric vessels, until the top of the greater curvature of the stomach is reached and a complete devascularization of the greater curvature above the distal antrum has been achieved.

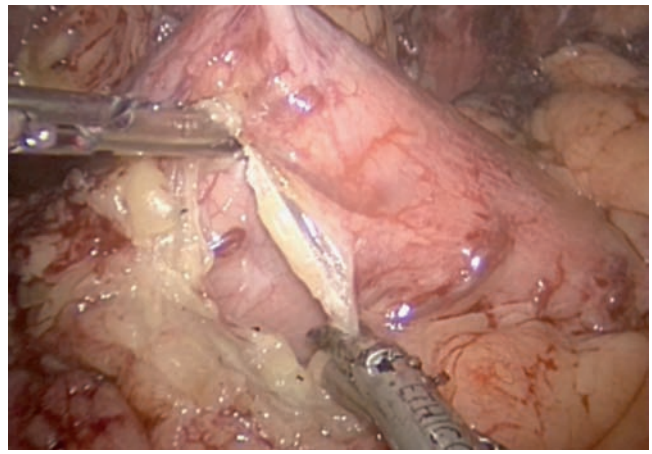


FIGURE 27-10 Dividing the greater curvature vessels during laparoscopic sleeve gastrectomy (LSG) with a harmonic.

A bougie, dilator, or comparable space-occupying device (some surgeons prefer a flexible endoscope) is positioned along the lesser curvature of the stomach. This bougie may be in the 32–40F range, based on surgeon preference and experience. The smaller the bougie, the better the postoperative weight loss, but also the greater the potential for a stricture of the gastric channel. A linear stapler is now used to begin dividing the stomach. In the antrum area, the height of the staples used should be longer than in the upper stomach. Division of the stomach is begun from the area where devascularization was initiated. The stomach is divided adjacent to the bougie or endoscope, leaving only a relatively narrow tube of lesser curvature stomach to serve as the passageway for ingested food (Fig. 27-11). Care should be taken not to divide the proximal fundus portion of the stomach too close to the gastroesophageal junction and the angle of His. Devascularization of this narrow segment of tissue may produce

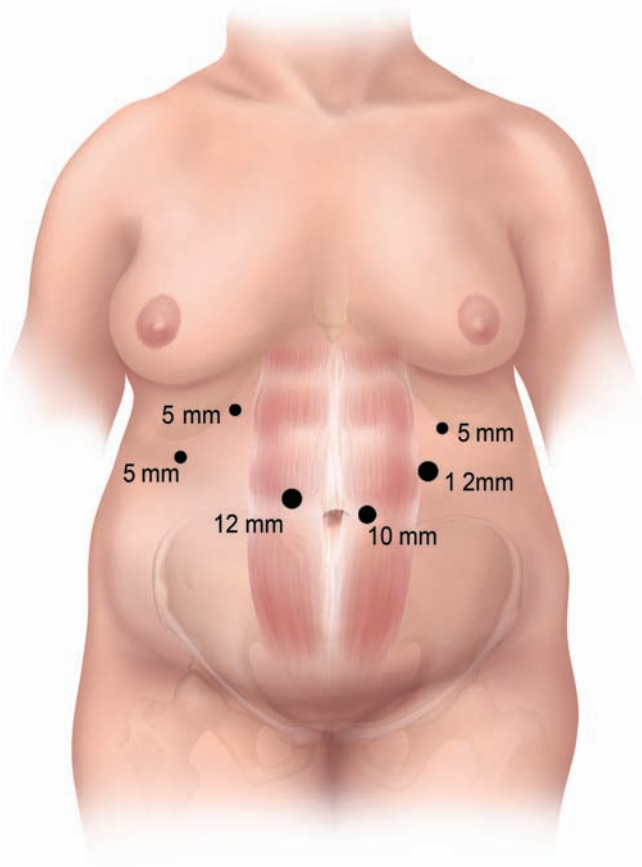

FIGURE 27-9 Picture of ports for laparoscopic sleeve gastrectomy (LSG).

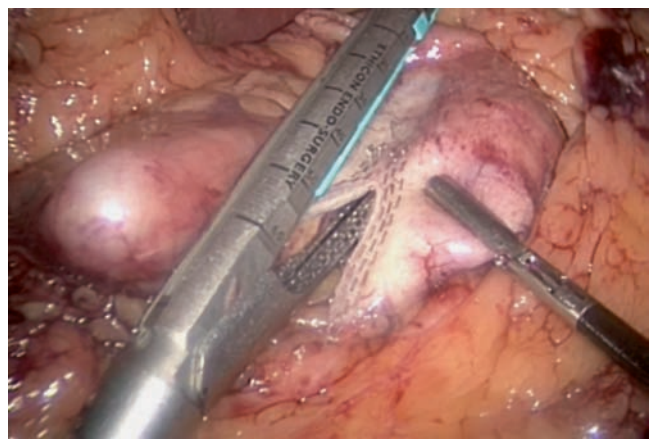

FIGURE 27-11 Stapling the stomach during laparoscopic sleeve gastrectomy (LSG).

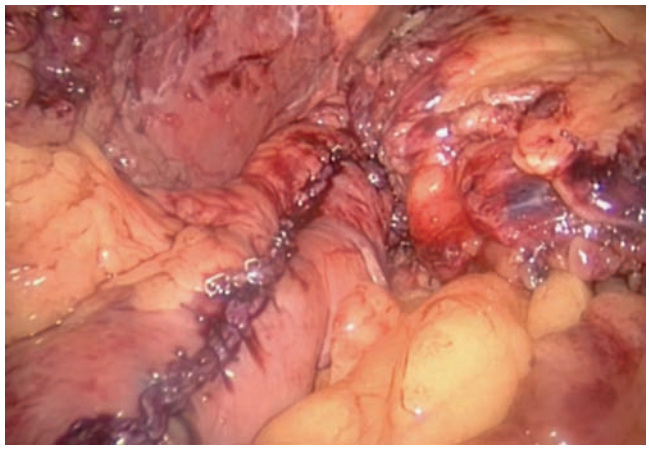

FIGURE 27-12 Completed laparoscopic sleeve gastrectomy (LSG).

an ischemic leak postoperatively, which is a difficult and persistent problem to heal. Some surgeons feel that staple line reinforcement material offers the advantage of decreasing bleeding and leakage, while others feel this is not established and the material is too costly. In either case, it is appropriate to take particular care to avoid the complications of staple line bleeding or leakage after surgery during the stapled division of the stomach. Similarly, stenosis must be avoided as well. The completed division of the stomach and thus the operation is pictured in Fig. 27-12. The devascularized piece of greater curvature stomach is removed through the largest of the ports in a laparoscopic bag. Intraoperative performance of a leak test is not uniform but often done by surgeons at the completion of the operation.

POSTOPERATIVE CARE

LSG is normally performed as an inpatient procedure, though the stay in the hospital may be as short as 24 hours. Postoperative length of stay is often determined by the patient's medical comorbidities. Pain control is initially achieved with appropriate parenteral medications. Once oral medications are begun, usually within 24 hours, a liquid form of narcotic medication is preferred initially for pain control. Routine radiographic study on the first postoperative day is performed by many surgeons. Whether this becomes standard or optional is still controversial, as it is with LRYGB, which has a much longer history. Once the patient takes adequate liquid intake, has adequate pain control, and shows no signs of leakage, hemorrhage, or stenosis from the operation, they are discharged from the hospital.

Following LSG, patients must adhere to a liquid diet until they become accustomed to the restriction of the long and narrow gastric lumen. The length of such a liquid diet is variable, but usually in the 2- to 3-week range. Thereafter, initiation of soft followed by well-chewed solid food over the next few weeks ensues. Patients have a limited appetite due to the anatomic arrangement of the operation. This facilitates the diet and slow progression to solid food.

Follow-up for the first year should be frequently enough to detect problems of long-term stenosis, and occasional nutritional issues that may arise. Protein intake must be encouraged, and liquid protein supplements as well as dairy-related protein foods often serve as the initial largest component of protein intake. Later, once a larger volume of solid food is consumed, standard protein sources in the diet serve to meet protein needs. Vitamin B_{12} needs supplementation for most patients in the long term, and levels should be checked beginning a few months after surgery. Iron intake, due to low intake of iron-rich foods, may need supplementation. A multivitamin is a standard recommendation for daily intake by patients. LSG is still in its early phases of follow-up, and thus far no other major nutritional deficiencies have been identified after the procedure.

OUTCOMES

LSG has produced excellent weight loss as a primary bariatric operation. Reports in the literature show 1-year follow-up of 50–70% EWL.[31,32] Resolution of comorbidities has also been reported, and is excellent and mirrors the percentage of excess weight lost. Patient satisfaction with the operation has been reported to be very high as well.

LSG is currently in its "honeymoon" period as a bariatric operation. The short-term results have been excellent, overall, in most reported series. However, the operation does not have a long enough track record to determine what will be the long-term problems seen with the operation. Particularly, the incidence of weight regain or recidivism is not yet reported after this procedure. An anatomically similar operation, the vertical banded gastroplasty, relied on a shorter lesser curvature tunnel of stomach with a band to constrict outflow.[33] It too enjoyed immense initial popularity in the 1980s and, like LSG, was a technically easier operation to perform than a procedure like RYGB. During the1980s, the vertical banded gastroplasty was the most commonly performed bariatric operation in the United States. However, long-term follow-up showed a high incidence of patients changing their diet to accommodate for the restriction, and eating a high-calorie liquid diet. Weight regain slowly resulted, and after a decade one institution reported the number of patients with still successful weight loss after vertical banded gastroplasty was under 25%.[34]

COMPLICATIONS

Mortality for the operation has been under 1% in all major series and generally in the 0.2–0.3% range. Complications include bleeding, stenosis, and staple line leakage as problems arising soon after surgery, with overall short-term complication incidences reported in the range of 2–5%.[29,35,36] Stenosis, food intolerance, and reflux are the most commonly cited problems after the immediate postoperative period.

Treatment of postoperative hemorrhage may be difficult endoscopically, due to the tightness of the lumen of the gastric tube. Operative treatment may be needed if initial

conservative therapy with transfusions fails or hemodynamic instability occurs.

Leaks from the staple line are probably best treated initially with operative intervention to repair them. Depending on the circumstances, tissue quality, degree of peritonitis and soiling, a jejunal feeding tube may be appropriately placed for a safe site for enteral nutrition. Drainage of the repaired area is always indicated. Recurrent leakage may be amenable to endoscopic stent placement as treatment, depending on the lumen of the gastric pouch and the location of the leakage.

Stenosis of the gastric lumen after LSG is a difficult problem. Balloon endoscopic or fluoroscopic dilation is indicated as the initial treatment of choice if feasible. Few results have been published in the literature. The role of temporary endoscopic stents in treating this problem is also not established but potentially may prove effective.[37]

Longer-term problems of reflux and food intolerance have been reported, but the number of reports is still small and the relative frequency and severity of these problems have yet to be accurately determined.

Nutritional complications have not been reported with any significant frequency as of yet after LSG. Because most of the stomach is removed, it is anticipated that low vitamin B_{12} levels and potential megaloblastic anemia and vitamin B_{12}–related neuropathy could result from LSG. Other nutritional deficiencies would, based on the anatomy of the operation, need to arise from inadequate intake of nutrients, because there is no malabsorption associated with LSG.

Laparoscopic Roux-en-Y Gastric Bypass

Laparoscopic Roux-en-Y gastric bypass is the most frequently performed bariatric operation in the United States. While there are many variations on the theme, there are certain defined characteristics and components of the operation that are common to all procedures bearing this name. The operative description below will favor our own approach at the University of Virginia, although the two coauthors of this chapter also have differences in their own techniques. Wherever possible, mention of common variations on each step of the operation will be included.

PATIENT POSITIONING AND PREPARATION IN THE OPERATING ROOM

The operation is performed with the patient in the supine position, with the legs together. The surgeon gains little from operating between the patient's legs, and allowing the legs to be together and supported directly in line on the operating table decreases the potential for neural injuries to the legs if they were to be placed in any spread or supported position that would allow the surgeon to work between them. We also have found that the use of a footboard, large sponge cushion blocks to surround the feet, and taping those blocks securely to the operating table all allow the patient to be more easily placed into the reverse Trendelenburg position, which is advantageous for the gastric portion of the operation. The supine position also likely results in less venous thromboembolism (VTE) than if the legs are apart and supported.

The patient is positioned initially supine for the intestinal part of the operation but later in steep reverse Trendelenburg's position for the gastric portion. Both arms are normally out to the sides for vascular access, and supported appropriately. It is key to place padding under the axillary/upper arm areas of extremely obese individuals, as the body is so massive that the arms are not supported adequately in the supine position.

Preoperative antibiotics, of an appropriate dose, are indicated. Normally a first-generation cephalosporin will suffice to cover the proximal gut floras that are potential pathogens in this operation. The severity of wound infections has dramatically decreased with laparoscopic surgery as compared to open surgery in the past.

Prophylaxis against VTE is more controversial. Pulmonary embolism is one of the leading causes of death after bariatric surgery, and many surgeons use all measures feasible to decrease its incidence. This includes early ambulation after surgery. However, measures prior to surgery usually are at least foot or leg sequential compression devices or some form of heparin therapy. At our institution, after having had 1 year with a high incidence of VTE in the past, we use low-molecular-weight heparin subcutaneously, given just prior to the start of surgery, as well as sequential compression boots. Many papers have been written on this subject in the literature, without a clear consensus.[38] However, it is now the practice of most bariatric surgeons to use both mechanical and chemical prophylaxis against VTE. Very high-risk patients, such as those with a hypercoagulable state or who have a history of VTE, may be candidates for use of a temporary prophylactic inferior vena cava (IVC) filter as the ultimate measure of protection against pulmonary embolism.

Skin preparation is with a standard chlorhexidine or iodine-based solution, with coverage of the entire abdominal wall up to a level 2 in above the xyphoid.

OPERATIVE PROCEDURE

Pneumoperitoneum and Port Placement. The pneumoperitoneum in the severely obese patient is best established, in our experience, using a Veress needle. A Hasson trocar has almost no place in bariatric surgery: it is difficult to make a deep incision to place it while maintaining tissue security around it to seal the pneumoperitoneum. Instead, using a standard tracheostomy hook to elevate the fascia produces an excellent countertraction of the abdominal wall that allows the Veress needle to penetrate the peritoneal cavity despite the thickness of the abdominal wall. The tracheostomy hook must continue to hold up the abdominal wall during the initial phase of insufflation, until there is an adequate pneumoperitoneum such that the tip of the Veress needle no longer touches any tissue or organs when this traction is released. Our preferred site of creation of the pneumoperitoneum is the left upper quadrant, near the costal margin, where the assistant will have his or her right hand 12-mm trocar port. This quadrant of the

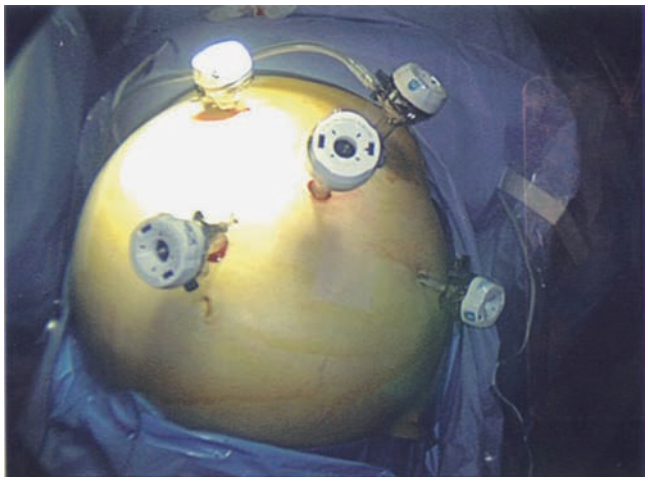

FIGURE 27-13 Port position for laparoscopic Roux-en-Y gastric bypass (LRYGB).

abdomen has, on average, the least amount of adhesions from previous surgery. If there has been surgery in this quadrant but not on the right, we will use a site in the right upper quadrant, where the surgeon's left-hand port is to be positioned. In super obese patients, a pneumoperitoneum pressure of 18 is often required for adequate visualization. Extremely thick abdominal walls may require extra long ports.

While there are a variety of port positions used for the performance of LRYGB, the configuration in Fig. 27-13 is our preference. The camera is placed through a port above the umbilicus, usually at the maximum of the "dome" created by the pneumoperitoneum. The ports are 12 mm for the surgeon's right and left hands and the assistant's right hand. These positions are chosen because of the ease and advantage of the angles created by these positions for firing the stapler during various steps of the operation. The assistant's left hand is a 5-mm trocar. At times, in extremely obese individuals, the addition of an extra port or two is needed. The intestinal portion of the operation may be difficult if the camera port is too close to the operative field. If this proves to be the case, we simply insert an additional port lower in the midline. The gastric stapling portion may also prove difficult, and the supraumbilical camera port may be very far from the operative field. In this situation, we do not hesitate to move the camera to the assistant's right-hand port, and add another 5-mm trocar higher up along the costal margin on the left for the assistant's right hand.

Liver retraction may be performed using one of several liver retraction devices. The T-Boone (Haynes and Boone, Dallas, TX) retractor, a simple tubular-shaped slightly curved piece of metal with a short cross bar, holds the left lobe of the liver out of the way adequately for most patients. Larger livers require the Nathanson retractor. The liver retractor is optimally placed in the epigastric region, high enough to be above the liver edge and hence hold the liver up when the retractor is inserted directly downward into the peritoneal cavity.

Intestinal Portion: Creating the Roux limb. This portion of the operation is begun by identifying the ligament of Treitz. This is only possible by having the omentum free from adhesions to other abdominal structures, at least for the midportion and left half of the omentum. Adhesions to the right lateral side wall can be usually ignored. Once the omentum is free, is it placed above the level of the transverse colon, and the transverse colon mesentery then grasped and elevated to help expose the ligament of Treitz. Once identified, the proximal jejunum is then divided between 30 and 50 cm distal to the ligament. The shorter the distance, the better iron and calcium absorption occur. However, longer distances are needed for larger patients where there is a greater distance to the proximal stomach and the Roux limb must therefore be able to reach more proximally. Generally, dividing the bowel at the 50 cm level provides a proximal end of the Roux limb that can reach the proximal stomach in even very large patients.

The jejunum is divided using one or two firings of the GIA-type stapler, using a white staple cartridge load. It is placed through the surgeon's right hand port, which gives a good angle for dividing the bowel (Fig. 27-14). The second staple load may often extend into the mesentery. This is helpful to begin increasing the mobility of the Roux limb. However, the division of the mesentery must continue in a direction directly downward on the mesentery, equally dividing the mesentery between the two segments of divided bowel. Straying to either side will cause ischemia to one of the bowel segments, requiring further resection back to viable tissue. The ultrasonic scalpel is used to continue the division of the mesentery below the staple load, carrying this division down to the root of the mesentery (Fig. 27-15). Care should be taken to apply slow application of energy in several adjacent points when dividing the major crossing vessels of the jejunal mesentery. Once the base of the leaflet of mesentery is reached, no further division should be attempted due to the

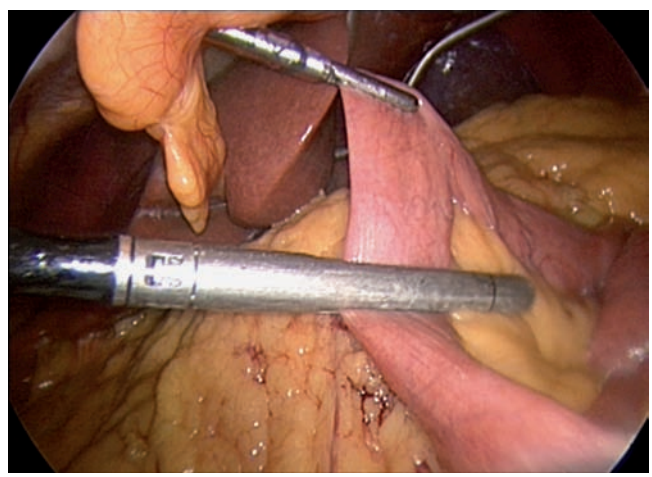

FIGURE 27-14 Stapling the proximal jejunum in laparoscopic Roux-en-Y gastric bypass (LRYGB).

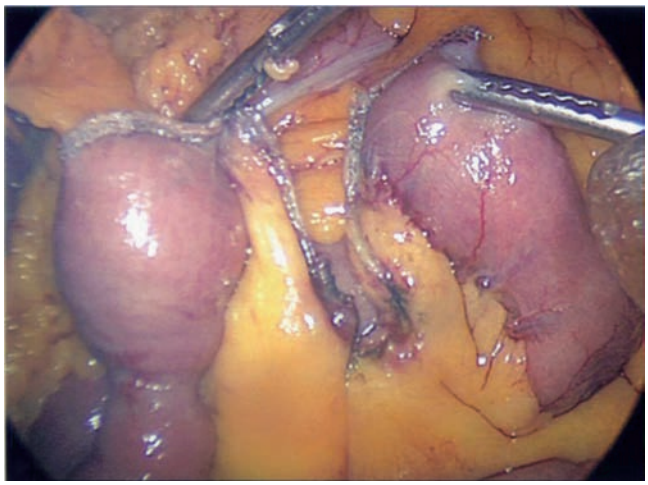

FIGURE 27-15 Harmonic division of mesentery of Roux limb.

risk of encountering major hemorrhage from vessels not easily controlled with laparoscopic energy devices.

The ends of the jejunum are assessed for viability. Any ischemic portion is resected back. Resected pieces of intestine are either removed directly now or placed in a specimen bag for later removal, depending on their size. If the end of the Roux limb is quite healthy, a 0.25-in Penrose drain is sewn to its end immediately (Fig. 27-16). If it needs resection, the drain is placed as soon as resection is performed. The end of the Roux limb should always be held by a grasper until the drain is attached. This is done to prevent any possibility of confusing the Roux limb with the biliopancreatic limb.

The proximal jejunum is now oriented adjacent to the ligament of Treitz, with its mesentery straight and pointed caudally. This leaves the stapled end of the biliopancreatic limb (the proximal jejunal segment) facing the camera and on the left of the operative field. The Roux limb is now measured for length. With experience this can be done by visual estimate,

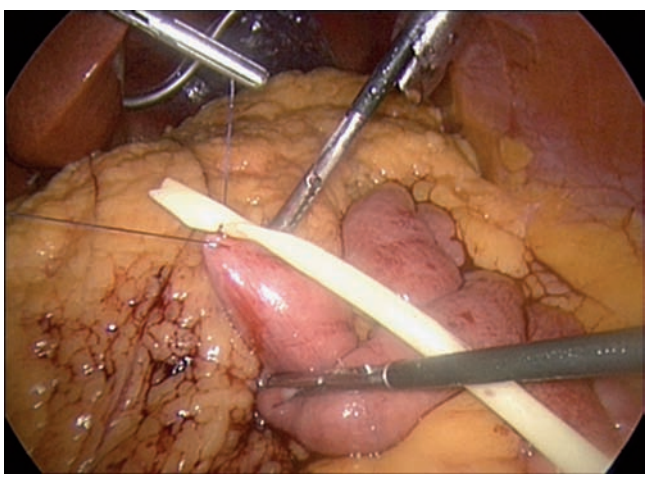

FIGURE 27-16 Sewing on Penrose drain.

but in the beginning the surgeon may wish to use an instrument or some marker that helps estimate intestinal length. As the Roux limb is measured, it is pulled up and to the right on the screen, or to the patient's left upper quadrant. In this way the mesentery of the Roux limb has a continuous bend in a counter-clockwise direction as the limb is being measured. We generally make our Roux limb lengths approximately 100 cm for the patients with a BMI of 40–50, 125–130 cm for patients with a BMI of 50–55, and 150 cm for a BMI over 55. Once the appropriate length of Roux limb is measured, that point is sutured to the biliopancreatic limb with a single suture on the antimesenteric side of the Roux limb connecting to the antimesenteric surface of the biliopancreatic limb about 6 cm proximal to its end.

Enteroenterostomy. The harmonic scalpel is now used to create enterotomies 1 cm distal to the suture holding the two segments of bowel together, on the antimesenteric sides of each segment of bowel. These enterotomies should be adjacent to each other. The white load 45-mm GIA stapler legs are now placed into each enterotomy from the surgeon's left-hand port, and the stapler is fully inserted into the bowel lumen, closed and fired (Fig. 27-17). A second white load is placed into the enterotomy site from the assistant's right hand, which usually is in a good position for the easy placement of the stapler in the opposite direction. The stapler is placed fully into the bowel lumen, which usually is just long enough to accommodate the upper leg in the short segment of the distal biliopancreatic limb. The stapler is closed and fired. We have found that this double-firing technique essentially eliminates the occasional issue of stenosis of this distal anastomosis, a complication that can prove fatal. The enterotomy is now sutured closed, beginning at the alimentary side of the opening and closing it upward toward the biliopancreatic limb (Fig. 27-18). Finally, the mesenteric defect of the enteroenterostomy is closed with a running permanent suture, beginning at the base of the mesenteric defect and completing the suture by sutures between the end of the biliopancreatic limb and the side of the Roux limb a few centimeters beyond the enteroenterostomy (Fig. 27-19).

Some surgeons choose to create the enteroenterostomy using a single-stapled technique. If this is done, it is highly advisable to suture the stapler defect, as trying to close it with a stapler may cause stenosis. The double staple technique is more amenable to stapling closed the stapler defect. Some surgeons also prefer to create this anastomosis with a hand-sutured technique.

Passing the Roux Limb. Our preference is to perform a retrocolic retrogastric pathway for the Roux limb. The authors prefer this configuration because it allows the Roux limb to pass via the shortest distance to the proximal stomach, minimizing the risk of tension on the anastomosis. It also minimizes the risk for Petersen's hernia, based on the configuration of the Roux limb and biliopancreatic limb. Proponents for an antecolic Roux limb argue that this method is quicker and has little risk of anastomotic problems due to tension. They

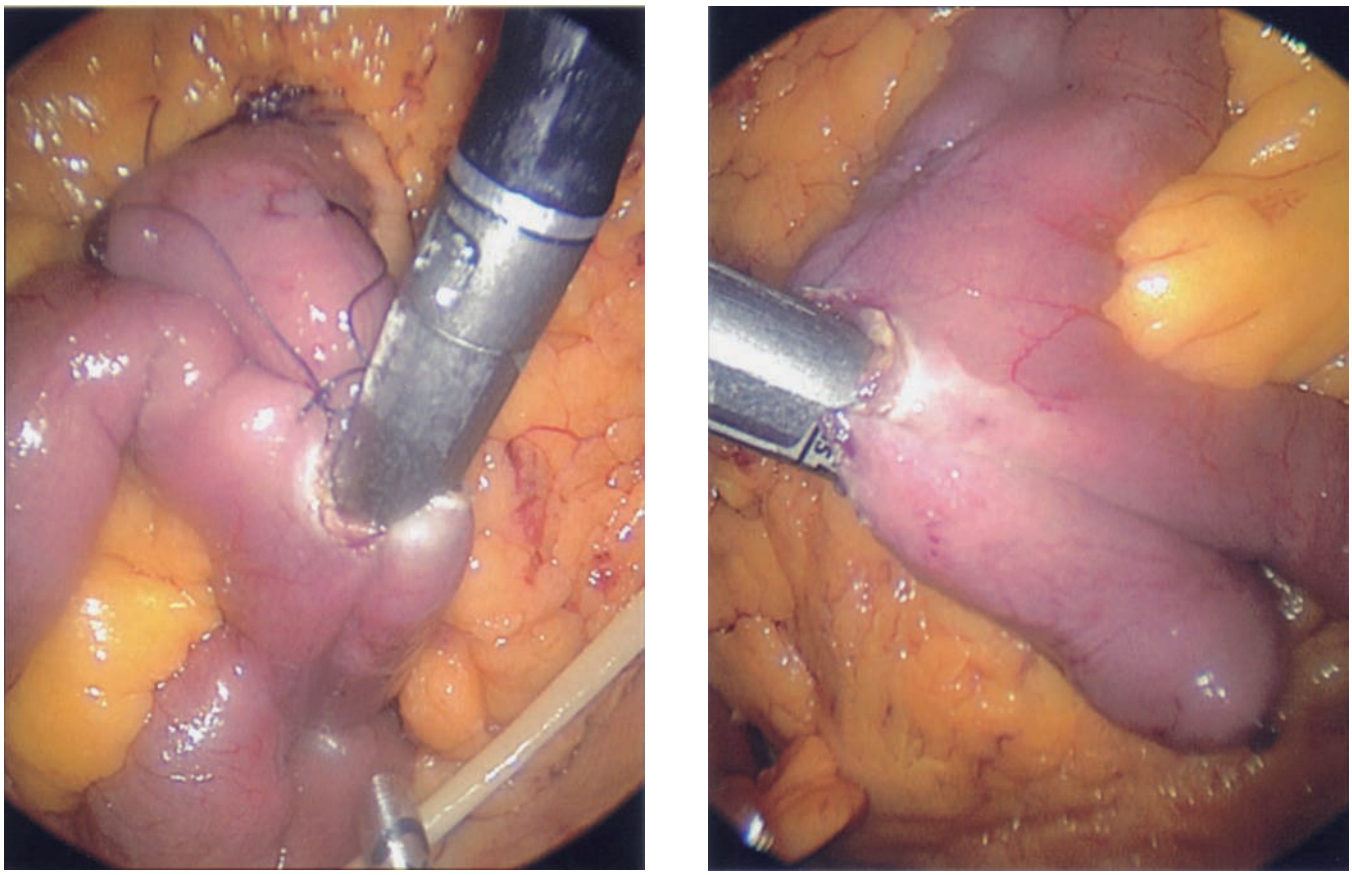

FIGURE 27-17 Stapling enteroenterostomy.

also argue there is a decreased incidence of internal hernias without a defect in the transverse colon mesentery.[39]

The biliopancreatic limb is now traced back to find the ligament of Treitz again. Then the transverse colon mesentery just to the left of the ligament of Treitz is held up and stretched so that it presents a solid flat surface. We find that the area just to the left and above the ligament of Treitz usually serves as a safe location to create an opening in the transverse colon mesentery with the ultrasonic scalpel. A longitudinal opening several centimeters in length is made, and the mesentery is then carefully divided with the ultrasonic scalpel. Usually larger vessels are not encountered, but caution must be taken in case of aberrant vascular distribution. Once an opening is made into the lesser sac, the stomach is usually readily visible and can be grasped and pulled up to the opening in the mesentery. Enlarging the mesenteric opening allows enough room to pass the Roux limb into the retrogastric space. This is facilitated by locating the Penrose drain and passing it into the space first, followed by the first 2–3 in of the Roux limb (Fig. 27-20). Care must be taken that the mesentery of the Roux limb is not twisted but instead is oriented straight up and down below the bowel as it is being passed through the transverse colon mesentery.

Difficulties in passing the Roux limb can be overcome with several tricks that have been learned over the years. The large and bulky mesentery presents more difficulty. In this situation the gastrocolic ligament often needs to be opened with the ultrasonic scalpel over a 4- to 6-in area. This allows a wide visualization of the superior surface of the transverse colon mesentery. The assistant then grasps the end of the Penrose drain, pushes it into the transverse colon mesentery through the standard incision in the inferior surface of the mesentery. The distention of the superior surface of the mesentery usually allows identification of the grasper and the Penrose drain just under the mesenteric surface. The surface can then be pierced with the grasper under direct vision, and the opening in the mesentery then also enlarged under direct vision to allow the Roux limb to pass through. A careful check of the mesentery is also needed in this situation as well.

Creating the Proximal Gastric Pouch. The proximal gastric pouch is best constructed from the upper lesser curvature of the stomach, with only a minimal amount of fundus included. In order to better expose the stomach, we place the patient in relatively steep reverse *Trendelenburg's* position, after first placing the liver retractor (which is not needed until this point). The ultrasonic scalpel is then used to create an opening in the lesser curvature mesentery adjacent to the lesser curvature of the stomach. If the patient is larger, the pouch is best made a bit longer, starting within 1 or 2 cm

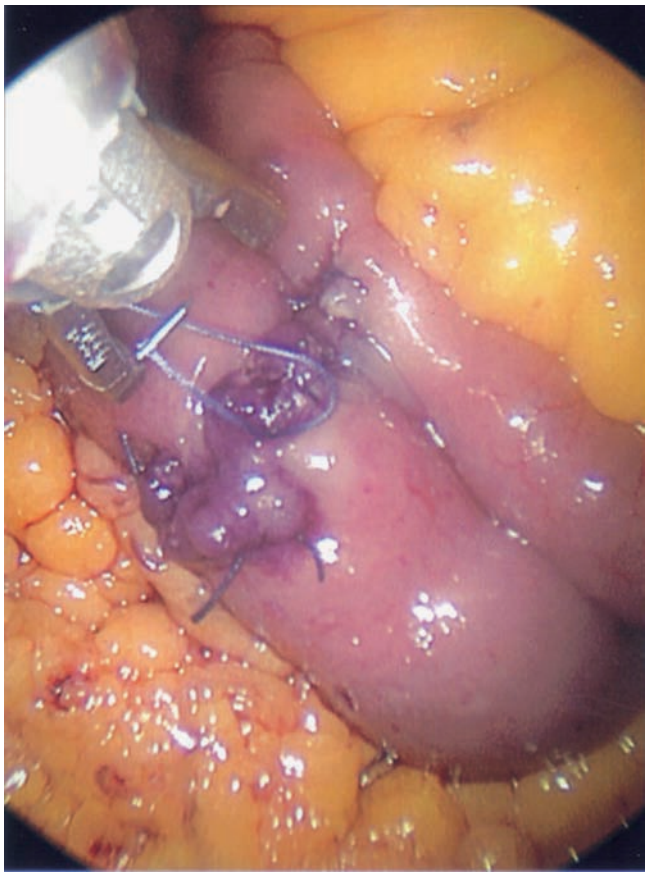

FIGURE 27-18 Sewing closed stapler defect of enteroenterostomy.

above the incisura, to ensure that the Roux limb will reach the pouch. More often, the pouch is created starting several centimeters above the incisura. Once an opening is made, the blue load (or green load for thicker stomach) GIA stapler is fired directly across the stomach, creating a divided cut into

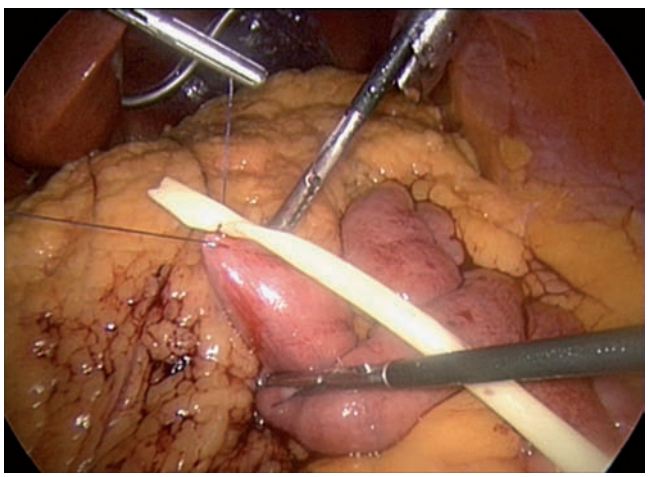

FIGURE 27-19 Completion of suturing closed the mesenteric defect of the enteroenterostomy.

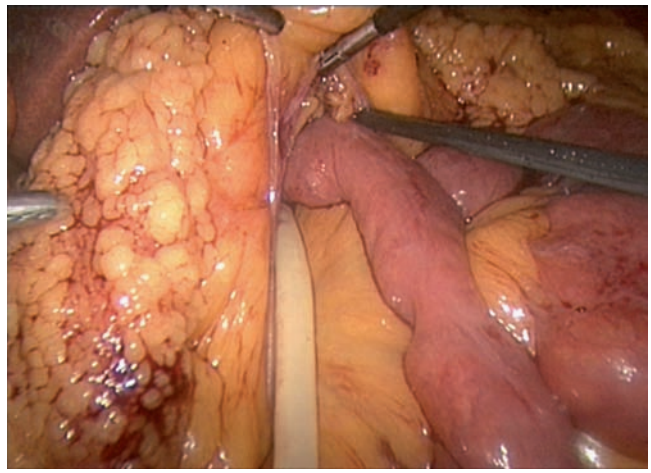

FIGURE 27-20 Passage of the Roux limb.

the stomach from the lesser curvature side (Fig. 27-21). The surgeon must double-confirm with the anesthesiologist that any nasogastric tubes, temperature probes, or other tubes that could possibly be in the lumen of the stomach have been removed prior to firing the stapler.

We have found the next best step for guiding the size of the pouch is to have the anesthesiologist pass an Ewald tube, which is a gastric lavage tube used to evacuate the stomach of large clot or particles, measuring 32F in diameter. This tube is then positioned along the lesser curvature of the stomach, and it serves as a guide for creating the pouch size. The pouch is created just slightly larger than the size of the tube. The GIA stapler is then fired several times adjacent to the side of the tube until the top of the stomach is reached in the area of the angle of His (Fig. 27-22). An opening through the mesentery underneath the edge of the top of the fundus should be created to facilitate the final firing of the stapler and allow

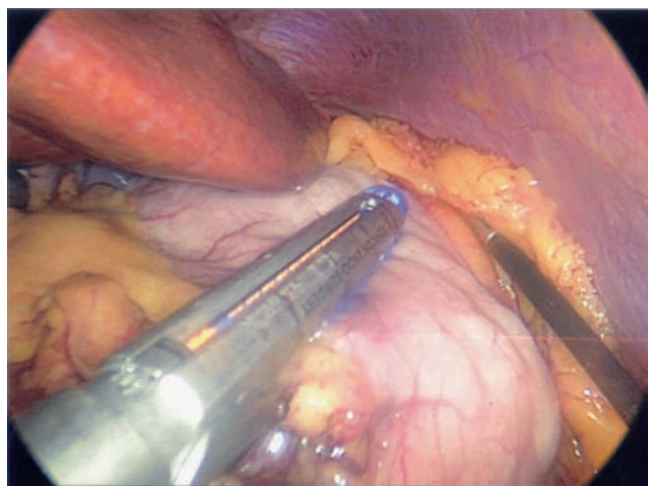

FIGURE 27-21 First stapling to begin creation of proximal gastric pouch.

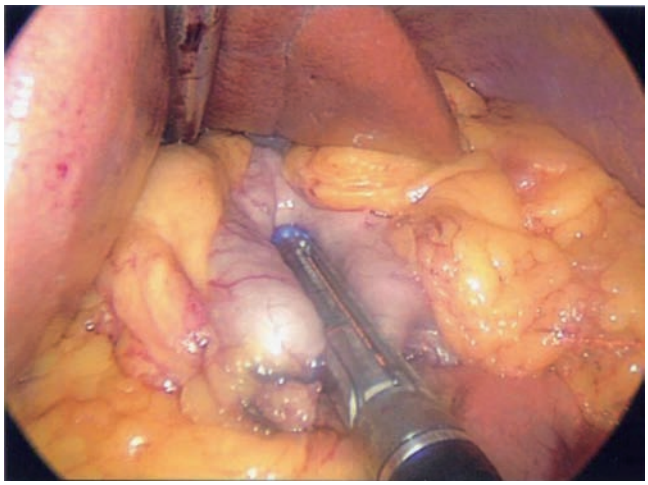

FIGURE 27-22 Stapling to create proximal gastric pouch.

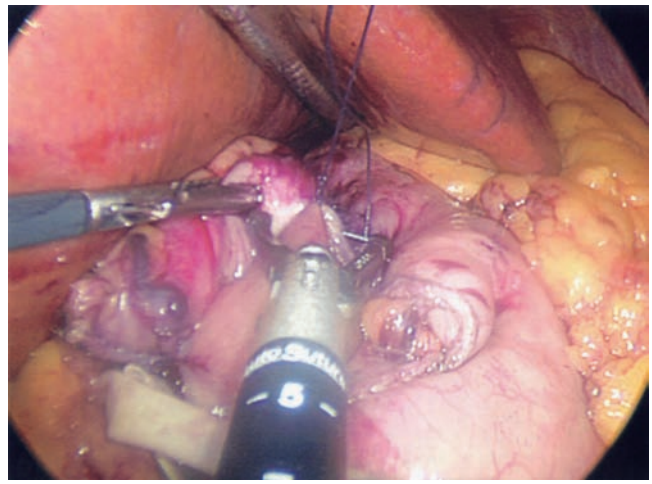

FIGURE 27-23 Starting the suture line to approximate Roux limb adjacent to gastric pouch.

complete division of the stomach and thus complete separation of the proximal gastric pouch from the distal stomach.

Some surgeons prefer to use a flexible endoscope, esophageal dilator, or other space-occupying tube to help as a guide to create the proximal gastric pouch.

Creating the Gastrojejunostomy. Once the gastric pouch is created, the Penrose drain is usually visible behind the lower stomach. If not, the gastrocolic ligament may need to be opened to locate it and facilitate passage of the Roux limb up to the proximal gastric pouch. Retrogastric adhesions are a problem that must be recognized if they prevent easy passage of the Roux limb. They can act as a barrier for passage of the Roux limb or, worse, act as a bowstring across the mesentery of the proximal Roux limb, rendering it ischemic. Any limitation to the easy passage of the Roux limb should be investigated by opening the gastrocolic ligament and assessing the posterior gastric surface.

Once the Penrose drain is located, it is used to gently pull the Roux limb up past the lower stomach. The proximal end of the Roux limb is placed adjacent to the lowermost end of the proximal gastric pouch, and the more distal Roux limb is gently teased up to approximate the entire length of the proximal gastric pouch. Once the two organs are thus aligned, a running suture is used to connect the side of the Roux limb to the staple line of the proximal gastric pouch. The suture is begun at the top end of the gastric staple line, and, when completed and tied, one end is left long for later use (Fig. 27-23). The Ewald tube is now used as a backstop to create a gastrotomy in the distal stomach pouch, about 1 cm from the end. An adjacent enterotomy is made in the Roux limb, using the ultrasonic scalpel for both. The anesthesiologist is asked to withdraw the Ewald tube 6–8 cm, so as to avoid stapling it. Visual confirmation of this is mandatory. The blue load of the GIA stapler is now inserted into the two lumens, one leg in each, and is best passed from the surgeon's left-hand port. This aligns it with the natural direction of the organs. Once the stapler is inserted to its full length, it is fired (Fig. 27-24). The enterotomy remaining is now closed using a running layer of absorbable suture, starting at the inferior apex of the opening near the knot of the running suture used to approximate the organs. This enterotomy closure is then reinforced with an outer layer of absorbable suture, after first having the anesthesiologist advance the Ewald tube so that it is just across the anastomosis, and thus stenting it open to prevent any stenosis by the second layer of closure. We then test the anastomosis for leaks by forcefully injecting methylene blue into the Ewald tube while holding pressure on the Roux limb just beyond the anastomosis. Distention without leakage must be accomplished.

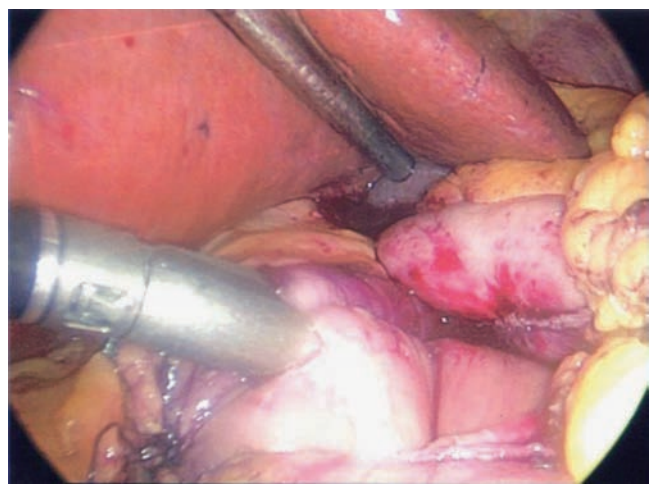

FIGURE 27-24 Stapler placement for gastrojejunostomy.

Many surgeons use the circular stapler to create the gastrojejunostomy. The first author also used this technique for many years but has abandoned it in favor of the linear stapler. Using the linear stapler, without trying to limit anastomotic size, we have experienced that the incidence of anastomotic stenosis is under 2% (it was 10–14% with the circular stapler) and the amount of weight loss is comparable to that seen with the circular-stapled anastomosis.[40] The linear stapler is also technically easier than the circular one for the surgeon to use if he or she does not have a highly skilled first assistant.

Closure of the Mesenteric Defects. The retrocolic Roux limb must be secured to a reliable structure to keep it from telescoping up behind the stomach. Should it do so, the Roux limb will assume the shape of an accordion, and multiple partial obstructions or a single dominant point of obstruction will often then result. We prevent this by tacking the Roux limb to the adjacent proximal portion of the biliopancreatic limb, just distal to the ligament of Treitz, with several nonabsorbable sutures (Fig. 27-25). We also suture the Roux limb to the mesenteric defect both above and laterally to the patient's left side, to prevent herniation in either of these areas. Although our incidence of internal hernias is low with this technique, it is not zero, as sometimes sutures will fail or spaces develop between sutures that allow an internal herniation.

Completion of the Operation. The 12-mm port sites are closed at the fascial/peritoneal level using a suture passer to pass absorbable 0 weight sutures. Then all ports are removed and the pneumoperitoneum decompressed. Skin closure is with subcuticular absorbable suture, and the skin sites are dressed with Dermabond (cyanoacrylate). Bupivacaine (0.25%) with epinephrine is infiltrated at all port sites, as it was when they were created.

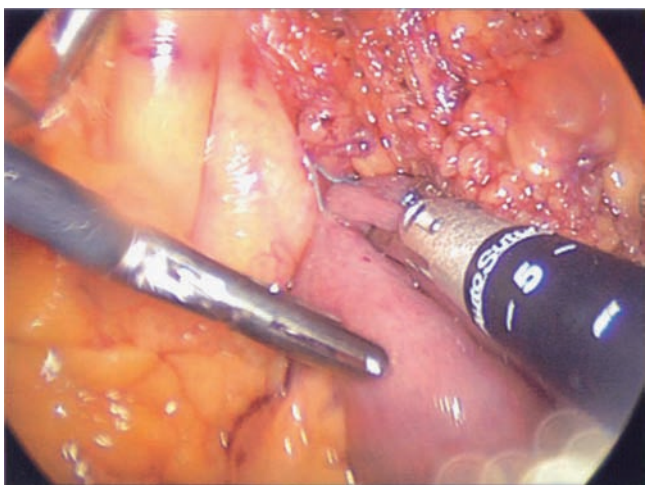

FIGURE 27-25 Triple stitch suturing mesentery.

Open Roux-en-Y Gastric Bypass

OPERATIVE PROCEDURE

The open approach to performing Roux-en-Y gastric bypass (RYGB) is a time-tested bariatric operation that is the only procedure with considerable longevity. However, the benefits of doing the same operation laparoscopically cannot be denied, because there is a clear decrease in wound complications, incisional hernias, and also a more rapid return to normal function after surgery. The bariatric surgeon must, however, be able to perform an open operation if needed, as certain patients will require this approach. The most common reasons that a laparoscopic approach cannot be performed include excessive intra-abdominal scarring (almost always present at revision operations), massively thick abdominal wall precluding adequate mobility of the ports, a massive liver unable to be retracted using laparoscopic retractors, and intraoperative complications requiring conversion to an open incision for optimal treatment.

The open RYGB that we now perform is modeled on the laparoscopic operation, because we now have so much more experience with the latter approach and use it as our routine or default operation. There are a few differences, summarized in the following text.

Incision and Exposure. The open incision must be made high enough to expose the diaphragm. Usually the skin incision must extend above the xyphoid by about 1–2 cm, and the division of the fascia and muscle should continue alongside the left side of the xyphoid process. This will allow the surgeon to look down and visualize the diaphragm. If the diaphragm is not visible, the exposure is not high enough to allow a safe procedure. Use of mechanical retractors is mandatory to help maintain adequate exposure. Human retractors are not adequate or appropriate. The length of the incision should be long enough to allow good exposure of the transverse colon and a few inches below it, where the enteroenterostomy is created.

Liver retraction using the open approach may be different than the laparoscopic one. Because there is no telescope to look up at the stomach from a lower plane, simple elevation of the left lobe of the liver with a retractor under it often does not move it adequately out of the field of vision of the operation. Instead, division of the triangular ligament of the left lobe of the liver and folding the liver inferiorly and medially exposes the gastroesophageal junction area much more adequately. This liver retraction should only be maintained during the gastric portion of the operation to prevent excessive compression of the liver over a longer time.

Enteroenterostomy. We now begin the open operation with this part of the procedure and perform it in an identical manner as the laparoscopic approach. The Roux limb is marked with a suture instead of a Penrose drain. It is not passed until the gastric pouch is created, however.

Creation of the Gastric Pouch. The proximal gastric pouch is created in a similar manner, except that the open approach allows the easy division of the gastrocolic ligament, and thus the placement of the surgeon's finger behind the stomach when creating the mesenteric defect along the lesser curvature. Palpation and upward pressure of the mesentery from behind the stomach facilitates creating the opening in the mesentery adjacent to the stomach. The pouch is then created in a similar manner with the stapler. The green load is more often used with the open approach, because the individuals having open surgery are often larger with thicker stomachs.

Passage of the Roux Limb. The opening in the gastrocolic ligament allows the surgeon to palpate the superior surface of the transverse colon mesentery, exposing the inferior surface of it for division in an optimal place where palpation ensures a thin layer of tissue. The opening is usually made in about the same location as the laparoscopic procedure, but the manual palpation assists its creation in this setting. The Roux limb is now gently passed both retrocolic and retrogastric manually, positioning it adjacent to the proximal gastric pouch. Confirmation that the mesentery is not twisted is again mandatory.

The remainder of the operation is done essentially the same as the laparoscopic approach, with of course the exception of closing the incision. We favor the use of a looped no. 1 PDS-type suture to close fascia and peritoneum in a single layer. The subcutaneous tissues are copiously irrigated before the skin is stapled closed and dressed with sterile gauze.

Drains, Oversewing, and Gastrostomies. In general, it is the authors' contention that a gastrointestinal anastomosis should be closed, not drained. However, if the intraoperative methylene blue test has shown a leak that needed repair, or if the quality of the tissue or the anastomosis is at all in doubt, or for those extremely technically challenging operations where visualization was just barely optimal, then in those situations the patient is treated in a manner to prophylactically anticipate a possible leak. If there is any concern about the stapling during the creation of the proximal gastric pouch, the staple line is oversewn with a running absorbable suture. If the gastrojejunostomy is of concern, a closed-suction drain is left adjacent to it, placed just inferior to it and coursing behind the spleen and out through the left flank. It is usually removed before discharge, or at latest on the first clinic visit. A distal gastrostomy is also placed during difficult open operations or converted operations where complications may have arisen. A standard Stamm-type gastrostomy with a 28- to 32-size tube is created to access and drain the distal stomach.

POSTOPERATIVE CARE

Postoperative care for LRYGB has now been formulated into a protocol at our institution that serves to generally avoid lapses in major postoperative desired treatments or orders, facilitates nursing care by following a routine, and promotes earlier discharge while maintaining attention to important postoperative needs of the patient. Major aspects of this protocol are as follows:

Intravenous isotonic fluids are given at a rate of 250 mL/h for the first 12–24 hours and adjusted as needed based on urine output. Some bariatric patients have been on diuretics for many years. In these individuals, care must be taken not to excessively bolus them postoperatively with multiple liters of fluid to treat oliguria, If no evidence of bleeding or other signs of fluid loss are present, we will give several liters of volume at most, then give a dose of intravenous diuretic, which usually produces appropriate urine output.

Early ambulation is a key component to the prevention of VTE. Patients are expected to ambulate within a few hours of their operation. Getting out of bed frequently is encouraged and stressed. Sequential compression foot devices are to be worn by the patient when in bed. Low-molecular-weight subcutaneous heparin is used for VTE prophylaxis until discharge in average risk patients. In high-risk patients, it is continued at home for 3 more weeks on a twice daily subcutaneous injection dosing.

Oral intake is limited to ice chips the night after surgery. An upper GI study with water-soluble contrast is done the following day. If there are no problems on the study, a clear liquid diet is begun. This is advanced to a blenderized diet the next day. While many authorities have written that such a postoperative study is inaccurate and cost-ineffective,[41] we still use it to detect any potential problems of obstruction distal to the anastomosis and to document gastric pouch size.

Pain control is achieved through a combination of intravenous medications graduated to oral medications by the first postoperative day. Patient-controlled analgesia (PCA) pumps are often used in the first 24 hours and then stopped as oral medications are introduced.

Intravenous antibiotics are stopped after a postoperative dose in addition to the preoperative dose.

Wound care is simplified by the Dermabond, which allows wounds to be exposed to water if needed. No special care is required.

Oxygen is supplied the first 24 hours and then removed as appropriate based on oxygen saturation levels. As per our policy, patients with obstructive sleep apnea are required to bring their continuous positive airway pressure (CPAP) masks and use them while in the hospital. High-risk pulmonary patients all have a mandatory arterial blood gas done preoperatively to determine their "baseline" status. This is important in case postoperative ventilatory support is needed, which is rare. If it is, the pre-op ABG serves as a guideline for extubation. Otherwise, the surgeon is often confronted with an intensive care unit (ICU) team who wants to see "normal" blood gases prior to any extubation attempt.

Our normal protocol for patients undergoing LRYGB is for discharge at noon on the second postoperative day. Most patients achieve this timeframe for discharge, while occasional patients are detained an extra day for issues, including hypoxia, urinary retention, pain control, other medical

problems, or social issues. Patients undergoing open RYGB undergo the same postoperative protocol, except they often are not able to wean off intravenous narcotic pain medications or are not adequately ambulatory until the third postoperative day.

FOLLOW-UP

Patients undergoing LRYGB are seen back for follow-up clinic visits at approximately 3 weeks, 3 months, 6 months, and 1 year after surgery, then annually thereafter. More frequent visits are scheduled as needed. The 3-week visit is focused on adjustment issues to new eating habits, recovery from postoperative problems, advancement of diet, initiation of an exercise program, and adjustment of any medications (always done in coordination with the patient's primary care physician). The 3-month visit confirms the effectiveness of the diet and exercise plans, as well as improvements in comorbid medical problems and further medication adjustments as indicated. The 6-month visit assesses for any potential diet or nutrient deficiencies and reemphasizes the need for a consistent exercise program. Medications are again reviewed. Medication that is being taken to prevent gallstone formation with rapid weight loss (ursodiol 400 mg twice daily) is discontinued. The 1-year visit assesses changes in comorbid medical conditions, reviews the improvements that have resulted from the operation, and emphasizes the need to continue the diet and exercise changes that the patient has established during the year. The patients are cautioned that weight regain is a major issue if such diet and exercise habits are abandoned, because adaptation to the operation will allow greater oral intake than before (though still limited) and often is accompanied by a return of appetite as well.

It cannot be emphasized enough that *any and all* bariatric operations will not produce the durable weight loss sought and the long-term improvements in health and comorbid medical problems desired unless the adjustments to eating, exercise habits, and lifestyle produced by the operation are maintained long term. Regaining weight, or recidivism, is the single greatest long-term problem facing the patient who undergoes bariatric surgery.

OUTCOMES

Laparoscopic RYGB produces excellent weight loss, with 1 year percentage of excess body weight loss (%EBWL) being reported as between 60 and 75% in most series.[42–44] The laparoscopic approach has only been commonly used for a decade, and it did not achieve a position as being more frequently done than the open RYGB until probably 2003. Therefore, most of the long-term outcomes of RYGB have been published about patients who underwent open RYGB. For this approach, the weight loss was very comparable to that of LRYGB, although there were few reports of %EBWL of over 70%. Long-term maintenance of weight loss has been reported by Pories et al[45] and the Swedish Obesity Study[46] that included RYGB as well as gastroplasty for its

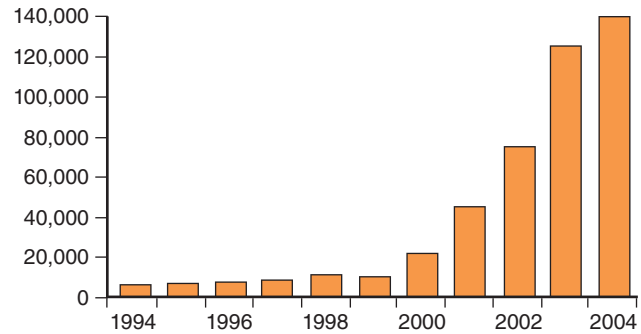

FIGURE 27-26 Graph of increase in Roux-en-Y gastric bypass (RYGB) during era around 2000.

operative procedures. The laparoscopic approach has probably been associated with slightly higher weight loss in many series because of two factors. The first is the average size of patients undergoing RYGB since the laparoscopic era has decreased. Prior to having a laparoscopic option for the operation, not nearly as many patients with BMI in the 40–50 range wished to undergo surgery, especially when it entailed an open incision. The popularity of RYGB was immeasurably enhanced by having the laparoscopic option, as evidenced by the rapid rise in popularity of RYGB being performed in the United States. between 1999 and 2003, during which time the number of procedures went from approximately 25,000 to 120,000 per year (Fig. 27-26). While other factors, such as Internet communication and publicity in national media probably also contributed to the rise in popularity of the procedure, they were most likely a secondary by-product of the sudden increase in demand and popularity of the operation. The costs of performing RYGB have been shown to be less, over a short follow-up period of 5 years, than the costs of medical care for patients who qualified for but do not undergo surgery.[47]

RYGB is known to have had many beneficial effects for patients who have undergone the procedure. It has been shown to improve longevity.[48–50] It has been shown to reduce medical comorbidities, the results of which are summarized

TABLE 27-4: RESULTS OF RYGB ON COMORBID MEDICAL PROBLEMS

Excess weight loss (EWL)	62%
Mortality	0.5%
Resolution of diabetes	84%
Resolution of hyperlipidemia	97%
Resolution of hypertension	68%
Resolution of sleep apnea	80%

Based on references 51–53.

in Table 27-4.[51–53] Certain specific medical problems merit more detail in terms of the effect of RYGB on them.

DIABETES

RYGB has been shown to be a highly effective treatment for type 2 adult-onset diabetes. Patients suffering from this disease will often experience remission of symptoms of the disease after only a few weeks of time have passed since surgery. The amount of weight lost during such a period of time does not alone explain this rapid amelioration of the disease. This clinical observation had been made by many surgeons performing RYGB and was best summarized in a study by Pories et al.[54] Over the past decade, a significant amount of research work on the mechanism of how RYGB improves diabetes has been performed. Studies in obese mice done by Rubino et al[55] demonstrated that the diversion of the food stream from the proximal intestinal tract resulted in remission of the animal's obesity and diabetes, and reversal of the operation resulted in reappearance of both conditions. The metabolic aspects of how RYGB may change the entero-insular axis are still being debated.[56] It appears that glucagon-like peptide-1 (GLP-1) is important in the process, but other gut hormones have also been implicated as potentially having a role in the metabolic changes seen after RYGB. Entire conferences and symposia have been held since 2007 on this topic, and the subject continues to be one of intense interest among scientists studying the metabolic effect of RYGB on diabetes, the metabolic syndrome, hyperlipidemia, and other metabolic conditions.

CHOLELITHIASIS

Gallstones may form with rapid weight loss for any reason, be it surgical or diet-induced. This was first observed after subjects following diet programs in the 1980s were noted to have high incidences of gallstones. Subsequent studies have shown that the incidence of sludge or stone formation after rapid weight loss to be in the 30% range.[57] This condition must be therefore considered in the planning of LRYGB, LSG, and DS for patients. Fortunately, it has also been shown that the consumption of prophylactic bile acids, specifically ursodiol at a dose of 300 mg twice daily for 6 months following RYGB surgery, can decrease the incidence of gallstone formation to 4%.[58]

Performance of synchronous therapeutic cholecystectomy is generally recognized as appropriate for patients with symptomatic cholelithiasis. There are some surgeons, however, that do not direct preoperative attention to the biliary system or feel such attention is unwarranted. Historical data do not support such a position, but some recent short-term follow-up studies have suggested a low incidence of biliary complications within the first year or two after surgery using such an approach.[59,60] However, studies with longer follow-up are more likely to document the not insignificant incidence of biliary complications that result from untreated cholelithiasis long term.[61–63]

More controversial is the question of whether to treat asymptomatic cholelithiasis if discovered prior to elective bariatric surgery. While some studies have concluded that the length of hospital stay or the complications associated with performing simultaneous cholecystectomy do not warrant its performance,[64] our experience has shown that synchronous prophylactic cholecystectomy, when performed with RYGB, either open or laparoscopic, has little effect on outcomes other than to lengthen operating time slightly.[65]

During the era of open bariatric surgery, performing a synchronous cholecystectomy was commonplace among many practices, including our own. The rationale was that the incidence of postoperative development of cholelithiasis and the need for subsequent operation outweighed the risk of performing a synchronous prophylactic procedure, provided the latter was done under good operative conditions following the successful completion of the bariatric operation. Now with most bariatric operations being done laparoscopically, the ability to perform a laparoscopic cholecystectomy as a second procedure is very high, and hence the need for the prophylactic cholecystectomy for the patient with a normal gallbladder has greatly diminished.

Our current recommendation for this issue is synchronous cholecystectomy for any patient with biliary pathology undergoing RYGB, strong consideration for synchronous cholecystectomy for all patients undergoing malabsorptive operations where bile salt pool will be depleted, and use of oral chemoprophylaxis in the form of ursodiol 400 mg BID for 6 months following performance of an operation that will produce rapid (>50 lb/3 mo) weight loss. Because most patients who undergo LAGB will not lose weight as rapidly as with malabsorptive or RYGB operations, the need for prophylactic cholecystectomy is minimal and not indicated. Nor is the routine use of ursodiol. However, for patients with cholelithiasis, it should be the judgment by the surgeon as to whether synchronous cholecystectomy at the time of LAGB is indicated, based on comfort of not spilling bile during the procedure as well as the patient's preoperative symptoms.

GASTROESOPHAGEAL REFLUX DISEASE

This comorbid medical problem also warrants some special consideration in the recommendation of operative bariatric choices for patients. Patients with gastroesophageal reflux disease (GERD) will have significantly greater improvement in symptoms after RYGB[66] than after LAGB[67] or LSG.[32] Patients who undergo RYGB have as higher a symptomatic relief from preoperative GERD than those who undergo specific surgical fundoplication for GERD.[66,68] In fact, patients who are referred for surgical fundoplication with a BMI of greater than 35 should be offered the option of having a LRGYB as an alternative to a laparoscopic fundoplication. The former will treat the patient's reflux symptoms as well as improve their physical and medical issues related to severe obesity.[69]

COMPLICATIONS

Mortality from LRYGB has now decreased considerably from the figure of approximately 1% reported in the literature a decade ago. Recent reports from very large databases have given the incidence as 0.13–0.18%.[70,71] Increased experience of surgeons, an overall less ill and less large patient population undergoing surgery, improvements in care through centers of excellence programs, and the decreased burden of an open incision have all likely contributed to this decrease in mortality. LRYGB is now safer than almost all intra-abdominal operations with perhaps the exception of cholecystectomy.

Morbidity from LRYGB has also decreased as well with improving experience over the past decade. Major operative morbidity is now given as under 2% in most series and total 30-day comprehensive morbidity as reported by our NSQIP (National Surgical Quality Improvement Program) database and for the University Health System Consortium (UHC) has been 15 and 14% respectively.[72] NSQIP outcomes data for our institution and the UHC consortium are summarized in Table 27-5.

SPECIFIC COMPLICATIONS AND THEIR TREATMENT

Complications after LRYGB and open RYGB are comparable except the latter has a higher incidence of wound complications and incisional hernias. Intraoperative complications are generally low in incidence, in the 2% range. These include hemorrhage, organ injury, twisting the Roux limb during performance of anastomosis, and anastomotic leakage as documented by intraoperative testing. Postoperative complications that are commonly described in the early postoperative period include intra-abdominal and anastomotic hemorrhage[73]; mechanical bowel obstruction due to technical error, severe edema, or intraluminal hematoma[74]; and anastomotic leakage.[75,76] Other nonbariatric specific complications also certainly occur, including VTE, cardiac arrhythmias, pulmonary atelectasis, and pneumonia.

Of these immediate postoperative complications, anastomotic leak is the one that is most feared by bariatric surgeons, because of its potentially fatal consequences. The condition may be difficult to diagnose clinically, with many documented cases of patients having isolated tachycardia as the only presenting symptom. Other common symptoms and signs suggesting a leak include fever, abdominal pain, tachypnea, a sense of impending doom, oliguria, and hypotension. In general, after RYGB, a patient who becomes ill in the first week after surgery has a leak until proven otherwise. Radiographic testing may not always diagnose the problem, because of the combination of lack of 100% sensitivity as well as the fact that leaks may occur in the distal gastric staple line or at the enteroenterostomy, where little or no contrast may be present on a fluoroscopic study.[77] If clinical symptoms are concerning for a leak, lack of radiographic confirmation should not keep the surgeon from reexploring the patient for the problem. While very small leaks that already are drained may be considered for conservative treatment,[78] in general the appropriate treatment of a leak is operative.[79] Treatment includes primary repair, placement of adequate drains in case of releakage, provision of an enteral feeding route (usually a gastrostomy in the lower defunctionalized stomach), and, for persistent or severe cases, consideration of use of an endoscopic stent.[80]

Vomiting within the first week after LRYGB or RYGB should be considered a very worrisome sign of potential early bowel obstruction. Stenosis, mechanical or technical issues, edema, and hematoma at the enteroenterostomy can all produce a relative or near-complete obstruction of the alimentary tract in this location. While the patient may vomit to clear the Roux limb, the biliopancreatic limb and distal stomach cannot be decompressed and are subject to massive distention and staple line rupture, with potentially fatal consequence (Fig. 27-27). Thus vomiting must be considered a sign of obstruction requiring vigorous investigation and reoperation if at all in doubt about the patient's condition.[81]

Long-term complications of RYGB are less numerous in terms of type, but several conditions are common and must be recognized to prevent life-threatening situations. By far the most dangerous and life-threatening is that of small bowel obstruction from an internal hernia.[82,83] Loss of a significant portion of the small bowel from ischemic necrosis may result if this condition is not promptly appreciated, diagnosed, and treated when it occurs. *Any patient who has had a LRYGB and presents with abdominal pain and signs of a bowel obstruction should be considered to have a bowel obstruction with internal herniation until proven otherwise. The surgeon should NEVER treat this condition with a nasogastric tube and observation if there is any doubt this condition may exist.* Operative treatment is the only appropriate approach. This diagnosis requires a high index of suspicion and can be compared to the diagnosis of ischemic bowel in the nonbariatric patient population. Symptoms usually are present in greater severity than physical, radiographic, or laboratory findings. Sometimes there may be a "swirling" pattern on the CT scan (Fig. 27-28). The

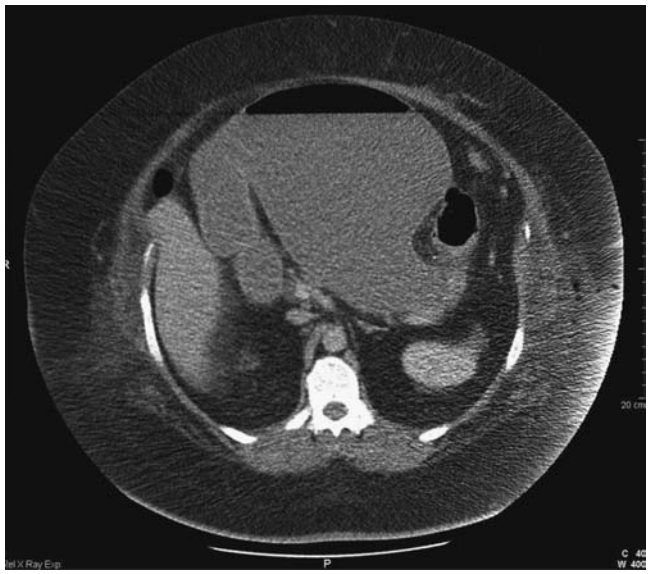

FIGURE 27-27 Picture of distended distal stomach due to entero-enterostomy obstruction.

authors have had several patients who presented with intermittent pain after eating but without confirmatory laboratory or radiographic signs. In these cases, much of the small bowel had herniated through an internal hernia and fortunately had not yet developed strangulation. Reduction of the hernia is facilitated by beginning at the terminal ileum in these cases, as this will reliably identify the more distal bowel and allow reduction in the correct direction. Many of these cases may be treated laparoscopically, but distention preventing visualization and edema to the bowel precluding safe laparoscopic manipulation are the limiting factors.

Stenosis of the gastrojejunostomy following LRYGB presents as progressive food intolerance in the 4–12 week period after surgery. The symptoms should prompt the performance of a flexible upper endoscopy, which may then be both diagnostic for the condition as well as therapeutic. The opening of the anastomosis may be very stenotic. Fortunately, however, the use of an endoscopic balloon can usually produce significant, if not complete, remission of the obstruction. If one endoscopic balloon dilation does not produce relief of symptoms, either another endoscopic or a subsequent fluoroscopic dilation with a larger-size balloon usually treats this condition quite adequately.[84,85]

FIGURE 27-28 Swirling pattern on CT seen with internal hernia obstruction after laparoscopic Roux-en-Y gastric bypass (LRYGB).

Reoperation for stenosis is usually not needed unless the condition has been allowed to persist or is secondary to the presence of a marginal ulcer, which then causes further scarring and stenosis.[86] We have found by experience that the use of a linear stapler dramatically reduces the incidence of stenosis of the gastrojejunostomy after LRYGB when compared to the use of a circular stapler for this anastomosis.[40]

Marginal ulcer is the other major long-term problem after LRYGB or RYGB that deserves special discussion as well. The etiology of marginal ulcers is still controversial and felt to likely be multifactorial.[87] The incidence is increased in the setting of mechanical stapling or permanent suture to create the anastomosis.[88] The presence of *Helicobacter pylori* colonization leads to a higher incidence of marginal ulcer postoperatively than if the condition is treated preoperatively.[89] Ischemia is also felt to play a role in the formation of some marginal ulcers. Cigarette smoking is a risk factor for persistence, recurrence, and nonhealing of a marginal ulcer.[90] Many bariatric surgeons will not offer an LRYGB to a patient who is a smoker for this reason.

Persistent burning epigastric pain, relatively unchanged by eating, though possibly slightly relieved in some cases, is the hallmark for marginal ulcer. A high index of suspicion and performance of endoscopy will yield the diagnosis. The incidence of the problem is between 2 and 14%.[91,92] This variability is likely based on aggressiveness of diagnosis as well as risk factors. Treatment of the problem is medical, which is effective in the vast majority of cases. Nonhealing of a marginal ulcer should precipitate performance of a Gastrografin (diatrizoate meglumine) contrast study to rule out the possibility of the ulcer having penetrated into the lower stomach. If that has happened, surgical intervention is needed as the gastrogastric fistula tract is unlikely to close spontaneously.[93] Similarly, if the patient had an RYGB without a divided stomach and the gastric staple line has broken down to allow communication from lower to upper stomach, surgery is needed to separate the lower stomach from the proximal gastric pouch and thereby eliminate the backwash of acid onto the anastomosis and ulcer.

NUTRITIONAL ISSUES AND COMPLICATIONS

Because LRYGB diverts food only from the majority of the stomach and the duodenum and up to 50 cm of proximal jejunum, the incidence of major malnutrition issues or nutrient deficiencies is limited to those nutrients specifically absorbed in those areas or those nutrients taken at a significantly lower volume after surgery. Protein malnutrition is rare without the presence of depression or other illness essentially

minimizing intake. Liver disease can contribute to hypoalbuminemia. Much more common nutritional problems arise from the lack of ability to absorb iron and calcium due to the diversion of the alimentary stream from the proximal small bowel. Similarly, lack of gastric nutrient presence decreases the secretion of vitamin B_{12} because of lack of gastric production of intrinsic factor required to absorb the nutrient. These three elements should be measured for all patients undergoing RYGB. Folate can, on occasion, also be deficient in these patients. Another uncommon but problematic vitamin deficiency is thiamine deficiency. This may arise in the setting of progressive and significant vomiting and can, if untreated, result in permanent neurologic sequelae such as Korsakoff's syndrome.[94] Vitamin D has been shown to be deficient in a high percentage of the obese population and therefore is, as expected, also deficient in a high percentage of postoperative patients.[95] While the incidence of significant osteoporosis is not known after RYGB, the prudent approach to vitamin D deficiency is to treat it with supplementation.[96]

Summarizing the vitamin and nutrient needs of patients undergoing LRYGB, we follow what is likely a common set of recommendations for postoperative vitamin supplementation. This includes the following:

1. A daily multivitamin with iron (ferrous gluconate or fumarate)
2. Ferrous gluconate 300 mg BID for women of reproductive age or with documented iron deficiency
3. Calcium citrate 400–600 mg with vitamin D 300–400 IU BID for most individuals who have had RYGB and especially for those who have documented low levels of vitamin D_3
4. Vitamin B_{12} intramuscular injection (usually 1000 μg) or sublingual tablets (1000 μg combined with folate, vitamin B_6, and biotin, one or two daily) as needed for biochemically low levels of vitamin B_{12} on testing

Probably the most common clinically significant vitamin deficiency is iron deficiency anemia. This is usually adequately treated with the appropriate oral supplement. Ferrous sulfate requires an acid medium for optimal breakdown and absorption and should not be prescribed in this patient population. Ferrous gluconate is appropriate instead. Low biochemical levels of vitamin D_3 are common, and, if significant, we treat those with additional vitamin D beyond the amount in the usual vitamin plus calcium supplements. Clinically significant vitamin B_{12} deficiency after RYGB is rare, but despite this, patients with biochemically low levels do receive parenteral or sublingual supplementation until normal levels are achieved.

Biliopancreatic Diversion and Duodenal Switch

Biliopancreatic diversion (BPD) was first described by Scopinaro et al in 1976.[97] The modification of the BPD to a duodenal switch (DS) was performed by Hess and Hess in 1988.[98] These are some of the most difficult bariatric operations to perform and have the highest postoperative complications. They also produce the most durable weight loss, especially in superobese patients. BPD and DS procedures together used to represent less than 5% of all bariatric cases performed in the United States[99] and now represent perhaps fewer than 1% of cases.[70] These operations are best suited to the superobese, for those patients who have failed a restrictive operation, or for those patients who value the ability to continue to eat larger portions of food as a most important aspect of life after bariatric surgery. Patients must be prepared to take a significant number of vitamin supplements after these operations.

OPERATIVE PROCEDURE

The BPD and DS have been performed using both laparoscopic and open approaches. The technical details are similar other than the access to the abdomen, which is similar to all other laparoscopic bariatric operations. Port positions for doing the operation may vary among surgeons, but one example of port placement for laparoscopic DS (LDS) is given in Fig. 27-29.

In performing the BPD, a subtotal horizontal distal gastrectomy is performed, leaving a 200- to 400-mL gastric remnant. The ileocecal valve is identified and the bowel is

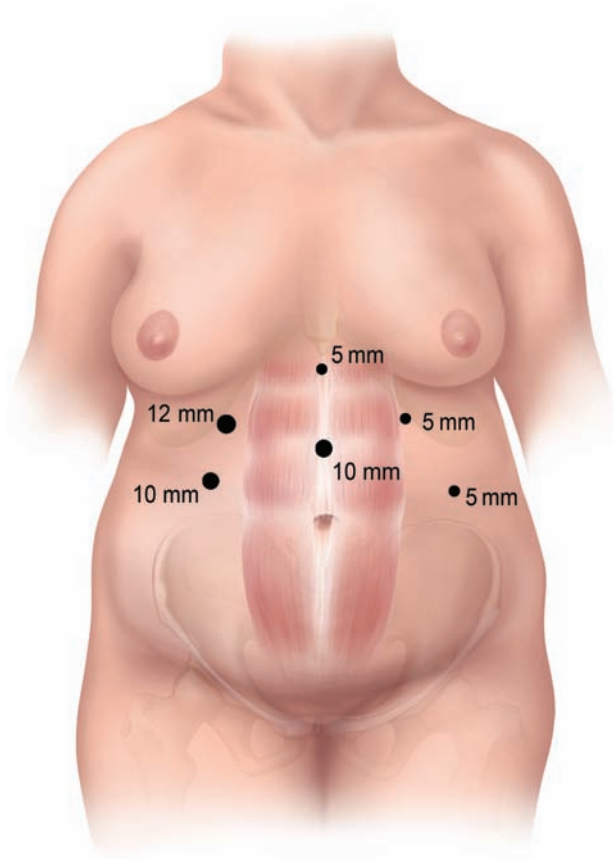

FIGURE 27-29 Picture of ports for laparoscopic duodenal switch (LDS).

measured back 250 cm and divided. The distal end of the divided bowel is anastomosed to the proximal gastric pouch. Either a linear or circular stapler may be used, with the linear the most common choice. The proximal end of the divided ileum is then anastomosed side to side using a linear stapler to the terminal ileum at a point 100 cm from the ileocecal valve. The completed operation is shown in Fig. 27-30. Previously surgeons performed this anastomosis 50 cm proximal to the valve, but this produced higher complications with protein malabsorption. Even Scopinaro and associates described the need to make this "common channel" longer in patients from southern Italy who ate a less protein-rich diet than those from northern Italy.[100] A prophylactic cholecystectomy should be performed due to the high risk of postoperative cholelithiasis.

The DS differs from BPD in the type of gastrectomy. It was developed to reduce the incidence of dumping syndrome and marginal ulceration. In a DS a vertical or sleeve gastrectomy based on the lesser curve of the stomach is performed (Fig. 27-31). The sleeve is calibrated over a bougie typically

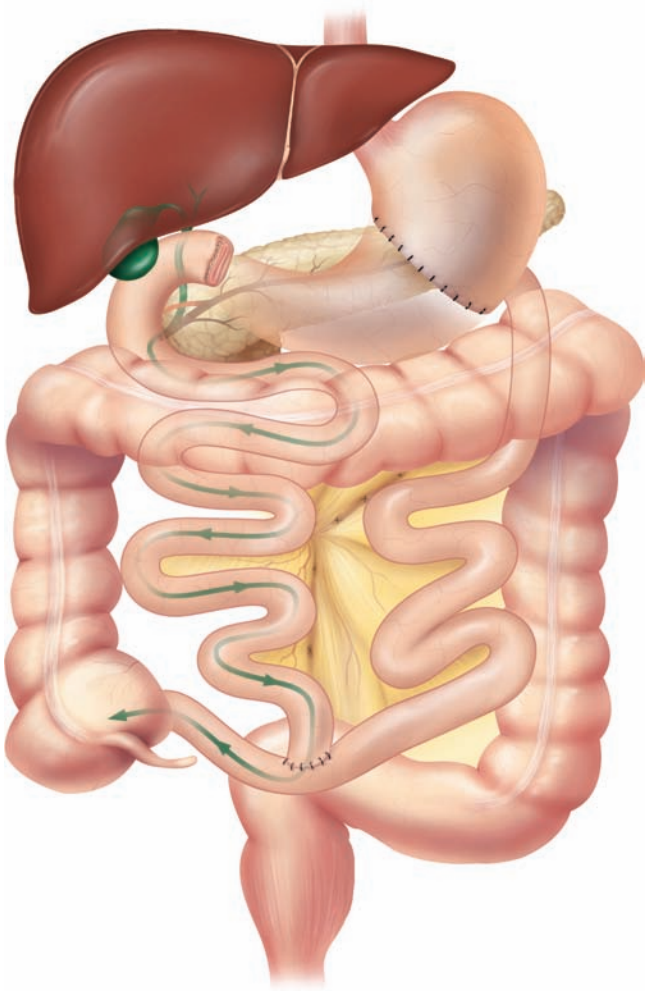

FIGURE 27-30 Picture of completed biliopancreatic diversion (BPD).

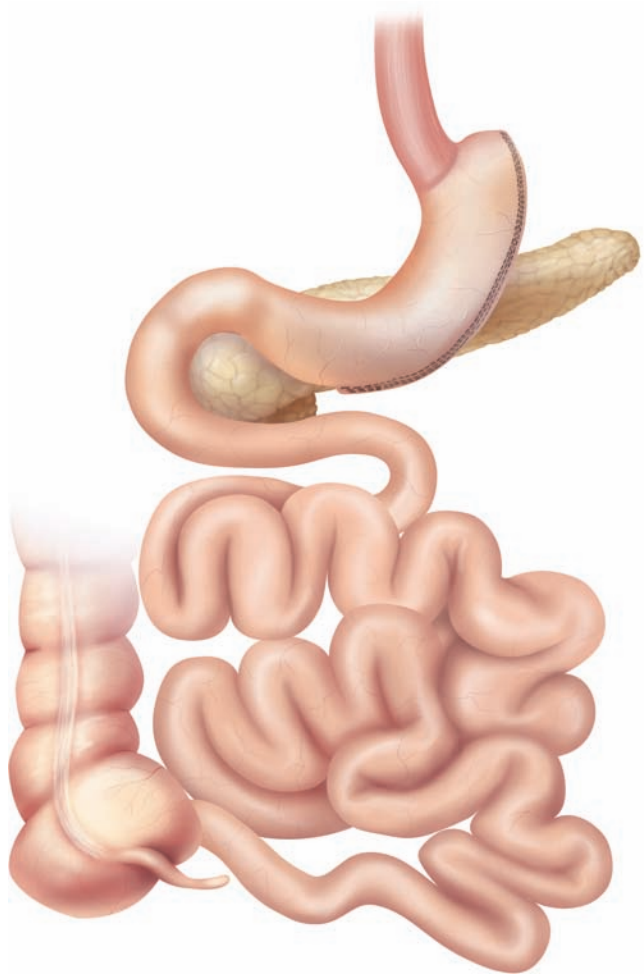

FIGURE 27-31 Sleeve part of duodenal switch (DS).

32–40F leaving a gastric volume of approximately 100–200 mL. The first portion of the duodenum is then divided approximately 2 cm from the pylorus. The end of the distal ileum and the duodenal cuff are then anastomosed. Usually this anastomosis is best done using a hand suturing technique, whether open or laparoscopic. The distal small bowel anastomosis proceeds as previously mentioned, and this is most often performed with a standard linear stapling device. The completed DS is shown in Fig. 27-32. A cholecystectomy should also be performed.

POSTOPERATIVE CARE

Both BPD and DS operations are comparable in terms of most of the issues that must be addressed both in postoperative care and follow-up. The DS is now an accepted procedure in the United States and reimbursed by most third-party payers. The BPD is rarely done in the United States. Thus the remaining discussion pertains to the DS rather than the BPD, unless specified. It should be reemphasized that the BPD poses virtually the same risk and complication spectrum.

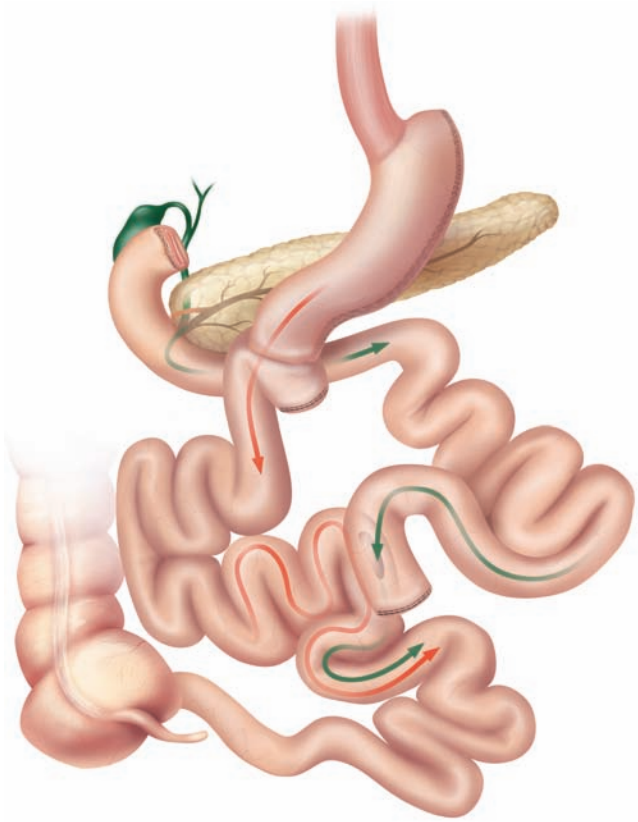

FIGURE 27-32 Completed duodenal switch (DS).

Following DS, patients are at risk for anastomotic leak, gastrointestinal bleeding, pulmonary embolism, bowel obstruction, and stenosis. The complications present with a similar clinical picture to their counterparts after LRYGB. Treatment is also usually similar and outlined in the section under complications later.

The BPD and DS procedures are primarily malabsorptive. Patients must be educated as to the consequences of the operation. They should be instructed to expect diarrhea after any large meal. This diarrhea serves as a powerful behavioral modification to eating. DS patients eat, on average, more calories per day than LRYGB patients but surprisingly only a small amount more.[101] The prolific diarrhea that follows overeating precludes significant excessive food intake. Patients also will learn which foods, primarily those high in fat content, produce the worst diarrhea. Patients should be cautioned about the potential perianal problems that can follow prolific diarrhea, as well as eating patterns that will improve the situation.

Nutritional deficiencies are inherently likely after malabsorptive operations. Education as to proper intake of nutrients and supplements is essential. These patients are at risk for protein-calorie malnutrition, fat-soluble vitamin,, and micronutrient deficiency. Because the duodenum and proximal jejunum are diverted from the food stream, they are as at risk for iron and calcium deficiency as patients undergoing RYGB. Vitamin B_{12} must also be supplemented because of the lack of much of the stomach. Thus one of the main issues regarding postoperative care in DS patients is to ensure that they understand the need for, and have obtained and are taking the proper vitamin and mineral supplements. These may be costly, and that cost should have been part of the preoperative discussion with the patient prior to undertaking the procedure. Magnesium deficiency may also result from short gut syndrome and malabsorption, which was more commonly seen after intestinal bypass operations. It is less common but still possible after DS.

1. A typical recommended supplementation scheme for patients undergoing DS is as follows:
2. Parenteral fat-soluble vitamin injections to include vitamins A, D, and K
3. Oral ferrous gluconate supplementation and oral vitamin D and calcium supplementation
4. Parenteral or sublingual vitamin B_{12} supplements monthly or weekly, respectively
5. Standard multivitamin supplementation orally daily

FOLLOW-UP

Following DS, patients *must* be closely followed by the surgical team, as other care providers may not fully appreciate the problems related to malabsorption. This is particularly true of longer-term protein malnutrition. The primary care physician may mistake the protein-calorie malnutrition seen after DS with manifestations of congestive heart failure or liver disease, which can produce peripheral edema and hypoalbuminemia. If an exacerbation of protein-calorie malnutrition occurs, hospitalization and parenteral nutrition may be needed. Multiple such admissions are an indication to revise the operation and make the common channel longer. The potential for vitamin or mineral deficiency or protein malnutrition never is eliminated for patients after DS; it is a lifetime condition. Thus semiannual blood testing is recommended for such patients even years after surgery.

OUTCOMES

DS produces the best weight loss and the most durable weight loss of any of the commonly recognized and reimbursed bariatric operations.[40] Weight loss in the 75% of EWL is expected after this operation. Furthermore, the weight loss after DS is usually preserved, and recidivism is lower than after either LAGB or LRYGB.[102] Patient satisfaction is generally given as high after the operation.

Resolution of comorbidities after DS is also remarkably good. Conditions that are especially well treated after this procedure include hyperlipidemia, diabetes, and metabolic syndrome.[40,103]

COMPLICATIONS

Immediate postoperative complications that are seen after LRYGB are also seen after DS. These complications present in

a similar manner to those described previously after LRYGB, with the exception of stenosis. This may occur at the proximal anastomosis but may also occur along the length of the sleeve gastrectomy. Such a stenosis may be amenable to balloon dilation, but success is not as likely as with the stenosis of the gastrojejunostomy after LRYGB. Options to treat the ischemic stricture or a severely stenotic stricture of the gastric sleeve are limited to local revision versus a gastrojejunostomy to a Roux limb brought above the stenosis, effectively converting the operation to a RYGB. Bowel obstruction from an internal hernia is also possible after DS, although just at the enteroenterostomy from an internal hernia. Leak at the duodenoileostomy is the most common site of leakage after DS and occurs in the 2–4% range. Treatment of this problem may require a period of parenteral nutritional support before eating is possible.

Fat-soluble vitamin deficiencies may result as a consequence of DS. Vitamin A deficiency, which clinically presents as night blindness, was present in over 70% of patients in one series.[104] In that same series, vitamin D was found deficient in 63% of patients after 4 years. Vitamin K deficiency, manifested as coagulopathy, is more uncommon. Vitamin D deficiency is very prevalent in the population as a whole, and so supplementation after DS is always indicated and low levels are not uncommon. Osteoporosis may result from chronic vitamin D deficiency. The condition is further exacerbated by the fact that calcium is poorly absorbed after DS as well. Iron deficiency anemia will invariably also arise if no supplementation occurs. Although there is no consensus, generally it is recommended to supplement all the above elements as needed, with careful monitoring by serum blood tests serving as the ultimate guide for each patient.[105]

The most feared nutritional complication after DS is protein-calorie malnutrition. Clinical manifestations of this problem include edema, weight loss, skin and nail problems, hair loss, and general malaise. Laboratory tests reveal low albumin and serum protein levels. Increasing oral intake of high-quality proteins may help, but, if the condition is more advanced, parenteral nutrition is often needed. When parenteral nutrition is consistently required, reoperation to lengthen the distance of the "common channel" or intestine below the level of the enteroenterostomy is indicated. Most surgeons make that initial channel about 100 cm. If revision is required, there is no exact formula as to the appropriate length of the revised common channel, but most surgeons would consider adding at least 50 cm if not more to the length to prevent recurrence of protein-calorie malnutrition. Long-term follow-up studies of DS show the incidence of reoperation to be in the 3–5% range.[106]

The BPD has a higher rate of marginal ulcers than DS, with the incidence being over 12% in the original report by Scopinaro et al.[100]

Revisional Surgery

Revisional surgery is a highly controversial area of bariatric surgery. Wide variability exists in the philosophies of bariatric surgeons as to the appropriateness as well as their enthusiasm for performing revisional surgery. A few generalized statements regarding revisional surgery are as follows:

1. The revisional operation will usually produce less of a major change in the patient's weight or reduction in comorbid medical problems than did the index operation.
2. The complications of the revisional operations are higher than the index operation.
3. There should be even greater scrutiny and assessment of patients undergoing revisional surgery than initial operations.
4. Care should be taken to avoid severe nutritional complications that may accompany the combination of too much restriction and malabsorption with revisional surgery.

In general, revisional operations fall under two broad categories:

1. Those done to correct technical shortcomings of the index operation, or complications developing as a result of it
2. Those done as a consequence of poor weight loss from the index operation

Because only RYGB has a track record of durable success of more than two decades among all the restrictive operations, the revision of the others has been a frequent issue. Malabsorptive operations have also enjoyed two decades of success, though their popularity has been significantly lower than restrictive operations. Few patients who have had either a BPD or DS have had the operation reversed, or at least there are few publications reporting this process. The jejunoileal bypass, commonly performed 35 years ago, resulted in an extremely high incidence of revisional surgery for consequences of its malabsorption.[107] Most of these revisional operations were performed years ago. Reversal of the operation was done, and those patients who did not have an associated new bariatric operation performed often regained weight and suffered from recurrent severe obesity.[108]

The vertical banded gastroplasty (VBG) was performed with high frequency in the 1980s but was found to have poor long-term weight loss preservation. As a result, many of the patients who underwent VBG have subsequently undergone revisional surgery. There are numerous accounts in the literature of conversion of VBG to RYGB.[109–111] Most of these accounts include a mixture of patients who had poor weight loss as well as other complications or shortcomings, such as the reported 17% incidence of stenosis after VBG,[112] as the reason for reoperation. Thus the indications for reoperation for VBG have been both as a consequence of both poor weight loss and technical complications. Most of the series of VBG revised to RYGB have had acceptable results in terms of weight loss and resolution of comorbidities. However, these revisional surgeries have also been accomplished with a higher incidence of morbidity than index operations of RYGB.[113]

During the 1970s and 1980s there were a number of gastric stapling operations performed to provide weight loss for patients.[114] Unfortunately, these had uniformly poor long-term outcomes in terms of durable weight loss. Many

patients undergoing those procedures were then converted to operations with a better results record, including VBG and RYGB. This text does not belabor the numerous accounts of these revisions, all of which proved no more effective than an index operation of either RYGB or VGB, and often less effective as a revisional procedure.

Current candidates for revisional surgery include patients who have failed any of the current commonly performed operations. There are increasing reports of poor long-term weight loss outcomes of LAGB from some centers in Europe.[115] Increasing percentages of patients who have requested band removal for poor results are seen in more recent reports regarding LAGB. For patients wishing revision after LAGB, the options would include conversion to LRYGB or to LSG or to DS. Reports of successful conversion to both exist in the literature, but the complication rate is still higher than for the index operation.[116,117]

Revision of RYGB has focused on several different types of problems with the index operation and thus several alternative treatments. Prior to the laparoscopic era, many surgeons performing open RYGB did not actually divide the stomach, but stapled across it with multiple staple rows to create the proximal gastric pouch. Long-term follow-up studies have shown that the risk of dividing the stomach at the index operation proved to be less than the risk of that staple line subsequently breaking down and allowing loss of restriction of the gastric pouch with weight regain, marginal ulcer, or both resulting in the need for reoperation.[118]

Another theory of failure of RYGB is that if the anastomotic opening of the RYGB is too large, it has resulted in the weight regain. From that theory follows the recommendation that an operation or endoscopic procedure to narrow the anastomosis in patients who have regained weight after LRYGB or RYGB will be effective in reversing the weight gain and produce new weight loss. As a result, over the past several years, there have been several reports in the literature about endoscopic[119,120] or other operative procedures to restrict the anastomosis of the RYGB.[121] Unfortunately, the long-term follow-up of those procedures to produce durable weight loss has shown that they are likely to accomplish limited short-term weight loss but not significant durable long-term weight loss.[122,123] The fact that increasing the anastomotic size after LRYGB was associated with a decrease in stomal stenosis after surgery, while still producing comparable weight loss, should have been ample evidence to demonstrate that anastomotic size has only minimal effect on the overall weight loss for patients after LRYGB. This observation is likely true for other operations as well but has not been nearly as well documented. The failure of VBG, however, which depended on the restriction of a small outflow and maintained a fixed small gastric outfow, should have also provided evidence that anastomotic size is not an important determinant of weight loss after bariatric surgery.

Revisional bariatric surgery could encompass quite a long list of relatively small series of revisional procedures of all existing operations. The success of any of these series has been limited. Clearly if one overwhelmingly successful bariatric operation had been discovered among these perturbations and variations on the theme, it is likely it would have been greeted with considerable enthusiasm and publicity. This has not occurred. Therefore, this text does not delve into further details regarding revisional bariatric surgery until data exist supporting its use for improved outcomes over any of the existing index bariatric operations. To date no such data exist.

It also should be freely admitted that the lead author follows the philosophy noted previously, as to whether the operation or the patient has failed as being the determinant of whether revisional surgery is indicated.

Special Situations

PREGNANCY

It has been well established that the desire to bear children does not preclude a woman from having bariatric surgery. Normal pregnancy and childbirth without risk to the fetus is the norm for patients who have had LAGB.[124] The ability to loosen the band by removing fluid from the reservoir is a feature that is desirable for pregnancy, especially if the pregnancy produces any limited ability to eat and drink itself. It has also been well established that patients who have recovered from LRYGB are at minimal to no risk for any problems during pregnancy and childbirth due to the operation.[125] It is generally recommended that patients undergoing LRYGB not become pregnant soon after surgery, during the rapid weight loss phase of the postoperative period. While even this probably has only small risks to the pregnancy, it is best to avoid pregnancy during this time, when weight loss is inevitable and the change in body hormone composition is ongoing due to the operation. Pregnancy during this rapid weight loss phase is a more challenging problem to ensure that the mother has adequate nutrition for the fetus.

AGE LIMIT

There is no distinct guideline for age limit for bariatric surgery. On the younger side, performing bariatric operations for teenagers is well established.[126,127] The youngest appropriate age for a bariatric operation is controversial and still unknown. Limiting further growth potential is a concern when performing bariatric surgery on the adolescent population. This must be weighed against the risk of a high likelihood of lifelong of severe obesity if the adolescent does not lose weight and become closer to normal weight by the time adulthood has arrived. Currently in the United States, the laparoscopic adjustable band is not FDA approved for individuals younger than 18 years of age. This is somewhat ironic in that many bariatric surgeons who perform bariatric surgery for the pediatric age group feel that LAGB offers the best option for this age group, providing weight loss with the least amount of nutrient malabsorption and the most ability to reverse or revise the operation in the future. Indications for performing bariatric surgery itself for adolescent individuals involve all

the same steps and precautions as for adults. Parental consent is obviously needed, and preoperative education, planning, and counseling for a bariatric operation must by necessity be a family affair in the pediatric and adolescent age group. It is controversial as to which operation is best performed for individuals younger than 18 years of age, but currently in the United States LRYGB seems to be the procedure of choice for severely obese adolescents.

Upper age limit for bariatric surgery is similarly controversial. Data do show that in experienced surgeon's hands, individuals who are older than 65 will still have comparable outcomes to their younger counterparts after bariatric surgery.[128,129] However, there must be some limitation of age after which the natural aging process and the toll of organ dysfunction at that age make performance of bariatric surgery an unwise decision. This age is likely more a functional than a chronologic one, and it should be the judgment of the bariatric surgeon to determine age appropriateness for patients for surgery. Individuals who present as candidates for surgery and have been severely obese all their lives are less likely to have good organ function than those prospective patients who became severely obese later in life. The lead author's personal philosophy on this topic is that individuals who have been severely obese all their lives tend to have significant organ dysfunction over age 60 and more so over age 65, and become less optimal candidates for any bariatric operation at that age. However, there are always exceptions to this general guideline. It should also be remembered that the goal of bariatric surgery is to produce improved function and quality of life for a significant period of time in the foreseeable future to warrant the risk of the operation. When life expectancy is limited by age, the potential gain from the operation is thus limited as well.

WEIGHT LIMITS

While the NIH guidelines are clear as to when bariatric surgery should be performed for individuals in terms of being heavy enough to warrant surgery, there are no guidelines as to the patient who presents at the upper echelons of weight. Certainly it has been shown that patients with a BMI exceeding 50 have increased risk of mortality from any complication after bariatric surgery.[130] There are few reports in the literature about performing bariatric surgery for patients with BMI over 70 on a regular basis. We have recently reviewed our own institutional experience and found that patients with a BMI over 60 have had a surprisingly low mortality of under 2% after LRYGB and RYGB. Based on the follow-up study of Christou et al,[50] this patient population would have had a much higher mortality than observed without bariatric surgery. Surgery on individuals with exceedingly high weights is complicated by the logistics of providing care for them as well as the ability to safely complete any bariatric operation. Assuming the latter itself could be overcome, the former still poses a major problem for hospitals in terms of imaging capacity, nursing care and patient hygiene, transportation, and the capacity of hospital clothing, instruments such as blood pressure cuffs, and other aspects of patient care. The Centers of Excellence model of the ACS and ASMBS have required institutions to provide such special availability of equipment for individuals undergoing bariatric surgery, but even those institutions are hard pressed to have any capacity to routinely accommodate the patient with a BMI over 80 or a weight over 500 lb for the above list of needs and equipment. No clear guidelines exist as to what an appropriate upper weight or BMI limit should be for the performance of bariatric surgery at this time.

ENDOSCOPIC SURGERY

The ideal operation to produce weight loss in the bariatric population would be one that could be done without any incisions, but endoscopically. Currently no procedure has been established as having the ability to endoscopically convey durable weight loss for patients. Recent trials of such endoscopic procedures have taken place, only to fail to produce durable weight loss. Short-term nondurable weight loss has been reported for space-occupying devices such as intragastric balloons. However, these procedures are to be viewed with great skepticism, as they can only produce short-term weight loss that must then be followed by performance of a more established bariatric operation if the benefits of any weight loss are to be preserved or enhanced. Performing a single procedure for patients is always more desirable.[13]

It is likely that more trials of endoscopic procedures will continue as the ability of technology to perform endoscopic suturing, tissue approximation, and other key steps in the performance of surgical operations evolves. Perhaps at the next edition of this text, such an operation will be included in a chapter on this subject.

PERSPECTIVE ON MORBID OBESITY AND ITS SURGICAL TREATMENT

Stacy A. Brethauer • Philip R. Schauer

In this chapter, Dr Schirmer and Dr Hallowell provide a detailed and comprehensive overview of the surgical management of morbid obesity. The authors appropriately point out the tremendous worldwide impact that the obesity epidemic will have in the coming years. The chapter provides excellent clinical and technical advice from two experienced bariatric surgeons, and there is little to add regarding the thoughtful approach to patient care that the authors outline. There are, however, several areas within bariatric surgery that remain controversial. The field of bariatric surgery continues to evolve, and new procedures, new technologies, and expanding indications for surgery provide excellent opportunities for research, innovation, and debate. We address several of these areas in our commentary to this excellent chapter.

DIABETES SURGERY

As the obesity epidemic has gained recognition as a major public health issue, though, the closely associated epidemic of type 2 diabetes mellitus (T2DM) has also emerged. In fact, the number of people with diabetes mellitus worldwide has more than doubled in the last three decades.[1] In 2010, an estimated 285 million people worldwide had diabetes and this is projected to increase to 439 million by the year 2030.[2] This staggering number represents nearly 8% of the world population between ages 20 and 79. In addition, while there is little argument that preventative and societal measures must be taken to mitigate this crisis, the importance of having safe, effective, and durable therapies for patients who already have these diseases has taken on greater importance.

The surgical treatment of diabetes, or metabolic surgery, is now gaining acceptance even among physicians who were ardent critics of this concept several years ago. Important advances in our understanding of how these operations effect glucose homeostasis are emerging and partly account for the increased acceptance. Insulin sensitivity improves due to weight loss (visceral fat loss). In addition, several studies suggest that an enhanced incretin effect driven by increased secretion of gut hormones such as glucagon-like peptide 1 (GLP-1) and peptide YY (PYY) may account for improvement in insulin secretion following bypass procedures but not purely restrictive operations.[3,4] Improvements in insulin secretion occur rapidly, even before much weight loss occurs, explaining why remission of diabetes may occur so quickly after bypass surgery.[5] Much more investigation into mechanisms of diabetes improvement after metabolic surgery is required to gain a clear understanding of how these operations effect glucose homeostasis.

Convincing clinical outcomes resulting in diabetes remission rates of 40–80% have provided a foundation for a more collaborative effort between medical and surgical colleagues in treating this disease. This effort began in earnest at the 2007 Diabetes Surgery Summit in Rome[6] and was followed by the American Diabetes Association's recognition of the role of bariatric surgery in the treatment of diabetes in 2009.[7] More recently, the International Diabetes Federation (IDF), an umbrella organization of more than 200 national diabetes associations in more than 160 countries, published a position statement on bariatric surgery concluding that "Bariatric surgery is an appropriate treatment for people with type 2 diabetes and severe obesity (BMI ≥ 35 kg/m^2)." The IDF statement states that surgery "should be prioritized for severely obese patients (BMI 35 kg/m^2) with T2DM," instead of suggesting that it is merely "an option."[8]

Further high-quality evidence is needed to support this change in management strategy, and there are many ongoing prospective randomized trials that will provide more definitive evidence in the next 2–3 years. Of note, many of these trials include patients with body mass index (BMI) in the 30–35 range and these data will hopefully provide further evidence regarding the role of metabolic surgery, even in the absence of severe obesity.

SLEEVE GASTRECTOMY

The authors discuss sleeve gastrectomy as a relatively new procedure and offer some skepticism regarding this procedure's future as a bariatric operation. While it is certainly true that there is not one perfect bariatric procedure, it is important to develop and investigate new procedures that offer various risk/benefit profiles to our patients. The sleeve gastrectomy has now clearly established itself as a procedure with a risk/benefit profile that lies between the laparoscopic adjustable gastric band and the gastric bypass.[9,10] Laparoscopic sleeve gastrectomy's (LSG) irreversibility and the potential for complications are detractors for some patients, but the lack of a foreign body and paucity of long-term complications make it very appealing to others.

Sleeve gastrectomy is often compared to the now abandoned vertical banded gastroplasty (VBG) by some critics, but sleeve gastrectomy is a fundamentally different operation than VBG. First, it is a resectional procedure and this seems to have a powerful effect on hunger and satiety. Second, the LSG does not include a prosthetic band as the VBG did. The presence of a fixed, nonadjustable, stenotic ring in the middle of the stomach was a major reason the VBG failed from an anatomic and behavioral standpoint. Intolerance to solid food, severe refractory gastroesophageal reflux, maladaptive eating behaviors, and loss of restriction (gastrogastric fistula) are either not possible or are rarely seen after sleeve gastrectomy. As with any bariatric procedure, there are a percentage of patients who will require revisional surgery for inadequate weight loss. In the current literature, the percentage of patients undergoing a second operation ranges from 3 to 20%.[11,12] The major advantage of LSG over other procedures in this regard is the relative ease of converting LSG to a bypass procedure. Revision of LSG to a gastric bypass or duodenal switch for patients who require further weight loss can be done safely and is effective.[12,13]

Additionally, there are good data to support the concept that the sleeve gastrectomy is a metabolic procedure and not just a restrictive operation. Ghrelin is suppressed immediately after LSG and this effect is durable.[13] Rapid gastric emptying and nutrient transport after LSG also results in early stimulation of the L cells in the distal bowel.[14–16] This early, exaggerated production of gut hormones like GLP-1 and PYY after LSG certainly places this operation in the category of metabolic procedures.

Another criticism of LSG is the lack of long-term data. As more surgeons used this operation as a primary procedure in the last 5 years, a robust body of literature, supporting LSG as a safe operation, developed. Current data also include many comparative studies and six randomized controlled trials that demonstrate equivalence or superiority to other accepted procedures. Most of the early published series, though, had follow-up periods of less than 3 years. More recently, though, there are several studies that report the long-term efficacy of LSG. In these series, the overall average excess weight loss (EWL) 5–8 years after LSG ranges between 53 and 69%.[12,13,17–19] These long-term results compare favorably to other widely accepted procedures. Based on these data, the American Society for Metabolic and Bariatric Surgery has recently endorsed sleeve gastrectomy as a primary operation and as a first-stage procedure in high-risk patients (www.asmbs.org).

INNOVATION

There is currently a large gap in our therapeutic armamentarium between medical therapy and surgery. Endoscopic therapy for the treatment of obesity is an appealing concept that could potentially fill this gap. As the authors point out, there have been several small trials and a few multicenter studies investigating

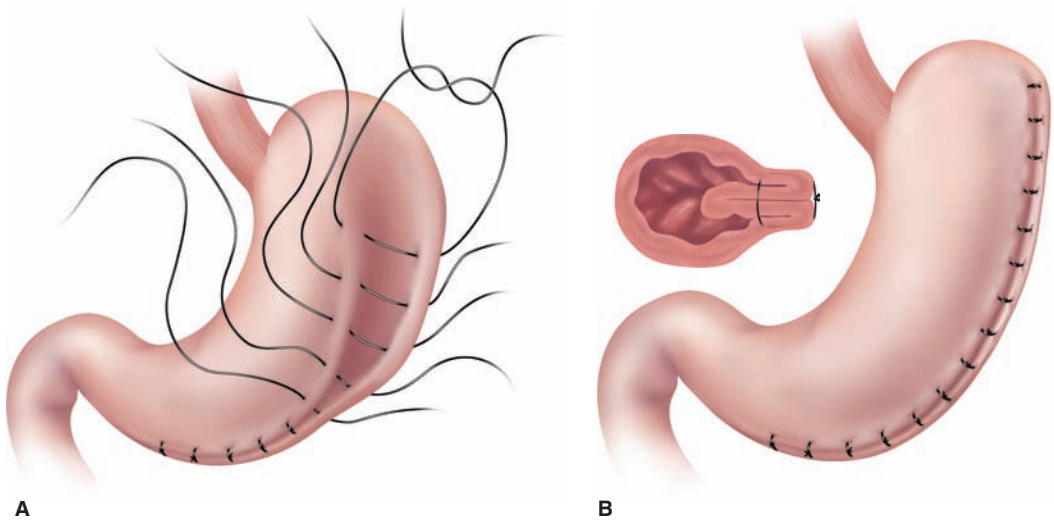

FIGURE 28-1 Laparoscopic greater curvature plication.

endoluminal suturing and stapling devices to achieve gastric restriction.[20,21] These early results have provided a starting point for this emerging field. There are many obstacles to overcome before endoluminal procedures, and devices are ready for general use. Developing devices and procedures that are reproducible with durable results is a formidable challenge. Replaceable devices or repeated therapy with suturing or plication may be a more reasonable clinical goal, but this paradigm is unlikely to be embraced by third-party payers or regulatory agencies.

In the meantime, developing new and less invasive surgical procedures is important to help broaden the options we have for patients. Investigational procedures such as greater curvature plication or the combination of gastric plication and banding have some promising early results (Fig. 28-1).[22] Identifying the true risk/benefit profiles of these new procedures and determining the optimal patients for them remain a challenge and require further long-term investigation.

Innovation has played an important role in the history of bariatric surgery and it should continue to do so. As new technologies and procedures emerge, they should be developed and investigated responsibly with patient safety as the primary goal.

SMALL BOWEL OBSTRUCTION

Guido M. Sclabas • George A. Sarosi • Saboor Khan • Michael G. Sarr • Kevin E. Behrns

Hippocrates, the father of medicine, recognized, described, and treated bowel obstruction many years ago. Praxagoras appears to have performed the earliest recorded operation for bowel obstruction circa 350 BC when he relieved the obstruction of a bowel segment by creating a decompressive, diverting enterocutaneous fistula.

Bowel obstruction continues to be one of the most common intra-abdominal problems faced by general surgeons in their practice. Independent of the underlying etiology, bowel obstruction remains a major cause of morbidity and mortality. Early recognition and aggressive treatment are crucial in preventing irreversible ischemia and transmural necrosis and thereby in decreasing mortality and long-term morbidity. Despite multiple recent advances in diagnostic imaging and marked advances in our treatment armamentarium, intestinal obstruction will continue to occur. The aim of this chapter is to review the etiologies, pathogenesis, diagnosis, and management in the current era with emphasis on early diagnosis and aggressive management, both operative and nonoperative.

DEFINITION

Bowel obstruction occurs when the normal propulsion and passage of intestinal contents cannot occur for whatever reason. This obstruction can involve only the small intestine (small bowel obstruction), the large intestine (large bowel obstruction), or via systemic alterations in metabolism, electrolyte balance, or neuroregulatory mechanisms involving both the small and large intestine (generalized ileus). Mechanical obstruction is due to physical obstruction of the intestinal lumen either from something within the lumen in the wall of the intestine or from an extraluminal cause, while ineffective motility without any physical obstruction causes functional obstruction, also called "pseudo-obstruction," or (paralytic) ileus. Classification can also be based on duration (acute vs chronic), extent (partial vs complete), and type of obstruction (simple vs closed-loop vs strangulation). Closed-loop and strangulation obstruction fall into the category of complicated obstruction and require emergent intervention.

Mechanical Bowel Obstruction

Mechanical bowel obstruction is defined as a physical blockage of the intestinal lumen. This blockage may be intrinsic or extrinsic to the wall of the intestine or secondary to luminal obstruction arising from the intraluminal contents (eg, an intraluminal gallstone or other foreign body) (Table 29-1). Partial obstruction implies that the intestinal lumen is narrowed, but some intestinal content still can transit aborally. In the presence of a complete obstruction, the lumen is obliterated, and no intestinal content can get beyond this point of obstruction. The risk of so-called strangulation, that is, vascular compromise of the intestine, is increased markedly in the presence of a complete obstruction, especially when caused by an extraluminal etiology such as a hernia defect of an adhesive band compressing the small bowel mesentery. Accordingly, complete obstruction can be categorized further into simple, closed-loop, and strangulation obstruction. A simple obstruction is an obstruction without any vascular compromise and the intestine can be decompressed proximally. Closed-loop obstruction occurs when both ends of the involved intestinal segment are obstructed (eg, volvulus or a compressive adhesive band), and results in increased intraluminal pressure secondary to increased intestinal secretion and accumulation of fluid in the involved intestinal segment. Closed-loop obstruction carries a much greater risk of vascular compromise and irreversible intestinal ischemia of the intestinal loop. Finally, strangulation occurs when the blood supply to the affected intestinal segment is compromised, leading to focal or segmental transmural necrosis. The affected segment may involve only a portion of the gut bowel wall compressed by a tight adhesive band or an entire intestinal segment as occurs with a strangulated hernia or a closed loop. If viability of the bowel is maintained after relief of the obstruction, strangulation can be reversed (reversible strangulation obstruction). In contrast, irreversible strangulation occurs if the vascular

compromise has caused irreversible bowel ischemia that will progress to transmural necrosis whether or not the strangulation is relieved. All irreversible strangulation obstructions start as a reversible strangulation obstruction and, thus, the urgency and importance of early diagnosis.

Functional Bowel Obstruction

Functional obstruction or pseudo-obstruction is present when factors causing either paralysis or dysmotility of intestinal peristalsis prevent the coordinated transport of the luminal content aborally (distally) (Table 29-2); the term "paralytic ileus" is used for this condition in most of Europe and Asia and should be distinguished from mechanical ileus. In the United States, the term "ileus" usually refers to functional obstruction, while outside the United States, the term "ileus" is synonymous with intestinal obstruction of any cause—thus, the use of the terms "mechanical ileus" and "paralytic ileus." With a functional obstruction, no physical site of mechanical obstruction is present. The most common form of functional bowel obstruction is postoperative ileus, because it is present to some extent after most all intra-abdominal operative procedures. Various types of extra-abdominal medical and surgical conditions may also cause a transient functional ileus. Besides these more frequent forms of functional bowel obstruction caused by a response to local or systemic stimuli, there is a group of rare, chronic, progressive, gastrointestinal (GI) "pseudo-obstructions." These rare forms of functional obstruction are related either to hereditary or acquired visceral myopathies, visceral neuropathies, or a poorly understood disruption of myoneural coordination of organized contractile activity.

Postoperative ileus represents the most common cause of delayed hospital discharge after abdominal operations.

Its duration tends to correlate with the degree of surgical trauma as well as the type of operation, and it might even be considered a "physiologic" response. A prolonged "pathophysiologic" postoperative ileus may develop in patients operated on for radiation enteropathy, chronic obstruction, or severe peritonitis; with radiation enteropathy, the ileus is probably related to radiation-induced damage to neuromuscular coordination in the irradiated segments. Recovery from a functional ileus after manipulation and local trauma differs among anatomic segments of the GI tract. The small bowel generally recovers effective motor function within several hours after the operation; indeed, contractile activity in the small intestine is evident even during a celiotomy as is demonstrable easily by transient focal intestinal compression. In contrast, it may take 24–48 hours for the stomach to regain normal motor activity leading to delayed gastric emptying, while the colon may take 3–5 days to recover propulsive activity postoperatively; neither spontaneous contractions nor response to manual compression are evident in these organs during celiotomy.[1] The differentiation of postoperative ileus from early postoperative mechanical bowel obstruction and from postoperative paralytic ileus is important, because they are caused by different pathophysiologic mechanisms.[2] In paralytic ileus, there is a prolonged inhibition of coordinated bowel activity that can take days or even weeks to resolve, depending on the etiology. Currently, there are no good pharmacologic agents to prevent or reverse the short-lived "physiologic" process of delayed gastric emptying or the "pathophysiologic" development of postoperative ileus.

Early Postoperative (Mechanical) Bowel Obstruction

Early postoperative bowel obstruction is defined as bowel obstruction occurring within the first 6 postoperative weeks. This type of intestinal obstruction represents a distinct clinical entity with a unique pathophysiology and should be differentiated from both the classic mechanical bowel obstruction as well as from postoperative ileus. The formation of acute adhesions is the responsible cause in over 90% of early postoperative bowel obstructions necessitating surgical management. Other causes include internal herniation, fascial herniation especially after laparoscopic surgery, intra-abdominal abscess, intramural intestinal hematoma, and anastomotic edema or leak. Differential diagnosis may be difficult, and it is not always easy or possible to differentiate early postoperative mechanical obstruction from postoperative ileus. Nausea, vomiting, abdominal distention, and obstipation are themselves relatively common findings in the early postoperative period. Because the initial symptoms of early postoperative mechanical obstruction tend to be vague, patients are often considered to have "physiologic" postoperative ileus. Pain secondary to the recent incision and masked by the use of narcotic analgesics makes the physical examination often unreliable. Interpretation of imaging studies may be difficult, because early postoperative bowel obstruction and ileus can present with similar findings on plain abdominal radiographs. Computed tomography (CT) and contrast studies can help differentiate patients who can be treated conservatively from those who may need operative intervention, especially those with either a focal site of obstruction or the presence of dilated proximal and decompressed distal small bowel; the latter defines a mechanical etiology.[3]

EPIDEMIOLOGY

The etiologies and thereby the prevalence of bowel obstruction vary widely throughout the world depending on ethnicity, the age group considered, dietary habits, geographic location, and even time of the year among other factors. For instance, during Ramadan in Ibadan, the most common cause of small bowel obstruction is small bowel volvulus, believed secondary to the combination of a congenitally narrow base of the small bowel mesentery combined with a large volume of oral intake after sundown. Similarly, in the 18- to 30-year-old age group in Miami, FL, intestinal obstruction secondary to ingestion of drug-filled condoms is not an uncommon cause of intestinal obstruction.

There was a dramatic change in etiology and frequency during the 1900s. Incarcerated hernia used to be the most common cause of bowel obstruction during the first third of the 20th century combined with elective repair of inguinal hernias. The widespread performance of therapeutic intra-abdominal surgery in the second half of the 20th century led to an increase in the frequency of postoperative adhesive obstruction and a decrease in the relative frequency of obstruction secondary to hernias. In addition, early diagnosis and surgical treatment of most abdominal wall hernias resulted in a substantial decrease in intestinal obstruction secondary to incarcerated hernias, especially in industrialized countries where health care is readily available. In the underdeveloped world, however, bowel obstruction still manifests with a clinical picture resembling that found in the early 20th century in Western societies with incarcerated hernias leading the list in frequency. The wider application of minimal invasive surgical procedures with less adhesions may decrease the frequency of bowel obstruction secondary to postoperative adhesions,[4] but long-term follow-up is still short compared to the experience with open procedures.

Obstetric, gynecologic, and other pelvic surgical procedures represent important etiologies for the development of postoperative adhesions. It is not surprising that a slightly greater frequency of bowel obstruction is observed in women.

About 80–90% of bowel obstructions occur in the small intestine; the other 10–20% occur in the colon. Colorectal cancer is responsible for 60–70% of all large bowel obstructions, while diverticulitis and volvulus account for the majority of the remaining 30%. In contrast, small bowel obstruction in most advanced Western societies is caused most commonly by adhesions, abdominal wall hernias, or neoplasms.

Resources expended and costs incurred in the treatment of intestinal obstruction represent a substantive burden on the national health care system of any country. One study estimated that bowel obstruction accounted for over 1 million days of inpatient care and $1.33 billion in health care expenditures in the United States in 1994. Indeed, it has been estimated that 1% of all hospitalizations, 3% of emergency surgical admissions to general hospitals, and 4% of major celiotomies (about 250,000) are undertaken because of bowel obstruction or procedures necessitating adhesiolysis.[5] Another study showed that between 12 and 17% of patients who have undergone a total colectomy are admitted for small bowel obstruction within 2 years of their index operation, while approximately 3% will require an operation to treat an established small bowel obstruction.

Bowel obstruction results in substantial overall mortality and morbidity. Depending on the clinical setting and the presence of related or unrelated comorbidities, mortality rates range from up to 3% for simple obstructions to as great as 30% when there is vascular compromise or perforation of the obstructed bowel. Further, bowel obstruction is frequently a recurrent problem, adding to the overall morbidity of an operation or even repetitive successful nonoperative management. Recurrence rates vary according to method of management (conservative or operative). Future intestinal obstruction will recur in about 12% of patients after a successful primary conservative treatment and in between 8 and 32% of patients after operative management for adhesive bowel obstruction. Another study showed that operatively treated patients had a decreased frequency of recurrence and a greater time interval to recurrence; however, they also had a greater hospital stay than patients treated conservatively. Also, there was no significant difference in incidence, type of treatment, or type of prior operative procedure among patients presenting with early or late small bowel obstruction. In this study, none of the analyzed variables were predictive of success of a particular treatment.[6]

PATHOPHYSIOLOGY

Mechanical bowel obstruction results in numerous alterations of the normal intestinal physiology. The pathophysiology of bowel obstruction remains incompletely understood despite the many changes observed. Bowel distension, decreased absorption, intraluminal hypersecretion, and alterations in motility are found universally, but the mechanisms mediating these relatively dramatic pathophysiologic derangements are not clear. There also appears to be a considerable disruption of mechanisms of neural and hormonal control, the type and quantity of endogenous bacterial flora, and the innate immunity of the gut.

The older, classic literature addressing the pathophysiology of bowel obstruction considered a decrease in blood flow as the sentinel event leading to most of the observed pathophysiologic changes. More recent experimental work, however, suggests that many of the pathophysiologic changes observed in bowel obstruction are related in part to an increase in blood flow in the early phase of bowel obstruction in association with an intense intramural inflammatory reaction. Indeed, there is strong evidence suggesting that this inflammatory reaction plays a key role in the pathophysiology of the intestinal response to obstruction. A recent study showed that mucosal production of reactive oxygen species may be one important mediator of changes observed in simple mechanical bowel obstruction.[7]

Distension, Absorption, and Secretion

Bowel distension is a characteristic, fundamental, and constant physiologic derangement found in mechanical bowel obstruction, although its mechanism has not been fully elucidated. Accumulation of swallowed air is responsible for much of the small bowel distention in the early phases of obstruction. As would be expected, intraluminal gas consists of approximately 75% nitrogen in the obstructed bowel. Fermentation of sugars, production of carbon dioxide by interaction of gastric acid and bicarbonates from pancreatic and biliary secretions, and diffusion of oxygen and carbon dioxide from the blood are other sources of gas early in the obstruction. Dilation and inflammation of the bowel wall cause the accumulation of activated neutrophils and stimulation of resident macrophages within the muscular layer of the bowel wall, inhibiting or causing damage to secretory and motor processes by release of reactive proteolytic enzymes, cytokines, and other locally active substances. Local release of nitric oxide, a potent inhibitor of smooth muscle tone and contractility by the inflammatory response, aggravates intestinal dilation and inhibition of contractile activity. There is a correlation between the amount and activity of nitric oxide synthase, the enzyme responsible for nitric oxide synthesis, and the severity of intestinal dilation observed. Based on experimental data, there is also evidence that there is a close relationship between distention and the intramural production of reactive oxygen metabolites; in addition to disrupting gut motility, these metabolites also modulate permeability of the vasculature as well as the gut mucosa.

Secondary to a prominent decrease in net absorption, water and electrolytes accumulate within the lumen during the first 12 hours of small bowel obstruction. By 24 hours, intraluminal water and electrolytes accumulate more rapidly secondary to a further decrease in absorptive flux; this decrease in net absorptive reflux occurs via stimulation of a concomitant increase in net intestinal secretion (secretory flux). These changes are caused apparently by increased permeability due to secondary mucosal injury resulting in intraluminal leakage of plasma, electrolytes, and extracellular fluid. Whether associated neural or systemic humoral/hormonal mechanisms aggravate this upregulation of unidirectional secretory flux also remains likely but poorly investigated or explained.

This net secretion of fluid into the lumen of the obstructed bowel is exacerbated further by the accumulation of intraluminal bacteria-derived toxins, bile acids, prostaglandins,

vasoactive intestinal polypeptide, and mucosa-derived oxygen-free radicals. With a more chronic obstruction, bacterial proliferation occurs in the lumen, further disrupting absorption, secretion, and mucosal integrity. The decrease in the absorptive capacity and increase in secretion lead to important fluid losses (enterosecretion) that can lead to dehydration if not appreciated and treated. Although the intestinal wall distal to the obstruction maintains a relatively normal function, the inability of the luminal content to reach the unobstructed small bowel and colonic absorptive surface is an important component of the overall dehydration.

Intestinal Motility

In an attempt to propel intraluminal contents past the obstruction, intestinal contractile activity increases in the early phase of bowel obstruction, probably in large part related to the intestinal distention. Later in the course of the bowel obstruction, however, contractile activity decreases, probably secondary to a relative hypoxia of the intestinal wall and the exaggerated intramural inflammation; although the exact mechanisms have not been described adequately, this response may be similar to the changes found early after an abdominal operation, again related to inflammation of the intestinal wall.[8,9] Some investigators[10] have suggested that the alterations in intestinal motility are secondary to a disruption of the normal autonomic parasympathetic (vagal) and sympathetic splanchnic innervation, while others related these changes more to a local effect of inflammation of the intestinal wall.

The splanchnic innervation has been the focus of extensive research, and especially so in the pathogenesis of paralytic ileus. Chemical sympathectomy has been successful in ameliorating the ileus in several experimental models of ileus. Other pharmacologic approaches have focused on blocking the neural inhibitory mechanisms affecting enteric neuromuscular coordination via sympatholytics and cholinergic agonists.[11,12] Still other experimental approaches have been designed to prevent or inhibit the inflammatory response that accompanies the "physiologic" response to celiotomy or the abnormal inflammatory response accompanying generalized ileus.

Circulatory Changes

Different mechanisms can lead to bowel wall ischemia. Extrinsic compression of the mesenteric arcades by adhesions, fibrosis, a mass, or a hernia defect, an axial twist of the mesentery, local chronic, serosal-based pressure on a segment of the bowel wall (eg, a fibrous band), or progressive distention in the presence of a closed-loop bowel obstruction can all cause vascular compromise or strangulation. Large bowel obstruction is especially susceptible to vascular compromise, because about 40% of people have a competent ileocecal valve, setting up a functional "closed-loop" in the presence of a distal obstruction, leading to intense, acute proximal colonic distention; bacterial proliferation and generation of luminal gas further exacerbate the distention.

Progressive distention of the bowel lumen with a concomitant increase in intraluminal pressure results in increased transmural pressure on capillary blood flow within the bowel wall. Severe decreases in perfusion occur in simple, non–closed-loop obstruction, because the obstructed, distended bowel can decompress proximally. In contrast, the possibility of intestinal wall ischemia is a very real concern in a closed-loop small bowel obstruction and especially in large bowel obstruction when the ileocecal valve is competent, and the distended colon cannot decompress retrograde into the small bowel. The resultant increase in intraluminal pressure may compromise blood flow by exceeding venous pressure. This scenario occurs most commonly in the ascending colon where the luminal diameter and resulting wall tension are the greatest based on the law of Laplace. This difference actually makes large bowel obstruction more of a surgical emergency than small bowel obstruction. This type of bowel wall ischemia will lead to a further disruption of intestinal absorption with a relative increase in net secretion, an unregulated increase in mucosal permeability, and intramural production of reactive oxygen species by activated resident and recruited leukocytes; these reactive oxygen species cause peroxidation of the lipid components of the cellular membrane, release of cytokines and other inflammatory mediators, and systemic toxicity. With strangulation, there can also be blood loss into the infarcted bowel, which, together with the preexistent fluid loss, leads to more hemodynamic instability, further exacerbating the already compromised blood flow to the intestinal wall.

Microbiology and Bacterial Translocation

The resident and transient flora of the upper small intestine consists mainly of gram-positive, facultative, anaerobic organisms in small concentrations, usually less than 10^6 colonies/mL. The bacterial count increases more distally to about 10^8 colonies/mL in the distal ileum; along with this increase in number of bacteria is a change of flora to primarily coliform and anaerobic organisms. In the presence of obstruction, however, a rapid proliferation of bacteria occurs proximal to the point of obstruction, consisting predominantly of fecal-type organisms. The proliferation of this fecal flora, proportional to the duration of obstruction, reaches a plateau of 10^9–10^{10} colonies/mL after 12–48 hours of an established obstruction. The bowel distal to the obstruction tends to maintain its usual bacterial flora until the onset of a generalized ileus, resulting only then in bacterial proliferation distal to the point of obstruction. Bacterial toxins have an important role in the mucosal response to bowel obstruction. Experiments in germ-free dogs with a mechanical bowel obstruction have shown that a net intraluminal accumulation of fluid and electrolytes does not tend to occur, and net absorption continues.

Experiments primarily in rodents have shown that bacterial translocation occurs secondary to impairment of the barrier function of the intestinal mucosa if bowel obstruction persists.

This disruption of the mucosal barrier becomes established early after the onset of bowel obstruction. The cellular response to obstruction is multifactorial. In the enterocyte, the endoplasmic reticulum dilates as early as 4 hours after onset of bowel obstruction. Mitochondrial edema, focal epithelial necrosis, intracellular swelling, and degenerative lesions in the nucleus of epithelial cells (apoptosis) have been demonstrated as early as 6–12 hours after the onset of obstruction in this experimental model.[13] The mucosal defense is compromised further by a decrease in perfusion of the intestinal wall. The loss of the mucosal integrity allows luminal bacteria to both translocate as well as to invade the submucosa and enter the systemic circulation via the portal venous and lymphatic systems. Several bacterial substances can be retrieved from peritoneal fluid and lymphatic channels even in the absence of perforation. In the rodent model, bacteria can be cultured from the spleen, liver, and mesenteric lymph nodes, indicating a marked increase in bacterial translocation. Concomitant with bacterial translocation, lymph fluid contains numerous bacterial proteins and lipoproteins which further disrupt normal gut function.

The demonstration of bacterial translocation in these elegant studies with rodent models led to the erroneous assumption of the existence of a similar bacterial translocation in humans. Reproducible documentation of true bacterial translocation in man is notably lacking, and existence of a true bacterial translocation seems unlikely. Several studies have unsuccessfully tried to document the presence of bacteria in intra-abdominal lymph nodes, spleen, liver, and even lymphatics. In contrast, more recent work has shown that lipopolysaccharide and other inflammatory vasoregulatory mediators, but not bacteria, can be recovered from the mesenteric lymphatics. The eventual drainage of these inflammatory substances into the systemic circulation may lead both to the systemic manifestations of sepsis and further disruption of the mucosal barrier function.

The change in the intraluminal bacteriology in simple intestinal obstruction is important clinically, because it increases markedly the risk of infective complications, especially if an intestinal resection is required or if an inadvertent enterotomy occurs with intraperitoneal spillage of "obstructed" enteric contents. In contrast, with irreversible strangulation obstruction, it is clear that a myriad of local and systemic alterations, such as systemic entry of bacterial products, activation of immunocompetent cells, release of cytokines, and increased formation of reactive oxygen intermediates, can promote the systemic inflammatory response syndrome and progress to multiple organ dysfunction with all its consequences.

ETIOLOGY

Adhesions

Adhesions may be defined as abnormal, inflammatory attachments of connective tissue between tissue surfaces. Adhesions can be so-called congenital or acquired (postinflammatory and postoperative). Congenital or inflammatory adhesions are infrequent causes of bowel obstruction, except in selected circumstances, such as rotational disorders (malrotation) or a persistent urachus, among others. The leading cause of small bowel obstruction in Western societies is postoperative adhesions, which are responsible for 40–80% of bowel obstructions seen in most hospital surgical services. This wide variation in incidence of adhesive obstruction varies with different referral patterns, community settings, racial cultures, and countries.

Adhesion formation to some degree is nearly universal after celiotomy and starts as early as the first postoperative hours.[14] While the exact pathogenesis of adhesion formation remains still incompletely understood, experts in this field agree that adhesion formation is a surface event associated with some form of peritoneal injury. The inciting trauma triggers a local inflammatory response leading to activation of the complement and coagulation cascades along with exudation of fibrinogen-rich fluid; the full establishment of this fibrinous inflammatory response is present 5-7 days after the trauma of a celiotomy.[15] Recent findings have identified the presence of sensory nerve fibers in human peritoneal adhesions, suggesting that these structures may even be capable of conducting pain[16] or other neural responses.

Peritoneal healing (mesothelialization) appears to differ from the response in skin, where reepithelialization occurs from the periphery inward. In the peritoneum, operative or traumatic defects are reperitonealized by implantation of mesothelial cells in multiple areas of the defect. This mesothelialization takes place quite rapidly, and resurfacing is often complete by 2–5 days after the injury, depending on local conditions.[17]

Normal peritoneal healing, however, is a complex, interrelated, programmed inflammatory process. The initial response involves infiltration of the wound area with polymorphonuclear leukocytes and lymphocytes. During the ensuing 24–36 hours, circulating and local macrophages are recruited by various chemokines. By 48 hours, a fibrin scaffold overlying the defect has been established; covered by macrophages and a few mesothelial cells, these mesothelial cells then coalesce to fully mesothelialize the defect over the next 2–5 days. Fibroblasts and other mesenchymal cells populate the underlying fibrin scaffold and begin to lay down a basement membrane. By 8–10 days, a single layer of mesothelial cells resting on a continuous basement membrane has been established, and the underlying reactive matrix and inflammatory cells start to regress. This process describes the simple resurfacing of an uncomplicated peritoneal defect.

In contrast, in certain situations, adhesion formation can be considered a pathologic process in comparison to the previously described physiologic process of normal peritoneal healing. It appears that adhesions form in response to the initial fibrin gel matrix combined with the local microenvironment. This fibrin gel matrix consists of numerous types of cells, including the initial leukocytes, but also other humorally active cells such as platelets,

mast cells, and erythrocytes, in conjunction with surgical debris, nonviable tissue, foreign bodies, and possibly bacteria. The resultant spectrum of fibroinflammatory changes between physiologic mesothelial healing versus pathologic adhesion formation varies not only among individuals but is dependent also on many other conditions, such as inflammation, infection, devitalized tissue, and foreign bodies.

If the fibrin gel allows apposition of adjacent surfaces, a band or bridge may form (ie, an adhesion). This process of adhesion formation is a dynamic process, consisting predominantly of macrophages early on, but by 2–4 days, larger strands of fibrin begin to appear along with fibroblasts. By 5 days, distinct bundles of collagen are apparent, and the fibroblasts begin to form a syncytium within the matrix. These cells predominate thereafter, and eventually the fibrin matrix and cellular elements are replaced by a vascularized, granulation-type tissue containing macrophages, fibroblasts, giant cells, and a rich vascular supply. Eventually, the surface of the adhesions are covered by a mesothelial layer, but only after formation of the underlying fibrous scar leading to surface opposition and transperitoneal fibroinflammatory bands of varying severity and extent.

An important factor in the spectrum of adhesion formation that in part determines the risk of future adhesive bowel obstruction is the type of surgical procedure performed. The operations associated most frequently with adhesive bowel obstruction are those involving the structures in the inframesocolic compartment and especially in the pelvic region, such as colonic, rectal, and gynecologic procedures. Adhesive bowel obstruction may occur at any time postoperatively after a celiotomy, with reports ranging as early as within the first postoperative month to more than eight decades after the index operation. A study by Menzies and Ellis[18] found that about 20% of adhesive bowel obstructions occur within 30 days after the initial celiotomy, about 20% occur between 1 and 12 months postoperatively, another 20% tend to occur between 1 and 5 years postoperatively, and the remainder (~40%) occur after even 5 years. A Norwegian study of patients requiring an operation for adhesive bowel obstruction found that most episodes of recurrent bowel obstruction occurred within 5 years after the previous episode, but the risk of bowel obstruction persisted for more than 20 years after a prior episode, reaching an incidence as great as 29% at 25 years.[19] Therefore, a common predisposition to adhesive obstruction is the presence of a prior episode of adhesive obstruction. Numerous surgical attempts to decrease or prevent the development of postoperative adhesions have been reported and are discussed in the following text. The literature on pharmacologic prophylaxis against postoperative adhesion formation is extensive and riddled with numerous false claims of benefit. Suffice it to say that no reliable or truly effective pharmacologic agent has been developed to augment mesothelialization and prevent adhesion formation. Several proprietary barrier products of variable efficacy have been developed and are discussed in the following text.

Hernia

Congenital, abdominal wall hernias (umbilical, epigastric, inguinal, femoral, Spigelian, obturator, sciatic, lumbar, and perineal), congenital internal hernias, or postoperative hernias (incisional, ostomy-related, or mesenteric defects after intestinal resection) with incarceration of the bowel within the hernia are the second most common cause of bowel obstruction in most series. Hernias as an etiology are more common in males than in females, primarily because of the predominance of inguinal hernias in men. In contrast, incarcerated femoral or obturator hernias are more common in women.

Approximately 5% of external hernias will require emergency operation if they are not repaired electively. These hernias are usually incisional hernias, umbilical hernias, and indirect inguinal or femoral hernias. Direct inguinal hernias incarcerate only rarely, and, because of this, the current thinking about the necessity to repair direct inguinal hernias has changed to a more conservative observational approach in the asymptomatic patient. The presence of acute incarceration should prompt emergent operative management, because 10–15% of incarcerated hernias contain necrotic bowel at exploration (Figs. 29-1 and 29-2); chronically incarcerated hernias can develop strangulation, but most chronically incarcerated hernias can be managed electively.

Internal Hernia After Laparoscopic Gastric Bypass

Minimally invasive surgery has brought new etiologies of intestinal obstruction. The reported incidence of internal hernia after laparoscopic intestinal surgery and especially after Roux-en-Y gastric bypass (RYGB) is 0.2–3% and is much greater in incidence than with the open approach.[20,21] Factors contributing to the increased risk of internal hernia after a laparoscopic approach may be the relative lack of adhesion formation combined with increased small bowel mobility, marked weight loss with the associated decrease of mesenteric fat with enlargement of potential hernia openings, and failure to close appropriately all mesenteric defects. There are two or three mesenteric defects created during laparoscopic RYGB depending on retrocolic or antecolic technique[22] (Fig. 29-3). Petersen's defect or space is the best known site of herniation and can be created with either an antecolic or retrocolic position of the alimentary limb.[23] It is named after Petersen, who in 1900 described two cases of internal herniation posterior to a loop gastrojejunostomy.[24] Internal hernias are often difficult to diagnose; indeed, patients with internal hernias present often with nonspecific or intermittent symptoms (periumbilical pain, nausea, vomiting, anorexia, abdominal distention). Spontaneous reduction in the hernia can occur, and CT, upper GI contrast series, and plain abdominal films may be nondiagnostic.[22] Symptoms of intermittent bowel obstruction after laparoscopic

FIGURE 29-2 Umbilical hernia. Operative en bloc resection of hernia sac, umbilical skin, and irreversible strangulation obstruction.

gastric bypass should raise suspicion for occurrence of an internal hernia, especially after weight loss. The best measure to prevent these hernias is the meticulous closure of the created mesenteric defects, and suspicion of an internal hernia may itself be appropriate justification for operative exploration, especially via a diagnostic laparoscopy.

Trocar Site Hernia

The reported incidence of trocar site herniation is 0.2–3%; the true long-term incidence, however, might even be greater.[25] Trocar site hernias are observed rarely with 5-mm trocars but more frequently with the use of 10-mm, 12-mm, or bigger trocars and especially with the "cutting" trocars. Closure of the fascial defect and the use of noncutting, radial expanding trocars have been recommended to decrease the risk for formation of trocar site hernias.[25–27] Trocar site hernias can lead to small bowel obstruction early or late after a minimal access, intra-abdominal procedure. It is also important to think of a Richter-type hernia if the patient has a history of a laparoscopic procedure and is complaining about abdominal pain in the area of the trocar site, even in the absence of (intermittent) symptoms of bowel obstruction. Richter's hernia occurs when the antimesenteric wall of the intestine protrudes through a hernia defect but does not cause luminal obstruction. Richter's hernias are dangerous, because reduction in the necrotic bowel wall during hernia repair can result in missed perforation and peritonitis. A Richter hernia can result in strangulation and necrosis in the absence of intestinal obstruction. Although Richter's hernias are rare, with the widespread use of laparoscopy they have become a well-known trocar site complication.

Malignant Bowel Obstruction

Primary intra-abdominal neoplasms are a common cause of both large and small bowel obstruction. Colorectal, gastric, small bowel, and ovarian neoplasms are among the most frequent causes of malignant bowel obstruction, either from the primary lesion (colon and small bowel neoplasms) or from peritoneal metastases (ovarian, colonic, and gastric neoplasms). In many of these patients, bowel obstruction is associated with a high rate of recurrence and morbidity and may often be a terminal event.

Metastatic cancer can also cause bowel obstruction. The most common form of obstructing metastatic lesion is peritoneal carcinomatosis, but localized hematogenous metastases to the wall of the small intestine from melanoma and carcinoma of the breast, kidney, or lung can also cause intraperitoneal metastases that can obstruct the bowel (Fig. 29-4).

Granulomatous Diseases and Crohn's Disease

Crohn's disease is a chronic, transmural, inflammatory disease of the GI tract that may affect any part of the alimentary tract from the mouth to the anus. Despite often intense involvement of the bowel wall, Crohn's disease is responsible for about fewer than 5% of cases of small bowel obstruction. When true mechanical obstruction is present, the cause is usually secondary to the inflammatory process or to stricture formation. Other granulomatous diseases causing obstruction, such as tuberculosis and actinomycosis, are much less common in Western countries, but in the developing world where acquired immune deficiency syndrome (AIDS) and human immunodeficiency virus (HIV) infection are endemic, intra-abdominal tuberculosis must be entertained in the diagnosis of intestinal obstruction.

Intussusception

Intussusception is a relatively frequent cause of bowel obstruction in infancy (in the first 2 years of life) but accounts for only 2% of bowel obstruction in the adult population.[28] The median age of presentation in adults with intussusception is the sixth to seventh decade. The etiology of intussusception differs greatly between adult and pediatric patients. In the vast majority of adult intussusceptions, there is a demonstrable inflammatory lesion or

FIGURE 29-4 Renal cell carcinoma metastatic to small intestine.

a neoplasm that serves as the lead point of the intussusceptions. Neoplasms causing intussusception in adults are malignant in almost 50% of patients. Although rare in the Western Hemisphere, intussusception is one of the most common causes of bowel obstruction in central Africa for reasons as yet not fully explained.

Volvulus

Volvulus represents an axial twist of the bowel and its mesentery. This entity is an infrequent cause of small or large bowel obstruction in the Western Hemisphere (Figs. 29-5 and 29-6). Volvulus is encountered more frequently in the geriatric

population, in individuals with a long history of constipation, or in institutionalized, neurologically impaired, or psychiatric patients. Colonic volvulus comprises about 1–4% of all bowel obstructions and about 10–15% of all large bowel obstructions. The volvulated segment has to be relatively mobile to allow the degree of freedom necessary to permit an axial twist of the mesentery. Either the affected segment has an especially long, narrow mesentery (eg, malrotation or cecal volvulus) and/or a lack of bowel wall fixation (floppy cecum syndrome) or one aspect of the affected segment is fixed, around which the contiguous segment can twist (eg, a deep fibrous band fixing the other end of the segment).

Other variables also appear to play a role in the etiology of volvulus. In the Bolivian and Peruvian Andes at more than 10,000 ft above sea level, sigmoid volvulus represents 79% of all bowel obstructions. The high altitude plays a role somehow in the high incidence in this population, but the mechanism is not well understood.

Overall, sigmoid volvulus accounts for 75% of all patients with volvulus. In contrast, cecal volvulus is responsible for the majority of the remaining 25% of bowel volvulus incidences in the United States and is the most common cause of large bowel obstruction in pregnancy. The "cecal bascule" is a somewhat unique, though less common, form of cecal volvulus that occurs when the true anatomic cecum (ie, the part of the ascending colon that lies caudal to the entrance of the ileocecal valve) flops anteriorly over onto the ascending colon, obstructing the lumen. This form of cecal volvulus may be intermittent and recurrent and is often difficult to diagnose.

Primary volvulus of the small intestine is extremely rare in the United States but is quite prevalent in central Africa, India, and the Middle East. Speculation about etiology has been related to abrupt dietary changes that occur during the religious holiday when the people celebrating Ramadan fast during the day and then consume a large meal after dark. Some investigators, however, maintain that this racial group has an exceedingly long, floppy small bowel mesentery that permits generous mobility of the small bowel.

Other Causes

Other causes of bowel obstruction include the following: congenital lesions such as Meckel's diverticula, duplication cysts, rotational disorders of the intestine, annular pancreas, and omphalomesenteric duct remnant; infections such as appendicitis, Meckel's or cecal diverticulitis, the latter more common in the Asian population, and complicated diverticulitis; inflammatory conditions like starch peritonitis, intra-abdominal abscess, and localized perforations; intraluminal obstruction from stricture, gallstones, phytobezoar, swallowed foreign body, and parasitic infestation; posttraumatic lesions like mesenteric or intramural hematomas; and miscellaneous extraluminal conditions such as radiation enteropathy (Figs. 29-7 and 29-8), endometriosis, and superior mesenteric artery syndrome.

FIGURE 29-7 Radiation changes in distal colon/rectum (*arrows*).

FIGURE 29-8 Radiation enteropathy. Note the narrowed segments of ileum with much thickened bowel walls (separation between adjacent loops).

DIAGNOSIS

The diagnosis of bowel obstruction is suspected clinically based on the presence of classic signs and symptoms and then confirmed by some form of imaging modality, such as abdominal radiography or CT. The etiology can often be pinpointed by careful history taking complemented with imaging studies.

History and Physical Examination

The classic clinical picture of a patient suffering from bowel obstruction includes intermittent crampy abdominal pain, distention, acute obstipation, nausea, and vomiting. Abdominal pain and then distention usually precede the appearance of nausea and vomiting by several hours. The more proximal the obstruction, the earlier and more prominent are the symptoms of nausea and vomiting, while distension is usually less. In contrast, the more distal the obstruction, the more prominent the abdominal distention. Vomiting is relatively uncommon in colonic obstruction until its later stages. The abrupt onset of symptoms makes an acute obstructive cause more likely and may herald the presence of a closed-loop obstruction. The location and character of pain may be helpful in differentiating mechanical bowel obstruction from ileus. Mechanical bowel obstruction usually presents as severe, truly crampy pain localized to the midabdomen, while ileus tends to have a more diffuse and mild pain, often without the waves of colic. Both, however, are associated with nausea and vomiting.

Characteristically, the pain associated with mechanical small bowel obstruction is usually described as visceral, poorly localized, and crampy with recurrent paroxysms occurring in short (10–30 seconds) crescendo-decrescendo episodes. In contrast, in mechanical large bowel obstruction, the episodes are usually spaced farther apart in time and tend to last longer (1 or 2 minutes rather than seconds) compared to small bowel obstruction. Classically, the presence of constant or a localized pain has been regarded as a sign of strangulation. Several studies, however, have shown that these findings are neither specific nor sensitive for the detection of strangulation.

Obtaining a complete medical history is of utmost importance. The past medical history may be key in making both the diagnosis and establishing the cause of bowel obstruction. It is especially important to inquire about previous episodes of bowel obstruction, recent and distant abdominal operations, current medications, a history of chronic constipation, recent changes in the caliber of stools, a history of cancer, its stage at presentation and related treatments (operative therapy, chemotherapy, or radiation therapy), and a history of Crohn's disease.

A thorough physical examination is mandatory and should include assessment of vital signs and hydration status as part of the initial resuscitation. Thereafter, abdominal inspection, auscultation, palpation, a search for potential hernia defects of all external aspects of the abdominal wall, and a rectal examination (palpation and test for occult blood). It is important to look closely for previous surgical incisions, including inguinal incisions for previous "extraperitoneal" herniorrhaphies (recurrent hernias are common). Differential diagnosis should also include consideration given to the possibility of internal hernias or those "external" hernias not necessarily associated with an obvious "bulge," such as obturator, femoral, or intramural Spigelian hernias.

Tachycardia, hypotension, and oliguria are signs of advanced dehydration that require aggressive resuscitation while continuing with further evaluation. Fever may be associated with an infectious cause or with strangulation. Auscultation can determine the presence, frequency, and quality of the "obstructed" bowel sounds. Mechanical bowel obstruction presents with an increase in the frequency of bowel sounds, but more specifically the high-pitched "rushes" and "groans" followed by the metallic tinkling sounds of "water dripping into a large hollow container," indicative of dilated bowel with an air-fluid interface. In contrast, functional bowel obstruction lacks the rushes and groans but continues to have the metallic tinkling indicative of dilated bowel. Sometimes functional obstruction (ileus) may present with an absence of bowel sounds. In both mechanical and functional bowel obstruction, a succussion splash is usually present (dilated stomach or markedly dilated small bowel filled with an air-fluid interface); the presence of a succussion splash is not normal in a patient who has not eaten or ingested liquids in the previous 1–2 hours and should be regarded as an important, abnormal, and often underappreciated sign of bowel obstruction (unless the patient just recently vomited his or her gastric contents).

Abdominal palpation should reveal the presence of peritoneal signs, such as rebound, localized tenderness, and involuntary guarding that herald vascular compromise or perforation. The presence of these findings cannot be ignored. Abdominal masses should be sought and noted. A meticulous search for inguinal and femoral hernias is essential, because they can be overlooked easily. The rectal examination should rule out fecal impaction and should be evaluated for occult or macroscopic blood in the stool.

Laboratory

There is no laboratory test sensitive and specific enough to diagnose mesenteric ischemia reliably. A spectrum of laboratory tests may, however, be helpful in determining the condition of the patient and should guide the resuscitation. A complete blood cell count and differential, electrolyte panel, blood urea nitrogen, creatinine, and urinalysis should be obtained to evaluate fluid and electrolyte imbalance and to rule out sepsis. Arterial blood pH, serum lactate concentrations, and amylase and lactic dehydrogenase activity may be useful (but not overly sensitive) tests in the evaluation of bowel obstruction, especially when trying to exclude the presence of strangulation, obstruction, or underlying bowel necrosis. An increase in serum lactate concentrations should raise the suspicion of intestinal ischemia; however, it is often a late finding.[29,30] D-dimer was proposed as an early marker of acute mesenteric ischemia, but it appears to be insensitive.[31,32] Intestinal fatty acid–binding protein (I-FABP) is a highly sensitive marker for extensive mesenteric infarction; however, it does not appear sensitive enough to detect more limited intestinal ischemia in strangulated bowel.[33,34] Others have suggested that serum concentrations of phosphate and isoforms of creatine phosphokinase (isoform B),[35,36] plasma level of ischemia-modified albumin,[37] and gut luminal tyrosine concentrations[38] may identify the presence of intestinal cell necrosis. Yet, the specificity and especially the sensitivity are not accurate enough to base a management decision solely on these values. Recently, the presence of a spectrum of findings on CT, including mesenteric edema, free peritoneal fluid, intestinal wall thickness, and the absence of fecalization of the small bowel content appear to offer additional signs of underlying strangulation obstruction.[39]

Radiologic Findings

The management of small bowel obstruction has changed little in recent decades and remains reliant heavily on excellent clinical acumen and appropriate imaging. The clinician is faced with answering the critical questions, "Is this complete obstruction and is the intestine ischemic?" Recently, the literature is replete with clinical studies examining the prognostic value of various forms of imaging in terms of predicting the need for operative management or the presence of intestinal ischemia. Most of these series have investigated the role of CT, and we will highlight these findings.

FLAT AND UPRIGHT ABDOMINAL RADIOGRAPHS

Plain radiographs, including a chest x-ray and flat and upright films of the abdomen, remain a valuable initial imaging modality in patients with clinical small bowel obstruction. An initial chest x-ray may reveal extra-abdominal processes such as pneumonia that could be associated with an ileus rather than bowel obstruction. In addition, the presence of free air from a perforated viscus may indicate a diagnosis other than small bowel obstruction or a serious complication of small bowel obstruction requiring emergent treatment.

Flat and upright films of the abdomen in patients with a small bowel obstruction characteristically have multiple air-fluid levels in dilated loops of bowel and a paucity of gas in the distal (decompressed) small bowel and colon (Fig. 29-9). The location of the obstruction in the proximal or distal small intestine, however, influences greatly the findings on the plain abdominal films. A very proximal small bowel obstruction may be associated with films that demonstrate few, if any, air-fluid levels with a relatively small gastric air-fluid level resulting from a fluid-filled stomach. Conversely, a distal small bowel obstruction likely will have multiple air-fluid levels with dilated loops of small bowel stacked on one another (Figs. 29-10 and 29-11). Similarly, the pattern of bowel gas may assist in determining whether the obstruction represents a small or large bowel process. On a plain abdominal film, the small bowel lies centrally, and intestinal

markings from the valvulae conniventes or plicae circulares encompass the entire diameter of the bowel, whereas the large bowel lies at the periphery of the abdomen and haustral markings only partially cross the bowel. Furthermore, the appearance of the bowel gas may also give a clue as to the duration of the obstruction. So-called "fecalization" of

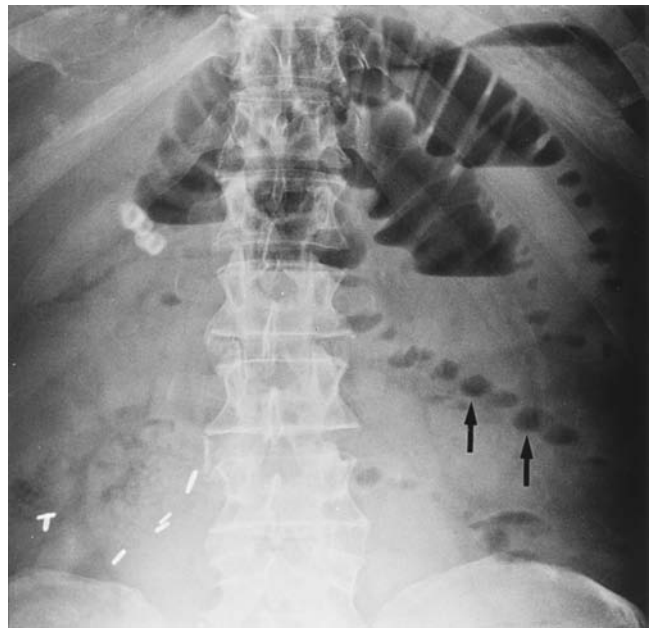

FIGURE 29-11 Small bowel obstruction with fluid-filled loops of small bowel in left lower quadrant (*arrows*).

the small bowel content, whereby the luminal content shows less of an air-fluid level and more of an appearance of semisolid content with pockets of gas, suggests a more chronic obstruction and may be helpful in supporting the need for operative intervention, not because of worry of strangulation but rather a chronic, established, nonresolving process.

Uncommonly, a plain film of the abdomen will contain a pathognomic sign of intestinal obstruction from gallstone ileus (a misnomer because it is a true mechanical obstruction) as is the case with pneumobilia in a patient with gallstones and no history of biliary instrumentation. Importantly, plain films of the abdomen are notoriously poor indicators of bowel involved with vascular compromise unless the devastating signs of portal venous gas and intestinal pneumatosis are evident. Closed-loop bowel obstructions are also difficult to be diagnosed on plain x-rays, because the involved bowel with a proximal and distal occlusion may be fluid filled and lack any gas. Thus, alternative imaging procedures should be contemplated in patients with any suspicion of compromised bowel.

CONTRAST STUDIES

Though contrast studies using either dilute barium or hyperosmotic, water-soluble contrast of the small and large bowel were an integral component of the diagnostic evaluation previously, enthusiasm for these studies has waned substantially. The radiologic literature and various guidelines developed by the radiologic community support strongly the use of contrast-enhanced CT as the diagnostic imaging modality of choice.[40] Nonetheless, in specific clinical situations, such as in a patient with an obstructing sigmoid or rectal tumor, a radiograph with

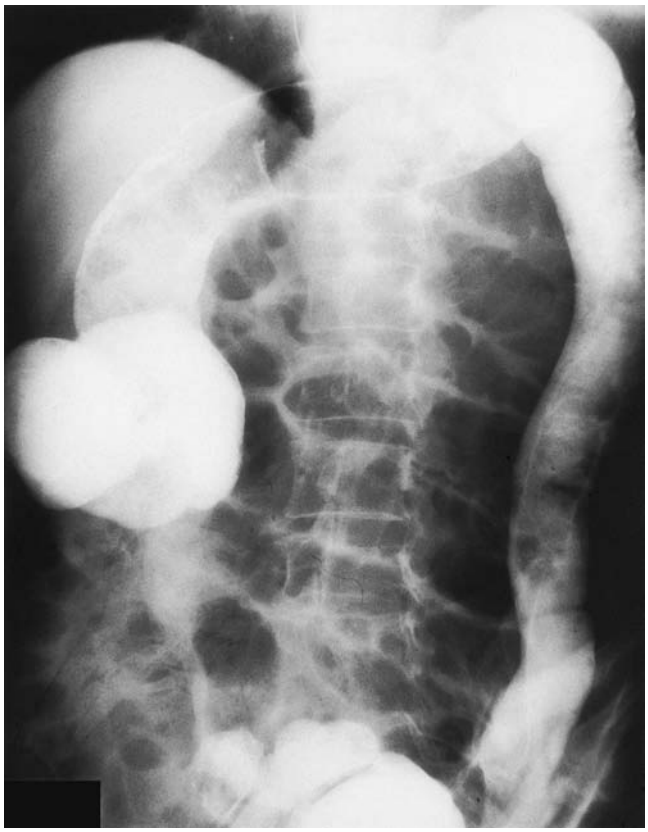

FIGURE 29-12 Barium enema showing complete large bowel obstruction in the ascending colon.

rectally administered contrast may provide diagnostic information that is timely, economical, and clinically important (Fig. 29-12). CT offers information concerning the extraintestinal anatomy as well as showing obstruction. On occasion, a small bowel follow-through series may be helpful in distinguishing between mucosal inflammation versus extraluminal compromise from adhesions as the etiology of bowel obstruction in a patient with Crohn's disease. This diagnostic information may alter the therapeutic approach.

Furthermore, contrast studies using water-soluble, hyperosmotic contrast have been used as a therapeutic modality in patients with intestinal obstruction. The mechanism(s) by which administration of this contrast agent may result in relief of an obstruction is not completely understood. A number of studies have examined the therapeutic benefit of contrast studies. In 1994, a study by Assalia et al found that patients receiving gastrografin had a much lesser time to their first bowel movement (6.2 vs 23.3 hours), a lesser rate of operative treatment (10 vs 21%), and lesser mean hospital stay (2.2 vs 4.4 days) when compared to those who did not receive the water-soluble contrast.[41] In 2002, Choi and coworkers[42] reported a prospective, randomized study that showed that the therapeutic use of Gastrografin not only had a role in determining the need for eventual operative management of patients with a presumed small bowel obstruction, but also appeared to decrease the need for an operation by 74%. Similarly, Chen et al[43] used the findings of gastric emptying of the orally administered contrast and whether the contrast reached the colon within 8 hours to determine the eventual need for operative treatment. Recently, Abbas et al performed a meta-analysis that showed that Gastrografin did not influence the need for operative therapy but did decrease the duration of hospital stay of patients treated nonoperatively.[44] Alternatively, Feigin and associates could not confirm any benefit of the use of water-soluble contrast in patients with small bowel obstruction.[45] Thus, this topic remains unresolved.

When contrast agents are utilized, the risks of each agent must be considered carefully. The primary side effects of barium include inspissation in the obstructed large bowel (not the small bowel because the obstructed small bowel is filled with liquid). Also, barium results in severe intraperitoneal infection/barium peritonitis when extravasated in the face of small intestinal perforation. Gastrografin, if aspirated, can cause a severe pneumonitis; moreover, this contrast agent becomes diluted rapidly with an established small bowel obstruction and thereby yields little information in a distal small bowel obstruction. Finally, most surgeons agree that contrast studies are contraindicated in patients with a clear diagnosis of complete bowel obstruction and when strangulation or perforation is suspected.

COMPUTED TOMOGRAPHY

In many centers, computed tomography (CT) has become the primary diagnostic imaging modality for the diagnosis of suspected intestinal obstruction, and, in fact, in some institutions, it has replaced plain radiographs as the initial imaging test. This increased use of CT reflects the preference of clinicians for the additional diagnostic information garnered from this examination. CT does not only provide information about the presence or absence of a luminal obstruction, but it can also define both the site of obstruction and the existence of extraluminal processes, associated inflammation, fluid collections, masses, abdominal wall or internal hernias, and free intraperitoneal fluid.

Several studies have reported a diagnostic accuracy of greater than 90% with the use of CT in intestinal obstruction.[46–48] In addition, some studies suggest that a CT scoring system may predict accurately the need for operative intervention. Jones et al found that a scoring system with the criteria of a dilated small bowel, identification of a transition point, ascites, complete obstruction, partial obstruction, evidence of a closed-loop obstruction, and/or free air predicted the need for operative treatment in 75% of patients.[49] Of particular note, O'Daly and colleagues found the association of peritoneal fluid with small bowel obstruction to be a strong predictor for the need for operative treatment.[50] Moreover, surgeons are interested keenly in the capability of CT to predict ischemia or strangulation of the bowel; however, the evidence for this is contradictory. In a systematic review, Mallo et al found that the sensitivity, specificity, positive predictive value, and negative predictive value of CT for predicting ischemia were 83, 92, 79, and

93%, respectively.[51] Conversely, Sheedy et al noted that with CT, sensitivity was 15% and specificity 94% for identifying bowel ischemia prospectively in patients with small bowel obstruction.[52] A recent study by Zielinski et al suggested that CT findings of free peritoneal fluid, thickened bowel, and mesenteric edema, combined with vomiting, were predictive of the need for eventual operative management, but, though relatively sensitive for ischemia, CT was not very specific.[39] In the face of conflicting evidence regarding the ability of CT to predict intestinal ischemia, the importance of obtaining and/or following selected clinical parameters (eg, peritonitis, worsening acidosis) of intestinal ischemia cannot be underemphasized. It is important to remember that CT is better at identifying rather than excluding the presence of ischemia.

Although the increased use of CT in patients with bowel obstruction has provided greater diagnostic information, caution must be exercised in the use of this modality in distinguishing mechanical small bowel obstruction versus ileus. In one study, up to 20% of patients with a CT diagnosis of ileus required operative intervention eventually.[53] Overall, the current preference for the use of CT is associated with an increased likelihood of operative intervention and decreased mortality; however, whether these associations are causal or coincidental remains unknown.[54]

ULTRASONOGRAPHY

Ultrasonography (US) is used infrequently in the diagnosis of intestinal obstruction. Even though the reported specificity is 82%, sensitivity is 95%, and overall accuracy is 81%, this modality is highly operator-dependent and the results are unlikely to be reproduced consistently in many institutions. US has been reported to be useful for the early recognition of strangulation obstruction in several Japanese and European studies[55,56]; however, in the absence of an experienced ultrasonographer, the reliability of US remains questionable. Furthermore, US is difficult to perform in obese patients, and extensive bowel gas may obscure the pattern of intestinal obstruction.

MAGNETIC RESONANCE ENTEROGRAPHY

Magnetic resonance enterography (MRE) has not been utilized as frequently as CT, because performance of this examination is more time consuming and requires substantial expertise in interpretation. Additionally, in general practice MRE does not have a greater diagnostic accuracy than CT. In contrast, in centers that use MRE frequently, diagnostic accuracy exceeding 90% is achievable.[57,58] MRE may have an advantage of distinguishing benign from malignant bowel strictures in patients with suspected malignant bowel obstruction.[59]

VIDEO CAPSULE ENDOSCOPY

Video capsule endoscopy (VCE) may be a valuable diagnostic tool in patients with subacute or chronic intestinal obstruction where other imaging techniques have not revealed an etiology. VCE is particularly helpful in patients with obstruction related to a stricture caused by inflammation or malignancy.[60] Overall, VCE may provide a diagnosis in nearly 40% of previously undiagnosed patients.[61] A major concern with the use of VCE, however, is retention or impaction of the capsule either at a stricture or in any area of severe kinking related to adhesions in a patient who otherwise may have resolution of the obstruction without an operation; the incidence of this circumstance appears infrequent, but impaction may require celiotomy.

Detection of Ischemia

Identification of strangulation obstruction caused by ischemia of the intestine is a critical diagnosis, because the mortality associated with strangulated bowel obstruction is 9–40% compared to less than 5% in nonstrangulated intestinal obstruction.[62] Unfortunately, clinical and imaging parameters claimed to permit early detection and operative intervention remain unreliable and, in fact, do not lead to early diagnosis. Jancelewicz et al found that decreased bowel wall enhancement on CT, leukocytosis, and peritoneal signs were the only independent predictors of strangulation obstruction on a multiple logistic regression analysis.[62] Historically, acidosis, increased serum amylase activity, and increased serum lactate concentrations were also claimed to be indicators of strangulation. While abnormalities of these parameters may prove to be sensitive markers of strangulation, they generally neither lack specificity nor offer useful positive or negative predictive value. Abdominal US and pulsed-Doppler US have been reported to be useful in identifying patients with strangulation. Ogata and associates reported that an akinetic, dilated loop of bowel observed on real-time US has a high sensitivity (90%) and specificity (93%) for the recognition of strangulation; the positive predictive value was 73%. The presence of free peritoneal fluid seen on US was also sensitive for strangulation.[63] Further studies of the usefulness of US are needed.

MANAGEMENT

Small Bowel Obstruction

The initial management of patients with small bowel obstruction should focus on aggressive fluid resuscitation and nasogastric decompression of the stomach to prevent further accumulation of intestinal fluid and air; in addition, nasogastric decompression decreases the potential for aspiration and relieves vomiting. These therapies should be instituted in all patients, whether they are treated operatively or undergo a trial of nonoperative management. Blood should be analyzed for serum electrolyte concentrations, typed and screened for potential transfusion, and, when necessary, arterial blood gases should be analyzed as well.

The most important initial step in management is vigorous crystalloid fluid resuscitation. Patients with small bowel obstruction often present with profound volume losses and

may require large amounts of isotonic crystalloid solutions, such as normal saline (0.9% NaCl) or lactated Ringer's solution with additional potassium when necessary. Resuscitation should be guided by urine output, provided the patient is hemodynamically stable and has normal renal function. Patients who are hemodynamically unstable or have impaired cardiac, pulmonary, or renal function may require monitoring of central venous or pulmonary arterial pressure to better evaluate their volume status. Colloid solutions, such as 5% albumin or hetastarch, have little or no role in the resuscitation of patients with a small bowel obstruction. Steps should also be taken to correct metabolic or electrolyte imbalances, which may be severe. Specifically, in patients who have experienced prolonged vomiting, potassium and chloride should be measured to diagnose hypokalemic, hypochloremic alkalosis and replaced appropriately. Though potassium replacement is a critical component of therapy, replenishment of this electrolyte should begin only after renal function has been established by good urine output. Volume resuscitation, electrolyte replacement, and establishment of adequate urine output are critical before operative therapy is undertaken. Broad-spectrum antibiotics should be given to patients within an hour of the incision to prophylaxis against surgical site infection, but, otherwise, antibiotics have no defined utility in the later postoperative period or in those patients initially managed nonoperatively.

Most surgeons believe that nasogastric decompression is important to prevent further intestinal distention from swallowed air and to limit aborad transit of gastric contents. In addition, nasogastric decompression also helps to prevent aspiration during vomiting and on induction of general anesthesia. Symptomatically, gastric decompression helps relieve abdominal distension and can improve ventilation in patients with respiratory compromise.

Historically, long intestinal tubes placed distal to the pylorus were used to relieve small intestinal distention under the assumption that intestinal decompression may be therapeutic if related to adhesions, because the decompressed bowel may detort and thereby relieve the mechanical obstruction (Fig. 29-13). Success rates of up to 90% have been reported in some series of patients treated with a long nasointestinal tube.[64] In contrast, however, most prospective and retrospective studies have failed to demonstrate the superiority of nasointestinal versus nasogastric intubation,[64,65] making the added expense of fluoroscopic or endoscopic placement of a nasointestinal tube unwarranted. Use of these long intestinal tubes has fallen out of favor, and they are of historic interest in the preoperative treatment of small bowel obstruction.

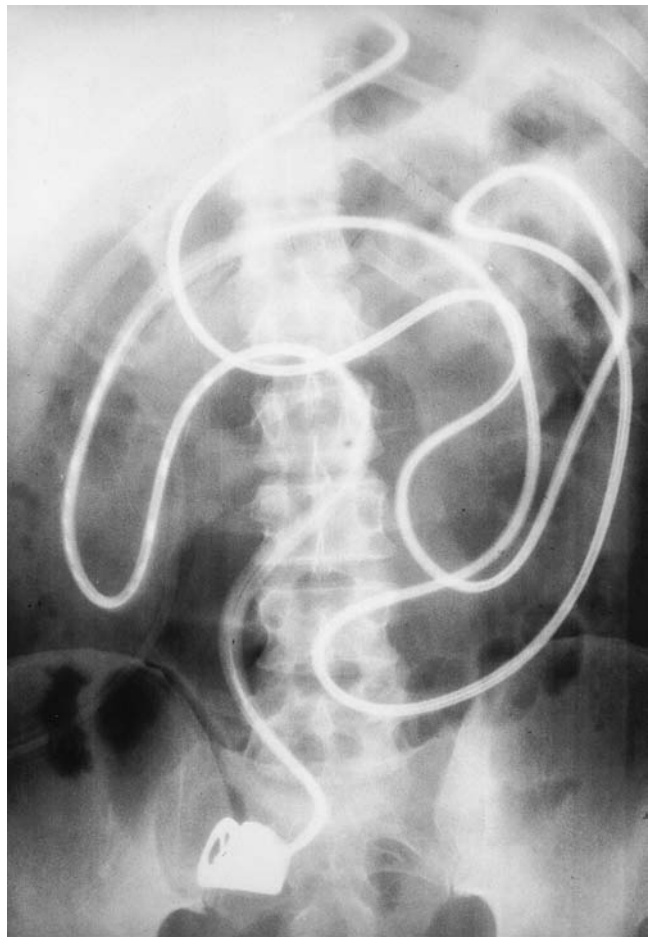

FIGURE 29-13 Abdominal radiograph showing distal passage of a long nasointestinal decompression tube into the small bowel distal to the ligament of Treitz.

Nonoperative Management

Nonoperative management of intestinal obstruction should be considered only in patients with uncomplicated intestinal obstruction in the absence of peritonitis, a progressive leukocytosis, or impaired bowel wall perfusion on imaging. When indicated, this approach is reported to be successful in 62–85% of patients.[43,66–69] The rate of success is influenced likely by patient selection, type of bowel obstruction (complete versus partial), etiology (eg, adhesions, hernia, or neoplasm), and the surgeon's threshold for conversion to operative management. Patients successfully managed nonoperatively require lesser hospital stays[66,67] and avoid the morbidity or convalescence necessitated by an operation. Few studies have compared the long-term outcomes of patients with a small bowel obstruction treated nonoperatively versus operatively. One such study with over 4 years of follow-up reported by Landercasper and colleagues[70] found a recurrence rate of 29% in patients managed operatively versus a recurrence rate of 53% for patients managed nonoperatively. Even though the recurrence rates may be greater with nonoperative management, the authors point out that about half of the patients managed nonoperatively never developed a recurrent small bowel obstruction.

A recent study by Rocha et al[71] used the radiologist definition of "high-grade" obstruction and reported that in these patients, comparing those treated conservatively versus those

treated by operation, the conservatively treated patients had a significantly greater readmission rate at 5 years (24 vs 9%) than those treated operatively. Use of this radiologic finding may potentially extend the "indication" when criteria are met for high grade but not complete obstruction.

Absolute contraindications to nonoperative management include suspected ischemia, large bowel obstruction, closed-loop obstruction, acutely incarcerated or strangulated hernia, and perforation. In an attempt to define which patients with an uncomplicated small bowel obstruction can be successfully treated nonoperatively, Chen and colleagues[43] used an orally administered, water-soluble contrast agent (Urografin) to study 116 patients with small bowel obstruction. The presence of contrast material within the colonic lumen within 8 hours of oral administration had an accuracy of 93% for predicting which patients would benefit from nonoperative therapy. In their study, only 19% of patients with a small bowel transit time of more than 8 hours had resolution of their obstruction with nonoperative treatment. One of the criteria for conversion to operative treatment was the failure of contrast to reach the colon within 8 hours. Therefore, the 81% failure rate in patients in whom contrast never reached the colon within 8 hours after administration may be artificially high based on study design.

A relative contraindication to nonoperative management is complete small bowel obstruction, that is, dilated small intestine with no air in the bowel distally. In a prospective study by Fleshner and associates,[67] all patients with an uncomplicated small bowel obstruction underwent an initial trial of nonoperative management. They were able to manage 45% of patients successfully with a complete obstruction (by their definition), while 66% of patients with a partial obstruction were successfully managed nonoperatively, all with no mortality. These investigators, however, did not describe the incidence of intestinal ischemia at operation based on the presence or absence of complete versus partial obstruction. Another study by Fevang and colleagues[66] reported a 42% success rate in managing patients with a complete small bowel obstruction nonoperatively. When they compared complete and partial obstructions managed nonoperatively, there was a greater rate of bowel strangulation (10 vs 4%) and need for resection (14 vs 8%) in the group with complete obstruction at the time of operation for treatment failure. This group noted a mortality of 6% in patients with a complete obstruction initially managed nonoperatively versus 0% mortality for patients with a partial obstruction initially managed nonoperatively. Other groups have also noted a greater rate of ischemic bowel coupled with a lesser success rate in those patients with a complete obstruction managed nonoperatively.[65,72] These studies and the unreliability of clinical acumen to recognize strangulation obstruction accurately have led many surgeons to favor early operation for all patients with a complete small bowel obstruction,[69] leading to the often-quoted phrase "The sun should never rise or set on a (complete) small bowel obstruction." If nonoperative management is attempted in a patient with complete obstruction, the decision should be made with the understanding that there is a definite risk of overlooking an underlying strangulation obstruction,[72] and thus there should be a low threshold for operative intervention in patients with complete obstruction.

When patients with a small bowel obstruction are initially managed nonoperatively, vigilant attention must be paid to volume resuscitation, electrolyte homeostasis, and nasogastric decompression. Patients managed nonoperatively require the same aggressive resuscitation and realistic replacement of daily losses with an appropriate crystalloid solution and electrolyte replacement as patients who are managed operatively. Fluid replacement should take into consideration the volume and electrolyte loss in the output of the nasogastric tube, urinary output, and insensible losses. Electrolytes should be monitored frequently and corrected as necessary. Delayed correction of potassium and magnesium concentrations may lead to delayed return of bowel function and misdiagnosis of obstruction versus ileus.

Adequate proximal decompression is important to allow the bowel an opportunity to become unobstructed. This concept is accomplished by maintaining a functioning nasogastric tube. If the patient becomes progressively more distended or develops vomiting, tube placement should be evaluated and tube function confirmed by bedside evaluation. Standard nasogastric tubes should be inserted, such that the second of four marks is evident at the tip of the nares. The first mark is 40 cm from the tip of the tube, that is, the normal distance from the nares to the esophagogastric junction. Thus, if all four marks are outside the nares, the tube most likely is not in the stomach. Likewise, if no marks are visible, the tube is coiled within the stomach or is in the duodenum. On occasion, an abdominal radiograph is necessary to confirm placement. If the tube is noted on radiograph to be out of position, it should be repositioned and imaged again for proper placement. On evaluation, the tube should be connected to the suction apparatus, sumping properly (if the tube has a sump port), and should be checked for patency by flushing and aspirating water through the suction lumen. Oral intake should be minimized in the presence of a nasogastric tube, and, when allowed for patient comfort, the volume of ingested fluid should be recorded carefully to allow quantitation of gastric aspiration. In addition, the tube should never be "clamped" for prolonged periods of time, because by traversing the esophagogastric junction, the tube will lead to an incompetent lower esophagogastric sphincter and potential aspiration. Connection of the tube to a drainage bag for a brief trial is an appropriate alternative to clamping and may be used as a test to determine patient readiness for nasogastric tube removal.

When to Convert to Operative Management

Prompt operative intervention is mandatory in patients who develop signs and symptoms suggestive of a strangulation obstruction. These parameters include fever, tachycardia,

leukocytosis, localized tenderness, continuous abdominal pain, and peritonitis. The presence of any three of these signs has an 82% predictive value for strangulation obstruction.[72] Similarly, the presence of any four of the above signs has a near 100% predictive value for strangulation obstruction. Obviously, patients who develop free air, signs of a closed-loop obstruction on abdominal radiograph, or gross peritonitis require emergent operative exploration. If CT demonstrates evidence of ischemia, such as pneumatosis intestinalis, bowel wall thickening, portal venous gas, generalized ascites, or nonenhancement of the bowel wall, operative intervention should be considered strongly.[69]

The timing of conversion to operative management in a patient with a small bowel obstruction who is not improving with nonoperative management is more controversial. Some surgeons advocate operative intervention in any patient who fails to show improvement within 48 hours of initiating therapy.[65,68] Others advocate a more liberal use of nonoperative therapy, citing a mean time to successful resolution of up to 4.6 days.[67] The authors believe that nonoperative management can be continued greater than 48 hours with the understanding that delaying inevitable operative treatment will result in a greater overall hospital stay and increased costs and may place the patient at increased risk for perioperative morbidity. It is important for the surgeon to remember that nonoperative management always carries a calculated risk of overlooking an underlying strangulation obstruction.[72]

Operative Management

Once the decision has been made to pursue operative management, steps should be taken to prevent peri- and postoperative complications. Preoperative preparation includes assessing the medical fitness of the patient and, as time allows, taking steps to optimize the patient's medical status. Special consideration should be given to ensure that the patient has been resuscitated adequately, appropriate antibiotics have been given, and any electrolyte abnormalities have been addressed. Consideration should be given to the administration of beta-blockers to patients with cardiovascular comorbidities and especially to those who were on beta-blockers prior to admission.[73] A nasogastric tube should already be in place to decrease the risk of aspiration during the induction of anesthesia; nevertheless, a "crash," rapid-sequence induction will still be necessary to protect the airway during intubation, despite the presence of a nasogastric tube.

Several decisions must be made with regard to operative planning to provide the safest approach that will afford the best outcome for each individual patient. The choice of operative approach and incision is important to allow the surgeon adequate exposure and visibility. A laparoscopic approach should at least be considered in some patients.[74] When an obstruction develops in the early postoperative period, the original incision should be reopened provided extensive adhesions were not present originally. Safe entrance into the peritoneal cavity may be best achieved by approaching this from the extremes of the previous incision rather than going directly through the midportion of the incision. In patients without a history of prior abdominal operation or those who are remote from their original operation, a midline celiotomy affords the best exposure to all four quadrants of the abdomen. For example, patients with upper oblique, transverse, or subcostal type incisions may have pelvic adhesions that are difficult to address from the upper abdomen, especially through a high transverse incision.

Once within the abdominal cavity, the first step is to identify the site and cause of obstruction. If the point of obstruction is not obvious, decompressed bowel distal to the obstruction can be identified and followed proximally to the point of obstruction. Care should be taken when handling the obstructed bowel at or near the point of obstruction when acutely obstructed, especially if it is fixed at an apparent site of obstruction or if it is ischemic. This region is at high risk for strangulation and infarction, making it more likely to rupture with spillage of bacteria-laden enteric contents into the abdomen. The dilated bowel proximal to the offending obstruction is often thin-walled and at increased risk for perforation if the obstruction is acute. After the offending obstruction has been corrected, a thorough exploration of all four quadrants should always be undertaken to ensure that all intestinal injuries are repaired, nonviable segments are resected, and a second site of obstruction or fixation is not overlooked; this concept is especially true for volvulated segments of small bowel where two points of fixation are often present. Sometimes obstructing bands traversing a sizeable part of the peritoneum can affect more than one loop of bowel. When a small bowel resection is necessary, intestinal continuity of the small bowel can be accomplished generally with a primary anastomosis unless there is generalized peritonitis and the edges of the remnant bowel are of questionable viability. When an intestinal anastomosis is performed, the discrepancy in bowel diameter and wall thickness between the obstructed proximal bowel and decompressed distal bowel are important factors in choosing anastomotic techniques. The surgeon may consider a side-to-side or end-to-side anastomosis in situations where massive dilation of the proximal bowel makes an end-to-end anastomosis difficult technically. In addition, a stapled anastomosis may be less safe in cases where a large discrepancy in bowel wall thickness exists or when there is bowel wall edema, because uniform approximation of the tissue for a given staple height may not be possible.

Abdominal closure may be difficult to achieve when the small bowel is massively dilated. In these cases, intraoperative intestinal decompression will facilitate closure. Techniques described for intraoperative decompression include manual retrograde decompression into the stomach (with careful handling of the obstructed bowel), intraoperative passage of a long nasointestinal tube, and, rarely, performance of a controlled enterotomy with passage of a decompressing tube; the latter technique is strongly discouraged except under very select circumstances, such as tremendous intestinal distention preventing abdominal closure or distention threatening bowel

viability. Manual retrograde decompression of luminal contents around the ligament of Treitz, through the pylorus, and into the stomach allows for aspiration through the nasogastric tube by the anesthetist.[75] This maneuver is the safest and quickest technique, because it allows closure of the abdominal wall while avoiding an enterotomy and excessive manipulation of the bowel. When decompressing the bowel, care must be taken to handle the inflamed and distended bowel gently, because experimental studies have demonstrated an increased rate of bacteremia after extensive manipulation of obstructed bowel.[76] In addition, the anesthesia team should be alerted to the maneuver to be certain that their nasogastric tube is functioning well. Although intraoperative decompression has not been shown to decrease the rate of postoperative complications or the speed of return of bowel function, it certainly does make the closure easier, faster, and safer.

Nonviable bowel needs to be identified and resected. Resection should be undertaken with caution, especially in patients with a limited length of bowel from a previous resection or those with large sections of ischemia. Adjuncts for determining bowel viability include the use of Doppler US and intravenous fluorescein. These tests are relatively subjective, should be used with caution, and are only adjuncts to sound clinical judgment. In patients who would otherwise be left with less than two-thirds of their original bowel length after resection of all bowel of questionable ischemia, consideration may be given to resecting all the grossly necrotic or obviously nonviable bowel, but preserving bowel of questionable viability and performing an end ostomy or a second-look procedure 12–24 hours later, particularly if the viability of the ends to be anastomosed is in question.

BYPASS VERSUS RESECTION

In patients with an incurable malignant small bowel obstruction, if the offending obstruction is unable to be released or it is deemed unsafe to attempt to dissect out the point of obstruction, intestinal bypass can be performed. Bypass relieves the obstruction while reestablishing intestinal continuity and preventing a closed-loop obstruction; however, the advisability of a bypass procedure should be considered. For instance, in the presence of carcinomatosis, a bypass may prove fastest and safest, because patient survival will be short. In contrast, patients with certain chronic inflammatory diseases will remain at risk for ongoing problems (eg, Crohn's disease or tuberculosis) related to the inflammation in any "bypassed" segment and therefore such patients may be served better by resection than simple bypass.

The surgeon should at least consider an initial laparoscopic, minimal access approach in patients with uncomplicated small bowel obstruction. Laparoscopy is known to cause fewer adhesions than open laparotomy[77] and in that regard may be superior to laparotomy for the treatment of adhesive small bowel obstruction. Several studies have shown laparoscopy to be a safe and effective means of access for the operative treatment of small bowel obstruction.[74,78–80] When successful, a laparoscopic approach decreases both the duration of hospital stay[74,78,80] and the complication rate.[78,80] Patients successfully treated laparoscopically appear to have more rapid return of bowel function.[78,80] These reports showing a large benefit to laparoscopic treatment for small bowel obstruction, however, need to be interpreted carefully. Many series compare patients treated laparoscopically to those who failed initial laparoscopic treatment. Those patients unable to be treated laparoscopically likely had more extensive adhesions or complicated pathology possibly requiring resection. Operative intervention in these patients would be more involved and complex whether done open or laparoscopically. One would expect these patients to have greater hospital stays, greater complication rates, and slower return of bowel function independent of the method of abdominal access. In addition, the skill and confidence level of the surgeon should weigh in the decision to approach the obstruction laparoscopically. First, if the surgeon lacks skill in using moderately advanced laparoscopic techniques, an open operation may be a better choice. Similarly, if the patient is known to have a frozen abdomen or has either a severely distended, tense abdomen with markedly distended bowel or multiple dense adhesions at the time of insertion of the laparoscope, conversion to an open procedure is wise. Initial access for creating the pneumoperitoneum in a patient with a small bowel obstruction is achieved best by a fully open approach under total visual control, but limited data support this concept.

RECURRENT SMALL BOWEL OBSTRUCTION

Although the results of individual studies vary, between 4 and 34% of patients will experience recurrent small bowel obstruction regardless of management modality.[5,66,68–70,81,82] This wide range of recurrence rates likely results from variations both in the duration and quality of follow-up between studies as well as the etiology of the original bowel obstruction. Recurrent obstruction is more common in patients with multiple adhesions, matted adhesions, previous admissions for small bowel obstruction, and previous pelvic, colonic, and rectal surgery.[5,70]

In the past, numerous attempts have been made by surgeons to control the formation of adhesions in an effort to prevent future mechanical obstruction. A simple technique to prevent adherence of the bowel to the undersurface of the fascial incision is to interpose the omentum between the bowel and the incision. Theoretically, when adhesions from the posterior surface of the anterior abdominal wall form after omental interposition, they will involve the omentum and not the underlying bowel. Other more intricate techniques, such as the Noble plication and the Childs-Phillips transmesenteric placation, have been described in the more distant past. These procedures involve the suturing adjacent loops of small bowel into an orderly pattern in an attempt to plicate the bowel permanently in a position that will not allow mechanical obstruction.[82] Although initial reports were encouraging, the Noble and Childs-Phillips procedures have multiple complications and are of historic interest only. The problems associated with plication procedures have included

prolonged operative times and high rates of enterocutaneous and enteroenteric fistula, abdominal abscess, and wound infection; moreover, the rate of recurrent obstruction is as great as 19%, questioning seriously their efficacy. Attempts to "plicate" the bowel with a long intestinal tube, so-called intraluminal plication, are also of questionable efficacy.

In some patients, it will become evident during the course of the operation that complete or adequate adhesiolysis is not possible or may risk vascular injury to a substantial segment of bowel because of the acute inflammatory nature or tenacity of the adhesions. This situation is especially common when celiotomy is deemed necessary or performed too soon after a previous intra-abdominal procedure (see the following section on early postoperative small bowel obstruction). This situation is especially common when the previous operation involved an extensive adhesiolysis. In such situations, it may be important to control any bowel injuries present, end any further dissection, and conclude the operation to prevent further bowel injury and its potential sequelae. This approach has been used by the senior author five times in 25 years of practice. This "conservative" approach may allow the acute inflammatory process to resolve or regress (often 3–6 months); should the obstruction not resolve by 6 months, the plan should be to reoperate at a time when the adhesions have matured, allowing a more controllable and much safer adhesiolysis. In some situations, the mature decision might be to provide proximal diversion with a proximal enterostomy if the obstruction has no chance for resolution (eg, due to malignancy or radiation) or if a more distal bowel repair is tenuous, or to place a tube gastrostomy for diversion and patient comfort. Pursuing a futile attempt to complete the adhesiolysis puts the patient at risk for serious bowel injury or devascularization injury necessitating resection of otherwise normal bowel with the risk of enterocutaneous fistulation or subsequent short bowel syndrome.

ADHESION PREVENTION

Over the last 100 years, multiple approaches have been employed in an attempt to prevent the formation of unwanted postoperative adhesions. These attempts include, among others, the use of cow cecum, shark peritoneum, sea snake venom, and fish bladder, as well as multiple fluids, mechanical barriers, and gels.[81] The concept of separating injured surfaces mechanically to prevent adhesions is a very attractive one. The formation of fibrin bridges (and thus adhesions) may be preventable by separating injured surfaces in the postoperative interval during the critical period of healing and mesothelialization by application of an absorbable "biofilm." Estimates of the minimum amount of time necessary for an impermeable or semipermeable barrier to prevent adhesion formation appear to be about 36 hours. Some authors have placed a Silastic sheet between two injured peritoneal surfaces; when left in place for 36 hours, no adhesions formed between these surfaces thereafter.[17] Others have postulated that separating the surfaces at risk for the first 5–7 days until full mesothelialization occurs would seem to be most effective; however, the barrier should not incite its own inflammatory response and should not decrease fibrinolytic activity or suppress access to oxygen. The ideal product, therefore, should be bioabsorbable (preferably via a process such as hydrolysis), last only about 5–7 days, be easy to apply, be interposed between all injured surfaces, and not itself incite an inflammatory reaction.

The most effective method to date has been the application of a sheet of bioresorbable, hyaluronate membrane; this approach has been shown to decrease the formation of adhesions at the site of application.[81,83] In addition, two recent systematic reviews have demonstrated that use of this product, indeed, decreases adhesion formation at the site of application.[84,85] These reviews, however, both support the observation that use of a hyaluronate membrane application did not decrease the incidence of postoperative bowel obstruction nor did it decrease the need for operative intervention for intestinal obstruction. Furthermore, if the membrane is wrapped around an intestinal anastomosis, the leak rate is increased.

Initial concerns that were raised over the safety of hyaluronate barriers appear unfounded, with the exception of iron cross-lined hyaluronate that was withdrawn from the market. A prospective, randomized, controlled trial showed that hyaluronate barriers did not increase the risk of intra-abdominal abscess or pulmonary embolism[83]; however, in a post-hoc subgroup analysis of 289 patients in whom the hyaluronate membrane was wrapped around a fresh anastomosis, the rates of leak, fistula formation, peritonitis, abscess, and sepsis were increased. Based on these studies and assumptions, the use of hyaluronate membranes in elective abdominal surgery does decrease the amount of postoperative adhesions at the site of application but does not decrease the incidence of intestinal obstruction or the need for future reoperation for obstruction. Use of these products requires careful consideration, because they are expensive and their clinical benefit appears to be relatively low.

Other materials or substances are being developed that someday may move to the forefront of adhesion prevention. These include gel and liquid preparations such as hyaluronic acid and carboxymethylcellulose, hydrogel, fibrin sealant, and protein polymers. Other adhesion barriers include oxidized regenerated cellulose (ORC). ORC has been well studied and does help prevent adhesion formation, but its use requires a blood-free field that at times is not practical to achieve. The use of ORC, like hyaluronate membranes, has not been shown to decrease the incidence of subsequent adhesive small bowel obstruction.[86]

EARLY POSTOPERATIVE SMALL BOWEL OBSTRUCTION

Early postoperative small bowel obstruction is a relatively uncommon problem but remains a very real dilemma encountered in every practice performing abdominal operations. Although the surgery literature defines early obstruction from 30 days to 6 weeks after the original operation, for the purposes

of this chapter, we will consider early intestinal obstructions as those occurring within 6 weeks of operation. Obstructions occurring after 6 weeks are managed similarly to other bowel obstructions.

It is often difficult, if not impossible, to distinguish early obstruction from postoperative ileus, but fortunately the management is usually quite similar. Patients with suspected early mechanical small bowel obstruction should be managed initially by nasogastric decompression, fluid resuscitation, and correction of any electrolyte abnormalities. After a thorough physical examination and the decision that emergent intervention is not indicated, a search for the cause of obstruction should be undertaken. CT can be helpful in determining the etiology of an obstruction but is notoriously unreliable at differentiating ileus versus partial obstruction. Obstructions caused by extrinsic bowel compression amenable to percutaneous correction, including fluid collections, abscesses, and hematomas, may be diagnosed and treated by CT-guided drainage. CT may be able to detect those causes of obstruction that will likely require operative intervention, such as internal hernia, fascial dehiscence, and uncontrolled anastomotic leak. Early CT may be warranted in patients who had a laparoscopic operation and have signs of early obstruction, because a port site hernia may be evident and would require prompt operation.

Generally, two categories of patients with early postoperative small bowel obstruction have been recognized.[69] The first category includes those in whom the obstruction becomes evident within 10 days of an abdominal operation. Conservative management is advised usually as long as signs and symptoms of ischemia and strangulation obstruction are not present and other remediable causes have been excluded. Patients within this time frame are not at a substantially increased risk of bowel-related complications after celiotomy, provided there are no internal hernias and, if the original operation was done laparoscopically, that port site hernias can be excluded. It is important to rule out correctable causes of extrinsic compression and reverse any electrolyte abnormalities, especially if ileus is also suspected. Strangulation obstruction, albeit rare, can occur in this group of patients, and thus a high index of suspicion must always be maintained; the etiology of a strangulation obstruction in this group is almost never related to adhesions but rather to some surgical misadventure, such as internal hernia, an overlooked segment of ischemia at the original celiotomy, bowel entrapped in the fascial closure, or an overlooked abdominal wall hernia.

The second category of patients is those presenting between 10 days and 6 weeks after operation.[69] Conservative management is also advised strongly whenever possible for patients in this category as well. The risk of iatrogenic bowel complications during and after reoperation so early after celiotomy increases dramatically in this group secondary to the dense adhesions often present during this period after abdominal operation. The time period from 7–10 days up until 6–12 weeks postoperatively represents the window when the greatest inflammatory reaction is present intraperitoneally. The developing adhesions are highly vascular and friable. If the patient had no or very minimal adhesions at the time of celiotomy, reoperation is warranted; however, in a small, unpredictable group of patients without any previous adhesions and reliably so in those with dense adhesions that had required substantial adhesiolysis at the time of original celiotomy, an acute inflammatory reaction involving the peritoneal surfaces may agglutinate adjacent loops of bowel, often involving the omentum and mesenteric surfaces.

Operations performed during this period have a much greater rate of iatrogenic injury and subsequent fistula formation. Those patients not responding to conservative management during this period are best placed on parenteral nutrition until the obstruction resolves or they are more than 6–12 weeks out from their last celiotomy. At this time, the decision to reoperate is made based on several considerations. First, if the patient had relatively few adhesions at the time of celiotomy, reexploration at 6 weeks to 3 months postoperatively may be warranted. In contrast, in those patients who required an extensive adhesiolysis at the time of original celiotomy, many experienced surgeons wait for a full 6 months prior to reoperation for several reasons: (1) by 6 months, the adhesions are reliably less vascular and more mature; (2) reoperation prior to 3 months may reveal a frozen abdomen in which the obstruction may be unable to be dissected free safely; and (3) about half the time, the obstruction will resolve as the adhesions mature (see the earlier section on recurrent small bowel obstruction).

BOWEL OBSTRUCTION AFTER ROUX-EN Y GASTRIC BYPASS SURGERY

As with all other operations and maybe more so in the current era of laparoscopic Roux-en-Y gastric bypass (RYGB), bowel obstruction is a worrisome complication after bariatric surgery for morbid obesity. Estimates of the rate of bowel obstruction after RYGB vary within a reported range of 0.3% to greater than 9% depending on the technique used to perform the operation. The rate of bowel obstruction appears to be less after open RYGB, but there are no large prospective studies comparing laparoscopic to open procedures at this time. In a large, collected review of more than 9500 patients undergoing laparoscopic RYGB, the rate of bowel obstruction was 3.6%.[87] Although some controversy exists, most authors suggest that the rate of bowel obstruction is less with use of an antecolic versus a retrocolic orientation of the Roux limb for the gastric bypass.[87–90] Bowel obstruction after RYGB can occur secondary to a variety of etiologies; however, the four most common etiologies in decreasing order of frequency are internal hernia, adhesive obstruction, stenosis at the jejunojejunostomy, and incisional hernia.

The diagnosis of bowel obstruction after laparoscopic RYGB is more difficult than after other surgical procedures secondary to the altered GI anatomy produced by the procedure and the often less typical response of the patient with morbid obesity. After RYGB, the symptoms of bowel obstruction can be vague, and, because the most common etiology is internal hernia, the symptoms are often intermittent. Abdominal pain is the most common symptom present

in 82% of patients in one large series and, importantly, nausea and vomiting were seen in fewer than 50% of patients in this series. All three symptoms were present in only 28% of patients.[89] Unfortunately, imaging studies also have a lesser sensitivity for bowel obstruction in patients after RYGB, with reported sensitivities of 51, 57, and 33% for CT, UGI contrast study, and plain abdominal radiography, respectively.[89] When patients with unexpected GI symptoms after RYGB are assessed, a very high index of suspicion for bowel obstruction is warranted. Given the frequency of internal hernia as a cause of postoperative bowel obstruction and the low sensitivity of radiologic evaluation for bowel obstruction in patients after RYGB, a low threshold for laparoscopic exploration is warranted in patients with suspected bowel obstruction.

Internal hernia is the most common cause of bowel obstruction after RYGB. Anatomically, there are three different types of internal hernias seen after RYGB. All three types of internal hernias are transmesenteric defects created during the formation of the Roux limb and are illustrated in Fig. 29-3. The so-called Peterson hernia occurs in the infracolic compartment through the potential space between the mesentery of the Roux limb, the transverse mesocolon, and the retroperitoneum and can be seen with either an antecolic or retrocolic Roux limb. Herniation through the mesenteric defect created by the jejunojejunostomy is the second site of internal hernia observed after RYGB and can occur with both antecolic and retrocolic gastric bypass. Herniation through the mesenteric defect in the transverse mesocolon created by passage of the retrocolic Roux limb is the third type of internal hernia observed in RYGB and is only seen in retrocolic gastric bypass; this type of internal hernia was the most common type before the importance of meticulous closure of this defect was appreciated. Most authors believe that bowel obstruction after RYGB is substantially more common after laparoscopic retrocolic bypass, with reported rates of 3.2–5.1 % after retrocolic and 0.3–1.7% after antecolic bypass reported in the largest series.[87,90] Meticulous closure of all potential hernia spaces with nonabsorbable suture at the time of RYGB is the best way to prevent internal hernia; however, care must be taken when closing the mesocolic defect, because obstruction at the mesocolic window from tight scar formation has also been reported as a cause of bowel obstruction after RYGB.[91] When operating on a patient with internal hernia after RYGB, careful closure of the hernia defect with nonabsorbable suture after reduction in the hernia is the treatment of choice.

RADIATION ENTEROPATHY

The management of radiation enteropathy is often difficult and frustrating. The clinical presentation can be quite diverse with recurrent intermittent small bowel obstruction, a true, chronic, persistent partial small bowel obstruction, or chronic diarrhea/malabsorption. Operative management is often extremely challenging secondary to the dense adhesions and chronic inflammatory reaction present after radiation. These patients also tend to develop recurrent areas of enteropathy (progression of disease) in bowel that appeared normal previously, because this ischemic disease is an ongoing and progressive chronic process. The need for operative correction with a resection and anastomosis has been reported to have a mortality rate as high as 21% in some series.[82] Patients with radiation enteropathy also have a high rate of anastomotic leak and fistulation after operation because of the compromised vascular supply to the bowel. These effects are magnified in patients with atherosclerosis, hyperlipidemia, or type 2 diabetes. For these reasons, a cautious, conservative approach to the patient with radiation enteropathy is warranted whenever possible.

When operative management is necessary, the surgeon must decide between resection, bypass of the affected segment, or adhesiolysis. As mentioned previously, resection has been reported to have a high mortality rate with a 36% incidence of leak after primary anastomosis.[82] In the same study, bypass of the affected segment had a 10% mortality and 6% leak rate. Surgeons advocating aggressive resection back to healthy bowel, however, have reported leak rates between 0 and 8% when confounding conditions (abscess, fistula, necrosis, or recurrent cancer) were absent; such an aggressive approach may require an extensive resection but often involves resection of nonfunctional bowel anyway. Worry of a short bowel syndrome is always a concern, especially because the involved bowel is usually the distal ileum.

Most surgeons approach the treatment of radiation enteropathy cautiously. In those patients with recurrent cancer and radiation enteropathy, treatment should consist of palliative bypass of the diseased segment with creation of an anastomosis in visibly normal tissue. If the obstructive process is localized, wide resection back to healthy, nonirradiated tissue (if possible) with primary anastomosis is acceptable, provided adequate absorptive area is preserved. Usually this means anastomosis from small bowel to the ascending colon, because the terminal ileum has usually been involved in the radiation field. While ideally a complete resection of the entire involved small bowel is optimal, the surgeon must consider the extent of the resection necessary as well as the anatomic segment involved. Usually, the involved small intestine is the distal ileum; major resection back to reliably normal, nonirradiated small bowel may require a total or subtotal ileal resection that carries its own nutritional complications, and a decision will need to be made concerning preservation of mildly involved but functional ileum if the only alternative is complete resection. In contrast, if the bowel is severely involved and nonfunctional, resection (despite its side effects) may be the best option. When the affected area contains dense adhesions or is stuck deep within the pelvis, bypass may be a better choice to avoid the very real concern of potential iatrogenic injury to the bowel, bladder, pelvic organs, and ureters; however, if there is a localized abscess or associated septic process, bypass is not a good option, just as with Crohn's disease, because the ischemic inflammatory process will continue. Attempts at complete lysis of adhesions alone without resection are controversial due to the risk of traumatizing the intestine with potential fistula formation. For the patient with advanced disease who

presents years after irradiation, adhesiolysis may not be a good option, especially if the bowel is matted and agglutinated. In contrast, in the case of isolated adhesive bands and the patient being early (<2 years) after irradiation, lysis alone may be warranted; much of the decision needs to be based on the quality of the involved bowel and the site of obstruction. If the bowel is thickened, woody, and strictured, resection or bypass is best.

CARCINOMATOSIS AND MALIGNANT OBSTRUCTION

Bowel obstruction in the setting of carcinomatosis often represents the terminal phase of the malignant disease. Operative management is entirely palliative and needs to be applied selectively. In the case of limited life expectancy and malignant cachexia or ascites, nonoperative palliative measures are advised, because operative intervention would be unnecessary and associated with a lesser, end-of-life, quality of life due to the convalescence required after a noncurative celiotomy. In contrast, other patients with a good performance status may have a long life expectancy, and in this case, operative bypass with the idea of permitting renewed oral intake may be indicated. Patients and their families should be counseled that the relief of their obstruction will not affect disease progression but may improve quality of life. In addition, the surgeon should remember that up to one-third of bowel obstructions presenting in the setting of carcinomatosis are due to adhesions and not to malignant obstruction.[68] Therefore, a short trial of conservative therapy with rehydration and nasogastric decompression is usually advisable, although many (possibly most) patients with carcinomatosis will fail this intervention. In addition, depending on the location and extent of the malignant disease involving the GI tract, a palliative endoscopic stent placement may relieve the obstruction (Fig. 29-14).

An initial minimal access, laparoscopic approach should at least be entertained in patients with a malignant obstruction provided the access to the peritoneal cavity is safe. The least invasive approach is best for these patients, and if palliation, such as a bypass or gastrostomy tube, can be achieved laparoscopically, the patient would benefit substantially with decreased pain, possibly a shorter convalescence, and decreased duration of hospital stay, all of which are important considerations in the palliative care of patients with a limited life expectancy.

At exploration, multiple scenarios may be encountered. Some patients will have an isolated area of adhesions and require only adhesiolysis. Others will have a solitary metastasis causing either an intra- or extraluminal obstruction that can be corrected with a limited resection or bypass. If multiple areas of adhesions are present or the affected area is adherent to the abdominal wall or intra-abdominal structures in the patients with incurable malignant obstruction, bypass of the involved segment will provide symptom relief and the fewest opportunities for complication. One should consider placement of a tube gastrostomy if there is any question of the success of the operation, if impending obstruction seems imminent, or if relief of the obstruction is not possible. In the event of reobstruction, a tube gastrostomy can be used to decompress the stomach and avoid the discomfort associated with a nasogastric tube. The decision to place a palliative, decompressive, tube gastrostomy is more difficult in the presence of ascites. In this situation, a better option would be a

tube pharyngostomy.[92] Additionally, if histologic diagnosis of the neoplasm had been obtained previously, a repeat biopsy should be entertained to ensure that the neoplasm has histologic characteristics consistent with the original biopsy.

TUMORS OF THE SMALL INTESTINE

Craig Fischer • Barbara Lee Bass

Tumors of the small intestine, both benign and malignant, are rare. With the potential to arise from virtually every cell type within the small intestine—the epithelium, neural tissues, lymphatic and mesenchymal cells—the small bowel may also be the site of metastases from other primary tumors. The variety and uncommon nature of these tumors makes generalizations regarding their management difficult. In this chapter we review the epidemiology and clinical diagnostic and management strategies for benign and malignant neoplasms of the small bowel.

EPIDEMIOLOGY

While the small bowel accounts for 75% of the length and 90% of the mucosal surface area of the gastrointestinal tract, fewer than 3% of gastrointestinal malignancies arise in this organ. Most of these tumors are clinically silent. Autopsy series have identified incidental small bowel tumors in 0.2–0.3% of hospital deaths—a rate 15 times the operative incidence of small bowel resections for tumors.[1]

Given the rare nature of these tumors, most published reports are collections of relatively small series of tumors accrued over a period of many years. Hence, interestingly, these reports differ regarding the type of small bowel tumors, the distribution of tumors, and until the advent of molecular diagnostic criteria for GIST (gastrointestinal stromal tumors), in the classification of tumors of stromal origin. Nonetheless, in most series adenocarcinoma, GIST, carcinoid tumor, and lymphoma comprise the most common malignant tumors and are approximately equally represented.[2,3] Small bowel tumors are more prevalent in older than in younger patients, and a recent analysis identified that over 65% of patients with small bowel adenocarcinoma were age 60 or older.[3] The proportion of small bowel tumors that are benign varies from 14 to 52% in different series, a disparity explained by the failure to detect the typically asymptomatic benign lesions.

There are no satisfactory explanations for the observed variation in prevalence of small bowel tumors around the world. Carcinoids are uncommon tumors in Asian series, while GIST comprise a higher proportion of reported series in the East.[4,5] Men are more likely to develop small bowel neoplasms than women, with a male preponderance reported for both benign and malignant tumors.

PATHOGENESIS

Given the length of the small bowel and its large mucosal surface, it is intriguing that it is such an uncommon site for malignancy. Unlike the adenoma-carcinoma sequence seen in the colon, a clear molecular progression sequence has not been defined in the small bowel outside the known polyposis syndromes. Only periampullary adenomas are known to be premalignant lesions with the potential to progress to adenocarcinomas. Adenomatous polyps arising elsewhere in the small bowel presumably have similar potential for malignant transformation, although the molecular traits of this transformation remain unknown. Such progression has not been definitively documented at other sites in the small bowel.

Based on theories of luminal injury defined in the colonic mucosa, several hypotheses are proposed regarding the pathogenesis of epithelial-derived small bowel tumors. Unlike the colon with its high bacterial luminal content, the lumen of the healthy small bowel is largely free of bacteria; bacterial metabolites implicated in the genetic alterations of colon carcinogenesis are absent. Transit through the small bowel is rapid—30 minutes to 2 hours—so exposure to potential toxins and metabolites is much more limited. The alkaline, mucus-rich succus entericus of the small bowel may have protective capacity and less noxious potential than the more solid contents of the colon. Enterocytes of the brush border epithelium express the enzyme benzopyrene hydroxylase, possibly protecting against mucosal damage by detoxifying the carcinogen benzopyrene. And last, high levels of luminal IgA and greater distribution of lymphoid tissue in the small intestinal epithelium and submucosa may provide an additional protective mechanism via an immune surveillance mechanism.

Bile acids and their metabolites have been implicated in the pathogenesis of small bowel adenocarcinoma.

Postcholecystectomy patients may be at greater risk for the development of small bowel malignancy. In one study of patients with small intestinal malignancy, 12% had a history of cholecystectomy, and of those with duodenal adenocarcinoma, 25% had prior cholecystectomy. However, a causative relationship between cholecystectomy and small intestinal adenocarcinoma remains unproven.

High-Risk Population

Several heritable and inflammatory gastrointestinal conditions are associated with an increased risk for development of small bowel tumors.

FAMILIAL ADENOMATOUS POLYPOSIS

Patients with familial adenomatous polyposis (FAP) carry a lifetime risk approaching 100% for the development of adenomatous polyps of the duodenum, and these lesions may progress to adenocarcinoma. FAP patients have a 331-fold increased risk for development of adenocarcinoma of the duodenum over the normal population,[3] and this is the leading cause of cancer death in patients with FAP previously treated by colectomy. These patients require regular screening esophagogastroduodenoscopy (EGD) and endoscopic or surgical excision of enlarging adenomas.

CROHN'S DISEASE

Patients with active jejunoileitis of Crohn's disease have a 100-fold increased incidence of adenocarcinoma. Active disease in the terminal ileum is the most frequent site of malignancy.[6] Abdominal complaints and symptoms consistent with their primary condition may delay evaluation and diagnosis, leading to detection of tumors at advanced stages. The prognosis for patients with adenocarcinoma arising in Crohn's disease is poor.[7] For patients undergoing bowel-preserving procedures such as stricturoplasty, a biopsy of the site of past or active disease is advocated to look for dysplasia or in situ carcinoma. Such findings, while rare, would warrant resection rather than bowel-preserving approaches.

CELIAC DISEASE

Celiac disease is associated with increased risk of lymphoma and is seen in up to 14% of patients.[8] A gluten-free diet has been postulated to decrease this risk, although this has not been substantiated by a recent study.[9]

MISCELLANEOUS CONDITIONS ASSOCIATED WITH SMALL BOWEL NEOPLASMS

Patients with Peutz-Jeghers syndrome develop benign hamartomas throughout the intestinal tract. Surveillance is indicated, as these lesions are at risk of malignant transformation into adenocarcinoma.[10] Patients with von Recklinghausen's disease may develop neurofibromas in the gastrointestinal tract that can undergo malignant transformation. Patients on chronic immune suppression therapy are at particular risk for small bowel malignancies, especially lymphomas and sarcomas. Transplant recipients on immunosuppression have a 45- to 100-fold increase in non-Hodgkin's lymphoma (NHL), a condition termed *posttransplant lymphoproliferative disorder* (PTLD).[11] PTLD accounts for 30% of all malignancies in cyclosporine-treated patients but accounts for only 12% of malignancies in patients without cyclosporine in their regimen. PTLD tends to develop rapidly, often within 12 months of transplant. Greater degrees of immunosuppression carry greater risk for development of PTLD. Human immunodeficiency virus (HIV) infection is also associated with the development of lymphoma in up to 30% of patients. Most are extranodal and the gastrointestinal tract is the involved site in 10–25% of cases. More than 90% of patients present with stage IV disease and median survival is only 6 months.

CLINICAL PRESENTATION

Patients with small bowel tumors present with nonspecific gastrointestinal and constitutional complaints. In hindsight, the gradual development of symptoms is usually evident. The most common symptoms include vague abdominal discomfort and cramps, gradual weight loss, anemia, nausea, and vomiting. These nonspecific complaints, coupled with the fact that most patients are older and often on medications that may also elicit these complaints, result in a high rate of misdiagnosis and delay in diagnosis. In most series, the average duration of symptoms prior to diagnosis ranges from weeks to many months. Initial evaluation to exclude more common conditions, including evaluation of the gastroduodenum, colon, and biliary tract are completed, but, when negative, further evaluation of the small bowel is delayed or deferred.

Benign lesions rarely cause abdominal pain or obstruction; rather, their presence is often heralded by acute gastrointestinal hemorrhage. Benign neoplasms may grow to a large size prior to detection and may simply be discovered incidentally on a radiological examination or at laparotomy.

DIAGNOSIS

The diagnosis of small bowel tumors is hampered by a number of factors. In addition to the fact that these are rare tumors that produce nonspecific gastrointestinal complaints, the ability to fully image and observe the small intestine is limited. Despite the introduction of capsule endoscopy, which allows for luminal visualization of the entire small bowel mucosal surface, accurate preoperative diagnosis is in fact uncommon prior to surgery.[12,13]

History and physical examination are nonspecific. Abdominal mass, heme-positive stool, or signs of intestinal obstruction are usually absent. Laboratory data may demonstrate iron deficiency anemia in a minority of patients.

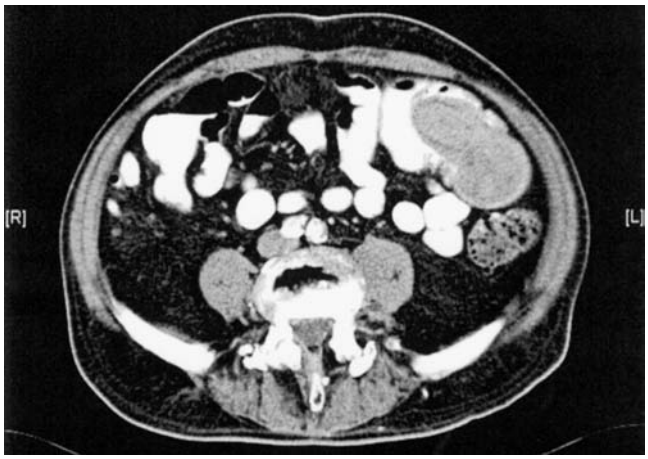

FIGURE 30-1 Adenocarcinoma in the ileum is obvious as a mass in the left midabdomen.

Plain abdominal films are an appropriate initial diagnostic test, although they are rarely helpful unless the patient presents with obstructive symptoms.

After ruling out more common conditions that could elicit similar gastrointestinal and abdominal complaints with endoscopic evaluation of the gastroduodenum and colon, computed tomography (CT) of the abdomen is the appropriate initial imaging test. CT may reveal bulky tumors (Fig. 30-1) or more subtle findings suggestive of small bowel tumors, such as thickening of the small bowel wall. Thickening of the bowel wall to greater than 1.5 cm or the detection of discrete mesenteric lymph nodes or masses greater than 1.5 cm in diameter is highly suggestive of malignancy. If obstructing lesions are present, CT scan may reveal a transition zone demarcating dilated proximal bowel from decompressed distal bowel.

Tumors of the distal small bowel may cause jejunoileal or ileocolic intussusception. During intussusception, the small bowel tumor serves as the lead point to pull the small bowel into the distal small bowel or colonic lumen; the mass lesion precludes spontaneous reduction. CT findings of ileocolic or jejunoileal intussusception include the presence of concentric rings with a donut appearance involving the bowel. This sign is nearly pathognomonic for small bowel tumor. In adults, radiographic attempts to reduce an intussusception should not be made. Rather, prompt surgical exploration and resection of the nonreduced intussuscepted bowel segment with mesenteric resection should be completed without intraoperative attempts at complete reduction; rather, the intestine should be reduced gently to the palpated lead point, followed by intestinal resection and primary anastomosis. Attempts at complete reduction often lead to inadvertent enterotomy or exposure of a perforation within the intussusception.

Luminal contrast radiographic studies may be used if abdominal CT imaging fails to reveal evidence of a small bowel tumor, usually an upper gastrointestinal contrast series with small bowel follow-through. A small bowel follow-through study will show an abnormality in 53–83% of cases, although direct evidence of a tumor is detected in only 30–44%.

While enteroclysis (a dynamic contrast technique using a slurry of barium and methylcellulose infused into the small bowel via a nasoduodenal tube to uniformly distend the small bowel lumen) was formerly utilized to study the mucosal surface of the small bowel lumen, this procedure has been largely replaced by video capsule endoscopy (VCE). Similarly, small bowel enteroscopy is far less commonly utilized with the advent of VCE.

For proximal jejunal lesions that cannot be visualized by routine EGD, "push" enteroscopy utilizes a pediatric colonoscope for direct examination of the lumen of the proximal 2–3 ft of small bowel.[14] Formerly utilized, Sonde "pull" small bowel enteroscopy, which relied on peristalsis to passively pull an enteroscope with a wide-angle lens into the distal ileum or colon, is now a procedure of only historical interest.

Intraoperative enteroscopy allows a much more complete evaluation of the small bowel. It is of value in detection of occult bleeding from the small bowel but is rarely utilized for the diagnosis of small bowel tumors, for most can usually be readily identified by careful palpation or visualization of the bowel once operation is pursued.

VCE is now widely employed in the diagnosis of small bowel tumors in patients with otherwise negative diagnostic studies. The device is an ingestible 11-×26-mm capsule, swallowed by the patient, that contains a miniature video camera, light source, battery, and transmitter that sends images (up to 50,000 overall) to a recording device worn by the patient.[15] Currently the device does not have the capacity for biopsies or for precise localization of lesions, although such capability is in development. The device can be very useful in identifying lesions within the lumen of the small bowel (Fig. 30-2).

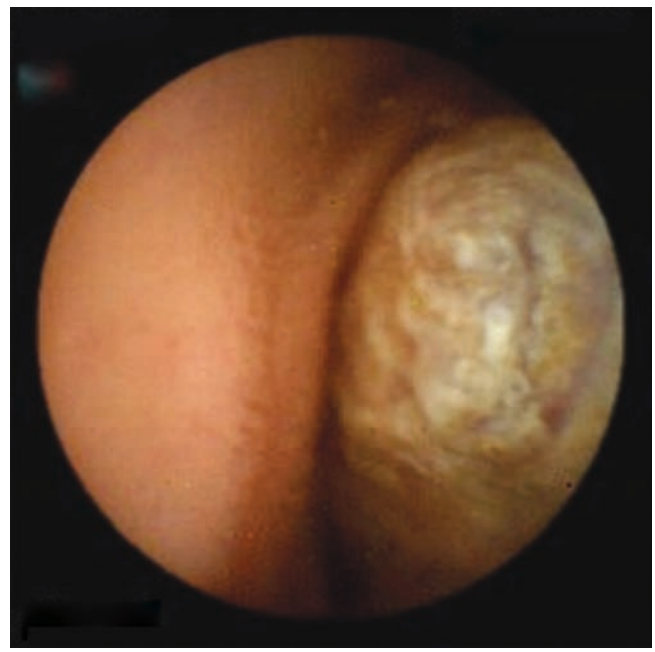

FIGURE 30-2 Video capsule endoscopy (VCE) image of the adenocarcinoma.

The major complication of VCE is capsule retention, which is reported in 5% of cases, although the rate of requirement for surgical retrieval is less than 1%.[16]

While a number of small intestinal tumors are metabolically active and express hormones, somatostatin scintigraphy (octreotide scanning) is of limited use in detection of primary small bowel carcinoids or other neuroendocrine tumors. Positron emission tomography (PET) scanning also has limited utility in providing a discriminate diagnosis, as there is significant overlap between benign and malignant conditions. While diagnostic methods continue to improve, many patients with small bowel neoplasms still have initial presentation as a surgical emergency, and more than half of patients with malignant disease have metastatic spread at the time of operation.

BENIGN TUMORS OF THE SMALL INTESTINE

Although accounting for 30–50% of primary neoplasms of the small bowel, benign tumors are poorly characterized. Half the patients with benign tumors are symptom free, and most will be diagnosed at the time of presentation with a surgical emergency such as obstruction, gastrointestinal hemorrhage, or perforation. Gastrointestinal bleeding is the most common presenting complication, presumably a consequence of spontaneous necrosis when the benign lesion outgrows the available blood supply.[5]

Once these lesions are diagnosed, surgical segmental intestinal resection is appropriate. While local excision via endoscopic mucosal resection or operative enterotomy with submucosal excision is feasible, it is generally not possible to grossly differentiate between benign and malignant lesions. Hence, transmural resection is preferred for indeterminate lesions. Open and laparoscopic approaches have been described.

Brunner Gland Adenomas

Brunner gland adenomas are rare tumors of the proximal duodenum.[17] Originating in the Brunner glands of the duodenal submucosa that secrete alkaline bicarbonate-rich fluid and mucus, the pathogenesis of glandular hyperplasia and subsequent adenoma formation from this cell population remains unknown. Although Brunner gland adenomas have not been described to transform into carcinomas, endoscopic mucosal resection is advised to prevent complications, including acute and chronic bleeding.

Adenomas

As in the colon, small bowel adenomas are histologically classified as tubular, tubulovillous, or villous. Most common in the periampullary region, they can develop throughout the small bowel mucosa. Increased size correlates with malignant potential, and excision is advised when diagnosis is established, often as an incidental finding. Adenomas larger than 2 cm in diameter should be considered worrisome for malignancy. Large, periampullary duodenal adenomas may present with obstructive jaundice. In these cases ultrasound will reveal evidence of biliary obstruction, prompting upper endoscopy with endoscopic retrograde biliary and pancreatic duct evaluation (endoscopic retrograde cholangiopancreatography), which will reveal the presence of the ampullary lesion. Without these physical signs to direct the workup, duodenal adenomas are detected during evaluation of gastrointestinal blood loss or other abdominal complaints, with either contrast upper gastrointestinal series or EGD, which are equally sensitive in most series. Adenomas usually appear as intraluminal filling defects and may be pedunculated (Fig. 30-3). CT scan may differentiate adenoma from carcinoma, as carcinomas are often associated with bowel wall thickening. Endoscopic ultrasound is becoming essential in the evaluation of duodenal adenomas to evaluate depth and to determine if mucosal excision or surgical resection is more appropriate. Transduodenal local excision for small lesions is appropriate, while lesions larger than 3 cm in size have a high rate of associated malignancy and are most appropriately treated with either pancreas-sparing duodenectomy, or pancreaticoduodenectomy for larger lesions or periampullary tumors in suitable operative candidates.[18] Surgical series of resected ampullary adenoma report in situ or frank adenocarcinoma in 34–40%

FIGURE 30-3 Filling defect in the duodenum caused by a large benign adenoma.

of patients. Local recurrence is common for periampullary adenomas treated with excision only: 40% at 10 years, 25% of which were malignant, in a recent retrospective series from the Mayo clinic. For those treated with excision only, annual surveillance with endoscopy is appropriate.[19]

Lipomas

Lipomas of the gastrointestinal tract are typically identified as incidental findings on abdominal imaging. They rarely cause symptoms; although as polypoid, compressible intraluminal lesions, they may serve as lead points for intussusception. Lipomas are circumscribed lesions arising in the bowel wall appearing as fat density on CT imaging. Small tumors under 2 cm require no intervention, while larger lesions or growing lesions should be resected to rule out malignant liposarcoma.

Hamartomas

The hamartoma is the characteristic lesion of Peutz-Jeghers syndrome, an autosomal dominant condition characterized by multiple gastrointestinal hamartomas and mucocutaneous pigmentation. The tumors are widely distributed throughout the bowel in affected individuals and in rare cases are associated with intussusception, bleeding, or obstruction. While malignant transformation has been described, this is a rare event. Given the broad distribution of the tumors, prophylactic excision is not feasible and surgical intervention is appropriate only to treat complications caused by the tumors.[10]

Hemangiomas

Hemangiomas are rare congenital lesions of the small bowel. They appear to grow slowly and may become symptomatic in midlife, when acute or chronic bleeding may develop. Arising from the submucosal vascular plexuses, hemangiomas are usually solitary and not at risk for malignant transformation. Hemangiomas associated with bleeding should be locally excised or resected with a limited small bowel resection. Endoscopic sclerotherapy or angiographic embolization has also been reported as a treatment option depending on the size and position of the tumor.

MALIGNANT NEOPLASMS

The small bowel can give rise to a number of different primary tumors and is also a site for metastasis from tumors of other origins. Primary malignancies include adenocarcinoma, GIST, carcinoid, lymphoma, and leiomyosarcoma, with rare reports of other lesions, including liposarcoma, myxoliposarcoma, and lymphangiosarcoma. Metastatic tumors may come from any other cancer, but the most common metastatic lesions are from melanoma and lymphomas.

Malignant tumors are much more likely to elicit symptoms than benign tumors, including abdominal pain, weight loss, anorexia, and acute or chronic blood loss. As a group, patients with malignant small bowel tumors present at advanced stages and have a poor prognosis.

Up to 30% of patients with small bowel malignancy develop a second primary tumor in another organ. For patients with GI carcinoid tumors, the incidence of second primaries is 50%. The second primary cancer may arise in any organ, but the most frequent second primary sites are the colorectum and breast.[20,21]

ADENOCARCINOMA

EPIDEMIOLOGY

Adenocarcinoma accounts for about 35% of small bowel tumors, making it the most common primary malignancy.[7] The frequency of small bowel tumors decreases along the length of the small bowel, with 80% located in the duodenum and proximal jejunum. Men are slightly more likely to develop adenocarcinoma than women. Risk factors for development of adenocarcinoma include polyposis syndromes, Crohn's disease, and celiac disease.

CLINICAL PRESENTATION

Clinical presentation is dictated by the size and position of the tumor. Large tumors form the classic circumferential annular "apple core" constriction leading to obstruction with symptoms of anorexia, vomiting, and crampy pain (Fig. 30-4).

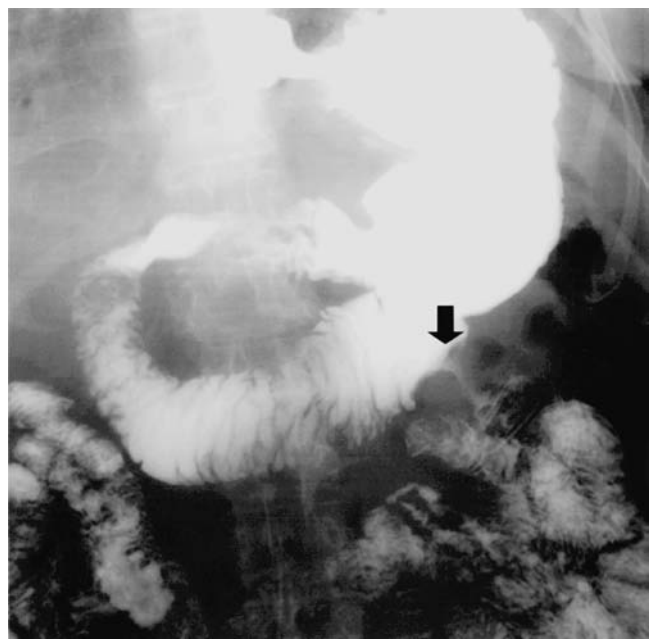

FIGURE 30-4 "Apple core" constricting adenocarcinoma of the proximal jejunum causing proximal partial bowel obstruction.

Periampullary lesions may cause biliary obstruction with secondary jaundice. In absent advanced or strategically placed lesions with obstruction, the only complaint may be vague, persistent abdominal pain.

DIAGNOSIS

For patients with advanced lesions, plain abdominal films may show gastric distention or proximal small bowel obstruction. For the jaundiced patient, ultrasound or abdominal CT or magnetic resonance cholangiopancreatography may demonstrate the duodenal mass and site of biliary obstruction. Upper gastrointestinal contrast studies or EGD have equal diagnostic rates of 85–90%, while EGD allows diagnostic tissue biopsy. CT reveals approximately 50% of small bowel adenocarcinomas, and the appearance is that of a heterogeneous infiltrating mass. Despite diagnostic strategies, preoperative diagnosis of cancers beyond the duodenum is achieved in only 20–50% of cases.

MANAGEMENT

Surgical resection offers the only potential cure. Many patients have intra-abdominal metastases at initial surgery, with R0 resection (ie, no gross or microscopic disease left) achieved in only 50–65% of cases. Pancreaticoduodenectomy is appropriate for proximal duodenal tumors. In the third and fourth portions of the duodenum and in the mesenteric small bowel, a segmental resection with lymphadenectomy should be performed. Palliative procedures to relieve obstruction or control hemorrhage should be completed at the time of exploration for patients with metastatic disease. Endoscopic expandable stents (Wall type) may be the best strategy to palliate proximal gastrointestinal obstruction from recurrent or metastatic disease. Gastrojejunal bypass or gastrostomy tubes may be of palliative value for decompression or nutritional support in patients with carcinomatosis or unresectable disease.

STAGING AND PROGNOSIS

The American Joint Committee on Cancer staging system applies to small bowel adenocarcinoma.[22] The tumor (T) classification describes depth of invasion with T1 and T2 within the bowel wall and T3 and T4 lesions penetrating the bowel wall. The node (N) classification is defined by the presence or absence of lymph node metastases, and distant metastases are classified by M. Most patients present with stage III (lymph node involvement) or IV disease (distant metastases), which carry a poor prognosis.

The most significant prognostic factor is lymph node metastases, with poor survival linked to node-positive disease. Likely because of limited reported experience, the primary tumor features, including the degree of differentiation, do not appear to impact survival. A recent retrospective analysis showed that positive margins, extramural venous spread, positive lymph nodes, and a history of Crohn's disease are associated with poor prognosis.[6]

Adjuvant therapies including chemotherapy and/or radiation therapy have not demonstrated efficacy, although clinical trials are ongoing.[20]

Non-Hodgkin's Lymphoma

The gastrointestinal tract is the most common extranodal site for development of non-Hodgkin's lymphoma (NHL), comprising approximately 20% of all cases of NHL. Most GI lymphomas arise in the stomach (60%), followed by the small bowel (30%), and then in the colon. Most small bowel lymphomas are distributed in the jejunum and ileum reflecting the distribution of lymphoid tissue in the bowel. Diagnostic criteria for primary GI NHL include the absence of superficial adenopathy on physical examination, absence of mediastinal adenopathy by chest imaging, normal peripheral blood cell counts, and absence of splenic or hepatic involvement. At surgery, disease must be restricted to the primary tumor with mesenteric lymph node involvement.[23]

The majority of cases of primary intestinal NHL are B-cell type with T-cell lymphoma comprising only 10–25%. Low-grade lymphomas derived from mucosal-associated lymphoid tissue (MALT) typically arise in the stomach in association with *Helicobacter pylori* infection. These tumors may regress with treatment of this infection.[24] T-cell lymphomas tend to have a worse prognosis than B-cell tumors.

CLINICAL PRESENTATION

The majority of patients present with nonspecific abdominal complaints. Malabsorption, obstruction, or palpable mass may be present. Although rare, small intestinal lymphomas may present with perforation.

DIAGNOSIS

Lymphomas may grow to large size before clinical symptoms present. Most small bowel lymphomas will be demonstrable on CT scan as a mass, bowel wall thickening, displacement of adjacent organs, or luminal obstruction (Fig. 30-5). Multiple lesions are present in 10–25% of patients. Tissue diagnosis requires biopsy of the submucosal lesion by endoscopy or CT-guided biopsy.

STAGING AND PROGNOSIS

Staging is based on site involvement as outlined in Table 30-1. Like tumors elsewhere in the small intestine, most patients present with stage III or IV disease. Fewer than 30% of patients have surgically resectable tumors and prognosis, although improving with new chemotherapy regimens, is poor.[22]

TREATMENT

With no randomized series and small numbers of cases at single institutions, the optimal treatment of GI NHL remains

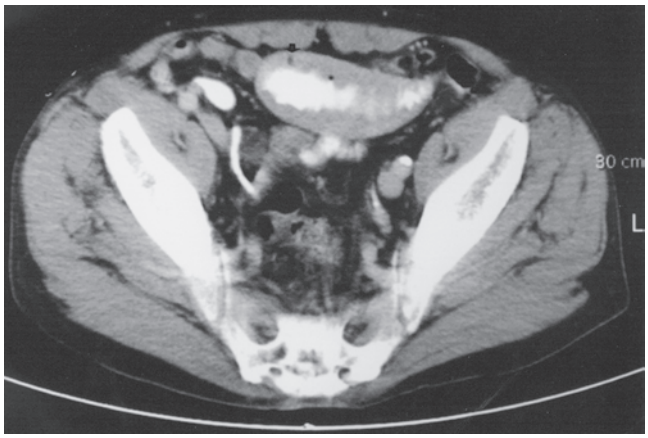

FIGURE 30-5 Thickening of the bowel wall on abdominal CT scan characteristic of lymphoma.

controversial. Most agree that surgical resection of isolated small bowel lymphoma for local control and prevention of perforation and bleeding are the cornerstones of treatment. For more extensive gastrointestinal lymphoma, there is no evidence-based consensus on optimal management, although a variety of chemotherapeutic regimens have been utilized.[23,24]

TABLE 30-1: STAGING FOR LYMPHOMA

Stage I	Involvement of a single lymph node region; or localized involvement of a single extralymphatic organ or site in the absence of any lymph node involvement
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm; or localized involvement of a single extralymphatic organ or site in association with regional lymph node involvement, with or without involvement of other lymph node regions on the same side of the diaphragm
Stage III	Involvement of lymph node regions on both sides of the diaphragm, which also may be accompanied by extralymphatic extension in association with adjacent lymph node involvement, or by involvement of the spleen, or both
Stage IV	Diffuse or disseminated involvement of one or more extralymphatic organs, with or without associated lymph node involvement; or isolated extralymphatic organ involvement in the absence of adjacent regional lymph node involvement, but in conjunction with disease in distant site(s); any involvement of the liver or bone marrow, or nodular involvement of the lungs

Data from American Joint Commission on Cancer. *Cancer Staging Handbook*. 6th ed. New York, NY: Springer; 2002.

Carcinoid Tumors

Carcinoid tumors arise from the enterochromaffin cells at the base of the crypts of Lieberkühn. Enterochromaffin cells are capable of amine precursor uptake and decarboxylation (APUD) and tumors derived from these can secrete vasoactive peptides responsible for the carcinoid syndrome. Eighty percent of carcinoids arise in the gastrointestinal tract, 10% in the bronchus or lung, and others in rare sites, including the ovaries, testicles, pancreas, and kidneys. The appendix is the most common site in the GI tract for primary carcinoid tumors, followed by the small bowel. Thirty percent of GI carcinoids arise in the jejunum or ileum and have the most aggressive clinical features.

Carcinoids represent 5–35% of small bowel neoplasms; the mean age of presentation is 60 years with a slight male preponderance. Autopsy rates reveal an incidence of occult tumors approximately 2000 times that of the annual clinical incidence rate, indicating that the overwhelming majority never develop clinical findings.[24,25]

CLINICAL PRESENTATION AND DIAGNOSIS

Most carcinoids grow slowly and have insidious clinical manifestations; in hindsight, symptoms may be present for 2–20 years prior to diagnosis. Carcinoid syndrome secondary to metastatic disease is the presenting sign in 40% of patients. Rarely, intestinal necrosis secondary to desmoplastic occlusion of the mesenteric vessels may develop, leading to initial presentation as a surgical emergency.

The most common presenting symptom for patients with small bowel carcinoid is abdominal pain. The polypoid lesions serve as a lead point for intussusception characterized by intermittent symptoms and signs of obstruction. Abdominal films often demonstrate a distal small bowel obstruction, and the CT findings of intussusception are distinctive, demonstrating a multilayer ringed structure in the ileocolic region (Fig. 30-6).

Appendiceal carcinoids are typically solitary lesions. However, for carcinoids arising in other areas of the gut, multiple tumors are observed in 30–40% of patients.[26] In addition, 30–50% of small bowel carcinoids are associated with second primary malignancies, most frequently of the breast and colon. Gastrointestinal carcinoids have the capacity to elicit a marked desmoplastic reaction in the mesentery of the small bowel. The fibrotic reaction can cause sclerosis of mesenteric vessels, leading to kinking of the bowel or intestinal ischemia and necrosis. The fibrosis affects not only peritumoral tissues, but distant tissues in the heart and lungs and is attributed to the humoral products of the tumors, although the specific factors are unknown.[27,28]

STAGING AND PROGNOSIS

Appendiceal carcinoids, even at a small size, may cause appendicitis due to luminal compression; hence, early diagnosis of appendiceal carcinoid is common. In contrast, small bowel carcinoids exhibit a more aggressive phenotype and are

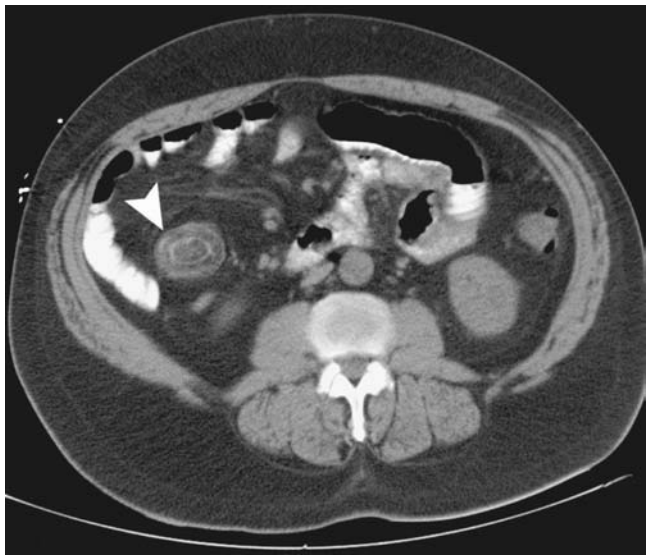

FIGURE 30-6 Concentric rings in the soft tissue mass in the right lower quadrant reveal an ileocolic intussusception. An ileal carcinoid tumor was the lead point.

frequently associated with lymph node spread and hepatic metastasis at initial presentation. Tumor size is proportional to the risk for metastatic spread. For jejunoileal carcinoids smaller than 1 cm, there is a 20–30% incidence of nodal and hepatic spread. Tumors 1–2 cm in size have nodal spread in 60–80% and hepatic disease in 20%. The rate of nodal and hepatic metastasis for tumors larger than 2 cm is greater than 80% and 40–50%, respectively.[25] Only very small jejunoileal carcinoid tumors, those less than 1 cm, can be treated with local excision. All others should be treated with segmental bowel and mesenteric resection.[29]

CARCINOID SYNDROME

Carcinoid syndrome refers to vasomotor, gastrointestinal, and cardiac manifestations induced by systemic circulation of peptides produced by carcinoid tumors. The APUD cells of carcinoid tumors can produce vasoactive products, including serotonin, histamine, kallikrein, bradykinin, and prostaglandins, although the specific mediator or mediators of the syndrome remain unknown. Carcinoid syndrome is confirmed by finding elevated 24-hour 5-hydroxyindoleacetic acid (5-HIAA) urinary excretion, the primary stable metabolite of serotonin.

Attacks are characterized by intense flushing and tachycardia. Watery diarrhea, at times explosive and associated with cramping, may occur in some patients. Attacks may be spontaneous or precipitated by stress, alcohol, a large meal, or sexual intercourse. Flushing, a 5- to 10-minute sensation of heat associated with facial and truncal erythema, is the most common finding and affects approximately 80% of patients. Diarrhea occurs in most patients and is likely related to serotonin release, as serotonin antagonists can effectively treat this symptom. Abdominal cramps and malabsorption may occur. Cardiac manifestations are present in 60–70% of patients with advanced disease, due to tricuspid and pulmonary valve endocardial fibrosis, possibly secondary to high levels of 5-HIAA. As the disease progresses, the fibrotic plaque stiffens, leading eventually to right heart failure.

Carcinoid syndrome is due to metastatic disease in either the liver or retroperitoneum. Monoamine oxidase in the liver metabolizes serotonin to metabolites without vasomotor activity, one of the major effector hormones. Carcinoid syndrome occurs when metabolically active tumor is present in a site without portal drainage, such as a bronchial carcinoid or retroperitoneal tumor, or when hepatic metastatic tumor burden exceeds the capacity of hepatic monoamine oxidase to metabolize serotonin. Patients with gastrointestinal carcinoids that drain into the portal circulation must have metastatic disease prior to the development of the syndrome.

Management of patients with carcinoid syndrome due to metastatic hepatic tumor burden is optimized by utilization of surgical, imaging-guided interventional procedures and medical therapies. Given the relatively slow growth of carcinoid tumors, including metastatic disease, surgical debulking of extensive hepatic disease or formal hepatic resection for resectable metastases can improve symptoms and prolong life. Five- and 10-year survival for patients with residual abdominal tumor and hepatic metastases approaches 60%. While in general the initial surgery for resection of carcinoid tumor burden, including hepatic metastases, should attempt to debulk as much tumor as possible, the procedure must be planned to avoid catastrophic injuries such as those to the superior mesenteric vessels that could lead to short gut syndrome.[30] Hepatic artery embolization or radiofrequency ablation may be more appropriate for widespread hepatic metastases and can give marked symptomatic relief and durable tumor control.[31]

Medical therapy is based on somatostatin analogues (octreotide), including short- and long-acting peptides for relief of carcinoid syndrome symptoms. Carcinoid tumors express somatostatin receptors, and the somatostatin analogues inhibit vasoactive peptide release from carcinoid tumors. Palliation of symptoms is effective in 90% of patients with octreotide. Some studies have demonstrated a tumorstatic or tumor reduction effect after the administration of somatostatin, although these latter findings have not been consistently reproduced. Efficacy of treatment can be documented by following excretion of the tumor marker 5-HIAA.

Chemotherapeutic agents for the treatment of metastatic carcinoid tumor include doxorubicin, 5-fluorouracil, dacarbazine, and interferon-α, with response rates of approximately 20%. Combination protocols most often utilize streptozotocin and 5-fluorouracil.

Preliminary reports on the use of targeted radiotherapeutics have been presented. Somatostatin analogues bind to somatostatin receptors on carcinoid tumors with high affinity. After binding is done, the ligand-receptor complex is internalized. This internalization has led to the development of "smart bombs"—radiolabeled somatostatin analogues that

theoretically deliver radiation specifically to carcinoid cells. ^{111}Indium-labeled pentetreotide demonstrated an enhanced tumor regression response compared to unlabeled analogue in one study.[32]

Gastrointestinal Stromal Tumors

Although gastrointestinal stromal tumors (GIST) are the most common nonepithelial tumors of the small bowel, they are in fact rare tumors of the GI tract, representing only 0.2% of all GI tumors. Approximately 25% of GIST arise in the small bowel, with 50% gastric, 15% rectal, and 10% colonic in origin.[33] Men and women are equally at risk and peak incidence occurs in patients aged between 50 and 70 years. GIST tumors arise from the interstitial cell of Cajal, the pacemaker cell of the GI tract intercalated between the intramural neurons and the smooth muscle cells. The molecular diagnostic feature of GIST is the presence of activating c-kit mutations, a transmembrane receptor tyrosine kinase involved in the regulation of cellular proliferation, apoptosis, and differentiation. Over 95% of GIST express kit (CD117) mutations, a molecular marker that distinguishes them from histologically similar mesenchymal tumors of the small bowel, including leiomyomas, leiomyosarcoma, schwannomas, and others.[34] Retrospective molecular analysis of mesenchymal tumors has led to reclassification of up to 70% small bowel tumors as GIST that had previously been classified as a variety of mesenchymal tumors.[35]

GISTs are characterized by indolent clinical symptoms, including vague abdominal pain, weight loss, and occult gastrointestinal bleeding. Of all small bowel tumors, GISTs often grow to a large size prior to surgical presentation. They tend to grow insidiously as extraluminal masses from their submucosal origin in a noninvasive manner, characteristically pushing adjacent organs away from the expanding mass. Gastrointestinal hemorrhage may develop in patients with necrotic GIST in communication with the bowel lumen.

Given the propensity of GIST to grow to a large size prior to diagnosis, CT scan is most likely to be the initial positive test. A characteristic finding is the presence of a large space-occupying mass, often with evidence of central necrosis and compression of adjacent organs and calcifications (Fig. 30-7).

Regardless of size, all GIST tumors should be considered to be malignant.[33] Malignant potential is determined by two major criteria: tumor size and mitotic rate. Biologically aggressive tumors are large tumors with a high mitotic index, while tumors with benign features are small and exhibit a low mitotic index. Tumors are thus classified into very low- to high-risk for malignant potential, a classification that has prognostic significance.

TREATMENT

Surgery is the primary therapeutic option with the goal being complete resection. At operation, wide local excision of the primary tumor to achieve gross negative margins with

FIGURE 30-7 Large gastrointestinal stromal tumor (GIST) arising from the stomach in the left upper quadrant. The diaphragm and the spleen were invaded by the tumor.

incontinuity resection of adherent organs is appropriate to attain curative resection. Lymph node metastasis is rare, negating the need for wide mesenteric resection. Wedge resection of gastric lesions of amenable shape and position in the gastric wall provides equivalent outcomes to partial gastrectomy without the negative side effects of partial gastrectomy.

MOLECULAR THERAPEUTICS AND GISTs.

Given the central role of activating mutations in the tyrosine kinases kit and more recently platelet-derived growth factor receptor alpha (PDGFRA) in the pathogenesis of GIST,[34] this tumor has served as a prototype for molecular therapeutic drug development. Activation of kit leads to phosphorylation of a receptor substrate protein, initiating an intracellular phosphorylation cascade leading to nuclear activation of transcription events, resulting in cell proliferation and survival. The discovery of a drug that inactivates kit with a safe therapeutic margin has revolutionized the treatment of metastatic GIST. Imatinib mesylate is a small molecule that occupies the adenosine triphosphate (ATP)–binding pocket of the kit kinase domain, blocking phosphorylation of the receptor and intracellular signaling. This binding arrests cellular proliferation and survival signaling.

Clinical use of imatinib is now routine in the management of GIST. This oral agent is well tolerated and highly effective for patients with metastatic GIST. While complete regression of tumor is rare, partial regression of disease and arrest of progression of disease can be achieved for durable intervals with continuous treatment in up to 80% of patients. Efficacy of treatment can be predicted and followed using fluorodeoxyglucose-positron emission tomography scanning; these highly biologically active tumors will become metabolically silent with imatinib therapy in those patients with responsive tumors. Emergence of resistant clones within tumors has been recognized with prolonged use of imatinib. Newer receptor

tyrosine kinase inhibitors, including sunitinib malate, have demonstrated efficacy for patients with tumor recurrence and resistance to imatinib with increased progression-free survival and overall survival.[36,37]

Neoadjuvant use of imatinib has been shown to result in a 70% response rate; although based on current available evidence, it is still unclear if preoperative therapy for GIST results in a clinically significant effect, leading to increased resectibility or enhanced long-term survival.[38] The efficacy of imatinib in the adjuvant setting has been evaluated in the ACOSOG Z9001 (American College of Surgeons Clinical Oncology Group Z9001) trial, finding improved disease-free survival for patients with tumors greater than 3 cm who received imatinib. For these patients, imatinib is indicated for life. Although overall survival advantage was not achieved in this trial, adjuvant trials in North America and Europe continue.

Metastatic Lesions to the Small Bowel

While metastases to the small bowel are rare as a group, they are in fact more common than primary small bowel neoplasms.

Metastatic spread can occur by direct invasion, hematogenous spread, or intraperitoneal seeding. Colon and pancreatic cancers are the most common primary sites for direct invasion. Hematogenous metastases spread most frequently from lung and breast carcinoma or melanoma. Peritoneal seeding may arise from any intra-abdominal malignancy including gastric, hepatic, ovarian, appendiceal, and colonic primary tumors.[39]

CT scan may identify metastatic lesions or reveal sites of partial or complete luminal obstruction. Metastases can be identified as bowel wall thickening or mesenteric masses. For small lesions, CT scan may be negative, while small bowel follow-through study may reveal an irregular luminal filling defect. Carcinomatosis is frequently not specifically identifiable on imaging studies, although PET-CT is useful for identification of small bowel metastases in some tumor types.

Optimal palliative management is based on clinical criteria. Segmental intestinal resection or bypass to relieve hemorrhage, obstruction, or pain is indicated except in the most terminal stages of disease. While cases of prolonged survival after intestinal resection of solitary metastases have been reported, progression of metastatic disease is more common.

Management of patients with carcinomatosis, regardless of tumor origin, remains challenging. Endoscopic luminal stents for obstructing duodenal lesions may offer short-term palliation, while intestinal bypasses and decompressive gastrostomy tubes are indicated for patients with advanced or more distal disease to enhance palliative care.

APPENDIX, MECKEL'S, AND OTHER SMALL BOWEL DIVERTICULA

William H. Peranteau • Douglas S. Smink

HISTORY

The first descriptions of the appendix date to the 16th century.[1–3] Although sketched in the anatomic notebooks of Leonardo da Vinci around 1500, the appendix was not formally described until 1524 by da Capri[4] and 1543 by Vesalius.[5] Perhaps the first description of a case of appendicitis was by Fernel in 1554,[6] in which a 7-year-old girl with diarrhea was treated with a large quince. Soon thereafter, she developed severe abdominal pain and died. Autopsy showed that the quince had obstructed the appendiceal lumen, resulting in appendiceal necrosis and perforation. For the next few centuries, such cases of appendicitis were typically diagnosed at autopsy.

Amyand is credited with the first appendectomy in 1736, when he operated on a boy with an enterocutaneous fistula within an inguinal hernia.[7] On exploration of the hernia sac, he discovered the appendix, which had been perforated by a pin resulting in a fecal fistula. As a result of his original description, an inguinal hernia containing the appendix carries Amyand's eponym to this day.[8] Nearly 150 years passed until Lawson Tait in London presented the first successful transabdominal appendectomy for gangrenous appendix in 1880.[9] Less than a decade later, in 1886, Reginald Fitz of Harvard Medical School first described the natural history of the inflamed appendix, coining the term "appendicitis."[10] In 1889, Charles McBurney of the Columbia College of Physicians and Surgeons in New York presented his series of cases of surgically treated appendicitis and in so doing described the anatomic landmark that now bears his name. McBurney's point is the location of maximal tenderness "very exactly between an inch and a half and two inches from the anterior spinous process of the ileum on a straight line drawn from that process to the umbilicus."[11] In the 1890s, Sir Frederick Treves of London Hospital advocated conservative management of acute appendicitis followed by appendectomy after the infection had subsided[12]; unfortunately, his youngest daughter developed perforated appendicitis and died from such treatment.

Numerous advances in the diagnosis and treatment of appendicitis have emerged in the past 125 years. Nonetheless, acute appendicitis continues to challenge surgeons to this day.

ANATOMY

Embryologically, the appendix and cecum develop as outpouchings of the caudal limb of the midgut loop in the 6th week of human development. By the 5th month, the appendix elongates into its vermiform shape. At birth, the appendix is located at the tip of the cecum, but, because of unequal elongation of the lateral wall of the cecum, the adult appendix typically originates from the posteromedial wall of the cecum, caudal to the ileocecal valve. The appendix averages 9 cm in length,[3] with its outside diameter ranging from 3 to 8 mm and its lumen ranging from 1 to 3 mm. The base of the appendix is consistently found by following the teniae coli of the colon to their confluence at the base of the cecum. The appendiceal tip, however, can vary significantly in location (Fig. 31-1). Although usually located in the right lower quadrant (RLQ) or pelvis, the tip can occasionally reside in the left lower or right upper quadrants (RUQ).

The arterial supply of the appendix comes from the appendicular branch of the ileocolic artery, which originates posterior to the terminal ileum and enters the mesoappendix near the base of the appendix (Fig. 31-2). Lymphatic drainage flows to lymph nodes along the ileocolic artery.

ACUTE APPENDICITIS

Epidemiology

Addiss and associates[13] estimated the incidence of acute appendicitis in the United States to be 11 cases per 10,000 population annually. The disease is slightly more common in

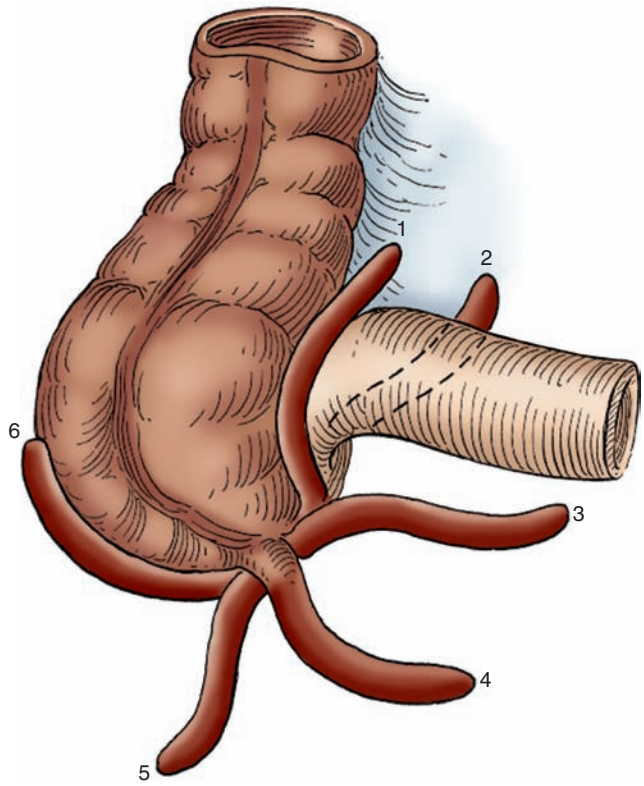

FIGURE 31-1 Anatomic variation in the position of the appendix. (1) Preilieal; (2) postilieal; (3) promontoric; (4) pelvic; (5) subcecal; (6) paracolic or prececal. (Redrawn from Wakeley CP. The position on the vermiform appendix as ascertained by analysis of 10,000 cases. *J Anat*. 1933;67:277. After Waldron.)

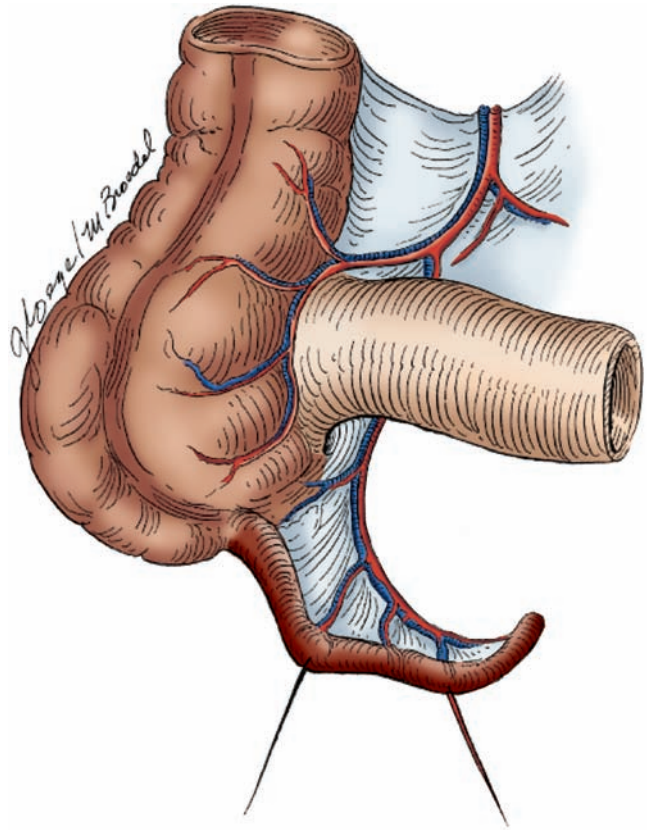

FIGURE 31-2 The appendix and its arterial supply.

males, with a male: female ratio of 1.4:1. In a lifetime, 8.6% of males and 6.7% of females can be expected to develop acute appendicitis. Young age is a risk factor, as nearly 70% of patients with acute appendicitis are younger than 30 years. The highest incidence of appendicitis in males is in the 10- to 14-year-old age group (27.6 cases per 10,000 population), while the highest female incidence is in the 15- to 19-year-old age group (20.5 cases per 10,000 population). Patients at extremes of age are more likely to develop perforated appendicitis. Overall, perforation was present in 19.2% of cases of acute appendicitis. This number was significantly higher, however, in patients younger than 5 and older than 65 years. Although less common in people older than 65 years, acute appendicitis in the elderly progresses to perforation more than 50% of the time.[13]

Etiology and Pathophysiology

Appendicitis, diverticular disease, and colorectal carcinoma have been shown to be diseases of developed civilizations. Burkitt[14] found an increased incidence of appendicitis in Western countries compared to Africa, as well as in wealthy, urban communities compared to rural areas. He attributed this to the Western diet, which is low in dietary fiber and high in refined sugars and fat, and postulated that low-fiber diets lead to less bulky bowel contents, prolonged intestinal transit time, and increased intraluminal pressure. Burkitt theorized that the combination of firm stool leading to appendiceal obstruction and increased intraluminal pressure causing bacterial translocation across the bowel wall resulted in appendicitis. In examining appendixes removed for reasons other than appendicitis, he found fecaliths to be more prevalent in Canadian (32%) than in South African (4%) adults. In a group of patients with appendicitis, fecaliths were more common in Canadians (52%) than in South Africans (23%).[15] He felt this was confirmation that appendiceal obstruction resulted in appendicitis. Of note, however, the majority of patients with appendicitis in his study did not have evidence of a fecalith.

Wangensteen extensively studied the structure and function of the appendix and the role of obstruction in appendicitis.[16,17] Based on anatomic studies, he postulated that mucosal folds and a sphincter-like orientation of muscle fibers at the appendiceal orifice make the appendix susceptible to obstruction. He proposed the following sequence of events to explain appendicitis: (1) Closed-loop obstruction is caused by a fecalith and swelling of the mucosal and submucosal lymphoid tissue at the base of the appendix; (2) intraluminal pressure rises as the appendiceal mucosa secretes fluid against the fixed

obstruction; (3) increased pressure in the appendiceal wall exceeds capillary pressure and causes mucosal ischemia; and (4) luminal bacterial overgrowth and translocation of bacteria across the appendiceal wall result in inflammation, edema, and ultimately necrosis. If the appendix is not removed, perforation can ensue.

Although appendiceal obstruction is widely accepted as the primary cause of appendicitis, evidence suggests that this may be only one of many possible etiologies. First, some patients with a fecalith have a histologically normal appendix, and the majority of patients with appendicitis show no evidence for a fecalith.[15,18,19] Arnbjornsson and Bengmark[20] studied at laparotomy the appendixes of patients with suspected appendicitis. They found the intraluminal pressure of the appendix prior to removal to be elevated in only 8 of 27 patients with nonperforated appendicitis. They found no signs of obstruction in the remaining patients with nonperforated appendicitis, as well as all patients with a normal appendix. Taken together, these studies imply that obstruction is but one of the possible etiologies of acute appendicitis.

Presentation

Perhaps the most common surgically correctable cause of abdominal pain, the diagnosis of acute appendicitis remains difficult in many instances. Some of the signs and symptoms can be subtle to both the clinician and the patient and may not be present in all instances. Arriving at the correct diagnosis is essential, however, as a delay in diagnosis may allow progression to perforation and significantly increased morbidity and mortality. Incorrectly diagnosing a patient with appendicitis, although not catastrophic, often subjects the patient to an unnecessary operation.

The classic presentation of acute appendicitis begins with crampy, intermittent abdominal pain, thought to be due to obstruction of the appendiceal lumen. The pain may be either periumbilical or diffuse and difficult to localize. This is typically followed shortly thereafter with nausea; vomiting may or may not be present. If nausea and vomiting precede the pain, patients are likely to have another cause for their abdominal pain, such as gastroenteritis. Classically, the pain migrates to the right lower quadrant as transmural inflammation of the appendix leads to inflammation of the peritoneal lining of the right lower abdomen. This usually occurs within 12–24 hours of the onset of symptoms. The character of the pain also changes from dull and colicky to sharp and constant. Movement or Valsalva maneuver often worsens this pain, so that the patient typically desires to lie still; some patients describe pain with every bump in the car or ambulance ride to the hospital. Patients may report low-grade fever up to 101°F (38.3°C). Higher temperatures and shaking chills should again alert the surgeon to other diagnoses, including appendiceal perforation or nonappendiceal sources. When questioned, patients who have appendicitis commonly report anorexia; appendicitis is unlikely in those with a normal appetite.

The surgeon is constantly reminded that in practice, the classic presentation of acute appendicitis is not present in all patients. Patients may have none or only a few of the symptoms just described. For instance, they may not notice or recall the initial colicky pain. When the pain becomes constant, it may localize to other quadrants of the abdomen due to an alteration in appendiceal anatomy as in late pregnancy or malrotation. In patients with a retrocecal appendix, the pain may never localize until generalized peritonitis from perforated appendicitis occurs. Urinary or bowel frequency may be present due to appendiceal inflammation irritating the adjacent bladder or rectum. Because appendicitis is so common, a high index of suspicion for appendicitis is warranted in all patients with abdominal pain.

Perforated Appendicitis

It is a commonly held belief that if left untreated, appendiceal inflammation will progress inevitably to necrosis, and ultimately to perforation. The time course of this progression varies among patients. In one study of the natural history of appendicitis, the authors questioned patients undergoing appendectomy for suspected appendicitis about their duration of symptoms.[21] Patients with nonperforated appendicitis reported an average of 22 hours of symptoms prior to presentation to the hospital, while patients with perforated appendicitis reported an average of 57 hours. However, 20% of cases of perforated appendicitis presented within 24 hours of the onset of symptoms; one of those patients had symptoms for only 11 hours. Although concern for perforation should be present when evaluating a patient with more than 24 hours of symptoms, the clinician must remember that perforation can develop more rapidly.

Some authors have questioned whether some perforations in acute appendicitis are attributable to delay in diagnosis after a patient seeks medical attention. Velanovich and Satava postulated a surgeon's misdiagnosis rate (the percentage of normal appendixes found at appendectomy) to be inversely related to the perforation rate (the percentage of perforated appendixes found at laparotomy).[22] They believed that surgeons are obliged to operate quickly when appendicitis is suspected, thus minimizing the likelihood of perforation in exchange for a higher rate of misdiagnosis. More recent studies suggest that this reasoning is flawed. Temple and colleagues showed that patients with perforated appendicitis were operated on more quickly than those with nonperforated appendicitis (6.5 vs 9 hours), but perforated patients had significantly longer prehospital symptoms (57 vs 22 hours).[21] These findings are confirmed by two other studies, both showing that longer duration of prehospital delay is the major contributor to perforation.[23,24] Perforation after presenting to surgical attention appears to be uncommon.

When acute appendicitis has progressed to appendiceal perforation, other symptoms may be present. Patients will often complain of two or more days of abdominal pain, but their duration of symptoms may be shorter, as previously

discussed. The pain usually localizes to the right lower quadrant if the perforation has been walled off by surrounding intra-abdominal structures including the omentum, but it may be diffuse if generalized peritonitis ensues. The pain may be so severe that patients do not remember the antecedent colicky pain. Patients with perforation often have rigors and high fevers to 102°F (38.9°C) or above. A history of poor oral intake and dehydration may also be present.

Most patients with perforated appendicitis present with symptoms related to the inflamed appendix itself or to a localized intraperitoneal abscess from perforation. Other more rare presentations do occur, however. These are most likely to occur in the very young and very old, who cannot express their symptoms and often present late in the course of their disease. For instance, abscesses can also form in the retroperitoneum due to perforation of a retrocecal appendix, or in the liver from hematogenous spread of infection through the portal venous system. An intraperitoneal abscess could fistulize to the skin, resulting in an enterocutaneous fistula. Pylephlebitis (septic portal vein thrombosis) presents with high fevers and jaundice and can be confused with cholangitis; it is a dreaded complication of acute appendicitis and carries a high mortality.[25] On occasion, patients will have bilious vomiting and obstipation due to a small bowel obstruction resulting from appendiceal perforation. Because appendicitis is so common, these rare presentations should alert the surgeon to the possibility of appendicitis.

Diagnosis

HISTORY AND PHYSICAL EXAMINATION

As always, the diagnosis begins with a thorough history and physical examination. The patient should be asked about the classic symptoms of appendicitis, but the surgeon should not be dissuaded by the absence of many of the symptoms. Many patients with acute appendicitis do not have a classic history. Because the differential diagnosis of appendicitis is extensive, patients should be queried about certain symptoms that may suggest an alternative diagnosis. Surgeons must also remember that a previous appendectomy does not definitively exclude the diagnosis of appendicitis, as "stump appendicitis" (appendicitis in the remaining appendiceal stump after appendectomy), although rare, has been described.[26]

On inspection, patients look mildly ill and may have slightly elevated temperature and pulse. They often lie still to avoid the peritoneal irritation caused by movement. The surgeon should systematically examine the entire abdomen, starting in the left upper quadrant away from the patient's described pain. Maximal tenderness is typically in the right lower quadrant, at or near McBurney's point, located one-third of the way from the anterior superior iliac spine to the umbilicus. This tenderness is often associated with localized muscle rigidity and signs of peritoneal inflammation, including rebound, shake, or tap tenderness. RLQ tenderness is most consistent of all signs of acute appendicitis[27,28]; its presence should always raise the specter of appendicitis, even in the absence of other signs and symptoms. Because of the various anatomic locations of the appendix, however, it is possible for the tenderness to be in the right flank or right upper quadrant, the suprapubic region, or the left lower quadrant. Patients with a retrocecal or pelvic appendix may have no abdominal tenderness whatsoever. In such cases, rectal examination can be helpful to elicit right-sided pelvic tenderness.

Multiple signs can be detected on physical examination to contribute to the diagnosis of appendicitis. Rovsing's sign, pain in the right lower quadrant on palpation of the left lower quadrant, results from localized peritoneal inflammation in the right lower quadrant. Psoas sign, pain with flexion of the leg at the right hip, can be seen with a retrocecal appendix due to inflammation adjacent to the psoas muscle. The obturator sign, pain with rotating the flexed right thigh internally, indicates inflammation adjacent to the obturator muscle in the pelvis.

In cases of perforated appendicitis, patients can look gravely ill, appearing flushed with dry mucous membranes and considerable elevations in temperature or pulse. If sepsis has developed, blood pressure can be depressed. If the perforation has been walled off by surrounding structures to create an abscess or phlegmon, a mass may be palpable in the right lower quadrant. If free intraperitoneal rupture has occurred, the patient can have signs of generalized peritonitis with diffuse rebound tenderness.

LABORATORY STUDIES

Laboratory studies can be helpful in the diagnosis of appendicitis, but no single test is definitive. A white blood cell count (WBC) is perhaps the most useful laboratory test. Typically, the WBC is slightly elevated in nonperforated appendicitis but may be quite elevated in the presence of perforation. The clinician must remember, however, that the WBC can be normal in patients with acute appendicitis, particularly in early cases. Serial WBC measurements improve the diagnostic accuracy, with a rising value over time commonly seen in patients with appendicitis.[29] Urinalysis is performed to diagnose other potential causes for abdominal pain, specifically urinary tract infection and ureteral stone. Significant hematuria with colicky abdominal pain suggests ureterolithiasis, and testing directed at this diagnosis is indicated. A urinary tract infection, on the other hand, is not uncommon in patients with appendicitis. Its presence does not exclude the diagnosis of acute appendicitis, but it should be identified and treated. Although pyuria suggests urinary tract infection, it is not uncommon for the urinalysis in a patient with appendicitis to show a few white blood cells solely due to inflammation of the ureter by the adjacent appendix.

In certain patient populations, other laboratory tests are indicated. Measurement of serum liver enzymes and amylase can be helpful in diagnosing liver, gallbladder, or pancreatic disease in patients complaining of midabdominal or RUQ pain. In women of childbearing age, the urine β-human chorionic gonadotropin should be checked to alert the clinician

to the possibility of ectopic or concurrent pregnancy. Ectopic pregnancy is another cause of RLQ pain that demands emergent diagnosis and treatment. Concurrent pregnancy should be known before a patient with suspected appendicitis is subjected to ionizing radiation from imaging studies or to general anesthesia.

DIAGNOSTIC SCORES

Diagnostic scoring systems have been developed in an attempt to improve the diagnostic accuracy of acute appendicitis.[18,30] The most prominent of those scores, developed by Alvarado,[30] was based on a retrospective analysis of 305 patients with abdominal pain suspicious for appendicitis. This scoring system gives points for symptoms (migration of pain, anorexia, and nausea), physical signs (RLQ tenderness, rebound tenderness, and pyrexia), and laboratory values (leukocytosis and a left shift). Although these scores can help guide clinical thinking, they do not markedly improve diagnostic accuracy.[31] With the recent improvement in imaging studies, these scores play a smaller role in diagnosis.

IMAGING STUDIES

The potential imaging modalities for diagnosis of acute appendicitis include plain radiographs, ultrasound (US), and computed tomography (CT). Prior to the widespread use of modern imaging techniques, plain abdominal films were often obtained in patients with abdominal pain, and a right lower quadrant fecalith (or appendicolith) was considered pathognomonic for acute appendicitis. A number of studies question this teaching, however. Teicher and colleagues[18] reviewed the abdominal radiographs of 200 appendectomy patients—100 with pathologically proven appendicitis and 100 with a normal appendix. Of those with appendicitis, 10.5% had an appendicolith on x-ray, compared to 3.3% of those without appendicitis. An extensive review of appendectomy specimens at the Mayo Clinic[19] showed that fecaliths or appendiceal calculi were present in 9% of patients with nonperforated appendicitis and 21% of those with perforated appendicitis. Interestingly, fecaliths were also present in 7% of patients with suspected appendicitis who had a pathologically normal appendix and in 2% of patients who had an appendectomy for other reasons.

These studies show that fecaliths are not pathognomonic for appendicitis, as some patients with abdominal pain and a fecalith have a normal appendix. In addition, fecaliths are not common enough in patients with appendicitis to be used as a reliable sign. As a result, plain abdominal radiographs are neither helpful nor cost-effective and are not recommended for the diagnosis of acute appendicitis. Plain radiographs are indicated in elderly patients with severe abdominal pain, in whom a perforated viscus is included in the differential diagnosis. In this patient population, an upright chest x-ray can assess for the presence of free air.

Abdominal ultrasonography is a popular imaging modality for acute appendicitis. Findings that suggest appendicitis include thickening of the appendiceal wall, loss of wall compressibility, increased echogenicity of the surrounding fat signifying inflammation, and loculated pericecal fluid (Fig. 31-3). The advantages of ultrasound include its widespread availability, as well as the avoidance of ionizing radiation and the side effects of intravenous contrast such as renal toxicity and allergic reactions. In addition, ultrasound (both abdominal and transvaginal) is particularly useful in assessing obstetric and gynecological causes of abdominal pain in women of childbearing age. Ultrasound is highly operator-dependent, however, and it is frequently unable to visualize the normal appendix.[32] A recent meta-analysis of 14 prospective studies showed ultrasound to have a sensitivity of 0.86 and a specificity of 0.81.[33]

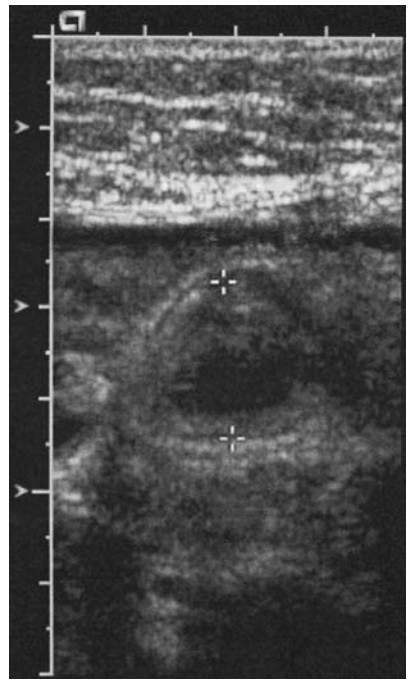

FIGURE 31-3 Appendiceal ultrasound showing distended, noncompressible appendix measuring 1.7 cm in transverse dimension (>0.6 cm is abnormal). (Used, with permission, from M. Stephen Ledbetter, MD, MPH, Brigham and Women's Hospital, Boston, MA.)

CT is yet another imaging modality for acute appendicitis. CT benefits from a high diagnostic accuracy for appendicitis[33] and visualization and diagnosis of many of the other causes of abdominal pain that can be confused with appendicitis. The radiographic findings of appendicitis on CT include a dilated (>6 mm), thick-walled appendix that does not fill with enteric contrast or air, as well as surrounding fat stranding to suggest inflammation (Fig. 31-4).[34] In a meta-analysis of 12 prospective studies, CT demonstrated a sensitivity of 0.94 and a specificity of 0.95.[33] CT thus has a high negative predictive value, making it particularly useful in excluding appendicitis in patients for whom the diagnosis is in doubt. Appendicitis is highly unlikely if enteric contrast fills the lumen of the appendix and no surrounding inflammation is present. The clinician must remember, however, that a CT performed early in the course of appendicitis might not show

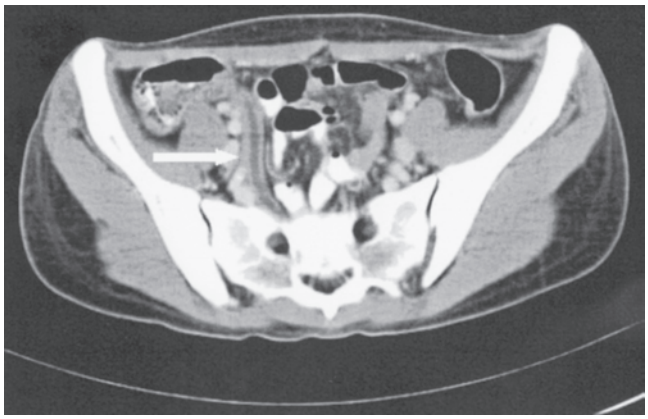

FIGURE 31-4 CT of acute appendicitis. The *arrow* points to an enlarged, fluid-filled appendix with wall hyperemia that does not fill with oral contrast. The paucity of intra-abdominal fat limits identification of fat stranding. (Used, with permission, from M. Stephen Ledbetter, MD, MPH, Brigham and Women's Hospital, Boston, MA.)

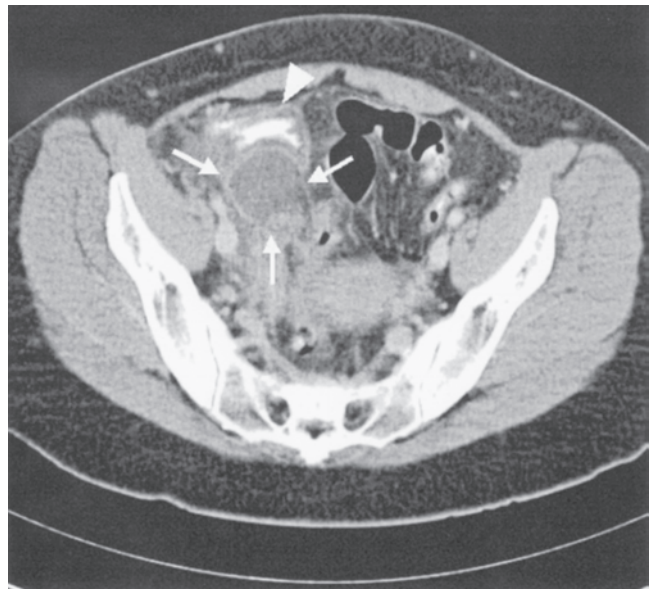

FIGURE 31-5 CT of perforated appendix. Note retrocecal abscess (*arrows*) with enhancing wall and periappendiceal fat stranding and adjacent cecal thickening (*arrowhead*). (Used, with permission, from M. Stephen Ledbetter, MD, MPH, Brigham and Women's Hospital, Boston, MA.)

the typical radiographic findings. In confusing cases, it is reasonable to repeat the CT after 24 hours of observation.

A number of recent prospective studies have compared the accuracy of CT and ultrasound in imaging the appendix (Table 31-1).[32,35,36] Balthazar and associates[35] performed CT and ultrasound on 100 consecutive patients with suspected appendicitis. The sensitivity of CT was considerably higher (96% for CT, 76% for US), while the specificity was comparable (89% for CT, 91% for US), yielding a higher accuracy for CT (94 vs 83%). CT was also able to provide an alternative diagnosis in more patients and was better able to visualize abscesses or phlegmons (Fig. 31-5). Horton and colleagues[36] randomized patients with suspected appendicitis to either CT or ultrasound. Their findings echo those of Balthazar, with both CT and ultrasound having high specificity (100% for CT, 90% for US) but CT having significantly higher sensitivity (97 vs 76%). Yet another prospective study showed similar results, with CT having higher sensitivity (96 vs 62%) and specificity (92 vs 71%) than ultrasound.[32] Again, CT was also better able to visualize other intra-abdominal pathology in the absence of appendicitis.

In a study of 100 patients evaluated by CT with rectal and intravenous contrast, Rao and coworkers[37] showed that CT can reduce the use of hospital resources and costs. CT changed the management of 59 patients, avoiding 13 unnecessary appendectomies and eliminating a total of 50 inpatient hospital days for observation of unexplained abdominal pain. Even factoring in the cost of the CT scans, the authors calculated a net savings of US$447 per patient.

Taken together, these studies suggest an algorithm for evaluation of patients with suspected acute appendicitis. Patients with a history, physical examination, and laboratory studies classic for appendicitis should undergo appendectomy. In those with an evaluation suggestive but not convincing for appendicitis, further imaging is warranted. In women of childbearing age, this should begin with a pelvic ultrasound to evaluate for ovarian pathology. In other patients, transabdominal ultrasound or abdominopelvic CT should be considered, depending on study availability and expertise of the consulting radiologist. CT does have the advantage of improved accuracy in diagnosing both appendiceal and other intra-abdominal pathology. This can be supplemented with rectal contrast CT, if needed, to better visualize the appendix.[32,37] Patients with a CT showing nonperforated appendicitis should undergo appendectomy. In many instances, patients with a normal CT do not require hospital admission. If symptoms persist, admission to the hospital for observation, and perhaps a repeat CT scan, is warranted.

TABLE 31-1: ACCURACY OF CT AND US FOR THE DIAGNOSIS OF ACUTE APPENDICITIS

		Sensitivity (%)	Specificity (%)	Accuracy (%)
Balthazar et al[35]	CT	96	89	94
	US	76	91	83
Horton et al[36]	CT	97	100	98
	US	76	90	80
Wise et al[32]	CT	96	92	93
	US	62	71	69
Terasawa et al[33] (meta-analysis)	CT	94	95	N/A
	US	86	81	N/A

CT, computed tomography; N/A, not applicable; US, ultrasound.

DIFFERENTIAL DIAGNOSIS

Because many of its signs and symptoms are nonspecific, the differential diagnosis of acute appendicitis is extensive and includes virtually all possible abdominal sources of pain, as well as some nonabdominal sources (Table 31-2). However, some diagnoses are more likely than others in certain patient groups. For instance, in young males with a suggestive history and physical examination, acute appendicitis is the most likely cause of RLQ pain. Meckel's diverticulitis causes similar symptoms but is relatively uncommon.[38] Gastroenteritis is considerably more common and should be expected when nausea and vomiting precede the abdominal pain, or when diarrhea is a prominent symptom. Crohn's disease affecting the terminal ileum may resemble appendicitis in its initial presentation, but on further questioning the patient typically describes a subacute course, including fever, weight loss, and pain.

In middle-aged and older adults, other inflammatory conditions should be considered, including peptic or duodenal ulcer (with fluid tracking into the right paracolic gutter), cholecystitis, and pancreatitis. In addition, cecal or sigmoid diverticulitis can be confused with acute appendicitis. Cecal diverticulitis is quite similar in pathogenesis and presentation to appendicitis, because cecal diverticula, like the appendix, are true diverticula containing all layers of the intestinal wall. Because a redundant, floppy sigmoid colon can extend to the right side of the abdomen, patients with sigmoid diverticulitis can sometimes present with RLQ pain. Those patients typically describe a quicker progression to localized tenderness, as well as a prodrome of an alteration in bowel habits. Malignancies can present with acute RLQ pain due to perforation of a cecal carcinoma or appendicitis caused by a mass obstructing the appendiceal orifice.[39] These patients will also typically have guaiac-positive stools, anemia, and a history of weight loss.

In women of childbearing years, the diagnosis of RLQ pain can be even more difficult. In addition to the causes of RLQ pain mentioned for young men, young women can also have pain from obstetric and gynecological causes such as ruptured ovarian cyst or follicle, ovarian torsion, ectopic pregnancy, acute salpingitis, and tubo-ovarian abscess. A complete history including recent menstrual history, as well as pelvic examination, can be helpful in differentiating these causes of pain from acute appendicitis. Nonetheless, appendicitis can be difficult to diagnose in this patient population, and higher rates of misdiagnosis have been described in women of childbearing age.[40]

TABLE 31-2: DIFFERENTIAL DIAGNOSIS OF ACUTE APPENDICITIS

Gastrointestinal causes
- Cecal diverticulitis
- Sigmoid diverticulitis
- Meckel's diverticulitis
- Epiploica appendicitis
- Mesenteric adenitis
- Omental torsion
- Crohn's disease
- Cecal carcinoma
- Appendiceal neoplasm
- Lymphoma
- Typhlitis
- Small bowel obstruction
- Perforated duodenal ulcer
- Intussusception
- Acute cholecystitis
- Hepatitis
- Pancreatitis

Infectious causes
- Infectious terminal ileitis (*Yersinia*, tuberculosis, or cytomegalovirus)
- Gastroenteritis
- Cytomegalovirus colitis

Genitourinary causes
- Pyelonephritis or perinephric abscess
- Nephrolithiasis
- Hydronephrosis
- Urinary tract infection

Nonabdominal causes
- *Streptococcal pharyngitis*
- Lower lobe pneumonia
- Rectus muscle hematoma

In women
- Ovarian cyst (ruptured or not ruptured)
- Corpus luteal cyst (ruptured or not ruptured)
- Ovarian torsion
- Endometriosis
- Pelvic inflammatory disease
- Tubo-ovarian abscess

In pregnancy
- Ectopic pregnancy
- Round ligament pain
- Chorioamnionitis
- Placental abruption
- Preterm labor

SPECIAL CONSIDERATIONS

Children. Appendicitis most commonly affects children age 10–19, with an overall incidence of approximately 20 cases per 10,000 population annually.[13] Among those younger than 20, infants aged 0–4 have the lowest incidence of appendicitis (2 cases per 10,000 annually), but up to two-thirds will present with perforation.[41] Perforation is common because infants often present later in their disease course and because of the difficulty in obtaining an accurate history. The diagnosis is further complicated by diseases of childhood that can mimic appendicitis. For instance, mesenteric adenitis, an inflammation of the mesenteric lymph nodes secondary to

upper respiratory tract infection, can present with fever and RLQ pain. Streptococcal pharyngitis and bacterial meningitis can also present with fever, nausea, and abdominal pain. These diagnoses and others including ovarian cysts, ovarian torsion, urinary tract infection, pelvic inflammatory disease, and complications of a Meckel's diverticulum should be considered when evaluating children or adolescents for suspected appendicitis.

In children with an equivocal history and physical examination, imaging with either a CT scan or US can significantly reduce the negative appendectomy rate from 14 to 37% down to 2 to 10%.[42] The pertinent question is which study is preferable. As with adults, both CT and US have been shown to be highly accurate in diagnosing appendicitis in children, although CT scan is believed to have a higher specificity and sensitivity. In an early study Garcia Pena and associates compared ultrasonography and rectal contrast CT in 139 children with suspected appendicitis and found CT to be more sensitive (97% for CT, 44% for US), more specific (94% for CT, 93% for US), and more accurate (94% for CT, 76% for US).[43] CT correctly changed the management of 73% of patients, while ultrasound correctly changed 19%. More recent meta-analysis and reviews evaluating CT and/or ultrasound in pediatric populations found the specificity of the two imaging modalities to be similar (92–95%) but the sensitivity of ultrasound (88–90%) to be less than that of CT scan (94–95%).[42,44] An important determinant in the diagnostic success of ultrasound is the body mass index (BMI) of the child. The sensitivity of ultrasound has been reported by some to be 76% in children with a BMI below 25, 37% in children with a BMI greater than 25, and 82% in one study in which the patient population had a mean BMI of 17.[42,45,46]

The use of CT can be recommended for children with one caveat. The radiation from a CT in childhood theoretically causes a small increase in the lifetime risk of certain cancers.[47] Based on estimated radiation exposure from a CT scan, studies have hypothesized that a 1-year-old and 15-year-old would have a 0.18 and 0.11% lifetime risk, respectively, of fatal radiation-induced malignancy following a CT scan.[42] Therefore, clinicians should consider the risks and benefits of CT, and efforts should be directed toward reducing radiation dose when imaging children.[48] In the pediatric patients with suspected appendicitis, an algorithm starting with an ultrasound, especially in low BMI children and females, followed by CT scan if the ultrasound is equivocal may allow the maximum benefit of radiologic imaging while minimizing potential deleterious radiation effects. The use of magnetic resonance imaging (MRI) in the evaluation of children has only recently begun to be investigated. Although its ability to identify the appendix has been established, the use of MRI in the diagnosis of appendicitis in children requires further study.

Elderly. Although appendicitis is more common in younger age groups, it is still an important cause of abdominal pain in the elderly. Perhaps because of a diminished inflammatory response, the elderly can present with less impressive symptoms and physical signs, longer duration of symptoms, and decreased leukocytosis compared to younger patients.[49] Perforation is thus more common, occurring in as many as 50% of patients older than 65.[13] These patients may have cardiac, pulmonary, and renal conditions, resulting in considerable morbidity and mortality from perforation. In one series, the mortality from perforated appendicitis in patients older than 80 was 21%.[50] These factors argue that RLQ pain in elderly patients must be aggressively investigated. Because of the multiple other possible causes of abdominal pain in this patient population (including malignancy, diverticulitis, and perforated peptic ulcer disease), prompt CT scan is advocated when the diagnosis is in question.

Pregnancy. The diagnosis of acute appendicitis in the pregnant patient can be particularly challenging, as nausea, anorexia, and abdominal pain may be symptoms of both appendicitis and normal pregnancy. In addition, the gravid uterus can displace the abdominal viscera, shifting the location of the appendix from the right lower quadrant. Appendicitis affects 1 in every 1400 pregnancies, an incidence similar to that of the nonpregnant female population.[51] It can occur in any trimester, with perhaps a slight increase in frequency during the second trimester.[51,52] Perforation is more common in the third trimester, however, and results from a longer duration from the onset of symptoms to operation.[53] The differential diagnosis of appendicitis includes not only the conditions possible in nonpregnant women but also certain conditions specific to pregnancy: ectopic pregnancy, chorioamnionitis, preterm labor, placental abruption, and round ligament pain.

In the first and early second trimesters, the presentation of appendicitis is similar to that seen in nonpregnant women. In the third trimester, women may not present with RLQ pain due to displacement of the appendix by the gravid uterus. Baer and associates performed barium enemas on normal pregnant women and found the appendix to migrate superiorly toward the right upper quadrant in later stages of pregnancy.[54] Their findings suggest that appendicitis should present with RUQ or flank pain in late pregnancy. Two retrospective studies contradict this, however, showing that even in the third trimester, pain and tenderness are more common in the right lower than the right upper quadrant.[51,52] Nonetheless, RUQ pain did predominate in some third-trimester patients with appendicitis in each study,[51,52] reminding the clinician that right upper quadrant and right flank symptoms could be due to appendicitis in an appendix displaced by the gravid uterus. Recent studies highlight the difficulty of assigning a clinical picture to a pregnant patient with appendicitis. Brown et al[55] reviewed case-control studies attempting to correlate preoperative signs and symptoms with the postoperative diagnosis of appendicitis in pregnant patients. Although patients presented with RUQ pain, RLQ pain, and fevers, only nausea, vomiting, and peritonitis were found to significantly correlate with the diagnosis of appendicitis.

Ultrasound is accurate in pregnancy[56] and is a useful first radiological study because it has no known adverse fetal effects.[57] Rectal contrast CT has also been shown to be highly

accurate in the pregnant population.[58] Although ionizing radiation has risks to the fetus, the radiation from a typical abdominopelvic CT is below the threshold of 5 rad at which teratogenic effects are seen.[59] When the diagnosis is in doubt, the risk of radiation should be weighed against the risk of spontaneous abortion from an unnecessary laparotomy or from undiagnosed appendicitis progressing to perforation. Hospital admission with close observation for progression of symptoms is a viable alternative if the risks of radiation from CT scan are deemed excessive. Additionally, MRI has been recently used to aid in the diagnosis of appendicitis in the pregnant patient when ultrasound results are equivocal. In those pregnant patients with a normal or inconclusive ultrasound, MRI is a diagnostic option, with accuracy that rivals CT; MRI has a sensitivity of 80% and specificity of 99%, compared with 85.7 and 97.4% for CT. Although MRI does not carry a risk of radiation, it does have theoretical risks of static and time-varying magnetic fields, heating effects of the radiofrequency pulses and acoustic noise generated by the spatial encoding gradients do exist. To date, however, no adverse effects of MRI on the developing fetus have been reported.[60]

The pregnant patient should proceed directly to appendectomy if appendicitis is suspected. A normal appendix is not an uncommon finding, as negative appendectomy has been reported in approximately one-third of cases due to the difficulty of diagnosis in this population.[51,52,61] Negative appendectomy should not be considered an error in diagnosis, because the risk to the fetus varies directly with the severity of appendicitis. In one series, fetal loss occurred in only 1 (3%) of 30 negative laparotomies.[51] Fetal mortality rises to 5% in cases of nonperforated appendicitis and increases to 20–35% when the appendix perforates.[55,61] These data warrant an aggressive approach to appendectomy. Early negative exploration is justified to minimize the likelihood of progression to perforation.

As laparoscopic appendectomy has become increasingly popular, it has been utilized more frequently during pregnancy.[62] Pregnancy can increase the complexity of the procedure, as the gravid uterus can make laparoscopic visualization difficult, particularly if the appendix is located in the pelvis. In addition, carbon dioxide insufflation of the abdomen results in fetal hypercarbia and decreased placental blood flow, the effects of which have not been completely studied.[63] Recent case series, however, have supported the safety of laparoscopic appendectomy in the pregnant patient. In a retrospective review of 45 cases, Lemieux et al[64] demonstrated that 4% of patients had a major complication (uterine perforation, intra-abdominal abscess), 4% of patients had a minor complication (cystitis, ileus), 18% delivered before 37 weeks gestation, and there was no fetal loss. There was also no difference in complications, preterm delivery, or operative time associated with performing the appendectomy during the first, second, or third trimester. A retrospective review directly comparing laparoscopic to open appendectomy in 42 pregnant women found no intra- or postoperative complications in either group and one fetal loss in both groups.[65] Thus, the feasibility and safety of laparoscopy during pregnancy are supported by these studies, but larger studies are required for it to become fully accepted.

Immunocompromise. The immunocompromised state alters the normal response to acute infection and wound healing. Appendicitis affects all types of patients and must be considered in those who have undergone organ transplant, are receiving chemotherapy, have hematological malignancy, or are infected with the human immunodeficiency virus (HIV). The differential diagnosis of abdominal pain in this population is broad and includes hepatitis, pancreatitis (from medications or cytomegalovirus infection), acalculous cholecystitis, intra-abdominal opportunistic infections (cytomegalovirus colitis or mycobacterial ileitis), secondary malignancies (lymphoma or Kaposi's sarcoma), graft-versus-host disease, and typhlitis. This broad differential diagnosis often results in delay in diagnosis and late presentation to surgical evaluation, at which time perforation may be more likely.[66,67]

Appendicitis in patients with HIV and acquired immunodeficiency syndrome (AIDS) presents unique challenges. Abdominal pain is not an uncommon symptom in these patients, making differentiation between surgical and nonsurgical causes difficult. Nonetheless, immunocompromised patients with appendicitis present with symptoms similar to those of the general population,[66] and RLQ pain, nausea, and anorexia. Fever and WBC may not be helpful in this population, so imaging studies, particularly CT, have been supported by some authors.[67] There is no specific contraindication to operation in immunocompromised patients, so once diagnosed with appendicitis, appendectomy should be performed promptly.

Treatment

NONOPERATIVE MANAGEMENT

Appendectomy was one of the first intra-abdominal operations performed, and appendicitis has long been a surgically treated disease. Rare descriptions of nonsurgical management dot the surgical literature, however. Treves was an advocate of early nonoperative management of acute appendicitis, even prior to the advent of antibiotics.[12] In the postantibiotic era, Coldrey presented his retrospective series of 471 patients with appendicitis treated with antibiotics.[68] This treatment failed in at least 57 patients, with 48 requiring appendectomy and 9 requiring drainage of an appendiceal abscess. An early randomized controlled trial, performed by Eriksson and associates, sought to address this issue.[69] Their results show a high rate of recurrence of appendicitis treated nonsurgically. The authors randomized 40 adults with presumed appendicitis to appendectomy or 10 days of intravenous and oral antibiotics. Eight (40%) of the 20 patients in the antibiotic group required appendectomy within 1 year: one patient for perforation within 12 hours of randomization and another seven for recurrent appendicitis (one of whom had perforation). Based on the high rate of failure

with antibiotics alone, nonoperative management of acute appendicitis has not been recommended.

Recently, a larger randomized clinical trial evaluating antibiotic therapy versus appendectomy as the primary treatment for acute appendicitis in unselected patients was performed.[70] In this study 202 patients were assigned to antibiotic treatment and 167 patients to appendectomy. Treatment efficacy, defined as definite improvement without the need for surgery within a median follow-up of 1 year for the antibiotic group and confirmed appendicitis or another appropriate surgical indication at the time of the operation for the appendectomy group, was found to be similar between the antibiotic and appendectomy groups (90.8 and 89.2% respectively). In the antibiotic group, recurrent appendicitis occurred in 13.9% after a median of 1 year. A third of the recurrences occurred within 10 days and two-thirds occurred within 3 and 16 months after discharge. Minor complications were similar between the two groups while major complications, defined as the need for reoperation, abscess, bowel obstruction, wound rupture or hernia, and serious anesthesia or cardiac-related problems, were three times higher in the appendectomy group. Close evaluation of this study, however, highlights the need for further studies and caution when applying their findings to clinical practice. Specifically, only 52.5% of those allocated to the antibiotic group completed antibiotic treatment. The remaining patients were transferred to the appendectomy group based on either the patient's or surgeon's discretion. Evaluation of those patients transferred to the surgery group indicate that they had a higher WBC and elevated temperature suggesting that they may have been clinically sicker. The efficacy of the antibiotic group reported as 90.8% was based only on those that completed antibiotic therapy and thus excluded the potentially sicker patients who crossed over from the antibiotic group to the surgery group. Evaluation of efficacy based on intention-to-treat (all 202 patients originally allocated to the antibiotic group including the 47.5% that switched to surgery) results in an efficacy of 48% for the antibiotic group. These studies suggest that antibiotic treatment may be a useful first-line treatment for acute appendicitis in selected patients; however, further studies are required to determine their usefulness as the lone treatment option. Nevertheless, antibiotic treatment may be a useful temporizing measure in environments with no surgical capabilities such as in space flight and submarine travel.[71]

PREOPERATIVE PREPARATION

When the decision is made to perform an appendectomy for acute appendicitis, the patient should proceed to the operating room with little delay to minimize the chance of progression to perforation. Such occurrences are rare, however, as most cases of appendiceal perforation occur prior to surgical evaluation.[23,24] Patients with appendicitis may be dehydrated from fever and poor oral intake, so intravenous fluids should be begun, and pulse, blood pressure, and urine output should be closely monitored. Markedly dehydrated patients may require a Foley catheter to ensure adequate urine output. Severe electrolyte abnormalities are uncommon with nonperforated appendicitis, as vomiting and fever have typically been present for 24 hours or less but may be significant in cases of perforation. Any electrolyte deficiencies should be corrected prior to the induction of general anesthesia.

Intravenous antibiotics have been shown to reduce significantly the incidence of postoperative wound infection and intra-abdominal abscess.[72] Antibiotics should be administered 30 minutes prior to incision to achieve adequate tissue levels. The typical flora of the appendix resembles that of the colon and includes gram-negative aerobes (primarily *Escherichia coli*) and anaerobes (*Bacteroides* spp.). No standardized antibiotic regimen exists. Acceptable options include a second-generation cephalosporin or a combination of antibiotics directed at gram negatives and anaerobes. In nonperforated appendicitis, a single preoperative dose of cefoxitin suffices.[73] In cases of perforation, an extended course of at least 5 days of antibiotics is advocated.[74]

OPEN VERSUS LAPAROSCOPIC APPENDECTOMY

Once the diagnosis of appendicitis is made, the surgeon must decide whether to perform an open (OA) or laparoscopic (LA) appendectomy. Numerous randomized controlled trials have compared these two methods, sometimes with conflicting results.[75,76] Meta-analyses and systematic reviews have combined these studies to address the controversy (Table 31-3).[77–79] These meta-analyses have similar findings, which can be summarized as follows: (1) OA can be performed more quickly; (2) LA patients have less postoperative pain and reduced narcotic requirements; (3) there is a trend toward reduced length of stay with LA; (4) LA patients have fewer wound infections; (5) OA patients develop fewer intra-abdominal abscesses; (6) LA patients return to work more quickly; (7) operating room and hospital costs are less with OA; and (8) societal costs may be less with LA.[77–79]

TABLE 31-3: LAPAROSCOPIC VERSUS OPEN APPENDECTOMY

Favors Laparoscopy	Favors Open
Diagnosis of other conditions	
Decreased pain and lower narcotic requirement	Shorter operating room time
Reduced length of stay	Lower operating room costs
Fewer wound infections	Fewer intra-abdominal abscesses
Quicker return to usual activities	Lower hospital costs
Lower societal cost	

Data from McCall JL, Sharples K, Jadallah F. Systemic review of randomized controlled trials comparing laparoscopic with open appendicectomy: a meta-analysis. *J Am Coll Surg*. 1998; 186:545–553; and Sauerland S, Lefering R, Neugebaur EA. Laparoscopic versus open surgery for suspected appendicitis. *Cochrane Database Syst Rev*. 2004;4:CD001546.

Based on the data available, one cannot convincingly recommend either OA or LA over the other. Each method has its advantages and disadvantages that should be considered when deciding how to perform appendectomy.

One situation in which laparoscopic appendectomy may be advisable is when the diagnosis of appendicitis is in doubt. This can be particularly useful in women of childbearing age, in whom obstetric and gynecological pathology may also be likely. In this population, a normal appendix can be found in more than 40% of patients with suspected appendicitis.[80] Laparoscopy can thus be both diagnostic and therapeutic, and a laparotomy can be avoided if gynecologic pathology is found. The ovaries, fallopian tubes, and uterus can be examined for nonappendiceal causes of abdominal pain, including ovarian cyst or torsion, endometriosis, or pelvic inflammatory disease. Laparoscopy makes this evaluation considerably easier and less morbid for the patient. In one study, when a normal appendix was discovered, gynecological pathology was found in 73% of women explored laparoscopically but only 17% of women who had an open appendectomy.[81] Although diagnostic accuracy will likely improve in young women with more widespread use of CT scans, this population will continue to provide diagnostic dilemmas that may be aided by laparoscopy.

Open Appendectomy. If open appendectomy is chosen, the surgeon must then decide on the location and type of incision. Prior to incision, a single dose of antibiotics should be administered, typically a second-generation cephalosporin.[73] The patient should be reexamined after the induction of general anesthesia, which enables deep palpation of the abdomen. If a mass representing the inflamed appendix can be palpated, the incision can be centered at that location. If no appendiceal mass is detected, the incision should be centered over McBurney's point, one-third of the distance from the anterior superior iliac spine to the umbilicus. A curvilinear incision, now known as *McBurney's incision*, is made in a natural skin fold. It is important not to make the incision too medial or too lateral. An incision placed too medial opens onto the anterior rectus sheath, rather than the desired oblique muscles, while an incision placed too lateral may be lateral to the abdominal cavity.

The operation proceeds much as McBurney first described it in 1894.[82] The incision extends through the subcutaneous tissue, exposing the aponeurosis of the external oblique muscle, which is divided, either sharply or with electrocautery, in the direction of its fibers (Fig. 31-6). A muscle-splitting technique is typically used, in which the external oblique, internal oblique, and transversus abdominis muscles are separated along the orientation of their muscle fibers. The peritoneum is thus exposed, grasped with forceps, and opened sharply along the orientation of the incision, taking care not to injure the underlying abdominal contents. Hemostats can be placed on the peritoneum to facilitate its identification at the time of wound closure. Cloudy fluid may be encountered on entering the peritoneum. Although some advocate bacterial culture of the peritoneal fluid, studies show that this neither helps direct the antibiotic regimen[83] nor reduces infectious complications.[84]

With a correctly placed incision, the cecum will be visible at the base of the wound. The incision should be explored with a finger in an attempt to locate the appendix. If the appendix is palpable and free from surrounding structures, it can be delivered into the incision. Frequently, the appendix is palpable, but it adheres to surrounding structures. Filmy adhesions can be divided using blunt dissection, but thicker adhesions should be divided under direct vision. To facilitate this, the cecum can be partially delivered into the incision to provide better exposure of the appendix. If necessary to improve exposure, the incision can be extended medially by partially dividing the rectus muscle or laterally by further dividing the oblique and transversus abdominis muscles. If the appendix cannot be visualized, it can be located by following the teniae coli of the cecum to the cecal base, from which the appendix invariably originates. Once located, the appendix is delivered through the incision. Grasping the mesentery with a Babcock clamp can sometimes facilitate this maneuver. Care should be taken to avoid perforation of the appendix, with spillage of pus or enteric contents into the abdomen.

The arterial supply to the appendix, which runs in the mesoappendix, is now divided between clamps and tied with 3-0 polyglactin or silk suture. This is usually performed in an antegrade fashion, from the appendiceal tip toward the base. Division of the artery to the appendiceal base is necessary to ensure that the entire appendix can be removed without leaving an excessively long appendiceal stump.

In excising the appendix, the surgeon must decide whether or not to invert the appendiceal stump. Traditionally, the appendix was ligated and divided, and its stump was inverted with a purse-string suture for the theoretical purpose of avoiding bacterial contamination of the peritoneum and subsequent adhesion formation.[85,86] However, recent prospective studies show no advantages to appendiceal stump inversion.[87,88] In one such study, 735 appendectomy patients were randomly assigned to ligation plus inversion or simple ligation of the appendiceal stump. There was no difference between the two groups in the incidence of wound infection or adhesion formation, and operating time was shorter in the simple ligation group. Inversion may also have the deleterious effect of deforming the cecal wall, which could be misinterpreted as a cecal mass on future contrast radiographs.[88] Furthermore, the long-standing notion that stump inversion reduces postoperative adhesions was discredited by Street and colleagues.[89] In their analysis, postoperative adhesions requiring operation were significantly increased in the inversion group.

To divide the appendix, the surgeon can use either suture ligation or a gastrointestinal stapler. For ligation, two hemostat clamps are placed at the base of the appendix. The clamp closest to the cecum is removed, having crushed the appendix at that site. Two heavy, absorbable sutures such as 0 chromic gut is used to doubly ligate the appendix, and the appendix is subsequently divided proximal to the second clamp. The exposed mucosa of the appendiceal stump can be cauterized to minimize the theoretical risk of postoperative mucocele, although

no data exist to support this. If appendiceal stump inversion is chosen, a seromuscular purse-string 3-0 silk suture is placed in the cecum around the appendiceal base after ligation but prior to division of the appendix. The purse-string suture should be placed approximately 1 cm from the base of the appendix, as placing it too close to the appendix makes stump inversion difficult. After the appendix is divided, the purse-string suture is tightened and tied while the assistant uses forceps to invaginate the appendiceal stump. Alternatively, the appendix can be divided at its base using a TA-30 stapler. Again, the stump need not be inverted, but can be if desired, using interrupted Lembert sutures with 3-0 silk suture. No matter how the appendix is divided, the residual appendiceal stump should be no longer than 3 mm to minimize the possibility of stump appendicitis in the future.[26]

Occasionally, inflammation at the tip of the appendix makes antegrade removal of the appendix difficult. In such cases, the appendix can be removed in a retrograde fashion. In so doing, the appendix is divided at its base using one of the methods described previously. The mesoappendix is then divided between clamps, starting at the appendiceal base and progressing toward the tip (Fig. 31-7).

In certain cases, the appendiceal inflammation extends to the base of the appendix or beyond to the cecum. Division of the appendix through inflamed, infected tissue leaves the potential for leakage of cecal contents with a resultant abscess or fistula. Ensuring that the resection margin is grossly free of active inflammation can minimize this risk. If the base of the cecum is also inflamed but there is sufficient uninflamed cecum between the appendix and the ileocecal valve, an appendectomy with partial cecectomy can be performed using a stapling device.[90] Care should be taken to avoid narrowing the cecum at the ileocecal valve. If the inflammation extends to the ileocecal junction, an ileocecectomy with primary anastomosis may be necessary.

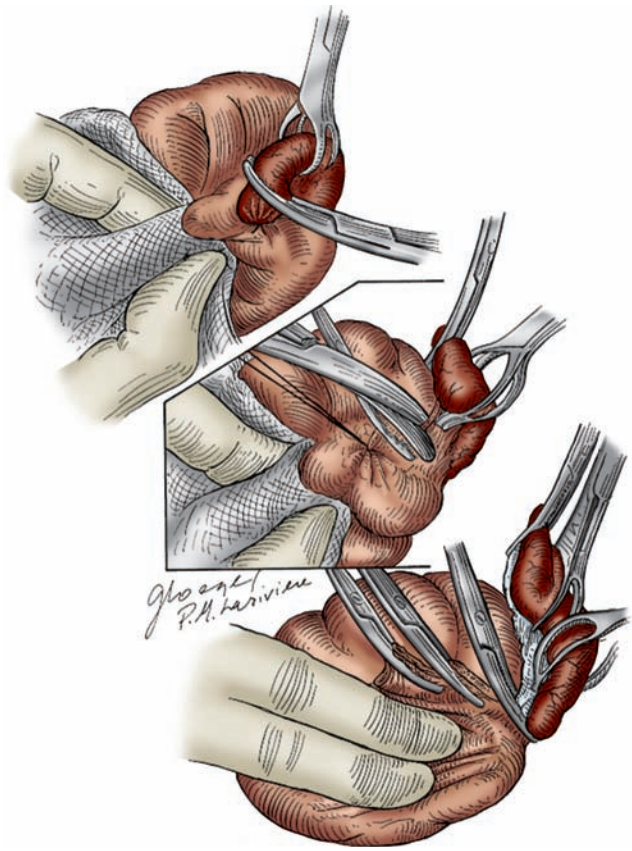

FIGURE 31-7 Retrograde dissection of the appendix.

After the appendix is removed, hemostasis is achieved and the right lower quadrant and pelvis are irrigated with warm saline. The peritoneum is closed with a continuous 0 absorbable suture; this layer provides no strength but helps to contain the abdominal contents during abdominal wall closure. The internal and external oblique muscles are then closed in succession using continuous 0 absorbable suture. To decrease postoperative narcotic requirements, the external oblique fascia can be infused with local anesthetic. Interrupted absorbable sutures are typically placed in Scarpa's fascia, and the skin can be closed with a subcuticular absorbable suture. With a preoperative dose of intravenous antibiotics and primary closure of the skin, fewer than 5% of patients with nonperforated appendicitis can be expected to develop a wound infection.[91]

Laparoscopic Appendectomy. Multiple port placements for laparoscopic appendectomy exist. The authors utilize a three-port technique, with one umbilical and one suprapubic port. Although the third port can be placed in either the left or right lower quadrant, we prefer the left lower quadrant. This follows the laparoscopic principle of triangulation, such that the port locations direct the camera and instruments toward the right lower quadrant for optimal visualization of the appendix.

The patient is positioned supine on the operating room table with the left arm tucked (Fig. 31-8). The video monitor is placed at the patient's right side, because once pneumoperitoneum is performed, the surgeon and assistant both stand on the patient's left. A single dose of a second-generation cephalosporin is administered prophylactically. Prior to incision, a nasogastric tube and a Foley catheter are placed to decompress the stomach and urinary bladder. A Foley catheter can be avoided if a reliable patient urinates immediately prior to entering the operating room. A 1- to 2-cm vertical or transverse incision is made just inferior to the umbilicus and carried down to the midline fascia. A 12-mm trocar is placed using either Hassan or Veress technique, depending on surgeon preference. After insufflation of the abdomen and inspection through the umbilical port, a 5-mm suprapubic port is placed in the midline, taking care to avoid injury to the bladder, and another 5-mm port is placed in the left lower quadrant. These port sites typically provide excellent cosmesis postoperatively due to their small size and peripheral location on the abdomen.

A 5-mm, 30-degree laparoscope is inserted through the left lower quadrant trocar. Placing the laparoscope in the left lower quadrant allows triangulation of the appendix in the right lower quadrant by instruments placed through the two midline trocars. The surgeon operates the two dissecting instruments and the assistant operates the laparoscope. The appendix is identified at the base of the cecum, and any adhesions to surrounding structures can be lysed with a combination of blunt and sharp dissection supplemented with electrocautery. If a retrocecal appendix is encountered, division of the lateral peritoneal attachments of the cecum to the abdominal wall often improves visualization. Care must be taken to avoid underlying retroperitoneal structures, specifically the right ureter and iliac vessels. The appendix or mesoappendix can be gently grasped with a Babcock clamp placed through the suprapubic port and retracted anteriorly. A dissecting forceps placed through the umbilical port creates a window in the mesoappendix at the appendiceal base. Caution should be taken not to injure the appendiceal artery during this maneuver. As in the open procedure, the base of the appendix should be adequately dissected so that it can be divided without leaving a significant stump.[26] The appendix should be divided at the confluence of the appendix and cecum, or just onto the cecal wall, to avoid the possibility of stump appendicitis or mucocele (see Fig. 31-8).

The appendix can be removed in a retrograde fashion, first dividing the appendix, followed by division of the mesoappendix. A laparoscopic gastrointestinal anastomosis (GIA) stapler is placed through the umbilical port and fired across the appendiceal base. After reloading, the stapler is again inserted through the umbilical port and placed across the mesoappendix, which is divided with firing of the stapler. Alternatively, the appendix can be secured using an Endoloop[92] (Ethicon, Endo-Surgery, Cincinnati, Ohio) and the mesoappendix with an Endoloop of cautery device. If desired, the appendix can be removed antegrade, by first dividing the mesoappendix prior to directing attention to the base. The appendix should be placed in a retrieval bag and removed through the umbilical port site to minimize the risk of wound infection. The operative field is inspected

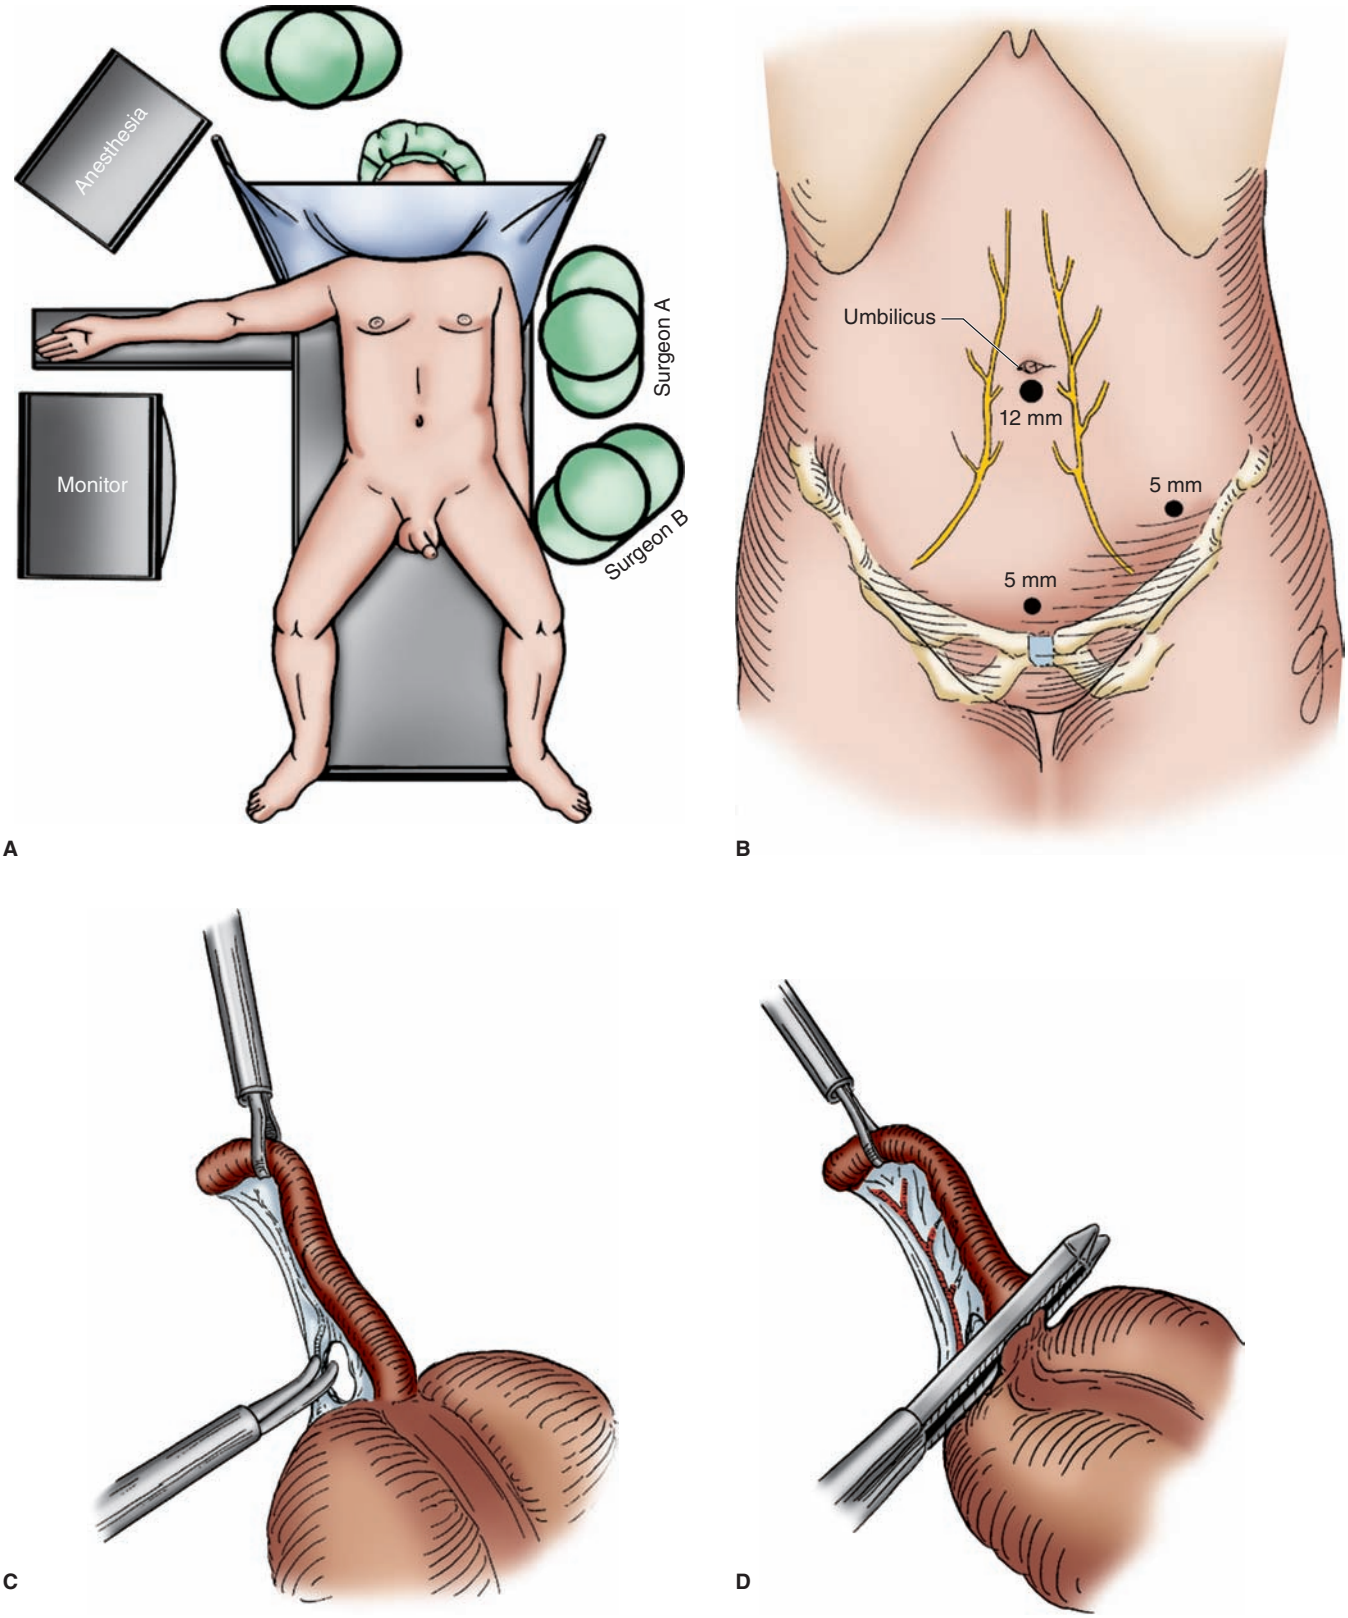

FIGURE 31-8 Laparoscopic appendectomy technique.

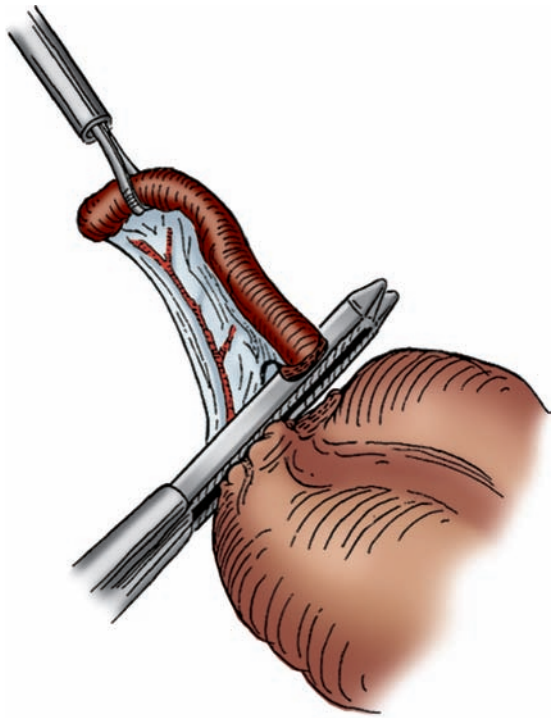
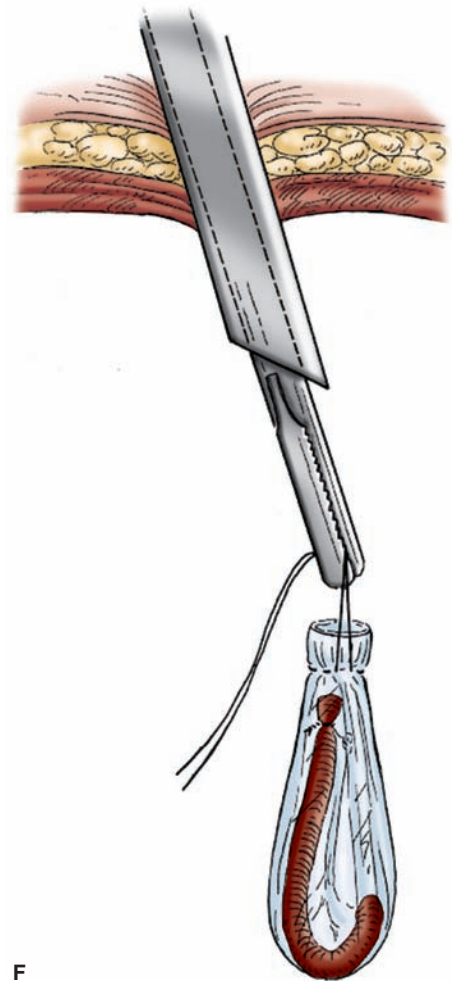


E



F

FIGURE 31-8 (*Continued*)

for hemostasis and can be irrigated with saline. Finally, the fascial defect at the umbilicus is closed with interrupted 0 absorbable suture, and all skin incisions are closed with fine subcuticular absorbable suture.

Postoperative Care

Patients with nonperforated appendicitis typically require a 24- to 48-hour hospital stay. Postoperative care for both the laparoscopic and open approaches is similar. Patients can be started on a clear liquid diet immediately, and their diet can be advanced as tolerated. No postoperative doses of antibiotics are required. Patients can be discharged when they tolerate a regular diet and oral analgesics.

Perforated Appendicitis

When appendicitis progresses to perforation, management depends on the nature of the perforation. If the perforation is contained, a solid or semisolid periappendiceal mass of inflammatory tissue can form, referred to as a *phlegmon*. In other cases, contained perforation may result in a pus-filled abscess cavity. Finally, free perforation can occur, causing intraperitoneal dissemination of pus and fecal material. In the case of free perforation, the patient is typically quite ill and perhaps septic. Urgent laparotomy is necessary for appendectomy and irrigation and drainage of the peritoneal cavity. If the diagnosis of perforated appendicitis is known, the appendectomy can be performed through an RLQ incision, and the technique follows that previously described for open appendectomy. Sometimes patients with free perforation present with an acute abdomen and generalized peritonitis, and the decision to perform a laparotomy is made without a definitive diagnosis. In such instances, a midline incision is prudent. Once perforated appendicitis is discovered, appendectomy again proceeds as described previously. Peritoneal drains are not necessary, as they do not reduce the incidence of wound infection or abscess after appendectomy for perforated appendicitis.[93,94] The final operative decision is whether or not to close the incision. Because of wound infection rates ranging from 30 to 50% with primary closure of grossly contaminated

wounds, many advocate delayed primary or secondary closure.[91,95] However, a cost-utility analysis of contaminated appendectomy wounds showed primary closure to be the most cost-effective method of wound management.[96] Our technique of skin closure is interrupted permanent sutures or staples every 2 cm with loose wound packing in between. Removal of the packing in 48 hours often leaves an excellent cosmetic result with an acceptable incidence of wound infection. Patients are often continued on broad-spectrum antibiotics for 5–7 days and should remain in the hospital until afebrile and tolerating a regular diet.

If the patient does not have signs of generalized peritonitis but an abscess or phlegmon is suspected by history and physical exam, a CT scan can be particularly helpful to confirm the diagnosis. A solid, inflammatory mass in the RLQ without evidence of a fluid-filled abscess cavity suggests a phlegmon. In such instances, appendectomy can be difficult due to dense adhesions and inflammation. Ileocecectomy may be necessary if the inflammation extends to the wall of the cecum. Complications such as inadvertent enterotomy, postoperative abscess, or enterocutaneous fistula may ensue. Because of these potential complications, many support an initially nonoperative approach.[97–99] Such an approach is only advisable if the patient is not ill appearing. Nonoperative management includes intravenous antibiotics and fluids as well as bowel rest. Patients should be closely monitored in the hospital during this time. Treatment failure, as evidenced by bowel obstruction, sepsis, or persistent pain, fever, or leukocytosis, requires immediate appendectomy. If fever, tenderness, and leukocytosis improve, diet can be slowly advanced, usually within 3–5 days. Patients are discharged home when clinical parameters have normalized. Using this approach, more than 80% of patients can be spared an appendectomy at the time of initial presentation.[97,98]

If imaging studies demonstrate an abscess cavity, CT- or ultrasound-guided drainage can often be performed percutaneously or transrectally.[100,101] Studies suggest that this approach to appendiceal abscesses results in fewer complications and shorter overall length of stay.[99,102] Again, following drainage the patient is closely monitored in the hospital and is placed on bowel rest with intravenous antibiotics and fluids. Advancement of diet and hospital discharge progress as clinically indicated.

Interval Appendectomy

Treatment following initial nonoperative management of an appendiceal phlegmon or abscess is controversial. Some recommend interval appendectomy[102–105] (appendectomy performed approximately 6 weeks after inflammation has subsided), while others consider subsequent appendectomy unnecessary.[98,106,107] Factors to be considered when advising patients on interval appendectomy include a relatively low incidence of future appendicitis (8–10% and often associated with an appendicolith) and a morbidity associated with an interval appendectomy of approximately 11%.[106] These factors must be weighed against the higher morbidity associated with an immediate appendectomy in the setting of acute recurrent appendicitis in the future (as high as 36% when appendicitis is associated with a phlegmon or abscess)[106] as well as the possibility of an ongoing appendiceal pathology, including inflammatory bowel disease and cancer.[103,105,106] Because it can now be performed laparoscopically on an outpatient basis with low morbidity,[104,108] interval appendectomy should be considered for patients who were initially treated with nonoperative management, but there is not convincing evidence to recommend this approach.

Normal Appendix

Because of the difficulty in diagnosing appendicitis, it is not uncommon for a normal appendix to be found at appendectomy. Sometimes referred to as misdiagnosis, this can occur more than 15% of the time, with considerably higher percentages in infants, the elderly, and young women.[40] Negative appendectomy is to be avoided when possible, because of the risk of surgical complications and the cost associated with unnecessary surgery.[109] Nonetheless, in certain instances, the diagnosis is in doubt, and a noninflamed appendix is found at laparotomy or laparoscopy. The surgeon must then decide whether or not to remove the appendix. For multiple reasons, it is advisable to remove the grossly normal appendix. First, if the pain recurs and the appendix has been removed, appendicitis will no longer be a possibility and can be removed from the differential diagnosis. If the patient suffers RLQ pain in the future and the appendix has not been removed, but the patient has a classic RLQ scar, a surgeon evaluating the patient may assume a history of appendectomy and erroneously remove appendicitis from consideration. As laparoscopic appendectomy becomes more popular, this may even be true for patients with port site scars suggestive of appendectomy. Finally, there is strong evidence that a surgeon's gross assessment of the appendix can be inaccurate. In one study, 11 (26%) out of 43 appendectomy specimens described as normal by the surgeon showed acute appendicitis on pathological examination.[110] As a result, removal of a grossly normal appendix at the time of appendectomy is recommended.

When a normal appendix is discovered at appendectomy, it is important to search for other possible causes of the patient's symptoms. The terminal ileum can be inspected for evidence of terminal ileitis, which could be from infectious causes (*Yersinia* or tuberculosis) or Crohn's disease. In the absence of perforation, resection should not be performed for Crohn's disease and appropriate medical therapy should be initiated postoperatively. The ileum should also be evaluated for an inflamed or perforated Meckel's diverticulum, which should be excised. In females, the ovaries, fallopian tubes, and uterus should be examined for pathology as well. Evaluation of the left adnexa can be difficult through an RLQ incision, highlighting the utility of laparoscopy in female patients.

Chronic Appendicitis

Although rare, chronic appendicitis can explain persistent abdominal pain in some patients. Patients do not present with the typical symptoms of acute appendicitis. Instead, they complain of weeks to years of RLQ pain and may have had multiple medical evaluations in the past. When queried, they may describe an initial episode with more classic symptoms of acute appendicitis, for which no treatment was delivered.[111] Diagnosis can be difficult, as laboratory and radiological studies are typically normal. Pathology evaluation revealing chronic inflammation confirms the diagnosis. Because the diagnosis is often uncertain preoperatively, laparoscopy can be a useful tool to allow exploration of the abdomen.[112]

Asymptomatic Appendicolith

As CT scans become more widely utilized, it is likely that an increasing number of asymptomatic appendicoliths will be discovered. As discussed previously, appendicoliths are not pathognomonic for appendicitis but should only be considered in conjunction with the clinical presentation and other diagnostic studies. Lowe and associates[113] studied CT scans of children with suspected appendicitis and compared them to CT scans of children with abdominal trauma. Six (14%) of 44 patients with suspected appendicitis had an appendicolith but proved not to have appendicitis. In addition, 2 (3%) of the 74 trauma patients had an appendicolith on CT. These children were not followed to see if appendicitis developed later in life, but the considerable number of asymptomatic appendicoliths seen on adult abdominal radiographs suggests that many patients with an appendicolith will never develop appendicitis.[18,19] Based on this, appendectomy for asymptomatic appendicolith cannot be recommended.

NEOPLASMS OF THE APPENDIX

Neoplasms of the appendix are rare, affecting less than 1% of appendectomies. Signs and symptoms of appendicitis prompt appendectomy in up to 50% of patients, and it is not uncommon for the patients with an appendiceal neoplasm to have acute appendicitis as well.[114] Patients may also present with a palpable mass, intussusception, urologic symptoms, or an incidentally discovered mass on abdominal imaging or at laparotomy for another purpose. Typically, the diagnosis is not known until laparotomy or pathologic evaluation of the appendectomy specimen, but preoperative diagnosis may become more common as imaging techniques become more widely used. Because of their common embryologic origin, the appendix and colon are susceptible to many of the same neoplastic growths. The most common appendiceal tumors include cystic neoplasms, carcinoid tumors, adenocarcinoma, and metastases. Other tumors have been reported but are extremely rare, such as lymphoma, stromal tumors (leiomyoma and leiomyosarcoma), and Kaposi's sarcoma.[115]

Cystic Neoplasms and Pseudomyxoma Peritonei

Sometimes referred to as *mucoceles*, mucinous neoplasms of the appendix include a spectrum of diseases, including simple cyst, mucinous cystadenoma, mucinous cystadenocarcinoma, and pseudomyxoma peritonei. Mucocele is not a true pathologic diagnosis and instead refers to the macroscopic appearance of an appendix distended with mucus. Any of the above conditions can form a mucocele, but the more specific diagnostic term is preferable.[116] A simple cyst results from nonneoplastic occlusion of the appendiceal lumen, is usually less than 2 cm in diameter, and is often an incidental finding at appendectomy. In contrast, mucinous cystadenomas, benign tumors that represent the majority of "mucoceles," can grow to 8 cm or larger (Fig. 31-9).[117] They typically remain asymptomatic due to slow-growing distension of the appendix and instead present incidentally as a mass on physical examination or abdominal imaging (Fig. 31-10). On plain radiograph or CT, wall calcification is characteristic.[116]

It is recommended that all mucinous appendiceal masses 2 cm or larger be surgically removed.[117] For mucinous cystadenoma, appendectomy is sufficient if the lesion does not involve the appendiceal base. Occasionally, the mass will rupture prior to or at the time of removal, but this rupture is typically contained to the right lower quadrant and is considered localized pseudomyxoma peritonei. If the mass is benign, appendectomy and removal of any residual mucin is curative.[118] Laparoscopic appendectomy is not currently recommended because of the possibility of malignancy and spillage of mucin-secreting cells throughout the abdomen.[119] Because of an association with colon and rectal carcinoma, a screening colonoscopy is recommended postoperatively.[117]

Mucinous cystadenocarcinoma represents the malignant form of cystic neoplasms of the appendix. In contrast to cystadenoma, patients are usually symptomatic with abdominal

FIGURE 31-9 A 14-cm mucinous cystadenoma of the appendix. The appendiceal tip is to the left, the base to the right. (Used, with permission, from Jacqueline M. Wilson, MD, PhD, Brigham and Women's Hospital, Boston, MA.)

FIGURE 31-10 CT axial image at the level of the terminal ileum shows a fluid-filled mass (*arrowhead*) corresponding to the mucinous cystadenoma seen in Fig 31-9. The more proximal appendix (*arrow*) is seen between the mass and cecum. (Used, with permission, from M. Stephen Ledbetter, MD, Brigham and Women's Hospital, Boston, MA.)

pain, weight loss, an abdominal mass, or signs of acute appendicitis. Increasing abdominal girth may also be present and suggests development of pseudomyxoma peritonei from perforation and peritoneal dissemination of mucin-secreting cells. Diffuse pseudomyxoma peritonei is highly predictive of malignancy; in one series, 95% of patients with pseudomyxoma had an associated mucinous cystadenocarcinoma.[117] The recommended treatment consists of right hemicolectomy with debulking of any gross spread of disease and removal of all mucin. It is not uncommon, however, for the diagnosis to be unknown until the time of pathologic evaluation of the appendectomy specimen. In such cases, reoperation with right hemicolectomy is recommended, as 5-year survival for mucinous cystadenocarcinoma is 75% after hemicolectomy and less than 50% after appendectomy alone.[120] Some referral centers advocate extensive initial resections including omentectomy, as well as repeated debulking procedures for recurrent disease.[121]

Adenocarcinoma

Primary adenocarcinoma of the appendix is classified into two types: mucinous (discussed previously) and colonic. The colonic type is less common, less likely to secrete mucus, and more likely to present with acute appendicitis due to obstruction of the appendiceal lumen.[116] Because of similarities with colon carcinoma, appendiceal adenocarcinomas are classified as Dukes stage A, B, C, and D, with 5-year survival rates of 100, 67, 50, and 6%, respectively. The colonic type has a less favorable prognosis, with only 41% 5-year survival after treatment, compared to 71% for the mucinous type. The optimal treatment is right hemicolectomy, and reoperation should be recommended if the diagnosis is made on pathologic evaluation of an appendectomy specimen.[120]

Carcinoid Tumors

The most common neoplasm of the appendix, carcinoid tumors comprise more than 50% of all appendiceal tumors.[114] Among malignant tumors of the appendix, carcinoids are less aggressive and carry a much more favorable prognosis than adenocarcinomas, with 5-year survival approaching 90%.[122] Most appendiceal carcinoids are found incidentally at the time of appendectomy for appendicitis. However, because the majority of appendiceal carcinoids are located at the tip of the appendix, the carcinoid mass is the cause of appendicitis only 25% of the time.[115] Tumor size is the primary determinant of malignant potential. About 75% of carcinoids are less than 1 cm in size and 5–10% are over 2 cm. Lymph node invasion and distant metastases are exceedingly rare except in tumors over 2 cm.[123] Histologically, carcinoids of the appendix are categorized as goblet cell and classic carcinoid. Mortality is higher for goblet cell but is still lower than that of adenocarcinoma.[122]

Treatment of appendiceal carcinoids is dictated primarily by tumor size. Simple appendectomy is sufficient for tumors less than 1 cm because of the low likelihood of lymph node involvement. For masses larger than 2 cm, right hemicolectomy is recommended. Because of a concern for increased metastatic potential, some authors also advocate right hemicolectomy in young patients; in carcinoids at the appendiceal base; and when there is evidence of lymphatic invasion, lymph node involvement, spread to the mesoappendix, tumor-positive resection margins, or cellular pleomorphism with a high mitotic index.[123–125]

Small Bowel Diverticula

Small bowel diverticula can be characterized according to their anatomic location (duodenal, jejunoileal, and distal ileal diverticula) or the type of diverticula (false or true diverticula). False diverticula do not contain all the layers of the bowel wall. They are acquired defects predominantly located in the duodenal and jejunoileal portions of the small bowel. These diverticula involve herniated mucosa and submucosa and typically occur at points of weakness, where blood vessels enter the mesenteric border of the small bowel. In contrast, a distal ileal (Meckel's) diverticulum is a true diverticulum containing all of the layers of the small bowel. It is a congenital anomaly resulting from the failure of the vitelline duct to obliterate and is located along the antimesenteric border of the distal ileum. Although the presence of small bowel diverticula is not uncommon, most are asymptomatic and thus not appreciated. Less than 4% of small bowel diverticula cause

symptoms, including inflammation, hemorrhage, obstruction, perforation, and malabsorption.

DUODENAL DIVERTICULA

Duodenal diverticula (DD) account for approximately 45% of small bowel diverticula and have a reported incidence on radiologic and autopsy studies of 5–22%.[126,127] They are rarely multiple (12%) and are predominantly located in the medial wall of the second portion of the duodenum (88%).[128] When the diverticulum is located adjacent to the ampulla of Vater, as is often the case, it is known as a perivaterian or periampullary diverticulum. DD typically occur in patients aged 50–65 years and are often asymptomatic at presentation. Less than 5% of patients with DD present with symptoms, including nausea, vomiting, RUQ abdominal pain, fevers, chills, and bleeding. These presentations result from one of many potential complications, including inflammation, obstruction of the duodenum or biliary-pancreatic duct, fistula formation in the bile duct, bezoar formation inside the diverticulum, and perforation. Although it is the most unusual complication, DD perforation is the most serious and can carry a mortality of up to 20%. Perforation usually results from acute inflammation but may also result from enterolithiasis, ulceration, increased intraluminal pressure (eg, during endoscopy), abdominal trauma, gallstones, or ischemia. Perforation usually occurs posteriorly and can result in a retroperitoneal abscess and sepsis. Anterior perforation can also occur, resulting in intraperitoneal spillage or communication with the pancreas, colon, gallbladder, or aorta causing a duodenocolic fistula or acute gastrointestinal hemorrhage secondary to perforation into the aorta.[126,129]

The nonspecific nature of the presenting symptoms and their commonality with other gastrointestinal diseases such as pancreatitis, cholecystitis, cholangitis, and peptic ulcer disease highlight the fact that the diagnosis of a complicated DD is often one of exclusion. Radiologic studies including plain abdominal films and ultrasound may be helpful to exclude other etiologies but are not definitive. CT scan and upper endoscopy are the modalities of choice for evaluation. In the case of an inflamed diverticulum, CT may demonstrate a thickened duodenal wall and surrounding fat inflammation. If perforation has occurred, an extraluminal collection of air and fluid (predominantly retroperitoneal) may be identified. Additionally, the administration of oral contrast with a CT scan or an upper gastrointestinal swallow study may define the extent of a leak in the case of a perforation. However, it is not uncommon to be unable to identify a DD on CT scan, and additional studies may be required. Side-viewing endoscopy and endoscopic retrograde cholangiopancreatography (ERCP) are very valuable in correctly diagnosing the presence of a DD as well as potentially treating some of the associated complications. Successful endoscopic management of hemorrhage, duodenal obstruction, pancreatobiliary obstruction resulting in pancreatitis or cholangitis, and retroperitoneal abscess drainage associated with a DD have been reported.[130–133]

The management of DD depends on the presence or absence of symptoms and the clinical stability of the patient. Given the precarious location of a DD and the morbidity associated with resection, asymptomatic DD discovered on imaging or endoscopy for other reasons should be observed. Symptomatic DD can be managed endoscopically, nonoperatively, or with surgical exploration and resection or bypass. If inflammation with or without perforation is present, nonoperative management, including nasogastric decompression, antibiotics, serial examinations, and radiologic-guided drainage if an abscess is present, has been reported. This approach can be considered in patients with mild symptoms who are clinically stable or when CT confirms a contained leak.[126,128,130,134] If the patient is not a candidate for nonoperative management because of hemodynamic instability, generalized peritonitis, or persistent severe symptoms, the choice of surgical intervention depends on such factors as the location of the diverticulum and other intraoperative findings. A simple closure of the perforated diverticulum or diverticulectomy with single- or double-layer duodenal closure after kocherizing the duodenum is the treatment of choice if there is minimal inflammation and the anatomy of the diverticulum permits. After repair, appropriate drainage tubes should be placed and the greater omentum can be used to reinforce the repair. It is imperative to avoid damaging the pancreatic and distal common bile duct during the repair, so cannulation of the ampulla of Vater either retrograde or antegrade through the cystic duct (with subsequent cholecystectomy) can be performed to help visualize the ampulla prior to dissecting the diverticulum. If there is significant inflammation at the site of the diverticulum or the diverticulum lays buried in the pancreatic head or the papilla lays deep in the diverticulum, a diversion should be performed. Diversion can be performed by either a distal gastrectomy with a Billroth-II reconstruction or a Roux-en-Y gastrojejunostomy. Again, appropriate drainage tubes are typically placed to drain the affected area. In addition to diversion and diverticulectomy, segmental duodenal resection for a perforated DD has also been reported for the rare case of a DD located in segment III or IV of the duodenum. A pancreaticoduodenectomy may also be necessary if the DD lies in close proximity to the common bile and pancreatic ducts and the inflammation is thought to be too severe for safe diversion or drainage.[126,129,130] If symptoms are related not to perforation of the DD but to obstruction of the pancreaticobiliary system causing cholangitis or pancreatitis, resection of the duodenum may not be required and treatment may consist of diversion of bile flow with a Roux-en-Y choledochojejunostomy and duodenojejnuostomy.[130,135]

JEJUNOILEAL DIVERTICULA

Least common of the small bowel diverticula, jejunoileal diverticula (JID) have an incidence of 0.002–5% based on postmortem and enteroclysis studies. Their incidence increases with age and peaks in the sixth and seventh decades of life. JID are

acquired pseudodiverticula believed to result from a jejunoileal dyskinesia causing increased intraluminal pressures and herniation of the mucosa and submucosa through the weakest site of the muscularis of the bowel wall (ie, the mesenteric border where paired blood vessels enter the bowel wall). They can be single (33%) or multiple (66%) and located in the jejunum (55–80%), ileum (15–38%), or both (5–7%).[136] Interestingly, patients with JID also frequently have other coexisting gastrointestinal diverticula, including those found in the colon (20–70%), duodenum (10–40%), esophagus, and stomach (2%) highlighting a potential common etiology.[137–139]

The diagnosis of a JID is often challenging because most patients are asymptomatic (up to 70%) or present with vague abdominal complaints. There is, in fact, no gold standard imaging technique used to diagnose a JID. Upper gastrointestinal studies with small bowel follow-through as well as traditional enteroclysis and CT enteroclysis studies are beneficial. CT, tagged red blood cell scan, or angiogram may demonstrate findings consistent with a complication of a JID such as inflammation, perforation, or bleeding. Capsule endoscopy and double-balloon endoscopy are useful in diagnosing small bowel disorders and may be of benefit in identifying JID in a nonacute setting.[137,140,141] Ultimately, JID are often identified on exploratory laparotomy or laparoscopy for other indications or for the evaluation of chronic or acute symptoms.[137]

Asymptomatic, incidentally discovered JID need not be resected. When symptomatic, patients with JID can be divided into those with acute or chronic symptoms. Forty to sixty percent of patients with a known diagnosis of JID present with chronic symptoms. These symptoms are often nonspecific and include nausea, vomiting, postprandial bloating, recurrent abdominal pain, cramping, weight loss, fatigue, and failure to thrive. Because of the vague nature of the presenting symptoms, these patients often go undiagnosed or misdiagnosed for several months (average 22 months) prior to being correctly diagnosed.[136,141,142] The pathophysiology of the chronic symptoms is believed to be related to either intestinal dyskinesia or bacterial overgrowth from blind loop syndrome due to stasis in the diverticular lumen. When bacterial overgrowth and a blind loop syndrome are present, the patient may develop malabsorption, steatorrhea, and megaloblastic anemia resulting from vitamin B_{12} deficiency. Frequently, chronic symptoms from JID can be successfully managed medically. Medical management consists of a low-residue diet, antispasmodics, antacids, analgesics, and vitamin B_{12} supplementation. Bacterial overgrowth and blind loop syndrome can be initially managed with antibiotics. If medical management fails, patients may require resection of the segment of bowel containing the diverticulum with subsequent primary anastomosis.

Approximately 10–19% of patients with JID present with acute, often emergent, symptoms resulting from a complication of the diverticulum, including gastrointestinal hemorrhage, diverticulitis with or without perforation, obstruction, fistula formation, sepsis, liver abscesses and pneumoperitoneum. The presentation and management of a patient with an acute complication of a JID depends on the complication. Inflammation resulting in diverticulitis occurs in 2.3–6.4% of patients with JID and can present as mild abdominal pain or diffuse peritonitis associated with free perforation.[136] If perforation occurs in the setting of full-thickness necrosis, it can be associated with a mortality of up to 40%.[136,143] Traumatic and foreign body perforations of JID have also been described. If the perforation is contained within the mesentery, nonoperative management with bowel rest and antibiotics with or without percutaneous drainage can be attempted. Similarly, asymptomatic pneumoperitoneum in the setting of a known JID is not an indication for surgery and can be managed conservatively.[136,144,145] Lack of clinical improvement after a period of nonoperative management mandates resection of the affected segment of bowel with a primary anastomosis. Similarly, patients presenting with a more significant findings of fever, elevated WBC, peritonitis, and septic physiology require immediate laparotomy with resection of the affected segment of bowel.[136]

Of patients with JID, 2–4.6% present with obstruction related to adhesions, intussusception, volvulus, and extrinsic compression from a fluid-filled diverticulum or, rarely, from an enterolith formed in the diverticulum causing obstruction at the diverticulum or at the ileocecal valve. Obstruction believed to be secondary to adhesions can initially be managed conservatively. However, if nonoperative management fails, lysis of adhesions and segmental bowel resection of the JID with a primary anastomosis are required. Similarly, surgical resection is indicated for the management of obstruction resulting from intussusception, volvulus, or extrinsic compression.[137] Enterolith ileus associated with a JID is best managed by an initial attempt at manual lysis of the stone without an enterotomy. If not possible, the stone can be removed through an enterotomy made in a nonedematous segment of bowel. If one or multiple diverticula appear inflamed or scarred, segmental resection of the involved bowel with a primary anastomosis is mandated. However, many patients often have multiple diverticula over a long stretch of bowel, and thus, if no evidence of inflammation or scarring is present, no resection is indicated.[136] Approximately 3–8% of patients with JID present with bleeding complications. Hemorrhage from a JID can be slow and chronic in nature or acute and massive presenting with hemorrhagic shock. Upper and lower endoscopies are often negative, and the diagnosis is made with angiographic and radioactive red blood cell studies. Although treatment with angiographic embolization has been documented, segmental bowel resection is frequently the required treatment.[136,146]

MECKEL'S DIVERTICULA

Meckel's diverticula are the most common congenital malformation of the gastrointestinal tract, occurring in approximately 1% of the population.[147–149] A Meckel's diverticulum is a true diverticulum containing all three layers of the intestinal wall and results from the failure of the obliteration of the omphalomesenteric duct during fetal life. It is typically

located on the antimesenteric border of the small bowel within 100 cm of the ileocecal valve. Although often lined with ileal mucosa, ectopic gastric, duodenal, colonic, and endometrial mucosa as well as pancreatic tissue, carcinoid tissue, Brunner's glands, and hepatobiliary tissue have been found in Meckel's diverticula.[147]

Similar to other small bowel diverticula, the majority of Meckel's diverticula are asymptomatic and discovered incidentally at the time of an operation for other indications. Recent reviews indicate that up to 84% of Meckel's diverticula found at operation were asymptomatic. A symptomatic Meckel diverticulum can present in both the pediatric and adult population; the frequency of presentation decreases with increasing age. There is a male predominance (3:1) of both symptomatic and asymptomatic Meckel's diverticula in both the pediatric and adult population.[147,149]

Symptomatic presentation results from one of many potential complications, including bleeding, obstruction, diverticulitis, perforation, intussusception, ulceration, and rarely the presence of malignancy (carcinoid tumor, sarcoma, stromal tumors, carcinoma, adenocarcinoma, intraductal papillary mucinous adenoma of pancreatic tissue) within the Meckel diverticulum. In the adult population the most common presentations are bleeding (38%), obstruction (34%), and diverticulitis (28%). In the pediatric population the most common presentations are obstruction (40%), bleeding (31%), and diverticulitis (29%).[147,149] Obstruction may result from the Meckel diverticulum serving as a lead point for intussusception or volvulus or as a result of an adhesive band to the diverticulum. Bleeding in the setting of a Meckel diverticulum is believed to result from acid secretion from ectopic gastric mucosa leading to ulceration of and subsequent bleeding from adjacent ileal mucosa.

Preoperative diagnosis of a symptomatic Meckel diverticulum can be difficult. A technetium-99m pertechnetate scan is the most common and accurate noninvasive study used to evaluate the presence of a Meckel diverticulum. The tracer used in this study is specific for ectopic gastric mucosa, and thus false-positive results may occur when a duplication cyst containing gastric mucosa is present. Moreover, a Meckel diverticulum can be missed if it does not contain ectopic gastric mucosa. Studies have found technetium-99m pertechnetate scans to be highly sensitive and specific in both the pediatric and adult populations.[149–151] In cases of a suspected bleeding, Meckel's diverticulum, angiography, and a tagged RBC scan may be of diagnostic value. If suspicion is high, other etiologies have been ruled out, and noninvasive diagnostic tools exhausted, exploratory laparoscopy may be required to diagnose and treat a complicated Meckel diverticulum.

Surgical resection is indicated for symptomatic Meckel's diverticula. Options for resection include a diverticulectomy or a segmental bowel resection with a primary anastomosis. A diverticulectomy can be performed if amputating the diverticulum at its base will not compromise the ileal lumen. If diverticulitis is present, the line of resection should be free of inflammation. Amputation should be performed in a transverse orientation and can utilize a surgical stapling device. The staple line can then be oversewn with interrupted 3-0 silk Lembert sutures. Alternatively, the diverticulum can be resected between bowel clamps and the defect sutured closed in two layers, using a continuous inner layer of 3-0 Vicryl or chromic suture followed by an outer layer of 3-0 silk Lembert sutures.

In certain cases, simple diverticulectomy is not recommended. Such instances include the presence of diverticulitis or palpable ectopic tissue at the diverticular-intestinal junction.[147] In such cases, or if the Meckel diverticulum is associated with ischemia, perforation, or an ulcer in the adjacent intestine, a segmental ileal resection with a primary anastomosis is indicated.

The optimum management of an asymptomatic Meckel diverticulum discovered at laparotomy for a separate indication remains unclear. Some authors argue that certain asymptomatic patients are more likely to develop symptoms and thus recommend resection of an incidentally detected diverticulum in a patient who fulfills any of the following criteria: (1) younger than 50 years, (2) male sex, (3) diverticulum greater than 2 cm in length, and (4) ectopic or abnormal features within a diverticulum.[147] A recent review contradicts these findings, however. In this study, the risk of postoperative complications, including infection and intestinal obstruction, was significantly higher following resection than leaving the diverticulum in situ (5.3 vs 1.3%). Moreover, of the 64 patients in this study who did not undergo resection of their asymptomatic Meckel's diverticulum, no patient developed complications with long-term follow-up.[148] Another study found the morbidity associated with the resection of an incidental Meckel diverticulum to be higher than that associated with the resection of a symptomatic Meckel diverticulum (20 vs 13%).[147] Based on these studies, there is no convincing evidence to recommend resection of a Meckel diverticulum detected incidentally at laparotomy, but it should be considered in certain patient populations.

DIVERTICULAR DISEASE AND COLONIC VOLVULUS

Thang C. Nguyen • Frank A. Frizelle

Diverticular disease and colonic volvulus are common colonic conditions. Though benign in pathology, their management results in a major workload and the diseases are not without risk of major complications, including death. In this chapter we discuss the current understanding of these two pathologies.

DIVERTICULAR DISEASE

Colonic diverticula are the most common structural abnormality of the bowel and is the fifth most costly gastrointestinal disorder in Western society.[1,2] An acquired condition, diverticula usually affect the sigmoid colon in Western societies, but they are also found on the right colon in countries with diets rich in fiber. The prevalence of diverticular disease has increased during the last century,[3] which probably reflects both an increase in detection and an aging population. Until 30 years ago, the proportion of patients requiring surgery or dying from diverticular disease was decreasing[4]; however, during the last 20 years, the rates of hospital admission and surgical intervention have increased, while inpatient and population mortality rates from diverticular disease have remained unchanged.[5]

Colonic diverticulum is an acquired condition with increased prevalence with increasing age. It affects fewer than 10% of people in their fifth decade of life, increasing to around 50–66% in their ninth decade.[6] Most patients with diverticulosis don't require surgery; however, complications of diverticular disease may. Such surgery can be challenging and good outcomes rely on timely and appropriate intervention.

The terminologies used include diverticulum (diverticula—plural); diverticulosis—asymptomatic diverticula; diverticulitis (simple or complicated)—diverticula with inflammation; diverticular disease—diverticula with or without inflammation.

History

Diverticular disease was initially described by Littré in 1700 as saccular outpouchings of the colon.[7] Cruveilhier is credited with the first clear and detailed description of the pathogenesis of diverticulitis and complicated diverticular disease.[8] In 1899 Graser introduced the term "peridiverticulitis" and suggested that diverticula were caused by herniation of colonic mucosa through areas of penetration of the vasa recta. This is now well established as the pathogenesis of colonic diverticulosis.[9] In contrast, the mechanism for diverticulitis was not identified until 1904 by Beer.[10] He proposed that impacted fecal matter at the neck of the diverticulum caused inflammation and subsequent abscess and fistula formation.

Moynihan reported a case of peridiverticulitis in 1907 and underlined the difficulties in distinguishing diverticular disease from malignancy.[11] Telling and Gruner's classic paper describing complex diverticular disease was not published until 1917.[12] At this time the prevalence and pathophysiology of diverticular disease were well recognized, as were the complications, including acute diverticulitis, abscess, fistula, perforation, and obstruction.

The development of radiological imaging of the large intestine was important in establishing a diagnosis and documenting the extent of diverticular disease.[13] In 1914, De Quervain and Case were the first to demonstrate colonic diverticula with x-rays.[14,15]

Etiology

Diverticular disease is a disease of Western populations. A number of studies have shown an increase in incidence over the last 30 years.[5,16] Migrant studies likewise confirm an increase in incidence when populations move to a Western country. There is a widely held view that fiber content of food is important, and that the high intraluminal pressure associated with low-fiber diets precipitated by colonic compartmentalization causes an unsustainable increase in tension within the bowel wall. This is compounded by the hyperelastosis and altered collagen structure seen in the colon due to aging.[17,18] Both mechanisms ultimately lead to a loss of bowel wall integrity and the formation of diverticula. Exercise and a reduction in the intraluminal pressure associated with a high-fiber diet may be protective.[19]

High intraluminal pressures are generated because of colonic motility. Colonic motility is complex and not easily studied.

The most common motor patterns are tonic segmenting and rhythmic contraction. Tonic segmentation creates stationary narrow rings that appear as haustral markings. Their purpose is to slow the fecal stream and to permit water absorption and electrolyte exchange. Infrequent propulsive peristaltic contractions move fecal matter in a caudal direction; these occur around six times a day.[20]

The alteration in pressure caused by these movements has been implicated in the pathogenesis of colonic diverticulosis. Several groups have studied colonic motility with intraluminal manometry in humans and animals. Most studies agree that there is increased phasic pressure activity, but this relates more to the presence of symptoms rather than diverticula. The results, however, are heterogenous, principally because of methodological differences, in particular relating to bowel preparation and pressure sensors.[21] It may therefore be unreasonable to draw firm conclusions from these investigations.[22]

More generalized alterations in colonic motility have been implicated in the pathogenesis of colonic diverticular disease. In vitro and in vivo studies, however, are conflicting. Some demonstrate an absence of slow-wave activity (favoring nonpropagating contractile activity) and some demonstrate unimpaired or increased slow-wave activity.[23,24] Others have demonstrated an increase in fast-wave activity, which persists after resectional surgery.[25] The exact relevance of these myoelectric changes remains uncertain.

Diverticulosis is a Western disease that has a striking geographic distribution. The disease is rare in rural Africa and Asia with the highest prevalence seen in the United States, Europe, and Australia.[26] Within a single country, the disease incidence can vary depending on ethnicity.[27] Urbanization can also increase diverticular disease incidence, possibly attributable to a dietary change.[28,29] The incidence of complicated diverticular disease also seems to be increasing.[30]

Diverticular disease in Asian patients is often right-sided with manifestations early in life and is often multiple. The reasons for this variation are unknown; however, it has been suggested that both diet and elastin/collagen differences may play a role.[31]

Morphologic Features

Colonic diverticula are false diverticula most commonly found in the sigmoid colon (95%). The sigmoid colon is the exclusive site in about 50% and the entire colon is involved in just 5%. The muscular colonic wall is composed of both longitudinal and circular layers. The circular layer of the muscularis propria forms a continuous sheet of muscle throughout the large bowel. The longitudinal layer forms three discrete condensations called *taeniae*; one of these is adjacent to the mesentery while the other two are antimesenteric. The taeniae coalesce to form an enveloping muscular layer in the rectum. Much of the colonic wall is therefore devoid of longitudinal muscle and it is in these areas that diverticula form. Herniations of muscularis mucosa occur between the taeniae along the arteries (vasa recta) that penetrate the muscle wall en route to the submucosa and mucosa (Figs. 32-1 and 32-2).

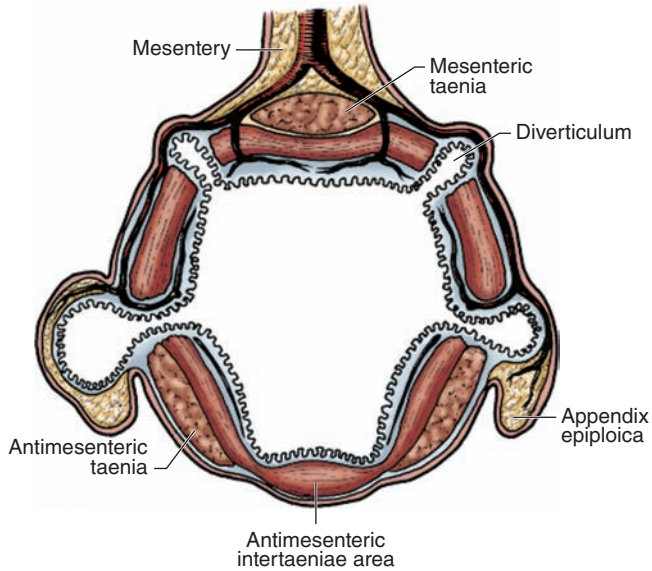

FIGURE 32-1 Relationship of diverticulum and vasa recta.

Many studies have demonstrated a change in the histological structure of the muscularis propria in diverticular disease. In a classic study, Whiteway and Morson found the muscle cells to be normal with no evidence of hyperplasia or hypertrophy, but both layers were thickened. They demonstrated excessive amounts of elastin in the taeniae but not in the circular muscle.[17] Repeated intermittent distension of the colon can result in increased synthesis of connective tissue components.[32] It may be that the Western diet with its lower fecal load only intermittently distends the bowel wall and encourages elastin deposition.

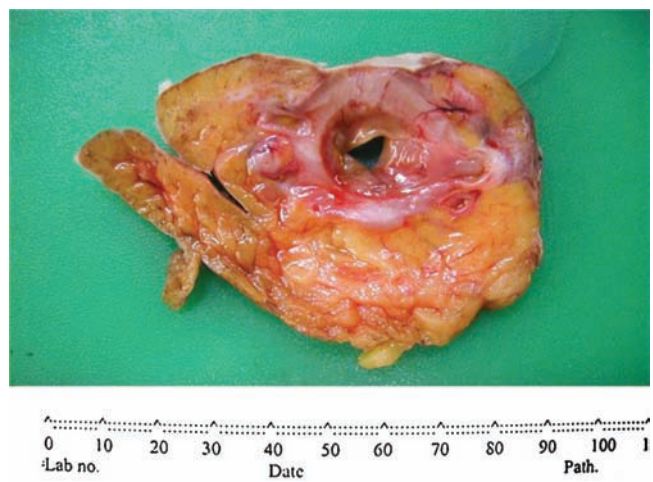

FIGURE 32-2 Cross section through the sigmoid colon containing diverticula (*arrows*).

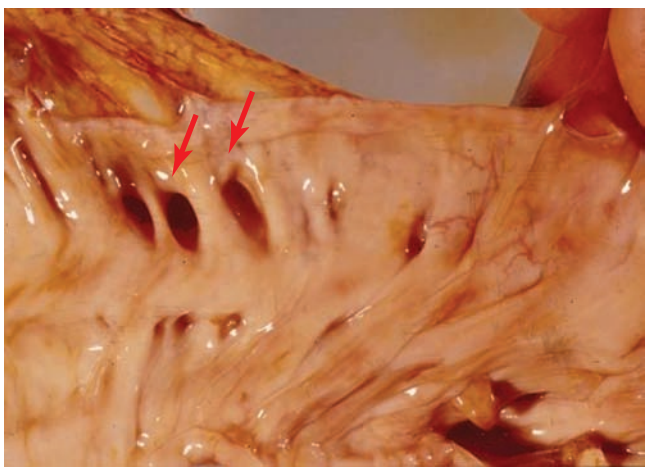
The importance of collagen and elastin types in the colonic wall is increasingly being recognized. Elastin deposition, termed "elastosis," explains the contracted and thickened appearance of the diverticulum-affected colon. The taeniae shorten, and, because of fascial linkage between the longitudinal and circular muscles, the colonic wall looks like a concertina. Thickened circular muscle folds project into the lumen causing a decrease in caliber. The mesocolon is also foreshortened, possibly as a result of chronic inflammation. Other studies have suggested that the type of collagen may be important.[33] One study has shown that in the bowel sections of patients with diverticulitis, there were decreased levels of mature collagen type I and increased levels of collagen type III with a resulting lower collagen I:III ratio. The expression of matrix metalloproteinase 1 was reduced significantly in the diverticulitis group.[33] These findings support the theory of structural changes in the colonic wall as one of the predisposing pathogenic factors for the development of diverticula (Fig. 32-3A and 32-3B).[33] In those with certain connective tissue diseases, such as Marfan's and Ehlers-Danlos syndromes, diverticular disease is a common association.

A



B

FIGURE 32-3 **A.** Sigmoid colon with diverticula. **B.** Mucosal view of colonic diverticula.

Diverticulitis always starts with a microperforation leading to peridiverticulitis. This is instigated by either a rise in intraluminal pressure and/or erosion by inspissated feces. Nonresolution of this initial injury leads to complications of diverticulitis.

Presentation

Given the high incidence of diverticulosis, it is surprising that clinical manifestations are relatively infrequent. Many patients are unaware that they have colonic diverticula until they develop acute symptoms or when colonic diverticulosis may be found as an incidental finding when patients are undergoing colonic investigations. Typically an acute attack of diverticulitis begins with lower abdominal pain that then localizes to the left iliac fossa. An inflamed sigmoid colon can lie against the dome of the bladder or the cecum, mimicking a urinary tract infection or appendicitis. Fever, tachycardia, and a leukocytosis accompany the acute attack. The inflammatory response starts at the site of a blocked diverticulum, and bacterial proliferation eventually leads to abscess formation. Minor episodes may be self-limiting, but an abscess can develop and then rupture into the abdomen causing a purulent peritonitis. More rarely, feculent peritonitis occurs when a diverticulum ruptures freely into the peritoneum.[34–41]

Physical examination will often reveal peritonitis localized to the left iliac fossa or suprapubic area; a palpable mass is not uncommon.

The differential diagnosis includes appendicitis, segmental ischemic colitis, colorectal cancer, inflammatory bowel disease, gastroenteritis, and irritable bowel disease.

In the absence of complications, patients with acute diverticulitis are best managed conservatively with antibiotics. Generalized rigidity suggests purulent or fecal peritonitis, and early surgery is required in this situation. Once fluid and electrolyte resuscitation has begun, an emergency laparotomy or laparoscopy with an appropriate colonic resection should be performed.

Often, diverticular disease presents in a more indolent manner with nagging left iliac fossa pain, abdominal distension, and a change in bowel habits. In the course of investigations to exclude colon cancer, diverticular disease may be discovered by barium enema, computed tomographic (CT) colonography, or colonoscopy (Figs. 32-4, 32-5A, and 32-5B). In the majority of these patients, education about the natural history of the disease with advice on dietary modification and supplementary written information will suffice. A very limited number of patients, who continue to have symptoms despite long periods of medical management, may benefit from surgery in the absence of other specific complications of the disease; however, determining who has symptoms from their diverticula and who has irritable bowel can be difficult. These patients often have persisting symptoms following surgery.

FIGURE 32-5 CT coronal view of sigmoid diverticula.

COMPLICATIONS

Free Perforation. Feculent peritonitis is usually associated with toxemia and signs of generalized peritonitis. These patients will require an immediate laparotomy, resection, and diversion. Mortality rates for emergency operations have remained unchanged at 12–36% for the last 20 years and are most often affected by the patient's underlying fitness for surgery.

Fistula. An inflamed segment of sigmoid colon can adhere to a number of intra-abdominal structures or to the abdominal wall. A fistula may arise spontaneously as a result of the inflammatory condition itself or as a result of surgical intervention. It is more common in males, in those with previous abdominal surgery and in immunocompromised patients. Diverticular fistulas can drain either internally or externally. Often, these fistulas are single tracts, but in about 8% of patients they are multiple. Rare sites of fistulous involvement include the ureters, other colonic segments, and stomach.

Colocutaneous. Occasionally a paracolic diverticular abscess will discharge spontaneously through the abdominal wall causing a colocutaneous fistula. More often, a fistula will result from incision and drainage of a pointing paracolic abscess or from a drain placed under radiological control. A fistula can arise from a leaking colonic anastomosis in patients who have undergone resection for diverticular disease.

Colovesical. This is the most common fistula accounting for about two-thirds of diverticular fistulae. It is more common in men because in women the uterus is interposed between the bladder and the colon. A relatively mobile sigmoid colon becomes adherent to the dome of the bladder and a communication develops. Patients present with recurrent urinary sepsis, urgency, frequency, and pneumaturia. Fecaluria is uncommon. Cystoscopy sometimes identifies an area of inflamed transitional epithelium but is more useful to exclude bladder cancer. A double-contrast enema or CT colonography provides a useful map of the anatomy and in some cases can confirm the presence of a fistula. Caution should be exercised when using barium in an acute situation to avoid peritoneal contamination.

Coloenteric. Small bowel can become adherent to an inflamed diverticulum-affected colon. Fistulas form when an abscess discharges through the small bowel wall. This may be asymptomatic.

Colovaginal. This is a particularly debilitating fistula. The patient may pass flatus and feces through the vagina and suffer

recurrent vaginal infections. Colovaginal fistulas usually only occur if a previous hysterectomy has been performed. Barium studies of both the bowel and the vagina or pelvic magnetic resonance imaging (MRI) usually can confirm the diagnosis. They are also helpful to exclude colonic malignancy as a cause; however, an examination of the vagina may also be required to exclude the rare possibility of a gynecological malignancy.

Single-stage operative resection with primary anastomosis and repair of the contiguous organ can be performed in most circumstances.[42] Interposition of the pedicalized greater omentum between the anastomosis and the site of the fistula is a useful adjunct in preventing recurrent fistula formation.

Bleeding. Severe hemorrhage from diverticular disease is rare (5%).[43,44] However, distinguishing diverticular bleeding from other causes can be a diagnostic challenge, particularly because diverticular disease is so prevalent.[45,46] In elderly patients, angiodysplasia is the most common colonic cause for rectal bleeding. Taken together, bleeding from angiodysplasia and diverticula account for 90% of cases of severe lower intestinal hemorrhage. In diverticular bleeding the penetrating vasa recta that has led to the development of the diverticulum is easily eroded as it is only separated from the bowel lumen and its contents by a thin layer of mucosa. On histology there is thinning of the media and thickening of the intima of the vasa recta with rupture of the vessel usually at the dome of the diverticulum. There usually is no inflammation associated with the bleeding diverticulum.[47,48]

Diverticular hemorrhage presents with abrupt passage of large-volume bright or dark red blood per rectum and may be associated with lower abdominal pain probably related with colonic distension. Most diverticular bleeding occurs from left-sided diverticula except in patients of Asian ethnic origin, in whom it is more common to find the bleeding occurring on the right side.[31] Diverticular bleeding is more common in those on nonsteroidal anti-inflammatory drugs (NSAIDs). Colonoscopy in situations of large-volume bleeding is considered futile if not dangerous. CT angiography is now considered the most useful diagnostic test as it more readily localizes the site of bleeding should the bleeding rate exceed 0.5mL/min. Formal mesenteric angiography to embolize the segmental vessel is then undertaken with good bleeding control and low associated complications (Fig. 32-6).[49,50] Failing this, other techniques to control or localize the bleeding site include vasopressin injection or methylene blue. A more sensitive test for colonic bleeding is a radio-labeled red blood cell scan or technetium-99m–labeled sulfur colloid (>0.1 mL/min), but they are poorer in localizing the bleeding site.[51] Colonoscopy can be used before a laparotomy or as an adjunct with the abdomen open if all else fails in a patient who continues to bleed. It is useful in an attempt to localize and control the bleeding or to minimize the amount of colonic resection. It is also important to note that in these situations a preoperative gastroscopy is mandatory to exclude an upper gastrointestinal tract (GIT) source of bleeding. Most diverticular hemorrhage ceases spontaneously (70–80%) with rebleeding rates of 22–38%.[44,45,52] CT colonography or colonoscopy in patients who have stopped bleeding is useful to exclude malignancy particularly in those with smaller-volume bleeding, with associated suspicious symptoms or where a personal/family history of cancer is significant.

B

FIGURE 32-6 Formal angiography demonstrating "contrast blush"—active bleeding from sigmoid colon.

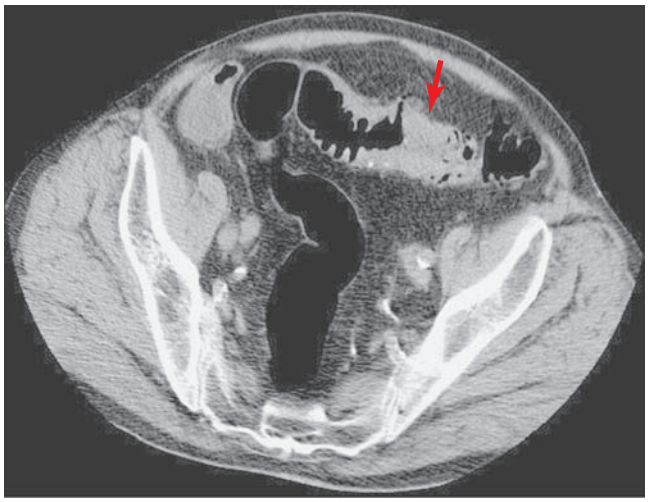

FIGURE 32-7 CT scan of active diverticulitis with occlusion of colonic lumen secondary to inflammation (*arrow*). Differential diagnosis is a sigmoid colon malignancy.

Obstruction. Obstruction due to diverticular disease accounts for 10–20% of large bowel obstructions (LBOs) in Western society. Diverticular disease causes colonic obstruction through either luminal stenosis as a result of wall edema on top of the already thick walled, fibrotic colon or extrinsic compression from an abscess (Fig. 32-7). Often the obstruction is incomplete. Small bowel obstruction can occur if a loop of small bowel becomes adherent to the inflamed sigmoid colon. The diagnosis is usually apparent from the patient's history. Radiological confirmation either by contrast enema or by CT with oral and rectal contrast should be obtained. Caution is wise in those with questionable underlying active diverticulitis particularly if complicated by localized perforation. Direct visualization and histological exclusion of malignancy are mandatory but at times difficult.

Management of colonic obstruction in this setting depends on the mode of presentation and the medical fitness of the patient. An insidious onset is characterized by pain, increasing constipation, and the passage of ribbon-like stools. The majority of patients, however, will present acutely with a classic LBO. The surgical options include a Hartmann resection and resection with primary anastomosis or rarely with a diverting loop ostomy. In those patients deemed unfit for surgery, the endoscopic or fluoroscopic deployment of a colon stent is a useful alternative procedure with a high clinical success rate.[53]

Abscess. Abscess formation is the most common complication of acute diverticulitis. It occurs when the center of the inflammatory mass or phlegmon becomes necrotic. The patient presents with worsening abdominal pain, undulating fever, leukocytosis, and raised inflammatory markers. A mass is often palpable in the left iliac fossa or suprapubic region. It may also be felt transvaginally or transrectally. The most common site for a diverticular abscess is in the sigmoid mesocolon, although a variety of unusual presentations have been described.[54] A significant number of abscesses are detected radiologically on CT or ultrasound scanning. Most small (<5 cm) pericolic abscesses can be treated medically with bowel rest and antibiotics.[55] CT- or ultrasound-guided drainage is indicated for larger or unresolving abscesses via a transabdominal approach when accessible.[41,56–58] (Fig. 32-8) Alternatively, these abscesses may also be drained transanally or transvaginally depending on their location. This is successful in up to 90% and will allow subsequent observational management or a single-stage resection.[58–61] Factors that limit success with management include abscess that involve enteric fistulae or multilocular collections especially those containing solid feces. More recently, laparoscopic lavage and drainage have been taken up with enthusiasm by several groups with some promising results.[62–65]

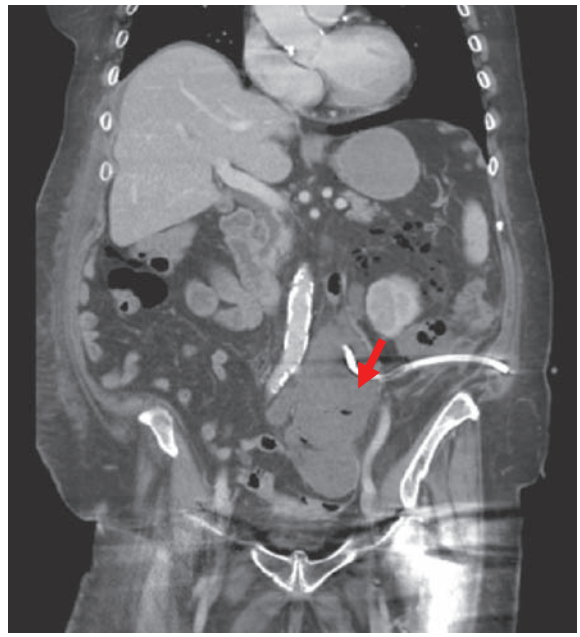

FIGURE 32-8 Sigmoid diverticulitis complicated by a paracolic abscess (with a percutaneous drainage tube in situ).

Giant Colonic Diverticulum. Giant colonic diverticulum (GCD) was first described in 1946 by Bonvin and Bonte[66] in the French literature. The first radiological description was by Hughes and Greene in the American literature in 1953.[67] Various names have been used to describe GCD, including solitary air cyst, giant air cyst, giant gas cyst, encysted pneumatocele, colonic pneumocyst, and giant diverticulum. The variety of names highlights the fact that there has been no clear definition or a single accepted name for these poorly defined lesions that present as large gas-filled cysts attached to the colon (diverticulum). GCD are rare clinical entities with just over 100 cases reported. The age at presentation is comparable to that of patients with conventional diverticular disease. Abdominal pain is the most common symptom, affecting 70% of patients, while 10% are asymptomatic. The most common physical finding is an abdominal mass, affecting 60%

of patients, while 4% have normal physical examinations. Plain abdominal radiology is usually diagnostic of GCD. Treatment is recommended early, preferably soon after presentation, because of the high complication rate. Surgical treatment may either require a diverticulectomy or segmental resection, and the outcome is usually good.[68]

Cancer. There is little evidence to support an association of diverticular disease and colorectal cancer; however, a recent population-based, case-control study from Sweden identified a causal association between sigmoid diverticulitis and a long-term increased risk of left-sided colon cancer.[42]

Investigations

The spiral CT scan has changed the investigation of acute diverticular disease with sensitivities of 90–95%. Although it is debatable whether CT alters disease management in minor diverticular disease, it is invaluable in excluding other causes of abdominal pain and documenting the extent of extraluminal disease. In circumstances in which access to CT is limited, a water-soluble contrast study may show mucosal thickening, edema, irregularity, and occasional extravasation of contrast (Fig. 32-9). Sensitivity is high.[69] Any free perforation is usually contained in an abscess cavity. Contrast enemas are particularly useful for demonstrating the presence and course of an enteric fistula. Barium should be avoided in the emergency setting, as the consequences of barium-induced peritonitis are catastrophic.

The real advantage that CT scanning affords, in addition to confirmation of the diagnosis, is to direct the treatment of complicated diverticular disease.[70–72] Radiologically guided drainage of diverticular abscesses is a useful adjunct to medical management, and can, if successful, avoid the requirement for emergency surgery (see Fig. 32-8).

The role of ultrasound scanning in patients suspected of having diverticular disease has been confined to the treatment and follow-up of diverticular abscess. It is highly operator-dependent, but it can be used to insert drains and to measure the response of the abscess to drainage.

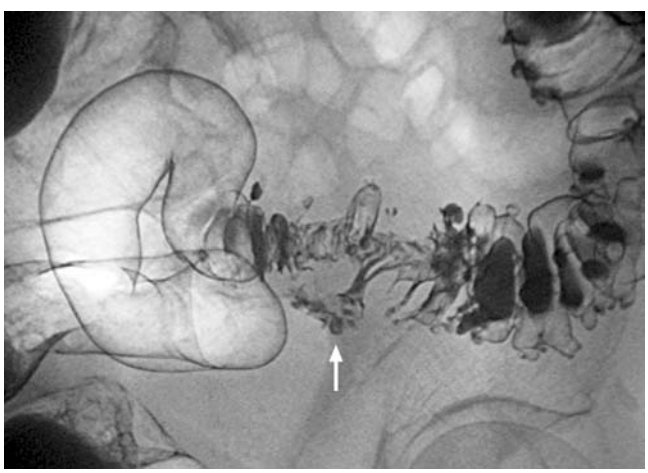

FIGURE 32-9 Localized perforation with contrast extravasation into abscess cavity as demonstrated on double-contrast study.

It is normal practice following resolution of the first episode of diverticulitis to assess the colon for extent of disease and to exclude colorectal malignancy. This can be undertaken with colonoscopy, CT colonography, or barium enema. Care must be taken to wait for full resolution of the attack as an inflamed colon is easy to perforate; also, at times colonoscopy may be very difficult or impossible due to inflammatory adhesions. Colonoscopy generally underestimates the extent of the disease.

Other tests available that may be useful in assessing fistulous disease include MRI scans, cystoscopy, fistulogram, vaginogram, or vaginoscopy.

Classification of Diverticulitis

The Hinchey classification is a useful grading system for diverticulitis.[34]

Stage I	Diverticulitis with associated pericolic abscess
Stage II	Diverticulitis associated with distant abscess (retroperitoneal or pelvic)
Stage III	Diverticulitis associated with purulent peritonitis
Stage IV	Diverticulitis associated with fecal peritonitis

More recently, the modified Hinchey classification has been proposed to further subclassify these stages. Stage 0 is clinical, mild diverticulitis without imaging information. Stage I has been subdivided into Ia that is pericolic inflammation. Stage Ib is diverticulitis associated with pericolic abscess. Stage IIa is distant abscess amenable to percutaneous drainage. Stage IIb is complex abscess with or without fistula. Stages III and IV are the same as for the original Hinchey staging.

Management

The majority of patients with acute diverticular disease can be managed conservatively with intravenous antibiotics.[73] In the absence of complications, most patients will respond to a targeted course of antimicrobial therapy against predominantly gram-negative rods and anaerobes especially bacteroides species. A combination of metronidazole and ciprofloxacin or a broad-spectrum antibiotic such as meropenem or amoxicillin and clavulanate (Augmentin) is most commonly used.[74] There is, however, quite a variation in the treatment regime used among clinicians, and there is no specific regime that has been shown to be superior.[75] The decision to operate should be made at a senior level, as the actual number of patients who require resectional surgery for diverticular disease is small.[76] The increasing use of interventional radiology and laparoscopic surgery has impacted how diverticular disease is

currently managed. This is coupled with a trend to not perform any resectional surgery but, when necessary, to do so with a primary anastomosis in patients presenting with acute complicated diverticulitis.

ELECTIVE SURGERY

Surgery in this setting should be reserved for patients who are medically fit with several proven attacks of acute diverticulitis or who have ongoing sequelae from complicated diverticular disease. Even then, caution should be exercised, as a significant minority of patients whose principal symptom is chronic pain will continue to be symptomatic after resectional surgery.[77] The patient should be fully informed of this possibility before proceeding with the surgery.

Elective resection has generally been offered to patients who have suffered two attacks of acute diverticulitis in a short period of time, but recommendations have ranged from one to four episodes.[55,78,79] The argument has been that this will prevent recurrent diverticulitis as well as its associated complications.[81–93] This is based on historical data that suggest recurrences of up to 67%, with higher morbidity (up to 60%) and mortality associated with recurrent diverticulitis particularly after two episodes.[35,37,55,79,92,94–105] It was also previously demonstrated that patients older than 50 years respond less well to conservative treatment following successive attacks of diverticulitis; a response rate of only about 6% was reported for the third recurrence.[103] In another series re-recurrence was estimated at 2% per year with the first recurrence being the most significant predictor of this.[98] Most often, any recurrence that occurs does so in the first 6 months after the initial attack, and recent data would suggest that it is in fact failure of resolution of the inflammation from their first episode rather than a true recurrence. Some have argued that there is a reduction in the recurrence rate of diverticulitis from 12.5 to 6%[106,107] with good long-term results following surgery.[91,108]

There is still a lack of good prospective data comparing surgical intervention with conservative management in this situation. A large population-based study recently has shown very few patients going on to have surgery after initial conservative treatment of diverticulitis.[73] Another group showed that successful conservatively treated complicated diseases, in particular abscesses, are not associated with further recurrence or complicated recurrences.[98] Recent evidence suggests that less than a quarter of patients having emergency surgery for acute diverticulitis have a previous history, and often complications arise during the first attack of diverticulitis rather than during subsequent episodes.[109–111] Such episodes were associated with a more benign course and responded well to nonoperative management.[101,112] Two groups have shown that the less severe and more readily conservatively managed complications of pericolic abscess occur in recurrent cases rather than free perforation.[39,113] Following elective resection, up to 25% will continue to have symptoms suggesting a coexistent pathology such as irritable bowel.[6,77] Up to 16% will develop recurrent diverticulitis with a small percentage requiring further surgery.[107,114–118] Furthermore, prophylactic colectomy has a mortality risk of up to 4% and a covering stoma is used in up to 14%, necessitating further operation to reverse.[39]

Risk-reducing measures in elective surgery include weight control, routine administration of prophylactic preoperative antibiotics, and preoperative optimization of the respiratory status of the patient with chronic pulmonary disease. Attempts have been made to stratify the management of diverticular disease by pathological and radiological means.[119,120] In one study patients characterized as having a mild attack of diverticulitis had a 14% risk of having a recurrent episode, whereas severe forms had a risk of 39%. Ultimately, the wide spectrum of disease encountered makes dogmatic statements about intervention unreliable, and sound clinical judgment is still required to decide when to intervene.

Indications for operative intervention are different in two patient subgroups: those younger than 50 years and the immunocompromised. Data on young patients with diverticular disease are mainly retrospective. The prevalence of colonic diverticula has been estimated at between 6 and 9% in the general population 40 years of age or younger, with a male preponderance (62–100%).[87,121–123] Patients in this group are thought to have a more virulent course with more complicated recurrences and an aggressive policy of surgical resection has been proposed,[80,87,93,95,112,123–127] particularly in obese males.[87,128,129] Others more recently have challenged this opinion, arguing that there is no difference between the young and old population.[130] There were very few free perforations with recurrent attacks and certainly no increased mortality in this age group[73,97,99,122,127,131–134] Whether the higher propensity for a complicated course in this age group is a true association or the presentation has been altered because of delayed diagnosis remains debatable.[118,135–137] Between 29 and 55% of younger patients will be readmitted to the hospital with acute diverticulitis following their initial presentation, with the majority (up to 88%) of these subsequently undergoing elective or emergency surgery.[76,80,112,123,124,138] A number of these patients were diagnosed at operation for another surgical condition, most often with appendicitis, and were thus often unnecessarily operated on.[73,133,134] It is unclear whether there is an advantage to operating after the initial acute attack of diverticulitis in this age group, especially if it is uncomplicated.

It is uncertain whether patients who are chronically immunosuppressed are more at risk of developing diverticular disease. It is thought that patients who have long-term uremia have a higher incidence of diverticulosis, possibly due to chronic constipation and generalized tissue weakness. Patients with polycystic kidney disease have a very high incidence of colonic diverticular disease.[139] Several groups have reported that immunocompromised patients with acute diverticulitis have a more complicated course compared to nonimmunosuppressed patients.[140–142] Patients who are recipients of renal transplants have a high mortality rate from acute complicated diverticular disease. In some centers, routine colonic screening of patients awaiting renal allografts is performed.[143]

There is limited evidence that the cessation of smoking and stopping NSAIDs will reduce the rate of recurrent attacks of diverticulitis. There is some evidence that the long-term

administration of a poorly absorbed antibiotic will have such an effect.[144–148]

EMERGENT ACUTE DIVERTICULITIS WITH LOCALIZED PERITONITIS

Patients with acute diverticulitis present with localized left iliac fossa peritonitis, fever, tachycardia, and a leukocytosis. Tenderness can spread to the hypogastrium and even to the right iliac fossa. Generalized peritonitis is highly suspicious for a free diverticular perforation. Patients should be rehydrated with an intravenous infusion; in septic patients a urinary catheter is invaluable for assessing an adequate hourly urine output. Other supportive measures include oxygen therapy, adequate opioid analgesia, and antimicrobial therapy.

Early oral feeding may commence when tolerated, and a switch to oral antibiotics can be made with signs of resolution of inflammation. In the majority of patients, this conservative therapy will lead to the resolution of symptoms.

The operative rate for complicated diverticulitis overall in the past has been between 19 and 55%.[79,84,94,98,99,149] Complicated diverticulitis has been shown by some to be associated with high rates of recurrent complications and high rates of mortality.[39,78] The mortality in some reports approaches 40% especially in immunocompromised patients,[39,109,150,151] and similarly in those with an ASA of 3 or greater, there is a mortality rate ranging of up to 28%.[35–37,39,83,85,94,109,152–154]

EMERGENT ACUTE DIVERTICULITIS WITH GENERALIZED PERITONITIS

When either an abscess or a diverticulum ruptures into the peritoneal cavity, widespread bacterial contamination ensues with resultant generalized peritonitis. Surgery is principally directed at controlling peritoneal sepsis and should be tailored to each situation. A conservative approach can be taken with elderly and medically unfit patients who are unlikely to survive surgical intervention. The combined use of appropriate antibiotic therapy and regular review is surprisingly successful in this cohort, even in the presence of a pneumoperitoneum.

In patients who are fit for surgery, a period of vigorous resuscitation and antibiotic therapy is still warranted. Even in the face of advanced peritoneal signs, a number of patients will respond to these measures and avoid the requirement for surgery. Serial clinical observation is of greatest benefit when pursuing this course. If there is no sustained improvement in 24 hours, the patient should be offered surgery.

The days of the routine three-staged procedures are gone as there is little place for nonresectional surgery in the emergent situation involving feculent peritonitis. Resection of the affected colon is associated with a lower morbidity and up to three times less mortality compared with nonresection procedures.[109,155] The aim of surgery is clear: to remove the source of sepsis and to toilet the abdominal cavity. More recently with the advances in laparoscopic surgery, lavage and drainage of Hinchey types 1–3 have been successfully performed. This avoids unnecessary resection surgery and its associated morbidity and mortality, as well as stoma formation and reversal.[156] The apparent confusing and conflicting evidence that outcomes are better following open resection than nonresection and laparoscopic nonresection being better still than open resection still need to be resolved.

The amount of resected tissue depends on the extent of the diverticular disease. At the time of the initial acute surgery, the inflamed bowel needs to be resected. The extent of this resection depends on whether a primary anastomosis is being undertaken or a Hartmann procedure is being performed. When bowel continuity is restored after a Hartmann procedure, total sigmoid colectomy plus removing all of the diverticula- bearing colon and a rectal anastomosis has been shown to reduce the risk of recurrence by some[107,115] but not others.[118]

The decision of whether to undertake an anastomosis in the acute setting is dependent on a number of criteria: the frailty of the patient, the degree of contamination and sepsis, the preparedness of the bowel, and the experience of the surgeon. Hartmann's procedure entails resection of the sigmoid colon with formation of end colostomy and is the safest option when conditions do not favor primary anastomosis. Hartmann's resections are not without their own complications. Up to 50% of patients will never have their stoma closed, particularly the elderly.[39,79,157,158] There is also definite morbidity (up to 16%) and mortality (up to 4%) related to restoration of continuity.[36,152,157–160] Occasionally there are complications related to rectal stump dehiscence.[161]

Primary anastomosis can be performed in the emergency setting but only if conditions are wholly favorable.[162,163] Performing anastomoses in the presence of gross purulent or fecal contamination is controversial and should only be performed by experienced hands. The requirement for bowel preparation for left-sided anastomosis is equally controversial, but recent studies have cast doubt on the need for this.[164] Presacral drainage is often used at the end of the operation but without evidence to its effectiveness.[165]

LAPAROSCOPIC SURGERY FOR DIVERTICULAR DISEASE

The widespread acceptance of laparoscopic surgery has led to its use in both benign and malignant colorectal disease. Laparoscopic surgery in colon cancer is oncologically equivalent to the open approach with better cosmesis, less analgesic usage, and shorter hospital stays.[166–168] In the acute situation there is growing popularity of laparoscopic exploration and drainage of Hinchey's stages I and II diverticulitis.[41,56–58,169] This is particularly useful in cases of misdiagnosis where diverticulitis is instead found, avoiding the need for a colectomy or stoma. Laparoscopic drainage has even been utilized in some centers for Hinchey's stages III and IV complicated diverticulitis.[170] Laparoscopic repair of colonoscopic perforations recently has been successful in numerous cases even with associated diverticular disease of the colon, especially when the pathology is recognized early and there is minimal contamination.[171]

Laparoscopic colonic resection for diverticular disease is challenging and is being increasingly utilized by specialist

centers with good results.[172,173] Some groups have included complicated cases, including abscesses and fistulas.[174–177] Published studies comparing laparoscopic and open resection of left-sided colonic diverticular disease have demonstrated benefits in terms of shorter hospital stay and convalescence despite a longer operating time.[178,179] Major complications as well as the length of the colon resection are generally the same when compared with the traditional open approaches.[174–176] Conversions to open depend on factors such as the clinician's surgical experience and the complexity of the diverticular complications involved.[180]

Publication bias, however, is likely to promote laparoscopic resection as being more favorable, and the true morbidity, cost, and conversion rates may differ from figures published in the medical literature. In over 1100 patients reported over the last 5 years, the postoperative complication rates range from 7.3 to 21%. Conversion rates range between 4 and 14%, operating time from 141 to 300 minutes, and return of bowel activity takes between 2 and 2.9 days.[174–176,178] A recent analysis of the cost of laparoscopic surgery compared with open surgery demonstrated that the total cost of the laparoscopic approach was significantly less (US$S3458 vs US$4321; $p < .05$).[178] Clearly this may have economic ramifications for the future.

Summary

The prevalence of diverticular disease has increased and is continuing to do so in Western countries. The management of diverticular disease is becoming an increasing financial burden to health systems with limited resources. There is little evidence that a change in lifestyle measures can reduce the prevalence of diverticular disease. Fortunately colonic diverticula are usually asymptomatic.

The acute management of diverticulitis is usually conservative with antibiotics and bowel rest, with few patients needing emergency operations. Abscesses can be adequately treated with percutaneous drainage. When an operation is required, the quality of the surgery appears to be more important than whether the operation is undertaken open or laparoscopically. In the acute setting, the affected segment of colon should be resected. The place of elective resection is uncertain. The wide spectrum of disease encountered makes dogmatic statements about intervention unreliable, and sound clinical judgment is still required to decide when to intervene. Further prospective trials investigating recurrence rates, and in particular risk factors for recurrence, as well as the role of prophylactic surgery in the various subgroups is required.

COLONIC VOLVULUS

A colonic volvulus occurs when a segment of colon twists around its mesentery giving rise to a partial or complete bowel obstruction. It is not just confined to humans with dogs and horses both for suffering from this disease.

Epidemiology

Colonic volvulus occurs frequently in third-world countries such as Africa and South America, accounting for at least 50% of causes of LBO, but in developed nations it is third after cancer and diverticular disease at about 10%.[181,182]

In developed countries, sigmoid and cecal volvulus are the two most common forms of colonic volvulus with the former increasing in incidence with age especially in those older than 60 years. In sigmoid volvulus, there is a higher incidence in males due to their dolichomesocolic anatomy (sigmoid mesocolon is longer than wide) compared to females.[181–183] In cecal volvulus there is a younger age of presentation, usually around 40 years of age and particularly in women. Overall, the ratio of sigmoid to cecal volvulus is about 4:1. The other sites including the descending colon, flexures, and transverse colon are rarely involved. In developing countries the peak incidence is in males in the 40- to 60-year age group that account for up to 90%.[182]

Etiology

A redundant colon that is mobile on a long mesentery is a prerequisite that predisposes to colonic volvulus. Redundancy of a colon is due to either colonic dysmotility, excessive fiber intake, or a genetic predisposition. A dynamic ileus and distal obstruction are also predisposing factors. In cecal volvulus, up to 50% will have a history of prior abdominal surgery. Volvulus in Western society is often seen in institutionalized, bed-bound elderly patients with an acquired megacolon. Mobility of the sigmoid colon is obvious with a long and narrow mesentery. In the right colon, poor fixation is often related to partial or complete malrotation of the bowel and, in the splenic flexure, volvulus occurs when there is congenital lack of fixation of the splenocolic, gastrocolic, and phrenocolic ligaments.[181,182]

Morphological Features

In colonic volvulus there is axial twisting of the bowel loops around the vascular axis, leading to a closed-loop obstruction with bowel ischemia and potential gangrene. If neglected, perforation of this bowel loop may occur. In cecal volvulus there is usually a counter-clockwise axial twisting of the cecum, ascending colon and terminal ileum around the mesenteric pedicle. Cecal bascule is a variant of the true cecal volvulus with the difference being an absence of the axial twist but rather the redundant cecum folds back transversely and upward over the ascending colon. True cecal volvulus is about nine times more common than cecal bascule. Bowel ischemia or infarction in this group can occur but is unusual.[184] In ileosigmoid, knotting occurs when the ileum gets caught up in the sigmoid volvulus and an ischemic process ensues in both the twisted bowel loops.

Presentation

Colonic volvulus commonly presents with bowel obstruction, vomiting, obstipation, abdominal pain, and distension. About half will have symptoms suggestive of a previous attack. Clinical examination usually reveals a massively distended abdomen that is asymmetrical and tympanitic. The rectum is invariably empty. Signs of peritonitis often indicate underlying complications of perforation or gangrene.

Complications

Perforation of the twisted segment of bowel (closed-loop obstruction) or bowel ischemia and infarction may occur. Secondary renal failure or multiorgan failure could arise because of third-space loss or loss from vomiting. Alternatively, this may be due to reperfusion injury after the volvulus is untwisted. Abdominal compartment syndrome is a rare complication.

Investigations

A plain supine abdominal x-ray is usually sufficient in the diagnosis of sigmoid and cecal volvulus (Figs. 32-10 and 32-11). Up to 40% cases of cecal volvulus are in fact misdiagnosed as sigmoid volvulus. In cecal volvulus the dilated colon assumes the shape of a large coffee bean ("tear drop" or "comma" appearance) with one fluid level and the point directed toward the left upper quadrant (see Fig. 32-11). There is often a lack of gas in the distal colon and up to half will have dilated small bowel as well. In sigmoid volvulus the shape is that of a "bent inner tube" with its point aimed at the right upper quadrant (see Fig. 32-10). Other features include "2 air to 1 fluid level" and a "pair of scales" whereby the fluid levels are at different horizontal levels. Dilated proximal large bowel and small bowel may be evident. Very rarely, even when present, is there free air under the hemidiaphragms due to the overwhelming amounts of colonic luminal gas that is present in the background. To confirm the diagnosis, a Gastrografin (diatrizoate meglumine) or barium enema study is performed to look for the "bird beak" sign that indicates the site of twisting of the colon. This, however, is becoming obsolete as CT scan is now readily available and commonly used to differentiate causes of abdominal pain. The "bird beak," whirl or coffee bean signs are the most diagnostic features of volvulus on CT scan (Figs. 32-12 through 32-14).[185] CT scans can also be used to help exclude other diagnoses, including causes of distal bowel obstruction that may be associated with the volvulus, as well as help determine if the volvulus is complicated by ischemia or perforation.[182] Alternatively, a rigid or flexible sigmoidoscopy or colonoscopy can be performed. It has a higher rate of therapeutic success than an enema study in particular for the sigmoid volvulus.

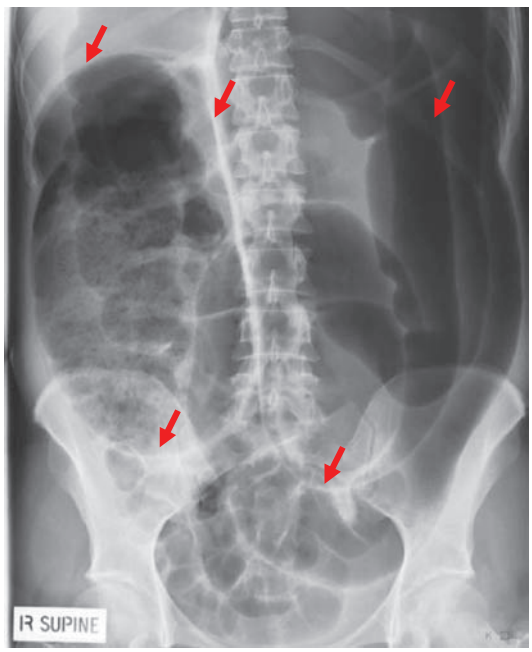

FIGURE 32-10 Plain supine abdominal x-ray of sigmoid volvulus (*arrows* showing margins of volvulized sigmoid loop in a background of dilated proximal bowel).

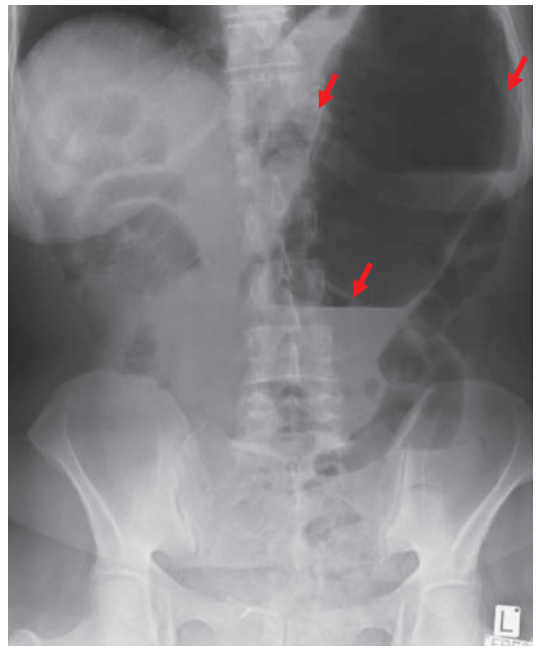

FIGURE 32-11 Cecal volvulus with proximal small bowel obstruction.

Management

In Western countries the mortality associated with colonic volvulus is high at about 20% overall and even higher when there is concomitant gangrenous colon. This is primarily

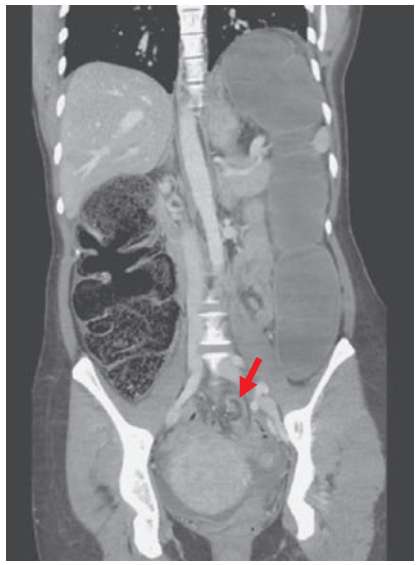

FIGURE 32-12 Coronal CT scan section. Sigmoid volvulus with the "swirl sign."

due to the high comorbidities of this particular group of patients.[183]

Management of colonic volvulus should include a combination of careful resuscitation, urgent diagnosis, and decompression as soon as feasible. Of note reperfusion syndrome is a real phenomenon following detorsion of an ischemic or gangrenous bowel segment. Potential serious bacterial/toxin translocation and multiorgan failure are consequences that the treating clinician must constantly keep in check.[186,187]

Colonic volvulus especially involving the sigmoid colon may be decompressed by a rigid sigmoidoscope or colonoscope.

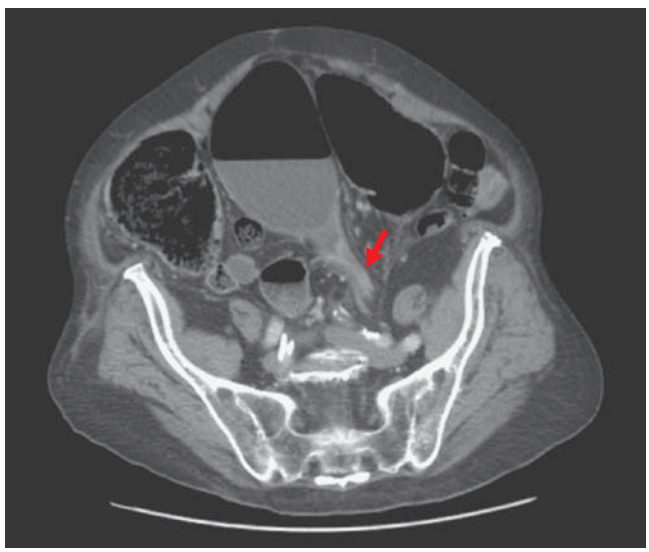

FIGURE 32-13 Transverse CT scan section showing beaking at site of sigmoid volvulus.

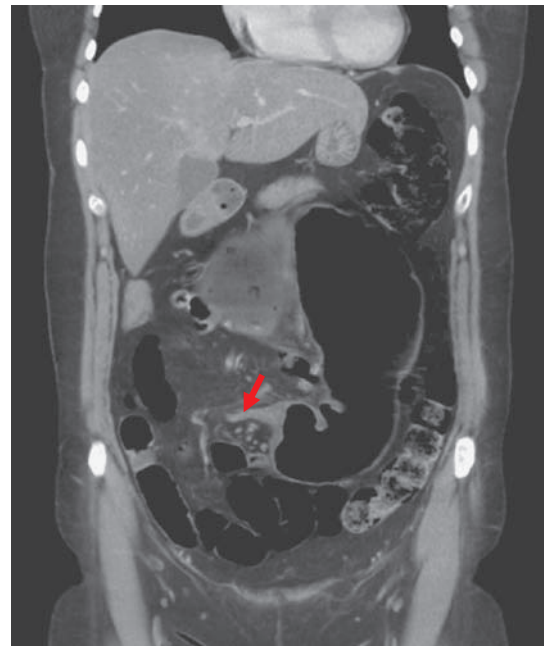

FIGURE 32-14 Cecal volvulus on transverse CT scan section with the beaking effect (*arrow*).

The latter has been shown to be more effective at decompression and with lower risk of complications.[183] The twisting point is often found high above the anal verge with decompression manifesting as a sudden rush of flatus and liquid feces via the anus or sigmoidoscope. The mucosa of the obstructed loop and the site of twisting should be inspected to evaluate the level of bowel ischemia. If no immediate surgery is required, a rectal tube should be placed to prevent further recurrences of the volvulus to allow the continuing decompression of the obstructed colon. For recurrent sigmoid volvulus in a patient who may withstand surgery, a sigmoid colectomy with or without anastomosis, once the bowel is adequately decompressed, is warranted. In the absence of perforation, there is no difference in outcome between a primary anastomosis and Hartmann's procedure for gangrenous disease.[188] The mortality of this is only slightly higher at 5.5% (primary resection and anastomosis) versus 4.2% (Hartmann's).[189] The recurrence rate of resectional therapies is almost zero.[190]

Laparotomy and detorsion with or without colopexy is a poorer alternative with similar morbidity but higher recurrences up to 40%.[191] Similarly, there is a high recurrence rate for mesosigmoidoplasty.[189] Surgery undertaken in these emergency situations had mortalities of 40% compared to 5.9% for elective operations.[184] In those patients who are medically at too high risk for an anesthetic, removing the rectal tube 48 hours later to allow the obstructed colon to deflate and then 24 hours of observation for recurrence before discharge is an option. Alternatively, colonoscopic-assisted placement of two colostomy tubes (percutaneous endoscopic colostomy

[PEC]) to fix the offending bowel loop to the anterior abdominal wall has recently been described in a series of 19 patients with good success and low morbidity. Only one patient had a recurrence requiring another tube colostomy to be inserted because of recurrence. Another patient died from tube dislodgement and peritonitis.[192] Laparoscopic colopexy, extraperitonealization of the sigmoid colon, and laparoscopic colectomies have more recently been widely used.[193–195] A medial to lateral approach for laparoscopic-assisted resection has been found to be advantageous.[196]

Cecal volvulus is more difficult to rectify via a colonoscope primarily because of an inability to reach the obstructed right colon. There is also a higher risk of perforation.[197] Consequently, surgery is often required. If feasible, an ileocolic resection with or without anastomosis is performed. This has the lowest recurrence rate but a high morbidity at about 30% and a mortality of up to 20%.[197,198] Alternatively, cecopexy may be performed but is associated with about a 20% recurrence rate. A tube cecostomy fixation (Fig. 32-15) has been advocated by some, claiming a low recurrence rate of about 2% and low morbidity, but others have shown that it has a morbidity of about 52% and mortality of 22%.[197,199]

Conclusion

Colonic volvulus most commonly occurs in the sigmoid and is the third most common cause of bowel obstruction. It is readily seen on plain abdominal x-ray and CT scan. Sigmoid volvulus can often be nonoperatively decompressed before a decision is made for definitive resection that rarely leads to recurrence. Cecal volvulus often requires an operation to fix it. Delayed management of volvulus may result in perforation, leading to high rates of complications and mortality, especially in this elderly age group.

CROHN'S DISEASE

Fabrizio Michelassi • Roger D. Hurst • Alessandro Fichera

Crohn's disease is a chronic inflammatory condition of the gastrointestinal (GI) tract that can give rise to strictures, inflammatory masses, fistulas, abscesses, hemorrhage, and cancer. This disease commonly affects the small bowel, colon, rectum, or anus. Less commonly, it can also involve the stomach, esophagus, and mouth. Often, the disease will simultaneously affect multiple areas of the GI tract.

The cause of Crohn's disease is not known and there is no curative treatment. Current medical and surgical treatment is effective at controlling the disease, but even with optimal treatment recurrences and relapses are frequent. The combined approach of optimal medical treatment with timely and strategic surgical intervention offers the most effective management to patients affected by Crohn's disease. Crohn's disease, however, can be particularly challenging, as it has a myriad of manifestations and potential complications. Additionally, its course and response to therapy can be difficult to predict. To add to the overall complexity, there are many therapeutic options that must be tailored to each individual patient and to each site of involvement to achieve optimal outcomes.

HISTORY

Crohn's disease was fully recognized as a specific pathological entity in 1932 when Crohn et al first identified regional enteritis as a unique clinical entity.[1] In retrospect, case descriptions of what appeared to be Crohn's disease date back to at least 1612, when Fabry reported on the death of a boy experiencing severe abdominal pain.[2] Autopsy revealed a contracted ulcerated cecum and ileum with complete bowel obstruction. In 1761, Morgagni described a case of an inflamed ileum with perforation and thickened mesentery in a young man with a history of diarrhea and fever.[3,4]

It is unclear how common Crohn's disease might have been before 1932, as it is likely that cases of this disease occurring in an era of limited abdominal surgery may have been mistaken for other processes such as tumor or intestinal tuberculosis. In 1913, Sir Dalziel of Glasgow, Scotland, reported in the *British Medical Journal* on 13 patients and provided what is now recognized as a classic clinical and pathologic description of Crohn's disease.[5] Although not often cited, Dalziel's description predates the one by Crohn et al, and some have argued that the disease should be known by the eponym "Dalziel-Crohn disease."

After the report by Crohn et al, increased awareness of the disease led to a marked increase in reported cases in the 1930s through the 1950s. The general public's awareness of the disease increased when, in 1956, one of the most famous figures of the 20th century, President Dwight Eisenhower, was diagnosed with Crohn's disease at the terminal ileum. That same year, President Eisenhower underwent intestinal bypass surgery with the small intestine proximal to the area of disease anastomosed to the transverse colon.[6] Following this operation, he remained relatively free of symptoms for the remainder of his life.[7]

Early in the history of Crohn's disease, optimal surgical management remained disputed. Initially, many thought that the disease was one of both the bowel and the mesentery and, much like malignancies, wide excision with radical dissection of the mesentery was believed to be the best way to provide for the optimal long-term outcome.[8] It was also appreciated that diversion of the fecal stream was effective at decreasing active inflammation and ameliorating symptoms. Frequently performed in the 1940s and 1950s, bypass operations are now only rarely undertaken for Crohn's disease.[9–11] Additionally, a greater understanding of the clinical course of Crohn's disease has led to more conservative resections, as it is appreciated that wide surgical margins of normal tissue and radical resection of the mesentery are not necessary to avoid early recurrence of disease.

In spite of the increased attention given to Crohn's disease of the ileum, Crohn's colitis was not widely recognized as a form of Crohn's disease until 1960 when Lockhart-Mummery and Morson firmly established the pathologic criteria for distinguishing Crohn's disease from idiopathic ulcerative colitis.[12]

EPIDEMIOLOGY

After the original description of Crohn's disease in 1932, the number of reported cases increased greatly. Today it

is estimated that the incidence of Crohn's disease in the United States is approximately four new cases per year for every 100,000 persons. This disease is chronic and patients live for many years with the ailment; thus the prevalence is much higher and is reported to be between 80 and 150 cases per 100,000 persons.[13,14] The incidence of Crohn's disease increased rapidly from 1930 to at least the 1980s, but the incidence of new cases now appears to have stabilized.

The United States, Canada, and Europe have the highest incidence of Crohn's disease. It is much less common in Asia, South America, and Japan. Crohn's disease is believed to be uncommon in Africa, but accurate data regarding the incidence of inflammatory bowel disease in this region of the world are lacking. The peak age for contracting Crohn's disease is between 15 and 25 years. As such, Crohn's disease typically affects young adults, yet the disease can occur at almost any age. It should be noted, however, that Crohn's disease is very rare in children younger than 6 years.[15]

In the United States, the incidence of Crohn's disease is highest among Caucasians, low among blacks, and lowest among Hispanics and Asians. It is three to four times more common among ethnic Jews than non-Jewish whites. It also appears to be slightly more common in women than in men, although a slight male predominance has been reported in some populations.[16]

Familial clusters of Crohn's disease are not uncommon, with a 6- to 10-fold increase in the risk of this disease in first-degree relatives of those affected by this disease or its sister ailment, ulcerative colitis. Although familial aggregations are common, the distribution within families does not indicate a pattern of simple mendelian inheritance.

ETIOLOGY

The etiology of Crohn's disease is not known. Many possible causes have been the subject of both speculation and investigation.[4] Basic science research into the molecular biology of Crohn's disease has begun to give some better insight into the genetics of this condition, but much regarding its ultimate causes remains unclear.

It is known that Crohn's disease is an altered immune response that results in inflammation and destruction of intestinal tissues. It is not clear if this altered immune response is the result of a primary dysfunction in the gut-related immune system or whether an unknown pathological trigger induces an otherwise normal immune system to overreact. Most believe that Crohn's disease occurs in individuals with a genetic predisposition and that development of the disease is dependent on exposure to environmental triggers that start the pathological sequence that ultimately manifests as Crohn's disease.

To date, no specific primary defect in the systemic or mucosal immune system has been identified. Studies of intestinal transport mechanisms have demonstrated an increase in intestinal permeability in both Crohn's disease patients and their symptom-free first-degree relatives.[17–21] This has led some to speculate that Crohn's disease is the result of an altered mucosal barrier function that allows abnormal interactions to take place between the multitude of antigenic substrates normally found in the gut lumen and the immunocompetent tissue of the submucosa.

As indicated by the observed familial aggregations and variability of risks among differing ethnic and racial groups, a genetic predisposition is very likely to have a major role in the etiology of Crohn's disease. The distribution of Crohn's disease within family aggregates is complex and defies classification with simple mendelian transmission of disease. Genetic linkage studies have identified susceptibility to Crohn's disease to the *CARD15/NOD2* gene mapped to chromosome 16q12.[22,23] CARD15 is a gene product related to innate immunity and it is preferentially expressed to Paneth's cells of the ileum.[24,25] While the *CARD15/NOD2* gene has been linked to susceptibility to Crohn's disease, the known mutations of CARD15 are neither necessary nor sufficient to contract this disease. Hence, it appears that the genetic relationship of *CARD15/NOD2* to Crohn's disease is complex and still poorly understood.

The suspicion that infectious agents may play a role, either directly as a primary cause of Crohn's disease or indirectly as a trigger to stimulate a defective immune system, has generated much attention. This hypothesis has always found strength in the identification of noncaseating granulomas as the characteristic histopathologic lesion found in Crohn's specimens and in the isolation of *Mycobacterium paratuberculosis* from resected Crohn's disease specimens. This finding has been far from consistent, and even sensitive preliminary chain reaction studies have been unable to provide definitive evidence for the presence of *M. paratuberculosis*–specific DNA in Crohn's disease–affected segments of the bowel. Other infectious agents have been studied and shown not to be causative agents for Crohn's disease. These include measles virus, non-pylori *Helicobacter* species, *Pseudomonas*, and *Listeria monocytogenes*.[26] To date, no single infectious agent has been consistently associated with Crohn's disease.

Although diet modification can ameliorate the symptoms of Crohn's disease, no dietary factor has been identified as its cause. Smoking, however, has been associated with the development of Crohn's disease, with smokers having a substantially higher risk for contracting this disease than nonsmokers.[27–30] Additionally, smoking is known to exacerbate existing Crohn's disease and can accelerate its recurrence after resection.[31,32] The component of cigarette smoke that is responsible for these deleterious effects on the clinical course of Crohn's disease is not known.

PATHOLOGY

Histopathologic examination of Crohn's disease typically demonstrates transmural inflammation characterized by multiple lymphoid aggregates in a thickened submucosa. Lymphoid aggregates may extend beyond the mucosa and can be found within the muscularis propria.[33] The presence of

well-formed lymphoid aggregates in an edematous fibrotic submucosa is a classic histological feature of the disease. Another sentinel microscopic feature of Crohn's disease is the presence of noncaseating granulomas. Noncaseating granulomas are a valuable diagnostic feature of Crohn's disease, but they are seen in only 50% of resected specimens and are rarely seen on endoscopic biopsies. Additionally, the presence of granulomas does not correlate with disease activity, as areas of active inflammation are no more likely to contain granulomas than areas of quiescent disease.[34]

The earliest gross manifestations of Crohn's disease are the development of small mucosal ulcerations call aphthous ulcers.[33] Aphthous ulcers appear as red spots or focal mucosal depressions and typically occur directly over submucosal lymphoid aggregates. As the inflammation progresses, the aphthous ulcers enlarge and become stellate. The enlarging ulcerations then coalesce to form longitudinal mucosal ulcerations. In Crohn's disease of the small bowel, these linear ulcerations always occur along the mesenteric aspect of the bowel lumen. Further progression leads to a serpiginous network of linear ulcerations that surround islands of edematous mucosa producing the classic "cobblestone" appearance. Mucosal ulcerations may penetrate through the submucosa to form intramural channels that can bore deeply into the bowel wall and create sinuses, abscesses, or fistulas.

The inflammation process progresses to extend through all layers of the bowel wall. The inflammation of Crohn's disease also involves the mesentery and regional lymph nodes such that the mesentery may become massively thickened. With early acute intestinal inflammation, the bowel wall is hyperemic and boggy. As the inflammation becomes chronic, fibrotic scarring develops and the bowel wall becomes thickened and leathery in texture.

CLINICAL PRESENTATION

The clinical presentation and symptoms of Crohn's disease vary greatly depending on the segment of intestine involved[35] and the predominant features of the disease: stricturing, perforating, or inflammatory. In the next few paragraphs the influence of disease pattern and location is described.

Patterns of Disease

Crohn's disease can be categorized into three general manifestations: stricturing disease, perforating disease, and inflammatory disease.[36] These three classes do not represent truly distinct forms of the disease; rather they are terms that are used to describe the predominant gross manifestation of the disease.[37] It is typical for more than one pattern to occur in the same patient or even the same segment of intestine; even so, one pattern tends to predominate in most cases. It is generally the predominant pattern of disease that determines the clinical presentation and affects the therapeutic options.

STRICTURING PATTERN

Chronic inflammation of Crohn's disease results in the development of fibrotic scar tissue that constricts the intestinal lumen with cicatricial strictures, often referred to as "fibrostenotic lesions." Patients with a stricturing pattern of this disease generally develop partial or complete intestinal obstruction, and hence their symptoms are primarily obstructive in nature. Being the result of scar tissue, fibrostenotic strictures are not reversible with medical therapy. Once fibrostenotic areas become symptomatic, significant improvement rarely occurs and surgical intervention is often required.

PERFORATING PATTERN

Perforating Crohn's disease is characterized by the development of sinus tracts, fistulas, and abscesses. Penetrating sinus tracts develop from deep mucosal ulcerations. These sinus tracts penetrate through the muscularis propria and give rise to abscesses or to fistulas if they penetrate into surrounding structures. The term "perforating" disease can be misleading, as free perforation with spillage of intestinal contents into the abdominal cavity is not a common phenomenon with Crohn's disease. Inflammatory response around the advancing sinus tract typically results in adhesion to surrounding structures. The sinus usually bores through the area of adhesion such that abscess formation or fistulization to other structures occurs much more often than free perforation into the abdominal cavity. Typically, perforating disease is accompanied by a degree of stricture formation, but the fistula or abscess generated by the perforating component of the disease dominates the clinical picture.

INFLAMMATORY PATTERN

The inflammatory pattern of Crohn's disease is characterized by mucosal ulceration and bowel wall thickening. The edema that results from inflammation can lead to an adynamic segment of intestine and luminal narrowing. This pattern often gives rise to obstructive symptoms in the small intestine and diarrhea in the colon. Of the three patterns of Crohn's disease, the inflammatory pattern is much more likely to respond to medical therapy.

Location of Disease

Crohn's disease is a panintestinal condition that may affect any area from the mouth to the anus. The most commonly affected location is the terminal ileum, and one-fifth of all patients have more than one intestinal segment affected simultaneously.

GASTRODUODENAL AND ESOPHAGEAL CROHN'S DISEASE

Crohn's disease of the upper GI tract gives rise to symptoms of nausea, vomiting, dysphagia, or odynophagia.[38] Oral

Crohn's disease usually manifests with aphthous ulcers in the hard palate that may cause discomfort, especially during mastication and deglutition. Esophageal Crohn's disease is uncommon in both children and adults, but it is believed to be more frequent in children than in adult patients.[39] Esophageal involvement with Crohn's disease may be asymptomatic or may give rise to dysphagia or odynophagia. Esophageal Crohn's disease is associated with Crohn's disease elsewhere within the GI tract, as disease isolated to the esophagus is almost never seen. Symptomatic Crohn's disease of the stomach and duodenum is more common than disease of the esophagus, yet both locations are the least frequently involved by Crohn's disease. The symptoms are usually related to the obstructive nature of the disease with delayed gastric emptying, a sense of postprandial gastric fullness, nausea, and vomiting.

CROHN'S DISEASE OF THE SMALL INTESTINE

Abdominal pain is the predominant symptom of small bowel Crohn's disease, as it occurs in 90% of cases.[35] Abdominal pain may be the result of obstructive or septic complications. Pain related to partial obstruction is mostly postprandial and crampy in nature; pain from septic complications is typically steady and associated with fevers. Other common symptoms and findings include anorexia and weight loss. Weight loss is usually related to food avoidance, but in severe cases it may be the result of malabsorption. With disease of the small intestine, patients may develop a palpable mass, usually located in the right lower quadrant, related to an abscess or phlegmon in perforating disease or a thickened loop of intestine in obstructive disease. Evidence of fistulization to the skin, urinary bladder, or vagina may also be elicited with an accurate history and physical examination.

CROHN'S COLITIS

Crohn's involvement of the colon typically results in diarrhea that may or may not be bloody. Acute flares of Crohn's colitis are often associated with fever and abdominal pain that is often exacerbated by bowel movements. Stricturing of the colon with more advanced disease can give rise to colonic obstruction. Like Crohn's disease of the small intestine, Crohn's colitis can give rise to abscess formation and fistulas. Toxic megacolon can occur with Crohn's disease, but this severe complication is rare and less frequently seen than in ulcerative colitis.[40]

PERINEAL CROHN'S DISEASE

Crohn's disease frequently affects the anal crypts and gives rise to perianal fistulas, abscesses, and anal strictures. Perineal Crohn's disease is also associated with hypertrophic perianal skin tags, fissures, and perineal scarring. Approximately 40% of patients will develop perineal manifestations of Crohn's disease.[41,42] Anal Crohn's disease is almost always associated with Crohn's disease present elsewhere in the GI tract, although perianal disease can be the initial symptomatic manifestation of Crohn's disease.

EXTRAINTESTINAL CROHN'S DISEASE

In addition to the inflammation of the GI tract, a variety of extraintestinal manifestations can occur in Crohn's disease. These include ocular, dermatological, hepatobiliary, and joint disorders.[43,44] Such extraintestinal manifestations occur in a minority of patients, but, when present, they produce symptoms that can be more severe than those of the primary intestinal disease. Ocular manifestations of Crohn's disease include uveitis and episcleritis.[45] Cutaneous manifestations of Crohn's disease include erythema nodosum and pyoderma gangrenosum. Joint disorders such as ankylosing spondylitis, sacroiliitis, and seronegative polyarteritis can occur. Patients with Crohn's disease are also at risk for the development of primary sclerosing cholangitis. However, the risk for primary sclerosing cholangitis is much less in Crohn's disease patients than in patients who suffer from ulcerative colitis.

Peripheral polyarteritis, episcleritis, uveitis, and erythema nodosum typically correlate with the activity of intestinal Crohn's disease. These particular extraintestinal manifestations typically regress with complete surgical resection of the affected segment of intestine or with successful medical control of the intestinal inflammation. Pyoderma gangrenosum may also improve with treatment of primary intestinal disease, but available clinical data on this particular issue have not always been consistent. The clinical course of ankylosing spondylitis and primary sclerosing cholangitis tend to be independent of the level of disease activity within the intestine. Ankylosing spondylitis and primary sclerosing cholangitis do not improve with surgical resection of the Crohn's disease–affected bowel.

DIAGNOSIS

The onset of Crohn's disease is often insidious and many patients will experience some symptoms for months or even years before the diagnosis is made. The diagnosis of Crohn's disease is typically made by a thorough history and physical examination along with intestinal radiography and endoscopy. There is no specific laboratory test that is diagnostic for Crohn's disease. Advanced imaging studies such as computed tomography (CT) scan or magnetic resonance imaging (MRI) can assess or detect some of the complications and manifestations of Crohn's disease,[46] but they are generally not useful in making the initial diagnosis of Crohn's disease.[47]

History and Physical Examination

The symptoms of Crohn's disease are dependent on the location of the involved segment, the pattern and the severity of

disease, and the associated complications. As noted previously, in most cases the onset of disease is gradual with the most common complaints being intermittent abdominal pain, bloating, diarrhea, nausea, vomiting, weight loss, and fever.[48] Patients may also have symptoms related to complications of the disease, including abdominal masses, pneumaturia, perianal pain and swelling, or skin rash. In some cases the onset of symptoms can be more sudden, with patients relating a history reminiscent of acute appendicitis. In these cases, pain in the right lower quadrant may have been present only for a few hours or days. However, a brief history of symptoms such as this is atypical.

In patients suspected of having Crohn's disease, a complete physical examination should include a thorough abdominal assessment. In cases of ileal Crohn's disease, tenderness is typically present in the right lower quadrant and occasionally a palpable mass is present. The oral cavity should be examined for the presence of aphthous ulcers. The perianal area should be examined for the presence of fistulas, abscesses, or enlarged skin tags. A digital rectal examination should assess for the presence of anal strictures, fissures, and rectal mucosal ulcerations. The skin in the extremities should be examined for erythema nodosum and pyoderma gangrenosum.

Imaging

SMALL BOWEL RADIOGRAPHY

Upper intestinal contrast studies, either small bowel follow-through or enteroclysis, are the best means for assessing the small bowel for Crohn's disease.[49–52] The radiographic abnormalities of small bowel Crohn's disease are often distinctive[53] (Fig. 33-1). With early Crohn's disease, mucosal granulations with ulceration and nodularity can be identified. Thickening of the mucosal folds and edema of the bowel wall itself can be demonstrated as the disease progresses. With more advanced disease, cobblestoning becomes radiographically apparent. Small bowel contrast studies can also provide information regarding enlargement of the mesentery, as well as formation of an inflammatory mass or abscess. Such findings are demonstrated by a general mass effect separating and displacing contrast-filled loops of small intestine (see Fig. 33-1; Fig. 33-2). Small bowel contrast studies can demonstrate some of the complications of Crohn's disease, including high-grade strictures and fistulas. It is important to note, however, that small bowel radiography may not identify all such lesions. For instance, many enteric fistulas including ileosigmoid and ileovesical fistulas are not typically demonstrated on contrast radiography.[54,55] Thus the absence of radiographic evidence for fistulization does not exclude this possibility. Additionally, small bowel studies may not demonstrate all the areas of disease with significant strictures.[56] While small bowel radiographs may underestimate the extent of complicated Crohn's disease, small bowel studies performed by an experienced GI radiologist are very effective as a diagnostic tool for this disease. Besides their diagnostic utility, small

FIGURE 33-2 Small bowel radiograph demonstrating Crohn's disease of the terminal ileum with high-grade strictures and ulcerations. (Reprinted, with permission, from the University of Chicago General Surgery Archives.)

FIGURE 33-3 Small bowel radiograph demonstrating Crohn's disease with strictures in the jejunum. (Reprinted, with permission, from the University of Chicago General Surgery Archives.)

bowel radiographs can also help in assessing the extent of the disease by identifying the location and length of involved and uninvolved intestine, and by recognizing whether the disease is continuous or discontinuous with skip lesions separated by areas of normal intestine (Fig. 33-3). Experienced radiologists can also assess areas of luminal narrowing and determine if they are the result of acute inflammatory swelling or are the result of fibrostenotic scar tissue. Such a distinction provides valuable information regarding the value of medical therapy versus early surgical intervention, as inflammatory stenoses are likely to respond to medical therapy while fibrotic strictures are best treated with surgery.

ENDOSCOPY

Upper and lower endoscopies allow for inspection of mucosal disease and provide an opportunity for a biopsy for histologic evaluation. Upper endoscopy is useful in the diagnosis of mucosal lesions of the esophagus, stomach, and duodenum; it also easily identifies strictures and grades their severity. Characteristic colonoscopic features of Crohn's disease include aphthous ulcers, longitudinal ulcerations, skip lesions often with rectal sparing, pseudopolyps, and strictures.[53] In many cases the terminal ileum can be entered and evaluated.

CAPSULE ENDOSCOPY

Capsule endoscopy is a new tool in the diagnosis and evaluation of Crohn's disease.[57,58] With this study, a small camera embedded within a capsule-size casing is swallowed and images from the camera are transmitted to a small electronic receiver worn by the patient. Images from the capsule endoscopy can detect subtle mucosal lesions that may not be apparent on small bowel x-rays. Prior to the capsule endoscopy, patients with suspected Crohn's disease should undergo a small bowel contrast study to exclude stricture formation, as the capsule may fail to pass through areas of narrowing and result in intestinal obstruction. The value of capsule endoscopy in the diagnosis of Crohn's disease has been recently evaluated in a prospective study from the Mayo clinic.[59] This study compared capsule endoscopy, CT enterography (CTE), ileocolonoscopy, and small bowel follow-through in the diagnosis of small bowel Crohn's disease in a prospective blinded trial and found that the sensitivity of capsule endoscopy was not significantly different from that of the other tests. A meta-analysis of capsule endoscopy studies comparing it to CTE suggested that the prevalence of abnormalities detected on capsule endoscopy was 38% higher than that of CTE.[60] However, this value was significantly higher than CTE only for the subgroup of patients with known Crohn's disease. The need for a preliminary small bowel contrast study to detect asymptomatic partial small bowel obstruction before the capsule endoscopy can be safely performed, and the lack of a clear advantage over other imaging studies limits the utility of capsule endoscopy as a first-line test in Crohn's disease and perhaps reserves this study for those cases in which there is a substantial diagnostic uncertainty.

COMPUTED TOMOGRAPHY

Computed tomography (CT) findings of uncomplicated Crohn's disease are nonspecific, and routine CT is not necessary for the diagnosis of Crohn's disease. CT, however, is very useful in identifying the complications associated with Crohn's disease.[61,62] Specifically, CT can readily identify thickened and dilated intestinal loops, inflammatory masses, abscesses, and hydronephrosis resulting from retroperitoneal fibrosis and ureteral narrowing. CT scans are also the most sensitive indicator of an enterovesical fistula as suggested by the presence of air within the urinary bladder. More recently, cross-sectional imaging techniques have assumed an increasing role in the imaging of patients with Crohn's disease. Using ileoscopy and biopsy of the terminal ileum as reference to evaluate the performance characteristics of cross-sectional enterography,[63] CTE has been shown to have a higher sensitivity than barium small bowel follow-through.[59] These findings have convinced many to use CTE combined with ileocolonoscopy as a first-line test for the diagnosis and staging of Crohn's disease.[59] CTE exploits the high spatial resolution and speed of modern CT, using large volumes of neutral oral contrast agents to generate detailed images of the small bowel wall, lumen, and mesentery.[64] In addition, CTE has several potential advantages over barium studies in the identification of fistulizing disease. Unlike traditional fistulography, CTE does not suffer from superimposition of bowel loops and displays the mesentery, retroperitoneal, and abdominal wall

musculature, typically involved by fistulas. Sinus tracts and abscesses can also be readily characterized by CTE.[64] However, recent concerns about radiation-induced cancer arising from medically related CT[65] have stimulated a reassessment of the role of CTE in young Crohn's disease patients[66] and have encouraged the use of magnetic resonance enterography (MRE). MRE has the advantages of CTE, such as the ability to show the entire small bowel, detect transmural inflammation, grade the severity of inflammation, and detect extracolonic inflammation, but it does not require ionizing radiation. In a recent study, MRE has been shown to have similar sensitivities to CTE for detecting active small bowel inflammation, although image quality across the study cohort was better with CTE.[67] Therefore, MRE should be considered an alternative to CTE when radiation exposure is a concern to provide complementary information to ileocolonoscopy in the diagnosis of Crohn's disease.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for small bowel Crohn's disease includes irritable bowel syndrome, acute appendicitis, intestinal ischemia, pelvic inflammatory disease, endometriosis, and gynecological malignancies. Other disorders that are within the differential diagnosis include radiation enteritis, *Yersinia* infections, intestinal injury from nonsteroidal anti-inflammatory agents, intestinal tuberculosis, and small bowel tumors.

Among the most important ailments to consider are small bowel malignancy and intestinal tuberculosis. In patients in whom small bowel malignancy is suspected, resection should be undertaken to make certain the diagnosis. The exclusion of intestinal tuberculosis can be difficult, as the inflammation and stricturing of the terminal ileum can occur in a manner that closely mimics Crohn's disease. The patient should be assessed for exposure to tuberculosis and screened for tuberculosis with a purified protein derivative skin test. Chest radiography should also be considered. Even when the diagnosis of Crohn's disease is certain, patients who coincidentally are found to also have latent tuberculosis should be treated in accordance with American Thoracic Society guidelines prior to the initiation of immunosuppressive therapy for management of their Crohn's disease.[68]

Intestinal injury from nonsteroidal anti-inflammatory drugs (NSAIDs) can result in focal enteritis with ulceration and stricture formation.[69,70] These manifestations can be very difficult to distinguish from Crohn's disease of the small bowel. This rare side effect from the very commonly used NSAIDs often requires resection or biopsy to confirm the diagnosis.

For Crohn's disease of the colon, the differential diagnosis includes ulcerative colitis, infectious colitis, collagenous colitis, ischemic colitis, diverticular disease, Behçet's disease, colonic neoplasm, solitary rectal ulcer syndrome, and NSAID colopathy.

The entity that is most difficult to distinguish from Crohn's colitis is ulcerative colitis. The diagnosis of ulcerative colitis cannot be made with absolute certainty, as it is possible for Crohn's disease of the colon to reproduce all the features of ulcerative colitis. It is only when features appear that are unique to Crohn's disease that the diagnosis of Crohn's disease can be made. Such distinguishing features of Crohn's disease include small bowel involvement, perianal disease, skip lesions, transmural inflammation, fistulas, abscesses, and noncaseating granulomas. After a complete history and physical examination complemented by appropriate radiological, endoscopic, and humoral studies, Crohn's and ulcerative colitis can be distinguished with a high degree of confidence in as many as 85–90% of cases, yet in the remaining 10–15% of cases the differential diagnosis will remain indeterminate. This has major bearing on the surgical options available for such patients.

MEDICAL MANAGEMENT

The goal of medical treatment of Crohn's disease is to provide long-lasting symptomatic relief while avoiding excessive morbidity. Crohn's disease cannot be cured by medical treatment, but it may afford long periods of disease control and avoidance of surgical intervention. Thus it is important that the surgeon have an understanding of the basics of medical therapy for Crohn's disease. Selecting the optimal medical treatment for each individual requires experience and special expertise because of the variable course of the disease, the myriad of different clinical presentations and associated complications, and the desire to optimize medical treatment for each clinical situation.

Corticosteroids

Corticosteroids are the most effective agents for controlling acute exacerbations of Crohn's disease, but their use is limited due to the risk of serious side effects. The majority of patients with active small bowel Crohn's disease will experience clinical remission with a short course of oral prednisone given in a dose between 0.25 and 0.5 mg/kg/d.[71] For patients unable to take oral medications, methylprednisolone can be administered in the adult at doses of 40–60 mg given as a daily infusion.[72] Common side effects from corticosteroids include diabetes, osteoporosis, cataracts, osteonecrosis, myopathy, psychosis, opportunistic infections, and adrenal suppression. The risks for these side effects are related to both the dose and the duration of steroid therapy.

5-Aminosalicylic Acid

The aminosalicylates as a group of medications include sulfasalazine and 5-aminosalicylic acid (5-ASA) derivatives. The exact mechanism of action for these agents is not clear, but 5-ASA is thought to function through various pathways.[73] 5-ASA compounds inhibit leukotriene production by inhibition of

5-lipooxygenase activity. 5-ASA also inhibits the production of interleukin-1 and tumor necrosis factor (TNF). 5-ASA compounds are weak inhibitors of cyclooxygenase (COX) activity, and it is unlikely that they act through the inhibition of prostaglandin production. Aminosalicylates are effective in the treatment of mild to moderate Crohn's disease. 5-ASA given in a controlled-release preparation is also effective as maintenance therapy to prevent recurrence after a flare of disease has been effectively managed either medically or surgically.[74–77]

Aminosalicylates come in a variety of preparations, each designed to deliver the drug in a topical fashion to the affected segments of intestine.[78] For instance, Asacol (mesalamine) is 5-ASA contained within a pH-dependent resin designed to release the drug in the terminal ileum and colon where the pH is typically greater than 7.0. Pentasa (mesalamine) is 5-ASA contained within ethylcellulose-coated microgranules designed to slowly release the active compound throughout the entire small bowel and colon. Colazal (balsalazide) is 5-ASA bound to an inert carrier by an AZO bond. This bond is broken by bacterial enzymes found within the colon, releasing the active 5-ASA compound to the colonic mucosa.

It is important to emphasize that mesalamine and its derivatives should not be confused with acetylsalicylic acid (aspirin) and other NSAIDs. Unlike 5-ASA compounds, classic NSAIDs are powerful inhibitors of COX-1 and COX-2. Many clinicians have had concerns that NSAIDs may exacerbate Crohn's disease.[79–81] Although the basis of these concerns has been challenged,[82–84] it is recommended that patients with Crohn's disease avoid NSAIDs and use alternative medications when appropriate.

Immunomodulators (Azathioprine and 6-Mercaptopurine)

Azathioprine and 6-mercaptopurine (6-MP) are immunosuppressive agents that inhibit cytotoxic T-cell and natural killer cell function. These agents are effective in treating mild to moderate Crohn's disease.[72,85] Azathioprine given at 2.0–2.5 mg/kg/d or 6-MP in doses of 1.0–1.5 mg/kg/d will result in a 50–60% response rate in patients with active Crohn's disease.[72,86] Both 6-MP and azathioprine are also effective in maintaining remission following surgery or successful medical management.[75]

Infliximab

Infliximab is a chimeric mouse-human monoclonal antibody to TNF. TNF is a proinflammatory cytokine that is believed to be important in the pathophysiology of Crohn's disease. Infliximab binds to both free and membrane-bound TNF and prevents TNF from binding to its cell surface receptors.[73] Clinical trials have demonstrated an 80% response rate with a single dose of infliximab.[87,88] It is important to note that the doses and dosing intervals of infliximab must be individualized, but a typical regimen would include 5 mg/kg of infliximab given IV at weeks 0, 2, and 6, with a dose of 5 mg/kg every 8 weeks thereafter. Because infliximab is a potent immunosuppressive agent, concerns have been raised about the risk for poor wound healing and postoperative septic complications. Current available data on the perioperative risks associated with infliximab are somewhat conflicting. Early studies have suggested that preoperative infliximab use does not appear to increase the risk for postoperative complications following abdominal surgery for Crohn's disease.[89–91] More recently, however, a study from the Cleveland clinic demonstrated an increased risk for infectious complications and intra-abdominal abscesses in Crohn's disease patients undergoing surgery who received infliximab.[92] This study also found that the presence of adverting stoma significantly decreased the risk for septic complications in patients who had been treated with infliximab.

Other Medical Therapies

Other agents that are used with varying success in the treatment of Crohn's disease include methotrexate, metronidazole, cyclosporine, tacrolimus, and thalidomide. With the exception of metronidazole, each one of these agents requires a complete and sophisticated knowledge of appropriate dosing, side effects, and therapeutic efficacy, which is beyond the scope of this chapter. Metronidazole is indicated in the maintenance therapy of chronic perineal septic complications and in the treatment of bacterial overgrowth associated with chronic obstructive disease of the small bowel. Long-term side effects include peripheral paresthesias, which are usually transient if the drug is discontinued as soon as they are experienced.

SURGICAL TREATMENT

Similarly to medical treatment, the goal of surgical treatment of Crohn's disease is to provide long-lasting symptomatic relief while avoiding excessive morbidity. Crohn's disease cannot be cured by surgical therapy, and thus surgery, like medical treatment, should be considered palliative. Complete extirpation of disease should not be the primary goal of surgery, as this does not produce cure and is frequently counterproductive. Rather, treatment of complications and palliation of symptoms while avoiding excessive loss of intestine should be the main aims of surgical treatment.

To avoid excessive loss of intestine, nonresectional techniques such as strictureplasty may be required. Additionally, optimal surgical therapy may require leaving behind segments of the intestinal tract affected by mild but asymptomatic disease with resection of only the areas of severe and symptomatic Crohn's disease. The best surgical strategy for each patient with Crohn's disease takes into account the indications for surgical treatment and the natural history of the disease, with its high risk for recurrence and the need for repeated surgeries.

Indications for Surgery

FAILURE OF MEDICAL TREATMENT

The failure to respond to medical treatment or the inability to tolerate effective therapy are the most common indications for surgical treatment of Crohn's disease.[93] Some patients may respond to the initial medical therapy only to rapidly relapse with tapering of the medical treatment. For example, some patients respond well to steroid therapy but become steroid-dependent as tapering of the steroid dose results in recurrent symptoms. Because of the severe complications that are virtually inevitable with prolonged steroid treatment, surgery is warranted if the patient cannot be weaned from systemic steroids within 3–6 months. The occurrence of complications related to the medical treatment or the progression of disease while on maximal medical treatment represent additional indications for surgical treatment.

INTESTINAL OBSTRUCTION

Partial or complete intestinal obstruction is a common indication for operation for Crohn's disease.[94] The clinical presentation of chronic partial small bowel obstruction is much more typical than complete obstruction. Patients with chronic partial small bowel obstruction due to Crohn's disease may experience postprandial cramps, abdominal distension, borborygmi, and weight loss. To avoid symptoms, many patients will restrict their diets to soft foods or even liquids. If partial obstruction from Crohn's disease is primarily due to acute inflammation and bowel wall thickening, initial medical therapy is warranted. If, however, the obstructive symptoms are due to high-grade fibrostenotic lesions, medical treatment will not reverse these lesions and surgery is indicated.

When complete intestinal obstruction occurs, initial conservative treatment with nasogastric decompression and intravenous hydration is warranted.[34,95] Intravenous steroids are also administered. This allows for decompression of acutely distended and edematous bowel and, in most cases, for resolution of the complete obstruction. Resolution of the complete obstruction should not lead the physician to attempt treating the patient with continuing medical therapy. Patients with complete obstruction who respond well to initial conservative therapy are at high risk for persistent or recurrent symptoms of obstruction and are best managed with surgery once adequate decompression is achieved. The surgery can be performed under elective and safer conditions after appropriate bowel preparation.

FISTULAS

Intestinal fistulas occur in one-third of Crohn's disease patients.[54] Intestinal fistulas, however, are the primary indication for surgery in only a minority of patients. Thus the presence of an intestinal fistula is not in and of itself an indication for surgery.[96,97] In general, intestinal fistulas are the primary indication for surgical treatment if they connect with the genitourinary tract, or if their drainage is cause for personal embarrassment and discomfort (enterocutaneous and enterovaginal fistulas), or if they create a bypass of such magnitude as to cause intestinal malabsorption.

Fistulas between the ileum and the urinary bladder often result in recurrent urinary tract infections, including pyelonephritis. While it is not mandatory to operate on all cases of enterovesical fistulas, surgery is warranted to avoid deterioration of renal function with recurrent infections or if symptoms persist in spite of appropriate medical therapy.

Enterocutaneous fistulas and enterovaginal fistulas often cause physical discomfort and personal embarrassment. A trial of medical therapy may be elected for enterocutaneous and enterovaginal fistulas, but most such cases will require surgery.[98,99]

Occasionally, an enteroenteric fistula can result in significant symptoms. Fistulas that result in functional bypass of a major intestinal segment can result in malabsorption or diarrhea. These fistulas need to be addressed surgically.

ABSCESSES AND INFLAMMATORY MASSES

Intra-abdominal abscesses and inflammatory masses occur less frequently than fistulas but are more often an indication for operative intervention.[100] Small abscesses seen on CT may warrant a trial of treatment with antibiotics, but almost all intra-abdominal abscesses will require drainage. In a vast majority of cases, Crohn's abscesses can be drained percutaneously with CT or ultrasound guidance.[101–103] The rare large intraloop abscesses may require open surgical drainage. Often, in such cases the abscess can be completely extirpated with the resection of the diseased segment of intestine.

Crohn's abscesses usually originate from a severely diseased segment of bowel. A Crohn's abscess that has been drained percutaneously is very likely to recur or result in an enterocutaneous fistula, and surgical resection is often advised even after successful drainage.[103] Inflammatory masses indicate severe disease and often harbor an unrecognized abscess.[100] Thus, inflammatory masses that do not readily respond to antibiotic treatment should be considered for surgical treatment.

PERFORATION

Free perforation is a rare complication of Crohn's disease occurring in fewer than 1% of cases.[104] When this complication occurs, it is an obvious indication for urgent operation. The diagnosis of free perforation is made by detecting a sudden change in the patient's symptoms along with the development of the physical findings of peritonitis or the identification of free intraperitoneal air as demonstrated on plain x-rays or CT scans. The use of immunosuppressants and glucocorticosteroids can blunt many of the physical findings of acute perforation; therefore the index of suspicion for perforation must be higher in immunocompromised patients

who complain of worsening symptoms or show early signs of sepsis. Most patients, however, will demonstrate classic signs of peritonitis with rebound, rigidity, guarding, and loss of bowel sounds.

HEMORRHAGE

Hemorrhage is an uncommon complication from Crohn's disease. Massive GI hemorrhage is rare and occurs more frequently from Crohn's colitis than in small bowel Crohn's disease.[105] Hemorrhage from small bowel Crohn's disease tends to be indolent with episodic or chronic bleeding requiring intermittent transfusions, but it rarely requires emergent surgery. Localization of the site of bleeding is accomplished by angiography in the presence of brisk bleeding; otherwise colonoscopy can be attempted preoperatively to localize a source of lower GI hemorrhage. Intraoperative localization can be aided by enteroscopy or colonoscopy.

When severe hemorrhage occurs in Crohn's disease, it is usually due to erosion of a single vessel by a deep ulcer or fissure. Recurrent bleeding in an area of small bowel disease is a common phenomenon, and it has been argued that even after control of hemorrhage from small bowel Crohn's disease with conservative management, elective resection of the areas of Crohn's disease should be undertaken to prevent recurrent bleeding.

Patients with Crohn's disease are also at risk for bleeding from peptic ulcer disease. This is particularly true for patients receiving corticosteroid therapy. For this reason, Crohn's disease patients who develop GI bleeding should undergo an upper endoscopy to rule out gastric or duodenal ulcers.

CANCER OR SUSPICION OF CANCER

The presence of Crohn's disease increases the risk of adenocarcinoma of the colon and small intestine.[106] The diagnosis of adenocarcinoma of the small bowel is difficult because symptoms and radiographic findings of small bowel malignancy can be similar to those of the underlying Crohn's disease. Male patients and patients with long-standing disease appear to be at increased risk for small bowel adenocarcinoma.[106] Defunctionalized segments of bowel also seem to be at particular risk for malignancy.[107] For this reason, bypass surgery should be avoided for Crohn's disease of the small intestine, and defunctionalized rectal stumps should either be restored to their function or excised.

Adenocarcinoma of the small intestine should be suspected in any patient with long-standing disease whose symptoms of obstruction progress after a lengthy quiescent period. Surveillance for colonic malignancies can be undertaken by colonoscopy with random mucosal biopsy. If dysplasia is encountered, resection of the areas of Crohn's disease should be considered.[108,109] Areas of stricture formation within the colon should be closely examined and biopsied. Strictures that are too narrow to allow passage of the colonoscope or cannot be adequately assessed colonoscopically should be resected.

GROWTH RETARDATION

Growth retardation occurs in a quarter of children affected by Crohn's disease. Although steroid treatment may delay growth in children, the major cause of growth retardation in Crohn's disease patients is the malnutrition associated with active intestinal disease.[110,111]

Preoperative Preparation and Evaluation

A complete assessment of the GI tract is required prior to surgery. Full delineation of the extent of disease and associated complications is necessary to plan for the optimal surgical strategies.

Assessment of the small intestine can be performed with a small bowel follow-through, an enteroclysis study or a CTE. The colon and rectum are best evaluated by colonoscopy. Barium enema studies can also be used to evaluate for colonic disease, particularly in cases in which strictures do not allow passage of the colonoscope. If the patient has had a previous resection of the ileocecal valve, a contrast enema can be a useful means of evaluating the ileocolonic anastomosis and the preanastomotic segment for recurrent disease. If an abscess, fistula or inflammatory mass is suspected, a CT scan of the abdomen and pelvis with both oral and IV contrast should be obtained. CTE combined with ileocolonoscopy is used by many as a first-line test for the staging of Crohn's disease.[59] In patients in whom urgent surgery is required, a full evaluation of the GI tract prior to surgery may not be feasible. In these cases, evaluation of disease must be accomplished intraoperatively, and both the patient and the surgeon must be prepared for a wide variety of surgical possibilities.

As with preparation for any major operation, metabolic derangements must be treated prior to surgery. Fluid and electrolyte abnormalities must be corrected. Patients with profound anemia need to be transfused and coagulopathies must be addressed. Patients with cardiovascular or pulmonary disease should have the condition stabilized and their functional capacity optimized prior to operation. Most patients with Crohn's disease will not require preoperative parenteral nutrition, as most suffer from only a minor degree of malnutrition. There are rare cases, however, in which the nutritional status of the patient has been so severely compromised that they benefit from several weeks of bowel rest, hyperalimentation, and ongoing medical treatment before operation.

The absolute need for mechanical bowel preparation is controversial.[112–114] Traditionally mechanical bowel preparations have been an unquestioned standard to lessen the risks of sepsis and to allow for a safe anastomosis. Recently these advantages have been challenged.[112,113] Even so, it is common practice for patients undergoing intestinal resection for Crohn's disease to undergo a complete mechanical bowel preparation with either polyethylene glycol or sodium phosphate. Should the patient be unable to tolerate oral preparations, enemas can be utilized. Prophylactic broad-spectrum antibiotics are administered perioperatively,[115] and stress dose

steroids must be given to patients suspected of hypothalamic-pituitary-adrenal suppression. If feasible, well-contained intra-abdominal abscesses should be drained percutaneously prior to surgery. If an abdominal stoma is contemplated, the optimal site for the stoma location should be marked preoperatively. In patients in whom preoperative CT scan suggests significant inflammation in proximity to the ureters, preoperative ureteral stenting can be helpful.

Some have suggested that, to improve the safety of surgery for Crohn's disease, anti-inflammatory Crohn's medication should be either lowered or discontinued prior to elective surgery. Recent studies, however, have shown that preoperative use of steroids and antimetabolites does not appear to affect the perioperative morbidity, and hence discontinuation of these medications is not likely to result in significant benefit. Methotrexate and infliximab, on the other hand, are two medications that may be worth discontinuing at least 2 weeks and 2–3 months, respectively, prior to surgery. Laboratory studies have shown decreased wound healing with methotrexate,[116] and clinical data to evaluate the safety of methotrexate in patients undergoing bowel resection with anastomosis are lacking. A recent study from the Cleveland clinic has demonstrated an increased risk for infectious complications and intra-abdominal abscesses after recent treatment with infliximab.[92] If surgical treatment is necessary within 2 months after an infliximab infusion, consideration should be given to postpone reestablishment of the GI continuity or to protecting a newly fashioned anastomosis with a diverting stoma.

Surgical Options

INTESTINAL RESECTION

Intestinal resection with anastomosis or stoma formation is the most common surgical procedure performed for the treatment of Crohn's disease. Most cases of Crohn's disease require only limited resections that are generally well tolerated and do not place these patients at risk for short bowel syndrome. Cumulative clinical data including randomized studies have indicated that resection of Crohn's disease need only encompass the grossly apparent disease, as wider resections do not improve the outcome after surgery.[117–120] Microscopic resection margins that are grossly normal but demonstrate microscopic evidence for Crohn's activity do not result in early recurrence or other complications. Hence, intraoperative frozen section of the resection margins is not necessary.[121]

The extent of mesenteric dissection does not affect the long-term results either; hence the mesentery can be divided at the most advantageous level. Division of the thickened mesentery of small bowel Crohn's disease can be the most challenging aspect of the procedure. Identification and isolation of individual mesenteric vessels is not feasible with a thickened Crohn's mesentery. Although many approaches to this problem have been described, a common technique is to apply overlapping clamps on either side of the intended line of transection. The mesentery is then divided between the clamps, and the tissue contained within the clamps is suture-ligated (Fig. 33-4). In severe cases, a vascular clamp may be used at the root of the small bowel mesentery to obtain proximal control: mattress sutures may then need to be applied to the cut edge of the mesentery to control bleeding. The use of tissue welding devices such as the LigaSure device (Valleylab, Boulder, CO) can be useful for sealing vessels within the thickened mesentery. Even with these devices, mattress sutures in the mesentery are commonly needed for complete hemostasis. In spite of the difficulty dealing with the thickened and often hyperemic mesentery, resection can be performed with a low risk for postoperative hemorrhage and the risk for postoperative hemoperitoneum requiring reexploration has been reported to be less than 0.5%.[93]

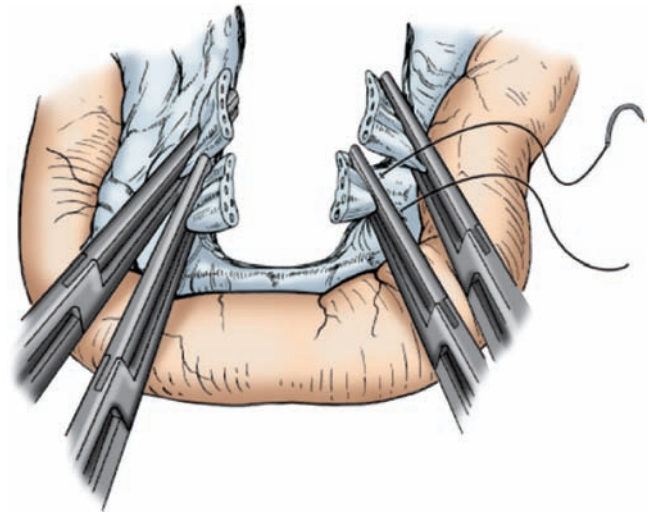

FIGURE 33-4 Technique for division of thickened Crohn's mesentery.

ANASTOMOSIS

There is no overriding consensus regarding the optimal technique for intestinal anastomosis in Crohn's disease.[74,122–126] It is well established that recurrent Crohn's disease after resection of terminal ileal disease is most likely to occur at the ileocolonic anastomosis or at the preanastomotic ileum. It has been proposed that large-caliber anastomoses require a longer period to stricture down to a critical diameter that becomes symptomatic. The argument is made that a longer side-to-side anastomosis may be beneficial over an end-to-end or end-to-side anastomosis.[125] To date, however, clinical data do not indicate a benefit for one particular intestinal configuration over another.[124] Intestinal anastomosis for Crohn's disease cases can be fashioned with a stapling device or may be hand-sutured. When performed under selective conditions, resection with primary anastomosis for Crohn's disease can be performed with a high degree of safety and small bowel anastomotic dehiscence rates can be kept under 1%.[93] In the presence of sepsis, severe scarring, malnutrition, or recent use of methotrexate or infliximab, it may be wise to protect

the anastomosis with a proximal loop stoma or to forego the anastomosis altogether and bring out an end stoma at the point of resection.

STOMA FORMATION

Permanent stomas are required for the surgical treatment of Crohn's proctitis and occasionally required for the management of severe, unrelenting perianal disease. Temporary stomas are much more common and typically used as a means of protecting a distal anastomosis or when an anastomosis is not advisable.

If an ileostomy or colostomy is contemplated, selection of the optimal placement of the stoma should be determined preoperatively.[127] Proper stoma location is critical to achieve a satisfactory stoma. It is preferable to locate the ileostomy over the left or right rectus abdominis muscle on a flat area away from deep skin folds and bony prominences.[128] The surface of the abdomen must be evaluated in both the sitting and standing positions, as this will often demonstrate skin folds and creases not evident in the supine position. Attention must be paid to determining the level of the patient's belt line and every effort is made to place the stoma below it. Once the optimal position of the stoma has been identified, it is marked in a manner that will remain visible at the time of surgery.

Complications related to intestinal stomas are common. They include peristomal hernia, prolapse, and stricture. Peristomal hernia is the most common ostomy-related complication. It can be anticipated that approximately 25% of patients with a permanent stoma will require surgical revision of their ostomy to deal with one or more of these complications.[129]

BYPASS PROCEDURES

Bypass procedures became popular in the 1940s and 1950s once physicians and surgeons realized that aggressive enterectomies did not reduce the incidence of recurrence and were fraught with the development of short gut syndrome. Initially conceived to bypass an area of stricture or obstruction, the use of bypass procedures was eventually extended to Crohn's disease complicated by septic complications. Increased experience with bypass procedures revealed that persistence of disease put patients at risk of persistent sepsis and eventually neoplastic transformation. Because of these complications, bypass procedures were supplanted by limited intestinal resection as the main surgical option in the late 1960s in all intestinal districts except the duodenum, where a simple side-to-side retrocolic gastrojejunostomy adequately relieves the obstructive symptoms. With increased experience and confidence in the performance of strictureplasty, duodenal disease is nowadays more and more commonly handled with strictureplasties.

STRICTUREPLASTY

Strictureplasty techniques have gained popularity as a safe and effective means of treating stricturing Crohn's disease of the small intestine without resorting to lengthy resections. Strictureplasties are best used when resection would otherwise result in loss of a lengthy segment of bowel and thus place the patient at risk for short bowel syndrome. This would include cases with long segments of stricturing disease and patients with multiple prior resections. They are also indicated when they offer a simpler alternative to resection, such as in short recurrent disease at a previous ileocolic or enteroenteric anastomosis.

It is generally accepted that the advantage conferred by a strictureplasty over a resection in the preservation of intestinal absorptive capacity is mainly due to the sparing of normal areas in between strictures that would be otherwise sacrificed. Although this is true, there is increased evidence that the acuity of the disease decreases at the site of the strictureplasty and the disease becomes quiescent.[130] Whether this correlates with a simultaneous restoration of absorptive function has not yet been established.

The most commonly performed strictureplasty is the Heinecke-Mikulicz strictureplasty.[131–133] The Heinecke-Mikulicz is named after the pyloroplasty technique from which this procedure is derived. With the Heinecke-Mikulicz strictureplasty, a longitudinal incision is made along the antimesenteric border of the stricture (Fig. 33-5). This incision should extend for 1–2 cm into the normal elastic bowel on either side of the stricture. Once the enterotomy is made, the area of the stricture should be closely examined. If there is any concern that the stricture may harbor a malignancy, a biopsy with frozen section must be obtained. Complete hemostasis should be obtained with precise application of electrocautery.

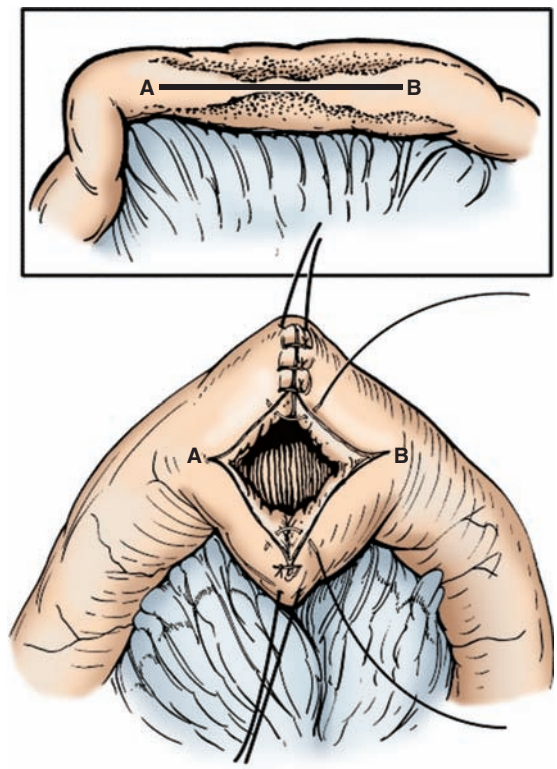

FIGURE 33-5 Heineke-Mikulicz strictureplasty.

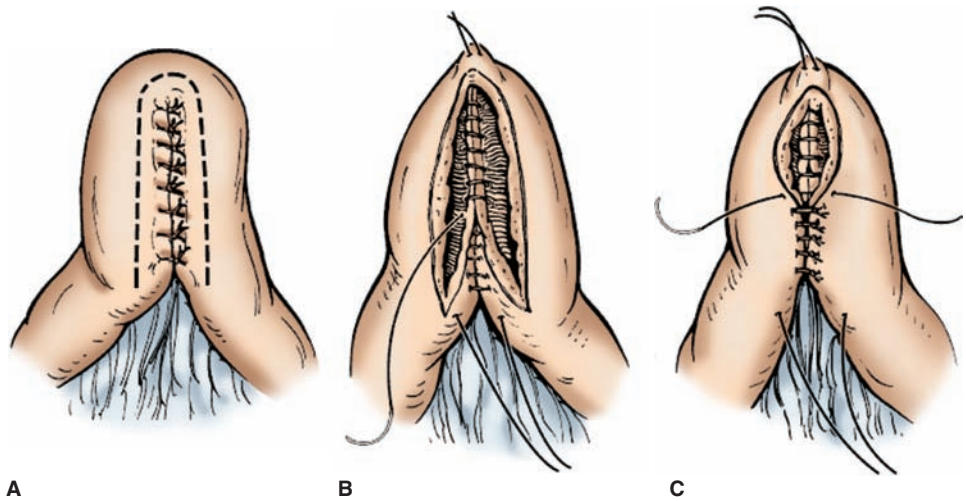

FIGURE 33-6 Finney strictureplasty.

The longitudinal enterotomy of the Heinecke-Mikulicz strictureplasty is then closed in a transverse fashion. The closure can be accomplished with either single- or double-layered sutures. The Heinecke-Mikulicz stricture technique is appropriate for short-segment strictures of 2–5 cm in length.

The Finney strictureplasty, also named for the pyloroplasty technique from which this approach is derived, can be used for strictures up to 15 cm in length.[131] With the Finney strictureplasty technique, the strictured segment is folded onto itself in a U-shape[134] (Fig. 33-6). A row of seromuscular sutures is placed between the two arms of the U, and a longitudinal U-shaped enterotomy is then made paralleling the row of sutures. The mucosal surface is examined and biopsies are taken as necessary. Hemostasis is obtained with electrocautery. Full-thickness sutures are then placed beginning at the posterior wall of the apex of the strictureplasty and then continued down to approximate the proximal and distal ends of the enterotomy. This full-thickness suture line is then continued anteriorly to close the strictureplasty. To complete the procedure, a row of seromuscular Lembert sutures is placed anteriorly. In essence, the Finney is a short side-to-side functional anastomosis. A very long Finney strictureplasty may result in a functional bypass with a large lateral diverticulum. This diverticulum, in theory, could be at risk for bacterial overgrowth and the blind loop syndrome. Fortunately, this theoretical concern has not been observed in clinical practice.

The purpose of the strictureplasty is to preserve intestinal length that otherwise would be sacrificed with resection. Those cases with long segments of stricturing disease are the ones in which nonresectional methods should be aggressively pursued. To manage such cases, multiple strictureplasties are typically required. In general, however, repeated Heinecke-Mikulicz or Finney strictureplasties should be separated from each other by at least 5 cm. Otherwise the result can be a bulky and relatively unyielding segment of intestine with considerable tension placed on each suture line.

Patients with long-segment stricturing disease and multiple strictures grouped close together are best managed with a side-to-side isoperistaltic strictureplasty, also called *Michelassi strictureplasty*.[135] With this technique, the segment of stricturing disease is divided at its midpoint. The proximal and distal ends are then drawn onto each other in a side-to-side fashion (Fig. 33-7). Division of some of the mesenteric vascular arcades facilitates the positioning of the two limbs over each other. The proximal and distal loops are then sutured together with a layer of interrupted seromuscular sutures. A longitudinal enterotomy is then made along both of the loops (Fig. 33-8). The intestinal ends are spatulated to provide a smoothly tailored fit to the ultimate closure of the strictureplasty. Again, this is the time to examine the mucosal surface of the intestine to detect potential areas of neoplastic transformation and control bleeding. The outer suture line is

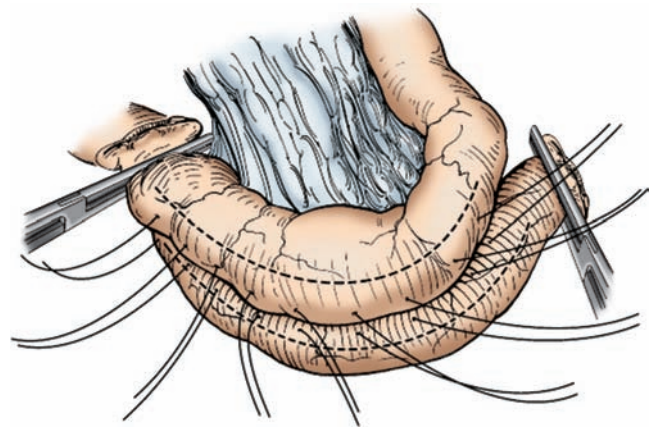

FIGURE 33-7 Isoperistaltic side-to-side strictureplasty. The segment of intestine affected by Crohn's strictures is divided and the two limbs are drawn onto each other.

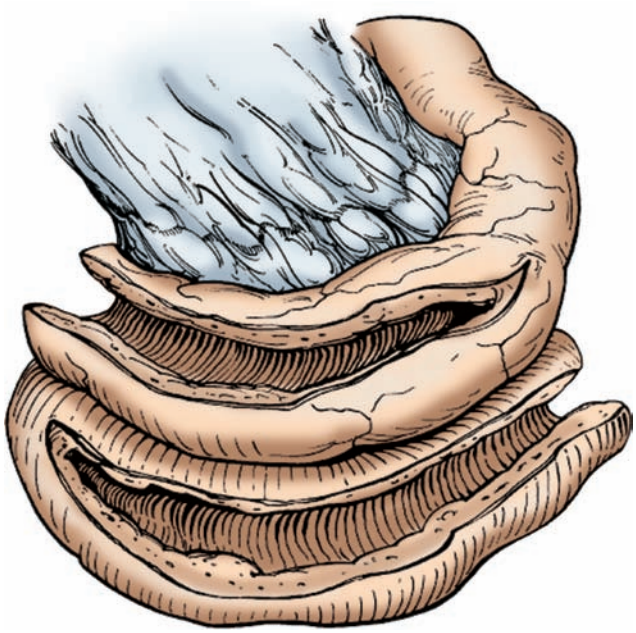

FIGURE 33-8 Isoperistaltic side-to-side strictureplasty. Longitudinal enterotomies are made along the antimesenteric borders of the two limbs.

reinforced with an interior row of either interrupted or running full-thickness sutures. This inner suture line is continued anteriorly. The anterior closure is then reinforced with an outer layer of interrupted seromuscular sutures to complete the strictureplasty (Fig. 33-9).

Originally described in 1996, this procedure has been utilized with increasing frequency. The isoperistaltic side-to-side strictureplasty is recognized as an effective means of treating extensive small bowel Crohn's disease and provides the best option for those cases that would otherwise require extensive intestinal resection with loss of significant length of small bowel.[130,133,136,137]

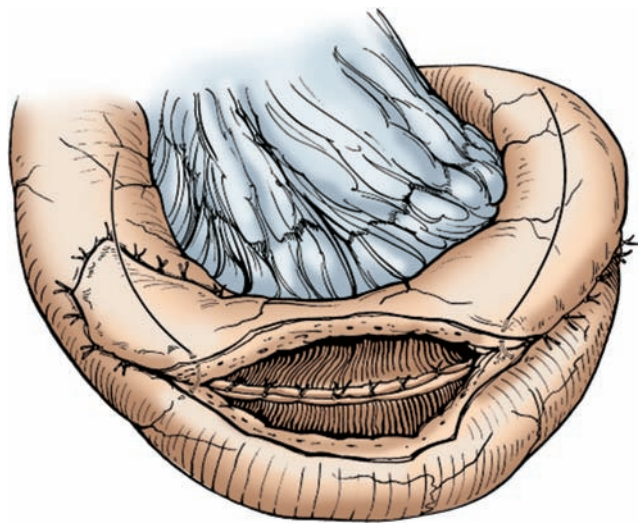

FIGURE 33-9 Isoperistaltic side-to-side strictureplasty. The two limbs are anastomosed together in a lengthy side-to-side fashion.

Unlike resection, diseased segments are retained with strictureplasty and suture lines are placed in Crohn's disease–affected tissue. This has been a cause of concern regarding the risk of intestinal suture line dehiscence, long-term recurrences, and risk for malignancy. The ongoing and now substantial clinical experience with these techniques has allayed these concerns.[138] In appropriately selected patients, perioperative morbidity from strictureplasty appears to be similar to that of resection and primary anastomosis. Specifically, intestinal suture line dehiscence appears to be uncommon with any of the described strictureplasty techniques.[139,140] The most common postoperative complication directly related to strictureplasty is hemorrhage from the strictureplasty site. This has been reported to occur in up to 9% of cases. Fortunately, the GI hemorrhage following strictureplasty is typically minor and can be managed conservatively with transfusions alone. Rarely, more persistent bleeding may require intra-arterial infusion of vasopressin, but the need for reoperation to control hemorrhage after strictureplasty is very rare. It is by now also well established that strictureplasty techniques provide excellent long-term symptomatic relief that is comparable to resections with anastomosis. Although there are no controlled studies directly comparing strictureplasty to resection, multiple reports of the observed symptomatic recurrence rates after strictureplasty compare well with published recurrence rates after resection and anastomosis.[133,140,141]

Epidemiological studies have shown an increased risk for small bowel adenocarcinoma in Crohn's disease patients.[108] This risk is increased in patients with long-standing disease. It is not known if strictureplasty by virtue of its retention of diseased tissue increases this risk. At the time of the writing of this chapter, there have been only two reported cases of an adenocarcinoma developing at a site of previous small bowel strictureplasty, and it is thus believed that the risk of malignancy after strictureplasty is low.[142,143]

Laparoscopy

Over the past two decades, laparoscopy has been dramatically changing all aspects of GI surgery. Specifically in colon and rectal surgery, laparoscopy has been widely used in benign disease,[144,145] including inflammatory bowel disease, and more recently in colon cancer.[146] Several single-institution small reports suggest that not only is laparoscopic surgery for Crohn's disease feasible and safe, but also it reduces length of hospitalization and recovery and allows for a smaller wound, with an overall reduction in morbidity.[147–160]

Most Crohn's disease patients are well suited for laparoscopy. They are usually young, otherwise healthy, and interested in undergoing an operation that involves minimal scarring, because they face the risk of multiple major abdominal operations in their lifetime. On the other hand, Crohn's disease represents a difficult arena even for the experienced open

colorectal surgeon. Many of the unique features of Crohn's disease, such as the intense inflammation and thickened mesentery, enteric fistula, inflammatory masses or abscesses, and the multiplicity of areas of intestinal involvement, have deterred many surgeons from even considering a laparoscopic approach.

Two prospective controlled studies have shown several advantages of the laparoscopic-assisted approach over the conventional approach.[147,149] Bemelman and colleagues compared 48 open ileocolic resections with 30 laparoscopic-assisted resections. This study showed similarly low morbidity rates in both groups but a shorter hospital stay and improved cosmetic results in favor of the laparoscopic group.[149] Alabaz and associates compared 48 open ileocolic resections with 26 laparoscopic-assisted resections. The patients in the laparoscopic group returned to work more quickly, had better cosmetic results, and were more likely to have improved postoperative quality of life.[147] A prospective randomized trial comparing open and laparoscopic-assisted resections in 60 patients undergoing elective ileocecectomy for Crohn's disease not complicated by abscess formation or complex fistula showed a faster postoperative recovery of respiratory function (measured as recovery of 80% of forced respiratory volume and forced vital capacity), shorter abdominal incisions, and longer performance time in the laparoscopic-assisted group. These differences were all statistically significant. With limited follow-up, there was no difference in recurrence rate.[154] This paper demonstrated that in experienced hands, morbidity from the laparoscopic approach compares favorably with that of a conventional open approach. Obviously these results need to be confirmed by larger series with longer follow-up.

The indications for laparoscopic surgery for Crohn's disease should not differ from conventional open surgery as described previously. Contraindications to a laparoscopic approach include patients who are critically ill and unable to tolerate the pneumoperitoneum due to hypotension or hypercarbia, patients with extensive intra-abdominal sepsis (abscess, free perforation, or complex fistula), and difficulty in identifying the anatomy (previous surgery, obesity, or adhesions). The same variety of surgical procedures described previously can be performed laparoscopically.

After induction of general anesthesia, the patient is placed on the operating table supine or in the modified lithotomy position. Rectal irrigation with diluted iodine solution is performed, especially in patients with involvement of the rectum and sigmoid colon. An epidural catheter is usually inserted at the time of surgery. The sympathetic blockade achieved with epidural administration of local anesthetics and opioids prevents bowel distension, hence facilitating exploration of the GI tract and handling of the bowel. Depending on the procedure planned, four or five trocars are utilized, with the camera placed at the level of the umbilicus.

Every operation for Crohn's disease, whether open or laparoscopic, should start with a complete examination of the entire GI tract starting from the ligament of Treitz. The patient is placed in the reverse Trendelenburg position and right lateral decubitus with the assistant standing on the patient's left side retracting the transverse colon into the upper quadrants and the surgeon at the right of the patient or in between the patient's legs, tracing the intestine from the ligament of Treitz all the way to the ileocolic pedicle. This maneuver is facilitated by progressively rotating the patient from the reverse Trendelenburg to a full Trendelenburg position and left lateral decubitus. In the presence of skip areas of involvement from Crohn's disease, these are marked intracorporeally with sutures in order to facilitate retrieval of the diseased segments when the specimen is exteriorized.

Laparoscopic-assisted ileocolic resection is the most commonly performed laparoscopic procedure for Crohn's disease. For laparoscopic ileocolectomy, a four-trocar technique is utilized (Fig. 33-10). Trocars of 5 mm can be used exclusively, as a 5-mm, 30-degree camera offers the same resolution as larger ones and the vascular pedicles can be divided intracorporeally with 5-mm instruments. After the bowel has been evaluated in its entirety as previously described, the assistant, standing on the right of the patient or in between the patient's legs, places the ileocolic pedicle under tension with an intesti-

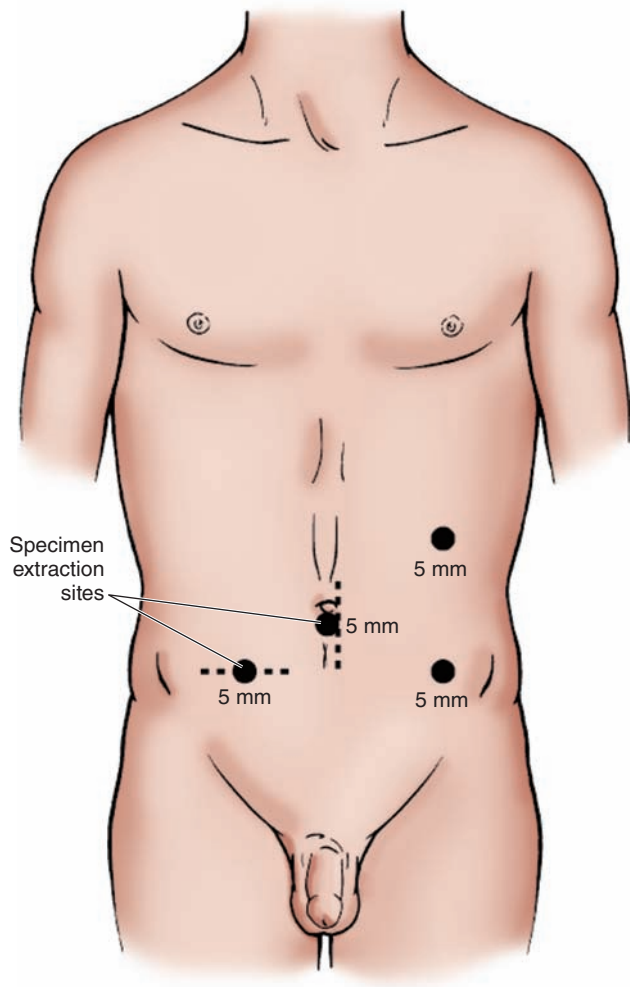

FIGURE 33-10 Port site locations for laparoscopic ileocecectomy.

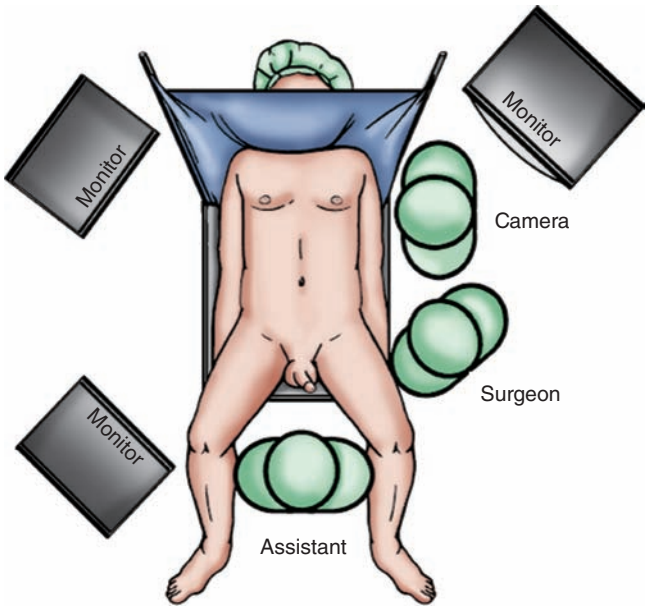

FIGURE 33-11 Optimal position of the surgeons and assistants for laparoscopic ileocecectomy.

nal grasper placed through the right lower quadrant trocar (Fig. 33-11). The surgeon on the patient's left side dissects and divides it (Fig. 33-12). Once this is accomplished, a medial-to-lateral submesenteric mobilization of the ascending colon all the way to the hepatic flexure is completed (Fig. 33-13). When the submesenteric mobilization is completed, the lateral colonic peritoneal reflection is divided all the way to the hepatic flexure (Fig. 33-14). The terminal ileum is completely mobilized by dividing the peritoneum at the level of the pelvic rim to allow a tension-free anastomosis through a small incision. It is often necessary to completely mobilize the hepatic flexure without dividing the right branch of the ileocolic vessels in order to facilitate exteriorization of the specimen (Fig. 33-15). It is imperative to make sure that the mobilization is adequate before evacuating the pneumoperitoneum and making an incision to avoid a difficult anastomosis through a small incision or the need for a larger incision to exteriorize the specimen. Should this occur, a gel port can be applied through the abdominal incision to allow for creation of the pneumoperitoneum again and further intra-abdominal dissection.

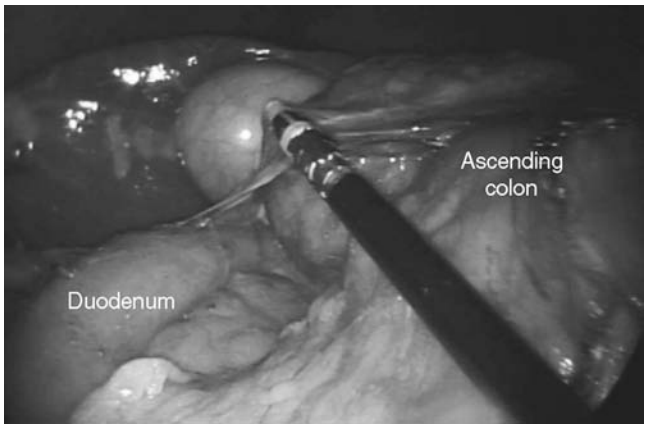

FIGURE 33-15 Final mobilization of the hepatic flexure. (Reprinted, with permission, from the University of Chicago General Surgery Archives.)

Once the ileum, cecum, and ascending colon are fully mobilized, the instruments are removed. With the pneumoperitoneum still in place, the umbilical port site or the right lower quadrant port site is enlarged. The pneumoperitoneum is evacuated and the specimen is exteriorized. The ileocolonic resection is then completed by dividing the remainder of the mesentery and the bowel extracorporeally. An anastomosis is then constructed in a standard fashion.

MANAGEMENT OF COMPLICATED CROHN'S DISEASE

Crohn's Disease of the Duodenum

Primary Crohn's disease of the duodenum almost always manifests with stricturing disease that can be managed by strictureplasty or with bypass procedures (Fig. 33-16). Fortunately, resection of the duodenum for Crohn's disease is almost never required.[161–163] Perforating Crohn's disease almost never affects the duodenum. When the duodenum is involved with Crohn's fistulas, it is always the result of disease within a distal segment (typically the terminal ileum or neoterminal ileum) that fistulizes into an otherwise normal duodenum.[164] Yet, Crohn's disease of the duodenum can offer a particularly challenging problem due to the retroperitoneal location of the organ and its intimate proximity with the pancreas.

Stricturing disease of the duodenum is often focal and many cases can be managed with a strictureplasty.[165] In order to safely accomplish a strictureplasty, the duodenum must be fully mobilized with a generous Kocher maneuver. Heinecke-Mikulicz strictureplasties can be safely performed in the first, second, and proximal third portion of the duodenum. Strictures of the last portion of the duodenum are better handled with a Finney strictureplasty constructed by creating an enteroenterostomy between the fourth portion of the duodenum and the first loop of the jejunum.

FIGURE 33-16 Upper GI study demonstrating Crohn's strictures of the duodenum. Contrast seen within the biliary ducts is due to deformity and incompetence of the ampullary sphincter secondary to the Crohn's disease. (Reprinted, with permission, from the University of Chicago General Surgery Archives.)

If the duodenal stricture is lengthy or the tissues around the stricture are too rigid or unyielding, a strictureplasty should not be performed and an intestinal bypass procedure should be undertaken. The most common bypass procedure performed for duodenal Crohn's disease is a simple side-to-side retrocolic gastrojejunostomy.[121] This procedure effectively relieves the symptoms of duodenal obstruction related to Crohn's strictures but carries a high risk for stomal ulcerations. To lessen the likelihood of ulcerations forming at the anastomosis, it has been recommended that a vagotomy be performed along with the gastrojejunostomy.[121] Because of the concerns of vagotomy-related diarrhea, a highly selective vagotomy is preferred to a truncal vagotomy. If the stricturing Crohn's disease is limited to the third or fourth portions of the duodenum, a Roux-en-Y duodenojejunostomy to the proximal duodenum is preferred to a gastrojejunostomy.[164] The Roux-en-Y duodenojejunostomy has the advantage of bypassing strictures and eliminates the concern regarding acid-induced marginal ulceration and the need for vagotomy.

As noted previously, when the duodenum is involved with a Crohn's fistula, it is almost always the case that the diseased segment is located distal in the GI tract and the duodenum itself is otherwise free of active Crohn's disease.[164] Most of these duodenal fistulas are small in caliber and asymptomatic, but larger fistulas may shunt the duodenal contents to the distal small bowel such that malabsorption and diarrhea result. In the majority of cases, duodenoenteric fistulas are identified

with preoperative small bowel radiography; however, many are discovered only at the time of surgery.[166] With complex fistulizing disease involving an inflammatory mass, great care at the time of surgery should be undertaken to limit the size of the duodenal defect resulting from the resection of the fistula. Most duodenal fistulas are located away from the pancreaticoduodenal margin, and thus these fistulas can be managed by resection of the primary Crohn's disease with primary closure of the duodenal defect. Larger fistulas or fistulas that are involved with a large degree of inflammation may result in a sizable duodenal defect. Such large defects may require closure with a Roux-en-Y duodenojejunostomy or with a jejunal serosal patch.[166,167] As noted previously, duodenal resections are almost never necessary for Crohn's disease and they should be considered the surgical option of last resort.

Crohn's Disease of the Small Bowel

COMPLETE INTESTINAL OBSTRUCTION

Complete small intestinal obstruction resulting from Crohn's disease only rarely requires urgent surgical intervention, as the vascular supply to the intestinal loop is never compromised and almost all cases of complete or high-grade partial small bowel obstruction from Crohn's disease respond to conservative management. Such patients should be treated with nasogastric decompression, intravenous hydration, and steroid therapy.[121] This program allows for resolution of the acute episode of obstruction in a vast majority of cases. Unfortunately, most patients whose Crohn's disease is severe enough to experience an episode of complete or high-grade partial obstruction are at high risk for recurrent episodes and persistent symptoms. For this reason, elective surgery should be considered once the episode of complete obstruction has resolved. The advantage of this approach is that surgery can be performed under safer conditions when the obstruction has resolved, the bowel is not distended or edematous, and an appropriate bowel preparation has been performed. If the obstruction fails to respond to appropriate conservative treatment, surgery is required. In these situations, the surgeon needs to have a high index of suspicion for small bowel cancer as the cause of the obstruction, as obstructions from cancers do not respond to bowel decompression and steroid treatment.

ILEOSIGMOID FISTULAS

Ileosigmoid fistula is a common complication of perforating Crohn's disease of the terminal ileum. Typically, the inflamed terminal ileum adheres to the sigmoid colon that is otherwise normal and free of primary involvement of Crohn's disease. Most ileosigmoid fistulas are small and do not produce any symptoms. Asymptomatic ileosigmoid fistulas do not in and of themselves require operative management. On the other hand, large ileosigmoid fistulas can result in bypass of the intestinal contents from the terminal ileum to the distal colon and thus give rise to debilitating diarrhea (Fig. 33-17). Such

FIGURE 33-17 Contrast enema demonstrating large ileosigmoid fistula. (Reprinted, with permission, from the University of Chicago General Surgery Archives.)

symptomatic fistulas often fail to respond to medical therapy and should be managed surgically.

More than half of the ileosigmoid fistulas from Crohn's disease are not recognized prior to surgery.[168] For this reason, the surgeon should be prepared to deal with this complication in any case of Crohn's disease that involves the terminal ileum. Ileosigmoid fistulas can be managed by simple division of the fistulous adhesion and resection of the ileal disease. The defect in the sigmoid colon is then débrided and simple closure is undertaken. In this manner, 75% of ileosigmoid fistulas can be managed.[55,168] The remainder require resection of the sigmoid colon. Sigmoid colon resection is necessary when primary closure of the fistula is at risk for poor healing. This is the case either when the sigmoid is also involved in Crohn's disease when the fistulous opening is particularly large, or when there is extensive fibrosis extending along the sigmoid colon. Also, fistulous tracts that enter the sigmoid colon in proximity to the mesentery can be difficult to close and often require resection and primary anastomosis.

ILEOVESICAL FISTULA

Ileovesical fistulas occur in approximately 5% of Crohn's disease patients.[93] Hematuria and fecaluria are virtually diagnostic of ileovesical fistula, but these symptoms are absent in one-third of cases.[169] Small bowel x-rays, cystograms, and cystoscopy often do not detect the fistula. Air within the bladder, as noted on CT scan, is often the best indirect evidence for the presence of an enterovesical fistula. An ileovesical fistula is an indicator of complex fistulizing disease, as most ileovesical fistulas occur along with other enteric fistulas. For example,

as many as 60% of patients with an ileovesical fistula will also have an ileosigmoid fistula.[55]

The necessity for surgery for ileovesical fistula is controversial. Many patients with ileovesical fistulas can be managed medically for extended periods of time without significant complications. Healing rates with medical treatment are not clearly defined, but they are probably low and most patients with ileovesical fistulas will ultimately come to surgery. Surgery is indicated when recurring urinary infections occur, particularly pyelonephritis, with concomitant potential for worsening of renal function.

Surgical treatment of ileovesical fistulas requires resection of the ileal disease with closure of the bladder defect. Most ileovesical fistulas involve the dome of the bladder, and thus débridement and primary closure can be accomplished without risk of injury to the trigone. Decompression of the bladder with an indwelling Foley catheter should be continued postoperatively until the bladder is confidently healed without leaks. A cystogram taken on postoperative day 5 is a convenient means for confirming the seal of the bladder repair and the safety of removing the Foley catheter.

ENTEROVAGINAL AND ENTEROCUTANEOUS FISTULAS

These are rare fistulas caused by perforating small bowel disease draining through the vaginal stump in a female who has previously undergone a hysterectomy or through the abdominal wall, usually at the site of a previous scar. These fistulas often require surgical intervention because they cause physical discomfort and personal embarrassment. Surgical treatment requires resection of the small bowel disease. The vaginal cuff does not need to be closed; the chronic infection along the abdominal wall fistulous tract requires debridement and wide drainage to allow healing by secondary intention.

ABSCESS

Intra-abdominal abscesses that result from Crohn's disease tend to follow an indolent course with modest fever, abdominal pain, and leukocytosis. Rapidly progressive and overwhelming sepsis is not typical for the clinical course of Crohn's disease–related abscesses. In fact, in up to one-third of intra-abdominal Crohn's abscesses preoperative clinical signs of localized infection are absent and the abscesses are discovered only at the time of operation. When an abscess is suspected or an abdominal mass is palpated, a CT scan should be obtained, as 50% of tender intra-abdominal masses will harbor an abscess collection within.[100] The CT scan can detect most chronic abscesses and can also delineate the size and location of the abscess as well as the relationship of the abscess to critical structures such as the ureters, duodenum, and the inferior vena cava (Fig. 33-18).

Most abscesses with Crohn's disease are in fact very small collections that are contained within the area of diseased intestine and its mesentery. In the case of small intraloop or intramesenteric abscesses, resection of the defective segment and its mesentery often extirpates the abscess such that drains are not necessary and primary anastomosis can be performed without risk.

FIGURE 33-18 CT scan of the pelvis demonstrating large Crohn's abscess. (Reprinted, with permission, from the University of Chicago General Surgery Archives.)

Large abscesses related to Crohn's disease are best managed with CT-guided percutaneous drainage.[102] Percutaneous drainage is often very effective at controlling the sepsis and healing the abscess cavity.[101] With percutaneous drainage of a Crohn's disease abscess, an enterocutaneous fistula often occurs as the abscess typically connects to a deeply penetrating sinus emanating from a segment of Crohn's disease–affected intestine. Percutaneous drainage then completes the fistulous tract from the intestine through the sinus to the abscess cavity and out the drain. Such a fistula may spontaneously close or it may persist, and the intestine may continue to be a source of sepsis. With successful drainage of the abscess, the sepsis often clears well enough that it can be tempting to try to manage the disease without subsequent surgery. Published clinical data on the optimal approach to such patients are unfortunately lacking. Even so, in the absence of Crohn's symptoms, initial nonoperative management after successful percutaneous drainage can be undertaken in carefully selected patients.[103] On the other hand, if drainage through the fistula continues, surgical resection of the affected segment of intestine becomes necessary.

PERFORATION

Free perforation is a surprisingly uncommon phenomenon because the chronic progressive inflammation of Crohn's disease normally leads to adhesions with adjacent structures. Most perforations from Crohn's disease occur in the ileum and are usually proximal to a stenotic lesion.[104,121] The diagnosis of free perforation is made by detecting a sudden change in the patient's symptoms along with the development of the physical findings of peritonitis or the identification of free intraperitoneal air as demonstrated on plain x-rays or CT scans. Free perforation is an absolute indication for emergent laparotomy with resection of the diseased segment and exteriorization of the proximal bowel as an end ileostomy. The distal bowel end

can be exteriorized as a mucous fistula or closed as a defunctionalized pouch, depending on the degree of peritoneal contamination. Creation of a primary anastomosis even with a proximal protecting loop ileostomy carries a high risk of anastomotic breakdown and should be avoided. Primary closure of the perforation should never be attempted, as sutures will not be able to approximate the edges of the perforated, edematous, and diseased bowel in a satisfactory and tension-free way and the presence of a distal intestinal stenosis or partial obstruction will cause an increase in the intraluminal pressure at the level of the local repair with subsequent dehiscence.

HEMORRHAGE

Hemorrhage from small bowel Crohn's disease is managed by resection of the diseased portion of intestine. For patients with multiple skip areas of Crohn's disease, small bowel angiography may be attempted to localize the exact site of bleeding.[105] Localization with angiography may be unsuccessful if the bleeding is episodic or insufficiently brisk to be identified with angiography. In patients in whom small bowel hemorrhage stops spontaneously, the risk for rebleeding is high. Thus elective resection of active Crohn's disease after the first episode of hemorrhage should be considered.

Crohn's Disease of the Colon

The optimal management of Crohn's disease of the colon is dependent on the distribution and the location of the disease (Fig. 33-19).

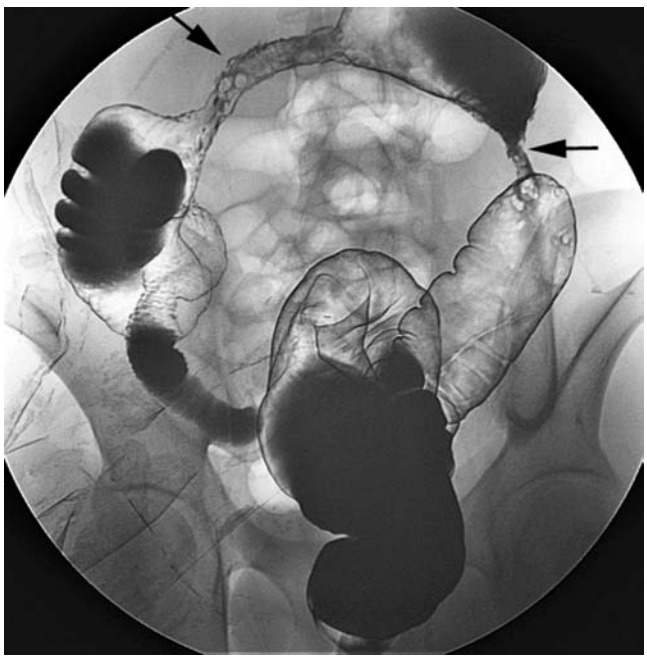

FIGURE 33-19 Contrast enema demonstrating severe Crohn's colitis with multiple high-grade strictures. (Reprinted, with permission, from the University of Chicago General Surgery Archives.)

CECAL DISEASE

Colonic disease limited to the cecum is almost always associated with terminal ileal disease. The terminal ileitis is the predominant component of the ileocecal disease. Terminal ileal disease with extension into the cecum behaves much like disease limited to the terminal ileum. For this pattern of disease, surgical resection should encompass the margins of gross disease with an anastomosis between the neoterminal ileum and the proximal ascending colon. Recurrence of disease at the anastomosis or at the preanastomotic ileum is common, but the risk for recurrent disease within the distal colon or the rectum is low. This pattern of disease does not imply a predisposition to more extensive colonic disease.

RIGHT-SIDED COLITIS

Disease involving the entire right colon can occur alone but more typically occurs along with disease of the terminal ileum. Extensive involvement of the right colon as a form of ileocolonic disease is less common than the ileocecal pattern. Surgical treatment involves a standard right hemicolectomy to encompass the gross limits of the disease. An anastomosis between the ileum and the transverse colon is then fashioned. With a standard right hemicolectomy, the anastomosis may rest in proximity to the duodenum. Recurrent disease at the preanastomotic ileum may thus secondarily involve the duodenum. This phenomenon can place the patient at risk for substantial morbidity should inflammatory encasement of the duodenum or fistulization into the duodenum occur. For this reason it is advantageous to protect the duodenum by interposing omentum between the duodenum and the ileocolonic anastomosis.

EXTENSIVE COLITIS WITH RECTAL SPARING

Extensive colitis with sparing of the rectum occurs in approximately 20% of individuals suffering from Crohn's colitis. In such cases, the rectum should be closely examined endoscopically, and, should the rectum be truly free of disease, a total abdominal colectomy with ileorectal anastomosis can be performed when fecal continence is adequate and the patient does not have extensive perineal septic complications. This procedure often results in good long-term function and enables many patients to avoid an ileostomy. Older patients or patients who have undergone an extensive small bowel resection may experience frequent and loose stools to the point that incontinence may develop after an ileorectal anastomosis. Additionally, recurrent disease within the rectum can result in significant deterioration of bowel function requiring further medical or even surgical intervention. Up to 50% of patients who undergo an ileorectal anastomosis for colonic Crohn's disease will ultimately require a proctectomy with permanent ileostomy because of poor bowel function with incontinence or recurrence of disease in the rectum.[170]

PROCTOCOLITIS

Surgical management of extensive involvement of the colon and rectum requires total proctocolectomy with permanent ileostomy in almost all cases. In most instances, a total proctocolectomy can be performed in a single step. The presence of severe perianal disease, however, may require that the procedure be performed in two stages. At the first stage, the intra-abdominal colon and majority of the rectum are removed and a short rectal stump is created at the level of the levator muscles. At the same time, perineal abscesses are drained and fistulas are laid open. This first step removes the diseased colon and rectum without creating a perineal wound that may be difficult to heal in the presence of active perineal sepsis. Once the perineal sepsis is cleared and the perineum is healed, the short anorectal stump can be removed through a perineal approach. At the second stage, primary closure of the perineum can be accomplished without the high risk of persistent perineal wounds.

Restorative procedures such as an ileal pouch–anal anastomosis or continent ileostomy have traditionally not been offered to patients who have Crohn's colitis because of the recurrent nature of the disease. Even so, some of these procedures have been performed in patients whose diagnosis of Crohn's disease was not known or suspected at the time of surgery. Various reports indicate that recurrence of Crohn's disease within the pouch is common and removal of the pouch is often necessary. On the other hand, those patients who do not suffer from recurrent disease generally do well and typically experience good pouch function.

While it is commonly accepted that restorative proctocolectomy with J-pouch ileoanal anastomosis should not be undertaken for Crohn's colitis, there is a specific pattern of Crohn's disease that appears to be at low risk for problems with recurrence after an ileoanal anastomosis.[171,172] In cases in whom Crohn's disease is limited to the colon and rectum without any history of small bowel involvement and without any perineal manifestations, the risk for pouch failure after ileoanal anastomosis appears to be low and such patients can be considered for the ileoanal procedure. This particular pattern of Crohn's disease, however, is rare, as most patients with Crohn's proctocolitis will have some degree of small bowel involvement or perineal manifestations and thus would not be considered candidates for the ileoanal procedure.

PROCTITIS

Crohn's inflammation limited to the rectum is unusual. Surgical management of Crohn's proctitis mandates proctectomy with permanent stoma. The need for resection of the normal proximal colon is controversial. Abdominoperineal resection with end sigmoid colostomy has been associated in some reports with a high risk for stomal complications and recurrent disease in the proximal intestine when compared to total proctocolectomy with end ileostomy. For these reasons, total proctocolectomy with ileostomy has been recommended for Crohn's disease limited to the rectum and distal colon. This more extensive resection may be of greater value in younger patients who have no history of small bowel Crohn's disease, as it appears that colorectal Crohn's disease without small bowel involvement is unlikely to result in recurrence within the small bowel once a proctocolectomy is performed.[40] If the patient has undergone a prior resection for small bowel Crohn's disease, they may be at risk for high output from the ileostomy and therefore may benefit from the preservation of colonic absorptive capacity. Preservation of the colonic absorptive capacity may be beneficial also in the elderly patient. Thus these patients may be better managed with a proctectomy and end sigmoid colostomy.

Proctectomy for Crohn's disease does not require a wide excision of perirectal tissue. To avoid injury to pelvic sympathetic and parasympathetic nerves, the dissection should be undertaken close to the rectal wall. This is sometimes challenging in the presence of severe rectal mesenteric inflammatory reaction. In the absence of significant perianal disease, the perineal dissection is best carried out along the plane between the internal and external sphincters.[173] This intersphincteric dissection allows for a perineal closure that is associated with fewer complications and better healing than wider dissections that encompass the entire sphincter mechanism. In some patients, fistula from the perianal Crohn's disease can traverse the intersphincteric plane and a wider dissection is required in order to encompass the diseased tissue. In the presence of significant perianal disease, a staged approach, as described previously, can be utilized as an option. Occasionally, however, because of extensive rectal disease, closure of the rectal stump may be technically challenging or not feasible, forcing the surgeon to proceed with a proctectomy in the face of perianal sepsis. These dissections may need to be carried out widely and extensive loss of perianal skin and subcutaneous tissue may occur. The resultant defects are often too large for primary closure, and closure may require advanced tissue transfer techniques such as gluteal flaps, gracilis flaps, or myocutaneous rectus abdominis pedicle flaps. These closures may have to be staged as well in the presence of perineal sepsis. Large open perineal wounds may be managed temporarily or definitively with the assistance of the vacuum-assisted closure device. This device allows for rapid contracture of the wound and facilitates healing.

SEGMENTAL COLITIS

The optimal management of segmental colitis is dependent primarily on the location of the disease and secondarily on the presence and severity of concurrent perineal complications, the degree of fecal continence, and the natural history of the disease in the residual colon. Segmental involvement of the right colon should be managed by simple right hemicolectomy with ileotransverse anastomosis. For segmental disease involving the transverse colon, an extended right hemicolectomy is generally preferred to a segmental transverse colectomy. Such an approach may have a lower risk of recurrence compared to a segmental resection of the transverse colon.

Additionally, the extended right hemicolectomy avoids a colocolonic anastomosis that is associated with a higher risk for anastomotic dehiscences and strictures.

For disease in the descending or sigmoid colon, the appropriate surgery is more controversial. Presence and severity of concurrent perineal complications, the degree of fecal continence, and the natural history of the disease in the residual colon all play a role in deciding on the approach for each individual patient. Studies have indicated that segmental colonic resection with colocolonic anastomosis or even colonic strictureplasty can be performed with overall good results.[174,175] However, such a strategy may be at risk for early disease recurrence within the colon.[40] Even if the risk for recurrence is higher with segmental resection, the benefits of preserving the absorptive capacity in appropriately selected cases may outweigh the higher risk of recurrence.

PERIANAL DISEASE

The perianal manifestations of Crohn's disease include abscesses, fistulas, fissures, anal stenosis, and hypertrophic skin tags.[176,177] Perianal Crohn's disease originates from inflammation within the anal crypts. This inflammation gives rise to sepsis and to fistulization (Fig. 33-20). Perianal Crohn's disease is common and occurs in one-third of the patients who suffer from intestinal Crohn's disease.[42] Perianal Crohn's disease is usually associated with active or quiescent disease elsewhere within the GI tract. It is controversial as to whether the activity of perianal Crohn's disease parallels that of the intestinal disease. There is also controversy over whether medical or surgical control of the intestinal disease can ameliorate the perianal manifestations. Unlike idiopathic perianal abscesses and fistula-in-ano that occur in patients without Crohn's disease, perianal Crohn's disease tends to be recurrent, complex, and sometimes progressive.

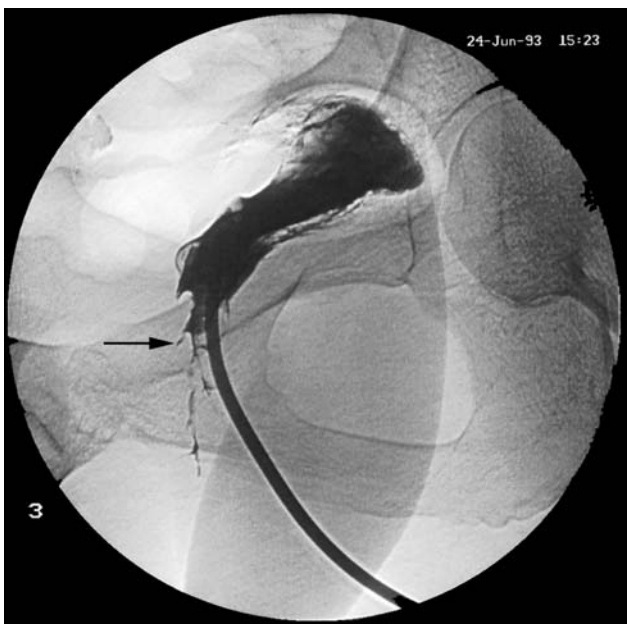

FIGURE 33-20 Dynamic proctogram demonstrating Crohn's fistula-in-ano. (Reprinted, with permission, from the University of Chicago General Surgery Archives.)

FIGURE 33-21 CT scan demonstrating a large perirectal abscess secondary to Crohn's disease. (Reprinted, with permission, from the University of Chicago General Surgery Archives.)

Surgical incision and drainage are required to manage perianal abscesses (Fig. 33-21). Attempts at treating purulent collections with antibiotics alone are invariably unsuccessful. With surgical drainage of the abscess, the incision should be placed close to the anal margin. The cavity may be packed with ribbon gauze or drained with a 10–16F mushroom catheter. If a fistula tract can be identified at the time of drainage of the suppuration, a loose seton may be placed to ensure adequate drainage.

Uncomplicated submucosal or intersphincteric fistulas are best treated with an initial trial of either metronidazole or ciprofloxacin. These antibiotics are moderately effective in promoting healing of Crohn's fistulas and are associated with a low risk of complication.[178,179] If a low-lying submucosal or intersphincteric fistula fails to heal with antibiotic treatment, a surgical fistulotomy can be performed. These low-lying fistulas typically heal well after fistulotomy and the risk of incontinence is low.

Surgical fistulotomies and cutting setons should not be used for suprasphincteric fistulas and should also be avoided for most transsphincteric fistulas. For complex fistulas, the risk for surgical complications is higher and more aggressive medical therapy is warranted before surgery is recommended. Medical treatment for extensive Crohn's fistulas includes the use of 6-MP, azathioprine, and cyclosporine. Probably the most effective agent at promoting healing of perianal fistulas related to Crohn's disease is infliximab. With infliximab treatment, healing of complex perianal fistulas is seen in 60% of cases.[180,181] Recurrence of the fistula after infliximab is discontinued, however, may be high. Additionally, persistent stasis

or sepsis within the fistula tract can impede effective healing with medical treatment. To provide for adequate drainage throughout the fistula tract, many patients may benefit from placement of setons. The use of setons with infliximab therapy can improve the overall effectiveness of infliximab.[182] Typically the seton is placed prior to the initiation of infliximab therapy and then it is removed after the second or third dose.

Fibrin glue has been used for the treatment of Crohn's disease–related fistulas, but reported experience is limited. Success rates with this approach are low, but, given the low risk of complications, an attempt at fibrin glue may be worthwhile in selected cases.[183,184]

Closure of the internal opening of the fistula with a rectal advancement flap can be considered in cases of Crohn's disease.[185] With this approach, an incision is made at the dentate line, and a flap of mucosa and muscularis is undermined and advanced down over the internal opening of the fistula. The advancement flap is then sutured into position with absorbable sutures. Rectal advancement flaps for Crohn's disease have a low risk for anal incontinence but are associated with a high failure rate. Rectal advancement flaps are not appropriate in patients in whom the rectal mucosa is involved with Crohn's disease. In severe cases of perianal disease that do not respond to aggressive medical and surgical therapy, fecal diversion with a stoma may be necessary. Diversion of the fecal stream typically results in significant relief of local inflammation and can assist in the healing of perianal fistulas. Proctectomy is indicated when perianal disease is unrelenting or when damage to the sphincters results in debilitating incontinence.

Recurrent Disease

Crohn's disease carries a high risk for recurrence after surgery. The actual incidence of recurrent disease depends on the defining parameters of recurrence. For example, histological evidence for recurrence can be seen in many patients within days of surgical resection.[186] Endoscopic evidence for recurrent Crohn's disease can be seen in over 80% of patients within 3 years.[187] Most cases of histological or endoscopically detected recurrences, however, do not go on to produce symptoms of Crohn's disease. For this reason, histological or endoscopic evidence of recurrent disease may be used as an end point in investigative studies but are not typically used as a guide for clinical management.[188]

The development of symptoms related to recurrent Crohn's disease activity is the most commonly applied definition of disease recurrence, as it is the recurrence of symptoms that has the most relevance to the patient. The onset of symptoms of recurrent Crohn's disease is often insidious and the severity of symptoms varies greatly. To create a reproducible standard for recurrence of Crohn's disease symptoms, the Crohn's Disease Activity Index (CDAI) can be applied as a means of measuring recurrent disease.[189,190] A CDAI of greater than 150 is generally accepted as defining clinical recurrence. Once symptoms suggestive of recurrent disease occur, it is still necessary to carry out radiological and endoscopic tests to confirm that the symptoms are in fact related to Crohn's disease.

The clearest end point as a definition of recurrence is the need for reoperation. Dates of surgery are readily documented even in a retrospective fashion. While reoperation is the most precise definition of recurrence, even this standard does not allow for accurate and reproducible comparisons between series as some centers may submit patients to surgery earlier than other centers.

Reported crude and cumulative recurrence rates vary greatly. Symptomatic or clinical recurrence occurs in about 60% of patients at 5 years, and recurrences increase with time such that at 20 years clinical recurrence can occur in between 75 and 95% of cases.[35,191,192] Reports of surgical recurrence rates range from 10 to 30% at 5 years, 20 to 45% at 10 years, and 50 to 70% at 20 years.[70,94,191–195] Some interesting observations regarding the pattern of recurrent disease have been made. Recurrent Crohn's disease is most likely to occur in proximity to the location of the previously resected intestinal segment, typically at the anastomosis and preanastomotic bowel.[94] This is particularly true for terminal ileal disease. Additionally, the length of small bowel involved with recurrent disease parallels the length of disease originally resected.[196,197] Short-segment disease tends to recur over a short segment of the preanastomotic bowel, and lengthy disease typically is followed by lengthy recurrence. Also, to a lesser degree of concordance, stenotic disease tends to recur as stenotic disease and perforating disease tends to recur as perforating disease.[197]

While many factors that may influence the risk of recurrence have been studied, the cumulative literature has validated very few as true risk factors. The data are conflicting for most of the proposed predictors of recurrent Crohn's disease. Much of the clinical data examining potential risk factors are confounded by poorly defined end points and improper study design. There is, however, general consensus that cigarette smoking has a significant effect on the clinical course of Crohn's disease.[30] Smoking not only exacerbates existing Crohn's disease but also has been identified as a risk factor for the development of Crohn's.[27,28,30] What is so striking about the effect of cigarettes on Crohn's disease is that smoking has the opposite effect on what is thought to be a very similar disease, ulcerative colitis.[29] While smoking exacerbates Crohn's disease, it seems to lessen the activity of ulcerative colitis.

The mechanism by which smoking results in exacerbation of Crohn's disease is not known. Smoking is an independent risk factor for endoscopic, symptomatic, and surgical recurrence.[31,32] The risk from smoking appeared to be dose-related with heavy smokers being at higher risk. This effect is reversible, as smokers who quit smoking prior to surgery can lower their risk of recurrence to a level similar to that of nonsmokers. Because of the harmful effects on the clinical course of Crohn's disease combined with the many other clearly established health hazards caused by cigarette smoking, all patients

with Crohn's disease should be strongly counseled to quit smoking.

There is concern that NSAIDs may exacerbate the activity of both ulcerative colitis and Crohn's disease.[70,80] Although there are no studies that have examined the specific issue of NSAIDs and the risks for postoperative recurrence of Crohn's disease, the currently available data certainly warrant some caution and patients with Crohn's disease should be advised to avoid NSAIDs.

POSTOPERATIVE MAINTENANCE THERAPY

The risk for recurrent disease can be lessened with postoperative maintenance therapy. The most common agents used for postoperative suppression of disease are controlled-release 5-ASA (Pentasa) and 6-MP.[75–77] Maintenance with 5-ASA is associated with few side effects, but up to 16 pills have to be taken daily. 6-MP is less expensive and is taken on a once-daily basis. Additionally, 6-MP may be more effective in diminishing the risk of recurrence.[75] 6-MP, however, is associated with potential bone marrow suppression, so that patients on 6-MP maintenance must be followed with periodic blood cell counts. The effect of these agents on the natural course of Crohn's disease is not dramatic, and many patients will go on to develop recurrence while on maintenance therapy. The largest benefit demonstrated with 6-MP in a multicenter trial showed a decrease of symptomatic recurrence from 77% with placebo to 50% with 6-MP.[75] The option for maintenance therapy should be considered for Crohn's disease patients, but the decision for such therapy must be individualized for each patient.

ULCERATIVE COLITIS

Shawn Forbes • David Messenger • Robin S. McLeod

INTRODUCTION

Ulcerative colitis, one of the idiopathic inflammatory bowel diseases (IBDs), is a chronic disease that affects the mucosa of the rectum and colon. Although Hippocrates described diarrheal diseases that were colitis-like well before 360 BC, it was not until the late 1800s that ulcerative colitis was distinguished clinically from common infectious enteritis. Sir Samuel Wilks of London is credited with the first medical account of colitis. In 1859, he described a 42-year-old woman who died after several months of diarrhea and fever. Postmortem examination revealed a transmural ulcerative inflammation of the colon and terminal ileum that, while originally designated as "simple ulcerative colitis," may in fact have been Crohn's disease. A subsequent case report in 1875, again by Wilks and Walter Moxon, described ulceration and inflammation of the entire colon in a young woman who had succumbed to severe bloody diarrhea, and it is more likely the first detailed account of ulcerative colitis.

The landmark description of regional enteritis in the 1930s, by Crohn, Ginzburg, and Oppenheimer, led to the recognition of the existence of two IBDs: Crohn's disease and ulcerative colitis. Although the two diseases initially appeared to have distinct pathologic features, it is now recognized that there can be significant overlap not only pathologically but also in anatomic distribution and clinical manifestations. Furthermore, there may be overlap in the underlying cause of the two diseases.

Ulcerative colitis typically manifests with periods of remission and exacerbations characterized by rectal bleeding and diarrhea. Because ulcerative colitis most commonly affects patients in their youth or early middle age, the disease can have serious long-term local and systemic consequences. The etiology remains essentially unknown, but there have been significant advances in identifying likely genetic and environmental factors that contribute to its pathogenesis. Despite this, there is no definitive medical treatment for the disease. Medical therapy can only ameliorate the inflammatory process and control symptomatic flares. Thus, surgery has an important role in the management of ulcerative colitis as it is estimated that approximately 40% of patients with ulcerative colitis will ultimately require surgery.[1]

Proctocolectomy or total removal of the colon and rectum has been the standard surgical treatment for ulcerative colitis. In recent years, a number of other options have become available so a permanent ileostomy is not required. Irrespective of the surgical procedure, most patients can expect to lead normal lives with a high quality of life. However, in order to achieve these outcomes, patients must be carefully assessed and selected for surgery and receive optimal perioperative care. The surgery itself can be technically challenging, and postoperative complications must be recognized and managed appropriately. All of these require that surgeons have an understanding of the epidemiology and pathophysiology of ulcerative colitis, its clinical manifestations, medical management as well as issues related to surgical technique, preoperative assessment, and postoperative care of patients.

EPIDEMIOLOGY

Ulcerative colitis poses many challenges to the epidemiologist because the incidence of the disease is low and it is rarely fatal. Its clinical presentation can be variable and often insidious. The interval between the onset of symptoms and the diagnosis can be decades, and there are no universal diagnostic criteria.[2] Despite these limitations, epidemiological studies can provide valuable insight into numerous potential etiologic factors.

In the United States, IBD afflicts approximately 2–6% of the population or up to 1.5 million individuals. Although there has been a noteworthy rise in the incidence of Crohn's disease in the United States, the incidence of ulcerative colitis has risen only slightly in recent years. As a result, the annual incidence of Crohn's disease is nearly equal to that of ulcerative colitis.

Worldwide, there is significant variation in the incidence of ulcerative colitis and may serve as a valuable etiologic clue. It appears that there is a distinct north-to-south gradation in risk in developed countries, with the greatest incidence and prevalence occurring in countries of the northern hemisphere such as the United Kingdom, Norway, Sweden, Canada, and the United States[3] where the annual incidence of ulcerative colitis is about 6–12 per 100,000. In more southern countries

such as Australia, South Africa, and countries of southern Europe the annual incidence of ulcerative colitis is about two to eight per 100,000. The incidence in Asia and South America is also considerably lower.[3] These trends also suggest that the incidence of ulcerative colitis is highest in developed or urban regions of the world and lowest in developing regions; however, it appears that the incidence of ulcerative colitis may be leveling off in developed countries and starting to rise in the developing nations. Epidemiologic studies have also shown that the incidence of ulcerative colitis among Jewish populations is two to four times higher than that in non-Jewish populations while the age-adjusted incidence for white men is about twice that of nonwhite men and the rate for nonwhite women is actually higher than that for white women.[2]

Although the onset age of ulcerative colitis is bimodal and typically occurs between the ages of 15 and 40 years and again after age 60, the disease can present at any age from infancy to the elderly. In fact, nearly 5% of new cases occur after age 60. Throughout the age range, men and women are affected about equally.

PATHOPHYSIOLOGY

Although the pathogenesis of IBD has been studied intently for the past several decades, it is only recently that there have been significant advances leading to an appreciation that genes, the environment, as well as the immune response play important roles in the development of ulcerative colitis.[4] The evidence now suggests that there is an inappropriate inflammatory response to intestinal bacteria in genetically susceptible individuals leading to a sustained mucosal inflammatory response that the host is unable to downregulate. Failure to attenuate this response leads to increased recruitment and activation of immune and inflammatory cells, leading to the release of proinflammatory mediators and perpetuation of inflammation and damage to intestinal tissues.

Both Crohn's disease and ulcerative colitis often affect several members of families providing strong evidence that there is a genetic basis to both diseases. However, while there appears to be a genetic predisposition among family members of patients with ulcerative colitis, a much stronger familial predisposition is seen in Crohn's disease. Furthermore, Crohn's disease and ulcerative colitis can be seen within the same family, reflected by an 80–90% concordance for the same disease category. This suggests that there are many overlapping genetic loci.

In recent genome-wide association studies in patients with ulcerative colitis, a highly significant association was observed for a common polymorphism in a region on chromosome 1q32 containing the *IL10* gene.[5] This family of cytokines mediate host defense against infection as well as tissue inflammation in chronic immune-mediated diseases. The other identified associations have been within the major histocompatibility complex class II region near HLA-DRA.[6] However, even with the identification of new genetic susceptibility loci, the identified IBD markers account for only 20% of the heritable risk, emphasizing that there are other unidentified mutations that probably play a role in the development of ulcerative colitis.

While genetic susceptibility is important, studies in monozygotic twins have shown that the concordance between twins is only 40–60%, suggesting that environmental factors are also necessary to trigger the disease.[7] The likely triggers appear to be agents that affect the mucosal barrier of the bowel. There is some evidence that bacterial and viral infections are associated with IBD, although no specific species have been implicated. Similarly, nonsteroidal anti-inflammatory drugs (NSAIDs) are associated with IBD, and last, while smoking is associated with Crohn's disease, it is protective in ulcerative colitis. Diet may be an environmental factor in that it may alter the flora.

It is currently thought that loss of tolerance against indigenous enteric flora is the fundamental event in the pathogenesis of ulcerative colitis. The intestinal mucosa is continually exposed to bacteria. There are two basic components to the immune response: innate and adaptive. Innate immunity is the more basic form and is the initial response to invading pathogens.[4] The epithelial barrier and phagocytes within the lamina propria are the main components of innate immunity. The protective effect of innate immunity is limited because it does not have a memory, and therefore the immune response is not increased upon reinfection. It is for this reason that adaptive immunity, which is largely mediated by lymphocytes, T and B cells, that express antigen receptors on their surface, evolved. Cytokines, which are produced by T cells in response to infection, eradicate infection and also give rise to memory cells that prevent infection upon reinfection.

IBD occurs as result of the abnormal and sustained mucosal inflammatory response that the host is unable to downregulate. Recent evidence suggests that the initial response by the innate immune system is inadequate and initiates this process. The T lymphocytes, which are part of the adaptive immune response, however, appear to play a key role in the disease pathogenesis. There are various subpopulations of T cells that secrete cytokines. Once activated, there is a persistent uncontrolled inflammatory response with further recruitment of unregulated cells. A different subset of T cells is activated in ulcerative colitis compared to Crohn's disease. This subset produces interleukin 13 (IL-13) as well as interferon-γ (IFN-γ), resulting in epithelial dysfunction, antibody production, and immune complex formation resulting in complement activation and mast cell degranulation. The effects of these activating events may account for distinct pathologic findings and specific disease expression.

PATHOLOGY

Gross Findings

Ulcerative colitis begins in the rectum above the dentate line and progresses proximally.[8] Involvement is classically diffuse. Rectal sparing or a patchy distribution throughout the colon

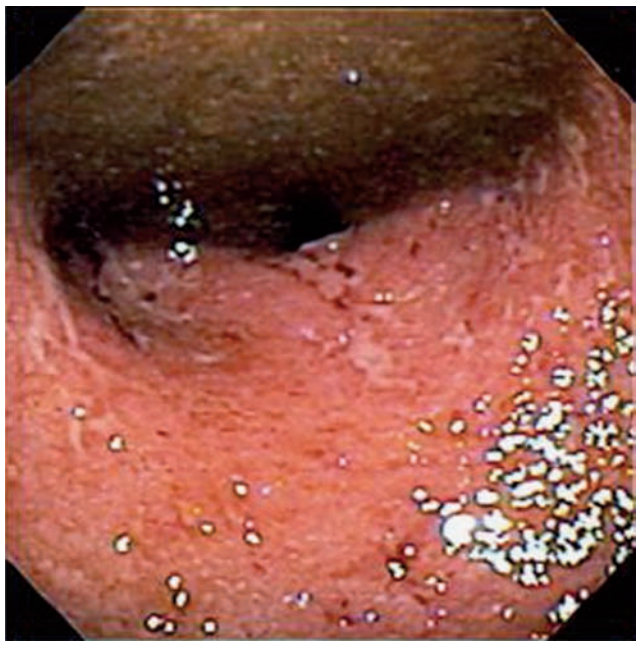

FIGURE 34-1 Endoscopic appearance of ulcerative colitis.

should lead to a suspicion of Crohn's disease. Often, the disease may be limited to the rectum at first but can progress proximally over time. Changes are typically limited to the mucosa and superficial submucosa, although full-thickness inflammation may be seen in fulminant cases and may lead to a diagnosis of indeterminate colitis in patients having surgery for severe disease. The serosa is otherwise preserved. Mucosal changes seen at endoscopy or on gross pathologic examination include edema, hyperemia, and granularity of the mucosal lining (Figs. 34-1 and 34-2). The tissues are often friable and may bleed easily with contact in the acute setting. Over time, mucosal erosions occur, coalescing to form linear ulcers and leaving mucosal islands, commonly referred to as *pseudopolyps* due to their polypoid appearance. The colon will often develop a "burnt-out" appearance after long-standing disease with loss of mucosal folds (atrophy). The chronic inflammatory process may lead to shortening of the colon and loss of rectal compliance, leading to frequent bowel movements, even if no or minimal active inflammation is present. Stricturing is uncommon and, if present, should raise the suspicion of a malignancy. As many as 24% of strictures found in the setting of ulcerative colitis are malignant.[9]

While ulcerative colitis is limited to the colon and rectum, a phenomenon known as "backwash ileitis" has been described. This terminal ileal inflammatory change is believed to be consequent to the reflux of colonic contents into the terminal ileum through an incompetent ileocecal valve in patients with pancolitis. Endoscopically, backwash ileitis is evident by a patulous ileocecal valve and terminal ileum. The histologic appearance resembles pouchitis and the finding should not be dismissed as indicative of Crohn's disease.[10]

Microscopic Findings

Crypt infiltration with neutrophils causing so-called "cryptitis" and "crypt abscesses" are pathognomonic for active ulcerative colitis. This is accompanied by diffuse chronic inflammation in the lamina propria, often with deep plasma cells, and mucosal architectural distortion (crypt branching, shortening, or atrophy). Crypt abscesses may coalesce giving rise to erosions or linear ulcers (Fig. 34-3). Undermining of adjacent mucosa by such ulcers may lead to the formation of pseudopolyps. Ulcerative colitis is classically a mucosal disease, and the transmural inflammation, stricturing fibrosis, and fissuring ulcers of Crohn's disease are not features of this disease. An exception is fulminant ulcerative colitis in which deep, sometimes fissuring, ulcers as well as transmural

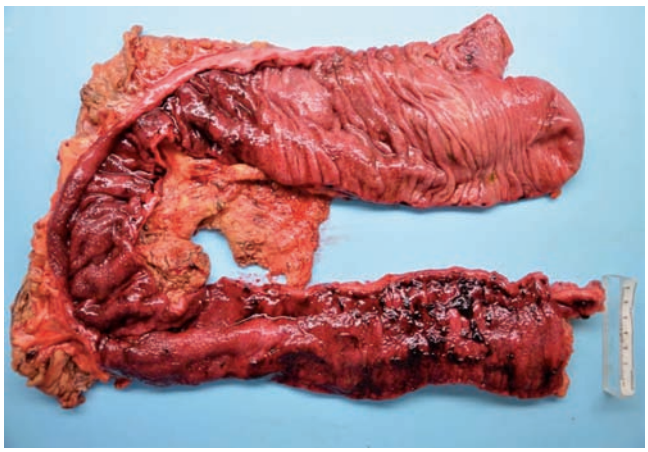

FIGURE 34-2 Colectomy specimen showing typical features of ulcerative colitis.

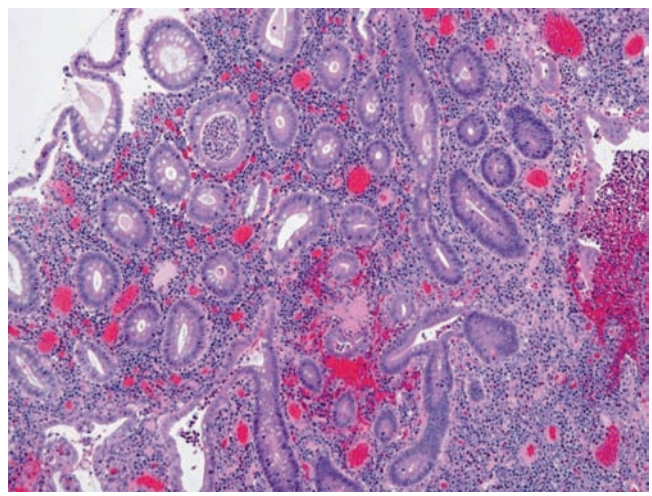

FIGURE 34-3 Histologic features of ulcerative colitis.

inflammation may be seen, sometimes leading to confusion with Crohn's disease. However, unlike in Crohn's disease, transmural inflammation is confined to areas of ulceration, and discrete transmural lymphoid aggregates and granulomas are not seen. In quiescent ulcerative colitis, cryptitis, and crypt abscess resolve, but a mild chronic inflammatory infiltrate and crypt distortion typically persist.

CLINICAL FEATURES

The initial presentation of ulcerative colitis can vary widely from a minor disturbance in bowel function, to a rapidly progressive and fulminant course with toxicity and impending perforation. The time between onset of symptoms and diagnosis often varies with the severity of the presentation. Many patients initially have disease limited to the rectosigmoid region and present with cramping abdominal pain relieved with defecation, rectal bleeding, and diarrhea. With time, the severity of the disease may progress, with increasing involvement of the remaining colon until pancolitis results. As the disease worsens, patients often report more frequent bowel movements, 10 or more per day, tenesmus, and ongoing blood loss either as bloody stools or passage of mucus and blood alone. An acute severe episode is the initial mode of presentation in approximately 10% of patients with ulcerative colitis, with many requiring an emergent colectomy before any definitive diagnosis is made.[11] Fulminant colitis occurs infrequently, having decreased in incidence markedly over the past 50 years.

The most common patterns of disease are those of chronic, unrelenting symptoms or intermittent flare-ups of symptoms, interspersed between episodes of relative quiescence. Patients with chronic symptoms often become dependent on immunosuppressive therapy, or their response to medical therapies may at best be partial. Patients who have intermittent flare-ups of symptoms may have long periods where the disease is quiescent. They also may benefit from maintenance therapy.

According to the Truelove and Witt criteria, patients with severe episodes of colitis are defined as those having six or more stools per day, with one or more of the following: large amounts of blood; fevers greater than 37.5°C, heart rates of 90 beats/min or more, anemia with hemoglobin levels less than 75% of normal, and erythrocyte sedimentation rates (ESR) of 30 mm/h or more.[12] Mild cases have none of these features, whereas moderate cases exhibit a less marked physiologic derangement (Table 34-1). The severity of disease may vary over time and with medical therapy. Over time, the sequelae of long-standing ulcerative colitis may show if the disease is poorly controlled. These include anemia, weight loss, and growth retardation in the young, as well as metabolic derangements.

The symptoms of ulcerative colitis are not limited to the colon. Extraintestinal manifestations of the disease may be present at initial presentation or at any time during the course of the disease.[13] As many as 40% of patients may have associated disease involving the eyes (uveitis and iritis), skin (pyoderma gangrenosum Fig. 34-4A and erythema nodosa), joints (arthritis, sacroiliitis), or hepatobiliary tract (primary sclerosing cholangitis [PSC]) (Fig. 34-4B). The severity of these extraintestinal manifestations of disease may coincide with the severity of the colitis. Some of these, including arthritis and skin manifestations, tend to respond to treatment or surgical extirpation of the colon. Hepatic manifestations of disease are the most common extracolonic disease site. Asymptomatic fatty infiltration of the liver seen on histologic examination is the most common extraintestinal manifestation. As many as 2–7% of patients with ulcerative colitis develop PSC. The symptoms and progression of PSC are not affected by the management of the colonic disease. Patients with progressive liver failure from PSC ultimately may require liver transplant. Affected patients are also at greater risk of developing carcinoma of the bile duct, although this may also develop de novo in patients with ulcerative colitis.

DIAGNOSIS

Endoscopy

The diagnosis of ulcerative colitis is usually made based on clinical symptoms confirmed by endoscopy. Barium enema

TABLE 34-1: DISEASE ACTIVITY IN ULCERATIVE COLITIS

	Mild	Moderate	Severe
Bloody stools/day	<4	4 or more	≥6
Pulse	<90 beats/min	≤90 beats/min	>90 beats/min
Temperature	<37.5°C	≤37.8°C	>37.8°C
Hemoglobin	>11.5 g/dL	≥10.5 g/dL	<10.5 g/dL
ESR	<20 mm/h	≤30 mm/h	>30 mm/h
CRP	Normal	≤30 mg/L	>30 mg/L

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate.

and air contrast barium enema are no longer used to make the diagnosis because they are less sensitive in detecting early changes and assessing the severity and extent of disease.

Differentiating ulcerative colitis from Crohn's disease is especially important because the treatment differs. This is especially true for surgical management. In mild cases, there is loss of the normal vascular pattern, a granular texture and microhemorrhages when the friable mucosa is touched or wiped. When the disease is moderately active, the mucosa becomes more grossly pitted and spontaneous bleeding is often present. In severe cases, there are macroulcerations and profuse bleeding, usually accompanied by a purulent exudate (Table 34-2).

Chronic ulcerative colitis is frequently associated with the appearance of small pseudopolyps, which represent areas of regenerating mucosa in the midst of diffuse mucosal destruction. Also, the colon tends to be foreshortened and lacks distensibility. This is particularly true of the rectum and may account for increased stool frequency in the absence of acute inflammation.

In patients who have severe acute ulcerative colitis, colonoscopy is generally contraindicated because of the concern of perforation. However, flexible sigmoidoscopy should be performed to assess the disease status of the colon prior to surgery. Occasionally, the pathologic diagnosis may change to Crohn's disease postoperatively. Because generally the patient would not be a candidate for an ileal-pouch anal anastomosis (IPAA), it is important to know the status of the rectum to determine if he or she is a candidate for an ileorectal anastomosis (IRA). Postoperatively, there may be changes of disuse colitis so preoperative assessment of the rectum is preferred. In addition to endoscopy playing an important role in the diagnosis and assessment of acute ulcerative colitis, it should be performed for surveillance of cancer. Screening colonoscopy should begin 8–10 years after the onset of symptoms and be performed every 1–2 years. Four-quadrant biopsies should be taken at 10-cm intervals. A minimum of 33 biopsies should be taken. In addition, raised lesions and strictures should be biopsied. Dye spraying with methylene blue or indigo carmine dye may be helpful in identifying raised lesions. Confocal laser endomicroscopy is another technique that may be useful in identifying suspicious lesions and guide biopsies.

Typically, dysplasia is a histologic diagnosis and can only be made by histologic examination (Fig. 34-5). Raised dysplastic lesions, commonly referred to as *dysplasia-associated lesions or masses* (DALM), are significant because 25–50% have been reported to harbor cancer.[14] Some may appear irregular and sessile whereas others may have a typical appearance of adenomas. The area surrounding a raised lesion should be biopsied because lesions typical of adenomas without dysplasia in either the surrounding area or other areas of the colon may be treated by polypectomy provided they occur in patients in an age group when polyps typically occur and they have no other risk factors for cancer. On the other hand, sessile lesions or those having evidence of dysplasia in the surrounding area require colectomy.[14]

TABLE 34-2: DIFFERENTIATION OF ULCERATIVE COLITIS AND CROHN'S DISEASE

	Crohn's Disease	Ulcerative Colitis
Lesions (early to severe disease)	Aphthous ulcers, stellate ulcers, serpiginous "bear claw" ulcers, cobblestoning	Loss of fine vascular markings, hyperemia friable, granular mucosa, occasional large ulcers surrounded by inflammed mucosa pseudopolyps
Distribution along colon	Patchy, skip lesions with intervening areas of normal mucosa	Continuos involvement throughout affected segments, cecal patch also possible
Rectal involvement	Usually spared	Usually involved with disease spread extending proximally
Perianal involvement	Anal skin tags, fissures, complicated fistulas, abscesses	Rare, uncomplicated fissures and fistulas may be present
Ileal involvement	Involvement in most cases	Occasionally backwash ileitis in pancolitis
Fistulization	Common, including: enterocutaneous, perianal, rectovaginal, enterovesicular	Rare

Strictures are also an important finding in chronic ulcerative colitis. Benign strictures may occur, but one must always be suspicious that they are malignant in nature and should be biopsied.[9]

Serologic Markers

While in most cases ulcerative colitis can be readily differentiated from Crohn's disease, this may not be true if the disease is limited to the colon. The past two decades have witnessed a growing interest in the use of serum biomarkers to aid in the diagnosis and management of patients with IBD. The two most widely studied biomarkers include atypical perinuclear antineutrophil cytoplasm antibodies (pANCAs) and anti-*Sacchromyces cerevisiae* antibodies (ASCAs). Their main clinical indication appears to be in the differentiation of ulcerative colitis from Crohn's disease. Atypical pANCA is present in approximately 70% of patients with ulcerative colitis but in only 20% of patients with Crohn's disease.[15] In contrast, the presence of IgG and IgA ASCAs has been demonstrated in 60–70% of patients with Crohn's disease but only 10–15% of patients with ulcerative colitis.[16] Combining the results of atypical pANCA and ASCA assays provides the most effective means of distinguishing ulcerative colitis from Crohn's disease, with most studies reporting a specificity of more than 90%. The $pANCA^{+}/ASCA^{-}$ combination is specific for ulcerative colitis, whereas $pANCA^{-}/ASCA^{+}$ is specific for Crohn's disease. However, the combined sensitivity of pANCA and ASCA is roughly 50%, which limits their use as a primary means of diagnosis.

New antiglycan (antichitobioside IgA, antilaminaribioside IgG, and antimannobioside IgG) and antimicrobial (anti-outer membrane porin C, anti–*Pseudomonas fluorescens* bacterial sequence I2, and antiflagellin) antibodies have recently been developed. The advent of array technology has facilitated the combined study of these serologic markers, and early results suggest that they may have a greater capacity to distinguish between ulcerative colitis and Crohn's disease than the traditional combination of pANCA and ASCA.[17] Despite these technological advances, the role of serologic markers in current practice is limited to that of an adjunct in the clinical workup of patients with suspected IBD. Further studies are required to see if serologic markers will prove useful in predicting the course of IBD and its development in the relatives of affected individuals.

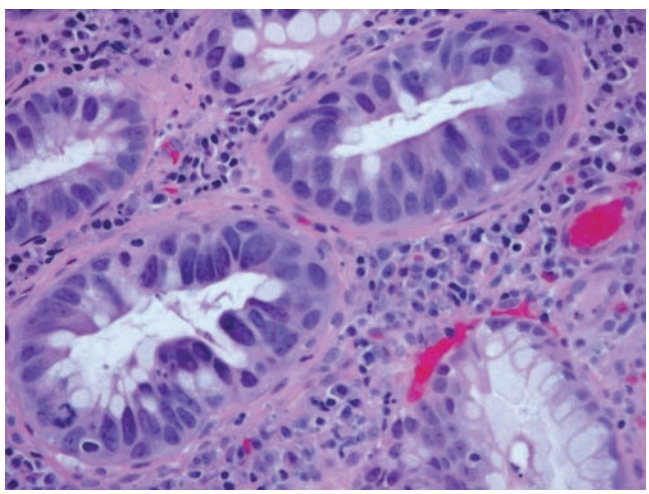

FIGURE 34-5 Histologic features of dysplasia.

MEDICAL MANAGEMENT

The spectrum of disease severity can range from mild to severe, and disease extent can vary from proctitis to pancolitis. Surgical involvement tends to be limited to cases where complications arise in acute severe disease, for example toxic megacolon and perforation, or chronic colitis unresponsive to medical therapy. Surgeons should have a broad understanding of the medical treatment options to help inform their decision making. The ability to discriminate between patients

requiring surgery and those that will respond to medical therapy is of paramount importance. Medical therapy should be targeted at controlling the underlying inflammatory process in order to induce remission. Prior to commencing therapy, a careful assessment of disease severity should be made, including a detailed history and physical examination in conjunction with endoscopic and radiologic findings. Treatment regimens should be based on both disease extent and severity. A tailored immunosuppressive regimen may be required to treat chronic active colitis and to maintain remission in the long term.

Mild to Moderate Colitis

Mild to moderate colitis is often treated with 5-aminosalicylic acid (5-ASA) products. Topical application of 5-ASA or steroid products is recommended for the initial treatment of distal colitis.[18] Trial data suggest that 5-ASA preparations are superior to steroids with foams being better tolerated than enemas during flares of proctitis.[19] Disease extending to the splenic flexure warrants the addition of an oral 5-ASA agent in combination with topical therapy.[20] The minimum recommended duration of treatment to induce remission is 4 weeks.[21] For topically acting therapy, a dose of 1 g 5-ASA per day has been shown to be as effective as higher doses at achieving remission.[22] Typical oral maintenance doses range from 2 to 4 g/d. In more severe cases of left-sided colitis, the use of oral steroids should be considered, preferably in combination with a topical 5-ASA preparation.[23]

Pancolitis should initially be treated with oral 5-ASA therapy. If symptoms worsen or the disease becomes refractory to 5-ASA, oral steroids should be commenced. Most patients will respond to the addition of steroids, although a prolonged response will only be achieved in 50% after 1 year.

Severe Colitis

Treatment of severe colitis with intravenous corticosteroids has been the mainstay of therapy for over 50 years. Optimal regimens include 400 mg of hydrocortisone per day[24] or 40–60 mg of methylprednisolone per day.[25] Infusions have been shown to be no more effective than bolus injections. Evidence suggests that 40% will achieve a complete response, although 30% will require colectomy during admission. In patients achieving a partial response to steroids, over 50% will come to colectomy in the next year and 70% within 5 years.[26]

If a treatment response is not observed within 3–5 days and there is no clear indication for surgery, rescue therapy with a daily cyclosporin infusion of 4 mg/kg[27] or a single infusion of infliximab (5 mg/kg) has been shown to be effective.[28] A comparison of cyclosporin and infliximab is currently the subject of a randomized controlled trial being undertaken in the United Kingdom (CONSTRUCT trial, ISRCTN 22663589). Anecdotal evidence suggests that a prolonged response to rescue therapy can be achieved, allowing patients to avoid colectomy for several years. However, it appears that rescue therapy merely delays colectomy in the short term for the majority of patients. There may be some merit in this strategy as it allows surgery to be performed when patients are in better condition. Several case series report that tacrolimus is comparable to cyclosporin as a rescue therapy, but experience in its use is not widespread.

It is important not to overlook additional measures that can optimize patient management of severe colitis. Appropriate intravenous replacement of fluids and electrolytes is necessary to prevent dehydration and the harmful effects of electrolyte imbalance. Symptomatic anemia should also be corrected by blood transfusion. Malnutrition can be avoided by instituting feeding via the enteral or parenteral route. Enteral nutrition has been shown to be superior in reducing the rate of complications in acute colitis[29] although its use may be limited in the presence of ileus. A randomized controlled trial of bowel rest with parenteral nutrition has not been shown to alter outcome.[30] Subcutaneous heparin should be commenced on admission as severe colitis is a prothrombogenic state. It is important to identify the presence of any superimposed enteric infections, namely *Clostridium difficile* and cytomegalovirus, with stool sampling or biopsy at endoscopy and then treat accordingly. There is no evidence to suggest that empirical treatment with antibiotics in severe colitis is beneficial. Agents that could potentially precipitate the effects of toxic megacolon, such as anticholinergics, antidiarrheals, NSAIDs, and opiates, should be discontinued.

MAINTENANCE OF REMISSION

Criteria for remission include the absence of diarrhea (less than three bowel movements per day), no visible blood in the stools, as well as no ulcerative colitis-associated intestinal or extraintestinal manifestations of disease.[31] First-line therapy is oral or topical 5-ASA. There is some evidence that the combination of oral and topical 5-ASA is superior to oral maintenance therapy alone.[32] Probiotic pathogen preparations have also shown similar clinical efficacy to standard 5-ASA preparations in maintaining remission.

In patients who are steroid-dependent or suffer with relapsing disease, azathioprine and its metabolite 6-mercaptopurine are effective at maintaining remission.[33] It is recommended that maintenance therapy should be continued for at least 3–5 years. Prior to commencing treatment with azathioprine, thiopurine methyltransferase levels should be checked, with monthly monitoring of the full blood count, renal and liver function thereafter. Development of leukopenia, thrombocytopenia, pancreatitis, or a gross derangement in transaminase levels are indications for the termination of treatment. In recent years, infliximab has been used increasingly as a therapeutic alternative to azathioprine. It is generally safe and well tolerated, although screening for tuberculosis is warranted prior to commencing therapy. The active colitis trials have demonstrated a rapid response with infliximab, although only 22% of patients will stay in remission without the use

of additional steroids.[34] Methotrexate may be considered in individual cases if infliximab is unavailable, although evidence for its use is limited to one small trial. The prolonged use of systemic steroids to maintain remission should not be encouraged because of their well-documented side effects.

SURGICAL MANAGEMENT

Indications for Surgery

The indications for surgery can be classified as those requiring emergent or urgent surgery and those where surgery is performed electively. Acute colitis and toxic megacolon often require urgent or emergent surgery. Massive hemorrhage and perforation are also indications for emergency surgery, but these complications are usually seen in association with acute colitis. Overall, the most common indication is failure of medical therapy. Other indications include stricture, dysplasia or cancer, and systemic complications.

ACUTE COLITIS AND TOXIC MEGACOLON

Acute severe colitis, complicated by the presence of toxic megacolon, often requires early surgical intervention (Fig. 34-6). However, patients with acute colitis, without toxic megacolon, can be equally ill, and the risk of perforation is not closely correlated with the amount of colonic dilation. It is recommended that failure after a 24-hour trial of intensive medical therapy is an indication for urgent colectomy in patients with toxic megacolon.[35] The timing of surgery in patients with severe colitis who exhibit an incomplete response to medical therapy is less clear-cut. Joint involvement of gastroenterologists and surgeons at an early stage and frequent reassessment of patients is critical in making decisions about treatment as well as the timing of various interventions. It may also help patients mentally prepare for the possibility of colectomy, especially if a trial of rescue therapy is being considered. Objective predictive indices, such as C-reactive protein (CRP) of greater than 45 mg/L and a stool frequency of eight per day on day 3, can be used to guide the timing of surgical intervention,[36] but they should also be interpreted in light of the clinical, radiologic, and endoscopic findings.

When toxic acute severe colitis is successfully treated nonoperatively, approximately 50% of patients will require surgery within 1 year.[37] There are obvious advantages to attempting to settle the disease even if it means the patient will subsequently require surgery. On the other hand, acute colitis or toxic megacolon is still a life-threatening illness especially if a perforation occurs or the patient develops other septic complications. Thus, surgery should be performed immediately if there are any signs of peritonitis clinically, evidence of perforation, extreme dilation of the colon on CT scan, or if the patient fails to improve after several days of optimal medical management.

PERFORATION

Acute perforation is an infrequent occurrence, with the risk directly related to both the extent of bowel disease and the severity of the acute attack of colitis. Although the overall risk of perforation during an attack is less than 4%, the risk may rise to about 10% if the attack is severe. Perforations occur more frequently in the presence of toxic megacolon, but it is important to remember that megacolon is not a prerequisite for the development of perforation. Thus, surgery should be considered early in patients with acute colitis who are not responding to medical treatment in order to prevent this complication because postoperative morbidity increases significantly if a perforation does occur. In the presence of a colonic perforation, subtotal colectomy with ileostomy is the procedure of choice.

FIGURE 34-6 Toxic megacolon. Note the dilation of the transverse colon with loss of the haustral markings.

HEMORRHAGE

Massive hemorrhage secondary to ulcerative colitis is rare, occurring in fewer than 1% of patients and accounting for about 10% of urgent colectomies performed for ulcerative colitis. Prompt surgical intervention is indicated after hemodynamic stabilization. Rarely is there one bleeding point. More often, there is diffuse bleeding from the severely inflamed mucosal surface of the bowel. Therefore, rarely is it necessary to perform a total proctocolectomy. Instead, a subtotal colectomy is usually the preferred option, because these patients tend to be very ill and a lesser operation that does not expose the patient to a potentially hazardous pelvic dissection is better tolerated. Also, preservation of the rectum allows the patient to have a reconstructive procedure in the future. With this approach, some patients may have continued bleeding from the retained rectal segment, but rarely will urgent proctectomy have to be performed. Again, it is important to emphasize that timely surgical intervention in patients with severe acute colitis should be considered because it may obviate this life-threatening complication.

INTRACTABILITY

For most patients with ulcerative colitis, a colectomy is performed when the disease enters an intractable, chronic phase and becomes a physical and social burden to the patient. This end point is somewhat subjective and therefore requires discussion with the patient and family. Furthermore, the opinion of the gastroenterologist is equally important because he or she has usually followed the patient for a long time and has knowledge of the chronicity and severity of the symptoms as well as the response to medical therapy, whereas the surgeon is disadvantaged because he or she is seeing the patient only at one point in time. Thus, if the patient's disease is relatively settled at that time, he or she may not think that surgery is indicated when the pattern of disease has actually been characterized by frequent flare-ups or chronic symptoms.

Corticosteroids are still the mainstay of medical management of ulcerative colitis, and patients who are steroid-dependent or have quick flare-ups of the disease when the steroids are tapered should be advised to have surgery. The development of side effects of, or intolerance to, medications such as steroids, including diabetes, cataracts, and mood disorders, may also be an indication for surgery. The goal of treatment should not be preservation of the colon at all costs. Rather, the therapeutic option that will maximize the well-being, and the patient's quality of life should be chosen whether it is continuation of medical treatment or surgery. As stated previously, this is the most subjective indication for surgery and patients will vary in their preferences, and therefore it is important that they be fully informed about the risks and the outcomes that can be expected following surgery.

DYSPLASIA AND CANCER

Colorectal cancer is the most serious long-term consequence of ulcerative colitis. The reported risk of colorectal cancer is estimated to be 2% after 10 years, 8% after 20 years, and 18% after 30 years of the disease.[38]

Surveillance colonoscopy with targeted biopsies should be performed in individuals with long-standing disease. Prophylactic colectomy is not recommended. However, there are a few situations where colectomy may be performed where cancer or dysplasia is not confirmed. This includes patients with a long history of disease and multiple pseudopolyps where there is concern that it might be difficult to identify a cancer or premalignant lesion. Also, pseudopolyps, while benign and with no malignant potential, have been identified as a predictor of malignancy. Second, individuals who have a stricture generally should be advised to have surgery because it may be impossible to keep the rest of the colon under surveillance. Also, it may not be possible to ensure that the stricture is not malignant.

Recent studies have shown that raised lesions that have the endoscopic appearance of sporadic adenomas can be treated safely by polypectomy as long as there are no other areas of dysplasia.[39] However, colectomy is indicated when there is flat, high-grade dysplasia because the risk of cancer being present at the time of surgery is approximately 40%.[14] There is more controversy about the natural history of low-grade dysplasia. However, several studies have shown that the risk of a cancer being present at surgery may be as high as 15–20% and the risk of progression of these lesions over the next 5 years is in the similar range.[40] Also, because of the possibility of sampling error, repeat colonoscopy with negative biopsies may not be reassuring. Thus, most surgeons would recommend colectomy for individuals with low-grade dysplasia, the caveat being that the slides have been reviewed by an experienced GI pathologist. It is important to remember that the objective of screening is to identify and treat individuals before they develop cancer, not detect early cancer.

Because dysplasia is usually multifocal in ulcerative colitis, the entire colon and rectum should be removed. There is no role for segmental resection of dysplastic lesions or cancers.

SURGERY FOR SYSTEMIC COMPLICATIONS

In occasional patients, surgery is indicated because of the severity of extraintestinal manifestations. However, more commonly if patients are suffering from severe extraintestinal manifestations, the intestinal disease is also active. This is often the case in patients with pyoderma gangrenosum and erythema nodosa. Others such as PSC, uveitis, and iritis are usually not improved by colectomy.

GROWTH RETARDATION

Growth retardation may be an indication for surgery in the pediatric population. *Growth failure* is defined as a cessation of linear growth over a 6-month period or a decrease exceeding one or more standard deviations. There may be multiple causes of growth retardation, including inadequate intake, increased losses due to secretory diarrhea, and increased requirements because of associated sepsis or drug-nutrient interactions.

Preoperative Evaluation and Management

If possible, one should try to optimize the patient's medical status and fully evaluate the gastrointestinal tract prior to undertaking surgery. This may not be possible because of the urgency of the condition or status of the underlying disease. However, even with emergency surgery, there are certain measures, such as correction of fluid and electrolyte abnormalities, administration of antibiotic and thromboembolic prophylaxis, and stoma marking that should be done. Thromboembolic prophylaxis is required because the risk of deep vein thrombosis and pulmonary embolism is increased in patients with IBD.[40–42] In randomized controlled trials, the risk of postoperative deep venous thrombosis, as measured by venography, may be as high as 10% even in those individuals receiving prophylaxis with unfractionated or low-molecular-weight heparin. However, the risk of symptomatic thromboembolic complications is approximately 0.5% if there is adequate prophylaxis.[43]

To the contrary, the need for a mechanical bowel preparation in patients undergoing colorectal resection has been challenged. A recent meta-analysis of almost 5000 patients showed that the anastomotic leak rate and surgical site infection rate were the same in patients in whom the mechanical bowel preparation was omitted compared to those who did receive a mechanical bowel preparation.[44]

Many patients having surgery will be on high doses of steroids or will have been on steroids for a prolonged period. Brown and Buie reviewed the literature and concluded that there is no evidence that supraphysiologic doses of corticosteroids are necessary to prevent hemodynamic instability or adrenal insufficiency in patients who have been on steroids preoperatively.[45] They recommended that patients should continue on the same dose of steroids throughout the perioperative period. Postoperatively steroids should be weaned slowly to avoid adrenal insufficiency, especially in individuals who have been on steroids for a prolonged period.

If possible, the nutritional status of the patient should be optimized. While there is little evidence to support a course of preoperative total parenteral nutrition (TPN), in some situations it may be worthwhile. Alternatively, if enteral feeds are tolerated, surgery may be delayed while the nutritional status of the severely malnourished patient is improved.

An ileostomy is frequently required in patients having surgery for ulcerative colitis. It may be permanent or temporary. Preoperative marking of the stoma is essential because how well the stoma functions may have a profound effect on outcome and the patient's acceptance of it. When a stoma is sited, it should be placed away from scars and creases and in a location where the patient can visualize it adequately when sitting or lying. If not, the patient may have difficulty changing the appliance. Both stoma placement and siting of incisions are extremely important in patients with ulcerative colitis. These patients will often require multiple operations, possibly require stoma revisions in the future, and may have significant weight gain or loss in the future. Thus, not only must the stoma be placed well initially but other sites, say in the left lower quadrant, should be preserved. For this reason, midline incisions are preferred.

Serious cardiac and respiratory complications are unusual because most patients having surgery for ulcerative colitis are young. However, if there are associated medical conditions, they should be treated. Finally, patient education is an important aspect of surgical management. The patient should be prepared both physically and psychologically for surgery.

SURGICAL OPTIONS

Historical Perspective

Sigmoid colostomy was the first documented surgical procedure for ulcerative colitis. It was not until the 1940s when it became clear that the only definitively curative treatment of chronic ulcerative colitis is total proctocolectomy or, as a compromise, subtotal abdominal colectomy with ileostomy. However, the ileostomy was fraught with technical problems from the outset, including the optimal location of the ostomy site, surgical construction and attachment techniques, and leak proof collection pouches and skin barriers. All of these contributed to a high complication rate and patient dissatisfaction. It was not until the early 1950s when Brooke in the United Kingdom and Crile and Turnbull in the United States proposed that the ileal stoma could be immediately matured into the skin with primary mucocutaneous suturing.[46,47] This innovative procedure, coined the "Brooke ileostomy" (Fig. 34-7), when performed after a proctocolectomy, rapidly emerged as the surgical procedure of choice for ulcerative colitis and finally offered patients a curative operation with a reasonably manageable outcome.

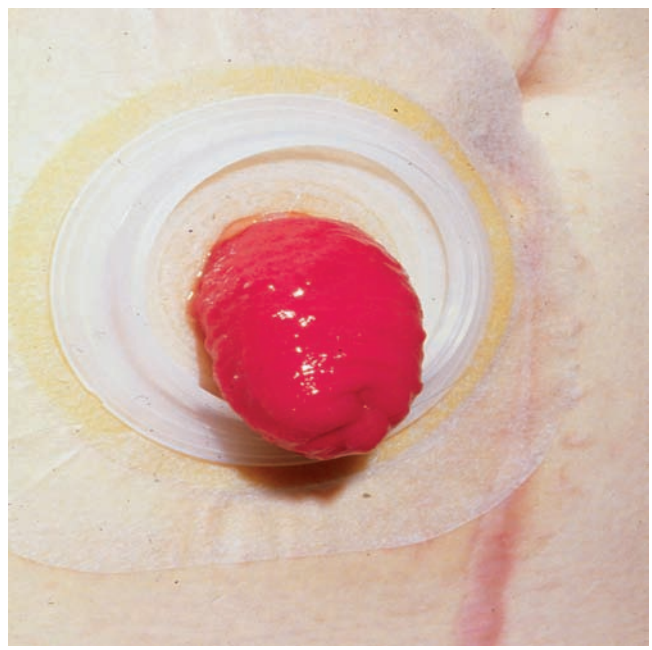

FIGURE 34-7 Ileostomy.

Perhaps the earliest attempt to promote a more functional and continent alternative to a permanent ileostomy was proposed by Stanley Aylett of the United Kingdom, who in the early 1950s began performing colectomy and IRA for ulcerative colitis.[48] Despite the fact that diseased mucosa remaining in the rectal segment clearly increased the risk of persistent symptoms and cancer of the rectum, he performed nearly 400 such procedures through the mid-1970s, with relatively satisfactory functional outcomes and a low cancer rate.[49] The next major advance in the surgical treatment of ulcerative colitis was the description of the continent ileostomy, or Kock pouch by Kock[50] in the late 1960s. It was his reasoning that a high-volume, low-pressure reservoir could be constructed and attached to the abdominal wall, which could be emptied using a catheter but otherwise would be continent. To make the reservoir, Kock initially described taking an isolated loop of small bowel that was divided at its antimesenteric border and folded into a U and closed side to side. However, continence was not maintained, and subsequently a valve made out of an intussuscepted segment of small bowel was interposed between the reservoir and the outlet. Patients then passed a tube through the flush stoma to empty the pouch. Patients searching for an alternative to a Brooke ileostomy enthusiastically received the Kock pouch. Although they still had a stoma, they did not have to wear an appliance. Unfortunately, the procedure is technically difficult and despite multiple technical revisions to the procedure, there is a high complication rate and need for reoperation. In addition, the patient still has a stoma, leading surgeons to seek other alternatives. Thus, in the early 1970s, Parks and Nicholls[51] and Utsunomiya et al[52] independently adopted the concept of the ileal reservoir that Kock had described and anastomosed it to the anal sphincter. Continence and stool frequency was acceptable, and the patients could evacuate via the normal route. In addition, following multiple technical changes, the procedure could be performed with relatively low morbidity, good functional results, improved quality of life, and patient satisfaction. Thus, the IPAA, ileoanal "pull-through" or restorative proctocolectomy, is currently the procedure of choice for most patients requiring surgery.

Currently, there are several options for patients requiring surgery for ulcerative colitis. Subtotal colectomy and ileostomy is often performed in patients requiring surgery urgently or emergently. The more definitive options include colectomy and IRA, total proctocolectomy and end ileostomy or Kock pouch, and IPAA. All have advantages and disadvantages, and the patient must be fully informed about the procedures, including the risks and functional results so that he or she may partake in the decision making. However, irrespective of the procedure, most patients following surgery have an improved quality of life.

Subtotal Colectomy and Ileostomy

Subtotal colectomy and ileostomy is often performed as the first stage prior to a more definitive procedure. The most common indication is in the emergency or urgent situation in patients with acute colitis. Even in patients with severe colitis, including those with severe bleeding, colectomy alone usually results in a dramatic clinical improvement without the morbidity associated with a potentially hazardous pelvic dissection. The inflammatory process may persist in the retained rectum, but it is usually not severe and requires no treatment or perhaps topical medical therapy. Proctocolectomy is only rarely indicated if there is profound hemorrhage from rectal ulceration. A second indication is in individuals with chronic disease who are malnourished and are on high doses of corticosteroids (the equivalent of 30 mg or more of prednisone/day). Finally, if there is uncertainty about whether the diagnosis is ulcerative colitis or Crohn's disease, by removing the colon first, a formal pathologic assessment of the specimen can be made and the rectal disease can be dealt with at a subsequent operation.

While subtotal colectomy is an excellent operation in these situations, it is not a definitive procedure, and unless there is a contraindication, proctectomy should be performed in the future as there is an ongoing risk of malignancy. A cancer may occur without symptoms until it is quite advanced. Surveillance of the rectum in the long term is usually inadequate.

SURGICAL TECHNIQUE

After induction of general anesthesia with endotracheal intubation, patients are placed in the lithotomy position. The bladder should be catheterized. A midline incision provides wide access to the abdomen and does not compromise placement of a stoma on either side of the abdomen. Upon entering the abdomen, an exploratory laparotomy should be performed with particular attention to the terminal ileum to ensure that there is no disease because this would make one think the patient has Crohn's disease. Great care should be taken in the handling of the tissues as they may be extremely friable in severe disease or in cases of prolonged steroid use. This is especially true of the flexures where a walled off perforation may not be apparent. Mobilization usually begins with the right colon. In some patients, the flexures may be easier to mobilize owing to the shortening of the bowel seen in chronic disease. Care must be taken to protect the ureters, duodenum, and spleen. Our preference is to remove the omentum because preserving it may increase the risk of adhesional obstruction. Some surgeons preserve it, arguing that it may limit sepsis from an anastomotic leak in a subsequent IPAA.

The terminal ileum should be divided immediately proximal to the ileocecal valve to preserve bowel length if an IPAA will be performed at a later date. Our preference is to divide the colon in the distal sigmoid with preservation of the inferior mesenteric and superior rectal arteries, as it is easier to mobilize the rectum subsequently and decreases the risk of injury to the left ureter and sympathetic nerves. Perhaps the most important reason, though, is that it permits exteriorization of the rectal stump in patients with severe colitis. Breakdown of the rectal stump occurs infrequently but is the most significant complication following this procedure. In our own

series of patients, between 5 and 10% of patients experienced a blown rectal stump depending on the severity of the disease at surgery when the rectum was closed and left within the abdomen.[53,54] There is significant morbidity associated with a blown rectal stump, including development of a pelvic abscess or even generalized peritonitis. There are three options for handling the rectum including an exteriorized mucous fistula, closure of the rectum with exteriorization in the subcutaneous tissue, or Hartmann's procedure with placement of a 30F Foley catheter to decompress the stump. The decision about how to handle the rectal stump should be based on the severity of disease and the friability of the rectosigmoid at the time of surgery. An exteriorized mucous fistula is the safest method if the rectosigmoid is very friable but may continually drain a large volume of mucous and blood, necessitating the wearing of a second appliance. Closure of the rectum and its exteriorization in the subcutaneous tissue is often a good compromise in the presence of friable tissue, although outcomes have only been reported by a few centres.[53,55,56] In our own experience, one-third of patients with subcutaneous stump closure will go on to develop breakdown of the rectum with persistent drainage and possible wound infections.[53] However, serious intra-abdominal septic complications are avoided. The rectal stump may be stapled off in patients where the risk of a leak from the rectal stump is deemed to be small.

There is increasing evidence that laparoscopic subtotal colectomy, even in acute colitis, can be performed safely. Initially, a 12-mm port is inserted at the umbilicus, with ports then inserted in each of the four quadrants lateral to the rectus sheath. Mobilization of the colon from its peritoneal attachments is performed in much the same fashion as in the open approach. Retraction of the small bowel is facilitated by tilting of the operating table. Division of the mesocolic vessels is made close to the bowel wall and can be achieved intracorporeally with use of clips, vascular staplers, or an energy device. Mobilization of the transverse colon and division of the middle colic vessels may be difficult and tedious. Thus, the colon can be delivered through the umbilical port site, and division of the mesentery of the transverse colon can be completed extracorporeally. The terminal ileum and distal sigmoid colon can be divided using stapling devices and extracted through the umbilical site. Alternatively, the specimen can be extracted through a Pfannenstiel incision, through which a subsequent proctectomy can be performed or through the ileostomy site that may provide some additional cosmetic benefit.

Early concerns about the safety of the laparoscopic approach, particularly in cases of acute severe colitis, limited its introduction. Evidence is now emerging from specialist centers that laparoscopic subtotal colectomy is not only safe but may confer potential benefits in terms of postoperative recovery. However, many studies are limited by the inclusion of patients with noncolitic indications for colectomy. Several series have reported a reduced length of stay and time to bowel function, at the expense of an increase in operating time with the laparoscopic approach.[54,57–59] A few comparative observational studies have even suggested that time to restorative proctocolectomy may be reduced by employing the laparoscopic approach to initial subtotal colectomy.[60,61] There are currently no randomized controlled trials comparing outcomes between the laparoscopic and open approaches, so the benefits reported in these studies should be viewed with caution in light of their inherent selection bias. Data on the late complications of laparoscopic subtotal colectomy, such as incisional herniation and small bowel obstruction, are lacking, which may reflect the fact that many of these patients go on to subsequent proctectomy within a few months of surgery.

Colectomy and Ileorectal Anastomosis

Because ulcerative colitis almost always involves the rectum, there are limited indications for colectomy and ileorectal anastomosis (IRA). If there is sparing of the rectum, a colectomy and IRA may be preferred over IPAA because of the concern that the patient might have Crohn's rather than ulcerative colitis. However, this is an infrequent occurrence.

Patients may continue to suffer from symptoms of proctitis following surgery. They also continue to be at risk of developing dysplasia and cancer, so they require ongoing surveillance. On the other hand, the advantages to an IRA are that it avoids the risk of pelvic nerve injury and poor perineal wound healing. Generally, the procedure can be performed in one stage.

SURGICAL TECHNIQUE

The extirpative phase of the operation is similar to that of colectomy and ileostomy. The superior hemorrhoidal vessels may be preserved if the anastomosis is performed in the distal sigmoid. More often, the anastomosis is performed at the level of the sacral promontory, and the superior hemorrhoidal vessels are divided. Our preference is to perform a hand-sewn anastomosis because usually the rectal wall is inflamed and the risk of a leak may be lower when a hand-sewn anastomosis is performed rather than a stapled anastomosis. The anastomosis may be performed either as an end-to-end or end-to-side anastomosis. Some suggest defunctioning the anastomosis with a loop ileostomy, but, in this era, if the anastomosis is that tenuous, another surgical option should be considered.

Proctocolectomy and Ileostomy

The intestinal component of chronic ulcerative colitis is cured once the colon and rectum are removed. Therefore, total proctocolectomy with the Brooke ileostomy has historically been the operation of choice. The advantages of this procedure are the following: It can often be performed as a one-stage procedure, the disease is eliminated so patients no longer require medical therapy, and there is no longer the risk of developing a malignancy. The disadvantage is that individuals have a permanent ileostomy. Patients having surgery

for ulcerative colitis tend to be young, physically active, and single, so there may be social implications associated with a permanent stoma. While patients feel quite negatively about the prospect of having a stoma preoperatively, studies have consistently shown that most patients are accepting of an ileostomy and that their quality of life is very high postoperatively.[62–64] Only a very small proportion of patients have significant psychological problems dealing with the stoma.

In the modern era, total proctocolectomy is typically performed in older patients, in those with significant comorbidities or in those who are not candidates for IPAA. The latter includes patients with low rectal cancers, and those who have perianal disease, have had a prior anorectal surgery or a small bowel resection.

SURGICAL TECHNIQUE

Total proctocolectomy can be performed either as a single-stage procedure, or in the two stages: subtotal colectomy followed by abdominoperineal resection of the rectum.

Patients are placed in the lithotomy position with the buttocks over the edge of the table. The buttocks should be taped apart and the anus sewn shut with a silk purse-string suture. A 1 L of saline bag may be placed under the sacrum to aid with exposure. The perineum should be widely prepped and draped. The vagina should be prepped to allow the surgeon to insert a finger into the vagina to guide the perineal dissection. Care should be taken to protect the peroneal nerves and avoid compression of the posterior compartments of the lower leg. Compartment syndrome after an extended period of time in lithotomy has been described. The arms should be tucked to the patient's sides and padded to protect the hands and forearms. A urinary catheter is mandatory to decompress the bladder. The use of a nasogastric tube is usually not necessary. The abdomen should be entered through a long midline incision, and the colectomy is performed as described previously. In this case, the inferior mesenteric vessels should be divided. A low ligation is preferred to minimize the likelihood of sympathetic nerve injury, unless dysplasia or a cancer was identified preoperatively.

The rectum is mobilized posteriorly in the plane between the fascia propria of the rectum and the presacral fascia posteriorly similar to that for a total mesorectal excision for rectal cancer. The plane is entered after ligating the superior hemorrhoidal/inferior mesenteric vessels. Care is taken to identify and protect the left ureter and the sympathetic nerves. The serosa covering the rectum is scored anteriorly and laterally on both sides. The dissection to the pelvic floor is carried out posteriorly first, extending laterally and then anteriorly. The dissection below the peritoneal reflection differs from that of a cancer operation in that the rectum is skeletonized of its mesorectum in order to reduce the risk of parasympathetic nerve injury. Anteriorly, the dissection is performed on the rectal side of Denonvilliers' fascia to avoid injury to the vagina or the seminal vesicles and prostate. Massive hemorrhage due to injury to the presacral or internal iliac vessels can occur during this part of the dissection, but it should be a rare event as compared to when a more radical oncologic procedure is performed. Bleeding occurs due to misadventure when the wrong planes are entered posteriorly or laterally. Control of bleeding from the presacral veins can be particularly problematic as these vessels can retract into the sacrum and are not easily clamped or tied off. A suture ligature through the periosteum of the sacrum or a sterile tack nailed into the sacrum may be required. On rare occasions, tight packing of the pelvis with sponges may be required with removal of packs 24 to 48 hours later. Similarly, injuries to the vagina in women, or the urethra in men, are possible complications during pelvic and perineal dissection, but they occur rarely and are due to dissection in the wrong plane. Vaginal injuries can be repaired primarily whereas urethral injuries are best managed by a urologist.

Once the abdominal dissection is completed to the level of the levator muscles, the perineal dissection is performed. An intersphincteric dissection is preferred to a wide resection as performed in patients with rectal cancer unless a low-lying cancer is identified preoperatively. In so doing, the external sphincter and levator muscles are preserved. This minimizes the size of the perineal defect and decreases bleeding and wound complications. A solution of dilute epinephrine is injected into the intersphincteric plane to decrease bleeding and make the intersphincteric plane more obvious. The dissection begins posteriorly until the perineal and abdominal operators hand-touch, whereupon, guided by the abdominal operator with a hand in the pelvis posterior to the rectum, the perineal surgeon enters the pelvis just anterior to the tip of the coccyx with a pair of curved Mayo scissors. The perineal surgeon may then hook the levator muscles with a finger laterally in either direction and divide the muscles with electrocautery. Once the posterior and lateral dissection has been completed, the rectum can be brought out of the perineum to facilitate anterior dissection. Alternatively, the abdominal surgeon may direct the perineal surgeon as he or she passes scissors anteriorly between the rectum and the vagina or prostate into the abdominal cavity. Then the levator muscles may be divided laterally to complete the dissection. Once hemostasis is achieved, the pelvis is irrigated through the abdominal wound and drained through the perineal wound. A drain is placed in the pelvis through a separate incision in the abdominal wall to prevent accumulation of blood or serous fluid that may subsequently drain through the perineum. The skin may be closed or the perineum may be closed in layers, approximating the pelvic floor muscles and skin. Absorbable sutures are typically used in the skin.

An ileostomy is constructed in the right lower quadrant that has been marked preoperatively. In order to facilitate its construction, a high ligation of the ileocolic vessels may be performed. There is usually an avascular window approximately 15 cm in length between the ileocolic vessels and the superior mesenteric vessels. The mesentery of this segment of bowel can be narrowed so the bowel is supplied by a marginal artery running along its edge. The ileostomy should be brought out through the aperture so it is not under tension. The fascia and skin of the abdominal wall should then be

closed prior to maturation of the ileostomy. Also, before doing so, the mesentery can be sutured to the posterior abdominal wall to prevent an internal hernia. The ileostomy should be matured so it has a height of approximately 2 cm and it sits upright (see Fig. 43-7).

Kock Pouch

Following total proctocolectomy, a Kock pouch or continent ileostomy may be constructed instead of a conventional ileostomy. The advantage of this operation is that it is a curative procedure that potentially offers improved quality of life because patients are continent and do not have to wear an appliance. The main disadvantage is that the procedure is technically challenging and therefore the complication rate is high. Most of the complications are valve related, and, if they do occur, patients generally require reoperation. Reported long-term failure rates are in the order of 10–40%.[65–68] The second disadvantage is that even though patients are continent, they still do not evacuate via the normal route and must insert a tube to empty the pouch. For both of these reasons, the Kock pouch has been rarely performed since the introduction of IPAA. The main indication now is in patients who have already undergone a total proctocolectomy and ileostomy and thus are not candidates for an IPAA. Also, individuals who have had a failed IPAA or who have anal disease may be candidates.

SURGICAL TECHNIQUE

The Kock pouch can be constructed following extirpation of the colon and rectum as described previously or, alternatively, it can be constructed at a later date with takedown of the conventional ileostomy.

The reservoir is made from two or three limbs of small bowel. Although the initial description was that of a two-limb pouch, a three-limb pouch is usually performed now. Approximately 55 cm of terminal ileum is used to construct the continent ileostomy: a 5- to 10-cm segment for the outlet, 15-cm for the nipple valve, and 30-cm for the reservoir itself. The reservoir is constructed by suturing the three 10-cm limbs of small bowel to form the posterior wall of the reservoir. Then the 15-cm segment of small bowel is intussuscepted to form the nipple valve. The valve is maintained by stapling the intussuscepted segment with three firings of the GIA 80-mm stapler, two of those firings being on either side of the mesentery. Then the anterior wall of the reservoir is suture-closed. Because of the problems of slippage of the valve, the valve can be stabilized with several maneuvers, including a sling of fascia or soft mesh through the mesentery and around the fundus of the pouch.[69–71] This anchors the pouch to the posterior wall of the abdomen and provides support for the mesentery of the small bowel that forms the nipple valve. Other maneuvers include defatting the mesentery or stapling the valve to the wall of the pouch.[71] All of these have been used by proponents, but unfortunately valve slippage continues to be a significant complication. Of all the maneuvers, insertion of a mesh is most effective, but it is at the expense of fistula formation from erosion of the mesh into the fundus of the pouch.

Once the pouch is completed, the outlet can be brought up through an aperture low in the abdomen and sutured to the fascia of the anterior abdominal wall. Then the stoma is matured flush with the skin. A catheter is inserted to ensure that it can be passed easily. It is usually left in situ for 2–3 weeks until the pouch has become fully adherent to the abdominal wall (Fig. 34-8).

Ileal-Pouch Anal Anastomosis

Ileal-pouch anal anastomosis (IPAA) is the procedure of choice for most patients requiring surgery for ulcerative colitis. Its major advantage over other procedures is that the normal route of evacuation is maintained and a permanent ileostomy is avoided. The reported outcome is also satisfactory in patients who have indeterminate colitis, but Crohn's disease is generally considered a contraindication.[72,73] Regimbeau and colleagues reported a low failure rate of 10% in a series of 41 patients who had an IPAA constructed for Crohn's disease, but most other series report failure rates up to 50%.[74] Furthermore, there do not appear to be any factors that predict which patients will have a good outcome.[72]

Because IPAA can now be performed safely with relatively few complications, there are fewer relative contraindications. IPAA may be performed in older patients although functional results tend to worsen with age.[75] Thus, individuals older than 60 years should be fully informed of all options, particularly total proctocolectomy and ileostomy. While most patients dread the thought of having an ileostomy when they are considering surgical options, in reality quality of life tends to be excellent with an ileostomy and most patients adjust well to it. A decision whether to perform an IPAA should be based on the age and comorbidities of the patient as well as the status of the anal sphincter. Perianal disease is usually a contraindication because of the concern that the patient may have Crohn's disease, as well as concerns about healing. However, IPAA may be considered in selected patients provided the anal disease can be eradicated prior to performing IPAA without compromising the sphincter.[76]

Patients with cancer may also be considered for IPAA provided the oncologic operation is not compromised. Thus, while IPAA may be a satisfactory option for patients with colon cancer, patients with low rectal cancers or those requiring neoadjuvant or postoperative radiation generally are not candidates. Furthermore, patients who do not have a confirmed cancer in the rectum but have high-grade dysplasia also should not have IPAA because of the high probability that cancer is in fact present and it may be inadequately excised. Although there are a limited number of reports, most patients who have a pouch and have had pre- or postoperative radiation have poor functional results and often lose the pouch. Last, patients with advanced disease should probably undergo

FIGURE 34-8 The stoma of a Kock pouch is made flush with the skin. A tube is inserted into the pouch to empty it.

one of the other less complicated surgical options such as subtotal colectomy or total proctocolectomy. Depending on the site of the cancer, colectomy may be a good alternative because it can be performed with low morbidity and in the future an IPAA could be considered if the patient survives.

SURGICAL TECHNIQUE

Various modifications to IPAA have been described since it was initially introduced and there still is some variability in how the procedure is performed. First, the procedure can be performed in one, two, or three stages. A one stage operation (removal of the colon and rectum and construction of the pouch without a defunctioning ileostomy) is generally not performed because the reported ileoanal anastomotic leak rate is high. However, several authors have reported acceptable results with this surgical approach.[77–79] Generally, though, a one-stage procedure should not be performed by the inexperienced surgeon or in patients who are in suboptimal condition.

Two-stage procedures can be performed as colectomy, IPAA construction and a defunctioning ileostomy initially followed by closure of the ileostomy at a later date. Alternatively, a subtotal colectomy can be performed first, and at a subsequent procedure a proctectomy can be performed with construction of a pouch. Then, the defunctioning ileostomy can be omitted (two-stage procedure) or can be performed (three-stage procedure).

Our preference is to perform a two-stage procedure. In patients who require surgery urgently for acute colitis or are in suboptimal condition caused by poor nutritional status or are on more than the equivalent of 30 mg of prednisone per day, a subtotal colectomy is usually performed. At a second operation we would plan to do a proctectomy and construct the pouch without constructing an ileostomy unless there were intraoperative complications, the pelvic dissection was particularly difficult with significant blood loss, there was tension on the ileoanal anastomosis (IAA), or the IAA was incomplete. Patients who have surgery electively usually have a two-stage procedure also, but this includes proctocolectomy, pouch construction, and a defunctioning ileostomy. After 3–4 months, the ileostomy is closed after a Hypaque study has shown that the IAA and pouch are intact.

Several pouch configurations have been described, including J-, S-, and W-shaped pouches.[80] The J-pouch is the preferred type as it is technically easier to create and can be fashioned using a linear stapler. W-pouches are advocated because of their increased reservoir capacity, but this effect is seen only initially; long-term studies have shown no difference in bowel function between pouch types. S-pouches tend to be tedious to construct as they must be hand-sewn, but they are preferred when a hand-sewn IAA is required as they provide more length to reach the anal canal, the pouch fits through the canal easier, and the configuration allows for an end-to-end IAA.

The last area of controversy is whether the IAA should be hand-sewn or stapled.[81,82] Although mucosectomy and hand-sewn anastomosis was the technique described in the first descriptions, stapled anastomosis is now the preferred method. It is technically easier and quicker. Performing a hand-sewn IAA is usually more difficult, especially in obese individuals, because the pouch may be under tension. This is rarely the case if the anastomosis is stapled. Functional results also tend to be better with a stapled IAA. On the other hand, a few centimeters of rectal mucosa remain if the anastomosis is stapled and thus the disease is not eliminated. Concern has been raised over the risk of ongoing inflammation or cancer developing in the rectal remnant. In fact, even if a mucosectomy is performed, the disease is not completely eradicated and there have been a few reported cases of cancer arising after mucosectomy.[83] Ongoing inflammation requiring treatment is a rare occurrence.[84] Thus, it is our preference to perform a stapled IAA unless the patient has a cancer or dysplasia elsewhere in the colon and, if so, then perform a mucosectomy and hand-sewn IAA if it is technically possible.

SURGICAL TECHNIQUE—OPEN IPAA

IPAA surgery can be divided into two phases: extirpative and reconstructive. The colonic and rectal dissection is performed similar to the abdominal dissection performed for total proctocolectomy. If a stapled IAA is planned, a 30-mm transverse linear cutting stapler can be used to staple off the rectum at the level of the levator muscles. The intent is to leave 1–2 cm of rectal mucosa. If a hand-sewn anastomosis is planned, the rectum can be divided at this level.

Some surgeons preserve the ileocolic vessels and divide one of the arcades to increase the length of the mesentery, but this is not necessary in our experience.[85] Rather, it is our preference to divide the ileocolic vessels close to their takeoff from the superior mesenteric vessels. That will add a few centimeters of length to bring the pouch down to form the IAA. The terminal ileum is divided with a linear stapler just proximal to the ileocecal valve.

The reconstructive phase of IPAA begins with full mobilization of the small bowel. If the patient had a subtotal colectomy previously, this begins with takedown of the patient's end ileostomy. The distal 1–2 cm of the ileum is resected with a linear stapler. At our center, this staple line is oversewn with 3-0 absorbable suture in a Lembert fashion, as leaks from the staple line have occurred. All adhesions between loops of small bowel are divided, and the mesentery of the small bowel is mobilized up to the level of the duodenum. If the IAA is stapled, "length" is usually not a concern, but, if a mucosectomy and hand-sewn anastomosis is performed, the small bowel mesentery must be fully mobilized back to the duodenum. Some authors have recommended scoring the peritoneum, but, if this is done, there is a risk of tearing the mesentery and vessels if there is tension on the mesentery when the small bowel is brought down to the pelvis to construct the IAA.

Next, the ileal pouch is fashioned (Fig. 34-9). Before doing so, the bowel should be assessed to see if it will reach the anus. Generally, if the small bowel mesentery in the line of the superior mesenteric vessels stretches beyond the pubic symphysis, it should be adequate to perform a stapled IAA. To construct a J-pouch, the terminal ileum is folded over on itself creating two limbs approximately 15 cm long. Our preference is to orient the pouch so the mesentery lies on the right side somewhat anteriorly and the pouch lies in the hollow of the sacrum with the afferent limb of small bowel entering the pouch on the left side of the pouch. An enterotomy is made on the antimesenteric aspect of the apex of this fold, and two passes of an 80-mm linear stapler are used to create the pouch. A 2-0 polypropylene purse-string suture is placed at the enterotomy to secure the endoanal stapler anvil in place, and a double-staple IAA is constructed using a 28-mm circular stapler. The anvil in the pouch is attached, and the stapler is closed with care not to incorporate adjacent tissue, such as the vagina in women, into the staple line. The orientation of the pouch is confirmed, and the stapler is fired and removed. The proximal and distal tissue donuts are inspected for size and continuity. The pouch is then tested for a leak by advancing a 30F rectal tube into the pouch through the anus. A rectal tube is inserted and secured in place if no ileostomy is constructed and the abdomen is then closed. Otherwise, an ileostomy is brought up through an aperture in the right lower quadrant. Typically the ileostomy is constructed approximately 30 cm proximal to the pouch but varies depending on several factors, the most significant being the weight of the patient.

If a hand-sewn anastomosis is planned preoperatively, the buttocks are taped apart to facilitate access. A Lone Star retractor (CooperSurgical, Inc., Trumbull, CT) is placed at the dentate line to draw the rectal mucosa into the anal canal. A solution of dilute epinephrine is injected submucosally, and the mucosectomy is performed with Metzenbaum scissors or electrocautery starting at the top of the dentate line. Our preference in this situation is to construct an S-shaped pouch that is performed by leaving a 1- to 2-cm outlet and then suturing three limbs of approximately 10 cm of small bowel together. A Babcock clamp is inserted through the anus to grasp the pouch, and the pouch outlet is brought through the anal canal to the anus. This can be difficult, and having two experienced surgeons, one guiding the pouch from above and the second one as the perineal operator, is advantageous during this short but critical part of the operation. Once the pouch is positioned in the pelvis, the stapled end of the S-pouch can be excised or an enterotomy at the apex of the J-pouch can be made and a hand-sewn anastomosis between the ileal pouch and the dentate line can be completed using interrupted 2-0 absorbable sutures beginning with sutures placed in the anterior, posterior, and either lateral position, and then circumferentially until the anastomosis is complete.

SURGICAL TECHNIQUE—LAPAROSCOPIC IPAA

Evidence regarding outcome following laparoscopic IPAA is more widespread than for subtotal colectomy. Laparoscopic IPAA appears to confer similar short-term advantages as

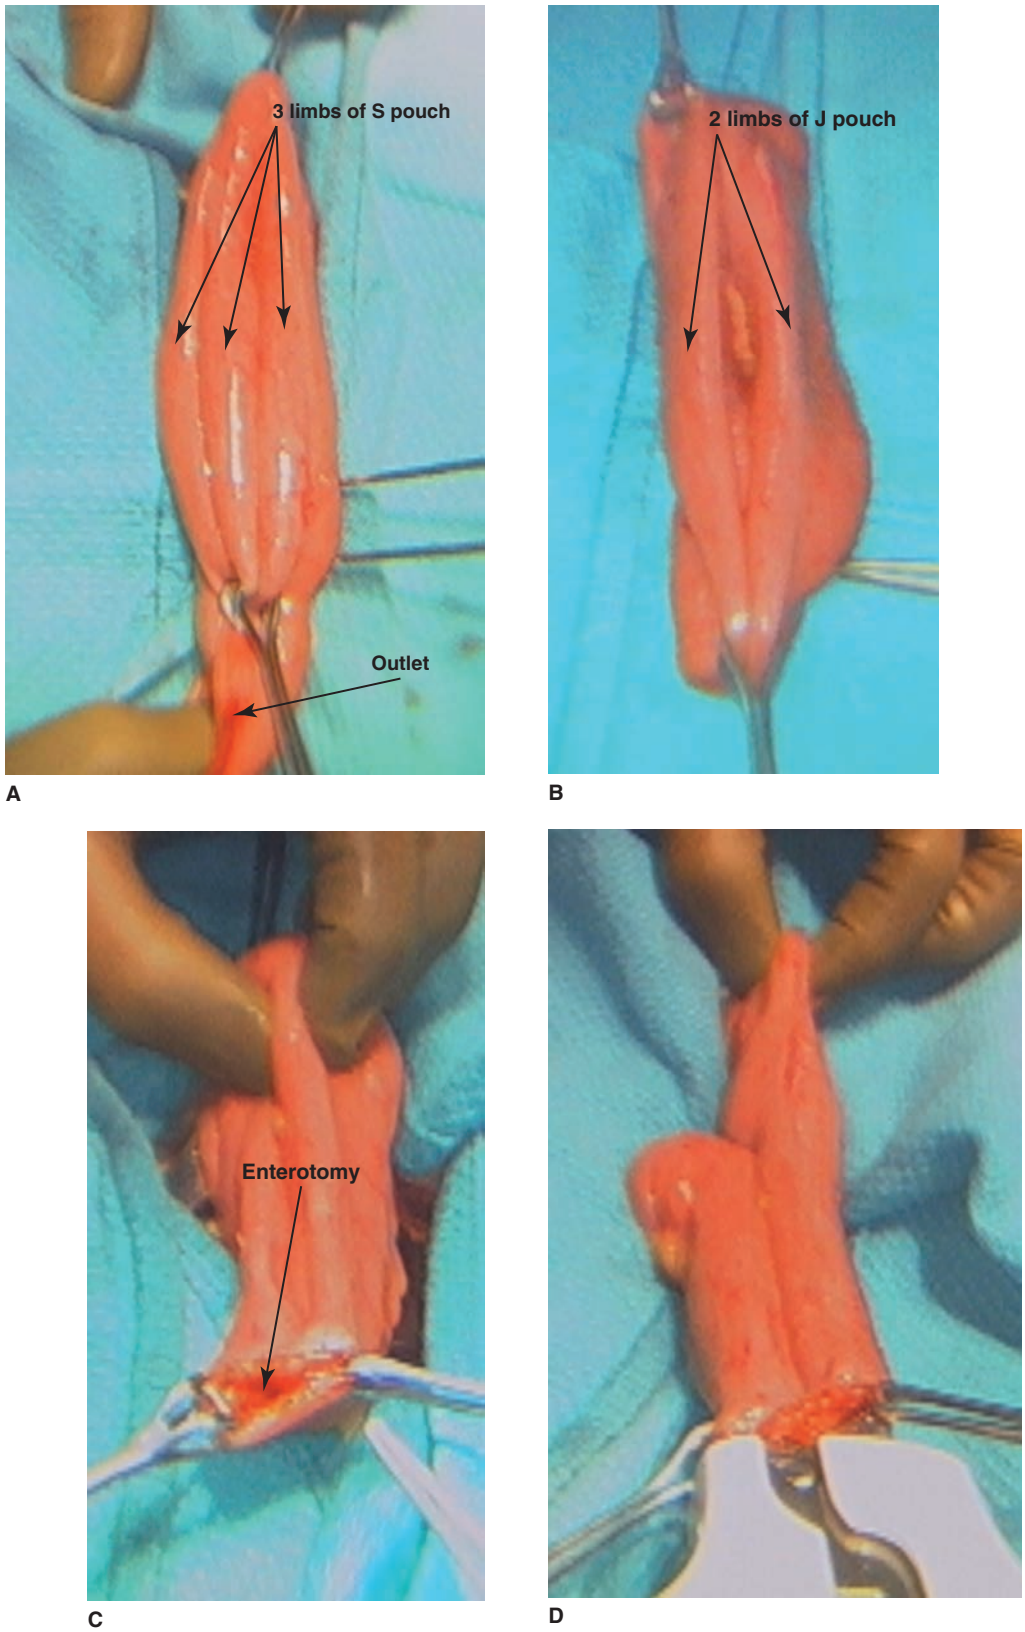

FIGURE 34-9 **A.** S pouch is constructed from 3 limbs of small bowel each approximately 10 cm in length. The outlet should be approximately 1–2 cm in length. **B.** J pouch is constructed with 2 limbs of terminal ileum each approximately 15 cm in length. **C.** An enterotomy is made at the apex of the J pouch. **D.** Two passes of an 8 cm linear stapler is passed through the apex of the J pouch to construct the pouch.

The rectum is then divided so approximately 1–2 cm of rectum is left. **G.** The circular stapler is passed through the rectum and the anvil is opened and the center peg pierces the stapled rectum. **H.** The anastomosis is completed and then checked for an air leak. Note the afferent limb coming down into the pelvis on the lefthand side of the pouch.

laparoscopic subtotal colectomy, with a reduction in length of stay, blood loss, and return of bowel function being reported by several large case-matched series.[86,87] Only one randomized controlled trial has been published to date and this showed that laparoscopic proctocolectomy and ileal anal-pouch anastomosis took 77 minutes longer.[88] No differences in length of stay, morbidity, or long-term functional outcome were demonstrated in this trial, although higher body image and cosmesis scores were reported in the laparoscopic arm.[89] Laparoscopic surgery has been associated with a reduced tendency to adhesion formation,[90] but there are insufficient long-term follow-up data to determine whether there will be a subsequent reduction in the incidence of small bowel obstruction in patients undergoing restorative proctocolectomy. The risk of infertility in women may be decreased with the laparoscopic approach. A marked increase in operating time appears to be a universal finding as surgeons seek to overcome their learning curve with this procedure.

The colectomy is performed as described previously. The vascular supply of the colon is best divided intracorporeally. Similarly, the rectal dissection is performed in the same fashion as the open approach with dissection in the mesorectal plane above the peritoneal reflection and close to the rectal wall below it, continuing to the level of the levators. The rectum is divided at the pelvic floor, 1–2 cm above the dentate line, with a 30-mm stapler.

Our preference is to make a Pfannenstiel incision for the extraction site. If necessary, dissection of the lower rectum can also be completed through this incision. Also, it allows for better positioning of the transverse linear stapler on the rectum. The pouch is fashioned extracorporeally, and the IAA is constructed using the double-stapled technique. Care must be taken to ensure that the mesentery of the pouch is oriented correctly without any twisting. Indications for defunctioning the IPIAA are the same as for the open procedure.

The technical complexity of laparoscopic subtotal colectomy and IPAA has renewed focus on the potential benefits of the hand-assisted technique. Recent studies have demonstrated that the hand-assisted technique significantly reduces operating times in restorative proctocolectomy without compromising short-term outcomes.[91,92] A longer incision is usually required to permit manual access, and this has raised concerns about subjecting the abdominal viscera to excessive trauma.[93] It is not clear whether the hand-assisted technique actually maintains the true minimally invasive characteristics of straight laparoscopic surgery, as it may provoke a more dramatic inflammatory response. Data are lacking on the long-term outcomes between the two techniques, although early reports suggest that there is no difference in the rate of incisional herniation and small bowel obstruction.[94] A more selective approach to the use of the hand-assisted or straight laparoscopic technique may eventually develop. For example, a troublesome colonic mobilization may be facilitated by the use of a hand port, whereas a more straightforward case could be continued using the straight laparoscopic technique.

Complications of Surgery

SMALL BOWEL OBSTRUCTION

Intra-abdominal adhesions develop in virtually all patients undergoing major abdominal and pelvic procedures. Although adhesions do have beneficial effects, they are also the primary cause of small bowel obstruction after abdominal surgery. Patients who have a total extirpation of the colon and rectum are at particularly high risk for the development of small bowel obstruction, possibly because of the combined abdominal and pelvic dissection, and sometimes need for multiple operations.

In patients having IPAA, the reported cumulative risk of small bowel obstruction ranges from 12 to 35% with follow-ups of 2.5–68 months.[95] The risk of small bowel obstruction was 8.7% at 30 days, 18.1% at 1 year, 26.7% at 5 years, and 31.4% at 10 years in our own series. However, most patients did not require reoperation. The reoperative rate was 2.7% at 1 year, 6.7% at 5 years, and 7.5% at 10 years. For patients requiring surgery, the most common sites of the obstruction were pelvic adhesions in approximately a third and the ileostomy closure site in 21%. The risk factors for developing a late small bowel obstruction were a previous diverting ileostomy and pouch reconstruction.

Because of the importance of the problem, various strategies have been tried. Beck and colleagues reported on 183 patients who had a barrier substance (Seprafilm) inserted at the time of construction of the pouch.[96] A significantly smaller proportion of patients in the Seprafilm group had adhesions to the abdominal wall (49 vs 94%). However, the rate of septic complication rate was significantly higher (13.5 vs 5.1%, $p < .001$) when Seprafilm was placed around the anastomosis.[96] Subsequently, in a larger study that included over 1700 patients, these authors reported that the rate of small bowel obstruction was not decreased as a result of Seprafilm use, although significantly fewer patients required surgery for small bowel obstruction over a 5-year follow-up period (1.8 vs 3.4%, $p < .05$).[97]

A laparoscopic approach to surgery is thought to result in decreased adhesion formation and a lower risk of subsequent small bowel obstruction. Indar et al reported on a series of patients who had undergone laparoscopic IPAA and found that the majority (68%) had no adhesions to the abdominal wall and 71% of women had no adnexal adhesions.[98] The long-term effect on the incidence of small bowel obstructions remains to be demonstrated.

ILEOSTOMY COMPLICATIONS

Complications related to the ileostomy occur frequently. A wide range of complications may occur and they may occur immediately after surgery as well as later in follow-up (Table 34-3). Many can be dealt with nonoperatively. An experienced enterostomal nurse is essential to provide education to the patient and handle skin problems, including those related to irritation, allergies, and yeast infections. In addition, he

TABLE 34-3: ILEOSTOMY COMPLICATIONS

Early Complications	Late Complications
Bleeding	Skin irritation
Ischemia/necrosis	Parastomal ulcers and abscesses
Mucocutaneous separation	High ileostomy outputs
	Stricture
	Fistulas
	Retraction
	Prolapse
	Peristomal hernia

or she can advise on appliance-related problems. A well-constructed stoma is essential as quality of life is directly correlated with the function of the stoma.[99]

Complications are frequent occurrences in patients with loop ileostomies performed to defunction IAA. Approximately one-third of patients will experience high ileostomy outputs. In most instances, this complication can be managed with dietary modifications and antidiarrheal agents such as loperamide and/or codeine. If the outputs remain high, intravenous fluid supplements may have to be given on a regular basis until the ileostomy is closed. Feinberg and colleagues reported that approximately 20% of patients required hospital admission for dehydration.[100] Occasionally the ileostomy has to be closed early.

Closure of the loop ileostomy is also associated with a relatively high risk of complications, the most significant of which is an anastomotic leak.[100–102] Delaying closure for several months may decrease the difficulty of mobilizing the bowel and decrease the risk of complications. The high complication rate related to the ileostomy has led some surgeons to question the need for an ileostomy. However, the morbidity of a loop ileostomy must be balanced against the potential morbidity of a leak if the pouch is not protected.

Patients who have permanent ileostomies may suffer from problems such as retraction, prolapse, and parastomal hernia. Approximately 10–20% of patients will require revision of their stoma after ten to 20 years of follow-up. Parastomal hernia is caused by enlargement of the stomal aperture. It is seen more frequently in obese patients. If the patient is asymptomatic, no treatment is required. If, however, the patient has problems with retraction of the stoma, difficulty maintaining an appliance, or recurrent small bowel obstructions, surgery may be required. A number of options are available. Local repair of the hernia performed by tightening the fascia is usually unsuccessful. Thus, the recommended treatment has been resiting of the stoma to another location. However, more recently various repairs, performed either open or laparoscopically, have been described where mesh is inserted to repair the defect. Promising results have been reported although most series are small and have short follow-up. It is a difficult problem because the risk factors that led to the hernia initially are usually still present and therefore the recurrence rate is high.

FIGURE 34-10 Pyoderma gangrenosum affecting the peristomal region.

Peristomal ulcers and fistulas occur more commonly in Crohn's disease than in ulcerative colitis. Often, it is a signal that the patient has recurrent disease in the prestomal small bowel. Thus, if a fistula occurs in a patient who is presumed to have ulcerative colitis, one should be suspicious that the diagnosis is incorrect and the small bowel should be examined for signs of Crohn's disease. On the other hand, pyoderma gangrenosa is seen more frequently in patients with ulcerative colitis (Fig. 34-10). Because pyoderma is related to disease activity, it may occur following subtotal colectomy in patients whose rectum has been left in situ. If so, proctectomy should be performed as well as resiting of the ileostomy.

PERINEAL COMPLICATIONS

Minor wound infections, defined as wound dehiscence of less than two cm in length, stitch abscesses, or sinus tracts have been found to occur in as many as 45% of IBD patients undergoing resection.[103] Major complications, including wound failures of more than 2 cm in length, perineal abscesses, or any wound complication requiring readmission or reoperation, occur in as many as 8% of IBD patients undergoing resection. Perineal wound infections and/or dehiscence leads to prolonged and/or delayed healing of the wound, and, in some cases, nonhealing.

Approximately 10–20% patients may have chronic perineal sinuses, defined as a perineal wound that fails to heal by 6 months following surgery. In many cases, it may be relatively asymptomatic and then nothing may need to be done. Management of symptomatic chronic perineal sinuses can be extremely challenging and may require repeated debridement

under anesthesia with multiple dressing changes, including the use of vacuum-assisted closure techniques and even flap closure for larger, more complicated wounds.[104,105]

GENITOURINARY DYSFUNCTION

Genitourinary dysfunction is not an infrequent complication of pelvic surgery. The cause is probably multifactorial. It is likely due to both physical and psychological factors. Injury to the sympathetic and parasympathetic nerves may occur during the pelvic dissection. Several maneuvers should be performed to minimize the risk, including ligation of the inferior mesenteric vessels beyond the takeoff of the left colic vessels, ensuring that the dissection is in the plane of the fascia propria of the rectum at the sacral promontory and close dissection of the mesorectum at and below the level of the peritoneal reflection. Retrograde ejaculation is due to injury to the sympathetic nerves whereas impotence is a result of injury to the parasympathetic nerves. Both may occur temporarily or permanently and partially or totally. Referral to a urologist with appropriate urodynamic testing is indicated if dysfunction persists. The reported rates for impotence and retrograde ejaculation are less than 5%. However, most studies do not use validated instruments to assess sexual dysfunction. Davies et al reported on a cohort of 59 male patients who were assessed prospectively before and again after having IPAA using a validated instrument.[106] They found that male sexual function and erectile function scores remained high 12 months following surgery (mean International Index of Erective Function score 51.7 preoperatively versus 58.3 at 12 months postoperatively). Furthermore, the prevalence of abnormal sexual function decreased from 33.3% before to 22.7% after surgery.

It is only recently female sexual function following pelvic surgery has been assessed. Bambrick and colleagues reported that women reported a significant increase in vaginal dryness, dyspareunia, pain interfering with sexual pleasure and limitation of sexual activity because of concerns of stool leakage following IPAA.[107] On the other hand, there was no significant change in sexual desire, frequency of sexual intercourse or satisfaction of sexual relationship. The findings are interesting although, due to the sensitive nature of the questions, the response rate was only 35% so the results may be biased. In a recent prospective study by Davies et al, approximately 70% of female patients were found to have scores indicating sexual dysfunction preoperatively using a validated instrument, the IIEF.[106] Postoperatively, there was a significant improvement with only 26% reporting sexual dysfunction 6 months following surgery. Improved overall physical well-being after surgery has been suggested as the reason for the improvement.

Infertility

It is becoming more evident that female fertility is reduced following surgery for ulcerative colitis although it varies with the operative procedure. Oresland and colleagues performed hysterosalpingograms on 20 women who had had a total proctocolectomy and found occlusion of one or both of the tubes in 18.3%.[108] Olsen and colleagues reported on 343 female patients followed 10–40 years following surgery for ulcerative colitis and compared them to a reference population of 1200 women in Denmark.[109] Surgery significantly reduced the ratio of patient to reference population fecundability (ability to conceive) to 0.20 whereas there was no significant difference in the rates following diagnosis of ulcerative colitis until the time to surgery. They also reported that 29% of women who did conceive required in vitro fertilization. Johnson and colleagues reported similar findings.[110] In a cohort of 147 female patients who had IPAA with a mean follow-up of 7.2 years, 38.1% reported problems with fertility compared to a Canadian national average of 8%. Furthermore, 96% of women who wished to become pregnant preoperatively were successful compared to only 55% postoperatively.

The impairment is likely due to adhesions caused by pelvic surgery. This is supported by the results of another study by Olsen and colleagues that showed that fecundity was not decreased in women having an IRA for familial polyposis.[111] A study in female patients suffering from ulcerative colitis showed similar results.[112] Colectomy and IRA likely has a minimal effect on fertility in women having surgery for ulcerative colitis because there is no pelvic dissection whereas following IPAA the tubes and ovaries are often buried behind or adherent to the pouch.

To date, there are no maneuvers that have been shown to be effective in reducing the risk of infertility. One simple maneuver is to ensure that the ovaries lie above the pouch and perhaps are tacked in this position. Application of barrier agents, although unproven, may be worthwhile. A laparoscopic approach has been shown to decrease adhesions within the abdomen, but less is known about scarring in the pelvis and whether there is less effect on fertility.

Many women who have had IPAA have not started or completed their family. Studies have reported that approximately 45% of women attempted to become pregnant following surgery, but only 56% were successful following IPAA.[110] Thus, women must be counseled regarding this risk preoperatively. Although infertility may be increased following total proctocolectomy or IPAA, deferring surgery until a woman has completed her family is unlikely to be a feasible option. Women who are referred for surgery typically have active disease that has become refractory to medical management. For women with active disease who require surgery, one consideration is to perform a colectomy with end ileostomy and defer IPAA because previous studies have shown that colectomy alone does not decrease fertility. While this may be acceptable to some patients, having a stoma for a prolonged period is unlikely to appeal to most women, especially young women who might be in dating relationships.

Pregnancy and Delivery

While becoming pregnant may pose problems, most studies have shown that pregnancy following IPAA is safe and

without an associated increase in maternal or fetal morbidity or mortality.[113] Furthermore, there appears to be no increase in pouch-related complications or bowel obstruction during pregnancy. The concern with pregnancy is whether vaginal delivery should be recommended. Because of stool generally being semiformed in individuals with an IPAA, any degree of anal sphincter injury may lead to deterioration of functional results and, in particular, incontinence. For this reason many colorectal surgeons and obstetricians have recommended that women with an IPAA have a planned cesarean section. This is reflected by cesarean section rates of 38–78% after IPAA, which are considerably higher than the North American average of 22%.[114] There are multiple retrospective studies, and no data to suggest that the risk of an anal sphincter tear is increased. Some women do experience transient worsening of their functional results during pregnancy, but there are no long-term differences in functional outcomes between patients who have a vaginal delivery compared with a cesarean section. Furthermore, there are data to suggest that women who have a pregnancy and vaginal delivery following IPAA have similar long-term function compared to those who did not have a pregnancy following IPAA. The difficulty with these data is that the series are small, and therefore the true rate of sphincter injury in this group is uncertain. The counter argument to planned cesarean section is that the morbidity to both the mother and fetus with cesarean section is generally higher than that with a vaginal delivery.

Complications Related to Colectomy and Ileorectal Anastomosis

ANASTOMOTIC LEAK

The most significant complication following colectomy and ileorectal anastomosis (IRA) is an anastomotic leak. The reported rate is less than 5% indicating that patients who have a colectomy and IRA are highly selected.[115,116] The presentation can vary from a small abscess treated with antibiotics and percutaneous drainage to a free leak within the abdominal cavity with peritonitis and overwhelming sepsis. The frequent use of steroids in this population can make the diagnosis of an anastomotic leak very difficult, with only subtle symptoms present at first, although rapid deterioration can occur and thus a high index of suspicion must be maintained at all times. In the event of a serious leak, reoperation with creation of an end ileostomy and mucous fistula is necessary.

CANCER IN THE RECTAL REMNANT

Patients who have had a colectomy and IRA continue to be at risk for cancer. Thus, surveillance of the rectum is required. The risk is increased if there was dysplasia or cancer in the resected colon, and this supports the view that colectomy and IRA is contraindicated in patients who have dysplasia or a cancer in the colon. The cumulative risk of cancer in a series of 374 patients who had been followed up to 23 years was 6% at 20 years and 15% at 30 years.[49] Grundfest and colleagues reported a cumulative risk of cancer of 5% at 20 years and 12.9% at 25 years.[117]

Complications Related to the Kock Pouch

NIPPLE VALVE SLIPPAGE

Valve malfunction, in particular valve slippage, has been the most frequent complication of the Kock pouch. In fact, it has been the Achilles heel of this procedure. Despite modifications in surgical technique, this complication occurs in 20–40% of individuals.[65–67] Reoperation is required to repair the valve in virtually all patients.

Slippage of the valve refers to dessusception of the segment of bowel, used to create the nipple valve. Intussusception of the bowel is an abnormal physiologic state, and the bowel attempts to relieve it causing dessusception of the bowel and slippage of the valve. Detachment of the pouch from the abdominal wall likely precedes the actual dessusception. In fact, with modifications such as a mesenteric sling, it is unusual for the valve to completely dessuscept and more often the valve protrudes through the side of the pouch. This complication may occur any time after surgery but is most common in the first year after surgery. There are two characteristic manifestations: intubation of the pouch becomes difficult or impossible because of the angulation of the path of the bowel. In some instances, the patient may have to leave the catheter in continuously because reinsertion is impossible. The second symptom is incontinence, total or partial, depending on the degree of extrusion. The latter may be problematic because it is difficult for the patient to wear an appliance with the stoma being flush with the skin.

Patients suffering from valve slippage may present acutely because they are not been able to insert a catheter and empty the pouch. In these situations, sometimes a flexible scope can be used to intubate the pouch or, alternatively, an interventional radiologist may be able to insert a tube over a guide wire under fluoroscopy. As stated previously, surgery is required to definitively repair the valve. Most often, the valve can be reintussuscepted and fixed. Sometimes, however, the valve must be excised and another valve created from the afferent limb of the pouch.

NIPPLE VALVE PROLAPSE

Prolapse or procidentia of the valve is a less frequent complication. The valve remains intact but prolapses through the stoma. It is usually the result of an excessively large fascial opening. When pressure increases in the reservoir, there is no resistance to extrusion of the valve though the fascial opening. It can be prevented by creating a snug fascial opening. However, it may occur over time as the fascial opening enlarges. It may be corrected with a skin-level procedure in which the fascia is tightened by insertion of a few sutures or insertion of

a piece of mesh. If this fails, the pouch may have to be resited at another site on the abdomen.

FISTULIZATION

As with any gastrointestinal operation, fistulas may occur postoperatively due to inadvertant injury to the small bowel during the procedure, leaks from anastomotic suture lines, or erosion of intra-abdominal abscesses into the bowel. In addition, fistulas may arise from the nipple valve in this procedure. Most often, they arise from the fundus of the pouch at the base of the nipple valve or from the valve itself. Several factors make the fundus of the pouch a vulnerable site. First, there is often tension on this suture line because the valve is large and edematous when constructed while the reservoir has not yet dilated. Second, an anchoring suture placed between the fundus of the pouch and the abdominal wall might cut out, creating a perforation and fistula. Third, the bowel may be ischemic from passage of the stapler to maintain the valve. Finally, and probably most important, there may be erosion of the bowel in patients where a synthetic mesh has been used to stabilize the valve.[67,71] In fact, when mesh is inserted, valve fistulas have been reported in approximately 25% of patients so many surgeons no longer use a mesh to stabilize the valve for this reason. Although the mesh decreases the risk of valve slippage, the risk of fistulization and septic complications is increased.[67]

Patients may present early or late. Often, they present first with a peristomal abscess or cellulitis. Subsequently there may be drainage of fecal material. Sometimes on scoping the patient, the mesh can be visualized at the base of the valve if it has eroded through. If a mesh has been used, the fistula will not close and surgery is required. This will require takedown of the pouch, excision of the valve, and creation of a new valve using the afferent limb of small bowel.

CANCER OF THE POUCH

Cox and colleagues have reported the only case of adenocarcinoma involving a Kock pouch 28 years following construction.[118] Hulten and colleagues examined and biopsied a cohort of 40 patients who had their Kock pouch for a mean duration of 30 years. There were no cases of high-grade dysplasia or cancer in any patients. This provides further evidence that cancer and dysplasia are rare events in the long term.[119]

OTHER COMPLICATIONS

Volvulus of the pouch is a rare complication but has been reported.[118] Unfortunately, the diagnosis is usually made at laparotomy. In some instances, it may not be able to preserve the pouch.

It is likely that transient ischemia of the valve occurs frequently caused by the two to three rows of staples inserted to maintain the valve. Despite the valve and efferent conduit often appearing congested and dusky at the end of the procedure, it is unusual for this complication to occur. Ischemia and sloughing of the entire valve is a rare complication.

Complications Related to IPAA

LEAKS, FISTULAS, AND SEPTIC COMPLICATIONS

The most important complication of IPAA surgery is an anastomotic leak. Leaks may occur either from the IAA or from the pouch itself. They may manifest as an asymptomatic leak found on contrast studies, a perianal, pelvic, or intra-abdominal abscess or a fistula. The latter may be communications from the pouch or IAA to other intra-abdominal structures, including the vagina or the abdominal or perianal skin. Most frequently, they occur within a few days of the procedure but may also occur many months after the procedure or closure of the ileostomy.[120]

Anastomotic leaks are significant not only because of their frequency but because they are the most common reason for pouch excision. In those in whom the pouch is not excised, functional results may be impaired. In our series of 1554 patients, septic complications occurred in 206 (13.3%) patients, and it was identified as the reason for pouch excision in 49 (46.2%) of all pouch excisions. IAA leaks accounted for 35% of septic complications while leaks from the pouch itself accounted for 19.4%.[120] Gemlo and colleagues reported that perianal sepsis or pouch fistulas were the indication for pouch excision in 24% of their patients.[121]

The reported risk of an anastomotic leak is quite variable. Several factors may account for the variability. First, there is variability in reporting with some centers separating leaks, abscesses, and fistulas while others combining them. Second, this is a complication that has decreased significantly over time probably due to modifications in surgical technique as well as increasing experience with the procedure. Reported rates vary between 5 and 15%.[120,122,123]

Various patient factors may affect the leak rate, including disease activity and if the patient is on high doses of sterods. Higher leaks have also been reported in hand-sewn compared with stapled anastomosis. Ziv and colleagues analyzed 692 patients and found the rate of septic complications to be 10.5% in patients with hand-sewn anastomoses compared with 4.6% in those with stapled IPAA.[81] In our series, the leak rate is 13.4% in patients having a hand-sewn anastomosis compared with 7.7% in those having a stapled anastomosis.[82]

A leak may manifest in various ways. One should have a high degree of suspicion that there may be a leak in individuals having a pouch without a covering ileostomy who develop a low-grade fever, pelvic or suprapubic pain, and/or an ileus. In these patients, a CT scan or pouchogram should be performed immediately. It is our experience that it is unusual for patients who do not have an ileostomy to develop generalized peritonitis and require an emergency operation. More often, they can be treated with antibiotics and prolonged drainage of the pouch. If there is an intra-abdominal or pelvic abscess, percutaneous drainage should be attempted. Even patients with a covering ileostomy may develop an intra-abdominal abscess that should be drained percutaneously. Sometimes a leak is not identified, but one must always be suspicious that there was one. One must also be cautious in

closing the ileostomy of patients who had either a clinical or even a radiologic leak that appears to have healed on repeat pouchogram. Sometimes the leak may have sealed due to the pouch being defunctioned but has not healed fully, and the patient becomes symptomatic once the ileostomy is closed. In these individuals, an examination under anesthesia is warranted prior to ileostomy closure or sometimes a laparotomy depending on the degree of suspicion. However, despite these maneuvers, some patients will manifest with another leak or fistula following closure of the ileostomy.

While early on a leak most often led to excision of the pouch, now most pouches can be salvaged.[124–126] Various modalities can be used, including antibiotics and drainage of the pouch (if there is no covering ileostomy), delayed closure of the ileostomy, and local techniques for repair of the anastomosis and reconstruction of the pouch with a combined abdominoperineal approach. It is our preference now is to undertake a combined abdominoperineal approach in most patients as the first procedure.[127] It is often difficult to perform a local repair and advance the pouch in patients who had a stapled anastomosis previously. An advancement procedure is easier in patients who had a hand-sewn anastomosis, but there is more likely to be tension on the anastomosis. Also, with each attempt at repair, there is some degree of injury to the anal sphincter, and therefore, while a combined procedure is a major operation, it also may be more successful and lead to better long-term outcome. Reported rates of pouch salvage range from 70 to 80% of patients who suffer an anastomotic leak.

POUCH-VAGINAL FISTULA

Pouch-vaginal fistula is a major complication following ileal pouch surgery. It is often more difficult to treat than other fistulas. The reported risk is in the range of 4–14%.[128–130] It may develop early before ileostomy closure or more commonly a few months later. The vast majority occur at the ileoanal anastomotic level. It is likely that there are two mechanisms for their development. In women having a stapled IPAA, it is possible that the posterior wall of the vagina may be incorporated into the stapled anastomosis if care is not taken. Alternatively, and probably more commonly, a pouch-vaginal fistula is due to sepsis secondary to a leak at the IAA. Some women who develop a pouch-vaginal fistula are often diagnosed, in retrospect, to have Crohn's disease. In fact, if the fistula occurs a long time following surgery or there are other anal disease or pouch abnormalities, one should be suspicious of Crohn's disease.

Multiple treatment options have been described. The most common are local advancement of the pouch and combined abdominoperineal reconstruction of the pouch. Other methods include local repair, transvaginal repair, and interposition of a gracilis muscle. The choice of operation may depend on several factors. We have found local repairs to be more difficult to perform following stapled IPAA and prefer to perform a combined abdominoperineal operation especially if the fistula is at the anastomotic site. The pouch can be brought down beyond the fistula and the anastomosis performed at the dentate line. A local repair either performed transanally or transvaginally may be attempted in patients who had a hand-sewn anastomosis. Treatment in patients with suspected Crohn's disease may have to be dictated by the status of the pouch and whether there is other anal disease.

Unfortunately, the failure rate is higher than following repair of other IPAA fistulas, probably because of the scarring of the rectovaginal septum. Reported success rates are in the range of 60–70%.

ANAL COMPLICATIONS

Anal complications may occur early after the operation or many years later. The most common complication is anal stenosis. Rates of 11–38% have been reported.[131,132] They occur more commonly after a hand-sewn anastomosis although many patients who have a stapled IPAA have a tight stricture while they are defunctioned with an ileostomy. However, in these patients, digital dilation at the time of closure of the ileostomy is usually adequate and recurrence is infrequent. Some stenoses are fibrostenotic in nature and likely occur secondary to a leak or sepsis. Tension on the anastomosis may also be a factor in their occurrence. Most strictures are mild and, because the stool is semiformed, they do not cause problems with evacuation. A small proportion may require dilation in the operating room. In the Mayo Clinic series, only one patient out of 1884 required excision of the pouch because of an anal stricture.[133]

In the long term, some patients may develop anal complications, especially fistulas and abscesses. One must always be suspicious that they have Crohn's disease. Abscesses should be drained. However, treatment of a fistula may be difficult. Fistulotomy should be discouraged because of the risk of incontinence even if the fistula is superficial. If the fistula is cryptoglandular in origin, it is usually not possible to perform an advancement procedure. Thus, if an abscess occurs infrequently, it may be prudent simply to treat symptomatically with antibiotics. For more symptomatic fistulas, a seton may be inserted. If the fistula is low, one might be able to use it as a cutting seton. Alternatively, one can allow the tract to epithelialize and then remove the seton. The patient may experience some minimal discharge from the fistula but not have recurrent abscesses, which is usually acceptable to most patients. Fibrin glue may be tried but has been unsuccessful in most patients in our experience.

Anal skin tags may be a problem for some patients. They may cause severe pain and irritation because of the stool frequency experienced by most patients with a pouch. As in other patients, excision of the tags should be avoided. However, if the tags are large and extremely symptomatic, they can be locally excised. If so, the patient should be warned of problems with nonhealing.

CUFFITIS

Because most surgeons prefer to perform the IPAA without performing a mucosectomy and instead perform a stapled

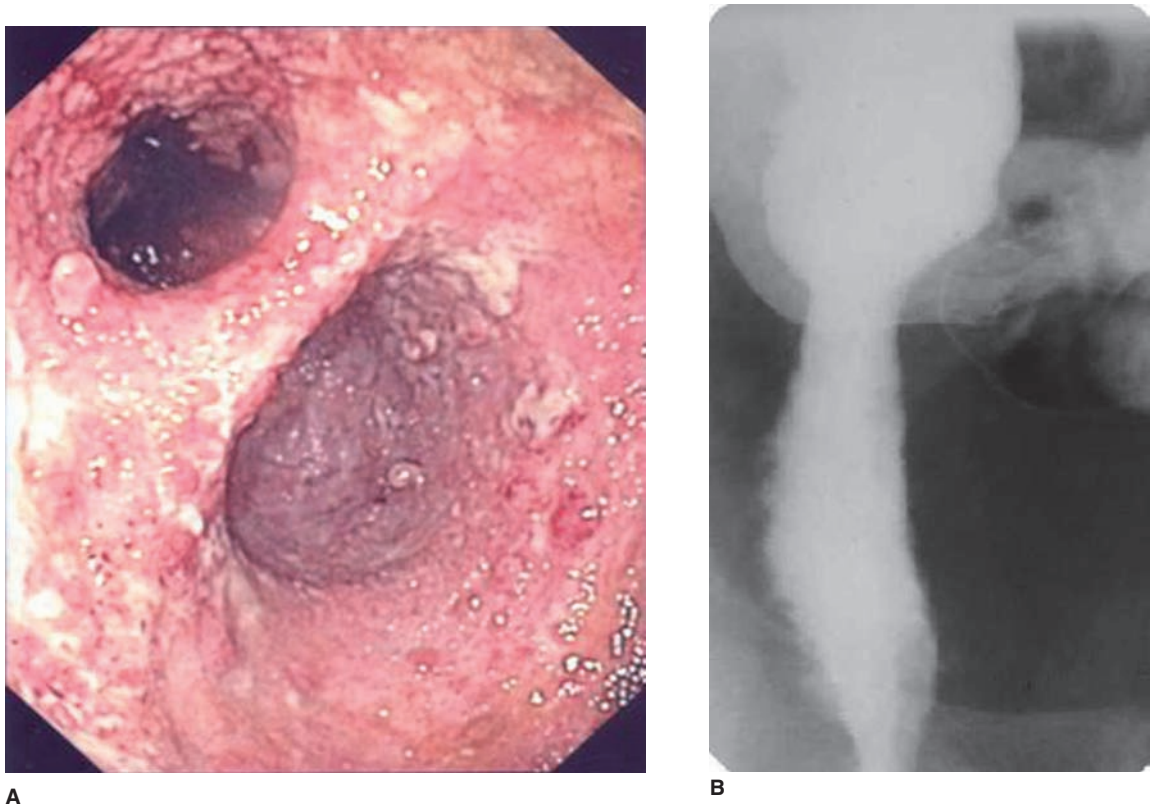
anastomosis above the dentate line, a small segment of rectal mucosa remains. Ideally, only 1–2 cm of mucosa should be left behind. Most patients will have evidence of inflammation in this segment, but, despite this, most patients are asymptomatic or may complain of a small amount of blood within the stool.[84] 5-ASA or steroid suppositories can be prescribed, but often they are poorly tolerated. Rarely are the symptoms severe enough to require surgery, but, if so, a mucosectomy with advancement of the pouch can be performed or alternatively a combined reconstructive procedure with mucosectomy and hand-sewn anastomosis at the dentate line. Before embarking on treatment, the pouch should be scoped to confirm the diagnosis of cuffitis and rule out pouchitis.

POUCHITIS

Pouchitis is a nonspecific inflammation of the pouch mucosa, which is seen in patients with IPAA as well as those with a Kock pouch (Fig. 34-11).[134] Clinically, pouchitis manifests with a variable spectrum of clinical symptoms, including increased stool frequency, rectal bleeding, abdominal cramping, rectal urgency and tenesmus, incontinence, and low-grade fever. On endoscopy, there are inflammatory changes that usually include mucosal edema, granularity, contact bleeding, loss of the vascular pattern, hemorrhage, and superficial ulceration. It is important that on histologic examination, there is evidence of acute inflammation including neutrophil infiltration.

Patients often are labeled as having pouchitis when they have suboptimal function of the pouch. However, pouchitis is a specific diagnosis and should be based on clinical symptoms plus endoscopic and histologic changes. Svaninger and colleagues reported a cumulative risk of 34% in Kock pouch patients and 51% in IPAA patients at 5 years.[135] However, approximately two-thirds had only one or a few episodes of pouchitis. Sandborn reported a risk of 15% at 1 year, 36% at 5 years, and 46% at 10 years.[134] The etiology of pouchitis is unknown but is believed to be due to bacterial overgrowth. In addition, there may be an immune component because pouchitis rarely occurs in patients who have familial adenomatous polyposis. Other risk factors for pouchitis are anal strictures possibly leading to impaired pouch emptying. Also, patients with PSC appear to be at increased risk.[136] High pANCA levels appear to be associated with the development of chronic pouchitis.[137] In a series of 95 patients with ulcerative colitis who had IPAA, pouchitis developed in 42% of patients who were $pANCA^+$ compared with 20% $pANCA^-$ patients. Similarly 56% of patients with high pANCA levels developed chronic pouchitis compared with only 20% who were $pANCA^-$.

Antibiotics have been the mainstay of treatment for pouchitis. There is level I evidence that metronidazole and ciprofloxacin are effective in the treatment of pouchitis.[138] Usually a 2-week course is instituted with response rates in the order of 75%. In most patients, the episode is short lived and rarely do patients develop recurrent episodes or chronic pouchitis.



A B

FIGURE 34-11 Pouchitis. **A.** Endoscopic appearance. **B.** Radiologic appearance.

However, approximately 10–20% of patients may develop recurrent or chronic episodes of pouchitis. Probiotic therapy has been shown to decrease the risk of pouchitis and maintain a remission following an episode of pouchitis. Other agents including anti-inflammatory medications; steroids; immunosuppressive agents; free radical scavengers such as allopurinol, bismuth, and butyrate; and glutamine enemas have been tried with limited success.

CANCER AND DYSPLASIA

Dysplasia and Malignancy Affecting the Pouch Mucosa. Creation of the pouch results in stasis, creating a new ileal environment and mucosal adaptation of the pouch mucosa that may predispose to dysplasia. Lofberg et al published the first report of a patient who developed dysplasia and aneuploidy.[139] Subsequently this group reported that 5 of 149 patients followed with serial biopsies were found to have dysplasia.[140] The median time since construction of the pouch was 54 months (5–152 months). Four patients had low-grade dysplasia and one patient had sequential transformation into multifocal high-grade dysplasia. This group classified the histology of pouches as type A, B, or C. The five cases of dysplasia were found in the seven patients with persistent severe villous atrophy (type C histology).

Despite this finding, dysplasia appears to be a rare occurrence.[141] There are only a few other reports in the literature. Thompson-Fawcett and colleagues examined a cohort of 116 patients considered to be at potentially high risk for developing dysplasia.[142] Only one patient, a woman with a 23-year history of ulcerative colitis who had a pouch performed 14 years earlier, had low-grade dysplasia on one of the eight biopsies taken.

There are a few reports of cancer arising in the pouch, but, given the number of IPAA that have been performed in the past 30 years, it is not possible to conclude that the risk of cancer is in fact increased in patients with pouches because adenocarcinoma, although rare, does occur in the small bowel of normal individuals.[141] However, it may be that there is a delay in the development of dysplasia, and with increasing time there may be more cases. Thus, it is difficult to make recommendations for follow-up at this time. It does appear that patients with chronic pouchitis and severe villous atrophy may be the group at highest risk and perhaps this is the group that should be followed with regular endoscopies and serial biopsies.

Dysplasia and Malignancy Affecting the Rectal Outlet. Given that there is an increased risk of cancer in patients with ulcerative colitis, it is reasonable to expect that there may be an increased risk of cancer in the rectal outlet. Controversy exists as to whether a mucosectomy and hand-sewn anastomosis or a double-stapled anastomosis is preferable, especially in patients known to have cancer and dysplasia elsewhere. When this procedure was first described, it was assumed that by performing a mucosectomy that all mucosal cells would be extirpated. However, in O'Connell and colleagues' report of 29 patients who had excision of their pouches because of septic complications after mucosectomy and hand-sewn anastomosis[83] 14% had evidence of residual mucosa in the muscular cuff. They concluded that either mucosal cells remained following mucosectomy or there was regeneration of mucosa following mucosectomy. In either case, it is obvious that mucosectomy does not eliminate the risk of cancer.

There are nine reported cases of cancers involving the anal outlet.[141] In three patients a mucosectomy had been performed while the rest had a stapled anastomosis. Of note is the fact that cancer or dysplasia was present in eight of the colectomy specimens. The data on dysplasia occurring in the anal outlet are less complete. O'Riordain and colleagues from the Cleveland Clinic have reported that dysplasia developed in the residual epithelial cuff in 7 of 210 patients who had had stapled ileal pouch anal anastomoses between 1987 and 1992.[143] Dysplasia was high grade in one and low grade in six. Two patients had a mucosectomy performed while five were treated expectantly. In three of the seven patients, cancer or dysplasia had been present in the colectomy specimen suggesting that the dysplasia had been present at the time of surgery.

Thus, while patients with IPAA require follow-up, the method and frequency is not certain. It appears that the risk of cancer is low. Based on guidelines for surveillance of patients with ulcerative colitis who have not had surgery, a reasonable follow-up strategy would be to begin endoscopy and biopsy of the rectal outlet at 10 years and continue at 2-year intervals for individuals who have had a stapled anastomosis. For those who have had a mucosectomy and hand-sewn anastomosis, endoscopy and biopsy are not possible.

If one detects dysplasia, it is also difficult to know what to recommend. The biopsy specimens should definitely be reviewed by an experienced pathologist. Surgeons at the Cleveland Clinic have recommended performing a mucosectomy and advancement of the pouch with a hand-sewn IAA.[143] However, this likely does not eliminate the risk of cancer given the experience with hand-sewn anastomosis and mucosectomy. Thus, excision of the pouch would be another option and would be our recommendation. However, this is a difficult decision, and certainly the alternatives should be discussed with the patient and the patient should participate in the decision making.

Outcome

Mortality following surgery for ulcerative colitis is low. The contemporary mortality rate for subtotal colectomy in acute severe ulcerative colitis is 0–3%,[56,144] but it increases dramatically when there is a colonic perforation. The mortality rate from large series of patients having IPAA is similarly low, in the range of 0–2%.[145] This is probably because most patients undergoing IPAA are young and free of comorbid diseases.

On the other hand, morbidity rates are high following both urgent and elective procedures. Morbidity rates of 33–66% have been reported for patients having subtotal colectomy for acute colitis with the main complications being

wound infection, ileus, small bowel obstruction, and a blown rectal stump.[56,144] In patients having an IPAA, complication rates are nearly as high. In a Cochrane Review, complication rates (from all causes) were as high as 53%, including both procedure-specific and general complications following pouch construction.[145] The rate of complications after laparoscopic IPAA were no different.

LONG-TERM OUTCOME FOLLOWING COLECTOMY AND ILEORECTAL ANASTOMOSIS

In a small series from the Mayo Clinic, 82% of patients had a functioning ileorectal anastomosis (IRA) at 5 years.[116] The probability of having a functioning IRA in a series of 32 patients followed for an average of 3.5 years was 88%.[146] Finally, a study from the Cleveland Clinic demonstrated that 54% of patients required excision of the rectum within 20 years of construction of an IRA, most commonly for ongoing symptoms, dysplasia, or malignancy.[115] The same study, however, reported reasonable functional results, with patients having fewer bowel movements than matched controls who had an IPAA, but with more urgency.

LONG-TERM OUTCOME FOLLOWING KOCK POUCH

Revisional surgery is necessary in a large proportion of patients mainly because of valve complications. Kock reported a reoperative rate of 54% in his early series of patients, but the rate decreased to 16% subsequently.[147] Despite the frequency of complications, most patients retain their pouch in the long term. Lepisto and Jarvinen reported a cumulative success rate of 96% at 1 year, 86% at 10 years, 77% at 15 years, and 71% at 29 years.[65] In this series of 96 patients, 59% had required reconstructive surgery. Nessar et al reported 10- and 20-year pouch survival rates of 87–77%.[66] In our own series of 194 patients, 81% of patients at 10 years and 67% at 20 years had a functioning Kock pouch.[67] Wasmuth and Myrvold reported a failure rate of 11.6% at 20 years.[68]

LONG-TERM OUTCOME FOLLOWING IPAA

The reported failure rates are in the range of 5–10%. Many failures occur early, but there are an increased number of failures over time. In our own series of patients over 25 years, the failure rate was 6.8%.[120] Median time to failure was 3.5 years. The risk factors for failure included Crohn's disease and a leak from the pouch or IAA on multivariable analysis. Gemlo et al reported a failure rate of 9.9% in 253 patients having surgery at the University of Minnesota.[121] Poor functional results was the most common cause (28%), followed by unsuspected Crohn's disease (5%) and pelvic sepsis. Lepisto and Jarvinen reported an overall failure rate of 5.3%.[65] The cumulative probability of pouch failure was 1% at 1 year, 5% at 5 years, and 7% at 10 years.

Experience with the procedure is also a factor in predicting success. In our own series, the complication, reoperative and failure rates dropped significantly over time. In the period 1981–84, the overall complication rate was 37.5%, the IAA leak rate was 30%, and the failure rate was 30%. There was a steady decrease so the respective rates in the period 1997–2000 were 10.6, 5.2, and 1.5%.[148] Outcome was assessed in patients undergoing an IPAA over the period 1992–1998 using population data from the province of Ontario.[149] Even though the surgical procedure had undergone significant modifications and been performed for more than 10 years by this time, a decrease in the complication rate as measured by readmission rate, reoperative rate, and failure rate was observed during that period. Also, outcome was significantly better in individuals having surgery in high-volume hospitals compared with medium- and low-volume hospitals.

Quality of Life and Functional Results

Ulcerative colitis has been shown to have a significant impact on quality of life, with disease activity being one of the largest predictors of outcome.[150–152] In a population-based study from Norway, 328 patients with ulcerative colitis were evaluated with a Norwegian variation of the IBDQ (Inflammatory Bowel Disease Questionnaire). The frequency of disease relapse over a 5-year follow-up period was independently associated with a decrease in IBDQ scores.[153] Thus, it is not surprising, given that surgery eliminates the disease, that most individuals who have had surgery for ulcerative colitis have a high quality of life. In fact, one of the first studies to document this was a study by Provenzale and colleagues who compared the outcome of 22 patients with IPAA to a normal population using the Short Form 36 (SF-36).[61] They found that the quality of life of the individuals with IPAA was similar to that of the normal population. They also reported that the median utility for this cohort was 1.0 signifying normal health-related quality of life. Using the time trade-off technique, our group was able to show that the mean utility increased from 0.58 preoperatively to 0.98 at 1 year postoperatively in a cohort of 20 patients.[62]

As discussed previously in this chapter, surgeons have been innovative over the past 50 years in developing new procedures so that patients do not have to have a permanent ileostomy. In reality, most patients with conventional ileostomy have a high quality of life using the SF-36, time trade-off technique, and IBDQ; investigators have shown that not only is quality of life excellent following surgery but is similar irrespective of the procedure. Our group interviewed three cohorts of patients: 28 with conventional ileostomies, 28 with continent ileostomates, and 37 with pelvic pouches.[62] The mean utilities, using the time trade-off technique were not significantly different with utilities ranging from 0.87 to 0.97 with a utility of one signifying perfect health. Jimmo and Hyman studied 12 patients who had a total proctocolectomy and ileostomy and 55 who had an IPAA. Overall, 46 of 55 (83.3%) patients with an IPAA and 10 of 12 (83.3%) with a proctocolectomy and ileostomy were satisfied with the procedure. All patients completed the IBDQ, and there was no

significant difference between the two groups regarding the overall score or by category.[63] Using a modified version of the SF-36, Thirlby and colleagues also showed that quality of life was equal or better than norms for the general population.[64]

This finding seems to contradict what occurs in clinical practice; that is, most patients, given the option, choose a pelvic pouch. Several reasons may explain the discrepancy. First, patients in these studies were not randomly allocated and they may choose their preferable option. Second, there may be an aspect of patients accepting their current health status and rationalizing that it is superior to other alternatives. Finally, the most important determinant of quality of life in these patients may be physical well-being that is improved in almost all patients after all procedures. What is important about these findings is that all of the various options should be presented to patients so they may choose which procedure is most acceptable to them and their lifestyle.

Recently, there have been several studies that have shown that quality of life is similar in patients having open or laparoscopic IPAA, but cosmesis and body image is better in patients having a laparoscopic IPAA.[154]

Following IPAA, the average number of bowel movements is approximately six per day. In a series of over 1300 patients followed for a median of 8 years, Farouk et al reported that 85% of patients were totally continent during the day but only 52% were totally continent at night. However, frequent incontinence was reported in less than 5% of patients.[155] Several studies have shown that functional results deteriorate with advancing age. Also, functional results have been shown to correlate with quality of life.[156] Kirat et al also reported better outcomes in patients having a stapled versus a hand-sewn IAA.[157]

Conclusion

Patients requiring surgery for ulcerative colitis have several options to choose from. A thorough understanding of the technical aspects of each procedure, their complications, and outcomes is essential in order to discuss the options with patients. Patients should be fully informed and they participate in the decision making. Although IPAA is the procedure of choice for most patients, they will have a good outcome with excellent quality of life irrespective of the procedure that is performed. However, to achieve such results, patients must be selected carefully and surgeons should be well versed in the technical details of the surgery as well as the pre- and postoperative care of patients and management of complications.

PERSPECTIVE ON INFLAMMATORY BOWEL DISEASE

Anthony J. Senagore

Fichera et al provide a comprehensive review of the surgical approach to Crohn's disease from indications for surgery to the surgical approaches to the management of the various patterns of disease.[1] There are several areas that may benefit from expanded coverage so that the surgeon managing this difficult chronic disease can understand more regarding some of the current areas of controversy.

IS CROHN'S DISEASE A LYMPHOOBLITERATIVE DISEASE?

The onset of Crohn's disease has consistently been blamed on a yet to be identified alteration in mucosal immune response, possible in response to an altered susceptibility to luminal bacteria or other environmental exposures.[2,3] Interestingly, there has been greater recognition of the consistent histopathologic changes of mucosal exudation, submucosal edema, and extensive dilation of lacteals seen in Crohn's disease lymphatics.[4] These findings have correlated with animal models of lymphatic sclerosing agents leading to similar findings of inflammatory bowel disease. The inflammatory response was reduced with administration of cyclooxygenase (COX) inhibitors suggesting an arachidonic acid role. It is believed that the early lymphatic obstruction blocks the transfer of inflammatory cells to regional lymph nodes and the process of lymphoid neogenesis that produces lymphoid aggregates in the mesentery. Trapping the activated B lymphocytes in the region, coupled with an ongoing pattern of neoangiogenesis of lymphatics in the intestinal wall may be causally related to the development of the disease. Further credence is given to the theory because the virtual pathognomonic finding of fat wrapping is the result of cytokine and tumor necrosis factor (TNF) release from adjacent lymphatic tissue. These response leads to hypertrophy of fat cells in the mesentery that may be related to the common finding of thickened mesentery in patients with Crohn's disease. Although considerably more work is required to fully understand the interaction of abnormal lymph drainage and mucosal inflammation, it is intriguing to hypothesis that early resection of the draining mesentery might be an effective surgical strategy prior to the onset of chronic disease and extensive mesenteric involvement.

AGGRESSIVE EARLY MEDICAL THERAPY VERSUS SURGICAL THERAPY

The availability of an increasing number of biologic agents capable of creating greater immunosuppression has led to the suggestion of a so called "top-down" strategy of more aggressive medical therapy at diagnosis. This is contradistinction to the more typical "bottom-up" approach of beginning with corticosteroids or even 5-aminosalicylic acid (5-ASA) preparations and escalating only after persistent symptoms. Markowitz et al reported an almost 90% remission rate in children using a strategy of corticosteroids and 6-mercaptopurine (6-MP) as induction therapy.[5] Similar benefits have been described with the use of either certolizumab pegol therapy, where superior response was seen in patients with disease duration of shorter than 1 year compared to patients with longer than 5 years of disease (75 vs 52%).[6] A prospective trial assessing patients naive to any immunomodulator reported both an improved clinical remission rate at 52 weeks (62 vs 42%) and longer time to relapse (329 vs 174 days) with a strategy of infliximab infusion and azathioprine/6-MP compared to corticosteroids and azathioprine.[7] Infliximab was reserved for intractable disease that failed corticosteroids initially. Proponents of the top-down approach suggest that the benefit derives from management of a predominant Th1 immune response with excessive interferon-γ (IFN-γ) secretion. This response is lost with chronicity of disease accounting for a current management within a multidisciplinary approach because there still remains a 25–40% failure rate with the top-down management approach. In addition, the ACCENT-1 trial confirmed that scheduled long-term administration of infliximab was associated with a significant reduction in the development of anti-TNF antibodies

compared to episodic therapy (1 vs 38%).[7] This would indicate that selection of a top-down methodology could lead to expensive long-term therapy with these agents. Therefore, reassessment for medical failure may identify patients who would benefit from a surgical intervention prior to the onset of significant impact from poorly controlled inflammation, worsening nutritional onset, or masked complications from perforation. Surgical approaches may need to be modified for patients with recent exposure to anti-TNF agents, as suggested by the authors, and may require judicious use of diverting stomas to protect anastomoses in difficult cases.

The countervailing argument to aggressive early medical therapy is aggressive surgical therapy, primarily for ileocolic disease. There is limited data available comparing quality of life and cost-effectiveness for early surgery versus top-down medical therapy. Aratari et al reported on a retrospective analysis of patients and found that "early" operated patients had prolonged clinical remission.[8] An interesting survey study demonstrated that gastroenterologists had a 2-fold higher desire to prevent an ileocolic resection compared to either colorectal surgeons or patients.[9] These data support the same potential benefit of earlier intervention in localized Crohn's disease prior to the onset of a more problematic and difficult-to-manage inflammatory response. A current prospective randomized trial being performed in the Netherlands assessing the role of early resection of terminal ileal Crohn's disease should provide interesting data regarding risk of complications versus restoration of quality of life. The risk and timing of recurrent disease will also be an important outcome of the study. One could see an evolving strategy of early laparoscopic resection of localized terminal ileal disease with the aggressive top-down strategy reserved for early surgical recurrences or patients with multisegment disease.

THE ROLE OF PROPHYLACTIC MEDICAL THERAPY POSTRESECTION

As outlined by Fichera et al, surgical management is highly effective in managing complications of Crohn's disease, including obstruction, fistula, and perforation.[1] Surgery is highly effective at restoring quality-of-life measures. However, current data suggest that 70–80% of patients will develop mucosal evidence of disease within 1 year postresection that is highly correlated with clinical recurrence. Approximately 25–30% of patients will develop significant recurrences requiring repeat surgical resection within 5 years and almost 70% of patients will need an additional surgical procedure by 10 years. Options for prophylaxis include probiotics. A variety of different bacteria have been assessed in probiotic formulae for Crohn's prophylaxis further complicating assessment. However, two recent meta-analyses failed to identify a benefit associated with probiotic whether it be clinical or endoscopic recurrence.[10,11] Conversely, two limited trials suggested that nitroimidazole antibiotics may be beneficial in reducing clinical recurrence.[12] These data are limited and would require confirmatory data prior to widespread adoption. Mesalamine is probably the best evaluated anti-inflammatory agent assessed as a postresection prophylactic strategy in Crohn's disease. The Cochrane meta-analysis reported a modest but significant benefit for this strategy with a risk ratio of 0.76 (0.62, 0.94).[13] Azathioprine also enjoys a long history of evaluation and has demonstrated superiority over 5-ASA treatment albeit at an increased risk for adverse treatment events. Given these current data, a reasonable clinical strategy may be to withhold prophylaxis in patients with localized and fully resected disease and reserve prophylaxis for early recurrence or multiple prior resections. It would also be reasonable to consider prophylaxis when resection is combined with stricturoplasty.

CONCLUSION

The ongoing work in evaluating the immunologic components of Crohn's disease, and the related proteogenomic assessments may lead to a better understanding of the initial insult in patients with this complicated chronic disorder. The hope remains for refined and focused clinical strategies that minimize the impact of chronic illness and/or treatment-related morbidity while restoring quality of life. The authors are to be commended on an excellent clinical review of this broad topic.

PERSPECTIVE ON INFLAMMATORY BOWEL DISEASE (ULCERATIVE COLITIS AND CROHN'S DISEASE)

Patricia L. Roberts

Ulcerative colitis and Crohn's disease, collectively known as *inflammatory bowel disease* (IBD), are estimated to affect 2–6% of the population of the United States. Despite advances in medical therapy and a larger number of effective medications for treatment of this disease, up to 46% of patients with ulcerative colitis and 80% of patients with Crohn's disease ultimately require surgery.[1,2] While many of the operative procedures have remained the same, the approach has changed with the advent of minimally invasive surgery. Laparoscopic colorectal surgery, initially reported in the 1990s, has increased in frequency and is associated with a faster recovery, potentially less complications, better cosmesis, and a shorter length of stay.

The goals of medical therapy for IBD include controlling symptoms of the disease, inducing remission, improving quality of life, and minimizing the complications of the disease and treatment. While surgical intervention is aimed at treating both complications of IBD and intractability to medical management, the timing and role of surgical therapy has become more complex. Surgery should be aimed at optimizing quality of life and at not unnecessarily delaying the inevitable if an operation is required. Additional considerations include the role of biologic agents and the optimal timing of surgery. Furthermore, the Internet has increased access to information for patients and providers, and patients appear to be better educated about their disease and about further therapies. These additional considerations mandate close interaction and consultation with the patient and all providers, including the gastroenterologist, surgeon, primary care physician, and enterostomal nurse.

The cause of IBD remains elusive, but there is increasing evidence of a genetic predisposition to ulcerative colitis and Crohn's disease. The association is strongest in patients with Crohn's disease where three mutations of the *NOD2/CARD15* gene affecting the short arm of chromosome 16 have been identified as being associated with the disease.[3,4] Mutations in the gene are found in 10–30% of patients with Crohn's disease and are associated with ileal disease, earlier age of onset, and possibly fibrostenosing characteristics. The relative risk of developing Crohn's disease in patients with such mutations is 10–40 times that of the general population.[5] Genetic predictors of patients who have medically refractory ulcerative colitis are also being explored.[6]

A major development in the treatment of IBD in the last two decades has been a number of randomized clinical trials on the use of infliximab, both for Crohn's disease and more recently for ulcerative colitis. Infliximab was shown to be effective for inflammatory disease in 1997 and for perforating disease in 1999.[7,8] Infliximab was subsequently shown to be effective for maintenance therapy in Crohn's disease in 2002.[9] More recently, it has proven effective for use in ulcerative colitis.[10]

The role of infliximab is best defined in patients with Crohn's disease where it has been used to treat and induce remission in patients with moderate to severe Crohn's disease. Infliximab is also effective in patients with corticosteroid-dependent disease and fistulizing disease and may decrease extraintestinal manifestations such as arthralgias and pyoderma gangrenosum. More recently, it has been suggested that infliximab be given earlier in the course of the disease and with an immunomodulator such as azathioprine. Such treatment has been termed "top-down therapy," and several studies have shown improved outcome for induction of remission and reduction in corticosteroid use.[11]

Additional concerns about infliximab include the impact on postoperative complications, wound healing, and the

development of infections. The data are limited with two retrospective studies showing that use of infliximab in patients with Crohn's diseases within 8–12 weeks of surgery was not associated with an increased risk of postoperative complications[12,13] and another retrospective series showing an increase in the rate of postoperative sepsis, abscess, and hospital readmission.[14] For ulcerative colitis, some have suggested that a three-stage ileoanal pouch procedure with initial colectomy and ileostomy should be considered in patients with refractory ulcerative colitis on infliximab because of the increased risk of infectious complications.[15]

The cost of infliximab is considerable and could potentially be offset by a decrease in the rate of hospitalization and the rate of surgery for Crohn's disease. Infliximab was approved by the Food and Drug Administration (FDA) for treatment of Crohn's disease in 1998 and for treatment of ulcerative colitis in 2006. According to Centocor, 390,000 patients with IBD have been treated with infliximab since 1998.[16] Two studies suggested a decrease in the number of hospitalizations and operations.[17,18] In a retrospective single-institution study of 79 patients with Crohn's disease, 1 year after treatment with infliximab, the rate of hospitalization and gastrointestinal surgery decreased by 18% and the rate of all surgeries decreased by 66%.[17] An additional study that looked at fistulizing Crohn's disease found a 50% reduction in the mean number of all surgeries in patients receiving infliximab compared to the placebo group.[18] These studies were from single institutions, and data from the Nationwide Inpatient Sample, the largest all payer database of hospitalized patients in the United States, suggest otherwise. Data from the Nationwide Inpatient Sample was combined with census data to look at trends in population-based rates of treatment for IBD from 1998 through 2005.[16] These trends are most likely reflective of use of infliximab for Crohn's disease as use of infliximab was not approved by the FDA for treatment of ulcerative colitis until 2006. The rates of hospitalization for both Crohn's disease and ulcerative colitis increased by 5.1 and 3.4% per year ($p < .001$) from 1998 through 2005, respectively, while the overall rate of surgery did not change.[16] An additional analysis of health care utilization among patients with Crohn's disease using infliximab in Manitoba, Canada also showed an increase in hospitalizations for 18–24 months after initial prescription of infliximab, which fell to the level of hospitalization of the azathioprine and steroid group at 2–5 years time.[19] The likelihood of surgery was still greater in the infliximab group than in the group who were treated with azathioprine and the group not prescribed these drugs for up to 36 months. Thus, although small single-institution studies show decreased hospitalizations and decreased surgeries, larger population-based studies suggest that the rate of hospitalization has actually increased and the rate of surgery has not decreased.

Because the medical therapy of ulcerative colitis and Crohn's is similar, there is less importance to distinguish between ulcerative colitis and Crohn's disease. However, distinguishing the two entities is of paramount importance in patients being considered for surgery for colitis, because the ileoanal pouch procedure is generally not an option for patients with Crohn's colitis because of the high risk of recurrence and pouch failure in over one-third of patients with an ultimate diagnosis of Crohn's disease.

Biologics such as infliximab and adalimumab have also had an expanding role in patients with Crohn's disease–like complications following ileoanal pouch-anal anastomosis (IPAA). Such complications include antibiotic-resistant pouchitis, complex fistula of the pouch and/or small bowel, and stricturing and inflammation of the afferent limb of the pouch. There is no consensus about how to manage such patients medically, but overall goals include attempting to improve quality of life, preserving the pouch, and avoiding pouch failure. Generally, a combination of antibiotics, 5-aminosalicylic acid products, steroids, immunomodulators, and biologics such as infliximab and adalimumab has been used. While ileoanal pouch fistulizing disease is associated with a high pouch failure rate and a high rate of the need for fecal diversion, a number of studies have shown that over 50% of patients with fistulizing disease may be successfully treated with immunomodulators and biologics[20–23] while stricturing disease does not respond to biologics.[23]

Looking specifically at surgery for ulcerative colitis, since the late 1970s when the ileoanal pouch operation was described by Parks and Nicholls, the operation has become the preferred procedure of choice for the majority of patients undergoing surgery for ulcerative colitis. Excellent long-term results have been established in the majority of patients undergoing the procedure. Proctocolectomy and ileostomy remains a viable option, and quality-of-life studies have shown equivalent quality of life with the ileoanal pouch procedure, suggesting the colectomy is related to the improvement not necessarily the avoidance of a stoma. While the majority of patients do well, there are a number of ongoing concerns and complications of the procedure.

The most frequent long-term complication of the operation is the development of pouchitis, a nonspecific inflammation of the ileal pouch mucosa. Pouchitis is a clinical syndrome of increased stool frequency, rectal bleeding, abdominal cramping, blood and mucus. While many patients have an acute episode of pouchitis, a small subset of patients develops chronic pouchitis, which is a potential cause of pouch failure and poor quality of life. The cause of pouchitis remains elusive; it is disease-specific and most commonly seen in patients with ulcerative colitis and is uncommon in patients with familial adenomatous polyposis. Pouchitis has been called the "Achilles heel" of the ileoanal pouch operation, and further understanding of the etiology and ways to prevent this complication would benefit a number of patients.

Following construction, the ileoanal pouch undergoes a number of histologic changes and, with time, the metaplastic changes result in the ileal mucosa resembling colonic mucosa. These changes may also occur because of inflammation in the pouch and raise concern about the development of dysplasia and cancer in the pouch of the rectal remnant. Less than 20 cancers arising in the ileoanal pouch or transition zone have been reported with the majority of patients having cancer or

dysplasia in the original operative specimen.[24] As patients age, there has been increasing concern about the development of cancer or dysplasia and whether a surveillance program is justified. In a cohort of 160 patients in which over 50 % of the pouches were older than 10 years with over 1800 pouch years of surveillance, we found only one patient who had focal low-grade dysplasia of the pouch.[25] The most recent guidelines of the American Society of Colon and Rectal Surgeons have found insufficient evidence to endorse a surveillance program for ileoanal pouch patients.[26] Surveillance should be considered in higher-risk group patients, including those with dysplasia or carcinoma in the original specimen, type C ileal mucosal changes, and those with sclerosing cholangitis.[24] Biopsies should be obtained of the pouch and the rectal remnant (anorectal mucosa) distal to the ileoanal anastomosis.

The ileoanal pouch procedure is increasingly performed by a laparoscopic approach. Adoption rates are low across the country and data from the Nationwide Inpatient Sample suggest that less than 10% of ileoanal pouches across the United States are done laparoscopically. Retrospective case-matched comparative studies have shown a longer operative time (median 330 vs 230 minutes) but a quicker return of bowel function (2 vs 4 days) and a shorter hospital stay (7 vs 8 days) with a laparoscopic approach.[27] A recent meta-analysis of 10 studies with 329 patients confirmed that despite a longer operative time, patients had a lower blood loss, shorter hospital stay, and a smoother postoperative recovery compared to open surgery.[28] In a review of 100 laparoscopic versus 189 open ileoanal pouch procedures for ulcerative colitis, patients reported excellent body image and quality-of-life scores regardless of an open or laparoscopic approach.[29] Laparoscopic surgery is associated with fewer adhesions and may be associated with a lower incidence of small bowel obstruction and infertility although the data are largely speculative at present.

There are some additional considerations for the surgeon in approaching the operative management of Crohn's disease. Surgery should be planned with the caveat that there is no medical or surgical cure for the disease, the disease tends to recur, and that over the course of a lifetime patients may have a number of procedures. As such, there is no need to perform resection with wide margins and resection to grossly normal bowel is advisable. There is no role for frozen sections. Determining the extent of small bowel disease is performed intraoperatively by palpating (pinching) the mesenteric fat along the border with the bowel. With fat wrapping, the two opposing fingers cannot be well-palpated, but with normal uninvolved bowel palpation of the two opposing fingers is quite easy. My preference is to open the resected bowel in the operating room to assess the margins. Despite imaging and endoscopy preoperatively, the surgeon must be prepared to encounter "surprise" or unanticipated findings during surgery, including unsuspected abscesses or fistulas. Small bowel adenocarcinoma may be detected in patients who have long-standing stable disease with abrupt change in symptoms. Division of the mesentery can be challenging in Crohn's disease, and it is advisable to stay closer to the bowel. If bleeding occurs, the mesentery can be resected or suture-ligated more proximally. My preference is to use various vessel sealing devices for difficult Crohn's mesenteries.

All efforts should be made to preserve bowel length as Crohn's patients may require multiple resections over the years. Strictureplasty, a technique, adopted from tuberculous strictures, is a useful technique in patients who have multiple diffuse small bowel strictures or in patients with strictures who have had prior resections. Large bowel strictures are generally not amenable to strictureplasty.

As with ulcerative colitis, a laparoscopic approach is favored for selected cases. Patients with ileocolic disease undergoing their first resection are the more ideal candidates for laparoscopic resection. A meta-analysis examined 783 patients who underwent ileocolic resection for Crohn's disease, including 338 who had a laparoscopic approach.[30] Operative time was longer in the laparoscopic groups, although overall costs were the same. Patients in the laparoscopic group had a shorter length of stay and shorter time to first bowel movement and resuming a diet. Although complicated Crohn's disease may be approached laparoscopically, patients who have had multiple prior procedures, have disease in multiple sites, and who have a palpable mass or phlegmon generally require an open approach.

In summary, there have been a number of changes to both the medical and surgical approach to IBD in the last decade. Biologics have afforded patients periods of remission. While laparoscopic surgery has been adopted slowly, accumulating evidence shows quicker recovery, fewer complications, less trauma, less adhesions, and potentially enhanced fertility with a minimally invasive approach.

TUMORS OF THE COLON

36

Andreas M. Kaiser • David Etzioni • Robert W. Beart, Jr.

INTRODUCTION

Tumor is a descriptive term for a growth or mass of cells that are independent of the physiologic function or demand of their surrounding structures. The two characteristic biological growth patterns of tumors include the ability to (1) disrespect tissue boundaries and invade other structures (*invasiveness*) and (2) gain access to blood and lymph vessels or other structures to spread tumor cells to distant locations, and allow these specially equipped cells to survive and grow new remote tumors (*metastases*). If a tumor does not have either property, it is *benign*; if a tumor can invade locally but even at a large size does not have a tendency to metastasize, it is called *semimalignant*; and if a tumor has the ability to metastasize once a sufficient size is reached, it is a *malignant* tumor.

Colorectal lesions may be classified as either benign, potentially malignant, or malignant based on their pathological features (Table 36–1); the semimalignant variant with invasion only but no affinity to later form of metastases is not common in the colon. The overwhelming majority of colorectal tumors are of epithelial origin and arise from the mucosal surface, where they become visible descriptively as a polyp. Benign polyps include nonneoplastic polyps (eg, hyperplastic, hamartomatous, or inflammatory polyps); the potentially malignant group consists of adenomatous polyps. Once dysplastic cells in a polyp cross the boundaries of the mucosa (basement membrane and muscularis mucosae) and start to invade the submucosa and the muscularis mucosae, a true cancer (carcinoma) with the potential to metastasize is established. Tumors of nonepithelial or mesenchymal origin are comparably rare and include, among others, lipoma, lymphoma, carcinoid, and sarcoma.[1–3]

Colonic tumors are important for two reasons: First, they are frequent and account for both a significant mortality rate as well as high cumulative health care costs. Second, the sequence of events leading from a normal mucosa to a manifest cancer occurs through largely preventable precursor stages over the course of several years. This chapter therefore predominantly focuses on the detection, management, and prevention of these conditions.

EPIDEMIOLOGY

Colorectal cancer is the most common malignancy in the gastrointestinal tract. In the United States, colorectal cancer ranks fourth in terms of both gender-specific annual cancer incidence and cancer mortality (behind lung, prostate, and breast, respectively).[4] With an estimated 146,970 newly diagnosed cases, this disease will be responsible for an estimated 49,920 deaths or 10–15% of cancer-related deaths in the year 2009.[4,5] The lifetime risk of approximately 6% in our Western civilization means that 1 in 18 individuals of the general population will be affected by colorectal cancer and many more by polyps, making it an important public health issue.[6] Worldwide, colorectal cancer shows large geographical differences, with a crude incidence of 6.5/7.7 cases per 100,000 females/males in less developed areas as opposed to 50.9/60.8 in more developed regions.[7]

The colorectal cancer incidence has evolved in recent years to an overall predominance of males who represent in 51.4% of the cases.[4,8] Rectal cancer is more frequent in males (57.7%), while colon cancer is slightly more frequent in females, resulting in almost identical overall mortality rates for both genders.[4] The incidence of colorectal cancer in females is 44.8 per 100,000 and in males 61.2. Regardless of ethnicity, there is an age-dependent increase in incidence with each decade starting at age of 40 years, and the mean age at presentation is around 70–75 years.

In the period between 1975 and 2006, the Surveillance, Epidemiology and End Results (SEER) Registry of the National Cancer Institute (NCI) shows a gradual decline in all cases of colorectal cancer in the United States from 69.7 to 50.6 cases per 100,000.[9] However, although these numbers reflect the trend in Caucasians, the incidence of colorectal cancer in the United States for African Americans has remained at the same level of 59.3–61.5 cases per 100,000 individuals. African American males therefore now represent the ethnic subgroup with the highest risk.[10,11]

TABLE 36-1: INTRODUCTION: CLASSIFICATION OF COLON TUMORS

A. Epithelial Tumors of the Colon

Type	Class	Subclassification
Benign lesions	Hyperplastic polyps	—
	Noninherited gastrointestinal polyposis syndromes	Hyperplastic polyposis
	Hamartomas	Juvenile polyps Cowden syndrome Bannayan-Riley-Ruvalcaba syndrome Cronkite-Canada syndrome
	Inflammatory polyps	—
Potentially malignant lesions/ syndromes	Adenomatous polyps	Sporadic colon cancers Hereditary colon cancers
	Hereditary adenomatous polyposis syndromes	Familial adenomatous polyposis (FAP) Attenuated familial adenomatous polyposis (AFAP)
	Noninherited gastrointestinal polyposis syndromes	Cronkite-Canada syndrome
	Inherited hamartomatous polyposis syndromes	Juvenile polyposis syndromes Peutz-Jeghers syndrome
Malignant lesions	Epithelial tumors of the colon	Sporadic colon cancers Familial colorectal cancer Hereditary nonpolyposis colon cancers (HNPCC) Familial/Hereditary polyposis coli cancers

B. Nonepithelial Tumors of the Colon

Type	Class
Benign lesions	Lipomas and lipomatous polyposis
Potentially malignant lesions/ syndromes	Carcinoid/neuroendocrine tumors Gastrointestinal stromal tumors (GIST) Nodular lymphoid hyperplasia of the colon
Malignant lesions	Lymphoma

C. Secondary Tumors to the Colon

Type	Class
Benign lesions	Endometriosis
Potentially malignant lesions/ syndromes	Leukemia Endometriosis transforming to cancer
Malignant lesions	Lymphoma Malignant melanoma Carcinomas from other primary sites

RISK FACTORS, PREVENTION AND SCREENING

The specific cause of colorectal cancer is not known. However, a number of genetic and environmental risk factors have been associated with the disease.[12] From a practical and screening standpoint, it has been helpful to group individuals into three risk categories (ie, average risk, increased risk, high risk) based on their presumptive genetic profile as reflected in their individual and family history.[13,14] The high-risk and increased-risk groups consist of patients with known hereditary syndromes or bowel diseases or patients with a personal/family history of polyps or cancer, all of which are discussed in a later section of the chapter (Table 36-2).

TABLE 36-2: COMPARISON OF MAJOR RISK CATEGORIES

	SCC	FAP	HNPCC	IBD
Variants		AFAP, Gardner, Turcot	Lynch I/II	Ulcerative colitis Crohn's disease
Genetics		+ Autosomal-dominant	+ Autosomal-dominant	?
Genes	Chromosomal deletions, *K-ras, DCC, p53, APC*	*APC*	*MSH2, MLH1, PMS1/2, MSH6*	?
Age of onset	>40 y Average 70–75	Polyps start after age 10–20, cancer in 100% at age 40	<50 y	Any, often young patients
Number of polyps	Variable, <10	>100	<10	Inflammatory pseudopolyps
Risk	5–6% of population	100%	>80%	Depending on age at onset, duration of disease, extent of active disease
Location	Left > right colon	Any location	Right > left colon	Active disease
Chemoprevention	NSAID? vitamins? calcium?	NSAID	?	IBD suppression?
Screening	> 50 y (45 y in African Americans)	>10–15 y Genetic counseling	>25 or 10–15 y before cancer onset in youngest family member Genetic counseling	7 y post onset, annually
Associated risks	?	Desmoids	Endometrium and other cancers	Extracolonic disease

AFAP, attenuated FAP; FAP, familial polyposis syndromes; HNPCC, hereditary nonpolyposis colon cancer; IBD, inflammatory bowel disease; NSAID, nonsteroidal anti-inflammatory drug; SCC, sporadic colon cancer.

The majority of cases, however, are sporadic colon cancers that typically arise within a polyp. Geographic and migrational studies have suggested that the Western lifestyle increases the risk for colon cancer, hence suggesting that nutritional and environmental factors may play a key role.[15] A large number of epidemiological studies have been undertaken to identify these individual, nutritional, lifestyle, genetic, and environmental factors that would either predispose to or prevent the development of colorectal polyps and cancer (Table 36-3).[16–21]

Extrinsic Risk Factors

DIETARY FIBER, MEAT, AND FAT

One of the characteristics of a Western diet generally has been the lack of fiber as opposed to the increased amount of meat, total fat, and animal fats.[23,24] In view of the known geographic differences, with the highest colorectal cancer incidence in industrialized nations,[7] a high-fat and low-fiber diet generally has been considered a risk factor for the development of colorectal cancer.[25] This concept gained support from epidemiological studies[26] and resulted in common recommendations of high-fiber supplements in order to increase the stool bulk, dilute toxins, and reduce the colonic transit time and thus the exposure time to fecal carcinogens.[27–30] More recent prospective trials, however, have questioned the benefit of dietary fiber supplementation in that they were at best inconclusive and did not reduce the incidence of colorectal cancer.[31,32] On the other hand, selected fats such as *n*-3 fatty acids found in fish oils may have a protective effect,[33] even though a direct effect to the mucosa could not be observed.[34] It therefore could be concluded that the total amount of fats or fibers is of lesser importance than their quality and origin.[21,23,35] The protective effect of vegetables and fruits[36,37] may come not only from their fiber content but also from the content of antioxidative and antiproliferative agents such as isothiocyanates in cruciferous vegetables (eg, broccoli), which may enhance the expression of carcinogen-metabolizing enzymes and induce apoptosis in neoplastic cells.[18,38]

CALCIUM, VITAMINS, AND MICRONUTRIENTS

Several prospective studies suggested that increased oral calcium and selenium intake may protect from colorectal polyps and cancers,[39–44] whereas other studies could not verify a significant benefit.[45] The mechanism by which calcium supplements are thought to reduce the risk of colon cancer is twofold. First, calcium can bind bile and fatty acids in the stool to insoluble complexes that are less likely to attack the colonic mucosa, and second, it can interfere directly with the mucosal cells and decrease their proliferative potential on a cellular level.[26]

TABLE 36-3: RISK FACTORS ASSOCIATED WITH COLON CANCER

Risk Factor	Comment
Geographic variation	Highest risk in Western countries and lowest in developing countries
Age	Risk increase sharply after the fifth decade
Diet	Increased with total and animal-fat diets
Physical inactivity	Increased with obesity and sedentary lifestyle
Adenoma	Risk dependent on type and size
FAP penetrance in gene carriers	100%
HNPCC penetrance in gene carriers	80%
Hamartomatous syndromes	Risk increased with Peutz-Jeghers syndrome and juvenile polyposis but not isolated juvenile polyps
Previous history of colon cancer	Increased risk for recurrent cancer
Ulcerative colitis	10-20% after 20 y
Radiation	Associated with a mucinous histology and poor prognosis
Ureterosigmoidostomy	100-500 times increased risk at or adjacent to the ureterocolonic anastomosis

FAP, familial polyposis syndromes; HNPCC, hereditary nonpolyposis colon cancer.
Data from Wu JS, Fazio VW. Colon cancer. *Dis Colon Rectum*. 2000;43(11):1473–1486.[22]

Several vitamins were found to have a cancer-protective effect. Vitamins A, C, and E have been shown to have antioxidant activity. Results from interventional studies, however, have remained somewhat disappointing or controversial.[46,47]

In a study on postmenopausal women, another correlation was found between dietary heme iron and an increased risk of proximal colon cancer, especially in conjunction with alcohol consumption, whereas intake of dietary zinc reduced the risk of both proximal and distal colon cancer.[48]

ASPIRIN AND COX-2 INHIBITORS

Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) may interfere with the development of colorectal neoplasms by blocking the cyclooxygenase (COX)-dependent prostaglandin pathway.[49] The targets are the constitutive COX-1, as well as the cytokine-inducible COX-2, which has been found at increased expression levels in both polyps and cancers.[50] Several trials therefore have studied these agents (eg, aspirin and sulindac) for the chemoprevention of colorectal cancer both in sporadic polyps and cancers[51] and in familial adenomatous polyposis (FAP).[52–54] In both settings, controlled studies have provided contradictory results.[55] Regular prophylactic medication with low-dose aspirin may reduce the risk of sporadic colorectal cancer.[51,56] Data from chemoprevention trials in FAP suggest that COX inhibition may delay the onset and number of adenomatous polyps, but it is not yet clear whether it is able to prevent the cancers overall or reduce their respective risk.[52–54] COX-2–independent mechanisms may play a role for the beneficial effect of some COX-2 inhibitors.[49] A major recent concern, however, has been the documented increased risk of serious cardiovascular events with the use of COX-2 inhibitors.[57,58]

Because data on the benefits remain conflicting, physicians must decide how to use these pharmacologic tools in the management of their patients. Based on the presumed small risks in general and the supporting data on a possible benefit, most physicians would be inclined to err on the side of a potential benefit in preventing colon polyp formation. Low doses of aspirin and calcium may be helpful in preventing polyps and cancers. However, recent concern about cardiovascular side effects and increased mortality has resulted in a withdrawal of more potent COX-2 inhibitors until further redefinition of the indications and risk groups has been accomplished.[57,58]

CHOLECYSTECTOMY AND BILE ACIDS

Evidence that bile acids may act as cocarcinogens or tumor promoters comes from both experimental and epidemiological studies.[59,60] Bile acids can induce hyperproliferation of the intestinal mucosa via a number of intracellular mechanisms. Cholecystectomy, which alters the enterohepatic cycle of bile acids, has been associated with a moderately increased risk of proximal colon cancers.[61,62] It cannot be ruled out, however, that it is less the effect of the cholecystectomy than the impact of other, not yet identified factors in the lithogenic bile of such patients. A number of cofactors have been identified that may enhance or neutralize the carcinogenic effects of bile acids, for example the amount of dietary fat, fiber,[26] or calcium.[63] Calcium, in fact, binds bile acids and thus may reduce their negative impact. However, other more intrinsic mucosa-protective mechanisms of calcium supplements probably are more relevant for the demonstrated reduction of recurrent adenomatous colon polyps.

SMOKING AND ALCOHOL CONSUMPTION

The risk of colorectal cancer is increased, even though only modestly, among long-term smokers compared with nonsmokers.[29,48,64,65] The data suggested a dose-response relationship between pack-years of tobacco use and the development of adenomatous polyps.[66–69] Equally, excessive alcohol consumption has been associated with an increased risk for colon cancer.[29,48,64,65]

OTHER FACTORS

An ever-increasing number of other factors are accumulating that have been attributed to an increased risk of colon cancer, for example lack of physical activity, diabetes, serum insulin levels, elevated concentrations of insulin-like growth factor 1, and low concentrations of insulin-like growth factor–binding protein 3 (IGFBP-3).[70] The complexity of interactions between these factors and the previously mentioned parameters, however, makes it difficult at the present time to draw conclusions that have an impact on the clinical practice.

Intrinsic Risk Factors

PERSONAL AND FAMILY HISTORY

There is generally little debate on whether the presence of an adenomatous pathology or chronic inflammatory bowel disease (IBD) in itself represents a risk factor for a subsequent colon cancer. In patients with a colon cancer, synchronous colorectal cancers are found in 5–10%, whereas about 10–20% of patients with a history of colorectal cancer will develop metachronous primary cancers in the large intestine. A personal history of adenomatous colonic polyps is an indicator for an increased colonic predisposition to develop subsequent adenomatous or cancerous changes.[14,71–75]

Compared with the general population, relatives of patients with colon cancer have a two to four times increased risk of developing the disease themselves (Table 36-4).[29,76,77] A similar, even though proportionally lesser, risk is observed for family members of individuals with colonic adenomatous polyps.[77]

TABLE 36-4: LIFETIME RISKS OF COLORECTAL CANCER IN FIRST-DEGREE RELATIVES OF PATIENTS WITH COLON CANCER

Population risk without risk factors	1 in 50
One relative affected	1 in 17
One first-degree relative and one second-degree relative affected	1 in 12
One relative aged <45 y affected	1 in 10
Two first-degree relatives affected	1 in 6
Dominant pedigree	1 in 2

INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) is a strong risk factor for colorectal cancer. The risk correlates with the age of onset and extent and duration of active disease (Table 36-5 and Fig. 36-1).[79,80] In contrast, however, the disease activity historically was not thought to be correlated with the risk, but recent studies have challenged this view.[81] In ulcerative colitis, the risk of colorectal cancer increases from approximately 3% in the first decade to 10–20% in the second decade.[79,80] In patients with Crohn's disease with colonic involvement, the disease-associated risk for colorectal cancer is also elevated but generally to a lesser extent.[82–84]

TABLE 36-5: RELATIVE RISK OF COLORECTAL CANCER AMONG PATIENTS WITH ULCERATIVE COLITIS ACCORDING TO SEX, EXTENT OF DISEASE AT DIAGNOSIS, AND AGE AT DIAGNOSIS

Variable	Observed Cases	Person-years of Follow-up	SIR (95% CI)[a]
Sex			
Male	52	19,312	5.6 (4.2–7.4)
Female	39	16,268	5.9 (4.2–8.0)
Extent of disease			
Proctitis	9	11,170	1.7 (0.8–3.2)
Left-sided colitis	17	11,169	2.8 (1.6–4.4)
Pancolitis	65	13,241	14.8 (11.4–18.9)
Age at onset (y)			
0–14	13	4,220	118.3 (63.0–202.3)
15–29	21	14,047	16.5 (10.2–25.2)
30–39	15	6,892	8.2 (4.6–13.6)
40–49	16	4,119	6.1 (3.5–9.8)
50–59	11	3,294	3.4 (1.7–6.1)
≥60	15	3,008	2.2 (1.2–3.6)

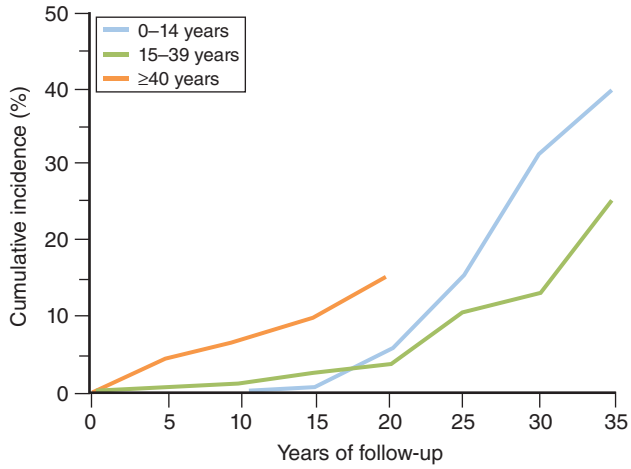

FIGURE 36-1 Impact of the age at diagnosis on the cumulative incidence of colorectal cancer in patients with pancolitis. Patients diagnosed with pancolitis when they were younger than 15 years are represented by solid line, when they were 15–39 years by dashed line, and when they were 40 years or older by the dotted line. (Reproduced, with permission, from Ekbom A, Helmick C, Zack M, Adami HO. Ulcerative colitis and colorectal cancer: a population-based study. *N Engl J Med*. 1990;323:1228–1233.)

OTHER FACTORS

Less frequent risk factors for colorectal cancers may include a history of a ureterocolostomy[85] or previous radiation treatment.[86,60] The former requires the combination of fecal bacteria and urine because the microbes degrade urinary metabolites into strong carcinogens.[85,87,88] When colonic mucosa is used for bladder augmentation, no increased cancer risk is observed owing to the absence of bacteria. Radiation-induced colorectal cancer is little less clear, but it has been suggested that it may be associated with a mucinous histology and poor prognosis.[86]

Prevention and Screening

Because symptoms are not reliable for early detection of colorectal cancer, risk-adjusted screening programs for asymptomatic individuals are important. Effective screening has to be based on an understanding of the adenoma-carcinoma sequence, which may take up to 5–10 years from the first molecular change to a clinically manifest cancer, and should reflect an individual's genetic and disease- or age-dependent risk for the development of colorectal cancer.[13,14,89–91] Any prevention program has to be sensitive but also practical and cost-effective in order to achieve a broad screening of the population at risk. The term "screening" is applicable only to asymptomatic people; if symptoms are present, it is not screening but diagnostic tests that are initiated. Common tools for screening include fecal occult blood tests (FOBTs), flexible sigmoidoscopies or colonoscopies, and contrast enemas or CT colonography.[92]

The American Cancer Society, endorsed by the major professional societies, recommends starting colorectal cancer screening in asymptomatic average-risk adults at age 50.[13,14,89–91] A slightly earlier screening start at age of 45 has been recommended recently for African American patients based on their statistically increased risk.[11] A first baseline colonoscopy is to be performed and, if no pathology is found, repeated every 10 years. In addition, an FOBT should be done at an annual basis, and any positive result should precipitate a full colonic evaluation. Every 5 years, a limited endoscopy (flexible sigmoidoscopy) or barium enema is indicated. If precursor lesions are found, they should be removed and a colonoscopy be performed after 1–3 years to detect missed (20%) or recurrent polyps.[93–95]

In individuals at increased risk (eg, personal/family history of polyps or cancer or African American ethnicity) or at high risk (eg, cancer syndromes or IBD), the screening has to start earlier (see Table 36-2) and has to be performed at a higher frequency.[11] Successful screening programs have been shown to reduce the colorectal cancer incidence by 76–90%.[96]

PATHOGENESIS OF COLONIC CANCER

Carcinogenesis in the colon is a complex multistep process in which a multitude of alterations must coincide in order to transform a normal cell into a malignant cell. Several categories of genes are involved that normally are regulated in a sophisticated network to keep a tight balance between cell growth and turnover, cell death, DNA replication, and mismatch repair. Disruption of the fine balance between oncogenes, which promote cell proliferation, and tumor suppressor genes, which inhibit excessive growth, results in a growth advantage and allows malignant cells to expand.

Colon Cancer: A Genetic Disease

All cells of even such a complex organism as a human being have DNA that is virtually identical to the DNA found in the zygotes. DNA mutations can occur either as a germline mutation or as a somatic mutation. The former may be transmitted from one to the next generation as an inherited defect. More commonly, a spontaneous mutation occurs in a non–germline cell during the growth, development, and maintenance of a tissue or organ (somatic mutation). Even in the cycle of a normally functioning cell, there is a high chance of spontaneous gene mutations, most of which will not result in a growth advantage to the harboring cell. Genesis of a cancer therefore requires several independent accidents to occur in one cell. One can assume that a normal cell will be able to detect damage to its own DNA and maintain an effective repair mechanism. However, if the cell is too severely damaged, it might rather initiate the inherent suicide program called *apoptosis*. When a cell fails to recognize or correct a DNA

damage and continues to replicate, accumulation of faulty gene products within the cell may eventually lead to a proliferative response. If that replication exceeds the growth potential of the neighboring normal cells, the mutation provides a growth advantage that will increase the state of "genetic instability" and hence lead toward a malignant cell.[97] Despite this potential, most mutations are silent or lethal to the cell rather than beneficial in terms of providing the cell a biologic advantage. The triggers and the step-by-step cumulative failures that lead to carcinogenesis still are relatively poorly understood.

Two types of genetic instability may occur: at the chromosome level or at the DNA level. A loss of chromosomal material, that is, a *chromosomal instability* (CIN), results when the chromosomes are not divided symmetrically during mitosis such that one daughter cell receives both copies and the other cell receives none. On an electrophoretic gel, this can be visualized as a loss of one or more bands, which is described as *loss of heterozygosity* (LOH), and has been associated with a worse prognosis of colorectal cancer.[2] The second form of genetic instability, at the DNA level, occurs when replication errors in repetitive short polymorphisms lead to an additional band or bands.[98] This phenomenon is described as *microsatellite instability* (MSI), and it has been a characteristic feature of hereditary nonpolyposis colon cancers (HNPCCs).[99]

During the process of cell division, DNA is duplicated, with the original DNA serving as a template for the replicated copy. DNA polymerase serves as a "proofreader" that recognizes mismatched genes, halts the DNA synthesis, removes the defective sequence, and then resynthesizes the DNA. Failure of the DNA mismatch repair system predisposes to the development of mutations within daughter cells. Enzymes that monitor newly formed DNA and correct replication errors are called *DNA mismatch repair* (MMR) systems.

Specific gene functions are lost when both copies (alleles) of a gene are inactivated. Thus, when a germline mutation occurs in a suppressor gene, only the mutation of the remaining normal allele is required for the gene's loss of function. When both copies of the gene are normal, two mutational events are required for the gene's loss of function. This two-hit hypothesis may explain why inherited diseases usually manifest at an earlier age than sporadic disease.[6]

The Adenoma-Carcinoma Model

After identifying several genetic alterations in colorectal specimens at various stages of their neoplastic transformation and progression, Vogelstein and colleagues in 1988 pioneered a genetic model for colorectal tumorigenesis that since has been known as the *adenoma-carcinoma sequence*[3] (Fig. 36-2). This multistep model described the carcinogenesis as an accumulation of genetic events, uninhibited cell growth, and proliferation and clonal development. Gene mutations and chromosomal/gene losses that were observed in sporadic colon cancer include the *APC* gene (adenoma–polyposis coli), *MMC gene* (mutated in colon cancer), *K-ras*, *DCC* (deleted in colon cancer), and *p53*.[2,100,101] Mutations of the *APC* gene, which is involved in the control of cell-to-cell adhesions and intercellular communication, are found in 60% of even small adenomatous polyps, as well as in carcinomas,[102] and therefore are believed to occur as a very early event in carcinogenesis. Mutations of *K-ras*, which under normal function plays a role in intracellular signal transduction and stimulated cell division, occur in larger adenomas and carcinomas and are thought to stimulate cell growth. Deletion of the tumor suppressor gene *DCC* may be important in the progression from a benign polyp toward a malignant condition.[103] Mutations of the *p53* gene, which are among the most frequent gene mutations in human cancers, are also common in invasive colon cancers but rare in adenomas, suggesting that *p53* mutations occur as a late event in the development of the invasive phenotype.[104] The wide range of gene mutations, inactivations, and deletions in the progression to carcinoma seem to hold the secret code for the various tumor behaviors observed in the clinical setting. It is important to note, however, that an increasing number of other genetic events have been observed and reported and that no single event seems to be equally present in all colon cancers. One therefore should caution that the described sequence is only one possible model and that the scenario may not reflect all aspects of colonic carcinogenesis.

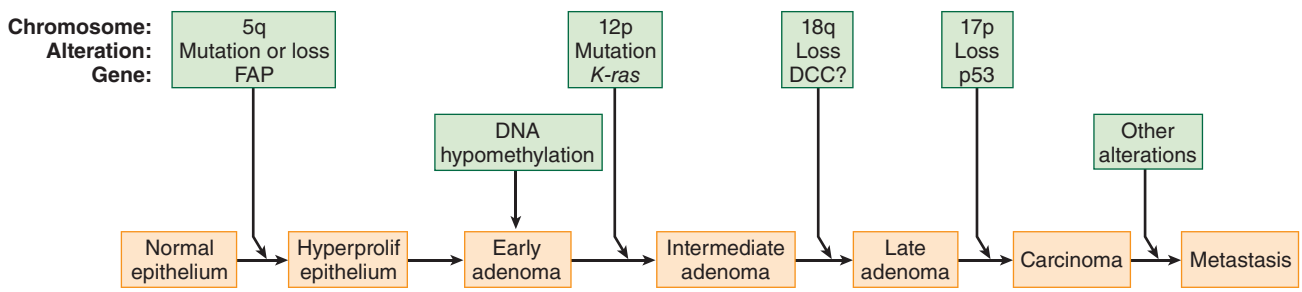

FIGURE 36-2 Genetic model for colorectal tumorigenesis (adenoma-carcinoma sequence). FAP, familial adenomatous polyposis. (Reproduced, with permission, from Fearon ER, Vogelstein B. A genetic model for colorectal tumorigenesis. *Cell.* 1990;61:759–767.)

HEREDITARY AND NONHEREDITARY COLON TUMORS

Nonhereditary Colon Cancer

SPORADIC COLON CANCER

Sporadic colon cancer, that is, colon cancer arising in individuals without a family history or an inherited predisposition, accounts for approximately 60% of all colorectal cancers and affects patients commonly older than 50 years. The risk factors associated with sporadic development of colon cancer have been discussed previously in the epidemiological section of this chapter (see Table 36-3).

FAMILIAL COLON CANCER

Familial colon cancer is the second most common (25–30%)[6] and at the same time least understood pattern of genetic colon cancer development. In affected families, colon cancer develops too frequently to be considered a sporadic colon cancer, but the pattern is not consistent with the known inherited syndromes.[78] An association of familial colon cancer has been found with polymorphisms, which reflect subtle genetic changes in the form of variations in the nucleotide base sequences but which do not affect protein structure.[6] Familial colon cancer in the Ashkenazi Jewish population probably is the result of an *APC* germline mutation on codon 1307 (I1307K). This mutation, which predisposes to sporadic mutations at distant sites of the gene and later results in structural protein abnormalities, is found in 6% of all Ashkenazi Jews and in 28% of those with both a personal and a family history of colon cancer.[105]

Hereditary Colon Cancer

FAMILIAL ADENOMATOUS POLYPOSIS

Familial adenomatous polyposis (FAP) is an autosomal dominant inherited syndrome with near-complete penetrance. The offspring of affected individuals thus have a 50% risk of inheriting FAP. However, up to 20% of patients with FAP are new mutations without a family history. This condition is attributed to a truncating mutation in the germline adenomatous polyposis coli (*APC*) gene on chromosome 5q21.[106] Variants of the polyposis syndrome are classified as Gardener's syndrome (ie, osteomas, desmoid tumors, thyroid neoplasms, and congenital hypertrophy of the retinal pigment epithelium) and Turcot's syndrome (ie, brain tumors).

The inherited syndrome of FAP and its variants accounts for less than 1% of all colon cancers. It is characterized by greater than 100 and often several thousands of adenomatous intestinal polyps that start to develop in the late teens and early twenties and turn into cancer by age 40–45. An attenuated variant of the disease is relatively rare and is characterized by a lower number and a later onset of both the polyps and the resulting cancer (see the following text). Nearly all FAP patients develop duodenal adenomas that are severe in 10% and account for the group's second highest cancer risk, with adenocarcinoma developing in the periampullary region in 3–10% of patients.[107,108] Carcinoma arising in the antrum and duodenum after colectomy is the main cause of cancer-related deaths in FAP patients.[107,109,110] Nonadenomatous fundic gastric polyps develop in approximately 10–30% of patients with FAP[110] but usually do not have a malignant potential. Ten percent of FAP patients develop desmoid tumors either intra-abdominally or on the abdominal wall, extremities, and trunk.[111] Histologically, desmoids are fibromatous lesions consisting of large proliferation of myofibroblasts. Even though they do not necessarily carry features of a malignant lesion, the recent literature suggests a low-grade sarcoma-like behavior. Desmoids are lethal in 10% and are the third most frequent cause for mortality of FAP patients, mainly owing to the intra-abdominal variants, which cause small bowel and ureteral obstructions.[111,112]

Approximately 25% of FAP patients remain without an identified *APC* mutation (*APC*-negative)[112,113] and, using a detailed analysis, they seem to differ in terms of lower polyp number, later age at diagnosis, and lower occurrence of extracolonic manifestations as compared with classic FAP patients.[110,114] This variant of FAP is known as *attenuated familial adenomatous polyposis* (AFAP).

HEREDITARY NONPOLYPOSIS COLON CANCERS

Hereditary nonpolyposis colon cancer (HNPCC), also known as *Lynch I* and *II syndromes*, is an inherited autosomal dominant disease that accounts for 3–5% of all colorectal cancers.[115] It is characterized by an early onset of colorectal cancers predominantly but not exclusively on the right side of the colon with synchronous and metachronous cancers. Despite its name, these cancers typically arise from colonic polyps, but a diffuse polyposis is not present. The penetrance of the HNPCC predisposition is high and results in an 80–85% lifetime risk of colorectal cancer and a 40–50% risk of endometrial cancer.[17,116,117] Furthermore, HNPCC patients are at increased risk of developing extracolonic malignancies, such as cancer of the small bowel, stomach, hepatobiliary tract, urinary tract, ovary, and brain. The Lynch variants describe patients with predominantly colorectal cancer at a young age (Lynch I) and those with both colorectal and extracolonic cancers (Lynch II).[115]

An initial observation of expansions and contractions of microsatellite DNA in the genome of colorectal tumor specimens from HNPCC patients established a link between HNPCC and the DNA MMR system.[118–120] In contrast to the gatekeeper concept applicable to the APC gene in FAP, the DNA MMR genes belong to the so-called caretakers, which, when inactivated, do not promote tumorigenesis directly but rather lead to a genetic instability that then promotes tumor growth indirectly.[121]

In order to facilitate the clinical diagnosis of HNPCC, the International Collaborative Group on HNPCC (ICG-HNPCC) proposed the Amsterdam Criteria in 1990.[115] Linkage studies in

TABLE 36-6: AMSTERDAM CRITERIA I AND II

Amsterdam Criteria I (1990)	Amsterdam Criteria II (1999)
At least three relatives with colorectal cancer, one of whom should be a first-degree relative of the other two.	There should be at least three relatives with HNPCC-associated cancer (colorectal cancer, cancer of the endometrium, small bowel, and ureter), one of whom should be a first-degree relative of the other two.
At least two successive generations should be affected.	At least two successive generations should be affected.
At least one colorectal cancer should be diagnosed before the age 50 y.	At least one colorectal cancer should be diagnosed before the age 50 y.
FAP should be excluded.	FAP should be excluded.
Tumors should be verified by a pathologist.	Tumors should be verified by a pathologist.
	Benign tumors, by definition, do not invade adjacent tissue borders, nor do they metastasize to distal sites. By contrast, malignant tumors have the added property of invading contiguous tissues and metastasizing to distant size.
	A polyp is defined as a mass that protrudes into the lumen of the colon. They are subdivided according to the attachment to the bowel wall (eg, sessile or pedunculated), their histologic appearance (eg, hyperplastic or adenomas), and their neoplastic potential (ie, benign or malignant).

FAP, familial polyposis syndromes; HNPCC, hereditary nonpolyposis colon cancer.
Data from Vasen HFA. Clinical diagnosis and management of hereditary colorectal cancer syndromes. *J Clin Oncol.* 2000;18(21 suppl):81S–92S.[125]

HNPCC families fulfilling Amsterdam Criteria I (Table 36-6) led to the discovery of the first two human MMR genes—*hMSH2* and *hMLH1*. These genes accounted for 45–86% of all classic HNPCC families.[122] There also was a higher risk for *hMSH2* mutation carriers to develop extracolonic cancers, in particular endometrial cancer, as compared with *hMLH1* mutation carriers.[117,123] Several other MMR genes have been identified in conjunction with HNPCC and include *hPMS1*, *hPMS2*, and *hMSH6*. A recent study reported that endometrial cancer represents the most common clinical manifestation of HNPCC among female *hMSH6* mutation carriers and that colorectal cancer cannot be considered an obligate requisite to define HNPCC.[124] The ICG-HNPCC therefore revised the criteria (Amsterdam Criteria II), which now better weighs extracolonic manifestations (eg, endometrial, breast, small bowel, and upper renal tract cancers) as part of the family history (see Table 36-6). In addition, the less restrictive revised Bethesda Criteria (Table 36-7) were adopted to better serve patients who carry *hMSH2* or *hMLH1* gene mutations but otherwise do not fulfill the Amsterdam Criteria. Testing for MSI has become a valuable diagnostic tool to identify individuals with suspected HNPCC because 85–90% of HNPCC tumors have MSI as opposed to only 15–20% of sporadic colon cancers.[99]

HAMARTOMATOUS POLYPOSIS SYNDROMES

Approximately 4% of colonic cancers are seen in the context of rare syndromes. Among these are inherited hamartomatous polyposis syndromes that are characterized by the presence of gastrointestinal hamartomatous polyps and an increased risk of gastrointestinal malignancy. Hamartomas result from a disordered differentiation during embryonic development and are characterized morphologically by disrupted representations of normal tissue components.

TABLE 36-7: REVISED BETHESDA GUIDELINES (2002) FOR TESTING COLORECTAL TUMORS FOR MSI

Criterion	Comment
Colorectal cancer diagnosed in a patient aged <50 y	
Presence of synchronous, metachronous colorectal cancer, or other HNPCC-associated tumor, regardless of age	Stomach, ovarian, pancreas, ureter and renal pelvis, biliary tract, and brain, sebaceous gland adenomas and keratoacanthomas, and small bowel
Colorectal cancer with MSI-high histology diagnosed in a patient aged <60 y	Tumor infiltrating lymphocytes, Crohn's-like lymphocytic reaction, mucinous/signet-ring differentiation, or medullary growth pattern
Colorectal cancer diagnosed in at least on first-degree relative with an HNPCC-related tumor diagnosed under age 50	
Colorectal cancer diagnosed in two or more first- or second-degree relatives with HNPCC-related tumors, regardless of age	

HNPCC, hereditary nonpolyposis colon cancer; MSI, microsatellite instability.
Data from Umar A, Boland CR, Terdiman JP, et al. Revised Bethesda Guidelines for hereditary nonpolyposis colorectal cancer (Lynch syndrome) and microsatellite instability. *J Natl Cancer Inst.* 2004;96(4):261–268.[126]

Peutz-Jeghers Syndrome. Peutz-Jeghers syndrome is the second most common hamartomatous syndrome, occurring as an autosomal dominant condition with variable penetrance. Genetic alterations in the *LKB1/STK* (19p13) gene are responsible for approximately 50% of the cases of Peutz-Jeghers syndrome.[127] The syndrome is associated with hamartomatous polyps of the gastrointestinal tract and cutaneous melanin deposition. The most common location of Peutz-Jeghers polyps is in the upper gastrointestinal tract, specifically the upper jejunum. One of the most characteristic features is the melanin depositions that is seen most frequently in the perioral region or buccal mucosa but also can occur in the genital region and on the hands and the feet. While a majority of these patients remain relatively asymptomatic, some may present with abdominal pain secondary to obstruction or impending obstruction owing to an intussuscepted polyp and others with gastrointestinal bleeding. Patients with Peutz-Jeghers syndrome have a moderately increased risk in the range of 2–3% to develop gastrointestinal malignancies as well as extraintestinal malignancies.

Juvenile Polyposis Syndrome. Juvenile polyposis syndrome is the most common hamartomatous syndrome and is inherited as an autosomal dominant trait. The average age of onset is approximately 18 years, and there is an association with congenital birth defects in 15% of patients.[128] Although the diagnostic criteria for juvenile polyposis syndrome are somewhat controversial, the most commonly used criteria include three or more juvenile polyps of the colon, polyposis involving the entire gastrointestinal tract, or any number of polyps in a member of a family with a known history of juvenile polyps.[129]

In infancy, patients may present with acute or chronic gastrointestinal bleeding, intussusception, rectal prolapse, or a protein-losing enteropathy. In adulthood, patients commonly present with either acute or chronic gastrointestinal blood loss. Most of these patients will be found to have polyps, which are located most frequently in the rectosigmoid region.

A germline mutation in the *SMAD-4* gene (18q21) accounts for approximately 50% of the reported cases of the syndrome.[130] A significant risk of colorectal cancer is associated with juvenile polyposis syndrome, and should not be confused with isolated juvenile polyps because the latter have virtually no malignant potential.

Cowden Syndrome. Cowden's disease, first described in 1963, is known as multiple hamartoma-neoplasia syndrome. It is an autosomal dominant condition with nearly complete penetrance by age 20 that is caused by germline mutations in the *PTEN* tumor suppressor gene located at 10q22.[131,132] Cowden's disease is unique among the hamartomatous syndromes because polyps arise more commonly from ectodermal rather than endodermal elements. Eighty percent of patients present with tricholemmoma, a benign tumor of the hair shaft. The central nervous system is the second most involved system, with approximately 40% of affected individuals suffering from macrocephaly. Only 35% of patients who meet the diagnostic criteria for Cowden's disease have gastrointestinal polyposis, but no increased risk of invasive gastrointestinal malignancy has been reported to date. The majority of patients with Cowden's disease suffer from benign thyroid or breast disease, on top of which adds a projected lifetime risk of 10% for thyroid cancer and of 30–50% for breast cancer.

Bannayan-Riley-Ruvalcaba Syndrome. Formerly known as its subentity, the Ruvalcaba-Myhre-Smith syndrome, this rare autosomal dominant condition includes two other syndromes, both of which, like Cowden's disease, are associated with genetic alterations in the *PTEN* gene on chromosome 10q23 and may be considered a variant of juvenile polyposis coli.[133–135] It is characterized by hamartomatous polyps of the gastrointestinal tract, macrocephaly, mental retardation, delayed psychomotor development, lipid storage myopathy, Hashimoto's thyroiditis, and hyperpigmentation of the skin of the penis. No increased risk of colorectal carcinoma, other gastrointestinal malignancies, or extraintestinal malignancy has been documented in these patients.

Cronkite-Canada Syndrome. Cronkite-Canada syndrome is characterized by diffuse polyposis and ectodermal abnormalities such as alopecia, onychodystrophy, and skin hyperpigmentation. The syndrome can be distinguished by the diffuse distribution of polyps throughout the entire gastrointestinal tract with exception of the esophagus, which is spared.[136] Symptoms include diarrhea, weight loss, nausea, vomiting, and anorexia, as well as paresthesias, seizures, and tetany related to electrolyte abnormalities. Cancer occurs in the stomach, colon, and rectum, but it remains controversial whether polyps in Cronkite-Canada syndrome possess malignant potential. As many as 15% of patients with Cronkite-Canada syndrome have a malignant tumor at the time of diagnosis.

PATHOLOGY AND STAGING

Polyps

Polyp is a descriptive clinical term for any mucosal elevation. Polyps are further categorized along several dimensions, including

1. Size
2. Character of their attachment to the bowel wall (eg, sessile or pedunculated)
3. Cellular architecture (eg, adenomas, hyperplastic, hamartomas, inflammatory) and histologic appearance (eg, tubulous, tubulovillous, villous)
4. Progression from benign to malignant behavior (eg, benign, dysplastic, cancer)

TABLE 36-8: RISK OF INVASIVE CARCINOMA IN ADENOMATOUS POLYPS

Polyp Size (mm)	Number	% With Invasive Carcinoma
≤5	5137	0
6–15	3581	2.2
16–25	1069	18.6
16–36	516	42.8
37–42	219	63.9
>42	677	78.9

Data from Nusko G, Mansmann U, Kirchner T, Hahn EG. Risk related surveillance following colorectal polypectomy. *Gut*. 2002;51(3):424–428.[137]

Most polyps are neoplastic but not necessarily malignancies. Neoplastic polyps consist of cells with the potential to acquire over time the ability to invade and to spread, that is, metastasize. *Dysplasia* is a term used to describe the intervening state between normal tissue and invasive malignancy.

POLYP SIZE

The most immediate way in which a polyp can be described is by its size. Intuitively, polyps with a larger mass have a greater volume of neoplastic cells, and hence a higher likelihood of harboring cancer. The relationship between adenomatous polyp size and the presence of invasive malignancy was analyzed elegantly by Nusko et al (Table 36-8).[137]

POLYP ATTACHMENT TO BOWEL WALL

Polyps of any size or architecture may be pedunculated, sessile, or some combination of both. The main clinical relevance of this distinction lies in the ease of endoscopic removal, with pedunculated polyps being clearly more amenable to removal without surgical intervention.[138,139]

It is important to note that the way in which a polyp is attached to the wall of the colorectum does not accurately predict the presence versus absence of an invasive malignancy. Malignant polyps of the colon can be either pedunculated or sessile. The type of treatment that should be offered to a patient depends much more on the other characteristics of the polyp.

POLYP ARCHITECTURE

Based on their histological structure, polyps can be categorized into adenomatous and nonadenomatous polyps, the latter of which consists of hyperplastic, hamartomatous, and inflammatory polyps.

Adenomatous Polyps (Adenomas). The most common type of polyp in the colon is the adenomatous polyp. Adenomatous polyps are categorized as tubular, tubulovillous, or villous based on the extent to which the dysplastic epithelium is organized with the normal-appearing tubular architecture.[140] Tubular adenomas are defined by the presence of tubules within 80% or more of the lesion; adenomas with less than 20% showing a tubular configuration are villous lesions; and the remainder is considered tubulovillous. The majority of polyps are tubular (87%), with a minority either tubulovillous (8%) or villous (5%).[141]

With few exceptions, the treatment for an adenomatous polyp is endoscopic polypectomy. Colorectal cancer screening programs that include colonoscopy with polypectomy have demonstrated a reduction in the incidence of colorectal cancer and colorectal cancer mortality.[142] It is difficult, however, to estimate the likelihood that a small adenoma will progress to a dysplastic adenoma and eventually into cancer. A number of biologic and molecular markers have been analyzed as predictors of a malignant potential, but these are not widely utilized.[143] Longitudinal and comparative data suggest that polyps not only progress but also may regress.[144] Despite these vagaries, any adenomatous polyp should be considered a premalignant lesion and be treated as such.

Invasive carcinoma is present in 5% of all adenomas, but the incidence correlates with the size and type of the adenoma (Table 36-9).[137,145]

The Haggitt classification, which defines four levels within the polyp, has evolved as a useful tool to describe the degree of cancer invasion into a pedunculated or sessile adenomatous

TABLE 36-9: ADENOMATOUS POLYPS AND VILLOUS ADENOMA: SIZE, HISTOLOGICAL TYPE, AND PERCENT OF CARCINOMA

	Size		
Histological Type	<1 cm	1–2 cm	>2 cm
Tubular adenoma	1% (1382)	10.2% (392)	34.7% (101)
Intermediate type	3.9% (76)	7.4% (149)	45.8% (155)
Villous adenoma	9.5% (21)	10.3% (39)	52.9% (174)

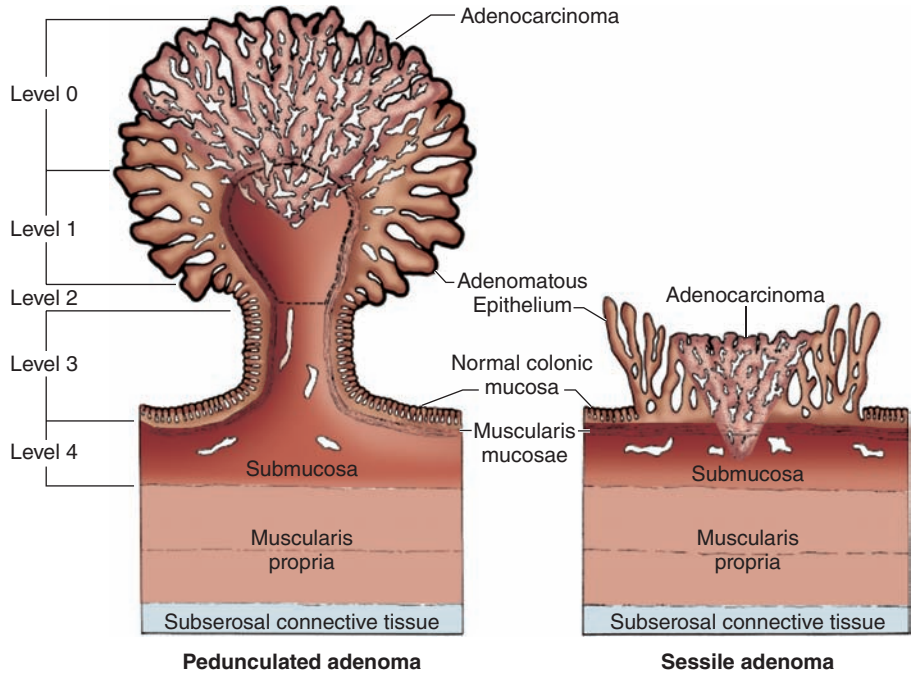

FIGURE 36-3 Haggitt's classification of tumor invasion in pedunculated or sessile polyp. Pedunculated polyps: level 0—not invasive carcinoma; level 1—invasion to the head of the pedunculated polyp; level 2—invasion to the neck of the pedunculated polyp; level 3—invasion to the stalk of the pedunculated polyp; level 4—invasion to the base of the pedunculated polyp. Sessile polyps: All lesions are level 4. (Reproduced, with permission, from Haggitt RC, Glotzbach RE, Soffer EE, Wruble LD. Prognostic factors in colorectal carcinomas arising in adenomas: Implications for lesions removed by endoscopic polypectomy. *Gastroenterology*. 1985;89:328–336.)

polyp.[147] This classification forms the basis of the management of malignant polyps (Fig. 36-3). In Haggitt's levels 1, 2, and 3, the risk of lymph node metastasis in a surgical specimen is less than 1%, whereas a level 4 invasion of the stalk behaves like a sessile T1 lesion and carries a higher risk of 12–25% of having lymph node metastases. A similar, but less well-known, classification was developed in 1993 by Kudo and associates, who for prognostic purposes suggested to divide the submucosal invasion of sessile malignant lesions into three levels (Sm1, Sm2, Sm3) (Fig. 36-4).[148]

Flat and/or depressed adenomas are a subtype of colonic adenoma with a propensity for high-grade dysplasia in 10–41% of affected patients regardless of the small size of these lesions.[149] The entity was first described in Japan, where they seem to occur at a regular frequency. These lesions, which are flat or slightly raised to less than 2 mm and commonly less than 1 cm in size, may be overlooked easily on colonoscopy and turn into a cancer before having reached a size comparable with classic cancers.[149–152] Recent screening studies, which took advantage of chromoendoscopy techniques, have confirmed that flat adenomas represent up to 25–36% of all polyps found in a random cohort and are present in 8–11% of the population.[152,153]

Hamartomatous Polyps. A hamartomatous polyp is composed of a spectrum of different cellular elements and is considered a nonneoplastic entity with no significant premalignant potential.[154,155] Several clinical syndromes manifest with a polyposis of hamartomatous polyps (Juvenile polyposis, Cowden syndrome, Bannayan-Riley-Ruvalcaba syndrome, Cronkite-Canada syndrome) and these have been discussed earlier in this chapter. These syndromes carry varying risks of

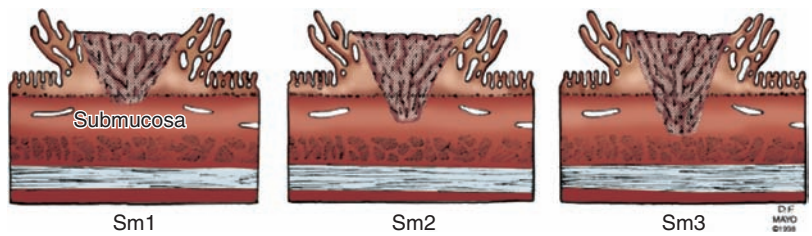

FIGURE 36-4 Depth of submucosal invasion in sessile malignant polyps. Sm1—invasion into upper third of submucosa; Sm2—invasion into middle third of submucosa; Sm3—invasion into lower third of submucosa. (Reproduced, with permission, from Nivatvongs S. Surgical management of early colorectal cancer. *World J Surg*. 2000;24:1052–1055.)

intestinal and extraintestinal disease, and several also impose an increased likelihood of developing intestinal cancer due to immature glandular elements in the hamartomatous polyp. Stable estimates of this risk are difficult to calculate because of the relative rarity of these diseases.

Hyperplastic Polyps. Hyperplastic polyps are small, sessile mucosal outgrowths that display an exaggerated crypt architecture. They are usually small, with only very few (1–4%) larger than 1 cm; however, these larger polyps actually may be serrated adenomas rather than hyperplastic polyps (see the following text).[156] Within the colorectum, hyperplastic polyps commonly have a distal distribution pattern, predominantly in the rectum and sigmoid colon, and they have been reported in up to 75% of patients older than 60 years at autopsy.[157] It is not unusual to find several of these polyps in a single individual.

Histologically, hyperplastic polyps display well-formed glands and crypts that are lined by nonneoplastic epithelial cells. Because of their small size, hyperplastic polyps are generally clinically silent, but large or multiple hyperplastic polyps occasionally can be responsible for gastrointestinal symptoms.

Historically, hyperplastic polyps have been considered benign and not premalignant.[156] This paradigm has been increasingly questioned, beginning in 1990 with work by Longacre and Fenoglio-Preiser.[158] The ability of hyperplastic polyps to develop defective mismatch repair genes and foci of microsatellite unstable cancers has been documented, strengthening this concept.[159] Additional research has illuminated an epigenetic pathway, whereby a promoter region in the DNA of hyperplastic polyps is methylated, resulting in progression along a sequence of steps that leads to a serrated adenoma and eventually carcinoma.[160] The clinical significance of hyperplastic polyps and serrated adenomas is a topic of emerging importance in the field of colorectal cancer prevention.

As with adenomatous polyps, individuals who have a predisposition to developing hyperplastic polyps may be at increased risk for developing colorectal cancer. The endoscopic and radiologic appearance of the mucosal abnormalities in hyperplastic polyposis closely resembles FAP, but the syndrome is not believed to be heritable and does not have any extraintestinal manifestations. The World Health Organization (WHO) has defined criteria for this entity as follows: (1) at least five histologically diagnosed hyperplastic polyps of which two are greater than 20 mm or (2) any number of hyperplastic polyps occurring proximal to the sigmoid colon in someone who has a first-degree relative with hyperplastic polyposis, or (3) more than 30 hyperplastic polyps of any size that are distributed throughout the colon and rectum.[161] The risk of colorectal cancer being present or developing subsequently in a patient meeting these criteria are high in case series, but population-based studies have not yet been performed.[162] While prophylactic colectomy has been proposed for patients with hyperplastic polyposis, there are no consensus opinions at this time regarding the appropriateness of this approach.[163] At a minimum, a program of intensive colonic surveillance is indicated.

Inflammatory Polyps. Inflammatory polyps are the result of reactive regenerative processes occurring in or next to a damaged epithelium. Because of the extent and chronicity of IBD, inflammatory polyps are most commonly seen in that context. The prominence of inflammatory pseudopolyps often is the result to the presence of adjacent ulcerations. Histologically, a combination of distorted crypt architecture in conjunction with granulation tissue and inflammatory infiltrates is characteristic. Even though the underlying chronic IBD represents a high risk for colorectal cancer, the inflammatory polyps as such do not carry a malignant potential. Biopsies in IBD should therefore also include the more flat-appearing areas rather than the polyps only.

POLYP TRANSFORMATION

By definition, the neoplastic nature of an adenomatous polyp represents dysplasia. In an effort to quantify the clinical severity/importance of dysplasia, however, the degree of dysplasia is categorized and reported in three grades. This categorization is based on the histopathologic differentiation and architecture of the epithelial cells within the polyp.

Common terms for polyps include *low-grade dysplasia*, *intermediate-grade dysplasia*, and *high-grade dysplasia* (by some also referred to as *in situ* [*Tis*] *adenocarcinoma*). Once there are clear microscopic features of tumor invasion through the muscularis mucosa of the colorectum, an invasive cancer (T1 or greater) is present. This important demarcation is based on the finding that lymphatic vessels are almost never found superficial to the muscularis mucosa. The descriptive terms for invasive cancer include *well-differentiated* (grade I), *moderately differentiated* (grade II), or *poorly differentiated* (grade III) adenocarcinoma.

MANAGEMENT OF COLORECTAL POLYPS

The overarching goal of physicians treating patients with colorectal polyps is to minimize the risks associated with invasive malignancy, while simultaneously avoiding complications of diagnosis and treatment. Colorectal cancer prevention programs are widely believed to reduce the risk of colorectal cancer mortality through endoscopic removal of premalignant lesions and the detection of invasive lesions at a point in their progression where they are asymptomatic. The efficacy of colorectal cancer prevention programs has been proven in multiple randomized and nonrandomized studies.[142,164–168]

The majority of colonic polyps can be removed via colonoscopy, but this may not be the case for one of two reasons. First, a polyp may not be resectable due to size, attachment to bowel wall, or other reasons related to the anatomy of the patient or polyp. In these situations, a careful assessment of the risks of surgical resection versus observational management is warranted, as 12–18% of these polyps harbor an

invasive malignancy.[169–171] Second, polypectomy may not be reasonable in the presence of innumerable polyps.

When invasive cancer is found in a polyp, the management is based mainly on the level of invasion and the completeness of the polypectomy. Based on Haggitt's observations (see Fig. 36-3), it has been suggested that colonic cancers invasive to Haggitt's levels 1, 2, and 3 can be adequately treated with polypectomy (2-mm margin), whereas polyps with invasion into Haggitt's level 4 should be treated like a sessile lesion.[147,172]

Management of sessile lesions is more controversial. If a sessile lesion cannot be snared in one intact piece with a microscopically clear margin of at least 2 mm, or if it demonstrates lymphovascular invasion or deep invasion into level Sm3 (lower third of submucosa) (see Fig. 36-4), the patient should undergo a formal oncologic resection of the colon. The approach for an adequately removed lesion with a lesser extent of invasion into the submucosa—Sm1 (invasion only into upper third of submucosa), Sm2 (invasion only into upper two-thirds of submucosa)—should be individualized based on the risk of a surgery versus the risk of lymph node metastases.[172,173] It is advisable in any case to tattoo the area of a suspect polyp endoscopically with India Ink for later identification of the site.

Malignant Tumors of the Colon

The vast majority of malignant colon neoplasms are cancers (carcinoma), that is, malignant neoplasms of epithelial origin. Based on the endodermal glandular tissue origin, adenocarcinoma and its histologic variants are by far the predominant histopathology and account for 90–95% of all colorectal malignancies. The majority of this section is therefore devoted to these types of tumors, but it also briefly discusses nonepithelial tumors of the colon.

ADENOCARCINOMA

Colorectal cancer (adenocarcinoma) is the most frequent malignancy of the gastrointestinal tract, the fourth most frequently diagnosed malignancy, and the fourth most common cause of cancer-related mortality in the world.[174] Squamous and adenosquamous carcinomas are exceptionally rare and are located characteristically in the rectoanal junction. The histopathologic classification of colorectal cancer as defined by the WHO is illustrated in Table 36-10.

Macroscopically, most colorectal cancers have either a polypoid or an ulcerative-infiltrating appearance, but combinations are frequent. Very rarely, colorectal cancer may have a dissolute growth pattern and resemble linitis plastica of the stomach, in which case a metastatic lesion from another primary site (eg, lobular breast cancer, stomach cancer) or a nonepithelial neoplasia (eg, lymphoma, carcinoid) would need to be ruled out.

Adenocarcinoma, the exceedingly predominant histopathology of colon cancer, has a less frequent variant of mucinous adenocarcinoma that includes signet ring cell carcinoma and accounts for approximately 10% of all colorectal cancers. Compared to nonmucinous colon cancers, mucinous carcinomas usually present at a more advanced stage and thus have an overall poorer prognosis.[8,175,176]

A rare variant of colorectal cancer is small cell cancer, which accounts for less than 1% of all cases and, similar to small cell cancer of the lung, and appears to be related to some degree to a neuroendocrine origin. These tumors have a high tendency to develop widespread metastasis early in the course and have an extremely poor prognosis.

The distribution of colorectal cancers among the various segments has seen a continued shift toward right-sided colon cancer.[177,178] An estimated 45–55% of colorectal cancers are located in the rectum (10–15%) or sigmoid colon (40%), 25–35% in the cecum or ascending colon, whereas

TABLE 36-10: WHO HISTOPATHOLOGIC CLASSIFICATION OF COLORECTAL CANCERS AND THEIR SIGNIFICANCE

Histopathologic Types	Pathology	Prognosis
Adenocarcinoma	90–95% of the colorectal malignancies	
Mucinous adenocarcinoma	10% of all colorectal cancers; the extracellular type is more common than the intracellular type	Controversial whether mucinous histology itself is an independent negative prognostic factor
Signet ring cell carcinoma		
Small cell carcinoma (oat cell)	<1%; histologically identical to small cell carcinoma of the lung	Extremely poor prognosis and almost all cases have lymph node, liver, and brain metastasis
Small cell adenosquamous carcinoma		
Squamous cell carcinoma		
Undifferentiated carcinoma (medullary)		

the remaining are equally distributed through the rest of the colon. The local growth pattern for colorectal cancer involves circumferential and transmural invasion of the tumor through the intestinal wall into the peritoneal cavity or surrounding organ structures. Tumor dissemination primarily occurs through access to the lymphatic vessels into the locoregional lymph nodes or through access to the blood stream as hematogenous metastasis to distant organs. The most common site of blood-borne spread is via the portal venous system to the liver; other secondary locations include the lung or, less frequently kidneys, bone, etc. In addition, tumor dissemination can occur by transperitoneal seeding and result in peritoneal carcinomatosis.[179] Following gravity, peritoneal seeds may accumulate in the pelvic cul-de-sac or paracolic gutters where they can grow to a considerable size (Blumer's shelf). Growth by perineural infiltration may be seen on microscopic examination and has a negative prognostic impact. About 20% of the patients have evidence of distant metastases (stage IV disease) at the time of presentation.

STAGING OF COLON CANCER

Modern staging of colorectal cancer defines four clinical stages (I–IV) based on the TNM (tumor-node-metastasis) system, which has just recently been updated by the American Joint Committee on Cancer (AJCC) (Tables 36-11 and 36-12).[8,180,181] Independent parameters are (1) the depth of tumor invasion (T) into or through the layers of the intestinal wall with or without invasion of adjacent organs, (2) the number of regional lymph nodes involved (N), and (3) the presence or absence of distant metastases (M). Additional modifiers are used to reflect the method of stage determination (p for pathology, c for clinical, u for ultrasound), and y to indicate a status after neoadjuvant treatment.

Historical classifications such as Dukes and Astler-Coller are still sporadically in use but largely have been and should be abandoned.

Because the extent of tumor resection (complete vs incomplete) strongly correlates with prognosis, the AJCC released additional guidelines to reflect the extent of residual tumor after a surgical resection with the letter *R* (see Table 36-11).[181]

TABLE 36-11: TNM STAGING OF COLON CANCER (AJCC CANCER STAGING MANUAL, 7TH ED, 2010[181])

Stage	Definition
Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ: intraepithelial or invasion of lamina propria
T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through muscularis propria into the subserosa or into nonperitonealized pericolic or perirectal tissues
T4a	Tumor perforates visceral peritoneum
T4b	Tumor directly invades other organs or structures
Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis in 1–3 regional lymph nodes
N1a	1 positive lymph node
N1b	2–3 positive lymph nodes
N1c	extranodal tumor deposits
N2	Metastasis in 4 or more regional lymph nodes
N2a	4–6 positive lymph nodes
N2b	≥7 positive lymph nodes
Distant metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Metastases confined to 1 organ/site
M1b	Metastases in >1 organ/site
Extent of resection	
RX	Presence of residual tumor cannot be assessed
R0	No residual tumor
R1	Microscopic residual tumor
R2	Macroscopic residual tumor

TNM, tumor-node-metastasis.

Nonepithelial Tumors of the Colon

BENIGN NONEPITHELIAL TUMORS

Lipomas and Lipomatous Polyposis. Lipomas are submucosal lesions that develop in the fifth or sixth decade of life and are more common in the large than in the small intestine. Histologically, the polyps consist of a submucosal lump of adipose tissue that is covered with a normal colonic mucosa. Whereas solitary lipomas tend to occur more frequently on the right side of the colon in the vicinity of the ileocecal valve or the ascending colon, *lipomatous polyposis* may diffusely involve the entire small and large intestine.

Lipomas generally are asymptomatic but may be found incidentally on colonoscopy. The characteristic appearance is a smooth mass with normal overlying mucosa. The soft nature of the lipoma can be demonstrated by poking the tumor with an endoscopic instrument ("pillow test"). Asymptomatic, incidentally detected lesions should be left alone.

TABLE 36-12: STAGING SYSTEM BY AJCC (*AJCC CANCER STAGING MANUAL*, 7TH ED, 2010[181])

Stage	T	N	M
0	Tis	N0	M0
I	T1	N0	M0
	T2	N0	M0
II-A	T3	N0	M0
II-B	T4a	N0	M0
II-C	T4b	N0	M0
III-A	T1–T2	N1/N1c	M0
	T1	N2a	M0
III-B	T3–T4a	N1/N1c	M0
	T2–T3	N2a	M0
	T1–T2	N2b	M0
III-C	T4a	N2a	M0
	T3–T4a	N2b	M0
	T4b	N1-N2	M0
IV-A	Any T	Any N	M1a
IV-B	Any T	Any N	M1b

AJCC, American Joint Committee on Cancer.

Occasionally, when lipomas become large enough to protrude into the lumen, they may cause symptoms such as gastrointestinal bleeding, diarrhea, intussusception, or bowel obstruction.[182] Endoscopic removal of such a lipoma with a snare often is possible but has a risk of hemorrhage because the fat may prevent the cautery from adequately transmitting the energy to the blood vessels in the stalk. Surgery may be required if such a complication occurs; it should therefore be considered preemptively for very large symptomatic lipomas. Alternatively, the mucosa overlying the lipoma may be opened endoscopically to allow the lipoma to spontaneously enucleate into the lumen.

POTENTIALLY MALIGNANT NONEPITHELIAL TUMORS OF THE COLON

Carcinoid or Neuroendocrine Tumors. Modern nomenclature classifies carcinoids as neuroendocrine tumors, based on their neuroendocrine origin. They are characterized by subepithelial nests of epithelial-appearing cell elements. Carcinoid tumors may occur anywhere in the entire body. A recent study on 11,427 patients from the SEER database found that the gastrointestinal tract is affected in 55%, with the most frequent locations being the small intestine (44.7%), the rectum (19.6%), the appendix (16.7%), and the colon (10.6%),[183] a finding that contrasts with traditional reports that the appendix is the most frequent site in the gastrointestinal tract. The annual incidences for the colon and rectum were reported to be 2.0 and 4.2 cases per 100,000 people per year, the risk of metastasis proportional to the size of the carcinoid.[183] Unlike most neoplasms, invasiveness of carcinoid tumors is not entirely based on histological criteria (eg, invasion of muscularis propria) but includes clinical aspects. In absence of other definite indicators for malignant behavior, carcinoids smaller than 1 cm are considered benign, lesions larger than 2 cm are likely malignant, and the gray zone in between remains undetermined or potentially malignant.[184] Malignant carcinoids may spread locoregionally into the lymph nodes or directly to the liver.

Patients with a gastrointestinal carcinoid tumor may be either completely asymptomatic or present with intestinal obstruction, bleeding, carcinoid syndrome, or carcinoid heart disease, that is, acquired and commonly right-sided valvular heart disease.[185,186] Vasoactive substances (eg, serotonin and 5-hydroxyindolacetic acid [5-HIAA]) are released from carcinoid tumors but for the most part are eliminated in a hepatic first-pass effect before reaching the systemic circulation. Carcinoid syndrome is therefore a bad prognostic sign because it does not typically develop until metastatic lesions in the liver directly release their products into the systemic circulation. Hindgut carcinoid tumors (those located in the distal transverse colon and beyond) classically do not cause carcinoid syndrome because they are less endocrinologically active.

Diagnosis of a carcinoid may be suspected clinically but can be difficult to confirm histologically short of a surgical resection because the lesions are submucosal and not commonly in reach of an endoscopic biopsy. A preoperative workup for a carcinoid tumor should include a 24-hour urine collection of 5-HIAA and a plasma chromogranin A. Both parameters can also be used for postoperative surveillance. Cross-sectional imaging and somatostatin receptor scintigraphy are tools to evaluate for systemic disease. Multicentricity and associated high rates of synchronous gastrointestinal and genitourinary malignancies warrant both an upper and lower gastrointestinal endoscopy.[187]

An oncologic resection should be performed in all carcinoids larger than 2 cm unless contraindicated by clinical circumstances. Tumors of smaller than 1 cm size may be managed locally, whereas the management of lesions measuring 1–2 cm remains controversial.[184]

Gastrointestinal Stromal Tumors (GISTs). GISTs are the most common mesenchymal tumors of the gastrointestinal tracts and originate from the intestinal pacemaker cells, the interstitial cells of Cajal.[188] Sixty percent of GISTs are found in the stomach; 29% in the small intestine; 2% in the colon, rectum, and rectovaginal septum; and 9% in the esophagus.[189] Symptoms are nonspecific and include pain, obstruction, bleeding, and a mass. Distinction from other mesenchymal tumors (eg, leiomyosarcoma) is important from a prognostic point of view. Tumor size and light microscopic determination of the mitotic rate (mitotic figures per *x* number of high-power fields) are the most important conventional prognostic indicators.[188] The diagnosis of GISTs is based on morphologic features and

immunohistochemical demonstration of *c-kit* (CD117) expression. This marker is seen in almost all GISTs and is regarded as one of the key diagnostic elements, but a few otherwise characteristic tumors are found to be *c-kit* negative.[190] While the majority of GISTs have activating mutations of the KIT receptor tyrosine kinase, another subset of tumors show mutations in the KIT-related kinase gene platelet-derived growth factor receptor alpha (PDGFRA).[191] KIT and PDGFRA mutations appear to be alternative and mutually exclusive oncogenic mechanisms in GISTs.[192] Determination of CD117 expression is of practical importance because positivity correlates with a tumor response to treatment with imatinib (Gleevec), which inhibits KIT kinase activity. Surgical resection is the primary treatment for localized GISTs that are resectable without mutilation. Recurrent and locally advanced or metastatic tumors are treated increasingly with imatinib in a palliative, adjuvant, or neoadjuvant setting.

Nodular Lymphoid Hyperplasia. This condition is characterized by numerous polyps in the small and large intestine, rarely in the stomach, which consist of enlarged submucosal lymphoid follicles. Associated diseases are immune deficiencies of various origins (eg, tumors, hematoproliferative disorders, immunoglobulin A deficiency, and human immunodeficiency virus [HIV] infection), in which case recurrent infections (eg, giardiasis) appear to promote the nodular lymphoid hyperplasia. Immunocompetent patients usually are asymptomatic, and the nodular lymphoid hyperplasia is an incidental finding. Nodular lymphoid hyperplasia has been associated with an increased subsequent incidence of lymphoma (small bowel).[193]

MALIGNANT NONEPITHELIAL TUMORS OF THE COLON

Lymphoma. Primary malignant lymphoma of the colon is uncommon and accounts for only 0.2–0.4% of all colonic malignancies and 10–15% of all primary lymphomas of the gastrointestinal tract, which themselves account for about 30% of extranodal lymphomas.[194] The most frequent colonic location is the cecum (70%), followed by the rectum and ascending colon. The gross appearance may be a circumferential or polypoid mass, an ulceration, or a diffuse infiltration with stricturing and bowel wall thickening.[195] Eighty-six percent of the lesions are solitary, but they can be multiple and diffuse in nature. The intestinal lymphomas may be subclassified into B-cell lymphomas (85%) and T-cell lymphomas (15%). Among the B-cell lymphomas, mantle cell lymphoma has a worse prognosis, whereas mucosa-associated lymphoid tissue (MALT) lymphomas have a better prognosis than other B-cell tumor types.[195] While surgical treatment may be indicated for some localized tumors, many authors consider medical management to be the primary treatment. It may include new approaches such as anti-infectious treatment for MALT lymphoma or reconstitution of the patient's immune status, for example by means of antiretroviral treatment in HIV-associated B-cell lymphoma.[196]

Multiple lymphomatous polyposis of the gastrointestinal tract is a distinct clinicopathologic entity. This rare form of primary gastrointestinal lymphoma occurs most often in elderly patients and accounts for 9% of all gastrointestinal lymphomas.[197] The polyps can be widespread throughout multiple segments of the gastrointestinal tract. Histopathologic and immunohistochemical techniques are required to differentiate lymphomatous polyposis from other forms of gastrointestinal polyposis.

Kaposi Sarcoma. This commonly multifocal angiosarcoma has been associated with herpesvirus-8 (HHV-8) infection in conjunction with immunosuppression (eg, HIV/AIDS, chronic steroid or immunosuppressant medication, etc). The incidence in organ transplant recipients is about 0.5–0.6% but most frequently involves the skin. Extremely rarely, however, the anorectum or intestines are involved and shows characteristic bluish-purple submucosal nodules. Treatment primarily aims at improving the immune status, but chemotherapy and, rarely, radiotherapy may be indicated in patients in whom the immune status cannot be restored.[198]

Smooth Muscle Tumors. Smooth muscle tumors of the colon are rare and occur most commonly in the form of a pedunculated leiomyoma of the muscularis mucosa. Leiomyosarcomas, which consist histologically of spindle cells that resemble smooth muscle cells, are even less frequent but are characterized by an extremely aggressive and rapidly fatal growth pattern. Whenever possible, oncologic resection and adjuvant chemotherapy are the treatment of choice.[199]

SECONDARY TUMORS TO THE COLON

Endometriosis. Endometriosis may involve the colon or rectum in approximately 15–20% and may mimic colonic carcinoma. The lesions are rarely larger than 5 cm, involve the subserosa and muscle coats, and may project into the lumen of the bowel. When endometrial tissue extends through to the colonic mucosa, biopsy may be mistaken for adenocarcinoma.

Invasion From Extracolonic Cancers. Locally advanced tumors from noncolonic primary cancers may directly invade the colon and cause symptoms suggestive of colon cancer (bleeding, obstruction, fistula). These tumors originate from organs in close adjacency to the colon (female organs, bladder, prostate, kidneys, pancreas, duodenum, liver).

Metastatic Cancer. Carcinomas from other primary sites may metastasize to the colon and occasionally mimic a primary colon cancer. Metastases originate most commonly

from lobular breast cancer, stomach cancer, ovarian cancer, malignant melanoma, and leukemia, the latter of which can be diagnosed by the hematopoetic infiltrates.

SURGICAL ANATOMY OF THE COLON

A fundamental knowledge of the anatomy is unquestionably a key to success-oriented surgical technique aiming at the best oncological outcome and a minimized morbidity. The large intestine starts at the ileocecal junction and extends to the anus. It is about 5–6 ft (125–150 cm) long and can be divided into the cecum with the appendix, the ascending colon, the transverse colon, the descending colon, the sigmoid colon, and the rectum. Definitions of where the sigmoid colon ends and the rectum begins have not always been uniform. The best definition of the rectosigmoid junction from a functional as well as surgical viewpoint is the confluence of the teniae coli.[200] However, the inability to visualize this anatomic reference point endoscopically recently led the NCI and other expert committees to define the rectum for the purpose of uniformity in clinical trials as the last 12–15 cm above the anal verge as measured by rigid sigmoidoscopy.[201] This endoscopic definition is necessary in order to determine the appropriateness of preoperative (neoadjuvant) chemoradiation for rectal but not sigmoid cancer.[201] Obsolete because highly variable and therefore inaccurate definitions relate the rectosigmoid junction to the level of (1) the peritoneal reflection or (2) the sacral promontory.

The arterial and venous blood supply, as well as the lymphatics of the colon, is summarized in Fig. 36-5. The arterial blood supply to the colon comes from the superior mesenteric artery (SMA) and the inferior mesenteric artery (IMA), which communicate in a watershed area in the splenic flexure (artery of Drummond). The rectum has additional branches from the internal iliac vessels. With a significant degree of anatomic variation, the major vascular stalks to the colonic segments consist of the ileocecal and right colic artery (last branch of the SMA), the middle colic artery (second branch of the SMA), the left colic artery (first branch of the IMA), and the superior hemorrhoidal artery (distal branch of the IMA). The venous blood supply peripherally follows the arterial branches but more centrally divides into the superior mesenteric vein and the inferior mesenteric vein, which connect at separate levels to the portal system. The lymphatic drainage starts with lymphatic follicles in the colonic submucosa, drains through the colonic muscle wall into the epicolic nodes, and continues to the paracolic lymph nodes that follow the blood vessels to the bowel, along the major arteries to the principal lymph nodes at the level of the arterial runoff from the aorta. These lymph node groups consist of the celiac, the superior mesenteric, and the inferior mesenteric groups of lymph nodes.

For a safe surgical technique, the relationship of the colon with adjacent structures, mostly in the retroperitoneum, has to be fully understood. The colon is only a partially intraperitoneal organ. Only the transverse colon and the sigmoid colon are fully peritonealized and have a free mesocolon; the ascending colon and the descending colon, including both flexures, are partially located in the retroperitoneum and therefore reside in proximity to essential anatomic structures. The structures most at risk during a right hemicolectomy include the right ureter and the duodenum; during a transverse colon resection, the SMA/SMV (and its branches) and the gastroepiploic vessels at the gastric curvature; during a takedown of the splenic flexure, the spleen, pancreas, and left kidney; and during a left colon or sigmoid resection, the left ureter, the gonadal vessels, and the hypogastric nerves.

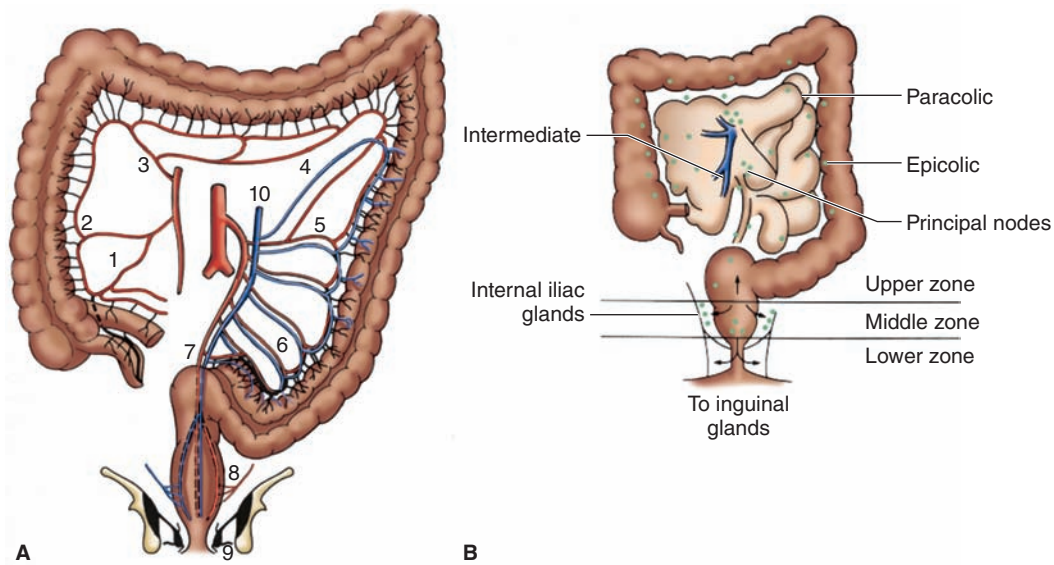

FIGURE 36-5 Anatomy of the colon. **A.** Arterial and venous supply of the colon. **B.** Lymphatic drainage of the colon.

CLINICAL PRESENTATION OF COLORECTAL CANCER

Symptoms and Differential Diagnosis

Colorectal cancer does not have any early signs. In fact, symptoms are often absent until a tumor has grown to a significant size. Unless a patient presents with a tumor complication (eg, bowel obstruction, bleeding, perforation, or fistula formation), symptoms mostly are subtle or uncharacteristic and vague. They may consist of unexplained weight loss, anemia and weakness from chronic blood loss, flatulence, or episodes of colicky abdominal pain. If present, these symptoms therefore always should be suspicious for a locally relatively advanced tumor stage, which is also reflected by the fact that about 20% of colorectal cancer patients at the time of their first presentation already have stage IV disease with distant metastases (Table 36-13). As the stool in the proximal colon is still liquid or at most semisolid, proximal colon tumors may grow to relatively large size before they cause an obstruction. The more distal a lesion is localized (eg, left colon or rectum), the more likely the changes in bowel habits occur. These include rectal bleeding or mucous discharge in or with the stool, sudden onset of constipation, alternating periods of diarrhea and constipation, or a decreasing diameter of the stool. Pelvic or anal pain is an ominous sign because it may occur with increasing size, perforation, or sphincter invasion of a rectal cancer.

Any large bowel obstruction, bleeding per rectum, gas or stool passage other than through the anus, or peritoneal signs should raise the index of suspicion for a colorectal malignancy until proven otherwise. Several other conditions and diseases have to be considered in the differential diagnosis. Obstructive symptoms may result from chronic diverticulitis, benign polyps, Crohn's disease, endometriosis, or a postischemic stricture. A fistula may suggest complicated diverticulitis, Crohn's disease, or tuberculosis. Bleeding per rectum may also be found in hemorrhoids and other benign anorectal conditions, diverticular disease, arteriovenous malformations, endometriosis, and proctitis or colitis. However, even if one of these benign diseases is found on clinical evaluation, the symptoms should not be attributed automatically to them before a malignant disease of the large intestine has been ruled out.

Because symptoms are not reliable for the prevention or early detection of colorectal cancer, risk-adjusted screening programs for otherwise asymptomatic individuals (as discussed in an earlier section of the chapter) are crucial in order to achieve a reduction in cancer mortality.

Not only management planning in a situation with acute cancer complications should include strategies to alleviate symptoms and minimize the morbidity from the complication but also should provide an oncologically adequate treatment for the tumor.

TABLE 36-13: DISTRIBUTION OF SINGLE COLON PRIMARY CANCER BY STAGE

Stage	Number	(%)
0,I	1845	(37.8)
II	1085	(22.2)
III	825	(16.9)
IV	955	(19.6)
Unspecified	168	(3.4)

History and Physical Examination

A careful history and physical examination remain the cornerstone in all patients presenting with gastrointestinal symptoms. This review should include questions about changes in bowel habits, time of last stool and gas passage, weight loss, and a personal or family history of cancer, particularly of colorectal cancer or its precursor lesions. Awareness of possible underlying diseases and genetics that predispose to colorectal cancer is of utmost importance not only for the management of the individual patient but also for adequate counseling of potentially affected family members.

A careful physical examination follows to identify any palpable tumor masses and/or signs of tumor complication or dissemination. Apart from vital signs and temperature, the patient's general appearance may reveal evidence of cachexia, dehydration, jaundice, or lymph node enlargements. For example, enlargement of the left supraclavicular nodes may be the first but late sign of a disseminated gastrointestinal malignancy (Troisier's sign). The abdomen is examined for a palpable primary tumor, hepatomegaly (liver metastasis?), distension and/or tympanitic bowel sounds (partial or complete bowel obstruction?). Presence of peritoneal signs such as guarding with local direct and rebound tenderness or percussion tenderness may indicate a tumor perforation. A digital rectal examination and proctoscopy are mandatory to rule out involvement of the rectum or to determine the exact distance of a distal and possibly palpable tumor from the anal verge, its axial and circumferential extent, and the mobility of the tumor against surrounding structures (eg, sacrum, prostate/ vagina, anal sphincter muscle). In addition, the checking finger should assess the rectal vault for the presence of stool, blood, or melena.

A thorough general physical examination is necessary to evaluate the patient's general health status regarding the ability to tolerate a major abdominal procedure under general anesthesia. Particular attention has to be paid to patients who present with acute symptoms in an emergency setting. Prolonged fasting, nausea or vomiting, and translocation of fluids into the third space during a period of bowel obstruction or after a perforation will rapidly result in a state of malnutrition and

dehydration. Developing sepsis or acute and recurrent blood loss potentially aggravate these symptoms and may result in a severe volume loss. Alarming signs are a decrease in urine output, tachycardia, hypotension, elevated temperature, short-term weight loss, standing skin folds, dry oral mucosa, and acidosis. Immediate fluid and volume resuscitation has to parallel the further clinical workup and monitoring. Blood tests have to be interpreted with caution; for example dehydration may result in an artificially high hematocrit and mask a significant loss of blood.

Investigations

Patients with symptoms suggestive of colorectal cancer should undergo a series of timely investigations with three goals: (1) to assess the large bowel regarding the primary lesion, concomitant lesions, and a potential underlying colonic disease, (2) to determine whether the tumor has metastasized, and (3) to assess the patient's operability (overall condition and comorbidities).

COMPLETE EVALUATION OF THE LARGE INTESTINE

Irrespective of the method used, the primary goal is to document the presence of a malignant pathology and to rule out concomitant lesions in other segments of the large intestine. Both endoscopic and radiological techniques are available for evaluation of the colon and rectum, and each type of examination has inherent strengths and weaknesses.

Rigid Proctoscopy and Flexible Sigmoidoscopy. These first-line diagnostic tools are used mostly in the outpatient setting to accurately assess lesions in the distal colon and rectum. The two methods are rapid, widely available, and require only minimal bowel preparation (enema). However, they do not provide complete information about the rest of the colon, and therefore a complementary study is indicated before surgery. Furthermore, the flexible sigmoidoscope is notorious for giving inaccurate measurements of the level of the tumor. Determination of the rectal versus colonic location of the tumor should be done with a rigid proctoscope.

Colonoscopy. Colonoscopy clearly has evolved as the method of choice because of its high sensitivity in detecting tumors and its ability to take biopsies. It provides accurate information about the entire colonic mucosa (ie, polyps, synchronous cancer, colitis, melanosis, and diverticula), and it may be used to remove synchronous neoplastic polyps. Apart from determining the circumferential and longitudinal extent of a colonic lesion, colonoscopy addresses functional aspects such as active bleeding or an imminent obstruction by cauterization, laser ablation, or placement of a self-expanding metallic wall stent, hence allowing for turning an emergency situation into an elective one.

While the overall risk of colonoscopy is very low with a much less than 1% incidence of a bowel perforation, there are some limitations to the technique. There is a 25% risk of smaller lesions to escape detection, and an estimated 10% incidence that the cecum for technical reasons may not be reached. In addition, the precise position of a lesion seen on colonoscopy may not be determined adequately unless one of the two absolute landmarks (dentate line, or the carpet-like villi of the terminal ileum) is in direct proximity. Relative landmarks (eg, assessment of the endoscopic shape of the colon, liver and spleen shadow, ileocecal valve, appendiceal orifice) or the length of instrument insertion from the anal verge vary considerably and should not be used. In practical terms, however, this handicap may be overcome by India Ink tattooing of the area of a lesion for better identification during surgery or repeat endoscopy.

Contrast Enema. Radiographic contrast enemas alternatively can be used for a colonic evaluation. Contrast enemas are an especially valuable adjunct to colonoscopy in patients with near-obstructing colonic lesions. Furthermore, they have the advantage of more accurately visualizing the anatomic position of a colonic lesion (road map). Ideally, a barium-air double-contrast technique will be used after bowel cleansing; however, in a more acute setting, particularly if there is suspicion of a colonic perforation, administration of barium is contraindicated (risk of barium peritonitis), and instead, a water-soluble contrast material (eg, Gastrografin [diatrizoate meglumine]) should be used in a single-column technique.

The typical aspect of a colon cancer is a fixed filling defect with destruction of the mucosal pattern in an annular configuration ("apple core"), as opposed to an intact mucosal pattern in a filling defect from an extramucosal compression or from chronic diverticulitis. Although preoperative histologic confirmation of a colon cancer is preferable, an unequivocal and characteristic morphology on a barium enema or endoscopy is sufficient evidence to proceed to surgery. Contrast studies have the advantages of a better passage through even severely obstructing lesions and that they commonly reach the cecum. In addition, they are superior in visualizing diverticula or a suspected fistula between the colorectum and other pelvic organs. The major disadvantage of contrast studies is the inability to take biopsies and to detect small lesions.[95]

Evolving Techniques. CT colonography ("virtual colonoscopy")[203,204] and the microcapsule study have evolved in the last decade as high-tech alternatives to the two previously described methods. It should be noted that CT colonography still requires patients to undergo a bowel preparation, and that air insufflation is necessary. While there is certainly a lot of promise for both new approaches, which likely will continue to improve over time, the definite role of these techniques awaits further clarification.

Early studies suggested that CT colonography had a considerable rate of false-negative and false-positive results.[204,205] In a recent study of 937 patients with risk factors for colorectal

cancer, CT colonography had a sensitivity of 85% for lesions 6 mm or larger.[92] So far, the technology has not been approved by Medicare for screening purposes, but this may change in the future with additional validation studies. Unfortunately, incidental extracolonic findings may precipitate a large number of unwarranted tests, which add tremendous cost to the health care system. Currently, CT colonography may serve a useful purpose in patients for whom a colonoscopy is undesirable or unsuccessful.

EVALUATION OF THE LOCAL TUMOR EXTENT AND OF METASTATIC DISSEMINATION

Traditionally, the preoperative staging for colon cancer did not mandate further imaging studies because in the majority of cases they do not change the local surgical approach. Increasingly, however, preoperative cross-sectional imaging (CT or MRI) has become the standard of care.[206,207] The justification for this shift is twofold. First, patients with a significant burden of liver disease (>50% liver replacement) may carry a prohibitive risk for general anesthesia and should be treated with chemotherapy either in advance of surgery or instead of it. CT scans are the most commonly used cross-sectional imaging technique in the United States and have a 90% and 95% sensitivity and specificity in detecting liver lesions larger than 1 cm.[208] Second, the surgeon can be alerted to evidence of advanced locoregional disease that may alter the operative plan and necessitate the involvement of other operative expertise (eg, hepatobiliary surgery, urology, gynecology, etc).

In order to rule out extrahepatic, in particular pulmonary metastases, a chest x-ray in two planes commonly is sufficient, although the yield of this test is relatively low. A CT scan of the chest may be necessary to substantiate a concern from conventional images and is only a minimal incremental burden for a patient who is already undergoing such a study of the abdomen and pelvis.

Positron emission tomography (PET) has an evolving role in the evaluation of metastatic disease. While the routine use of PET scanning in the primary management of colorectal cancer is not recommended at this time, this technology does appear to have greater sensitivity for metastatic disease.[209] The extent to which this greater sensitivity can be translated into an algorithmic approach to staging remains to be seen. Its greatest utility at the current time is (1) in patients where systemic disease is suspected (eg, high tumor markers) but not proven, and (2) under special circumstances where the presence of previously unknown tumor manifestations (eg, recurrence vs scar tissue, solitary vs multiple liver metastases, and presence of extrahepatic metastases) would have an impact on the treatment approach (eg, operative vs nonoperative).

LABORATORY AND PREOPERATIVE TESTS

Preoperative laboratory tests are aimed at providing evidence for pathophysiologic effects of the tumor and ruling out general health problems that could have an effect on the patient's general operability. A comprehensive workup includes a complete blood count, electrolytes, creatinine/blood urea nitrogen (BUN), glucose, liver function tests (alkaline phosphatase, aspartate aminotransferase [AST], alanine aminotransferase [ALT], bilirubin, total protein, albumin), and coagulation parameters (prothrombin time [PT], partial thromboplastin time [PTT], international normalized ratio [INR]). Arterial blood gas analysis and additional tests will be ordered in an emergency setting or according to the individual patient's risk assessment (eg, cardiac enzymes, etc).

Even though tumor markers such as carcinoembryonic antigen (CEA) are determined routinely, their role is limited because of the low sensitivity and specificity for colonic carcinoma and because the measured value virtually never changes the management. CEA can also be elevated in proximal gastrointestinal cancers, benign inflammatory conditions of the bowel, lung and breast cancer, and smoking. Nonetheless, CEA level determination may prove helpful in some settings, for example when the return of an elevated preoperative CEA level to normal indicates a complete tumor resection or when a postoperatively elevated level may indicate residual or recurrent disease.[210]

Preoperative standard evaluation includes a chest x-ray in two planes for cardiopulmonary assessment and for detection of pulmonary metastases (see previous sections). Electrocardiogram (ECG) and pulmonary function tests (forced vital capacity [FVC], forced expiratory volume in 1 second [FEV_1], residual volume [RV], and diffusion capacity) are indicated in patients either older than 40 years or with a respective personal history. Specialized tests such as cardiac stress tests, echocardiogram, perfusion scintigraphy, or interventional cardiologic studies depend on the individual patient's history and risk assessment.

TREATMENT

Principles of Surgical Management

As a basic principle, any colorectal cancer is an indication for surgery unless widespread tumor dissemination or general contraindications from the patient's overall health status are present. Furthermore, any precursor pathology with statistical risk for cancer (eg, large sessile polyp in an otherwise healthy individual or dysplasia in a patient with ulcerative colitis) that cannot be managed nonoperatively is an indication for surgery.

The general goal for surgical management is either to achieve cure from the tumor and extension of survival or at least disease-free survival or, in the case of a precursor pathology with or without an underlying disease (eg, ulcerative colitis or FAP), to prevent the cancer and ideally to remove the risk-bearing disease. In a palliative setting, the goal is to prolong the period of symptom-free survival.

Local tumor control generally is the primary treatment objective to prevent local tumor complications, that is,

obstruction, perforation, fistula formation, bleeding, and pain. Even in the presence of distant metastases in the liver or lung, resection of the primary tumor remains a reasonable priority. Because solitary or a limited number of metastases in the liver or lung often may be treated surgically by partial organ resection or metastasectomy with a cure rate of up to 35%, their presence should not necessarily alter the surgical approach to do a curative resection at the primary site. However, if there are extensive metastases or peritoneal carcinomatosis and cancer cure is not a reasonable goal, alleviation of symptoms and prevention of impending local complications, for example by restoring the intestinal continuity, is the best palliation.

The specific surgical and oncologic strategy planning is based on a number of factors. It has to take into account the exact localization of the tumor, the tumor stage, the presence of synchronous colonic lesions or an underlying colonic disease, the risk for metachronous lesions, the patient's age and general condition, the extent of the local procedure, and the timing. Only after the extent of the operation has been defined can the method and approach to be used be discussed as to whether the procedure is only suitable for an open laparotomy approach or laparoscopy may be reasonable and beneficial.

In contrast to rectal cancer, neoadjuvant treatment (ie, preoperative chemoradiation) is not indicated in the overwhelming majority of colonic cases. In patients with resectable metastases, preoperative chemotherapy followed by a combined colon and liver resection may be an attractive alternative to a staged resection and may help in assessing the tumor response to a particular chemotherapy regimen. Only rarely is a locally very advanced lesion treated with chemotherapy in anticipation of an otherwise unresectable mass. Adjuvant (ie, postoperative) treatment is discussed in a later section.

PREPARATION FOR SURGERY

When a patient is considered an operative candidate, several preparatory steps need to be addressed.

Transfusion. Most colonic operations can be performed without a blood transfusion. Blood-spearing surgical techniques have reduced the need while the threshold to transfuse has substantially increased. The indication will depend on the starting hemoglobin, the patient's age and physiologic status, a history of ischemic events (coronary, stroke, etc), and the extent of expected and real intraoperative blood loss. As a routine, it is recommended to have the patient's blood typed and screened, but to reserve crossmatching units of blood for these higher-risk situations.

While the risk of blood-borne infections is very low, there is some controversy as to the immunologic effect of blood transfusions on the overall prognosis of colorectal cancer. Because the initial report that transfusion may be associated with an increased likelihood of recurrence,[211] many subsequent reports have reached conflicting conclusions. Meta-analysis studies have strongly questioned whether there is a true causal effect present.[212] Other factors such as extent of resection required, tumor location, and experience of the surgeon actually may be the more relevant cause for recurrence, but transfusion may be an indirect reflection of extensive disease and surgery. Furthermore, a randomized trial comparing the use of autologous versus allogenic blood in patients undergoing colorectal resections did not show any statistical difference in prognosis.[213]

Bowel Cleansing. Traditionally, bowel cleansing was considered an essential preparation to any elective colon surgery. The rational is based on the colon being a large reservoir for numerous anaerobic and aerobic bacteria. However, recent prospective, randomized, controlled studies and meta-analyses comparing mechanical preparation versus no preparation for elective colorectal surgery have failed to demonstrate any appreciable decrease in infection rates, anastomotic leaks, or mortality rates in patients undergoing mechanical bowel preparation.[214–220] Contrasting with the evidence, however, the majority of colorectal surgeons still perform bowel cleansing in their patients. The indisputable advantages of a bowel preparation remain (1) the intraoperative ability to perform a colonoscopy if that were needed, and (2) the absence of a preanastomotic stool load if a primary anastomosis or the tissue quality were unexpectedly less than optimal and asked for a fecal diversion.

There are a wide variety of laxatives, washouts, and enemas available on the market for mechanical cleansing, but the products used generally are based on either polyethylene glycol (eg, GoLYTELY) or sodium phosphate (Fleet Phospho Soda), the latter of which is contraindicated in patients with renal failure and has come under more broad scrutiny in the United States. In the absence of a consensus regarding the best regimens (ie, orthograde cleansing alone or combined with retrograde enemas), the choice often is a matter of personal preference. Depending on an individual patient's constitution and the degree of obstruction, the bowel cleansing should be started 1 or even 2 days before surgery. The cathartic may result in significant fluid and electrolyte imbalances. Elderly patients, who are more prone to this adverse effect, therefore should preemptively be given intravenous fluids and electrolytes.

Antibiotic Prophylaxis. Perioperative administration of prophylactic antibiotics aims at reducing colonic and dermal bacterial concentrations and is considered a crucial component of colorectal procedures. The benchmark is the rate of surgical site infections in relation to the level of wound contamination. Prophylaxis has to be distinguished from therapeutic antibiotic treatment in patients who already have an established infection. Prophylaxis (ie, in patients who do not primarily suffer from an infection) should be targeted, adequately dosed, and short (ie, start within 1 hour of the incision and be limited to less than 24 hours) in order to

minimize antibiotic side effects and propagation of resistances. Coverage should include both aerobic bacteria (eg, *Staphylococcus*, *Escherichia coli*, *Klebsiella*, *Proteus*, etc) and anaerobic bacteria (eg, *Bacteroides fragilis*, *Clostridium*).

Intravenous administration of broad-spectrum antibiotics is the most common form of prophylaxis and includes several acceptable antibiotic selections: (1) single antibiotics (ertapenem, piperacillin-tazobactam); (2) combination of two antibiotics (second- or third-generation cephalosporin + metronidazole, fluoroquinolone + metronidazole, clindamycin + aminoglycoside, clindamycin + quinolone, clindamycin + aztreonam); or (3) triple combinations such as amoxicillin-clavulanic acid + metronidazole + aminoglycoside. Oral antibiotics (eg, metronidazole combined with nonabsorbable neomycin) in conjunction with a mechanical bowel preparation may yield similar results but may increase the risk of nosocomial superinfections, in particular with *Clostridium difficile*.

Special considerations according to national guidelines have to be followed for prophylaxis in patients at risk for endocarditis (eg, patients with mechanical heart valve).

Thromboembolic Prophylaxis. Thromboembolic prophylaxis is recommended in all patients undergoing major surgical procedures to reduce the incidence of postoperative deep venous thrombosis and pulmonary embolism. Both pharmacologic and physical prophylaxis (eg, pneumatic calf compression) have been proven to be effective,[221] but the use of pharmacologic prophylaxis has recently been endorsed by a task force recommendation.[222] Both low-dose unfractionated heparin and low-molecular-weight heparins (LMWHs) have been shown to be equally effective in reducing the incidence of postoperative thromboembolic events without resulting in significant complications.[223] A recent randomized study, however, showed that LMWHs have a slightly higher rate of minor bleeding events.[224] Based on economic analysis, the data favor the use of subcutaneous heparin as being more cost-effective than LMWHs.[225] It is recommended that these drugs be commenced at least 2 hours before surgery and continued postoperatively until the patient has obtained full ambulation. Intermittent pneumatic calf-compression boots are an alternative to heparin that has been demonstrated to be equally successful in preventing deep venous thrombosis and possessing the advantage of no risk of increased bleeding.[226] It remains to be determined whether a combination of chemical agents and pneumatic calf-compression boots for patients undergoing colonic resection will be an advantage.

Anticoagulated patients who need to take warfarin (eg, owing to a mechanical heart valve) should be switched perioperatively to intravenous heparin to allow for stopping the warfarin medication and antagonizing its effect with vitamin K. Four hours before incision, the heparin may be discontinued and resumed within 24 hours postoperatively with a stepwise increase in the dose.

Urinary Catheters/Stents. After induction of general anesthesia, bladder catheterization should be performed in all major cases to adequately monitor the urine output peri- and postoperatively. In selected patients with a previous history of colorectal or pelvic dissections, placement of ureteral stents allows better intraoperative identification and protection of these crucial structures. Laparoscopic colon procedures do not routinely need ureteral stents; however, selective use of lighted ureteral stents during challenging laparoscopic procedures may facilitate identification of these structures.

Nasogastric Tube. Placement of a nasogastric tube is not necessary on a routine basis for patients undergoing resection of the colon or rectum and should be avoided unless they present with a complete or partial bowel obstruction.[227]

Preoperative Marking of Ostomy Site. In patients who may need permanent or temporary placement of an ostomy during the surgical procedure, preoperative marking of the ideal stoma site by a stoma nurse helps to facilitate postoperative ostomy handling by the patient.

Preemptive Pain Management. Effective pain management is an important factor not just for patient comfort but to reduce the incidence of postoperative pulmonary complications. Preoperative placement of epidural analgesia is a very valuable strategy, which, in addition to its pain-relieving effect, promotes the earlier resumption of postoperative bowel function as a result of its suppression of sympathetic nerves. The relevant segments that need to be blocked for an abdominal incision are located at a thoracic level (T6–T12).

Surgery

GENERAL TECHNICAL PRINCIPLES

The objective of surgery for colonic cancer is to perform a curative resection by removing the cancerous segment of colon, the mesentery with the primary feeding vessel and the lymphatics, and any organ with direct tumor involvement. Because the lymphatics run with the arterial supply of the colon, the primary artery supplying the segment of the colon to be resected is divided at its origin. Ligation at the origin of the vessel ensures inclusion of apical nodes, which may convey prognostic significance for the patient.[228] While careful dissection in the right place is the mainstay of a successful surgery, the historical Turnbull no-touch technique with early vascular ligation and occlusion of the bowel with tapes to prevent embolization of tumor and improve survival has not shown any advantage.[229]

The length of bowel and mesentery resected is dictated by tumor location and distribution of the primary artery (Table 36-14), but a radical resection of a colonic tumor should achieve at least a 5-cm clearance at the proximal

TABLE 36-14: STANDARD RESECTIONS OF THE COLON

Tumor Location	Resection	Description of Extent	Major Blood Vessel	Safety Margin (cm)
Cecum	Right hemicolectomy	Terminal ileum to midtransverse colon, right flexure included	Ileocolic artery, right colic artery, right branch of mid colic artery	5
Ascending colon	Right hemicolectomy	Terminal ileum to midtransverse colon, right flexure included	Ileocolic artery, right colic artery, right branch of midcolic artery	5
Hepatic flexure	Extended right hemicolectomy	Terminal ileum to descending colon (distal to left flexure)	Ileocolic artery, right colic artery, midcolic artery	5
Transverse colon	Extended right hemicolectomy (Transverse colon resection)	Terminal ileum to descending colon (distal to left flexure) Transverse colon (including both flexures)	Ileocolic artery, right colic artery, midcolic artery Midcolic artery	5
Splenic flexure	Extended left hemicolectomy	Right flexure to rectosigmoid colon (sigmoid, beginning of rectum)	Midcolic artery, left colic artery, inferior mesenteric artery	5
Descending colon	Left hemicolectomy	Left flexure to sigmoid colon (beginning of rectum)	Inferior mesenteric artery, left branch of midcolic artery	5
Sigmoid colon	Rectosigmoid resection	Descending colon to rectum	Superior hemorrhoidal artery, inferior mesenteric artery	5

and distal margin. Extended resections for confined tumors outside of high-risk patients have not been shown to confer additional survival benefit[230]; however, tumors located in "border zones" should be resected with both neighboring lymphatics to encompass possible bidirectional spread. If a tumor is adherent to or invading an adjacent organ such as the kidney or small bowel, an en bloc resection should be performed where technically feasible. Because adhesions between the tumor and adjacent organ may not necessarily be inflammatory, but, because of carcinoma, mere division or "pinching" of a tumor from an adjacent organ is not an acceptable surgical technique because it may reduce the chance of cure.

When synchronous cancers are present in the colon, an extended resection or even total colectomy, with ideally only one anastomosis, should be performed. Occasionally, two separate resections (eg, right hemicolectomy and low anterior resection) with two anastomoses are preferable to preserve colon length and to avoid postcolectomy diarrhea. Cancer on the basis of an underlying pancolonic disease (eg, ulcerative colitis or FAP) requires a total proctocolectomy with either an ileoanal pull-through procedure or an ileostomy[80]; young patients (<50 years, with/without proven HNPCC gene constellation) presenting with tumors proximal to the sigmoid colon should be offered a total abdominal colectomy to reduce the risk of metachronous cancers and to facilitate surveillance.[231]

A limited wedge resection may be considered for an unfit patient or for palliative resection in those with widespread tumor. This will relieve the patient's symptoms and prevent future obstruction and bleeding from the primary tumor.

INTRAOPERATIVE SURGICAL TECHNIQUE

Positioning. For all left-sided colonic resections, it is advisable to place the patient in a modified lithotomy position, which gives access to the anus (eg, for a stapled anastomosis) and allows an assistant or the surgeon to stand between the legs for retraction or an excellent view to mobilize the splenic flexure, respectively. The same positioning obviously also can be used for all other colon resections, but a supine position usually is sufficient and faster. Laparoscopic procedures typically require the operating table to be tilted and moved to steep Trendelenburg's position; appropriate fixation and securing of the patient is therefore mandatory.

Incision. For an open procedure, the peritoneal cavity is most commonly entered through a midline laparotomy incision. For a proctocolectomy, we usually recommend the use of an infraumbilical incision in order to provide good exposure for the pelvic dissection. For a more proximal segmental colon resection, however, an equally short but

higher midline incision may be more convenient. In addition, a transverse incision or even a subcostal incision may give excellent exposure for a right hemicolectomy.

For a laparoscopic procedure, a first camera trocar is placed in either Veress needle or in open Hasson technique. The site should be chosen such that additional working ports can be placed along a circle with the target in the center.

Exploration. After the peritoneal cavity is entered (open or laparoscopically), the abdomen is explored systematically to determine the resectability of the tumor. Special attention is addressed to the presence of distant metastases in the liver, peritoneal carcinomatosis, or additional synchronous lesions throughout the large intestine. Other accessible organ systems are assessed equally, for example the gallbladder and the female reproductive organs.

Colon Resection. The surgical technique has been standardized for three segments: right colon, left colon, and rectosigmoid. Depending on the extent of the resection eventually needed in an individual patient, the technique for those segments may be combined (see Table 36-14). With a detailed description of the maximal resection, that is, an open total colectomy/proctocolectomy, all information about the individual steps necessary to perform any colorectal resection of lesser extent will therefore be provided.

The same steps should be achieved with laparoscopic resections; however, depending on the surgeon's preference and skills, a medial-to-lateral mobilization of the colon (ie, starting at the feeding vascular stalks before moving to the retroperitoneal attachments) supports the autoretraction of the colon throughout the critical steps.

On careful exploration of the abdomen, mobilization of the colon starts on the right side. Use of a mobile (eg, Richardson retractor) instead of a fixed (eg, Balfour or Bookwalter retractor) abdominal wall retractor in this first phase will allow a more flexible and unidirectional exposure according to rapidly changing needs. The small bowel is eviscerated from the abdomen and moved to the left. The abdominal wall is retracted to the right side while exerting countertraction on the cecum and ascending colon. A small incision is made at the exposed white line of Toldt to enter the retroperitoneum. Elevating the ascending colon from the retroperitoneal structures, the peritoneum is divided along the lateral gutter from the terminal ileum to the hepatic flexure. On the right side, the ureter is at fairly low risk and routinely falls away; however, special care is needed to avoid damage to the third part of the duodenum. The mobilization is facilitated by firm traction placed on the colon and the surgeon's left hand inserted into the retroperitoneum as a guide to divide along the peritoneal reflection. Because of the limited view around the hepatic flexure and the presence of small vessels at this level, transsection of the peritoneum with cautery is often advisable.

As the right edge of the gastrocolic ligament is reached, it may be easier to complete the dissection of the hepatic flexure in retrograde direction. The abdominal wall retractor is moved quickly into the upper end of the incision in order to pull in a cephalad direction. The lesser sac is entered far to the left in an avascular portion of the omentum, and the greater omentum is divided inferior to the gastroepiploic vessels between clamps and ligatures. While the omentum may be preserved in benign diseases, its resection with the respective colon segment is part of an oncologic resection. Dissection of the gastrocolic ligament is carried out from the left to the right. Connective tissue attachments between the antrum, duodenum, and transverse mesocolon and the hepatic flexure are divided stepwise by a combination of blunt digital tunneling and sharp dissection using both hands. Care should be taken at this point to avoid dissecting too deeply into the retroperitoneum, where large blood vessels can be encountered. Once the mobilization has been completed around the hepatic flexure, the right colon and transverse colon are attached only to their vascular supply and are ready for resection. This would be used for any standard right hemicolectomy or the first part of an extended transverse colectomy. For total colectomy, mobilization of the whole colon commonly is continued before dividing the major vessels.

At this point, the abdominal wall retractor is moved to the left side of the abdomen, and traction is placed to expose the left portion of the colon. The dissection is initiated at the level of the sigmoid, where the white line of Toldt again is incised and the retroperitoneum entered. Once the areolar tissues are identified, a small sponge is taken, and with firm pressure against the sigmoid mesentery, the retroperitoneal tissues are bluntly reflected, and the left ureter is exposed. Only after the ureter has been clearly identified and moved out of the way is incision of the peritoneum continued into the pelvis for a short distance and up to the splenic flexure along the left gutter. The colon is reflected bluntly from the retroperitoneal tissues, and with firm traction the peritoneal incision is continued. Gentle traction on the transverse and descending colon will help to lower the splenic flexure until it can be visualized fully. A hand placed in the retroperitoneum will help to mobilize the splenic flexure, and under direct vision the peritoneum over the splenic flexure can be incised. Care must be taken at this point to protect the spleen from direct or traction injury. The final attachments of the splenocolic ligament that hold the splenic flexure are clamped and divided in appropriate tissue portions. Clamping and ligating this tissue are recommended because even small vessels retracting into the left upper quadrant can be a nuisance.

After completion of the first two parts, the colon is mobilized completely from its retroperitoneal attachments from the terminal ileum to the upper rectum. Elevation of the colon allows identification of all primary feeding vessels. In order to ligate the inferior mesenteric vessels, the surgeon is on the patient's left and the colon is reflected to the left. The attachments that run over the sacral promontory and up along the left gutter are incised, and a hand is used to dissect the tissues bluntly from behind the inferior mesenteric vessels. By identifying the inferior mesenteric vessels and making the window

just under those, the hypogastric nerves going down into the pelvis are protected routinely. Sometimes, for example if there is concern about cancer in the rectum or if the patient is very obese, these structures need to be freed up more to elevate the nerves initially and later to dissect them out under direct vision. The avascular window around the origin of feeding vessels then is opened. In the case of the inferior mesenteric vessels, the left hand is placed behind the inferior mesenteric stalk, and the thumb and opposing index finger can clear a window of avascular tissue above it. Dissection of redundant adipose tissue around the vessels is carried out under direct vision, before the vessels are clamped. Before transsection and ligature of the vessels, the remote location of the ureter is confirmed once more. If the ureter is not identified properly before dividing the vascular pedicle, accidental dissection of the ureter can occur and requires a repair. If unrecognized intraoperatively, the ureter injury may result in a urinoma. In difficult cases (eg, repeat operation or recurrence), it is therefore advisable to place preoperative ureteral stents to allow better identification. The whole vascular stalk may be ligated with a double ligature or a suture ligature. Individual ligature of the artery and vein is optional and has not been shown to provide an advantage. For the reason mentioned earlier, it is recommended to ligate the vessels as proximally as possible, but from an oncologic standpoint a high ligation of the IMA does not provide any advantage in comparison with a low ligature distal to the origin of the left colic artery.[232,233]

The vascular dissection is then continued around the colonic mesentery. The avascular tissue can be divided sharply while clamping is applied to vessels when they are encountered. The vascular anatomy of the colon is quite variable. However, if one is truly in the retroperitoneum and ligating named vessels at their origin, the colon can be taken out with as few as three to four clamps. In particular, the inferior mesenteric, middle colic, and ileocolic vessels need to be ligated. The presence of additional right and left colic vessels sometimes requires the use of five or six clamps. By taking the vessels closer to their origin, that is, before they branch off into multiple subsegments, fewer clamps are necessary and the dissection proceeds more rapidly.

Once the vessels have been ligated, the bowel may be divided by means of cutting linear stapling devices at the previously determined levels. In patients with an underlying disease (eg, ulcerative colitis or FAP), the dissection at this point would be continued as a total mesorectal excision down into the pelvis to the pelvic floor (see respective chapters). It is strongly recommended to have the specimen assessed macroscopically to verify the pathology. Tumor in the resection margin means an inadequate cancer operation requiring a re-resection. Intraoperative frozen sections of the resection margins should be requested whenever there is any doubt about the completeness of the resection.

Reconstruction/Diversion. After the resection has been completed, either the bowel ends can be reanastomosed or the proximal end may be brought out as an ostomy. Prerequisites for a successful anastomosis are meticulous technique, well-vascularized and healthy appearing tissues, apposition of bowel ends without any tension, and good nutritional status of the patient with an albumin level greater than 3.0 mg/dL. Constructing an anastomosis under tension and/or with poor blood supply increases the risk of an anastomotic leak that may cause an infection and sepsis. A protective diverting ostomy does not prevent the leak as such but should diminish the life-threatening complications of an anastomotic leak. While a stapled functional end-to-end anastomosis between the ileum and the colon (ie, an enterocolonic anastomosis) is reasonable, this type of anastomosis may potentially be less desirable between two colon segments (ie, a colocolonic anastomosis) because it can result in an iatrogenic giant diverticulum that may interfere with the propulsion of formed stool or impede the performance of a surveillance colonoscopy. Performing an end-to-end anastomosis, either hand-sewn or by means of a circular stapler, will avoid these problems. An ileocolonic anastomosis in most instances can be performed in an unprepared bowel, whereas a colocolonic anastomosis on the left side traditionally requires pre- or intraoperative reduction in the stool load unless a colostomy was performed. As mentioned previously, this view has come under scrutiny.

Drains. Placement of drains is more often a matter of personal preference than of scientific objectiveness.[234–236] Most bowel anastomoses, even colocolonic anastomoses, do not need to be drained. The use of drains generally may be recommended when a pelvic dissection and anastomosis have been performed and accumulation of fluid and blood in the dependent areas around the anastomosis should be avoided. Whether prospective, but underpowered, studies are sufficient evidence to effectuate a change in this practice needs to be determined.[237,238]

TECHNICAL CONSIDERATIONS

Laparotomy Versus Laparoscopy. Laparoscopic colon surgery has a clearly established place in the management of both benign and malignant colon diseases. In many specialized centers, it is even regarded the first-line approach unless patient-specific factors suggest otherwise. The path to a nearly unanimous endorsement of the technique at least for right-sided, left-sided, and sigmoid resections for colon cancer started in the early 1990s,[239] moved from palliative resections to institutional case series in curative intent, and culminated in several prospective randomized trials throughout the world,[240–245] the first large-scale trial being a multicenter study by the NCI.[241] This study, which enrolled 872 patients with stages I–III colon cancer, confirmed that there was a moderate quality-of-life benefit for the laparoscopic approach[246] but otherwise no difference in oncological outcome and survival between the laparoscopic and open-resection groups.[241] Subsequently, two large-scale European prospective multicenter trials (ie, the COLOR [COlon cancer Laparoscopic or Open Resection] trial with 1248 and the CLASICC [Conventional versus Laparoscopic-Assisted Surgery In Colorectal

Cancer] trial with 794 patients) have confirmed similar results.[247,248] This equality of the study results offered the unique opportunity for both opponents and proponents of the laparoscopic approach to justify their personal preference for either the open or laparoscopic technique depending on their background and skills. In contrast to one early report of a high incidence of port-site recurrences, it has become clear subsequently that with appropriate surgical technique, the incidence is in the range of 0.8–1.3% and, on a stage-by-stage comparison, not higher than wound implants after open surgery.

For the laparoscopic procedure, about three to five trocars are inserted. Lacking the tactile sensation of open procedures, tattooing of the target lesion should generally be performed prior to the surgery. The colon should be mobilized to the same extent as during open surgery, but it may be advantageous to start with the vascular pedicle rather than with the retroperitoneal attachments. The technical equipment to perform an intracorporeal resection and anastomosis is available, but it is questionable whether there is any advantage to this because at some point an incision must be made anyway to retrieve the specimen. In the laparoscopically assisted technique, the segment, once it has been mobilized to the required extent, therefore is exteriorized through a small sleeve-protected abdominal incision, and an extra-abdominal resection and anastomoses are performed. The bowels are returned into the abdomen, the fascia is closed, and the pneumoperitoneum may be reinstalled to inspect the peritoneal cavity again. To facilitate complex resections, some surgeons use hand-assisted laparoscopic surgery (HALS) to combine tactile sensation with a minimally invasive approach.

Sentinel Lymph Node Mapping. Although the interest in lymphatic mapping and sentinel lymph nodes has been derived from favorable experiences in breast cancer and melanoma, most recent data do not support the value of this technique for colon cancer. In particular, analysis of the recent intergroup study 0114 demonstrated a lack of correlation in an alarming 54% of the patients.[249] Sentinel lymph node mapping not only may be misleading and therefore not useful in the management of colorectal cancer, but there also is simply no need for this technique in colon resections because the lymphadenectomy—in contrast to breast and melanoma surgery—is not associated with any morbidity.

SPECIAL CIRCUMSTANCES IN EMERGENCY SURGERY

Approximately 20% of patients with colon cancer present as an emergency requiring an urgent operation for a tumor-related complication (eg, bowel obstruction, perforation, or massive bleeding).[250] Morbidity and mortality are significantly higher than under elective conditions. Contributing factors are the lack of a mechanical bowel preparation and the patient's impaired overall status, which typically is characterized by dehydration, third spacing of fluids, anemia, a deranged metabolism with electrolyte imbalances, and possible sepsis. The risks for wound and intra-abdominal infections and anastomotic leakages are three to six times higher.[251]

Tumor Obstruction. Sixteen percent of patients with colon cancer present with a bowel obstruction and complain of colicky abdominal pain, abdominal distension, vomiting, constipation, and, occasionally, paradoxical diarrhea. Imaging studies (abdominal x-ray or CT scan) characteristically demonstrate the features of a large or small bowel obstruction depending on how proximal in the colon the obstruction is located and whether the ileocecal valve is competent. Attention should be paid to the diameter of the cecum, which presents a risk of cecal perforation if the diameter reaches 12 cm or more. Urgent intervention is required in such circumstances to prevent cecal perforation. The most important differential diagnosis is pseudo-obstruction (Ogilvie's syndrome), which is seen as a result of various medical conditions and may mimic the features of bowel obstruction. Every patient therefore should have a rigid proctoscopy, followed by a water-soluble contrast enema, which should visualize only the colon up to the site of obstruction but not beyond the stenosis because the hyperosmolar nature of the contrast material can result in an increase in the intraluminal volume and trigger a perforation.

If the level of obstruction in the colon is proximal enough, a resection with primary enterocolonic anastomosis, for example right hemicolectomy, extended right hemicolectomy, or subtotal colectomy, may be carried out. If the tumor is located on the left side of the colon, adjustments to the surgical approach are necessary because the stool load proximal to the obstruction is of concern for a colocolonic anastomosis and because that segment of the colon could not be cleared before the operation. Synchronous lesions, which in the setting of an obstructing lesion may occur in up to 15%, may be missed and necessitate further intervention in the future. Strategies then include either (1) a subtotal colectomy, (2) an on-table lavage with segmental colon resection, intraoperative colonoscopy, and primary anastomosis, or (3) performance of a two- or even three-stage procedure instead of the elective one-stage approach. Historically, obstructed left-sided tumors were treated with a three-stage approach starting with a defunctioning loop colostomy, followed by resection and anastomosis and last by closure of the defunctioning stoma. The Hartmann procedure, the classic example among several two-stage procedures, consists of a discontinuous rectosigmoid resection with creation of a terminal colostomy and a blind rectal stump in the first stage, followed by a colostomy takedown and reanastomosis in a second operation.

More recently, there has been a trend toward attempting to relieve the acute obstruction at the tumor-bearing segment by colonoscopic insertion of a self-expanding metallic stent. Successful decompression of the prestenotic colon converts the emergency situation into an elective setting, allowing for stabilization of the patient and performance of bowel preparation. The risk of a colonic perforation during stent placement is relatively low but acceptable because an emergency

operation would be necessary anyway if the stent could not be placed successfully. Several nonrandomized, noncontrolled case series have demonstrated that colonic stenting for acute obstruction is safe and highly successful.[252–255] A proximal diversion hence may be avoided with this procedure.

Tumor-Related Perforation. Colonic perforation secondary to a tumor occurs in two different settings. Either a transmural tumor perforates itself, or the proximal colon becomes overdistended, particularly in the case of a competent ileocecal valve. Both conditions may result in diffuse fecal peritonitis with significant morbidity and mortality. In addition, the tumor perforation results in spillage of tumor cells and thus has to be considered a stage IV tumor. Surgical management is indicated in every case and requires not only addressing the site of colonic perforation but also removing the tumor in an oncologically correct fashion.[250] The same tactical principles described in the preceding section apply.

Massive Colonic Bleeding. Massive bleeding from a colonic tumor is a relatively rare complication. The general algorithms for the workup and management of lower gastrointestinal bleedings apply, but, most commonly, the bleeding site can be easily identified. If the bleeding is minor or self-limited, the standard workup can be performed. If the patient is or remains unstable and requires repeated transfusions, surgical management is indicated.

MANAGEMENT OF ADVANCED DISEASE

Locally Advanced Disease. It has been estimated that approximately 15% of colonic tumors will be adherent to adjacent organs.[256] With locally advanced colon tumors, it is still possible to achieve cure if the surgeon is prepared to resect involved adjacent organs. Unfortunately, it is often impossible to distinguish between malignant and inflammatory adhesions, but at least 40% of these adhesions are expected to harbor malignant cells. The surgeon therefore has to consider them malignant until proven otherwise and perform an en bloc resection to achieve a tumor-free margin.[257]

Operable Metastases. At the time of presentation, 20% of patients with colorectal cancer have stage IV disease. Distant metastasis, particularly liver and lung, is a major cause of death in patients with colorectal carcinoma. However, patients with asymptomatic liver metastases may have a statistically natural life expectancy of several months up to almost 2 years without any treatment. Chemotherapy and surgical metastasectomy in selected patients may improve disease-free and overall survival substantially, resulting in a cure rate of 30%.[258] In the case of potentially resectable metastases, resection of the colonic primary tumor therefore should be performed in an oncologic fashion.

Inoperable Disseminated Disease. In patients with unresectable metastatic disease, the surgical treatment goal is to provide palliation and to prevent predictable complications. In contrast to the oncologically defined standard resections, a limited segmental wedge resection of the colon is acceptable in this setting. In particular, tumors located in the sigmoid colon or in the cecum and ascending colon are suitable for a laparoscopic or laparoscopically assisted resection because these segments can be mobilized easily to a sufficient extent to ensure a safe anastomosis. If a tumor in a patient with metastatic disease is too advanced locally to be resected safely (eg, infiltration of other organs), palliation may be achieved by creating an internal bypass or a proximal diversion.

POSTOPERATIVE MANAGEMENT

Postoperative fast-track management after a colorectal resection has become very straightforward and routine. The immediate postoperative monitoring of vital signs, fluids, and electrolytes, as well as adequate pain control, is not different from any other major surgery. However, there has been an increased emphasis on epidural pain management, early mobilization and regular spirometry exercises, avoidance of tubes and drains (eg, nasogastric tubes), and early resumption of oral intake no later than on the first or second postoperative day with advancement to a regular diet as tolerated. Daily assessment of the abdomen and bowel activity is crucial, including careful auscultation and palpation of the abdomen to assess bowel sounds or peritoneal signs. Unless soaking, a wound dressing may be left in place until the second postoperative day or even for 5–10 days if an occlusive transparent dressing is used. The incision has to be checked daily for the presence of induration, hematoma, redness, dehiscence, or discharge of fluids (eg, pus, hematoma, or serosanguineous fluid). Large amounts of serous fluids draining from the wound should not be mistaken for a seroma but indicate a fascial dehiscence until proven otherwise. The average length of stay after colorectal resections depends on the patient's constitution but generally is in the range between 5 and 7 days for an open standard procedure, and 2 and 5 days for a laparoscopic approach. Before discharge, further tumor treatment should have been addressed with the patient. Adjuvant chemotherapy (and rarely radiation therapy) typically are not initiated before 3–4 weeks after surgery and may be delayed if infectious complications or anastomotic leaks occur.

Complications of Surgery

The overall perioperative mortality within 30 days of colorectal resections is between 3.5 and 6%,[259] with less than 2% after elective but up to 20% after emergency operations. Complications of surgery may be of a general or surgery-specific nature and can be classified based on the time of their occurrence as either early (within the first 30 days) or late (after 30 days). Intraoperative complications like injury to relevant anatomic structures such as ureters, spleen, bowel, and duodenum are related to the surgical technique, to

blurred anatomic landmarks and layers owing to the disease (eg, peritonitis or massive adhesions), or to the patient's habitus (eg, obesity). Early surgery-specific complications include bleeding, most frequently within the first few days of the resection, nonspecific infections, or infections related to an anastomotic dehiscence. Other more general complications in the early postoperative period (postoperative days 1–3) commonly are related to the cardiopulmonary system and include pulmonary problems (eg, atelectasis, pneumonia, aspiration, and pulmonary embolism) and cardiac events (eg, arrhythmia, myocardial ischemia, and dysfunction). Insufficient pain control has been recognized as an important factor promoting these conditions because it results in a poor respiratory effort by the patient and the inability to cough up sputum, leading to superficial respiration and suboptimal saturation. High fever in the 3 days therefore may be related to the development of an atelectasis rather than to an early infection.

Infectious complications usually occur after the third postoperative day and may be located either intra-abdominally, in the wound, in the urinary tract, or in the lungs. The primary workup therefore includes bacteriologic cultures and stains, blood and urine analysis, and a chest x-ray.

Abdominal complications consist of delayed return of upper and lower gastrointestinal function (also referred to as *postoperative ileus*), fascial dehiscence, and anastomotic breakdown. Clinical leaks occur in 1–2% of all colonic resections, but subclinical leaks are more frequent and may be seen incidentally on contrast studies in otherwise asymptomatic patients. A leak may present with insidious symptoms such as fever, tachycardia, abdominal distension, ileus, feces draining through a drain or the wound, or local and generalized peritonitis. Occasionally, a leak may present with sudden deterioration, generalized peritonitis, and septic shock as the result of a significant and rapid contamination of the peritoneal cavity. Owing to the heterogeneous symptoms, a leak should be suspected in any patient who is not progressing to the expected degree. Blood parameters such as white blood cell counts and C-reactive protein may be elevated but are nonspecific and difficult to distinguish from a normal postoperative reaction. After an abdominal operation, normal free air should be resorbed within 7–10 days.[260] The presence of substantial free subdiaphragmatic air later in the course should therefore raise the index of suspicion for an anastomotic leak.

Imaging studies to define the presence of an anastomotic leak include a water-soluble contrast enema to visualize extravasation of the contrast material and/or a CT scan with oral, intravenous, and possibly rectal contrast material. Apart from antibiotic treatment, the management of an anastomotic leak depends on its presumed extent and the clinical presentation. A patient with generalized peritonitis requires a relaparotomy after appropriate resuscitation. Depending on its location, the anastomosis either should be taken down and the ends should be exteriorized or, in more favorable conditions, resected, and a new anastomosis performed with healthy-looking bowel ends, either with or without proximal diversion. A local repair alone carries a high risk of failure but may succeed in combination with drain placement and a proximal diverting ostomy. By the time of the reexploration, the prolonged peritonitis in some cases already may have transformed the bowel loops into rigid pipes that would not allow any mobilization for an ostomy or for a new anastomosis. In such a case, creation of a confined leak by means of a catheter enterostomy may be a desperate attempt for local control. A fecal fistula can be managed in a conservative manner if there is no evidence of generalized peritonitis or uncontrolled sepsis. Under favorable conditions, including good nutritional support and absence of a distal obstruction or disease of the involved bowel segment, the fistula may close spontaneously. The surrounding skin will need special care, and a stoma therapist will be helpful in this regard.

Adjuvant Chemotherapy and Radiotherapy

The rationale for adjuvant chemotherapy is based on the fact that we are clearly not as successful with surgical treatment as we would like to be. 5-Fluorouracil (5-FU) was the first and most extensively evaluated drug for the treatment of colorectal cancer. Multiple studies had been completed without proof of value until Krook's study.[261] Subsequently, a review of 29 randomized trails concluded that adjuvant chemotherapy for colon cancer resulted in a 5% improvement in survival.[262] When studies using 5-FU–based regimens are analyzed, there is a 2.3–5.7% absolute improvement in 5-year overall survival. However, when just those at high risk of recurrence are treated, the improvement in survival in this group is closer to 30%. Patients with stage III colon cancer are recognized to be at high risk for recurrence, and administration of 5-FU/leucovorin (LV) for 6 months after surgery has proven to decrease recurrence and improve long-term survival.[263] The combination treatment of 5-FU/LV for 6 months was proven to be equivalent in efficacy to 12 months, and the addition of levamisole to 5-FU/LV did not seem to add any benefit.[264] Low-dose LV also was demonstrated to be equally efficacious as high-dose LV when used in combination with 5-FU. Thus the first-line standard of treatment from 1998 to 2000 was a combination of 5-FU and low-dose LV (folinic acid) given for 6 months on either a weekly schedule or 5 consecutive days every 4 weeks. At present, there is not enough evidence to recommend the routine use of adjuvant chemotherapy in stage II disease. Lenz and colleagues have demonstrated that molecular or genetic markers may better identify subgroups of patients who are likely to benefit from adjuvant chemotherapy.[265,266,267]

Several new agents, for example irinotecan (CPT-11)[268,269] and oxaliplatin,[270–272] have demonstrated significantly superior activity in combination with 5-FU/LV in the metastatic setting. Irinotecan/5-FU/LV (IFL)[268] and oxaliplatin/5-FU/LV (FOLFOX) have been entered into randomized clinical trials against 5-FU/LV in resected stage III colon cancer.[273] Both these studies prove that the new agents in association with 5-FU/LV were superior to 5-FU/LV alone. Because of these successes, IFL was approved as first-line chemotherapy in 2000. In 2005,

5-FU/LV with oxaliplatin (FOLFOX) was approved for adjuvant therapy and has evolved in most centers as the treatment of choice. The FOLFOX regime has been compared in a large randomized, controlled trial with IFL and irinotecan/oxaliplatin (IROX) in patients with previously untreated metastatic colorectal cancer.[273] This study showed significantly superior results of the FOLFOX regime for all end points. The median time to progression observed for FOLFOX was 8.7 months, response rate was 45%, and the median survival time was 19.5 months. The FOLFOX regimen had significantly lower rates of severe nausea, vomiting, diarrhea, febrile neutropenia, and dehydration. Sensory neuropathy and neutropenia were common with the regimens containing oxaliplatin.

Capecitabine (Xeloda), an oral agent designed to generate 5-FU preferentially in tumor tissue, is an exciting new development with improved convenience. A randomized phase III study comparing oral capecitabine versus intravenous 5-FU/LV concluded that capecitabine demonstrated a statistically significantly greater response rate compared with 5-FU/LV (26 vs 17%; $p < .002$) and an equivalent time to progression and overall survival.[274] This study demonstrated that capecitabine is a suitable alternative to IV 5-FU and perhaps a replacement in the future. There are currently phase II trails being conducted on capecitabine/oxaliplatin (CAPEOX) and capecitabine/irinotecan (CAPEIRI).[275–279]

Two of the most fascinating targets in the treatment of colorectal cancer are the epithelial growth factor receptor (EGFR) and vascular endothelial growth factor (VEGF) blockers.[280,281] Agents that inhibit the EGFR or bind to VEGF have demonstrated clinical activity as single agents and in combination with chemotherapy in phases II and III clinical trials. The most promising of these agents are the monoclonal antibodies cetuximab, which blocks the binding of epithelial growth factor, and bevacizumab, which binds free VEGF.[280,281] However, the benefit of cetuximab is limited to patients with a tumor bearing wild-type *K-ras* while tumors bearing mutated *K-ras* do not show any response.[282,283] Both agents have proven benefit and seem to work best as first-line therapy for metastatic colorectal cancer. Introduction into the primary adjuvant treatment after curative resection of stages II and III tumors will remain a subject of future trials. We await future developments of these and other newer drugs and their impact in the fight against colorectal cancer.

Generally, radiotherapy does not play a primary role in the adjuvant treatment of colon cancer. However, it may be considered as a locoregional field radiation in selected locally advanced T4N0–N1 tumors.[284–286]

Outcome and Prognosis

Recent years have produced a trend toward better outcome and survival in patients diagnosed with colorectal cancer. This may be related to safer and more successful surgical treatment in combination with better nonoperative and adjuvant treatments. The perioperative mortality within 30 days of elective colorectal resections is less than 2% even though it still may be relatively high after an emergency operation, thus resulting in an overall mortality of 3.5–5.5%.[259] SEER data demonstrate an overall decline in colorectal cancer mortality. While the overall 5-year survival of patients with colon cancer was at 41% between 1950 and 1952, it has since increased steadily to 63.8% between 1995 and 2000. Analyzed for each stage as defined by the AJCC sixth edition system (Table 36-15) separately, 5-year survival was 93.2% for stage I, 84.7% for stage IIa, 72.2% for stage IIb, 83.4% for stage IIIa, 64.1% for stage IIIb, 44.3% for stage IIIc, and 8.1% for stage IV.[8] The prognosis of patients with synchronous primary colon tumors is not different from that of patients with solitary tumors if they are compared on the basis of the most advanced stage (see Table 36-15).[202]

TABLE 36-15: FIVE-YEAR SURVIVAL FOR SINGLE AND SYNCHRONOUS COLON CANCER PRIMARIES

Stage	Single (n = 4817)	Synchronous by highest stage (n = 160)	*P* value[a]
	%	%	
0,I	83	87	NS[b]
II	71	67	NS
III	53	50	NS
IV	9	14	NS

[a] By long-rank test.
[b] Not significant.
Data from Passman MA, Pommier RF, Vetto JT. Synchronous colon primaries have the same prognosis as solitary colon cancers. *Dis Colon Rectum*. 1996;39(3):329–334.[202]

LAPAROSCOPIC COLORECTAL PROCEDURES

Rajesh Pendlimari • Heidi Nelson

INTRODUCTION

The practice of minimally invasive surgery has rapidly grown over the past two decades to the point that laparoscopic surgery has replaced open surgery for several abdominal procedures (such as cholecystectomy) and gained acceptance and implementation for many other procedures (such as colectomy).[1] For many surgical practices laparoscopic techniques have become common place for the patient-related advantages they offer (Table 37-1). In part, the introduction of hand-assisted laparoscopic surgery (HALS) and the early exposure of trainees to diverse laparoscopic techniques have facilitated the availability of laparoscopic surgery to more practitioners and patients.[2] Knowledge and experience gained from the evolving practice over the past nearly two decades has provided clarity on indications, contraindications, and technical advancements. This chapter provides a review of the principles behind the practice of laparoscopic colon and rectal surgery. It also provides a brief review of the special considerations for cancer of the colon and the rectum and focuses on providing a contemporary description of the technical approaches to laparoscopic and HALS approaches to segmental resections of the colon and the rectum, and the combined resections of the colon and rectum with creation of pelvic pouches. Finally, a perspective on NOSE (natural orifice specimen extraction), NOTES (natural orifice transluminal endoscopic surgery), and robotic surgery is offered at the conclusion of this chapter.

PATIENT SELECTION

Indications, Contraindications, Evaluations

With the exception of rectal cancer cases, laparoscopic surgery can be considered an option for virtually any patient with a colon or rectal condition requiring surgery. With that said, not all patients will be ideal candidates and not all procedures can be performed by all surgeons. All surgeons must find their comfort zone with laparoscopic cases. The initiate to laparoscopy should consider limiting their early practice to right colectomies in patients who are thin and have limited risks of adhesions as well as benign disease process such as polyps or ileocolonic Crohn's strictures. Surgeons with advanced skills may be comfortable doing an entire total proctocolectomy and ileal pouch-anal anastomosis. All of these procedures have been technically described in this chapter to provide a range of procedures that are feasible. In addition to the technical range of possibilities, there is a range with respect to which patients will do well with the laparoscopic approach. As with any laparoscopic approach, for example, there would be some cases where a pneumoperitoneum is contraindicated and others where the disease or technical considerations represent contraindications. Indications and contraindications and pre- and intraoperative evaluations specific to the colon and rectal diseases and patient conditions are provided, followed by focused discussion on oncologic issues relevant to colon and rectal cancer and key points.

INDICATIONS

The indications for laparoscopic surgery for conditions of the colon and rectum are predominantly the same as those for open surgery (Table 37-2). For inflammatory bowel disease, the list of indications includes symptomatic failure of medical therapy; dysplasia; and presence of strictures, abscess, and fistula. In acute colitis, urgent subtotal colectomy with end ileostomy may be performed initially as a part of a two- or three-stage procedure. Procedures may include strictureplasty, small bowel resection, segmental colonic resection, or proctocolectomy. For diverticulitis, the current American Society of Colon and Rectal Surgeons (ASCRS) guidelines recommend that the decision for elective resection of sigmoid after

TABLE 37-1: ADVANTAGES OF LAPAROSCOPY

1. Smaller incision
2. Less post-op pain
3. Shorter hospitalization
4. Improved quality of life
5. Shorter posthospital recovery
6. Better cosmetic result
7. Reduction in post-op adhesions

recovering from acute diverticulitis should be made on a case-by-case basis and recommend the laparoscopic approach in selected patients.[3] Large colonic polyps not amenable for resection through the endoscope may be resected through laparoscopic approach. The laparoscopic approach has been proved to produce equivalent outcomes with open resection for localized colon cancer, when oncological principles are practiced. Solitary metastatic lesion in the liver with localized tumor in the colon can also be resected laparoscopically in competent hands.

The laparoscopic approach is preferred in the repair of rectal prolapse. Resection rectopexy and mesh rectopexy both can be performed through the laparoscopic approach. Laparoscopic rectopexy has similar long-term functional outcomes and low recurrence rates.[4] As discussed previously, a number of technical challenges are involved in performing laparoscopic rectal cancer resection. Large multicenter trials are going on in North America and Europe to evaluate the outcomes of rectal cancer for laparoscopic approach.

CONTRAINDICATIONS

General health conditions that would contraindicate a minimally invasive approach requiring a pneumoperitoneum typically include any severe manifestation of organ failure (Table 37-3). Patients with severe chronic obstructive pulmonary disease (COPD), reactive airway disease, or other causes of respiratory compromise are usually not tolerant of the abdominal insufflation required for conducting intra-abdominal work. Patients with advanced cardiovascular disease are also typically intolerant of the pneumoperitoneum, as it can restrict the fragile dynamics of cardiac output. Finally, patients with end-organ renal failure and severe electrolyte or fluid disturbances and those with liver failure, ascites, or other sources of bleeding disorders are best served with a more controlled, open approach. At times, these conditions are not appreciated as problematic until the procedure is under way and the anesthesiologist is experiencing difficulties. Accordingly, open lines of communication between the surgeon and the anesthesiologist as well as a willingness to convert to open surgery should be the rule and not the exception.

Less absolute or relative contraindications of laparoscopy include the presence of adhesions, cardiac abnormalities, pulmonary gas exchange abnormalities, chronic liver disease, and obesity. None of these are clear-cut or absolute. For example, patients may have several abdominal scars and have undergone numerous prior procedures even near the site of the anticipated colon resection, but they may not

TABLE 37-2: INDICATIONS IN COLON AND RECTAL DISEASES

1. Ulcerative colitis—refractory disease, dysplasia
2. Crohn's disease—refractory disease, bleeding, strictures, confined abscess, fistula
3. Diverticular disease—recurrent, noncomplicated
4. Volvulus
5. Colon polyps—not amenable to endoscopic resection
6. Carcinoma colon—localized lesions amenable to 8-cm extraction site
7. Rectal prolapse
8. Rectal cancer (in controlled trials)

TABLE 37-3: CONTRAINDICATIONS TO LAPAROSCOPY

Absolute contraindications	• Inability to tolerate pneumoperitoneum • Poor risk for general anesthesia • Poorly controlled coagulopathy • Severe systemic disease that is constant threat to life • Moribund patient, unlikely to survive for 24 h with/without surgery
Relative contraindications	• Multiple abdominal procedures • Cardiac abnormalities • Pulmonary gas exchange abnormalities • Chronic liver disease • Morbid obesity
Contraindications in colon diseases	• Large phlegmon or mass • Complex fistulizing disease • Tumor infiltrated into adjacent structures (T4 disease) • Bowel obstruction • Toxic dilation of the colon • Perforation • Significant adhesions
Contraindications in rectal diseases	• Large phlegmon or mass • Complex fistulizing disease • Locally infiltrative rectal cancer • Recurrent rectal cancer • Bowel obstruction • Toxic dilation of the colon • Perforation • Significant adhesions

have prohibitive adhesions. Unless we know the patient has prohibitive adhesions, we would approach the case laparoscopically with a cautionary note to the patient that the risk of conversion may be higher than 10–15%. The same can be said for obesity. At times, managing obese patients is facilitated by laparoscopy, such as when the fat is predominantly in the abdominal wall. That being said, some obesity cases cannot be conducted using laparoscopic techniques, for example when the tools will not reach from the port to the site of the surgical resection.

A final category of absolute and relative contraindications includes those specific to the disease under treatment. For inflammatory bowel disease a large phlegmonous mass, complex or large abscess, or complex fistulizing disease are likely not suitable for the bulk of the specimen to be extracted, not to mention the challenges of mobilization. Similarly, a toxic abdomen from sepsis or fecal contamination would not be ideal for laparoscopic surgery. Massive dilation of the large or small bowel could prohibit both intra-abdominal visualization and the safe movement of instruments throughout the abdominal cavity. In cases of cancer, there is little evidence in support of tackling large fixed or recurrent tumors through small incisions. The risk-benefit ratio for large, fixed, and recurrent tumors would likely favor open surgery, although it has never been prospectively studied.

PREOPERATIVE EVALUATIONS UNIQUE TO LAPAROSCOPIC SURGERY

A word must be said about the workup of patients who are intended for the minimally invasive surgical approach. Although the preoperative evaluations are usually the same as for any other laparotomy approach, it is generally advised that the diagnostic tests for the disease and the treatment be as definitive and clear as possible before laparoscopic surgery. The absence of tactile information demands better preoperative assessments than historically considered necessary for open surgery. This was first realized with tumor staging. The traditional approach with open surgery was to palpate the liver at the time of laparotomy to locate metastatic tumor deposits in the abdomen, including such sites as the liver, ovaries, peritoneal cavity, omentum, or retroperitoneal lymph nodes. Current imaging with computerized tomography (CT) has improved to the point that such novel findings at surgery are rare. Surgeons may identify small superficial hepatic metastases or peritoneal tumors at the time of surgery, but this is less common than it was when laparoscopic surgery was initiated in the early 1990s.

In a similar fashion, primary tumors need to be well localized prior to surgery. For the most part this can be accomplished by combining endoscopy with tattooing for small, benign lesions, or with CT imaging for large or malignant neoplasms. Endoscopy, although usually accurate, can be misleading because there are no consistent endoluminal landmarks for identifying colonic location. Early experiences with missed lesions and wrong-site resections brought these lessons forward. For malignant lesions it is often possible to see the mass on staging CT scan; this can be very reassuring for accurate localization. In addition to the preoperative testing, we advise that one never leave the operating room without first confirming that the target lesion has been confidently removed and identified in a specimen. Because colonoscopy can misjudge, anatomic colonic location by more than one colonic segment, this safety measure seems simple and warranted.

For benign conditions, it is equally important to localize the site of diseased bowel and understand the exact extent of disease, that is, complex versus simple fistula, contained mesenteric abscess versus poorly contained complex or perforated abscess. Of course, the size of the specimen will dictate the size of the extraction site. The larger the lesion to be extracted and the larger the incision, the less the benefit there is to the laparoscopic approach. For Crohn's disease, CT enterography may help reveal secondary sites of disease. We would also advise a complete intraoperative assessment of the small bowel in cases of Crohn's disease, especially in cases of stricturing disease.

INTRAOPERATIVE EVALUATIONS AND REASONS FOR CONVERSION

Conversion of laparoscopic procedure to open procedure may be required when difficulties are encountered. The reasons for conversion may include unexpected disease, significant adhesions, and inability to identify vital structures such as ureters. It is important to remember that conversion itself is not a complication, even though intraoperative complications necessitate conversion. It should not be viewed as failure but rather as an application of sound surgical judgment. It is probably safer for a surgeon to have low threshold for conversion, because the timing of conversion is critical to reduce not only overall costs but also complications. A decision to convert is best made early in the procedure, thus avoiding an increased risk of complications and reducing operative time. An early decision to convert will ensure that the rates of morbidity and mortality are maintained at acceptable levels.

For patients who are known to have frail tissues from chronic immunosuppression or other systemic conditions with adverse affects on tissues, extra caution should be taken in handling the bowel in particular but other tissues as well during the surgery. It is more difficult to judge the impact of instruments when there is an inability to use tactile information. These cases may benefit from the hand-assisted approach for that reason.

A final note should be made about the use of ureteral stents in minimally invasive cases. In general, we would not use ureteral stents for any case when they are not required in the correlating open surgery. With that said, we have a low threshold for having ureteral stents placed either preoperatively or during surgery when an inflammatory or tumor process obscures the anatomic location of the either ureter. If they are available and make a difference, the lighted ureteral stents can also be used to get a visual sense of location of the ureter.

ONCOLOGIC ISSUES SPECIFIC TO LAPAROSCOPIC SURGERY IN COLON AND RECTAL CANCER

Because of the unique controversies that emerged with the introduction of laparoscopic colectomy for cancer, we offer here a section that specifically covers this topic for both colon cancer and rectal cancer. Soon after the introduction of the laparoscopic colectomy in 1991,[1] a number of concerns regarding the application of this technique in colon cancer arose, including reports of tumor wound recurrences at trocar sites and tumor extraction sites.[5–7] Such reports were frequent enough that national statements were issued recommending a moratorium on laparoscopic colectomy for cancer outside of clinical trials.[8] In response, a number of randomized clinical trials were initiated simultaneously in North America, Canada, and in Europe. At least four large prospective, randomized trials have been completed and have reported both short- and long-term outcomes. To date, 3133 patients have been studied by random allocation to laparoscopic versus open surgery and followed for cancer outcomes. These patients are reported from four international trials, including the Barcelona trial[9] (219 patients), the COST (Clinical Outcomes of Surgical Therapy) trial[10] (872 patients), the COLOR (COlon cancer Laparoscopic or Open Resection) trial[11,12] (1248 patients), and the CLASICC (Conventional versus Laparoscopic-Assisted Surgery In Colorectal Cancer) trial[13,14] (794 patients). Short-term results from all four studies confirm equivalent mortality and rates of morbidity between the laparoscopic and the open arms. They also consistently demonstrate reductions in length of hospital stay, time to first feed, and time to first bowel movement. Quality of life, although modest, has also been confirmed.

At least three of these trials, the Barcelona, COST and COLOR trials, have completed 5-year follow-up for the entire cohort of patients. It has been reassuring that these trials have not demonstrated inferiority for the laparoscopic arm with respect to overall survival or disease-free survival. A pooled analysis of all four trials examining 3-year median survival was also conducted and it confirms the same, that is, no difference in overall survival or disease-free survival between the open and laparoscopic arms.[15] These data have encouraged the adoption of laparoscopic colectomy for colon cancer in the absence of harm and in the presence of confirmed benefits.

The same is not true for laparoscopic rectal cancer. Indeed, although there have been several clinical trials testing the equivalence of laparoscopic colectomy in the setting of curable colon cancer, there are few studies available to examine the same question in rectal cancer. For rectal cancer, the concerns are different than they were for colon cancer. The initial concern with using laparoscopic techniques in colon cancer focused on the potential for abnormal distribution of cancer cells due to the pneumoperitoneum. It was thought that the pneumoperitoneum created a "chimney effect"[16] that caused a focusing of tumor cells at wound sites such as trocar sites or wound extraction sites and increased the risk of tumor implants.[17] There was also at least a theoretical risk that it could cause dissemination of tumor cells through abnormal patterns. This has not been borne out in colon cancer and is not considered relevant, therefore, in rectal cancer. What is considered of relevance in rectal cancer is whether laparoscopic techniques can achieve tumor-free margins with the same rate as open surgery.[18] Some might argue that the pelvic dissection is facilitated by laparoscopic equipment and access to the deep pelvis with lighting and visualization superior to open surgery in some cases. This has not been proven in diverse practice settings. An additional concern is the ability to achieve distal stapling due to the limits of current instrumentation. These issues are being addressed by a prospective randomized trial conducted by the American College of Surgeons Oncology Group (ACOSOG).[19]

The ACOSOG Z6051 trial is a multicenter, phase III, randomized clinical trial with the primary objective that laparoscopic-assisted resection for rectal cancer is not inferior to open rectal resection, based on composite primary end point of oncologic factors that are indicative of a safe and feasible operation. The end point of this noninferiority trial is based on detailed and standardized pathologic evaluation of the specimen, including circumferential and distal margins and the completeness of the total mesorectal excision. The primary end point is a novel, surrogate end point for long-term oncologic outcome that reduces both the necessary accrual target of the trial and its time to maturation. The secondary end points include patient-related benefits (blood loss, length of stay, pain medicine utilization), 2-year local recurrence, and quality of life. The eligible criteria for the disease include T3N0M0, T1-3N1M0 adenocarcinoma of the rectum with the lower edge 12 cm or less from the anal verge and completion of 5-fluorouracil (5-FU) or capecitabine-based chemotherapy/radiotherapy in the last 4 weeks. The other patient criteria include age 18 years or greater, ECOG (Eastern Cooperative Oncology Group) performance status 2 or less, body mass index (BMI) 34 or less, no evidence of laparoscopic contraindications, no evidence of systemic disease precluding surgery, nonpregnant, nonlactating, no history of current or previous invasive pelvic malignancy, and no history of psychiatric illness. Surgeon credentialing in both laparoscopic colon and laparoscopic rectal surgery is required for participation in this study. It is based on having completed 20 laparoscopic-assisted resections each of the colon and rectum. The operative reports and the pathology reports of those cases and an unedited videotape of their laparoscopic rectal technique are reviewed by two designated investigators. This noninferiority trial is projected to enroll 650 eligible patients in the United States and Canada. The trial is sponsored by the National Cancer Institute (NCI). Further details and contact information can be obtained from the following website: http://www.cancer.gov/clinicaltrials/ACOSOG-Z6051.

Key Points

1. Accurate preoperative defining of the extent of the disease is a prerequisite to make the procedure successful.
2. Preoperative tattooing of the lesion with colonoscopy will aid in the localization of the tumor during the procedure.

3. Dense adhesions or extensive disease that prevents accurate identification of the vital structures and increases the risk of complications should cause the surgeon to convert early to an open procedure.
4. Care should be taken during handling of bowel in patients particularly on high-dose steroids due to increased fragility of the tissues. Atraumatic graspers or the HALS approach should be preferred to avoid direct grasping of the colon.
5. Placement of a ureteral stent should be considered when there is difficulty in locating one or both ureters as a result of inflammation or tumor in the retroperitoneum.
6. In case of malignancy or dysplasia, it is essential to perform a complete oncological resection. This includes adequate mobilization, high vascular ligation, satisfactory lymph node harvest, and negative resection margins. Intracorporeal ligation is required to achieve high vascular ligation.

GENERAL TECHNICAL INFORMATION

Equipment and Instruments

Basic laparoscopic equipment is common for most of the cases and detailed in the previous chapters (Table 37-4 and Fig. 37-1). Surgeon acquaintance and comfort with the equipment is more important than the exact specifications. A 30-degree laparoscope is more useful than the 0-degree laparoscope, particularly for visualization during mobilization of the flexures and working in the pelvis. Trocars should have the ability to be sutured or have stability threads to prevent dislodgement or leakage during the case. Cautery attachment should be on the upper side of the instruments so it does not interfere with hand movements during dissection or slip off as a result of gravity and repeated hand movements. TV monitors, light source, camera unit, and CO_2 insufflator should be placed on readily mobile units, to allow easy positioning and provide the surgeon with better ergonomics. Bowel handling graspers should be atraumatic in order to prevent serosal injury. The Babcock forceps are best applied along side the bowel, on the mesentery, or on opposing peritoneal surface. The atraumatic alligator bowel grasper can supplement the Babcock graspers while mobilizing the bowel because of its large surface area.

Although some might prefer the Veress needle for insufflating, we prefer the Hassan-type cannula and open insertion technique as they minimize the risk of injury to intra-abdominal structures. Instruments should be of sufficient length to reach up to the flexures and down into the pelvis from centrally located ports; this minimizes the need for extra ports. Total proctocolectomy and abdominal perineal resection (APR) procedures in particular require long instruments that are at least 38–40 cm. Care should be taken with the use of cutting devices (electrocautery and ultrasonic cutting devices) to minimize the risk of complications from the exposed metal components of the tools. The curved scissors allow more maneuverability, and the ability to cauterize with the curved scissors can save time.

TABLE 37-4: COMMONLY USED LAPAROSCOPIC INSTRUMENTS

1. Video camera unit
2. Light source
3. CO_2 insufflator
4. 30-degree laparoscope (5 or 10 mm)
5. Suction/irrigator
6. Cannulas (Hassan and 10/12 or 5 mm)
7. Scissors with cautery attachment
8. Babcock graspers
9. Intracorporeal vascular ligation device
10. Circular stapler for pelvic cases
11. Linear stapler (optional)
12. Automatic clip applier (optional)
13. LigaSure (optional)
14. Harmonic scalpel (optional)

SPECIAL DEVICES IN COLON AND RECTAL LAPAROSCOPIC SURGERY

Several options are now available for handling the colon mesentery. The automatic clip applier can be useful for dissecting the mesenteric vessels or controlling small- to medium-size bleeding vessels. LigaSure (ValleyLab, Boulder, CO) is used to fuse tissue bundles and vessels up to 7 mm diameter using a combination of pressure and thermal energy. The Harmonic scalpel utilizes ultrasonic energy in cutting and coagulating the tissues simultaneously and offers better precision. The laparoscopic linear stapler can serve a dual purpose as it allows transection of the colon without contamination and a vascular load can be used to transect a vascular pedicle. Special maneuvers with the linear stapler aid in the preparation of J-pouch and making of side-to-side anastomosis. Circular anastomotic stapler is used for making colocolic or ileocolic anastomosis.

PATIENT POSITION AND ROOM SETUP

Careful positioning and securing of the patient on the operating table is essential for safety of the procedure because steep inclinations of the operating table are required to assist in achieving proper exposure of the operative field. For the supine position, ankle straps ensure that steep Trendelenburg's position is tolerated and shoulder straps or bean bags can ensure that the patient does not shift side to side when the table is "air-planed" to the left or right. For synchronous cases, having the lower extremities secured in stirrups creates the same effect as ankle straps. For most cases, it is ideal to have the arms securely padded and strapped to the sides of the table. Generous padding at the elbow and neutral positioning of the wrist will minimize the risk of ulnar or median nerve injury, respectively, from pressure during long-duration surgery. A urinary catheter decompresses the bladder and a nasogastric

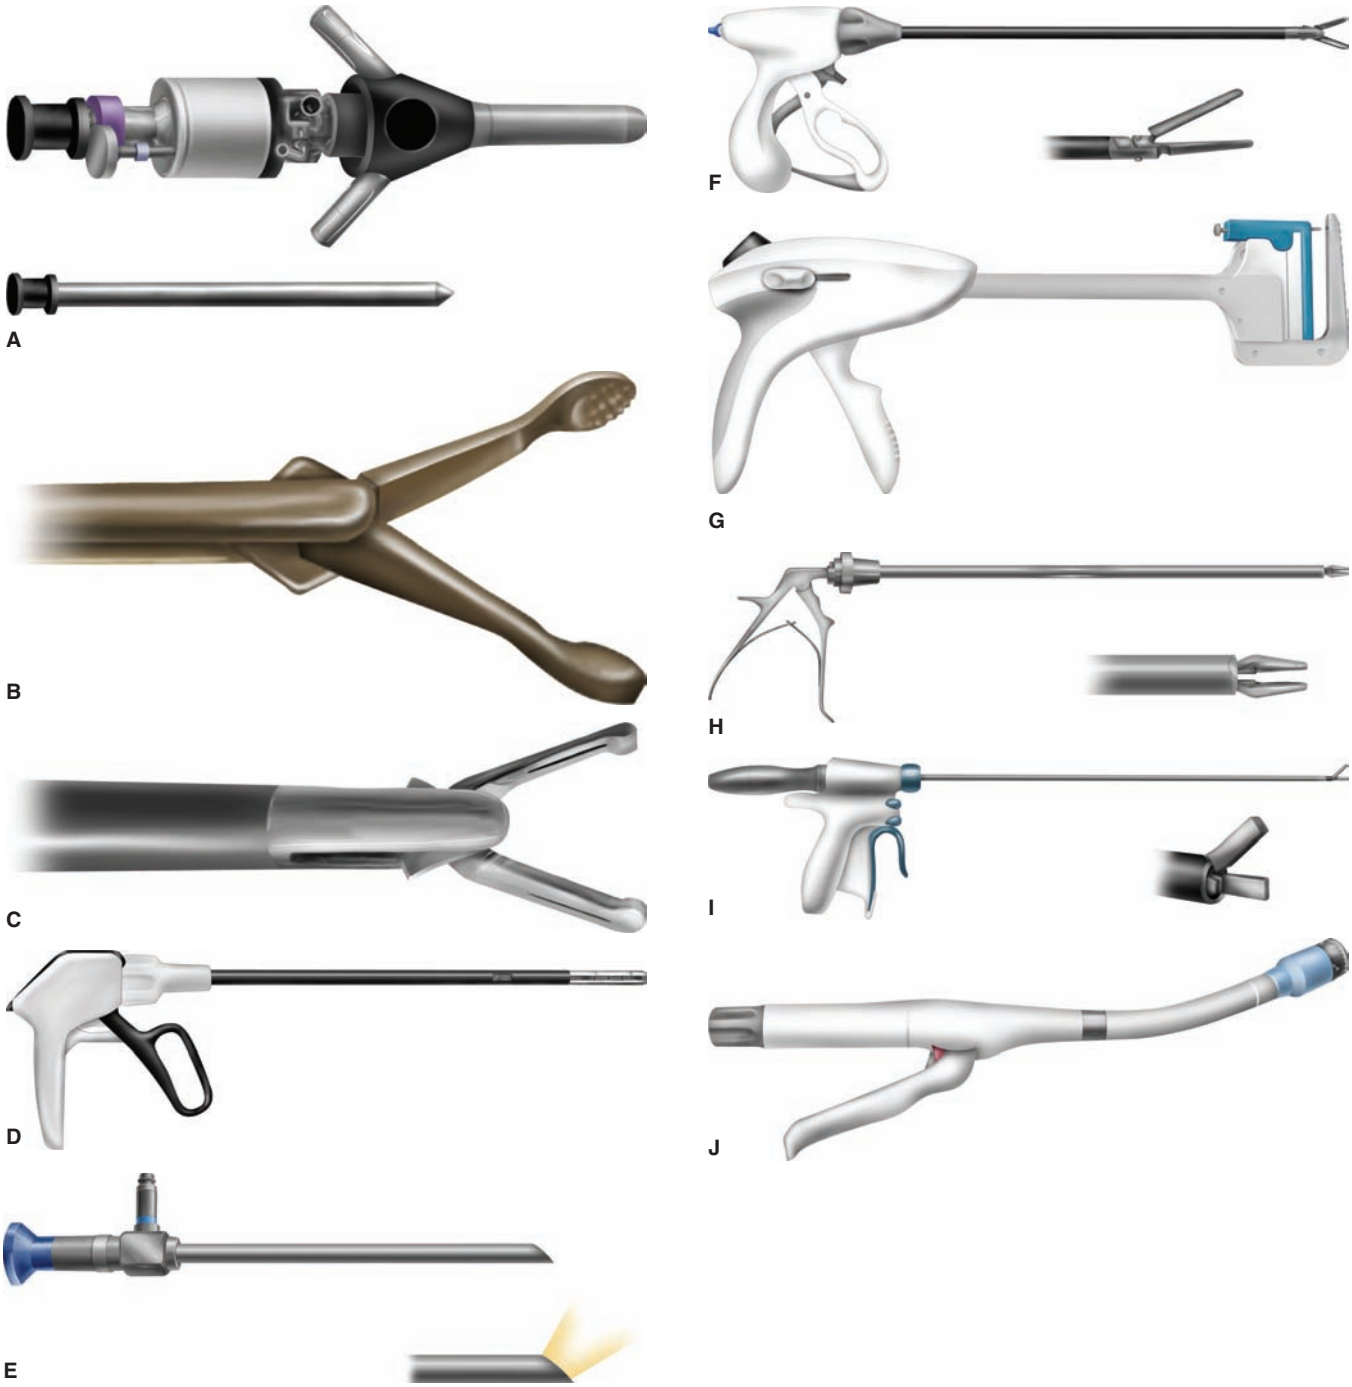

FIGURE 37-1 Laparoscopic instruments.

tube decompresses the stomach to avoid inadvertent injury and to maximize space in the abdominal cavity. The surgeon and the surgical assistant stand on the patient's side with the monitor on the opposite side to achieve consistent and in-line orientation of the field. The surgeon's eyes, hands, trocars, instrument tips, and monitor should all be directly parallel and closely aligned to minimize the difficulties associated with reverse image operating (Fig. 37-2).

PORT PLACEMENT TECHNIQUE

A cut-down technique is used to insert Hassan's trocar, with Hassan's cannula as the first port. Pneumoperitoneum is achieved by insufflation of carbon dioxide to 12–14 mm Hg. A 30-degree laparoscope is the preferred camera as it offers the optimal operative view. The rest of the ports are inserted under direct visual guidance.

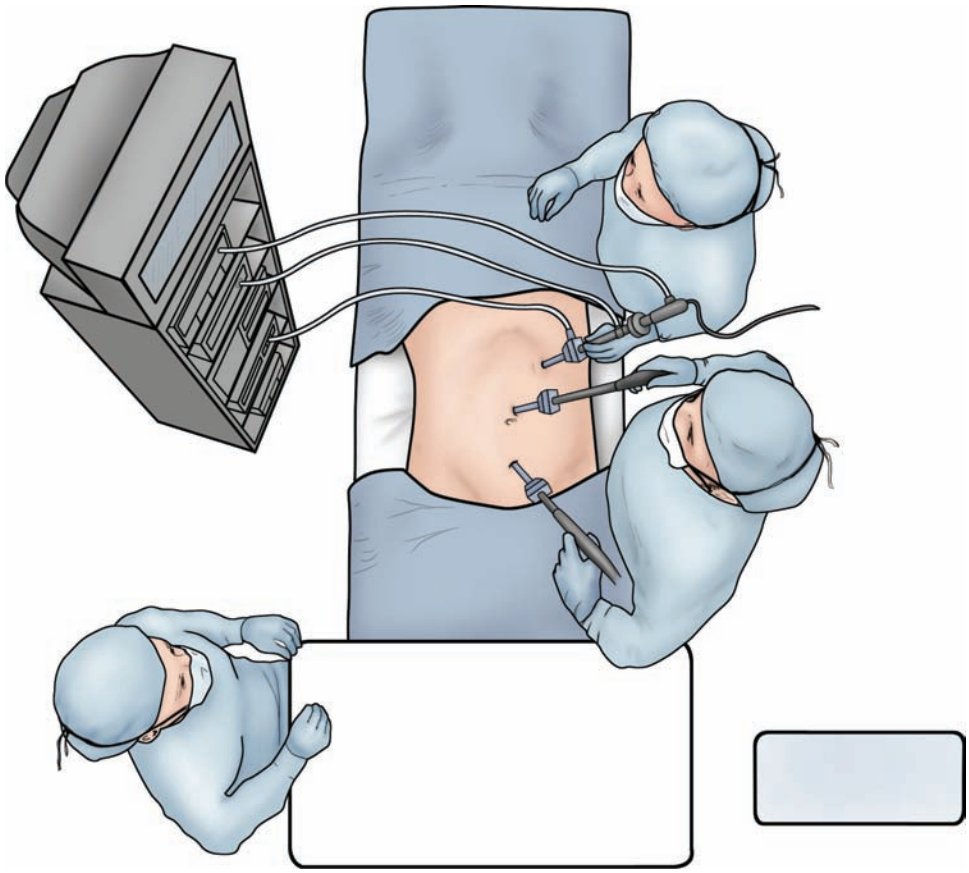

FIGURE 37-2 Position of equipment and the surgical team for laparoscopic right hemicolectomy. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

WOUND CLOSURE

Trocars are removed after the pneumoperitoneum is fully released through the cannulas to avoid sucking of the bowel into the port sites and to avoid the concentration of tumor cells at the trocar sites in cancer cases. The 5-mm port sites do not require fascial closure unless there is significant enlargement of the fascia during the procedure. Port site closure should include peritoneum and fascia when they are 10 mm or greater. The lateral ports are closed under direct visualization prior to closure of midline wounds. The "Endo Close" spring-loaded suturing device can be used to close the incision. The fascia is closed with a figure-of-eight suture and an extracorporeal knot is tied. A purse-string suture is an option for closing the periumbilical site.

Right Hemicolectomy

STEP 1: PATIENT POSITION AND ROOM SETUP

The patient is carefully positioned supine and secured on the operating table as described previously. The surgeon and the surgical assistant stand on the patient's left side with the monitor on the right side to achieve consistent and in-line orientation of the field. The instrument table is easily accommodated at the foot of the bed and the scrub nurse on the patient's right side.

STEP 2: PORT PLACEMENT AND EXPLORATION

A 10- to 12- mm port is placed in the supraumbilical area using an open cut-down technique. A different site is preferred (typically left upper quadrant [LUQ]) when a midline scar is present and extensive adhesions are anticipated. A 30-degree camera is passed through this port, and under direct vision two 5-mm trocars are placed—one in the LUQ lateral to the epigastric vessels and 2 cm below the costal margin and the other in the suprapubic midline (Fig. 37-3). As an alternative, one can place three 10- to 12-mm trocars; this allows maximum flexibility for placement of instruments and the camera, but the more experienced surgeon may exchange one or more for 5-mm trocars.

Simple adhesions encountered at this stage should be divided. Then, an inspection of the abdominal cavity should be performed to confirm the pathology for which surgery was indicated and to exclude other pathology. The presence of a locally adherent or bulky tumor should be approached with a conversion to open surgery. The liver is carefully inspected for metastatic disease. If resectable metastases are identified, we would convert to open surgery. Some surgeons are comfortable with laparoscopic removal of hepatic metastasis

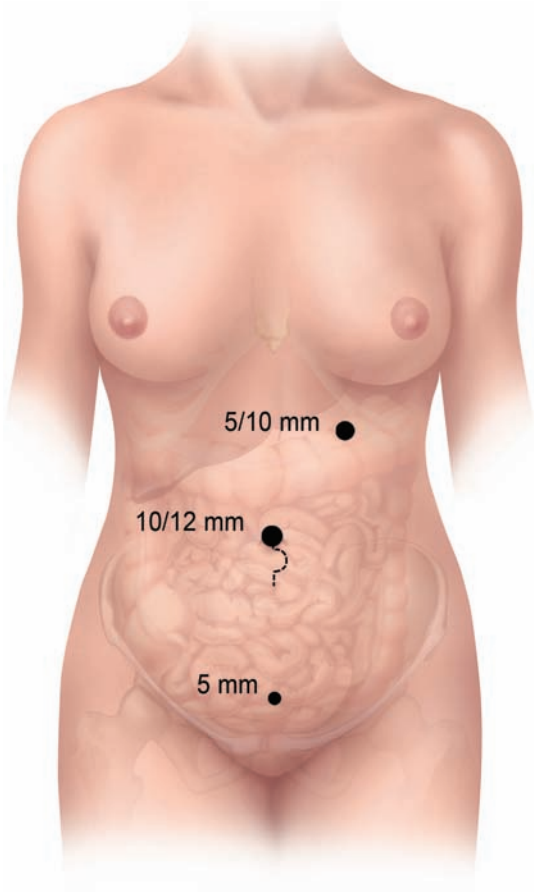

FIGURE 37-3 Position of laparoscopic instruments for right hemicolectomy. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

or choose to address at subsequent surgery. Alligator or Babcock graspers are preferred to raise each liver lobe to view all surfaces. The peritoneal surfaces should then be inspected to exclude metastases. In cases of Crohn's disease the entire small bowel should be inspected for secondary sites of disease not detected by preoperative imaging.

STEP 3: MOBILIZATION OF THE CECUM

The patient is placed in a steep Trendelenburg position, with the right side of the table inclined upward. The 30-degree laparoscope is deployed through the LUQ port. The pelvis is viewed to ensure that the small bowel loops can be moved up into the upper abdomen; in the absence of adhesions it is often simplest to sweep the mesentery of the bowel along with the bowel into the left upper quadrant. Right lower quadrant (RLQ) adhesions are not uncommon due to the prevalence of hysterectomy, oophorectomy, and appendectomy procedures in the general population. Presence of significant adhesions in the pelvis (eg, inability to extract terminal ileum from the pelvis) is an indication for early conversion to open procedure at this point, as full exteriorization will not be possible later.

The next step is to identify the right ureter at the pelvic brim, where it runs over the bifurcation of the common iliac artery (Fig. 37-4). In an obese patient, the ureter is identified after opening peritoneum. It is important to be patient and wait to observe peristalsis in the ureter to avoid mistaking the psoas tendon or the gonadal vessels for the ureter. The cecum is then pushed or gently grasped with a Babcock from the supra umbilical port and elevated medially and toward the head. The peritoneum around the base of the terminal ileum and the cecum is then opened with the scissors through supraumbilical port, and correct retroperitoneal plane is entered. Using a grasper on the cut peritoneal edge and not on the bowel, the right lateral peritoneal reflection is opened along the white line of Toldt toward the hepatic flexure. Care should be taken to initially divide only the superficial layer of the peritoneum. As the dissection proceeds toward the hepatic flexure, the pneumoperitoneum helps separate the tissue planes. The plane between the colon mesentery and the Gerota fascia is then developed using a combination of blunt dissection and cautery and care must be taken to avoid dissection behind the kidney.

The peritoneum on the medial side of the terminal ileum should be incised to allow full mobilization of the cecum. Upward tension should be applied on the peritoneal fold medial to the terminal ileum, and incision is made in the superficial peritoneal layer along side the pelvic brim superior and parallel to the right iliac artery. The dissection is continued up to the level of the duodenum. Then the lateral dissection is advanced medially with care until the inferior vena cava inferiorly and duodenum superiorly. These two structures indicate the achievement of sufficient dissection.

STEP 4: MOBILIZATION OF THE HEPATIC FLEXURE

The patient is now placed in reverse Trendelenburg's position with the right side steeply inclined upward. The laparoscope is shifted into the suprapubic port and the surgeon and the assistant trade positions. The hepatocolic ligaments are grasped just cephalad to the colon and traction placed obliquely to elevate the tissues toward the anterior abdominal wall and inferiorly. The hepatocolic ligament is divided with electrocautery scissors or an ultrasonic dissector, as preferred. Blunt dissection is then performed to separate the underlying tissue from the peritoneum. Occasionally larger vessels encountered require clips. The dissection is then continued along the gastrocolic ligament, identifying the plane between this and the transverse mesorectum, until the level of falciform ligament is reached. Care should be taken during this dissection not to damage the duodenum as the hepatic flexure is mobilized off the retroperitoneum in the right upper quadrant (RUQ) (Fig. 37-5). At this point, the whole right colon is mobilized to the midline and the right retroperitoneum is exposed, allowing visualization of the duodenum, Gerota's fascia, and the right ureter.

STEP 5: VASCULAR DIVISION

Vascular ligation and division of the mesenteric vessels can be performed either by intra- or extracorporeal method. The surgeon and the assistant are back to original positions with the

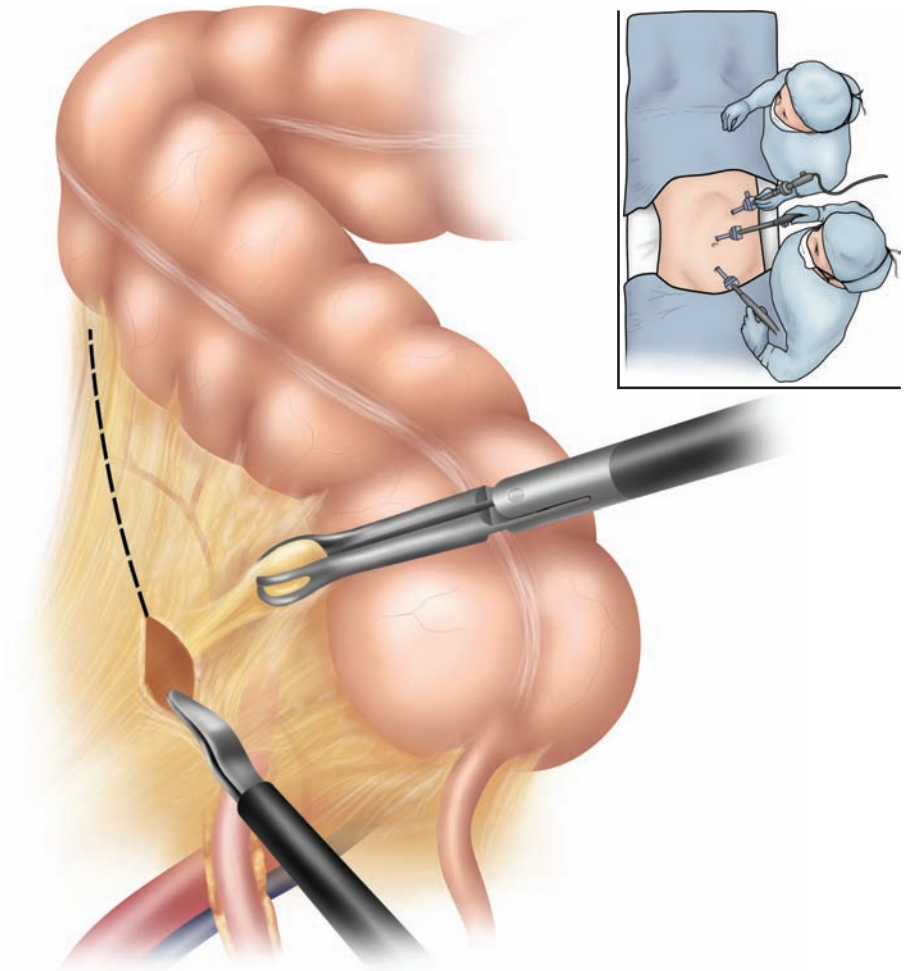

FIGURE 37-4 Mobilization of cecum. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

laparoscope placed through the LUQ port. The intracorporeal method should be used for obese patients as it is difficult to exteriorize the ileocolic pedicle. Intracorporeal ligation is preferred for the malignant diseases to ensure proximal ligation of the vessels (Fig. 37-6). Upward tension is applied on the right colon to display the ileocolic and right colic vessels, and, once mesenteric windows are created, the vessels are ligated with hemoclip, Endoloop devices (Ethicon, Cincinnati, OH), or a linear vascular stapler. It is important to visualize or palpate the junction of the ileocolic and superior mesenteric vessels to provide proximal resection of lymphatics in cancer cases without compromising blood flow to the rest of the small bowel.

STEP 6: EXTERIORIZATION

Once intracorporeal ligation has completed or if extracorporeal ligation has to be performed, the table is returned to a neutral position. A Babcock grasper is placed through the suprapubic port and applied to the appendix or ligament of Treves or the mesentery of the cecum. The pneumoperitoneum is vented out through the ports and the camera equipment removed. Then a small (4–6 cm) vertical incision is made for purposes of colon exteriorization; typically it is more cephalad than caudal to the umbilicus. The wound edges are protected with a wound guard and then the bowel is exteriorized with the help of Babcock grasper left already at the level of the cecum. The right colon is exteriorized from the terminal ileum to the transverse colon (Fig. 37-7). It is generally not necessary to have divided the omentum intracorporeally as it can also be exteriorized through the incision unless it is bulky. Once the bowel is exteriorized, vascular ligation is performed in a standard manner.

STEP 7: ANASTOMOSIS

The mesenteric and bowel division, vascular ligation if appropriate, and anastomosis can be completed after exteriorization in an identical way to standard laparotomy. This degree of mobilization allows for a hand-sewn end-to-end anastomosis or a wide, stapled side-to-side anastomosis. Following anastomosis, the bowel is then gently returned into the abdominal cavity. Irrigation of the abdominal cavity is performed at this time. The irrigation process is conducted through the open wound and can make use of standard suction devices without the need for the laparoscopic suction

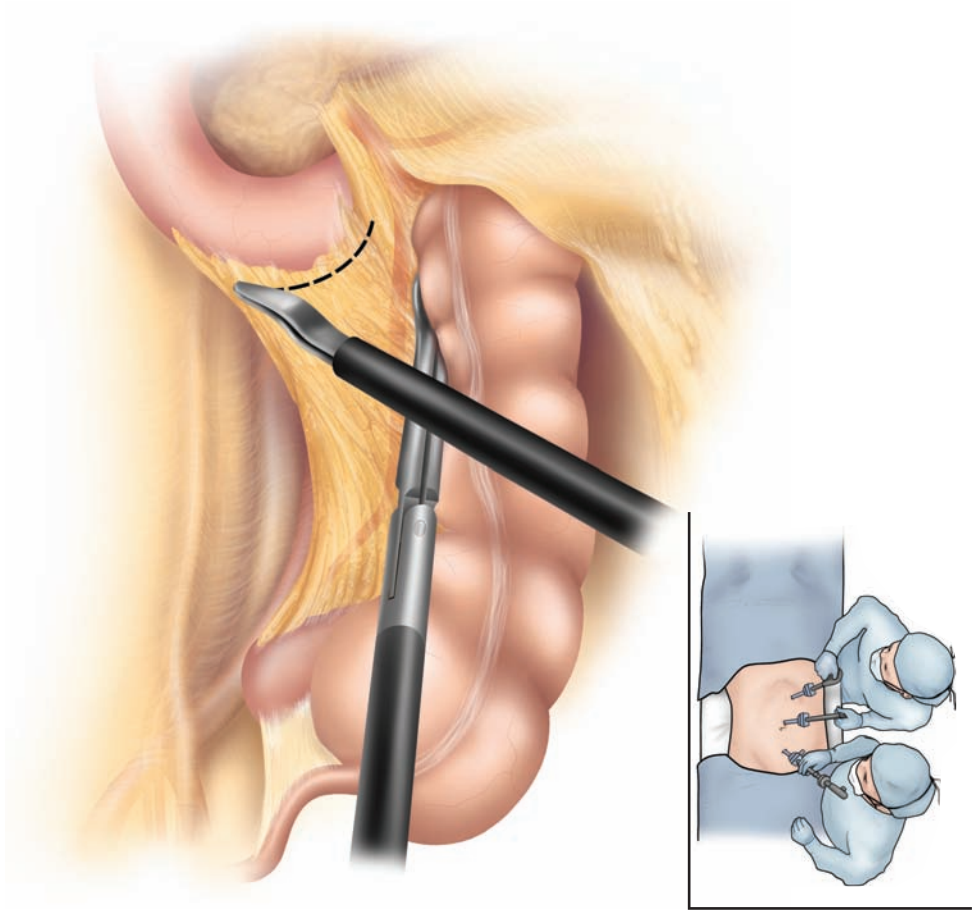

FIGURE 37-5 Mobilization of hepatic flexure. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

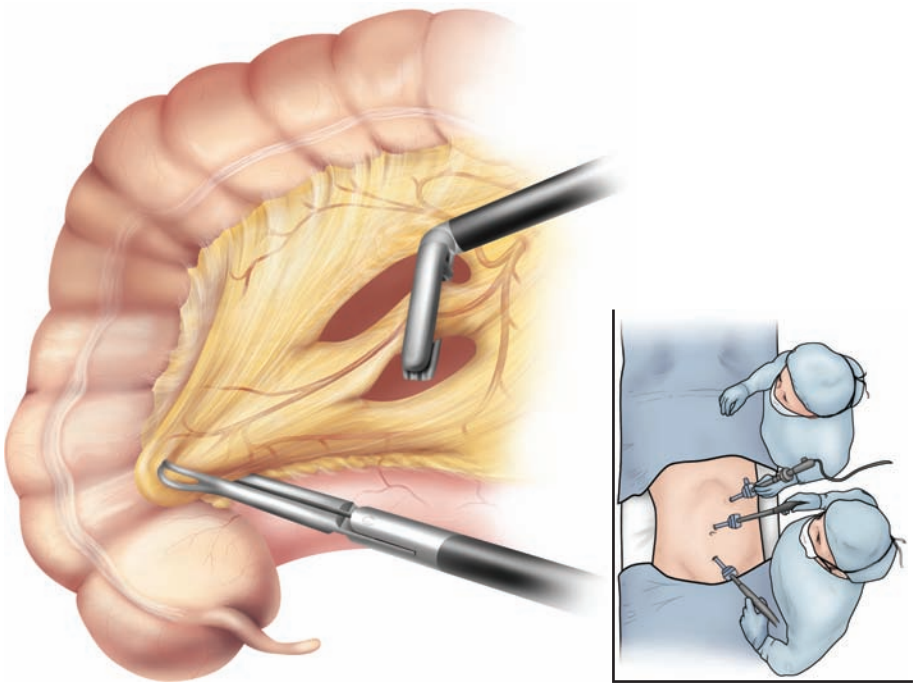

FIGURE 37-6 Intracorporeal division of vasculature of right colon. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

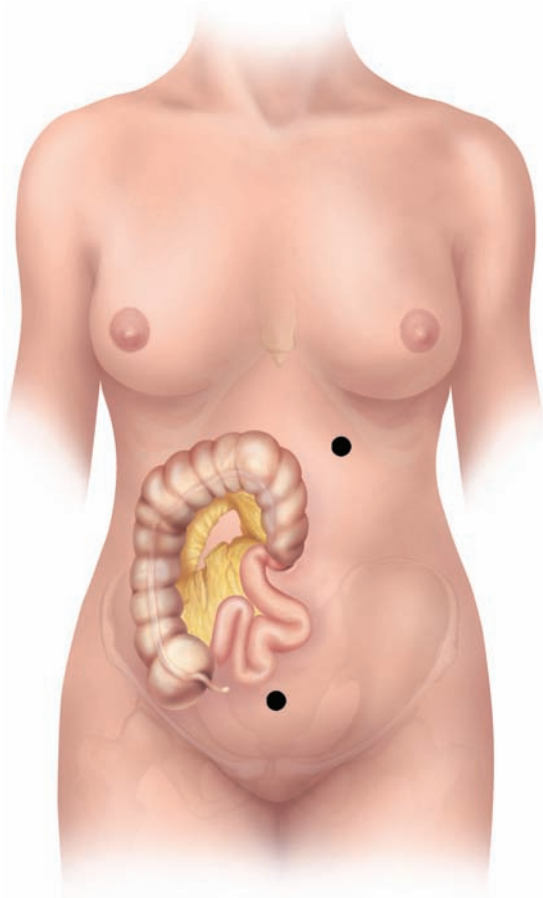

FIGURE 37-7 Exteriorization of right colon. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

irrigator equipment. The aspirate from the irrigation process is inspected to determine whether it is clear or bloody. If the aspirate is blood-stained, the abdomen may need to be reevaluated by reestablishing the pneumoperitoneum. In our experience, it is rare to have to reinspect using the pneumoperitoneum. By using Harrington-type retractor, inspection through the periumbilical incision allows for visualization of the port sites as the trocars are removed. Copious irrigation of all the wounds is then performed. The incisions are closed in two layers, fascia, and skin.

Alternative Technique for Right Hemicolectomy

An alternative technique, in which the dissection starts from the medial aspect and extends laterally, is also practiced for right hemicolectomy. The dissection commences with the opening the peritoneum of right mesocolon. This allows for the mobilization of the colon with minimal manipulations. The right colic and ileocolic vessels are identified first and ligated using clips or vascular stapler. Then the peritoneal incision is extended superiorly toward the transverse colon, and then the dissection continues along the transverse colon inferiorly and along hepatic flexure, ascending colon and cecum medially. After the colon is freed from the peritoneal attachments on the medial side, the dissection continues along the white line of Toldt, starting from the cecum to the hepatic flexure and the transverse colon (Fig. 37-8). The right colon is

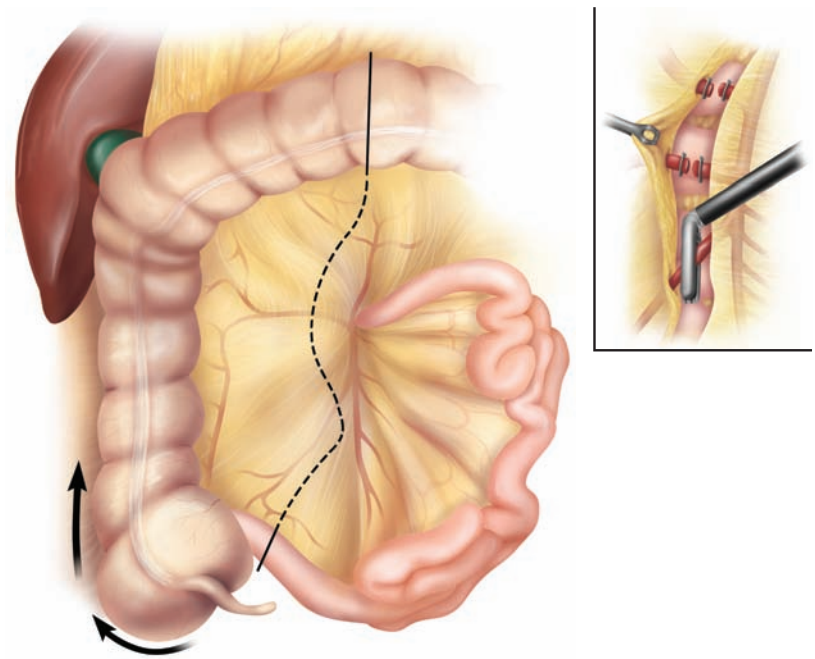

FIGURE 37-8 Alternative technique for right hemicolectomy—medial to lateral dissection. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

detached from all the attachments and it is then brought outside from the extended skin incision at the umbilicus. Then the right colon is resected extracorporeally and ileocolic anastomosis performed as described in the previously mentioned method. Although we do not practice this approach, it is gaining in popularity and seems to carry no major disadvantage.

Left Hemicolectomy

The left hemicolectomy procedure is similar to the right colectomy, only in mirror-image reverse. One major difference is the care that must be taken around the spleen. The hand-assisted approach can facilitate management of the splenic flexure and therefore it is described as an alternative approach.

STEP 1: PATIENT POSITION AND ROOM SETUP

Positioning and securing of the patient on the operating table is done in a similar fashion as right hemicolectomy. The surgeon and the surgical assistant stand on the right side with the monitor on the left side and parallel in-line orientation is maintained. The instrument table is accommodated at the foot of the bed and the scrub nurse on the patient's left side.

STEP 2: PORT PLACEMENT AND EXPLORATION

A four-port technique is used with ports in the supraumbilical area, suprapubic area, right upper quadrant, and left lower quadrant (LLQ) (Fig. 37-9). Simple adhesions encountered at this stage should be divided. Then a careful inspection should be done to confirm the pathology and any presence of additional disease. Conversion to open procedure should be made for the same conditions and indications as described for the right colectomy.

STEP 3: MOBILIZATION OF THE LEFT COLON

The patient is placed in a steep Trendelenburg position, with the left side of the table inclined upward, and the small bowel loops are swept to the right side of the abdominal cavity using the graspers. The left ureter is identified before proceeding with the dissection. The dissection commences lateral to the proximal sigmoid colon. The peritoneum is incised and then dissected along the white line of Toldt toward the splenic flexure (Fig. 37-10). The plane is developed carefully avoiding kidney injury, between the colon mesentery and the Gerota fascia. Then the lateral dissection is advanced medially until the aorta is reached.

STEP 4: MOBILIZATION OF THE SPLENIC FLEXURE

The patient is now placed in reverse Trendelenburg's position with the left side steeply inclined upward. The surgeon

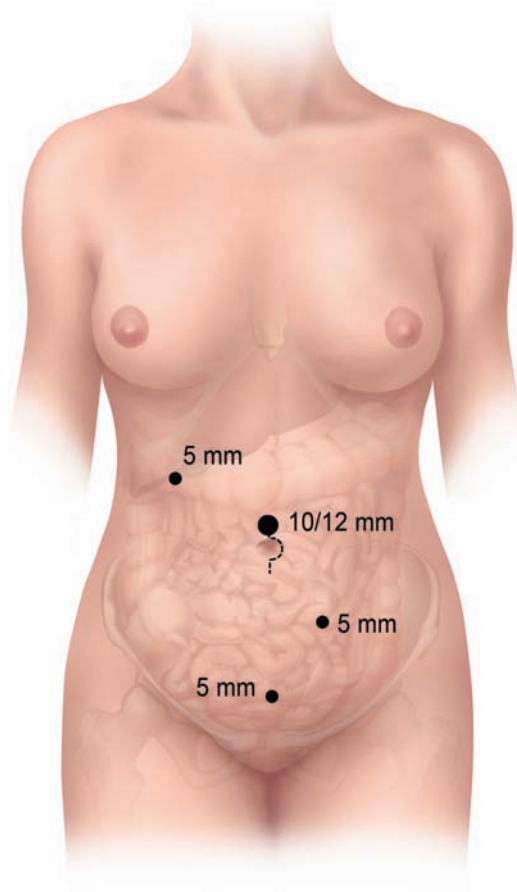

FIGURE 37-9 Position of laparoscopic ports for left hemicolectomy. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

standing between the legs of the patient and the assistant on the right side with in-line arrangement of camera, monitor, and the instruments provide better surgical ergonomics. The instruments are repositioned with grasper through the suprapubic port and the cutting instrument through the left lateral port. The assistant grasps the greater omentum superior to the distal transverse colon through right lateral port and retracts upward toward the abdominal wall cranially (Fig. 37-11). With the countertraction, the surgeon incises the peritoneum and enters the lesser sac. The dissection is then advanced parallel to the transverse colon to open up the lesser sac and mobilize the transverse colon. The dissection then advanced toward the lateral dissection so that the splenic flexure is completely mobilized to the level of the umbilicus.

STEPS 5–7: VASCULAR DIVISION, EXTERIORIZATION, AND ANASTOMOSIS

Vascular ligation and division of the mesenteric vessels are performed either by incorporeal or extracorporeal method. The colon is exteriorized through the 4- to 6-cm midline vertical incision and anastomosis is performed in a similar fashion as in right hemicolectomy.

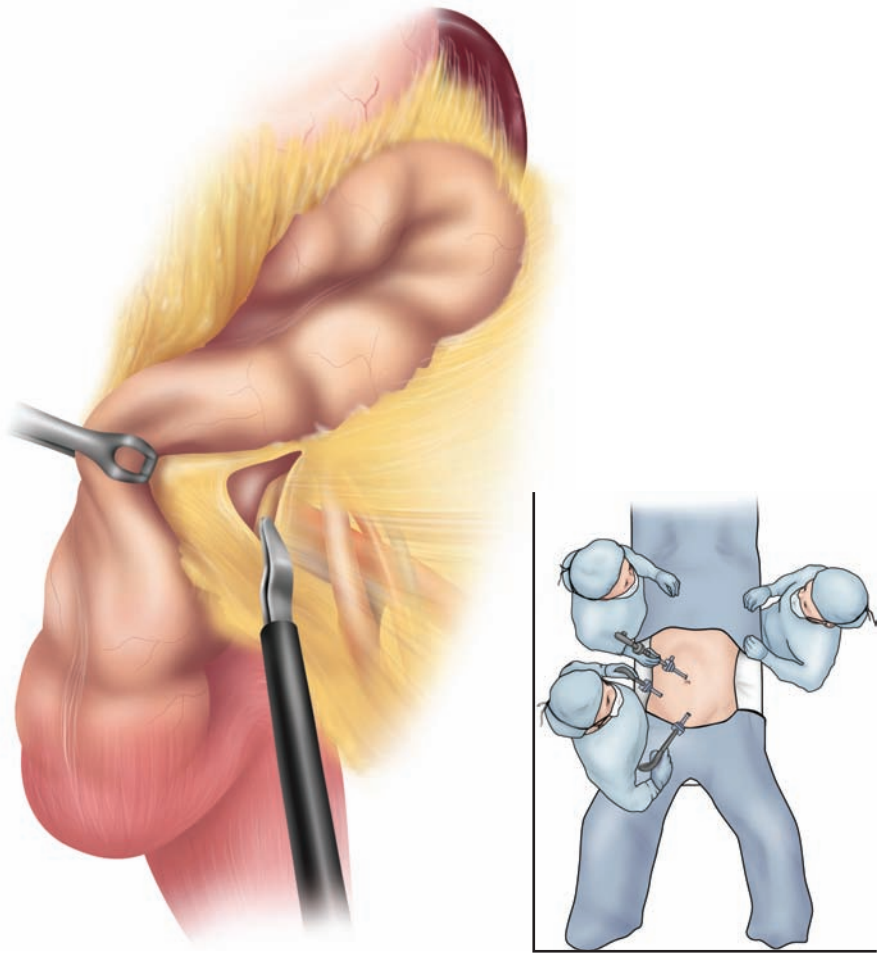

FIGURE 37-10 Mobilization of left colon. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

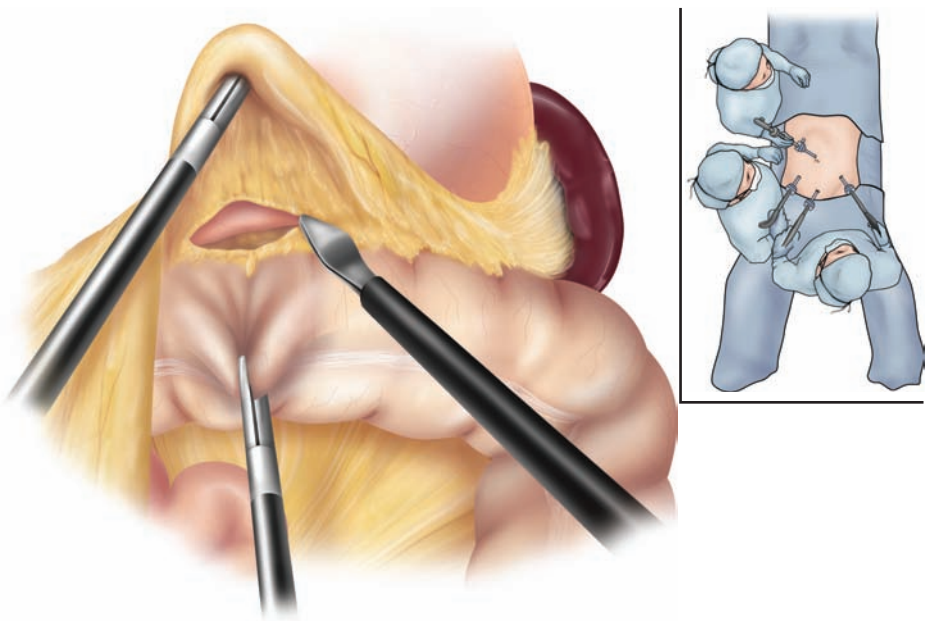

FIGURE 37-11 Mobilization of splenic flexure. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

HAND-ASSISTED LAPAROSCOPIC SURGERY

Hand-Assisted Laparoscopic Left Hemicolectomy

STEP 1: PATIENT POSITION AND ROOM SETUP

The patient is positioned and secured on the operating table in a similar fashion as for a laparoscopic-assisted procedure.

STEP 2: PORT PLACEMENT AND EXPLORATION

Lower midline incision is made below the umbilicus. The hand port should be placed in such a position where the nondominant hand acts like a laparoscopic retractor. The incision size should be one-half size smaller than the operator's hand size, and the incision length should remain the same through all layers of the abdomen to avoid leakage of air around the hand port (Fig. 37-12). Gelport is the new generation of multifunctional hand port that allows the usage of hand, laparoscope, and laparoscopic trocars, and maintains an airtight seal when the hand is removed. The surgeon's hand through the hand port guides the insertion of 30-degree laparoscope in the periumbilical region. A 5/10-mm port for scissors with cautery is made in the left lower quadrant under laparoscopic visualization (Fig. 37-13).

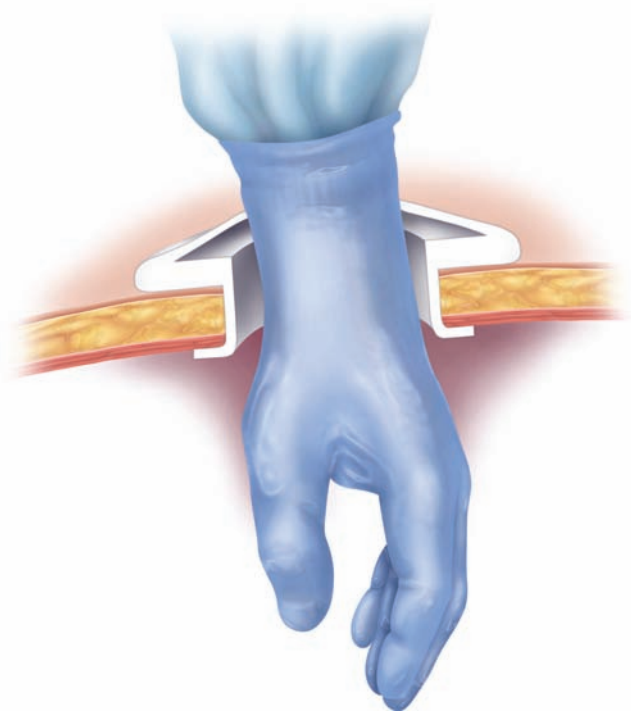

FIGURE 37-12 Position of hand following insertion through hand port. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

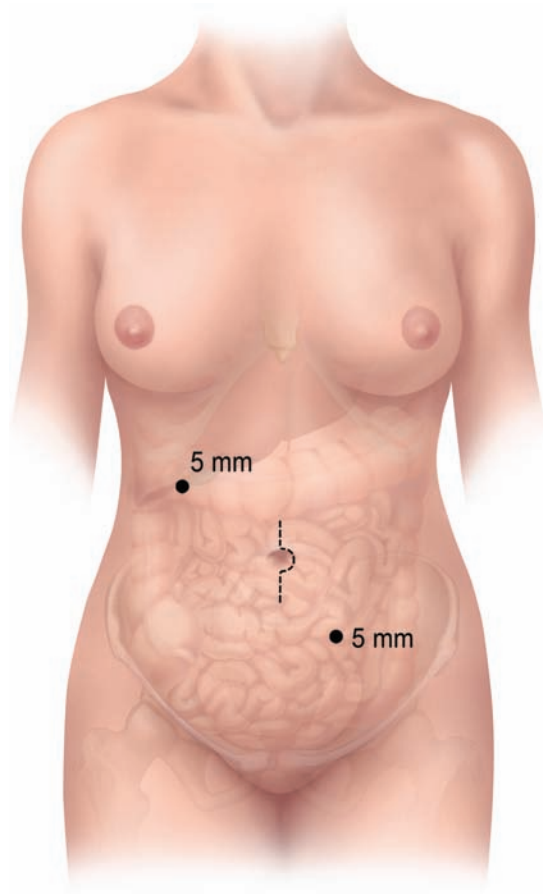

FIGURE 37-13 Position of incision for hand port and laparoscopic ports for left hemicolectomy. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

STEP 3: MOBILIZATION OF THE LEFT COLON AND SPLENIC FLEXURE

The traction is achieved when the hand and the colon is dissected in the similar fashion described previously for the laparoscopic hemicolectomy (Figs. 37-14 through and 37-16). A grasper can be introduced through 5-mm cannula in the right lower quadrant to achieve additional traction for adequate mobilization of the spleen.

STEPS 4–6: VASCULAR DIVISION, EXTERIORIZATION, AND ANASTOMOSIS

Vascular ligation and division of the vessels is typically performed using intracorporeal techniques. The colon is exteriorized through the hand port and divided, and anastomosis is performed with either hand-sewn technique or standard stapled method.

SIGMOID COLECTOMY:

STEP 1: PATIENT POSITION

The patient is placed and secured on the operating table in modified lithotomy position same as for left hemicolectomy.

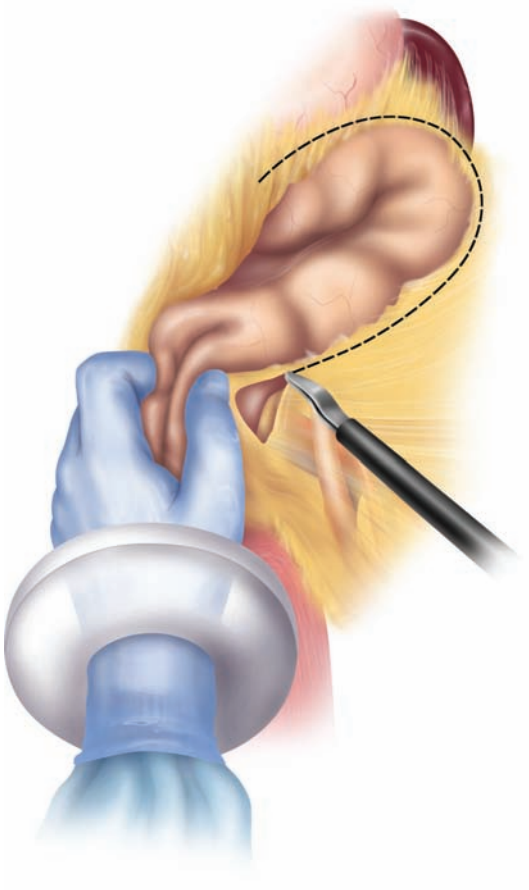

FIGURE 37-14 Hand-assisted mobilization of left colon. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

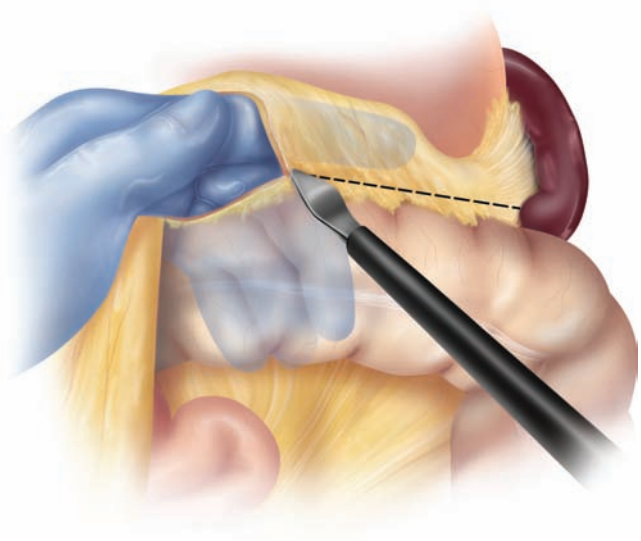

FIGURE 37-15 Hand-assisted mobilization of splenic flexure—omental attachments. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

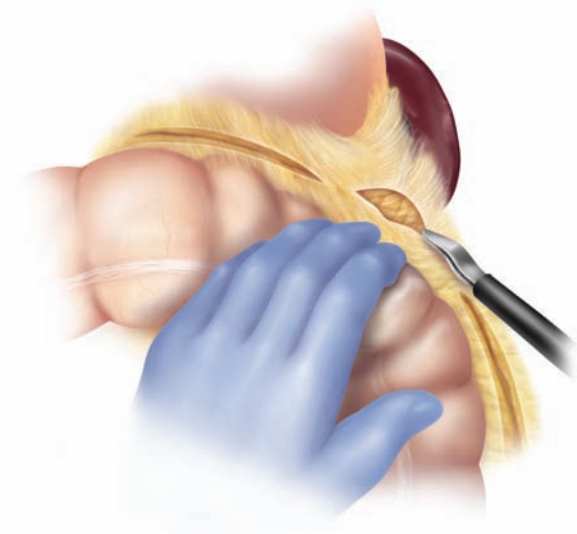

FIGURE 37-16 Hand-assisted mobilization of splenic flexure. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

The surgeon and the surgical assistant stand on the right side of the patient, and the camera, trocars, and the monitor are aligned parallel to minimize reverse image operating.

STEP 2: PORT PLACEMENT AND EXPLORATION

The laparoscope is inserted through the supraumbilical port and the trocars are placed under visualization in suprapubic, right, and left lower lateral positions (Fig. 37-17). The abdominal cavity should be inspected with confirmation of the indicated pathology and other pathology excluded, as previously described.

STEP 3: MOBILIZATION OF THE PROXIMAL SIGMOID AND DESCENDING COLON

The patient is placed in steep Trendelenburg's position with the left side of the table inclined upward. The 30-degree laparoscope is deployed through the supraumbilical port and the small bowel loops are swept to the right side. The left ureter is identified at the pelvic brim. Conversion to an open procedure is necessary if the ureter cannot be identified confidently. The ureter is swept down and away in order to avoid injury during ligation of the mesenteric vessels. The dissection commences lateral into the left ureter by incising peritoneum lateral to the sigmoid colon. The dissection continues along the white line of Toldt toward the splenic flexure in the same manner as done for left hemicolectomy. Mobilization of splenic flexure is performed as required.

STEP 4: MOBILIZATION OF THE DISTAL SIGMOID COLON AND UPPER RECTUM

After mobilizing the descending colon completely, the dissection is now directed caudally. With the retraction of the

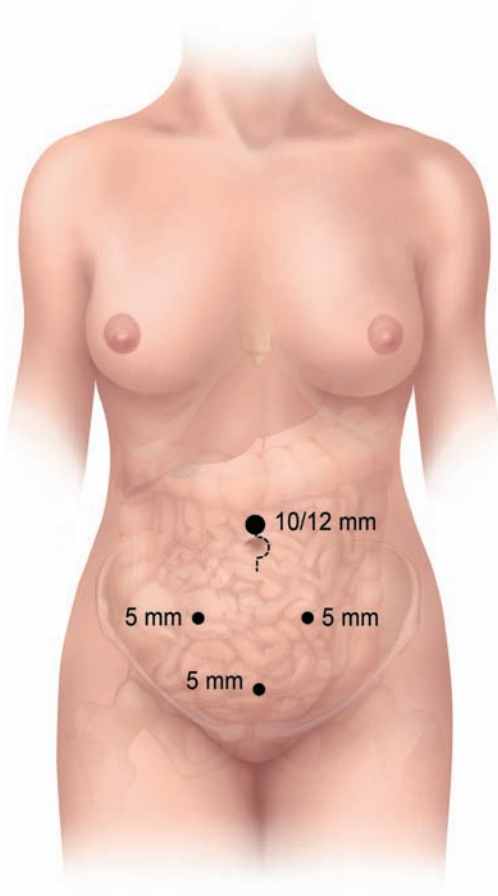

FIGURE 37-17 Position of laparoscopic ports for sigmoid colectomy and anterior resection. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

sigmoid colon cephalad and medially, the peritoneal incision is then extended distally to the midrectum entering the presacral space. The left ureter and the iliac vessels are identified and protected throughout this part of the procedure (Fig. 37-18). The presacral space is developed by the division of the fine adhesions and care should be taken to protect hypogastric nerves by sweeping them backward toward the sacrum.

STEPS 5 AND 6: VASCULAR LIGATION AND EXTERIORIZATION

The sigmoid colon is elevated anteriorly and inferiorly to expose the mesenteric vessels. Then incision is made in the avascular plane on both sides of the vessels. The superior hemorrhoidal and sigmoid vessels are isolated and ligated at the level of aortic bifurcation using vascular staplers, clips, or Endoloop devices (Fig. 37-19). We ligate just distal to the takeoff of the left colic vessel. Some surgeons express a preference for ligation at the origin of the inferior mesenteric artery, proximal to the left colic branch. The sigmoid becomes more mobile after the ligation of the vascular pedicle. The upper rectum is then divided using a linear cutting stapler (Fig. 37-20).

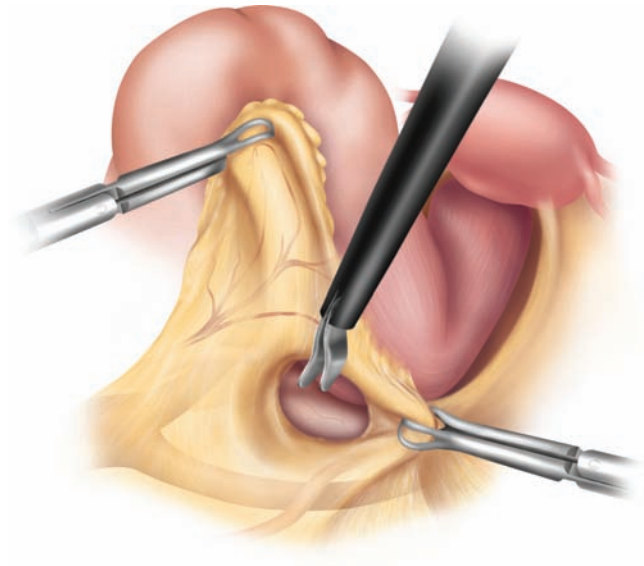

FIGURE 37-18 Mobilization of upper rectum. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

Then the pneumoperitoneum is vented out via the laparoscopic ports. The divided sigmoid colon is brought out through the extension of the LLQ incision. The proximal colon is divided at the sigmoid and descending colon junction.

STEP 7: ANASTOMOSIS

A purse-string suture is inserted around the colon that is tied around the anvil of the staple gun inserted into the lumen. Then the colon is returned to the abdominal cavity. The peritoneal

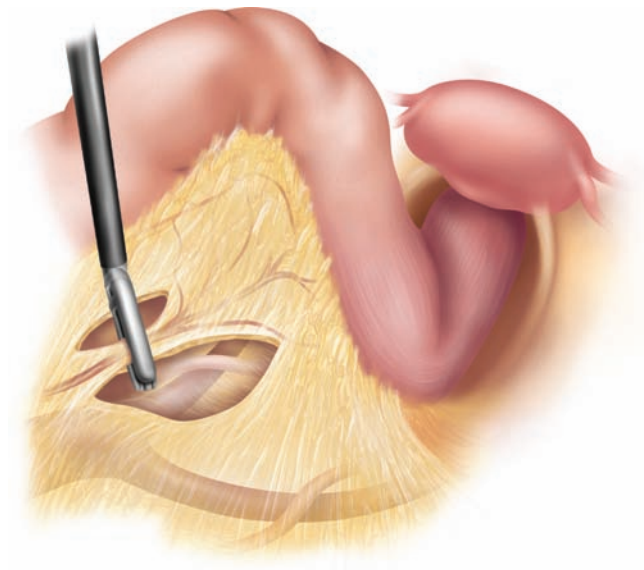

FIGURE 37-19 Intracorporeal vascular division of superior hemorrhoidal and sigmoidal vessels. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

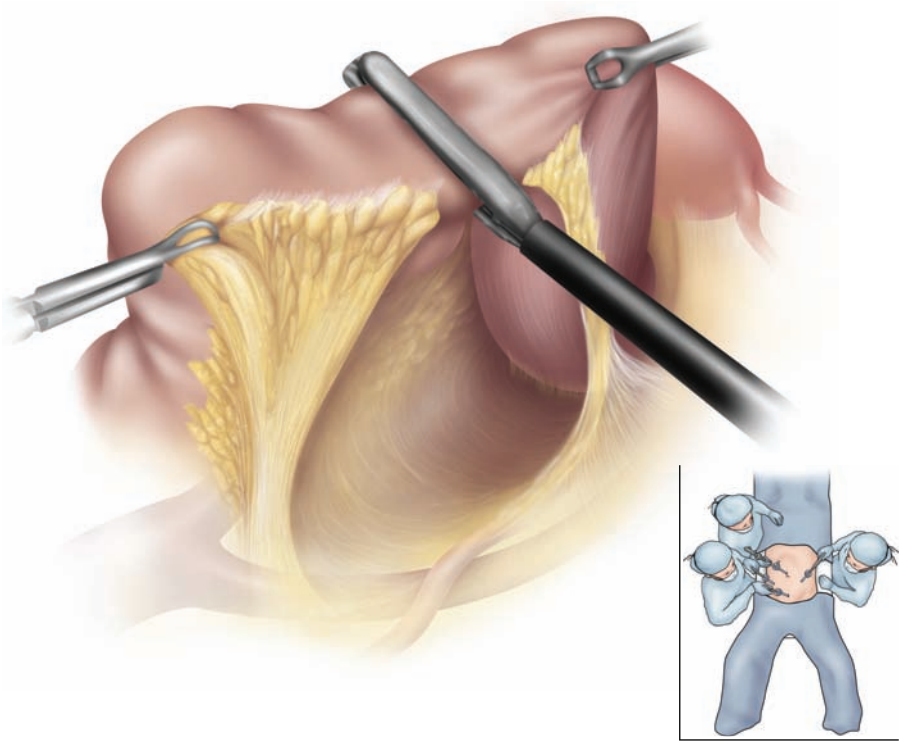

FIGURE 37-20 Division of upper rectum with linear stapler. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

cavity is irrigated and checked for blood, and the fascial defects are closed. After the reinsufflation of the abdominal cavity, the stapling device is introduced through the anus. The anvil attached to the shaft of the stapling device is advanced across the staple line under direct visualization. The anvil is attached to the gun, approximating the bowel ends, and then the device is fired. The anastomotic integrity and hemostasis can then be assessed using a proctoscope. The pneumoperitoneum is released after withdrawing cannulas under direct visualization.

The alternative approach is to perform a hand-sewn anastomosis through a small lower midline incision of 5–6 cm. After bowel exteriorization, the bowel is excised and end-to-end anastomosis is performed, taking care to ensure proper alignment of the mesentery.

Hand-Assisted Laparoscopic Sigmoidectomy

The patient is positioned in the same way as for the laparoscopic-assisted approach. The hand port is placed in the lower midline incision in the lower abdomen 1 cm above the pubic symphysis. The incision size should be one half-size smaller than the surgeon's hand to maintain effective pneumoperitoneum. Then the surgeon's left hand in the gel port guides the placement of other trocars. A 30-degree laparoscope is placed in the supraumbilical port and cautery attached to the scissors is placed in the RLQ port. The surgeon, standing on the left side of the patient, uses the left hand to provide retraction of the sigmoid colon while the cautery is operated with the right hand. The diseased specimen is extracted through the incision made for the hand port, and extracorporeal division of the vasculature can be performed. The anastomosis is made using the stapling device in the same manner as described previously. The pneumoperitoneum is reinstated, and the abdominal cavity is irrigated and inspected for hemostasis. Then the anastomotic site is inspected for leakage. Normal saline is placed in the abdomen and pelvis such that the anastomosis is submerged. A noncrushing clamp is placed proximal to the anastomosis and the rectum is then insufflated using a flexible sigmoidoscope. If bubbles are detected, either the anastomosis needs to be repaired at the site of the leak or the case needs proximal diversion with an ileostomy. Then the abdomen is closed after venting out the pneumoperitoneum.

Transverse Colectomy

STEP 1—PATIENT POSITION AND ROOM SETUP

The patient is placed and secured well on the operating table in supine or modified lithotomy position, depending on whether the pathology is closer to the right or left colon, respectively.

STEP 2: PORT PLACEMENT AND EXPLORATION

The laparoscope is inserted through the supraumbilical port, and two cannulas are inserted in the right and left lower quadrants under direct visualization. The surgeon shifts sides

depending on the mobilization of the hepatic flexure or the splenic flexure.

STEP 3: MOBILIZATION OF THE HEPATIC FLEXURE

Dissection and mobilization of the hepatic flexure is performed as described under right hemicolectomy.

STEP 4: MOBILIZATION OF THE SPLENIC FLEXURE

Dissection and mobilization of the splenic flexure is performed as described under left hemicolectomy.

STEP 5: MOBILIZATION OF THE TRANSVERSE COLON

The stomach is lifted up, and with retraction of transverse colon downward the omentum is divided. Thus transverse colon is freed from its attachments on either side.

STEPS 6–8: VASCULAR DIVISION, EXTERIORIZATION, AND ANASTOMOSIS

The vascular pedicle is divided intracorporeally, and the mobilized transverse colon is exteriorized through the extended incision in the supraumbilical area. Care should be taken around the vascular pedicle of the transverse colon. The middle colic vessels are quite short, and the vein branches easily tear and cause difficult bleeding. Too much traction on these vessels can result in disruption of venous branches and significant bleeding. The bowel is then divided and anastomosis of the free ends is done with hand-sewn technique or standard stapled technique.

TECHNICAL PROCEDURES FOR RECTAL DISEASES

Anterior resection, or sometimes referred to as a high anterior resection, is a surgical procedure used for resection of tumors or pathology present in the proximal rectum or distal sigmoid (>12 cm from the anal verge). In contrast to the anterior resection, the low anterior resection is used to treat tumors or pathology in the mid- to distal rectum, and an ultralow anterior resection is a sphincter-preserving approach where the anal canal is spared and a coloanal anastomosis or ileal J-pouch anastomosis is performed. APR is a two-part procedure that involves an abdominal and pelvic procedure where the rectum and colon is mobilized along with a perineal procedure where the rectum and the anus are resected. With this procedure, the patient is left with a permanent colostomy. An APR is required for tumors within 1 cm of the top of the anal canal (Fig. 37-21).

Rectopexy, or repair of rectum, is typically combined with sigmoid resection but can be performed by itself for treatment of rectal prolapse. We typically perform a sigmoid resection and colorectal anastomosis; also, we secure the lateral parts of the rectum to the presacrum to generate additional fixation.

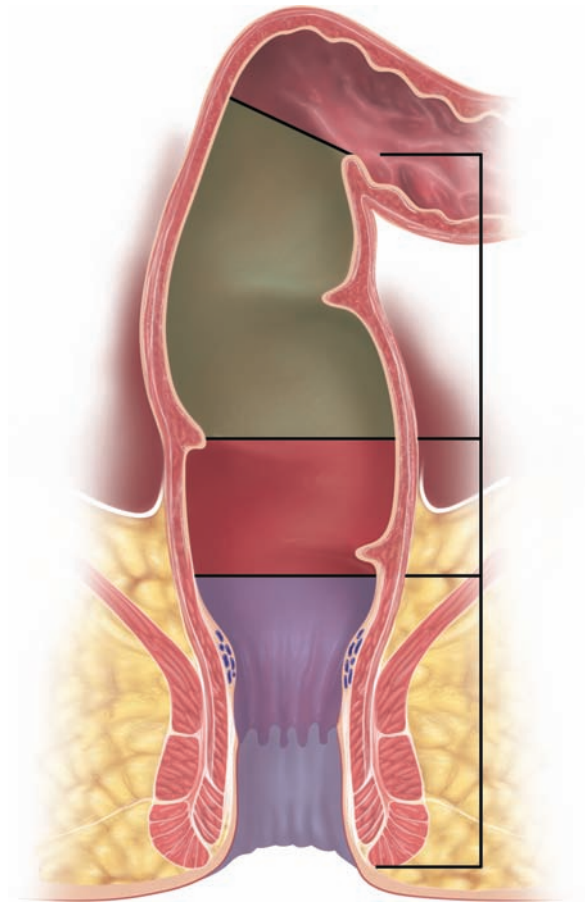

FIGURE 37-21 Levels of resection in rectal surgery—anterior resection, low anterior resection (LAR), coloanal, and abdominal perineal resection (APR). (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

Anterior Resection

STEP 1: PATIENT POSITION AND ROOM SETUP

The patient is placed in modified lithotomy position or synchronous position and securely strapped to the operating table. The setup is similar to that for sigmoid colectomy.

STEP 2: PORT PLACEMENT AND EXPLORATION

A four-port technique is used in which trocars are positioned at supraumbilical, suprapubic, and right and left lower quadrants. The abdomen is inspected to confirm the pathology and rule out metastases. Estimation of lower margins of the rectum and the pathology is crucial to decide the procedure in advance of conducting the operation.

STEP 3: MOBILIZATION OF THE LEFT COLON AND SIGMOID COLON

The dissection of the left colon and the sigmoid colon is carried out in the similar fashion as explained in the sigmoid resection.

STEP 4: VASCULAR LIGATION

For cancers, the vascular pedicle needs to be taken proximal, incorporating at least the superior hemorrhoidal and sigmoidal vessels. A vascular stapler, LigaSure, or a Harmonic scalpel can be utilized for intracorporeal ligation. Both ureters should be visualized and moved out of harm's way prior to vascular pedicle ligation. The left ureter courses close to the sigmoidal and hemorrhoidal vessel in the retroperitoneum above the pelvic brim. For nononcologic pathologies, vessels can be ligated at more distal locations. Extracorporeal ligation of the vessels is an alternative if adequate exposure can be obtained through the extraction site.

STEP 5: MOBILIZATION OF THE RECTUM

After vascular ligation, the presacral space is entered to start the dissection of the rectum. The ureters should be identified to avoid injury to them. Presacral nerves are carefully protected by gently sweeping them down and away from the dissection plane. The dissection continues laterally on either side until it meets posteriorly developing a presacral plane (see Fig. 37-18). The rectum is mobilized by creating a plane anteriorly between the rectum and seminal vesicles and prostate in men and between rectum and posterior vaginal wall in women. Complete mesorectal excision along with distal and circumferential clearance is the key factor for achieving complete oncologic resection. For cancers, the level of rectum for the site of transection is marked using ink tattoo preoperatively and this is visualized at the time of the surgery with endoscopy. The level of transection is typically identified and tattooed before starting neoadjuvant chemoradiation for patients requiring it.

STEP 6: EXCISION OF THE RECTUM AND EXTERIORIZATION

The rectum is excised at the marked position with the linear stapler gun (see Fig. 37-20) and then the specimen is extracted out through the extended incision in the supraumbilical region. Then the proximal end of the specimen is dissected extracorporeally and the remaining colon reintroduced with the anvil of the stapler gun held by the purse-string sutures.

STEP 7: ANASTOMOSIS

The anastomosis is performed in a fashion similar to what was described for sigmoid colectomy and low anterior resection using the circular stapler. The integrity of the anastomosis is always checked prior to closing the abdomen. Conversion is rarely needed when the anastomosis is at this high level and is typically reserved for circumstances where the tissue is of poor quality.

Low Anterior Resection

STEP 1: PATIENT POSITION AND ROOM SETUP

The patient is placed in the combined synchronous or modified lithotomy position and secured well on the operating table. The thighs can be kept more at the level of abdominal wall to avoid interference with the laparoscopic instruments used in the lower ports. The surgeon stands on the right side of the patient and faces toward the left lower quadrant of patient. The surgeon may have to shift to between the patient's legs if mobilization of the splenic flexure is required. The surgeon's assistant stands on the right while the scrub nurse on the left. The camera positioned to the left of patient's hips in the beginning is moved cephalad as the mobilization of the sigmoid colon and descending colon continues.

STEP 2: PORT PLACEMENT AND EXPLORATION

A 30-degree laparoscope is introduced through the supraumbilical position. Under direct visualization, three 5-mm trocars are in suprapubic position, right lower lateral quadrant, and left lower lateral quadrant positions (see Fig. 37-17). Lower quadrant trocars are inserted lateral to the epigastric vessels.

STEP 3: MOBILIZATION OF THE LEFT COLON

The patient is placed in the steep Trendelenburg position with the left side of the abdomen inclined upward. The peritoneum lateral to the sigmoid colon is grasped and pulled medially to expose the left peritoneal reflection, which is then opened along the white line of Toldt using cautery or scissors. The left ureter is identified at the base of the sigmoidal fossa on the medial aspect. Remaining in the correct retroperitoneal plane exposes Gerota's fascia and left ureter. Care should be taken to avoid injury to the ureter and left kidney. Depending on the need for splenic flexure mobilization, the dissection can be extended further cephalad at this moment. Mobilization of the splenic flexure is performed as described earlier in the Left Hemicolectomy section.

STEP 4: VASCULAR PEDICLE LIGATION

By scoring the right and perirectal peritoneum on a cephalad direction, the origin of superior hemorrhoidal and sigmoidal vessels can be exposed. The window in the mesentery on either side of the vessels is identified and developed. After ensuring that both ureters are not in the field, the vascular pedicle at the level of superior hemorrhoidal and sigmoidal vessels can be divided at the level of aortic bifurcation or just below the takeoff of the left colic vessels. The vascular stapler,

Harmonic scalpel, or LigaSure can be used according to the comfort of the surgeon.

STEP 5: MOBILIZATION OF THE RECTUM

During oncologic resection, care should be taken to avoid penetration of the mesorectal fascia. With the left side of the table inclined upward, the rectum is retracted anteriorly and right, and the left lateral dissection of the sigmoid is continued along the left lateral aspect of the rectum. The proximal aspect of the presacral space is exposed, which can be partially entered and developed. The operating table is now positioned with the right side inclined slightly upward. Retraction of the sigmoid colon and proximal rectum anteriorly, the right perirectal area is open and further retraction on the peritoneum allows for creating the presacral space. The presacral space is now developed with sharp dissection to the pelvic floor. Care should be taken to identify and protect the hypogastric nerves; they should be gently swept down toward the sacrum. The right presacral plane is opened to meet the left presacral plane. The rectum is then elevated anteriorly with sufficient traction that the presacral plane can be developed as far distally as needed to achieve at least 4 cm of distal mesorectal and 2 cm of distal bowel clearance below the tumor. It is generally necessary to work from the posterior section to the lateral section and anterior section and then again going deeper to all, repeating the steps until the dissection is carried well below the tumor. The anterior dissection should include the Denonvilliers fascia in cases of cancer. We would go above the peritoneal reflection anteriorly and take the anterior peritoneal reflection with the specimen. The lateral stalks would typically need to be divided to facilitate deep exposure of the pelvis and mobilization of the rectum for any tumors that present below the upper rectum.

Once the dissection is carried to levators, endoscopy can confirm the optimal level of rectal and mesorectal transection.

STEP 6: EXCISION OF THE RECTUM

The mesorectum can be divided with a LigaSure or Harmonic scalpel. A stapler is required to transect the rectum. The introduction of the stapler typically occurs through a small suprapubic incision or the hand port. The dissected rectum can be divided intracorporeally with a laparoscopic articulating linear stapler at both the ends. The resected specimen is then extracted out through the supraumbilical incision. Of note, it is also feasible to transect the distal rectum with a TA stapler, introduced through a small suprapubic incision that can be used later for specimen extraction (Fig. 37-22).

STEP 7: ANASTOMOSIS

A purse-string suture is placed in the proximal resection margin and the anvil is tied around the margin of the colon. Then the proximal colon with the anvil is returned to the abdomen. Then the incision is closed and the pneumoperitoneum is reestablished. The circular stapler is inserted through the anus, and the anvil attached to the shaft of the stapling device is advanced across the staple line under direct visualization (Fig. 37-23). The anvil of the proximal colon is attached to the stapler, approximating the bowel ends and then the device is fired under direct visualization. Then the abdomen is irrigated with saline and hemostasis ensured. The anastomosis is checked for any leaks by filling the pelvis

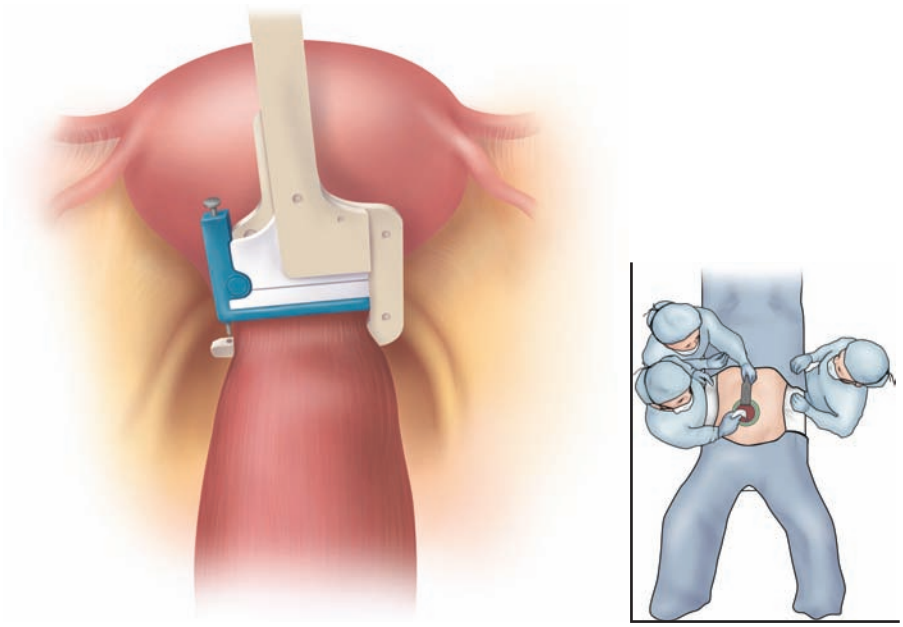

FIGURE 37-22 Division of lower rectum with transverse stapler.

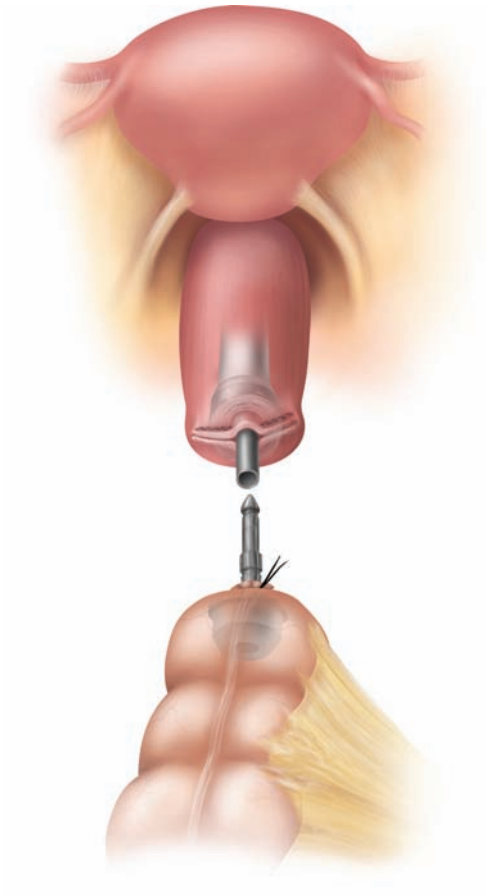

FIGURE 37-23 Colorectal anastomosis. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

with saline, insufflating the rectum with air from the flexible scope, including the proximal colon with an alligator clamp, and observing for any air bubbles. If there is evidence of a leak, that area should be reinforced with sutures or diversion created. The pneumoperitoneum is vented out and the port sites are closed as described previously.

Hand-Assisted Laparoscopic Low Anterior Resection

The patient is positioned in the same way as for the laparoscopic procedure. A 6- to 8-cm lower midline longitudinal incision is made to accommodate the hand port. The incision size should be a half-size smaller than the surgeon's hand to maintain effective pneumoperitoneum. Then the surgeon's left hand in the gel port guides the placement of other trocars. A 30-degree laparoscope is placed in the supraumbilical port and cautery attached to the scissors is placed in the RLQ port. The surgeon's left hand provides retraction of the sigmoid colon and the rectum to aid in the dissection. The vessels are divided intracorporeally with the help of LigaSure or vascular stapler. After a clear plane is developed around the rectum, the rectum is divided with the linear TA stapler at the marked site. The rectosigmoid along with the mesorectum is extracted out through the incision made for the hand port. The coloanal anastomosis is performed using the circular stapling device in the same manner as detailed for the laparoscopic procedure above. Then the anastomotic site is checked for any leakage before closing of the abdomen.

Laparoscopic Abdominal Perineal Resection

STEP 1: PATIENT POSITION AND ROOM SETUP

Preoperative marking of the stoma site is essential to ensure proper stomal positioning and optimal postoperative care and function. The patient is placed in a modified lithotomy position and securely strapped. The surgeon stands on the right side of the patient initially during sigmoid and left colon dissection and later moves toward the patient's left side for majority of the rectal dissection. The monitor should be positioned according to the position of the surgeon. Using two monitors can alleviate the problem of repositioning the monitor during surgeon relocation.

STEP 2: PORT PLACEMENT AND EXPLORATION

The use of five ports offers more flexibility in doing an abdominal perineal resection (APR). A 30-degree laparoscope is introduced through infraumbilical trocar. One of the trocars is introduced at the stoma site marking, while the other three trocars are inserted in the right upper, right lower, and left lower quadrants (Fig. 37-24). Using 10-mm trocars allow the surgeon to transfer the laparoscope to other ports to get better access in the procedure. Inspection of the abdomen is carried out to confirm the pathology.

STEP 3: VASCULAR LIGATION

The origin of the super hemorrhoidal and sigmoidal vessels can be exposed by scoring the right and perirectal peritoneum in the cephalad direction. After the window in the mesentery on either side of the vessels is developed and it is ensured that both ureters are not in the field, the vascular pedicle at the level of superior hemorrhoidal and sigmoidal vessels can be divided at the level of aortic bifurcation or just below the takeoff of the left colic vessels as described for the anterior resection.

STEP 4: MOBILIZATION OF THE SIGMOID COLON AND THE RECTUM (ABDOMINAL PORTION)

The mobilization of the sigmoid colon and the rectum is performed as described in low anterior resection. During oncologic resection, care should be taken to avoid penetration of the rectum or the mesorectal fascia. With the left side of the table inclined upward, the rectum is retracted anteriorly and

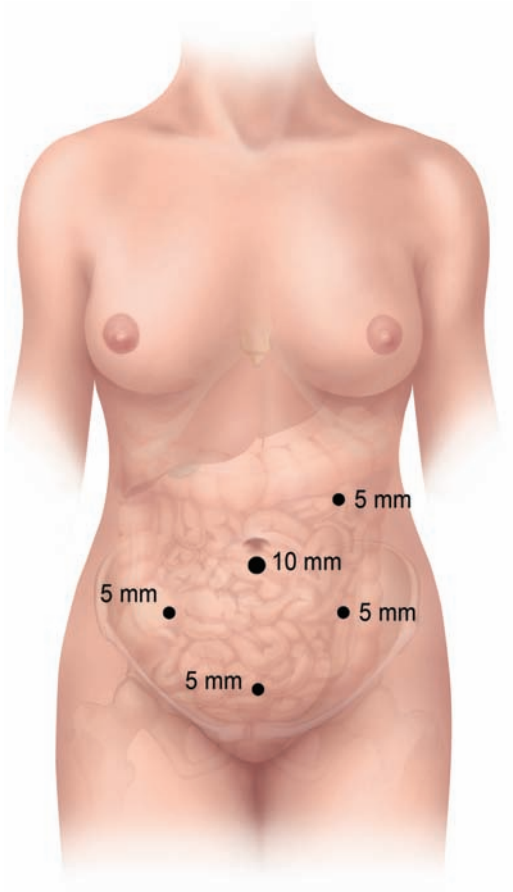

FIGURE 37-24 Position of laparoscopic ports for abdominal perineal resection (APR). (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

right, and the left lateral dissection of the sigmoid along the white line of Toldt is continued along the left lateral aspect of the rectum. Then the left ureter should be identified at the base of the sigmoidal fossa. The proximal aspect of the presacral space is exposed, which can be partially entered and developed (see Fig. 37-18). The operating table is now positioned with the right side inclined slightly upward. Retraction of the sigmoid colon and proximal rectum anteriorly, the right perirectal area is open and further retraction on the peritoneum allows for creating the presacral space. The presacral space is now developed with sharp dissection to the pelvic floor. Care should be taken to identify and protect the hypogastric nerves; they should be gently swept down toward the sacrum and to identify the ureters. The rectum is then elevated anteriorly with sufficient traction that the presacral plane can be developed as far distally as needed to achieve at least 4 cm of distal mesorectal and 2 cm of distal bowel clearance below the tumor. It is generally necessary to work from the posterior section to the lateral section and anterior section and then again going deeper to all, repeating the steps until the dissection is carried well below the tumor. The anterior dissection should include the Denonvilliers fascia in cases of cancer.

We would go above the peritoneal reflection anteriorly and take the anterior peritoneal reflection with the specimen. The lateral stalks should be divided to facilitate deep exposure of the pelvis and mobilization of the rectum for any tumors that present below the upper rectum. Then the mesorectum is divided at the chosen level with the ultrasonic scissors. The rectal dissection is now performed anteriorly without drifting away from the mesorectal plane into the seminal vesicles and prostate or the vagina anteriorly.

STEP 5: PERINEAL RESECTION

The perineal dissection is performed as for conventional APR. A purse-string suture is used to close the diamond-shaped perianal incision that is created just outside the sphincter complex to include the sphincters in the specimens. The dissection of the ischial rectal fat is carried out posteriorly all the way to level of levators. Next, the anterior fat is divided in a similar fashion. Using the tip of the coccyx as a guide, a scissors is brought just anterior to the tip of the coccyx and placed into the pelvis and spread. Withdrawing the scissors in a spread position creates a common hole between the pelvis and the perineum. A finger then can be placed along the left levator and the levators divided on both the left and right sides. Hemostasis is achieved with the cautery and suture ligation as need be. The resulting defect in the pelvic floor is typically large enough that the rectum can be brought out from the abdomen and pelvis through the posterior perineal wound.

STEP 6: EXTERIORIZATION OF THE SPECIMEN AND WOUND CLOSURE

Anterior levators are divided on both sides along the edge of the everted rectum. Care must be taken to avoid inadvertently creating a defect in the rectum in cases of cancer. Last, the direct anterior dissection is completed and here we would avoid any excessive use of cautery in the male in particular. The urethra is quite close to the rectal dissection and it is highly sensitive to heat. A delayed urethral leak will occur if excessive heat is applied during the anterior dissection. Finally, the rectum is extracted out through the perineal wound. The perineal wound is closed in sequential layers with absorbable sutures leaving closed-suction drains either from the abdomen down to the pelvis or, if preferred, through the perineum. The drains are clamped and pneumoperitoneum can be recreated. The descending colon is inspected to ensure that it is not twisted or rotated on its mesentery as it is going to be used for the colostomy.

STEP 7: COLOSTOMY

The distal end of the colon is now brought to the colostomy orifice using a grasper. At least 3 cm of colon is extracted out through the skin and the colostomy is matured in a Brooke fashion by inverting the bowel wall so that the stoma is slightly raised above the skin.

Hand-Assisted Laparoscopic Abdominal Perineal Resection

The abdominal portion of the procedure is assisted using the hand port. The sigmoid colon and the rectum are mobilized as detailed previously for the low anterior resection. The perineal resection is performed as for conventional APR.

LAPAROSCOPIC RECTOPEXY

Resection Rectopexy

This procedure is essentially the same as for anterior resection with the exception being the addition of presacral fixation.

STEP 1: PATIENT POSITION AND ROOM SETUP

The patient is placed in the modified lithotomy position and carefully positioned and strapped on the operating table. The surgeon and the assistant stand on the right side of the patient, while the monitor is placed on the patient's left side in the caudal end.

STEP 2: PORT POSITION AND EXPLORATION

A 30-degree laparoscope is introduced through the 10/12-mm subumbilical port. A careful inspection of the liver, small bowel, and the peritoneal surfaces is performed. Under direct visualization, three ports are made in right lower, right upper, and left lower quadrants.

STEP 3: VASCULAR LIGATION

The table is now positioned with left side and feet upward, and then the bowel loops are swept to the right side of the abdomen to make the operative field clear. The retroperitoneal structures are dissected to identify the sigmoidal and superior hemorrhoidal vessels and ureters. Because this procedure is indicated for benign cases, the vascular ligation can be performed more distally. The nerves should be spared and the ureters identified. The mesentery can be taken close to the bowel if surgeon attempts to preserve the vascular pedicle.

STEP 4: MOBILIZATION OF THE RECTOSIGMOID

The sigmoid colon is mobilized by developing a plane between the mesentery and the sigmoid colon. The rectosigmoid junction is drawn toward the patient's right side and the lateral attachments are divided. The dissection of the descending colon should be kept as minimal as possible.

STEP 5: MOBILIZATION OF THE RECTUM

The rectum is mobilized in the similar fashion as detailed in low anterior resection with some modifications. To minimize chances of rectal prolapse reoccurrence (particularly in patients presenting with early-onset prolapse), we would dissect the rectum all the way to the levators. Although we favor transection of the lateral stalks, this should be at the discretion of surgeon and based on factors of risk of recurrence versus risk of pelvic floor dysfunction. To not divide the rectal stalk puts the patient at a higher risk of recurrent prolapse. However, to transect both rectal stalks makes the patient at least theoretically at risk for more pelvic floor dysfunction and also removes a source of blood supply (ie, the middle hemorrhoidal). We typically preserve the superior hemorrhoidal and then transect the lateral stalks, so the rectum is supplied by inferior and superior hemorrhoidal vessels.

STEP 6: DIVISION OF THE RECTUM AND ANASTOMOSIS

Before the proximal or distal rectum is divided, careful measurements should be made of where the two ends of the colon and rectum match up. There should be no tension on the anastomosis once it is complete, and yet there should be little to no laxity in the residual bowel as it lies in the pelvis. This will help reduce the risk of recurrent prolapse. Of note, some do not prefer to conduct a colon resection, and we would agree that if there is no redundancy in the colon and the patient suffers from fecal incontinence rather than from constipation, we might also choose not to resect the bowel. Once the level of colon and rectal transsection has been determined to create a tension-free but nonlaxed anastomosis, the rectum is divided with a linear stapler. The division point of the rectum should be just below the level of the sacral promontory. The specimen is extracted through a small lower midline incision. In those cases where a hand port is performed, the specimen is readily extracted through the port site. The proximal end of the colon is divided, and the angle of the circular stapler is inserted and closed with a purse string suture. The circular stapler is inserted through the anus with the trocar brought out just in front of or behind the transverse staple line. The two parts of the stapler are coupled and the device then fired. We often place a row of seromuscular sutures around the anastomosis, especially if there is any evidence of leakage when it is tested in a saline-filled pelvis.

STEP 7: RECTOPEXY

Once the anastomosis is complete, the mesorectum is then attached to the sacral promontory or as one of two with two or three nonabsorbable sutures. We would incorporate the lateral edge of the rectal tissue with care being taken to find the mesorectal tissue without major vessels or nerves. We would also take care to offset the left and right sutures to avoid "crimping" or occluding the rectal lumen from this fixation process. Care should also be taken to insert the needle into some of the presacral periosteum and away from the area of the sacral nerve and internal iliac vessels.

Laparoscopic Subtotal Colectomy With Ileorectal Anastomosis

STEP 1: PATIENT POSITION AND ROOM SETUP

The patient is carefully placed in a modified lithotomy position and securely strapped and padded to the operating table, thus keeping the patient stable when the operating table is tilted side to side during surgery. The surgeon stands on the right or left side of the patient depending on the segment of the colon. The video monitors are adjusted according to the surgeon's position to maintain the alignment of the camera, instruments, and surgical fields. Two monitors are used for convenience because the surgeon will have to reposition at least twice. If an ileostomy is planned, the site should be identified by stomal therapists preoperatively and marked before surgery starts.

STEP 2: PORT PLACEMENT AND EXPLORATION

A 10/12-mm port is made in the supraumbilical region and laparoscope is introduced. Under direct visual guidance, four ports are placed, one each in all four quadrants of the abdomen. A 10-mm port is placed in the right lower quadrant to allow the endoscopic stapler; the remaining ports are 5 mm in size. If camera position needs to be changed, a 5-mm port can be changed to a 10-mm cannula.

STEP 3: MOBILIZATION OF THE COLON—LEFT COLON, SIGMOID COLON, AND RIGHT COLON

The colon is mobilized sequentially starting from splenic flexure and left colon, followed by right colon and then the sigmoid colon as previously described under individual hemicolectomies. The vessels are ligated intracorporeally and simultaneously along with the dissection of its respective segment. In case of benign pathology, the vessels can be ligated closer to the bowel and a LigaSure or other vascular transecting device can be used for most, if not all, of the vessels.

STEP 4: EXTERIORIZATION OF THE COLON AND DIVISION OF THE VASCULATURE

The colon is confirmed free from all attachments with the help of a grasper before exteriorization of the specimen. The pneumoperitoneum is vented out and supraumbilical incision is extended for 4–6 cm inferiorly. The colon is exteriorized through this incision. Any remaining vascular pedicles can be ligated using standard open technique extracorporeally. The orientation of the ileal mesentery should be preserved to prevent torsion and small bowel internal herniation.

STEP 5: FORMATION OF ILEORECTAL ANASTOMOSIS

An ileorectal anastomosis performed with help of the circular stapler in a fashion similar to what is described previously for colorectal anastomosis. The tricky part of the ileorectal anastomosis is finding the optimal orientation for the small bowel and its mesentery as it comes to a lie within the pelvis. It is often difficult to get the best orientation because the ileum typically is in the right lower quadrant, not in the left lower quadrant. In some cases, it will easily work end to end for an anastomosis, but in most other cases a side ileum to end of rectum may be best to achieve a mesenteric alignment to avoid seeping. If a side of ileum to end of rectum anastomosis looks best, the stapled distal end of the small bowel can be oversewn with seromuscular sutures and a separate antimesenteric site chosen to conduct the anastomosis. In this case, the anvil of the stapler can be placed in the bowel and closed with a purse-string suture and the shaft of the stapler brought across the anus into the rectum and coupled, closed, and fired in the typical fashion.

RESTORATIVE TOTAL PROCTOCOLECTOMY WITH ILEAL J-POUCH ANAL ANASTOMOSIS

Laparoscopic Ileal Pouch-Anal Anastomosis

This procedure is essentially the same as the subtotal colectomy plus ultralow anterior rectal resection. The main difference here is the creation of an ileal J-pouch rather than a colon J-pouch.

STEP 1: PATIENT POSITION AND ROOM SETUP

The patient is placed in modified lithotomy position and securely and safely strapped to avoid movements and injury during the procedure. The position of the surgeon should be ergonomically altered depending on the dissection of individual segment of the colon. The key to the appropriate position of the surgeon is to maintain a parallel view with the laparoscope, working instruments, and the monitors.

STEP 2: PORT PLACEMENT AND EXPLORATION

The 30-degree laparoscope is introduced through the 10-mm trocar in the infraumbilical site. The abdomen is inspected to confirm the pathology. Under direct visual guidance, four trocars are introduced in the four quadrants (Fig. 37-25). A 10-mm trocar is inserted in the right lower quadrant while the rest of the trocars can be of 5 mm caliber. Using 10-mm trocars at all the ports will allow flexibility to the surgeon in using the laparoscope from any of the ports.

STEP 3: COLON MOBILIZATION

The colon is mobilized sequentially starting from splenic flexure and left colon, followed by right colon and then the transverse and sigmoid colon as previously described under

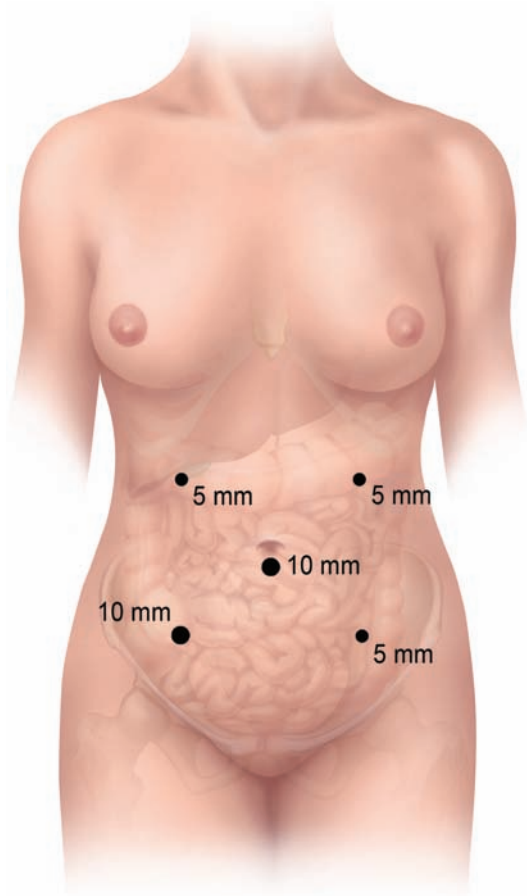

FIGURE 37-25 Position of laparoscopic ports for total proctocolectomy. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

individual hemicolectomies. We prefer to mobilize the splenic flexure early while all natural attachments are in tact. Intracorporeal vascular ligation and division is performed simultaneously with the dissection and mobilization of the colon using a vascular stapling device for larger vessels such as ileocolic and the LigaSure or similar device for smaller vessels.

STEP 4: RECTAL MOBILIZATION

The surgeon continues the dissection from the sigmoid colon toward the rectum. The rectum is fully mobilized to the pelvic floor as previously described in the section on ultralow anterior resection. The rectum is then divided at the pelvic floor using an Endo GIA (Covidien, Mansfield, MA) linear cutting stapler. If the stapler cannot reach the pelvic floor, the stapler can be introduced through a small suprapubic incision or the hand port incision or alternatively using a transanal approach. For the transanal approach, the anal canal is exposed using a Lone Star retractor (Lone Star Medical Products, Stafford, TX) or Gelpi retractor. Diluted epinephrine solution is then injected to raise the mucosal layer to assist in mucosectomy and to minimize bleeding. Cautery dissection starts at the dentate line and continued cephalad by lifting the mucosal layer up to the level of puborectalis, that is, the top of the anal canal. At this point, the dissection is carried full thickness to complete the distal transection of the rectum with complete mucosal removal but with the preservation of the internal sphincter. This approach is used when the entire specimen can be removed through the anus.

STEP 5: EXTERIORIZATION OF COLON AND RECTUM

The infraumbilical incision is extended by 4–6 cm inferiorly after the pneumoperitoneum is vented through the cannulas. The colon is exteriorized through this incision if it has not been removed through the anus while in transanal resection. The vascular pedicles are ligated and divided using standard open technique extracorporeally unless the vessels are ligated and cut intracorporeally. The ileum at the junction with the right colon is stapled and transected.

STEP 6: FORMATION OF ILEAL J-POUCH–ANAL ANASTOMOSIS

The distal staple line of the ileum is oversewn with a seromuscular layer. Next, one makes sure that the blood supply and the vascular pedicle of the ileum are properly oriented without twists. Further, at this juncture one needs to make sure that the apex of the pouch can reach the level of the top of the anal canal. Lengthening of the ileum to achieve the pouch-anal anastomosis must be performed before the pouch is stapled and actually created. The mesentery of the small bowel needs to be fully mobilized all the way up to the base of the stomach near the pancreas. Vascular arcades can be ligated in order to get the pouch to reach in extreme cases, and after a period of temporary bulldog clamping has been performed to ensure good blood supply. Once the pouch is thought to reach, the "J" configuration is created using two 15-cm limbs of small bowel. Seromuscular suture helps secure the correct orientation and reinforce the staple line that is to be created. At this juncture, a small enterotomy is made in the apex of the pouch, and this allows multiple firings of the 80- to 100-mm linear stapler to create the pouch itself. Once the stapling is completed (two, at most three firings), look for and correct any defects at the intersections of the staple line and check for pouch hemostasis prior to placing the handle and the purse string in the apex.

The purse string is made in the pouch apex, and the circular stapler is placed and suture is tightened. The pouch is returned to the abdominal cavity with proper orientation and laid in the pelvis. The midline incision is closed so that the pneumoperitoneum can be restored and the anastomosis completed. The circular stapling device is inserted through the anus and the trocar advanced under direct vision across the transverse staple line or purse string at the anal level. The anvil of the stapler is then attached using a specially designed laparoscopic instrument ensuring that the pouch and its mesentery are lying in the correct orientation and not rotated. The stapler is coupled, closed, fired, and withdrawn. Removing the purse strings allows us to see if the donuts are intact. Anastomotic integrity of the pouch is checked before wound closure (Fig. 37-26).

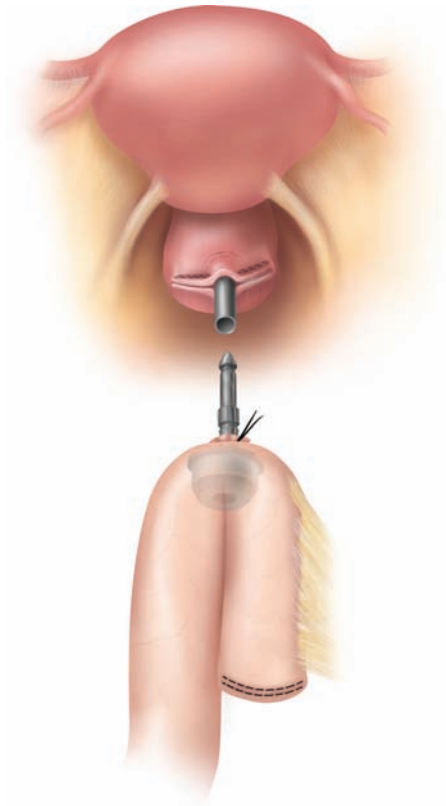

FIGURE 37-26 J-pouch–anal anastomosis. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

When a transanal approach is utilized to transect the distal end of the rectum, the pouch is delivered to the anal opening and two layers of absorbable sutures are placed. The first layer is seromuscular suturing of the pouch to the anal canal musculature, that is, an anchoring layer. The pouch is then opened and four quadrant sutures are next placed between the full thickness of the pouch and the residual anal mucosal layer. Supplemental sutures complete this layer.

STEP 7: FORMATION OF LOOP ILEOSTOMY

The ileum proximal to the pouch by roughly 30–50 cm is grasped and brought out to the RLQ port. A defunctioning loop ileostomy is made, ensuring that the orientation is properly defined. Pelvic drains are placed through the laparoscopic ports. The skin is then closed and the ileostomy matured.

Hand-Assisted Ileal J-Pouch–Anal Anastomosis

The patient is placed in modified lithotomy position and securely strapped to the operating table. The hand port is placed in a lower midline incision. Three ports are made respectively at supraumbilicus, right lower, and the left upper quadrants. The surgeon may stand on the right or left of the patient; alternatively it is often convenient for the surgeon to stand between the legs especially for takedown of flexures and the transverse colon. A 10-mm port is preferred to a 5-mm port as it allows the surgeon to use the laparoscope from any of the ports. The colonic mobilization commences at the splenic flexure. Additional assistance for the splenic mobilization can be provided with a grasper placed in the right lower quadrant. After mobilizing the splenic flexure and left colon, the surgeon shifts position to mobilize the right colon and the transverse colon. Vascular ligation and division can be performed in intra- or extracorporeal manner depending on the mobilization of the colon. The rectum can be mobilized and resected at the pelvic floor with a linear stapler or with a transverse stapler as described above. The rectum and colon are then delivered through the wound and the terminal ileum divided with the linear stapler. A J-pouch is then fashioned in the same manner as described previously and anastomosed to the anus with circular stapler inserted through the anus. If a defunctioning loop ileostomy is planned, a loop of proximal ileum is passed through the RLQ port and the ileostomy matured. Care should be taken to avoid torsion of the vascular pedicle and small bowel intussusception. Drains are placed into the pelvis through the lower quadrant port. After checking for anastomotic integrity and hemostasis is done, the hand port wound is closed in two layers as regular wound incision.

COMPLICATIONS

Intraoperative complications including management and prevention can be seen in the following tables (Tables 37-5 to 37-7). Table 37-8 shows the advantages and disadvantages with robotics.

TABLE 37-5: INTRAOPERATIVE COMPLICATIONS

Complications	
Patient position related	• Lower extremity neuropathies (peroneal nerve and compartment syndrome) • Upper extremity neuropathies (brachial plexus, median, and ulnar nerves) • Increased intra-abdominal pressure
Veress needle or trocar insertion related	• Vessel puncture and hemorrhage • Bowel perforation
Pneumoperitoneum related	• Increased intra-abdominal pressure • Hypothermia • Hypercarbia and acidemia • Insufflation with misplaced needle
Technique related	• Hemorrhage • Anastomotic leakage • Infection

TABLE 37-6: MANAGEMENT OF INTRAOPERATIVE COMPLICATIONS

Intraoperative Complications	Management
Perforation	Laparoscopic repair, if technically feasible, or conversion to open surgery
Splenic injury	Control of capsular bleeding, electrocautery, topical hemostatic agent, conversion, and/or splenectomy
Ureteral injury	Conversion to open surgery and repair over a stent
Bladder injury	Laparoscopic repair, if feasible, or conversion
Mesenteric bleeding	Laparoscopic clip, suture control, or conversion
Anastomotic leak	Repair and/or diversion

TABLE 37-7: PREVENTION OF INTRAOPERATIVE COMPLICATIONS

Technique-Related Complications	Prevention
Perforation	Use atraumatic instruments; exert traction on peritoneal attachments rather than on bowel; use gentle manipulation; avoid cautery injury to well-insulated laparoscopic tools and adequate visualization of tools during the application of cautery
Splenic injury	Ensure adequate visualization when at the splenic flexure, and place gentle traction on tissues attached to the spleen
Ureteral injury	Properly identify and avoid cautery in the ureter field; use ureteral stents as necessary
Bladder injury	Use catheter decompression
Mesenteric bleeding	Create mesenteric windows in avascular plane, use of double-clip technique or suture ligation for major vessels
Anastomotic leak	Ensure proper bowel alignment, avoid tension, and check for good vascularization of proximal and distal ends, use suturing or stapling techniques, and check bleeding
Wound/trocar site infection	Proper antibiotic prophylaxis and ensure hemostasis and irrigation of trocar site
Trocar site recurrence	Protect the port site, use bag for specimen extraction, and avoid chimney effect.

TABLE 37-8: ADVANTAGES AND DISADVANTAGES WITH ROBOTICS

Advantages	Disadvantages
1. 3D visualization	1. High initial maintenance and cost
2. Better movement of instruments	2. Absence of tactile sensation
3. Absence of fulcrum effect	3. Long setup time for instruments
4. Less fatigue	4. Technical experience required
5. Elimination of tremor	

LEARNING CURVE AND CREDENTIALING

Laparoscopic colectomy is different from other laparoscopic surgery as it requires working in multiple fields and different orientations. Proper training and experience along with appropriate help from the first assistant and the scrub nurse are vital in performing laparoscopic colectomy. There is a significant learning curve during which the length of each procedure may be longer and rate of conversion to open may be greater, although the incidence of complications is not altered.[20] It is recommended that surgeons develop their laparoscopic skills initially with simpler procedures such as appendectomy, cholecystectomy, and right colectomy before they graduate to benign complex operations and undertake cancer resections. Based on the prerequisite of 20 laparoscopic colectomies for COST trial, American Society of Colon and Rectal Surgeons (ASCRS) recommended that surgeons perform 20 laparoscopic resections before undertaking procedures for cancer. Hand-assisted laparoscopic surgery (HALS) is easily adaptable for routine and complex cases.[21] The steep learning curve of laparoscopic-assisted colectomy can be overcome by starting with the HALS approach.

FUTURE CONSIDERATIONS—ROBOTICS AND NOTES

Successful telerobotic-assisted laparoscopic sigmoid and right colectomies were first reported by Weber et al[22] in 2002 when actual dissection and mobilization were performed with robotic assistance and a lot of progress was achieved in technological inventions and its application in various operations. D'Annibale et al reported the results of 53 robotic colorectal surgeries in 2004 and concluded that the outcomes are similar to laparoscopic surgery.[23] Short-term outcomes of a randomized pilot study by Baik et all comparing robotic-assisted low anterior resection and laparoscopic low anterior resection concluded the safety and feasibility of robotics (da Vinci robots [Intuitive Surgical, Inc., Sunnyvale, CA]) in colorectal surgery.[24]

Robotic-assisted surgery (da Vinci robots) offers many advantages over laparoscopic surgery such as 3D visualization,

increased degrees of freedom of movement, absence of fulcrum effect, reduced fatigue, and elimination of tremor and better ergonomics for surgeon.[23] The biggest drawback for robotics is the high cost. Minor drawbacks include the absence of tactile sensation and the lengthy time required for setup.[23] In the future, robotics may find its applicability in rectal operations such as total mesorectal excision, rectal rectopexy, and pelvic floor reconstruction.[25] With the new technological advances rapidly developing in the field of robotics, robotic-assisted surgery may replace the laparoscopic-assisted surgeries in the future.

NOSE (natural orifice specimen extraction) technique was performed in colon and rectal surgery specimen extraction through transanal and transvaginal route in the recent past and was considered a prequel to NOTES (natural orifice transluminal endoscopic surgery).[26]

NOTES is an interesting concept that is gaining enthusiasm. It utilizes the concept of approaching the internal viscera through natural openings such as the mouth (stomach), the anus, and the vagina. NOTES was first performed in India by Reddy and Rao in a burn patient where abdominal incision was not feasible.[27] Initial studies were focused mainly on animal studies.[28] The Natural Orifice Surgery Consortium for Assessment for Research (NOSCAR) was formed in 2005, and it identified the potential barriers in clinical practice of NOTES and set guidelines for future research and development.[29] Patients prefer to undergo NOTES approach over laparoscopic cholecystectomy for lack of pain (99%) and external scarring (89%).[30] The potential advantages of NOTES include no scars, less pain, fewer wound complications, earlier mobility,[28] and potential to offer therapy outside operating room (intensive care unit [ICU]).[31]

38A

PERSPECTIVE ON COLONIC NEOPLASMS

José G. Guillem • Jeannine A. Ruby

The management of colorectal cancer has progressed over the past two decades because of many advances, including those in genetics, pathology, imaging, medical oncology, radiation oncology, and surgery. Within genetics, a number of mutations have been identified that play a causative role in colon carcinogenesis and have led to developments in targeted therapies and genetic testing for familial syndromes. Currently, most patients presenting with an inherited form of colorectal neoplasm can be classified as having adenomatous (familial adenomatous polyposis [FAP], attenuated FAP [AFAP], MUTYH-associated polyposis [MAP], Lynch syndrome, and familial colorectal cancer type X [FCC X])[1] or hamartomatous [juvenile polyposis syndrome [JPS] and Peutz-Jeghers syndrome [PJS]) polyps. With the exception of FCC X, genetic testing can now diagnose all of the aforementioned syndromes, thereby making prophylactic risk-reducing surgery a practical option.

MAP, a recently characterized hereditary adenomatous polyposis syndrome, should be suspected in patients who have greater than 10 colorectal adenomas and have a weak or negative family history of colorectal cancer. The seemingly negative family history is due to MAP's autosomal recessive inheritance and its low (~2%) carrier frequency.[2,3] While the vertical transmission rate is low, the siblings of biallelic carriers have a 25% risk of being biallelic carriers.[3]

FCC X describes a subset of patients who meet Amsterdam criteria II (at least three relatives with colorectal, endometrial, small bowel, ureteral, or renal pelvis cancer; one a first-degree relative of the other two; at least two successive generations affected; at least one diagnosed before age 50; FAP excluded; and tumors verified by pathologic examination) but lack an identifiable mismatch repair (*MMR*) gene mutation.[4] Patients with FCC X have been found to have a lower incidence of colonic and extracolonic cancers than those with Lynch syndrome.[5] Patients with Lynch syndrome are generally recommended to undergo colonoscopy every 1–2 years, endometrial cancer screening annually, urinalysis annually, and to consider prophylactic colectomy or hysterectomy.[6] Patients with the apparently less virulent phenotype of FCC X may require a less thorough approach.[5,7] Until more is known about the condition, patients with FCC X are recommended to undergo screening colonoscopy every 1–2 years.

Patients who meet Amsterdam criteria should be tested for *MMR* gene mutations either through immunohistochemistry (IHC) for loss of MMR protein expression or through molecular analysis for microsatellite instability (MSI). IHC may be the preferred test as it is less expensive, its sensitivity is comparable to MSI testing, and it allows for targeted germline testing by identifying a specific MMR protein loss. The routine testing of colorectal cancer patients younger than 50 years for loss of MMR protein expression via IHC can help identify Lynch syndrome in otherwise unsuspected cases.[8]

Within the field of pathology, sessile-serrated adenomas have received a lot of recent attention. They are characterized by saw-toothed crypt epithelial folds and are associated with MSI-high sporadic colorectal cancers.[9] These lesions are particularly interesting because the serrated tumorigenesis pathway is thought to be distinct from the traditional adenoma-carcinoma sequence.

The use of positron emission tomography with computed tomography (PET-CT) allows for both metabolic and anatomic evaluation and enhances the ability to differentiate malignant from fibrotic tissue. Currently, the National Comprehensive Cancer Network (NCCN) *Clinical Practice Guidelines in Oncology* suggest that PET-CT be considered for colorectal cancer patients with potentially resectable metastasis or with suspected recurrence based on serial carcinoembryonic antigen (CEA) elevation.[10] However, they do not recommend PET-CT for initial staging workup, routine surveillance, or monitoring of metastatic disease progression for colon or rectal cancer.[10]

The American Joint Committee on Cancer has updated the colorectal cancer TNM (tumor-node-metastasis) classification system within the past year. These changes include the subdivision of T4 lesions into T4a (penetrates visceral peritoneum) and T4b (invades or is histologically adherent to other organs or structures); the subdivision of N1 and N2 into N1a (one node), N1b (two to three nodes), N2a (four to six nodes), and

N2b (seven or more nodes); and the subdivision of M1 into M1a (single metastatic site) and M1b (multiple metastatic sites), among other changes.[11] It is expected that these changes will further assist clinicians in tailoring adjuvant therapy and surveillance strategies.

Targeted therapies such as cetuximab, a monoclonal antibody that inhibits epidermal growth factor receptor, and bevacizumab, a monoclonal antibody that inhibits vascular endothelial growth factor, are now available. The identification of the subset of patients who will benefit from these targeted therapies is under investigation; for example, patients bearing a tumor with a *K-ras* mutation have no improvement in progression-free or overall survival when given cetuximab.[12,13]

The delivery method of radiation therapy is progressing. Image-guided radiation therapy (IGRT) relies on the principle of modifying treatment based on frequent imaging during a course of radiation therapy, and intensity-modulated radiation therapy (IMRT) aims to increase dosing to the target volume and to limit dosing to surrounding normal tissue. There are few studies published on IMRT in the treatment of rectal cancer.

Following the German Rectal Cancer Trial (CAO/ARO/AIO-94) showing that neoadjuvant chemoradiation decreases local recurrence rates, neoadjuvant chemoradiation followed by total mesorectal excision and adjuvant chemotherapy is now the recommended management for patients with locally advanced rectal cancer.[14] With increasing pathologic complete response (pCR) rates due to evolving neoadjuvant chemoradiation regimens, investigators in Brazil have posited that radical rectal resection may be unnecessary in locally advanced rectal cancers that achieve a complete clinical response after neoadjuvant chemoradiation.[15] This provocative approach is currently being explored by several centers worldwide.

Another deviation in the standard treatment of rectal cancer is the proposal of using neoadjuvant chemotherapy alone followed by surgery. One recent trial gave neoadjuvant folinic acid/5-fluorouracil/oxaliplatin (FOLFOX) with bevacizumab and no radiation in 29 patients with non-T4 stages II and III rectal cancers and found a 27% pCR rate, 100% clinical regression rate, and a 100% R0 resection rate, suggesting that in carefully selected cases radiation therapy may be withheld.[16]

In the interest of sphincter preservation and avoidance of the morbidity and mortality associated with a radical rectal resection, the role of chemoradiation in stage I rectal tumors is under investigation. The American College of Surgeons Oncology Group (ACOSOG) Z6041 trial examines the efficacy of chemoradiation therapy and local excision in the treatment of uT2N0 rectal cancers.[17] Preliminary results show a 44% pCR rate, 64% tumor downstaging rate, and a 98% negative resection margin rate.[18] Long-term recurrence rates and survival outcomes are pending.

Since its controversial introduction in the 1990s, laparoscopic surgery for colon cancer has subsequently been shown to have similar outcomes to open surgery in large, multicenter trials, such as the Clinical Outcomes of Surgical Therapy (COST) study group trial, the European Colon Cancer Laparoscopic or Open Resection (COLOR) trial, and the Medical Research Council Conventional versus Laparoscopic-Assisted Surgery In Colorectal Cancer (MRC CLASICC) trial.[19–21] In contrast, laparoscopic surgery for rectal cancer is still under investigation. Three multicenter, randomized clinical trials are currently evaluating the role of laparoscopic surgery specifically in rectal cancer: the Comparison of Open versus laparoscopic surgery for mid and low REctal cancer After Neoadjuvant chemoradiotherapy (COREAN) trial (closed to accrual), the COLOR II trial (accruing), and the ACOSOG Z6051 trial (accruing).[22–24]

Surgeons have turned to robotic surgery to overcome some of the technical challenges of performing conventional laparoscopic surgery within the pelvis. A recent series of 64 stages I–III rectal cancer patients treated with robotic-assisted total mesorectal excision found that the approach allowed for an adequate oncologic resection, and acceptable 3-year overall (96.2%) and disease-free (73.7%) survival rates after a mean follow-up of 20.2 months.[25] Long-term studies of rectal cancer patients treated with robotic surgery remain to be performed.

Undoubtedly, the management of patients afflicted with colorectal cancer will evolve as advances continue to be made in the multiple disciplines that contribute to the diagnosis and treatment of colorectal cancer.

PERSPECTIVE ON COLONIC NEOPLASMS

David J. Schoetz, Jr.

Colon tumors remain one of the more common reasons for abdominal surgery. Adenocarcinoma of the colon is still the most common histology requiring operative intervention. Other types of malignant tumors and benign lesions make up a distinct minority of colonic neoplastic indications for operation.

The etiology of colorectal cancer remains elusive. Dietary factors, including macro- and micronutrients, have maintained a central importance in theories of the etiology of colon cancer. High dietary fiber, once felt to be protective, has more recently been demonstrated in a large prospective study to not prevent colorectal cancer.[1] Conversely, the breakdown products of cooked meat have clearly been implicated in the development of colorectal cancer.[2] Because rigid control of the constituents of diet over time is highly unlikely and even strict vegetarians have developed colorectal cancer, it is not likely that lifelong dietary manipulation will substantially alter the natural history of this disease.

Screening for colorectal cancer is clearly effective in reducing the overall mortality from colorectal cancer, presumably by discovery of tumors at an earlier and thus more curable stage. In this respect, it is an ideal disease for directed screening, because the precancerous phase is long and removal of the precancerous lesion is preventive of cancer. The incidence of colorectal cancer has been in a slow decline over the past 10–15 years, due in part to increased application of screening programs in the population as a whole.[3]

Because of noncompliance of the American population with Hemoccult testing programs or, in fact, any other procedures that require interacting with stool (such as stool DNA analysis), intermittent anatomic evaluation of the entire colon and rectum by some means has become the preferred manner of colorectal cancer screening. Practically, total colonoscopy has become the most common screening procedure, beginning at age 50 in normal-risk individuals. Alternatively, flexible sigmoidoscopy and air contrast barium enema are recommended at 5-year intervals; they are perceived by patients and primary care physicians to be more uncomfortable because of the lack of conscious sedation when compared to colonoscopy.

Radiographic screening with three-dimensional software for interpretation of cross-sectional images is popularly known as "virtual colonoscopy," a misnomer leading to misunderstandings about the procedure. Individuals undergoing computed tomographic (CT) colonography must mechanically cleanse the colon and then have air (or carbon dioxide) insufflation prior to imaging. Positive findings necessitate referral for optical colonoscopy. There are certain circumstances in which diagnostic CT imaging is indicated; comorbidities that preclude conscious sedation, refusal on the part of the patient to undergo colonoscopy or prior failed attempt(s) and obstruction preventing proximal passage of the instrument are all reasonable indications for CT colonography.

It must be stressed that no method of screening is infallible. Furthermore, there are some individuals who do not have any identifiable factors that would indicate surveillance at an earlier age or with greater frequency who develop colorectal cancer.

Among identifiable risk factors suggesting the need for surveillance beginning at an earlier age than 50 years, family history of cancer is the most common and arguably the most significant factor. Identification of individuals at risk for genetic syndromes begins with accurate history taking from the patient as well as construction of the family pedigree. In the current era of "endoscopy-on-demand" programs, the responsibility for identifying patients and families who would potentially benefit from genetic screening and more aggressive endoscopic surveillance shifts to the primary caregivers and ancillary personnel, because the endoscopists often do not know the patient or participate in the decision to perform endoscopy.

Ultimately, the genetics of all colorectal cancers will be elucidated, perhaps resulting in the development of reliable blood testing to replace screening tests that are expensive, resource intensive, and have some associated risk. At present, the variations of familial adenomatous polyposis (FAP) with mutations of the *APC* gene as well as the multiple mismatch repair (*MMR*) genes involved in the basic phenotype of hereditary nonpolyposis colon cancer (HNPCC) represent a minority of all colon cancer patients. Attenuated FAP,

a mutation of the *APC* gene, exhibits a different phenotype than classic FAP characterized by fewer polyps and later age of onset. More recently, the recessive *MYH* genes, with an attenuated FAP phenotype but a different genetic transmission, have been added to the better-known genetic syndromes.[4] As more of the genetic associations are elucidated, the molecular basis of sporadic colorectal cancers will become evident.

Preoperative localization of colonic neoplasms should be a priority in order to plan operative strategy. In some instances, colonoscopy to the cecum, traversing the lesion to exclude the presence of synchronous pathology that requires coincident attention, is not possible. In the elective situation, other strategies may be employed to visualize the proximal colon. Water-soluble contrast enema may be able to outline the colon above a lesion that does not allow the passage of a colonoscope; this requires communication with the radiologist to avoid excessive pressure and overinflation of the colon with a risk of perforation. As mentioned previously, CT colonography may be used to visualize the colon but has the limitation of not being able to cleanse the colon because of the obstruction. In the instances in which complete colonic evaluation is not accomplished preoperatively, the performance of intraoperative colonoscopy using carbon dioxide rather than air for insufflation to minimize the duration of colonic distention has been suggested. This requires on-table lavage to allow detailed mucosal inspection and is probably impractical in many instances of operation for obstruction. As a result, individuals undergoing urgent operation precluding preoperative colonic inspection should be evaluated by colonoscopy sooner in the postoperative period with the expectation that there will be discovery of the occasional synchronous neoplasm.

Preoperative marking of tumor location by the colonoscopist, most often by submucosal injection of India Ink, has become quite popular; this has been driven primarily by the relative loss of tactile sensory capability for the surgeon with the advent of laparoscopic colon resection. It is not unusual for the endoscopist to misinterpret the position of the tip and thus the tumor, leading in some instances to resection of the wrong segment of colon. This is obviated by India Ink marking.

Mechanical cleansing of the colon has recently been deemphasized as a necessary part of the routine preparation of a patient for colon resection.[5] While there is no evidence to support an increased risk of anastomotic or infectious complications for elective colon resections in stool-filled bowel, some find this situation aesthetically unpleasing and prefer a colon without formed stool upon which to work. In fact, patients have often had some form of amended bowel cleaning by not eating solids for a day or more, taking some laxative and/or using a disposable enema. This is particularly true for left-sided lesions.

In some instances, the degree of obstruction of the colon is such that preoperative preparation of the colon is not possible. Under these circumstances the options are to (1) perform a subtotal colectomy with anastomosis of the ileum to the colon distal to the lesion; (2) resect the lesion and perform on-table lavage with primary anastomosis; and (3) perform a staged procedure with resection and stoma. A more recent option is the placement by the endoscopist of an expandable metallic stent to relieve the acute obstruction and allow mechanical cleansing of the colon followed by an elective resection in the near future.[6]

Since the introduction of laparoscopic colon resection in the early 1990s, there has been a relative explosion of this technology. Data from the American Board of Colon and Rectal Surgery reflected utilization of laparoscopy for colon surgery beginning with resident case logs in 1994.[7] By continuing to record and analyze resident case lists from colorectal training programs, the percentage of abdominal colorectal resections performed laparoscopically increased from 3.6% in 1994 to 24.3% in 2005.[8] Analysis of the relative penetration of pathology indicating operation suggests that the application of laparoscopy for cancer somewhat awaited the publication of the multi-institutional trials outlined in Chap. 37. This fundamental change in the approach to colon surgery represents an enormous challenge for the education of residents and practicing surgeons alike.

Laparoscopic surgery represents an alternative means of accomplishing well-established operative procedures. These new skills must be incorporated into the new curriculum of teaching and learning technical surgery. Fortunately, laparoscopic skills lend themselves to the use of simulation technologies that have been designed, validated, and implemented. The Fundamentals of Laparoscopic Surgery (FLS) program, developed by the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES), is a combination of a didactic curriculum combined with skill assessment using box trainers, trained observers, and validated end points for evaluation of distinct psychomotor and cognitive skills necessary for basic laparoscopy.[9] All general surgery residents must have successfully completed the FLS program by graduation from residency. By extension, because all colon and rectal residents are fully trained general surgeons, they will also be FLS-certified.

Computer-based simulation is developing at a rapid pace and may well evolve into procedure-specific training devices. Credentialing of practicing surgeons will probably incorporate simulation exercises for competency determination in the future; perhaps there will also be review of videotapes of specific procedures by hospital credentialing committees or even the surgical boards for both primary certification and part IV of maintenance of certification.

As abdominal access shifts increasingly to laparoscopy, open surgical skills will atrophy, if they are developed at all, during general surgical residency. Volumes of some procedures are already a challenge, pushing many general surgery graduates into subspecialty training after completion of a standard 5-year residency program. Furthermore, the learning curve differs among individual surgeons; marketing pressures and financial incentives may push marginally capable surgeons to do procedures for which they are not yet prepared for safe independent performance.

The growth of laparoscopy has not all been fueled by randomized prospective data demonstrating its superiority over

open surgery. Proposed advantages such as shorter length of stay, less postoperative pain and more rapid return to work must be counterbalanced by longer operative times and greater procedural expense. Some of the enthusiasm among patients and referring physicians is stimulated and amplified by misunderstandings of the true benefits of the 'minimally invasive' approach. There are absolute and relative contraindications to performance of laparoscopic resection outlined in Table 37-3. These criteria must be scrupulously applied to patients seeking laparoscopic surgery.

As a general rule, the same procedural endpoints must be able to be accomplished by laparoscopic techniques; nowhere is this more evident than with cancer surgery. Oncologic results of laparoscopic colon resection for cancer must at least equal those obtained by traditional open surgery. Adequacy of mesenteric lymph node resection has gained considerable traction as a surrogate for quality surgery. Survival is dependent on numbers of lymph nodes harvested, with survival increasing with more resected nodes.[10] Numbers of nodes removed are a quality measure in addition to the time-honored outcomes of overall cure and disease-free survival.

Technical horizons awaiting scientific scrutiny are robotics as applied to colorectal surgery, single-port access surgery, and NOTES (natural orifice transluminal endoscopic surgery). While each of these techniques may find a place in the future, at present they must all be considered experimental in nature. Development of these expensive technologies should not be at the primary direction of market-driven forces; rather, there should be a concerted effort to develop and test new techniques, with at least proof of equivalence, before allowing them to permeate practice.

BENIGN DISORDERS OF THE ANORECTUM (PELVIC FLOOR, FISSURES, HEMORRHOIDS, AND FISTULAS)

Anne Y. Lin • James W. Fleshman, Jr.

Benign diseases of the anorectum range from relatively simple disorders such as hemorrhoids and fissures to extremely complex problems associated with pelvic floor abnormalities.

ANATOMY

The beginning of any evaluation of anorectal problems is the examination; therefore clinicians need to understand the anatomy. The normal anatomic relationships of the rectum and pelvis are important in understanding pelvic floor abnormalities and anorectal pathology. The rectum normally lies attached to its mesorectum within the curve of the sacrum with limited mobility. The junction of the rectosigmoid is most consistently found at the sacral promontory and descends only 2 or 3 cm during a Valsalva maneuver. The rectum exits the pelvis anteriorly surrounded by a sling of muscle from the pubis through a slit in the pelvic floor. The sling is created by the horseshoe-shaped puborectalis muscle that circles around behind the rectum and reinserts on the pubis anteriorly. Contraction of the muscle pulls the rectum forward, creating a more acute angle at the anal outlet. The anal canal itself measures 3–4 cm and is a funnel-shaped extension of the pelvic floor musculature. The pressure generated by this voluntary muscle prevents egress of rectal contents. The internal sphincter muscle is a continuation of the thickened circular muscle of the rectum. As such, it is an autonomic muscle and has no voluntary control.

The anorectum receives both sympathetic and parasympathetic nerves. The sympathetic nerves originate from thoracolumbar segments and unite below the inferior mesenteric artery to form the inferior mesenteric plexus. These fibers then descend to the superior hypogastric plexus located just inferior to the aortic bifurcation. These purely sympathetic fibers bifurcate and descend as the hypogastric nerves. Parasympathetic fibers from S2, S3, and S4 (the Nervi erigentes) join the hypogastric nerves anterolateral to the rectum to form the inferior hypogastric plexuses. Mixed fibers from the plexuses innervate the prostate, rectum, bladder, penis, and internal anal sphincter. These autonomic plexuses of the pelvic nerves run around the lateral aspect of the pelvic rim to enter the prostate and seminal vesicles anteriorly. The sympathetic innervation of the internal sphincter is motor, while the parasympathetic innervation is inhibitory. Injury to the pelvic autonomic nerves during pelvic surgery may result in bladder dysfunction, impotence, or both.

The innervation of the voluntary muscles of the pelvic floor is via direct fibers from S2, S3, and S4 in the pelvis from the sacrum (Fig. 39-1). The nerves of the external sphincter are derived from S2, S3, and S4 nerve roots from the sacral plexus and they arrive at the external sphincter via the pudendal nerve around the ischial spine at Alcock's canal. The uterus and vagina are closely approximated to the anterior surface of the rectum but not attached. There is no ligamentous suspension of the rectum or the uterus at the lower aspect of the pelvis. The slit-like defect in the pelvic floor through which the rectum passes also provides an outlet for the vagina and the urinary bladder.

The alimentary tract terminates at the anus, which provides continence of flatus and feces. It is useful to consider the anus and surrounding structures as a single unit, the anorectum (Fig. 39-2). The anorectum includes the perianal skin, the anal canal, the anal sphincters, and the distal rectum. The three main anatomic points of reference are the anal verge,

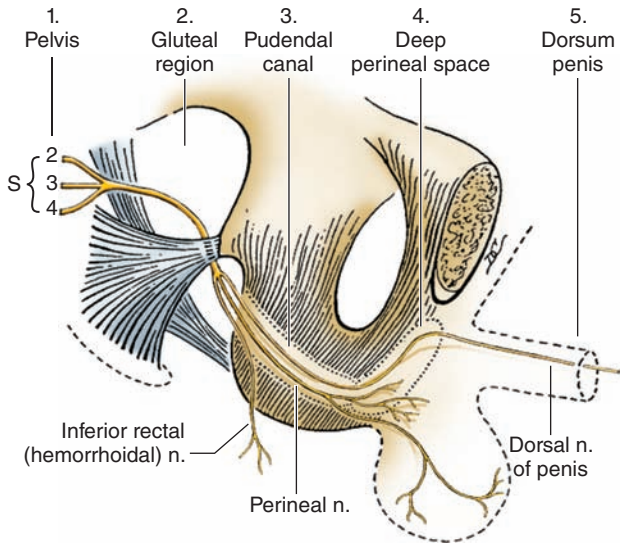

FIGURE 39-1 Diagram of the pudendal nerve. Note the five regions in which it runs and the three divisions into which it divides. (Reproduced, with permission, from Anderson JE. *Grant's Atlas of Anatomy*. 8th ed. Baltimore, MD: Williams & Wilkins; 1983.)

the dentate line, and the anorectal ring. The distal external boundary of the anal canal is the anal verge, which is also the junction between the anal and perianal skin. Anal epithelium (anoderm) is devoid of the hair follicles, sebaceous glands, and apocrine glands that are present in the perianal skin, a fact worth remembering when attempting to distinguish between hidradenitis (inflammation of the apocrine glands in the perianal skin) and cryptoglandular anal disease.

The cephalad border of the anal canal is a true mucocutaneous junction, the dentate line. This union of the embryonic ectoderm with the endodermal gut resides approximately 1.0–1.5 cm above the anal verge. In a transitional zone of 6–12 mm in length, the columnar epithelium of the rectum changes to cuboidal epithelium that joins the squamous epithelium at the dentate line.

The upper border of the anal sphincteric complex is the anorectal ring. It may be palpated by digital examination about 1.0–1.5 cm above the dentate line. Anatomists consider the anal canal to begin at the dentate line and end at the anal verge. However, most surgeons consider the anal canal to start at the anorectal ring and terminate at the anal verge. This latter definition of the anal canal is used throughout this chapter.

Just above the dentate line, the rectal mucosa forms 8–14 longitudinal folds known as the *rectal columns*. Between each two columns at the dentate line is a small pocket termed an *anal crypt*. Small, rudimentary anal glands open into some, but not all, of these anal crypts. The glands may extend through the internal sphincter as far as the intersphincteric plane, but they do not extend into the external sphincter.

Below the dentate line, cutaneous sensations of heat, cold, touch, and pain are conveyed by afferent fibers in the inferior rectal nerves. Cephalad to the dentate line, poorly defined dull sensations, elicited when the mucosa is pinched or internal hemorrhoids are ligated, are probably carried by parasympathetic fibers.

The superior rectal artery, the terminal branch of the inferior mesenteric artery, descends to the upper rectum where it divides into lateral branches. Subsequent smaller divisions penetrate the rectal wall. The middle rectal arteries arise from the internal iliac arteries and supply the distal rectum and upper anal canal. The inferior rectal arteries, branches from the internal pudendal arteries, cross the ischiorectal fossae to supply the anal sphincters (Fig. 39-3).

There are two paths for venous blood return from the anorectum. Above the dentate line, venous blood flows into the portal system through the superior rectal vein and inferior mesenteric vein. Below the dentate line, the external hemorrhoidal plexus drains into the internal iliac vein via the middle rectal vein or via the pudendal vein, which receives blood from the inferior rectal vein.

FECAL INCONTINENCE

Pathophysiology

Mechanical disruption is usually due to obstetric injury, trauma, or fistula disease in which the external muscle is divided or damaged (Table 39-1). Neurogenic incontinence is due to stretching of the pudendal nerves during prolonged labor, descent of the perineum and nerve stretch during straining at stool or rectal prolapse, or systemic disease such as multiple sclerosis, scleroderma, or spinal cord injury. Idiopathic incontinence is due to medical disease such as diarrhea in a patient with limited rectal capacity, irritable bowel syndrome, or sedatives that cause poor sensation in the anal canal in patients with no evidence of neurogenic or mechanical incontinence.

The normal continence mechanism has several components. Rectal capacitance and compliance are essential. The rectum normally holds between 200 and 250 mL. It distends readily with filling and has limited muscular activity intrinsically. The internal anal sphincter provides 80% of the resting anal sphincter pressure that provides the resistance to gas and mucus at the anal canal. The sampling reflex is a function of rectal distension causing internal anal sphincter relaxation via an intramural reflex to the internal sphincter. The rectal contents can then be sensed in the sensory nerve–rich transitional zone and anoderm to discriminate the true nature of the rectal contents. This sampling reflex occurs frequently throughout the day to provide continence and also serves to initiate the defecation process. The voluntary external sphincter muscle contraction in response to this sampling reflex provides the final active component of fecal continence. The subconscious voluntary contraction of the external sphincter, puborectalis, and pelvic floor muscles provide complete control of rectal contents. The pelvic floor muscles maintain continual activity, even during sleep, to provide fecal continence. This also

seems to be a learned response because infants and children require 1–2 years to achieve control.

Fecal incontinence is defined as the inability to control the passage of gas, liquid, or stool until a socially acceptable time or place for evacuation. The frequency of incontinence may vary, and the loss of control may involve solid stool, liquid stool, or gas only. Frequent episodes of incontinence to gas alone may be as incapacitating as infrequent episodes of solid stool. Evaluation of fecal incontinence should include assessment of severity as well as impact of disease. The American Society of Colon and Rectal Surgeons has validated a fecal incontinence severity index and a fecal incontinence quality-of-life index to help standardize the assessment of fecal incontinence.[1–3]

Diagnosis and Evaluation

A problem-focused history as well as physical examination should be performed. History should include information on gastrointestinal or neurologic disorders, obstetrics, and previous anorectal surgery. On physical examination, a thin perineal body with scarring between the vagina and the anal canal and a poor squeeze on command may indicate a sphincter problem. In the setting of an anterior sphincter injury, it is essential to evaluate for the presence of a rectovaginal fistula.

Anal manometry is useful to document reduced resting and squeeze pressures as well as sphincter length in individual sphincter quadrants. Normal resting pressure is at least 40 mm Hg. Normal squeeze pressure is 80 mm Hg, which is usually double the resting pressure. Sphincter length is greater than 3 cm. Normal sensation should allow detection of a balloon inflated with 10–20 mL of air in the distal rectum. Maximal tolerable volume is at least 100 mL of air-filled balloon distention.

ELECTROMYOGRAPHY

Pudendal nerve terminal motor latency (PNTML) determination measures the conduction velocity of the nerve action potential through the terminal 4 cm of the pudendal nerve between Alcock's canal and the external sphincter (Fig. 39-4). A delay in conduction reflects injury to the fast-conducting fibers of the nerve. This injury usually is the result of stretch, direct trauma, or systemic disease. The normal terminal motor latency is 2.0 ± 0.2 milliseconds. A delay in conduction velocity greater than this indicates nerve injury. Measurement of the PNTML has been shown to be clinically less useful than originally thought. The defect in the nerve must be fairly advanced to see a change in conduction and is therefore somewhat inaccurate for assessing minor defects. Single-fiber or concentric needle electromyography (EMG) is most accurate but not very useful clinically due to pain during the test.

TRANSRECTAL ULTRASOUND

The most sensitive method for documenting sphincter injury may be the anal ultrasound using a 360-degree rotating 10-MHz transducer covered with an anal cap and inserted into the anal canal. The focal length of the anal probe is approximately 1–2 cm and allows evaluation of the anal sphincter muscles in three dimensions as the probe is withdrawn from the rectum (Fig. 39-5). The ultrasound can detect scarring at the site of an injury, as well as rectovaginal fistula. The presence of a sphincter defect alone, however, may not correlate with fecal incontinence. Figure 39-6 shows an algorithm for the evaluation and management of fecal incontinence using these diagnostic techniques.

High-resolution magnetic resonance imaging (MRI) with an endoanal coil is a diagnostic modality that can detect sphincter defects similarly to endoanal ultrasound. Endoanal coil MRI may also show sphincter atrophy or thinning not detectable by endoanal ultrasound that may be useful for predicting success of surgical repair.[4] Focused pelvic floor MRI with a surface coil and dynamic MRI are being evaluated as methods of evaluating fecal incontinence.[5,6]

Treatment

Therapy depends on severity of symptoms. For milder forms of fecal incontinence, an improvement in symptoms may occur with dietary changes such as increased fiber intake or antidiarrheal agents. A bowel regimen with high fiber, suppositories, and enemas every morning may be appropriate in patients with incontinence that cannot be repaired because of comorbidities or other confounding factors.

MUSCLE SENSORY RETRAINING OR BIOFEEDBACK

Operant conditioning using surface EMG, manometric, and balloon sensation techniques may be helpful in patients who do not respond to dietary changes.[7] Biofeedback may improve symptoms in patients with a mechanical sphincter defect before repair or who have persistent or recurrent symptoms after sphincter repair. Improvement in symptoms is reported in 64–89% of patients.[8] Prediction of the subset of patients who may benefit from biofeedback is difficult, but in general those with poor pudendal nerve function or complete disruption of the anal sphincter have less benefit. A trained physical therapist or anal physiotherapist experienced with anal and pelvic floor treatment is critical to the degree of success achieved.

ANAL SPHINCTER RECONSTRUCTION

Anal sphincter repair can be performed successfully in most patients who have an isolated mechanical sphincter defect. A complete bowel preparation is highly recommended. The ends of the obstetrically injured sphincter are identified in the anterior perineum and either overlapped and sutured "pants over vest" or reefed in the midline to reconstruct the circular muscle (Fig. 39-7). Control of solid and liquid stool will be adequate in 90% of patients after this type of repair. However, complete continence is usually only achieved in 75% of patients and the long-term results may even be less satisfactory.[9] Leakage of liquid, mucus, and gas may continue to affect patients after repair. Improvement in squeeze pressures has been shown to correlate best with functional outcome.[10] The presence of at least one normal pudendal nerve is important for functional improvement after sphincter reconstruction. Complications of wound infection, fistula formation, and breakdown of the sphincter repair may be reduced by leaving a drain in the perineal body after the repair. A repeat procedure is equally successful in patients in whom the sphincter repair is noted to be disrupted by endoanal ultrasound.[11,12]

OTHER TREATMENTS AND NEW MODALITIES

Sacral nerve stimulation using implanted electrodes at the S2–4 foramen has been found to be of benefit for patients with fecal incontinence.[13–16] Complications requiring removal of the device seem to be uncommon. Rarely, infection and pain at the site can be encountered. This technique is now approved

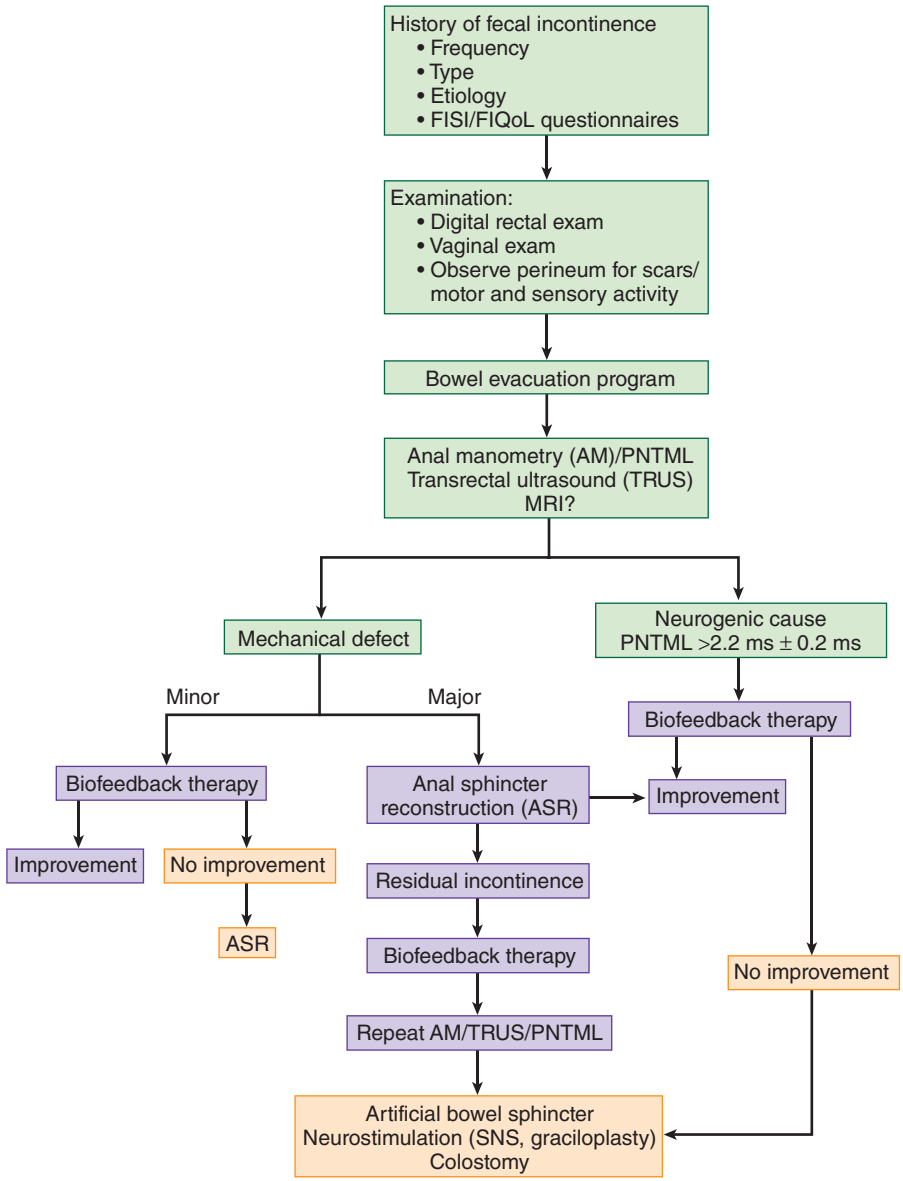

FIGURE 39-6 Algorithm for evaluation and management of anal incontinence. PNTML, pudendal nerve terminal motor latency; SNS, sacral nerve stimulation.

in the United States for fecal incontinence. The mechanism of action is not fully delineated but may be due to the lift of the pelvic floor provided by levator ani continual contraction. Placement of the electrodes can be performed as an outpatient under local anesthesia.

For patients with a severely damaged sphincter, dynamic graciloplasty or implantation of a neurostimulator that provides constant activity into a muscle transferred to the anal canal may be appropriate, but it has been discontinued in the United States.[17] Alternatively, an artificial sphincter of silicone with water-filled circum-anal cuff, called *artificial bowel sphincter*, may be implanted. Although the rate of explantation secondary to infection remains high, this technique can provide improvement in fecal continence. This technique has been removed from the market.[18,19]

When all other treatments fail, or if a patient desires, a stoma may be appropriate. Attention should be directed preoperatively to correct siting of the stoma to prevent pouching difficulties. Quality-of-life measures show that patients are generally satisfied. In a series from St. Mark's hospital, 83% of patients with a permanent colostomy reported improvement in lifestyle.[20]

Philadelphia, PA: WB Saunders; 1991:349–361.)

RECTAL PROLAPSE AND INTERNAL INTUSSUSCEPTION

Pathophysiology

The true etiology of rectal prolapse and intussusception is unknown. The mechanism is influenced by three components: (1) The rectum and rectosigmoid junction have increased mobility off the sacrum; (2) descent of the rectosigmoid junction into the pelvis allows a funnel-shaped intussusception into the rectum as the rectum attempts to expel itself; and (3) poor relaxation of the pelvic floor and external sphincter mechanism occurs during straining (Fig. 39-8). Persistent straining against this outlet obstruction may lead to descent of the perineum, expulsion of the rectum, and true rectal prolapse. This sequence of events from progression of internal intussusception (funnel formation) to full rectal prolapse is supported anecdotally. Consequences of rectal prolapse include anal canal injury from stretch of the internal sphincter during rectal prolapse and/or injury to the pudendal nerve during descent of the perineum. The classic defecographic

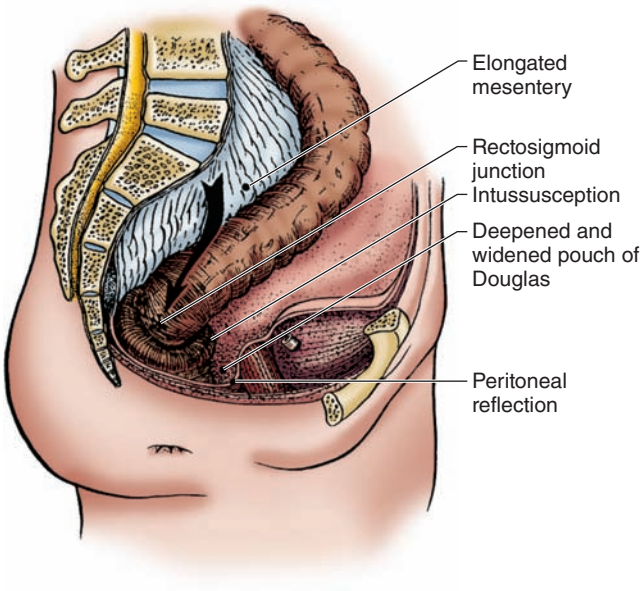

FIGURE 39-8 Rectum with internal intussusception. (Reproduced, with permission, from Hoffman MJ, Kodner IJ, Fry RD. Internal intussusception of the rectum: diagnosis and surgical management. *Dis Colon Rectum*. 1984;27:435.)

picture of rectal prolapse and severe intussusception is a funnel that descends into the deep pelvis as the rectosigmoid junction descends. A ball valve obstruction occurs at the level of the anal canal before it is pushed through to the outside.

A distal mucosal prolapse is occasionally mistaken for full rectal prolapse. The typical appearance of a mucosal prolapse is that of mucosa separated by radial lines around the anus (Fig. 39-9A). Concentric rings of mucosa are seen in true rectal prolapse (Fig. 39-9B). Defecography is helpful to distinguish between these two entities, as they are treated differently.

Diagnosis and Evaluation

Signs and symptoms of rectal prolapse include rectal pressure and pain, incomplete evacuation, outlet obstruction, and constipation causing prolonged straining. Mucus discharge and bleeding from the fully prolapsed tissue may also be present. Examination most often reveals concentric rings of rectal tissue with a patulous anal canal, poor voluntary tone, and a very mobile rectum within the vault. Proctosigmoidoscopy reveals descent of tissue during straining and occasionally an ulcer on the anterior wall (caused by ischemia at the lead point of the intussusception). Defecography reveals extreme mobility of the rectum from its point of fixation to the sacrum, redundancy of the mesorectum, and funnel formation as the rectum prepares to descend through the anal canal opening at the pelvic floor. Defecography is most useful in cases that cannot be visualized in an office setting. Thickened barium simulates stool and cinedefecography allows visualization

of the defecating process; this is particularly helpful in cases in which mucosal prolapse is suspected and the intent is to rule out full rectal prolapse. Triple-contrast cinedefecography (rectum, vagina, and small bowel and bladder as needed) also helps delineate complex pelvic floor abnormalities. This technique is gradually being replaced, or at least supplemented, by dynamic MRI and three-dimensional (3D) ultrasound of the pelvic floor.

A grading system of intussusception has been developed to assist one in planning management (Table 39-2). Mild to moderate intussusception with some mobility, some funnel formation, and descent of the rectum can usually be treated conservatively. However, grade 4 intussusception with severe outlet obstruction may require operative resection of the redundant rectum or rectopexy to secure the rectum to the sacrum.[21] The most appropriate setting for operative treatment of internal intussusception is the patient who has developed moderate incontinence from the intussusception and straining or the patient who has severe bleeding from the solitary rectal ulcer at the tip of the funnel.

Anal manometry can be useful to document the preoperative function of the sphincter if there is not an obvious patulous anal canal on examination. PNTMLs provide objective evidence of pudendal nerve injury and allow some prediction of continued recovery after repair.

Management

Rectal Prolapse. There are numerous techniques for management of rectal prolapse; over 100 procedures have been described. The four basic types of procedures include rectopexy, low anterior resection, perineal proctectomy, and anal encirclement procedures.[22]

Rectopexy relies on foreign material or sutures to attach the rectum to the sacrum. The rectum is mobilized down to the pelvic floor, and the rectum is stretched out of the pelvis to fit into the curve of the sacrum. For patients who report constipation preoperatively, the redundant sigmoid colon and rectum may be removed. The low anterior resection technique uses the standard technique for removal of the middle and upper portions of the rectum and redundant sigmoid colon. The left colon is reattached to the upper or middle third of the rectum by using either a double-staple or hand-sewn technique (Fig. 39-10). The rectum is mobilized to the level of the pelvic floor circumferentially, but preserving the anterolateral ligaments carrying the middle rectal arteries and splanchnic nerves. The left colon and rectum (now in continuity) are returned to the curve of the sacrum. The incidence of fecal incontinence may be higher after this procedure because the rectal capacitance is reduced. As well, postoperative evacuation difficulties may be noted if the anterolateral ligaments have been divided. Preoperative anal physiological testing may assist in the selection of patients who are candidates for low anterior resection (ie, no evidence of sphincter injury or dysfunction).

Suture rectopexy with or without sigmoid resection in patients with constipation-associated rectal prolapse have low recurrence rates in well-selected patients. Laparoscopic rectopexy is a reasonable alternative that may be associated with fewer complications and a shorter hospital stay.[23,24] A technique of anterior Prolene mesh rectopexy has been described by D'Hoore, which only mobilizes the anterior rectum to the anal canal and suspends the rectum with the mesh with sutures placed along the anterior rectum at the level of the rectovaginal septum and attached to the sacral promontory. The redundant cul-de-sac is excised and the peritoneum is closed over the mesh along its length.[25]

The use of a perineal proctectomy with anterior and posterior reefing of the sphincter muscle has become more popular for the treatment of rectal prolapse in the elderly patient with full rectal prolapse and comorbidities. This is a revival of the Altemeier perineal resection technique. The entire prolapsing rectum and redundant sigmoid are removed through a perineal approach beginning at the top of the transitional zone columns (Fig. 39-11). The left colon or proximal sigmoid is sutured to the transitional zone 1–2 cm above the dentate line. The external anal sphincter and pelvic floor muscles can be reefed in the anterior and posterior midline to restore anal tone in patients with incontinence as described by Prasad et al.[26] The incidence of recurrent prolapse is approximately 10% in patients with good sphincter function. Even though the operation is generally recommended for elderly patients, it may be appropriate for patients of all ages with severe compromise of sphincter tone and pronounced procidentia. This procedure is not technically possible in patients who have mucosal prolapse alone or patients with high rectal prolapse and an intact anal canal and normal sphincter.

Anal encirclement procedures have been mostly replaced by the perineal proctectomy. The anal encirclement procedure using synthetic material such as nylon mesh should be limited to the extremely debilitated patient or the elderly

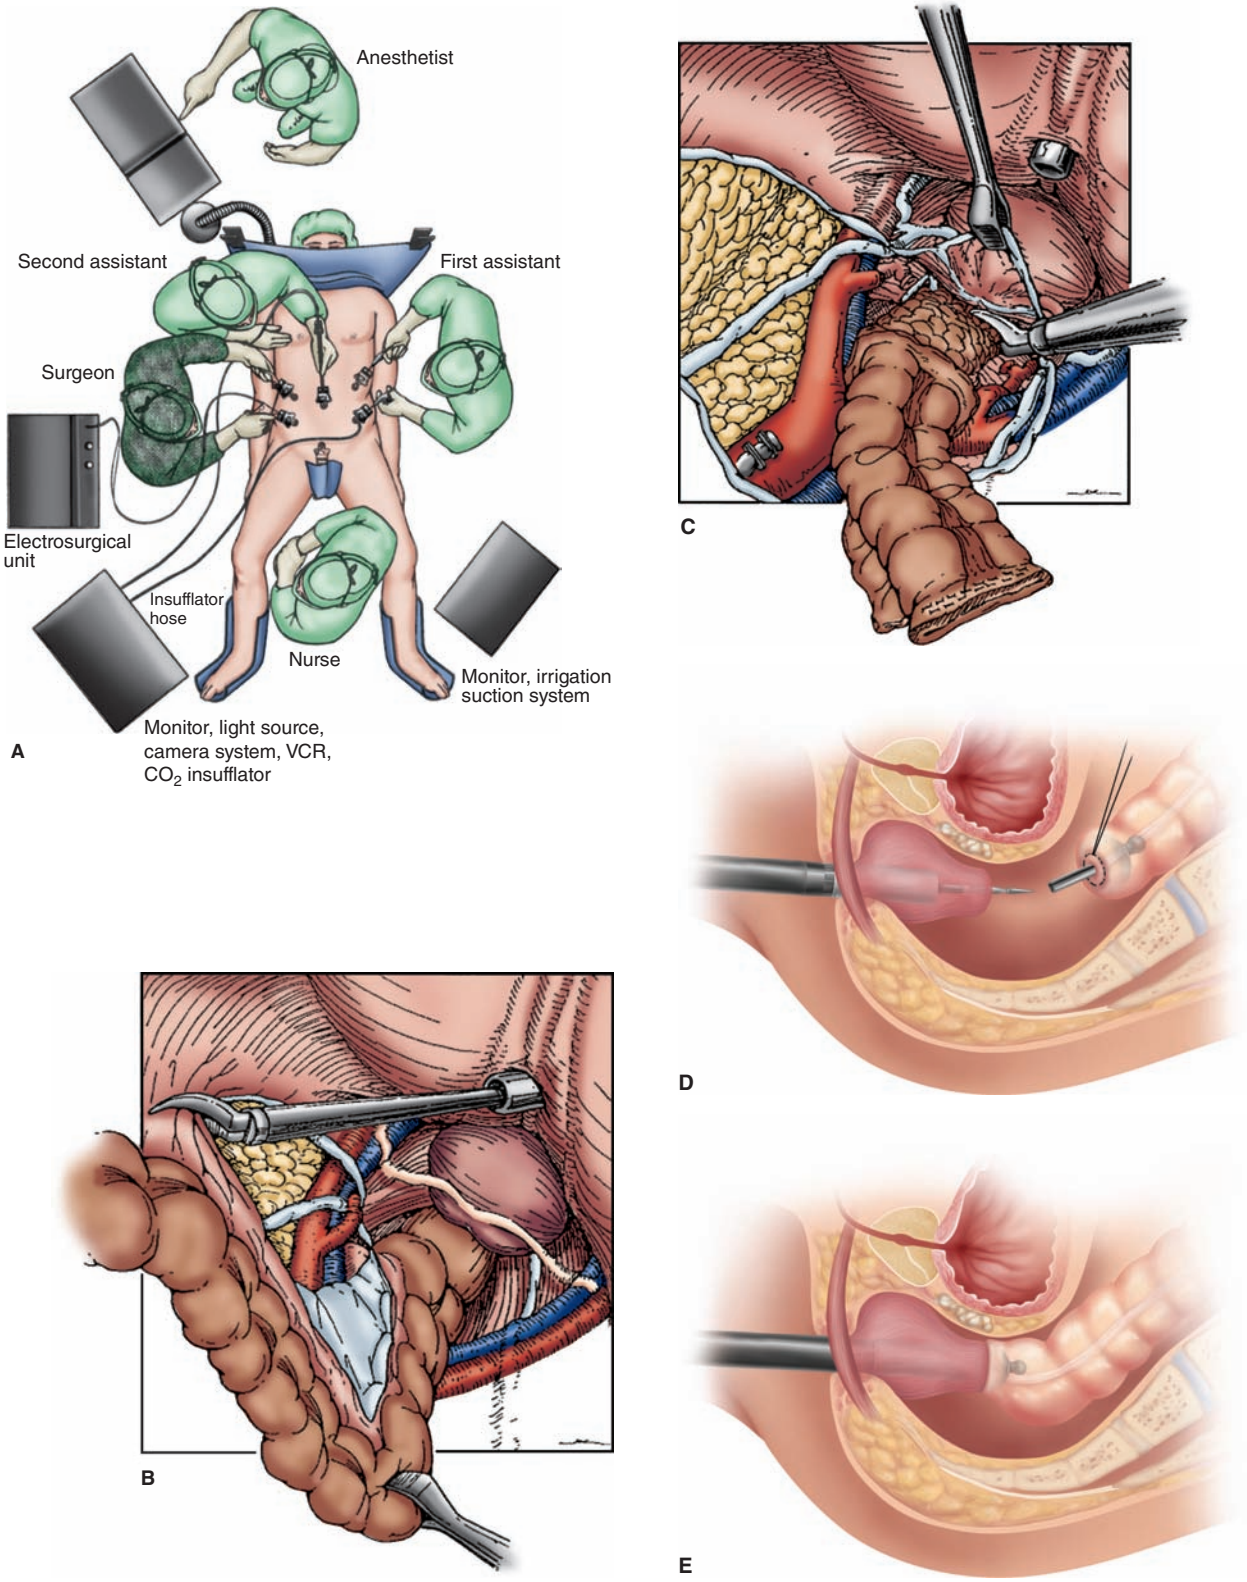

FIGURE 39-10 Laparoscopic low anterior resection with colorectal anastomosis—double-staple technique. **A.** Laparoscopic positioning of the patient and surgeon. The patient is secured to the table in modified lithotomy position. The operating surgeon stands to the right of the patient. Trocar placement is based on use of hand-assisting devices and surgeon preference. **B.** Lateral approach to mobilization of the sigmoid colon and identification of the left ureter. **C.** Laparoscopic mobilization and dissection of the rectum down to the lateral ligaments. **D.** Intracorporeal colorectal anastomosis: a descending colon purse-string suture is tied around the shaft of the anvil. This can also be performed extracorporeally with a hand-assisting device or via a small incision. **E.** Completed anastomosis with stapler still in place.

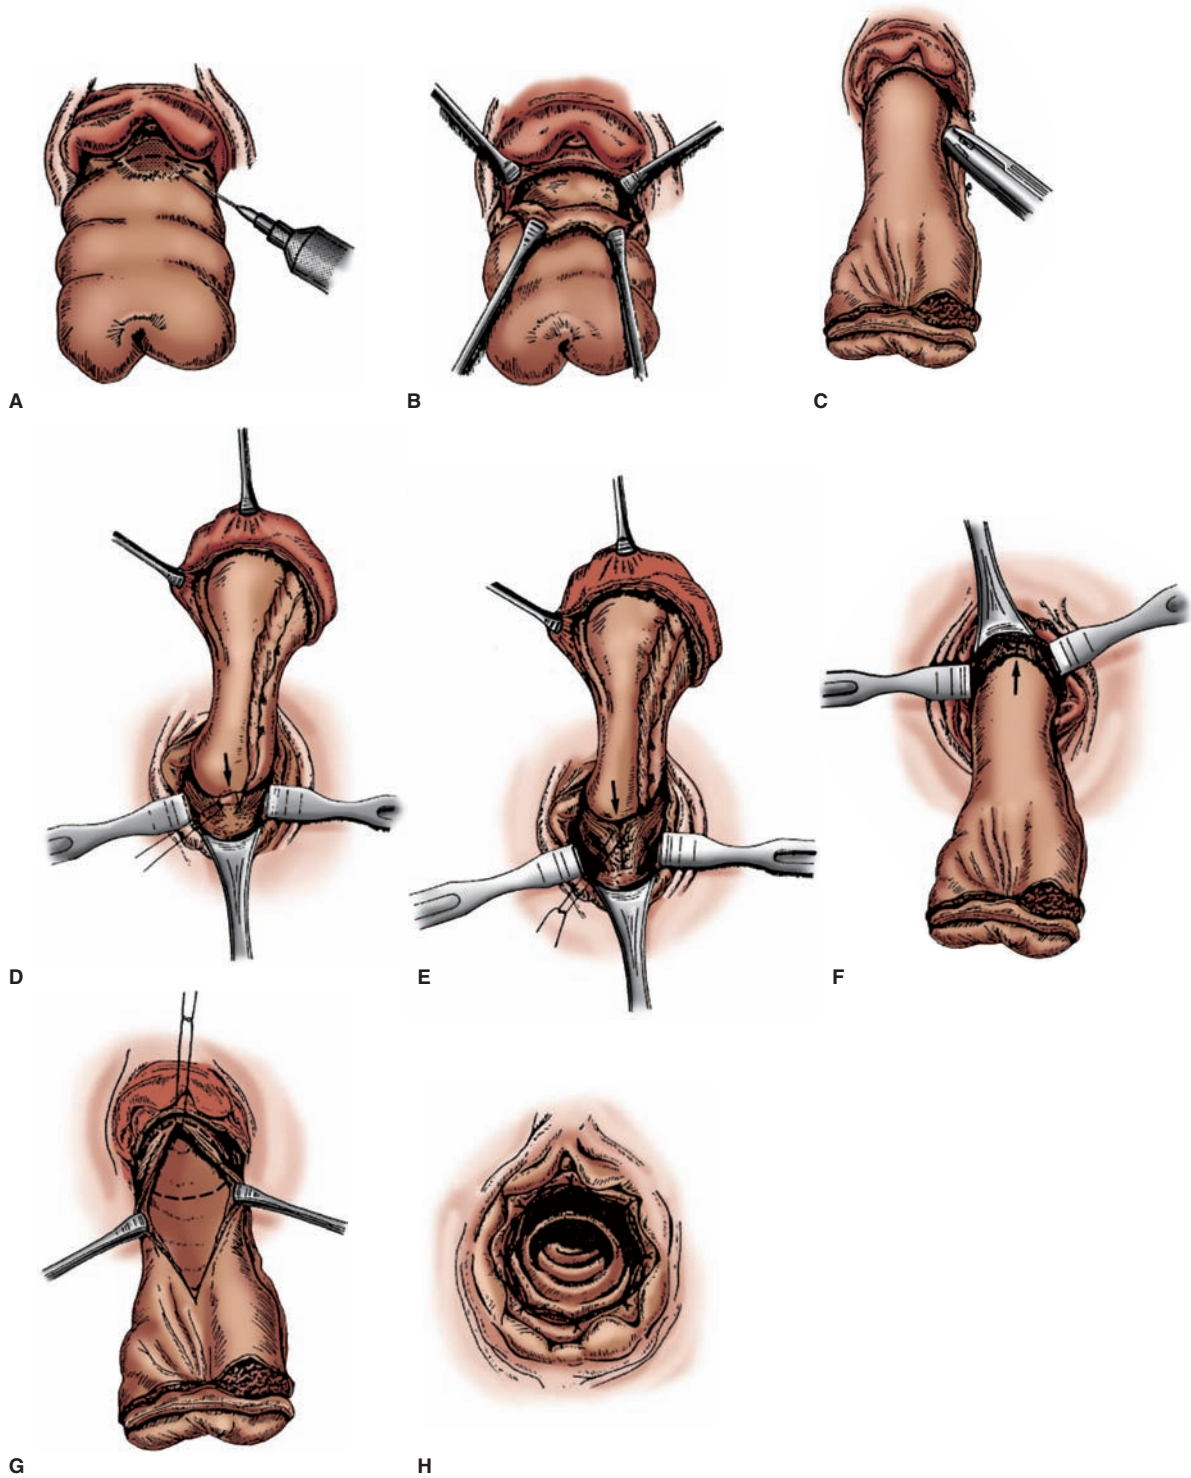

FIGURE 39-11 Perineal proctectomy. **A.** Patient in the prone jackknife position. After gentle traction is applied on the rectal wall, a diluted epinephrine solution is injected into the outer layer of the prolapsed rectal wall. **B.** A circular incision is made through the full thickness of the outer layer of the prolapsed segment just proximal to the everted dentate line. **C.** The rectal prolapse has been completely unfolded. The mesenteric vessels are carefully ligated close to the bowel wall. **D.** The rectum is elevated anteriorly to expose the presacral space. A posterior rectopexy is performed (*arrow*) by approximating the seromuscular layers of the bowel wall to the precoccygeal fascia above the levator ani muscles. **E.** The levator ani muscles are approximated posteriorly (*arrow*). This repair pushes the bowel anteriorly to help recreate the anorectal angle. **F.** One or two sutures are used to approximate the levators anterior to the rectum to reinforce the pelvic floor. **G.** The prolapse is amputated and the colon is sutured to the dentate line in a circumferential fashion (*dotted line*). **H.** Completed anastomosis. (Reproduced, with permission, from Prasad ML, Pearl RK, Abcarian H, Orsay CP, Nelson RL. Perineal proctectomy, posterior rectopexy, and postanal levator repair for the treatment of rectal prolapse. *Dis Colon Rectum.* 1986;29:547.)

patient who cannot withstand perineal proctectomy. It can be effectively performed under local anesthesia in patients with prohibitive surgical risks and decreased life expectancy.

Internal Intussusception of the Rectum

The treatment of internal intussusception of the rectum is primarily conservative with use of a high-fiber diet. High doses of psyllium may prevent formation of the funnel and outlet obstruction with normalization of bowel function. Patients with pelvic floor outlet obstruction (nonrelaxation of the puborectalis) may benefit from biofeedback. In patients without pelvic floor outlet obstruction and with severe symptoms from the intussusception (ie. bleeding or incontinence), an operation may be considered. A low anterior resection or rectopexy is appropriate for these patients depending on whether they have constipation or incontinence, respectively. The treatment of a bleeding solitary rectal ulcer by low anterior resection sometimes requires an ultralow anterior resection and coloanal anastomosis in the setting of an extremely thickened anterior rectal wall that overwhelms even the thickest staple height. Perineal proctectomy is not recommended because the sphincter mechanism is intact and resection of redundant rectum will be extremely difficult in patients with an incomplete prolapse. Tests that are obtained prior to operation for internal intussusception include colonic transit times to document normal colonic transit, defecography that shows the level of the funnel formation within the rectum, and a balloon expulsion test to eliminate pelvic floor outlet obstruction as a cause of the intussusception.

The use of transanal stapling (STARR [(stapled transanal rectal resection)] or Transtar) procedures has become popular in Europe. Patient selection is important as those with other abnormalities such as enteroceles, larger rectoceles, or nonrelaxation of the puborectalis were found not to have good response after the STARR procedure.[27] Complications include bleeding, perineal pain, recurrence, or incontinence. In a trial comparing STARR versus biofeedback, the STARR procedure was found to be more effective in improving symptoms of obstructed defecation. It may be performed in unhealthy individuals under local by a properly trained individual after failure of biofeedback.[28]

PELVIC FLOOR OUTLET OBSTRUCTION AND SOLITARY RECTAL ULCER SYNDROME

Pathophysiology

The presenting complaints of patients with pelvic floor outlet obstruction usually include some form of constipation and straining. Defecation is a learned process and pelvic floor outlet obstruction may be either a change in the defecating mechanism or a failure to learn the appropriate series of events to allow normal function. The muscle of the pelvic floor is completely normal, but the function and control are abnormal. There may be a psychologic influence in this syndrome because patients who have been sexually abused or have been psychologically traumatized may develop this outlet obstruction. The need to dominate and control has also been documented in these patients. The syndrome results from obstruction of the anal canal due to anterior displacement of the puborectalis muscle and contraction of the pelvic floor and external sphincter during straining to defecate. Attempts to defecate against a closed pelvic floor result in chronic funnel formation of the rectum and descent of the anterior rectal wall into the anal canal. This chronic trauma and ischemia may lead to the formation of an ulcer on the anterior wall of the rectum. The stimulus to defecate is often neglected. The end result is an uncoordinated effort at defecation with pelvic floor obstruction of the outlet, even as the rectum begins to distend and the autonomic muscles begin to relax.

It is possible that pelvic floor outlet obstruction is etiologically related to rectal prolapse and intussusception. However, no long-term studies have provided conclusive evidence. Patients may also present with megarectum from outlet obstruction, fecal incontinence due to nerve injury from chronic straining, or severe mucosal prolapse or hemorrhoids.

The solitary rectal ulcer is assumed to be due to ischemia of an isolated portion of the anterior rectal wall, approximately 10 cm above the anal verge, which prolapses partially into the anal canal and becomes ischemic during prolonged straining. The healing process may occasionally incorporate mucosal glands beneath the new mucosal surface and form a localized area of colitis cystica profunda. These entrapped glands continue to produce mucus and are occasionally mistaken for an early neoplasm of the rectum.

Diagnosis and Evaluation

Patients with pelvic floor outlet obstruction may complain of a number of problems that include constipation and straining at defecation, the need for digital maneuvers to evacuate the rectum, bleeding, mucosal prolapse, and hemorrhoids. They occasionally present with chronic pain of the anal canal and symptoms of severe spasm of the anal canal and pelvic floor. In the past this was classified as anismus, proctalgia fugax, or levator ani syndrome. Digital rectal examination may reveal paradoxical motion (tightening instead of relaxing) of the puborectalis muscle during attempts to push the finger out of the rectum. Defecography generally shows a persistent puborectalis impression on the posterior rectum as the patient attempts to evacuate the rectal contents. Defecography tends to overdiagnose the problem of nonrelaxing puborectalis. This may be due to an unnatural setting in a cold radiology suite or possible patient embarrassment. The presence of nonrelaxing puborectalis muscle must therefore be confirmed using some other technique. The method best suited to our practice has been to have the patient expel a 60-mL air-filled soft latex balloon while sitting in a private bathroom. This simple

technique of expulsion of the balloon within the confines of a private bathroom seems to be adequate.[29] Surface EMG is also useful in the diagnosis and treatment of nonrelaxing puborectalis muscle, as it documents decreased pelvic floor electrical activity during proper straining techniques and an increase during paradoxical contraction. Colonic transit study will demonstrate accumulation of all of the administered radiopaque markers within the rectum after an elapsed period adequate for clearance (>7 days). An algorithm used to deal with pelvic floor disorders is shown in Fig. 39-12.

Treatment and Management

The initial steps in the treatment of outlet obstruction problems include high doses of fiber and establishment of a normal bowel routine. Outpatient biofeedback using surface EMG, balloon expulsion, sensation techniques, and a simulated stool are also effective in severe cases of nonrelaxing puborectalis muscle.[30] Psychological counseling and relaxation techniques may be of help in patients who have a psychological component to their problem.

RECTOCELE, ENTEROCELE, AND COMPLEX PELVIC FLOOR ABNORMALITIES

Outpouching or bulging of the rectum into the vagina (rectocele) can be seen on defecography in patients with pelvic floor disorders. These findings, however, can also be found in patients without any pelvic or bowel complaints. Surgical repair does not always lead to resolution of symptoms. No predictors of successful outcome of surgery are universally accepted from various studies examining characteristics on defecography and symptomatology. Surgical technique is the surgeon's preference and can be performed via a transanal, transvaginal, or perineal approach to bolster, pleat, and reconstruct the muscle in the rectovaginal

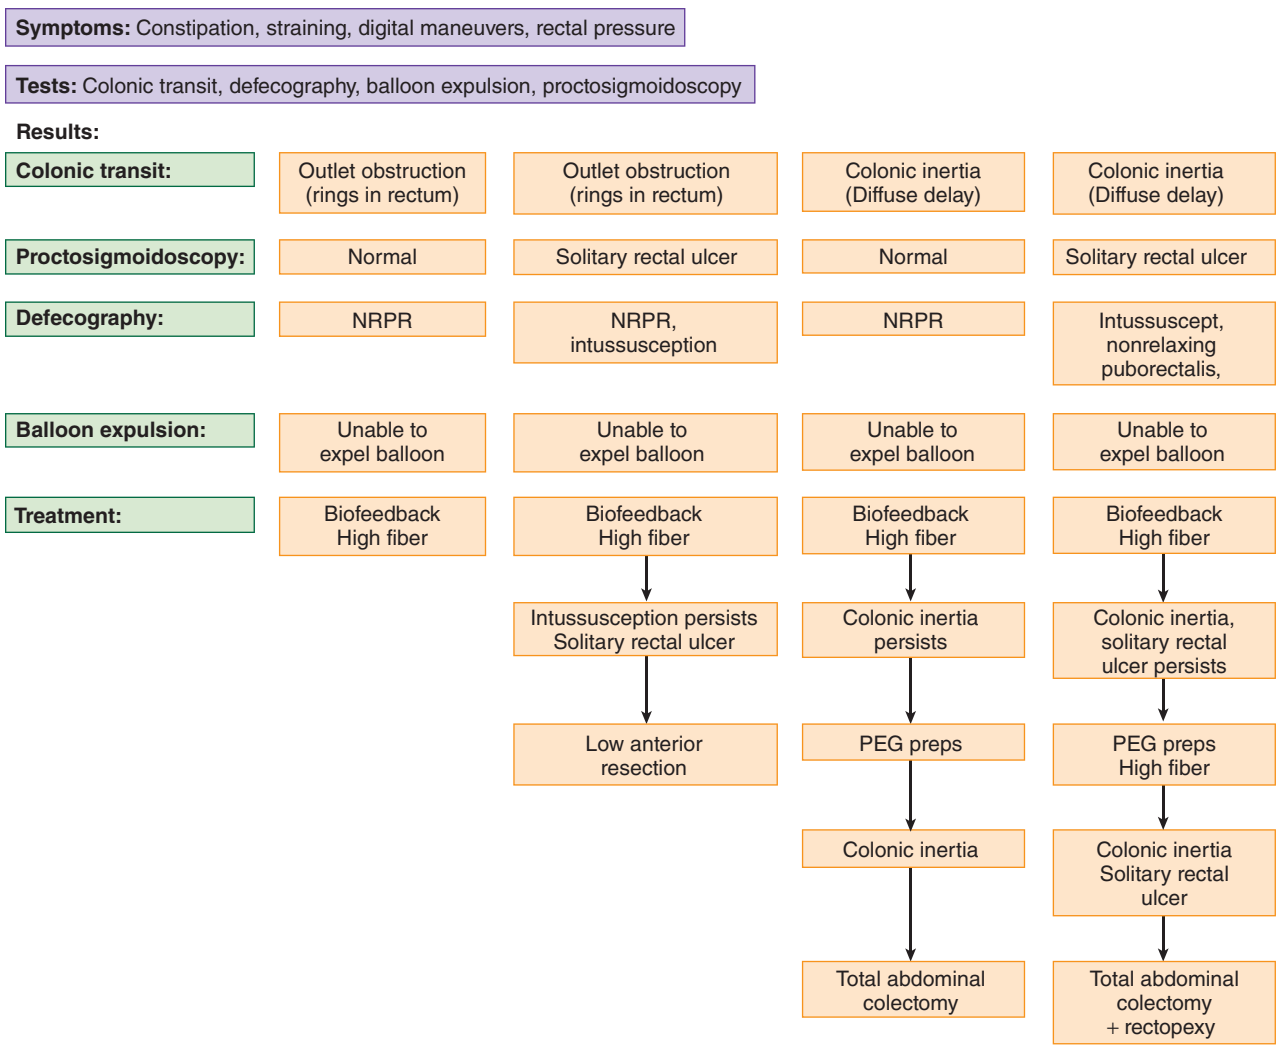

FIGURE 39-12 Algorithm for diagnosis and treatment of pelvic floor outlet obstruction. NRPR, nonrelaxing puborectalis.

septum. Fortunately, the majority of patients improve with medical management.[31,32] Rectoceles occurring in patients with rectal prolapse generally resolve after repair of the prolapse as long as the rectum is mobilized all along the rectovaginal septum.

Enteroceles or bulging of small bowel into the rectogenital area can also be detected on defecography. This is a common finding in patients who are status post hysterectomy, in patients with symptoms of obstructive defecation, or in asymptomatic patients. An enterocele can be repaired transabdominally in conjunction with operative management of other pelvic floor abnormalities by reefing or excising and reclosing the redundant pelvic peritoneum to prevent herniation of small bowel into the pelvic floor.

Pelvic floor disorders may also involve bladder or gynecological complaints. A multidisciplinary team approach for evaluation and operative management of complex pelvic floor abnormalities may include a urogynecologist for bladder or vaginal suspension in addition to rectopexy/resection, and pelvic floor suspension. Dynamic MRI may be a useful modality for the diagnosis of some of these challenging pelvic floor cases.[33] High-resolution 3D endovaginal and endorectal ultrasonographies are increasingly being used for evaluation of pelvic floor disorders.[34,35]

HEMORRHOIDS

Current theories about the development of hemorrhoids consider the nature of anal "cushions." Such cushions are aggregations of blood vessels (arterioles, venules, and arteriolar-venular communications), smooth muscle, and elastic connective tissue in the submucosa that normally reside in the left lateral, right posterolateral, and right anterolateral anal canal.[36] Smaller discrete secondary cushions may reside between the main cushions. Hemorrhoids are likely the result of a sliding downward of these anal cushions. Hemorrhoids provide tissue to close the anal canal during rest. It appears that the disintegration of the anchoring and supporting connective tissue and the terminal fibers of the longitudinal muscle above the hemorrhoids allows these structures to slide distally.

Classification

Anal skin tags are discrete folds of skin located at the anal verge. These may be the end result of resolved thrombosed external hemorrhoids or, more rarely, may be associated with inflammatory bowel disease. Internal hemorrhoids reside above the dentate line and are covered by transitional and columnar epithelium (Fig. 39-13). First-degree internal hemorrhoids cause painless bleeding with defecation. Second-degree hemorrhoids protrude through the anal canal at the time of defecation but spontaneously reduce. Third-degree internal hemorrhoids protrude and bleed with defecation, but they must be manually reduced. Fourth-degree internal hemorrhoids are permanently fixed below the dentate line and cannot be manually reduced.

External hemorrhoids consist of the dilated vascular plexus located below the dentate line and are covered by squamous epithelium. Mixed hemorrhoids are composed of elements of both internal and external hemorrhoids.

Evaluation of Internal Hemorrhoids

Even though internal hemorrhoids are the most common source of rectal bleeding, it is imperative that other causes be excluded. Because internal hemorrhoids cannot be detected by digital examination, diagnosis can only be made by anoscopy. It is mandatory that colonoscopy be performed in high-risk patients to exclude other sources of bleeding, such as carcinoma or proctitis (eg, for patients aged >40 years and those with a personal or family history of colorectal neoplasia or a change in bowel habits).

Treatment

Regulation of diet and avoidance of prolonged straining at the time of defecation comprise the initial treatment of mild symptoms of bleeding and protrusion. Increasing the fiber content of the diet to at least 25–35 g daily with raw vegetables, fruits, whole-grain cereals, and hydrophilic bulk-forming agents can reduce and often alleviate all symptoms. If bleeding and protrusion persist, however, the hemorrhoids should be treated surgically.

Elastic ligation of the friable redundant hemorrhoidal tissue is quite satisfactory for first-, second- and third-degree hemorrhoids. The procedure is quite simple. The hemorrhoid is visualized with the aid of an anoscope and grasped with forceps. The redundant tissue is pulled into a double-sleeved cylinder on which there are two latex bands. The bands are discharged from the cylinder, and the hemorrhoidal bundle is ligated (Fig. 39-14).

Certain precautions, however, must be taken with this form of treatment. The ligatures must be placed at least 1–2 cm above the dentate line to avoid extreme discomfort. Ideally, the ligatures should be placed at the top of the hemorrhoidal cushion. About 25% of patients experience mild, dull anorectal discomfort lasting for 2–3 days following the procedure. Mild analgesics and warm baths are usually sufficient to relieve the discomfort. In about 1% of patients, brisk bleeding that may require suture ligation occurs when the necrotic tissue sloughs off at 7–10 days. About 2% of patients treated with ligation of the internal hemorrhoid develop thrombosis of an external hemorrhoid, which may cause considerable discomfort. Necrotizing pelvic or perineal sepsis is rare and almost always associated with immune compromise but must be immediately recognized in the setting of increased pain, fever, or urinary dysfunction. Treatment requires immediate examination under anesthesia for debridement of all necrotic tissue, intravenous antibiotics, and observation

in the intensive care unit. Patients with poorly functioning neutrophils or reduced numbers of white blood cells for any reason should be treated with another method or at least warned of and observed for the occurrence of this potentially life-threatening complication.

Hemorrhoidal ligation is an office procedure, and no special preparation is required. Patients with a bleeding diathesis or with portal hypertension are not good candidates for ligation. Usually only one hemorrhoid is ligated on the first treatment visit. Ligations can be performed every 2–4 weeks until all symptoms of bleeding or prolapse are alleviated. The second ligation can be multiple if the first treatment is well tolerated. Other minimally invasive procedures such as infrared coagulation, diathermy coagulation, and ultrasound-guided vascular pedicle ligation achieve the same result with variable success and need for effort.

Although diet, bowel regulation, or elastic ligation will alleviate most symptoms of internal hemorrhoids, occasionally further surgical treatment may be needed. Excisional hemorrhoidectomy is indicated for large, mixed (combined internal/external) hemorrhoids that are not amenable to ligation because the ligature would have to incorporate pain-sensitive tissue at or below the dentate line.

Circular stapled hemorrhoidectomy is a newer technique indicated for the elective treatment of circumferential third- and fourth-degree hemorrhoids that are not permanently prolapsed due to scar.[37] This involves placing a purse-string suture incorporating the mucosa of the anal canal with a stapled circumferential mucosectomy at a level 4–5 cm above the dentate line. This can be performed under regional anesthesia with minimal morbidity in experienced hands. Potential complications include bleeding if the staple line is incomplete, pain if the staple line is too close to the dentate line, rectovaginal fistula if the purse string captures the rectovaginal septum, complete closure of the rectum if the stapler and purse string are malpositioned, and return of symptoms if the purse string is incomplete.

Occasionally, the internal hemorrhoidal tissue may be incarcerated outside the anal canal, resulting in spasm of the anal sphincter, massive local edema, and severe pain. In such circumstances, the edematous tissue may be injected with a local anesthetic containing epinephrine. Dissipation of the edema by manual compression then can be achieved, allowing reduction in the prolapsed tissue. Observation and use of stool softeners with tub soaks usually allow the acute episode to resolve without an operation because the hemorrhoidal

vessels have been naturally thrombosed. The thrombosed internal hemorrhoids will sclerose and may not require surgery. If symptoms persist or recur, a three-quadrant hemorrhoidectomy may then be necessary. If necrotic tissue is present at the time of acute thrombosis, emergent excisional hemorrhoidectomy is necessary. Care should be taken to preserve the anoderm. The patient should be kept in the hospital after the procedure until the pain is minimal and until spontaneous voiding is possible and to ensure resolution of any potential infection.

MIXED HEMORRHOIDS

The mucosal component of mixed hemorrhoids occasionally can be treated by elastic ligation. Large symptomatic, nonreducing mixed hemorrhoids generally are treated by excisional hemorrhoidectomy. The patient is placed in the prone flexed position under local anesthesia using a perianal field block with 0.25% bupivacaine with or without epinephrine. The apex of the vascular pedicle is ligated first with a 3-0 chromic catgut suture. An elliptical excision incorporates the external and internal hemorrhoids from the perianal skin to the anorectal ring. The hemorrhoidal tissue is sharply dissected from the underlying internal sphincter (Fig. 39-15). The entire wound is then closed by running the apex chromic catgut suture to the distal perianal skin edge. The largest hemorrhoid is excised first, with care taken not to excise excessive tissue that may result in a stricture. If there is any concern of leaving an adequate anal aperture covered by normal anoderm, it is best to modify a planned three-quadrant hemorrhoidectomy and instead perform a two-quadrant hemorrhoidectomy and band the remaining internal component.

THROMBOSED EXTERNAL HEMORRHOIDS

The external venous plexus is located at the anal verge and encircles the anal canal. A segmental thrombus is confined to the anoderm and perianal skin and does not extend above the dentate line. The problem presents as a painful perianal mass. The overlying skin may be stretched to 2 cm or more. Pain usually peaks within 48 hours and generally becomes minimal after the fourth day. If untreated, the thrombus is absorbed

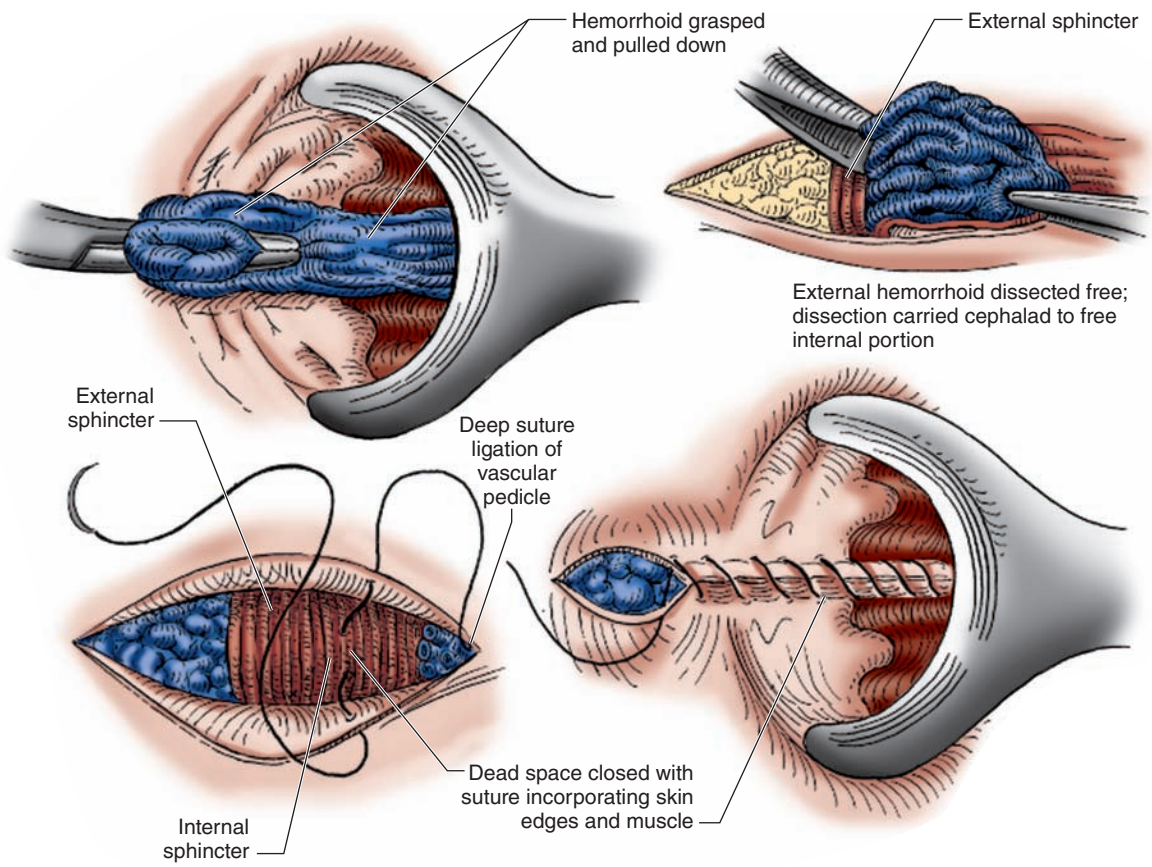

FIGURE 39-15 Excision technique for mixed hemorrhoids. (Redrawn, with permission, from Fry RD, Kodner IJ. Anorectal diseases. *Clin Symp*. 1985;37(6):2–32. Copyright 1985, Academy of Medical Sciences. Originally illustrated by John Craig, MD.)

within a few weeks. The pressure of the underlying clot will occasionally cause the adjacent skin to become necrotic, and the clot will be extruded through the area of necrosis. This is noted by the patient as rectal bleeding followed by relief of the anal pain. A partially extruded clot can be removed in the office to provide relief.

Treatment of thrombosed hemorrhoids is aimed at relief of the pain. If symptoms are minimal, mild analgesics, sitz baths, proper anal hygiene, and bulk-producing agents will suffice. However, if pain is severe, excision of the thrombosed hemorrhoid may be beneficial. Because numerous vessels usually are involved, it is necessary to excise the entire mass along with the overlying skin and subcutaneous tissue. The wound is left open without packing. Postoperative care consists of mild analgesics and warm sitz baths or showers.

ANAL FISSURE

An anal fissure is a split in the anoderm over the hypertrophied band of internal sphincter at the anal verge (Fig. 39-16). The fissure is almost always located close to the midline of the anal canal; in men, 95% are near the posterior midline and 5% near the anterior midline, whereas in women, about 80% will be located posteriorly and 20% anteriorly. The precise cause of an anal fissure has yet to be determined. However, fissures probably are related to tearing of the anoderm at the time of defecation. The increased anal canal pressure that accompanies an anal fissure is associated with ischemia in the area of the fissure and prevents healing, as spasm recurs with each bowel movement.[38] An anal ulcer is the chronic form of an anal fissure with heaped-up edges, sentinel skin tag, and occasionally hypertrophied anal papilla.

Clinical Features and Diagnosis

Most fissures are superficial and heal rapidly with no specific treatment. Occasionally, the fissure may extend deeply through the anoderm to expose the fibers of the internal sphincter. Surprisingly, secondary infection rarely occurs.

Fissures that are aberrantly located may be caused by previous anal operations that result in scarring, stenosis, and loss of anoderm. Individuals with chronic diarrhea may develop anal stenosis associated with a fissure. Crohn's disease often is complicated by anal fissures, which may be a primary manifestation of the disease. These fissures usually are associated with the shiny anal skin tags typical of anal Crohn's disease and may lie laterally instead of close to the midline of the anus.

Patients with anal fissures usually complain of anal pain accompanying and following defecation. Bright red bleeding may accompany a bowel movement, although it is usually minimal. A slight discharge also may be present.

An anal fissure is detected by gently separating the buttocks to reveal the lower edge of the fissure at the anal verge, where a sentinel tag also may be seen. A soft touch of a cotton swab to this area will elicit the pain and help with the diagnosis. A deep gluteal cleft or tight spasm of the sphincter may sometimes obscure the fissure, and, if the patient can tolerate, examination with a small anoscope may be required.

Anal sphincter hypertonicity and an increase in ultraslow waves on anal manometry characterize typical anal fissures.

Treatment

Dietary recommendations and prescription of bulking agents to promote soft stools are beneficial, and warm tub soaks may provide comfort. The majority of acute fissures will heal with conservative management. The use of 2% nifedipine ointment applied to the anoderm outside the anal verge relaxes the sphincter and dilates local vessels to promote healing. Most of the remainder of acute fissures will heal with this added therapy.[39]

The injection of 20–25 units of botulinum A toxin into both edges of an anal ulcer and directly into the internal sphincter muscle at the ulcer base (total of 75–1000 units) is a simple procedure that has had some mixed success in healing anal fissures.[40] It can be done with local anesthesia as an outpatient procedure, with delay of symptomatic relief by approximately 1 week. The paralysis of the internal sphincter reverses in several months, but the fissure may recur. Repeat treatments can be performed if the initial response was adequate, but it is expensive with at best modest healing rates.

Surgical treatment may be required for deep, chronic fissures associated with a sentinel skin tag, hypertrophied anal papilla, and exposed internal sphincter. Excellent results can be achieved if the internal sphincter is divided laterally rather than in the midline. Furthermore, lateral sphincterotomy is not associated with keyhole deformity. Only the thickened band of the internal sphincter is divided (ie, partial sphincterotomy), which limits the amount of internal sphincter transection and reduces the potential for fecal incontinence.

Sphincterotomy can be performed under local anesthesia, using either an open or closed technique (Fig. 39-17). The open technique consists of radial incision of the anoderm over the intersphincteric groove and limited division of the internal sphincter only up to the proximal extent of the fissure under direct vision. The closed method entails dividing the internal sphincter by a subcutaneous approach. Both techniques may be used in the outpatient setting and afford rapid pain relief. Approximately 98% of fissures heal following sphincterotomy. However, there is a small incidence of fecal incontinence following the procedure, so careful patient selection is mandatory. Elderly patients with decreased anorectal sensation are generally not ideal candidates for internal sphincterotomy because of this risk. Consideration should be given to a diamond skin advancement flap to cover the ulcer bed in women. This flap requires isolation of a postage stamp–sized island of skin based on a subcutaneous fat pedicle from the inner aspect of the buttock posteriorly or the perineum anteriorly. The ulcer is excised leaving a defect in the size of the flap. The flap is advanced to

the open area in the anoderm and secured to the freshly cut mucosal edges (Figs. 39-18 and 39-19).

ANORECTAL ABSCESS AND ANAL FISTULA

Diagnosis and Classification

More than 95% of all anorectal abscesses are caused by infections arising in the anal glands that communicate with the anal crypts (cryptoglandular disease). The acute phase of the infection causes an anorectal abscess, while the chronic stage is recognized as an anal fistula. The anal glands lie in the intersphincteric space between the internal and external anal sphincters. Inflammation of an anal gland leads to the formation of a local abscess in the intersphincteric plane. The clinical presentation, natural history, and proper treatment of anorectal abscess and fistula are understood easily if it is recognized that the disease originates as an intersphincteric abscess.

As the abscess enlarges, it escapes the confines of the intersphincteric plane and spreads in one of several possible directions (Fig. 39-20). The most common of all anorectal abscesses is a perianal abscess, which presents as a tender,

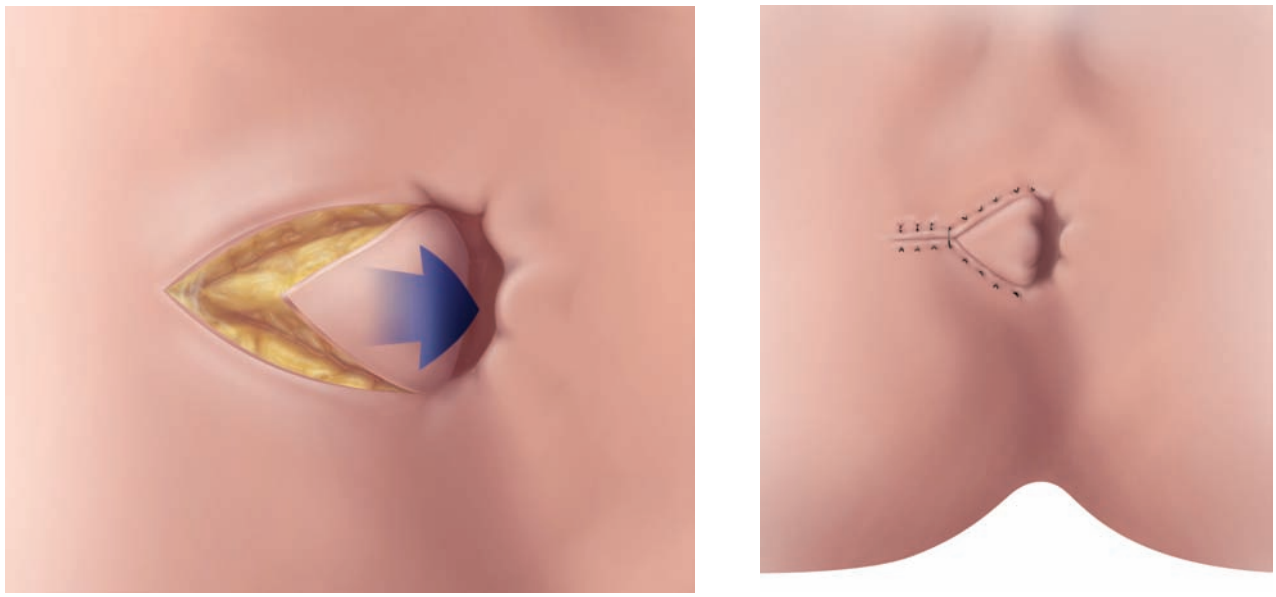

FIGURE 39-19 Flap mobilization. (Redrawn, with permission, from Caplin DA, Kodner IJ. Repair of anal stricture and mucosal ectropion by simple flap procedures. *Dis Colon Rectum*. 1986;29:92–94.)

erythematous bulge at the anal verge. An ischiorectal abscess is formed when a growing intersphincteric abscess penetrates the skeletal muscle of the external sphincter below the level of the puborectalis and expands into the fat of the ischiorectal fossa. These abscesses can become quite large, because the levator ani (the upper border of the ischiorectal fossa) slopes upward. Thus an ischiorectal abscess may be palpated as a bulge above the puborectalis, although it actually lies below the levator ani musculature. In contrast to the perianal abscess, this abscess seldom presents as a visible bulge because of the large potential space in the ischiorectal fossa. Thus the abscess preferentially expands upward rather than protruding through the skin of the buttock. Rarely, an intersphincteric abscess may expand upward between the circular internal sphincter and the external sphincter, forming a supralevator abscess.

Treatment

Perianal abscesses should be drained immediately, before wide fluctuance or cellulitis develops. Antibiotics are not indicated and should be used only in the presence of extensive cellulitis, valvular heart disease, diabetes, or compromised immunity. If the diagnosis is suspected but not readily evident, examination under regional anesthesia should be performed.

With adequate regional anesthesia, the abscess can be detected and localized by digital examination. An intersphincteric abscess is treated definitively by performing an internal sphincterotomy over the length of the abscess cavity, which serves to unroof and drain the abscess. However, if the infection has developed into a perianal or an ischiorectal abscess, adequate drainage of the abscess cavity first must be done by making a cruciate incision in the skin overlying the abscess as close to the anal canal as possible, or excising a small disc of overlying skin to permit complete evacuation of the contents of the abscess cavity. Incision and drainage alone will result in complete resolution of the infection in about half of patients. In the other half, an anal fistula occurs, which consists of a chronically infected tract with an internal opening located in a crypt at the level of the dentate line and an external opening located at the drainage site of the earlier abscess.

The appropriate treatment for an anal fistula is dependent on the anatomy and the location of the fistula tract. Goodsall's rule states that if the anus is bisected by a line in the frontal plane, an external opening anterior to the line (within 2 cm of the anal verge) will connect to an internal opening by a short, direct fistula tract (Fig. 39-21). However, if the external opening is located posterior to this imaginary line or anteriorly but outside 2 cm from the anal verge, the fistula tract follows a curved course to the crypt in the posterior midline. This rule, while useful, is not infallible.

Occasionally, an external opening located more than 2 cm from the anal verge anterior to the imaginary bisecting line connects to an internal opening in the posterior midline. Because of its shape, this fistula is usually called a *horseshoe fistula*. Horseshoe fistulas usually have an internal opening in the posterior midline of the anus and may extend anteriorly and laterally to both ischiorectal spaces by way of the deep space. The posterior opening is incised into the postanal space to deal with the primary cause. The anterior extensions of the horseshoe tracts then can be drained by a secondary

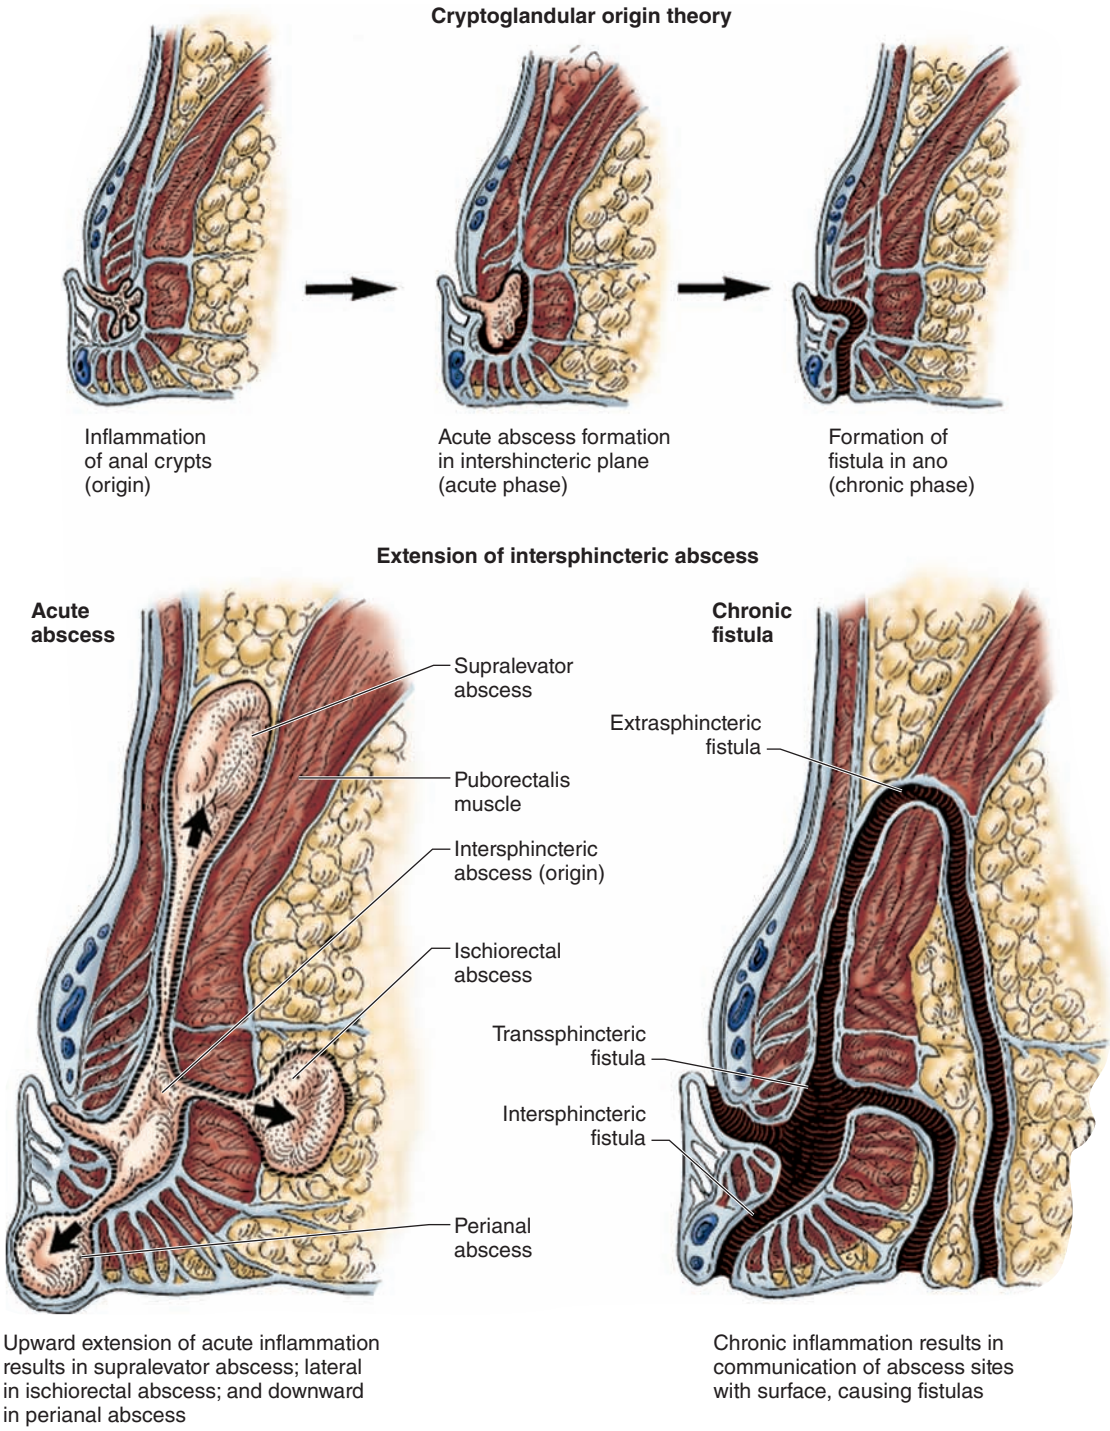

FIGURE 39-20 Anorectal abscess and fistula-in-ano cryptoglandular origin theory. (Redrawn, with permission, from Fry RD, Kodner IJ. Anorectal diseases. *Clin Symp*. 1985;37(6):2–32. Copyright 1985, Academy of Medical Sciences. Originally illustrated by John Craig, MD.)

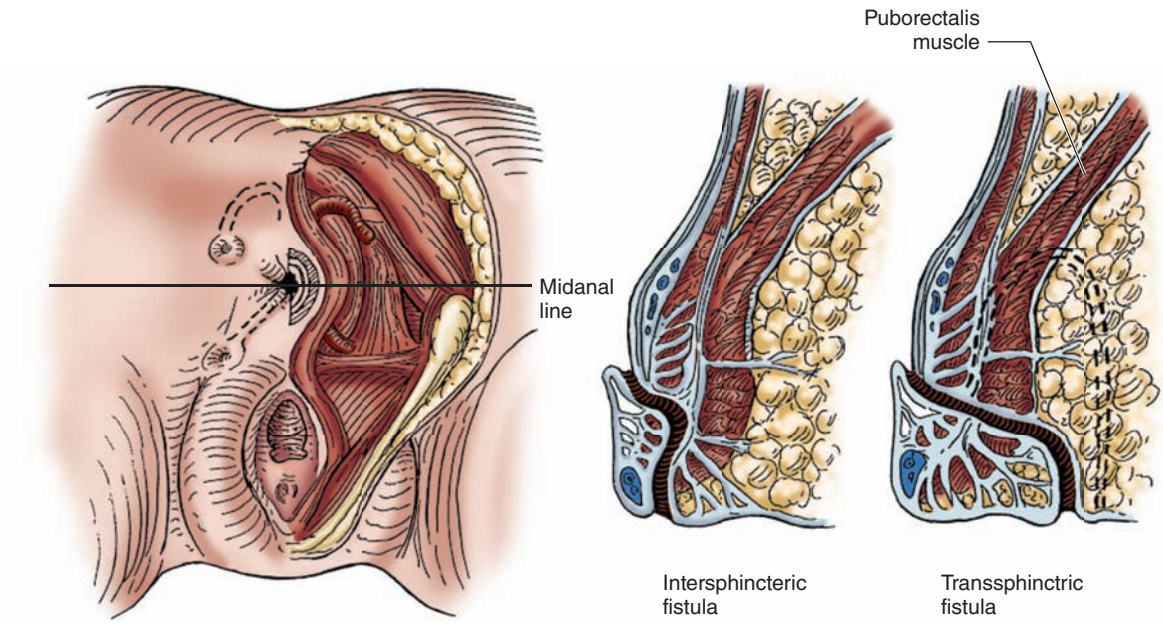

Goodsall's rule

Fistulas with external openings anterior to midanal line connected to internal opening by short, straight tract. Posterior external openings follow curved course to internal opening in posterior midline

Surgical management of intersphincteric and low (below puborectalis) transsphinteric fistuals involves unroofing tract. Only internal sphincterotomy in first case; internal sphincterotomy involving portion of external sphincter in latter case. Division of puborectalis muscle results in incontinence, so high fistulas are not treated by sphincterotomy

FIGURE 39-21 Surgical management of fistula-in-ano. (Redrawn, with permission, from Fry RD, Kodner IJ. Anorectal diseases. *Clin Symp.* 1985;37(6):2–32. Copyright 1985, Academy of Medical Sciences. Originally illustrated by John Craig, MD.)

opening, avoiding a long skin incision that would unroof the entire tract (Fig. 39-22). This is the Hanley procedure for a horseshoe abscess/fistula.

If a perianal abscess develops into a fistula and the fistula tract involves a small portion of the sphincter muscle, the condition can be treated by simple fistulotomy, which divides a portion of the internal sphincter and unroofs the tract entirely.

An anorectal fistula that persists after drainage of an ischiorectal fossa abscess usually is a transsphincteric fistula, because the tract crosses the lower portion of the external sphincter. The fistulotomy required to unroof this tract results in division of a portion of the internal sphincter as well as a portion of the lower external sphincter. If the tract lies below the posterior midline puborectalis, the external sphincter usually can be divided at the site of the fistula tract without loss of continence. However, the puborectalis must not be divided, or incontinence will invariably ensue.

The external anal sphincter is much less prominent in the anterior midline. Thus fistulotomy as treatment for an anterior midline anal fistula is associated with an increased risk of anal incontinence, particularly in women. Consequently, treatment of such fistulas often involves eradicating the internal opening of the fistula at the level of the dentate line by advancing a flap of rectal mucosa. It is important to ensure adequate drainage of the fistula through the external opening until the suture line of the advancement flap is well healed; otherwise an abscess can reform and disrupt the suture line, causing a recurrence of the fistula (Fig. 39-23). Injection of Fibrin glue and insertion of collagen plugs into the fistula tract is also an alternative with minimal morbidity and mixed success.[41,42] A newer technique involving ligation of the intersphincteric fistula tract (LIFT) has also been described with minimal morbidity and mixed success.[43,44] A dissection in the intersphincteric plane to the level of the fistula with double-suture ligation and partial excision of the intersphincteric portion of the tract will result in healing of approximately 50% of fistulas treated this way. Minimal damage to the sphincter mechanism and anal canal allows other treatments to be used if the technique fails.

Repair of rectovaginal fistulas after obstetric injury can also be performed in the same manner as the sliding advancement flap.[45,46] It is important to perform preoperative testing to evaluate for an associated external sphincter defect that may need to be repaired at the time of the advancement flap.

Although most anorectal abscesses originate in the anal crypts, other disease entities must be considered if the pathology appears atypical. Crohn's disease should be suspected if

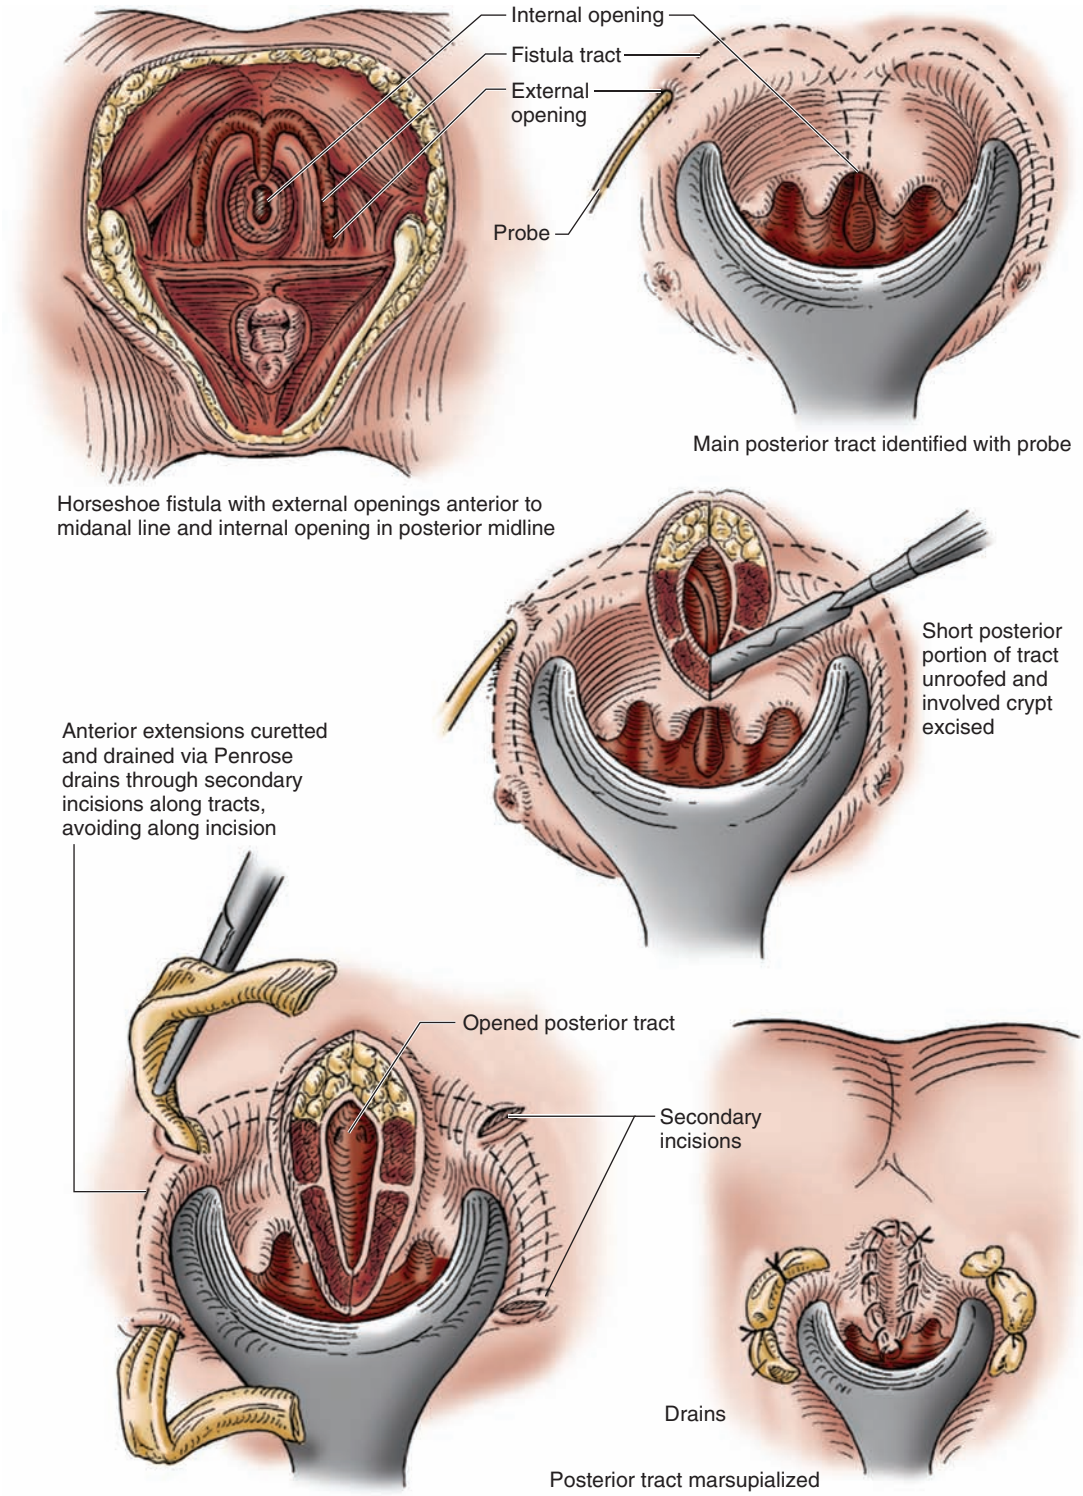

FIGURE 39-22 Surgical management of horseshoe fistula. (Redrawn, with permission, from Fry RD, Kodner IJ. Anorectal diseases. *Clin Symp*. 1985;37(6):2–32. Copyright 1985, Academy of Medical Sciences. Originally illustrated by John Craig, MD.)

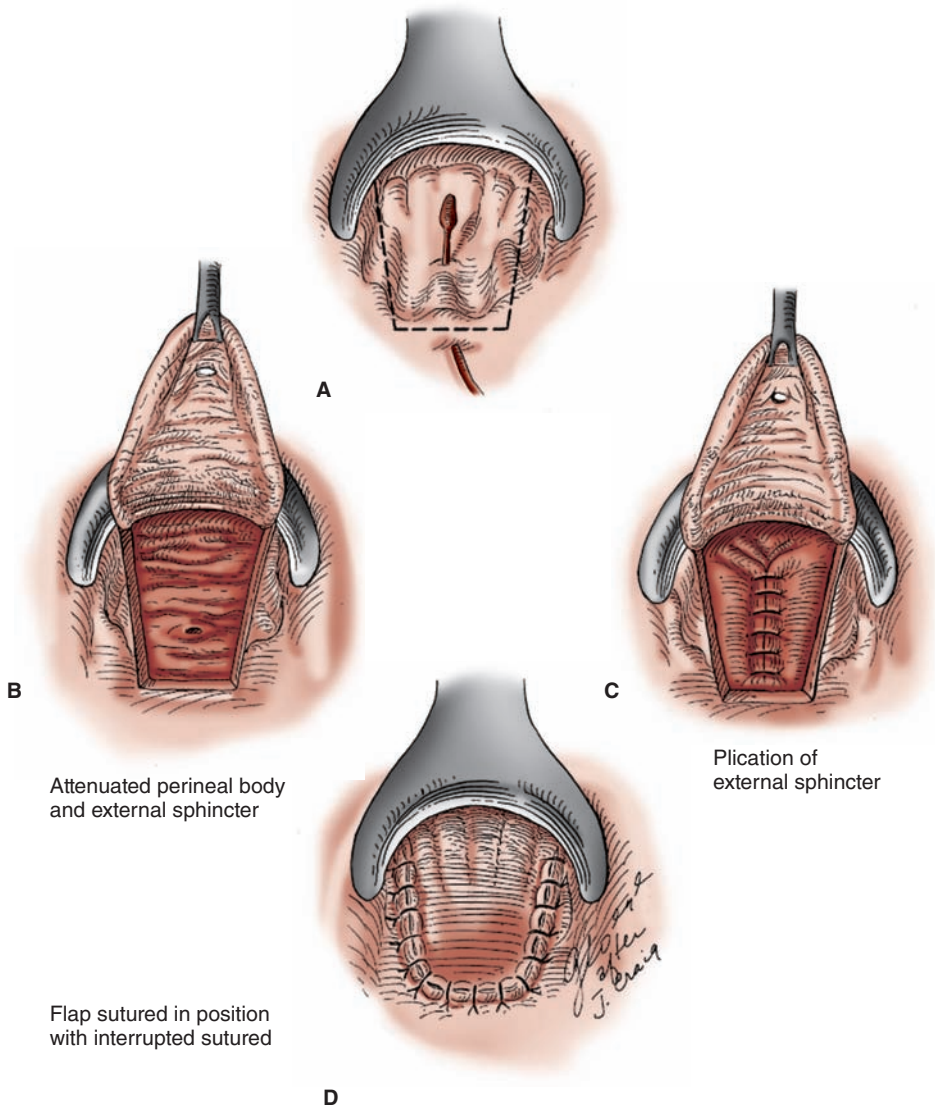

FIGURE 39-23 Endorectal advancement flap repair of complex anal-perineal or low rectal-perineal fistula. (Redrawn, with permission, from Kodner IJ, et al. Endorectal advancement flap repair of rectovaginal and other complicated anorectal fistulas. *Surgery*. 1993;114:682–690.)

there are numerous complex fistula tracts associated with edematous skin tags, or if there is inflammation of the rectal mucosa. Tuberculosis is now a rare cause of anal abscesses and fistulas but has recently been observed in immigrants to America. Hidradenitis suppurativa also may mimic cryptoglandular suppurative disease. Close examination, however, will reveal that the disease arises from the perianal skin and not the anal crypts. Actinomycosis should be suspected if typical sulfur-like granules are seen in the abscess cavity or fistula tract. Pilonidal disease sometimes can be confused with a posterior perianal abscess, but careful examination should reveal that there is no communication with the anus. Hair obtained from the abscess cavity when the pilonidal abscess is drained will indicate the true nature of the disease.

SEXUALLY TRANSMITTED ANAL DISEASE

During recent years there has been a profound change in the prevalence and types of sexually transmitted diseases. Genital-anal, oral-anal, and other anal-based practices among homosexual or bisexual men and among women who engage in anal receptive intercourse account for the transmission of most of these diseases.

The recognition of the acquired immunodeficiency syndrome (AIDS) has led to public concern over the transmission of the causative agent, the human immunodeficiency virus (HIV). The incidence of other venereal diseases appears to be increasing. Although a detailed discussion of

these infections is beyond the scope of this textbook, the surgeon will often be consulted for evaluation of complications of these diseases.[47]

Human Papillomavirus

Human papillomavirus (HPV) is the etiological agent causing venereal warts. These lesions are most common in homosexual men and can have a varied appearance, including (1) discrete warts: papillary or acuminate white lesions, usually occurring singly or in clusters at or below the dentate line; (2) circumferential wart ring lesions located at the dentate line and encompassing 60–100% of the anal canal; and (3) flat white epithelium: pale areas of smooth opaque epithelium that often extend cephalad to the dentate line. These latter lesions may be detected more easily by using a colposcope to magnify the anal canal. A high prevalence of histologically confirmed dysplasia in these internal lesions can be detected in asymptomatic homosexual men. Dysplasia was found in 70% of HIV-seronegative men and 85% and 90% of nonimmunosuppressed and immunosuppressed HIV-seropositive men, respectively. Biopsy of the lesions was necessary for detection, because it could not be predicted by the gross appearance of the warts.

The association of dysplasia with HPV is now well recognized. There are at least 60 different HPV types. Types 6 and 11 are associated with warts and low-grade dysplasia. Types 16 and 18 have been found in cervical cancer and high-grade cervical dysplasia, and type 16 has been found in high-grade anal dysplasia and invasive cancers. HPV types 31, 33, and 35 are thought to pose an intermediate cancer risk.

While it is clear that HPV is implicated in the pathogenesis of anal cancer in homosexual men, the rates of progression from dysplasia to cancer in the anal canal are unknown. It is likely that the progression rate is low, but further study is needed for documentation.

Anal intraepithelial neoplasia (AIN) is believed to be a precursor of anal neoplasm. Low-grade anal squamous intraepithelial lesion (LSIL) is equivalent to AIN grade I and high-grade anal squamous intraepithelial lesion (HSIL) is equivalent to AIN grade II or III. AIN III is defined as nuclear abnormalities that have penetrated through the full thickness of the epithelium. AIN III may be found in the pathology specimen after surgery for an unrelated problem such as hemorrhoids. One can apply acetic acid to the perianal area to visualize the lesions. The technique of anal mapping using biopsies at 1-cm intervals starting at the dentate line around the anus may also be used. Depending on the size and location of the lesion around the anus, the appropriate therapy for AIN is ablation of the lesions, either by excision, electrocautery, or laser. Medical options include topical 5-fluorouracil (5-FU) cream or imiquimod. Wide local excision may result in morbidity including anal stenosis or incontinence. Despite treatment of AIN, it is not known if treatment will reduce cancer risk. Thus, patients should be followed closely, especially those with immunocompromise.[48]

Chlamydial Infections

Chlamydial infections are now the most common sexually transmitted disease in the United States and they account for increasing numbers of cases of proctitis in patients who practice receptive anal intercourse. There are 15 recognized immunotypes of *Chlamydia trachomatis*, but for practical purposes it should be recognized that there are lymphogranulomatous causing lymphogranuloma venereum (LGV) and nonlymphogranulomatous (non-LGV) types. The non-LGV organisms are a common cause of urethritis, epididymitis, and pelvic inflammatory disease. At least half of the genital infections previously diagnosed as "nonspecific" or "nongonococcal" are caused by non-LGV *Chlamydia*. Chlamydial proctitis may coexist with other rectal infections, especially gonorrhea. Several serotypes are responsible for proctitis, and serotypes L1, L2, and L3 are responsible for lymphogranuloma venereum. The pathogen is introduced by either genital-anal or oral-anal intercourse. The non-LGV organisms are obligate intracellular parasites that can penetrate only columnar or transitional epithelium. The LGV organisms also can penetrate mononuclear cells, which may account for the prominent lymphadenopathy in patients with lymphogranuloma venereum.

Infection may be asymptomatic or may consist of nonspecific symptoms such as anal pain, pruritus, purulent discharge, and bleeding. More severe forms of infection, especially severe proctitis, usually indicate the presence of one of the LGV serotypes. Perianal fistulas and rectovaginal fistulas may develop, with untreated cases progressing to severe rectal stricture. Two weeks after the initial symptoms, inguinal lymphadenopathy becomes predominant and the inguinal nodes may fuse together in a large mass.

The organism is an obligate intracellular organism, and rectal cultures are usually inconclusive. A biopsy of the rectal mucosa is probably the most commonly used method to confirm the diagnosis. The diagnosis of chlamydial infections used to be difficult because satisfactory culture techniques were not widely available. Diagnosis usually required the detection of rising antibody titers. The organism, however, now can be identified by using tissue culture techniques or DNA probes.

Chlamydial infections should be treated as soon as the diagnosis is suspected. The recommended treatment for non-LGV chlamydial infection is doxycycline or, alternatively, erythromycin for 7–14 days. LGV chlamydial infection should be treated with tetracycline and sulfonamides for a minimum of 21 days.

As with all acute STDs, sexual abstinence until eradication is complete as well as education, testing, and treatment of sexual partners, when appropriate, is recommended.

Herpes Simplex Virus

Anorectal herpes is usually caused by the type 2 herpes simplex virus (HSV-2), although the HSV-l virus is responsible for approximately 10% of anal infections. Patients who have been previously infected have virus-specific antibodies. The first symptoms of infection are perianal pruritus or paresthesia, followed by intense anal pain. Small vesicles surrounded by red areolas may appear. These vesicles subsequently rupture, leaving small ulcers that appear on the perianal skin, in the anal canal, or even on the rectal mucosa. Fever and malaise are frequently present. The ulcerated lesions may become secondarily infected, with increased pain and discharge. The lesions usually heal in about 2 weeks. Unfortunately, a chronic relapsing course is common, although recurrent lesions are usually much less painful.

Scrapings from the base of a ruptured vesicle can be stained to show typical intranuclear inclusion bodies, but the diagnosis is most expeditiously made by viral HSV culture.

There is no known cure for herpes. Primary or initial infections are treated with oral acyclovir, famciclovir, or valacyclovir for 7–10 days.[49] Acyclovir should be taken at the onset of recurrent symptoms, which may reduce the formation of new vesicles. Chronic suppressive therapy or self-initiation of antiviral treatment with recurrent episodes may be helpful in patients with more than six recurrences per year. AIDS patients with perianal herpes resistant to acyclovir may benefit from two newer compounds, foscarnet or vidarabine.[50]

Patients are contagious while the lesions are present and should abstain from sexual activity until all lesions are completely healed. Even after the lesions have completely healed, a condom should be used during sexual intercourse.

Gonorrhea

Anorectal infections caused by the bacterium *Neisseria gonorrhoeae* are common in the male homosexual population and frequently accompany other venereal diseases. Over half of homosexual men seen in screening clinics have been found to be infected, with the rectum being the only site infected in about half of cases. The majority of these infections are asymptomatic.[51]

Symptoms vary from none to intense anorectal pain and tenesmus accompanied by a viscid, yellow anal discharge. Anoscopy may reveal anusitis or distal proctitis. Diagnosis is confirmed by obtaining cultures from the rectal discharge or mucosa, or more recently by DNA probes.

Treatment should be initiated if the disease is suspected. Untreated rectal gonorrhea can lead to septic arthritis, endocarditis, perihepatitis, and meningitis, as well as infection of sexual partners. Several drugs (penicillin, tetracycline, ampicillin, and spectinomycin) may be used for treatment, although increasing numbers of resistant strains are being recognized. Cultures should be repeated after treatment is completed, because antibiotic therapy may fail in as many as one-third of the patients. All sexual contacts also must be treated. All patients with confirmed rectal gonorrhea should have a serologic test for syphilis 3 months after treatment is completed.

Syphilis

The classic lesion of primary syphilis is a chancre on the genitalia, but in homosexual males the chancre usually presents in the anal canal or at the anal verge.[52] These ulcerated lesions may mimic an anal fissure, but an aberrant location of the lesion (eg, lateral anus instead of midline) should arouse suspicion. Classic descriptions indicate that the syphilitic chancre is a painless lesion, but anal chancres may be extremely painful. The causative organism is the spirochete, *Treponema pallidum*, which may occasionally cause severe proctitis without an accompanying chancre. Inguinal adenopathy is common.

Early syphilis can be diagnosed by examining scrapings from the base of the chancre with dark-field microscopy; these lesions teem with spirochetes that can be seen as corkscrew-shaped motile fluorescent yellowish-green organisms. Serology is also very helpful in establishing the diagnosis. In untreated primary syphilis, the Venereal Disease Research Laboratory assay is reactive in about 75% of cases, in early latent syphilis about 95%, and in the secondary state it is 100% reactive. The fluorescent treponemal antibody absorption test usually becomes positive about 4–6 weeks after the initial infection. Rapid plasma reagin and darkfield microscopy are the appropriate tests for suspected early syphilis.

The second stage of anal syphilis appears 6–8 weeks after the chancre has healed in untreated patients. It may present as condyloma latum, a pale-brown or flesh-colored flat verrucous lesion, or as a mucocutaneous rash. All three serologic tests for syphilis will be positive at this stage. Skin lesions are highly contagious.

Benzathine penicillin G is the treatment of choice for syphilis. Alternative treatments include doxycycline, tetracycline, or erythromycin. Patients with syphilis must abstain from sexual contact until treatment is complete. All sexual contacts within the preceding 90 days should be prophylactically treated.

CANCER OF THE RECTUM

40

Joel Goldberg • Ronald Bleday

INCIDENCE

At the beginning of the 21st century, rectal cancer continues to be a significant medical and social problem. Currently, there are approximately 149,000 cases of colorectal cancer diagnosed in the United States each year. Adenocarcinoma of the rectum accounts for nearly 30% of these cancers. This translates into 41,000 new diagnoses of rectal cancer each year and greater than 10,000 deaths attributable to this disease within the same time period.[1]

HISTORY

The history of modern rectal cancer resection dates back to 1884, when Czérny described the first abdominoperineal resection (APR). In 1885, Kraske pioneered the transsacral approach of rectal resection and anastomosis. In 1908, Miles improved on the APR by understanding that there was a "zone of upward spread."[2] He emphasized the importance of performing a wide perineal excision. Furthermore, he advocated removal of the rectum with a high ligation of the superior hemorrhoidal artery as well as excision of the abdominal attachments of the rectum and the iliac lymph nodes. Despite the improvements in oncologic resection, operative mortality in Miles' first series exceeded 42%. Over the next 80 years through the late 1980s, mortality and morbidity for rectal cancer surgery improved markedly in pace with improvements in intra-, peri-, and postoperative care. Unfortunately, there were few, if any, advancements in oncologic techniques during this period. Then, in the late 1980s, William Heald described and began popularizing total mesorectal excision (TME) for carcinoma of the rectum.[3] In this technique he advocates using sharp dissection to perform the complete excision of the mesorectum and its associated lymphatics along the subtle fascial planes that encompass the rectum. Moreover, Heald described a "zone of downward spread" within the mesorectum that requires complete excision in order to reduce local recurrence. Finally, local excision of small rectal cancers has been used for a 100 years in selected patients. More recently, local excision is being combined with neoadjuvant and adjuvant chemoradiotherapy to maximize local control with a minimally invasive approach.

ETIOLOGY AND RISK FACTORS

In Western industrialized nations the average lifetime risk for an individual to develop colorectal cancer is approximately 6%. This risk increases two- to fourfold if the patient has a personal history of a first-degree relative with colorectal cancer. Inflammatory bowel disease (IBD) is another risk factor. In the first 10 years after the initial diagnosis of ulcerative colitis (UC), the incidence of colorectal cancer ranges from 2 to 5%; however, this risk increases 1% for each year of disease thereafter. Pancolitis is associated with both an earlier and an increased risk for colorectal cancer when compared to left-sided colitis alone. For all patients with UC, the cumulative risk for colorectal cancer at 25 years is 25%. Screening the colon yearly starting at 10 years after the diagnosis with colonoscopy and multiple biopsies in four quadrants every 10 cm from the cecum to the distal rectum is used to predict when a patient is at risk for developing colorectal cancer. If high-grade dysplasia is detected in any of the biopsies, the patient needs to have a total proctocolectomy. Some practitioners advocate a surgical resection for low-grade dysplasia as well, whereas some are willing to repeat a colonoscopy with multiple biopsies. If low-grade dysplasia is found on the second short-interval colonoscopy, total proctocolectomy is indicated. Ultimately, the most effective method for preventing colon cancer in patients with UC is to remove the colon once any type of dysplasia has been identified. Crohn's colitis is associated with a similar increased risk for colorectal cancer. This is often not appreciated by clinicians because patients with severe Crohn's colitis often undergo proctocolectomy before their long-term risk becomes an issue.

Genetic risk factors also have been implicated in the development of colorectal cancer. One is familial adenomatous polyposis (FAP), an autosomal dominant syndrome with 100% risk of developing colorectal cancer. The abnormality is caused by a defect in the *APC* gene located on chromosome 5q21. Patients with FAP develop hundreds or thousands of adenomas by their 20s, and colorectal cancer develops in all patients by age 50 years if untreated. Extraintestinal manifestations of this genetic defect include desmoid tumors, periampullary masses, osteomas, and medulloblastomas. A second genetic abnormality associated with the development of colorectal cancer is related to defects in the mismatch repair genes *MSH2* and

MLH1. Mismatch repair genes affect the repair of DNA replication errors and spontaneous base repair loss and contribute to hereditary nonpolyposis colorectal cancer (HNPCC) that is also known as *Lynch syndrome*. Despite the name, these cancers arise from adenomas and may account for 5% of all colorectal malignancies. In this autosomal dominant syndrome, cancers occur more often on the right side of the colon. Despite developing at a younger age, there is a better prognosis with these cancers when compared with age-matched controls with a non-HNPCC colorectal cancer. In theory, a patient with HNPCC living to age 80 years would have an 80% risk for developing colorectal cancer; additionally, there is a risk of endometrial cancer (40%), gastric cancer (20%), biliary tract cancer (18%), urinary tract cancer (10%), and ovarian cancer (10%). Family members should be screened initially at age 20 years with colonoscopy for the presence of polyps or colon cancer. After age 40 years, colonoscopies should be performed yearly. If a polyp or cancer is detected, a total abdominal colectomy with an ileorectal anastomosis is recommended. Urine cytology to rule out dysplastic cells in the genitourinary tract (which is at risk for transitional cell carcinoma) is recommended. Women should get regular transvaginal pelvic ultrasounds and CA-125 levels. Any affected woman who has finished childbearing and requires a colectomy should give strong consideration to a prophylactic total abdominal hysterectomy and bilateral salpingo-oophorectomy.

Dietary fats, especially red-meat fats, have been implicated as a risk factor for colon and rectal cancer.[4] People who consume less than 15% of their diet as fat have a lower incidence of colorectal cancer, whereas those who take in 20% of their diet as fat, either as unsaturated animal fat or as highly saturated vegetable oils, have an increased risk of colorectal malignancy.

In the past few decades, several studies have linked alcohol consumption and tobacco use with an increased risk of colorectal neoplasia. Moreover, there appears to be a synergistic effect with an even greater increased risk of adenomatous polyps in people who are both smokers and drinkers.[5]

POLYPS

The concept that colorectal cancers develop from polyps, or the "adenoma-to-carcinoma sequence," was first described by Dukes in 1926. The majority of patients with rectal cancer have no inherited component; instead, there is an initiating genetic mutation, such as of an oncogene like *ras*, that leads to abnormal cell growth. Subsequently, mutations resulting in inactivation of tumor suppressor genes, such as *p53*, allow for progression to cancer.

The time course for polyp development and transformation to cancer is thought to be 5–10 years. Most adenomas remain benign; however, histologic type, polyp size, and evidence of dysplasia are associated with transformation. Data from the National Polyp Study and St. Mark's Hospital show that approximately 75–85% of adenomas are tubular, 8–15% are tubulovillous, and 5–10% are villous. Tubular adenomas usually form a stalk, whereas villous adenomas have a broad base (Fig. 40-1). Villous histology is associated with an

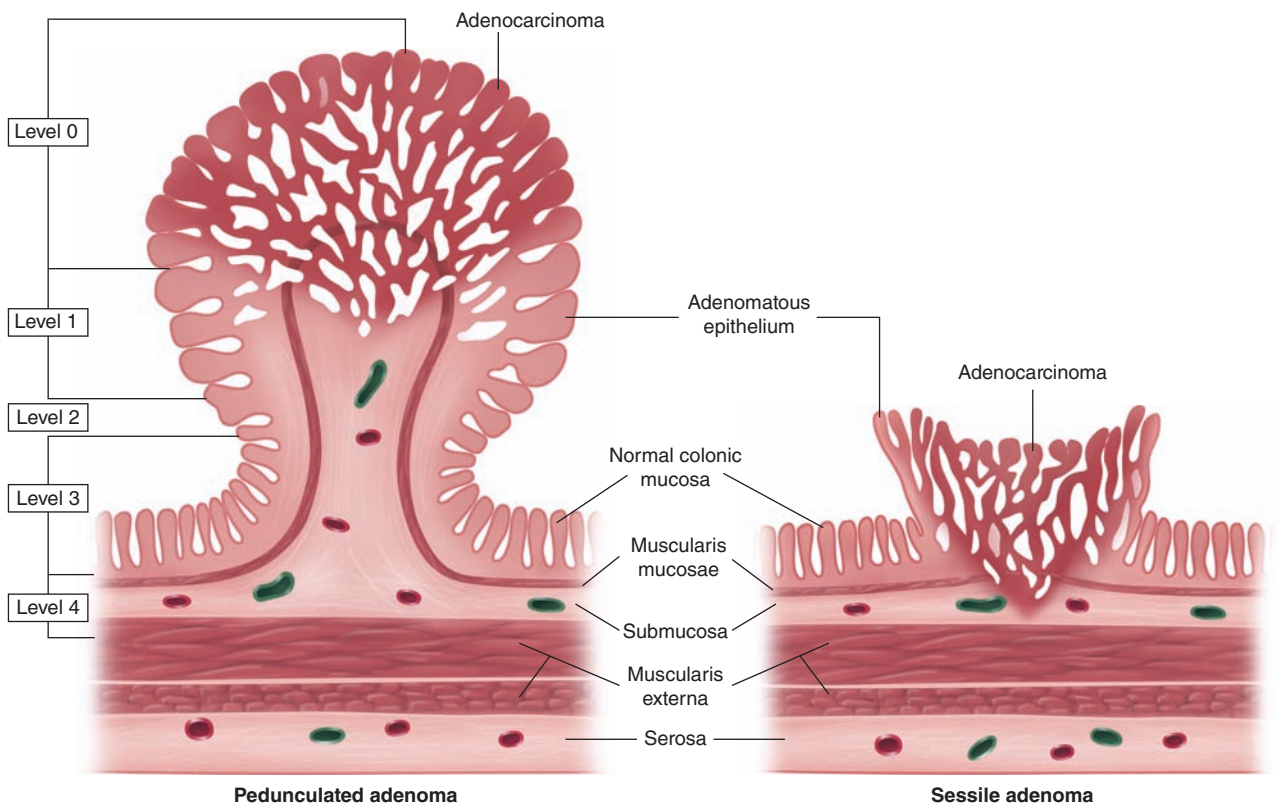

FIGURE 40-1 Haggitt classification of a pedunculated and sessile polyp, each of which contains an invasive cancer.

increased risk of cancer development. Only 1% of polyps less than 1 cm in diameter show evidence of malignant transformation, whereas 50% of polyps greater than 2 cm in diameter harbor areas of carcinoma.

Clinically, it is important to diagnose the type, size, and number of polyps to risk-stratify patients for treatment and future surveillance. Endoscopic treatment likely reduces or eliminates the risk of colorectal cancer in patients. Rigid sigmoidoscopy and flexible sigmoidoscopy are all that are necessary to screen the rectum. Sigmoidoscopic screening should be followed by a complete colonoscopy if biopsy of a small rectal or sigmoid polyp shows adenomatous changes. Colonoscopic screening as the first study is indicated in high-risk populations. Autopsy studies have reported that adenomas are present in 20–60% of patients with a colorectal cancer, and synchronous cancers are found in 3–9% of patients. In patients who cannot undergo a preoperative colonoscopy, either a virtual colonoscopy or barium enema should be performed. If both procedures are contraindicated in these patients, colonoscopic evaluation should be performed 3 months after resection.

Treatment of the malignant rectal polyp is becoming more common with the increase in colonoscopic screening and the early diagnosis of small distal rectal cancers. Surgical treatment in part depends on the morphology of the polyp and the histologic evaluation of the resected lesion. Pedunculated malignant polyps are classified by Haggitt according to the depth of invasion of the cancer within the head of the polyp and stalk[6] (see Fig. 40-1). Malignant polyps completely resected with greater than 2-mm margins and without stalk invasion are considered adequately treated with colonoscopic removal, provided there are no poor prognostic histologic features; tumors with poor differentiation or lymphatic or venous invasion are associated with an increased incidence of involved lymph nodes.[7]

ANATOMY

Anatomic Landmarks

The type of therapy offered to a patient with rectal cancer depends not only on the stage of the tumor but also on its location within the pelvis and its relation to the anal sphincters. Compared with colon cancer, knowledge and appreciation of anatomic landmarks are critical in determining resectability and sphincter preservation.

The rectum, usually 15–20 cm in length, extends from the rectosigmoid junction, marked by fusion of the taeniae coli into a completely circumferential muscular layer, to the anal canal. The rectum transitions from being intraperitoneal to being completely extraperitoneal 10–12 cm from the anus and the root of the sigmoid mesentery is approximately 19 cm from the anal verge on rigid sigmoidoscopy.[8] The rectum is "fixed" posteriorly and laterally by Waldeyer's fascia and the lateral stalks, respectively. In the male patient, the anterior rectum is fixed to Denonvilliers' fascia, a fold of two layers of peritoneum that separates the rectum from the posterior prostate and seminal vesicles. In the female patient, the peritoneal cavity descends to the pouch of Douglas, with its most dependent point being adjacent to the cervix anteriorly and midrectum posteriorly.[9] When seen endoscopically, the rectum has three valves of Houston, the middle of which corresponds to the anterior peritoneal reflection (Fig. 40-2A).

While many surgical descriptions for rectal cancer refer to the distance of the lesion from the anal verge or the *dentate line*, a more accurate description for distal (palpable lesions) is the distance above the anorectal ring as palpated by the examining surgeon. For nonpalpable lesions, we use a rigid sigmoidoscope to localize the lesion and then ascertain the distance from the anal verge to the mass. At the muscular level, the anal canal starts at the top of the "high-pressure zone" that is at the proximal aspect of the anorectal ring, a muscular structure consisting of the internal sphincter, external sphincter,

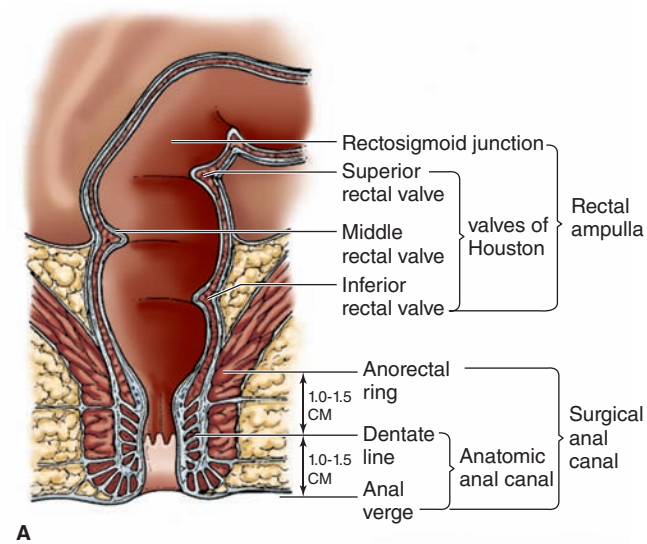

FIGURE 40-2 Anatomic landmarks of the rectum and anus.

and puborectalis (Figs. 40-2A and 40-2B). The high-pressure zone descends beyond the dentate line to the junction of the anal mucosa and the perianal skin; this junction is often referred to as the *anal verge.* In order to achieve an adequate distal margin (≥2 cm) with sphincter preservation, the lower border of a tumor must be located high enough above the top of the anorectal ring. If curative resection compromises perfect function of the sphincter apparatus, or if an adequate distal margin cannot be obtained while preserving the anorectal ring, an APR with a permanent colostomy should be constructed. Although a patient may assume that a colostomy indicates a hopelessly incurable cancer, we must emphasize that the colostomy is necessary because of the anatomic location, not necessarily the severity of the rectal cancer.

Vascular Supply

Arteriography demonstrates extensive intramural anastomoses between the superior, middle, and inferior rectal arteries. The superior rectal artery originates from the inferior mesenteric artery and descends in the mesorectum to supply the upper and middle rectum (Fig. 40-3). The inferior rectal arteries, branches of the internal pudendal arteries, enter posterolaterally and provide blood supply to the anal sphincters and epithelium. The middle rectal artery, often depicted in anatomic drawings as a large and significant artery branching off the internal iliac artery on each side, is seldom greater than 1 mm in diameter.[10] In one study, the middle rectal artery was observed in only 22% of cadaver specimens.[9] When actually present, the middle rectal artery is located near the lateral rectal stalks. These stalks are primarily nerves but have been confused previously with arterial supply.

The superior rectal vein drains the upper and middle thirds of the rectum and empties into the portal system via the inferior mesenteric vein. The middle rectal veins drain the lower rectum and upper anal canal into the internal iliac veins. The inferior rectal veins drain the lower anal canal, emptying into the internal iliac veins via the pudendal veins. Because the venous systems communicate, low rectal cancers may spread via the portal and systemic circulations.

Lymphatic Drainage

Local recurrence after resection is common and can occur with and without distant metastatic disease. Rectal cancer

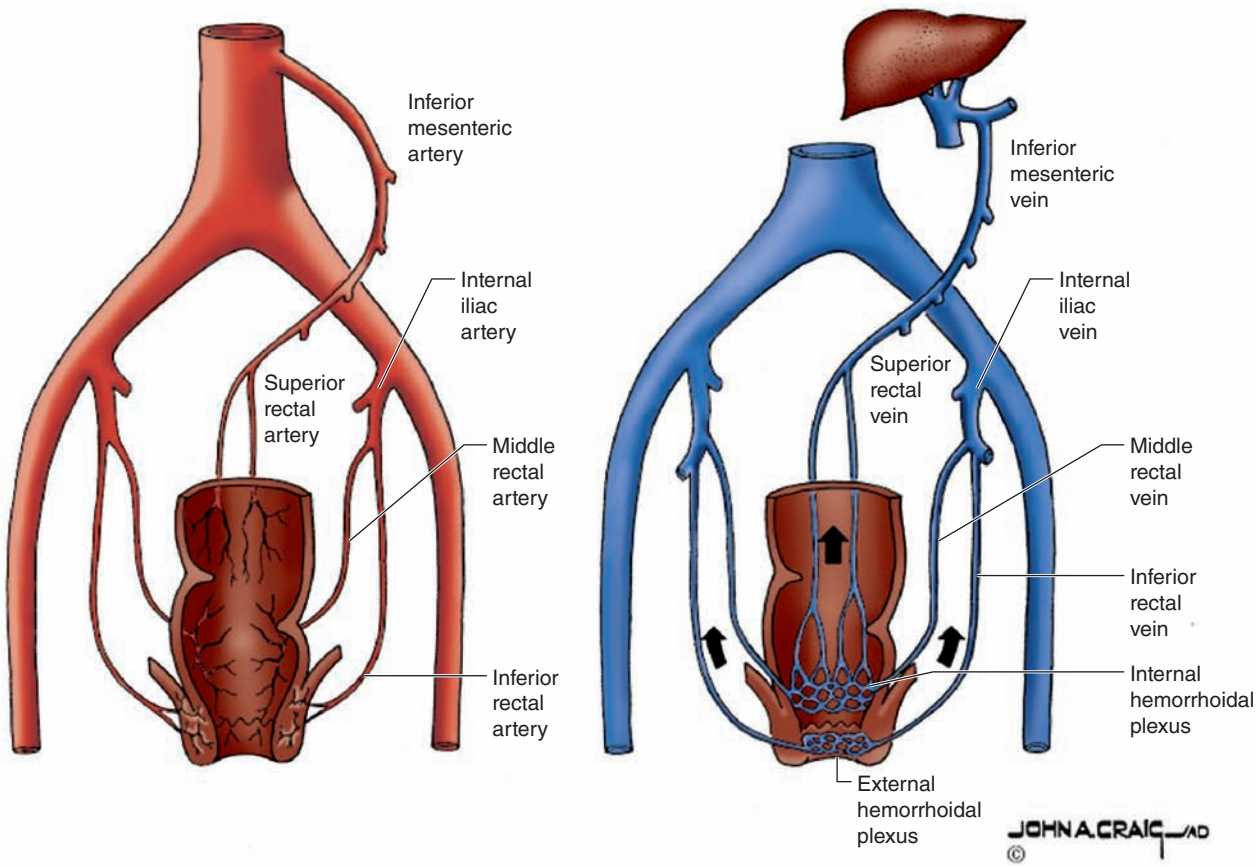

FIGURE 40-3 Vasculature of the rectum and anus. **A.** Arterial supply. **B.** Venous drainage.

can spread locally via lymphatics that follow cranially along the superior hemorrhoidal vessels. This "zone of upward spread" was described initially by Miles in his landmark paper describing the APR. Heald has described a "zone of downward spread" within the mesorectum[3]; this zone can encompass as much as 4 cm beyond the distal mucosal edge of the tumor.[11,12] Although some surgeons and pathologists describe tumor within this zone of downward spread as tumor implants, others believe that these implants are replaced nodes. Appreciation of the zones of upward and downward spread has influenced the extent of dissection surgeons now perform for curative resection of rectal cancers.

Lymph from the upper and middle rectum drains into the inferior mesenteric nodes (Fig. 40-4). Lymph from the lower rectum may drain into the inferior mesenteric system or into the network along the middle and inferior rectal arteries, posteriorly along the middle sacral artery, and anteriorly through the channels to the retrovesical or rectovaginal septum, to the iliac nodes, and ultimately, to the periaortic nodes. In a Japanese study, the obturator nodes, external to the hypogastric nerve plexus, were found to be involved with cancer in 8% of tumors located in the distal rectum, whereas these nodes were rarely, if ever, involved with proximal tumors.[13] Lymphatics from the anal canal above the dentate line usually drain via the superior rectal lymphatics to the inferior mesenteric lymph nodes and laterally to the obturator and internal iliac nodes. Below the dentate line, lymph drains primarily to the inguinal nodes but may empty into the inferior or superior rectal lymph nodes.

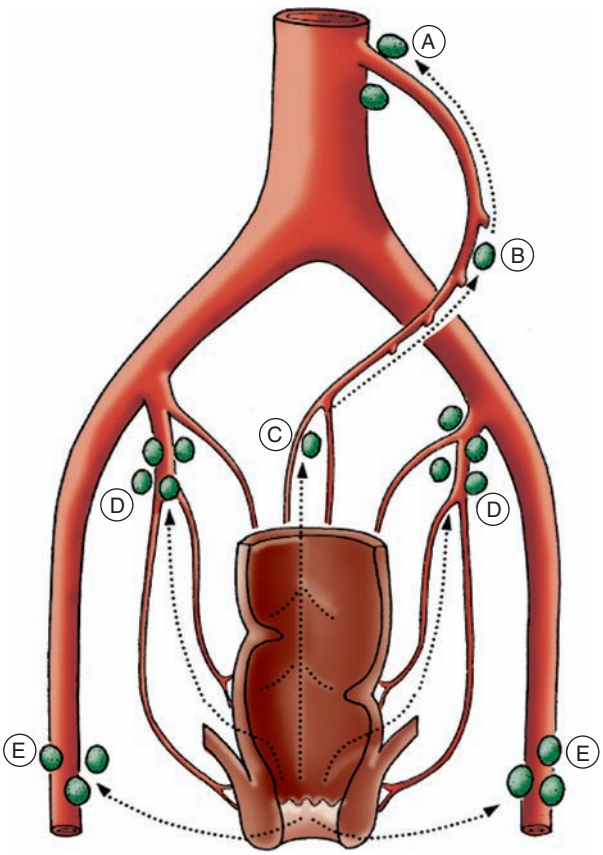

FIGURE 40-4 Lymphatic drainage of the rectum and anus. **A.** Nodes at the origin of the inferior mesenteric artery. **B.** Nodes at the origin of sigmoid branches. **C.** Sacral nodes. **D.** Internal iliac nodes. **E.** Inguinal nodes.

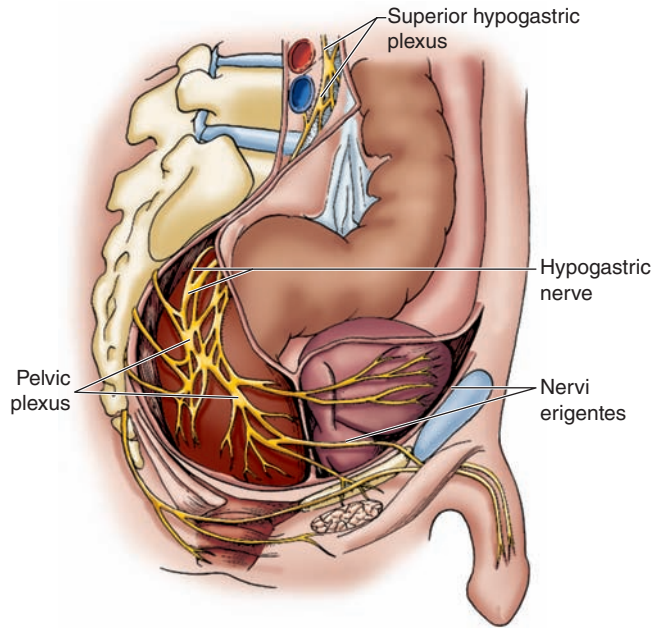

FIGURE 40-5 Nerve supply of pelvic organs.

Innervation

The pelvic autonomic nerves consist of the paired hypogastric (sympathetic), sacral (parasympathetic), and inferior hypogastric nerves (Fig. 40-5). Sympathetic nerves originate from L1–L3, form the inferior mesenteric plexus, travel through the superior hypogastric plexus, and descend as the hypogastric nerves to the pelvic plexus. The parasympathetic nerves, or nervi erigentes, arise from S2–S4 and join the hypogastric nerves anterior and lateral to the rectum to form the pelvic plexus and ultimately the periprostatic plexus. The inferior hypogastric nerve plexus arises from interlacing sympathetic and parasympathetic nerve fibers and forms a fenestrated rhomboid plate on the lateral pelvic sidewall. Fibers from this plexus innervate the rectum as well as the bladder, ureter, prostate, seminal vesicles, membranous urethra, and corpora cavernosa. Therefore, injury to these autonomic nerves can lead to impotence, bladder dysfunction, and loss of normal defecatory mechanisms.

Fascial Planes

The walls and floor of the pelvis are covered by the endopelvic, or parietal, fascia (Fig. 40-6). The fascia propria, an

extension of the endopelvic fascia, encloses the rectum and its mesorectal fat, lymphatics, and vascular supply as a single unit; forms the lateral stalks of the rectum; and connects to the parietal fascia on the pelvic sidewall. The presacral fascia is the parietal fascia that covers the sacrum and coccyx, presacral plexus, pelvic autonomic nerves, and the middle sacral artery. Posteriorly, a thickening of this fascia, called *Waldeyer's fascia*, is the anteroinferior fascial reflection from the presacral fascia at the level of S4. Anteriorly, *Denonvilliers' fascia* separates the anterior rectal wall from the prostate and seminal vesicles in the male and is thought to be an entrapped extension of the peritoneum.[14]

DIAGNOSIS AND EVALUATION

The preoperative evaluation is critically important to treat the cancer optimally and achieve sphincter preservation. With this information, surgeons must individualize the treatment and care of each patient.

History

The patient with rectal cancer usually presents to the surgeon after a definitive endoscopic diagnosis. The patient's initial

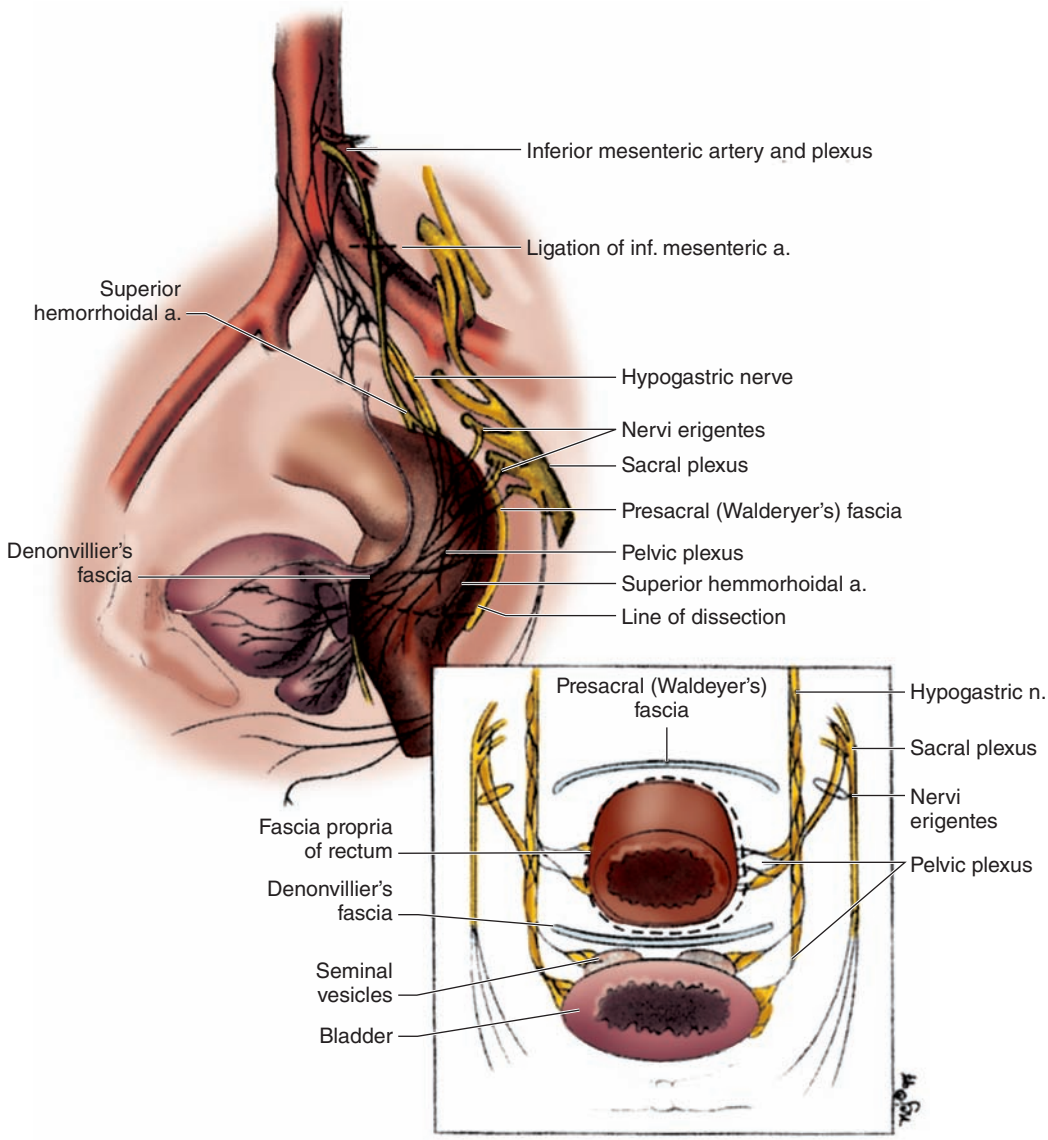

FIGURE 40-6 Fascial planes. (Used, with permission, from Michelassi F, Milsom JW, eds. *Operative Strategies in Inflammatory Bowel Disease.* New York, NY: Springer-Verlag; 1999.)

complaint may include rectal bleeding, a change in bowel habits or stool caliber, rectal pain, a sense of rectal "fullness," weight loss, nausea, vomiting, fatigue, or anorexia; however, many patients are completely asymptomatic. Specific symptoms may assist the surgeon in deciding on the optimal approach to therapy. Tenesmus, the constant sensation of needing to move one's bowels, usually is indicative of a large and possibly fixed stage II or III cancer. Pain with defecation suggests involvement of the anal sphincters; cancers growing directly into the anal sphincter usually are not amenable to sphincter-sparing procedures. Information pertaining to anal sphincter function is invaluable when one is contemplating a low anastomosis. If patients are incontinent, they are better served with an ostomy. Preoperative sexual function is important to know because one must discuss the risks of the procedure and possible diminution of sexual function postoperatively.

A comprehensive medical history should be aimed at identifying other medical conditions, such as cardiopulmonary, renal, and nutrition, that may require additional evaluation before surgical intervention and allow appropriate risk stratification. For patients with a cardiac history or symptoms, a stress test and cardiology evaluation are indicated.

Family history or factors predisposing the patient to rectal cancer, such as FAP, HNPCC, and IBD, are important to take into account as one plans the operative procedure.

Physical Examination

A careful and accurate digital rectal examination (DRE) is critical in determining the clinical stage and any plans for neoadjuvant therapy. DRE of a palpable lesion allows for the assessment of tumor size, mobility and fixation, anterior or posterior location, relationship to the sphincter mechanism and top of the anorectal ring, and distance from the anal verge.

Rigid proctoscopy is also essential to the evaluation of patients with rectal cancer because it demonstrates the proximal and distal levels of the mass from anal verge; extent of circumferential involvement; orientation within the lumen; and relationship to the vagina, prostate, or peritoneal reflection. All this information aids in determining the feasibility of local excision. Rigid proctoscopy also allows one to obtain an adequate tissue biopsy. Flexible sigmoidoscopy is not used routinely because the flexibility of the instrument can give a false distance between the tumor and the dentate line. Furthermore, a mass will often be described as being a sigmoid or rectosigmoid tumor on flexible colonoscopy, and, when the patient is evaluated in the office with rigid sigmoidoscopy, the lesion is often found to be much lower and in fact is often a true rectal cancer that qualifies for neoadjuvant chemoradiotherapy. Hence, rigid sigmoidoscopy is mandatory for all distal left sided lesions.

A complete colonoscopy to the cecum is essential to rule out synchronous cancers, which occur 2–8% of the time. We prefer colonoscopy over virtual colonoscopy so that we may not only diagnose but also excise any amenable polyps.

Women should undergo a complete pelvic examination in order to determine vaginal invasion or spread to the ovaries. Men should be evaluated for extension into the prostate or bladder.

Preoperative Staging

Following the initial history, DRE, and rigid proctoscopy, additional preoperative staging studies can help to determine the appropriate treatment for each patient, whether radical resection or local excision is warranted, and whether preoperative chemoradiation is recommended. Accurate preoperative staging is gaining increasing importance as combined-modality therapy and sphincter-preserving surgical approaches are considered.

Abdominal and pelvic computed tomographic (CT) scans can demonstrate regional tumor extension, lymphatic and distant metastases, and tumor-related complications such as perforation or fistula formation. Its accuracy in determining the depth of invasion, however, is less than that of endorectal ultrasound (ERUS) or specialized magnetic resonance imaging (MRI). Pelvic CT scan therefore is not recommended as the only modality for evaluation of a patient's primary tumor. For example, the sensitivity of CT scan for detecting distant metastasis is higher (75–87%) than that for detecting perirectal nodal involvement (45%) or the depth of transmural invasion (70%). If a node is seen on CT scan, it should be presumed to be malignant because benign adenopathy is not normally seen around the rectum.

Intravenous contrast material at the time of a CT scan is important to assess the liver for metastatic disease, as well as to evaluate the size and function of the kidneys. Ureteral involvement by the tumor can be assessed and allows for planning of ureteral stent placement preoperatively.

All patients should undergo a chest x-ray or chest CT scan to exclude pulmonary metastases. Although useful information for assessing long-term prognosis, the extra information obtained from a chest CT scan often does not influence the decisions that need to be made to treat the local/regional disease.

LABORATORY STUDIES

Complete blood count and electrolytes often are obtained. Liver enzymes may be normal in the setting of small hepatic metastases and are not a reliable marker for liver involvement.

Guidelines published by the American Society for Clinical Oncology (ASCO) recommend that serum carcinoembryonic antigen (CEA) levels be obtained preoperatively in patients with rectal cancer to aid in staging, surgical treatment planning, and assessment of prognosis. Although neither

sensitive nor specific enough to serve as a screening method for the detection of colorectal cancer, preoperative CEA levels greater than 5 ng/mL signify a worse prognosis, stage for stage, than those with lower levels. Additionally, elevated preoperative CEA levels that do not normalize following surgical resection imply the presence of persistent disease and the need for further evaluation. Furthermore, CEA is most helpful in identifying recurrent disease with an overall sensitivity rate of 70–80%.

ENDOLUMINAL ULTRASOUND

Compared with CT scanning, transrectal endoluminal or endoscopic ultrasound (TRUS) permits a more accurate characterization of the primary tumor and the status of the perirectal lymph nodes. Localized cancers involving only the mucosa and submucosa usually can be distinguished from tumors that penetrate the muscularis propria or extend through the rectal wall into the perirectal fat.

ERUS is an office-based procedure that is well tolerated and can be performed by the surgeon for preoperative planning. Figure 40-7 shows the schematic layers seen in TRUS.

T Stage. Several studies comparing the accuracy of TRUS with CT scan and MRI suggest that TRUS is superior for T staging of rectal cancer. The range of the accuracy of TRUS is 80–95% compared with 65–75% for CT scan, 75–85% for MRI, and 62% for DRE. In one review, the accuracy of TRUS was greatest (95%) in distinguishing whether a tumor was confined to the rectal wall (T1, T2) versus invading into the perirectal fat (T3 or greater) and less able to distinguish accurately T1 from T2 cancers.[15] Figure 40-8 demonstrates a uT2 lesion. Additionally, in patients who have received prior radiation, the accuracy decreases owing to edema and fibrosis.

Despite these data, there is considerable interobserver variability and a significant learning curve associated with performing TRUS. For these reasons, TRUS understages more frequently than overstages the primary rectal tumor. However, TRUS understages the cancer less often than CT scan (15 vs 39%). A modified TNM (tumor-node-metastasis) classification for rectal cancer has been proposed based on TRUS-derived T stage (Table 40-1).

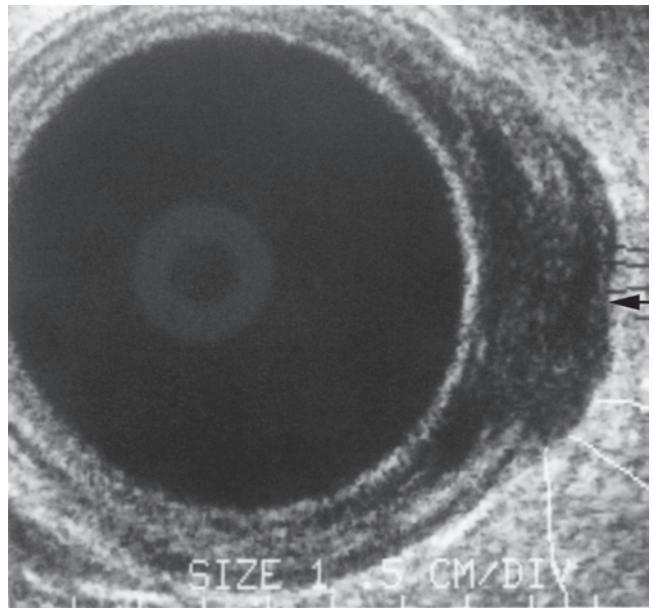

FIGURE 40-8 Transrectal endoluminal ultrasonography of a uT2 lesion. The *arrow* indicates the intact serosa.

N Stage. TRUS is less useful in predicting the status of perirectal lymph nodes. In a number of comparative studies, the accuracy of TRUS (70–75%) was similar to that of CT scan (55–65%) and MRI (60–65%). The accuracy of nodal staging with TRUS requires the nodes to be larger than 5 mm. The contribution of TRUS-guided fine-needle aspiration (FNA) biopsy to N-staging accuracy for rectal cancer is controversial.

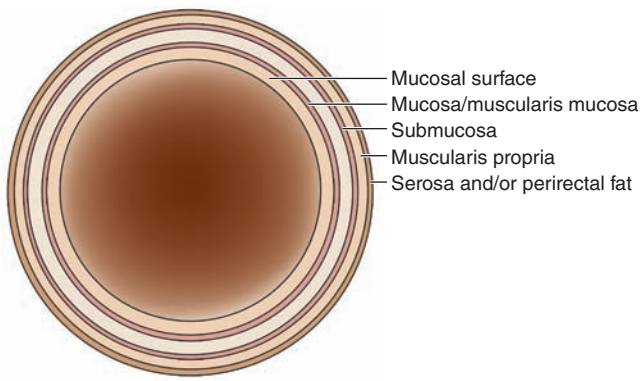

FIGURE 40-7 Schematic of transrectal endoluminal ultrasonography illustrates the five layers seen on ultrasound.

TABLE 40-1: ENDOSCOPIC ULTRASOUND STAGING OF RECTAL TUMORS

uT1	Invasion confined to the mucosa and submucosa
uT2	Penetration of the muscularis propria but not through to the mesorectal fat
uT3	Invasion into the perirectal fat
uT4	Invasion into the adjacent organ
uN0	No enlargement of lymph nodes
uN1	Perirectal lymph nodes enlarged

MAGNETIC RESONANCE IMAGING

Endorectal coil magnetic resonance imaging (ecMRI) and surface coil MRI are becoming more useful in the pretreatment evaluation of patients with rectal cancer. MRI offers some advantages compared with TRUS: It permits a larger field of view, it may be less operator- and technique-dependent, and it allows study of stenotic tumors that may not be even amenable to DRE.[16] Figure 40-9 illustrates a T_3 lesion. Like TRUS, ecMRI or phased-array MRI can discriminate small-volume nodal disease and subtle transmural invasion. These specialized MRI techniques can identify involved perirectal nodes on the basis of characteristics other than size, with reported accuracy rates of up to 95%. Another advantage over TRUS is identification of foci not only within the mesorectum but also outside the mesorectal fascia, such as the pelvic sidewall. We currently prefer phased-array MRI for staging of rectal cancers because it provides equal accuracy in staging compared to ecMRI but without the intrarectal coil.

Double-contrast MRI may permit more accurate T staging of rectal cancer by allowing better distinction between normal rectal wall, mucosa, muscularis, and perirectal tissues. In one report, the specificity and sensitivity of ecMRI with combined intravenous and endorectal contrast material to predict infiltration of the anal sphincter were 100 and 90%, respectively. However, N staging was not improved with this approach.

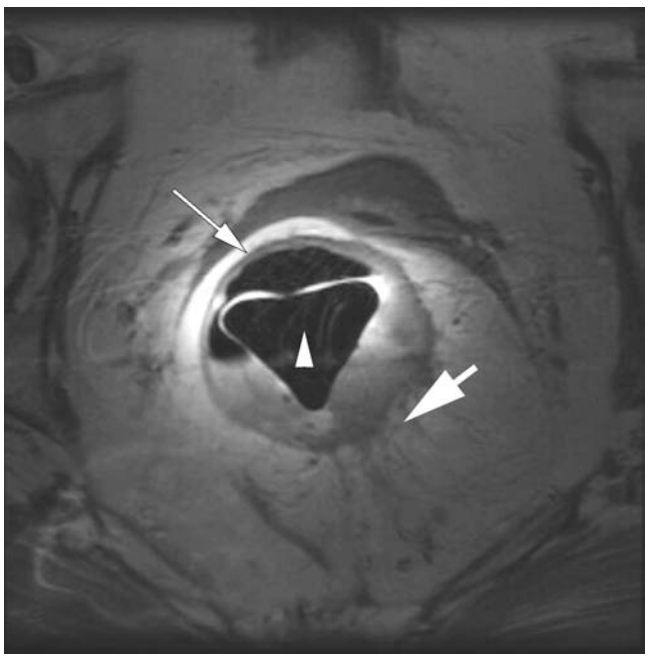

FIGURE 40-9 Endorectal MRI of a T3 lesion. *Arrowhead* indicates the site of the endorectal coil. *Large arrow* demonstrates finger-like projections of carcinoma invading into the mesorectal fat. *Small arrow* points to the anterior rectal wall. (Used with permission from Koenraad J. Mortele, MD, Beth Israel Deaconess Medical Center, Boston, MA.)

Phased-array surface coil MRI also may be beneficial in predicting the likelihood of a tumor-free resection margin by visualizing tumor involvement of the mesorectal fascia. If confirmed in other series, preoperative MRI may prove useful in selecting patients at high risk of local recurrence for therapy prior to resection.

POSITRON EMISSION TOMOGRAPHY

Fluorine-18 fluorodeoxyglucose–positron emission tomography (FDG-PET) is effective in assessing the extent of pathologic response of primary rectal cancer to preoperative chemoradiation and may predict long-term outcome.[17] Additionally, it has an accuracy of 87% for detecting recurrence of rectal cancer after surgical resection and full-dose external-beam radiation therapy.[18] While PET scans are positive in 90% of primary and recurrent tumors and in distant metastatic disease, they are relatively inaccurate for nodal metastases. Rectal cancer rarely metastasizes to the bones or to the brain, and without symptoms these two areas are not included routinely in surveillance imaging. They will, however, light up on PET scan. Current guidelines recommend that PET scans not be used routinely in the standard workup of a rectal cancer.

TNM STAGING

The purpose of staging any cancer is to describe the anatomic extent of the lesion. Staging by clinical examination, radiology, and pathology aids in planning treatment, evaluating response to treatment, comparing the results of various treatment regimens, and determining prognosis. Currently, the most widely accepted staging system for rectal cancer in the United States is the TNM classification system.

In 1987, the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (IUC) introduced the TNM staging system for colorectal cancer; this system was updated in 2010 (Tables 40-2 and 40-3). The TNM staging system is based on depth of tumor invasion as well as presence of lymph node or distant metastases. In stage I disease, the tumor may invade into the muscularis propria. In stage II disease, the tumor invades completely through this layer into the perirectal fat (T3) or adjacent organs (T4). Any lymph node metastasis represents stage III disease, and metastatic spread denotes stage IV disease. Depth of invasion (T stage) of the primary tumor is an important prognostic variable as increasing depth of invasion is correlated with an increasing chance of lymph node metastases. For instance, early-stage cancers extending into the muscularis mucosa (T1) will have a 10–13% incidence of metastasizing to perirectal lymph nodes.[19,20] In 805 pathology specimens Sitzler noted that 5.7% of T1 lesions, 19.6% of T2 lesions, 65.7% of T3 lesions, and 78.8% of T4 lesions had lymph node metastases.[21]

Generally, the biologic behavior of rectal cancer cannot be predicted by its location or size although there is a general

TABLE 40-2: TNM CLASSIFICATION OF RECTAL CANCER

Stage	Definition
Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ: intraepithelial or invasion of lamina propria
T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through muscularis propria into the subserosa or into nonperitonealized pericolic or perirectal tissues
T4a	Tumor perforates visceral peritoneum
T4b	Tumor directly invades other organs or structures
Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis in 1–3 regional lymph nodes
N1a	Metastasis in 1 regional lymph node
N1b	Metastasis in 2–3 regional lymph nodes
N1c	Tumor deposit(s) in the subserosa, mesentery, or nonperitonealized pericolic or perirectal tissues without regional nodal metastasis
N2	Metastasis in 4 or more regional lymph nodes
N2a	Metastasis in 4–6 regional lymph nodes
N2b	Metastasis in 7 or more regional lymph nodes
Distant metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis
M1a	Metastasis confined to one organ or site (for example, liver, lung, ovary, nonregional node)
M1b	Metastases in more than one organ/site or the peritoneum

consensus among experts that the more distal cancers have a poorer outcome when compared stage for stage with more proximal lesions. Poorly differentiated cancers have a worse long-term prognosis than well- or moderately differentiated tumors. Other factors that portend a poor prognosis include direct tumor extension into adjacent structures (T4 lesions); lymph node metastases; lymphatic, vascular, or perineural invasion; and bowel obstruction.

PRINCIPLES OF TREATMENT

Surgical resection is the cornerstone of curative therapy. Following a potentially curative resection, the 5-year survival rate varies according to disease extent[22,23] (Table 40-4). However, these survival figures may improve with the increased use of adjuvant therapy.

Surgical and oncologic management varies greatly depending on the stage and location of the tumor within the rectum. Superficially invasive, small cancers may be managed effectively with local excision. However, most patients have more deeply invasive tumors that require major surgery, such as low anterior resection (LAR) or abdominoperineal resection (APR). Yet others present with locally advanced tumors adherent to adjoining structures such as the sacrum, pelvic sidewall, vagina, uterus, cervix, prostate, or bladder, requiring an even more extensive operation.

After establishing the diagnosis and completing the staging workup, a decision is made whether to pursue immediate resection or administer preoperative chemoradiotherapy. For patients with stage II and III rectal cancer the authors advocate for combined preoperative chemoradiotherapy. The authors recommend this for all stage II and III patients with tumors located in the distal two-third of the rectum. For patients with rectal cancer in the proximal one-third of the rectum, the authors use preoperative chemoradiotherapy on a case by case basis depending on the size and bulkiness of the tumor as well as the patient's medical and surgical history.

Bowel Preparation

The high bacterial load in the intestinal tract requires preoperative bowel decontamination to reduce the incidence of infectious complications. Prior to the routine use of mechanical bowel preparation and preoperative antibiotics, the reported rate of infection following colorectal surgery was 60%.[24] A standard bowel preparation includes a clear-liquid diet 1–3 days prior to surgery, laxatives and/or enemas, and gastrointestinal tract irrigation with a solution of polyethylene glycol electrolyte lavage (GoLYTELY) or saline cathartics. In two separate surveys of North American colorectal surgeons, almost two-thirds preferred the polyethylene glycol electrolyte solutions because of the reliability of the cleansing results.[25,26] Certain preparations are contraindicated in patients with certain medical conditions. For example, patients with elevated creatinine or congestive heart failure should avoid the magnesium citrate preparation, whereas patients with gastroparesis should not take GoLYTELY.

Studies have shown that mechanical bowel preparation provides little, if any, additional benefit to reducing the perioperative infection rate. However, we still recommend to our patients that a mechanical bowel preparation be performed in large part because it allows for easier manipulation of the colon and rectum with both open and laparoscopic surgery.[27]

Oral antibiotics are also used to further decrease the incidence of postoperative infectious complications. Although mechanical cleansing decreases the total volume of stool in the colon, it does not affect the concentration of bacteria per milliliter of effluent. The most commonly used regimen is the Nichols/Condon preparation: neomycin 1 g and erythromycin base 1 g, both non-absorbable antibiotics, by mouth at 1:00 pm, 2:00 pm, and 10:00 pm on the day prior to surgery. Many surgeons substitute metronidazole 500 mg for the erythromycin base because it is active against a greater percentage of gastrointestinal anaerobes.

TABLE 40-3: ANATOMIC STAGE/PROGNOSTIC GROUPS

Stage	T	N	M	Dukes*	MAC*
0	Tis	N0	M0	-	-

NOTE: cTNM is the clinical classification, pTNM is the pathologic classification. They prefix is used for those cancers that are classified after neoadjuvant pretreatment (for example, ypTNM). Patients who have a complete pathologic response are ypT0N0cM0 that may be similar to Stage Group 0 or I. The r prefix is to be used for those cancers that have recurred after a disease-free interval (rTNM).
* Dukes B is a composite of better (T3 N0 M0) and worse (T4 N0 M0) prognostic groups, as is Dukes C (any TN1 M0 and Any T N2 M0). MAC is the modified Astler-Coller classification.

Instead of an oral antibiotic preparation most surgeons use perioperative systemic antibiotics. A typical choice to cover both aerobic and anaerobic intestinal bacteria is cefazolin and metronidazole administered intravenously just prior to the skin incision. A second dose of cefazolin is administered 4 hours into the case. Postoperative antibiotic prophylaxis usually is continued for 24 hours, although the perioperative dose is more critical. Some surgeons do "double" prophylaxis with oral and systemic antibiotics in all surgeries below the peritoneal reflection. Currently it is our practice to just use intravenous systemic antibiotics.

Perioperative systemic antibiotic coverage is broadened in patients with high-risk cardiac lesions such as prosthetic heart valves, a previous history of endocarditis, or a surgically constructed systemic-pulmonary shunt and with intermediate-risk cardiac lesions such as mitral valve prolapse, valvular heart disease, or idiopathic hypertrophic subaortic stenosis. Intravenous ampicillin 2 g and gentamycin 1.5 mg/kg are administered 30–60 minutes before the procedure, and ampicillin is repeated once 6 hours postoperatively in place of cefazolin; metronidazole is administered as usual. Vancomycin is substituted for ampicillin if the patient is allergic to penicillin or cephalosporin.

TABLE 40-4: SURVIVAL RATES

Stage I	80–90%
Stage II	62–76%
Stage III	30–40%
Stage IV	4–7%

Goals of Surgery for Rectal Cancer

The primary goal of surgical treatment for rectal cancer is complete eradication of the primary tumor along with the adjacent mesorectal tissue and the superior hemorrhoidal artery pedicle. Although reestablishment of bowel continuity at the time of surgery has become routine, cancer removal should not be compromised in an attempt to avoid a permanent colostomy.

For tumors located in the extraperitoneal rectum, resection margins are limited by the bony confines of the pelvis and the proximity of the bladder, prostate, and seminal vesicles in men and vagina in women. Although locoregional recurrence may be inevitable, local recurrence, cure, mortality, anastomotic leaks, and colostomy rates after rectal cancer surgery are related to surgical technique as well as to the experience and volume of the individual surgeon and institution.

Resection Margins

DISTAL MARGINS

The optimal distal resection margin for surgically treated rectal cancer remains controversial. Although the first line of

rectal cancer spread is upward along the lymphatics, tumors below the peritoneal reflection can spread distally via intra- or extramural lymphatic and vascular routes.

The use of APR for low rectal cancers traditionally has been based on the need for a 5-cm distal margin of normal tissue. However, in retrospective studies, margins as short as 1 cm have not been associated with an increased risk of local recurrence.[28–30] Distal intramural spread usually is limited to within 2.0 cm of the tumor unless the lesion is poorly differentiated or widely metastatic. Data from a randomized, prospective trial conducted by the National Surgical Adjuvant Breast and Bowel Project demonstrated no significant differences in survival or local recurrence when comparing distal rectal margins of less than 2, 2–2.9, and greater than 3 cm.[28] Therefore, a 2-cm distal margin is acceptable for resection of rectal carcinoma, although a 5-cm proximal margin is still recommended.[31]

RADIAL MARGINS

The importance of obtaining an adequate circumferential or radial margin has been appreciated more in the last decade. In fact, the circumferential radial margin (CRM) is more critical than the proximal or distal margin for local control. Tumor involvement of the circumferential margin has been shown to be an independent predictor of both local recurrence and survival. The Norwegian Rectal Cancer group reported on circumferential resection margins with 29-month median follow-up in 686 patients who had curative intent LAR with TME alone (no adjuvant radiotherapy) for rectal adenocarcinoma. The Norwegian group found that the overall local recurrence rate was 7% (22% with positive CRM and 5% with a negative CRM). Moreover, 40% of patients with a positive CRM developed distant metastases whereas only 12% of those with negative CRM developed distant disease.[32] In this study a positive CRM clearly affected survival. In another report of 90 patients undergoing resection for rectal cancer, when the radial margins were histologically positive, the hazard ratio (HR) for local recurrence was 12.2, and the HR for death was 3.2 when compared with those with clear circumferential margins. Furthermore, the length of mesorectum beyond the primary tumor that needs to be removed is thought to be between 3 and 5 cm because tumor implants usually are seen no further than 4 cm from the distal edge of the tumor within the mesorectum.[6,12] Therefore, in proximal rectal cancers, distal mesorectal excision 5 cm below the lower border of the tumor should be the goal.

LOCAL EXCISION

Oncologic Results

A number of retrospective studies of local excision since the 1970s have demonstrated a local recurrence rate of 7–33% and survival rates of 57–87%. Many of these reviews are limited, small, single-institution studies, often combining patients with tumors of different depths, including T3 lesions, positive margins, or who underwent different forms of local therapy, such as fulguration and snare cautery. Despite these limitations, many of these studies have demonstrated that local excision for superficial tumors with negative margins may provide similar survival and local control but without the morbidity of the APR. Major risk factors for local recurrence include positive surgical margins, transmural extension, and poorly differentiated histology. These retrospective studies suggest that local excision of selected distal rectal adenocarcinomas may provide adequate oncologic control at considerably less morbidity than APR.

Several prospective studies have been published (Table 40-5). In a study from the M.D. Anderson Cancer Center, 46 patients underwent transanal excision of small distal rectal cancer followed by postoperative radiation treatment.[33] Patients with T3 lesions also were given chemotherapy. For patients with negative margins, there was only a 6.5% local recurrence rate (all were T3 tumors) with a 93% overall 3-year survival. Local treatments combined with radiation provided similar oncologic control for T1 or T2 small distal rectal adenocarcinomas as compared with APR.

TABLE 40-5: RECURRENCE RATES AFTER LOCAL EXCISION AND ADJUVANT THERAPY

	Patients (n)	Treatment	Follow-Up (mo)	Local Recurrence	Survival
Ota et al[33]	46	LE and post-op XRT and 5-FU for T2, T3	36 (median)	6.5% (3/46) All T3s	Overall 3-y 93%
Bleday et al[34]	48	LE, post-op XRT and 5-FU for T2, T3	41 (mean)	8% (4/48)	Disease-specific 96%
Steele et al[35]	110	LE, post-op XRT and 5-FU for T2	48 (mean)	T—5.1% (3/59)	Overall 6-y 85%; disease-specific
Greenberg et al[36]	110	Same as Steele	85	T2—13.7% (7/51)	Overall 10-y T1 84% T2 66%

5-FU, 5-fluorouracil; LE, local excision; post-op, postoperative; XRT, radiation therapy.

From the New England Deaconess Hospital in Boston, patients with small distal cancers (<4 cm in diameter and <10 cm from the dentate line) with no evidence of metastatic disease were entered in a prospective study.[34] Patients with T1 lesions were observed after local excision. Patients with T2 lesions treated with local excision were given postoperative chemoradiation. Several patients were found to have T3 lesions and all were recommended further radical surgery. Those who refused had adjuvant chemoradiation therapy and were followed. All patients were followed every 3 months for 2 years and then every 6 months for 5 years. The local recurrence rate in this study was 8%, and the cancer-specific mortality rate was 4%. Risk factors associated with recurrence were T3 cancers or lymphatic invasion. Surgery alone was adequate for T1 lesions, and surgery combined with chemoradiation was appropriate for T2 lesions excised with negative margins. Radical resection was and still is appropriate for tumors with positive margins after local excision or for T3 cancers. Patients with lymphovenous invasion deserve further therapy, although that therapy was not defined.

In his initial report Steele and colleagues published the only large multicenter prospective trial of local excision (CALGB 8984 [Cancer and Leukemia Group B]).[35] Patients were eligible for the study if their cancer was within 10 cm of the dentate line and was less than 4 cm and involved less than 40% of the luminal circumference. All patients preoperatively were thought to have N0M0 disease, as determined clinically and by CT scan. All study patients had negative margins. T1 lesions had no further treatment, and T2 lesions were treated with chemoradiation. After 6 years of follow-up, the overall survival (OS) and the disease-free survival (DFS) were 85 and 78%, respectively. DFS was 84 and 71% for T1 and T2 lesions, respectively. Seven patients recurred with local disease only and underwent APR with a 70% salvage rate. This approach was no worse than that of radical resection. Longer-term follow-up (median 7.1 years) of CALGB 8984 revealed that 10-year overall survival rates were 84% for T1 lesions and 66% for T2 lesions. DFS was reported at 75% in T1 patients and 64% in those with a T2 lesion. Furthermore, local and distant recurrence rates were 8 and 5% versus 18 and 12% in T1 and T2 lesions, respectively. The longer-term follow-up of CALGB 8984 showed that the rates of local recurrence, OS, and DFS didn't change significantly for T1 lesions, but that there was a significant decrease in OS and DFS in the T2 lesions even though these patients received adjuvant therapy. It is clear that local excision is indicated for appropriately selected patients and that local excision with adjuvant therapy should be used more judiciously especially in medically fit patients.[36]

Patient Selection and Choice of Operation

Preoperative staging, primarily with ERUS or MRI, is most helpful in identifying appropriate patients for a local excision. Criteria for consideration for local excision are listed in Table 40-6. Patients with T3 or N1 disease are inappropriate for local excision. Given the low probability of microscopic nodal disease in T1 lesions, these patients are the best candidates for local excision. T3 and T4 lesions have a high probability of nodal involvement and therefore should be treated with radical resection. Controversy remains over the best therapy for T2 lesions. Most colorectal surgeons still believe that radical surgery with anLAR or APR remains the standard for T2 lesions. However, local excision combined with postoperative chemoradiation achieves similar rates of survival but not necessarily similar rates of DFS. In patients with a T2 lesion who undergo treatment with local excision and adjuvant chemoradiation, those who have a recurrence ultimately require a salvage APR for cure. The American College of Surgeons Oncology Cooperative group has just finished enrolling patients in a trial examining the benefit of preoperative chemoradiotherapy followed by local excision for appropriately staged T2N0Mx distal rectal adenocarcinoma. Preliminary results have just been reported and there was a 44% pathologic complete response rate, 64% pathologic downstaging rate, 5% had ypT3 tumors and 1–2% positive radial margin rate. These preliminary results show that there is excellent pathologic complete response and downstaging as well as good surgical outcomes with nearly all margins being negative. The ultimate efficacy of this technique will depend on long-term oncologic outcomes which are still pending at the time of this publication.[37] If the long-term oncologic outcomes are satisfactory, this approach of accurate staging and then the application of neoadjuvant therapy, followed by a local excision for small T2N0 lesions, may be the new paradigm for this subset of rectal cancer patients.

Tumors less than 3 cm from the dentate line but not invading the sphincters usually can be resected via a transanal procedure. Tumors 5 cm from the dentate line may need a transcoccygeal approach or transanal endoscopic microsurgery (TEM). Tumors 7–10 cm from the dentate line require TEM or should be considered for an LAR. Clearly, tumors tethered to the mesorectum or pelvic floor on physical examination, suggesting transmural involvement, are not amenable to local excision. Patients with such lesions should undergo preoperative radiation followed by a radical resection.

TABLE 40-6: CHARACTERISTICS OF TUMORS AMENABLE TO LOCAL EXCISION

T1N0 or T2N0 lesion
<4 cm in diameter
<40% circumference of the lumen
<10 cm from dentate line
Well- to moderately differentiated histology
No evidence of lymphatic or vascular invasion on biopsy
Patients with extensive metastatic disease and poor prognosis who require local control
Adjuvant treatment for patients with lymphatic invasion, T1 with poor prognosis features, T2 lesions

Patients considered medically unfit for a major resection are good candidates for local treatment of most small, mobile tumors, including T2 and T3 lesions, accepting a higher rate of local recurrence. In these circumstances, adjuvant chemoradiation is advocated, and close follow-up is mandatory.

After local excision, if the pathology is unfavorable, the patient should be counseled to have further therapy, including chemoradiation therapy and either an LAR or APR with TME. Local excision in these circumstances can be considered an open biopsy and not the definitive therapy.

Technique

There are four approaches to local excision: transsphincteric, transanal, transcoccygeal, and TEM. The transsphincteric technique, however, leads to significant dysfunction of the anal sphincters with subsequent moderate to severe fecal incontinence. Therefore, the transanal, transcoccygeal, and TEM approaches are the preferred techniques.

Transanal Excision

The majority of small distal rectal cancers can be excised locally via a transanal excision. Tumors amenable to this approach usually range from 6–8 cm above the anal verge which is the same as 3–4 cm above the anorectal ring.

Prior to the procedure, all patients should receive a full mechanical and antibiotic bowel preparation. Pre- and perioperative medications are similar to those administered for radical resection. Most patients are placed in the prone jackknife position, and the buttocks are taped apart. For lesions that are directly posterior, the lithotomy position can be used. The surgeon wears a fiberoptic headlight. A pudendal nerve block using 0.5% Marcaine (bupivacaine) with 1:100,000 units of epinephrine is administered to relax the sphincters and facilitate postoperative pain control. A Lone Star retractor (CooperSurgical, Inc., Trumbull, CT) can be used to expose the dentate line. A Pratt bivalve retractor (Pilling-Weck Instruments, Ft. Washington, PA), a Fansler operating speculum (HaydenMedical ,Inc., Santa Clarita, CA) or Parks anal retractor (CS Surgical, Inc., Slidell, LA) is inserted to dilate the anus and expose the lesion. Once the tumor is viewed adequately, traction sutures using 2-0 Vicryl (Ethicon, Somerville, NJ) are placed 2 cm proximal to the tumor. The circumferential dissection line is outlined on the mucosa using the cautery with a pinpoint Bovie tip approximately 1 cm from the border of the tumor; careful attention should be paid to maintaining a wide proximal margin. If an adequate view of the lesion cannot be obtained initially, serial traction sutures starting distally are used to prolapse the lesion into the field. Additional local anesthetic is injected submucosally circumferentially along the Bovie markings to provide hemostasis. Starting proximally and proceeding circumferentially, a full-thickness incision of bowel wall is made down to perirectal fat using the cautery along the previously marked mucosa (Fig. 40-10). Once fat is reached, the dissection is made through the fat to undercut the specimen. Anteriorly in a female patient, one must not injure the posterior wall of the vagina. In a male patient, one must avoid the prostate. Once the specimen is free, carefully maintain and mark the orientation for the pathologist (eg, proximal, anterior, left, right). Irrigate and check for hemostasis. After excision, the defect in the bowel wall is closed transversely with full-thickness bites using interrupted 3-0 Vicryl sutures. One stitch is placed in the center of the incision. One-half is closed, followed by the other. A rigid sigmoidoscope is inserted to visualize the suture line and to ensure patency of the rectal lumen. The patient then is placed supine. A pad is applied to the rectal area and secured with mesh rectal shorts. A pack in the anal canal or rectum is not used. These procedures can be done either as an outpatient or with a short stay. Potential complications include urinary retention, urinary tract infections, fecal impaction, infections in the perirectal and ischiorectal spaces, and delayed hemorrhage. The incidence of these complications is quite low; mortality in most series is zero.

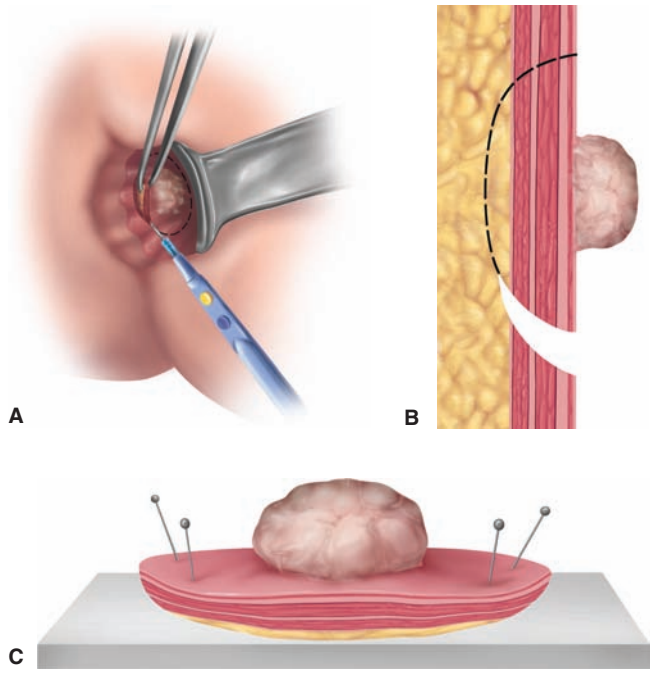

FIGURE 40-10 Approach to transanal excision of a rectal tumor. **A.** A 1- to 2-cm margin is marked circumferentially with Bovie electrocautery on the rectal mucosa. **B.** Full-thickness excision down to perirectal fat is performed. **C.** The specimen is oriented for the pathologist. (Reprinted, with permission, from Bleday R. Local excision of rectal cancer. *World J Surg.* 1997;21:706–714.)

Transcoccygeal Excision

Originally popularized by Kraske, the transcoccygeal excision is used for larger or more proximal lesions within the middle or distal third of the rectum. Bleday et al reported that the average distance of the distal margin of an appropriate tumor

that was selected for the posterior or Kraske approach was approximately 4.8 cm from the dentate line.[34] This approach is useful for lesions on the posterior wall of the rectum but can be used for anterior lesions.

Patients undergo similar bowel preparation and thrombosis precautions as the transanal excision patients. The patient is placed in the prone jackknife position. The buttocks are taped apart for better exposure, but at closure the tape is released to facilitate approximation of the subcutaneous tissues and skin. After prepping the skin, the rectum is irrigated with a Betadine (povidone/iodine) solution. The incision is made in the intergluteal fold over the sacrum and coccyx down to the upper border of the posterior aspect of the external sphincter. After division of the skin and subcutaneous tissues, one encounters the coccyx and anal coccygeal ligament. In order to obtain optimal exposure, the coccyx is removed by cauterizing its attachments, including the anal coccygeal ligament, from each side and from its lower edge and then proceeding with the dissection on its undersurface. A cutting wire is used to transect the sacral coccygeal joint. With removal of the coccyx, bleeding from an extension of the middle sacral artery is controlled with electrocautery. The levator ani muscles are separated in the midline, exposing a membrane that is just outside the mesorectal fat. Once this membrane is divided, the rectum can be completely mobilized within the intraperitoneal pelvis. For anterior lesions, a posterior proctotomy is made; the anterior rectum is approached under direct vision, with removal of the tumor along with a 1-cm margin (Fig. 40-11). For posterior-based lesions, after complete mobilization of the mesorectum, the distal margin of the tumor

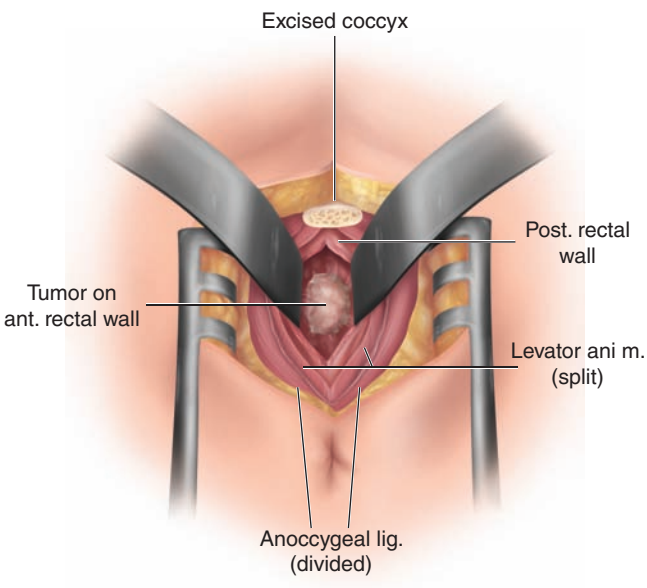

FIGURE 40-11 Kraske approach to an anterior lesion. The coccyx is excised, the levator is split in the midline, and the rectum is mobilized. The posterior rectal wall is opened to expose an anterior lesion. (Reprinted, with permission, from Bleday R. Local excision of rectal cancer. *World J Surg.* 1997;21:706–714.)

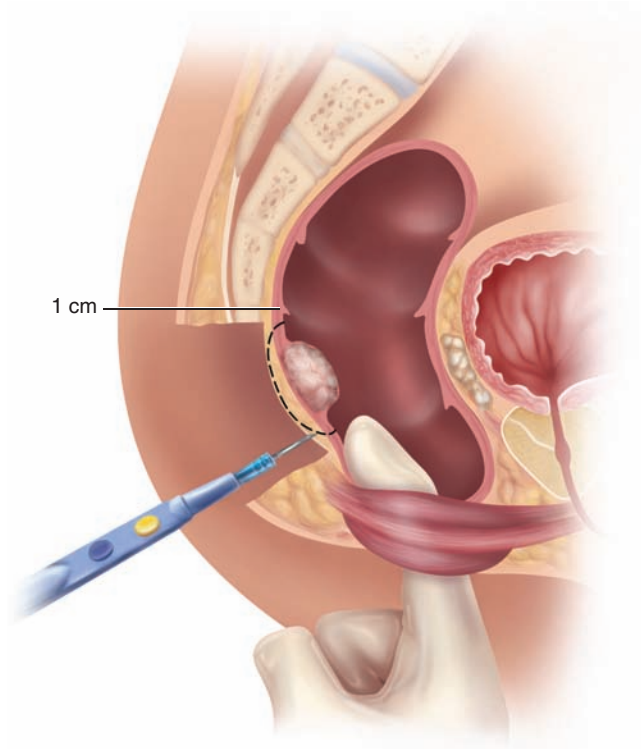

FIGURE 40-12 Kraske approach to a posterior lesion. After the rectum has been exposed, the surgeon may palpate the distal margin of the tumor. The tumor is excised with a 1-cm margin. (Reprinted, with permission, from Bleday R. Local excision of rectal cancer. *World J Surg.* 1997;21:706–714.)

can be palpated via a rectal examination; the mesorectum and rectum are transected approximately 1 cm distal to the tumor (Fig. 40-12). The tumor is excised with a 1-cm margin of normal tissue. The advantage of the posterior approach is that the immediate mesorectal tissue adjacent to the tumor is removed along with perirectal nodes. After removal, the specimen is oriented for the pathologist. The incision is closed in a transverse manner using an absorbable suture such as 3-0 Vicryl or 3-0 PDS (Ethicon, Somerville, NJ). After closure of the rectum, an air test is performed by insufflating the rectum with air and filling the operative field with sterile saline. After all air leaks are controlled, the levator ani musculature is reapproximated and the anal coccygeal ligament is reattached to the sacrum, followed by closure of the subcutaneous tissues and skin.

One of the most troubling complications of the transcoccygeal excision is a fecal fistula extending from the rectum to the posterior incision. The incidence of this complication ranges from 5 to 20%.[35] These fistulas usually heal after temporary fecal diversion.

Transanal Endoscopic Microsurgery

The transanal endoscopic microsurgery (TEM) technique was first described by Gerhard Buess of Tubingen, Germany

in 1980. It is especially useful for small benign and malignant lesions in the mid and proximal rectum that are too high for a traditional transanal excision. This technique is widely used in Europe but over the years has been underused in North America until recently. It is gradually becoming standard practice for early mid to upper rectal lesions. The specialized instrumentation includes a 4-cm Wolf operating proctoscope (Richard Wolf Company, Frankfurt am Main, Germany) in lengths of 12 and 20 cm with a flat or beveled end. The operating proctoscope is equipped with a binocular microscope and videoscope attachment for viewing on a standard laparoscopy tower. A CO_2 insufflator and long operating surgical instruments are needed as well. The surgeon must be trained in the technique, which follows the same principles as transanal excision described earlier using the pinpoint tip on the Bovie electrocautery. Preoperative localization in the office with a rigid sigmoidoscope is essential so that the patient can be appropriately positioned. The patient is positioned using a beanbag and fixation to the table with tape, which allows the patient to be rotated laterally during the procedure. For an anterior lesion, the patient is placed in the prone jackknife position. For a posterior lesion, the patient is placed in a modified lithotomy position. For lateral lesions, the patient can be placed on the appropriate side so that the lesion is at the inferior quadrant of the visual field. After the patient is appropriately positioned, the operating proctoscope is fixed to the table with a rigid support arm and a glass faceplate. The faceplate is equipped with two operating ports and a suction port. The rectum is distended with carbon dioxide anywhere from 15- to 26-cm water pressure so that the tumor can be visualized and the resection and closure of the rectum can be completed. After full-thickness excision of the lesion is completed, the defect is endoscopically closed with interrupted 3-0 PDS figure-of-eight sutures. If unable, the defect may be left open as in a standard transanal excision. The one caveat, however, is that extreme care must be taken to identify the peritoneal reflection, especially anteriorly. If dissection carries into the peritoneal cavity, the defect must be closed. If we enter the peritoneal cavity, after we close the defect, our practice is to observe these patients in hospital until they are passing flatus. In selected patients, temporary diversion is needed after entering the peritoneal cavity. Furthermore, patients in whom TEM is contemplated should be made aware that because of technical considerations (proctoscope won't fit or pass and/or poor visualization or entry into the peritoneal cavity), an LAR may need to be performed. This is especially true in patients with a known malignancy.

Unfortunately, the literature describing oncologic outcomes for TEM resection of early-stage rectal adenocarcinoma is mainly single institution, small series, and with short-term follow-up. Most of these studies make a comparison with radical surgery (LAR, APR) but never make a direct comparison with transanal resection. For the most part, the comparison of TEM to traditional transanal excision is made with historical data alone. This is in part because very distal lesions near the sphincter are difficult to excise with the TEM and a traditional transanal excision is easier, whereas the more proximal lesions are not amenable to a traditional approach and a TEM is more likely to succeed in removing these lesions per rectum. Hence, only a small number of tumors thatare above 8 cm and below 10 cm from the anal verge could ever be enrolled in a trial to make a direct comparison. To answer this question, a multicenter randomized trial comparing TEM to traditional transanal excision for early-stage rectal cancer with and without adjuvant radiotherapy needs to be performed. To date this trial has not been done.

TEM resection of low-risk T1 rectal adenocarcinoma results in a 0–11% local recurrence rate whereas local recurrence for T2 lesions without adjuvant therapy is approximately 19–35%. When T2 and T3 lesions are treated with adjuvant or neoadjuvant therapy and TEM resection, the local recurrence rates decrease to 14 and 3%, respectively. One caveat is that all of these studies have short-term follow-up with the longest being 4 years. Indirect comparisons of local excision with TEM for T1 lesions have similar local recurrence rates (7–18% TAE vs 0–11% TEM), and as a result the decision to perform traditional transanal excision versus TEM should depend on the location of the tumor and the individual surgeon's expertise. Local recurrence rates without chemoradiotherapy for either TEM or transanal excision, on the other hand, are not satisfactory. Local recurrence rates for T2 lesions excised by TEM range from 19 to 35% versus 26 to 47% for traditional transanal excision (see Table 12-2) In either case, the results are not adequate, and as a result medically fit patients with T2 lesions should not have either a TEM or a transanal excision without the addition of radiotherapy.

In summary, the results of TEM resection are as good as or better than traditional transanal resection for early rectal cancer. When deciding whether to utilize transanal excision or TEM, the surgeon should remember that TEM offers better visualization, almost complete intact excision, and access to lesions that are higher in the rectum and otherwise would need radical surgery. Cataldo's group from the University of Vermont has shown that TEM resection resulted in intact nonfragmented excision 94% of the time whereas transanal excision only accomplished intact nonfragmented excision 65% of the time ($p < .001$) and tumor-free margins were 98% with TEM versus 78% with TAE when resecting a rectal cancer ($p = .03$). Furthermore, they showed a nonstatistically significant trend to lower recurrence rates (22% for TAE and 3% for TEM).[38]

LOW ANTERIOR RESECTION WITH TOTAL MESORECTAL EXCISION

Oncologic Results

Local failures most often result from inadequate surgical clearance of the radial margin. The concept of total mesorectal excision (TME) proposed by Heald et al has been shown to improve both disease-free and overall survival.[3] TME in conjunction with an LAR or APR involves precise dissection

and removal of the entire rectal mesentery, including that distal to the tumor, as an intact unit. Unlike conventional blunt dissection, which may leave residual mesorectum in the pelvis, TME involves sharp dissection under direct vision in the avascular, areolar plane between the fascia propria of the rectum, which encompasses the mesorectum, and the parietal fascia overlying the pelvic wall structures. This procedure emphasizes autonomic nerve preservation (ANP) and complete hemostasis and avoids violation of the mesorectal envelope. This results in a characteristic bilobed, smooth, glistening surface of the excised mesorectum.

Because rectal cancer spread appears to be limited to the mesorectal envelope, its total removal should encompass virtually every tumor satellite, thus improving the likelihood of local control. The excellent results with TME may be attributed to improved lateral clearance with removal of potential tumor deposits in the mesentery and decreased risk of tumor spillage from a disrupted mesentery.[39] The completeness of the mesorectal excision influences local control, even if the surgical margins are uninvolved. In one report, both local (11.4 vs 5.5%) and distant recurrence rates (19.2 vs 12.2%) were higher in patients with an incomplete, as compared with a complete or nearly complete, mesorectal resection. These favorable results have led some to question the need for routine postoperative radiation in patients undergoing complete resection of rectal cancer with TME. However, the Dutch neoadjuvant trial that randomly assigned 1861 patients with resectable rectal cancer to TME alone or a short course of preoperative radiation (5 Gy daily for 5 days, in the "Swedish style") followed by TME demonstrated a significantly decreased rate of local recurrence 8.2 versus 2.4% at 2 years.[40]

Of greatest importance is that improved local control appears to result in better overall survival. In one of the earliest reports, Heald et al noted a local recurrence rate of 3.6% and a survival rate of 86% after 9 years of follow-up.[41] In 1994, the Norwegian Rectal Cancer Group was founded to improve the surgical standard by implementing TME on a national level and to evaluate the results; courses were arranged to teach surgeons the technique of TME. Optimized TME reduced the rate of local recurrence (6% TME vs 12% non-TME) and increased overall survival (73% TME vs 60% non-TME) within 2 years.[42] This led to a strategic change in both Norway and the United States to initiate quality assessment in the surgical treatment of rectal cancer.

Guillem et al recently demonstrated an improved overall and disease-free survival in patients with T3 or N1 tumors who underwent TME after preoperative combined-modality therapy.[43] With a median follow-up of 44 months, the estimated 10-year overall survival was 58% (Fig. 40-13) and 10-year recurrence-free survival was 62% (Fig. 40-14). On multivariate analysis, pathologic response greater than 95%, lack of lymphovascular invasion and/or perineural invasion (PNI), and lack of postoperative positive lymph nodes were significantly associated with improved overall and disease-free survival.

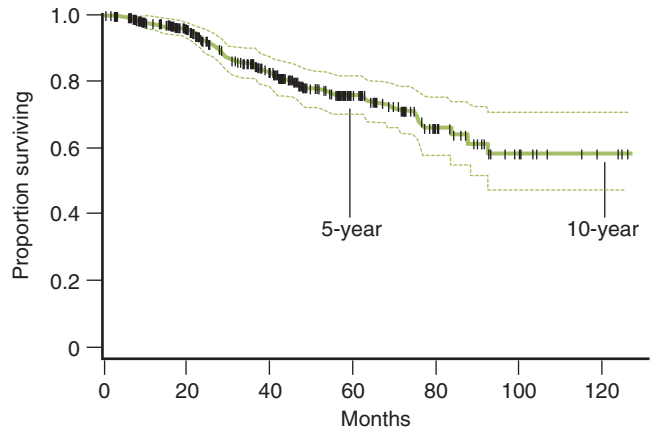

FIGURE 40-13 Five- and 10-year overall survival with 95% confidence intervals of rectal cancer patients following preoperative combined modality therapy and total mesorectal excision. (Used, with permission, from Guillem JG, Chessin DB, Cohen AM, et al. Long-term oncologic outcome following preoperative combined modality therapy and total mesorectal excision of locally advanced rectal cancer. *Ann Surg.* 2005;241:829–838.)

Lateral Nodal Dissection

Despite the advent of TME and the addition of neoadjuvant chemoradiotherapy to the treatment of patients with rectal cancer, there is still a risk of local pelvic recurrence and the appearance of distant metastatic disease. Lateral nodal spread, especially in distal rectal cancers, is one possible culprit for treatment failures in rectal cancer. It is well established that distal rectal adenocarcinomas have a worse prognosis than

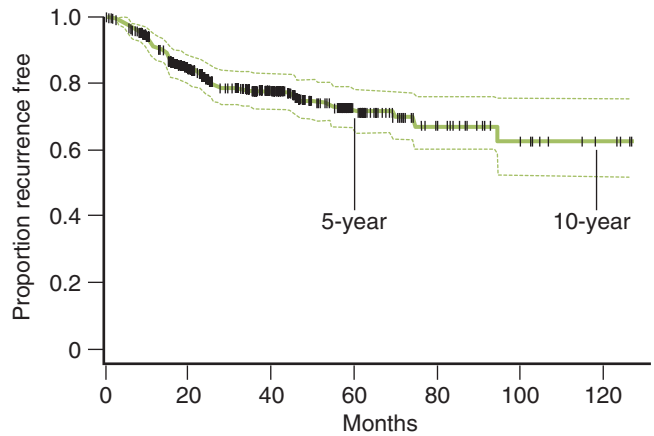

FIGURE 40-14 Five- and 10-year recurrence-free survival with 95% confidence intervals of rectal cancer patients following preoperative combined-modality therapy and total mesorectal excision (TME). (Used, with permission, from Guillem JG, Chessin DB, Cohen AM, et al. Long-term oncologic outcome following preoperative combined modality therapy and total mesorectal excision of locally advanced rectal cancer. *Ann Surg.* 2005;241:829–838.)

more proximally based lesions. Most surgeons attribute this to three factors: (1) Distal tumors require a more difficult low dissection in a narrow pelvis; (2) there are probably biologic differences in tumors with the low-lying tumors probably having a poorer biology; and (3) the more distal tumors have a predilection to more complex lymphatic channels and the possibility of lateral spread into the systemic circulation as well as the portal circulation. Takahashi et al performed a retrospective analysis of 764 patients over a 20-year period (1975–1995) who underwent a curative three-space dissection. The three spaces are defined as follows: (1) The inner space is encircled by the visceral pelvic fascia posteriorly and Denonvilliers' fascia anteriorly, and laterally the three spaces unite near the pelvic nerve plexus; (2) the intermediate space is defined by the parietal pelvic fascia posteriorly and the internal iliac arteries and branches laterally and anteriorly; and (3) the outer space is lateral to the internal iliac arteries. Takahashi found that 66 of 764 patients (8.6%) had lateral nodal spread of their rectal cancer. More importantly, 16.4% of the low-lying rectal cancers had their lower margins less than 5 cm above the dentate line. Lateral nodal spread is outside the traditional TME resection plane but can be encompassed by a three-space lateral nodal dissection in appropriate patients. When this was achieved, they had a 42.4% 5-year survival in their subgroup of patients who had lateral spread and a curative three-space dissection.[44]

A comparative study of Japanese and Dutch patients examined local recurrence in Dutch patients who received TME-alone versus TME-plus preoperative radiotherapy and Japanese patients who were treated with TME-plus lateral nodal dissection (LAR or APR). Most Japanese patients did not receive neoadjuvant therapy. Local recurrence, lateral pelvic recurrence, and presacral recurrence rates were analyzed and are shown in Table 40-7.

In summary, both TME with radiotherapy and lateral nodal dissection without radiotherapy result in excellent local control and have improved local control over TME alone. The conclusion is that the radiotherapy sterilizes the lateral space that has microscopic tumor extension beyond the traditional TME resection plane.[45] The major caveat is that patients who have TME alone have much better postoperative sexual and urinary function than those who have TME-plus lateral nodal dissection.[46]

TABLE 40-7: ANALYSIS OF LOCAL, LATERAL PELVIC, AND PRESACRAL RECURRENCE RATES

	TME Alone (%)	TME + RT (%)	TME + Lateral Dissection (%)
Local recurrence	12.1	5.8	6.9
Lateral pelvic recurrence	2.7	0.8	2.2
Presacral recurrence	3.2	3.7	0.6

Quality of Life

Quality of life has improved with TME and ANP. Conventional rectal surgery is associated with a significant incidence of impotence, retrograde ejaculation, and urinary incontinence, presumably owing to damage to the pelvic autonomic parasympathetic and sympathetic nerves by blunt dissection.[47] Postoperative impotence, retrograde ejaculation, or both are observed in 25–75% of conventionally treated patients compared with only 10–29% of patients after TME with its careful nerve-sparing dissection.[47]

Erectile capacity and normal ejaculation may be preserved in most male patients, especially those 60 years of age or younger. In one retrospective study of patients undergoing TME with ANP, 86% of male patients younger than 60 years and 67% of those 60 years or older were able both to engage in postoperative sexual intercourse and to achieve orgasm.[47] In female patients, sexual activity was maintained in 86%, sexual arousal with vaginal lubrication in 98%, and the ability to achieve orgasm in 91%. With the advent of pelvic dissections that preserve autonomic nerves, postoperative sexual dysfunction rates have been reduced from greater than 50% to 10–28%.[47]

Isolated urinary dysfunction is uncommon with preservation of the pelvic autonomic nerves. In a prospective study of rectal cancer patients undergoing TME with ANP, only 2 of 35 had difficulty with bladder emptying and possessed evidence of bladder denervation on postoperative studies.

Some studies, however, have demonstrated impaired quality of life owing to LAR with TME in part because of a temporary loop ileostomy or preoperative radiotherapy. Yet cost-utility analysis estimates that improved survival outweighs impaired quality of life.[48]

Technique of Total Mesorectal Excision

Prior to the procedure, all patients receive a full mechanical and antibiotic bowel preparation. The patient's abdomen is marked preoperatively by the enterostomal therapy nurse for potential stoma sites. An epidural catheter is placed by the anesthesia team for postoperative pain control. Sequential compression devices are applied to the lower extremities before general anesthesia is induced for deep vein thrombosis (DVT) prophylaxis. One dose of 5000 units of heparin is administered subcutaneously. Cefazolin and metronidazole are infused. After anesthesia is induced, the patient is brought down on the table so that the buttocks are at the edge; a gel pad placed under the buttocks facilitates access to the anus. The patient is placed in a modified lithotomy position using Allen or Yellow Fin stirrups (Fig. 40-15). The hips are minimally flexed and abducted. The feet are positioned flat in the stirrups; an imaginary line is visualized keeping the ankle, knee, and contralateral shoulder in a straight line. Care is paid to having no pressure on the peroneal nerve or bony prominences; a hand should be able to be placed easily between

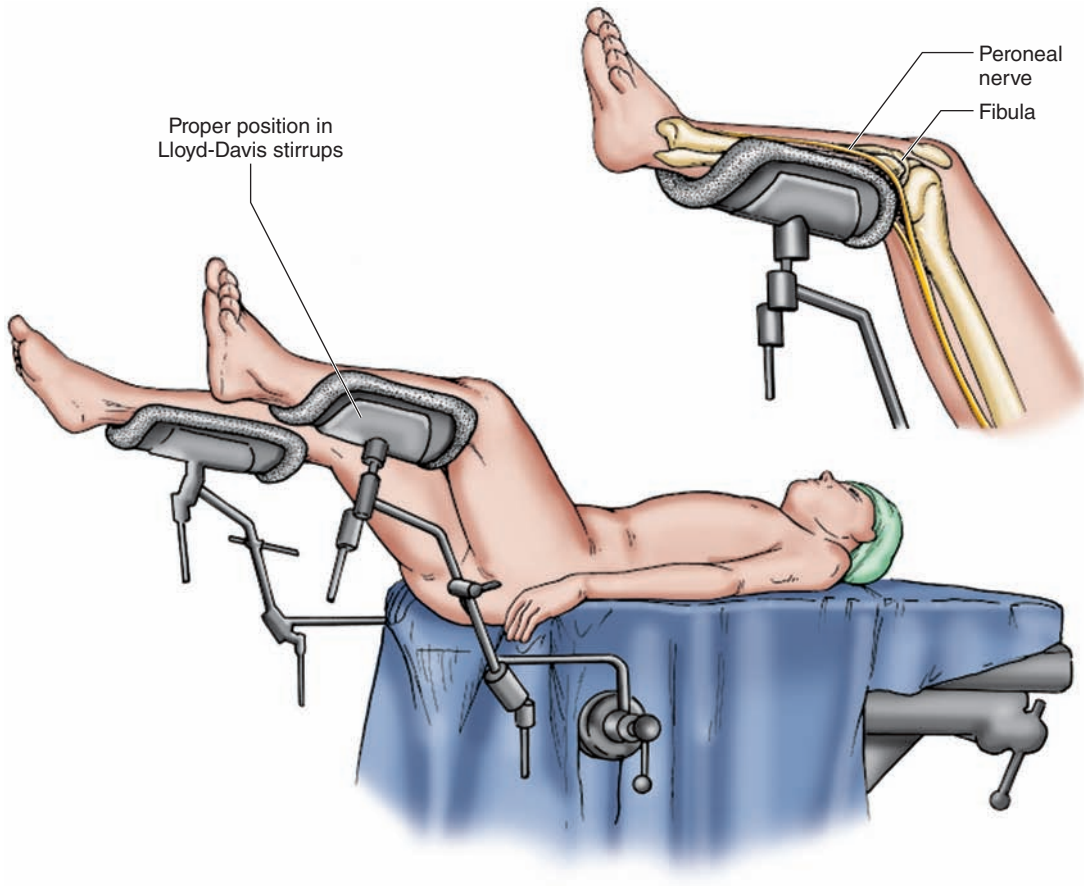

FIGURE 40-15 Position of patient for surgical treatment of rectal cancer allows access to both the abdomen and the perineum.

the posterolateral aspect of each lower leg and its respective stirrup. If the patient has had previous pelvic surgery or evidence of hydronephrosis on CT scan, consider bilateral ureteral stent placement. A Foley catheter is placed and is draped over one leg. A nasogastric tube is inserted by the anesthesia team. A DRE is performed. If there is any question regarding the distal or proximal limits of the tumor, rigid proctoscopy may be performed at this time. Preoperatively, the lesion may have been marked by an injection of India Ink. The surgeon should wear a headlight to help with visualization in the lower pelvis. Most surgeons stand on the patient's left, which allows them to operate more efficiently with their right hand in the lower pelvis. A low midline incision is made between the umbilicus and the pubis, keeping in mind potential stoma sites; cephalad extension may be necessary to mobilize the splenic flexure. The abdomen is explored to search for metastatic disease in the liver or peritoneal surfaces. The rectum is palpated to assess the primary mass. The colon is palpated for any synchronous lesions.

The abdominal self-retractor is set up. The patient is placed in slight Trendelenburg's position. The sigmoid is mobilized laterally by scoring the white line of Toldt (Fig. 40-16A). The left ureter is identified by several ways: visualizing it cross over the bifurcation of the common iliac artery, palpating the external iliac artery and pinching the tissue above it, locating it at the level where the sigmoid turns, or incising the peritoneum over the psoas muscle and finding the ureter on the medial aspect of the peritoneum (Fig. 40-16B). If it is clear that much length will be necessary for reconstruction, the splenic flexure is mobilized. Tension on the colon should be gentle but firm; too much traction on the colon or omentum can cause splenic injury. The transverse colon is freed from the omentum by sharp dissection along the avascular plane between the two structures. The bowel is packed into the upper abdomen. The sigmoid is held up in the air at the junction between the descending colon and sigmoid. Both sides of the mesentery are scored from this point down to the sacral promontory. The right ureter is identified. The colon usually is divided at the sigmoid-descending colon junction using a linear stapler (or may be divided between two bowel clamps, which would require a hand-sewn anastomosis). The sigmoidal vessels are isolated and divided using large Kelly clamps, two proximally and one distally. Metzenbaum scissors are used to divide the vessels. The vessels are doubly

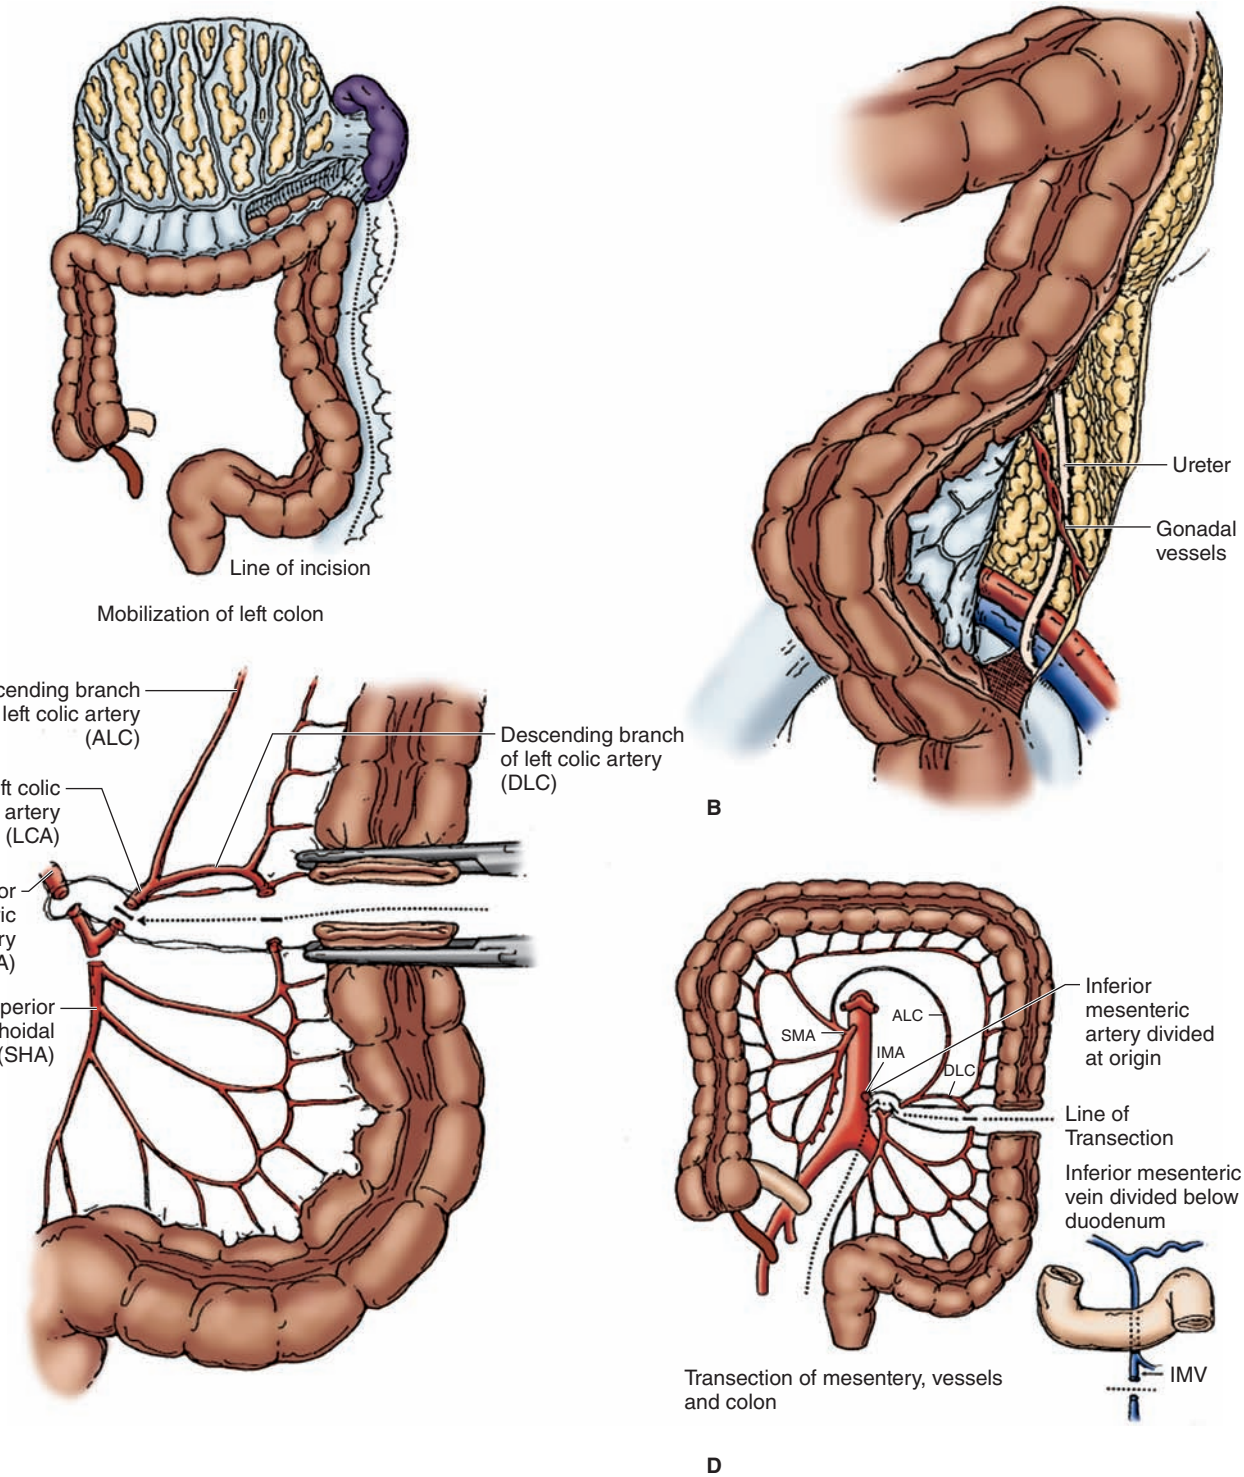

FIGURE 40-16 Mobilization of the left colon. **A.** Incision line around the left colon. **B.** Left colon reflected medially, exposing the ureter and gonadal vessels. **C.** Superior hemorrhoidal artery is divided close to the aorta to result in a high arterial ligation. The arcade of Riolan is preserved, and the left colon and mesentery are divided at the junction of the descending and sigmoid colon. **D.** Proximal ligation of the inferior mesenteric vein adds extra mobility.

ligated. The colon is packed cephalad, out of the field. The superior hemorrhoidal artery is then divided at the junction with the left colic artery (Fig. 40-16C). A more proximal ligation of the inferior mesenteric vessel can also be performed if extra length on the colon is needed, but it is not necessary to ligate the IMA flush with the aorta for oncologic reasons. One usually suture-ligates the superior hemorrhoidal vessels so as to ensure hemostasis.

After dividing the superior hemorrhoidal artery, it is important to find the proper plane of dissection at the sacral promontory. One first locates the sympathetic nerves along the pelvic brim. The rectum is retracted anteriorly. Electrocautery with a long Bovie tip is used to develop the loose areolar plane of avascular issue posteriorly (Fig 40-17B). The nerves are visualized and kept posterior to the plane of resection. The presacral fascia is incised down to Waldeyer's fascia, and the dissection is carried inferiorly to the coccyx. The St. Mark's abdominal retractor facilitates the deep pelvic dissection.

The anterior and lateral dissections are then started after the posterior dissection has been partially completed. The peritoneum is incised on each side and then across the anterior midline to meet at the deepest point in the cul-de-sac, the groove between the rectum and the anterior structures (uterus/vagina in women, seminal vesicles in men) (Fig. 40-17A). The mesorectum is separated from the pelvic sidewall using the cautery to divide the thin areolar tissue that is found when one is dissecting in the proper plane. The dissection is carried down anterolaterally to the lateral ligaments or "stalks" (Fig. 40-17C). Only 25% of patients have distinct branches of the middle rectal vessels in these ligaments. They can be divided flush with the pelvic sidewall, but care should be taken to preserve the hypogastric plexus that lies on the pelvic sidewall just lateral to the seminal vesicles in men or just lateral to the cardinal ligaments in women. Preservation of the plexus helps with avoiding postoperative potency or urinary problems, and resection of the plexus is rarely helpful for oncologic reasons. Throughout the lateral dissection, one should be aware of the nerves and vessels along the pelvic sidewall. Too lateral a dissection causes bleeding from the pelvic sidewall.

Anteriorly, the planes are less distinct, and the fat of the mesorectum is thin. The vaginal wall or seminal vesicles are elevated anteriorly using the lipped St. Mark's retractor while the surgeon places posterior traction on the rectum. In the male patient, the dissection is continued through or anterior to Denonvilliers' fascia (Fig. 40-17D). This fascia is often two layers of a thin membrane. When performing a cancer resection, one should take both layers of this membranous fascia off the seminal vesicles and upper prostate if possible.

POINT OF TRANSECTION

For middle to low rectal cancers, TME involves removing the entire mesorectum with its enveloping fascia as an intact unit. For tumors in the upper rectum (>10 cm from the anal verge), TME is extended to 5–6 cm below the level of the tumor, dividing the rectum and mesorectum at the same level. A number of pathologic studies demonstrate that tumor spread within the mesorectum rarely extends beyond 4 cm distal to the caudal edge of the tumor; usually most nodes or mesorectal implants are within 3 cm of the distal edge of the tumor.[6,12] However, multiple studies have shown that a 2-cm margin is adequate on the mucosa. Fewer than 2–4% of tumors will have mucosal or submucosal spread beyond 2 cm distally. Rigid sigmoidoscopy may be used to identify the appropriate site for transection if the cancer is not palpable, especially after neoadjuvant therapy.

Once the rectum has been mobilized, a tumor measured at 5 cm by rigid proctoscopy often may be moved to 8 cm from the dentate line, a distance that permits an adequate resection margin and sphincter preservation (Fig. 40-18).

When the distal extent of the tumor and the site of transection have been established, electrocautery is used to dissect the mesorectal fat away from the rectum. Vessels require ligation with 2-0 Vicryl ties. It is important to keep the dissection of the mesorectum perpendicular to the site of transection. "Coning in" as one divides the mesorectum prior to transection should be avoided.

Once the bowel has been cleared of mesorectal fat, a 30-, 45-, or 60-mm TA linear stapler is used to staple the rectum (Fig. 40-19A). This is the first staple line in the "double-stapling technique." The bowel is clamped just proximal to this point. A no. 10 blade on a long handle is used to transect the bowel. The specimen is handed off the field.

RECONSTRUCTION: DOUBLE-STAPLING TECHNIQUE

The proximal colon is unpacked, and the length required for a tension-free anastomosis is determined. If more colon is needed, the splenic flexure is mobilized further. This may require an extension of the incision cephalad. Proximal ligation of the inferior mesenteric vein also adds extra mobility (see Fig. 40-16D). The proximal bowel is cleaned by resecting residual fat and small vessels approximately 1 cm proximal to the staple line. The staple line is excised with Bovie electrocautery. Sizers may be inserted to select an end-to-end anastomosis (EEA) stapler diameter (25, 29, or 31 mm). A circular stapler is then chosen. The anvil is placed within the opened bowel. A 3-0 Prolene is used to take full-thickness, 1- to 2-mm bites to fashion a purse-string stitch around the anvil. The purse-string suture is tied gently but firmly around the shaft so that the shaft is completely encircled by bowel (Fig. 40-19C). If there are any gaps, an additional 3-0 Prolene suture can be used to take another full-thickness bite, and this suture may be tied around the shaft as well. The serosa of the bowel is cleaned further of fat and small vessels within 1 cm of the shaft of the anvil to optimize bowel-to-bowel contact when the circular stapler is applied. One can also perform a similar placement of the anvil on the antimesenteric side of the colon for a side-to-end anastomosis. The optimal placement of the anvil in this case is such that only a small blind end of colon remains distal to the anastomosis (1–5 cm).

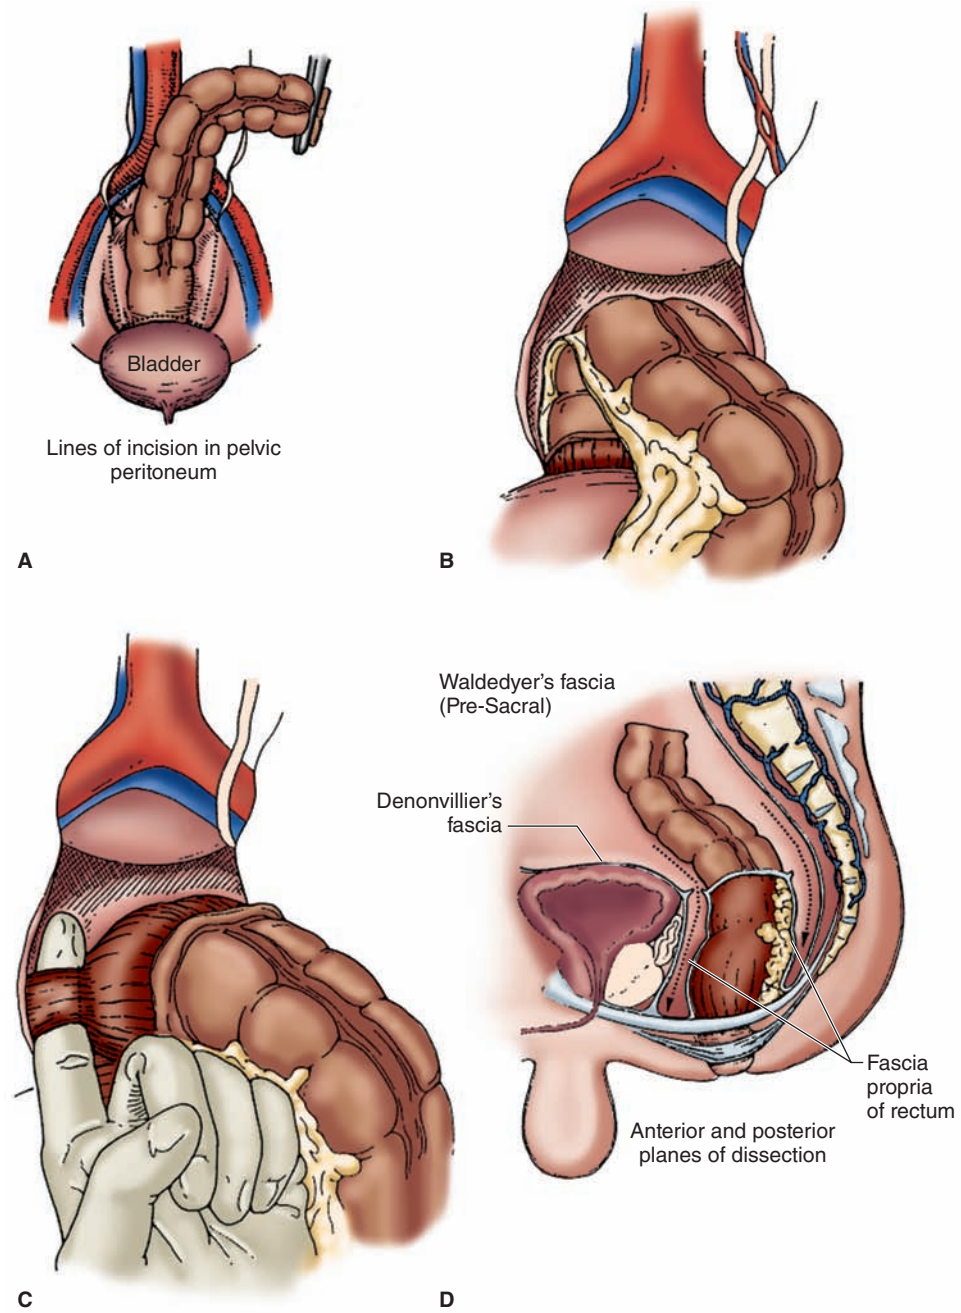

FIGURE 40-17 Mobilization of the rectum. **A.** Peritoneal incision of the pelvis. **B.** Rectum reflected anteriorly and posterior avascular plane entered between the presacral fascia of Waldeyer and the fascia propria of the rectum. **C.** Division of lateral stalks. **D.** Projected line of dissection in pelvis through Waldeyer's and Denonvilliers' fascia.

Attention then is turned to the pelvis, which is irrigated and inspected for hemostasis. This is one's truly last opportunity to inspect this area because one's exposure will be compromised once the anastomosis is completed.

One member of the team then stands between the patient's legs. The circular stapler tip is coated with lubricant on the outside of the stapler; we do not place lubricant on the staples themselves. The tip is retracted fully. A rectal examination is performed, and the anus is dilated gently with two to three fingers in order to accommodate the stapler. The circular stapler is inserted gently following the curve of the rectum—initially straight in and then the stapler is tilted posteriorly. Using close communication with the surgeon overlooking the abdomen, the assistant positions the circular stapler tip so

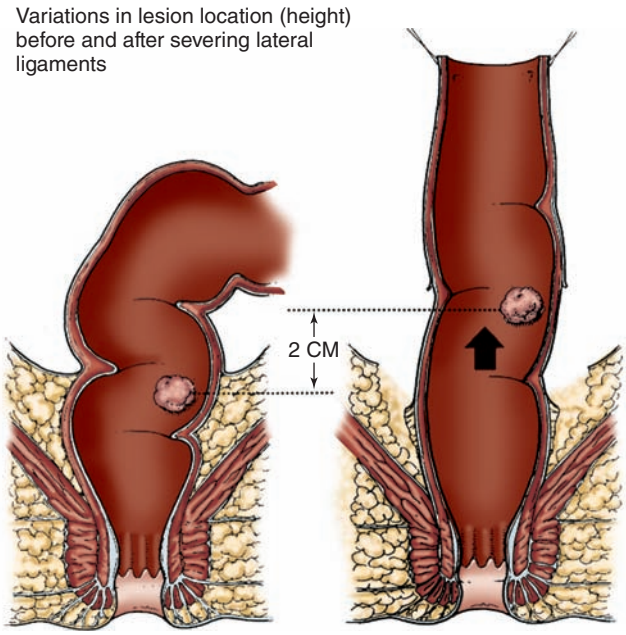

FIGURE 40-18 Tumor position relative to the dentate line after mobilization of the rectum. This may permit a sphincter-preserving resection.

that the trocar will exit either 2–3 mm anterior or posterior (we elect to do this posteriorly in women in order to avoid the vaginal wall) to the staple line (Fig. 40-19B). The trocar then is advanced slowly; the bowel continues to be adjusted as necessary. When the trocar protrudes through the bowel wall, be sure that the trocar is fully advanced so that its bottom is visualized (see Fig. 40-19C). The trocar is removed. Ensuring that the proximal bowel is not twisted and that the remaining bowel, mesentery, and epiploicae are held away, the anvil is brought down gently to the stapler and connected. The colon is inspected again to verify that no adjacent tissue is entrapped. The stapler is closed slowly until both pieces of colon are fully approximated (Fig. 40-19D). The stapler is fired, opened slightly, and gently removed as directed according to the type of stapler. This is the second staple line in the double-stapling technique (Fig. 40-19E). The stapler is opened, and the tissues from the proximal and distal bowel are inspected to make sure that the two rings of tissue, or "donuts," are intact (Fig. 40-19F). If they are not intact, additional sutures are placed if a visible gap is apparent. All anastomoses are checked for integrity. The surgeon fills the pelvis with saline and clamps the bowel proximal to the anastomosis gently with the hands; the assistant introduces a rigid sigmoidoscope through the rectum and insufflates air. If bubbles cannot be detected, one can be confident that the anastomosis is intact. If bubbles are detected, additional sutures are placed in suspected areas, and a diverting loop ileostomy is constructed. If the anastomosis is disrupted completely, it must be refashioned.

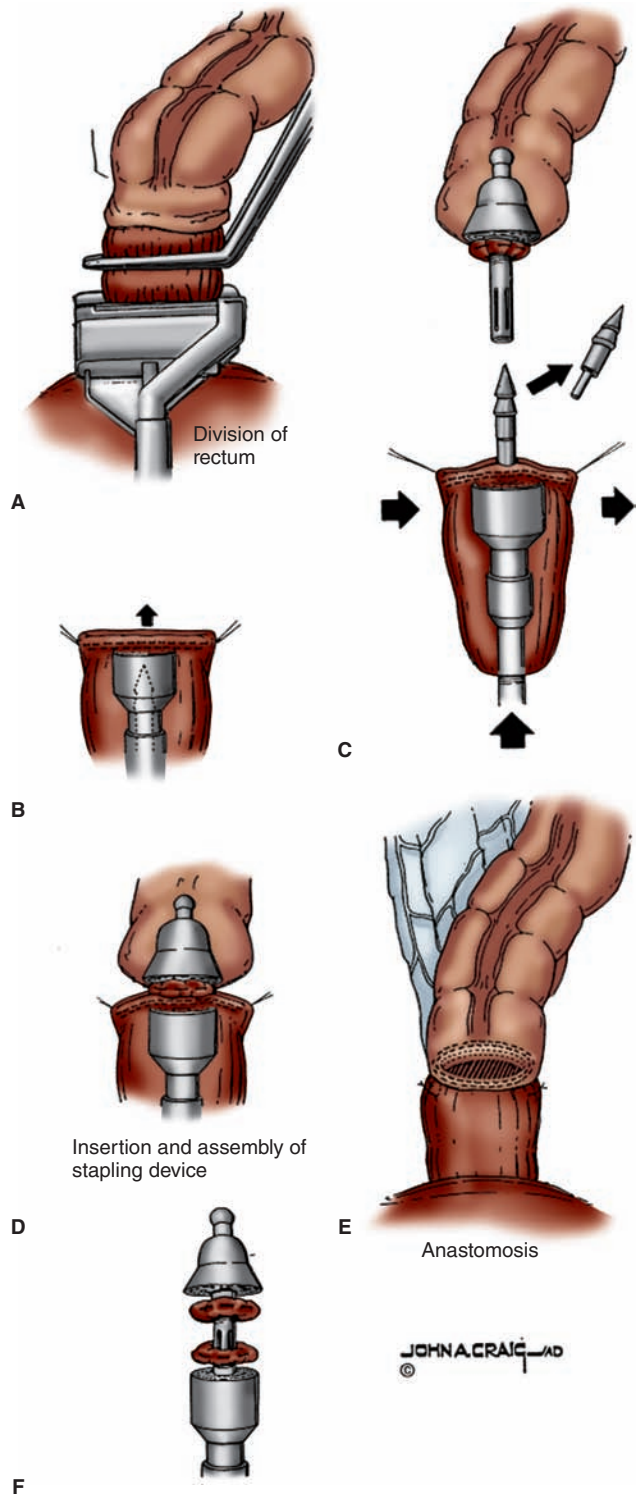

FIGURE 40-19 Colorectal anastomosis: double-staple technique. **A.** Transection of the distal rectum with a linear stapler. **B.** Stapling instrument introduced through rectum. **C.** Descending colon purse-string suture is tied around shaft of anvil. After the trocar of the circular stapler penetrates behind the staple line, the trocar is removed before reconnecting the anvil to the shaft. **D.** The circular stapler is reconnected, reapproximated, and fired. **E.** The anastomosis is complete. **F.** The proximal and distal staple lines are examined for intact inner "donuts."

DIVERTING LOOP ILEOSTOMY

A diverting loop ileostomy should be considered in any low anastomoses (<5 cm) from the dentate line, which are associated with anastomotic leak rates of up to 17%. Other risk factors for anastomotic breakdown include a history of radiation, perioperative steroid use, malnutrition, elderly women with a thin rectovaginal septum, or elderly patients undergoing preoperative combined-modality therapy with planned postoperative chemotherapy. Additionally, if there is any question regarding the integrity of the anastomosis, an ileostomy should be created.

Ileostomies can be closed within 8 weeks but often are left in place until the patient completes adjuvant chemotherapy. A Gastrografin (diatrizoate meglumine) enema is used to check the patency and integrity of the anastomosis prior to takedown of the anastomosis.

DRAIN PLACEMENT

Most surgeons continue to advocate routine use of drains after pelvic anastomoses. One prospective, randomized trial of 100 patients to receive either no drains or closed-suction drains demonstrated that the presence or absence of a drain did not influence the rate of morbidity and mortality. Although there is no evidence for the use of drains when an anastomosis has been made outside the pelvis, pelvic drainage may be important after anterior resection. We recommend placing a drain in extremely low resections, especially where the anastomosis was hand sewn or in patients who undergo an APR. For all other resections, placement of a drain may be determined on a case-by-case basis.

CLOSURE

We prefer to close the abdominal fascia with a looped no. 0 PDS suture starting at the cephalad and caudad ends and to run the suture toward the middle. The deep dermal layer is closed with 3-0 Vicryl. The skin is closed with either staples or a 4-0 Vicryl subcuticular suture followed by benzoin and Steri-Strips. A 4 × 8 gauze dressing is applied and covered with Tegaderm (3M, St. Paul, MN).

Postoperative Care

The nasogastric tube is removed at the end of the procedure or on postoperative day 1, and the patient can drink sips of clear liquids. The diet is advanced to low residue after flatus is passed. Cefazolin and metronidazole are continued for 24 hours postoperatively. Heparin is administered subcutaneously at a dose of 5000 units BID or TID depending on the patient's weight. Low-molecular-weight heparin also can be used in appropriate doses. Sequential compression devices are worn by the patient unless the patient is ambulating well. Most patients ambulate on postoperative day 1. The Foley catheter is kept in place for 3–5 days. If an epidural has been used for postoperative pain control, it is usually left in place until the patient is started on oral pain medication when he or she is tolerating clear liquids well.

Coloanal Anastomosis

Anastomoses at or just above the anorectal ring often result in increased frequency of stool, incontinence or soilage, and impaired quality of life owing to an insufficient reservoir. Diet restrictions and time after surgery usually will improve these symptoms, but two alternative techniques of reconstruction address these postoperative problems and often allow for improved function to be attained more quickly.

COLONIC POUCH

A 6-cm limb of sigmoid or descending colon is folded, and the apex is brought down to reach the rectal stump without tension. The splenic flexure may require additional mobilization. A colotomy is made at the apex with Bovie electrocautery, and a no. 75 GIA linear cutter is used to staple the pouch on itself to create a common lumen. A second fire of the stapler may be necessary. This pouch now serves as the neorectum. A double-stapled anastomosis as described or a hand-sewn anastomosis then is performed. A diverting loop ileostomy is used routinely for these ultralow anastomoses.

Multiple prospective, randomized studies have demonstrated superior function of a coloanal J-pouch over a straight coloanal anastomosis, especially in the first 6 months after ileostomy takedown.

TRANSVERSE COLOPLASTY

When the pelvis is too narrow for a J-pouch or the length of the pouch is inadequate, a transverse coloplasty may be fashioned. This is performed by placing the anvil of a 29- or 33-mm circular stapler into the cut end of the sigmoid as described under the section Low Anterior Resection. The colon should be mobilized to the level of the middle colic vessels. Beginning 2 cm proximal to the anvil, a 7- to 8-cm longitudinal colotomy is made. This colotomy then is closed transversely. The anastomosis is completed as described under Low Anterior Resection. A diverting loop ileostomy is created.

ABDOMINOPERINEAL RESECTION

Traditionally, distal rectal cancers have been treated with an abdominoperineal resection (APR), as first described by Miles, who noted high failure rates after local excision.[2] This procedure involves the en bloc resection of the tumor as well as the surrounding lymph nodes and the anal sphincters, resulting in a permanent colostomy.

The APR, although quite successful for early rectal cancers (stage I) in terms of survival, is associated with significant morbidity of 61% and mortality ranging from 0 to 6.3%.[49]

Urinary complications can be as high as 50% and perineal wound infections 16%. In addition to these perioperative problems, significant long-term morbidity is associated with a permanent colostomy. In a patient survey, 66% of patients complained of significant leaks from their stoma appliance, 67% experienced sexual dysfunction, and only 40% of patients working preoperatively ultimately returned to work.[50] There is also a significant change in body image when compared with sphincter-saving procedures. The 5-year survival rates following an APR range from 78 to 100% for stage I, 45 to 73% for stage II, and 22 to 66% for stage III disease.[51] Despite radical resection, 20% recur locally. Variations in recurrence rates depend on location of the tumor within the rectum, changes in surgical technique, and the addition of adjuvant therapy.

For patients with cancers that involve the sphincter apparatus or for those who are incontinent of feces, an APR is performed to remove the rectal specimen.

Technique

The patient is marked preoperatively by the enterostomal nurse for a permanent colostomy. Please see the section Low Anterior Resection With Total Mesorectal Excision for details regarding additional preoperative care, positioning, incision, and rectal mobilization. The dissection proceeds down to the striated muscles of the levator ani; one can confirm muscle contraction by using electrocautery. Once this level is reached, the perineal excision field can begin either by the surgeon or by a second team. The two-team approach saves time.

Perineal Dissection

The anus is closed with a no. 0 silk suture in a purse-string fashion (Fig. 40-20B). A marking pen is used to draw an ellipse 2 cm outside the superficial external sphincter and extending from the perineal body anteriorly, coccyx posteriorly, and ischial tuberosities laterally. The incision is made with a no. 10 blade and carried down through the dermis into ischiorectal fat (Fig. 40-20C). Two Gelpi retractors are placed at 45 degrees to the anus in order to facilitate deep dissection. The dissection is carried deep outside the external sphincter toward the tip of the coccyx, keeping in mind the planes of dissection (Figs. 40-20A and 40-20E). The anococcygeal ligament is palpated just anterior to the tip of the coccyx, and the palpating finger meets the fingers of a team member working from the abdominal field (Fig. 40-20D). A pair of large scissors is used to poke through the ligament; the scissors are fully spread and, while wide open, are pulled straight back. Hooking the index and middle fingers under the levator muscles and transecting with electrocautery frees the rectum laterally (Figs. 40-20F and 40-20G).

The anterior surface is dissected last (Figs. 40-20H and 40-20I). The rectum is delivered through the perineal opening. An assistant retracts the skin and subcutaneous tissue anteriorly with an army-navy retractor. Care is taken to keep the posterior wall of the vagina or the prostate anterior to the plane of dissection. The surgeon cups the hand around the rectum with traction posteriorly and inferiorly and uses cautery between the rectum and the anterior structures, often reassessing the plane of transection. Once freed circumferentially, the specimen is passed off the field.

The pelvic floor is irrigated and checked carefully for hemostasis. A tongue of omentum or omental pedicle flap may be used to cover the pelvis to prevent the small bowel from dropping deep into the pelvis if radiation is contemplated. Omentum also helps healing, especially in an irradiated perineum or when patients also have undergone prostate or vaginal resections. The descending colon is further mobilized in order to exit the skin without tension. The colostomy site is prepared similar to the diverting loop ileostomy as described under Low Anterior Resection. The colon is drawn through the colostomy site using a Babcock clamp, but it is not matured until the midline incision is closed.

Two no. 10 Jackson-Pratt drains are placed in the pelvis and are brought anteriorly out through the abdominal wall and secured to the skin using 3-0 nylon suture (Fig. 40-20J). The abdomen is closed as described under Low Anterior Resection. The colostomy is matured using interrupted 3-0 Vicryl suture.

If using a two-team approach, the perineal wound can be closed after the pelvis has been irrigated and hemostasis achieved. Two layers of interrupted 2-0 Vicryl suture are used to approximate the subcutaneous tissue. One layer of 3-0 Vicryl in a vertical mattress fashion is used to approximate the skin. Because this area is often radiated, multiple layers decrease the risk of the wound breakdown extending into the pelvis.

Initially the APR was performed utilizing an anterior approach and then flipping the patient for the perineal component. In this way, APR was done by completing the abdominal mobilization of the rectum to the levators circumferentially and then creating a colostomy and closing the abdomen and flipping the patient to complete the perineal portion of the operation. In most institutions two teams work simultaneously (as described previously) and two instrument tables are used with separate counts and often requiring additional OR support staff to assist. All of this increases utilization in order to save operative time. More recently, attention has reverted to the traditional anterior and posterior approach to the APR. In fact, there are recent data that support a better oncologic outcome using an anterior and posterior approach as described previously. This is known as the *cylindrical technique*. West et al reported more tissue excised in all pathologic resections and better margins from the muscularis to all resection margins. These results translated into a lower rate of positive circumferential resection margin with APE 14.8 versus 40.6% for traditional APR and a decrease in intraoperative perforations 22.8 to 3.7%, respectively.[52] In our experience we have also found better short-term outcomes with lower perineal wound infections and improved perineal healing.

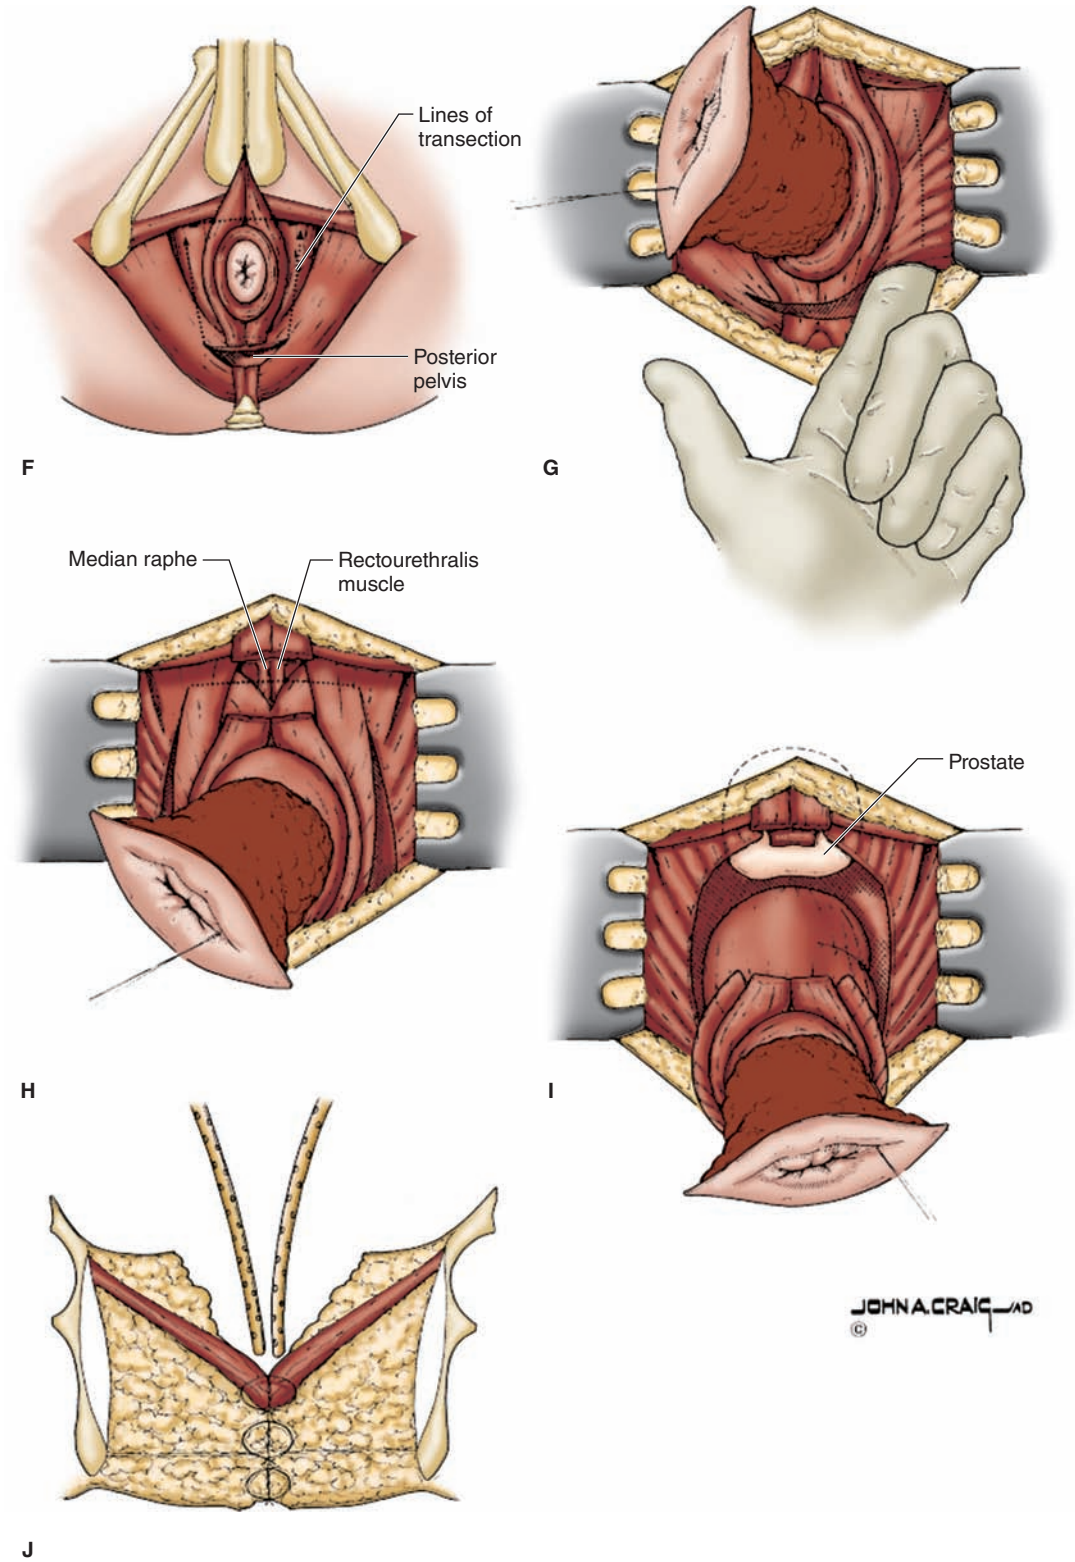

FIGURE 40-20 (*Continued*)

Postoperative Care

Postoperative care is similar to that described under Low Anterior Resection. The patient is not allowed to sit for 5 days but may only recline and ambulate. Thereafter, the patient may sit on a soft pillow; we do not advocate using a "donut" because perineum is not supported. The perineum is cleaned daily with dilute hydrogen peroxide. The Foley catheter remains in place for 3–5 days.

Complications

Perineal wound complications are common following APR and occur in up to 25% of patients. While most of these wound complications are minor, some may require operative débridement. We demonstrated previously that preoperative radiation and primary closure were not associated with an increased incidence of wound complications compared with nonirradiated patients following APR for rectal cancer.[53]

Stoma complications include ischemia, retraction, hernia, stenosis, and prolapse. The construction of a good colostomy will provide a patient with a superb quality of life after APR. Early education in the immediate postoperative period allows the patient to adjust to life with a stoma. The stoma shrinks to its final size approximately 3 weeks postoperatively when the edema has subsided. An end colostomy may be irrigated to establish regularity of bowel movements and further improve the patient's quality of life. The operative mortality for APRs is less than 2%.

EN BLOC EXCISION WITH RECTUM

Posterior Vaginectomy

Partial vaginectomy is indicated for locally advanced low rectal cancers involving the vagina. One study demonstrated a 5-year survival of 46% and a median survival of 44 months, with most favorable results from negative surgical margins and node-negative disease.[54]

If the patient undergoes an APR, the posterior wall of the vagina is removed as the anterior margin of the resection (Fig. 40-21). After completing the posterior and lateral dissections, the rectum is delivered through the perineum. The anterior aspect of the perineal incision includes the posterior introitus and is extended around the posterior third to half of the vagina only to avoid denervation of the urethra. To achieve hemostasis during the procedure, one can place interrupted 2-0 absorbable full-thickness sutures through the vagina from either side, starting at the apex of the incision, and tie the sutures as the specimen is being excised.

If the patient undergoes an LAR with a coloanal anastomosis, the partial vaginectomy may be performed through the abdominal approach. The involved area of the vagina is resected with a 1-cm margin and kept en bloc with the rectum. Subsequent closure of the vagina is completed by initially placing Allis clamps on the vaginal edges and then taking full-thickness bites with 2-0 Vicryl sutures in a figure-of-eight fashion.

Before abdominal closure, we recommend placing an omental flap around the vaginal cuff to prevent breakdown of the vaginal suture line. If a coloanal anastomosis is in place, we would position the omentum between the vaginal and the coloanal suture lines.

Prostatectomy

In locally advanced rectal cancer in which there appears to be possible involvement of the prostate, urethra, bladder, or ureterovesicular junction on CT scan of the abdomen and pelvis, an MRI of the pelvis should be obtained. Urology consult should be made because one must be prepared for radical prostatectomy and/or cystectomy with ileal conduit diversion. A prostatectomy en bloc with rectal resection is an alternative to total pelvic exenteration in patients whose rectal cancer is fixed only to the prostate. The reasons for involving urology are in part due to the vascularity of the prostate. In addition, one should be concerned about constructing any genitourinary anastomosis (eg, between bladder and urethra) in the presence of previous radiation and a rectal anastomosis. Attention should be paid to potential for autonomic nerve deficit if proximity and effacement of the neurovascular bundle are evident on MRI.

Pelvic Exenteration

Total pelvic exenteration is an alternative for patients with locally advanced rectal cancer in which the tumor is contiguous with adjacent organs, such as the prostate or bladder (Fig. 40-22). Long-term survival rates range from 20 to 70% and are improved in younger patients with no lymph node metastases.[55] Local recurrence rates range from 3 to 8%. An argument against performing total pelvic exenteration is the considerable morbidity (20–40%) and 0–20% mortality associated with this procedure. The most common complications are infection, small bowel obstruction, and problems with urinary diversion.

Prophylactic Bilateral Oophorectomy

Carcinoma of the rectum metastasizes readily to the ovaries, and prophylactic oophorectomy during rectal resection may diminish the morbidity of carcinoma of the rectum in women. Additionally, the incidence of ovarian cancer in women with a history of colorectal cancer is roughly five times the incidence in women without such a history. Although prophylactic bilateral oophorectomy does not significantly affect survival, the prevention of primary ovarian cancer in postmenopausal women is considered to be the main benefit of this procedure. We discuss this with our postmenopausal patients and offer this to them at the time of operation.

PALLIATIVE RESECTION IN STAGE IV DISEASE

Palliative resection of the primary colorectal tumor in stage IV rectal cancer depends on the degree of symptoms present. In patients who are symptomatic from bleeding, localized perforation and obstruction, there are several management options that can relieve the symptoms of the primary tumor:

1. Permanent diversion followed by chemotherapy (± radiotherapy depending on local symptoms)
2. Palliative resection with a permanent colostomy followed by chemotherapy (radiotherapy is not needed if the primary is successfully resected in the stage IV patient)
3. Palliative resection with restoration of GI continuity followed by chemotherapy (once again, radiotherapy is not needed if the primary is successfully resected in the stage IV patient)

In the symptomatic patient it is our practice to offer upfront surgical resection/diversion and additional therapy using one of the above three options. The surgical procedure depends on the performance status and the intraoperative findings at the time of exploration. In patients with distant spread to solid organs alone, it is our inclination to perform resection of the primary with restoration of GI continuity. In patients with significant peritoneal and pelvic carcinomatosis, we will offer either resection with end colostomy or just a diversion depending on the degree of pelvic peritoneal carcinomatosis. In the patient with a large burden of disease, it is better to just divert the patient and start chemotherapy and the offer palliative radiotherapy if the bulky primary continues to bleed or causes pain from infiltration of the sacral nerve roots.

On the other hand, resection in the asymptomatic patient with incurable stage IV disease is controversial. Resections for rectal cancer often have significant morbidity and measurable mortality but at the same time offer the best palliation of local symptoms. Moreover, in the last decade chemotherapy regimens have significantly extended the life expectancy of patients with colorectal cancer. The advent and widespread use of the FOLFOX (5-fluorouracil [5-FU], leucovorin, and oxaliplatin) and FOLFIRI (folinic acid, fluorouracil, and irinotecan) chemotherapy regimens have extended the median life expectancy of patients with stage IV disease from approximately 8 months to nearly 2 years (see Chap. 36). Many patients live much longer than this. Hence, it is our opinion that upfront palliative resection is warranted in the medically fit patient with a low burden of distant but traditionally incurable disease. In those who have significant distant disease, we prefer systemic therapy with restaging after several courses of chemotherapy.

In the medically fit patient with a good performance status that has substantial improvement in the metastatic burden, we will once again offer palliative resection. The choice of operation (see above choices) depends on the intraoperative findings. This approach has never been studied prospectively and the sparse literature is based solely on retrospective reviews. Despite this, patients who have had asymptomatic primary tumors resected have a substantial survival advantage over those who were never resected. Ruo et al showed that those who were resected versus the nonresected had a prolonged median survival of 16 versus 9 months and a 2-year survival of 25 versus 6% with both measures reaching statistical significance.[56]

LAPAROSCOPIC SURGERY

Minimally invasive laparoscopically assisted surgery was first considered in 1990 for patients undergoing colectomy for cancer. The technical feasibility of performing laparoscopic TME was demonstrated in several prospective studies. Preservation of the autonomic nerves is also possible during laparoscopic TME. Early results confirmed complete resection of the mesorectum with intact visceral fascia in all patients.[57] Because Nelson and other showed equivalent outcome, quality of life, and survival in laparoscopic surgery for colon cancer, there has been renewed interest in laparoscopic LAR for rectal cancer.[58] Currently a randomized prospective trial is ongoing in the United States. The Conventional versus Laparoscopic-Assisted Surgery In Colorectal Cancer (CLASSIC) trial group from the United Kingdom published the results of their randomized comparison of laparoscopic versus open LAR for rectal cancer in 794 patients (526 lap vs 268 open) with a median follow-up of 36.8 months and equivalent numbers or patients receiving chemoradiotherapy. The overall survival (open 66.7 vs lap 74.6%) and disease-free survival (open 70.4 vs lap 70.9%) were similar in both groups and were without statistical significance. The overall local recurrence rates were 7% in open resection and 7.8% in the laparoscopic group. Even though the laparoscopic group had a higher positive circumferential resection margin (CRM), there was no difference in local recurrence at 3-year follow-up. This increased positive CRM is certainly concerning with only 3-year follow-up and longer-term follow-up is certainly needed to ensure that this is not significant.[59,60] In addition to increased positive CRM, the above CLASSIC trial reported overall worse sexual function in men (not women) undergoing laparoscopic rectal cancer resection.[61] Both a positive CRM and worse sexual function are major potential complications, and, as a result, laparoscopic surgery for rectal cancer should still be limited to ongoing trials (especially in male patients) until long-term data show at least equivalent recurrence and complication rates. This is especially true because the same CLASSIC trial measured quality-of-life outcome for these patients and there was no difference between laparoscopic resection and open surgery.

OTHER TREATMENT OPTIONS

Besides surgical resection for rectal cancer, there are other options for patients who may not be candidates for surgery owing to their comorbidities, extent of disease, or preference. Endocavitary radiation may be delivered at doses of 50 cGy for palliation and for curative intent. Performed as an outpatient and well tolerated by patients, endocavitary radiation is delivered with sedation and local perineal block.
