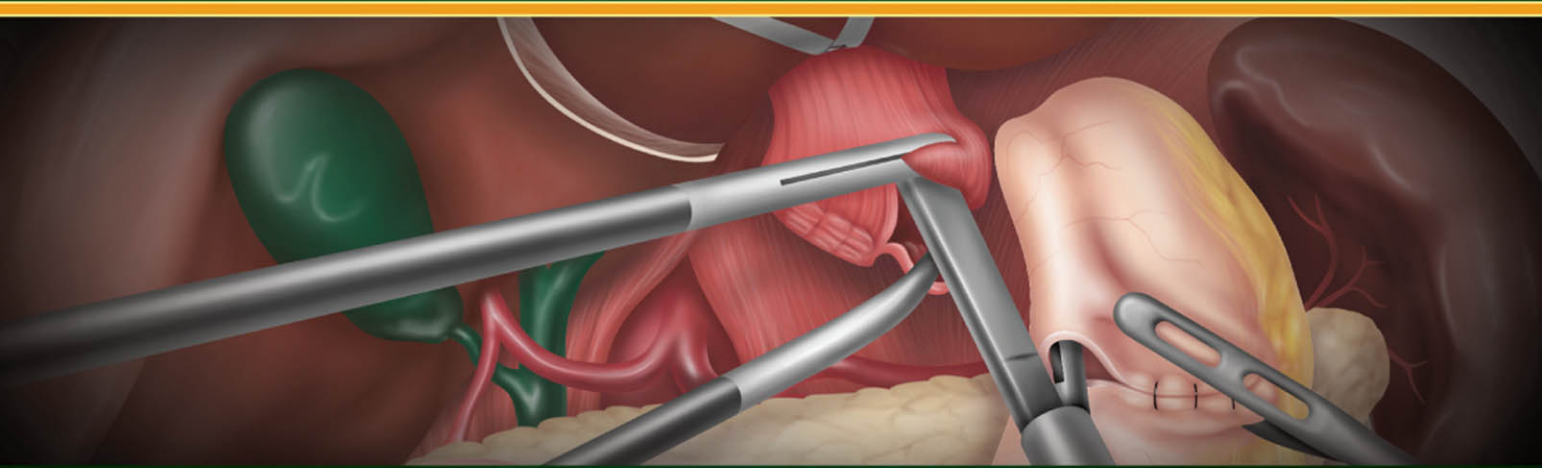
12TH EDITION

MAINGOT'S ABDOMINAL OPERATIONS



MICHAEL J. ZINNER
STANLEY W. ASHLEY

راهنمای نصب آخرین نسخه آپتودیت آفلاین

۱. برای نصب اپلیکشین درگوشی آیفون، برنامه App Store و درگوشی اندروید Play Store را اجرا کرده سپس عبارت Mehrsys medical library را جستجو کنید و برنامه را نصب کنید.

۲. بعد از نصب و اجرای اپلیکیشن در صفحه اول برنامه **برای دریافت** Username و Password به **به تلگرام پشتیبانی و فروش که در زیر تصویر اشاره شده است پیغام دهید.**

۳. در مرحله بعد حساب کاربری خود را بسازید.

۴. بعد از ورود به برنامه در قسمت یا منوی Download روی آیکون سه نقطه آبی رنگ که رو به روی UpToDate قرار دارد کلیک کنید و گزینه دانلود Download را انتخاب کنید با این عمل می توانید دانلود را به آسانی از طریق اینترنت انجام دهید.

قابلیتهای برنامه

- دسترسی به آخرین نسخه آپتودیت آفلاین با قابلیت بروز رسانی
- امکان جستجو بسیار سریع مطالب بدون نیاز به اینترنت
- امکان مشاهده **abstract** رفرنسهای داخل مقالات آپتودیت
- قابل نصب بر روی گوشی و کامپیوتر
- دسترسی به دیگر منابع پزشکی و دارویی به صورت رایگان
- امکان انتخاب متون، کپی و ارسال آن به برنامه های دیگر
- هایلایت کردن متون در برنامه به رنگهای مختلف
- ذخیره کردن مقالات و عکسهای آپتودیت
- تولید شده توسط شرکت معتبر نرم افزاری و مورد تایید نظام صنفی رایانه ای کشور و شورای عالی انفورماتیک

Maingot's
ABDOMINAL OPERATIONS

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

PREFACE

Maingot's Abdominal Operations has always filled a unique niche. For many surgeons, including the editors, the text has consistently offered a comprehensive discussion of surgical diseases of the abdomen with a focus on operative strategy and technique. The book has served as a needed reference to refresh our knowledge before a common operation or in preparation for a novel one. Our intended audience for this edition is the same as for the original publication; the book is meant for the surgical trainee as well as the practicing surgeon. We continue to have an international audience and have made every effort to produce a product that is equally valuable to readers in Malaysia and Montana. For both of us, in this third effort together, it continues to be both an honor and a privilege to have the opportunity to edit the twelfth edition of this classic textbook.

Abdominal surgery has clearly changed since Rodney Maingot's first edition in 1940. Not only has our knowledge base increased substantially but the procedures themselves have become more complex. The current subspecialization in abdominal surgery, a consequence of these changes, might even challenge the need for such a comprehensive text. Abdominal disease has been increasingly parceled up between foregut, hepatobiliary, pancreatic, colorectal, endocrine, acute care, and vascular. We continue to believe, however, that the basic principles of surgical care in each of the anatomical regions have more similarities than differences. Experience in any one of these organs can inform and strengthen the approach to each of the others. Few would question the need for the abdominal surgeon to be well versed in dealing with any unexpected disease that is encountered in the course of a planned procedure. For many of us, *Maingot's Abdominal Operations* has consistently helped to fill that need. We also intend for this textbook to remain disease-focused in addition to its organ/procedure format. In keeping with the growing opinion that minimally invasive surgery should be viewed not as a distinct subspecialty but rather as one tool employed in each of the anatomic or disease-based subspecialties, in this edition we have incorporated the chapters on minimally invasive surgery throughout the text rather than in a distinct section.

The new edition of this textbook is a significant revision—in most areas a completely new book. We have attempted to focus the text on operative procedures as well as on new concepts in diagnosis and management of abdominal disease. Although the new edition, like the last edition, is condensed compared with previous versions, we have continued to present the opinions and knowledge of more than one expert. In an effort to enhance this feature, in areas where opinions and approaches differ, we have added "Perspective" commentaries by experts in the field who we expected might have distinct opinions about approaches and/or operative techniques. In response to our international readers, we have added chapters on gastrointestinal bleeding, abdominal trauma, and vascular emergencies, all of which were removed for the previous edition. We have attempted to maintain an international flavor and have included a cross-section of both seasoned senior contributors and new leaders in gastrointestinal surgery. We continue to present a contemporary textbook on current diagnostic procedures and surgical techniques related to the management and care of patients with all types of surgical digestive disease.

An extensive artwork program was undertaken for this edition. Many line drawings have been recreated to reflect the contributors' preferred method for performing certain surgical procedures. Some of these drawings are new and give the book a more modern and overall consistent look. In addition, this edition is the first with full-color text and color line art.

In the preface to the sixth edition, Rodney Maingot noted, "As all literature is personal, the contributors have been given a free hand with their individual sections. Certain latitude in style and expression is stimulating to the thoughtful reader." Similarly, we have tried to maintain consistency for the reader, but the authors have also been given a free hand in their chapter submissions.

We would like to thank the publisher, McGraw-Hill, and in particular Robert Pancotti, for their unwavering support during the lengthy time of development of this project. Their guidance was invaluable to completing this project in a single comprehensive volume. Their suggestions and attention to detail made it possible to overcome the innumerable problems that occur in publishing such a large textbook.

Finally, to our editorial assistant who has survived the trials of this book, Linda Smith; she has been invaluable and we never would have been able to do it without her. Patrina Tucker and Colleen Larkin have also stepped up and made this project possible. We owe them a great debt of gratitude

for helping with every step of the work—from typing manuscripts to editing and reading page proofs, and providing encouragement during the prolonged dry periods and preparation of this textbook.

To all of those who have participated in the creation and publication of this text, we thank you very much.

Michael J. Zinner, MD, FACS
Stanley W. Ashley, MD, FACS

A FOCUSED HISTORY OF SURGERY

Seymour I. Schwartz

The word *surgery* derives from the French term "chirurgien," which came from the Latin and in turn from the Greek words "cheir," meaning "hand" and "ergon," meaning work. Surgery has a long history beginning with what is said to be the earliest scientific document known, *The Edwin Smith Surgical Papyrus*, dating from the 17th century before Christ, actually a copy of an Egyptian manuscript originally written circa 3000–2500 BC. The document deals with a variety of wounds and cauterization for breast cancer. No intraperitoneal operation is mentioned.

Although *Maingot's Abdominal Operations* had its genesis in England, elective abdominal operations had their beginning in Danville, Kentucky, a town of 1000 at the time, with the removal of a 22½-lb ovarian tumor by Ephraim McDowell on December 25, 1809. Throughout the 19th century, surgeons from Great Britain and the United States, the two countries that would eventually play major roles in the development of the multiple editions of *Maingot's Abdominal Operations*, contributed significantly to the evolution of abdominal operations. In 1804, Sir Astley Cooper published a *Treatise on Hernia.* In 1833, William Beaumont, an American military surgeon, published *Experiments and Observations on the Gastric Juice and the Physiology of Digestion.* The experiments conducted through a permanent gastric fistula constituted the first controlled clinical study on a human being and defined the process of intragastric digestion. On October 16, 1846, at the Massachusetts General Hospital, the birth of ether anesthesia took place and ushered in a new generation of possibilities for all of surgery. In 1867, John Stough Bobbs of Indianapolis reported the first successful elective operation on the gallbladder, a cholecystostomy with removal of stones and closure of the organ. The patient remained relatively asymptomatic for over 40 years. The 1886 landmark paper by the Boston pathologist Reginald H. Fitz established the entity of appendicitis and championed early operation. As the 19th century came to a close, the German schools of surgery became increasingly dominant, in large part related to Theodor Billroth and the surgeons he trained. Billroth is often referred to as "the father of abdominal surgery" based on his first resection of cancer of the pylorus in 1881 and also the numerous intestinal resections and enterorrhaphies that he performed.

As the first decade of the 21st century has come to an end, it is appropriate to focus on the developments that took place during the preceding 20th century, by dividing this period into two time spans: one before 1940, the year that the first edition of *Maingot's Abdominal Operations* was published, and the other considering the progress that has taken place in the ensuing 60 years.

In discussing the history of surgical advances pertaining to the gastrointestinal tract per se, it is reasonable to proceed aborally from esophagus to rectum. In regard to the esophagus, the first significant operation was reported in 1913 by Franz Torek of New York City, who removed the entire thoracic esophagus and connected the cervical esophagus with the stomach by means of an external tube. Although in 1935 Winkelstein first defined the clinical picture of esophageal reflux and indicted the erosive action of gastric juice as the culprit, the issue of a functioning gastroesophageal sphincter was not appreciated. Consequently, no corrective operation was devised prior to the publication of *Maingot's* first edition.

The surgical treatment of reflux esophagitis was first popularized by Allison, who defined a repair in 1951, mainly consisting of correction of the hiatal herniation. The high recurrence rate associated with that operation led to a consideration of fundoplication procedures, which were introduced in 1966 by Nissen and subsequently modified by Belsey, Hill, and Toupet. Since the advent of minimally invasive surgery in 1989, the majority of these fundoplications have been performed laparoscopically.

During the first four decades of the 20th century, there was considerable interest in the surgical treatment of peptic ulcer disease. Gastric resection was often the most commonly performed indexed operative procedure in a residency program. The operations were outgrowths of the procedures that were initially applied by Billroth and his associates for gastric cancer. In the early decades of the 20th century, excision of a gastric ulcer was widely practiced. When the excision, as was frequently the case, was extensive, there were problems with gastric emptying, prompting William Mayo in 1911 to add a complemental gastrojejunostomy. Then as now, the indications for surgical intervention in patients with peptic ulcer were obstruction, bleeding, perforation, and intractability.

Pyloroplasty and gastrojejunostomy were the most frequently performed procedures for obstruction, and as early as 1925 Lewisohn reported a 34% incidence of neostomal ulcer after gastrojejunostomy. Before 1940, the surgeons at the Mayo Clinic continued to champion the procedure for duodenal ulcer. In 1937, R.R. Graham introduced his patch procedure for perforation. Gradually partial gastrectomy became the preferred surgical treatment for the complications of peptic ulcer disease.

The modern era of vagotomy in the management of peptic ulcer began in January 1943, when Dragstedt performed a subdiaphragmatic resection of the vagal trunks in a patient with an active duodenal ulcer. Dragstedt's earlier approach was transthoracic. Later, when he appreciated that a significant percentage of his patients developed gastric stasis, Dragstedt added a drainage procedure, either gastroenterostomy or pyloroplasty, as an accompaniment to the truncal vagotomy. Farmer and Smithwick recommended a two-pronged attack against the ulcer diathesis, combining truncal vagotomy with hemigastrectomy. In 1960, Griffith introduced the concept of selective gastric vagotomy, preserving the nerve of Laterjet and thereby obviating the need for a gastric drainage procedure.[1]

The applicability of vagotomy and partial gastric resection has been greatly reduced over the past two decades by the introduction of acid suppressive pharmaceuticals, including the histamine receptor antagonists and proton pump inhibitors. The use of these preparations has also generally obviated partial gastrectomy for ulcer diathesis and total gastrectomy for the intractable ulcers associated with the Zollinger–Ellison syndrome. Perhaps the most significant factor causing a marked reduction in the need for surgical management of peptic ulcer disease was the discovery by Warren and Marshall in 1983 of an association between *Helicobacter pylori* and peptic ulcer that is readily treatable with the hopes of totally eradicating peptic ulcer disease. This transition of gastric surgery from the 19th-century understanding of anatomy, to the 20th-century understanding of physiology and pathophysiology, to the 21st-century understanding of pharmacology mirrors the growth, development, and progress of the understanding of surgical diseases.[2]

The greatest increase in gastric surgery since 1940 is the application of gastric reduction for obesity. The initial surgical approach to the management of extreme obesity, jejunoileal bypass, was introduced by Kremen, Linner, and Nelson in 1954. The procedure was popularized by Payne and DeWind in 1969, but had many hazardous consequences and has been essentially discarded. Gastric bypass, introduced by Mason in 1966, has been the preferred method of surgical management for the past four decades and has become increasingly popular with the advent of minimally invasive surgery.

The principles of intestinal anastomosis are in large part based on Halsted's late-19th century studies on the importance of the submucosa as the layer providing strength for the suture line. Most of the early-20th century procedures on the small intestine were related to the treatment of obstruction. In 1932, Crohn, Ginzburg, and Oppenheimer introduced a newly recognized pathologic entity they called regional ileitis, which has come to be known as Crohn's disease or regional enteritis.

The major operative changes in small intestinal surgery that have taken place over the past two decades have been brought about by the introduction of stapling techniques. These were preceded by John B. Murphy's button, when it was described in 1892. Mechanical suture instruments using staples began with Humer Hültl of Budapest, who in 1908 described an instrument for use in distal gastrectomy. It was modified by von Petz in 1924 and enjoyed a period of popularity in many centers. The next major step in stapling was the result of the dedicated efforts of the Scientific Research Institute for Experimental Surgical Apparatus and Instruments in Moscow. The investigators developed magazine-loaded instruments for vascular anastomosis, side-to-side intestinal anastomosis, and end-to-end intestinal anastomosis. These were imported to the United States and modified, beginning in 1958, largely due to the leadership of Ravitch and Steichen.[3] The introduction and widespread application of stapling devices helped revolutionize the technical aspects of surgery that have allowed minimally invasive procedures to be developed.

In the realm of colorectal surgery, although in 1883 Czerny introduced a technique for combined abdominal-peritoneal excision of rectal tumors, Miles' method, reported in 1907, popularized the procedure. The advent of stapling techniques during the past two decades has allowed for more anal preservation operations. The ileal pouch procedure represents a significant advance in the management of ulcerative colitis and familial polyposis. In 1947, Ravitch and Sabiston performed total colectomy, proximal proctectomy, mucosal distal proctectomy, and ileal anal anastomosis, but the results were generally not satisfactory with regard to frequency of defecation. The introduction in 1978 of a valveless ileal reservoir anastomosed to the anus addressed the problem and has become the standard.[4]

Over the past two decades, there have also been changes in the pathologic definitions of tumors of the gastrointestinal (GI) tract and there has been an increased recognition of gastrointestinal stromal tumors (GIST) in all regions of the GI tract.

The first successful elective hepatic resection for tumor was performed by Langenbuch in 1888. The first collective review of hepatic resections for tumor was reported by Keen in 1899 and included only 20 cases. In 1911, Wendell reported the first case of near total right lobectomy for a primary hepatic tumor, but the modern age of hepatic resection is generally dated to the 1952 report of Lortat-Jacob and Robert that detailed a right lobectomy using a technique designed to control hemorrhage with ligation of the blood vessels and bile ducts to the right lobe in the hepatoduodenal ligament followed by extrahepatic ligation of the right hepatic vein prior to transection of the hepatic parenchyma. In 1967, using corrosion casts, Couinaud demonstrated that the liver is made up of eight distinct segments, thereby opening the door for segmental hepatic resections. The recent applications

of new instruments such as the harmonic scalpel and LigaSure vessel sealing system have expedited the performance of major hepatic resections without a need for transfusion.[5]

The year 1945 marked the beginning of the modern era of surgical intervention for portal hypertension with the report by Whipple and associates of the performance of end-to-side portacaval anastomoses and end-to-end splenorenal anastomoses. In 1953 Marion and in 1955 Clatworthy and colleagues independently described a shunt between the proximal transected end of the inferior vena cava and the side of the superior mesenteric vein. In 1967, Gleidman performed the first Dacron interposition mesocaval shunt, and the same year, Warren and colleagues introduced the selective (distal) splenorenal shunt as a method of preserving flow to the liver. The shunt procedures are now performed infrequently, and are generally reserved for patients with massively bleeding esophagogastric varices and normal hepatocellular function. By contrast, in patients with uncontrollable bleeding varices and significant hepatocellular dysfunction, a TIPS (transjugular intrahepatic portosystemic shunt) procedure is generally used as a bridge to orthotopic liver transplantation. In 1959, Kasai and Suzuki introduced hepatic portoenterostomy for the management of biliary atresia. More recently, orthotopic liver transplantation has been employed for these patients because of uncorrectable hepatocellular dysfunction.

Fifteen years elapsed between Bobbs' cholecystotomy and the first successful cholecystectomy, which was performed by Carl Langenbuch in 1882. By 1919, William J. Mayo was able to report on 2147 cholecystectomies. In 1923, Graham and Cole introduced cholecystography, leading to a marked increase in biliary surgery. Operations for injuries and strictures of the common duct have undergone many refinements over the past century. An obstructed common bile duct was first successfully drained by a lateral anastomosis to the duodenum by Sprengel in 1891. A variety of plastic procedures and intestinal flap advancements were applied to bridge a gap between the common duct and the duodenum with minimal success. Beginning in 1941, Vitallium tubes were inserted into bile ducts as conduits, but all the tubes eventually became obstructed with sludge. The groups at the Mayo Clinic and Lahey Clinic, who both had extensive experience with these procedures, expressed a preference for choledochoduodenostomy, while most surgeons now employ a mucosal-to-mucosal anastomosis between the proximal duct and a Roux limb of jejunum.

Operations on the pancreas directed at the management of pancreatitis and neoplasms generally evolved subsequent to the publication of the first edition of Maingot's textbook. In 1958, Puestow introduced the popular lateral pancreaticojejunostomy. In 1965, Fry and Child reported their results with a 95% distal pancreatectomy. In 1985, Beger proposed resection of the head of the pancreas with duodenal preservation for pathology that was most marked in the head of the pancreas. In regard to the neuroendocrine tumors of the pancreas, Roscoe Graham performed the first successful resection of an insulinoma in 1929. In 1955, Zollinger and Ellison reported that nonbeta islet cell tumors produced an "ulcerogenic humoral factor." The pathophysiology often mandated total gastrectomy to control the massive gastric hypersecretion, but the therapy has been markedly altered with the advent of proton pump inhibitors.[6,7]

Although in 1912 Kausch successfully performed a partial pancreatectomy in two stages, the name of Allen O. Whipple has achieved eponymic status as far as resection of pancreatic neoplasms is concerned. In 1935, Whipple initially carried out a two-stage operation for carcinoma of the ampulla consisting of an initial cholecystojejunostomy followed by total duodenectomy. By 1945, he advocated a one-stage pancreatoduodenectomy as the treatment of choice.

Splenectomy is performed for trauma or hematologic disorders. The first recorded successful splenectomy for trauma is credited to a British naval surgeon, E. O'Brien, in 1816, who tied off the pedicle and removed a protruding spleen while stationed in San Francisco. In 1892, Reigner performed the first successful intraperitoneal splenectomy for trauma. In 1867, Péan successfully removed a spleen containing a large cyst. In 1911, Micheli reported the first splenectomy for a hematologic disorder in a patient with hemolytic anemia. Five years later, at the suggestion of Kaznelson, a Czech medical student, Schloffer, performed the first splenectomy for idiopathic thrombocytopenic purpura, the most common hematologic indication. The most recent changes in splenic surgery relate to an increased willingness to observe patients, particularly children, with blunt trauma to the spleen, and the fact that elective splenectomies are generally being performed laparoscopically, as championed by Phillips and Carroll, Cuschieri and associates, and Thibault and coworkers.[8]

Intra-abdominal vascular surgery traces its modern origin to Dubost and colleagues' 1951 resection of an abdominal aortic aneurysm with reestablishment of continuity. The introduction of a prosthetic material to create a conduit is credited to Voorhees, Jaretzki, and Blakemore, who used Vinyon "N" cloth in 1969. The same year, Wylie and associates described autogenous tissue revascularization techniques for correction of renovascular hypertension.

The major advances in abdominal surgery that took place in the second half of the 20th century relate to the fields of organ transplantation and minimally invasive procedures. On December 23, 1954, Murray, Merrill, and Harrison performed the first renal transplant in identical twins. Eight years later, the first successful cadaveric kidney transplant was performed by Murray in an immunosuppressed patient. The liver was the second visceral organ to be transplanted. In 1963, Starzl performed the first human liver transplant in a patient with biliary atresia. The patient died as did four other patients operated on by Starzl and one by Moore that year. In 1968, Starzl achieved the first success. The field recently has been extended by the use of live donors who provide a lobe for the recipient.

The first successful clinical pancreas transplant was performed by Kelly and Lillehei in 1966. In 1973, Gliedman and associates suggested using the ureter for exocrine pancreatic drainage. In 1982, the group at the University of Wisconsin developed the technique of direct drainage of the

pancreas into the urinary bladder. Now, most whole organ pancreas transplants use the intestine for drainage. Recently improved results have been reported with islet cell transplants.

The small intestine was the last of the abdominal organs to be transplanted successfully. In 1987, Starzl and associates performed a multivisceral organ transplant, including the small intestine. The following year, the same group performed a successful combined liver and small intestine transplant, and Grant reported a successful isolated intestinal transplant from a live donor. In 1989, the Pittsburgh group performed the first successful cadaveric small intestinal transplant.

Doubtless, the most dramatic development in abdominal surgery is the introduction and expansion of laparoscopic procedures. Kelling was the first to examine the peritoneal cavity with an endoscope. In 1901, using a Nitze cystoscope, he entered and visualized the peritoneal cavity of a dog and referred to the procedure as "Koelioskopie." The first major series of laparoscopies in humans is attributed to Jacobaeus, who in 1911 reported examining both the abdominal and thoracic cavities with a "Lapaothorakoscopie." In 1937, Ruddock published a paper on "Peritoneoscopy" in which he detailed his experience with 500 cases including 39 in which biopsies were performed.

Laparoscopy essentially remained a procedure performed by gynecologists for many years. In fact, it was a gynecologist, Mouret, who in 1987 performed the first laparoscopic cholecystectomy, using four trocars. But credit is generally assigned to Dubois, who described the procedure in 1988, for initiating interest in the procedure. In the 25 years that have ensued, there has been an explosive increase in the use of laparoscopic techniques for abdominal operations. Basic laparoscopic procedures include cholecystectomy, appendectomy, and hernia repair. Advanced procedures include fundoplication, Heller myotomy, gastrectomy, bariatric surgery, esophagectomy, enteral access, bile duct exploration, partial hepatectomy, partial pancreatectomy, colectomy, splenectomy, adrenalectomy, and nephrectomy in addition to the standard gynecologic applications.[9]

The most recent refinement has been the addition of robotics, or more currently, computer-assisted remote mechanical devices. The appropriateness of the application of robotics to cholecystectomy has not been demonstrated. An advantage, however, has been ascribed to robotics for adrenalectomy.[10] Paralleling the expansion of laparoscopic surgery, there has been an increased application of endovascular techniques for the repair of aneurysm of the abdominal aorta. Endovascular abdominal aortic repair was introduced independently by Parodi and associates and Volodos and coworkers in 1991. Over a dozen endovascular grafts have been developed, and in 2002, there were more abdominal aortic aneurysms repaired in the state of New York by endovascular procedures than open operations.[11]

The expansion in surgery that has occurred during the 20th and early 21st centuries has been a consequence of contributions by surgeons, unrelated to technical improvements. The critical maintenance of blood volume was instated by James Blundell in London over 150 years ago. In 1883, Halsted reported the first successful autoreinfusion of blood. In 1908, George W. Crile published a book detailing his laboratory and clinical experiences with transfusion. In 1915, Richard Lewisohn, a New York surgeon, introduced the sodium citrate method of blood preservation. The use of frozen blood was first reported in 1965 by Charles Huggins of Massachusetts General Hospital.

In reference to the use of intraoperative and postoperative fluid therapy, early contributions were made by John H. Gibbons in 1907, and Wilder Penfield and David Teplitsky in 1923. A year later, Rudolph Matas prescribed the intravenous administration of 4000–5000 mL of 5% glucose solution over 24 hours. After a period in which saline was avoided, the importance of saline and potassium was demonstrated by Francis D. Moore, Henry T. Randall, and G. Tom Shires. In 1959, Moore's *Metabolic Care of the Surgical Patient* brought into focus the importance of body composition, homeostasis, and endocrinology of the traumatized and surgical patient. The problem of nutritional support was resolved by Dudrick and associates in 1968 when they demonstrated that nutritional requirements could be satisfied totally by administration of high caloric fluid by a catheter position in the superior vena cava.

Over seven decades have elapsed since the first edition of *Maingot's Abdominal Operations* was published. As is true for all of the sciences, growth recently has been geometric. During the time from the initial publication to the present, there have been more new and refined operations introduced than throughout the preceding years. The accelerated rate of change can only ensure the viability of future editions.

PREOPERATIVE AND POSTOPERATIVE MANAGEMENT

Zara Cooper • Edward Kelly

Modern advances in patient care have enabled surgeons to treat more challenging and complicated surgical problems. In addition, surgical treatment can be offered to more fragile patients, with successful outcomes. In order to achieve these good results, it is vital to master the scientific fundamentals of perioperative management. The organ system–based approach allows the surgeon to address the patient's pre- and postoperative needs, and ensures that these needs are part of the surgical plan.

MANAGEMENT OF PAIN AND DELIRIUM

The most common neuropsychiatric complications following abdominal surgery are pain and delirium. Moreover, uncontrolled pain and delirium prevent the patient from contributing to vital aspects of his or her care such as walking and coughing, and promote an unsafe environment that may lead to the unwanted dislodgment of drains and other supportive devices, with potentially life-threatening consequences. Pain and delirium frequently coexist, and each can contribute to the development of the other. Despite high reported rates of overall patient satisfaction, pain control is frequently inadequate in the perioperative setting[1] with high rates of complications such as drowsiness and unacceptable levels of pain. Therefore, it is mandatory that the surgical plan for every patient include control of postoperative pain and delirium and regular monitoring of the efficacy of pain control.

Pain management, like all surgical planning, begins in the preoperative assessment. In the modern era, a large proportion of surgical patients will require special attention with respect to pain control. Patients with preexisting pain syndromes, such as sciatica or interspinal disc disease, or patients with a history of opioid use may have a high tolerance for opioid analgesics. Every patient's history should include a thorough investigation for chronic pain syndrome, addiction (active or in recovery), and adverse reactions to opioid, nonsteroidal, or epidural analgesia. The pain control strategy may include consultation with a pain control anesthesiology specialist, but it is the responsibility of the operating surgeon to identify complicated patients and construct an effective pain control plan.

Opioid Analgesia

Postoperative pain control using opioid medication has been in use for thousands of years. Hippocrates advocated the use of opium for pain control. The benefits of postoperative pain control are salutary, and include improved mobility and respiratory function, and earlier return to normal activities. The most effective strategy for pain control using opioid analgesia is patient-controlled analgesia (PCA), wherein the patient is instructed in the use of a preprogrammed intravenous pump that delivers measured doses of opioid (usually morphine or meperidine). In randomized trials, PCA has been shown to provide superior pain control and patient satisfaction compared to interval dosing,[2] but PCA has not been shown to improve rates of pulmonary and cardiac complications[3] or length of hospital stay,[4] and there is evidence that PCA may contribute to postoperative ileus.[5] In addition, PCA may be unsuitable for patients with a history of substance abuse, high opioid tolerance, or those with atypical reactions to opioids.

Epidural Analgesia

Due to the limitations of PCA, pain control clinicians have turned to epidural analgesia as an effective strategy for the management of postoperative pain. Postoperative epidural analgesia involves the insertion of a catheter into the epidural space of the lumbar or thoracic spine, enabling the delivery of local anesthetics or opioids directly to the nerve roots. The insertion procedure is generally safe, with complication rates of motor block and numbness between 0.5% and 7%,[6] and an epidural abscess rate of 0.5 per thousand.[7] Potential advantages of epidural analgesia include elimination of systemic

opioids, and thus less respiratory depression, and improvement in pulmonary complications and perioperative ileus. There have been several large trials,[8–10] a meta-analysis,[6] and a systematic review[11] comparing PCA with epidural analgesia in the setting of abdominal surgery. These studies indicate that epidural analgesia provides more complete analgesia than PCA throughout the postoperative course. Furthermore, in randomized prospective series of abdominal procedures, epidural analgesia has been associated with decreased rates of pulmonary complications[12,13] and postoperative ileus.[14,15] Epidural analgesia requires a skilled anesthesia clinician to insert and monitor the catheter and adjust the dosage of neuraxial medication. Some clinicians may prefer correction of coagulopathy before inserting or removing the catheter, although the American Society of Anesthesiologists (ASA) has not issued official guidelines on this issue.

Analgesia With Nonsteroidal Anti-Inflammatory Drugs

Oral nonsteroidal anti-inflammatory drugs (NSAIDs) have long been used for postoperative analgesia in the outpatient setting, and with the development of parenteral preparations, have come into use in the inpatient population. This class of medication has no respiratory side effects and is not associated with addiction potential, altered mental status, or ileus. In addition, these medications provide effective pain relief in the surgical population. However, use of NSAIDs has not been universally adopted in abdominal surgery due to concerns regarding the platelet dysfunction and erosive gastritis associated with heavy NSAID use. In prospective trials, NSAIDs were found to provide effective pain control without bleeding or gastritis symptoms following laparoscopic cholecystectomy,[16] abdominal hysterectomy,[17] and inguinal hernia repair.[18,19] NSAIDs have also been shown to improve pain control and decrease morphine dosage when used in combination following appendectomy.[20]

The sensation of pain is very subjective and personal. Accordingly, the surgeon must individualize the pain control plan to fit the needs of each patient. The pain control modalities discussed above can be used in any combination, and the surgeon should not hesitate to use all resources at his or her command to provide adequate relief of postoperative pain.

Postoperative Delirium

Delirium, defined as acute cognitive dysfunction marked by fluctuating disorientation, sensory disturbance, and decreased attention, is an all too common complication of surgical procedures, with reported rates of 11–25%, with the highest rates reported in the elderly population.[21,22] The postoperative phase of abdominal surgery exposes patients, some of whom may be quite vulnerable to delirium, to a large number of factors that may precipitate or exacerbate delirium (Table 2-1). These factors can augment each other: postoperative pain can lead to decreased mobility, causing respiratory compromise, atelectasis, and hypoxemia. Escalating doses of narcotics to treat pain can cause respiratory depression and respiratory acidosis. Hypoxemia and delirium can cause agitation, prompting treatment with benzodiazepines, further worsening respiratory function and delirium. This vicious cycle can play out right before the physician's eyes, and if not interrupted, can result in serious complications or death. Preoperative recognition of high-risk patients and meticulous monitoring of every patient's mental status are the most effective ways to prevent postoperative delirium; treatment can be remarkably difficult once the vicious cycle has begun.

TABLE 2-1: CAUSES OF PERIOPERATIVE DELIRIUM

Pain
Narcotic analgesics
Sleep deprivation
Hypoxemia
Hyperglycemia
Acidosis
Withdrawal (alcohol, narcotics, benzodiazepines)
Anemia
Dehydration
Electrolyte imbalance (sodium, potassium, magnesium, calcium, phosphate)
Fever
Hypotension
Infection (pneumonia, incision site infection, urinary tract infection)
Medication (antiemetics, antihistamines, sedatives, anesthetics)
Postoperative myocardial infarction (MI)

Patient factors that are associated with high risk of perioperative delirium include age greater than 70 years, preexisting cognitive impairment or prior episode of delirium, history of alcohol or narcotic abuse, and malnutrition.[21,23] Procedural factors associated with high delirium risk include operative time greater than 2 hours, prolonged use of restraints, presence of a urinary catheter, addition of more than three new medications, and reoperation.[22]

Once the patient's risk for postoperative delirium is identified, perioperative care should be planned carefully to decrease other controllable factors. Epidural analgesia has been associated with less delirium than PCA after abdominal surgery.[24] Sedation or "sleepers" should be used judiciously, if at all, with high-risk patients. If the patient requires sedation, neuroleptics such as haloperidol and the atypical neuroleptics such as olanzapine are tolerated much better than benzodiazepines.[25] The patient's mental status, including orientation and attention, should be assessed

with every visit, and care should be taken to avoid anemia, electrolyte imbalances, dehydration, and other contributing factors.

Once the diagnosis of postoperative delirium is established, it is important to recognize that some of the causes of delirium are potentially life-threatening, and immediate action is necessary. Evaluation begins with a thorough history and physical examination at the bedside by the surgeon. The history should focus on precipitating events such as falls (possible traumatic brain injury), recent procedures, use of opioids and sedatives, changes in existing medications (eg, withholding of thyroid replacement or antidepressants), and consideration of alcohol withdrawal. The vital signs and fluid balance may suggest sepsis, hypovolemia, anemia, or dehydration. The examination should include brief but complete sensory and motor neurological examinations to differentiate delirium from stroke. Pay attention to common sites of infection such as the surgical wound, the lungs, and intravenous catheters. Urinary retention may be present as a result of medication or infection. Deep venous thrombosis may be clinically evident as limb swelling. Postoperative myocardial infarction (MI) may often present as acute cardiogenic shock.

The history and physical examination should then direct the use of laboratory tests. Most useful are the electrolytes, blood glucose, and complete blood cell count. Pulse oximetry and arterial blood gases may disclose hypercapnia or hypoxemia. Chest x-ray may disclose atelectasis, pneumonia, acute pulmonary edema, or pneumothorax. Cultures may be indicated in the setting of fever or leukocytosis, but will not help immediately. Electrocardiogram (ECG) and cardiac troponin may be used to diagnose postoperative MI.

Resuscitative measures may be required if life-threatening causes of delirium are suspected. Airway control, supplemental oxygen, and fluid volume expansion should be considered in patients with unstable vital signs. The patient should not be sent out of the monitored environment for further tests, such as head computed tomography (CT), until the vital signs are stable and the agitation is controlled. Treatment of postoperative delirium depends on treatment of the underlying causes. Once the underlying cause has been treated, delirium may persist, especially in elderly or critically ill patients, who regain orientation and sleep cycles slowly. In these patients, it is important to provide orienting communication and mental stimulation during the day, and to promote sleep during the night. The simplest ways are the most effective: contact with family members and friends, use of hearing aids, engagement in activities of daily living, and regular mealtimes. Sleep can be promoted by keeping the room dark and quiet throughout the evening, and preventing unnecessary interruptions. If nighttime sedation is required, atypical neuroleptics or low-dose serotonin reuptake inhibitors such as trazodone are better tolerated than benzodiazepines. If agitation persists, escalating doses of neuroleptics (or benzodiazepines in the setting of alcohol withdrawal) can be used to control behavior, but hidden causes of delirium must be considered.

CARDIAC EVALUATION

Risk Assessment

It has been estimated that 1 million patients have a perioperative MI each year, and the contribution to medical costs is $20 billion annually.[26] Thoracic, upper abdominal, neurological, and major orthopedic procedures are associated with increased cardiac risk. Diabetes, prior MI, unstable angina, and decompensated congestive heart failure (CHF) are most predictive of perioperative cardiac morbidity and mortality, and patients with these conditions undergoing major surgery warrant further evaluation[27] (Table 2-2). Patient factors conferring intermediate risk include mild angina and chronic renal insufficiency with baseline creatinine ≥2 mg/dL.[28] It is worth noting that women were underrepresented in the studies on which the American College of Cardiology and the American Heart Association (ACC/AHA) guidelines are based.[29] A retrospective study in gynecological patients found that hypertension and previous MI were major predictors of postoperative cardiac events, as opposed to the ACC/AHA guidelines, which indicate that they are minor and intermediate criteria, respectively.[30] Therefore, vascular surgical patients are at highest risk because of the prevalence of underlying coronary disease in this population.[27,31] Other high-risk procedural factors include emergency surgery, long operative time, and high fluid replacement volume; these are associated with a more than 5% risk of perioperative cardiac

TABLE 2-2: CLINICAL PREDICTORS OF INCREASED RISK FOR PERIOPERATIVE CARDIAC COMPLICATIONS

Major
- Recent MI (within 30 days)
- Unstable or severe angina
- Decompensated CHF
- Significant arrhythmias (high-grade atrioventricular block, symptomatic ventricular arrhythmias with underlying heart disease, supraventricular arrhythmias with uncontrolled rate)
- Severe valvular disease

Intermediate
- Mild angina
- Any prior MI by history or ECG
- Compensated or prior CHF
- Diabetes mellitus
- Renal insufficiency

Minor
- Advanced age
- Abnormal ECG
- Rhythm other than sinus (eg, atrial fibrillation)
- Poor functional capacity
- History of stroke
- Uncontrolled hypertension (eg, diastolic blood pressure >10 mm Hg)

morbidity and mortality. Intraperitoneal procedures, carotid endarterectomy, thoracic surgery, head and neck procedures, and orthopedic procedures carry an intermediate risk, and are associated with a 1–5% risk of a perioperative cardiac event.[28]

Perioperative evaluation to identify patients at risk for cardiac complications is essential in minimizing morbidity and mortality. Workup should start with history, physical examination, and ECG to determine the existence of cardiac pathology. Screening with chest radiographs and ECG is required for men over 40 and women over 55. According to the ACC/AHA guidelines, indications for preoperative cardiac testing should mirror those in the nonoperative setting.[32] The preoperative evaluation should include the surgeon, anesthesiologist, primary care physician, and possibly a cardiologist. Cardiology consultations are recommended for patients with major clinical predictors, those with intermediate clinical predictors and poor functional status undergoing intermediate-risk procedures, or those undergoing high-risk procedures with poor functional status or intermediate clinical predictors (Table 2-3). Overall functional ability is the best measure of cardiac health. Patients who can exercise without limitations can generally tolerate the stress of major surgery.[33] Limited exercise capacity may indicate poor cardiopulmonary reserve and the inability to withstand the stress of surgery. Poor functional status is the inability to perform activities such as driving, cooking, or walking less than 5 km/h.

Intraoperative risk factors include operative site, inappropriate use of vasopressors, and unintended hypotension. Intra-abdominal pressure exceeding 20 mm Hg during laparoscopy can decrease venous return from the lower extremities and thus contribute to decreased cardiac output,[34] and Trendelenburg positioning can result in increased pressure on the diaphragm from the abdominal viscera, subsequently reducing vital capacity. Intraoperative hypertension has not been isolated as a risk factor for cardiac morbidity, but it is often associated with wide fluctuations in pressure, and has been more closely associated with cardiac morbidity than intraoperative hypotension. Preoperative anxiety can contribute to hypertension even in normotensive patients. Those patients with a history of hypertension, even medically controlled hypertension, are more likely to be hypertensive preoperatively. Those with poorly controlled hypertension are at greater risk of developing intraoperative ischemia, arrhythmias, and blood pressure derangements, particularly at induction and intubation. Twenty-five percent of patients will exhibit hypertension during laryngoscopy. Patients with chronic hypertension may not necessarily benefit from lower blood pressure during the preoperative period because they may depend on higher pressures for cerebral perfusion. Those receiving antihypertensive medications should continue them up until the time of surgery. Patients taking beta-blockers are at risk of withdrawal and rebound ischemia. Key findings on physical examination include retinal vascular changes and an S_4 gallop consistent with left ventricular (LV) hypertrophy. Chest radiography may show an enlarged heart, also suggesting LV hypertrophy.

Noninvasive cardiac testing is used to define risk in patients known to be at high or intermediate risk, and detect those with CHF or dyspnea. It is most useful in intermediate-risk patients. No special laboratory tests are necessary unless there is evidence of active ischemia. A baseline ECG is necessary to identify any new ECG findings, to rule out active ischemia, and as a baseline for comparison during the postoperative period. The baseline ECG will be normal in 25–50% of patients with coronary disease, but no history of MI. A 12-lead ECG should be obtained in patients with chest pain, diabetes, prior revascularization, prior hospitalization for cardiac causes, all men age 45 or older, and all women aged 55 with two or more risk factors. High- or intermediate-risk patients should also have a screening ECG. A lower-than-normal ejection fraction demonstrated on echocardiography is associated with the greatest perioperative cardiac risk, and should be obtained in all patients with symptoms suggesting heart failure or valvular disease. Tricuspid regurgitation indicates pulmonary hypertension and is often associated with sleep apnea. The chest x-ray is used to screen for cardiomegaly and pulmonary congestion, which may signify ventricular impairment.

Exercise testing demonstrates a propensity for ischemia and arrhythmias under conditions that increase myocardial oxygen consumption. Numerous studies have shown that performance during exercise testing is predictive of perioperative mortality in noncardiac surgery. ST-segment changes during exercise including horizontal depression greater than 2 mm, changes with low workload, and persistent changes after 5 minutes of exercise are seen in severe multivessel disease. Other findings include dysrhythmias at a low heart rate, an inability to raise the heart rate to 70% of predicted, and sustained decrease in systolic pressure during exercise.

Unfortunately, many patients are unable to achieve adequate workload in standard exercise testing because of osteoarthritis, low back pain, and pulmonary disease. In this case, pharmacological testing is indicated with a dobutamine echocardiogram. Dobutamine is a beta-agonist that increases myocardial oxygen demand and reveals impaired oxygen delivery in those with coronary disease. Echocardiography concurrently visualizes wall motion abnormalities due to ischemia. Transesophageal echocardiography may be preferable to transthoracic echocardiography in obese patients because of their body habitus, and has been shown to have high negative predictive value in this group.[35] Nuclear perfusion imaging with vasodilators such as adenosine or dipyridamole can identify coronary artery disease

TABLE 2-3: FACTORS THAT INCREASE THE RISK OF PERIOPERATIVE CARDIAC COMPLICATIONS

Risk Variable	Odds Ratio (95% Confidence Interval)
Poor functional status	1.8 (0.9–3.5)
Ischemic heart disease	2.4 (1.3–4.2)
Heart failure	1.9 (1.1–3.5)
Diabetes	3.0 (1.3–7.1)
Renal insufficiency	3.0 (1.4–6.8)
High-risk surgery	2.8 (1.6–4.9)

and demand ischemia. Heterogeneous perfusion after vasodilator administration demonstrates an inadequate response to stress. Wall motion abnormalities indicate ischemia and an ejection fraction lower than 50% increases the risk of perioperative mortality. Angiography should only be performed if the patient may be a candidate for revascularization.

Coronary Disease

Most perioperative MIs are caused by plaque rupture in lesions that do not produce ischemia during preoperative testing.[36] This presents an obvious challenge for detecting patients at risk. Stress testing has a low positive predictive value in patients with no cardiac risk factors, and has been associated with an unacceptably high rate of false-positives.[37]

Preoperative optimization may include medical management, percutaneous coronary interventions (PCI), or coronary artery bypass grafting (CABG).[38] The ACC/AHA guidelines (Fig. 2-1) recommend coronary revascularization prior to noncardiac surgery in the following situations:

1. The combined risk of the two procedures does not exceed the risk of the surgical procedure alone.

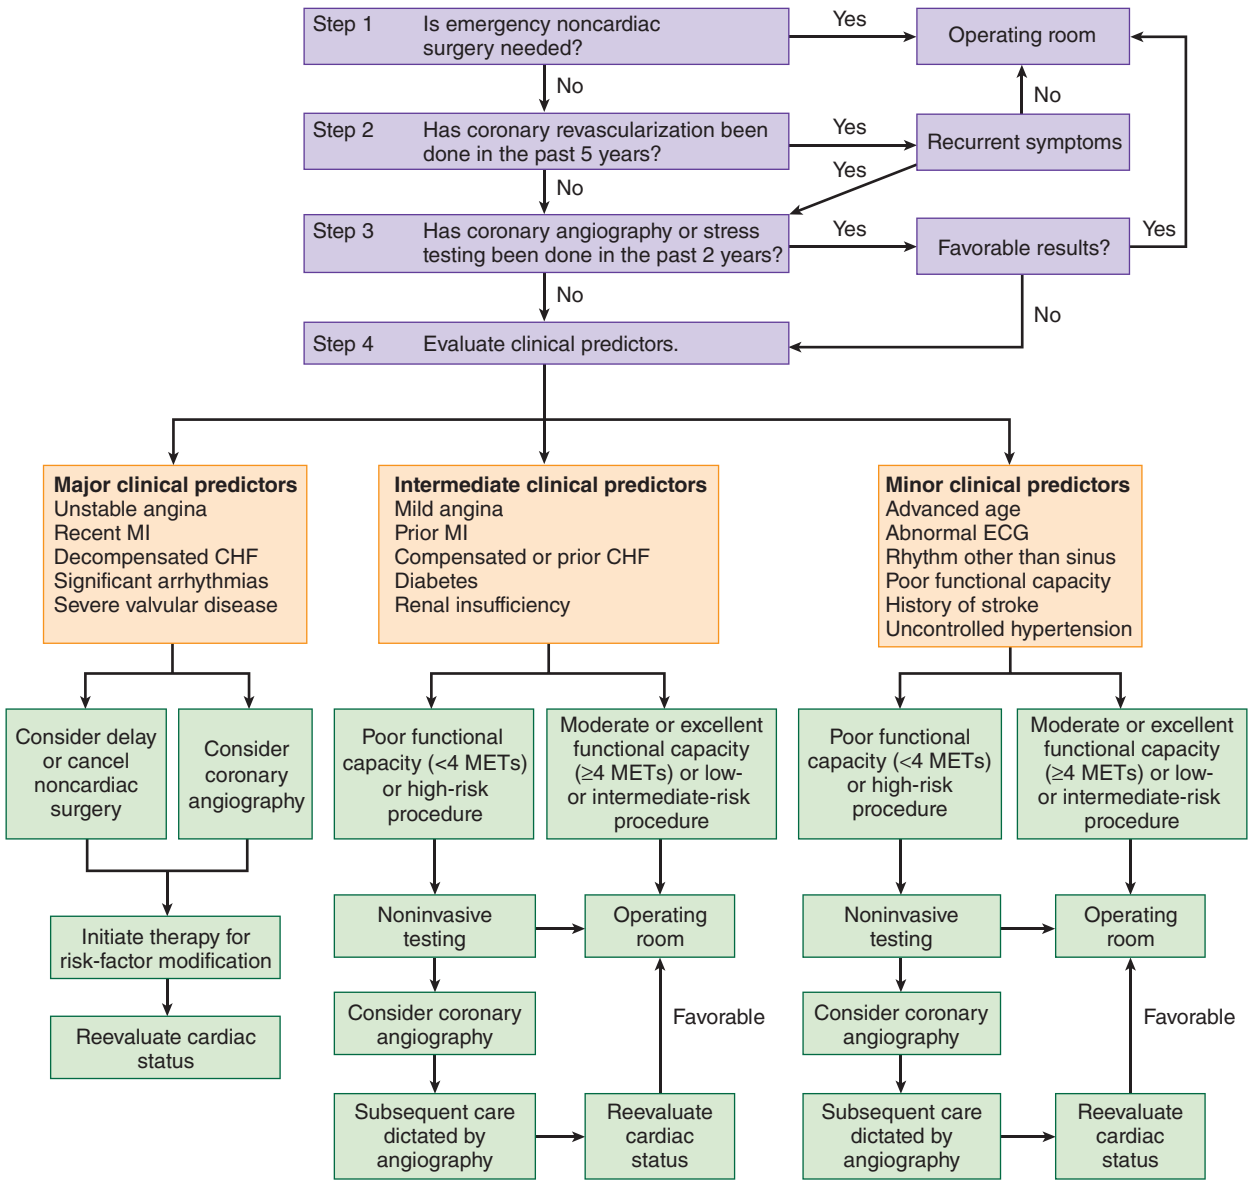

FIGURE 2-1 Preoperative cardiac risk assessment algorithm suggested by the ACC/AHA. (Adapted with permission from Eagle KA, Brundage BH, Chaitman BR, et al. Guidelines for perioperative cardiovascular evaluation for noncardiac surgery. Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee on Perioperative Cardiovascular Evaluation for Noncardiac Surgery]. *J Am Coll Cardiol.* 1996;27:921.) MI, myocardial infarction; CHF, congestive heart failure; ECG, electrocardiography; METs, metabolic equivalents.

2. Revascularization should reduce the risk of the noncardiac surgery more than the risk of the revascularization procedure itself.
3. Revascularization should not unduly delay the noncardiac surgery, especially if it is urgent.

Patients warranting emergent CABG will be at greatest risk for that procedure. A recent study from the Veterans Administration Hospitals recommends against revascularization in patients with stable cardiac symptoms.[39] Preoperative PCI does not decrease the risk of future MI or mortality in patients with stable coronary disease, and only targets stenotic lesions, rather than those most likely to rupture. One retrospective study found no reduction in morbidity or perioperative MI after percutaneous transluminal coronary angioplasty, and the authors proposed that surgery within 90 days of balloon angioplasty increased the risk of thrombosis.[40] However, PCI done more than 90 days before surgery did provide benefit when compared to those who had no intervention at all. Another retrospective study found that patients who have surgery within 2 weeks of stenting had a high incidence of perioperative MI, major bleeding, or death.[41] Although a retrospective review from the Coronary Artery Surgery Study registry showed a lower mortality rate in patients with coronary artery disease who were post-CABG than those without CABG (0.09 vs 2.4%), this benefit did not include the morbidity associated with CABG itself. Unfortunately, the benefit was overwhelmed by the 2.3% morbidity rate seen with CABG in this cohort.[42] Survival benefit of CABG over medical management is realized for 2 years after surgery[43] so that preoperative mortality may decrease overall short-term survival. Revascularization and bypass grafting should be restricted to patients who would benefit from the procedure independent of their need for noncardiac surgery. One of the disadvantages of PCI in the preoperative setting is the need for anticoagulation to prevent early stent occlusion. The use of platelet inhibitors to prevent stent occlusion must be included in the overall risk assessment, especially for surgery of the central nervous system.

Catecholamine surges can cause tachycardia, which may alter the tensile strength of coronary plaques and incite plaque rupture.[44,45] Catecholamine surges can also increase blood pressure and contractility, contributing to platelet aggregation and thrombosis after plaque rupture and increasing the possibility of complete occlusion of the arterial lumen.[46] Perioperative beta-blockade mitigates these effects and has been shown to reduce MI and mortality from MI by over 30% in vascular surgical patients with reversible ischemia.[44] Patients at highest risk still have a cardiac event rate of 10%, even with adequate perioperative beta-blockade.[37]

In 1998, a landmark study[47] demonstrated a 55% reduction in mortality in non-cardiac surgical patients with known coronary disease who were given atenolol perioperatively. This was followed by the DECREASE trial[48], which showed a 10-fold reduction in perioperative MI and death compared to placebo. Thereafter, perioperative beta-blockade was widely adopted as a quality measure. However, more recent investigations have shown that while perioperative beta-blockers benefit patients with known ischemia, low-risk patients may in fact be harmed.[49] Tight rate control has been associated with increased risk of hypotension and bradycardia requiring intervention, and stroke without any significant decrease in mortality.[50–53] Furthermore, critical analysis of the literature shows that studies have been inconsistent in the type of medication administered, the duration and timing of administration, or the target for heart rate control.[54] Consequently, results are difficult to interpret. Thus, prophylactic perioperative beta-blockade should be restricted to patients with cardiac ischemia and has a limited role in patients with low or moderate risk of postoperative cardiac events.

Congestive Heart Failure and Arrhythmia

Congestive heart failure (CHF) is associated with coronary disease, valvular disease, ventricular dysfunction, and all types of cardiomyopathy. These are all independent risk factors that should be identified prior to surgery. Even compensated heart failure may be aggravated by fluid shifts associated with anesthesia and abdominal surgery and deserves serious consideration. Perioperative mortality increases with higher New York Heart Association class and preoperative pulmonary congestion. CHF should be treated to lower filling pressures and improve cardiac output before elective surgery. Beta-blockers, angiotensin-converting enzyme inhibitors, and diuretics can be employed to this end. The patient should be stable for 1 week before surgery.[55]

Arrhythmias and conduction abnormalities elicited in the history, on examination, or on ECG, should prompt investigation into metabolic derangements, drug toxicities, or coronary disease. In the presence of symptoms or hemodynamic changes, the underlying condition should be reversed and then medication given to treat the arrhythmia. Indications for anti-arrhythmic medication and cardiac pacemakers are the same as in the nonoperative setting. Nonsustained ventricular tachycardia and premature ventricular contractions have not been associated with increased perioperative risk and do not require further intervention.[56,57]

Valvular Disease

Valvular disease should be considered in patients with symptoms of CHF, syncope, and a history of rheumatic heart disease (RHD). Aortic stenosis (AS) is a fixed obstruction to the LV outflow tract, limiting cardiac reserve and an appropriate response to stress. History should elicit symptoms of dyspnea, angina, and syncope; examination may reveal a soft S_2, a late peaking murmur, or a right-sided crescendo-decrescendo murmur radiating to the carotids. AS is usually caused by progressive calcification or congenital bicuspid valve. Critical stenosis exists when the valve area is less than 0.7 cm^2 or

transvalvular gradients are greater than 50 mm Hg, and is associated with an inability to increase cardiac output with demand. If uncorrected, AS is associated with a 13% risk of perioperative death. Valve replacement is indicated prior to elective surgery in patients with symptomatic stenosis.[58] Myocardial ischemia may occur in the absence of significant coronary artery occlusion in the presence of aortic valve disease. Perioperative management should include optimizing the heart rate to between 60 and 90 beats per minute and avoiding atrial fibrillation if possible. Because of the outflow obstruction, stroke volume may be fixed and bradycardia will lower cardiac output. Similarly, hypotension is also poorly tolerated.

Aortic regurgitation (AR) is associated with backward flow into the left ventricle during diastole and reduced forward stroke volume. Bradycardia facilitates regurgitation by increased diastolic time. Chronic AR causes massive LV dilatation (cor bovinum) and hypertrophy, which is associated with decreased LV function at later stages. AR is most often caused by rheumatic disease or congenital bicuspid valve. Medical treatment includes rate control and afterload reduction. Without valve replacement, survival is approximately 5 years once patients become symptomatic. This is an obvious consideration when planning any other surgical procedures.

Tricuspid regurgitation is usually caused by pulmonary hypertension secondary to severe left-sided failure. Other causes include endocarditis, carcinoid syndrome, and primary pulmonary hypertension. Hypovolemia, hypoxia, and acidosis can increase right ventricular afterload and should be avoided in the perioperative period.

Mitral stenosis is an inflow obstruction that prevents adequate LV filling. The transvalvular pressure gradient depends on atrial kick, heart rate, and diastolic filling time. Tachycardia decreases filling time and contributes to pulmonary congestion. Mitral regurgitation is also associated with pulmonary hypertension with congestion, as the pathologic valve prevents forward flow, causing left atrial dilatation, and subsequent atrial arrhythmias. History and physical examination should focus on signs of CHF such as orthopnea, pedal edema, dyspnea, reduced exercise tolerance, and auscultatory findings such as murmurs and an S_3 gallop. Neurological deficits may signify embolic sequelae of valve disease. Perioperative rate control is essential for maintaining adequate cardiac output. ECG findings will reflect related arrhythmias and medications, but will not be specific for valve disease. Laboratory studies should identify secondary hepatic dysfunction or pulmonary compromise. Left ventricular hypertrophy is an adaptive response, which may cause subsequent pulmonary hypertension and diastolic dysfunction.

Prosthetics in the mitral position pose the greatest risk for thromboembolism, and the risk increases with valve area and low flow. Mechanical valves pose a higher risk than tissue valves in patients with a history of valve replacement. Diuretics and afterload-reducing agents will enhance forward flow and minimize cardiopulmonary congestion. Patients with mitral valve prolapse (MVP) should receive antibiotics.

Mitral regurgitation may also impair LV function and lead to pulmonary hypertension. Stroke volume is reduced by backward flow into the atrium during systole. The left ventricle dilates to handle increasing end-systolic volume, eventually causing concentric hypertrophy and decreased contractility. The end result may be decreased ejection fraction and CHF. A decrease in systemic vascular resistance and an increase in atrial contribution to the ejection fraction can both improve forward flow and reduce the amount of regurgitation. Echocardiography can clarify the degree of valvular impairment. Medical treatment centers on afterload reduction with vasodilators and diuretics. MVP is present in up to 15% of women, and is usually associated with a midsystolic click and late systolic murmur on physical examination. Murmur is indicative of prolapse. Although MVP is associated with connective tissue disorders, it usually occurs in otherwise healthy, asymptomatic patients. Echocardiography is used to confirm the diagnosis and evaluate the degree of prolapse. Chronically, MVP may be associated with mitral regurgitation, emboli, and increased risk of endocarditis. Prolapse may be aggravated by decreased preload, which should be minimized in the perioperative period. Patients with MVP are at risk of ventricular arrhythmias with sympathetic stimulation and endocarditis, which can be addressed with pain control and antibiotic prophylaxis, respectively.

Individuals with underlying structural cardiac defects are at increased risk for developing endocarditis after invasive procedures. Surgical procedures involving mucosal surfaces or infected tissues may cause transient bacteremia that is usually short-lived. Certain procedures are associated with a greater risk of endocarditis and warrant prophylaxis (Table 2-4). Abnormal valves, endocardium, or endothelium can harbor the blood-borne bacteria for a longer period of time, and infection and inflammation can ensue. While there

TABLE 2-4: AHA ENDOCARDITIS PROPHYLAXIS RECOMMENDATIONS

Antibiotic Coverage Recommended:

Respiratory: tonsillectomy/adenoidectomy; rigid bronchoscopy; procedures involving respiratory mucosa

Gastrointestinal tract: sclerotherapy for esophageal varices; esophageal dilation; ERCP; biliary tract surgery; procedures involving intestinal mucosa

Genitourinary tract: prostatic surgery; cytoscopy; urethral dilation

Antibiotic Coverage Not Recommended:

Respiratory: endotracheal intubation; flexible bronchoscopy; tympanostomy tube insertion

Gastrointestinal tract: transesophageal echocardiography; endoscopy without biopsy

In uninfected tissue: urethral catheterization; uterine dilation and curettage; therapeutic abortion; manipulation of intrauterine devices

Other: cardiac catheterization; pacemaker placement; circumcision; incision or biopsy on prepped skin

are no randomized trials regarding endocarditis prophylaxis, the American Heart Association recommends prophylaxis for those[59] at high and moderate risk for developing the condition. Highest-risk patients have prosthetic heart valves, cyanotic congenital heart disease, or a history of endocarditis (even without structural abnormality).[60] Conditions associated with moderate risk include congenital septal defects, patent ductus arteriosus, coarctation of the aorta, and bicuspid aortic valve. Hypertrophic cardiomyopathy and acquired valvular disease also fall into this category. Mitral valve prolapse is a prevalent and often situational condition. Normal valves may prolapse in the event of tachycardia or hypovolemia, and may reflect normal growth patterns in young people. Prolapse without leak or regurgitation seen on Doppler studies is not associated with risk greater than that of the general population and no antibiotic prophylaxis is necessary.[61,62] However, the jet caused by the prolapsed valve increases the risk of bacteria sticking to the valve and subsequent endocarditis. Leaky valves detected by physical examination or Doppler warrant prophylactic antibiotics.[62] Those with significant regurgitation are more likely to be older and men, and other studies have shown that older men are more likely to develop endocarditis.[63–65] Some advocate prophylaxis for men older than 45 years with MVP even in the absence of audible regurgitation.[65] Prolapse secondary to myxomatous valve degeneration also warrants prophylactic antibiotics.[66,67] Prophylaxis is indicated in cases in whom mitral regurgitation cannot be determined.[68]

For patients at risk the goal should be administration of antibiotics in time to attain adequate serum levels during and after the procedure. For most operations, a single intravenous dose given 1 hour prior to incision will achieve this goal. Antibiotics should generally not be continued for more than 6–8 hours after the procedure to minimize the chance of bacterial resistance. In the case of oral, upper respiratory, and esophageal procedures, alpha-hemolytic streptococcus is the most common cause of endocarditis, and antibiotics should be targeted accordingly. Oral amoxicillin, parenteral ampicillin, and clindamycin for penicillin-allergic patients are suitable medications. Erythromycin is no longer recommended for penicillin-allergic patients because of gastrointestinal side effects and variable absorption.[69] Antibiotics given to those having genitourinary and nonesophageal gastrointestinal procedures should target enterococci.[69] While gram-negative bacteremia can occur, it rarely causes endocarditis. Parenteral ampicillin and gentamicin are recommended for highest-risk patients. Moderate-risk patients may receive amoxicillin or ampicillin. Vancomycin may be substituted in patients allergic to penicillin.

PERIOPERATIVE MANAGEMENT OF ANTITHROMBOTIC MEDICATION

Estimates suggest that 250,000 patients receiving chronic anticoagulation require surgery in the United States each year. Operative bleeding risk must be balanced against thromboembolic risk for the patient off of anticoagulation, and requires careful judgment. Factors that influence the risk of thromboembolism include the condition requiring chronic anticoagulation, the duration of the procedure, time expected off of anticoagulation, and the duration of perioperative immobility. Thromboembolic risk increases with the amount of time that the patient's anticoagulation is subtherapeutic.

Primary indications for chronic anticoagulation include arterial embolism associated with mechanical valves and atrial fibrillation and venous thromboembolism (VTE). Arterial events precipitate stroke, and valvular and atrial clot and systemic emboli are higher risk for morbidity and mortality than venous events. According to the American College of Chest Physicians Practice Guidelines for the Perioperative Management of Antithromotic Therapy,[70] patients at highest risk for perioperative embolism have mechanical mitral valves, aortic caged-ball and tilted valves, RHD, or history of stroke or transient ischemic attacks (TIA) in the past 3 months. The risk of thromboembolism without anticoagulation is higher than 10% per year in high-risk patients.

Patients at moderate risk of thromboembolism without anticoagulation, 4–10% per year, have atrial fibrillation, a bileaflet valve, or history of stroke or TIA. The congestive heart failure-hypertension-age-diabetes-stroke score ($CHADS_2$) further stratifies embolic risk for patients with atrial fibrillation based on comorbidities. One point is assigned for hypertension, diabetes, congestive heart failure, and age >75 years; two points are assigned for history of stroke or TIA. Patients with a cumulative score of 5–6 are highest risk; 3–4 are moderate risk, and 0–2 without history of stroke or TIA are low risk.

Chronic anticoagulation is indicated for VTE. Patients with VTE within 3 months of surgery and severe thrombophillia are at highest risk for perioperative events and should receive bridging anticoagulation with therapeutic doses of low-molecular weight heparin (LMWH) or intravenous unfractionated heparin (IV UFH). Patients at moderate risk include those with thromboembolic event 3–12 months before surgery and less severe thrombophillias. They can receive therapeutic or subtherapeutic doses of anticoagulation depending on the risk of bleeding associated with the procedure. Patients with a remote event are at lowest risk, and do not require bridging anticoagulation. It is generally recommended to stop Warfarin 5 days prior to surgery if a normal International Normalized Ratio (INR) is desired. Vitamin K may be administered in days leading up to the event if the INR is not coming down quickly enough.

LMWH should be held 24 hours before surgery, and IV UFH should be held 4 hours before surgery. Oral anticoagulants may be started 12–24 hours postoperatively because they take at least 48 hours to effect coagulation. The timing of resuming IV and SC anticoagulants should be determined on a case-by-case basis.

Low-risk patients receiving Clopidogrel or aspirin should have it held 5–10 days before surgery. Patients with coronary stents are chronically treated with Clopidogrel and aspirin to mitigate the risk of stent thrombosis. Interruptions in therapy are associated with high risk of thrombosis and infarct.

Patients with bare metal stents placed within 6 weeks of surgery, and drug-eluting stents within 12 months of surgery, should continue Clopiogrel and aspirin in the perioperative period.

PULMONARY EVALUATION

Pulmonary complications are common after surgery, and can prolong hospital stays for 1–2 weeks.[71] Complications include atelectasis, pneumonia, exacerbations of chronic pulmonary disorders, and respiratory failure requiring mechanical ventilation. Smoking, underlying chronic obstructive pulmonary disease (COPD), and poor exercise tolerance are the greatest risk factors for postoperative pulmonary complications. Physicians should ask about a history of smoking, decreased exercise capacity, dyspnea, and chronic cough. Examination should note pursed lip breathing, clubbing, and chest wall anatomy that could impair pulmonary function. Pulmonary testing is unnecessary in patients without a clear history of smoking or pulmonary disease. The predictive value of screening spirometry is unclear, and no threshold value has been identified to guide surgical decision making. Forced expiratory volume in 1 second less than 50% of predicted is indicative of exertional dyspnea and may herald the need for further testing. Preoperative chest x-ray abnormalities are associated with postoperative pulmonary complications,[71] but to this point there are no recommendations for screening radiographs in patients without pulmonary disease. Any preoperative chest x-ray must be examined for signs of hyperinflation consistent with COPD. While compensated hypercapnia has not been shown to be an independent predictor for postoperative ventilatory insufficiency in patients undergoing lung resection, preoperative arterial blood gas analysis provides useful baseline information for perioperative management of patients with chronic CO_2 retention. Transverse and upper abdominal incisions are associated with a higher rate of postoperative pulmonary complications than longitudinal midline incisions and lower abdominal incisions.[72] Surgery longer than 3 hours is also associated with higher risk.[73] General anesthesia is also associated with a higher risk of pulmonary complications than spinal, epidural, or regional anesthesia.[74]

Physiologic changes can be seen in the postoperative period, especially after thoracic and upper abdominal procedures. Vital capacity may decrease by 50–60%, and is accompanied by an increased respiratory rate to maintain tidal volumes. Normally, functional residual capacity usually exceeds the closing capacity of the alveoli, so they remain open throughout the respiratory cycle. Prolonged effects of anesthetics and narcotics reduce functional reserve capacity postoperatively, causing alveolar collapse. These changes can last for weeks to months. A distended abdomen can impair diaphragmatic excursion; painful incisions around the diaphragm and other respiratory muscles contribute to splinting and inadequate pulmonary toilet. Narcotics can inhibit sighing and coughing reflexes, which normally prevent alveolar collapse during periods of sleep and recumbency. Analgesics must be titrated carefully to permit deep breathing and avoid impairing respiratory effort.

Inspired nonhumidified oxygen and halogenated anesthetics are cytotoxic and interfere with surfactant production and mucociliary clearance. Depressed respiratory reflexes, diaphragm dysfunction, and decreased functional reserve capacity all contribute to alveolar collapse and pooling of secretions. Aspiration risk is also increased. Excess secretions cause further alveolar collapse and create a milieu ripe for bacterial infection and pneumonia. Intubated patients should receive antacid prophylaxis and gastric drainage to minimize the risk of aspiration.

Multiple analyses have found that poor exercise tolerance is the greatest predictor of postoperative pulmonary impairment. The ASA risk classification is a gauge of general status, and is highly predictive of both cardiac and pulmonary complications.[75,76] Although advanced age is associated with increased incidence of chronic pulmonary disease and underlying impairment, it is not an independent risk factor for pulmonary complications.

Clearly, all smokers should be urged to stop before surgery. Even in the absence of coexisting pulmonary disease, smoking increases the risk of perioperative complications. Smoking confers a relative risk of 1.4–4.3, but a reduced risk of pulmonary complications has been shown in patients who stop smoking at least 8 weeks before cardiac surgery.[77] Even 48 hours of abstinence can improve mucociliary clearance, decrease carboxyhemoglobin levels to those of nonsmokers, and reduce the cardiovascular effects of nicotine. A nicotine patch may help some patients with postoperative nicotine withdrawal, but may not be advisable in patients at risk for poor wound healing.

COPD confers a relative risk of 2.7–4.7 in various studies. Symptoms of bronchospasm and obstruction should be addressed before surgery and elective procedures should be deferred in patients having an acute exacerbation. Preoperative treatment may include bronchodilators, antibiotics, steroids, and physical therapy to increase exercise capacity. Patients with active pulmonary infections should have surgery delayed if possible. Asthmatics should have peak flow equivalent to their personal best or 80% of predicted, and should be medically optimized to achieve this goal. Pulse corticosteroids may be used without an increased risk of postoperative infection or other complication.[78,79]

Malnourished patients may not be able to meet the demands of the increased work of breathing, increasing their risk for respiratory failure. Obese patients have higher rates of oxygen consumption and carbon dioxide production, which increases their work of breathing. They may also exhibit restrictive physiology due to a large, stiff chest wall. A complete history should inquire about sleeping difficulty and snoring. Obesity increases the amount of soft tissue in the oropharynx, which can cause upper airway obstruction during sleep. Fifty-five percent of morbidly obese patients may have sleep-related breathing disorders such as obstructive sleep apnea and obesity-hypoventilation syndrome.[80]

Symptoms include snoring and daytime sleepiness, and formal sleep studies are employed for definitive diagnosis. Sleep-disordered breathing is associated with hypoxia, hypercapnia, changes in blood pressure, nocturnal angina, and increased cardiac morbidity and mortality including stroke and sudden death.[81] Arterial blood gas with partial arterial oxygen pressure less than 55 mm Hg or partial arterial carbon dioxide pressure greater than 47 mm Hg confirms the diagnosis. An increased incidence of pulmonary hypertension and right-sided heart failure is seen in patients with obesity hypoventilation syndrome and these patients should have an echocardiogram before surgery. In severe cases, intraoperative monitoring with a pulmonary artery catheter may be prudent.

In the patient who is awake, postoperative care should include coughing and deep breathing exercises, and in non-ambulatory patients, early mobilization should include turning every 2 hours. Early ambulation prevents atelectasis and pooling of secretions, and increases the ventilatory drive. Upright position distributes blood flow and minimizes shunting. Preoperative medications should be resumed expeditiously. Incentive spirometry and pulmonary toilet are pulmonary expansion maneuvers, which reduce the relative risk of pulmonary complications by 50%.[82] Patients should receive preoperative education about these techniques. Inhaled ipratropium and beta-agonists, used together, may prevent postoperative wheezing and bronchospasm, and should be prescribed in patients at risk. Intermittent positive pressure ventilation and nasal bi-level positive airway pressure may be enlisted for secondary prevention. Epidural analgesia is superior to parenteral narcotics in abdominal and thoracic procedures for preventing pulmonary complications.

GASTROINTESTINAL EVALUATION

Stress ulceration has been a well-recognized complication of surgery and trauma since 1932, when Cushing reported gastric bleeding accompanying head injury. With later research in gastric physiology and shock, it has been recognized that the appearance of gastric erosion results from failure of the protective function of gastric mucosa and back diffusion of hydrogen ion, enabling gastric acid to injure the mucosa. Once the mucosa is injured, the defenses are further weakened, leading to further injury in a vicious cycle. The protective functions of the mucosa rely on the stomach's rich blood flow to maintain high oxygen saturation. The most critical factor in the development of erosive ulceration now appears to be mucosal ischemia. Once the rich blood supply of the mucosa is compromised, the protective mechanisms are impaired, and gastric acid causes erosion, bleeding, and perforation.

In the late 1970s, the incidence of gastric bleeding in critically ill patients was 15%. Recognition of the importance of organ perfusion has resulted in decreased rates of erosive stress gastritis. Factors often cited for this observation are: improvement in resuscitation and monitoring technology, nutritional support, and effective agents for medical prophylaxis. The prophylactic medicines are targeted to reduce gastric acidity. Antacids have been shown to provide effective protection against erosive ulceration; however, there is some risk of aspiration pneumonia. Antagonists of the histamine-2 (H_2) receptors of the parietal cells impair gastric acid secretion and also are effective prophylaxis for erosive ulceration. Due to ease of use, H_2-blockers have become the mainstay of stress ulcer prophylaxis in abdominal surgery.[83]

In the setting of elective operations when the patients are not critically ill, the incidence of stress ulceration is now very low and routine use of ulcer prophylaxis medication has been questioned. In addition, the routine use of H_2-antagonists in this setting may lead to increased risk of pneumonia because of failure of the gastric juices to kill bacteria.

Postoperative Ileus

Ileus is a condition of generalized bowel dysmotility that frequently impairs feeding in the postoperative setting. Ileus typically occurs after abdominal surgery, even if the bowel itself is not altered. It has been shown that laparotomy alone, without intestinal manipulation, leads to impaired gastrointestinal motility. The small bowel is typically affected the least, and can maintain organized peristaltic contractions throughout the perioperative period. The stomach usually regains a normal pattern of emptying in 24 hours, and the colon is last to regain motility, usually in 48–72 hours.

The exact mechanism that causes postoperative ileus is not known; however, physiologic studies have demonstrated the significant contribution of both inhibitory neural reflexes and local mediators within the intestinal wall. Inhibitory neural reflexes have been shown to be present within the neural plexuses of the intestinal wall itself, and in the reflex arcs traveling back and forth from the intestine to the spinal cord. These neural pathways may account for the development of ileus during laparotomy without bowel manipulation. In addition, inflammatory mediators such as nitric oxide are present in manipulated bowel and in peritonitis and may play a role in the development of ileus.

Ileus can be recognized from clinical signs, such as abdominal distension, nausea, and the absence of bowel sounds and flatus, which should prompt the diagnosis. Abdominal x-ray imaging typically shows dilated loops of small bowel and colon. Bowel obstruction must also be considered with these clinical findings, however, and CT or other contrast imaging may be required to rule out obstruction.

Ileus can also appear following nonabdominal surgery, and can result from the effects of medications (most often narcotics), electrolyte abnormalities (especially hypokalemia), and a wide variety of other factors.

Occasionally, the patient sustains a prolonged period of postoperative ileus. This can be due to a large number of contributing factors, such as intra-abdominal infection, hematoma, effects of narcotics and other medications, electrolyte abnormalities, and pain. In addition, there can be prolonged

dysmotility from certain bowel operations, such as intestinal bypass.

The role of laparoscopic surgery in prevention of ileus is controversial. In theory, with less handling of the bowel laparoscopically and with smaller incisions, there should be less stimulation of the local mediators and neural reflexes. Animal studies comparing open and laparoscopic colon surgery indicate earlier resumption of normal motility studies and bowel movements with the laparoscopic approach. Human trials have not been conclusive. Several series demonstrate earlier tolerance of postoperative feeding with the laparoscopic approach to colon resection; however, these have been criticized for selection bias, and such studies are impossible to conduct in a blind fashion.

Early mobilization has long been held to be useful in prevention of postoperative ileus. While standing and walking in the early postoperative period have been proven to have major benefits in pulmonary function and prevention of pneumonia, mobilization has no demonstrable effect on postoperative ileus.

In the expected course of uncomplicated abdominal surgery, the stomach is frequently drained by a nasogastric tube for the first 24 hours after surgery, and the patient is not allowed oral intake until there is evidence that colonic motility has returned, usually best evidenced by the passage of flatus. Earlier feeding and no gastric drainage after bowel surgery can be attempted for healthy patients undergoing elective abdominal surgery, and has a high rate of success provided clinical symptoms of ileus are not present. In such patients, the use of effective preventive strategies is highly effective. These include maintenance of normal serum electrolytes, use of epidural analgesia, and avoidance of complications such as infection and bleeding. The routine use of nasogastric tubes for drainage in the postoperative period after abdominal surgery has come into question since the mid-1990s.

The most effective strategy for management of postoperative ileus following abdominal surgery has been the development of epidural analgesia. Randomized trials have shown that the use of nonnarcotic (local anesthetic–based) epidural analgesia at the thoracic level in the postoperative period results in a decreased period of postoperative ileus in elective abdominal surgery. Ileus reduction is not seen in lumbar level epidural analgesia, suggesting that inhibitory reflex arcs involving the thoracic spinal cord may play a major role in postoperative ileus.

Narcotic analgesia, while effective for postoperative pain, has been shown to lengthen the duration of postoperative ileus, especially when used as a continuous infusion or as PCA. Patients report better control of postoperative pain with continuous infusion or PCA as compared to intermittent parenteral dosing. Many studies have been done comparing various types of opioid analgesics, in attempts to find a type that does not prolong ileus. There has been no clearly superior drug identified; all currently available opioids cause ileus. Opioid antagonists such as naloxone have been used in trials to decrease ileus in chronic narcotic use, and there is evidence that antagonists are effective in that setting; however, in postoperative ileus, the antagonists have not been shown to be clinically useful, again suggesting that other mechanisms are contributing to postoperative ileus.

Early Postoperative Bowel Obstruction

Early postoperative bowel obstruction refers to mechanical bowel obstruction, primarily involving the small bowel, which occurs in the first 30 days following abdominal surgery. The clinical picture may frequently be mistaken for ileus, and these conditions can overlap. The clinical presentation of early postoperative bowel obstruction is similar to that of bowel obstruction arising de novo: crampy abdominal pain, vomiting, abdominal distention, and obstipation. The incidence of early postoperative bowel obstruction has been variable in published series, due to difficulty in differentiating ileus from early postoperative bowel obstruction, but the reported range is from 0.7% to 9.5% of abdominal operations.

Retrospective large series show that about 90% of early postoperative bowel obstruction is caused by inflammatory adhesions. These occur as a result of injury to the surfaces of the bowel and peritoneum during surgical manipulation. The injury prompts the release of inflammatory mediators that lead to formation of fibrinous adhesions between the serosal and peritoneal surfaces. As the inflammatory mediators are cleared and the injury subsides, these adhesions eventually mature into fibrous, firm, and bandlike structures. In the early postoperative period, the adhesions are in their inflammatory, fibrinous form, and as such do not usually cause complete mechanical obstruction.

Internal hernia is the next most common cause of early postoperative bowel obstruction, and can be difficult to diagnose short of repeat laparotomy. Internal hernia occurs when gaps or defects are left in the mesentery or omentum, or blind gutters or sacs are left in place during abdominal surgery. The typical scenario is colon resection involving extensive resection of the mesentery for lymph node clearance. If the resulting gap in the mesentery is not securely closed, small bowel loops may go through the opening and not be able to slide back out. A blind gutter may be constructed inadvertently during the creation of a colostomy. When the colostomy is brought up to the anterior abdominal wall, there is a space between the colon and the lateral abdominal wall, which may also trap the mobile loops of small bowel. Defects in the closure of the fascia during open or laparoscopic surgery can cause obstruction from incarcerated early postoperative abdominal wall hernia. Fortunately, internal hernia is a rare occurrence in the early postoperative period; however, it must be suspected in cases where bowel anastomoses or colostomies have been constructed. Unlike adhesive obstruction, internal hernia requires operative intervention due to the high potential for complete obstruction and strangulation of the bowel.

Intussusception is a rare cause of early postoperative bowel obstruction in adults, but occurs more frequently in children. Intussusception occurs when peristalsis carries a segment of the bowel (called the lead point) up inside the distal bowel

like a rolled up stocking. The lead point is usually abnormal in some way, and typically has some intraluminal mass, such as a tumor or the stump of an appendix after appendectomy. Other rare causes for early postoperative bowel obstruction include missed causes of primary obstruction at the index laparotomy, peritoneal carcinomatosis, obstructing hematoma, and ischemic stricture.

Management of early postoperative bowel obstruction depends on differentiation of adhesive bowel obstruction (the majority) from internal hernia and the other causes, and from ileus. Clinicians generally rely on radiographic imaging to discern ileus from obstruction. For many years, plain x-ray of the abdomen was used: if the abdominal plain film showed air-distended loops of bowel and air-fluid levels on upright views, the diagnosis of obstruction was favored. However, plain radiographs can be misleading in the postoperative setting, and the overlap of ileus and obstruction can be confusing. Upper GI contrast studies using a water-soluble agent has better accuracy, and abdominal CT using oral contrast has been shown to have 100% sensitivity and specificity in differentiating early postoperative bowel obstruction from postoperative ileus.

Once the diagnosis is made, management is tailored to the specific needs of the patient. Decompression via nasogastric tube is usually indicated, and ileus can be treated as discussed. Adhesive bowel obstruction warrants a period of expectant management and supportive care, as the majority of these problems will resolve spontaneously. Most surgical texts recommend that the waiting period can be extended to 14 days. If the early bowel obstruction lasts longer than 14 days, less than 10% resolve spontaneously, and exploratory laparotomy is indicated. The uncommon causes of early postoperative bowel obstruction, such as internal hernia, require more early surgical correction, and should be suspected in the setting of complete obstipation, or when abdominal CT suggests internal hernia or complete bowel obstruction.

Renal Evaluation

Patients without a clinical history suggesting renal disease have a low incidence of significant electrolyte disturbances on routine preoperative screening.[84] However, those patients with renal or cardiac disease who are taking digitalis or diuretics, or those with ongoing fluid losses (ie, diarrhea, vomiting, fistula, and bleeding) do have an increased risk of significant abnormalities and should have electrolytes measured and replaced preoperatively.

Preoperative urinalysis can be a useful screen for renal disease. Proteinuria marks intrinsic renal disease or congestive heart failure. Urinary glucose and ketones are suggestive of diabetes and starvation in the ketotic state, respectively. In the absence of recent genitourinary instrumentation, microscopic hematuria suggests calculi, vascular disease, or infection. A few leukocytes may be normal in female patients, but an increased number signifies infection. Epithelial cells are present in poorly collected specimens.

Patients with renal insufficiency or end-stage renal disease often have comorbidities that increase their overall risk in the perioperative period. Hypertension and diabetes correlate with increased risk of coronary artery disease and postoperative MI, impaired wound healing, wound infection, platelet dysfunction, and bleeding. Preoperative history should note the etiology of renal impairment, preoperative weight as a marker of volume status, and timing of last dialysis and the amount of fluid removed routinely. Evaluation should include a cardiac risk assessment. Physical examination should focus on signs of volume overload such as jugular venous distention and pulmonary crackles. In patients with clinically evident renal insufficiency, a full electrolyte panel (calcium, phosphorus, magnesium, sodium, and potassium) should be checked preoperatively, along with blood urea nitrogen and creatinine levels. Progressive renal failure is associated with catabolism and anorexia. Such patients need aggressive nutritional support during the perioperative periods to minimize the risk of infection and poor healing.

Dialysis-dependent patients should have dialysis within 24 hours before surgery, and may benefit from monitoring of intravascular volume status during surgery. Blood samples obtained immediately after dialysis, before equilibration occurs, should only be used in comparison to predialysis values to determine the efficacy of dialysis.[85]

Postoperatively, patients with chronic renal insufficiency or end-stage renal disease will need to have surgical volume losses replaced, but care should be taken to avoid excess. Replacement fluids should not contain potassium, and early dialysis should be employed to address volume overload and electrolyte derangements. Patients with impaired creatinine clearance should have their medications adjusted accordingly. For example, meperidine should be avoided because its metabolites accumulate in renal impairment and can lead to seizures.

The choice of postoperative fluid therapy depends on the patient's comorbidities, the type of surgery, and conditions that affect the patient's fluid balance. There is no evidence that colloid is better than crystalloid in the postoperative period, and it is considerably more expensive.[86] Sepsis and bowel obstruction will require ongoing volume replacement rather than maintenance. Ringer's solution provides six times the intravascular volume as an equivalent amount of hypotonic solution. In patients with normal renal function, clinical signs such as urine output, heart rate, and blood pressure should guide fluid management. Once the stress response subsides, fluid retention subsides and fluid is mobilized from the periphery, and fluid supplementation is unnecessary. This fluid mobilization is evident by decreased peripheral edema and increased urine output. Diuretics given in the period of fluid sequestration may cause intravascular volume depletion and symptomatic hypovolemia.

Postoperative management includes close monitoring of urine output and electrolytes, daily weight, elimination of nephrotoxic medications, and adjustment of all medications that are cleared by the kidney. Hyperkalemia, hyperphosphatemia, and metabolic acidosis may be seen and should

TABLE 2-5: GUIDELINES FOR PERIOPERATIVE MANAGEMENT OF ANTITHROMBOTIC MEDICATIONS

	Standard Anticoagulation	Antiplatelet Therapy	Should Warfarin or Antiplatelet Be Stopped Pre-operatively?	Is Bridging Anticoagulation Indicated?	When Should Anticoagulant or Antithrombotic Be Restarted Postoperatively?
Low-risk atrial fibrillation	Warfarin goal INR 2.0	None	Yes, 5 days	No	When taking orals
Moderate/ High-risk atrial fibrillation	Warfarin goal INR 2.0	None	Yes, 5 days	No	When taking orals
Mechanical mitral valve	Warfarin goal INR 2.5–3.0	None	Yes, 5 days	Yes	Low bleeding risk: 24 hours High bleeding risk: 48–72 hours
Mechanical aortic valve	Warfarin goal INR 2.0	None	Yes, 5 days	Yes	Low bleeding risk: 24 hours High bleeding risk: 48–72 hours
Coronary stent	None	Clopidogrel Aspirin	Yes, 5–10 daysNo	No	Low bleeding risk: 24 hours High bleeding risk: 48–72 hours
Bare metal coronary stent within 6 weeks	None	Aspirin and Clopidogrel	No	No	Low bleeding risk: 24 hours High bleeding risk: 48–72 hours
Drug-eluting stent within 12 months	None	Aspirin and Clopidogrel	No	No	Low bleeding risk: 24 hours High bleeding risk: 48–72 hours
History of VTE	Warfarin goal INR 2.0 for at least 3 months	No	Yes, 5–7 days	Low risk: No Moderate/high risk: yes	

Low risk: VTE >12 months ago; $CHADS_2$ score 0–2 without prior stroke or TIA
Moderate risk: VTE in last 3–12 months, moderate thrombophillia, recurrent VTE, cancer; $CHADS_2$ score 3–4
High risk: VTE in last 3 months, prior postoperative VTE, severe thrombophillia; $CHADS_2$ score 5–6, RHD, or stroke or TIA within 3 months
Data from Douketis, JD, Berger, PB, Dunn, AS, et al. The perioperative management of antithrombotic therapy: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th Edition). *Chest*. 2008;133:299S–339S.

be addressed accordingly. Indications for renal replacement therapy include severe intravascular overload, symptomatic hyperkalemia, metabolic acidosis, and complicated uremia (pericarditis and encephalopathy) (Table 2-5).

Postoperative renal failure increases perioperative mortality. Risk factors for postoperative renal failure include intraoperative hypotension, advanced age, congestive heart failure, aortic cross-clamping, administration of nephrotoxic drugs or radiocontrast, and preoperative elevation in renal insufficiency. Up to 10% of patients may experience acute renal failure after aortic cross-clamping. Postoperative renal failure rates are higher in hypovolemic patients, so preoperative dehydration should be avoided. Contrast nephropathy is a common cause of hospital-acquired renal failure, and manifests as a 25% increase in serum creatinine within 48 hours of contrast administration.

Nephropathy is caused by ischemia and direct toxicity to the renal tubules. Diabetes and chronic renal insufficiency are the greatest risk factors for dye nephropathy. Recent trials[87] have shown that patients receiving contrast have a lower incidence of contrast-induced nephropathy when treated with a sodium bicarbonate infusion. *N*-acetylcysteine given orally on the day prior to contrast exposure also decreases the incidence of radiocontrast nephropathy.[88]

Rising blood urea nitrogen and creatinine and postoperative oliguria (<500 mL/d) herald the onset of postoperative renal failure. Management is determined by the cause of renal insufficiency. Acute renal failure is classified into three categories: prerenal, intrarenal, and postrenal. Prerenal azotemia is common in the postoperative period. It is caused by decreased renal perfusion seen with hypotension and intravascular volume contraction. Intrarenal causes of oliguric renal failure include acute tubular necrosis (from aortic cross-clamping, shock, or renal ischemia), and less commonly, acute interstitial nephritis from nephrotoxic medication. Postrenal causes include obstruction in the collecting system (from bilateral ureteral injury, Foley catheter occlusion, or urethral obstruction). Workup should include urinalysis, serum chemistries, and measurement of the fractional excretion of sodium. Invasive monitoring and cardiac echocardiogram may be employed to evaluate volume status. Ultrasound is indicated if obstruction is suspected.

Initial management of oliguria in adults includes placement of a bladder catheter, and a challenge with isotonic fluids (500 mL of normal saline or Ringer's lactate). If a bladder catheter is already present, it should be checked to ensure that it is draining properly. A urinalysis should be obtained with special attention to specific gravity, casts, and evidence of

TABLE 2-6: OLIGURIA IN THE PERIOPERATIVE PATIENT

	Prerenal	Intrarenal	Postrenal
Causes	Bleeding Hypovolemia Cardiac failure Dehydration	Drugs Contrast medium Sepsis Myoglobinuria	Obstruction
UOsm	>500 mOsm/L	Equal to plasma	Variable
U_{Na}	<20 mOsm/L	>50 mOsm/L	>50 mOsm/L
Fe_{Na}	<1%	>3%	Indeterminate

Fe_{Na}, fractional excretion of sodium; U_{Na}, urinary sodium concentration; UOsm, urinary osmolality.

infection. Hematocrit should be evaluated to exclude bleeding and blood pressure measured to rule out hypotension as causes. The fractional excretion of sodium can help determine the etiology of the renal failure (Table 2-6). Serum creatinine is used to follow the course of acute renal failure. Patients who have been adequately resuscitated or who are in CHF require evaluation to rule out cardiogenic shock. Urinary retention can be treated with a Foley catheter, and ureteral obstruction can be addressed with percutaneous nephrostomy.

Intravascular volume depletion adversely affects cardiac output, tissue perfusion, and oxygen delivery. Monitoring includes total body weight, urine output, vital signs, and mental status. However, body weight should not be used alone because total volume overload can be seen in the setting of intravascular volume depletion. Most cases of postoperative renal failure are associated with an episode of hemodynamic instability,[47] and perioperative hemodynamic optimization has been shown to decrease acute kidney injury and mortality.[89] Invasive monitoring to measure cardiac filling pressures may be utilized when clinical assessment is unreliable.

Fluid overload may be seen in patients with renal, hepatic, and cardiac disease, and is associated with increased morbidity.[90] Critically ill patients may develop anasarca. It is difficult to determine volume status by observation alone, and invasive monitoring may be required.

Electrolyte abnormalities are common in the perioperative period. Serum sodium reflects intravascular volume status. Hyponatremia signifies excess free water in the intravascular space, and is caused by excess antidiuretic hormone in the postoperative period. It occurs in the setting of normo-, hypo-, or hypervolemia. It may be avoided by judicious use of isotonic fluids. Conversely, hypernatremia suggests a relative deficit of intravascular free water. Patients who are unable to drink, or those with large insensible losses, are most at risk. Treatment includes free water replacement.

Diuretics, malnutrition, and gastrointestinal losses may cause postoperative hypokalemia. Metabolic alkalosis shifts potassium into the intracellular compartment. Serum potassium levels less than 3 mEq/L warrant ECG monitoring and replacement in patients who are not anuric. Replacement in patients with renal insufficiency may be complex. Hyperkalemia is more commonly seen in renal patients. It may also be seen in myonecrosis, hemolysis, and acidosis. Cardiac arrhythmias are seen at levels above 6.5 mEq/L and death is associated with levels greater than 8 mEq/L. These patients should have cardiac monitoring until their levels normalize. ECG will show widened QRS interval, peaked T waves, and absent P waves. Hyperkalemia should be treated with sodium bicarbonate to stimulate acidosis, as well as intravenous calcium and insulin with glucose to drive potassium into the intracellular compartment. Cation exchange resins can be administered orally or per rectum to bind ions in the gastrointestinal tract, but care should be taken for the patient who is post–GI surgery or has underlying gastrointestinal problems. Dialysis can by employed if other measures fail.

GLYCEMIC CONTROL

Hyperglycemia is a risk factor for postoperative infection and perioperative mortality. Intensive insulin therapy (IIT) has been associated with improved outcomes for intensive care unit patients, and after cardiac surgery, in brain injury and after acute MI. However, early enthusiasm for IIT has waned as more recent studies have shown that it is not as beneficial in medical patients as it is in surgical patients, and has been associated with severe hypoglycemia.[91] More recently, a meta-analysis of 29 randomized trials of IIT in adult ICU patients showed no difference in mortality in patients receiving IIT versus conventional insulin therapy with goal blood sugar <200 mg/dL.[92]

Although there does appear to be consensus that controlling glucose is a worthwhile therapeutic goal in surgical patients in particular, appropriate targets for control remain controversial. While hyperglycemia is associated with increased infection and mortality,[93] IIT is associated with hypoglycemia and increased mortality. Results from a recent international, randomized controlled trial in ICU patients demonstrated a 2.6% increase in absolute risk of death in ICU patients with blood glucose target of 81–108 mg/dL versus 180 mg/dL.[94] Others suggest that the variability in glucose level may affect morbidity and mortality more than blood glucose levels alone.[95] More investigation is needed to determine the optimal way to manage blood glucose levels in the postoperative patient.

Our current recommendations for glucose control in noncardiac surgery patients is to maintain blood glucose less than 180 mg/dL.

HEMATOLOGICAL EVALUATION

A complete preoperative evaluation should include assessment of hematological disorders, which can increase the risk for postoperative bleeding or thromboembolism. Patients should be asked about a family history of bleeding disorders and personal history of bleeding problems, especially after procedures. Excessive bleeding after dental procedures and menorrhagia in women can alert the physician to undiagnosed hematologic disease. Risk factors for postoperative hemorrhage include known coagulopathy, trauma, hemorrhage, or potential factor deficiency.[96] Factor deficiencies can be seen with a history of liver disease, malabsorption, malnutrition, or chronic antibiotic use. Even high-risk patients have only a 1.7% risk of postoperative hemorrhage and a 0.21% risk of death related to postoperative hemorrhage.[96,97]

Routine tests may include a complete blood count, prothrombin time (PT), activated partial thromboplastin time (PTT), and INR, but are not required in the asymptomatic patient with no associated history. The complete blood count will reveal leukocytosis, anemia, and thrombocytopenia or thrombocytosis. A baseline hematocrit is useful for postoperative management when anemia is suspected. Platelet count also provides a useful baseline, but does not provide information about platelet function. A bleeding time may be required to provide more information in select patients. However, bleeding time results are operator dependent and highly variable, making it a poor screening tool for identifying high-risk patients.[98,99] An abnormal bleeding time is not associated with increased postoperative bleeding,[100] nor has it proven useful in identifying patients taking nonsteroidal anti-inflammatory medication or aspirin.[98] None of the aforementioned tests can be used to diagnose hereditary bleeding disorders. However, an elevated PTT may be seen in factor XI deficiency, and should be obtained in patients at risk for this deficiency. Low-risk patients are very unlikely to have bleeding complications even if the PTT is abnormal,[99] and have an increased risk of false-positives that can lead to unnecessary testing. PTT is not a reliable predictor of postoperative bleeding,[101] and should not be used to screen for bleeding abnormalities in patients without symptoms or risk factors.[102,103]

A platelet count of 20,000 or more is usually adequate for normal clotting. Aspirin causes irreversible impairment of platelet aggregation, and is commonly prescribed in patients at risk of cardiovascular and cerebrovascular disease. The clinical effect of aspirin lasts 10 days, and it is for this reason that patients are asked to stop taking aspirin 1 week before elective surgery. Desmopressin can be used to partially reverse platelet dysfunction caused by aspirin and uremia. Other NSAIDs cause reversible platelet dysfunction and should also be held before surgery. Glycoprotein IIb-IIIa inhibitors prevent platelet-fibrin binding and platelet aggregation, and are used for 2–4 weeks after coronary angioplasty. Elective surgery should be avoided during these 2–4 weeks, as stopping treatment increases the risk of thrombosis. Patients who do not receive 4 weeks of antiplatelet therapy are at risk of stent thrombosis.[104]

Indications for red blood cell transfusion remain somewhat controversial and are often empirical in practice. Transfusing one unit of red blood cells or whole blood can increase the hematocrit by approximately 3% or hemoglobin by 1 g/dL. Multiple studies have demonstrated that overutilizing transfusion may adversely affect patient outcome and increase risk of infection. ASA guidelines[105] suggest that transfusion should be based on risks of inadequate oxygenation, rather than a threshold hemoglobin level. Generally, transfusion is rarely indicated when the hemoglobin level exceeds 10 g/dL, but is almost always indicated when it is less than 6 g/dL, especially in the setting of acute anemia. Healthy individuals can usually tolerate up to 40% of blood loss without requiring blood cell transfusion, and blood products should not be used solely to expand volume or to improve wound healing. The decision to transfuse red cells or whole blood should be based on the patient's risk of complications associated with impaired oxygen delivery, including hemodynamic indices, history of cardiopulmonary disease, rate of blood loss, and preexisting anemia.

Conditions associated with abnormal platelets and low platelet counts can be treated with platelet transfusions. The usual dose, one unit of platelet concentrate per 10 kg body weight, can be expected to increase the platelet count by approximately 5,000–10,000 in an average adult. In patients without increased risk of bleeding, prophylactic platelet administration is not indicated until counts fall below 20,000. Higher thresholds may be indicated for patients at increased risk of bleeding, known platelet dysfunction, and microvascular bleeding. Desmopressin can augment platelet function in uremia and incite release of Von Willebrand's factor (VWF) from the endothelium, which can improve platelet function. The decision to transfuse platelets should be based on the amount of bleeding expected, the ability to control bleeding, and the presence of platelet dysfunction or destruction.

Transfusion of fresh frozen plasma (FFP) is indicated to reverse warfarin before procedures or in the presence of active bleeding, for inherited or acquired coagulopathy that can be treated with FFP, and for massive transfusion of more than one whole blood volume. Microvascular bleeding can be seen if the PT/PTT is greater than 1.5 times normal, and FFP can be used to reverse bleeding in this setting. Warfarin reversal can be achieved with doses of 5–8 mL/kg, and 30% factor concentration can be achieved with 10–15 mL/kg. FFP should not be used to address volume depletion alone. Cryoprecipitate contains factors VIII, VWF, XIII, fibrinogen, and fibronectin, and can be used preventively in patients with these factor deficiencies and uremia.

Endothelial injury and venous stasis are the greatest risk factors for VTE. The patient with hereditary thrombophilia, or a personal history of VTE, cancer, or recent surgery (within

4 weeks) has an increased risk of VTE.[106] Preventive measures include external pneumatic leg compression, early mobilization after surgery, and anticoagulation. Compression devices are contraindicated in patients with severe peripheral vascular disease, venous stasis, or risk of tissue necrosis. Inferior vena cava (IVC) filters are indicated in patients who cannot take anticoagulation or who have failed anticoagulation therapy. Patients with a history of VTE benefit from IVC filter placement in the short term, but IVC filter placement is accompanied by an increased incidence of deep venous thrombosis over the long term.[107] Systemic anticoagulation is the preferred long-term option. LMWH and UFH are equally effective for prevention of pulmonary embolism in patients with deep venous thrombosis.[107] Recent VTE, atrial fibrillation, and mechanical heart valves are common indications for warfarin treatment.

Clinically, UFH activity is measured by PTT and the therapeutic goal is usually 2.0–2.5 times normal. LMWH is a relatively stronger inhibitor of factor Xa and does not have the same effect on the PTT. The anticoagulant effect of LMWH is measured by factor Xa activity. Protamine can reverse the effects of heparin, but may cause allergic reactions and induce hypercoagulability, and should be used cautiously. FFP will not reverse heparin, and can actually increase heparin activity because it contains antithrombin III. Direct thrombin inhibitors can also prolong the PTT. Direct thrombin inhibitors are not reversible with protamine and may require large amounts of FFP for reversal.

Heparin can be used for the prevention and treatment of VTE. Surgical patients over age 40 or those at increased risk for VTE should receive 5,000 U SC every 8–12 hours, depending on their weight. High-risk patients with a history of VTE, cancer, morbid obesity, or those having orthopedic procedures should either receive SC heparin with a goal of high range of normal or LMWH. In the event of acute VTE intravenous heparin should be started promptly with a therapeutic goal of PTT 1.5–2.0 times normal. Oral anticoagulation should be started within 24 hours and continued for 3–6 months.[106]

Heparin-induced thrombocytopenia (HIT) is a potentially lethal complication of heparin therapy. HIT is caused by an IgG mediated hypersensitivity reaction between the heparin moiety and platelet factor 4 (PF4). Patients with previous heparin exposure, such as orthopedic and cardiac surgical patients, are at greatest risk. The incidence of HIT is 0.5–5.0% in patients receiving UFH. HIT occurs with UFH or low molecular weight heparin; the risk is highest with UFH.

Platelet counts usually drop 40–50% from baseline. Thrombosis can be venous or arterial leading to deep vein thrombosis, extremity ischemia, and mesenteric ischemia of stroke. Digital ischemia and skin necrosis can also be seen. HIT remains a clinical syndrome which can be diagnosed by a decrease in platelet count <405 of baseline in 4–14 days of heparin administration once other causes of thrombocytopenia have been ruled out. The diagnosis can be supported by the ELISA assay for antiplatelet antibodies.

Because HIT can be life-threatening, heparin should be stopped as soon as HIT is suspected, and treatment with an alternative anticoagulant, such as the thrombin inhibitor bivalrudin, should be started immediately. Platelets should return to baseline after therapy is initiated. If thrombosis is present, patients should be anticoagulated for 6 months with Coumadin. Coumadin should not be started until platelet counts have recovered.

Warfarin inhibits synthesis of vitamin K–dependent clotting factors (II, VII, IX, X, and proteins C and S). Poor diet, prolonged antibiotic use, and fat malabsorption can also cause vitamin K deficiency and cause abnormal coagulation. Liver disease can lead to multiple coagulation abnormalities including factor deficiencies, vitamin K deficiency, fibrinolysis, and elevated levels of fibrin degradation products. All patients with known or suspected liver disease should be tested for coagulopathy. Vitamin K can be administered subcutaneously or intravenously in deficient patients. The initiation of warfarin therapy is associated with a transient thrombotic state because plasma concentrations of protein C fall approximately 24 hours before concentrations of other clotting factors.

Heparin is the drug of choice for VTE during pregnancy because it does not cross the placenta. Adverse effects of heparin therapy may include hemorrhage, thrombocytopenia, and osteoporosis. HIT is an immune disorder seen in patients with prior exposure to heparin, which may cause thrombosis. Treatment includes cessation of heparin and utilization of alternative anticoagulants such as lepirudin, danaparoid, or argatroban. These should be given until platelet counts recover.

For patients on long-term anticoagulation therapy, the INR should be 1.5 or lower before elective surgery. After warfarin is discontinued, it takes about 4 days for an INR in the range of 2.0–3.0 to spontaneously reach 1.5, and about 3 days for the INR to reach 2.0 after it is restarted. If therapy is withheld preoperatively, most patients will have a window of 2–4 days when they are not anticoagulated and at risk for venous thrombosis. This risk is compounded by the increased risk of thromboembolism associated with surgery.[108,109] It has been estimated that surgery increases the risk of VTE by 100-fold in patients with recurrent disease.[110] Without anticoagulation, there is a 50% chance of recurrence within the 3 months after the first episode of venous thrombosis. Warfarin therapy reduces the risk to 10% after 1 month and 5% after 3 months. It is not advisable to interrupt anticoagulation within 1 month after an event of VTE, and if possible, surgery should be deferred until the patient has completed 3 months of therapy.[110] Chronic anticoagulation lowers the risk of thromboembolism in patients with atrial fibrillation and mechanical heart valves by 66% and 75%, respectively.[110]

Patients with prior embolic episodes are at increased risk for recurrence. Six percent of episodes of VTE and 20% of arterial thromboembolism may be fatal,[110] and a significant percentage cause disability. Alternatively, the risk of death after postoperative hemorrhage is less than 1%,[111] so the judicious use of postoperative anticoagulation can be relatively protective. Preoperative heparinization is not required during the second and third months of warfarin treatment for

deep vein thrombosis (DVT) because the risk is sufficiently low. Such patients have increased VTE risk after surgery and should receive postoperative anticoagulation. Patients who are at risk for recurrent DVT, and are within 2 weeks of the first episode, or who cannot tolerate anticoagulation are candidates for an IVC filter.[107]

Elective surgery should be deferred for the first month after arterial embolism because of the high risk of recurrence during this period. If necessary, patients should receive perioperative heparin while oral anticoagulation is held. Patients on long-term anticoagulation to prevent arterial thromboembolism do not need perioperative heparin because the risk of bleeding outweighs the risk of arterial embolism during this period.

Heparin should be titrated to a goal PTT of 1.5–2.0 times normal and given as a continuous intravenous infusion. It should be stopped 6 hours prior to a procedure, and can be restarted 12 hours after surgery if there was no evidence of bleeding at the end of the case. Heparin can be restarted without a bolus at the anticipated maintenance infusion rate.[110,111]

INFECTIOUS COMPLICATIONS

Infectious complications can be most unwelcome and difficult to control after major abdominal surgery, yet they are surprisingly frequent despite all modern prophylactic measures. Reported surgical wound infection rates in elective operations vary from 2% for inguinal hernia repair[112] to 26% for colectomy,[113] and are even higher for emergency surgery.[114] Surgical site infections (SSIs) increase overall mortality and morbidity, and increase hospital length of stay and overall costs. Therefore prevention and treatment of infectious complications should be included in surgical decision making for all abdominal procedures.

Prevention of SSIs begins with preoperative evaluation and identification of patients at high risk for SSI. Patient factors implicated in risk of SSI include age, diabetes mellitus, smoking, steroid use, malnutrition, obesity, active distant infection, prolonged hospital stay, and nasal colonization with *Staphylococcus aureus*.[115–118]

Standard basic surgical rules should be followed with every patient. These were codified as formal guidelines by the Centers for Disease Control and Prevention (CDC) in 1999[119] and include recommendations for skin preparation with alcohol or iodophor, surgical barriers such as drapes and gowns, careful hand scrubbing, and appropriate selection of prophylactic antibiotics. Preoperative hair removal and antiseptic shower have not been shown to decrease SSI rates, and shaving and clipping of hair can increase SSIs. The CDC recommendations are summarized in Table 2-7. (See Table 2-3 for extended recommendations.)

Antibiotic prophylaxis may be indicated for patients at high risk, or in contaminated surgical procedures, but antibiotics should not be used indiscriminately. Overuse of antibiotics is associated with emergence of multidrug-resistant bacteria and increased rates of hospital-acquired infections. Selection of patients for antimicrobial prophylaxis requires stratification of patient risk factors as discussed above and procedure-specific risk factors. The degree of contamination in the surgical site has long been recognized as an independent risk factor for SSI,[120] leading to the wound classification system (Table 2-8) in use since 1983.

Patients undergoing class I (clean) procedures have a very low infection rate and generally do not benefit from prophylactic antibiotics, unless there is some suspicion at the start of the procedure that some contamination may occur, such as unplanned enterotomy in a patient with many previous abdominal procedures. In addition, many surgeons prefer to use antibiotic prophylaxis in class I procedures when a prosthesis is implanted; examples include hernia repair and vascular bypass. In this setting, the risk of SSI is low, but the morbidity and mortality of an infected prosthesis are great, and prophylaxis may decrease the risk. To date, large prospective trials have not shown benefit of antibiotic prophylaxis in preventing prosthetic infections,[121,122] but smaller trials have suggested a decrease in site infection without

TABLE 2-7: CDC CATEGORY 1 RECOMMENDATIONS FOR REDUCTION OF SURGICAL SITE INFECTIONS

These are strongly recommended based on best clinical evidence:

Identify and treat distant infections prior to surgery
Do not remove hair routinely; if hair must be removed, use electric clippers immediately prior to surgery
Control hyperglycemia in the perioperative period
Cease tobacco smoking 30 days prior to surgery
Antiseptic shower the night prior to surgery
Antiseptic skin preparation
Surgery team should practice hand scrubs
Administer appropriate antimicrobial prophylaxis
Surgical barriers (gown, gloves, hat, mask)
Do not close contaminated skin incisions

TABLE 2-8: SURGICAL WOUND CLASSIFICATION

Class I. Clean
Uninfected wounds without contamination

Class II. Clean/contaminated
Uninfected wounds in procedures where the respiratory, gastrointestinal, or genitourinary tracts are entered in a controlled fashion without gross spillage

Class III. Contaminated
An operation with major breaks in sterile technique, gross spillage, or incisions into inflamed but not suppurating infections; fresh accidental wounds

Class IV. Dirty/infected
Wounds with necrotic or devitalized infected tissue

change in implant infection rate.[123,124] Therefore, there is no strict guideline for the use of systemic antibiotics for implant surgery, and the surgeon must tailor the use of antibiotics to the individual patient's risk.

Patients with class II (clean/contaminated) surgical wounds do benefit from systemic antibiotic prophylaxis. The most studied example of this class of wound is elective colon resection. Most current guidelines recommend systemic broad-spectrum antibiotic coverage using a second-generation cephalosporin plus metronidazole if the parenteral route is used, and neomycin plus metronidazole or erythromycin base (both as nonabsorbable antibiotics), if the oral route is used.[125] Published evidence supports administration of antibiotics preoperatively in order to achieve maximum therapeutic levels at the time of incision, and repeat dosing to maintain therapeutic levels during a long procedure. There is no documented study showing benefit to additional doses of antibiotics after the procedure is over and the skin is closed, and prolonged use of prophylactic antibiotics contributes to emergence of resistant bacteria.[126,127]

Patients with class III (contaminated) wounds are a mixed population. Some of these wounds are the result of inadvertent entry into a contaminated field, some result from traumatic injury, and some are planned operations for débridement of infected tissue. In the latter case, antibiotic therapy is indicated for specific therapy rather than prophylaxis. In the case of penetrating traumatic injury to the colon, there is strong evidence to support single-dose antibiotic prophylaxis at the time of laparotomy, similar to elective colon resection.[128,129] Surgical judgment must be individualized in these cases as to whether the risk of skin closure can be justified due to the high rate of wound infection despite antibiotic prophylaxis.

Patients with class IV (dirty) wounds are generally undergoing débridement of already infected and necrotic tissue, and should be receiving antibiotic therapy targeted to the relevant organisms. Skin wound closure is generally not advised in these patients.

The wound classification system does not take into account patient risk factors or site-specific risk factors. Various physiologic scoring systems including the Acute Physiology Score and the Acute Physiology, Age, and Chronic Health Evaluation index have been used to predict perioperative infection risk with some success. In an effort to provide more accurate risk stratification, the CDC's National Nosocomial Infection Surveillance project has developed a risk index that accounts for patient risk factors such as malnutrition and chronic medical conditions, and operative factors including duration and site of procedure.[130] Enlightened risk assessment of perioperative infections should be included in the discussion for informed surgical consent.

NUTRITIONAL EVALUATION

The importance of proper nutritional assessment and management cannot be overstressed. In surgical patients, malnutrition increases risk for major morbidity,[131,132] including wound infection, sepsis, pneumonia, delayed wound healing, and anastomotic complications. Careful preoperative clinical assessment can identify those patients at increased nutritional risk. The assessment should include a thorough history and physical examination with attention paid to usual weight, recent weight loss, changes in eating and bowel habits, changes in abdominal girth, loss of muscle bulk, and the presence of diseases that carry a risk of malnutrition such as COPD, diabetes mellitus, inflammatory bowel disease, and psychiatric conditions such as bulimia and anorexia nervosa. The history and physical examination should identify those patients with nutritional risk; that risk can be stratified by calculation of the Nutritional Risk Index (NRI). The NRI is a simple calculation ($15.19 \times$ serum albumin (g/dL) $+ 41.7 \times$ present weight/usual weight), which has been shown in prospective studies to correlate with increased rates of mortality and complications from major abdominal surgery.[133,134] NRI less than 83 indicates a significantly increased rate of mortality and complications, especially wound dehiscence and infection. Severely malnourished patients have been shown to benefit from preoperative nutritional support.[135,136]

Malnutrition can be classified into protein deficiency (kwashiorkor), calorie deficiency (marasmus), or mixed protein calorie deficiency. In order to complete the nutritional assessment and to guide nutritional support, it is useful to classify the patient's specific nutritional state (Table 2-9). Malnutrition states are much more common than is generally acknowledged, with 30–55% of hospital inpatients meeting criteria for one of the diagnoses.[137]

Some interval of deficient nutritional intake is expected after an abdominal operation. In uncomplicated cases, this is usually the result of postoperative adynamic ileus and resolves promptly, in less than 7 days. Traditional surgical management includes provision of dextrose-containing intravenous fluids. The goal of this therapy is not to provide sufficient calories for complete nutritional support, but simply to provide enough carbohydrate to prevent breakdown of lean body mass. Certain organs, including the heart and brain, have an obligate requirement for carbohydrate as a primary energy source, and do not store energy in the form of fat or glycogen. If intake is insufficient to meet this requirement, the body breaks down hepatic glycogen to provide glucose to the circulation, and ultimately the brain and heart. Once hepatic glycogen stores have been depleted (after about 1 day of no intake), lean muscle mass is converted to glucose via gluconeogenesis to produce carbohydrate. Provision of only 100 g of exogenous glucose per day is sufficient to prevent breakdown of lean muscle mass in otherwise healthy subjects.

In already malnourished patients, or in patients who do not return to normal bowel function promptly, nutritional support is indicated. As in the preoperative setting, a thorough evaluation of the patient's nutritional status is necessary, as is the identification of the cause of bowel dysfunction. In the postoperative setting, there are many potential causes of bowel dysfunction (Table 2-10), and nutritional support should be individualized for each patient's needs. Some patients may respond to enteral support and some may require parenteral support. Whenever available, the enteral

TABLE 2-9: ASSESSMENT OF NUTRITIONAL STATUS

Protein Deficiency Criteria

Albumin <2.2 g/dL
Total lymphocyte count 800/mm^3 or less
Weight maintained
Peripheral edema
Inadequate protein intake (<50% of goal for 3 days or <75% for 7 days)
Four criteria out of these five establish the diagnosis of protein deficiency

Calorie Deficiency Criteria

Weight loss: 5% over 1 month or 7.5% over 3 months or 10% over 6 months
Underweight: less then 94% ideal body weight (IBW)
Clinically measurable muscle wasting
Serum protein maintained
Inadequate calorie intake (50% for 3 days or <75% for 7 days)
Three criteria out of these five establish diagnosis of calorie deficiency

Mixed Protein Calorie Malnutrition Criteria

	Mild	Moderate	Severe
Weight loss	5–9%	10–15%	10–15% over 6 months
Underweight	94–85%	84–70%	<70% ideal weight
Albumin	2.8–3.4 g/dL	2.1–2.7 g/dL	<2.1 g/dL
Total lymphocytes	1499–1200/mm^3	1199–800/mm^3	<800/mm^3
Transferrin	199–150 mg/dL	149–100 mg/dL	<100 mg/dL
			Muscle wasting
			Deficient intake (at least 3 days)

route is the preferred route of support, as it has been shown to cause less morbidity and mortality.[138]

Enteral nutritional support is effective in patients that have functional small bowel; examples include esophageal or gastric resection, patients with postoperative delirium or dysphagia, and patients who have gastroparesis. In the short term, if the dysfunction is expected to respond to treatment, nasogastric tubes can be used effectively to deliver full support. Patients that need long-term enteral support are best served with gastrostomy or jejunostomy tubes, which may be placed operatively or percutaneously. With good preoperative nutritional assessment and sound surgical judgment, these patients' needs for long-term postoperative support can often be anticipated, and long-term feeding access can be included in the operative plan. Enteral support may not be suitable for some patients; examples include early postoperative bowel obstruction, fistula, or intestinal insufficiency (short-gut syndrome). In such patients, parenteral support is indicated, and should be initiated without delay, and futile attempts to use the enteral route should be avoided.

To establish the diagnoses of mild or moderate protein calorie malnutrition, two of the five criteria shown must be met; to establish the diagnosis of severe protein calorie malnutrition, three of the seven criteria must be met.

Irrespective of the route of support, every patient on nutritional support should have his or her nutritional needs assessed and provided. The assessment begins with the calorie requirement. There are several formulas and nomograms that estimate basal energy expenditure, taking into account height, weight, age, gender, stress factors, and activity factors.[139] All of these methods are estimations, and may underfeed or overfeed certain subgroups, especially the obese. The method in most common clinical use bases basal energy expenditure on adjusted body weight (ABW). Using this method, ABW is defined as the patient's ideal body weight (IBW) plus the difference between actual body weight (BW) and the IBW divided by two:

$$ABW = IBW + 0.5(BW - IBW)$$

The baseline caloric requirement for weight maintenance based on ABW is 25 kcal/kg/d. This target may be adjusted upward in patients with extreme metabolic demands, as is the case in burns or head injury.[126] Furthermore, the ABW can be used to establish the protein requirement. In unstressed normal subjects, the minimum daily protein requirement is 0.8 g protein/kg/d. In postoperative patients with healing wounds, this target is adjusted to 1.0–1.5 g/kg/d, and in severely ill patients to 2.0 g/kg/d. The highest requirements are seen in severe burn and bone marrow transplant patients.

Essential nutritional components must be provided, again irrespective of the route of support. These include water- and lipid-soluble vitamins, trace elements such as zinc and selenium, essential fatty acids such as linoleic and linolenic acids, and the eight essential amino acids. These trace elements are provided in abundance in all enteral feeds, and are part of the standard additives in parenteral formula.

Once nutritional support has been initiated, the patient's response to support must be followed closely, especially in parenteral support and in patients with preexisting metabolic conditions such as diabetes. Blood glucose should be

TABLE 2-10: POSTOPERATIVE CAUSES OF DEFICIENT NUTRITIONAL INTAKE

Ileus
Bowel obstruction
Colitis (ischemic, infectious)
Fistula
Dysphagia
Gastric dysmotility
Intestinal insufficiency (short-gut syndrome)

monitored regularly during the first few days of support. Recent evidence has linked hyperglycemia in the postoperative setting, especially in critically ill patients, with increased risk of death and infection.[140,141] In addition, electrolyte abnormalities (especially those of potassium, magnesium, and phosphate) are often seen in the early period of nutritional support, and should be corrected.

It is also important to follow the markers of nutrition repletion to ensure that the calories and protein provided (based on the initial estimate) are sufficient, and the patient is not mobilizing lean body mass due to inadequate support. Serum markers such as prealbumin, retinol binding protein, and transferrin can be useful in this regard. They are serum proteins with short (2–7 days) turnover times that reflect the body's ability to synthesize new protein.[139] Unfortunately, the serum concentrations of these proteins are also affected by acute disease states and renal and hepatic failure, and can be difficult to interpret in postoperative patients. Nitrogen balance can also be used to monitor nutritional support and reflects the ability to synthesize new protein. Nitrogen balance is calculated by subtracting nitrogen excretion from nitrogen intake. Nitrogen intake is calculated from the protein intake, where each gram of protein divided by 6.25 is equal to the number of grams of nitrogen. Nitrogen excretion has two components: urinary urea nitrogen (UUN) and insensible loss. UUN can be measured in a 24-hour urine collection; insensible loss is generally accepted to be 4 g/d, unless there is another source of loss, such as abdominal drainage of proteinaceous ascites, enterocutaneous fistula, or nephrotic syndrome. Thus, in most cases, nitrogen balance can be simplified to:

$$\text{Nitrogen balance} = \text{protein intake}/6.25 - 24 \text{ hour UUN} - 4\text{g (insensible loss)}$$

A patient that takes in more nitrogen than he or she excretes in the urine and feces is in positive nitrogen balance and is synthesizing new protein. On the other hand, a patient that is excreting more nitrogen than he or she is receiving in nutritional support is in negative nitrogen balance, and is therefore losing lean body mass, becoming more malnourished. These patients should be reevaluated for nutritional needs and for sources of nutritional depletion, such as uncontrolled diabetes mellitus, sepsis, and organ failure.

By itself, uncontrolled diabetes mellitus can be viewed as a perioperative nutritional complication, as it results in nutritional depletion, interferes with delivery of parenteral and enteral nutrition, and is associated with increased infectious morbidity.[140,141]

ENDOSCOPY AND ENDOSCOPIC INTERVENTION

Jeffrey M. Marks • Jeffrey L. Ponsky

Over the past several decades, flexible endoscopy has shifted the management of numerous gastrointestinal diseases from the surgeon to the endoscopist. What had started as a diagnostic discipline has now become one of advanced therapeutic potential. The concept of performing endoscopic surgery has become a reality with the advancement of endoluminal therapies for neoplasia, gastroesophageal reflux, and obesity. In addition, with the significant investigation into natural orifice translumenal endoscopic surgery (NOTES) and the development of advanced endoscopic tools, the ability to perform intraperitoneal therapies without abdominal scars continues to become more possible. This chapter will address the indications and techniques for upper and lower flexible endoscopy as well as the recent advances in imaging and interventional endoscopy.

THE FLEXIBLE ENDOSCOPE

Imaging

The flexible endoscope was initially developed in 1957 as an imaging device dependent on the delivery of light and transmission of the image along multiple bundles of chemically treated glass fibers. The fiberoptic bundle is 2–3 mm wide and is composed of 20,000–40,000 individual fine glass fibers, each approximately 10 μm in diameter.[1] The image undergoes a series of internal reflections within each fiber, which are coated with low optical density glass to prevent escape of light, as it is transmitted up the bundle. Due to formation of the fibers and surrounding material, a characteristic meshed image is seen in fiberoptic endoscopes, which inherently results in a lower resolution than that seen with rigid lens systems. In addition, if the fibers become cracked, the image is not generated at this site of the bundle and multiple black spots are seen.

When utilizing a fiberoptic endoscope, the endoscopist views the image through the eyepiece at the instrument head, or alternatively, a video camera can be affixed to the eyepiece to transmit the image to a video monitor. The progression from fiberoptic scopes to the videoendoscopes, we use today, has allowed for advancements in our ability to perform more involved therapies, educate physicians and endoscopic assistants, and obtain static and dynamic recorded data images for improved clinical management.

The majority of endoscopes in use today are videoscopic, although in many parts of the world, fiberoptic systems are still the standard. In these videoscopic systems, the visualized image is created from reflections onto a charge coupled device (CCD), which is a chip mounted at the end of the endoscope rather than via the fiberoptic bundles. The CCD chip has thousands of pixels (light-sensitive points), which directly increase image resolution.[2]

Imaging Advances

There have been many recent advances in endoscopic imaging techniques. The purpose of most of these techniques is early detection of dysplasia, which might elude standard endoscopic visualization. Clinical use of new imaging is limited principally to specialized centers, but future widespread application of an imaging method for early dysplasia detection is a certainty.

CHROMOENDOSCOPY

The aim of chromoendoscopy is to detect subtle mucosal abnormalities. Commonly used agents include Lugol's solution, methylene blue, indigo carmine, and Congo red. A 2–3% solution of potassium iodide (Lugol's solution) reacts with glycogen in keratinized squamous epithelium. Normal squamous epithelium stains a deep brown, but inflammation, dysplasia, and carcinoma do not stain because of a lack of glycogen. Lugol's solution has been shown to be effective in detecting Barrett's esophagus as well as screening for squamous cell carcinoma of the esophagus.[3]

MAGNIFICATION ENDOSCOPY

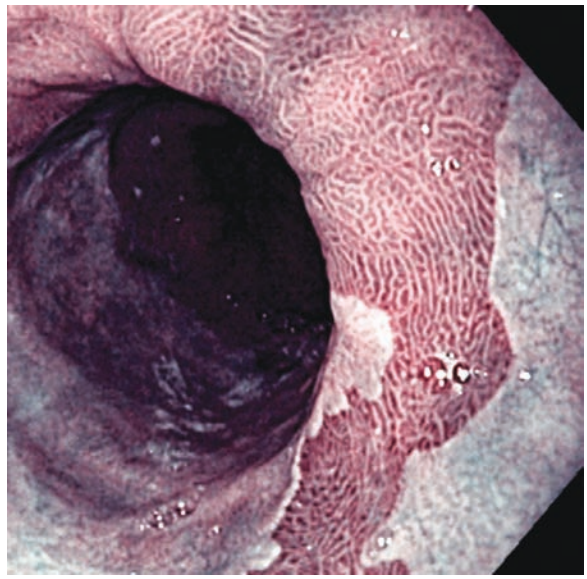
In magnification endoscopy, a cap with a magnifying lens is fitted to the tip of an endoscope. The mucosa in contact with the lens is magnified without impairing the maneuverability of the scope. Degrees of magnification range from 1.5× to 115× and can be changed on the scope by turning a dial at the hand controls. The technique of magnification endoscopy is frequently used in conjunction with chromoendoscopy. Chromoendoscopy is used for broad surveillance of the mucosa followed by focused examination of suspicious lesions in magnification mode. This combined examination has been reported in case series to enhance detection of Barrett's esophagus, chronic gastritis, Helicobacter pylori infection, gastric dysplasia, and early gastric cancer.[4–6]

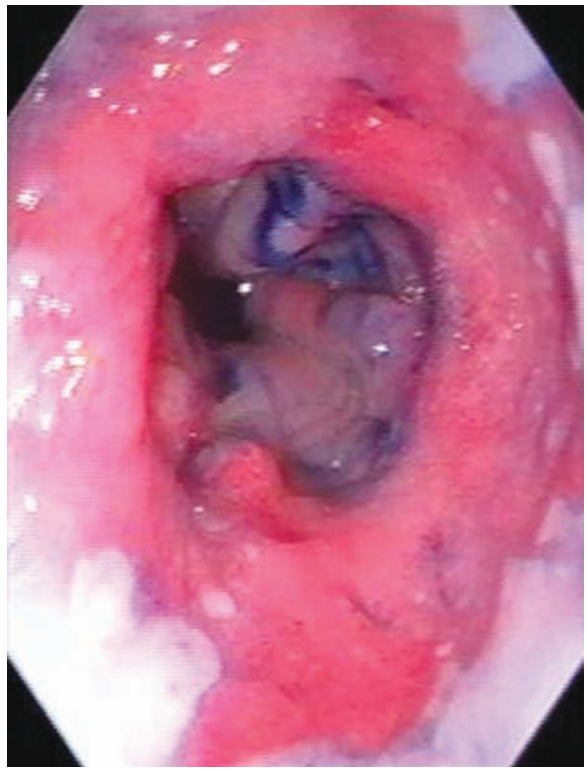
CONFOCAL FLUORESCENCE MICROENDOSCOPY

Standard endoscopy uses white light to visualize a large surface area with relatively low resolution. In contrast, confocal endoscopy aims to visualize the mucosa and submucosa with subcellular resolution, a technique deemed optical biopsy. The process of confocal magnification reduces out-of-focus light from above and below the focal plane at a magnification of 1000×. The system is designed to measure tissue fluorescence; therefore, an exogenous fluorophore (a molecule that causes another molecule to be fluorescent) is usually administered. Varying depths of tissue are examined by altering the focal plane, and images from different depths are stacked together to create an optical slice of tissue, thus the term optical biopsy.[4]

NARROW BAND IMAGING

Most endoscopes now have the ability to switch from standard to narrow band imaging (NBI) with the push of a button. In narrow band endoscopy, filtered light is used to preferentially enhance the mucosal surface, especially the network of superficial capillaries. Narrow band imaging is often combined with magnification endoscopy. Both adenomas and carcinomas have a rich network of underlying capillaries and enhance on NBI, thereby appearing dark brown against a blue-green mucosal background.[5] The use of white light as well as NBI has enabled endoscopists to provide an immediate assessment of small colonic lesions without histopathologic evaluation.[7] Gastric mucosal abnormalities are also differentiated by NBI with and without magnification endoscopy.[8] NBI can also differentiate squamous from nonsquamous epithelium to help identify Barrett's esophagus (Figs. 3-1 and 3-2).





FIGURES 3-1 AND 3-2 Standard white light versus NBI imaging of the distal esophagus in patients with Barrett's esophagus (top). Differentiation of the squamous and columnar mucosa is easily seen in the NBI image (bottom).

AUTOFLUORESCENCE

Autofluorescence endoscopy has been shown in pilot studies to improve the detection of dysplasia in Barrett's esophagus and chronic ulcerative colitis. Autofluorescence endoscopy relies on several principles: tissue architecture changes, such as mucosal thickening, dampen submucosal autofluorescence; neovascularization alters the light-emitting and scattering properties of surrounding tissue; the biochemical microenvironment, such as high oxidation-reduction activity, alters

autofluorescence; and different tissue types have unique distribution of fluorophores.[4,9]

OPTICAL COHERENCE TOMOGRAPHY

Endoscopic optical coherence tomography (OCT) is an emerging technology analogous to endoscopic ultrasound (EUS). OCT utilizes a probe passed via the endoscope, although it does not require tissue contact. The technique uses reflection of near-infrared light to produce real-time two-dimensional cross-sectional images of the gastrointestinal tract. These true anatomic images correspond to the histologic layers (mucosa, submucosa, and muscularis propria). The images obtained have a resolution 10-fold greater than EUS (Fig. 3-3). Preliminary studies have looked at the utility of OCT in the evaluation of Barrett's esophagus.[10] Endoscopic optical coherence tomography is not yet in widespread use.

LIGHT SCATTERING SPECTROSCOPY

Light scattering spectroscopy mathematically analyzes the intensity and wavelength of reflected light to estimate the size and degree of crowding of surface epithelial nuclei. The technique relies on absorption and scattering of white light. Light scattering spectroscopy has shown limited efficacy in detecting Barrett's esophagus and early colonic dysplasia. The technique relies on graphing mathematical computations rather than an optical biopsy as is done in other emerging imaging techniques. Light scattering spectroscopy might be used in combination with optical biopsy for detection of early dysplasia.[4]

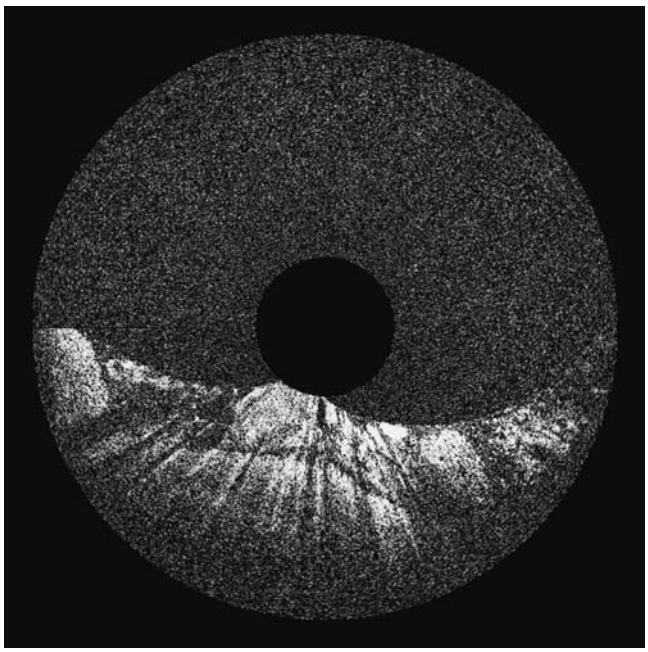


FIGURE 3-3 OCT image of the esophagus.

Image Documentation

Many gastrointestinal diseases require surveillance evaluation, and the progression or regression of identified disease state is vital to appropriate patient care. Video endoscopes produce digital signals that can be recorded on a variety of media, including film, hardcopy printout, disk, or a secure data file. During the procedure, it is imperative to visually document important findings and their location for comparison with previous or follow-up studies. This practice also allows other members of the health care team to understand and interpret the findings and plan for appropriate treatment. Additional documentation on anatomic diagrams will also facilitate interpretation. Pertinent negative findings should also be documented.

Endoscope Anatomy

Flexible endoscopes are being created in a wide variety of lengths and diameters, with an assortment of channel numbers and sizes, adjunct imaging modalities, and intrinsic and extrinsic scope mechanics for reducing scope looping and providing improved scope advancement. A basic understanding of the scope anatomy is vital to the performance of safe and effective flexible endosocpy.

Uniformally, the knobs for controlling manipulation of the scope tip are located on the right side of the headpiece, with an internal larger knob for upward and downward deflections and an external smaller knob, which manipulates the tip to the left and right. Locks accompany each knob to hold the deflection in position when needed. The ability for greater degree of deflection of the endoscope occurs with upward rather than downward manipulations. There is no variability in deflection provided by the right-left knob. In addition to manipulation of the deflecting knobs, significant scope rotation can be achieved by torquing the endoscope, altering the endoscopist's stance, or by rotating the headpiece while inserting or withdrawing the shaft of the endoscope.

There are two buttons on the front of the scope headpiece responsible for tip cleaning, air insufflation, and suction. The suction channel also functions as the biopsy channel so that any endoscopic tools placed into the biopsy channel will limit the ability to suction fluids through the endoscope. A small button on the front of the handpiece above the suction button allows for freezing of the image and digital recording by pressing the image capture button on the back of the handpiece. The endoscope is held in the left hand regardless of the individual physician's hand dominance. The internal up and downward deflection knob is controlled by the left thumb while the air, water, and suction by the left index and middle

fingers. The smaller left-right knob then is usually manipulated by the right hand.

One of the challenges in modern endoscopy, especially colonoscopy, is the formation of undesired loops in the shaft of a flexible scope. Loop formation impedes expeditious and safe passage to the cecum by transmitting the force of insertion to the colon wall or mesentery rather than to forward progression. Two technical advances aim to prevent loop formation: variable stiffness endoscopes and shape-locking overtubes.

VARIABLE STIFFNESS ENDOSCOPES

Conventional colonoscopes have a static level of column strength throughout the length of the insertion tube. The column strength determines the amount of buckling of the instrument that occurs during insertion and the level of elasticity that remains during reduction of loops. Variable stiffness endoscopes permit alteration of the column strength through an adjustable tensioning coil (Fig. 3-4). The data from studies comparing variable stiffness colonoscopes to conventional scopes are inconclusive. Some studies report faster cecal intubation using variable stiffness endoscopes with less need for adjunct maneuvers, while other similar studies report no significant differences.[11,12]

SHAPE-LOCKING DEVICE

The ShapeLock Endoscopic Guide (ShapeLock, USGI Medical, San Clemente, CA) consists of a reusable skeleton of multiple titanium links, a disposable inner plastic lining, an atraumatic foam tip, and a disposable smooth external skin. A squeeze handle at the base of the device converts it from a flexible mode to a rigid mode. The shape-locking device is made in 40 cm and 60 cm lengths with an inner diameter of 20 mm. A small clinical study has been reported using the shape-locking device. No device-related complications were noted, but the optimal strategy for employing the device was uncertain.[13]

FIGURE 3-4 The variable stiffness control is seen at the base of the head piece of the colonoscope.

New Scope Technology

While the construction of standard endoscopes has remained largely unchanged over many decades, novel scope designs are being developed to either simplify colonoscopic examinations or enhance mucosal visualization. Other than double balloon enteroscopy, these technologies are chiefly limited to small clinical trials, but their application could gain momentum in the coming years.

SELF-PROPELLED COLONOSCOPES

In an effort to simplify the process of colonoscopic screening, self-propelled endoscopes are in development. The Aer-O-Scope (GI View, Ltd, Ramat Gan, Israel) is a user-independent, self-propelled, self-navigating colonoscope. The device consists of a disposable rectal introducer, supply cable, and a scope embedded within a scanning balloon. The device contains no working channel for therapeutic interventions; therefore, it is intended for screening purposes only. A small pilot study examined the proof of concept of the Aer-O-Scope. There were no device-related complications.[4]

Another self-propelled colonoscope, the ColonoSight (Stryker Corp, Kalamazoo, MI) employs air-assisted propulsion in a disposable system. A pneumatic mechanism generates the pressure to create the forward force, while an operator directs the scope using handles. The system uses light-emitting diode optics, rather than video or fiber optics, and has disposable working channels. A pilot study for ColonoSight reported intubation of the cecum in 88% of cases at a mean time of 12 minutes without any device-related complications.[4]

Endoscopic Education

Recent mandates from the American Board of Surgery now require surgical residents to graduate with an increased number of flexible endoscopy cases (50 colonoscopies, 35 esophagogastroduodenoscopies [EGDs]). To provide this experience and to improve the overall endoscopic education of surgery residents, a cohesive curriculum is needed.[14] An iteration of such a curriculum might include periodic simulation training for first-year residents, formal endoscopy rotations for junior residents, and intraoperative and advanced endoscopy for senior and chief residents.[15]

Efforts to improve endoscopic training have led to the development of computer simulators for teaching endoscopic skills. Currently, simulators are available for training in flexible sigmoidoscopy, gastroscopy, endoscopic retrograde cholangiopancreatography (ERCP), EUS, and colonoscopy.[16]

PATIENT ASSESSMENT, SEDATION, AND MONITORING

Patient Assessment

Although both upper and lower endoscopy can be performed unsedated, the majority of patients undergoing endoscopic procedures receive agents to provide conscious sedation. Preprocedural patient risk assessment, intraprocedural cardiopulmonary monitoring, and postprocedural recovery are vital to the performance of safe and effective endoscopic interventions. Preprocedural evaluation for ASA risk classification and Malampati score have become standard guidelines for most endoscopy units.[17] Elderly patients or those with preexisting cardiopulmonary conditions are at increased risk for these complications, as are those undergoing more extensive endoscopic interventions. Patients with diseases associated with the oropharynx or trachea, and those with morbid obesity, sleep apnea, or neuromuscular degenerative diseases require extra vigilance during endoscopic procedures.[18]

Monitoring

Monitoring should be performed before, during, and after the procedure by a dedicated endoscopy assistant. Signs that are routinely monitored include the patient's level of consciousness, degree of pain, vital signs, and respiratory status.[19] Supplemental nasal oxygen is required to decrease the frequency of desaturation during endoscopic procedures. The patient's oxygenation status and cardiac electrical activity are also monitored by equipment throughout the procedure. It must be understood that pulsoximetry levels can rule out hypoxia and hypoventilation, and resultant hypercarbia can still go undetected. At this time, measurement of end tidal CO_2 monitoring, however, is just beginning to be utilized at the time of endoscopic interventions. In addition, external suction for clearing oropharyngeal secretions must be immediately available and within reach of the endoscopic assistant.

Sedation

The combination of narcotics (analgesia) and benzodizepines (sedation and amnesia) is commonly used to provide sedation during endoscopic procedures.[20] Although propofol has a more rapid onset and shorter half-life, its routine use during endoscopic procedures has been widely reserved for those performed in an operating room with an anesthesiologist.[21] Reversal agents (antagonists) for both class of drugs are now available and should be immediately ready for delivery in patients who show signs of oversedation. Titration of medications delivered in small increments allows for the safe performance of sedated endoscopy, especially in older patients with slower circulatory distribution.

Cardiopulmonary issues are the most commonly reported complications with endoscopic procedures. These complications include aspiration, oversedation, hypotension, hypoventilation, arrhythmia, bradycardia (vasovagal), and airway obstruction. Many of the latter are associated with use of intravenous moderate (formerly "conscious") sedation, defined as decreased consciousness associated with preservation of protective reflexes.

UPPER GASTROINTESTINAL ENDOSCOPY

Indications

The indications for upper gastrointestinal endoscopy (EGD) can be divided between those for diagnosis and those to provide for potential therapy. Diagnostic EGD is used for the evaluation or surveillance of patients who present with "alarm symptoms" (Table 3-1) as do those with abnormal or inconclusive radiographic studies. Follow-up evaluations for ulcers or surveillance for patients with Barrett's esophagus are also indications. Therapeutic upper endoscopic interventions include the management of bleeding, removal or ablation of premalignant or malignant lesions, management of upper gastrointestinal obstructions, leaks or fistulae, and the creation of enteral access for supplemental feeding or decompression.

Contraindications

The contraindications to EGD are related to the patient's associated comorbidities, underlying gastrointestinal disorders, or patient's inability to tolerate conscious sedation. Recent myocardial infarction, pneumonia, and recent foregut surgical procedure are relative contraindications for EGD, and the risks and benefits need to be weighed on an independent basis for each patient to determine appropriateness. A recent surgical anastomosis is most likely safe at any time during the postoperative period to be evaluated endoscopically, remembering

TABLE 3-1: INDICATIONS FOR EGD ("ALARM" SYMPTOMS)

1. Abdominal complaints not responsive to appropriate empiric therapy
2. Weight loss
3. Early satiety
4. Odynophagia
5. Dysphagia
6. Persistent nausea and vomiting
7. Hematemesis/melena
8. Foreign body impaction
9. Iron deficiency or unexplained chronic anemia

that tissue strength will be weakest on postoperative days five to seven.

Coagulopathy secondary to thrombocytopenia, liver failure, renal failure, or exogenous use of anticoagulants and platelet-inhibiting agents is a relative contraindication for a diagnostic EGD, but an absolute contraindication for a therapeutic intervention. Patient noncooperation and inability for a patient to be safely sedated due to high cardiopulmonary risk are also contraindications to EGD. Respiratory depression secondary to medications as well as inability to maintain an airway can occur in these high-risk patients. Preassessment with ASA classification and Malampatti scores will help predict this high-risk group. Patients with suspected perforation or caustic ingestion injury should not undergo EGD unless there are plans to provide palliative therapy such as endoscopic closure or stent placement.

Patient Preparation

Upper gastrointestinal endoscopy requires very little preparation other than fasting of solid food for 6–8 hours and liquids for 2–4 hours. Removable dentures and dental implants must be taken out to avoid dislodgement and aspiration during the procedure. The role of lavage in patients with bleeding is debatable, and if large volume lavage is to be used, care must be taken to avoid aspiration including the judicious use of endotracheal intubation. If intervention is anticipated, a recent coagulation profile and platelet count should be within safe ranges. The use of topical pharyngeal anesthetic spray is necessary in unsedated procedures in order to suppress the gag reflex, and is used based on physician preference for sedated cases.

The use of prophylactic antibiotics is rarely indicated for EGD, except in the scenario of esophageal sclerotherapy, dilation, and percutaneous endoscopic gastrostomy (PEG) tube placement. Discussion with the cardiologist as to the role of antibiotics is recommended for patients with prosthetic heart valves, previous endocarditis, systemic pulmonary shunts, or recent vascular prostheses.

Basic Endoscopic Techniques—EGD

The forward-viewing endoscope is preferred for routine diagnostic endoscopy. It should be noted that the medial duodenal wall, at the site of the ampulla, is preferentially seen with a side-viewing endoscope. More recently, the use of small diameter 5 mm transnasal endoscopes has allowed for the safe performance of unsedated endoscopy.

After appropriate preprocedural patient assessment and informed consent, the patient is routinely placed in a left side down lateral decubitus position. Patients undergoing PEG procedure or other therapies requiring access to the abdominal wall are left supine. Prior to delivery of sedation, a baseline set of vitals is taken and it is confirmed that the equipment is in proper working order and potentially necessary endoscopic tools are readily available. Following the slow delivery of medications, titrating the doses as needed based on the individual patient needs, the distal several centimeters of the endoscope are lubricated avoiding the actual tip of the endoscope as this will obscure the image and, even with irrigation, will make visualization difficult.

Intubation of the esophagus is best accomplished under direct vision by advancing the endoscope over the tongue, past the uvula and epiglottis, and then posterior to the arytenoid cartilages. This maneuver will impact the endoscope tip at the cricopharyngeal sphincter and allow entry into the cervical esophagus with gentle forward pressure once the patient swallows. Blind insertion with the endoscopist's hand in the patient's pharynx is not recommended as this is more dangerous for both the patient and the endoscopist.

Once in the cervical esophagus, the instrument is advanced under direct vision taking care to survey the mucosa during both insertion and withdrawal. The distance to the squamocolumnar junction, the "Z-line," where the white squamous esophageal mucosa meets the red columnar gastric epithelium, is recorded in the procedure report. The site of the diaphragmatic crura (hiatus) should also be recorded and is seen as impression into the esophageal or gastric lumen. This point can be accentuated by asking the patient to sniff while the area is visualized. The endoscope is then advanced into the gastric lumen under direct visualization. Unlike colonoscopy where there is a requirement for significant torquing or twisting of the scope, due to fixation of the esophagus in the mediastinum, EGD manuipulations can be more directly achieved with deflection of the wheels and movement of the handpiece ("dancing with the scope").

After aspirating any gastric contents, the four gastric walls are surveyed using combinations of tip deflection and shaft rotation, insertion, or withdrawal. During upper endoscopy, the endoscope will naturally follow the greater curvature as it advances toward the antrum and this is called the "long position." This affords an end-on view of the pylorus, which is approached directly. Passage through the pylorus can usually be facilitated by gentle pressure and air insufflation. Entry into the duodenal bulb is recognized by the typical granular, pale mucosa without the folds of the valvulae conivente. Finally, the second portion of the duodenum is entered with the associated folds, by deflecting the tip up and to the right. In addition, rotating the handpiece to the right will help facilitate this maneuver. Withdrawal of the endoscope at this point while keeping the tip deflected leads to paradoxical advancement of the endoscope down the duodenum. Withdrawl of the endoscope places the shaft along the lesser curvature of the stomach and allows for this paradoxical forward advancement of the tip. This is referred to the "short position." All areas should be carefully surveyed again as the endoscope is withdrawn.

The final component of a diagnostic EGD is evaluation of the cardia, fundus, and incisura along the lesser curvature. With a forward-viewing endoscope, these sites are visualized by a retroflexion maneuver with full upward tip deflection (Figs. 3-5 and 3-6).

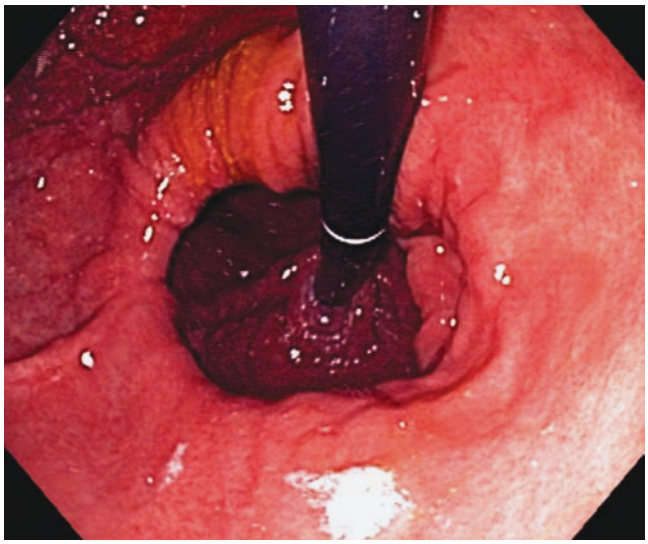

FIGURE 3-5 Retroflex view in the stomach, here revealing a large type III paraesophageal hernia.

Techniques of Endoscopic Tissue Sampling

Sampling of tissue is most frequently obtained by passage of a spiked forceps via the endoscope's biopsy channel. Multiple biopsies should usually be obtained. For ulcers, one should biopsy the edge of the lesion in at least four quadrants. Standard biopsy techniques are quite superficial; however, if deeper biopsies are desired, these can be obtained by using either a jumbo forceps or the practice of repetitive biopsies at the same site, which will lead to a deeper sampling.

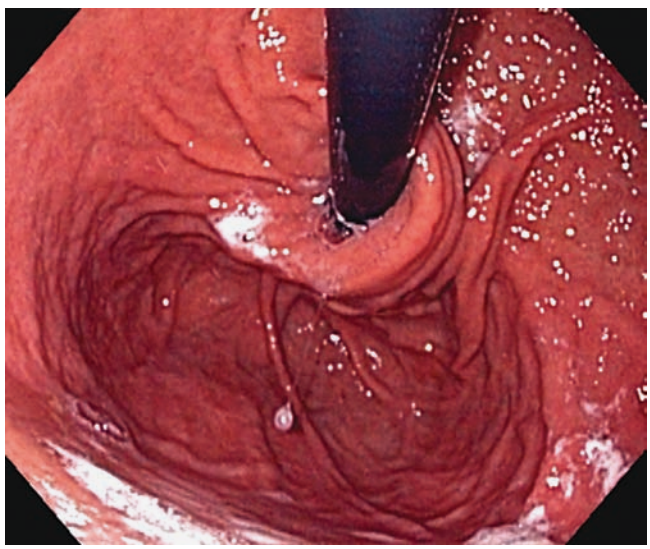

FIGURE 3-6 In another retroflex view, an intact surgical fundoplication is seen.

Surveillance in diseases such as ulcerative colitis and Barrett's esophagus require a standardized sampling technique. Ulcerative colitis protocols recommend biopsies every 10 cm throughout the entire colon, and Barrett's sampling per the Seattle protocol requires at minimum 4-quadrant biopsies every 1 cm using a jumbo forceps. The goal of these sampling techniques is to identify the presence of dysplastic tissue necessitating further intervention.

Tissue and lesions can also be sampled by the use of brush cytology. In this technique, a sleeved brush is passed through the biopsy channel of the scope and rubbed forcefully over the desired site. The brush head is extended, stirred in a fixative solution to be spun down for cell evaluation, and then transected and dropped into fixative for direct cytologic analysis. The sensitivity and specificity of this technique are dependent on direct approximation to the diseased mucosa, and should not replace a directed biopsy if attainable.

THERAPEUTIC ENDOSCOPIC INTERVENTIONS

Management of Bleeding

Endoscopy plays a critical role in evaluation and treatment of upper GI (UGI) bleeding. The degree of rapidity of UGI bleeding varies from severe with gross hematemesis to mild, presenting as either heme-positive stools or iron deficiency anemia. The timing for EGD should be based on each individual clinical scenario, understanding that endoscopy is both a diagnostic and a therapeutic tool. In all patients, hemodynamic stabilization and correction of any sources for ongoing coagulopathy are a priority.

Endoscopic hemostatic therapies can be divided into thermal and nonthermal categories. In addition, these hemostatic options can be further delineated based on specific ideal applications. There are associated risks with each of these techniques, which must be understood to allow for appropriate tool selection. It is also possible to treat bleeding with combined modalities such as coagulation and injection, or clipping and injection. When comparing individual therapeutic techniques, there is very little difference between them in terms of providing successful hemostasis. In fact, there are numerous studies to demonstrate the superiority of combined over single hemostatic therapy. Given the relatively high success rates of controlling UGI bleeding by endoscopic modalities, it is appropriate to pursue endoscopic means whenever available before seeking surgical or interventional radiology options.[22]

THERMAL TECHNIQUES

Thermal therapies control hemorrhage by inducing tissue coagulation, collagen contraction, and vessel shrinkage. Thermal energy is delivered via a contact or a noncontact device. Thermal therapies are successful in 80–95% of cases, with a

rebleed rate of 10–20%. These techniques are easy to use and safe, with a perforation rate of 0.5%, although this is dependent on the site of the gastrointestinal tract, with the cecum more likely to result in perforation than a thicker organ such as the stomach.[23]

Contact Thermal Techniques. Contact or coaptive techniques involve the use of probes passed via the biopsy channel, which allow for pressure tamponade of the bleeding point with simultaneous application of thermal energy for coagulation. The firmer one applies the device to the tissue, the greater the depth of energy penetration. In addition, the tamponade not only improves visualization, but also reduces the "heat sink" effect of active bleeding, and thereby improves the efficiency of the coagulation process. Multipolar (bipolar) cautery (Fig. 3-7) and heater probe devices are used most commonly, although monopolar cautery via a biopsy forceps or snare may also be employed, albeit with a potentially higher risk of injury. The heat generated, which can reach several thousand degrees, is sufficient to cause full-thickness tissue damage, so care is required when using this modality.

Both cautery and heater probe units allow pulse irrigation to be performed for visualization and clot clearance via foot pedal control. Variables important in achieving hemostasis include probe size, force of application, power setting, and duration of energy delivery.[23,24] Vessels of up to 2 mm in diameter appear to be able to be well controlled by these techniques although the overall surface area treated by these devices is limited by the size of the probes.

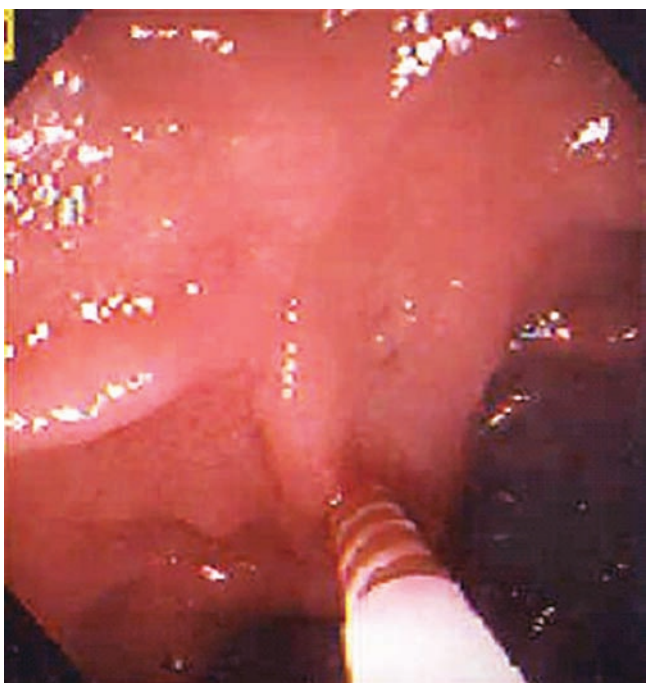

FIGURE 3-7 The bipolar endoscopic cautery device.

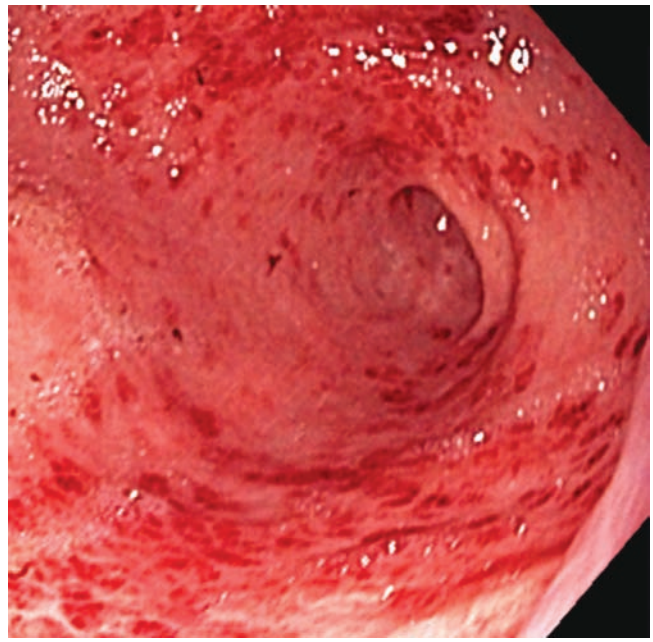

FIGURE 3-8 Endoscopic image of gastric antral vascular ectasia (GAVE) representing a diffuse disease best treated with argon plasma coagulation.

Noncontact Thermal Techniques. Argon plasma coagulation (APC) is a technique in which thermal energy is applied to tissue via ionized argon gas. This technique has the disadvantage of not allowing a tamponade effect, but conversely is not prone to adherence of the probe to the hemostatic coagulum. The gas has an effect of clearing luminal liquid from the point of application; however, due to the high pressure of gas delivery, one must be careful to avoid overdistention of the lumen by using frequent suctioning during APC usage. It is more widely utilized in most centers than laser, and in limited studies appears to have similar efficacy to contact probes.[24]

APC is particularly well-suited for settings where large mucosal areas require treatment such as gastric antral vascular ectasia (GAVE) (Fig. 3-8), or where the risk of deeper thermal injury leading to perforation is of heightened concern, for example, cecal angiodysplasia.

NONTHERMAL TECHNIQUES

Injection Sclerotherapy. Injection therapy is performed by passage of a catheter system through the biopsy channel of the endoscope. There is an internal 5-mm needle, which can be advanced and withdrawn as needed. The sclerosant is injected submucosally. Injection therapy at three or four sites surrounding a bleeding site prior to contact thermal techniques may prove more effective, as the created eschar is occasionally removed inadvertently affixed to the treating probe. If tamponade is provided first with injection

therapy, bleeding following initial thermal therapies can be reduced. The amount injected varies with different agents, and it must be remembered that systemic absorption will occur. Dilute 1:10,000 epinephrine solution is the most commonly used agent, and should be limited to less than 10 cc total volume. Other agents available include absolute alcohol, thrombin in normal saline, sodium tetradecyl sulfate, and polidocanol.[22,23] For esophageal varices, injections are begun just above the gastroesophageal junction. Sclerosants can be injected either directly into the varix or along side it, intravariceal or paravariceal. Variceal banding with endoscopic band ligators, although associated with a slightly higher rate of rebleeding, has predominantly supplanted injection sclerotherapy due to lower complication rates. In the absence of active bleeding or stigmata of bleeding, prophylactic endoscopic variceal eradication should not be performed because of the high risks of complications associated with the procedures. In patients with severe variceal bleeding or recurrent bleeding following endoscopic therapies, other options such as transjugular intrahepatic portosystemic shunt (TIPS) or surgical portosystemic shunting should be considered (see Chap. 47).

Endoscopic Ligation Techniques

Endoscopic Band Placement. Endoscopic band ligating systems are readily available and provide an alternative for management of variceal and nonvariceal bleeding, and are also routinely used in conjunction with endoscopic mucosal resection (EMR) techniques. This technique is based on the ability to suction tissue into a cap placed at the tip of the endoscope, and then with the turning of a control knob, fire a small tightly constricting rubber band. Single band devices were initially developed for the treatment of esophageal varices, but there are now numerous multiband ligating systems. This innovation provided an alternative to injection sclerotherapy, and although it proved to be slightly less effective in preventing recurrent bleeding, complications such as stricture formation have been dramatically reduced. Applications for endoscopic banding include treatment of internal hemmorhoids, dielufoy ulcers, esophageal and gastric varices, and mucosal neoplasia in conjunction with EMR.[25]

Endoscopic Suture Placement. Pretied endoscopic loops can also be applied through a standard endoscope biopsy channel, and can be used for ligation of pedunculated structures before or after endoscopic resection. These single application devices are similar to laparoscopic endoloops, although they are nylon sutures, and instead of an actual slip knot, a plastic cinching device holds the loop in place once deployed. Use of a double channel endoscope, allowing for a two-handed technique to grasp the desired tissue and deliver it throught the opened loop, is preferred. Similar to clips, these sutures will routinely slough off the tissue in 1–2 weeks.

Endoscopic Clipping. Endoscopic clip placement is an effective method to control bleeding and can be used safely

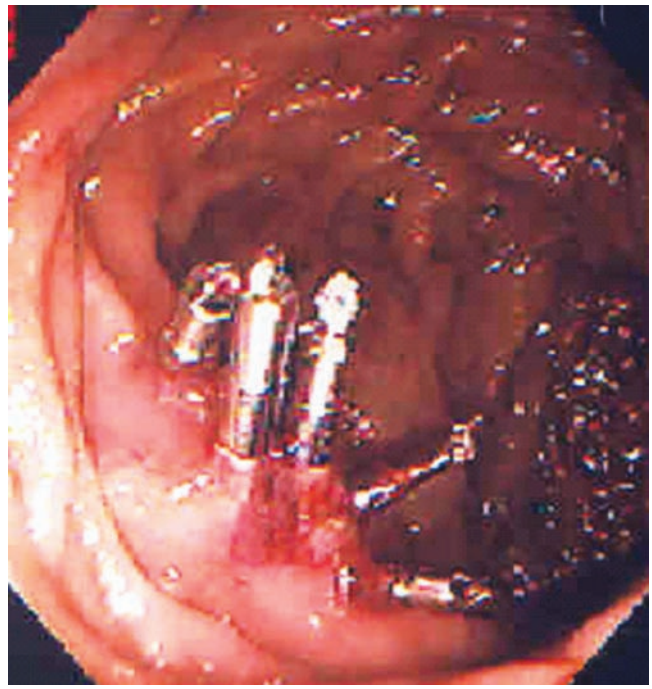

FIGURE 3-9 Endoscopic image of multiple clips placed to provide hemostasis.

at multiple sites throughout the gastrointestinal tract.[26–28] Frequently, more than one clip is necessary at the site of bleeding (Fig. 3-9). The depth of tissue obtained by endoscopic clip placement is quite superficial, with only the mucosa routinely being captured. Clips are placed via the biopsy channel of the scope and come with varied application and shape qualities. Rotatable clips as well as clips that can be opened and closed prior to final positioning are available. In addition, clips with both two arms and three arms, as well as those that have single use and multiple use deployment systems are manufactured. These clips can effectively control bleeding, and usually fall off in 1–2 weeks. Cases of clips remaining at the site with and without mucosal overgrowth months after placement have been reported.

Endoscopic Mucosal Resection

The treatment of premalignant as well as superficial cancers can now be managed by endoscopic resective techniques. EMR has been employed for adenomas, dysplastic lesions, and early-stage carcinomas, including lateral spreading tumors.[29] Carcinomas without submucosal invasion or nodal spread might be amenable to EMR. Although these diseases are less commonly seen in Western societies, the use of these techniques is routine throughout Asian populations for treatment of esophageal and gastric lesions. Conversely, colonic lesions in Western countries are routinely managed with these modalities. CT scan and EUS are recommended to assess for

nodal disease prior to EMR. Multiple technical variations of EMR for the upper and lower tract have been developed, including submucosal injection, "suck-and-cut," "suck-and-ligate," and strip biopsy.

SALINE LIFT EMR

The most commonly performed EMR technique employs submucosal injection of a fluid followed by electrosurgical polypectomy. Initially the margins of the lesion are clearly delineated, and the periphery is marked using short burst of electrocautery. A standard sclerotherapy needle is then used to perform a submucosal injection. The most commonly used fluid is saline with or without epinephrine, although hyaluronic acid, glycerol, and dextrose have all been described. A bleb is created with the submucosal injection creating space between the line of resection and the muscularis propria of the organ, and the lesion is resected (Figs. 3-10 to 3-12). Repeat injection of agent is commonly needed due to absorption as well as diffusion of the fluid. Injection beyond the lesion first allows for better imaging of the tissues. Intralesional injection can also be used prior to resection. One caveat to this technique is that if the submucosal injection does not result in elevation, one must consider that this mass is an invasive lesion and should not be resected endoscopically. Multiple biopsies as well as EUS should be performed.

"SUCK-AND-CUT" EMR

The "suck-and-cut" technique uses a specially designed cap attached to the tip of the endoscope. A submucosal injection may be created a priori and the lesion is sucked into the cap. A snare affixed to the cap is used to encircle the lesion, which is then resected by application of electrocautery. Similar to any thermal technique, risk of perforation exists. In addition, the depth of tissue acquisition is not well controlled, and care should be taken to avoid inadvertent perforation, especially in thinner walled organs such as the cecum.

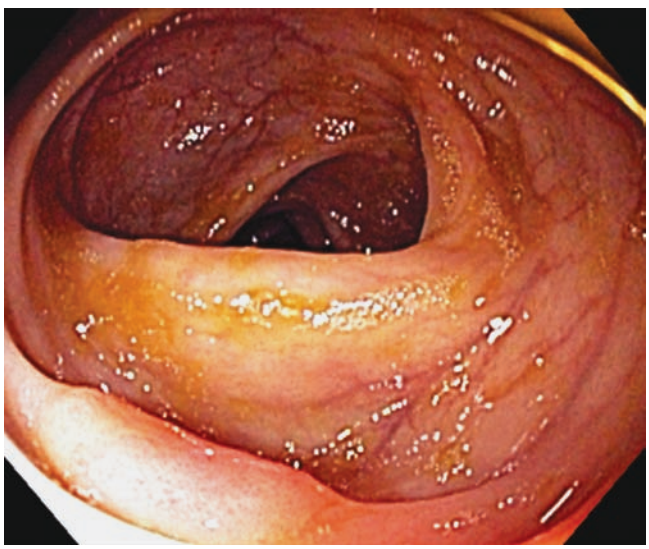

FIGURE 3-10 Sessile colon polyp prior to saline lift EMR polypectomy.

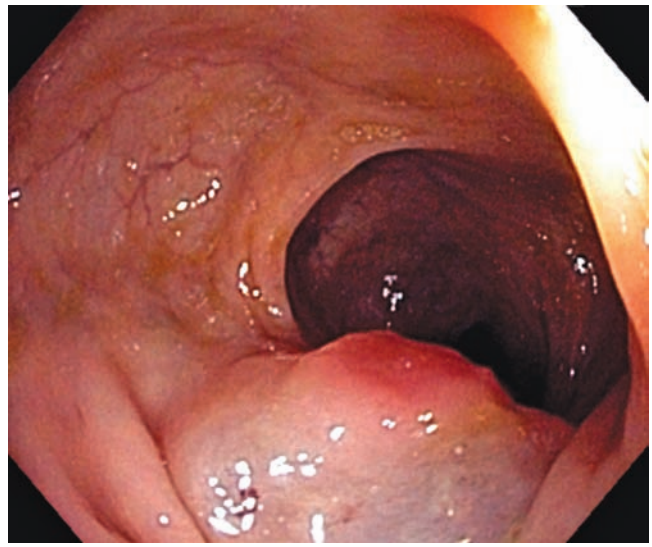

FIGURE 3-11 Sessile colon polyp following saline submucosal injection.

"SUCK-AND-LIGATE" EMR

The "suck-and-ligate" technique transforms a sessile or nodular lesion into an artificial pedunculated polyp, which can then be resected with standard polypectomy techniques. A band ligating device is attached to the tip of the endoscope

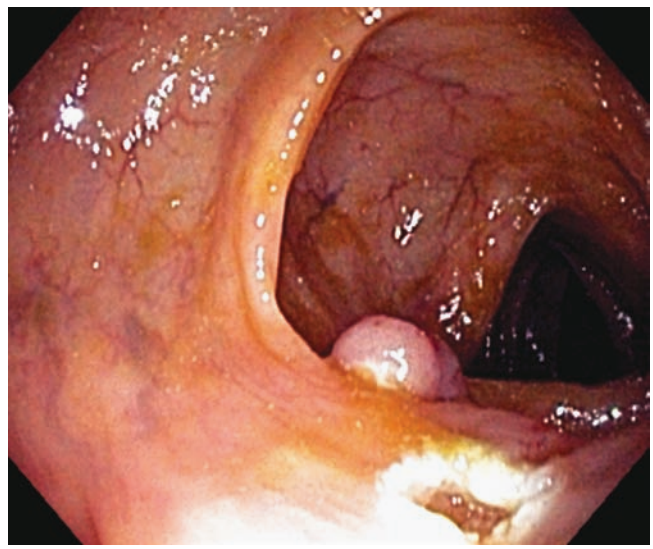

FIGURE 3-12 Saline lift EMR polypectomy of sessile colon polyp. Resected polyp is seen in the distance and the polypectomy site in the foreground.

and the tissue is sucked into the cap and a band is placed at the base of the lesion. This is done with or without saline lift injections prior to banding. This serves to separate the mucosal lesion from the submucosa, permitting safe resection using a standard polypectomy snare.

The most frequent complications of EMR are bleeding and perforation. Immediate bleeding can be controlled with endoscopically placed clips or injection of dilute epinephrine. Electrocautery should be used judiciously after EMR because the thin submucosa and serosa are susceptible to full-thickness injury with cautery. Delayed bleeding often requires repeat endoscopy with injection therapy or clip application, although angiography and embolization may be an alternative. Perforations can also be managed endoscopically with endsocopic clips as well as temporary enteral stent placement to cover the site of perforation.

ENDOSCOPIC SUBMUCOSAL DISSECTION

An extension of EMR that has been recently reported for endoscopic resection of more extensive lesions is endoscopic submucosal dissection (ESD). Utilizing a combination of needle cautery and blunt endoscope cap dissection, large segments of tissue can be resected. Two-handed techniques utilizing a double channel scope is vital. Circumferential segments of tissue can be removed, although these are lengthy and very challenging procedures. The advantage of ESD is that it represents a more classic oncologic maneuver, as compared to the piece meal resection that occurs with other EMR techniques, in that margins as well as lesion depth can be more accurately pathologically evaluated. Complications are higher than for the other EMR techniques, including bleeding, perforation, and stricture formation which can occur in almost 20% of cases.[29]

ENDOSCOPIC MUCOSAL ABLATION

Endoluminal therapies for ablation of mucosal-based diseases such as Barrett's esophagus have recently seen great advances. Previously, photodynamic therapy was the principal technique used, but the associated complications and the side effects related to the delivery of the sensitizing agent were high. Endoscopic radiofrequency ablation (RFA) is a relatively new technology that has recently gained acceptance for treatment of intestinal metaplasia as seen in Barrett's esophagus.[30] Its unique design incorporates bipolar radiofrequency energy and applies it directly to the esophageal epithelium for ablation. A balloon-based system, as well as a directed planar electrode device implementing this technology, has been used in this form of therapy. The balloon-based model has proved to be safe for Barrett's esophagus.[29] The HALO[90] system (BÂRRX Medical, Sunnyvale, CA) is an endoscopic RFA device composed of an ablation electrode that is mounted to the end of a flexible endoscope.

There is a 13 mm (width) × 20 mm (length) planar electrode on the face of the probe that delivers the designated energy. The electrode has a 4-mm diameter catheter that runs from the device along the endoscope and is connected to an RFA generator. The generator can be altered to vary energy density [joules/centimeter^2 (J/cm^2)] and power density (watts/cm^2). This endoscopic RFA technology also delivers a controlled amount of energy to the tissue that is predetermined prior to firing, whereby limiting unintentional transmural and potentially extralumenal injury.

Several studies have proven feasibility and safety for this novel therapy, with very few documented cases of postprocedural structuring as had been seen with photodynamic therapy (PDT).[31–33] Further studies documenting long-term effects of this therapy, as well as the absence of buried submucosal metaplastic glands or cancer, are still necessary.

Endsocopic Enteral Access

Endoscopic access to the gastrointestinal tract has become one of the most common endoscopic procedures now performed. What had previously required surgical intervention is routinely managed endoscopically. Gastric access (PEG), jejunal access (direct percutaneous endoscopic jejunostomy [PEJ]), or a combination of both (PEG with jejunostomy tube extension [PEG-J]) can be provided. Indications for access include supplemental feeding, decompression, fixation of structures, and access for meds. There are only a few absolute contraindications to endoscopic enteral access including esophageal obstruction and limited life expectancy. Patients with expected survival of less than 4 weeks should not undergo these procedures. Relative contraindications requiring individual patient selection include severe malnutrition, ascites, prior abdominal surgery, prior gastric resection, peritoneal dialysis, coagulopathy, and gastric malignancy.

PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

PEG is now the preferred method for long-term feeding in patients who are unable to swallow or who require supplemental nutrition or chronic gastric decompression. PEG may be preferable to surgical gastrostomy since it is safe, less expensive, and less invasive. A variety of PEG techniques are available including "pull," "push," and "introducer". "Pull" and "push" techniques require passage of the tube via the oropharynx and it is proposed that infectious risks and seeding of oropharyngeal cancers might be increased as compared to "introducer" technique, where the tube is placed percutaneously through the abdominal wall under endoscopic guidance. This theory has yet to be proven in randomized prospective trials.

Prior to any PEG procedure, a single dose of prophylactic cephalosporin (or equivalent) should be given intravenously. The patient is placed in the supine or semi-Fowler position with the head elevated and the arms held with soft restraints, after which the abdomen is prepared and draped using sterile technique. The endoscope is then passed into the stomach, which is distended with air insufflation. It is

recommended to perform a brief but complete endoscopic evaluation of the esophagus, stomach, and duodenum to rule out any coexistent disease, which might require treatment or complicate the PEG procedure. The assistant then presses on the abdomen with a single finger and the impact against the anterior gastric wall should be noted. Ideally, this point should be 2–3 cm below the costal margin and the maximal point of impression may be on either side of the abdominal wall or subxyphoid. Light transillumination from within the stomach to the skin surface may aid in identifying a safe landmark. Finally, it is imperative to perform a "safe tract" technique to assure that there is no intervening hollow viscus between the stomach and anterior abdominal wall. After anesthetizing the skin, a syringe with saline or local anesthetic is passed through the abdominal wall at the selected site while aspirating. As soon as air is appreciated in the syringe, the tip of the needle should be simultaneously visualized by the endoscopist in the gastric lumen. If not, an alternative site needs to be selected.

The endoscopist now passes a polypectomy snare through the endoscope channel at the selected intragastric site. A small transverse incision (approximately 7–9 mm) in the skin is created and the assistant then inserts a 14-gauge intravenous cannula through the incision into the gastric lumen. The snare is then tightened around the cannula and the inner stylet is removed.

"Pull" PEG. In the "pull technique," a long looped suture is placed through the cannula, after which the snare is released. The suture is then firmly grasped with the polypectomy snare. The endoscope and the tightened snare are removed together, bringing the suture out of the patient's mouth. The suture is secured to a well-lubricated gastrostomy tube at its tapered external end. The assistant then pulls on the suture until the attached tube exits the abdominal wall. The endoscope is then reinserted and used to view the tube's inner bolster (Fig. 3-13) as the stomach is loosely seated against the abdominal wall and the tube is properly positioned. This second intubation of the endoscope can be aided by grasping the PEG bumper with the snare passed through the endoscope. With withdrawl of the PEG through the mouth and out the abdominal wall, the endoscope is reintroduced into the esophagus. The snare is opened after esophageal intubation. The external bumper is placed loosely so that there is no tension at the PEG site and the endoscope is then removed.

"Push" PeG. In the "push technique," a guide wire rather than a looped suture is inserted through the cannula and pulled out the patient's mouth. The gastrostomy tube, called a Sachs-Vine tube, has a long tapered tip, which can be pushed over the wire until it exits the abdominal wall. A second endoscopic intubation is recommended similar to the "pull" technique.

"Introducer" PeG. In the "introducer technique," a guide wire is passed through the cannula placed into the stomach under endoscopic guidance. An introducer with a peel-away sheath is then passed over this wire, allowing removal of the wire and introducer. A Foley catheter or other similar gastrostomy tube is then placed through the sheath, its balloon is inflated, and the sheath is removed. The catheter is then secured to the abdominal wall. The placement of T-tags prior to performance of the introducer PEG can help to secure the stomach to the abdominal wall.

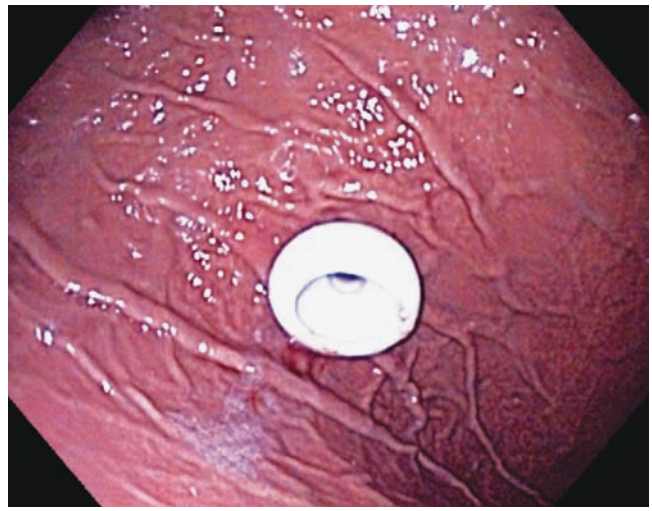

FIGURE 3-13 Second intubation is recommended after PEG placement to confirm the position of the internal bumper and to exclude any postprocedural bleeding.

Laparoscopic-Assisted PEG. In patients with morbid obesity, prior surgery, or intrathoracic gastric positioning, where safe access cannot be adequately determined by routine endoscopic techniques, simultaneous laparoscopy and endoscopy can be performed to complete the PEG safely. In this way, a long spinal needle can be passed under direct laparoscopic view from the abdominal wall into the gastric lumen and the PEG can be completed as described above.

Interventional Radiology–Assisted PEG. In patients with a "hostile" abdomen secondary to malignancy, multiple prior surgeries, or obesity where safe access cannot be endoscopically determined and laparoscopy would be challenging, a percutaneous intragastric pigtail catheter can be placed by interventional radiology under CT or ultrasound guidance. Utilizing a rendezvous technique, a guide wire is then advanced through the pigtail during upper endoscopy, and the PEG is completed.

PEG with Jejunostomy Tube Extension. In patients who fail to tolerate gastric feedings due to severe gastroesophageal reflux or gastroparesis, transpyloric feeding can be provided via a jejunostomy tube passed through the existing PEG. There are no prospective randomized trials, however, showing a difference between intragastric and transpyloric feeding, in terms of incidence of aspiration pneumonia. The majority of cases of

aspiration pneumonia are related to aspirated oropharyngeal secretions in a patient unable to protect their own airway.

PEG-J placement is achieved by passing a jejunal feeding tube through the PEG lumen (a 24 Fr PEG tube accommodates up to a 12.5 Fr J-tube; a standard 20 Fr PEG tube accommodates an 8.5 Fr J-tube). Endoscopically, the jejunal tube is guided into the duodenum under direct vision. A loop suture on the tip of the jejunostomy tube can be grasped by an endoscopic clip and once in the distal duodenum, the clip is deployed onto the small bowel mucosa to secure the tube in place. These clips routinely fall off in 1–2 weeks, but this technique allows for easier removal of the endoscope from the duodenum without simultaneous inadvertent withdrawal of the J-tube at the end of the procedure.

DIRECT PERCUTANEOUS ENDOSCOPIC JEJUNOSTOMY TUBE

In patients with confirmed aspiration secondary to gastroesophageal reflux of intragastric feedings, direct PEJ rather than PEG-J is of benefit. Feedings beyond the ligament of Treitz are associated with a lower incidence of gastroesohpageal-induced aspiration as compared to simple postpyloric feeding.[34] Direct PEJ, however, is associated with increased procedural risks including bleeding, inadvertent viscus injury, and leakage.[35–38] Performance of direct PEJ requires both endoscopic and fluoroscopic guidance. Utilizing a pediatric colonoscope, the proximal jejunum is intubated and the tip of the endoscope is fluoroscopically visualized. Abdominal wall depression with a haemostat is performed at this site to try to identify a loop of small bowel adjacent to the abdominal wall. Safe tract techniques are then used to access the identified bowel and a "pull" PEJ is performed with either a 16 Fr or 20 Fr tube. Second intubation with the endoscope to the PEJ site is mandatory to assure intraluminal positioning of the jejunostomy tube bumper.

Foreign Body Extraction. Foreign bodies are ingested predominantly by two groups of patients: children (ages 1–5 years) who accidentally swallow an object, and adults, who are obtunded or inebriated, have a psychiatric disorder, or are prisoners.[39,40] Food impaction may occur in patients who have an underlying benign or malignant esophageal stricture, or in patients with esophageal motility disorders.[41] Also, patients who are edentulous or have poor fitting dental prostheses are at risk for food impaction of poorly chewed meat boluses. Evidence of respiratory compromise or an inability to handle one's own secretions indicates an immediate need for endoscopic evaluation and extraction of the object.

When performing endoscopic extraction, protection of the airway is of vital importance. Endotracheal intubation is required in patients who are unable to handle their own secretions. An endoscopic overtube should be considered when there is concern for dropping pieces into the airway such as when removing sharp objects or multiple fragments. In addition, practicing with a similar foreign body prior to an attempted removal will allow for selection of the most appropriate endoscopic tool.

Coins represent the most object swallowed by children, and if seen to be in the esophagus should be removed promptly due to the risk of pressure necrosis and fistula formation.[39] The coin is localized and grasped with a polypectomy snare, net, or rat-tooth or tenaculum forceps. A Foley catheter is not recommended since it does not control the object well during removal and could become dislodged into the airway.

In the adult population, meat impaction represents the most common foreign body and should be removed if they remain for longer than 12 hours due to the risk of pressure necrosis.[41] Gentle scope advancement at the level of the obstruction can many times assist in passage of the food bolus. Piecemeal removal with baskets, nets, and snares may be needed, with care being taken to avoid passage of the foreign body into the airway. If the bolus should pass, EGD is still indicated to rule out an associated esophageal lesion.[41]

Use of an overtube or protective endoscopic hood may greatly facilitate removal of sharp objects such as toothpicks, fish or chicken bones, needles, and razor blades. When removing sharp objects it is important to follow the tenet of always having the sharp end trailing. If necessary, sharp objects can be carefully pushed into the stomach, rotated, and then brought out with the pointed end trailing.

Ingested button batteries must be removed immediately to prevent viscus injury secondary to a corrosive burn. These batteries usually pass readily in other parts of the gastrointestinal tract without causing harm, although all mucosal surfaces must be examined endoscopically to identify any resultant injury.

When encountered, cocaine-filled packets should never be removed endoscopically because of the risk of breakage. Close observation and expectant management is more appropriate, with expedient surgical intervention for any signs of bag rupture or bowel obstruction.

Following any foreign body removal, the endoscopist must exclude any associated underlying disease such as stricture, neoplasm, or motility disorder (Fig. 3-14). In addition, one must be aware of the possibility of delayed viscus injury secondary to pressure necrosis resulting in partial or full thickness injury. Emergent contrast study or CT should be used as needed to evaluate for these complications. Repeat endoscopy, motility study, or elective contrast studies may also be required based on patient's history or continued symptoms.

Other nonobstructing foreign bodies may be identified in postsurgical patients. Intraluminal suture migration may lead to symptoms of pain or dysphagia. (Fig. 3-15). Removal with endoscopic scissors may relieve the patient's symptoms of pain or dysphagia.

Endoscopic Dilation. Endoscopic dilation can be performed for any enteral stricture that can be accessed by endoscopic means. The endoscopic component of dilation may include identification, passage of a guide wire, or delivery of a dilating balloon via the endoscope channel. Strictures secondary to ischemia, inflammation, radiation, neoplasm, and

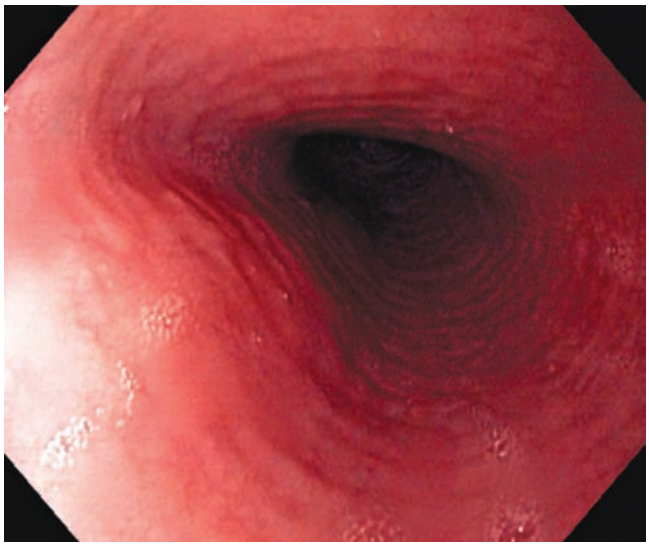

FIGURE 3-14 Classic eosinophilic esophagitis seen in a patient with history of dysphagia and prior food bolus. Endoscopic biopsies with identification of increased eosinophils confirms the diagnosis.

postsurgery are all amenable to endoscopic dilation. The use of fluoroscopy as an adjunct to endoscopic dilation is believed to decrease the risk of perforation, although this has not been fully proven in randomized prospective trials.[42] In addition, the type of sedation utilized is dependent on the clinical status of each individual patient, as those with tight esophageal strictures may be best served with elective airway protection.

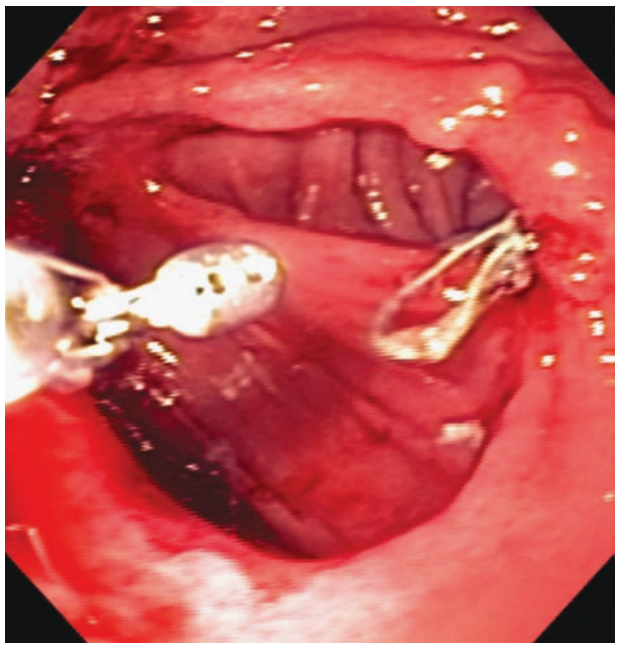

FIGURE 3-15 Sutures can be seen at the site of a prior gastrojejunostomy.

Although several types of dilators have been used, the two most common dilators used are the guide wire–driven type, which applies both axial and radial forces, and the balloon type, which applies only radial forces. Treatment is safer when performed by incremental dilations over successive sessions. A general approach is to limit the number of dilations to three successive balloon or dilator sizes in one session. Injection of steroid solutions (kenalog) into the stricture may reduce the severity of postdilation inflammation, scarring, and restricture. The frequency of dilation will depend on the severity of the stricture and the patient's symptoms.

Balloon dilators are used for short strictures, stenotic stomas, and achalasia. These dilators can be passed over a previously placed guide wire, and are delivered through the endoscope's therapeutic channel. Fluoroscopic guidance for balloon dilation allows the endoscopist to gauge several components of the procedure. First, it assures the positioning of the balloon in the viscus lumen. Second, if contrast is injected in the balloon as the dilating fluid, expansion of the balloon fully can be appreciated. This is termed "waist ablation" and refers to the full dilation of the balloon at the site of the stricture. The balloon changes from an hour glass appearance to a full elliptical-shaped figure.

Long, complex strictures may be less responsive to endoscopic dilation, and may also require repeat treatments. Aggressive biopsing of the mucosa after dilation is necessary in cases of unclear etiology. Complications secondary to endoscopic dilation include bleeding, perforation, mucosal tears, and recurrent structuring.

Enteral Stent Placement. Over the past several years, endoscopic stent technology has made impressive strides in providing tools for increasingly complex clinical scenarios. Both the delivery systems and the stents themselves have gone through significant changes and allowances for treatment of a multitude of benign and malignant disease processes. Strictures, leaks, fistulae, and obstructing neoplasms have all been approached with enteral stents.[43–50]

Stent Delivery Systems. Based on the location of the gastrointestinal tract that is to be treated, as well as the characteristics of the stent desired, endoscopic stent deployment is either through-the-scope (TTS), or wire guided. TTS stents are delivered through the endoscope channel and are routinely a 10 Fr system and require a therapeutic scope. Only uncovered self-expanding metal stents (SEMS) have a TTS characteristic. The remainder of stents all utilize wire guided systems and are placed under fluoroscopic guidance. Stent delivery systems are further categorized as proximal or distal deploying based on which end of the stent is opened first. In patients undergoing stent placement in the proximal esophagus, proximal deploying stents are preferred. Otherwise, most stent systems utilize a distal deployment pattern. Non-TTS stents are limited to the esophagus including the esophagogastric junction. In patients following gastric resection, these systems can also traverse a gatrojejunal anastomosis. TTS systems, conversely, can reach any site in the gastrointestinal tract that can be accessed by a therapeutic endoscope.[43]

Stent Characteristics. Covered endoscopic stents have been created for the sole purpose of temporarily bridging esophagaeal and proximal anastomotic leaks and fistulae.[45] The fully covered nature of the stent impedes tissue ingrowth as would occur with an uncovered enteral stent, and thereby allows removal after 2–3 months once the fistula has been cured. With the increased frequency of bariatric procedures, anastomotic complications secondary to Roux-en-Y bypass are routinely managed with placement of endoscopic stents.

Removable stents are subdivided into plastic or hybrid based on the underlying structural platform. As stated above, fully covered silicone stents which are self-expandable but require the use of a large deployment system, can reach as far as the proximal stomach. Similarly, covered SEMT (hybrid) are also placed outside of the endoscope under fluoroscopic guidance, and can reach the proximal stomach as well. The greatest problem with these stents is the high risk of migration.[45] If placed across a gastrojejunostomy, this can result in small bowel impaction of a migrated stent, resulting in the need for surgical extirpation. Bleeding, perforation, and obstruction are far less common complications.

Uncovered enteral stents, utilizing TTS deployment systems, are not intended for removal and can be placed for temporary relief of benign and malignant strictures throughout the gastrointestinal tract.[43,44,46–48] They are associated with increased tissue ingrowth and occlusion as compared to covered stents, but have a lower rate of migration. In unresectable disease states, palliation of obstruction with enteral stents can provide an alternative to surgical bypass procedures. In addition, endoscopic stent placement in patients with obstructing colon lesions can allow for immediate decompression followed by semielective resection and primary anastomosis, rather than an initial diverting stoma.[49,50]

Endoluminal Treatment of GERD

Numerous endoluminal treatments for gastroesophageal reflux disease (GERD) have been introduced over the past 10 years and have had varied clinical success. These technologies were based on either suturing, tissue bolstering, or energy delivery. Unfortunately, due to many factors including marginal patient improvement, limited physician acceptance, severe complications, and corporate financial difficulties, most of these treatments are not presently available in the United States. Examples of each of these modalities are described below.

ENDOCINCH (BARD, BILLERICA, MA)

The EndoCinch plication device (CR Bard, Inc, Murray Hill, NY) creates an internal mucosa-to-mucosa placation of the stomach. Using a standard endoscope outfitted with the device at its tip, the tissue is drawn into the suturing chamber by suction, and two sutures are placed. The knots are formed extracorporally and advanced to the gastric mucosa. While some of the short-term results were promising, the long-term results were bleak, confirming the lack of durability of a mucosa-to-mucosa apposition. This product is not presently being marketed for GERD treatment. Most authorities agree that technical refinements would be necessary before the EndoCinch can be effectively used for gastroplication.[51,52]

STRETTA (CURON MEDICAL, SUNNYVALE CA)

This is the only device that involves delivery of radio frequency energy to the lower esophageal sphincter (LES) muscles. Multiple applications at several levels are required to complete the treatment. The procedure is performed blindly after endoscopically confirming the location of the LES. The intention is to induce collagen deposition to the LES, thereby adding more bulk and reducing the compliance of the LES. The effects are generally not immediate, but are realized over time. Despite modest success with this device, the company declared bankruptcy in 2007.[53–57]

PLICATOR (NDO SURGICAL, MANSFIELD MA)

The NDO endoscopic plication system (NDO Surgical, Inc, Mansfield, MA) performed serosa-to-serosa apposition of the stomach just distal to the esophagogastric junction. The reusable device included a suturing mechanism at its tip and a channel for passage of a small bore endoscope for visualization. The single-use suturing implant used pretied polypropylene sutures with polytetrafluoroethylene bolsters. A proprietary retraction device selected the tissue for plication before deploying the sutures with a turn of the handle. Similar to Curon, this company also had significant financial difficulties and declared bankruptcy in 2008.[58–61]

ENTERYX (BOSTON SCIENTIFIC CORP, NATICK, MA)

For augmentation of the LES, the Enteryx system used a biocompatible, nonbiodegradable polymer. The solution contained a liquid polymer and radiopaque material to gauge the depth of injection. A circumferential injection of the polymer is performed, and its subsequent solidification tightens the esophagogastric junction. Multiple recent studies employing the Enteryx system have been published. Of note, Deviere and colleagues described the first sham-controlled trial with Enteryx in 2005.[62] Of the 64 patients, 83% reduced proton pump inhibitor (PPI) use by 50%, and 68% had discontinued PPIs. However, in the sham arm, 53% had halved their PPI use, and 40% discontinued PPIs. There was no objective improvement in pH values. Due to severe adverse events related to intra-aortic injections and subsequent fatal fistulization, the product was voluntarily discontinued by the company.[62–68]

GATEKEEPER (MEDTRONIC, INC, MINNEAPOLIS, MN)

The Gatekeeper reflux repair system alters esophagogastric junction anatomy in order to restrict the aperture for reflux.

A saline lift is performed above the squamocolumnar junction, and a biocompatible cylindrical prosthetic composed of polyacrylonitrite hydrogel is placed in the submucosa. The prosthetic subsequently enlarges with hydration, thereby impeding gastroesophageal reflux. There were two significant complications and the manufacturer has since withdrawn the Gatekeeper system from the market.[69,70]

ESOPHYX (ENDOGASTRIC SOLUTIONS, REDWOOD CITY, CA)

EsophyX is a novel endoluminal fundoplication technique using a trans-oral fastener-deploying device, attempting to mimic a Nissen fundoplication. In a feasibility study from Belgium, the results at 2 years supported long-term safety and durability with a sustained effect on the elimination of heartburn, esophagitis, hiatal hernia, and daily dependence on PPIs. At 2 years, no adverse events were reported, and a 50% or greater improvement in GERD-HRQL scores as compared with baseline on PPIs was sustained by 64% of patients. Esophyx was effective in eliminating heartburn in 93% of patients and daily PPI therapy in 71% of patients. Further clinical trials directly comparing this procedure to medical or surgical therapy are still necessary.[53]

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

History

William McKune, a surgeon, along with Paul Shorb, a gastroenterologist, were the first physicians to perform ERCP. In 1968, they reported on four cases of endoscopic identification and catheter placement into the ampulla of Vater. For the first time, imaging of the pancreatic ductal system could be seen and utilized for diagnostic purposes. Several years later in the mid-1970s, German and Japanese physicians described their experience in endoscopic sphincterotomy, the first therapeutic extension of ERCP. Other endoscopic adjuncts including stone lithotriptors, plastic and expandable metal stents, and intraductal imaging tools have fully changed ERCP from a diagnostic tool into one that is predominantly therapeutic.

Indications

There are numerous indications for ERCP as listed in Table 3-2. ERCP, however, is preferentially used as a therapeutic tool due to the high risk of serious complications.[71] In patients where a diagnostic imaging of the pancreticobiliary tree is desired, magnetic resonance cholangiopancreatography (MRCP) should be utilized.[72] Prior to cholecystectomy for symptomatic cholelithiasis, the presence of persistent jaundice or cholangitis is the indication for preoperative ERCP. Finally, as the number of patients undergoing bariatric procedures (Roux–en-Y gastric bypass) increases, access to the ampulla has become more challenging. Identification and access to the remnant stomach routinely require surgical or radiologic intervention for performance of ERCP.

TABLE 3-2: INDICATIONS FOR ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

1. Suspected choledocholithiasis
2. Identification and management of malignant or benign strictures
3. Investigation of abnormal radiographic imaging of the biliary tree
4. Persistent jaundice
5. Evaluation and treatment of sphincter of Oddi dysfunction (SOD)
6. Evaluation and treatment of pancreatic or biliary ductal injury/trauma or leaks
7. Treatment for identified ampullary adenoma
8. Recurrent or idiopathic pancreatitis
9. Treatment of complications of chronic pancreatitis including stones and/or strictures
10. Treatment for pancreatic fluid/cyst or pancreatic necrosis
11. Cytology of suspected pancreatic cancer and other pancreatic malignancies

Patient Preparation

Patient preparation, sedation, and monitoring for ERCP are similar to those for other upper endoscopic procedures, although the patient is routinely placed in the prone positon. Patients may require general anesthesia for airway protection, inability to tolerate conscious sedation, for expected lengthy or more complicated ERCP interventions, or in the presence of multiple comorbid diseases. ERCP can be performed in a supine position although this can make the procedure more challenging, as in patients undergoing ERCP at the time of laparoscopic cholecystectomy.

Techniques of ERCP

ERCP is performed using a side-viewing scope and requires both endoscopic and fluoroscopic skills for interpretation and intervention. As stated above, ERCP is predominantly a therapeutic technique. The scope is initially passed into the esophagus blindly to a position beyond the upper esophageal sphincter and then rapidly advanced into the proximal stomach where any residual secretions should be aspirated Unlike a forward-viewing endoscope, the pylorus cannot be visualized during intubation with a side-viewing scope.

Upward deflection of the side-viewing endoscope with continued advancement will allow easy passage into the duodenal bulb.

To manipulate around the superior duodenal angle, the endoscope is turned to the right, and the tip is deflected upward to reach the second portion of the duodenum. The endoscope is then withdrawn during this maneuver, leaving the scope in the ideal "short-scope" position.

With the "short-scope" position, the endoscopist views the papilla directly along the medial duodenal wall. Very minute movements of the tip and further withdrawl of the scope will bring the papilla into view. Intermittent doses of glucagon can be given to minimize duodenal peristaltic contractions. Dosing with glucagon, however, can lead to increased postprocedure nausea and vomiting. Fluoroscopy can also be used to determine appropriate scope position and to help identify the site of the major papilla. After the papilla is visualized, it is then cannulated using one of the various types of catheters available. As the majority of ERCP cases are potentially of a therapeutic nature, most endoscopists will start with a pull wire sphincterotome. Guide wire–assisted cannulation has also become a popular practice for several reasons. First, it may minimize the overall volume of contrast required, thereby hopefully decreasing the rates of pancreatitis and cholangitis. Second, it may increase the efficiency of selectively cannulating the desired duct. Finally, it can help maintain access into the duct during catheter exchanges.

Selective cannulation of the biliary and pancreatic ducts depends on the angle of the catheter and the position of the scope tip. The pancreatic duct tends to enter the papilla in a relatively perpendicular fashion at the 1-o'clock position. In contrast, the bile duct runs toward 11 o'clock below the "lip" of the papilla.

ERCP represents an endoscopic and radiographic intervention, and proper radiologic technique is critical to obtaining interpretable radiographs. Artifacts such as air bubbles, streaming and layering of contrast, and contrast spillage into the duodenum should be recognized and avoided.

ERCP Therapeutic Interventions

SPHINCTEROTOMY

There are two types of sphincterotomy that can be performed, needle knife sphincterotmy (precut sphincterotmy) or pull wire sphincterotomy. Needle knife sphincterotomy is performed when deep selective canulation is unable to be obtained, and can be done over a previously placed stent or guide wire, or when an impacted common bile duct (CBD) stone is protruding through the ampulla (Fig. 3-16). This technique is more technically challenging and also has a higher risk of bleeding, pancreatitis, and perforation. Pull wire sphincterotmy, conversely, requires deep selective canulation with or without previous wire placement.

FIGURE 3-16 An impacted common bile duct stone seen extruding through the ampulla. This is best treated by needle knife sphincterotomy to allow release of the stone.

Once proper selective ductal cannulation is verified, the sphincterotome is withdrawn until approximately half of the wire is visible outside of the papilla (Figs. 3-17 and 3-18). Biliary or pancreatic sphincterotomy can be done as needed. Indications for sphincterotomy include treatment of sphincter of Oddi dysfunction (SOD), improved access for stone removal or stent placement, and recurrent pancreatitis. To perform sphincterotomy, the pull-wire is tightened, bowing it against the papillary roof. Current is then applied while maintaining gentle upward force on the wire and gently lifting the sphincterotome, making the incision in small increments.

MANAGEMENT OF CHOLEDOCHOLITHIASIS

Retained or recurrent CBD stones represent the most common indication for endoscopic sphincterotomy, and ERCP with sphincterotomy successfully treats 95% of these cases.[73] In expert hands, over 90% of bile ducts can be successfully cleared of calculi with balloon catheters or Dormia baskets, resulting in an overall ductal clearance rate approximating 85% (Figs. 3-19 and 3-20). Stone size is often a limiting factor, as stones greater than 2 cm in diameter often require fragmentation prior to removal. The other reasons for unsuccessful ERCP include patient intolerance, inability to identify or access the papilla, and inability to selectively canulate the desired duct.

Routine preoperative ERCP and sphincterotomy are not warranted in patients undergoing biliary operations for

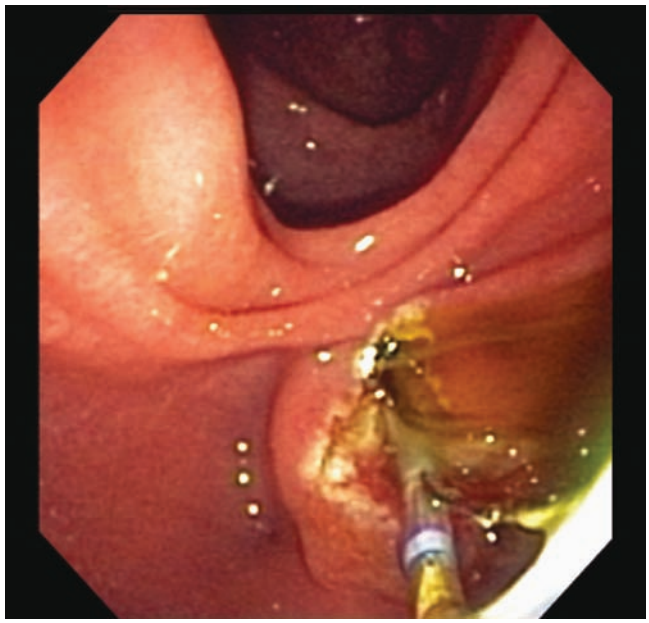

FIGURE 3-17 Following deep selective cannulation of the bile duct, a sphincterotomy is performed with a pull-wire sphincterotome.

symptomatic cholelithiasis.[73] Unfortunately, determining the presence of CBD stones is challenging, as ultrasound findings of biliary dilation, elevation of liver function tests (LFTs), and clinical factors such as pancreatitis are not always predictive of CBD stones. Only the actual radiographic finding of choledocholithiasis is statistically associated with the actual presence of CBD stones. As stated above, ERCP should rarely be utilized as a diagnostic procedure.[74]

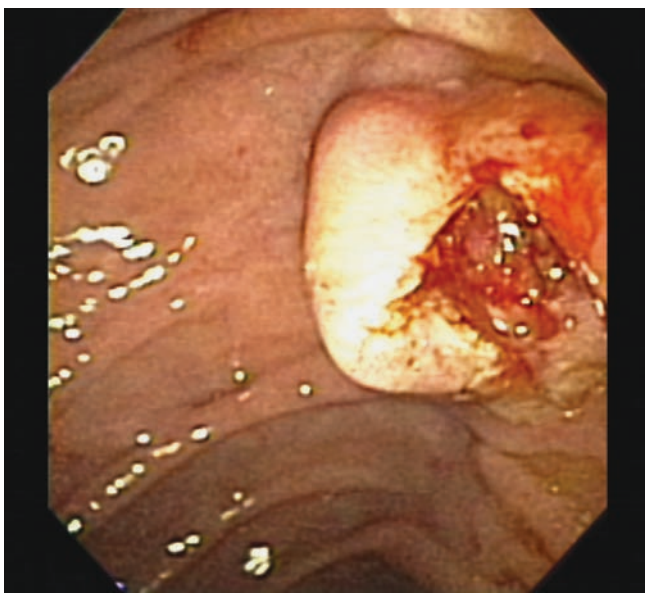

FIGURE 3-18 Postsphincterotmy image of the major papilla.

FIGURE 3-19 ERCP radiographic image of a distal common bile duct stone.

MANAGEMENT OF SOD

SOD represents a broad range of symptoms including pain, biliary colic, altered liver function tests, ductal dilation with delayed drainage, and elevated sphincteric pressures. Based on the number of associated symptoms, the response to endoscopic sphincterotomy can be predicted. This disease also has a close association with gallbladder dyskinesia, and may represent a parallel process in that many patients

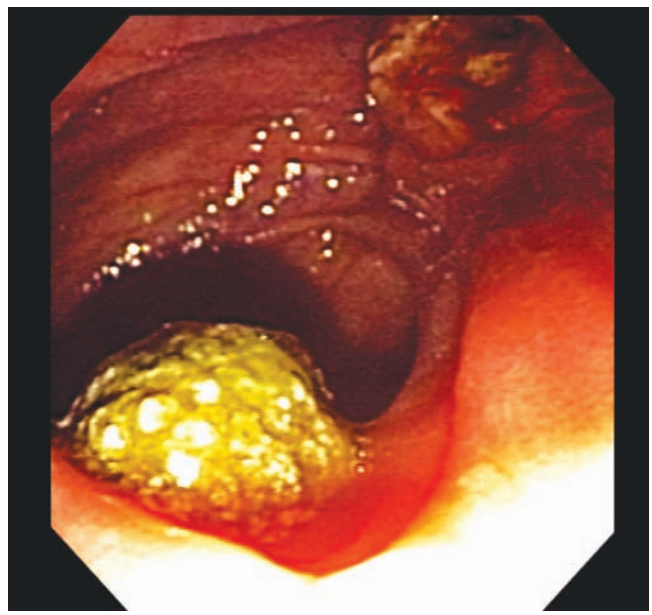

FIGURE 3-20 Following sphincterotmy (seen in the upper right-hand portion of the image) and balloon sweeping, the extracted common bile duct stone is seen in the duodenum.

following cholecystectomy for gallbladder dyskinesia will eventually be suspected of also having SOD. While multiple noninvasive tests have been evaluated in this disorder (eg, ultrasonography and scintigraphy), they all appear to lack adequate sensitivity or specificity. The development of endoscopic manometric techniques now allows direct measurement of motility and intraluminal pressures within both the biliary and pancreatic segments of the sphincter of Oddi.[75,76]

The common thread in patients with this disorder is elevated basal sphincter pressure. Criteria for abnormal manometry include basal pressure >40 mm Hg, peak sphincter pressure >240 mm Hg, >50% retrograde contractions, no relaxation with cholecystokinin administration, and contraction waves >8 per minute. Sphincter of Oddi manometry is technically challenging to perform and carries a high rate of post-ERCP pancreatitis. In addition, any ERCP intervention on patients with suspected SOD is associated with higher rates of postprocedural pancreatitis.[75]

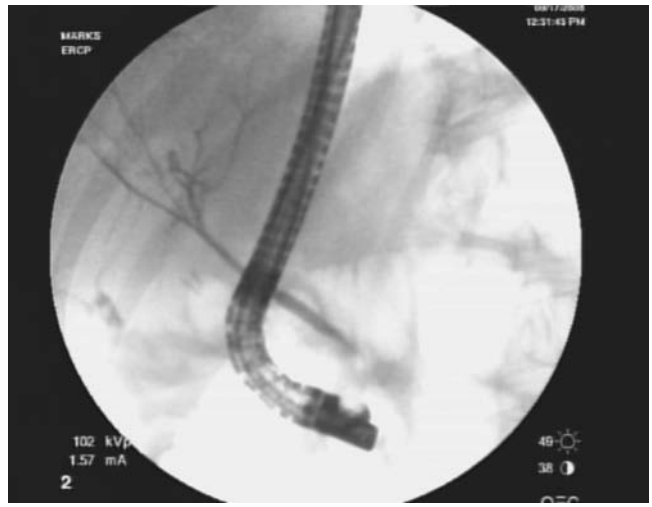

FIGURE 3-21 ERCP revealing extravasation of contrast from an accessory duct leak.

MANAGEMENT OF ACUTE CHOLANGITIS

Endoscopic biliary drainage has now been clearly shown to be the procedure of choice for patients with acute suppurative cholangitis. In critically ill patients, simple endoscopic stenting or nasobiliary drainage, with or without sphincterotomy, should be performed. Complete clearance of the duct is not necessary as long as drainage had been achieved. Stone extraction can be performed after the patient has stabilized, at the time of stent removal 4–6 weeks later.

MANAGEMENT OF ACUTE GALLSTONE PANCREATITIS

Patients with biliary pancreatitis can typically be managed conservatively, saving ERCP for those patients with worsening pancreatitis or concommittant evidence of biliary obstruction secondary to choledocholithiasis.[77] In these cases, early ERCP and sphincterotomy can significantly reduce morbidity and mortality.[77,78] The majority of patients who develop gallstone pancreatitis will have spontaneous passage of the CBD stone without intervention. Laparoscopic cholecystectomy should then be performed in the near future to prevent recurrence. Conversely, patients who are not an operative candidate, ERCP and sphincterotomy are effective in minimizing the risks of pancreatitis, but obviously will have no effect on the development of gallbladder complications related to the cholecystolithiasis.

ENDOPROSTHESIS INSERTION

Currently available endoprostheses or stents vary in their composition, shape, size, length, deployment system, and method of anchorage. The indications for stent insertion include cholangitis, benign/malignant biliary or pancreatic duct stricture, biliary or pancreatic duct leak, retained/unremovable CBD stones, and prophylactic pancreatic duct stent placement for pancreatitis protection.[79–82] In patients with biliary fistulae, the goal of the stent is to equilibrate the biliary and duodenal pressures to facilitate closure of the leak (Figs. 3-21 to 3-23).

Initially, a diagnostic cholangiogram or pancreatogram is obtained to identify the lesion's extent and to determine the length of endoprosthesis required, and a guide wire is maintained. If desired, a sphincterotomy can then be performed to facilitate subsequent manipulations, although stent placement can be performed without this maneuver. Ideally, the endoprosthesis will be located with its upper flap above the stricture and its lower flap just outside the papilla, although suprapapillary placement of metal stents is routinely

FIGURE 3-22 Following a 6-week course of biliary stenting, the leak has resolved.

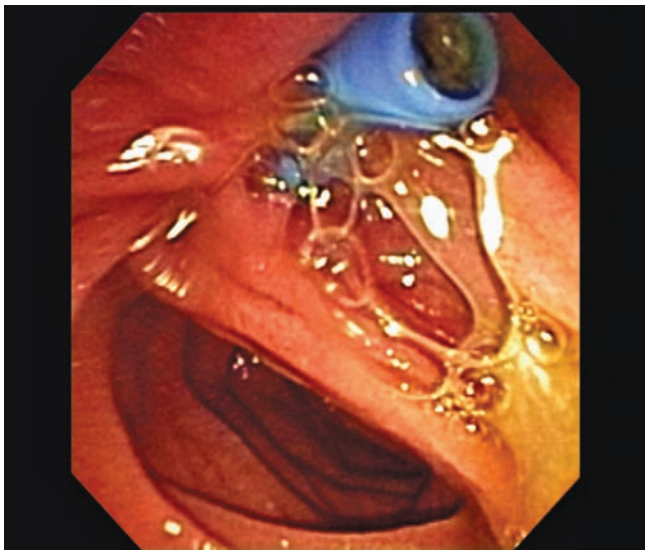

FIGURE 3-23 Transpapillary biliary stent placement for treatment of the biliary leak.

FIGURE 3-24 Distal common bile duct stricture secondary to a pancreatic head malignancy.

performed for more proximal malignant strictures. Transpapillary positon of plastic stents serves a function to ease removal as well as equilibrating biliary and duodenal pressures in cases of bile duct leaks.

All biliary and pancreatic stents are placed using TTS deployment systems. The diameters of these delivery systems vary based on the type of stent and the actual diameter of the stent. Straight biliary and pancreatic plastic stents come in 3, 4, 5, 7, 10, and 11.5 Fr diameters. For SEMT, a special delivery system is used to insert the stent in a collapsed state (10 Fr diameter). After release, there is shortening of the SEMS as the stent expands to its full diameter (8–10 mm).[80,81]

Straight plastic biliary stents are temporary and must be changed every 3–6 months.[79] Obstructive jaundice and cholangitis are common sequelae of occluded stents. Placing multiple stents may increase the length of overall patency, as bile can traverse around and between the stents even if the stent lumen becomes obstructed. SEMS carry a longer patency rate of 9–12 months as compared to plastic stents.[80,81] Uncovered metal stents are less likely to migrate as compared to covered ones, but have a shorter patency rate due to the allowance for ingrowth of tissue or tumor. Newer fully covered self-expanding metal biliary stents also allow for delayed removal, and can therefore be used in the management of chronic benign strictures.

Patients undergoing endoscpic palliation for obstructive jaundice secondary to malignancy who are not operative candidates may be better served with SEMS rather than plastic stents due to the decreased need for repeat endoscopic intervention in patients with a limited life expectancy.[80] If patients have both a biliary and duodenal obstruction secondary to malignancy, it is important to place the biliary SEMS prior to the duondenal stent as access to the papilla beomes very challenging.[44] Palliation of unresectable malignant biliary obstruction in elderly high-risk patients appears to be one of the most significant indications for biliary endoprostheses (Fig. 3-24).

In addition to biliary disorders, ERCP has been employed in the management of benign and malignant pancreatic disorders. Pancreatic duct stenting can be used successfully to decompress the ductal system, to bypass ductal leaks and strictures, and to treat pancreatic fistulas. Patients with pancreatic divisum may be treated with minor papilla stenting or sphincterotomy. Pancreatic stents are smaller than biliary stents and they contain side holes for drainage. Pancreatic duct stents also can be placed in patients with high risk for post-ERCP pancretitis including SOD, idiopathic/autoimmune pancreatitis, and those having had a complex ERCP with extensive pancreatic or bile duct manipulations (Figs. 3-25 and 3-26).[75] Pancreatic duct stents should be endoscopically removed within 2–3 weeks due to the risk of ductal inflammatory changes, whereas biliary stents can be used indefinitely and changed when there is evidence of obstruction. On many occasions, the pancreatic stents will pass spontaneously.

PANCREATIC DUCT STONES

ERCP for pancreatic ductal stone extraction is technically more challenging and is associated with a higher risk of complications such as pancreatitis. Some clinicians have reported success with the use of mechanical lithotripsy, contact lithotripsy, and/or extracorporeal shock wave lithotripsy to manage pancreaticolithiasis.[83] Pancreatic duct stones routinely are harder than biliary cholesterol-based stones and these patients may eventually require surgical intervention.

FIGURE 3-25 Radiographic image of a pancreatic duct wire prior to stent placement.

ENDOSCOPIC PSEUDOCYST DRAINAGE/ NECROSECTOMY

The management of pancreatic pseudocysts and necrotic debri is one of the more recent advances in the therapeutic armamentarium of the endoscopist. Pancreatic pseudocysts can be approached in a transpapillary or a transvisceral fashion based on the location and nature of the pseudocyst. Many pseudocysts have direct connection to the main pancreatic duct, and are referred to as "communicating" pseudocysts.

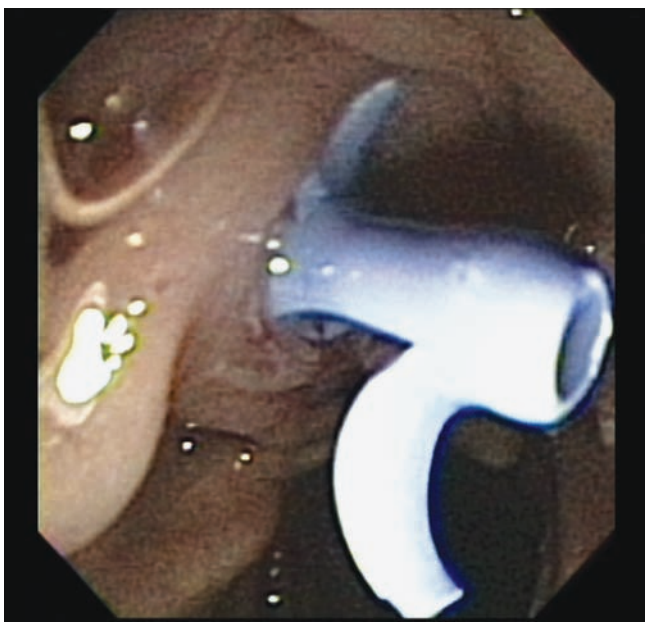

FIGURE 3-26 Temporary plastic 5 Fr pancreatic stent in place.

If wire access can be obtained via the pancreatic duct into the cyst cavity, a pancreatic stent can be placed to allow for drainage of the cystic cavity. Although this may result in initial resolution of the cyst, a high recurrence rate exists due to the continued communication to the ductal system. After drainage, subsequent stenting of the pancreatic duct across the site of leakage may be required.

Pancreatic pseudocysts directly adjacent to an endoscopically approachable lumen (ie, stomach, duodenum) may be amenable to a transvisceral approach.[84–87] Assuring maturity of the cyst, absence of concern for neoplasm, and no evidence of actual infection are important factors to determine prior to endoscopic drainage. The use of EUS is an invaluable adjunct to this procedure for several reasons.[85,87] It can rule out intervening organs or vasculature, determine if there is extensive debri rather than simple fluid collections, and assure proximity of the cyst to the selected viscus. EUS aspiration followed by guide wire placement is followed by tract dilation and eventual pigtail stent placement. Stents are removed in 6–12 weeks after confirming resolution of the pseudocyst.

Patients with pancreatic necrosis rather than simple pseudocyst formation have also been approached endoscopically.[88–92] Similar to transvisceral cyst drainage, EUS guidance is used to confirm the presence of a collection of debri, and following tract dilation, the endoscope is advanced directly into the adjacent cavity. Tissue is then removed using a combination of irrigation/suction and snare/basket tissue debridement. Stents are placed to maintain the tract to allow for serial debridement of the necrotic tissue.

Complications of ERCP

POST-ERCP PANCREATITIS

The occurrence of ERCP-induced pancreatitis is associated with both procedural factors and patient factors. Although the precise factor leading to postprocedural pancreatitis has yet to be elucidated, many factors including complex interventions including manometry, multiple pancreatic canulations or injections, excess delivery of thermal energy, and placement of covered SEMS have all been implicated. Prophylaxes with antibiotics, steroids, somatostatin, xanthine oxidase inhibitors, and immunologic agents such as IL-1 have been investigated in multiple prospective comparative trials without success in reduction of pancreatitis.[74,93] Patient factors associated with pancreatitis include SOD, idiopathic pancreatitis, and the prior history of acute or chronic pancretitis.[93] The use of short-term prophylactic pancreatic stent placement may eventually be proven beneficial in patients following higher risk procedures, or who have comorbid disease states increasing their risk for post-ERCP pancreatitis.[75]

Bacteremia or sepsis following ERCP, similar to pancreatitis, is secondary to procedural factors as well as underlying patient factors.[93] Patients undergoing ERCP for obstructive

jaundice or cholangitis have a high risk of sepsis if adequate drainage is not obtained. In addition, despite the use of sterile contrast agents, ERCP is a contaminated procedure related to the introduction of duodenal contents and bacteria into the biliary tree during canulation. If contrast is injected above a stricture that cannot be adequately drained, the development of cholangitis uniformly occurs. One method for preventing this is to attempt wire advancement across a stricture first before performing a cholangiogram. In complex strictures, this can be challenging, but it avoids contamination in cases where the stricture cannot be traversed. The performance of biliary dilation also carries a very high risk of bacteremia and prophylactic antibiotics are recommended. Finally, high pressure or high volume injections can also lead to cholangiovenous translocation of bacteria.

Bleeding following endoscopic sphincterotmy occurs in approximately 1% of all cases, and can occur immediately or up to 2 weeks postprocedure. Hemorrhage should be initially managed by repeat endoscopic intervention. Injection sclerotherapy, balloon tamponade, and endoscopic clip placement are the most common and effective ways to manage this complication.[94] If unsuccessful, angiographic embolization should be utilized before proceeding to surgical intervention.

Perforation is the least common complication and may occur secondary to the ERCP intervention (wire placement, canulation, sphincterotomy) or the actual advancement of the endoscope. Endoscope-induced perforations can occur at the level of the cervical esophagus due to the blind nature of the initial passage of the side-viewing endoscope, or in the duodenum, usually on the lateral aspect opposite the papilla. Proximal esophageal perforations usually can be managed with antibiotics, NPO status, and cervical drainage as needed. Duodenal perforations secondary to the endoscope may result in a large rent of the lateral wall and may require more aggressive therapy including surgical drainage, or in more serious situations, duodenal diversion techniques.

Perforations secondary to ERCP manipulations may occur in the periampullary duodenum or in the biliary tree. Perforations of the bile duct secondary to guide wires or catheter systems are rare but can result in bile peritonitis. Small perforations and leaks in patients without clinical deterioration can usually be managed with transpapillary stent placement and image-guided peritoneal drain placement as needed. CT scans are vital in the management of these patients.[95] Microperforation of the duodenum can lead to extensive retroperitneal, intraperitoneal, mediastinal, and subcutaneous air, which appears very concerning, but as long as the patients are clinically stable, this situation can routinely be managed conservatively with antibiotics, NPO status, and close observation. Conversely, patients identified to have retroperitoneal or intraperitoneal fluid collections will most likely require aggressive drainage via either surgical or image-guided techniques. Emergent resective therapy (pancreaticoduodenectomy) should be avoided in these situations.

SMALL BOWEL ENTEROSCOPY

The small bowel up until recently had been an elusive part of the gastrointestinal tract in terms of diagnostic and therapeutic endoscopic intervention. The advent of capsule endoscopy has permitted the endoscopist to obtain recorded images of the lumen of the small bowel for identification of obscure sites of bleeding, inflammatory changes, and neoplasia. Unlike contrast studies such as enteroclysis, capsule endoscopy simulated the visual advantages of flexible endoscopy, and with the time recording and navigation system, was able to approximate the actual site of the identified disease. Unfortunately, there was no potential for tissue sampling or providing therapy. This deficiency has now been addressed with the progression of deep bowel enteroscopy.

Previous endoscopic approaches to evaluate the small bowel included Sonde enteroscopy and push enteroscopy. Both of these were very challenging, time consuming, often unsuccessful, and provided limited alternatives for therapy. Intraoperative enteroscopy, either transoral or transanal, allowed for the manual pleating of the small bowel on the enteroscope, but was also very challenging.[96] Therapy would be provided surgically after the offending site was identified endoscopically. Intraoperative endoscopic evaluation of the small bowel can also be performed via an enterotomy in the midportion of the bowel allowing the endoscope to be advanced both proximally and distally. One of the undesired consequences of intraoperative endoscopy is massive bowel distention. The use of CO_2 insufflation rather than air insufflation has been shown to minimize the overall distention and length of time for resolution of this problem. Many endoscopists are looking to use CO_2 for all endoscopic interventions, especially those that are expected to be of longer duration.

Over the past 10 years, several new endoscopic systems have been developed and utilized for the evaluation and treatment of small bowel disease. Double balloon endsocopy (DBE) and single balloon endoscopy (SBE) have allowed the endoscopist to fully evaluate the small bowel, obtain tissue samples, and provide therapy for processes such as bleeding, obstruction, and occult neoplasia.[97–105] In addition, patients following surgical resection and reconstruction (ie, Roux-en-Y bypass, long afferent limb), balloon enteroscopy can allow access into the desired segment of the small bowel.[102]

Both systems utilize the principle of scope fixation with a soft balloon that is serially inflated and deflated as the scope is advanced. This permits the endoscopist to pleat the bowel over the endoscope. This is perfomed both antegrade and retrograde to visualize the entire mucosal surface of the small bowel, and can also be used for evaluation of the entire colon following unsuccessful standard colonoscopy.[104] Unique overtubes are also available for deep bowel enteroscopy, and are used in conjunction with the endoscopes.[101,103] As these techniques can be somewhat time consuming (1–4 hours), it is not uncommon to perform these under general anesthesia. The use of fluoroscopy is also helpful in guiding the endsocopist through the small bowel.

LOWER GASTROINTESTINAL ENDOSCOPY

The field of therapeutic lower endoscopy originated in 1975 when Shinya and Wolff reported the first series of colonoscopic polypectomies.[106] This groundbreaking report transformed colonoscopy from a purely diagnostic tool into an interventional modality. Since then, therapeutic colonoscopy has expanded to include resection of large neoplastic lesions, stenting for management of leaks, strictures, fistulae and obstructions, and bleeding. Advances in instrumentation and technique will continue to broaden the applications of interventional colonoscopy, possibly even using the colon as a portal to the peritoneal cavity.

Indications

Screening colonoscopy has become the standard of care for evaluation of average risk patients over the age of 50.[107–110] Prior screening tools such as fecal occult blood testing, sigmoidoscoy, and digital rectal exams no longer are considered as effective screening tools.[111] CT colonography, however, has gained some support due to improved abilities to identify colonic neoplasia; however, smaller lesions are still somewhat a challenge for this imaging tool. The indications for colonoscopy are listed in Table 3-3.

Contraindications

The contraindications for colonoscopy are in part similar to those for EGD, and are related to the patient's associated comorbidities, underlying gastrointestinal disorders, or patient's inability to tolerate conscious sedation. As with EGD, recent myocardial infarction, pneumonia, and recent foregut surgical procedure are relative contraindications for colonoscopy, and the risks and benefits need to be weighed on an independent basis for each patient to determine appropriateness. A recent surgical anastomosis is most likely safe at any time during the postoperative period to be evaluated endoscopically, remembering that tissue strength will be weakest on postoperative day's five to seven.

Coagulopathy secondary to thrombocytopenia, liver failure, renal failure, or exogenous use of anticoagulants and platelet-inhibiting agents is a relative contraindication for a diagnostic colonoscopy, but an absolute contraindication for a therapeutic intervention. Patient noncooperation or an inability for a patient to be safely sedated due to high cardiopulmonary risk is also contraindication to colonoscopy. Respiratory depression secondary to medications as well as inability to maintain an airway can occur in these high-risk patients even though there is no transorally placed scope. Preassessment with ASA classification and Malampatti scores will help predict this high-risk group.[16] Patients with suspected perforation, ischemic colitis, acute diverticulitis, or toxic megacolon should not undergo colonoscopy unless there are plans to provide immediate therapy such as endoscopic closure or stent placement, or surgical intervention.

TABLE 3-3: INDICATIONS FOR COLONOSCOPY

Diagnostic

1. Evaluate and confirm radiographic findings
2. Identify suspected polyps
3. Unexplained GI bleeding or iron deficiency anemia
4. Colon cancer screening and surveillance
5. Follow-up after intervention for polyp or cancer
6. Surveillance of inflammatory bowel disease
7. Significant unexplained diarrhea
8. Preoperative/intraoperative localization of lesions

Therapeutic

1. Control bleeding
2. Polypectomy
3. Remove foreign body
4. Reduce sigmoid volvulus
5. Decompress pseudo-obstruction (Ogilvie's)
6. Dilate or stent strictures/stenoses (malignant and benign)

Adapted, with permission, from the Society of American Gastrointestinal and Endoscopic Surgeons guidelines, www.colonoscopy.info, 2002; and the American Society of Colon and Rectal Surgeons parameters, 2004.

Patient Preparation

Most endoscopic evaluations of the lower gastrointestinal tract can be done under conscious sedation on an outpatient basis. Unsedated colonoscopy can be performed safely but requires a compliant, nonanxious patient, who understands that prior abdominal surgery as well as female gender increases the need for conversion to sedated endoscopy.

The day before the examination the patient should begin a light diet with only clear liquids at lunch. The most common bowel preparation for colonoscopy utilizes a sodium sulfate–based electrolyte solution containing polyethylene glycol as an osmotic agent (eg, GoLYTELY). Alternative regimens including magnesium citrate and multiple enema solutions have also been described. In addition to different agents for prep, endoscopists have also utilized varied timing for preps with the use of split doses, with the final dose being given four hours before the scheduled procedure. Fleet Phospho-soda, a small volume prep, is no longer an alternative due to the rare occurrence of cardiac complications.

Prophylactic antibiotics are usually not required for colonoscopy. Although diagnostic procedures can be performed in patients on anticoagulative therapy, these medications should be withdrawn if polypectomy or other therapeutic procedures are expected to be performed. Aspirin therapy, unlike other anticoagulative medications, probably does not alter the risk of postpolypectomy bleeding.

Basic Endoscopic Techniques—Colonoscopy

When performing colonoscopy, there are several universal principles to the technique similar to upper endoscopy, but there are also several specific caveats to assure performance of a safe procedure. Due to the tortuosity of the colon and the lack of fixation, manipulations such as scope torquing, loop reduction, patient position changes, and abdominal wall manual pressure are vital to the performance of colonoscopy. One other difference from upper endoscopy is the lack of reliability of correlation of shaft length inserted and actual anatomic position in the colon. Therefore, understanding specific colonoscopic landmarks is very important to interpreting actual lower gastrointestinal anatomy. In addition, surgical alterations to the anatomy must be recognizable (Fig. 3-27).

A digital rectal examination should always be performed prior to initiating the colonoscopic exam. This provides lubrication of the anal canal, relaxes the anal sphincters, provides evaluation of the prostate and lower rectal vault, and assesses the patient's level of sedation. The endoscope is introduced either by direct straight insertion or by rubbing the tip of the endoscope along the perineal body with the right index finger. Once reaching the anal verge, the tip of the endoscope is directed into the anal canal.

Once in the rectal vault, insufflation is initiated to allow view of the lumen. Although mucosal inspection occurs during advancement, principal evaluation for pathology occurs on scope withdrawal after the cecum is reached. Gentle advancement of the colonoscope is now performed. If the lumen is lost to view, termed a "red out," the scope is slightly pulled back and the wheels deflected in combination with scope torque to reestablish the lumen. Passage of the scope into the sigmoid colon can be challenging in patients with prior abdominal surgery, morbid obesity and a large pannus, or multiple diverticuli (Fig. 3-28). Abdominal compression and patient position change to supine may assist in this maneuver. Rarely, a "slide-by" maneuver is required to overcome the tight angulation in and out of the sigmoid colon. This technique entails careful insertion without complete luminal view but with appearance of the mucosa sliding by the scope. During all portions of the colonoscopy, however, increased patient discomfort, "redded out view," and excessive scope resistance with advancement are markers to the endoscopist to pull back one's colonoscope.

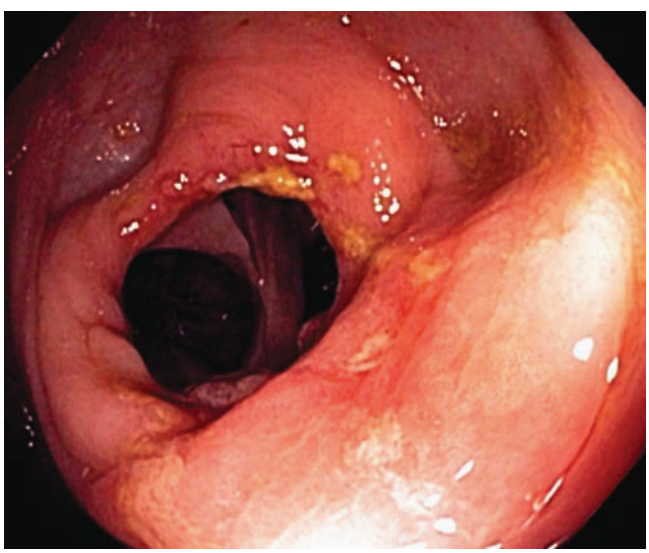

FIGURE 3-27 An EEA stapled anastomosis at the rectosigmoid level is seen in this image.

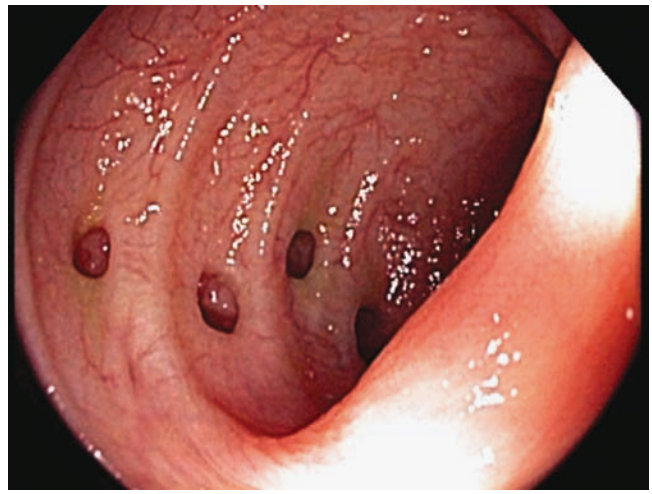

FIGURE 3-28 Multiple diverticuli seen in the sigmoid colon.

Exiting the sigmoid colon may require building up a "loop." This may lead to increased patient discomfort and may require additional medication. Once access into the descending colon is achieved, the loop is reduced by gentle withdrawl and slight torquing of the scope. Adding variable stiffness to the scope, if available, will now allow advancement in a one-to-one fashion, to the splenic flexure. "One-to-one" refers to equal scope tip advancement with scope insertion. The descending colon is usually quite straight, and the splenic flexure is identified by the extraluminal blue hue as well as the tight turn encountered as one enters into the distal transverse colon. Suctioning and scope withdrawal will assist in maintaining positioning beyond the splenic flexure.

Introduction of the scope, again with the addition of variable stiffness, should allow one-to-one progress through the transverse colon, which is easily identified by the triangular configuration. As one proceeds toward the hepatic flexure, the blue hue of the liver becomes apparent. At this time, paradoxical motion routinely will occur with scope introduction. Access into the ascending colon usually requires the endoscopist to make a sharp deflection at the hepatic flexure followed by withdrawal of the scope and simultaneous suctioning. The ascending colon may have a yellow discoloration due to the continued passage of succus entericus despite a complete bowel preparation. Asking the patient to take a deep breath

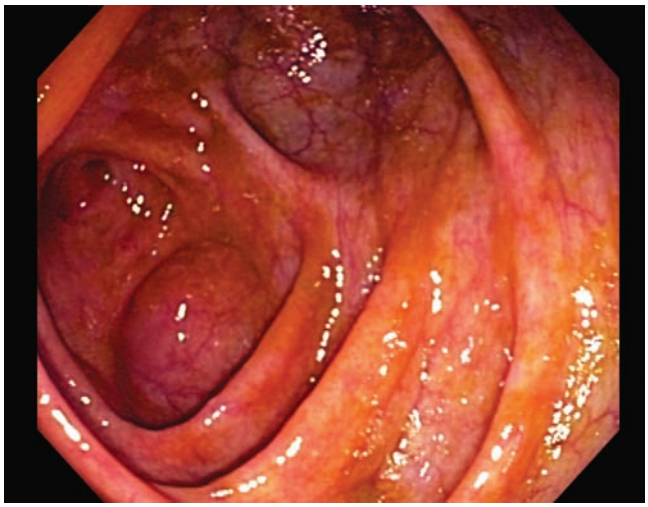

FIGURE 3-29 The cecum is seen here, identified by the ileocecal valve, appendiceal orifice, and classic cecal strap.

as well as placing them in supine position may assist in this maneuver. Eventually, the cecum is identified by the ileocecal valve, appendiceal orifice, cecal strap, abdominal wall transillumination, and right lower quadrant palpation (Figs. 3-29 and 3-30). Intubation of the ileum, however, is the only way to confirm 100% that you have actually reached the cecum. The terminal ileum can be intubated by deflecting the tip toward the ileocecal valve, gently withdrawing the scope, and prying open the upper lip of the valve. Throughout this maneuver, air insufflation is used. The scope is then slowly advanced into the terminal ileum.

The goal of the endoscopist is to reliably and safely gain access into the cecum, confirming one's position, and then

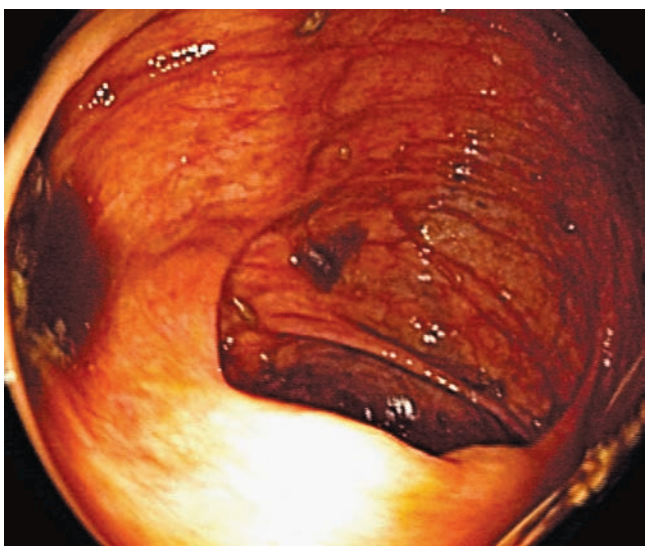

FIGURE 3-30 Classic lipomatous appearance of the ileocecal valve helps differentiate it from other colonic folds.

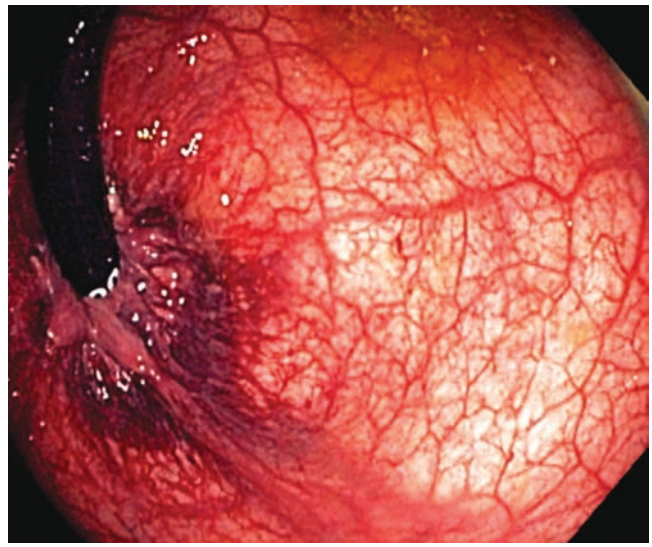

FIGURE 3-31 Retroflexed view in the rectal vault identifying the dentate line and excluding any anorectal disease not able to be seen on anteflex view.

performing a slow careful withdrawal evaluating the entire mucosal surface. Areas of excess stool must be flushed clear and extra care must be taken at the flexures and around larger folds to investigate for underlying disease. Retroflexion of the endoscope, which had been utilized for evaluation of the rectal vault, is now being performed with some regularity, in the cecum and flexures, as well as to see behind larger folds. Manipulation by patient position change, as with upper endoscpy, may aid in visualization of areas with excess stool. Retroflexion in the rectum can be done at the beginning or at the end of the procedure (Fig. 3-31). The colonoscope is withdrawn into the anal canal and then carefully advanced for several centimeters. Full upward deflection along with clockwise torquing and gentle advancement will result in the scope looking back toward the distal rectum and dentate line.

Complications

Complications specifically related to colonoscopy include hemorrhage and perforation. The former is most unusual following diagnostic colonoscopy, occurring in 0–0.07% of cases. Hemorrhage in this setting is usually intra-abdominal such as following injury to the colon mesentery or to the capsule of the spleen, resulting from the use of excessive force during manipulation. Hemorrhage is seen more often following polypectomy (1–3%).[112] Postpolypectomy bleeding can be immediate or delayed, and can occur up to 2 weeks after the procedure. Repeat colonoscopy is recommended for hemodynamic instability, transfusion requirement, and continued or recurrent episodes of bleeding.

Perforation is the most common complication of colonoscopy, occurring in <1% of cases.[111] These injuries are caused by mechanical or pneumatic pressure and are most common at the rectosigmoid or sigmoid–descending colon junctions along the antimesenteric border at the site of scope looping. Alternatively, cecal perforation can occur if the colon is excessively insufflated across a more distal nontraversable obstruction. In patients with a competent ileocecal valve, there is a resultant trapping of air between the distal obstruction and the valve, which prevents release of the insufflated air into the small bowel.

Therapeutic colonoscopy can also be complicated by perforation, at the site of therapy, as well as the other previously reported sites. Reported incidences are rare (<1%), with the greatest risks occurring with the removal of sessile polyps. Following polypectomy, patients occasionally develop localized pain secondary to peritoneal irritation, along with fever, tachycardia, and leukocytosis. There is usually no evidence of diffuse peritonitis or overt perforation (ie, no "free air"). This syndrome has been labeled postpolypectomy syndrome, and is probably attributable to a transmural electrocoagulation injury with microperforation. Patients usually can be managed conservatively with antibiotics, analgesics, and close observation with serial exams. Symptoms usually resolve within 48–72 hours and rarely are surgical interventions needed.

In patients with a suspected perforation, CT studies are recommended to evaluate for abscess formation or intra-abdominal fluid collections. Intra-abdominal fluid collection is a more concerning finding and these patients require close observation with a low tolerance for surgical intervention. It is important to base therapy on individual patient status, however, rather than just radiographic studies. The presence of intraperitoneal or retroperitoneal air in the absence of clinical peritonitis or hemodynamic instability does not warrant surgical exploration.

Polypectomy

By far, the most commonly performed colonoscopic intervention is polypectomy. When performed at regular intervals, removing adenomatous polyps has been shown to significantly reduce the incidence of colon cancer.[107] Small sessile lesions are amenable to hot or cold biopsy polypectomy. For hot polypectomy, standard biopsy forceps without spike are attached to an electrocautery unit set at 10 to 20 watts. The polyp is grasped and lifted from the surrounding mucosa, and monopolar cautery is applied in short bursts until the base of the polyp whitens. The biopsy forceps is sharply withdrawn and the polyp is then removed through the working channel of the colonoscope. Polypectomy serves to biopsy the polyp and ablate any residual tissue, thereby diminishing the risk of progression to carcinoma. Due to the concern for delayed bleeding following sloughing of the eschar as well as the risk of perforation, many endoscopists are now adopting cold polypectomy techniques. Several series have shown no difference in the rates of bleeding, and it presents a more easily evaluable specimen to the pathologist without cautery artifact.

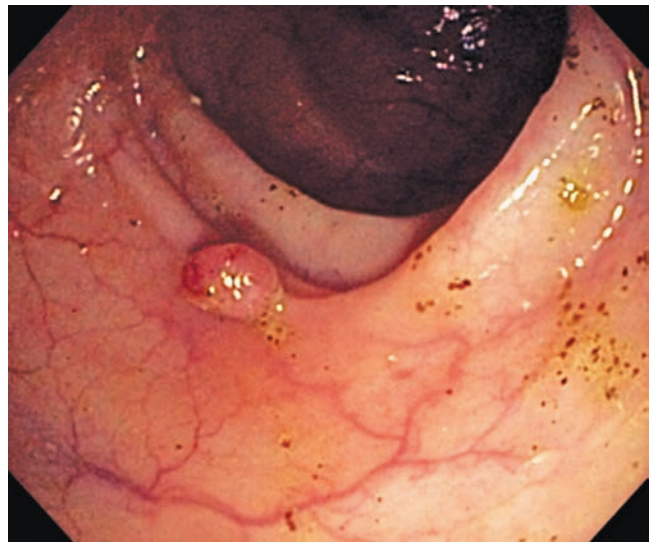

FIGURE 3-32 Small pedunculated polyp amenable to snare polypectomy technique.

Pedunculated polyps are suitable for snare polypectomy (Fig. 3-32). The base of the polyp is encircled with the snare several millimeters below the head-stalk junction. This allows removal of a portion of the stalk for pathologic evaluation to rule out invasion of the lamina or muscular layers, identifying a more advanced neoplasm. Cautery is applied as the snare is gradually closed, thus severing the polyp and cauterizing the base. Broader-based pedunculated polyps may be managed with placement of an endoscopic pretied endoloop proximal to the site of resection to help minimize bleeding. These loops usually will slough off within several weeks and pass spontaneously.

Sessile polyps are frequently more difficult to manage than pedunculated polyps. Small sessile lesions may be captured in a single application of a snare and resected, with (hot) or without (cold) cautery, while larger lesions might require resection in a piecemeal fashion. Piecemeal resection provides for removal of a larger lesion along with ablation of residual tissue, but may make pathologic interpretation more challenging.[113]

Resection of sessile polyps poses a higher risk of colonic perforation than pedunculated polyps. Given that, endoscopic mucosal resection has been developed to minimize the risk of perforation and ensure complete resection of the lesion. This is provided by submucosal injection of saline to create a cushion between the mucosa and muscularis, to help minimize the risk for perforation.[113–116] Lesions that do not easily elevate may have a component of invasisve carcinoma and these tumors should be biopsied and tattooed, rather than attempted to be endoscopically resected. Following removal of large sessile lesions, APC ablation of the site has been proposed to minimize adenoma recurrence.

POLYP RETRIEVAL

Small polyps may be retrieved through the suction channel of the endoscope and captured in a trap. Larger polyps may be recovered in a net placed through the working channel of the endoscope or apposed to the tip of the endoscope by constant application of suction and then withdrawn with the scope. Marking the site of resection with a carbon particle–based tattoo via a sclerotherapy needle will allow for more accurate surveillance, as well as to guide surgery if the polyp proves to be malignant. Injections should be placed at multiple sites circumferentially to allow for the most reliable visualization at the time of surgery or during subsequent surveillance endoscopy.

POLYP SURVEILLANCE

Over the past 15 years, much has been learned about the nature of the adenoma carcinoma sequence, leading to ongoing changes in the recommendations for polyp surveillance. Average risk patients with satisfactory bowel preps require repeat surveillance in 10 years, while patients with those with poorer preps might be recommened to have a shorter interval of 5 to 7 years.[107,109–111] Hyperplastic polyps carry an undetermined risk/association with advanced neoplasia, although there has been some suggestion that left-side hyperplastic lesions have a more aggressive nature than those in the rectosigmoid. Similar to fundic gland polyps of the stomach, these lesions may be sampled but do not need to be fully removed. Tubular adenomas, tubulovillous adenomas, and villous adenomas warrant a surveillance colonoscopy at 5, 3, and 1 year, respectively.[107]

Lower Gastrointestinal Bleeding

Sources of lower gastrointestinal bleeding include UGI bleeding, infection, ischemia, neoplasia, diverticulosis, angiodysplasia, and anorectal disease. A detailed history of the nature of bleeding is vital to the management of patients with lower gastrointestinal bleeding identifying underlying coagulopathy, recent surgical or colonoscopic interventions (polypectomy), and associated comorbid diseases. These factors are important in patient management and guiding surgical and nonsurgical interventions.

The role of bowel preparation prior to colonoscopy in the face of lower gastrointestinal bleeding is dependent on the rapidity of the bleeding. As blood is a very active cathartic, colonoscopy can be performed in the unprepped colon with extensive bleeding.[117–119] Otherwise, a rapid prep over 3 to 4 hours can be utilized in patients with less aggressive bleeding prior to endoscopic evaluation. The endoscopist must compare the need for a more urgent intervention versus the necessity of a more adequately cleared mucosal surface. In addition, newer irrigation devices are now available that can be affixed to the colonoscope to provide for high pressue and volume irrigation and cleaning.

Colonoscopic therapy for lower gastrointestinal hemorrhage within 6 to 24 hours of admission has been shown to diminish rates of rebleeding and reduce the necessity for urgent surgical intervention.[117] Various methods are available for hemostasis including thermal and nonthermal devices, and are described in the preceding sections of this chapter. One must always remember, however, that the colon wall is thinner, especially on the right side, as compared to the stomach. Depth of penetration of the varied thermal endoscopic devices must be closely considered to avoid full thickness perforations.

Diverticular disease is the most frequent cause of lower gastrointestinal hemorrhage. Up to 75% of diverticular bleeds are self-limited, but in those patients with transfusion requirements, massive hematochezia, or hemodynamic instability, colonoscopy may aid in confirming diagnosis, identifying the site, achieving hemostasis and limiting patient morbidity.[117–121] Locating the precise site of bleeding may be difficult in the face of multiple diverticula and a blood-stained colon. The bleeding diverticular vessel is frequently at the lip of the diverticulum, although bleeding vessels in the dome of the diverticulum may also occur. The use of endoscopic clips and ligation bands for treatment of bleeding diverticuli has also been reported.[120,121]

Vascular ectasia or angiodyspoasia, commonly in the right colon but also routinely multicentric, is another common cause of lower gastrointestinal hemorrhage. Argon plasma coagulation is invaluable in this situation, but care should be taken to avoid excessive distension of the bowel, as the argon gas accumulates and could lead to perforation.[122] Other thermal endoscopic contact probes, as described in previous sections of this chapter, can also be utilized.

Colonoscopic Decompression

Mechanical or nonmechanical obstructions with unrelieved distention of the colon, in addition to leading to patient discomfort, can result in bowel ischemia, perforation, and death. In patients with colonic distention secondary to acute pseudo-obstruction, Ogilvie's syndrome, colonoscopy provides both a diagnostic and therapeutic potential. Underlying etiologies including ischemia, infectious colitis, or an unsuspected obstructing lesion must be excluded.

Conservative treatment is initially indicated in patients with benign abdominal exams, clinical stability, and cecal diameters less than 12 cm. Patients should be maintained NPO, electrolyte imbalances corrected, narcotics withdrawn, and one should consider possible placement of nasogastric and rectal tubes.

Colonoscopic decompression is done without a routine bowel preparation, thus limiting the overall mucosal evaluation. The endoscope is advanced, with limited air insufflation, as far proximally as can be achieved without excessive bowel wall tension, minimizing any risk for perforation. Decompression is then performed upon withdrawal of the colonoscope, suctioning both fluid and intraluminal air. Although the cecum

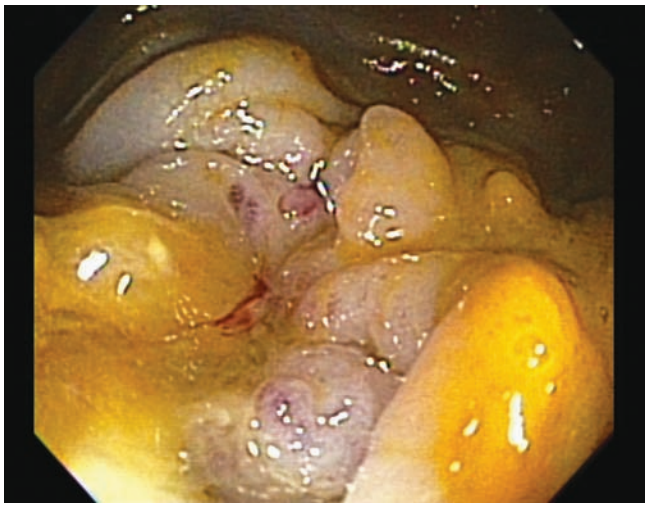

FIGURE 3-33 An obstructing sigmoid colon cancer prior to stent placement.

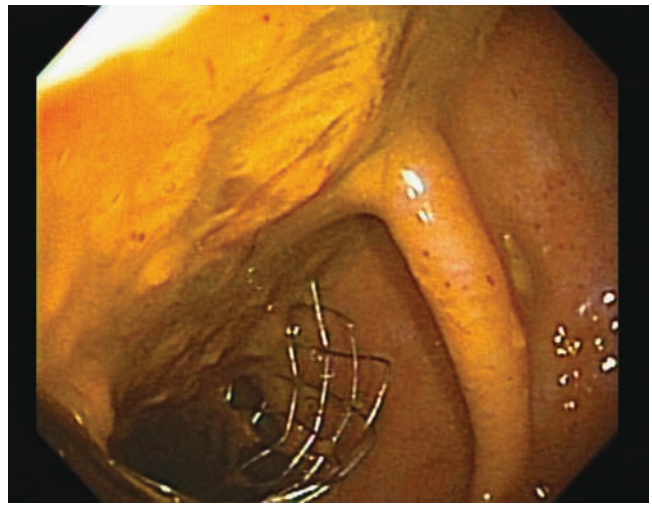

FIGURE 3-35 Following stent deployment, obstruction is relieved as seen by the large volume of liquid stool.

is the optimal endpoint, successful decompression can also be achieved with a less complete colonoscopy. Evaluation of visualized segments of the colon for ischemia and/or mechanical obstruction, possibly requiring stent placement or dilation, is crucial. It must be understood that repeat colonoscopic decompression is routinely required in patients with pseudo-obstruction, and they should be watched closely for several days.

Enteral Stents

Colonic stenting can provide relief of malignant colon obstruction or benign stricture and serve either as palliation or as a bridge to operation.[123–127] Permanent SEMT are commonly employed in large bowel obstruction. Through-the-scope stents are placed under endoscopic and fluoroscopic guidance. The malignant stricture is located endoscopically and a guide wire is passed through the narrowed lumen (Figs. 3-33 and 3-34). Contrast is injected into the bowel lumen, typically through an ERCP catheter, to define the borders of the stricture. If possible, the proximal and distal extents of the stricture are marked by injecting submucosal contrast. The stent is then placed over the wire, positioned properly, and deployed (Fig. 3-35). Self-expanding metal stents have shown efficacy in reducing the need for emergency operation in acute large bowel obstruction.[123,124,126] In patients who are not candidates for operation, metal stents may serve a palliative purpose.[125] Stenting is generally safe, although perforation has been reported in up to 10% of cases. Migration of stents can also occur, although is less likely due to tissue in-growth, which can also lead to subsequent stent occlusion.

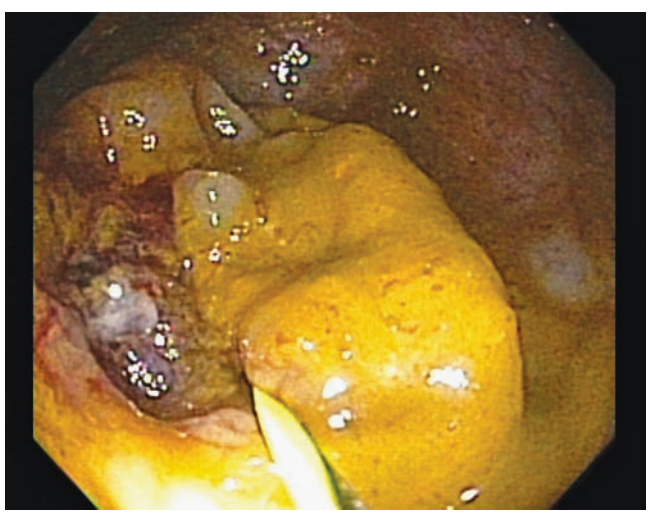

FIGURE 3-34 Guide wire placement across the obstructing lesion.

ENDOSCOPIC ULTRASOUND

Endoscopic ultrasound has become a mainstay in the diagnostic and therapeutic armamentarium of endoscopy (Table 3-4). The staging of neoplastic processes throughout the gastrointestinal tract, and those structures adjacent to the hollow viscera, can now be more accurately accomplished, with the addition of tissue sampling for confirmation of disease.[128–130] The use of neoadjuvant therapy has become closely tied to the results of endoscopic ultrasonographic findings, providing for more appropriate patient care. Finally, directed therapy for endoscopic removal, drainage, and palliation of gastrointestinal and extragastrointestinal diseases is now readily being performed with the assistance of EUS.[131]

TABLE 3-4: INDICATIONS FOR ENDOSCOPIC ULTRASOUND

Pancreatic
1. Fine-needle aspiration and cytology of cystic or solid lesions
2. Drainage of fluid collections
3. Lymph node sampling (to determine resectability)
4. Assess portal venous system
5. Intraductal ultrasound
6. Ampullary mass

Hepatobiliary
1. Detect stones (in conjunction with or in lieu of ERCP)
2. Intraductal ultrasound
3. Periportal lymph node sampling
4. Biopsy of liver mass

Mediastinal
1. Aortopulmonary window lymph node sampling (in lieu of mediastinoscopy)
2. Bronchial and carinal tissue sampling/cytology
3. Lung cancer staging

Esophageal
1. Esophageal cancer staging
2. Follow-up of hiatal hernia repair and antireflux surgery (under investigation)

Gastric
1. Gastric cancer staging
2. Evaluation of submucosal masses

Retroperitoneal
1. Lymph node cytology
2. Celiac axis nerve blocks
3. Retroperitoneal biopsies
4. Renal/adrenal biopsies

Colorectal
1. Anorectal cancer staging
2. Anorectal lymph node evaluation
3. Anal sphincter evaluation
4. Perirectal abscess detection and management

The echoscope endoscopically visualizes similar to a side-viewing duodenoscope. After providing appropriate sedation, endoscopic visualization is used initially to achieve appropriate scope position. Once the endoscope is in the desired position, a balloon on the endoscope tip is filled with deaerated water. The lumen of the GI tract is suctioned to affix the scope adjacent to the mucosal surface as excess air limits ultrasound views. Miniature probes as well as Doppler capabilities are also available. When a lesion is found, the working port of the scope allows for passage of a 19 or 20 gauge needle to obtain fine-needle aspiration biopsies. Immediate cytologic evaluation is recommended as repeat passes for further samples is commonly required.

FUTURE DEVELOPMENTS

The future developments in endoscopy will be based on advancements of both the tools and the applications available to endoluminal therapy. As surgery becomes less invasive with the advancement of laparoscopy, endoscopy is taking on an increasingly more invasive and therapeutic role. Intraluminal and translumenal procedures are being developed with the goal of further supplanting surgery. Recent interest in NOTES united surgeons and gastroenterologists with the desire to access the abdominal cavity via naturally existing orifices including the stomach, colon, bladder, and vagina. Using existing endoscopic technology, investigators have attempted numerous intra-abdominal procedures in porcine models, and eventually human cases under laparoscopic guidance have also been reported.[132,133] An appropriate application for this approach is still yet to be elucidated. It is theorized that NOTES may have distinct advantages over laparoscopy in that it may not necessarily require a sterile working environment to perform, and it possibly could also be completed under conscious sedation similar to other endoscopic procedures.[134,135]

The obvious limitations to NOTES were based on the lack of adequate and appropriate endoscopic equipment. The accessories were too flimsy to perform intra-abdominal manipulation of tissue, and the endoscopes were too flexible, inhibiting access and stable positioning once in the abdominal cavity. It was apparent early on that stable platforms would be necessary as well as endoscopic tools for cutting, hemostasis, and tissue manipulation. Transoral and transvaginal multichannel platforms with internal capability for manipulation and fixation are now becoming available. Scissors, suturing devices, bipolar forceps, and grasping devices are a few of the novel instruments soon to be added to the endoscopist's armamentarium.

These tools, however, will have a more likely impact on intraluminal endoscopic surgery.[136] The ability to perform full thickness resection, intraluminal anastomoses, and closure of perforations are all likely procedures to be seen in the very near future, and it is imperative that surgeons stay abreast of the numerous advancements in these technologies.

FUNDAMENTALS OF LAPAROSCOPIC SURGERY

Ashley H. Vernon • John G. Hunter

Tremendous growth in the use of minimally invasive techniques has occurred over the past decade. This was made possible by developments in technology and was fueled by patient demands for less painful operations and quicker postoperative recovery.

Almost all general surgical procedures can be performed using minimally invasive techniques. The greatest benefit is achieved in operations where the trauma of access exceeds that of the procedure. Procedures in the chest, upper abdomen, and pelvis, especially those not requiring tissue removal, are ideally suited for minimally invasive techniques. Conversely, other procedures may have less obvious benefits when performed with minimally invasive techniques, especially if a large specimen is to be removed. To be a proficient *laparoscopist,* one must become familiar with a new set of techniques and instruments, as well as knowing when to apply them and when to convert to an open operation.

PATIENT CONSIDERATIONS

Patient Selection

As in all surgery, choosing the right operation for the patient is the first step. Since all laparoscopic surgery of the abdomen requires the use of general anesthesia, the ability to tolerate anesthesia is an absolute requirement. Patients with impaired exercise tolerance or a history of shortness of breath will need a preoperative consultation with a cardiologist or pulmonologist. Patients with severe carbon dioxide (CO_2) retention can be difficult to manage intraoperatively because the use of carbon dioxide for pneumoperitoneum exacerbates the condition. By increasing the minute ventilation and decreasing the CO_2 pneumoperitoneum from 15 to 8–10 mm Hg, one can control metabolic acidosis. Rarely, when these measures are ineffective at controlling hypercarbia, we have resorted to using nitrous oxide (N_2O) for peritoneal insufflation. While not suppressing combustion (as does CO_2), N_2O supports combustion no more than air and has been proven safe for laparoscopic use. A single blind randomized trial has demonstrated that N_2O pneumoperitoneum is associated with decreased postoperative pain compared with CO_2.[1]

When deciding if a patient is a suitable candidate for a laparoscopic procedure, it is important to assess patient or procedure characteristics that will lengthen the operative time sufficiently to nullify the benefits of laparoscopy. If the laparoscopic operation takes substantially longer than the open equivalent or is more risky, then it is not prudent to proceed laparoscopically. A history of a prior open procedure or multiple open procedures can make access to the abdomen difficult and will be discussed in detail later in this chapter. Adhesions and scarring in the surgical field from prior surgery can make laparoscopic surgery very difficult and may require use of many novel dissecting and coagulating tools. Operating on patients with severe obesity is challenging specifically because torque on transabdominal ports leads to surgeon fatigue and diminishes surgical dexterity. In addition, the long distance from the insufflated abdominal wall to the abdominal organs can make laparoscopic surgery a "far reach." Special long ports and instruments are available to overcome this difficulty.

Inability to obtain an adequate working space makes laparoscopic surgery impossible. This is encountered most commonly in patients with dilation of the intestine from bowel obstruction. Often, laparoscopic lysis of adhesions for distal bowel obstruction is not technically feasible.[2] Some patients with appendicitis will have sufficient small bowel dilation that laparoscopic access to the right iliac fossa is not possible.

Patient Positioning

We rely on gravity for retraction of the abdominal contents to provide exposure. Sometimes this requires steep positional changes, and care must be taken to prevent nerve complications or neuropathies after laparoscopic surgery as in open surgery. Patients must be positioned properly at the beginning of the procedure, making certain that all pressure points are padded. Perineal nerve injury is caused by lateral pressure at the knee and may occur when the table is "airplaned" to the

side with a retractor holding the patient in place. Femoral and sciatic neuropathies are similar in that they are due to compression. Padding the retractor arms and securing the patient to the table can prevent these neuropathies.

It is best if the arms can be tucked for most laparoscopic procedures so that the surgeon may move freely up and down the table in order to line up instruments and the target tissue. This is most important for procedures in the pelvis, where the surgeon will want to stand adjacent to the contralateral thorax. However, even with upper abdominal laparoscopy, tucked arms allow more optimal positioning of instrument columns and monitors. If there is a need to extend the arms on arm boards, one must be very careful to avoid a brachial plexus injury that occurs when the arm is extended greater than 90 degrees at the shoulder. Usually, at the start of a procedure, the arm positioning is safe but may change as the patient slides down on the table. For this reason, when reverse Trendelenburg is expected, we place footplates at the feet. This prevents sliding on the table and does not cause any discomfort to the patient because it is much like standing. We secure the ankles as well to be sure they do not "twist" during the procedure. There are footplates available for split-leg tables that can be used when operating on the upper abdomen and steep reverse Trendelenburg is needed.

Patient Preparation

There may be an increased incidence of deep venous thrombosis after laparoscopic surgery that is due to pooling of blood in the venous system of the lower extremities. Venous return is impaired by compression of the iliac veins from the elevated intraabdominal pressure exerted by the pneumoperitoneum. Additionally, the positional effects of placing the patient in a steep reverse Trendelenburg position lead to further distension of the venous system. All patients undergoing laparoscopic procedures in reverse Trendelenburg, even short procedures such as laparoscopic cholecystectomy, should have sequential compression devices placed before the procedure begins, although this does not improve femoral blood flow entirely.[3] Patients at high risk for developing deep venous thrombosis should be treated with subcutaneous anticoagulants as either fractionated or unfractionated heparin.[4] This includes patients undergoing lengthy procedures, obese patients, patients with a prior history of deep venous thrombosis or pulmonary embolism, and patients in whom ambulation after surgery will be delayed. Some authors recommend placement of vena caval filters in patients with a prior history of deep venous thrombosis who are undergoing lengthy laparoscopic procedures.[5]

Laparoscopic surgery is associated with a high incidence of postoperative nausea and vomiting. A recent review asserts that serotonin receptor antagonists such as ondansetron (Zofran, GlaxoSmithKline) appear to be the most effective and should be considered for routine prophylaxis.[6] Another prospective, blinded, randomized trial shows a decrease in the postoperative nausea and vomiting when low-dose steroids are given to all patients.[7] There was no increased infection rate in the group that received steroids. Other preventive measures include ensuring adequate hydration[8,9] and decompression of the stomach with an orogastric tube before the end of the procedure. Intravenous nonsteroidal anti-inflammatory drugs (NSAIDs) such as ketorolac provide superb pain relief and diminish the need for postoperative narcotics, which may help to prevent nausea and vomiting.

PORT PLACEMENT

Site Selection

Proper placement of ports is important to facilitate completion of the laparoscopic procedure. The location of port sites depends on the type of procedure; the primary port should be placed with this in mind. We do not always place the primary port at the umbilicus but rather judge which site is best for the camera or which is the safest site for the primary puncture in a previously operated abdomen. The first laparoscopic port can be positioned anywhere in the abdomen after pneumoperitoneum has been created. The additional or secondary ports should not be placed too close to each other. The optimal pattern of port placement should form an equilateral triangle or a diamond array around the operative field. This "diamond of success" takes into account the optimal working distance from the operative target for each instrument and the telescope (Fig. 4-1). In laparoscopy, the standard instrument length is 30 cm. To produce a 1:1 translation and movement from the surgeon's hands to the operative field, the fulcrum of the instrument should be 15 cm from the target. A similar separation of the two working ports (surgeon's left and right hands) ensures that these two instruments will not be involved in "sword fighting" and that the angle between the two instruments at the target will be optimal (between 60 and 90 degrees). The secondary port site is chosen, and the abdominal wall is transilluminated to avoid large abdominal wall vessels.[10,11] The trocar is watched laparoscopically as it enters into the abdomen, and care is taken to avoid injuring the abdominal contents. During the procedure, the area beneath the primary trocar site is inspected for unexpected injuries.

Port Characteristics

There is a wide variety of ports, each with different characteristics, available on the market. The bladed trocars cut the abdominal wall fascia during entry. Because the nonbladed trocars do not cut the abdominal wall as much, they make smaller defects in the abdominal wall and may be less prone to hernia formation in the future. The most commonly used bladed ports have a shield that retracts as the blade is pushed through the fascia of the abdominal wall, and then it engages once inside the abdomen. When first introduced to the market, the shields were called safety shields, but they have lost

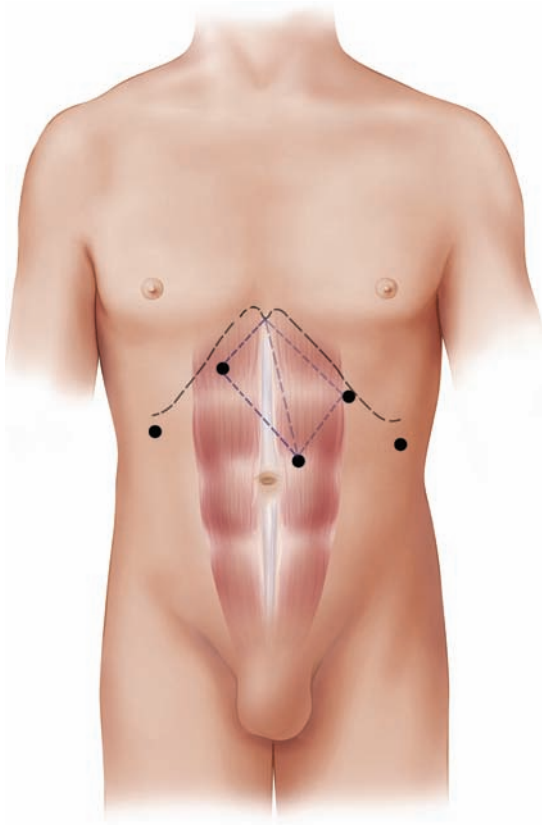

FIGURE 4-1 The "diamond of success" for optimal placement of laparoscopic ports. (Redrawn from Hunter JG, Trus TL, Branum GD, Waring JP. Laparoscopic Heller myotomy and fundoplication for achalasia. *Ann Surg.* 1997;225:655–665.)

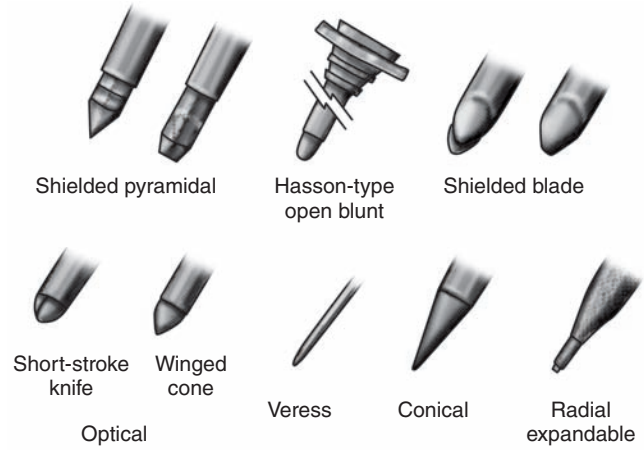

FIGURE 4-2 Various trocars for the introduction of laparoscopic ports through the abdominal wall. There are bladed and nonbladed types. Of the bladed trocars, there are shielded and nonshielded types. The Veress needle with a radially dilating sheath used in the Step system is an example of a nonbladed trocar. (Reprinted with permission from Chandler JG, Corson SL, Way LW. Three spectra of laparoscopic entry access injuries. *J Am Coll Surg.* 2001;192:478–490; discussion 490–471.)

that designation because the shield provides little protection. The nonbladed trocars come in many forms. One nonbladed trocar is used in the Step system (Covidien, Mansfield, MA), a modified Veress needle that locks inside an expandable sheath. Once inside the abdomen, the Veress needle is removed, and a blunt port is passed into the sheath that guides the port by dilating radially.[12] The Ethicon nonbladed trocar has a rough edge of plastic that is twisted and pushed through the layers of the abdominal wall. None of these technologies have proven safer than the more economical reusable nonshielded bladed trocar systems made by most instrument companies (Fig. 4-2).

Important characteristics of a port need to be considered when choosing which port to use. The advantage of a port introduced with a nonbladed trocar is that the abdominal wall defect is smaller, which does not allow gas to leak from the abdomen during the procedure. Because the fascia is not cut, there is a lower risk of port-site hernia, and the fascia of most 10-mm incisions does not have to be closed. Additionally, these ports tend not to slip out of the abdominal wall during manipulation. Other considerations when choosing a port are the size of the external component, the smoothness of entry and exit of the instruments and specimens, and whether an external reducer cap is needed.

Access or Placement of the First Port

No single access technique has emerged as the safest and best technique.[13,14] The techniques for abdominal access include direct-puncture and an open-access technique.[15] The direct-puncture technique can be performed either by direct trocar insertion without pneumoperitoneum or by first obtaining pneumoperitoneum using a Veress needle and then inserting the first trocar directly. The latter technique is performed most commonly in the United States. Each technique has a specific pattern of complications that must be considered when choosing among them.

The Veress needle access was first described in 1938.[16] This technique involves direct insertion of a needle into the peritoneum after lifting the abdominal wall with towel clips or a firm grip. The optimal site for insertion of the Veress needle is through the central scar at the umbilicus. One can make either a vertical skin incision through the umbilicus, hiding the incision in the base, or a curvilinear incision in an infraumbilical or supraumbilical position. Nevertheless, insertion of the Veress needle should be aimed at the central scar, where the layers of the abdominal wall are fused. This does not mean, though, that the first port inserted must be at the umbilicus. Advocates state that the benefits of this technique are the ability to place the initial port anywhere on the abdomen, that it is relatively quick, and that the skin and fascial openings are smaller, which prevents CO_2 leakage during the procedure.

For safe Veress needle insertion, first one must be certain to check the stylet and needle patency, especially when reinserting it after an unsuccessful initial pass. The Veress needle is available either as a reusable or disposable product and comes in two sizes, both long and short. The spring

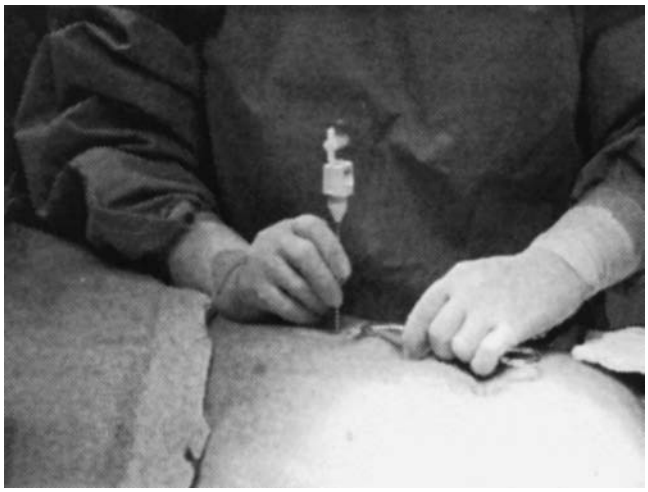

FIGURE 4-3 Proper Veress technique in the left upper quadrant using the dominant hand with the wrist stabilized on the patient. The nondominant hand is used to stabilize the abdominal wall.

mechanism that pushes the stylet out, thus protecting bowel from the needle, must be tested when using the reusable Veress needle.

The safest technique requires stabilizing the abdominal wall (we prefer penetrating towel clips in nonobese patients). It is important to have control over the force and depth of insertion of the needle. This is aided by either placing your wrist against the patient's abdomen or using the nondominant hand to support the hand wielding the needle. It is sometimes necessary to raise the operating table to achieve the proper control. One must be mindful of the fact that the most common catastrophic complication from Veress needle insertion is injury to major vessels. The trajectory of the needle should not be angled toward the aorta or iliac vessels (Fig. 4-3).

After placement of the Veress needle, one should perform an aspiration test by connecting a syringe filled with saline to the top of the Veress needle and aspirate. Aspiration of air, blood, or bile signifies incorrect placement and should prompt serious concern for an unexpected injury. If there is no aspirate, saline should be injected and should flow easily. The saline should flow down the Veress needle into the peritoneal cavity without pressure, a qualitative measure. Removing the plunger from the syringe and watching the saline level drop briskly may achieve a quantitative assessment of patency. If the saline flows slowly or not at all, the needle is likely in the wrong position, that is, up against an intra-abdominal organ, or it is in the preperitoneal space. Alternatively, the tip may be occluded with fat, or the system may have an "air lock." To test this, inject a little bit of fluid again gently, and retest by removing the plunger and allowing the saline to drop into the abdomen.

The Veress needle then is connected to the insufflation tubing. The expected initial insufflation pressure, assuming proper placement, should be less than 5–6 mm Hg. Abnormally high insufflation pressure is an indication that something is not right.[17] Because the insufflator is usually set to allow a maximum pressure of 15 mm Hg, a value greater than this suggests that the patient is not anesthetized adequately and is contracting his or her abdominal muscles. If the insufflator records a pressure of 15 mm Hg, there are a few explanations. The most ominous cause would be incorrect placement into an intra-abdominal organ. More likely, the Veress needle tip may be against omentum or is in the preperitoneal space. The insufflation line may be occluded at the stopcock, or there may be a kink in the tubing.

Direct trocar insertion without first establishing pneumoperitoneum is not used as frequently because many surgeons think that it is dangerous given that the bladed trocar must be pushed into the abdomen with significant force to penetrate the abdominal wall. Surgeons unfamiliar with the technique worry about injury to bowel and vessels when using excessive force. There are, however, many surgeons who perform this technique with no increased complication rate, confirming its safety.[18–22] Still other surgeons believe that the open-access technique that involves a "minilaparotomy" is the safest.[15,23–25]

The open, or Hasson, technique was first described in 1974.[15] A 1- to 2-cm skin incision is made at the umbilicus, and the soft tissue is divided to identify the abdominal wall. The fascia and muscles are opened with a knife, and the peritoneum is identified and grasped with Kocher or Allis clamps. A 0-0 absorbable suture is placed through the fascia, and the Hasson port is secured to the fascial sutures. Later, these sutures can be used to close the abdominal wall. The insufflation tubing is attached to the sideport of the trocar, and the abdomen is insufflated rapidly to 15 mm Hg.

Newer trocars, called *optical trocars*, allow visualization of the tip of the trocar as it passes through the layers of the abdominal wall (Fig. 4-4). A straight-viewing 0-degree scope is placed inside a clear trocar that is available with and without a bladed tip. Safe introduction of an optical trocar is a skill that requires judgment and experience and can best be learned in patients with no prior surgery after insufflation is established. Success depends on the operator's ability to see each of the layers of tissue, although visualization does not imply safety.[26] It is useful for the surgeon to have command of several access techniques because there is no single technique that is best for all circumstances.[27]

Difficult Access

Access can be the most challenging aspect of the procedure in some patients no matter which technique is used. This is especially true in obese patients. First, the site of the central scar is often judged inaccurately because the umbilicus is in a caudad position owing to the loose panniculus. Additionally, there is an increased distance between the skin and the abdominal wall fascia. The Veress needle may not penetrate the abdominal wall. If an open-access technique is chosen, it may be difficult to expose the abdominal wall through a small incision. Degenerated fascia in obese patients will make the abdominal wall bounce against the needle or finger,

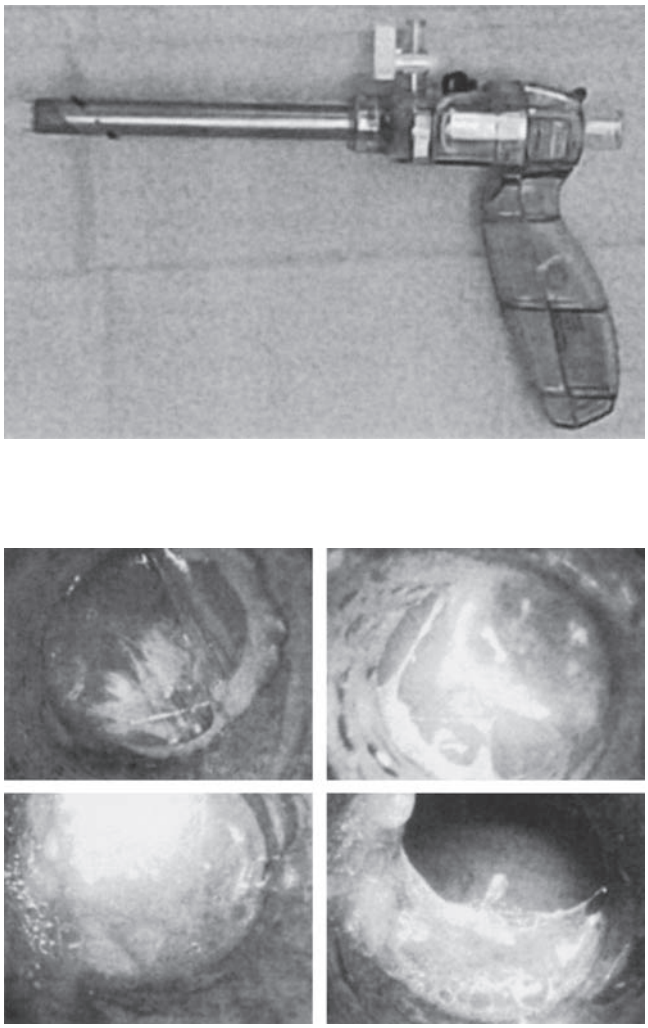

FIGURE 4-4 Optical trocar. (Used with permission of Ethicon.)

making its identification difficult. Raising the skin with penetrating towel clips does not facilitate this exposure and, in fact, distorts the anatomy, making it more difficult to identify the fascia. Sometimes a modified technique described by Vakili and Knight can be helpful.[28] This is a combination of open and Veress techniques in which a small skin incision is made in obese patients. Kochers are used to hold the abdominal wall fascia up, and a Veress needle is passed through the abdominal wall.

Access is also difficult in patients who have had prior surgery through a midline incision. In these patients, it is unsafe to perform the Hasson technique through the midline site because of the potential for adhesions of bowel to the posterior surface of the abdominal wall. Injury can occur when dividing the fascia or when sweeping adhesions away with a finger. It is difficult to perform the open technique at sites other than the umbilicus because of the multiple layers of the abdominal wall. In these patients, we prefer to place the Veress needle in the next safest location, which is the left upper quadrant along the costal margin. One must be certain that the table is flat because the spleen and liver are injured more easily in patients in the reverse Trendelenburg position. One must be certain that the stomach is decompressed with an orogastric tube before inserting the Veress needle in the left upper quadrant. Once insufflation is obtained, a port can be placed into the abdomen away from the previously operated field. We prefer entering with a 5-mm step port followed by a 30-degree 5-mm scope. Other surgeons recommend use of optical trocars in this situation.

Fascial Closure

Care should be taken to prevent port-site hernias, which occur in 0.65–2.80% of laparoscopic gastrointestinal operations,[29] because they can lead to bowel obstruction, incarceration, and/or Richter's hernias. All defects created with a 10-mm or greater bladed trocar should be closed, although this is not necessary when using some of the newer nonbladed trocars that create smaller fascial defects.[30,31] Most 5-mm defects do not require fascial closure in adults, although there are reported cases of hernias at these sites.[9,32,33] Because there is always a possibility of formation of a port-site hernia, the smallest possible port always should be used. When a port is manipulated excessively or has to be replaced multiple times, there may be a larger than expected fascial defect that may require closure. Additional recommendations are to place ports lateral to the rectus muscles when possible.[34] At the conclusion of the procedure, removal of ports from the abdomen should be observed to be certain that omentum or abdominal contents are not brought up through the abdominal wall.

Fascial closure can prevent trocar-site hernia.[35] A number of port-site closure devices have been developed[36] because small laparoscopic incisions make it difficult to close the abdominal wall with round needles. The closure devices function like crochet needles, passing a suture through the abdominal wall on one side of the fascial incision. The suture end is released intra-abdominally under laparoscopic visualization, and the needle is removed. The needle is replaced (without suture) on the other side of the incision, and the free end is secured and pulled back out through the abdominal wall. A knot is then tied that closes the trocar site, as viewed laparoscopically (Fig. 4-5).

Trocar Injury

The overall risk of a trocar injury to intra-abdominal structures is estimated to be between 5 in 10,000 and 3 in 1,000.[14] Almost all injuries occur during primary trocar insertion. According to Chandler and colleagues,[13] the most commonly injured organ is the small bowel (25.4%), followed by the iliac artery (18.5%), colon (12.2%), iliac vein (8.9%), mesenteric vessels (7.3%), and aorta (6.4%). All other organs were injured less than 5% of the time. The mortality from trocar injury is 13%, with 44% owing to major vessel injury, 26% to bowel injury with delayed diagnosis, and 20% to small

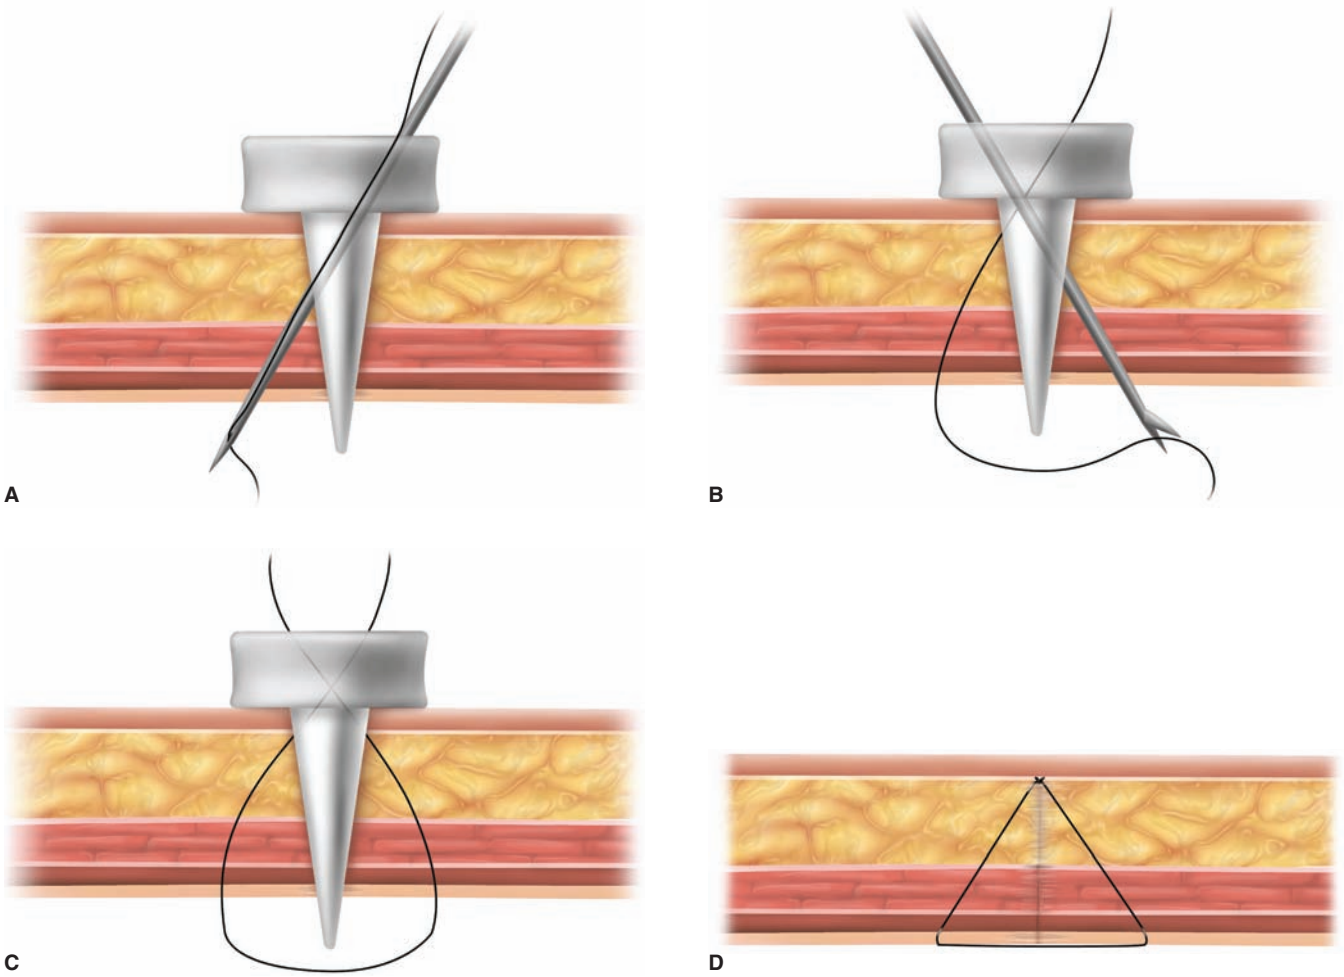

FIGURE 4-5 Using the Inlet device, the suture is passed through the abdominal wall on one side of the fascial incision. The suture end is released intra-abdominally under laparoscopic visualization, the suture then is pulled out on the other side of the incision using the device, and a knot is tied.

bowel injury. Major vascular injuries are noticed immediately and require rapid conversion to laparotomy. They are managed by applying pressure when possible to allow the anesthesia team to maintain and correct volume and prepare for rapid blood loss. Then the surgeon gets control of inflow and outflow to permit repair of the injury. Unfortunately, many bowel injuries are not recognized at the time of the procedure, and nearly half are not noticed until more than 24 hours postoperatively. This obviously leads to severe sequelae and may be prevented by careful dissection and inspection at the conclusion of the procedure.

EQUIPMENT

Telescope

Laparoscopic and thoracoscopic telescopes come in a variety of shapes and sizes, offering several different angles of view. The standard laparoscope consists of a metal shaft 24 cm in length containing a series of quartz-rod lenses that carry the image through the length of the scope to the eyepiece. The telescope also contains parallel optical fibers that transmit light into the abdomen from the light source via a cable attached to the side of the telescope. Telescopes offer either a straight-on view with the 0 degree or can be angled at 25–30 or 45–50 degrees. The 30-degree telescope provides a total field of view of 152 degrees compared with the 0-degree telescope, which only provides a field of view of 76 degrees (Fig. 4-6).

The most commonly used telescope has a diameter of 10 mm and provides the greatest light and visual acuity. The next most commonly used telescope is the 5-mm laparoscope, which can be placed through one of the working ports for an alternative view. Smaller-diameter laparoscopes, down to a 1.1-mm scope, are available and are used mostly in children. They are not used commonly in adult patients because of an inability to direct enough light into the larger abdominal cavity. The camera is attached to the eyepiece of the laparoscope for processing.

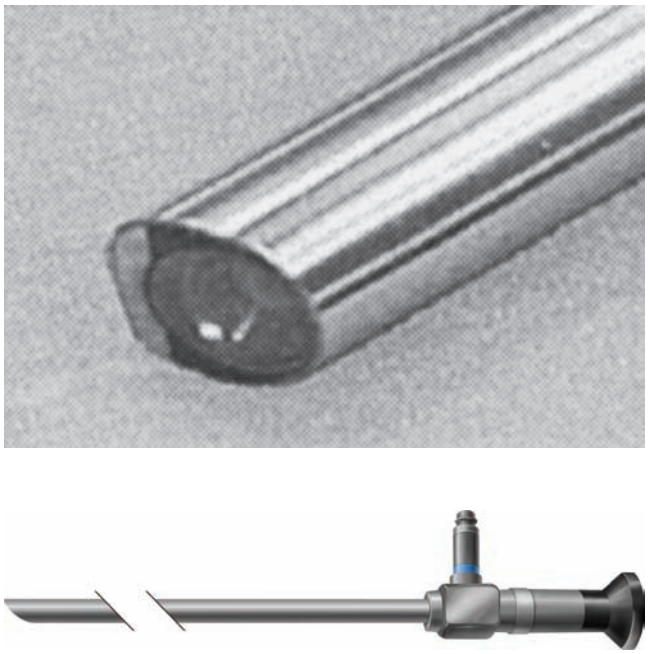

FIGURE 4-6 The 30-degree telescope (top) provides a total field of view of 152 degrees compared with the 0-degree telescope (bottom), which provides a field of view of only 76 degrees. (Used with permission of Storz.)

Video Camera

A high-resolution video camera is attached to the eyepiece of the telescope and acquires the image for projection on the monitor. The video image is transmitted via a cable to a video unit, where it is processed into either an analog or a digital form. Analog is an electrical signal with a continuously varying wave or shift of intensity or frequency of voltage. Digital is a data signal with information represented by ones and zeros and is interpreted by a computer. These are the methods by which the picture is transmitted to the video monitor. The camera and cable are designed so that they can be sterilized in glutaraldehyde.

The camera iris directly controls the amount of light processed by opening the aperture of the camera. The gain controls the brightness of the image under conditions of low light by recruiting pixels to increase signal strength. Clearly, this step results in some loss of image resolution. This increases light but results in a grainy picture with poorer resolution. It also may create a loss of color accuracy owing to amplification of the noise-to-signal ratio.

Light Sources

High-intensity light is created with bulbs of mercury, halogen vapor, or xenon. The bulbs are available in different wattages—150 and 300 W—and should be chosen based on the type of procedure being performed. Because light is absorbed by blood, any procedure in which bleeding is encountered may require more light. We use the stronger light sources for all advanced laparoscopy. Availability of light is a challenge in many bariatric procedures where the abdominal cavity is large. The light is carried to the fiberoptic bundles of the laparoscope via a fiberoptic cable. The current systems create even brightness across the field.

Insufflators

An insufflator delivers gas from a high-pressure cylinder to the patient at a high rate with low and accurately controlled pressure. Some insufflators have an internal filter that prevents contamination of the insufflator with the gas from the patient's abdomen and similarly filters any particulate matter that may be freed from the inside of an aging gas cylinder. Others require use with disposable insufflator tubing that has a filter on it. Some insufflators provide heated or humidified gas, but clinical benefit to these theoretically desirable features has not yet to be proven.

Video Monitors

High-resolution video monitors are used to display the image. Optimal monitor size varies but ranges from 19 to 21 in. Smaller monitors may be used if placed close to the operative field. Larger monitors provide little advantage outside of a display setting. Cathode-ray monitors (analog) are being replaced rapidly by flat-panel (digital) displays with excellent color and spatial resolution. These monitors may be positioned optimally when hung from the ceiling on light booms.

INSTRUMENTATION

The instruments used in laparoscopic surgery are similar to those of open surgery at the tips but are different in that they are attached to a long rod that can be placed through laparoscopic ports. Standard-length instruments possess a 30-cm-long shaft, but longer instruments (up to 45 cm in length) have been developed for bariatric surgery. The handles come in many varieties and must be chosen based on comfort and ergonomics, as well as the need for a locking or nonlocking mechanism. The shaft of most hand instruments is 5-mm wide; however, some specialized dissectors are available only in a 10-mm width. Pediatric laparoscopy instrumentation is generally 2–3 mm in diameter (Fig. 4-7). Bowel graspers come in a wide variety with different types of teeth (Fig. 4-8). The most atraumatic grasper has small, smooth teeth like a Debakey forceps. This has the advantage of not tearing the tissues and can be used on almost all organs. We use the Hunter

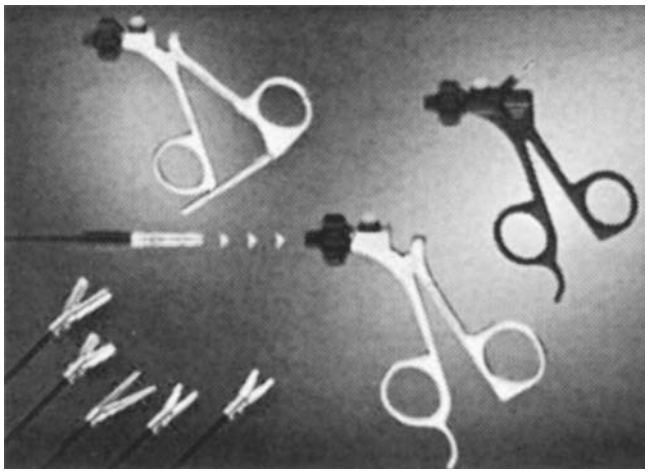

FIGURE 4-7 Instrument handles and tips. (Used with permission of Storz.)

grasper (Jarit), which, like a Debakey, can be used to grasp bowel and also can be used to grasp a needle. An additional benefit is that the tip is blunt and not prone to causing tissue trauma. Another commonly used bowel grasper is the Glassman (Storz), which is atraumatic and is slightly longer than the standard-sized Hunter grasper. It is fenestrated and cannot be used to grasp a needle. For some tissues, these instruments do not "grip" well enough, and bigger teeth or a different tip, such as those of Allis and Babcock clamps, is preferred. We reserve these larger-toothed instruments only for organs that are being removed, such as the gallbladder, or for thicker tissue, such as the stomach. The rule is to be gentle because small injuries can take a relatively long time to fix laparoscopically.

The most commonly used dissector is the Maryland dissector (Fig. 44-9). It is useful for dissecting small ductal structures such as the cystic duct and can be used when dissecting vessels. Another use for the Maryland dissector is that it can be attached to monopolar cautery and used to grasp and cauterize a bleeding vessel (this should not be done with bowel graspers). The Maryland dissector should not be used to grasp delicate tissue because too much pressure is applied over a very small area, much like erroneously using a Kelly clamp for grasping tissue. Very delicate right-angle dissectors can be used for renal, adrenal, and splenic vessels and are less traumatic than the Maryland dissector because there are no ridges.

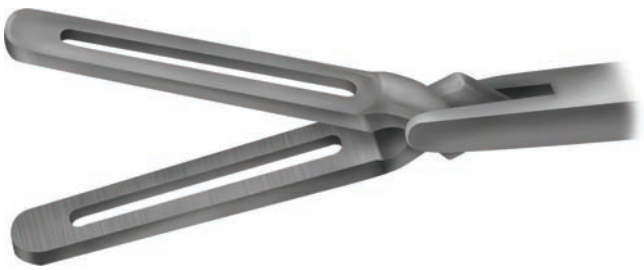

FIGURE 4-8 Atraumatic bowel graspers.

FIGURE 4-9 Maryland dissector.

Hemostasis

Hemostasis can be achieved using current from a monopolar electrosurgical generator applied to common instruments and controlled with a foot pedal. One of the most useful instruments for dissection is a disposable hook attached to the hand-held Bovie device for dissection (Valley Labs/Conmed and others). If a vessel has been transected and is bleeding but is too large to control with monopolar electrosurgery, a pretied lassolike suture (Endo-loop, Ethicon Endosurgery) can be helpful. Laparoscopic clips are handy for small identifiable vessels but should not be used when a vessel is not identified. The clip is only 7 mm in length and is not useful for vessels larger than this. When the vessel is not clearly identified but the bleeding site is, ultrasonic shears and some bipolar instruments such as the LigaSure device (Covidien, Mansfield, MA) can be helpful. These instruments have the advantage of facilitating dissection while providing hemostasis for larger bleeding vessels.

Monopolar Electrosurgery

Although hemostasis is obtained using the same electrosurgical generator that is used in open surgery, there are hazards that are unique to minimally invasive surgery. The most frequently used method of delivering electrosurgery is monopolar. The desired surgical effect is hemostasis, and this is obtained by production of heat. Alternating current at 50,000 Hz (household current is 60 Hz) is generated and travels through an active electrode. The active electrode can be a Bovie tip in open surgery or, in laparoscopy, an instrument that is connected to the generator by the monopolar cord. The current passes into the target tissue at sufficiently high current density to cause a great deal of heat. Depending on tissue heating, coagulation, fulguration, or vaporization of the tissue occurs. The circuit is completed by the return of the electrons broadly spread through the tissue (insufficiently dense to cause any adverse effect) back to the generator via the return electrode (grounding pad).

In open surgery, monopolar current sometimes is passed from the active electrode (Bovie tip) to the patient via another conductive instrument, the forceps. This is called *direct coupling*. In laparoscopy, it is not prudent to touch the active electrode (an activated instrument) on or near other conductive instruments within the abdominal cavity, that is, the laparoscope or other working instruments. Direct coupling in minimally invasive surgery always should be avoided because injury may occur out of the surgeon's field of view. It is also not prudent to activate the generator in "midair" because the current may travel out of the surgeon's field of view to a crack in the insulation of a laparoscopic instrument. This results in transfer of current to a small area that generates heat and can produce an injury. All laparoscopic instruments should be checked for cracks in the insulation before being used.

Ultrasonic Shears

Before the introduction of ultrasonic shears, larger vessels had to be tied off individually. This was very tedious laparoscopically, especially with the division of short gastric vessels during fundoplication. The development of the ultrasonic shears was revolutionary, allowing surgeons to divide larger vessels quickly and dissect simultaneously. Ultrasonic energy or sound waves are used to ablate, cauterize, and cut tissues. A generator produces a 55.5-kHz (55,500 Hz) electrical signal that travels via a cable to a piezoelectric crystal stack mounted in the transducer. The crystal stack converts the electrical signal to mechanical vibration at the same frequency. The ultrasonic vibration is amplified as it traverses the length of the titanium probe that is the active blade of the scalpel. Shearing forces separate tissue and heat the surrounding tissue, thereby coagulating and sealing blood vessels without burning. Damage to adjacent tissues is low, although the active blade can become quite hot, and burn injuries can occur.

Bipolar Electrosurgery

Bipolar electrosurgery coagulates tissue by passing a high-frequency, low-voltage electric current between two directly apposed electrodes. Laparoscopic general surgeons use it much less frequently because an additional maneuver must be made to divide the tissue. The LigaSure, a newer bipolar device, coagulates larger vessels (up to 7 mm in diameter) and seals tissue and has a knife available for subsequent division of the tissue between the jaws of the forceps. The instrument makes a sound when the tissue within the jaw has been coagulated safely. The advantage is that division of larger vessels can be performed safely. Unfortunately, it is relatively slow to use as a dissecting instrument, and the tip is not very useful for dissection because it is straight and wide.[37] It does not produce a large amount of heat, and damage to surrounding tissues is low.

SUTURING

Intracorporeal suturing may be out of the realm of the fundamentals of a laparoscopic surgery chapter. However, obtaining this skill is critical for successful performance of many laparoscopic procedures. A fundamental skill of laparoscopic surgery is the ability to place a suture accurately and tie a knot with a needle holder and a standard surgical suture. This skill can be mastered easily with a training box. Various suture aids have been developed, such as the EndoStitch (USSC), and can be used as a substitute. However, these devices are expensive, and the range of suture and needle sizes and types is limited. Many surgeons believe that an extracorporeal knot is acceptable because it is easier to create a knot outside the patient and slide it down with a knot pusher. In most settings, this is not true because securing an extracorporeal knot creates "sawing" of the tissue as the suture is pulled through or around it. This often results in tissue tearing. For interrupted suturing, the sliding square knot is the simplest most secure knot to master (Fig. 4-10).

THE PHYSIOLOGIC EFFECTS OF PNEUMOPERITONEUM

The pneumoperitoneum has many effects that are only partially known despite years of study in humans and in animal models. There are effects resulting from the pressure within the abdomen and effects resulting from the composition of the gas used, generally CO_2.

The pressure within the abdomen from pneumoperitoneum decreases venous return by collapsing the intra-abdominal veins, especially in volume-depleted patients. This decrease in venous return may lead to decreased cardiac output. To compensate, there is an elevation in the heart rate, which increases myocardial oxygen demand. High-risk cardiopulmonary patients cannot always meet the demand and may not tolerate a laparoscopic procedure.[38] In volume-expanded healthy patients with full intra-abdominal capacitance vessels (veins), the increased intra-abdominal pressure actually may serve as a pump that increases right atrial filling pressure.[39]

Through a different mechanism associated with catecholamine release triggered by CO_2 pneumoperitoneum, heart rate rises along with systemic vascular resistance. This may lead to hypertension and impair visceral blood flow. It is not uncommon after the induction of pneumoperitoneum for the heart rate to rise along with the mean arterial pressure. This leads to a minimal effect in a young, healthy patient[40]; however, in elderly, compromised patient, the strain on the heart can lead to hypotension, end-organ hypoperfusion, and ST-segment changes.

To minimize the cardiovascular effects of pneumoperitoneum, it is important that patients have adequate preoperative hydration. By insufflating the abdomen slowly, the vagal response to peritoneal stretching may be diminished and vagally mediated bradycardia avoided. Additionally, if cardiovascular effects are noted during insufflation or during the

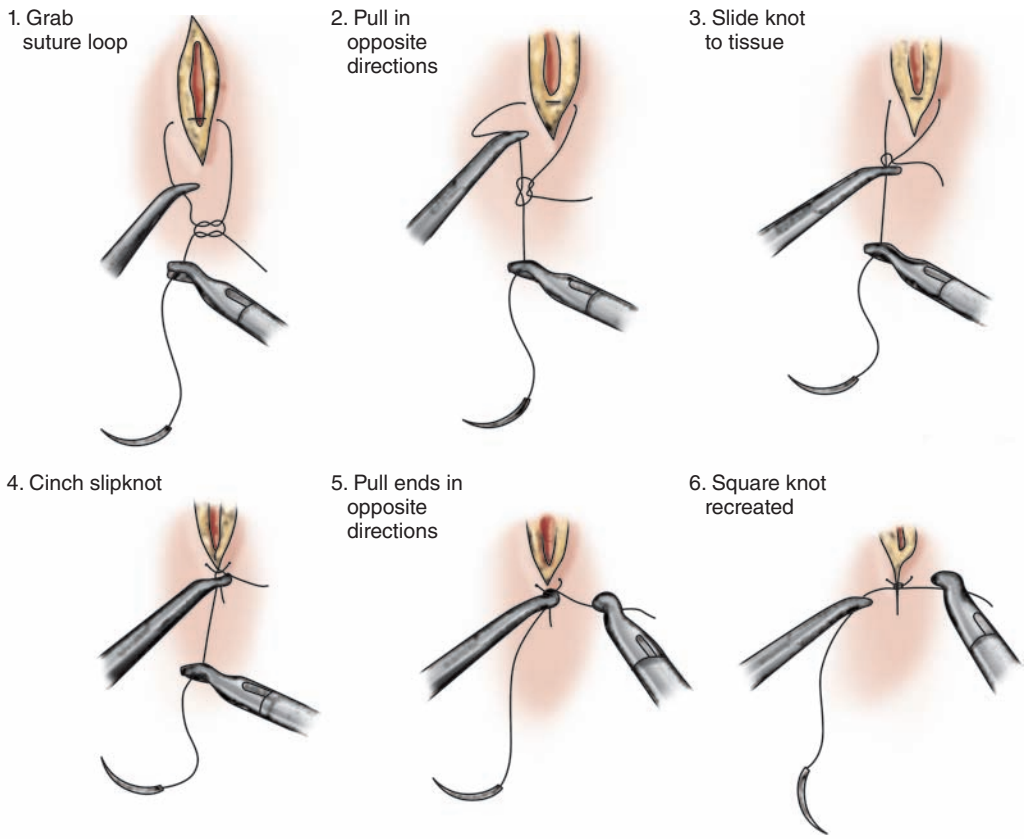

FIGURE 4-10 Suturing. (Reprinted with permission from Hunter JG, Terry. Minimally invasive surgery: fundamentals. In: Cameron JL, ed. *Current Surgical Therapies.* St. Louis: Mosby.)

maintenance of pneumoperitoneum, the insufflation pressures should be lowered from the usual 15 to 12 mm Hg, or pneumoperitoneum should be evacuated while the anesthesiologist sorts out the cardiovascular changes. Taking patients out of the steep reverse Trendelenburg position can help to increase venous return. Sometimes these effects can last for hours after desufflation.

The elevated intra-abdominal pressures restrict movement of the diaphragm, which reduces diaphragmatic excursion. This is represented as a decrease in functional residual capacity and pulmonary compliance and an increase in inspiratory pressure. Overall, there is no significant change in the physiologic dead space or shunt in patients without cardiovascular compromise. Bardoczky and colleagues studied seven healthy patients undergoing laparoscopy with CO_2 pneumoperitoneum.[41] After the induction of pneumoperitoneum, peak airway and plateau airway pressures increased by 50% and 81%, respectively. Bronchopulmonary compliance decreased by 47% during the period of increased intra-abdominal pressure. After desufflation, peak and plateau pressures remained elevated by 36% and 27%, respectively, for 2–6 hours. Compliance remained at 86% of the preinsufflation value.

Urine output often is diminished during laparoscopic procedures and usually is the result of diminished renal blood flow owing to the cardiovascular effects of pneumoperitoneum and direct pressure on the renal veins.[42] In addition to direct effects, elevated intra-abdominal pressure results in release of antidiuretic hormone (ADH) by the pituitary, resulting in oliguria that may last 30–60 minutes after the pneumoperitoneum is released. Aggressive fluid hydration during pneumoperitoneum increases urine output.[43] Positional changes can affect the collection of urine in the Foley catheter and must be taken into consideration if anuria is noted.

Carbon Dioxide–Related Effects

HYPERCAPNIA

Hypercapnia and acidosis are seen with pneumoperitoneum and are likely due to the absorption of CO_2 from the peritoneal cavity. In the ventilated patient, increasing respiratory rate or vital capacity must compensate for these changes. At extremes, increases in tidal volume may risk barotraumas, and increases in respiratory rates diminish time for gas mixing, increasing dead-space ventilation. A first steady state in $PaCO_2$ is reached around 15–30 minutes after introduction of

the pneumoperitoneum. After this period, increases in $PaCO_2$ suggest that existing body buffers (>90% exist in bone) have been exhausted. Sudden increases may be related to port slippage and extraperitoneal or subcutaneous diffusion of CO_2. This will resolve spontaneously once the port is repositioned.

Hypercapnia and acidosis that are difficult to control may follow, especially in elderly patients, those undergoing long operations, and patients with pulmonary insufficiency. Our response to this is to desufflate the abdomen for 10–15 minutes. If reinsufflation results in recurrent hypercapnia, then we change insufflation gases (see above) or convert to an open operation. Acidosis can persist for hours after desufflation. Other complications of pneumoperitoneum that are less frequent but may be life threatening include CO_2 embolism and capnothorax.

CARBON DIOXIDE EMBOLUS

The incidence of clinically significant CO_2 embolism is very low, although recent reports using more sensitive tests suggest that tiny bubbles of gas are present commonly in the right side of the heart during laparoscopic procedures. Clinically important CO_2 embolism may be noted by unexplained hypotension and hypoxia during the operation. There is a characteristic millwheel murmur that can be detected with auscultation of the chest. This is produced by contraction of the right ventricle against the blood–gas interface. Usually the anesthesiologist notes an exponential decrease in the end-tidal CO_2, which is consistent with complete right ventricular outflow obstruction. The mainstays of treatment are immediate evacuation of the pneumoperitoneum and placement of the patient in the left lateral decubitus, head down (Durant) position. This allows the CO_2 bubble to "float" to the apex of the right ventricle, where it is less likely to cause right ventricular outflow tract obstruction. It is important to administer 100% oxygen and hyperventilate the patient during this period. Additionally, aspiration of gas through a central venous line may be performed.

CAPNOTHORAX/PNEUMOTHORAX

Capnothorax can be caused by CO_2 escaping into the chest through a defect in the diaphragm or tracking through fascial planes during dissection of the esophageal hiatus. It also can be due to opening of pleuroperitoneal ducts most commonly seen on the right side. Pleural tears during fundoplication can lead to pneumothorax, and additionally, the usual causes of pneumotho rax, such as ruptured bullae, may be the etiology. The effects of CO_2 gas in the chest usually are noted as decreased O_2 saturation (a result of shunting induced by lung collapse), increased airway pressure, decreased pulmonary compliance, and increases in CO_2 and end-tidal CO_2. The treatment is to desufflate the abdomen, stop CO_2 administration, correct the hypoxemia by adjusting the ventilator, apply positive end-expiratory pressure (PEEP), if possible, and decrease the intra-abdominal pressure as much as possible. The recommendation is to avoid thoracentesis because this usually resolves with anesthetic management. We generally evacuate the capnothorax directly at the end of the procedure with a red rubber catheter placed across the diaphragm (through the pleural defect) and brought out a trocar site. The external end of the catheter is placed under water as the lung is inflated and then removed from the water when the bubbles stop. We do not obtain chest radiographs in the recovery room after these maneuvers if there is no evidence of hypoxia on 2 L/min of O_2 flow. Patients should be maintained on supplemental oxygen to help facilitate absorption of the CO_2 from the pleural space.

CONCLUSIONS

Although minimally invasive surgery is firmly established in modern surgery, its safe performance can be ensured only with mastery of the basics. Basic skills used in laparoscopy include evaluation of a patient based on a new set of considerations, safe use of devices for abdominal access and instrumentation, and mastery of complex manual skills and intraoperative assessment of novel physiologic parameters. Laparoscopic surgery will only be employed more in the future as technical innovations allow us to care for our patients in new and better ways.

LAPAROSCOPIC STAGING AND APPROACHES TO CANCER

Kevin C. Conlon • Tom K. Gallagher

INTRODUCTION

The role of laparoscopy in the staging of gastrointestinal malignancy has continued to evolve over the last decade. Improvements in noninvasive diagnostic modalities have led to a more selective approach being adopted. Nonetheless, minimally invasive surgical techniques for staging and palliative bypass continue to play an important role in the staging and management of patients with upper gastrointestinal malignancies.

RATIONALE FOR LAPAROSCOPIC STAGING

As the multidisciplinary management of gastrointestinal cancer has evolved over the last decade, an accurate extent of disease workup has become essential to treatment planning. Staging procedures should accurately define the extent of disease, direct appropriate therapy, facilitate the use of adjuvant therapies and avoid unnecessary interventions in a safe and cost-efficient fashion.

Recent advances in radiology have provided many noninvasive tools, such as multidetector computed tomographic (CT) scanning, magnetic resonance imaging (MRI) and combined CT with positron-emission tomographic (CT/PET) scanning, that have had a considerable impact on the extent of disease workup. Unfortunately, these modalities may underestimate the extent of disease, with small-volume metastatic disease being appreciated only at open surgical exploration. For over 100 years, laparoscopy has been suggested as a means for identifying such small-volume disease. Recently, a significant amount of data has been produced to suggest that the use of laparoscopy and laparoscopic ultrasound (LUS) in the staging of gastrointestinal malignancies has an impact on overall management.[1–7] The aim of laparoscopic staging (LS) is to mimic staging at open exploration while minimizing morbidity, enhancing recovery, and thus allowing for quicker administration of adjuvant therapies if indicated. Proponents believe that LS should be viewed as complementary and not as a replacement for other staging modalities such as CT scanning, MRI, or PET scanning. In simplistic terms, the advantages of laparoscopy are that it allows the surgeon to visualize the primary tumor, determine vascular involvement, identify regional nodal metastases, detect small-volume peritoneal/liver metastases, and obtain tissue for histologic diagnosis.

SURGICAL TECHNIQUE FOR LAPAROSCOPIC STAGING

Laparoscopic staging can be performed immediately before a planned open procedure or at a separate occasion. We have moved to the latter approach in the main because of logistical concerns around the availability and utilization of operating time. Generally the procedure is performed as an ambulatory/outpatient procedure with excellent patient satisfaction.

Laparoscopic staging usually is performed under general anesthesia with the patient positioned supine on the operating table. A warming blanket is placed underneath the patient, who is secured appropriately to the table with padding over the pressure points.

The following operative equipment is considered necessary for the procedure:

1. A 30-degree angled laparoscope either 5 or 10 mm in diameter
2. Five-millimeter laparoscopic instruments, including a Maryland dissector, a blunt-tip dissecting forceps, a cup/biopsy forceps, atraumatic grasping forceps, a liver retractor, and scissors
3. A 5- or 10-mm suction/irrigation device
4. An LUS probe (optional)

In general, we prefer a multiport technique. Access is gained into the peritoneal cavity using a blunt port placed

subumbilically by direct cutdown. By using forceps to grasp the fascial layers, retractors can be avoided and the wound size minimized. An alternative approach, particularly in patients with previous midline incisions, is to place the initial port in either the right or the left upper quadrant of the abdomen. Many surgeons prefer to use a Veress needle to achieve pneumoperitoneum prior to placing the surgical ports. In this case, care should be exercised to avoid visceral or vascular injury. Laparoscopic access using an optical trocar, which combines the advantages of the Hasson and Veress techniques, is a safe and feasible primary insertion method, which may alleviate this risk and is becoming an increasingly accepted technique.[8]

Pneumoperitoneum is achieved with CO_2 gas. Insufflation commences at a low flow rate until peritoneal entry is confirmed. An intraperitoneal pressure of 10–12 mm Hg is considered optimal. However, in patients with cardiopulmonary compromise, a lower maximum pressure may be chosen. A 5- to 10-mm 30-degree angled telescope is preferred, and systematic examination of the peritoneal cavity is performed. Additional trocars then are inserted under direct vision. Placement depends on the site of the primary tumor (ie, colonic, gastric, pancreatic, etc) and the findings at initial inspection (ie, whether obvious metastatic disease is present). In general, ports are placed along the planned open incision line (Fig. 5-1).

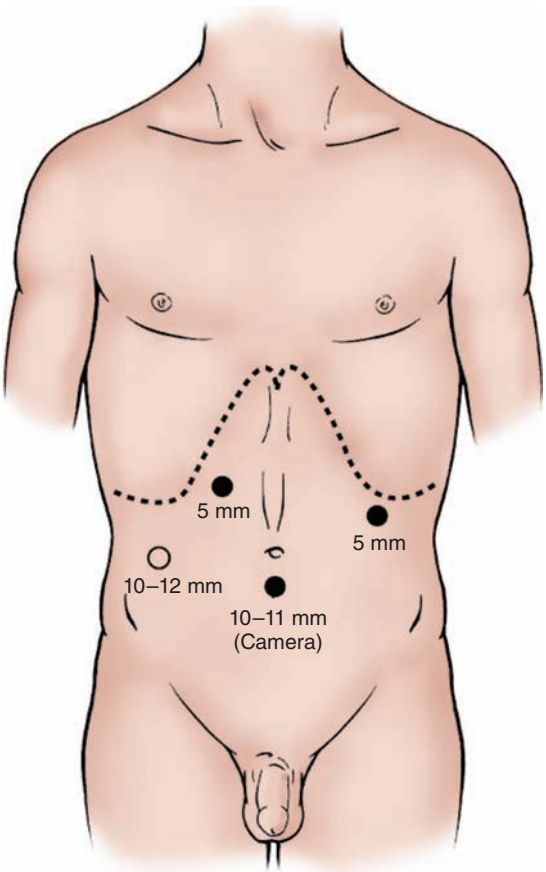

FIGURE 5-1 Port placement.

Following port placement, a detailed examination of the peritoneal cavity is performed in a similar fashion to an open exploration. The primary tumor is assessed. Any extension into contiguous organs can be identified. Following an initial survey, a systematic examination of the intra-abdominal viscera is performed commencing with the liver. To facilitate hepatic examination, the patient is placed in a 20-degree reverse Trendelenberg position with 10 degrees of left lateral tilt. The anterior and posterior surfaces of the left lateral segment of the liver are examined, followed by examination of the anterior and inferior surfaces of the right lobe. Despite the absence of tactile sensation, indirect palpation of the liver surface can be achieved by using two instruments (Fig. 5-2). A blunt suction device is particularly useful in compressing the liver tissue in order to detect small metastases. Improved visualization of diaphragmatic and posterior surfaces may be achieved by placing the camera in the right upper quadrant port. Any suspicious areas can be biopsied at this point. A cup biopsy forceps is the preferred instrument for obtaining adequate biopsies for diagnostic purposes. For this, we use a 5-mm biopsy forceps with a 2-mm cup as standard. Multiple samples may be taken to increase diagnostic yield. The cup is used to breech the liver capsule and a bite is taken out of the lesion. Further scoops can then be taken from the lesion and liver parenchyma as needed. Thorough hemostasis can easily be obtained with electrocautery or use of argon beam diathermy. If electrocautery is used, it is important to avoid direct coupling or capacitance coupling, which can lead to visceral injury. Direct coupling, when current flows directly from one instrument to the other, may occur when the instruments are too close together, especially if one is just outside of the field of view. Capacitance coupling occurs when two conductors have an insulator sandwiched between them. The high frequency AC current in the active conductor generates a magnetic field, which then induces current in the second conductor. Mixing of metal and plastic instruments and ports can lead to capacitance coupling and, at least in theory, severe burns. The incidence of complications is reduced by limiting

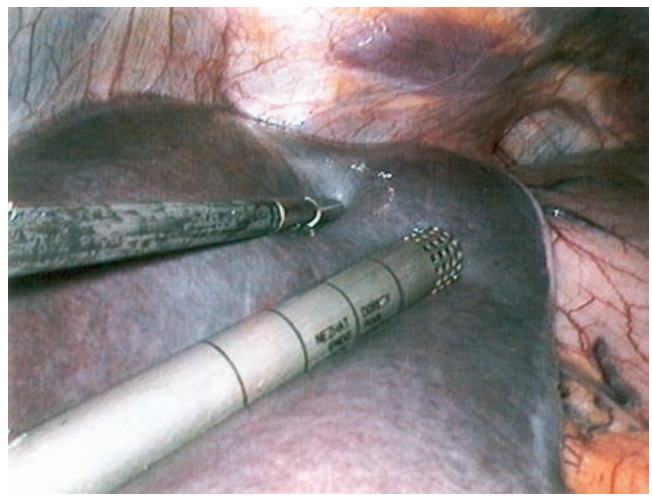

FIGURE 5-2 Examination of the liver.

the gain of electrocautery to 30 W and possibly by using plastic rather than metallic ports.

The hilus of the liver, hepatoduodenal ligament, and foramen of Winslow then are examined. Any abnormal lymphadenopathy can be identified. The suspicious node can be either excised or biopsied using the cup forceps. As in open surgery, care must be taken not to crush the node and possibly disseminate tumor cells during this procedure. In general, the duodenum is not mobilized. However, for patients with pancreatic or common bile duct tumors, close attention is paid to the presence or absence of tumor infiltration in the angle between the duodenum and the lateral aspect of the common bile duct because this may indicate significant vascular involvement.

The patient then is repositioned into a 10-degree Trendelenberg position without lateral tilt to facilitate examination of the transverse mesocolon and retroperitoneum. The omentum is retracted toward the left upper quadrant, elevating and enabling inspection of the transverse mesocolon an d the ligament of Treitz. The mesocolon is inspected carefully with particular attention to the middle colic vein, which usually is visible. Any abnormal adenopathy or infiltration (Fig. 5-3) around the middle colic vein is noted and may be biopsied. For patients with an upper gastrointestinal primary tumor, the lesser sac is examined. To facilitate this maneuver, the patient then is returned to a supine position, the left lobe of the liver is elevated, and the gastrohepatic omentum is incised (Fig. 5-4). This exposes the caudate lobe of the liver, the inferior vena cava, and the celiac axis. If present, an aberrant left hepatic artery should be identified and preserved. Often, adhesions between the stomach and the pancreas require division to allow entry into the lesser sac. By elevating the stomach, the "gastric pillar" can be clearly identified (Fig. 5-5). This "pillar" contains the left gastric artery and vein. This structure followed down leads us to the celiac axis, and any suspicious nodal tissue can be biopsied. The hepatic artery also is identified and followed to the hepatoduodenal ligament. The anterior aspect of pancreas, hepatic artery, and left gastric artery is also seen. Any suspicious periportal, hepatic, or celiac nodes can be biopsied.

The diagnostic yield for LS may be increased by performing peritoneal lavage cytology. In general, the specimens are taken at the start of the laparoscopy to avoid potential contamination following tumor manipulation or dissection. Between 200 and 400 mL of normal saline is instilled into the peritoneal cavity. The abdomen is agitated gently before aspiration. In pancreatic cases, samples are taken from the right and left upper quadrants. An additional sample is taken from the pelvis in patients with gastric cancer. Informing the pathologist/cytologist of the procedure timing and clinical question often leads to better clinical yields and is advisable prior to undertaking the laparoscopy.

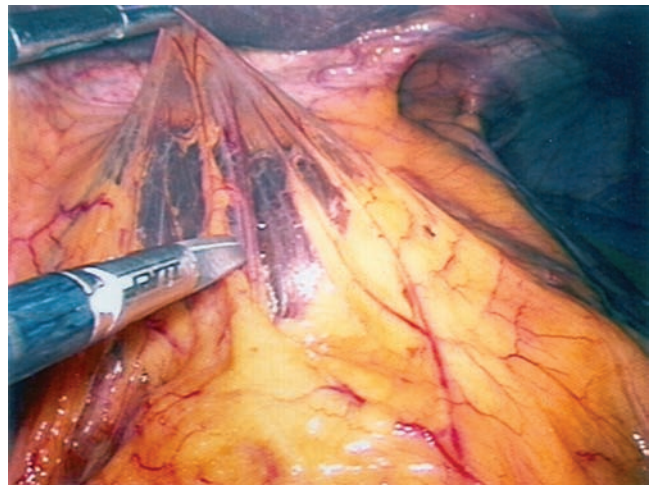

FIGURE 5-4 Incision of the gastrocolic omentum to gain access to the lesser sac.

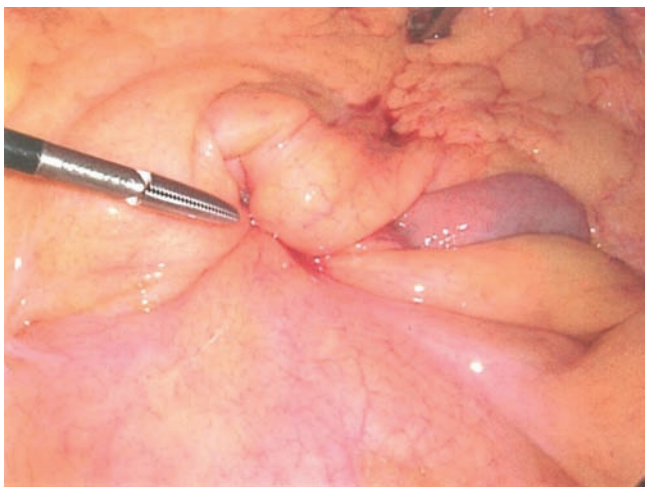

FIGURE 5-3 Infiltration of the colonic mesocolon.

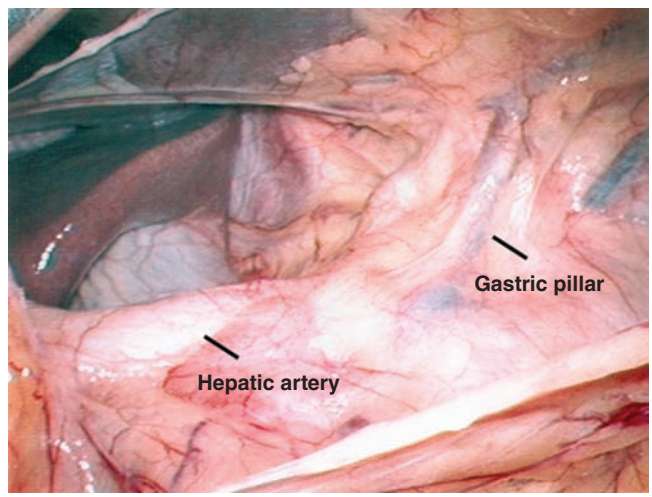

FIGURE 5-5 Lesser sac exposed. Solid arrow points to hepatic artery. Dashed arrow points to "gastric pillar."

If available, LUS can be performed at this stage. Laparoscopy by its nature is a two-dimensional modality, with the result that appreciation of deep or subsurface lesions in solid organs is often suboptimal. LUS can partially overcome this deficiency. Transducers in clinical use employ either curved or linear-array technology and have a high-frequency performance with a range in the region of 6–10 MHz, allowing for high-resolution images to be obtained that can detect lesions from 0.2 cm in size. In addition, Doppler flow capability, if present, allows for accurate vessel identification and facilitates assessment of the tumor-vessel interface. The LUS probe is inserted via a 10- to 12-mm port, usually in the right upper quadrant.

The LUS is an invaluable tool for examination of the liver. Initially, the transducer is placed over the left lateral segment (Fig. 5-6), allowing assessment of segments I, II, and III. It is important that the probe is placed in direct contact with the liver surface to maximize acoustic coupling. Examination of the right lobe commences with the probe on the dome of the liver. The vena cava is visualized at the back and as the probe is moved forward slowly to identify the hepatic and portal veins. Within the liver, these can be identified by virtue of their surrounding fibrous sheath. The remaining hepatic segments (IV, V, VI, VII, and VIII) are examined by rotating the probe over the rest of the liver. Suspicious lesions can be biopsied either by fine-needle aspiration (FNA) or by percutaneously inserting core biopsy needles under LUS guidance. With the probe over segment V, the gallbladder is assessed, and with transverse placement of the probe over the hepatoduodenal ligament, the common hepatic duct, common bile duct, and hepatic arteries along with the portal vein can be identified (Fig. 5-7). The portal vein can be followed to its confluence with the splenic and superior mesenteric vein. The superior mesenteric artery also can be seen and its relationship to a pancreatic tumor, if present, determined. The pancreas can be examined, and any lesion can be identified.

ESOPHAGEAL CARCINOMA

Esophageal cancer is the eighth most common cancer and is the sixth leading cause of cancer death worldwide.[9] Esophageal cancer was diagnosed in 16,470 new patients in the United States in 2008, with an overall annual incidence of approximately 5.4 cases per 100,000 population.[10] It is estimated that more than 14,000 patients will die of this disease each year. Unfortunately, the prognosis remains poor; with an overall survival rate of approximately 5–10% in spite of the availability of new chemotherapeutic and biologic agents in both neoadjuvant and adjuvant settings. Surgical resection remains the treatment of choice for patients with localized disease. In addition, in the last few years, there has been a significant progress in palliative nonsurgical treatment options. Therefore, accurate staging for esophageal cancer is of paramount importance.[7,11–14]

Common diagnostic modalities are listed in Table 5-1. The results of a meta-analysis in 2008 suggest that endoscopic ultrasonography (EUS), CT, and fluorine-18-flurodeoxyglucose (FDG)-PET each play a distinctive role in the detection of metastases in esophageal cancer patients. For the detection of regional lymph node metastases, EUS is most sensitive, whereas CT and FDG-PET are more specific tests. For the evaluation of distant metastases, FDG-PET has probably a higher sensitivity than CT.[15] These have been discussed in detail elsewhere in this book. Endoscopy remains the diagnostic gold standard. Biopsies can be

TABLE 5-1: DIAGNOSTIC MODALITIES FOR STAGING ESOPHAGOGASTRIC CANCERS

History and clinical examination

Laparoscopy
Laparoscopic ultrasonography

obtained and an assessment of local disease extent made. In patients considered unsuitable for surgical resection, a number of palliative options such as endoscopic dilation, laser ablation, or placement of luminal stents exist.

Multislice CT scanning of the thorax and abdomen is the radiologic staging modality of choice. The primary tumor can be visualized and metastatic disease detected. However, while data suggest that current-generation high-resolution multislice CT scanning is of significant value, its capacity to accurately T stage the disease and predict lymphatic and peritoneal spread remains between 65% and 80%.[16]

EUS enables detailed imaging of the esophageal wall, local lymph nodes, and contiguous structures, making it the ideal tool for tumor node metastasis (TNM) staging.[11,12,17] The shape, pattern, and demarcated borders of nodes are examined to assess metastatic potential.[18,19] EUS appears superior to CT scanning for locoregional staging.[13,20] Harewood and Wiersema from the Mayo Clinic compared the cost of EUS-FNA with CT-FNA and a surgical approach in staging patients with nonmetastatic esophageal cancer. They suggested that by avoiding unnecessary surgery, primarily by detecting celiac node involvement, EUS-FNA was the least costly strategy.[21]

It appears that combined CT scan and EUS is a better prediction of tumor resectability than CT scan alone (81% vs 65% with $p < 0.05$) reported by de Graaf et al.[22] In a study of the impact of EUS-FNA in the management of patients with esophageal cancer, Morris et al found that EUS-FNA altered management in 28 (67%) patients and appeared to help direct patients toward appropriate treatment strategies including palliative and neoadjuvant therapies.[23] In a meta-analysis and systematic review of studies that included over 2500 patients, Puli et al[24] concluded that EUS performs better with advanced (T4) than early (T1) disease and that FNA substantially improves the sensitivity and specificity of EUS in evaluating N stage disease (from 84.7% [95% CI: 82.9–86.4] to 96.7% [95% CI: 92.4–98.9]). However, while most thoracic surgeons have embraced EUS-FNA as the most accurate locoregional staging modality in esophageal cancer, this attitude is not fully reflected in utilization patterns due to a lack of quality EUS services in some centers.[25]

Several studies have investigated the detection of the primary tumor by FDG-PET. Increased uptake of FDG was seen in 68–100% of the esophageal tumors.[26–28] Undetected tumors are mostly stages T1 and T2. T1a tumors, remaining within the submucosa, are especially difficult to detect by FDG-PET.[29–30] Kato et al[31] found a significant relationship between the intensity of the primary tumor FDG-uptake, expressed as SUV, and the depth of the tumor invasion. However, Flamen et al[32] found no correlation between SUV and pT-stage.

To determine whether FDG-PET could delineate patients with esophageal cancer who may not benefit from esophagectomy after chemoradiotherapy, Monjazeb et al reviewed 163 patients with histologically confirmed stage I to IVA esophageal cancer receiving chemoradiotherapy with or without resection with curative intent and found that patients who achieved a complete response on FDG-PET imaging may not benefit from added resection given their excellent outcomes without resection.[33] These results should be validated in a prospective trial of FDG-PET-directed therapy for esophageal cancer.

It has been suggested that FDG-PET scanning has a role for the detection of metastatic disease and for restaging after neoadjuvant therapy or evaluation of recurrence. In the study by Flamen and colleagues, FDG-PET scanning had a significantly higher rate of detection of stage IV disease compared with the combination of CT scanning and EUS. It upstaged disease in 15% and downstaged disease in 7% of patients.[32] Other studies have reported similar results.[34–36]

In relation to the role of FDG-PET/CT in tumor delineation for radiotherapy, only three studies have reported a significant positive correlation between FDG-PET-based tumor lengths and pathological findings and so the authors of a systematic review on the role of FDG-PET/CT in tumor delineation and radiotherapy planning in patients with esophageal cancer concluded that standard implementation of FDG-PET/CT into the tumor delineation process for radiation treatment seems unjustified and needs further clinical validation first.[37]

Despite this increasingly sophisticated diagnostic armamentarium, between 15% and 20% of patients will continue to have radiologically occult peritoneal, nodal, or liver metastases detected at surgical exploration. Laparoscopy has been suggested as a means to detect such disease and thus exclude this cohort of patients from potentially ineffective treatment regimens.

The value of LS in esophageal cancer is accurate abdominal nodal staging and detection of occult distant mestastases. The procedure also allows for more detailed assessment of the tumor looking for serosal involvement, local invasion, or peritoneal cavity, liver, and omental disease. In a comparison of LS and EUS for esophageal cancer, Kaushik et al found an overall staging accuracy of EUS compared with LS of 72%.[38] Staging differences were mostly reflected in distant metastases detected at LS (17%). The yield of LS appears to be determined at least in part by the site of disease, histologic cell type, and noninvasive stage. There are several observational studies reporting the usefulness of LS in both gastric and oesophageal cancers, the largest and most recent of which includes 416 consecutive patients undergoing staging laparoscopy.[39] The

authors report an 88% sensitivity of laparoscopy for resectability, with avoidance of unnecessary laparotomy in 20.2% of all patients. Staging laparoscopy was most useful in patients with adenocarcinoma, distal oesophageal, and gastroesophageal cancer, with percentage change in treatment decision of 21.9%, 17.1%, and 17.2%, respectively. No patients in this study with upper two-third lesions had their treatment decision changed by staging laparoscopy. This would be in accordance with the general trend in the literature that the more distal the tumor in the esophagus, the greater the risk and likelihood of intra-abdominal metastases[40,41] and this is likely related to lymphatic anatomy.

In a well-designed study, Samee et al report that the addition of LUS in the staging of esophagogastric cancers increases the detection rate of metastasis by 8% but that there is little impact on the false-negative rate.[42] In their retrospective case series of 320 patients, LUS proved most useful in detecting metastatic lymphadenopathy beyond the limits of curative resection and liver metastasis. The main benefit appears to be in the assessment of nodal disease, particularly in the celiac axis, hepatoduodenal ligament, and para-aortic area as disease in these sites accounts for more than 40% of the positive findings at laparoscopy.

The combination of endoscopic and laparoscopic ultrasonography (EUS-LUS) is accurate for resectability assessment of patients with esophageal cancer. In a series of 256 consecutive esophageal cancer patients, Mortenson et al demonstrated a statistically significant survival difference ($p < 0.01$) between the different TNM stages and resectability groups predicted by a EUS-LUS combination.[43] The poor prognosis for the patients with irresectable or disseminated disease was accurately predicted by EUS and LUS.

The yield of LS appears to be determined at least in part by the site of disease, histologic cell type, and noninvasive stage. In an earlier review of 369 patients with carcinoma of the distal esophagus or gastric antrum, Dagnini and colleagues demonstrated occult disease in 33% at laparoscopy in patients with adenocarcinoma of either the distal esophagus or gastric cardia.[44] However, LS had a minimal impact for patients with squamous cell cancers in the upper third of the esophagus, changing management in only 3.5% of cases. Stein and colleagues reported similar results. At laparoscopy following radiologic staging, they found that 25% of patients with locally advanced (T3/T4) adenocarcinoma of the distal esophagus or gastric cardia had peritoneal or liver metastases.[45] Thus, for patients with squamous cell carcinoma of the esophagus, we believe that LS is not indicated in the absence of suspicious intra-abdominal imaging findings.

GASTRIC CANCER

The overall incidence of gastric cancers is declining; however, there has been a relative increase in the incidence of tumors of the esophagogastric junction (OGJ) and gastric cardia. The peak incidence is in the seventh decade, and the disease is approximately twice as common in men as in women.[46] Despite its apparent falling prevalence in the Western world, gastric cancer remains a significant public health problem and one of the leading causes of cancer death worldwide. The prognosis remains poor, with a current overall 5-year survival of 20%[47] and 50–90% of patients dying of the disease within 2 years of diagnosis, even in those who have undergone a potentially "curative" resection.[48–50] The poor outcome may be related in part to late presentation and inadequate staging and subsequent poor patient selection for surgery. Historically, following diagnosis and if medically fit, patients were subjected to open exploration for either resection or palliation. In a significant series of 916 patients in the mid-1990s, Pye and colleagues[51] reported that 23% of the operations were exploratory alone in nature. However, with the recent development of multidisciplinary approaches to the disease, improved staging, and the establishment of less invasive palliative algorithms, the need for operative intervention has been questioned.[52–54]

Accurate staging is essential for patient selection. A sophisticated and complex diagnostic armamentarium exists. While upper gastrointestinal endoscopy and biopsy remain the primary diagnostic tools, with multislice contrast-enhanced CT scanning, EUS, MRI, and CT/PET scanning being used increasingly for preoperative staging, laparoscopy and LUS continue to have an important role in the staging algorithm for selected patients with gastric cancer (Fig. 5-8).

While the literature would suggest that despite currently available imaging modalities, LS will continue to detect small-volume metastatic disease in 20–30% of cases, the identification of occult nodal disease remains problematic. EUS appears somewhat better than CT in this regard. Wakelin and colleagues have reported an overall accuracy of EUS in nodal staging for proximal or orogastric junction tumors of 72%.[55] If tumors that are nontraversable by endoscope are excluded, its accuracy increases by approximately 10%. Reported accuracy rates for laparoscopy and LUS vary from 60% to 90%. With LUS, direct biopsy of suspicious nodes can be obtained, which improves the utility of the modality. In distal gastric cancer, Finch and colleagues demonstrated an accuracy of 82% in T staging with the use of LUS.[56] This compares favorably with other studies looking at the use of EUS (83%) or CT scanning (66%) for T staging distal tumors.[57] In addition, the authors noted an accuracy rate of 89% for LUS in assessing lymph node status. In contrast, Wakelin noted that 38% of nodes were understaged. It would appear, therefore, that as with other ultrasound data, results are operator-dependent and reflect willingness or not to aggressively biopsy suspicious nodes.

While level I evidence does not exist for the use of LS in gastric cancer, a number of large single-institution studies have been carried out that allow us to make a number of conclusions regarding its role in the staging algorithm. As in esophageal cancer, laparoscopy will detect radiologically occult metastatic disease in a significant number of patients (Fig. 5-9). Muntean et al reported overall staging laparoscopy sensitivity for distant metastases of 89%, specificity 100%, and diagnostic accuracy 95.5%. The sensitivity for lymph node

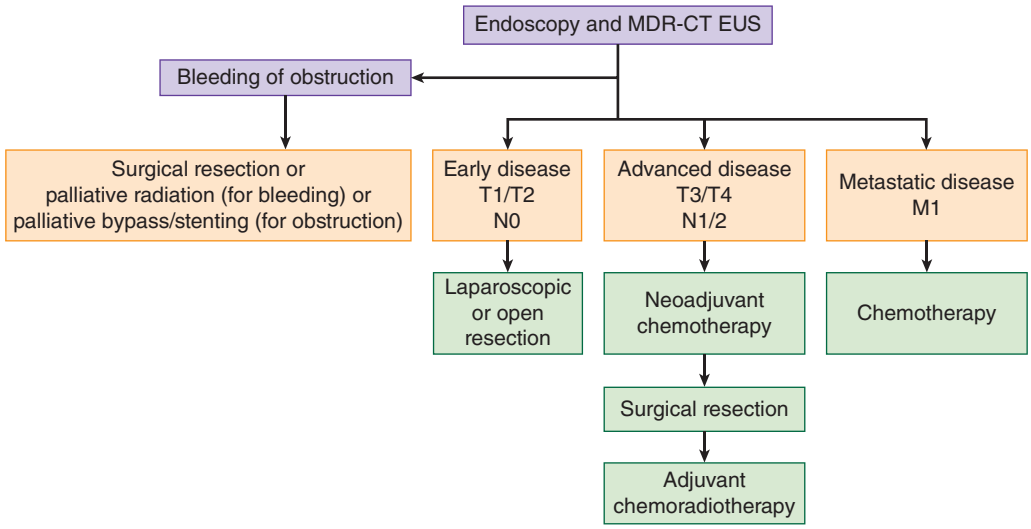

FIGURE 5-8 Treatment algorithm for gastric cancer.

metastases was 54.5%, with a specificity 100% and a diagnostic accuracy 64.3%. The positive predictive value for resectability was 96% and the negative predictive value was 50%.[58] Sotiropoulos et al reported that staging laparoscopy resulted in up staging 51.1% of patients, most commonly in the form of peritoneal seeding.[59] As a consequence, the therapy planning was changed and laparotomy was avoided in 14 of these patients as the first operative procedure. Sensitivity of clinical staging was especially poor for stage IV tumors (5.3%) and for the majority of stage IIIB tumors (42.9%) in this particular study.

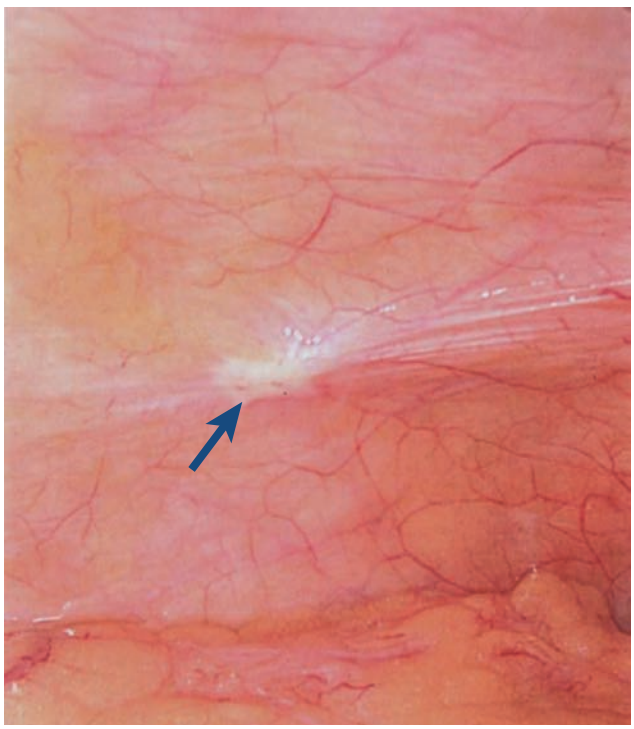

FIGURE 5-9 Peritoneal metastasis in gastric cancer.

It has been suggested that, with more advanced radiological imaging, the value of staging laparoscopy will somehow diminish; however, the literature has not borne this out. Kim et al retrospectively measured the diagnostic performance of prospective computed tomographic (CT) results obtained by using 16- or 64-detector row scanners in the detection of peritoneal metastases (PMs) in patients with advanced gastric cancer.[60] In 498 patients with T2 disease and above in a retrospective comparison of CT images with operative and pathological findings, a sensitivity and a specificity of 28.3% and 98.9%, respectively, were reported in scans demonstrating definite peritoneal deposits and 50.9% and 96.2% respectively in scans reported as equivocal. The authors concluded that even with modern CT techniques, the sensitivity for PM detection is limited. Similarly when evaluating preoperative local staging with 3D multidetector row CT, Chen et al reported that reconstructions yield significantly better overall accuracy than transverse images for tumor staging but not for lymph node staging.[61] This highlights the need for a multimodality staging process, including EUS, LS, and LUS.

As mentioned earlier, we routinely take peritoneal washings for cytologic examination at the time of LS. Positive cytology obtained during peritoneal lavage at staging laparoscopy is information potentially available preoperatively that identifies a patient population at very high risk for early recurrence and death after curative resection of gastric cancer. Mehzir and colleagues recently reviewed a prospectively maintained database of 1241 patients with gastric cancer who underwent laparoscopy with peritoneal washings.[62] Two hundred and ninety-one (23%) patients had positive cytology. A total of 48 of the 291 cytology-positive patients had repeat staging laparoscopy after chemotherapy. Compared with patients who had persistently positive cytology (n = 21), those who converted to negative

cytology (n = 27) had a significant improvement in disease-specific survival (2.5 years vs 1.4 years, $p = 0.0003$). In an earlier publication by the same group on a lesser number of patients in this database, multivariate analysis identified preoperative T stage, preoperative N stage, site, and cytology as significant predictors of outcome. Positive cytology was the preoperative factor most predictive of death from gastric cancer (RR 2.7, $p < 0.001$).[63] Although evaluated at laparotomy, La Torre et al reported similar results in their cohort of 64 patients.[64] Eighty-six percent of patients with positive peritoneal lavage cytology had a pT3/pT4 tumor and 100% of those positive had an N-positive tumor ($p < 0.001$). The median survival of patients presenting with positive cytology was significantly lower than that of patients with negative peritoneal cytology (19 and 38 months respectively, $p = 0.0001$). Multivariate analysis of this group of patients also identified cytology as a significant predictor of outcome ($p = 0.018$). Looking at the value of staging laparoscopy in advanced gastric cancer, Shimitzu et al stratified 34 patients into groups according to the presence of peritoneal deposits and/or positive peritoneal lavage cytology.[65] Those who were positive for both did not receive any operative intervention and were shown to do significantly worse over all, thus validating the argument for LS.

Taking the concept of intraperitoneal disease and its consequences even further, novel methods are being evaluated to increase the sensitivity of peritoneal lavage cytology. Wong et al have recently described a novel and very interesting method of detecting free peritoneal cancer cells in gastric cancer using cancer-specific Newcastle disease virus (NDV).[66] The green fluorescent protein of NDV appears to specifically infect and detect peritoneal gastric cancer cells and offers a more sensitive method compared with conventional cytology. Results were particularly impressive in advanced disease. Of patients with M1 disease discovered during laparoscopy, only 50% were cytology positive. All, however, were NDV-GFP positive. Cytology was positive in 9% of patients with T3 disease, 8% with N1 disease, and 50% with N2 disease. In contrast, NDV-GFP was positive in 95% of T3 patients and 100% of patients with N1 or N2 disease. This novel modality may offer enhanced detection of intraperitoneal cancer spread and provide important prognostic information. The same group has also looked at reverse transcriptase polymer chain reaction to detect micrometastases in peritoneal washings with promising results[67] and this reflects a growing area of research in gastric cancer staging today.

In this chapter, we have concentrated on the role of LS in determining unresectability. However, the advent of minimally invasive techniques applied to early gastric cancer has raised the possibility that LS may have an increasing role in treating that spectrum of the disease. It has been argued that gastric cancer is one of the most suitable targets for minimally invasive surgery (MIS) based on sentinel node status. Staging laparoscopy combined with sentinel node mapping may become a very important adjunct to laparoscopic local resection for curative treatment of sentinel-node-negative early gastric cancer.[68] More work is required before the true utility of this approach is understood.

LIVER AND GALLBLADDER CANCER

At present, surgical resection remains the most effective therapy for primary and metastatic disease of the liver. While there are no definitive criteria that define what constitutes resectable disease in part owing to differing therapeutic philosophies and surgical experience, most surgeons would consider extrahepatic disease, extensive bilobar disease, or the presence of extensive cirrhosis as the major factors that would preclude a potentially curative resection.

As with the other gastrointestinal malignancies, imaging modalities such as multidetector CT scanning, MRI, and CT/PET scanning are available for preoperative staging. Despite the use of these modalities, a significant number of patients continue to have exploration without resection.[48–50,69–71] Laparoscopy, therefore, can serve to improve curative resection rates and decrease unnecessary laparotomy with its associated morbidity and quality-of-life issues.

Laparoscopic staging detects subradiologic disease in 10–60% of cases.[72,73] As with other anatomical sites, variability in part relates to the completeness and quality of preoperative imaging. Jarnagin and colleagues from Memorial Sloan-Kettering Cancer Center (MSKCC) reviewed their experience with 186 patients who had either primary or secondary hepatic malignancies who underwent surgery at their institution.[70] Laparoscopy was attempted in 104 patients and completed successfully in 85%. Overall, 26 (25%) of these patients were noted to have unresectable disease at the time of LS, and although nine patients had subsequent laparotomy for palliation, 17 patients were spared a laparotomy. More extensive hepatic disease, peritoneal disease, and extensive cirrhosis were the main laparoscopic findings that precluded resection. Difficulties were encountered determining the true extent of tumor vascular invasion or extensive biliary involvement. In addition, findings at laparoscopy had an impact on the type of resection performed in a further 10%. The authors also compared the patients undergoing LS with a similar nonrandomized cohort of 82 patients who did not receive LS but went directly to operation during the same time period. At open laparotomy, 28 (34%) of this group were noted to have unresectable disease. Although nine patients had a palliative procedure, 19 patients had only an exploratory procedure, which the authors suggested potentially could have been avoided with laparoscopy. Comparing the two groups, LS was associated with increased resectability rates (83% vs 63%), shorter hospital stay (8.6 vs 11.9 days), and reduced hospital charges. A subsequent study from the same institution analyzed experience with 401 patients.[74] Prior surgery did not preclude staging because a complete laparoscopic examination was performed in 291 (73%) cases. Despite a false-negative rate of 22%, LS improved the overall resectability rate from 62% to 78%.

In an attempt to define the patients who would benefit from LS, the same group created a clinical risk score (CRS) based on five factors related to the primary tumor and the hepatic disease[75,76] (Table 5-2). Each criterion was assigned one point. Thus, 42% of patients with a CRS score of greater than 2 had unre-

TABLE 5-2: CLINICAL RISK SCORE FOR THE DETERMINATION OF RESPECTABILITY IN HEPATIC COLORECTAL DISEASE

Lymph node–positive tumor
Disease-free interval between primary colonic surgery and detection of metastatic disease <12 months
Number of hepatic tumors greater than one (based on pre-operative staging)
CEA greater than 200ng/mL within one month of surgery
Size of the largest hepatic tumor greater than 5 cm

sectable disease detected at laparoscopy versus 0% of patients with CRS scores of 0–1. Therefore, targeting laparoscopy to high-risk patients should avoid unnecessary LS in low-risk patients, whereas performing it in the high-risk group should prevent needless staging laparotomies and overall improve the yield from laparoscopy. This scoring scheme has recently been validated by a number of groups. Mann and coworkers noted that an increasing CRS correlated with the likelihood of detecting incurable disease. Management was altered in 0%, 14%, and 53% of cases if the CRS was 0–1, 2–3, or 4–5, respectively.[77] Shah and colleagues reported that in patients with a CRS ≤2 laparoscopy and LUS prevented an operation in only 7% compared to 24% in those with a CRS >2.[78] This data suggests that a focused use of LS is warranted.

Others have argued that improved imaging, particularly the increased availability of preoperative CT/PET, coupled with a more aggressive surgical approach have reduced the potential yield of LS in patients with colorectal metastases to the liver. However, data to support this hypothesis is lacking and in the main relies on review of the findings at open exploration, which were noted to preclude resection and potentially would have been detected by laparoscopy if it had been performed.

The history of a prior colectomy does not preclude accurate LS. Rahusen and colleagues performed laparoscopy in 50 patients with colorectal metastases, laparoscopy completing the examination in 94% and demonstrating unresectable disease in 38%.[79] Similar results have been reported by others.[80,81] Failure to accurately stage patients may occur due to adhesions from the prior open surgery in up to 20% of patients.[80,81]

Thaler and colleagues have suggested that the addition of intraoperative ultrasonography (IUS) improves the yield of LS (Fig. 5-10). In a review of 136 patients, LS/IUS changed the treatment plan in 48% of patients. Surgically untreatable disease was noted in 25% owing to PMs, nodal involvement, or diffuse hepatic disease.[82] Others have also noted the added value of LUS to LS.[73,79,83,84] Foroutani and colleagues reported their experience with LUS and biopsy in 310 patients with 1080 primary and metastatic liver lesions.[85] Using a linear side-viewing transducer, core needle biopsies were taken using an 18-gauge spring-loaded biopsy gun. Histologic confirmation was obtained in all patients, with no

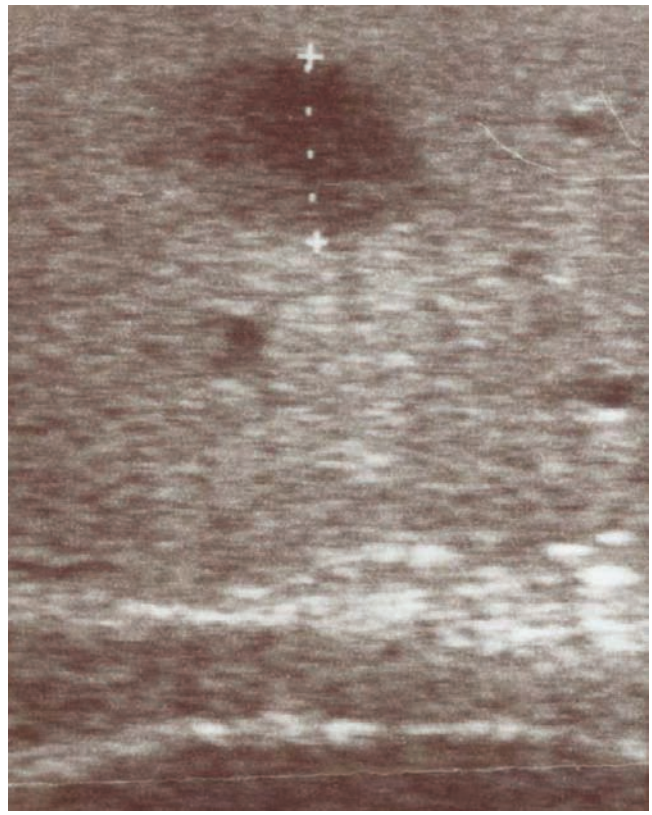

FIGURE 5-10 Isolated metastasis in a patient with gallbladder cancer as demonstrated by LUS.

bleeding complications or visceral injuries. A recent report has suggested that the combined use of laparoscopic and LUS-guided biopsies changed patient management in 27% of patients with upper gastrointestinal cancers (including primary and secondary liver tumors). LUS–guided biopsies were supplementary to laparoscopic biopsies and accounted for 44% of the clinical impact, suggesting that LUS should be an integral component of the staging procedure.[86] Hartley and colleagues reported that LUS was equivalent to MRI in determining resectability, particularly for primary hepatic tumors.[87] However, they and others also have noted that determining the extent of vascular and biliary involvement was problematic.[83]

For primary hepatocellular disease, experience is similar.[88,89] Lo and colleagues performed staging laparoscopy with LUS in 91 patients with primary hepatocellular carcinoma (HCC), identifying unresectable disease in 16%, two-thirds of whom avoided any further surgical intervention and commenced nonoperative treatment earlier.[71] As the use of laparoscopic resection and radiofrequency ablation for HCC has increased, it has been suggested that the role of LS has also expanded to not only identify unresectable disease but also aid selection of the optimal therapy. Lai and coworkers described a cohort of 122 patients with potentially resectable HCC who underwent LS prior to planned open laparotomy. Laparoscopic staging was performed in 119 patients, 44 of

whom were noted to have unresectable disease. Overall 25% of patients had their therapy delivered laparoscopically (22 curative resection, 8 palliative ablation/resection) with a significant reduction in median hospital stay compared to those who underwent open surgery.[90] In an interesting publication, Casaccia et al noted that, while laparoscopic ultrasonography accurately staged HCC in patients with advanced cirrhosis, it also allowed for laparoscopic radiofrequency ablation to be safely performed.[91]

The role of LS in the evaluation of noncolorectal nonneuroendocrine tumors was studied by D'Angelica and colleagues from MSKCC.[92] Following preoperative staging, 30 patients considered to have resectable disease underwent laparoscopy. Staging was completed in 80% and correctly identified six patients of the nine finally found to have unresectable disease.

There has been little work specifically directed to determining the utility of LS for gallbladder cancer. Agrawal and colleagues reported on a cohort of 91 patients with apparent resectable disease who underwent staging laparoscopy. Laparoscopic findings of either locally advanced or disseminated disease avoided open exploration in 35 cases.[93] Similar results were reported by Goere and coworkers from France who noted that LS detected unresectable disease in 36% of patients with potentially resectable biliary cholangiocarcinoma or gallbladder cancers. Peritoneal and liver metastases were detected but vascular and lymphatic extension was not diagnosed leading the authors to suggest that laparoscopy was more useful in extrahepatic cholangiocarcinomas and gallbladder cancer and should only be considered in selected cases with hilar cholangiocarcinomas.[94]

PANCREAS CANCER

Adenocarcinoma of the pancreas remains a lethal disease.[95] Despite increased awareness and improved diagnostic modalities, most patients continue to present with advanced disease at the time of diagnosis. Actual 5-year survival is between 3% and 5%, with surgical resection offering the only chance of cure. However, resection is only appropriate for a minority of patients. For the majority, the need for surgical intervention is controversial. In common with esophagogastric cancers, the notion that all patients require an operative procedure for accurate staging or palliation no longer is true. Our increased understanding of the natural history of the disease, coupled with the improvements in nonoperative palliative techniques, suggests that effective palliation does not require an open surgical procedure. Proponents of LS argue that the combination of dynamic contrast-enhanced CT scanning and/or MRI with laparoscopy remains the most effective means of staging, preventing needless open surgery for those who would not benefit, while not precluding resection for those who would benefit. Avoidance of unnecessary open procedures potentially will result in reduced perioperative morbidity and mortality, decreased hospital stay, shorter time to appropriate therapy, improved quality of life, and overall reduced treatment costs.

Laparoscopic staging for pancreatic cancer is not a new concept. In fact, the first published case in the United States of a minimally invasive approach to cancer staging was in a patient with pancreatic cancer. Bernheim in 1911 staged a patient of W. S. Halstead with presumed pancreatic cancer prior to laparotomy.[96] He stated that the procedure he termed *organoscopy* "may reveal general metastases or a secondary nodule in the liver, thus rendering further procedures unnecessary and saving the patient a rather prolonged convalescence." The use of laparoscopy was sporadic and not widespread until the seminal works of Alfred Cuschieri from Scotland and Andrew Warshaw from the United States.[97–100] Both used the technique before the laparoscopic revolution and began to define the role it would have in the staging algorithm.

The yield of positive laparoscopy that avoids unnecessary laparotomy is highly dependent on the quality of the preoperative radiologic studies. The yield of laparoscopy cannot be assessed from studies that have not included state-of-the-art CT scans.[101] Currently, the standard protocol should include a contrast-enhanced thin-cut dynamic CT scan of the pancreas. Initial reports from MSKCC concerning LS of peripancreatic malignancy reported an improvement in resectability from 50% based on standard CT scanning alone to 92% when staging laparoscopy was performed.[73,102] Compared with previous reports, improvements in technology and better patient selection have reduced the benefit of laparoscopy. However, laparoscopy continues to consistently upstage approximately 15–20% of patients with radiologically resectable disease.[73,97,102–107]

An early study at MSKCC examined 577 patients who following contrast-enhanced CT scans were considered to have potentially resectable disease and underwent staging laparoscopy.[108] Unresectability was determined at laparoscopy if histologic proof was obtained of:

1. Metastasis (hepatic, serosal, and/or peritoneal) (Fig. 5-11)
2. Extrapancreatic extension of the tumor (ie, mesocolic involvement)

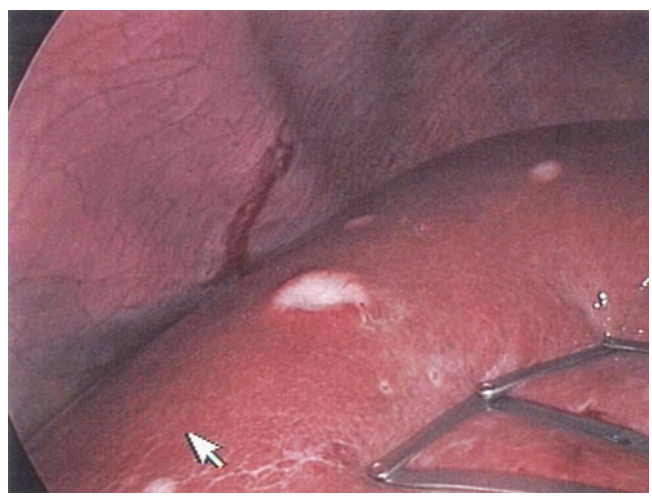

FIGURE 5-11 Hepatic metastases in pancreas cancer.

3. Celiac or high portal node involvement
4. Invasion or encasement of the celiac or hepatic artery
5. Involvement by tumor of the superior mesenteric artery

Portal or superior mesenteric venous involvement was considered a relative contraindication to resection depending on the degree and extent of involvement.

In the MSKCC series, 366 patients were considered to have resectable disease after LS and subsequently underwent open exploration, with 92% (338 patients) being resected. The predominant sites for metastases were the liver and the peritoneal cavity. The resectability rate was compared with results from the decade before the introduction of LS, during which 1135 patients at MSKCC were explored but only 35% were resected. In a recent update from the same group examining 1045 patients with radiographically resectable disease who underwent LS between 1995 and 2005, it was reported that the yield of LS had decreased to 14% for patients with pancreatic adenocarcinoma. The predominant reason for unresectability at lapaproscopy was metastatic liver disease. Only seven patients were noted to have locoregional disease highlighting the improvements in CT imaging. Of the patients considered resectable at laparoscopy 99% were subsequently resected.[109] A similar yield was reported by Doran and colleagues; 239 patients with suspected periampullary cancer underwent staging laparoscopy following dual-phase helical CT scanning.[110] CT "resectable" disease was noted in 190 patients, of whom laparoscopy correctly identified unresectable disease in 28 patients. Overall, owing to findings at laparoscopy, 15% of patients were spared a further procedure, leading the authors to conclude that when added to CT scanning, LS provides valuable information that improves the selection of patients for surgical or nonsurgical treatment significantly. Many other authors have reported similar results (Table 5-3).

TABLE 5-3: DETECTION OF INTRA-ABDOMINAL METASTASES AT LAPAROSCOPY

Author	Year	Number of patients	Yield (%)
John	1995	40	14 (35%)
Fernandez-del Castello	1995	114	27 (24%)
Conlon	1996	108	28 (26%)
Holzman	1997	28	14 (50%)
Jiminez	2000	125	30 (24%)
White	2001	45	8 (18%)
Vollmer	2002	72	16 (22%)
Doran	2004	45	8 (18%)
Karachristos	2005	63	63 (19%)
Ahmed	2006	37	9 (24%)
Ferrone	2006	297	68 (23%)

Carbohydrate Antigen 19-9

The use of tumor markers such as the carbohydrate antigen 19-9 (CA-19-9) to further select patients for staging laparoscopy has been proposed. Halloran and colleagues used a cut off value for CA-19-9 of 150 kU/L improving resectability levels and reducing nontherapeutic laparotomies.[111] Using a receiver operating characteristics (ROC) curve for preoperative CA-19-9 values and tumor respectability, Maithel and coworkers demonstrated a statistically optimal cutoff of 130 U/mL. Unresectable disease was identified in 38 of 144 patients (26%) with a preoperative level ≥130 U/mL compared to 13 of 118 patients (11%) with a value <130 U/mL.[112] We believe that this added information does allow for better selection of patients. Figure 5-12 details a recommended clinical algorithm. The use of such a strategy is supported by the analyses of population-based administrative databases. Mayo and colleagues reviewed the experience in Oregon and noted that the majority of patients did not undergo LS.[113] However, in the subset that did undergo LS metastatic disease, which precluded resection, was noted in 27.6%. These patients were spared an unnecessary laparotomy.

Laparoscopic Ultrasonography

To further increase the added value, we use LUS. LUS has been used by a number of groups in an attempt to increase the yield of LS.[114,115] John and colleagues showed that laparoscopy demonstrated unsuspected metastatic disease in 14 of 40 patients considered to have resectable disease.[103] However, laparoscopy had only 50% sensitivity in predicting tumor resectability. The accuracy in predicting resectability increased to 89% with the addition of LUS. Several other studies have demonstrated that the added value of LUS to standard laparoscopy is on the order of 14–25%.[73,116–119] Callery and colleagues analyzed the effect of routine implementation of laparoscopy with LUS, determining that the addition of LUS improved staging by identifying an additional 22% of patients with unresectable disease.[73] Minnard and colleagues reported the benefit of LUS over laparoscopy alone in evaluating the primary tumor and the presence of vascular involvement.[117] LUS findings resulted in a change in surgical treatment in 14% of patients in whom standard laparoscopic examination was equivocal. A further study by Schachter and colleagues demonstrated a change in surgical intervention in 36% of patients, with avoidance of unnecessary laparotomy in 31%.[120] Catheline and colleagues reported that LUS altered therapy in 41% of cases, avoiding open exploration in 46%.[121] This group reported a 90% sensitivity for assessing positive nodal disease and 100% for hepatic and peritoneal disease. Vollmer and colleagues similarly reported an improvement in resection rates using LUS (84% with LS vs 58% without)[122]. Merchant and colleagues concluded that the addition of LUS during LS enhances the ability of laparoscopy to determine resectability and approaches the accuracy of open exploration without increasing morbidity or mortality

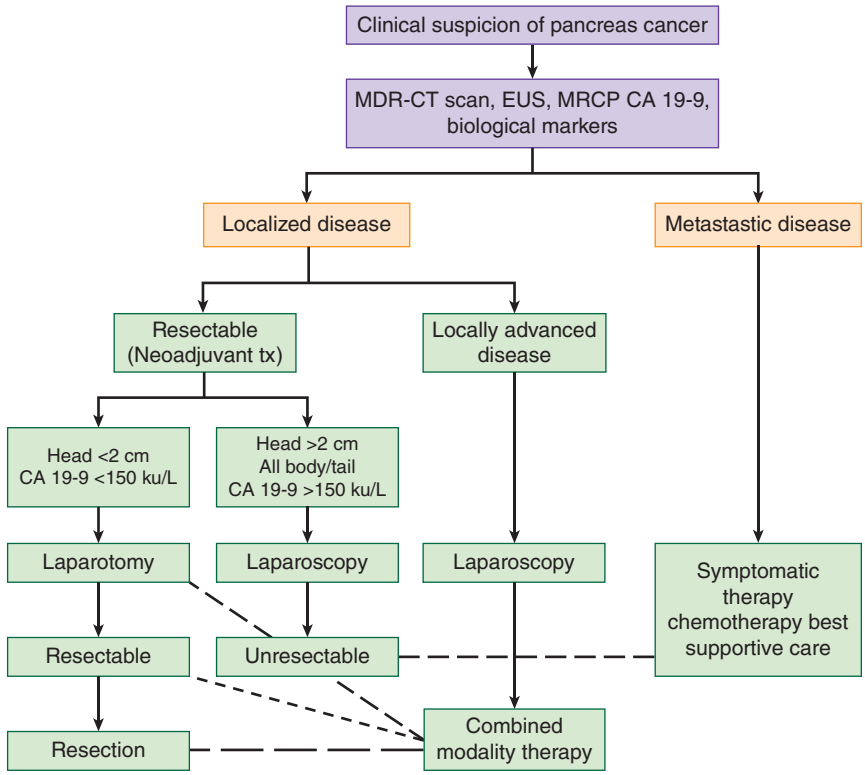

FIGURE 5-12 Treatment algorithm for pancreas cancer.

significantly.[123] As clinical experience has developed it appears that the main utility remains in assessment of the liver or vascular involvement (Fig. 5-13). In patients with portal/superior mesenteric vein involvement, determining (i) resectability and/or if resectable (ii) the amount of venous resection required to obtain clear margins. This approach is supported by Thomson and colleagues using the widely accepted CT classification of vascular involvement, which examined the relationship between the tumor and the major vasculature and grades the involvement between A and F.[124] Tumors graded A to D were generally resectable while those graded E and F were invariably unresectable.[125] The authors suggest that, using these criteria, the selective use of LUS in LS is indicated. A meta-analysis examining the role of laparoscopy and LUS was performed by Hariharan and coworkers.[126] They identified 29 studies in which 3305 patients underwent LS. The true yield was 25% (95% CI 24–27). The authors suggested that this represents a significant benefit to patients with potentially resectable adenocarcinoma of the pancreas in avoiding nontherapeutic laparotomy.

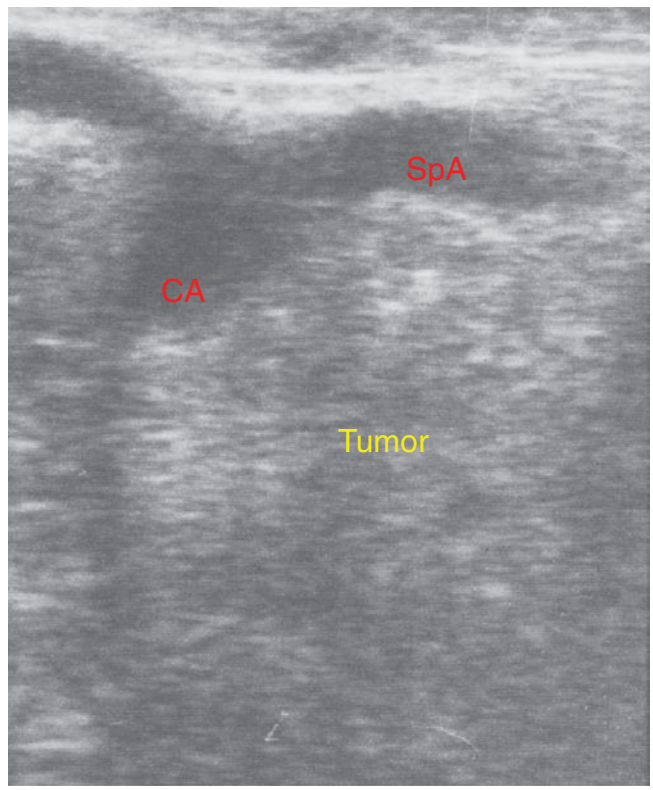

FIGURE 5-13 LUS examination demonstrating infiltration of the celiac axis (CA) and splenic artery (SpA).

Peritoneal Cytology

Cytologic examination of peritoneal washing obtained at the time of laparoscopy has also been suggested to enhance the sensitivity of staging laparoscopy.[127] Laparoscopy combined with peritoneal cytology is reported to upstage approximately 10% of patients.[123,128] Peritoneal recurrence is a significant

site of failure following a potentially curative pancreaticoduodenectomy. Leach and colleagues studied a consecutive series of patients with suspected or biopsy-proven radiologically resectable adenocarcinoma of the pancreatic head.[129] Peritoneal washings were obtained at the time of staging laparoscopy and/or at subsequent laparotomy. Positive peritoneal cytology (PPC) was noted in 7% of patients, all of whom had overt metastatic disease at a median of 4.8 months. Merchant and colleagues examined 228 patients with radiographically resectable pancreatic adenocarcinoma who underwent LS.[123] Peritoneal washings were taken from both upper quadrants at the beginning of laparoscopy. Overall survival was significantly higher in patients with negative peritoneal cytology. The authors determined that PPC had a positive predictive value of 94.1%, a specificity of 98.1%, and a sensitivity of 25.6% for determining unresectability. Quantitative real time-polymerase chain reaction (RT-PCR) assay was used by Dalal and coworkers to detect tumor cells in a cohort of 35 patients undergoing staging laparoscopy.[130] Positive cytology was noted in eight cases and appeared to be stage-related. However, 25 patients were RT-PCR positive suggesting that this methodology could represent a more sensitive method for the detection of subclinical disease and enable improved selection for operative therapies and clinical trials. This intriguing pilot study requires further confirmation.

Despite the above, there is no consensus around the value of LS. Critics argue that confining laparoscopy to the setting of determination of resectability overestimates the usefulness of laparoscopy because it fails to account for patients who require open procedures for palliation of unresectable disease.[101]

Pisters and colleagues from the MD Anderson Cancer Center reported resectability rates of 80% using high-quality CT scanning alone.[101] Based on these data, the authors proposed that the maximum positive yield of routine staging laparoscopy in patients with potentially resectable disease on high-quality CT scanning would be 20%, assuming a false-negative result of zero. This group did not perform routine staging laparoscopy but rather used selective laparoscopy at the time of planned laparotomy for tumor resection in patients with localized disease on CT scan and patients at high risk for occult M1 disease.[131,132] This is a strategy that has been advocated by others.[133] Gouma and colleagues from Amsterdam assessed the role of LS in patients with periampullary tumors compared with standard radiologic staging with helical CT scanning.[134] Laparoscopic staging identified biopsy-proven unresectable disease in only 13% of 297 patients, with a detection rate of 35%. Based on the findings, the authors proposed that LS should be performed selectively. Since their practice is to recommend a surgical bypass as palliation for patients with locally advanced unresectable disease, they believe that LS only adds value in the presence of metastatic disease.

Locally Advanced Disease

Recent reports have focused on the role of LS in patients with locally advanced unresectable disease who were considered for adjuvant chemoradiotherapy. Shoup and colleagues reviewed 100 consecutive patients with locally advanced disease who underwent LS.[135] Contemporary imaging studies failed to detect metastatic disease in 37% of cases. Peritoneal disease was noted in 12 cases, liver metastases in 18, and 7 patients had both. Similar results were reported by Liu and Traverso, who described their experience with 74 patients, all of whom had undergone high-quality pancreas protocol CT examination prior to LS.[136] Occult tumor was found in 34% of patients. The authors reported that tumors situated in the body and tail of the gland were more likely than head lesions to have unsuspected metastases (53% vs 28%). Morak and coworkers in a prospective cohort study reported that 24 of 68 (35%) patients with locally advanced disease on CT had metastatic disease at laparoscopy.[137] These studies emphasize that despite the improvements in imaging modalities, LS should be performed in patients considered to have locally advanced disease prior to the start of combined modality therapy.

The studies cited earlier focus on invasive ductal adenocarcinoma of the pancreas. For other cell types, including neuroendocrine tumors, intraductal papillary mucinous neoplasms, and cystadenocarcinomas, the data are sparse. A review of the MSKCC experience with laparoscopy in nonfunctioning islet cell tumors by Hochwald and colleagues found a high incidence of occult metastases at laparoscopy.[138] CT scan followed by laparoscopy was significantly more sensitive than CT scan alone in predicting resectability (93% vs 50%; $p = 0.03$). This resulted from a high false-negative rate on CT scan for small-volume metastatic disease, hepatic disease being the most common site. The predictive value for tumor resectability also was much higher for CT scan followed by laparoscopy than for CT scan alone (95% vs 74%). Brooks and colleagues examined the role of LS in 144 patients with ampullary, duodenal, and distal bile duct tumors.[139] Patients with distal bile duct tumors also appeared to benefit from LS in terms of both determining resectability and avoiding unnecessary surgery. In contrast, patients with known duodenal or ampullary tumors gained little added value from LS.

COMPLICATIONS OF STAGING LAPAROSCOPY

In experienced hands, the procedure is safe and well tolerated as a day case procedure. Complications are low with few specific reports in the literature. Of those, only one identifies a series of complications directly attributable to the LS procedure.[140] In their series published in 2003, Rodgers et al report a complication rate of 2.8% (3/106 patients), one of which was unrecognized at laparoscopy and which eventually contributed directly to the patients' death. In general, major morbidity such as hemorrhage, visceral perforation, and intra-abdominal infection may occur in 1–2% of cases.

As the use of laparoscopy in malignant disease increased, concern was expressed regarding the potential risk of disseminating disease at the time of pneumoperitoneum. An initial case report in 1978 by Dobronte and colleagues described a "port site" tumor implant in a patient with malignant ascites 2 weeks following laparoscopy.[141] A number of similar reports followed, again involving patients who had disseminated disease at the time of their laparoscopic examination. Nieveen van Dijkum and colleagues from Amsterdam demonstrated an overall 2% port-site recurrence, with all cases having advanced peritoneal disease.[142]

Clinical experience over the last two decades appears to support the hypothesis that LS is safe from the oncologic standpoint. Pearlstone and colleagues from the MD Anderson Cancer Center described their experience with laparoscopy in 533 patients with nongynecologic intra-abdominal cancer, 339 of whom had laparoscopic procedures for upper gastrointestinal malignancies.[143] They reported port-site recurrences in four patients (0.88%), three of whom had advanced disease at the time of initial laparoscopy. Similar results were noted in a report from MSKCC, which reviewed a prospective database of 1650 diagnostic laparoscopic procedures performed in 1548 patients with upper gastrointestinal malignancies, in which a total of 4299 trocars were inserted.[144] The most frequent diagnosis was pancreatic cancer (51.2%). At a median follow-up of 18 months, a port-site recurrence was noted in 13 patients (0.8%). An open operation was performed in 1040 patients, of whom 9 (0.9%) developed a wound recurrence. This latter figure is similar to the 0.8% incisional recurrence rate noted by Hughes and colleagues in a review of 1600 open laparotomies for colon cancer.[145] Median time for the development of the port-site recurrence in the MSKCC study was 8.2 months. Eight occurred in patients with documented metastatic disease at the time of laparoscopy, and the remaining five had local or distant disease at the time of diagnosis of the port-site implant, and therefore, the recurrence did not appear to be an isolated event but rather a marker for more advanced disease. The authors concluded that LS appeared safe from an oncologic standpoint. This is further supported by a retrospective review of 235 patients who had laparoscopy to stage pancreatic cancer. This study demonstrated a port-site recurrence rate of 3% versus a 3.9% incisional recurrence rate in those patients who had an exploratory laparotomy alone.[146]

A number of hypotheses have been suggested to explain port-site implantation. Tumor seeding has been associated with carbon dioxide pneumoperitoneum in animal studies; however, reports that tumor growth is established more easily after open laparotomy would appear to refute this theory.[147–149] Other mechanisms, such as tissue manipulation, direct wound contamination, poor surgical technique, or immunologic effects such as changes in host immune responses, also have been suggested.[150] It appears so far, however, in most studies that port-site implantation is uncommon, differs little from open surgical incision recurrence, and is more likely to reflect the underlying biologic behavior of the disease rather than the type of surgery.

LAPAROSCOPIC BILIARY AND GASTRIC BYPASS

Since the majority of patients with pancreatic cancer have unresectable disease at the time of presentation, palliation to minimize symptoms and maximize quality of life has a major role in the care of these patients. Palliation most commonly is required for one of three problems: biliary obstruction, gastric outlet obstruction (GOO), and relief of pain.

While both cholecystoenteric and choledochoenteric bypasses have been performed laparoscopically, the latter is much more difficult technically, requiring a high level of laparoscopic skills. A sufficient length of common duct needs to be exposed, and a difficult intracorporeal anastomosis between the small bowel and the common duct must be performed. Cholecystojejunostomy is the more commonly performed laparoscopic procedure (Fig. 5-14). Patient selection is critical. A low insertion of the cystic duct into the common bile duct or tumor impingement within 1 cm of the duct is a predictor of early technical failure. The anastomosis can be performed with either a stapled or hand-sewn technique. In patients who have experienced a prior cholecystectomy or who have a diseased gallbladder, blocked cystic duct, low insertion of the cystic duct, or tumor encroachment on the cystic duct or gallbladder, a cholecystojejunostomy is not possible; therefore, either a laparoscopic cholodochojejunostomy is performed, or the procedure is converted to open and a standard surgical bypass is performed.

Rhodes and colleagues presented in 1995 one of the first series of patients who underwent laparoscopic palliation for advanced pancreatic carcinoma. From the 16 patients, 7 underwent laparoscopic cholecystojejunostomy, 5 had laparoscopic gastroenterostomy, 3 had both procedures, and in 1 patient laparoscopic palliation failed. The median operating time was 75 minutes, the hospital stay was 4 days, the morbidity was 13%, and the median survival in 10 patients was 201 days, with the rest of the patients remaining alive at the

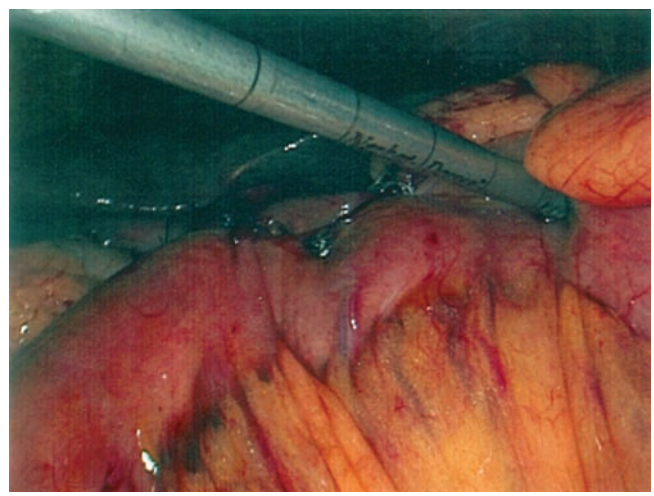

FIGURE 5-14 Laparoscopic cholecystojejunostomy.

time of the publication.[151] In 1999, Rothlin and colleagues published a case-controlled study of 28 patients with pancreatic cancer divided in two groups; in one group, laparoscopic palliation was performed, and the other group underwent conventional surgical palliation.[152] Of the 14 patients in the laparoscopic group, 7 had laparoscopic gastroenterostomy, 3 had gastoenterostomy and hepaticojejunostomy, and 4 had staging laparoscopy only.

Postoperative morbidity was 7% for the laparoscopic group compared with 43% for the open palliation group. There were no deaths in the laparoscopic group versus 29% mortality in the open group. Average postoperative hospital stay was 9 days for the laparoscopic group versus 21 days for the open group. Finally, the laparoscopic group required significantly less analgesia postoperatively. Choi presented a series of 78 gastrojejunostomies, 45 open and 33 laparoscopic, performed for palliation of gastric outflow obstruction caused by advanced gastric, duodenal, ampullary, and pancreatic cancers.[153] In the laparoscopic group, there was less suppression of immune function, lower morbidity, and earlier recovery of bowel function. A randomized trial reported by Navarra and colleagues demonstrated that patients undergoing a laparoscopic gastrojejunostomy had significantly less intraoperative blood loss and resumed oral intake sooner than those patients undergoing an open palliative antecolic gastrojejunostomy.[154]

The technique for a transumbilical single-incision laparoscopic gastrojejunostomy has recently been reported.[155] While this is technically feasible, the benefits compared to the conventional laparoscopic approach remain to be determined.

The true incidence of symptomatic GOO in pancreatic cancer remains unclear. Historically, it was considered that more than 25% of patients would develop GOO during the course of their illness, and therefore, prophylaxic gastric bypass was recommended at the time of exploratory laparotomy. However, as the need for open exploration for staging purposes has decreased, the need for prophylaxic bypass for the majority of patients has been questioned. GOO is a late complication of advanced pancreatic cancer affecting 10–20% of patients who survive more than 15 months.[156–158] However, fewer than 3% of the patients who develop GOO require surgical bypass.[156,159,160] Most important, 60% of patients with advanced pancreatic cancer have delayed gastric emptying with no evidence of gastric or duodenal invasion. This may be explained by tumor infiltration of the celiac plexus causing gastric stasis, nausea, and vomiting.[161]

Espat and colleagues examined in a prospective but nonrandom study of 155 patients undergoing LS.[156] Following laparoscopy, 40 patients had locally advanced unresectable disease, and the remainder had metastatic disease. In follow-up, only 3% of patients required a subsequent open operation for biliary drainage or GOO. A subsequent update of this experience has confirmed the results, with over 90% of patients dead of disease. This low incidence of patients requiring operation for symptomatic GOO is consistent with the data seen from the nonoperative control groups in randomized trials of endoscopic biliary drainage versus surgery.

A laparoscopic gastroenterostomy is a relatively straightforward procedure. Nagy and colleagues reported a series of laparoscopic gastrojejunostomies.[162] Nine of 10 patients in this series had GOO from pancreatic malignancy. The laparoscopic method was successful in 90%. There was no postoperative morbidity or mortality associated with the surgical technique.

Surgical Technique for Biliary and Gastric Bypass

The patient is placed supine on the operating table in 10 degrees of reverse Tredelenberg position with 10 degrees of left lateral tilt. The placement of trocars is similar to that for a standard staging procedure. However, in order to accommodate a linear stapler, the right upper quadrant 10-mm trocar is converted into a 12- to 15-mm size. Following exploration, the ligament of Trietz is identified, and a loop of jejunum approximately 30 cm distal to the ligament of Treitz is brought in an antecolic position to the gallbladder (Fig. 5-15). Using an intracorporeal suturing technique, the jejunum is approximated to the gallbladder by two 3-0 coated, braided lactomer sutures (Polysorb, US Surgical, Norwalk, CT). The distended gallbladder may be decompressed using a Veress needle attached to a suction device. There is usually minimal biliary spillage owing to the raised intra-abdominal pressure consequent on the pneumoperitoneum. Small enterotomy incisions (10 mm) are made in the gallbladder and jejunum using either scissors or a device such as the ultrasonic shears (Fig. 5-16). Hemostasis is achieved with electrocautery. Any spillage can be dealt with by suction device placed through the left upper quadrant port. An endoscopic 30-mm linear stapler using 3.5-mm staples is introduced through the right upper quadrant port, and the "jaws" are manipulated into the gallbladder and jejunum in a standard fashion. Often, this is difficult because of the proximity of the port site to the gallbladder. A reticulating stapler facilitates this maneuver. The stapler heads are approximated, and the instrument is fired (Fig. 5-17). After removing the stapler, the anastomosis is inspected, hemostasis is confirmed, and the gallbladder interior is aspirated and irrigated with saline.

The resulting enterotomy can be closed by using either a completely intracorporeal or laparoscopically assisted approach. Using an intracorporeal technique, the defect is closed with a continuous seromuscular 3-0 coated, braided lactomer suture, with knots tied using an intracorporeal technique (Fig. 5-18).

An alternative method is to create a completely hand-sewn anastomosis using 3-0 coated, braided lactomer suture. If a running suture is used, the assistant should maintain tension on the suture with an atraumatic grasping forceps following placement of each stitch. Knots can be tied either using an intracorporeal or extracorporeal technique.

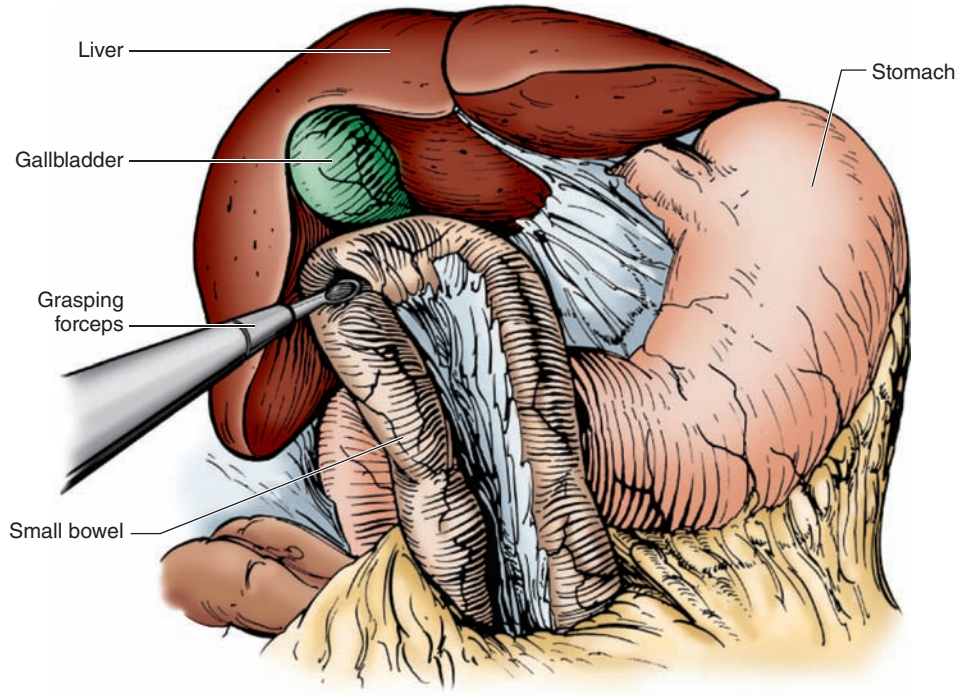

FIGURE 5-15 Laparoscopic cholecystojejunostomy.

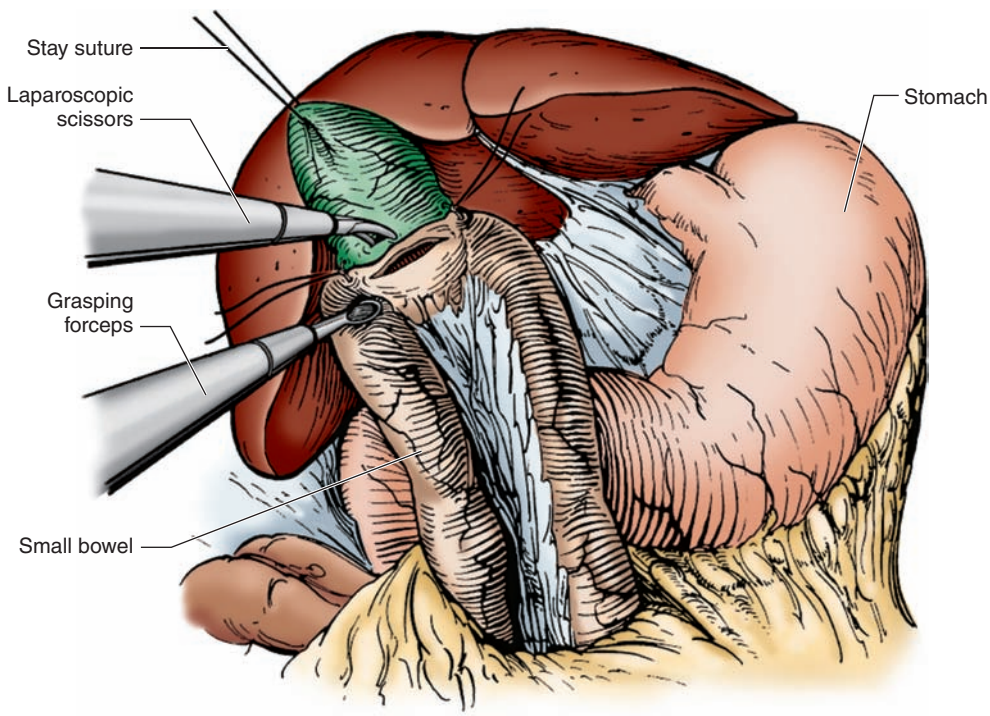

FIGURE 5-16 Approximation of small bowel to gallbladder, creation of enterostomy.

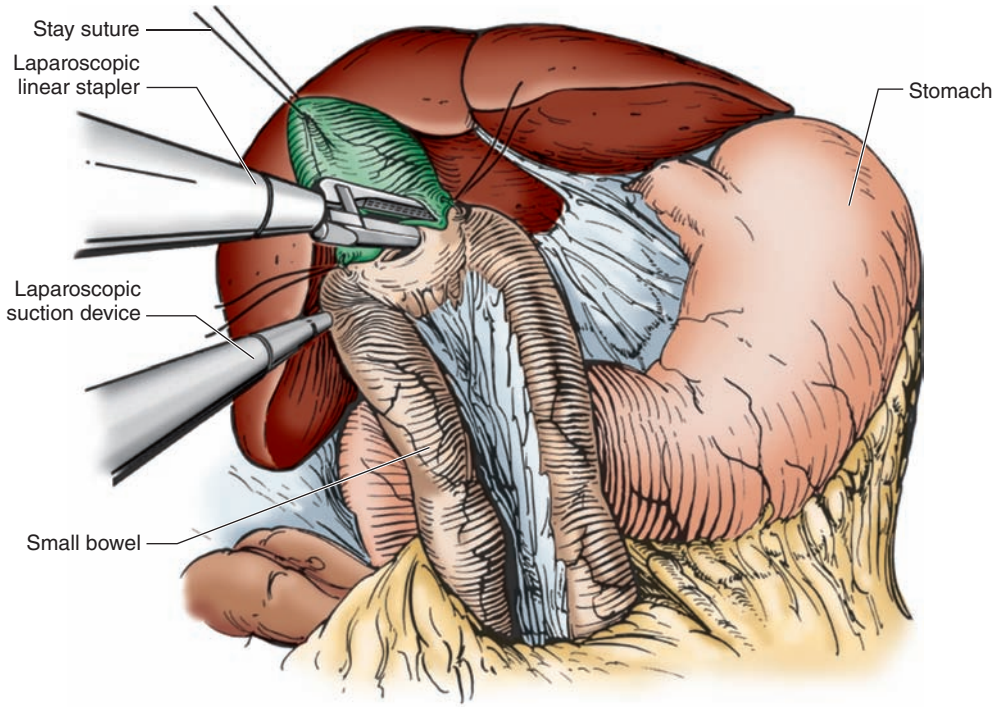

FIGURE 5-17 Stapled anastomosis.

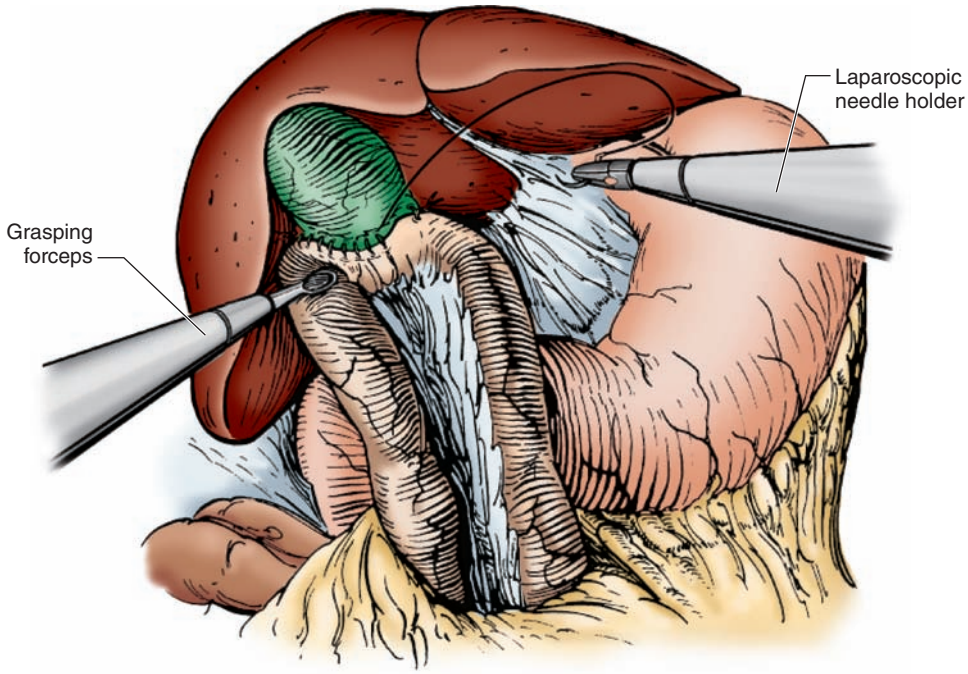

FIGURE 5-18 Closure of enterotomy.

A laparoscopically assisted method is suitable in thin patients. Two stay sutures are placed on either side of the anastomotic defect. These sutures are cut long. The 12-mm trocar is removed, and the incision is enlarged to 20 mm. Using retraction on the stay sutures, the newly created biliary-enteric anastomosis can be exteriorized and the enterotomy closed in a standard fashion. When this is completed, the bowel is returned to the abdominal cavity, and the wound is closed. The abdomen is reinsufflated and the anastomosis inspected. This technique allows for the construction of a 2.5-cm cholecystojejunal anastomosis without any bowel narrowing. No intra-abdominal drains are used.

The technique for fashioning a gastrojejunostomy is similar. In this case, a proximal loop of jejunum is brought in an antecolic position to the stomach. The left upper quadrant 5-mm laparoscopic trocar is converted to a 12-mm trocar. Two 3-0 coated, braided lactomer sutures (Polysorb, US Surgical) are used to approximate the jejunum to the stomach. Enterotomies are made in both stomach and jejunum. In cases in which there has been a significant period of gastric obstruction, the gastric wall may be hypertrophied, making creation of the gastrotomy difficult. Confirmation that one is inside the stomach is required before placement of the stapler. When this is achieved, a 30-mm linear stapler is inserted through the 12-mm left upper quadrant port and manipulated into both enterotomies. The instrument is positioned and fired. The stapler is removed and reloaded, returned into the anastomosis, and refired. This creates an anastomosis approximately 5 cm in length. The anterior defect can be closed in a fashion similar to the cholecystojejunostomy (Fig. 5-19). Any defects in the anastomosis can be repaired with individual 3-0 sutures.

The ideal palliative procedure for biliary or gastric obstruction should be effective in relieving jaundice or GOO, have minimal morbidity, be associated with a short hospital stay, have a low symptomatic recurrence, and maintain quality of life. Laparoscopic procedures have the potential to achieve these goals, although data do not support prophylactic bypass procedures in patients who do not otherwise require surgery.

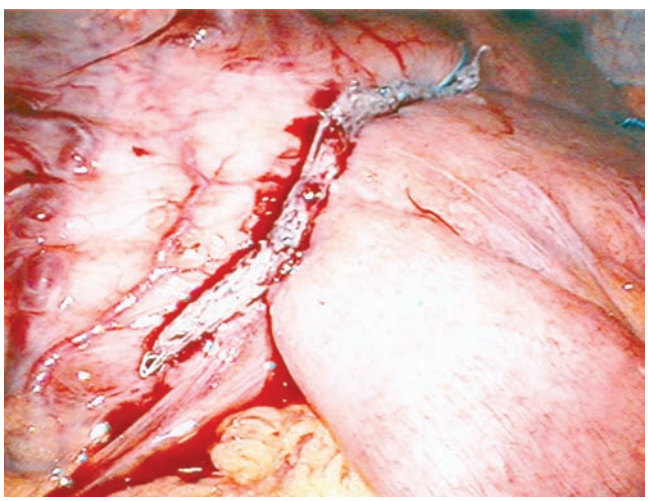

FIGURE 5-19 Laparoscopic gastrojejunostomy.

SUMMARY

Laparoscopy is no longer a tool of limited use and now has widespread indications within surgical oncologic practice. Despite improvements in noninvasive imaging, there is still an added value to use LS in selected patients with upper gastrointestinal cancers. In the future, the combination of NOTES technology and MIS techniques offers further exciting potential to enhance staging of these patients.

INCISIONS, CLOSURES, AND MANAGEMENT OF THE ABDOMINAL WOUND

Robert E. Roses • Jon B. Morris

INCISIONS

The impact that the planning, execution, and closure of an incision has on the outcome of an abdominal operation should not be underestimated. The high combined incidence of surgical site infection (SSI), wound dehiscence, and hernia formation suggests a dominant contribution of wound complications to surgical morbidity. Moreover, the quality of exposure provided by an incision influences the ease and safety with which an operation can be undertaken and the outcome in ways which defy easy quantification.

An incision must provide access to the site of abdominal pathology and allow easy extension if greater exposure than originally anticipated is required. Indeed, the adequacy of an incision is determined above all else by the safety with which an operation can be undertaken. Nothing should compromise this and a larger incision or even, on occasion, a second incision should be created without hesitation if exposure is inadequate. Notwithstanding this, the incision should be executed in a fashion that anticipates a secure wound closure and interferes as little as possible with the function and cosmesis of the abdominal wall. These principles apply to both open and laparoscopic incisions. While the vertical midline incision remains most popular, and is, perhaps the most flexible, a variety of other incisions may have distinct advantages in specific settings.

Choice of Incision

Abdominal incisions can be vertically, transversely, or obliquely oriented. The avascular linea alba affords the vertical midline its superior flexibility. Indeed, when optimal exposure of the abdominal cavity is necessary (eg, exploration for abdominal trauma), the vertical midline incision is preferred and can be extended superiorly to the xiphoid process and inferiorly to the symphysis pubis. Alternatively, vertical incisions may be placed in a paramedian position, an approach that was previously more popular than it is today but continues to have its proponents. Transverse and oblique incisions can be placed in any of the four quadrants of the abdomen depending on the site of pathology. Common examples include the Kocher subcostal incision for biliary surgery, the Pfannenstiel infraumbilical incision for gynecologic surgery, and the McBurney and Rockey-Davis incisions for appendectomy. A bilateral subcostal incision affords excellent exposure of the upper abdomen. Alternatively, when superior exposure of upper abdominal organs (eg, the esophagogastric junction) is required, thoracoabdominal incisions may be used.

The relative merit of vertical versus transverse incisions remains a topic of active debate. Proponents of transverse incisions argue that they anticipate a more secure closure than do vertical incisions, a hypothesis supported by anatomic and surgical principle. The fascial fibers of the anterior abdominal wall are oriented transversely or obliquely. Therefore, transverse incisions parallel the direction of the fascial fibers and allow for ready reapproximation with sutures placed perpendicular to these fibers. In contrast, vertical incisions disrupt fascial fibers and must be reapproximated with sutures placed between fibers.[1] In the latter case, the absence of an anatomic barrier may predispose such sutures to pull through tissue resulting in dehiscence or hernia formation. Despite these concerns, little evidence supports a substantial benefit of transverse incisions. A number of retrospective clinical studies and a meta-analysis do suggest that transverse incisions are superior to vertical incisions with regard to long-term and short-term outcomes (eg, postoperative pain, pulmonary complications, and frequencies of incisional hernia and dehiscence).[1] Prospective data has been less definitive, however. One randomized controlled trial compared vertical and transverse incisions with regards to the frequency of evisceration; no significant difference in outcome was observed with either technique.[2] In a more recent prospective randomized trial, no significant differences in 30-day mortality, pulmonary complications, median length of hospital stay, median time to tolerate

solid food, and incisional hernia formation at 1 year were observed. More wound infections were seen with transverse incisions.[3]

Likewise, some controversy persists regarding the relative advantages of midline versus paramedian incisions. The theoretical advantage of a paramedian over a midline incision is a diminished risk of wound dehiscence and incisional hernia owing to the presence of rectus muscle interposed between layers of divided fascia. In practice, when these incisions are reopened, the medial edge of the rectus muscle is frequently found to be adherent to the posterior sheath incision and does not effectively buttress the wound. The potential advantages of the paramedian incision have also been investigated in prospective randomized trials which fail to demonstrate any advantage with regards to wound failure rates when compared to midline or transverse incisions.[4] A "lateral paramedian incision" refers to a vertical incision created several centimeters lateral to the location of the traditional paramedian incision.[5] One randomized prospective study suggested a statistically significant decrease in the incidence of incisional hernia following closure of lateral paramedian incisions (0%) compared to medial paramedian incisions (14.9%)[6] and midline incisions (6.9%).[7] A disadvantage of the paramedian incision is the greater length of time needed to create the wound, which increases with the distance from the midline.

In the patient who has had prior abdominal surgery, the cosmetic advantages of re-entering the abdomen through a preexisting scar must be balanced against the challenges associated with dissection in a reoperative field. Close proximity of a new incision to an old one should be avoided in order to minimize the risk of ischemic necrosis of intervening skin and fascial bridges.

Preparation of the Surgical Site

Prior to incision, the surgical field is prepared with antiseptic solution and draped in order to reduce skin bacterial counts and the likelihood of subsequent wound infection. Shaving prior to operation has been associated with an increased rate of SSI and should, therefore, be avoided. If hair at the surgical site will interfere with accurate wound closure or precludes thorough application of the sterile preparation, the use of clippers is preferred to a razor.[8] A variety of antiseptic solutions are commonly used to prepare the skin, including povidone-iodine, alcohol, and chlorhexidene. The efficacy of povidine-iodine depends on the release of the active iodine from a carrier molecule. The solution should, therefore, be applied several minutes prior to incision to maximize its efficacy. The use of chlorhexidine gluconate has been associated with greater reductions in skin bacterial counts and lower rates of SSI when compared to povidine-iodine in a number of studies[6,9,10] and is emerging as the preferred skin antiseptic.

Incisions: Technical Considerations

VERTICAL INCISIONS

Midline Incision. The midline incision allows rapid access to, and adequate exposure of, almost every region of the abdominal cavity and retroperitoneum. It is typically associated with little blood loss and does not require transection of muscle fibers or nerves. The upper midline incision (ie, above the umbilicus) may be used to expose the esophageal hiatus, abdominal esophagus and vagus nerves, stomach, duodenum, gallbladder, pancreas, and spleen (Fig. 6-1). The lower midline incision (ie, below the umbilicus) provides exposure of lower abdominal and pelvic organs. When broad exposure is required, as in an exploration for trauma, the midline incision can be extended to the xiphoid process superiorly and to the pubic symphysis inferiorly.

In creating a midline incision, the operating surgeon and assistant apply opposing traction to the skin on both sides of the abdomen. The skin is then incised with a scalpel. Gauze pads are applied to the skin edges to tamponade bleeding cutaneous vessels and lateral traction is placed on the subcutaneous fat on both sides of the incision. The incision is then carried down to the linea alba using either electrocautery or a scalpel; the decussation of fascial fibers in the upper abdomen serves as an important landmark for the midline. The linea alba, extraperitoneal fat, and peritoneum are then divided sequentially. If exposure of both the upper and lower peritoneal cavities is required, the incision is carried around the umbilicus in a curvilinear fashion. The peritoneum itself is best divided with scissors or scalpel to avoid coagulation injury to underlying intraabdominal organs. Additionally, safe entry may be facilitated by picking up a fold of peritoneum, palpating it to ensure that no bowel has been drawn up, and sharply incising the raised fold. The falciform ligament is best avoided by entering the peritoneum to the left or right of the midline in the upper abdomen.

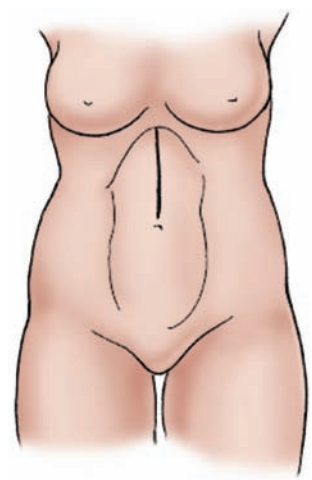

FIGURE 6-1 Epigastric midline incision: surface markings.

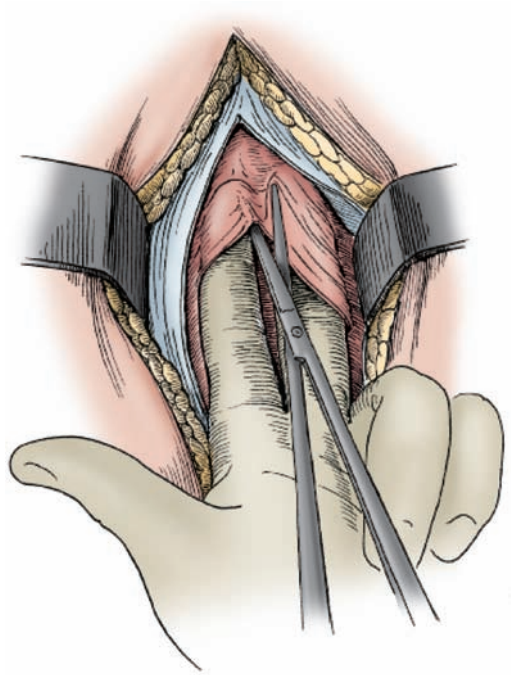

FIGURE 6-2 Vertical midline incision: the linea alba and peritoneum are divided.

To avoid injuries to the bladder, the peritoneum is entered in the upper portion of the incision. After a small opening is created in the midline, it is enlarged to accommodate two fingers that are then used to protect the underlying viscera as the peritoneum is further divided along the length of the wound (Fig. 6-2).

Paramedian Incision. Paramedian incisions are vertical incisions placed either to the right or the left of the midline on the abdominal wall. Like midline incisions, paramedian incisions obviate division of nerves and the rectus muscle and may be made in the upper or lower abdomen. Superiorly, additional access can be obtained by curving the upper portion of the incision along the costal margin toward the xiphoid process (Fig. 6-3). The anterior border of the rectus sheath is exposed and incised across the entire length of the wound. The medial aspect of the anterior rectus sheath is then dissected away from the rectus muscle to its medial edge (Fig. 6-4). Particular care must be taken during this dissection in the upper abdomen where tendinous inscriptions that attach the rectus muscle to the anterior fascia are associated with segmental vessels. These vessels should be clipped or ligated when encountered to avoid significant bleeding. Once free, the rectus muscle is retracted laterally. The posterior sheath (above the arcuate line) and peritoneum are then incised to gain entry into the abdomen. During creation of a paramedian incision in the lower abdomen, the inferior epigastric vessels may be encountered and must be ligated prior to division (Fig. 6-5).

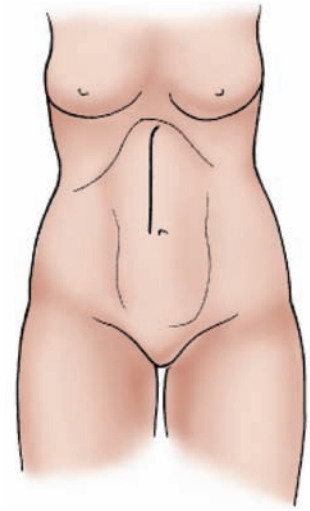

FIGURE 6-3 Upper paramedian incision: surface markings. Additional exposure can be obtained by sloping the upper portion of the incision upward toward the xiphoid process.

Vertical Muscle-Splitting Incision. The vertical muscle-splitting incision is made in much the same way as the traditional paramedian incision except that the rectus muscle is split, rather than retracted laterally. This wound can be opened and closed quickly and is of particular value in reopening a previous paramedian incision where dissection of the rectus muscle away from the rectus sheath can be difficult. Longer incisions should be avoided, however, because they result in significantly more bleeding and sacrifice of nerves that may lead to weakening of the corresponding area of the abdominal wall.

TRANSVERSE AND OBLIQUE INCISIONS

Transverse and oblique incisions generally follow Langer's lines of tension and usually allow a more cosmetic closure than do vertical incisions. Importantly, the rectus muscle has a segmental nerve supply derived from intercostal nerves, which enter the rectus sheath laterally. Transverse or slightly oblique incisions through the rectus most often spare these nerves. Provided that the anterior and posterior sheaths are closed, the rectus muscle can therefore be divided transversely without significantly compromising the integrity of the abdominal wall. Although properly placed transverse incisions can provide exposure of specific organs, they may be limiting when pathology is located in both the upper and lower abdomen.

Kocher Subcostal Incision. A right subcostal incision is used commonly for operations in which exposure of the gallbladder and biliary tree is necessary. The left-sided subcostal incision is used less often, mainly for splenectomy. A bilateral subcostal incision provides excellent exposure of the upper abdomen and can be employed for hepatic resections, liver transplantation, total gastrectomy, and for anterior access to both adrenal glands.

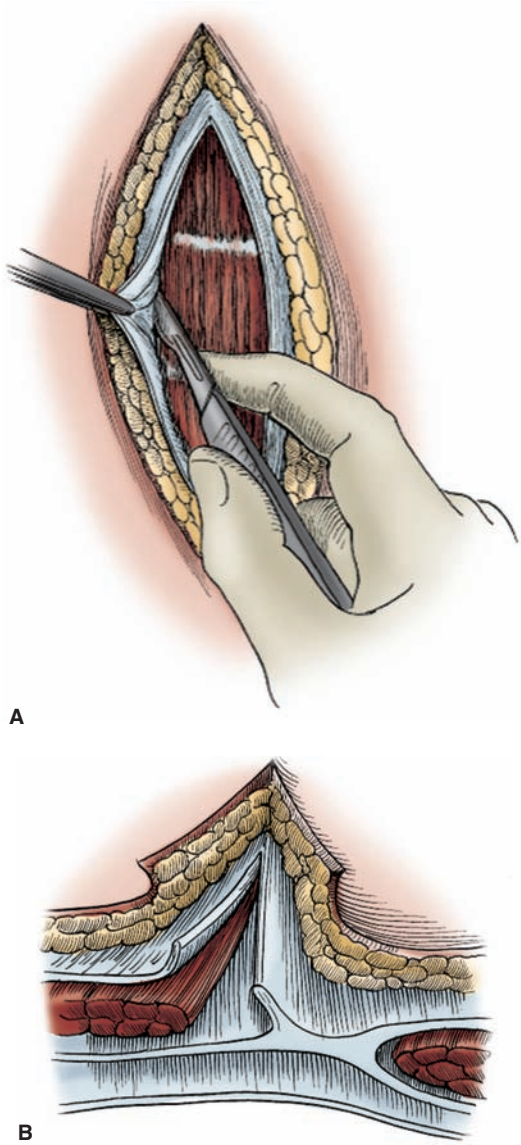

FIGURE 6-4 **A.** Paramedian incision: dissection of the rectus muscle from the anterior rectus sheath. **B.** Paramedian incision in transverse section.

The standard subcostal incision begins at the midline, two fingerbreadths below the xiphoid process and is extended laterally and inferiorly, parallel to the costal margin (Fig. 6-6). The incision should not be placed too far superiorly as sufficient fascia must be preserved to allow a secure abdominal closure. Following incision of the rectus sheath along the plane of the skin incision, the rectus muscle is divided using electrocautery or ligatures to control branches of the superior epigastric artery. The peritoneum is then divided in the plane of the skin incision. The incision can be extended beyond the lateral aspect of the rectus muscle if necessary to facilitate exposure.

McBurney and Rockey-Davis Incisions. Originally described by Charles McBurney in 1894,[11] the muscle-splitting right iliac fossa incision known as the *McBurney* incision is well suited for appendectomy. This incision is oriented obliquely. The McBurney incision has largely been supplanted by the Rockey-Davis incision, which is oriented transversely as opposed to obliquely, allowing for better cosmesis (Fig. 6-7).

The suspected position of the appendix and the thickness of the abdominal wall influence the placement of the incision as well as its length. Examination of the anesthetized patient's abdomen will often reveal a mass, guiding placement of the incision directly over the appendix. If no mass is palpable, the incision is centered over McBurney's point at the junction of the middle and outer thirds of the line between the umbilicus and the anterior superior iliac spine. If the patient is obese, or if extension of the incision is anticipated, the incision should be placed obliquely, allowing ready lateral extension.

After skin and subcutaneous tissues are incised, the external oblique aponeurosis is exposed and divided parallel to the direction of its fibers to reveal the underlying internal oblique muscle. At a point adjacent to the lateral border of the rectus sheath, a small incision is made in the internal oblique muscle, which is similarly opened in the direction of its fibers. Once the underlying transversalis muscle is exposed, it is split to reveal the transversalis fascia and peritoneum. These are sharply divided and the appendix and cecum are exposed (Fig. 6-8). If further exposure is necessary, the wound can be enlarged by dividing the rectus sheath, retracting the rectus muscle medially, and extending the peritoneal defect. If the operation requires extension of the wound laterally, this can be accomplished through division of the oblique muscles.

Pfannenstiel Incision. The Pfannenstiel incision is used frequently for gynecologic operations and for access to the retropubic space (eg, for extraperitoneal retropubic prostatectomy). The skin incision is placed in the interspinous crease above the symphysis pubis. The anterior rectus sheath is exposed and divided transversely. The superior and inferior leaflets of the divided sheath are dissected from the underlying rectus muscles superiorly to the umbilicus and inferiorly to the pubic symphysis. The recti are retracted laterally and the peritoneum is opened vertically in the midline. At the inferior aspect of the wound, the bladder is protected to avoid injury (Fig. 6-9). An advantage of this incision is that it affords a cosmetic closure because it is placed in a skin crease at the level of the belt line; however, exposure may be somewhat limited.

ABDOMINOTHORACIC INCISIONS

The thoracoabdominal incision provides enhanced exposure of upper abdominal organs. A left thoracoabdominal incision is useful for access to the left hemidiaphragm, gastroesophageal junction, gastric cardia and stomach, distal pancreas and spleen, left kidney and adrenal gland, and aorta. A right thoracoabdominal incision can be used to expose the right hemidiaphragm, esophagus, liver, portal triad, inferior vena cava, right kidney, right adrenal gland, and proximal pancreas.

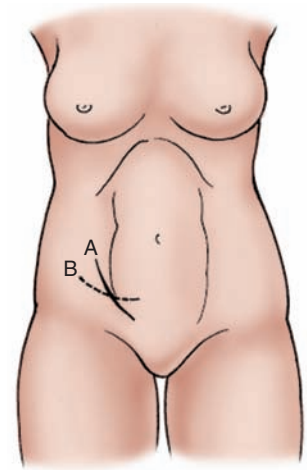

FIGURE 6-7 Surface markings of the right iliac fossa appendectomy incisions. **A.** The classic McBurney incision is obliquely placed. **B.** The Rockey-Davis incision is transversely placed in a skin crease.

These incisions are reserved for circumstances in which an operation cannot safely be performed through an abdominal incision, as they are theoretically associated with increased morbidity relating to a more difficult pulmonary recovery and risk of phrenic nerve injury.

The patient is placed in the "corkscrew" position on the operating room table to enhance access to both the abdominal and thoracic cavities. The abdomen is tilted approximately 45 degrees from the horizontal plane and the thorax is oriented in full lateral position (Fig. 6-10A). Positioning is aided by the use of a bean bag. The abdominal part of the incision may consist of a midline or upper paramedian incision, which allows exploration of the abdomen. The incision is extended obliquely along the line of the eighth interspace just beneath the inferior pole of the scapula (Fig. 6-10B). Alternatively, an oblique upper abdominal incision can be used and extended directly into the thoracic portion of the incision.

After entry into the peritoneal cavity through the abdominal portion of the incision, the incision is extended onto the chest wall and the latissimus dorsi and serratus anterior muscles, and then the external oblique muscle and aponeurosis are divided. The intercostal muscles of the eighth interspace are divided to allow entry into the chest cavity and the incision is extended across the costal margin, which is divided with a scalpel. It is often useful to resect a short segment of costal cartilage to facilitate closure of the chest wall. A self-retaining rib retractor is inserted and the intercostal space is gently spread. The diaphragm is either incised radially toward the esophageal or aortic hiatus, or in a curvilinear fashion if less exposure is required. This incision also preserves phrenic nerve function and is useful for patients with pulmonary compromise.[12]

At the completion of the operation, chest tubes placed in the pleural cavity are brought out through the chest or upper abdominal wall through separate incisions. The diaphragm is repaired in two layers using nonresorbable sutures. Pericostal sutures are placed to reapproximate the ribs. The chest muscles and abdominal wall are then closed in layers.

RETROPERITONEAL AND EXTRAPERITONEAL INCISIONS

Retroperitoneal and extraperitoneal approaches to the abdomen have several advantages over transperitoneal exposures. Manipulation and retraction of intraabdominal viscera are limited and postoperative ileus is reduced. Hemorrhage is more likely to be tamponaded in the retroperitoneum than when it occurs in the peritoneal cavity. Retroperitoneal and

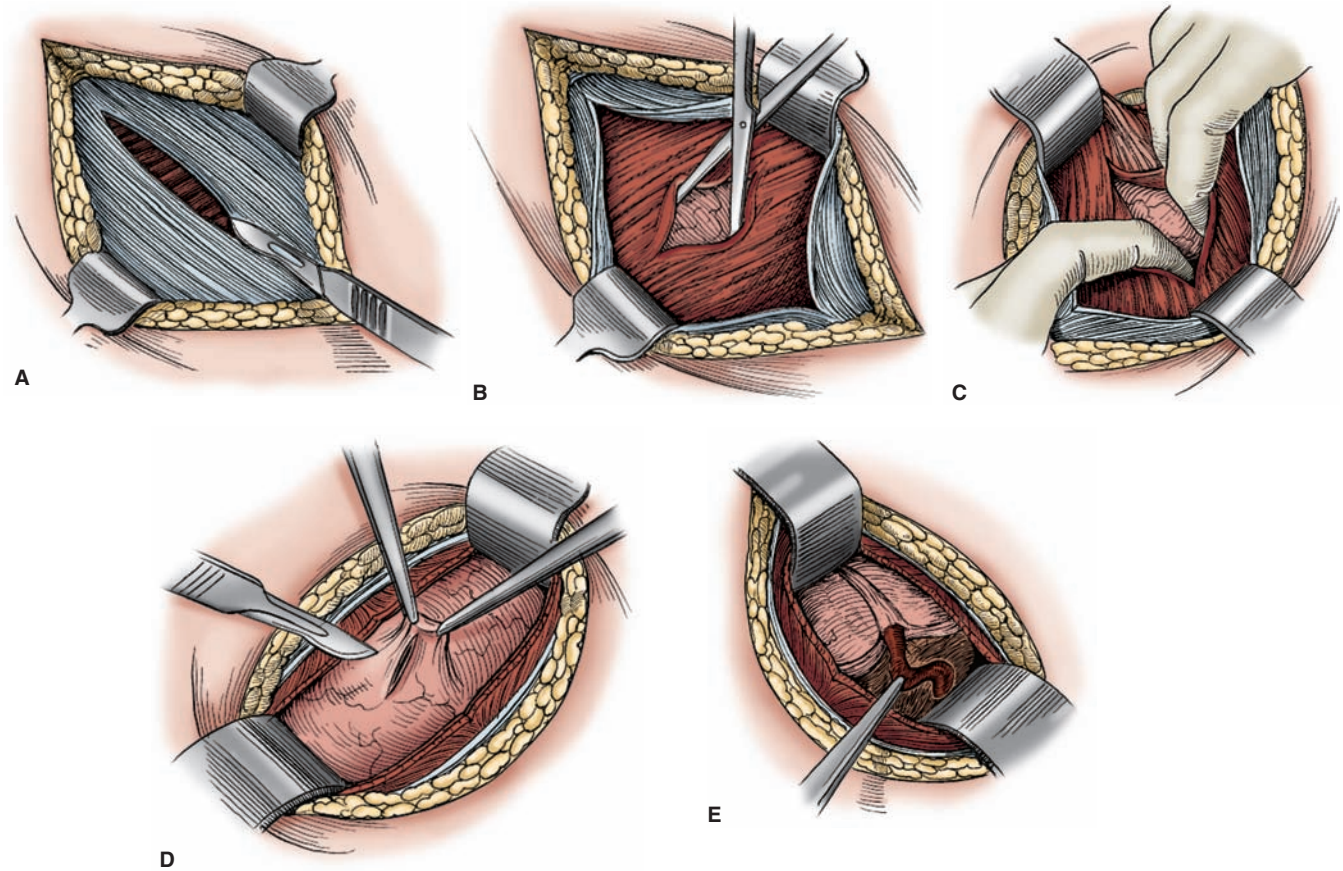

FIGURE 6-8 McBurney muscle-splitting incision. **A.** Division of the external oblique aponeurosis. **B.** The internal oblique and transversus muscles are split. **C.** The index fingers of each hand enlarge the opening. **D.** Incision of the peritoneum. **E.** Exposure of the appendix.

extraperitoneal approaches can be used for operations on the kidney, ureter, adrenal gland, bladder, splenic artery and vein, vena cava, lumbar sympathetic chain, abdominal aorta, iliac vessels, and on groin hernias.

Retroperitoneal Approach to the Lumbar Area. The retroperitoneal approach to the lumbar area is frequently used for aortic surgery, nephrectomy, lumbar symphathectomy, and ureterolithomy. The patient is positioned with the operative side elevated 30–45 degrees with the knees and hips flexed. The incision extends from the lateral margin of the rectus sheath at the level of the umbilicus toward the twelfth rib for approximately 12–14 cm (Fig. 6-11). A portion of the twelfth rib is resected if necessary. The external oblique, internal oblique, and transversalis muscles are exposed, and divided in the direction of their fibers. The retroperitoneum is entered and the peritoneum and retroperitoneal fat are swept anteriorly. The lower pole of the kidney, ureter, and sympathetic chain are easily identified. The vena cava is exposed on the right and the aorta is exposed on the left. If the peritoneum is unintentionally entered, it is closed immediately with continuous absorbable suture. At the conclusion of the procedure, the retroperitoneal fat and viscera fall back into place and the muscles of the abdominal wall are reapproximated in layers.

Posterior Approach to the Adrenal Glands. With the posterior approach, dissection is performed entirely in the retroperitoneal space. The patient is placed in the prone jackknife position. A curvilinear incision is made beginning on the tenth rib approximately three fingerbreadths lateral to the midline and carried inferiorly and laterally toward the iliac crest, ending approximately four fingerbreadths lateral to the midline (Fig. 6-12). The subcutaneous tissues are divided to expose the posterior layer of the lumbodorsal fascia. This fascia and the fibers of the latissimus dorsi muscle, which originate from it, are divided. The erector spinae muscle is exposed and retracted medially to uncover the twelfth rib and the middle layer of the lumbodorsal fascia. The attachments of the erector spinae to the twelfth rib are divided with electrocautery; the vessels and nerves that penetrate the fascia are secured with clamps and ligated. The twelfth rib is then resected. Gerota's fascia is exposed by incising the lumbodorsal fascia along the lateral margin of the quadratus lumborum muscle. The intercostal neurovascular bundle should now become visible directly below the bed of the resected twelfth rib.

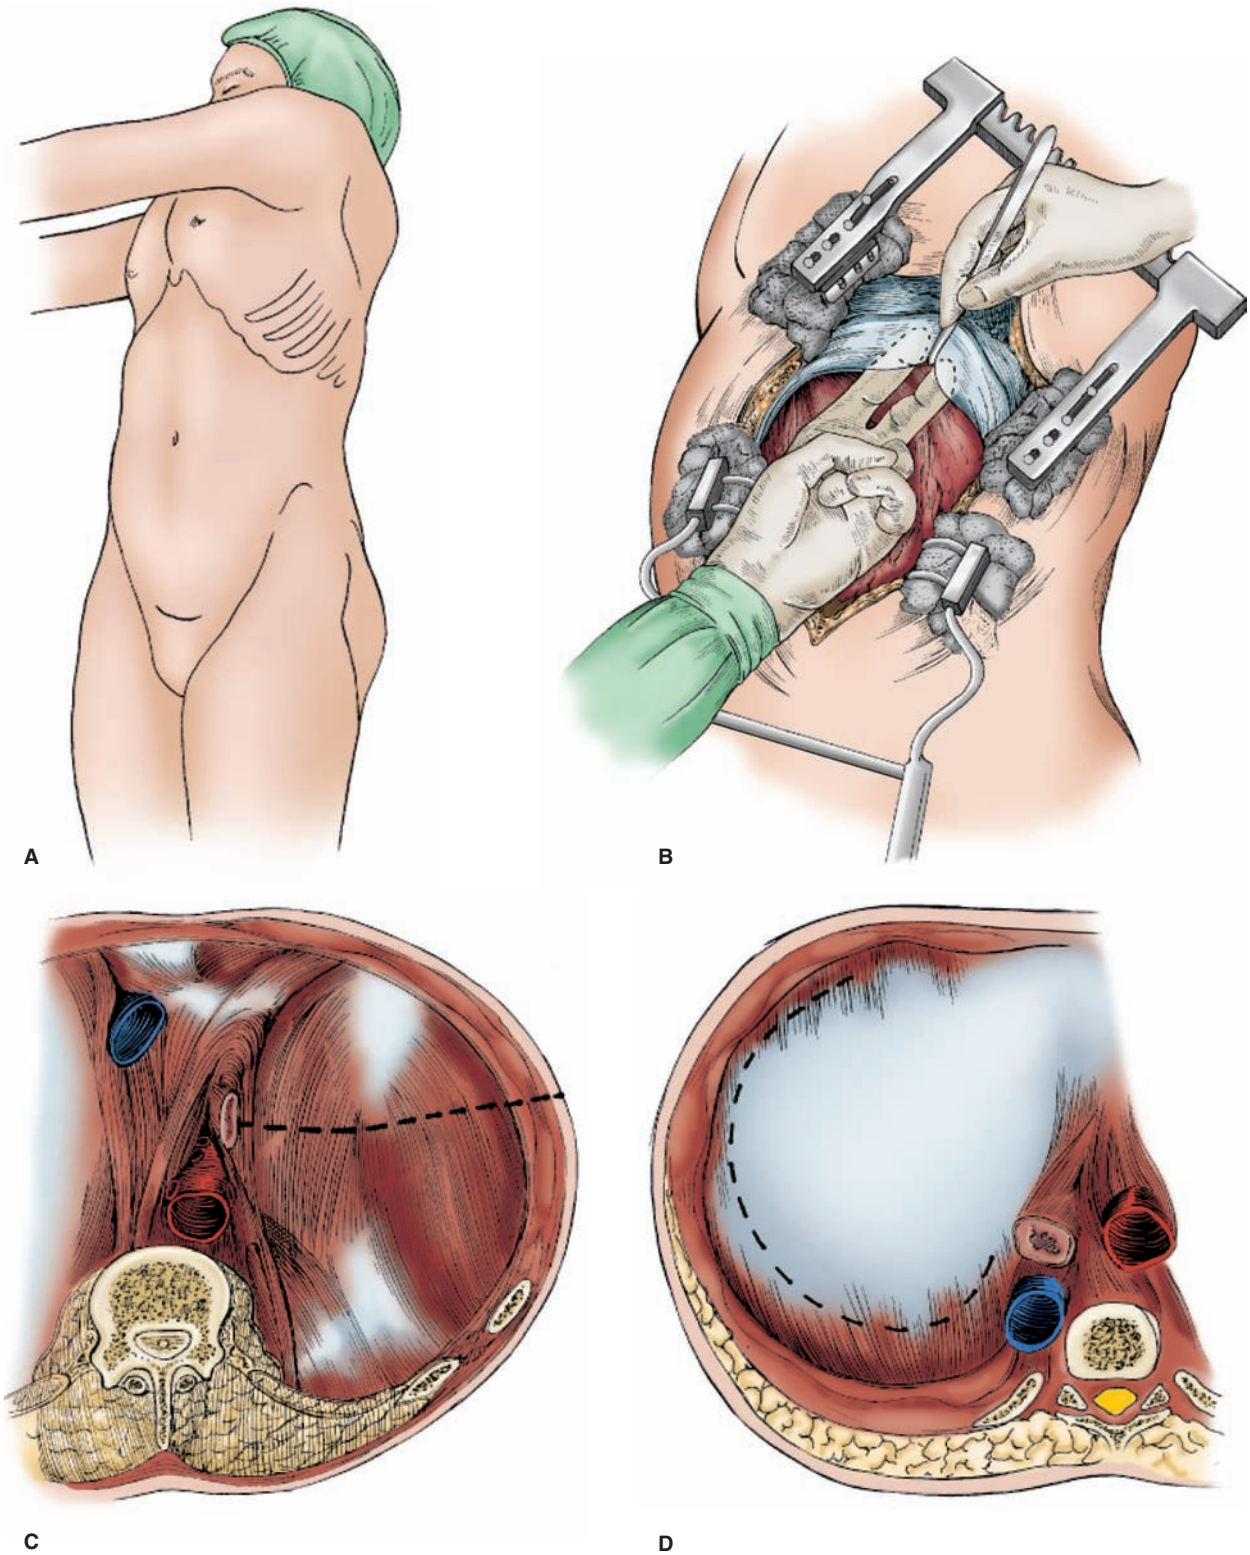

FIGURE 6-10 Anterolateral thoracoabdominal incision. **A.** The "corkscrew" position, with the thorax in the lateral position and the abdomen at 45 degrees from the horizontal plane. Appropriate positioning on the operating table is essential to prevent injury to the brachial plexus and minimize pressure on peripheral nerves. **B.** The abdominal incision is made first; usually a vertical midline incision that is extended into the chest through the eighth intercostal space. The pleural space is then entered. **C.** The diaphragm is usually opened in a radial fashion with an incision directed toward the esophageal or aortic hiatus. **D.** The diaphragm can alternatively be opened with a hemielliptical incision 2–3 cm from the lateral chest wall; this incision preserves phrenic nerve function, of particular importance in patients with impaired pulmonary function. The intercostal vessels are clamped, divided, and ligated and the intercostal nerve is retracted downward. The posterior fibers of the diaphragm are identified and divided where they insert on the periosteum of the twelfth rib. The lower margin of the lung will enter the field with hyperinflation. If the pleura are inadvertently injured, the resulting pneumothorax is handled at closure by insertion of a large-bore rubber catheter into the pleural cavity, which is brought out through the wound. After closure of the fascial fibers around the catheter, the lung is hyperinflated evacuating all air from the pleural space, and the catheter is briskly removed.

Retroperitoneal Approach to the Iliac Fossa. The retroperitoneal approach to the iliac fossa provides access to the bladder, distal ureter, and common, internal, and external iliac vessels. It is often employed for surgery on the iliac arteries and for kidney transplantation. It may also be used to drain psoas or retrocecal abscesses and to resect retroperitoneal tumors. The skin incision is oriented obliquely and extends from approximately 2 cm above the anterosuperior iliac spine to a point just lateral to the pubic symphysis (Fig. 6-13). The incision can also be extended superiorly as far as the costal margin, if necessary. The external oblique, internal oblique, and transversus abdominis muscles are divided in line with the skin incision. The retroperitoneum is entered and the retroperitoneal fat and peritoneum are swept superomedially. If the peritoneum is inadvertently entered, it is closed immediately. At the conclusion of the procedure, the retroperitoneal fat and viscera fall back into place and the muscles of the abdominal wall are reapproximated in layers.

LAPAROSCOPIC INCISIONS

As with open abdominal incisions, laparoscopic access must allow optimal exposure without unnecessarily compromising abdominal wall function or cosmesis. Laparoscopic incisions may be placed anywhere on the abdominal wall. When appropriate, laparoscopic incisions should allow for ready extension should conversion to open operation become necessary. Additionally, laparoscopic access may be combined with small

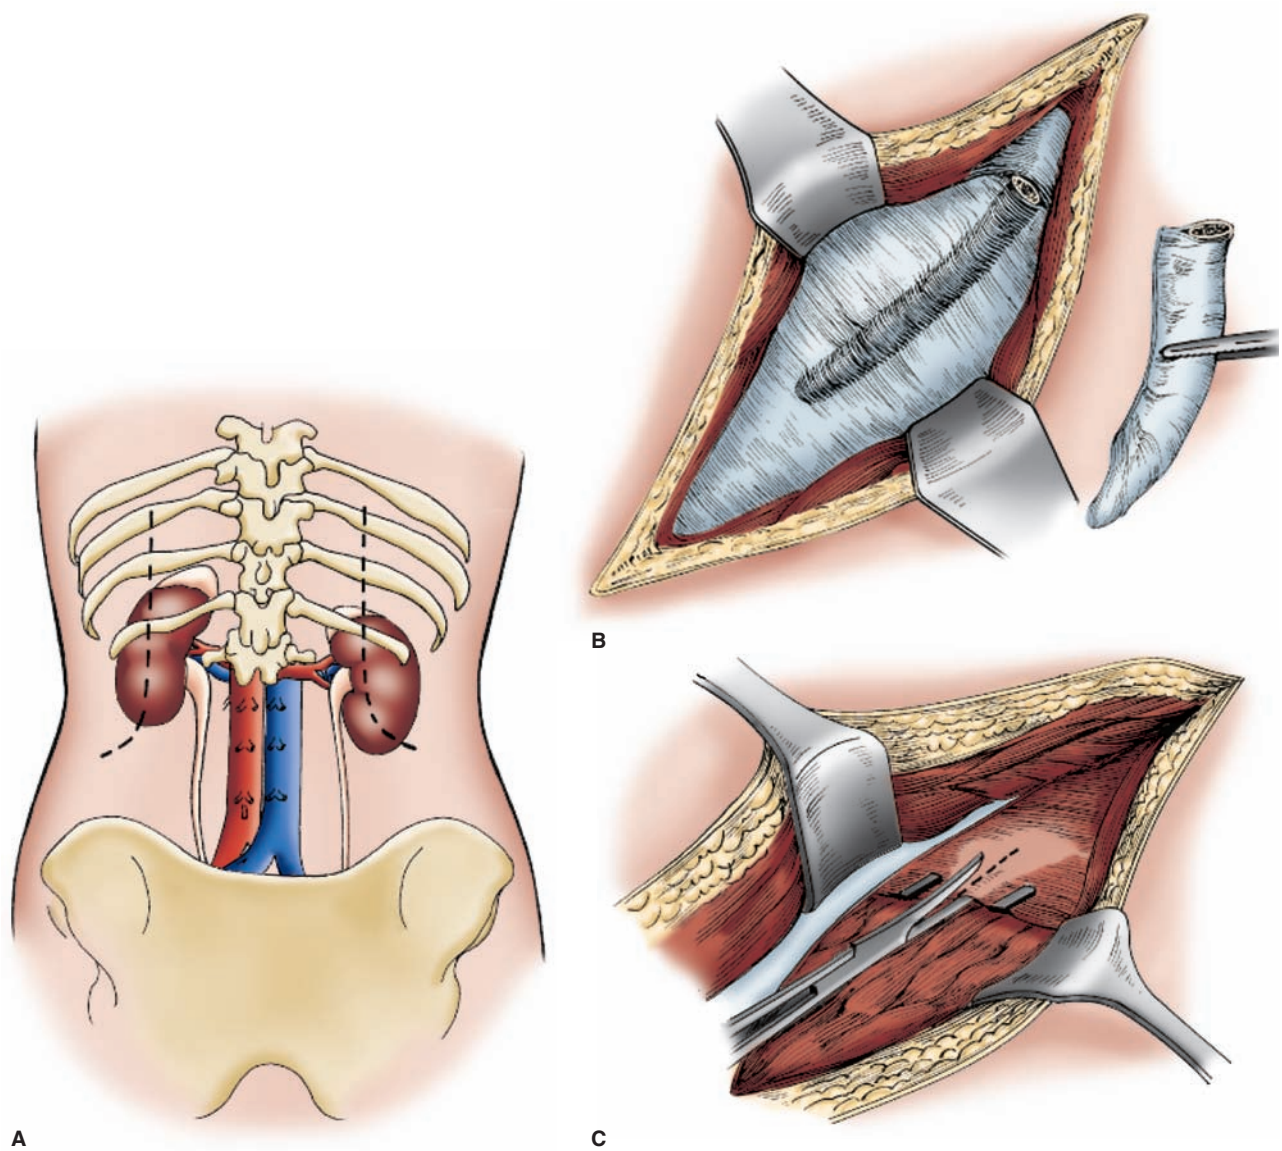

FIGURE 6-12 The posterior approach to the kidney and adrenal. **A.** J-shaped incision over the tenth to twelfth ribs, extending inferiorly 6–10 cm below the twelfth rib. **B.** Resection of the twelfth rib facilitates exposure. **C.** The diaphragmatic attachment to the twelfth rib is taken down, with care taken not to enter the pleura. If the pleura are opened, the wound closure is performed over a pleural suction catheter, which is removed with simultaneous positive airway pressure by the anesthetist as the skin is being closed. (Reproduced, with permission, from Penn I, Baker RJ. Abdominal wall incisions and repair. In: Baker RJ, Fischer JE, eds. *Mastery of Surgery.* 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001:195.)

open incisions that accommodate appliances through which a hand can be inserted into the peritoneal cavity without the loss of pneumoperitoneum. Such *hand-assisted laparoscopic* approaches are frequently associated with shorter operative times than are purely laparoscopic approaches and may have particular advantages for operation in which a larger incision is necessary to remove the surgical specimen (eg, laparoscopic colectomy) and more complex procedures.[13] The initial step of any laparoscopic procedure is the establishment of pneumoperitoneum. This can be achieved using an open or closed technique. Access is most often obtained at a site just above or below the umbilicus; the thinnest portion of the abdominal wall and a central location from which all quadrants of the abdominal cavity can be visualized. Other sites are preferable in specific circumstances (eg, left upper quadrant access in a patient with a previous midline incision).

INITIAL ACCESS

The open approach involves the creation of a small incision, generally 1.5 cm, through which the abdominal fascia is grasped with straight clamps and elevated toward the wound. Exposure of the fascia is often enhanced with the use of S-shaped retractors. The fascia and then peritoneum are

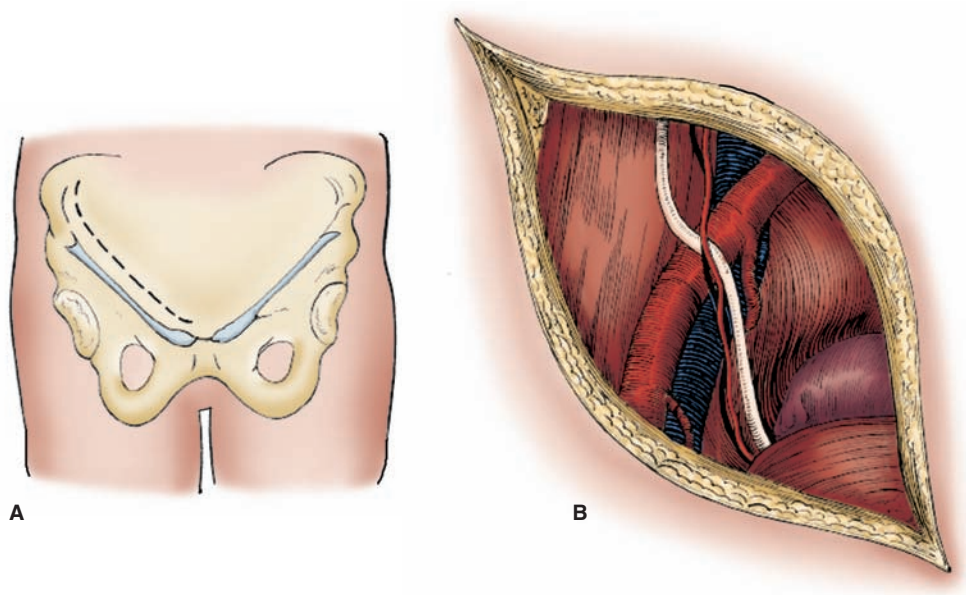

FIGURE 6-13 Right lower quadrant extraperitoneal approach to the iliac vessels, ureter, and bladder. **A.** The skin incision may be shorter than depicted in thinner patients or if an abscess is to be drained. **B.** Peritoneum is retracted medially by blunt dissection, which exposes the psoas muscle and gonadal artery and vein, shown anterior to the ureter. (Reproduced, with permission, from Penn I, Baker RJ. Abdominal wall incisions and repair. In: Baker RJ, Fischer JE, eds. *Mastery of Surgery*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001:196.)

divided under direct vision. Abdominal entry is confirmed by digital palpation. Heavy stay sutures are then placed in each fascial edge and are lifted up while a blunt-tipped (Hasson) obturator and cannula are inserted through the opening in the abdominal wall. The stay sutures are then wrapped around the struts on the cannula to secure it in position. Insufflation tubing is then attached to the cannula and the obturator is withdrawn. Carbon dioxide is insufflated into the abdomen to a pressure of 12–15 mm Hg.

The closed technique involves the passage of a sharp needle (*Veress needle*) through the abdominal wall into the abdominal cavity. A small skin incision is made in the skin through which the needle is inserted, generally at an angle of 45 degrees to the abdominal wall; an angle of 90 degrees is sometimes necessary in the obese patient. As the needle passes through the fascia and then the peritoneum, a sensation of overcoming resistance is appreciated, often reinforced by an audible *click* as the blunt tip of the needle springs forward. A 10 cc syringe containing 5 cc of saline is attached to the end of the needle and is aspirated. If enteric contents, blood or urine, are not aspirated, the saline is instilled through the needle. If the needle is appropriately placed in the peritoneal cavity, saline should pass through the needle without resistance and the meniscus should descend down the hub of the needle when the syringe is detached (the so-called *drop test*); free descent of the meniscus sometimes requires manual elevation of the abdominal wall. The presence of significant resistance in the syringe or failure of the meniscus to descend usually indicates extraperitoneal placement or apposition of the needle against the underlying omentum and usually mandates replacement. Insufflation tubing is then attached to the needle. An initial pressure reading of less than 10 mm Hg further suggests appropriate placement, whereas higher pressures generally indicate extraperitoneal placement. Once satisfactory placement of the needle has been achieved, CO_2 is insufflated through the needle to a pressure of 12–15 mm Hg. The needle is then removed and a cannula and sharp trocar are inserted though an appropriately sized skin incision.

A variety of instrumentation has been developed to facilitate the closed approach. This includes expandable sheaths, which are introduced over the needle and can accommodate larger ports which dilate open the fascial opening (or *radially expanding trocars*), and devices that dilate the fascial opening under direct vision (or *optical access trocars*). Such instrumentation may also obviate formal fascial closure because the resulting fascial defect is small after removal of the port.

The open approach holds the theoretical advantage of minimizing the potential for injury to intra-abdominal visceral and vascular structures. Disadvantages include the generally longer-associated operative time and the occasional need for larger skin incisions, particularly in obese patients. In contrast, the closed approach is generally faster and may allow better cosmesis. Contraindications to the closed approach include the suspected or known presence of extensive intra-abdominal adhesions and pregnancy. However, in patients who have had limited prior surgery, the closed approach may be used to gain access at a site remote from the previous surgical site. The safety of open and closed approaches has been compared in several studies. A large retrospective review of closed laparoscopy in 489,335 patients and open laparoscopy in 12,444

suggested higher rates of visceral and vascular injury in closed laparoscopy. Rates of visceral and vascular injury were 0.083% and 0.075% after closed laparoscopy, and 0.048% and 0% open laparoscopy, respectively ($p = 0.002$). Mortality rates after closed and open laparoscopy were not statistically different.[14] Notably, this small difference was not evident in several other meta-analyses.[15,16]

PLACEMENT OF ADDITIONAL PORTS

The approach to the placement of secondary cannulas is highly surgeon and operation specific. Some basic principles, however, should always be adhered to. These include: (1) all cannulas should be inserted with the aid of laparoscopic visualization; (2) cannulas must be placed far apart from one another to avoid frequent crossing of instruments (generally 10 cm or more apart); and (3) the cannulas should be placed at a distance from the operative site, which maximizes range of motion at the cannula site and minimizes operator discomfort (approximately 15 cm). Additionally, skin incisions, while often small, should never compromise easy passage of trocars through the abdominal fascia. Undue resistance at the level of the skin can undermine the surgeon's control of the trocar as it passes through the peritoneum and lead to injury of underlying viscera or vascular structures.

CLOSURE OF ABDOMINAL INCISIONS

As noted above, wound complications make a dominant contribution to surgical morbidity. Indeed, wound infection is the most common early complication and incisional hernia is the most common long-term complication of open abdominal surgery. Multiple factors contribute to the incidence of wound failure, including diabetes mellitus, malnutrition, obesity, and corticosteroid use. Surgical technique also appears to influence rates of wound failure; however, there has been little consensus regarding the optimal approach to closure. An evolving literature focuses on the relative merits of multiple-layered versus single-layer closure, closure with different suture materials, and interrupted versus continuous closures.

Closure of the Fascia

The abdomen can be closed in multiple layers or en mass. The former technique reconstructs the anterior and posterior aponeurotic sheaths separately with the posterior layer generally incorporating the peritoneum. Mass closure involves a single-layer closure of all layers and may or may not include the peritoneum. Numerous clinical trials have compared multiple-layered closure to mass abdominal closure. Some studies have shown an increased incidence of dehiscence and incisional hernia formation with multiple-layered closure,[17,18] while other studies show no difference in the incidences of these complications.[19] Given the shorter time required to close the fascial layers en mass, this method is generally preferred.

TABLE 6-1: RATE OF RESORPTION OF DIFFERENT SUTURE MATERIALS

Suture Material	Time Until Total Resorption (days)
Rapidly resorbable	
Catgut	15
Chromic catgut	90
Polyglycolic acid (Dexon)	20
Polyglactin 910 (Vicryl)	60–90
Slowly resorbable	
Polydioxanone (PDS)	180
Polyglyconate (Maxon)	180
Nonresorbable	
Nylon (Nurulon)	–
Polypropylene (Prolene)	–
Polyethylene (Ethibond)	–
Polyamide (Ethilon)	–

Dexon (Davis and Geck, Wayne, NJ, USA), Vicryl (Ethicon, Somerville, NJ, USA), PDS (Ethicon), Maxon (Davis and Geck), Nurulon (Ethicon), Prolene (Ethicon), Ethibond (Ethicon), Ethilon (Ethicon). Modified from van't Riet, et al.[32]

The relative advantages of resorbable versus nonresorbable suture for use in closing the fascia have long been debated. Opponents of closure with nonresorbable suture invoke higher rates of suture sinus formation and increased postoperative pain; the incidences of these complications have been estimated at 8% and 17%, respectively. In contrast, it has been suggested that closure with resorbable suture may lead to increased incidences of dehiscence and hernia formation owing to an intrinsic loss of tensile strength during the postoperative period. While these complications are certainly seen with increased frequency when absorbable catgut suture is used,[19] the literature has not consistently borne out an association between wound failure and the use of resorbable sutures such as polyglycolic acid (Dexon), polyglactic acid (Vicryl), polydioxanone (PDS), and polyglyconate (Maxon).[20–25] In particular, several studies comparing permanent (Prolene, Ethicon, or Nylon) and slowly absorbable suture (PDS and Maxon) have failed to demonstrate any advantage to the use of nonresorbable suture. There may be some advantage to the use of slowly resorbable compared to rapidly resorbable suture; one study demonstrated a significant decrease in the rate of hernia formation when slowly resorbable suture (PDS and Maxon) were used compared to more rapidly resorbable sutures (catgut, Dexon, and Vicryl) ($p = 0.009$).[25,26] Nonresorbable suture does appear to be associated with a higher incidence of suture sinus formation. This association may be greatest with multifilament permanent suture, which may abet bacterial ingrowth and infection.[21,24] Table 6-1 shows the rates of resorption for different suture materials.

It has been suggested that a continuous, running closure will result in a more durable wound than an interrupted closure. The former may allow the more even distribution of tension across the suture line with less resultant tissue strangulation and wound disruption. The obvious disadvantage of a continuous closure is its dependence on a single suture. The majority of studies comparing interrupted and continuous closure, however, demonstrate similar incidences of wound dehiscence, incisional hernia, wound infection, wound pain, and suture sinus formation.[25,27–30] One recent randomized trial compared interrupted and continuous closure with resorbable suture. No significant difference in the rates of incisional hernia, dehiscence, or wound infection was observed.[31]

In summary, an evidence-based approach to laparotomy closure narrowly favors the use of nonresorbable or slowly resorbable suture in order to minimize the risk of hernia formation. The latter is preferred because of the lower-associated risk of suture sinus formation and decreased postoperative pain. A running closure is associated with either an equivalent or lower risk of hernia formation and, given the ease and speed with which it can be performed, is to be preferred. Importantly, undue tension should not be placed on the running closure to avoid strangulation of the fascia.

Technique of Mass Closure of the Abdomen

When closing a midline laparotomy incision, two size #0 looped or size #1 nonlooped slowly resorbable monofilament sutures are generally used. One suture is anchored at the upper extent and one at the lower extent of the wound. A malleable retractor can be used to protect the underlying viscera while the fascia is closed. The suture is run in a continuous manner, taking full-thickness bites of the linea alba fascia incorporating both the anterior and posterior rectus aponeuroses (Fig. 6-14). Sutures are passed through the fascia a minimum of 1 cm from the wound edge at 1 cm intervals. An assistant holds steady tensions on the suture while the closure progresses. Repetitive relaxation and application of tension of the suture is avoided to limit injury to the fascia. Likewise, it is unnecessary and probably counterproductive to overly tighten the suture as closure progresses, as this may lead to fascial necrosis. This point has been illustrated in a study associating evisceration and hernia formation with a lower suture length to wound length ratio.[33] The two sutures are run toward one another and then tied together in the center of the wound.

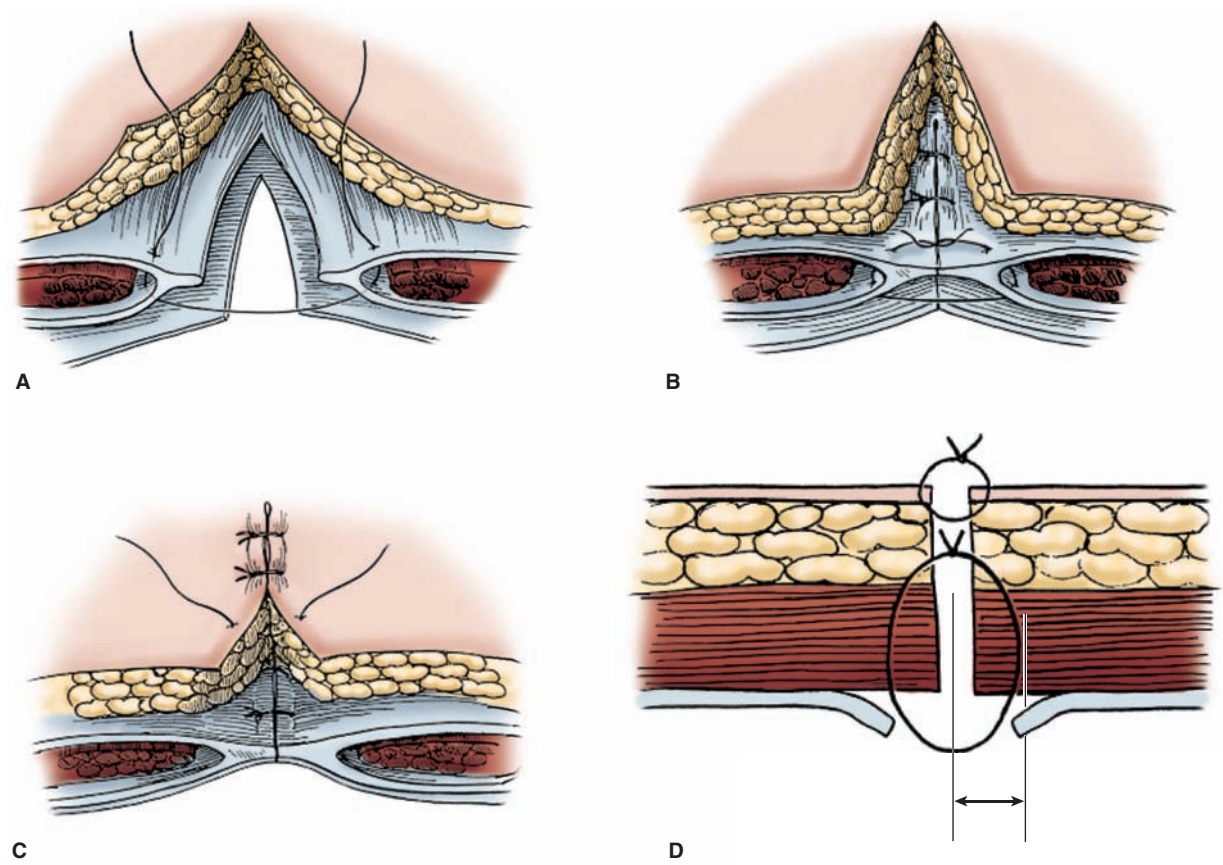

FIGURE 6-14 Mass closure of the midline abdominal incision.

Skin Closure

A number of skin closure techniques can be used following clean (class I) or clean-contaminated (class II) operations; these include interrupted suture, subcuticular suture, stapled, and adhesive glue. Three randomized-controlled studies have compared stapled to subcuticular suture closures. Both techniques are associated with equivalent rates of wound infection.[34–36] Two of the studies suggested that subcuticular suture closure is associated with less postoperative pain than is stapled closure.[34,36] Two studies also demonstrated a superior cosmetic result early following suture closure; however, this difference was insignificant by 6 months after operation.[35,36]

Glues are used with increasing frequency for skin closure. Advantages of glues include ease and rapidity of application and simplification of wound care; generally, no additional dressing is required. Closure with glues has been compared to traditional skin closure methods in several clinical trials. Wound durability appears to be comparable,[37,38] although there are conflicting data on cosmesis, and postoperative pain.[38,39] If the surgical site is contaminated (class III or class IV wound), the skin should be left open to heal by secondary intention or by delayed primary skin closure.[40]

Retention Sutures

The incidence of fascial dehiscence after major abdominal operations is 1–3% and is associated with a mortality rate of 15–20%.[41] Several patient-related factors are associated with an increased risk of fascial dehiscence, including advanced age, male gender, malnutrition, anemia, and steroids use; however, local mechanical factors and closure technique appear to have a greater influence on the rate of dehiscence.[41] Placement of drains or ostomies through the main incision compromises fascial integrity and should be avoided. Wound sepsis and increased intra-abdominal pressure, whether from ileus, bowel obstruction, atelectasis, or after hernia repair, also compromise the integrity of a fascial closure. Indications for prophylactic placement of retention sutures at initial operation remain controversial. The purpose of retention sutures in this setting is to relieve tension along the suture line in order to prevent significant wound disruption and evisceration in the patient at high risk.

There has been only one randomized trial comparing closure with and without retention suture placement. Hubbard and associates could not identify a benefit of retention suture closure over standard mass closure of the abdominal wall.[42] The potential disadvantages of retention sutures, however, are well known and include entrapment of underlying viscera, increased postoperative pain, poor cosmesis, and leakage of intraperitoneal fluid through the wound.[43] Some surgeons advocate primary closure with retention sutures in selected circumstances. In a retrospective study of midline abdominal wound dehiscence, Makela and colleagues identified preoperative variables that are significantly associated with fascial disruption, including hypoalbuminemia, anemia, malnutrition, chronic pulmonary disease, and emergent operation. For patients with three or more of these preoperative risk factors, this group recommended internal retention suture closure.[44]

When employed, retention sutures are placed across the wound prior to formal fascial closure. Interrupted permanent monofilament sutures are passed through skin and fascia approximately 2 cm from the wound margin at intervals of several centimeters. Placement is facilitated by the use of a long cutting needle. It may be advantageous to omit the peritoneum from the retention closure in order to protect underlying viscera from injury or entrapment. After conventional closure of the fascia, the sutures are threaded through rubber tubing bolsters or commercially available plastic bolster devices and tied at the skin level.

Mesh and Biologic Implant Placement

Placement of a mesh underlay represents an alternative approach to the prophylactic placement of retention sutures for the *at risk* abdominal closure.[45,46] Additionally, the occasional operation that requires resection of a significant portion of the abdominal wall, as well as transection of bowel, sometimes necessitates the placement of a prosthesis in a potentially contaminated field. Interposition placement of resorbable mesh accepts a hernia that will require complex abdominal wall reconstruction to repair. Moreover, high rates of fistula formation and mesh infection have been described with resorbable as well as nonresorbable mesh in this setting.[46] Biologic implants, such as human and porcine acellular dermal allograft, are an attractive alternative to meshes when faced with a difficult-to-close abdominal wall, particularly in the setting of contamination. As with resorbable meshes, underlay rather than interposition placement likely yields a much more durable result. While the use of these products in acute clinical settings has been described,[47] there is little definitive data to guide selective application of such techniques. More complex abdominal reconstructions utilizing component separation techniques, releasing incisions or rectus mobilization in conjunction with mesh or biologic implants, may be undertaken in appropriately selected patients when primary closure is not possible. More often, such approaches are utilized in a delayed fashion after development of an abdominal wall hernia.[48]

Closure of Laparoscopic Incisions

The closure of laparoscopic incisions poses particular challenges. Reapproximation of the fascia is made more challenging in the presence of small skin incisions, which limit visualization. While small fascial defects may be left open, any fascial defect 10 mm or greater in the midline or below the arcuate line should generally be closed to reduce the risk of port-site hernia formation.[49] The use of radially expanding

trocars obviates the need for formal closure in many cases, although larger midline defects still generally require suture reapproximation.[50–52]

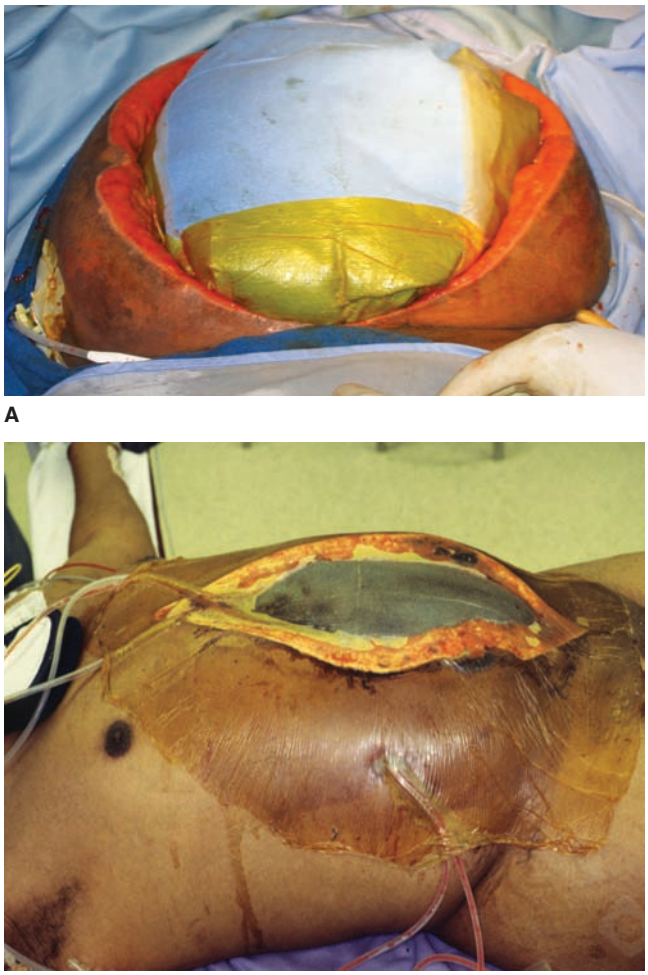
While sometimes challenging, particularly in obese patients, secure reapproximation of the fascia, usually with several interrupted sutures, can be achieved under direct visualization. Alternatively, a variety of instrumentation may be used to facilitate closure, usually in combination with laparoscopic visualization and maintenance of pneumoperitoneum. The Endoclose device (Tyco Healthcare, Mansfield, Massachusetts) has a sharp tip, which also functions as a grasper. The tip of a suture is grasped with the device and driven through the fascia adjacent to the cannula (and fascial defect) under laparoscopic visualization. The end of the suture is left free inside the abdomen. The grasper is then placed through the fascia a second time on the opposite side of the defect, and the free end of the suture is grasped inside the abdominal cavity and pulled out through the fascia. The suture is then tied to close the defect. The Carter-Thomason System (Inlet Medical, Eden Prairie, Minnesota) additionally includes a needle director, which is inserted through the fascia instead of the cannula, which ensures that adequate fascia is obtained by directing the needle at an appropriate angle, and may expedite closure.[53]

Temporary Closure of the Abdomen

Despite the frequent misconception that temporary abdominal closure techniques are a recent innovation, such approaches have long been utilized. Pringle reported his experience with temporary packing of hepatic injuries in 1908.[54] In 1913, Halsted recommended interposition of a nonadherent layer between the injured liver and packs.[55] Such an approach did fall out of favor in the period following the World War II owing to the very highly observed incidences of late hemorrhage and sepsis. However, beginning in 1973 with a report by Lucas and Ledgerwood, a number of investigators suggested the feasibility of utility and temporary abdominal closure, particularly in the setting of massive traumatic injury.[56–58] In 1993, Rotondo and Schwab introduced the term "damage control" and outlined a three-phase approach to the management of major abdominal injuries. The first phase consists of rapid control of hemorrhage and contamination followed by temporary abdominal closure; the second phase focuses on the restoration of normal body temperature, correction of coagulopathy, and optimization of ventilation; and the third phase involves removal of abdominal packs, definitive operation, and abdominal closure. In their initial series, Rotondo and Schwab demonstrated a marked survival advantage in patients with major vascular injury and two or more visceral injuries treated using the damage control approach (10 of 13, 77%) compared to those definitively closed at the time of initial operation (1 of 9, 11%) ($p < 0.02$).[59] The applications of this approach have broadened with greater experience. Patients who may benefit from this damage control approach include those at risk of developing abdominal hypertension (eg, hypothermia, coagulopathy, acidosis, large transfusion requirement) and those who require a *second-look laparotomy* (eg, intestinal ischemia).

This approach has necessitated the evolution of temporary closure techniques. These range from the very simple and inexpensive (eg, towel clip closure, running nylon suture close) to more sophisticated vacuum-assisted closure (VAC) systems. No single approach is clearly superior and multiple techniques may have advantages in specific clinical settings. The Bogota bag utilizes a large IV bag, secured to the skin or fascia. Impermeable plastic drapes may be used alternatively in a similar fashion. This approach is fast, inexpensive, minimizes fluid losses, and is easily removed. It may be less durable than other closures; tearing of sutures through the periphery of the bag can result in evisceration. Absorbable meshes such as polyglactin 910 (Vicryl; Ethicon, Somerville, NJ) and polyglycolic acid (Dexon; Davis & Geck, Danbury, CT) can be sutured to the skin or fascia. This approach allows for a degree of flexibility as definitive closure can subsequently be undertaken without removal of the mesh. Alternatively, the mesh can serve as a bed for the elaboration of granulation tissue. If reapproximation of the fascia is not feasible or needs to be substantially delayed, a skin graft can be placed over the granulation bed. A variation on mesh closure utilizes the *Wittman patch*, a device made of two adherent sheets of biocompatible polymeric material. The edges of the patch are sewn to the surrounding abdominal fascia. As edema resolves, the fascial edges are gradually reapproximated by drawing the two sheets closer together and cutting away excess material.

An increasingly popular alternative to these temporary closures has been termed the "open abdomen technique."[60] Generally, a nonadherent barrier (eg, a towel covered with an adhesive plastic drape) is placed on top of the intra-abdominal contents, below the fascia. Jackson-Pratt drains are placed above this barrier to control drainage and maintain the integrity of an adhesive dressing placed over the entire wound and skin (Fig. 6-15). This dressing is readily applied, inexpensive, and facilitates multiple re-explorations. Loss of abdominal domain can be limited with the additional placement of *lacing* across the wound; generally, vessel loops laced through skin staples are placed along the edges of the wound, which can be progressively tightened as intra-abdominal hypertension resolves. Maintenance of the open abdomen may be facilitated with the use of the commercially available abdominal VAC. The abdominal VAC comprises a barrier enveloped in nonadherent plastic, which is placed over the intra-abdominal contents below the fascial edges. A polyurethane sponge is cut to the size of the wound and placed over the barrier. The sponge is then covered with an adherent dressing. A small defect is created in the dressing and suction tubing with an adherent appliance is applied over this defect and attached to a vacuum device. Drainage is drawn out through the sponge through the vacuum tubing and into a vacuum canister. This system is particularly useful when multiple re-explorations are anticipated. Additionally, loss of abdominal domain is minimized by the negative pressure exerted on the dressing. While the use of the abdominal VAC may facilitate a more delayed definitive closure, the risk of



A

B

FIGURE 6-15 Open abdominal dressing. *Top*. A towel wrapped in adhesive plastic is placed between the abdominal contents and the fascia. *Bottom*. Jackson Pratt drains and an impermeable dressing are applied over the barrier. (*Images used with permission from Benjamin Braslow, MD.*)

injury to underlying viscera and fistula formation does increase with additional dressing changes.[61] In the patient who cannot undergo definitive closure after approximately 1 week, transition to a Vicryl mesh closure may be advantageous.

MANAGEMENT OF THE POSTOPERATIVE WOUND

Dressing the Wound

At the conclusion of a procedure, a sterile dressing is typically applied to the wound before removal of the sterile drapes. Theoretically, this dressing prevents bacterial colonization of the wound during the initial 24–48 hours of healing, allowing for epithelialization and the formation of coagulum. Before application of the dressing, excess antiseptic solution should be washed off with sterile saline. In general, the dressing should be secured without the use of excessive tape, which may be irritating to the skin. In most cases, the dressing can be removed within 48 hours of application. This practice is supported by studies from the 1960s documenting that exposure of clean, closed wounds to the atmosphere on postoperative day two, is not associated with an increased incidence of infection.[62] In many cases, after closure of a clean wound, no dressing is necessary. Indeed, in a randomized study of patients undergoing either inguinal hernia repair or high saphenous ligation, there was no significant difference in the rate of wound infection whether wounds were immediately exposed, covered with a dry gauze dressing, or covered with an occlusive film dressing.[63]

A variety of dressing types are used in the management of surgical wounds and may have advantages in some specific clinical settings. A simple dry dressing composed of gauze secured with sparing use of tape is generally sufficient. Wet-to-dry dressings are commonly used to dress open and contaminated wounds; mechanical debridement of the wound results from removal of dried packing material with adherent devitalized tissue. Enzymatic agents (eg, papain/urea [Accuzyme]) may be used in conjunction with wet-to-dry dressings to gently debride fibrinous exudate. In addition, application of broad-spectrum antibacterials (eg, silver sulfadiazine) may limit bacterial colonization and promote wound healing.

Recently, VAC dressings have gained great popularity for the management of open wounds. The VAC dressing has three components: (1) the VAC sponge, which is applied directly to the wound bed; (2) an occlusive dressing, which is applied over the sponge to seal it to the surrounding skin; and (3) a suction pump, which provides regulated negative pressure through the sponge. The VAC dressing has been used extensively in a variety of clinical settings and appears to promote granulation tissue formation and wound contraction. A major advantage of the VAC is the need for fewer dressing changes compared with conventional wet-to-dry dressings. As discussed above, the VAC has become a prominent part of the armamentarium for treating abdominal wounds that cannot be definitively closed at the time of initial operation.

Surgical Site Infections

Surgical site infections (SSIs) are the most common nosocomial infections in surgical patients. It has been estimated that each SSI results in 7.3 additional inpatient days and adds over $3000 to the hospital charges.[40] The bacterial colony count at the surgical site makes a dominant contribution to the risk of wound infection; colony counts per gram of tissue of 10^5 or greater are associated with a marked-increased risk. In the presence of a foreign body, however, a much lower count may lead to infection. Other risk factors for the development of wound infections include advanced age, obesity, diabetes mellitus, smoking, malnutrition, altered immune response, preoperative hospitalization, presence of infection at a remote body site, length of operation, and use of surgical drains.[40]

TABLE 6-2: CRITERIA FOR DEFINING SURGICAL SITE INFECTIONS

Incisional SSI		
Superficial Incisional	**Deep Incisional**	**Organ/Space SSI**
Infection occurring within 30 days of surgery, **and** Infection involves only skin and subcutaneous tissue; **and** At least one of the following: 1. Purulent discharge 2. Organisms isolated from aseptically cultured fluid or tissue 3. At least one sign of infection: pain or tenderness, localized swelling, redness, or heat **and** the incision is deliberately opened by the surgeon unless the incision is culture negative 4. Diagnosis of SSI by the surgeon or attending physician	Infection occurring within 30 days of surgery; or within 1 year of operation if implants are in place; **and** Infection involves deep soft tissue; **and** At least one of the following: 1. Purulent discharge 2. Deep incision spontaneously dehiscences or is deliberately opened by a surgeon when the patient has at least one of the following symptoms: fever (>38°C), localized pain or tenderness unless the site is culture negative 3. Evidence of deep infection on direct examination, during reoperation, or on radiological examinations 4. Diagnosis of SSI by the surgeon or attending physician	Infection occurs within 30 days of surgery, or within 1 year of operation if implants are in place; **and** Infection involves any part of anatomy that was manipulated during an operation, other than the incision; **and** At least one of the following 1. Purulent drainage that is placed through a stab wound into the organ space 2. Organism isolated from and aseptically cultured fluid or tissue 3. Evidence of deep infection on the direct examination, during reoperation, or on radiological examinations 4. Diagnosis of SSI by the surgeon or attending physician

SSIs are subdivided into two categories: incisional and organ/space (Table 6-2). Incisional SSIs are limited to the surgical site. They are further divided into superficial SSIs, which involve the skin and subcutaneous tissue and deep SSIs, which involve the fascial and muscle layers. Organ/space SSIs can involve any part of the anatomy that was manipulated during the surgery excepting the incision.

Wounds can be classified by degree of contamination (Table 6-3). The risk of a postoperative SSI reflects, in part, the wound classification; however, infection rates vary widely within each classification group.[64,65] Other risk-scoring systems have, therefore, been developed to better anticipate the risk of wound infections. Examples of such scoring systems are the SENIC (Study of the Efficacy of Nosocomial Infection Control) and NNIS (National Nosocomial Infection Surveillance) risk indexes. The SENIC system predicts risk associated with abdominal surgery, operations lasting longer than 2 hours, contaminated or dirty wound classifications, and operation on patients with three or more discharge diagnoses.[64] The NNIS system predicts risk associated with American Society of Anesthesiologists preoperative assessment scores of greater than 2, wound classifications of contaminated or dirty, and increased duration of the operation.[65]

The organisms most commonly responsible for SSIs are *Staphylococcus aureus* and coagulase-negative staphylococci. After abdominal surgery, infection with enteric organisms (*Escherichia coli* and *Enterobacter* species) is also prevalent. The Centers for Disease Control and Prevention recommendations for the prevention of SSIs are summarized in Table 6-4.[40] The use of preoperative prophylactic antibiotics in all clean-contaminated and clean cases with associated risk factors is recommended. The antibiotic of choice for most upper gastrointestinal procedures is cefazolin or a comparable first-generation cephalosporin. For colorectal surgery, metronidazole is added to this regimen. The administration of a mechanical and oral antibiotic bowel preparation has been recommended prior to colorectal surgery, although this practice has been challenged by recent meta-analyses suggesting no benefit.[66,67] Preoperative intravenous antibiotics should be administered 30–60 minutes before the incision is made to allow the agent to reach maximal tissue concentration. In obese patients, the antibiotic should be adjusted appropriately. For long procedures, the antibiotic should be readministered after every two half-lives to maintain an effective serum concentration.

The treatment for incisional SSIs includes removal of skin stitches or staples to allow drainage of any underlying collection. Antibiotics are indicated in the presence of cellulitis. The effective use of antibiotics depends on (1) appropriate coverage of the offending organisms and (2) maintenance of an adequate tissue concentration of the drug. Cefazolin or an equivalent first- or second-generation cephalosporin is appropriate for uncomplicated incisional SSI. Wound cultures are obtained in the presence of purulence and are used to guide antibiotic selection. Following abscess drainage, wounds are left open and allowed to close by secondary intention.

Deep space SSIs also require drainage. Increasingly, this is achieved by percutaneous placement of a drain under CT or ultrasound guidance. Deep space infections that are not

TABLE 6-3: CLASSIFICATION OF SURGICAL WOUNDS

Type of Wound	Definition	Risk of SSI
Class I: Clean	An uninfected operative wound in which no inflammation is encountered and respiratory, alimentary, genital, or uninfected urinary is not entered. They are primarily closed, and if necessary, drained with close drainage.	1–5%
Class II: Clean-contaminated	An operative wound in which the respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions and without unusual contamination. In particular, surgeries involving the biliary tract, appendix, vagina, and oropharynx are included in this category provided no evidence of infection or a major break in technique is encountered.	2–9%
Class III: Contaminated	Open fresh accidental wounds. In addition, surgeries with major breaks in sterile technique (eg, open cardiac massage) or gross spillage from the gastrointestinal tract, and incisions in which acute, nonpurulent inflammation is encountered are included in this category.	3–13%
Class IV: Dirty-infected	Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera.	3–13%

amenable to percutaneous drainage require operative drainage. Broad-spectrum antibiotics are indicated until culture data is obtained at which point the spectrum should be narrowed to target the offending organism.

NECROTIZING WOUND INFECTIONS

Necrotizing soft tissue infections are a heterogeneous group of clinical entities[68]; however, several fundamental concepts govern the treatment of all. Paramount is early identification followed by operative debridement and initiation of antibiotic therapy. Patients often present early in the postoperative period (ie, within 48 hours) with incisional pain followed by the rapid onset of signs and symptoms of sepsis. While the incision may initially appear benign, more often serous drainage is noted. Patients may also present with bulla or blebs, crepitus, cutaneous anesthesia, and cellulitis that are refractory to antibiotic therapy.[69] Tenderness that extends beyond the borders of the apparent cellulitis suggests progression of the infection to the deeper cutaneous layers and should raise suspicion for an early necrotizing process. Importantly, fewer than 40% of patients exhibit the classic symptoms and signs described and a high degree of suspicion should be maintained in the postoperative patient with early signs of sepsis.[70,71]

In the absence of characteristic clinical features, diagnosis can be challenging. An elevated white blood cell (WBC) count (≤15,400/mm^3) and hyponatremia (serum sodium level lower than 135 mmol/L) are sensitive markers for the presence of a necrotizing soft tissue infection; however, they are fairly nonspecific.[72] Imaging studies, including plain x-ray and CT, may reveal the presence of soft tissue gas, though this finding is present in a minority of cases.[69,73] The reported sensitivity of MRI for diagnosis of necrotizing soft tissue infection ranges from 89% to 100%, and its specificity ranges from 46% to 86%.[74,75] However, the frequent presence of subcutaneous air in an early postoperative wound precludes reliable imaging in most cases and, more importantly, imaging may delay appropriate treatment.

In suspected cases, immediate surgical exploration and debridement is recommended and constitutes the most important single therapy. *Clostridium perfringens* or group A beta-hemolytic streptococci are the most frequently implicated organisms, but necrotizing infections are often polymicrobial. A sample of debrided tissue should be sent for gram stain and culture, and initial therapy should have a broad spectrum of coverage (eg, penicillin, clindamycin, and an aminoglycoside). Following initial debridement, the wound should be reexamined frequently. Any evidence of extension of the necrotizing process should prompt further debridement. Although the initial management of all necrotizing infections is essentially the same, there are several specific clinical entities that deserve special mention, as they may require unique therapies.

Gas Gangrene. Gas gangrene infection following abdominal surgery results from contamination with clostridia, typically from the alimentary tract or biliary system. Patients usually present with severe wound pain often associated with fever and tachycardia. Such wounds often appear edematous and erythematous; they later become dusky and necrotic.

TABLE 6-4: CDC RECOMMENDATIONS TO PREVENT SURGICAL SITE INFECTIONS

Preoperative Factors

Preparation of the patient:

1. Identify and treat all infections remote from the surgical site and postpone elective surgery until infection has resolved.
2. Do not remove hair unless it interferes with surgery.
3. If hair is to be removed, remove immediately preoperatively using clippers.
4. Ensure good blood glucose control in diabetic patients and avoid hyperglycemia.
5. Encourage cessation of tobacco use (at least for 30 days before surgery, if possible).
6. Do not withhold blood products, as transfusion does not affect rates of SSI.
7. Require the patient to shower or bathe with an antiseptic solution the night before surgery.
8. Remove gross contamination from the surgical site before performing antiseptic skin preparation.
9. Use an appropriate antiseptic solution for skin preparation.
10. Apply preoperative antiseptic solution for skin preparation in concentric circles moving outward toward the periphery.
11. Keep the preoperative hospital stay as short as possible.

Hand/forearm antisepsis for surgical team:

1. Keep nails short and do not wear artificial nails.
2. Perform a preoperative scrub for at least 2–5 minutes up to the elbows.
3. After performing the surgical scrub, keep the hands up and away from the body (elbows flexed) so that the water runs from the tips of fingers toward the elbows. Dry hands with a sterile towel and don a sterile gown and gloves.
4. Clean underneath each fingernail.
5. Do not wear hand or arm jewelry.

Management of infected or colonized surgical personnel:

1. Educate and encourage surgical personnel who have signs and symptoms of a transmissible infectious illness to report promptly to their supervisor and occupational health personnel.
2. Develop well-defined policies concerning patient care responsibilities when personnel have potentially transmissible infectious conditions. These policies should govern: (1) responsibility of personnel in using health services and reporting illness, (2) work restrictions, and (3) clearance to resume work after an illness that required work restriction. The policies should also identify staff members that have the authority to remove personnel from duty.
3. Obtain appropriate cultures and exclude from duty surgical personnel who have draining skin lesions until infection has been ruled out, or until these personnel have received adequate therapy and infection has been resolved.
4. Do not routinely exclude surgical personnel who are colonized with organisms such as Staphylococcus aureus or group A streptococci, unless they have been linked epidemiologically to dissemination of the organism.

Antibiotic prophylaxis:

1. Administer a prophylactic antimicrobial agent only when indicated, and select it based on its efficacy against the most common pathogens causing SSIs for a specific operation, and in accordance with published recommendations.
2. Administer by the IV route the initial dose of prophylactic antimicrobial agent, timed such that bactericidal concentration of the drug is established in serum and tissue when the incision is made. Maintain therapeutic levels of the agent in serum and tissues throughout the operation, and for a few hours after the incision has been closed.
3. Before elective colorectal operations, in addition to the above measures, mechanically prepare the bowel by using enemas and cathartic agents. Give nonabsorbable oral antimicrobial agents in divided doses on the day before the operation.
4. For high-risk cesarean sections, administer the prophylactic antimicrobial agent immediately after the umbilical cord is clamped.
5. Do not routinely use vancomycin for prophylaxis.

Intraoperative

Ventilation:

1. Maintain positive pressure ventilation in the operating room with respect to the corridors and adjacent area.
2. Maintain a minimum of 15 air changes per hour, of which at least 3 should be fresh air.
3. Filter all air, recirculated and fresh, through the appropriate filters per the American Institute of Architects' recommendations.
4. Introduce all air at the ceiling, and exhaust air near the floor.
5. Do not use ultraviolet radiation in the operating room.
6. Keep operating suite doors closed except as need for passage of equipment, personnel, or patients.
7. Consider performing orthopedic implant operations in an operating suite supplied with ultraclean air.
8. Limit the number of personnel entering the operating room.

Cleaning and disinfection of environmental surfaces:

1. When visible soiling or contamination of surfaces or equipment with blood or other body fluids occurs during an operation, use an Environmental Protection Agency (EPA)-approved hospital disinfectant to clean the affected areas before the next operation.
2. Do not perform special cleaning (in addition to cleaning with routine EPA-approved hospital disinfectant) or closing of operating rooms after contaminated or dirty operations.
3. Do not use tacky mats at the entrance to the operating room suite or individual operating rooms for infection control.
4. Wet vacuum the operating floor with an EPA-approved disinfectant after the last operation of the day or night.

Microbiological sampling:

1. Do not perform routine environmental sampling of the operating room.

Sterilization of surgical instruments:

1. Sterilize all surgical instruments according to published guidelines.
2. Perform flash sterilization only for patient care items that will be used immediately. Do not flash sterilize for reasons of convenience or to save time.

Surgical attire and drapes:

1. Wear a surgical mask that fully covers the mouth and nose when entering the operating room if an operation is about to begin or is underway, or if sterilized instruments are exposed. Wear the mask throughout the operation.

(*continued*)

TABLE 6-4: CDC RECOMMENDATIONS TO PREVENT SURGICAL SITE INFECTIONS *(Continued)*

2. Wear a cap or hood to fully cover hair on the head and face.
3. Do not wear shoe covers for prevention of SSIs.
4. Wear sterile gloves if scrubbed as a surgical team member. Put on gloves after donning the sterile gown.
5. Use surgical gowns and drapes that are effective barriers when wet.
6. Change scrub suits that are visibly soiled, contaminated, and/or penetrated by blood or other potentially infectious material.

Asepsis and surgical technique:

1. Adhere to principles of asepsis when placing intravascular devices, spinal or epidural anesthesia catheters, or when dispensing or administering IV drugs.
2. Assemble sterile equipment and solutions immediately prior to use.
3. Handle tissue gently, maintain effective hemostasis, minimize devitalized tissue and foreign bodies, and eradicate dead space at the surgical site.
4. Use delayed primary skin closure or leave an incision open if the surgeon considers the surgical site to be heavily contaminated.
5. If drain is necessary, use closed suction drain, and place it through a separate incision distant from the operating incision. Remove the drain as soon as possible.

Postoperative Incision Care

1. Protect an incision that has been closed primarily with a sterile dressing for 24–48 hours postoperatively.
2. Wash hands before and after dressing changes and before and after any contact with surgical site.
3. When an incision dressing must be changed, use a sterile technique.
4. Educate the patient and family regarding proper incision care, symptoms of SSI, and the need to report such symptoms.

Surveillance

1. Use CDC definitions of SSI without modification for identifying SSIs among surgical inpatients and outpatients.
2. For inpatient cases, use direct prospective observation, indirect prospective detection, or a combination of both for the duration of the patient's hospitalization.
3. When postdischarge surveillance is performed for detecting SSIs following certain operations, use a method that accommodates available resources and data needs.
4. For outpatient cases, use a method that accommodates available resources and data needs.
5. Assign a surgical wound classification upon completion of an operation. A surgical team member should make the assignment.
6. For a patient undergoing an operation chosen for surveillance, record those variables shown to be associated with increased risk of SSI.
7. Periodically calculate operation-specific SSI rates stratified by variables shown to be associated with increased risk of SSI.
8. Report appropriately stratified operation-specific SSI rates to surgical team members. The optimum frequency and format of such rate computations will be determined by stratified case-load sizes and the objectives of local, continuous quality improvement initiatives.

Wound crepitus and foul smelling watery discharge, so-called "dishwater drainage," are characteristics. Early surgical intervention with debridement of all infected and nonviable tissue is recommended in suspected cases. Although there have been no controlled clinical trials, there is some evidence that hyperbaric oxygen is of considerable value in treating clostridial infection, and reduces the mortality rate by some reports from 66% to 23%.[76] The potential benefits of hyperbaric oxygen include improved leukocyte function and increased tissue oxygen levels; it is bactericidal for *C. perfringens* and bacteriostatic for other anaerobic bacteria.[77]

Necrotizing Fascitis. This syndrome has been divided into two subcategories depending on the implicated organisms. Type I necrotizing fasciitis is a polymicrobial process; Type II necrotizing fasciitis is caused by group A streptococci.[68,78] Polymicrobial necrotizing infections are generally slowly progressive and affect the total thickness of the skin, but do not involve the deep fascia. Purulence may or may not be present. Most often, such infections are heralded by a nonspecific cellulitis around the wound that slowly extends over days. Later, the central area of the cellulitis becomes purple and then develops typical features of gangrene. These infections are referred to as Fournier's gangrene when they affect the perineum. The causative organisms are usually a mixture of anaerobes, gram-negative rods, and enterococcus species. Broad-spectrum antibiotics should be initiated early and then tailored pending the result of microbial cultures.

Necrotizing infections caused by group A streptococci are more rapidly progressive and can involve the subcutaneous fat, the superficial fascia, and the deep fascia. Early in the process, the overlying skin is often intact, but later may become compromised following interruption of the deep blood supply. The condition is clinically distinguished from gas gangrene by the absence of crepitus and muscle involvement. Early operative exploration is recommended in suspected cases. Group A streptococcus is highly sensitive to penicillin; however, the addition of clindamycin appears to have clinical benefit.[78] Treatment must include early surgical exploration with debridement of involved tissues.

Seroma and Hematoma

Superficial seroma formation is exceedingly common but rarely has significant clinical consequence. Most seromas can be observed; the rare large seroma that causes troubling symptoms (eg, discomfort) or is cosmetically unacceptable to the patient can usually be managed with a single aspiration, or serial aspirations in the office. Refractory large seromas can

be treated with percutaneous placement of a drain, which is maintained until the output is low (usually less than 30 cc per day) or, rarely, excision (ie, capsulectomy).

The more liberal use of aspirin, plavix, and heparins in the perioperative period has likely resulted in an increased incidence of wound hematoma following abdominal surgery; now in the range of 4–8%.[79,80] Small wound hematomas are of little consequence and usually resolve without intervention. If larger, hematomas may lead to compromise of the overlying skin or predispose to infection. Such hematomas can be aspirated with a large-bore needle, or evacuated by opening the wound. If the overlying skin is under tension or ongoing extravasation of blood is noted, hematomas are often better managed in the operating room where active bleeding can be controlled, if encountered.

Stitch Abscess

Stitch abscesses or suture sinuses are most often seen at approximately the 10th postoperative day, but may occur earlier or weeks after operation. Stitch abscesses may be superficial or deep. When superficial, they typically present as brown or mauve-colored circumscribed blisters in the line of the incision. The associated pain can be resolved by incising the overlying skin, evacuating the contents, and, if possible, excising residual suture material. Antibiotic treatment is rarely necessary. Deeper stitch abscesses typically present with an indurated mass. As noted above, the use of nonabsorbable suture, such as polypropylene, has been associated with an increased incidence of deep stitch abscesses when compared to closure with a slowly absorbing suture such as polydioxanone.[32,81] When permanent suture has been used, treatment requires removal of the residual suture material.

Wound Dehiscence and Evisceration

Separation of abdominal wounds (ie, dehiscence) with or without protrusion of intraabdominal contents (ie, evisceration) causes considerable morbidity and mortality. Historically, wound dehiscence rates of up to 10% were reported; contemporary series estimate an incidence between 1% and 3%.[82,83] Mortality associated with dehiscence has been estimated at 16%.[84] The mean time to wound dehiscence is 8–10 days after operation.[32,84] Classically, dehiscence is heralded by a sudden rush of pink serosanguinous discharge from the wound. Sometimes, the acute evolution of a large subcutaneous hematoma or tympanitic swelling that distends the wound reflecting herniation of bowel through the abdominal fascia is also noted.

As mentioned above, the literature on abdominal closure appears to favor a running mass closure with slowly resorbable or nonresorbable suture. Notwithstanding such technical considerations, a variety of patient-associated risk factors for dehiscence must be recognized and include advanced age (>65 years), hypoalbuminemia, wound infection, ascites, obesity, steroid use, chronic obstructive pulmonary disease, pneumonia, cerebrovascular accident with residual deficit, anemia (ie, hematocrit <30), prolonged ileus, coughing, emergency operation, and operative time greater than 2.5 hours.[44,83,85] Although some surgeons advocate prophylactic placement of retention sutures in those at high risk for dehiscence, there is little data to support this practice.

Fundamentally, the treatment for a disrupted wound is reclosure of the wound; this is particularly true when dehiscence occurs early in the postoperative period. If evisceration is present, the wound and protruding viscera should be bathed with warm normal saline solution and covered with a large sterile dressing prior to prompt transport to the operating room. In the operating room, the prolapsed bowel is replaced below the level of the fascial edges. Residual suture material is extracted, and necrotic wound edges are debrided. Reclosure of the fascia is then performed, typically using a monofilament nonabsorbable suture such as polypropylene. Although some surgeons advocate interrupted closure of the fascia following dehiscence, two retrospective analyses have failed to demonstrate a reduction in the incidence of late ventral hernia formation with this technique compared to a running closure.[32,84] The advantage of retention suture placement in this setting is similarly unproven. Retrospective analyses fail to demonstrate any benefit, although a reduction in recurrent evisceration is frequently invoked. Retention sutures are associated with increased discomfort for the patient.[43] Placement of resorbable mesh as an underlay may serve to reinforce the abdominal closure.

On occasion, if the dehiscence is small, the patient is critically ill, or there is no evisceration, nonoperative management is appropriate. In such cases, the wound is packed with a moist sterile dressing. An abdominal binder can be used for further support. The dressing should be changed at regular intervals until the wound fills in with granulation tissue. In some cases, delayed reclosure of the skin can be carried out at this stage. Alternatively, the use of a VAC dressing has been described in this setting.[86]

Incisional Hernia

Incisional hernia formation is the most common long-term complication of abdominal surgery and is discussed extensively in Chapter 7.

Acknowledgements

We would like to thank Bryan M. Burt, Ali Tavakkolizadeh, and Stephen J. Ferzoco for their contribution to the previous edition of this text, which served as the foundation for this revised chapter. We would also like to thank Benjamin Braslow and Bilal Shafi for their valuable suggestions.

HERNIAS

Patrick J. Javid • Jacob A. Greenberg • David C. Brooks

A hernia is defined as an area of weakness or complete disruption of the fibromuscular tissues of the body wall. Structures arising from the cavity contained by the body wall can pass through, or herniate, through such a defect. While the definition is straightforward, the terminology is often misrepresented. It should be clear that *hernia* refers to the actual anatomic weakness or defect, and *hernia contents* describe those structures that pass through the defect.

Hernias are among the oldest known afflictions of humankind, and surgical repair of the inguinal hernia is the most common general surgery procedure performed today.[1] Despite the high incidence, the technical aspects of hernia repair continue to evolve.

INGUINAL HERNIA

History

The word "hernia" is derived from a Latin term meaning "a rupture." The earliest reports of abdominal wall hernias date back to 1500 BC. During this early era, abdominal wall hernias were treated with trusses or bandage dressings. The first evidence of operative repair of a groin hernia dates back to the first century AD. The original hernia repairs involved wide operative exposures through scrotal incisions requiring orchiectomy on the involved side. Centuries later, around 700 AD, principles of operative hernia repair evolved to emphasize mass ligation and en bloc excision of the hernia sac, cord, and testis distal to the external ring. The first report of groin hernia classification based on the anatomy of the defect (ie, inguinal versus femoral) dates back to the 14th century, and the anatomical descriptions of direct and indirect types of inguinal hernia were first reported in 1559.

Bassini revolutionized the surgical repair of the groin hernia with his novel anatomical dissection and low recurrence rates. He first performed his operation in 1884, and published his initial outcomes in 1889.[2] Bassini reported 100% follow-up of patients over a 5-year period, with just five recurrences in over 250 patients. This rate of recurrence was unheard of at the time and marked a distinct turning point in the evolution of herniorraphy. Bassini's repair emphasizes both the high ligation of the hernia sac in the internal ring, as well as suture reinforcement of the posterior inguinal canal. The operation utilizes a deep and superficial closure of the inguinal canal. In the deep portion of the repair, the canal is repaired by interrupted sutures affixing the transversalis fascia medially to the inguinal ligament laterally. This requires an incision through the transversalis fascia. The superficial closure is provided by the external oblique fascia.

In addition to Bassini's contributions, the first true Cooper's ligament repair, which affixes the pectineal ligament to Poupart's ligament and thereby repairs both inguinal and femoral hernia defects, was introduced by Lotheissen in 1898. McVay further popularized the Cooper's ligament repair with the addition of a relaxing incision to reduce the increased wound tension.

The advances in groin hernia repair in the century following Bassini have shared the primary goal of reducing long-term hernia recurrence rates. To this end, efforts have been directed at developing a repair that imparts the least tension on the tissues that are brought together to repair the hernia defect. Darn repairs were first introduced in the early 20th century to reduce wound tension by using either autologous tissue or synthetic suture to bridge the gap between fascial tissues. Muscle and fascial flaps were attempted without consistent success. In 1918, Handley introduced the first use of silk as a prosthetic darn and nylon followed several years later. However, it was found that heavy prosthetic material increased the risk of wound infection, and the silk suture ultimately lost its strength over time. The use of autologous or synthetic patches was also attempted in order to reduce wound tension and improve rates of recurrence. The first patches, beginning in the early 20th century, consisted of silver wire filigree sheets that were placed along the inguinal canal. Over time, the sheets suffered from metal fatigue leading to hernia recurrence. Reports of the wire patches eroding into adjacent inguinal structures and even the peritoneal cavity itself caused even more concern with this technique. The modern synthetic patch, made of a plastic monofilament polymer (polyethylene), was introduced by Usher in 1958. Lichtenstein, who developed a sutureless hernia repair using a plastic

mesh patch placed across the inguinal floor, further popularized this technique.

In the search for a technical means to reduce recurrence, emphasis was also placed on a meticulous dissection that would avoid placement of a prosthetic mesh. The most popular version was the Shouldice technique, initially introduced in 1958, and in essence a modification of the Bassini operation. This technique involves meticulous dissection of the entire inguinal floor and closure of the inguinal canal in four layers. The transversalis fascial layer itself is closed in two layers, as opposed to the single layer of interrupted suture advocated by Bassini. While the operation can be technically challenging to the beginner, it has been associated with excellent long-term outcomes and low recurrence rates.

Today, laparoscopic techniques have been validated as safe and effective in the treatment of groin hernias and have become commonplace. The laparoscopic approaches were initially developed in the early 1990s as laparoscopic techniques diffused throughout other specialties of general surgery.

Epidemiology

Seventy-five percent of all abdominal wall hernias are found in the groin, making it the most common location for an abdominal wall hernia. Of all groin hernias, 95% are hernias of the inguinal canal with the remainder being femoral hernia defects. Inguinal hernias are nine times more common in men than in women. Although femoral hernias are found more often in women, the inguinal hernia is still the most common hernia in women.[3] The overall lifetime risk of developing a groin hernia is approximately 15% in males and less than 5% in females. There is clearly an association between age and hernia diagnosis. After an initial peak in the infant, groin hernias become more prevalent with advancing age. In the same way, the complications of hernias (incarceration, strangulation, and bowel obstruction) are found more commonly at the extremes of age.

Currently in this country, approximately 700,000 operations for inguinal hernia repair are performed annually.[4]

Anatomic Classification

A thorough classification system has been developed to assist in the proper diagnosis and management of the inguinal hernia. All hernias can be broadly classified as congenital or acquired, and it is thought that the vast majority of inguinal hernias are congenital in nature. Acquired groin hernias develop after surgical incision and manipulation of the involved abdominal wall tissues. Given the paucity of primary groin incisions utilized in modern general surgery, acquired hernias of the inguinal or femoral region are rare.

Inguinal hernias are further divided by anatomical location into direct and indirect types. This differentiation is based on the location of the actual hernia defect in relation to the inferior epigastric vessels. The inferior epigastric vessels are continuous with the superior epigastric vessels that originate from the internal mammary artery cephalad and ultimately course caudally into the common femoral artery and vein. These vascular structures make up the lateral axis of Hesselbach's triangle, which includes the lateral border of the rectus sheath as its medial border and the inguinal (Poupart's) ligament itself as the inferior border. Hernias that develop lateral to the inferior epigastric vessels are termed *indirect* inguinal hernias, and those that develop medial to the vessels are *direct* inguinal hernias. In this way, direct hernia defects are found *within* Hesselbach's triangle. Hernias of the femoral type are located caudal or inferior to the inguinal ligament in a medial position.

The indirect inguinal hernia develops at the site of the internal ring, or the location where the spermatic cord in men and the round ligament in women enters the abdomen. While they may present at any age, indirect inguinal hernias are thought to be congenital in etiology. The accepted hypothesis is that these hernias arise from the incomplete or defective obliteration of the processus vaginalis during the fetal period. The processus is the peritoneal layer that covers the testicle or ovary as it passes through the inguinal canal and into the scrotum in men or the broad ligament in women. The internal ring closes, and the processus vaginalis becomes obliterated following the migration of the testicle into the inguinal canal. The failure of this closure provides an environment for the indirect inguinal hernia to develop. In this way, the remnant layer of peritoneum forms a sac at the internal ring through which intra-abdominal contents may herniate, thereby resulting in a clinically detectable inguinal hernia. Anatomically, the internal ring is lateral to the external ring and the remainder of the inguinal canal, and this explains the lateral relationship of the indirect inguinal hernia to the inferior epigastric vessels. It is noteworthy that indirect inguinal hernia develops more frequently on the right, where descent of the gonads occurs later during fetal development.

Direct inguinal hernias, in contrast, are found medial to the inferior epigastric artery and vein, and within Hesselbach's triangle. These hernias are acquired and only rarely found in the youngest age groups. They are thought to develop from an acquired weakness in the fibromuscular structures of the inguinal floor, so that the abdominal wall in this region can no longer adequately contain the intra-abdominal contents. The exact relationship between direct inguinal hernias and heavy lifting or straining remains unclear, and some studies suggest that the incidence of direct hernia is no greater in people in professions that routinely involve heavy manual labor.[5]

While femoral hernias account for less than 10% of all groin hernias, their presentation can be more acute in nature. In fact, it is estimated that up to 40% of femoral hernias present as emergencies with hernia incarceration or strangulation.[3] In this way, femoral hernias may also present with bowel obstruction. The empty space through which a femoral hernia forms is medial to the femoral vessels and nerve in the femoral canal and adjacent to the major femoral lymphatics. The inguinal ligament forms

the cephalad border of the empty space. However, while the empty space is inferior to the ligament, the herniated contents may present superior to the ligament, thereby making an accurate diagnosis difficult.

Femoral hernias are much more common in females than in males, although inguinal hernias are still the most common hernia in women. The predilection for femoral hernias in women may be secondary to less bulky groin musculature or weakness in the pelvic floor tissues from previous childbirth. It has been shown that previous inguinal hernia repair may be a risk factor for the subsequent development of a femoral hernia.[3]

Anatomy of the Groin

The boundaries of the inguinal canal must be understood to comprehend the principles of hernia repair. In the inguinal canal, the anterior boundary is the external oblique aponeurosis; the posterior boundary is composed of the transversalis fascia with some contribution from the aponeurosis of the transversus abdominis muscle; the inferior border is imparted by the inguinal and lacunar ligaments; and the superior boundary is formed by the arching fibers of the internal oblique musculature.

The internal (or deep) inguinal ring is formed by a normal defect in the transversalis fascia through which the spermatic cord in men and the round ligament in women pass into the abdomen from the extraperitoneal plane. The external (or superficial) ring is inferior and medial to the internal ring and represents an opening of the aponeurosis of the external oblique. The spermatic cord passes from the peritoneum through the internal ring and then caudally into the external ring before entering the scrotum in males.

From superficial to deep, the surgeon first encounters Scarpa's fascia after incising the skin and subcutaneous tissue. Deep to Scarpa's layer is the external oblique aponeurosis, which must be incised and spread to identify the cord structures. The inguinal ligament represents the inferior extension of the external oblique aponeurosis, and extends from the anterior superior iliac spine to the pubic tubercle. The medial extension of the external oblique aponeurosis forms the anterior rectus sheath. The iliohypogastric and ilioinguinal nerves, which provide sensation to the skin, penis, and the upper medial thigh, lie deep to the external oblique aponeurosis in the groin region. The internal oblique aponeurosis is more prominent cephalad in the inguinal canal, and its fibers form the superior border of the canal itself. The cremaster muscle, which envelops the cord structures, originates from the internal oblique musculature. The transversus abdominis muscle and its fascia represent the true floor of the inguinal canal. Deep to the floor is the preperitoneal space, which houses the inferior epigastric artery and vein, the genitofemoral and lateral femoral cutaneous nerves, and the vas deferens, which traverses this space to join the remaining cord structures at the internal inguinal ring.

Etiology

The indirect inguinal hernia, the most common form of groin hernia across all ages and both genders, is thought to be congenital in etiology. The processus vaginalis is the pocket of peritoneum that forms around the testicle as it descends through the internal ring and along the inguinal canal into the scrotum during the 28th week of gestation. The primary etiology behind the indirect inguinal hernia is believed to be a patent processus vaginalis, which in essence represents a hernia sac. In this way, the hernia defect is the internal ring itself, and the sac is preformed but never closes at the end of gestation. Once intra-abdominal contents find their way into the sac, an indirect inguinal hernia is formed.

It is likely, however, that every person with a patent processus vaginalis does not develop an inguinal hernia during his or her lifetime. Thus, other predisposing factors must aid in indirect inguinal hernia formation. It is commonly thought that repeated increases in intra-abdominal pressure contribute to hernia formation; hence, inguinal hernias are commonly associated with pregnancy, chronic obstructive pulmonary disease, abdominal ascites, patients who undergo peritoneal dialysis, laborers who repeatedly flex the abdominal wall musculature, and individuals who strain from constipation. It is also thought that collagen formation and structure deteriorates with age, and thus hernia formation is more common in the older individual.

Several inborn errors of metabolism can lead to hernia formation. Specifically, conditions such as Ehlers–Danlos syndrome, Marfan's syndrome, Hunter's syndrome, and Hurler's syndrome can predispose to defects in collagen formation. There is evidence that cigarette smoking is associated with connective tissue disruption, and hernia formation is more common in the chronic smoker.

Clinical Manifestations

The groin hernia can present in a variety of ways, from the asymptomatic hernia to frank peritonitis in a strangulated hernia. Many hernias are found on routine physical examination or on a focused examination for an unrelated complaint. These groin hernias are usually fully reducible and chronic in nature. Such hernias are still referred for repair since they invariably develop symptoms, and asymptomatic hernias still have an inherent risk of incarceration and strangulation.

The most common presenting symptomatology for a groin hernia is a dull feeling of discomfort or heaviness in the groin region that is exacerbated by straining the abdominal musculature, lifting heavy objects, or defecating. These maneuvers worsen the feeling of discomfort by increasing the intra-abdominal pressure and forcing the hernia contents through the hernia defect. Pain develops as a tight ring of fascia outlining the hernia defect compresses intra-abdominal structures with a visceral neuronal supply. With a reducible hernia, the feeling of discomfort resolves as the pressure is released when the patient stops straining the abdominal muscles. The pain is often worse

at the end of the day, and patients in physically active professions may experience the pain more often than those who lead a sedentary lifestyle.

Overwhelming or focal pain from a groin hernia is unusual and should raise the suspicion of hernia incarceration or strangulation. An incarcerated hernia occurs when the hernia contents are trapped in the hernia defect so that the contents cannot be reduced back into the abdominal cavity. The tight circumferential pressure applied by the hernia defect serves to impede the venous outflow from the hernia contents, resulting in congestion, edema, and tissue ischemia. Ultimately, the arterial inflow to the hernia contents is compromised as well, resulting in tissue loss and necrosis, termed strangulation of the hernia.

All types of groin hernias are at risk for incarceration and strangulation, although the femoral hernia seems to be predisposed to this complication. Incarceration and strangulation of a groin hernia may present as a bowel obstruction when the tight hernia defect constricts the lumen of the viscus. Hence, all patients presenting with bowel obstruction require a thorough physical examination of the groin region for inguinal and femoral hernias. If there is no bowel in the hernia sac, an incarcerated groin hernia may alternatively present as a hard, painful mass that is tender to palpation.

The physical examination differs between an incarcerated hernia and a strangulated hernia. The incarcerated hernia may be mildly tender due to venous congestion from the tight defect. The strangulated hernia will be tender and warm and may have surrounding skin erythema secondary to the inflammatory reaction from the ischemic bowel. The patient with the strangulated hernia may have a fever, hypotension from early bacteremia, and a leukocytosis. The incarcerated hernia requires operation on an urgent basis within 6–12 hours of presentation. If the operation is delayed for any reason, serial physical examinations are mandated to follow any change in the hernia site indicating the onset of tissue loss. The strangulated hernia clearly requires emergent operation immediately following diagnosis.

It may also be difficult to differentiate fat from bowel contents in the hernia sac. It is important to recognize that incarcerated omental fat alone can produce significant pain and tenderness on physical examination.

Pregnancy and Groin Hernia

Not surprisingly, groin hernias during pregnancy may become symptomatic. This is related to the increased intra-abdominal pressure from the growing fetus and enlarging uterus. The symptomatic groin discomfort may become positional later in pregnancy as the uterus shifts location with movement. While the risk of complications of groin hernias still exists during pregnancy, the enlarging uterus may in theory protect against incarceration by physically blocking the intra-abdominal contents from the inlet of the defect.

In general, elective repair of groin hernias during pregnancy is not recommended, even if they become increasingly symptomatic. Emergent repair of the incarcerated or strangulated hernia is undertaken as needed.

Physical Examination

As with any hernia, the groin hernia should be properly examined with the patient in the standing position. This allows the hernia contents to fill the hernia sac and make the hernia obvious on physical examination. Some hernias, however, may be easily identifiable in the supine position. It should be noted that the exact anatomical classification of the inguinal hernia (ie, indirect vs direct) is impossible to accurately predict based on physical examination alone.

In the male patient, using the second or third finger, the examiner should invaginate the scrotum near the external ring and direct the finger medial toward the pubic tubercle. The examiner's finger will thus lie on the spermatic cord with the tip of the finger within the external ring. The patient is then asked to cough or perform a Valsalva maneuver. A true inguinal hernia will be felt as a silklike sensation against the gloved finger of the examiner. This is the infamous "silk glove" sign.

The female patient does not have the long and stretched spermatic cord to follow with the examiner's finger during the physical examination. Instead, two fingers can be placed along the inguinal canal, and the patient is asked to cough or strain. If present, the examiner should feel the sensation of the hernia sac against the gloved finger. Particular attention in the female patient should be paid to the location of the sensation; femoral hernia sacs will present medial and just inferior to the lower border of the inguinal ligament.

While the physical examination does not differ in the infant, it can be more challenging to elicit the hernia impulse given the compressed groin anatomy of the young child. It is well known that a groin hernia can be more readily diagnosed in the infant who is actively crying and hence increasing the intra-abdominal pressure through flexion of the abdominal wall musculature.

The examination for the femoral hernia in both genders involves palpation of the femoral canal just below the inguinal ligament in the upper thigh. In this way, the most easily palpable landmark is the femoral artery, which is located lateral in the canal. Medial to the femoral artery is the femoral vein, and the femoral empty space is just medial to the vein. This area can be located easily, palpated with two fingers, and then examined closely while the patient coughs or strains. In general, a focused groin hernia examination should involve the investigation for both inguinal and femoral hernias in both genders.

Treatment

The treatment of all hernias, regardless of their location or type, is surgical repair. Elective repair is performed to alleviate symptoms and to prevent the significant complications

of hernias, such as incarceration or strangulation. While the limited data available on the natural history of groin hernias show that these complications are rare, the complications are associated with a high rate of morbidity and mortality when they occur. At the same time, the risks of elective groin hernia repair, even in the patient with a complicated medical history, are exceedingly low. Outcomes of surgical repair are generally excellent with minimal morbidity and relatively rapid return to baseline health.

The major risk with delayed surgical repair is the risk of incarceration and/or strangulation. It is not possible to reliably identify those hernias that are at an increased risk for these complications. It is known that the risk of incarceration of a hernia is greatest soon after the hernia manifests itself. This is likely due to the fact that at the early stage of the hernia, the defect is small and fits tightly around the hernia sac; therefore, any contents that fill the sac may quickly become trapped within the hernia. Over time, the hernia defect stretches due to the tissue that enters and leaves the sac with changes in intra-abdominal pressure. After 6 months, the risk of hernia incarceration decreases from 5% per year to 1–2% per year. In general, the larger the palpable defect on physical examination, the lower the risk of incarceration. Clearly, all risks of tissue loss aside, elective hernia repair is still preferred to emergent repair.

Anesthesia

Groin hernia repair can be performed using a variety of anesthesia options, including general, regional (such as spinal or epidural), and local anesthesia.[6] Laparoscopic repairs usually require general anesthesia in order to provide the complete muscle relaxation needed to achieve insufflation of the preperitoneal or peritoneal space.

Open groin hernia repairs are most often performed using either regional or local anesthesia. Local anesthesia with controlled intravenous sedation, referred to as monitored anesthesia care, is often preferred in the repair of the reducible inguinal hernia. Its advantages include the ease of induction and awakening, the short postanesthesia recovery period, and the fact that its intensity can easily be titrated up or down based on patient comfort levels intraoperatively. The only major disadvantage to this approach is in patients who experience considerable pain during repairs of large groin hernias.

In groin hernia repair, local anesthesia can be administered as a direct infiltration of the tissues to be incised or as a local nerve block of the ilioinguinal and iliohypogastric nerves. The latter is associated with improved local pain control, but may be difficult to achieve. The local nerve block also spares the soft tissue of edema from diffuse infiltration of local anesthesia.

Spinal or continuous epidural anesthesia allows the surgeon greater freedom to maneuver within the operative field since the anesthetized region is larger than in local anesthesia. However, these modes of anesthesia carry their own infrequent risks such as urinary retention, prolonged anesthetic effect, hypotension, and spinal headache. They may also be associated with longer in-hospital recovery times on the day of surgery.

A randomized trial of local, regional, and general anesthesia in 616 adult patients undergoing open inguinal hernia repair in 10 hospitals found that local anesthesia was superior in the early postoperative period.[7] Compared to those who received regional or general anesthesia, patients who received local anesthesia had less postoperative pain and nausea, shorter time spent in the hospital, and fewer unplanned overnight admissions (3% vs 14% and 22%, respectively).

Operative Techniques

Successful surgical repair of a hernia depends on a tension-free closure of the hernia defect to attain the lowest possible recurrence rate. Previous efforts to simply identify the defect and suture it closed resulted in unacceptably high recurrence rates of up to 15%. Modern techniques have improved upon this recurrence rate by placement of mesh over the hernia defect, or in the case of laparoscopic repair, behind the hernia defect. One exception to this rule is the classic Shouldice repair, which uses meticulous dissection and closure without mesh placement to obtain a consistently low recurrence rate. Another benefit of the tension-free closure is that it has been shown to cause the patient significantly less pain and discomfort in the short-term postoperative period.

Figure 7-1 illustrates the essential steps to the modern open inguinal hernia repair. All of the open anterior herniorraphy techniques begin with a transversely oriented, slightly curvilinear skin incision of approximately 6–8 cm positioned one to two fingerbreadths above the inguinal ligament. Dissection is carried down through the subcutaneous and Scarpa's layers. The external oblique aponeurosis is identified and cleaned so that the external ring is identified inferomedially. Being careful to avoid injury to the iliohypogastric and ilioinguinal nerves, the aponeurosis is incised sharply and opened along its length through the external ring with fine scissors. The nerves underlying the external oblique fascia are then identified and isolated for protection. The soft tissue is cleared off the posterior surface of the external oblique aponeurosis on both sides and the spermatic cord is mobilized. Using a combination of blunt and sharp dissection, the cremaster muscle fibers enveloping the cord are separated from the cord structures and the cord itself is isolated. At this point, it is possible to accurately define the anatomy of the hernia. An indirect hernia will present with a sac attached to the cord in an anteromedial position extending superiorly through the internal ring. A direct inguinal hernia will present as a weakness in the floor of the canal posterior to the cord. A pantaloon defect will present as both a direct and an indirect defect in the same inguinal canal.

The specifics of the common modern techniques for hernia repair will be discussed further.

THE SHOULDICE TECHNIQUE

The Shouldice technique is commonly used for open repair of inguinal hernias and is the most popular pure tissue hernia repair. It is in essence the modern evolution of the Bassini repair performed in a multilayered fashion. Both operations use a tightening of the internal ring and closure of the transversalis fascia to the inguinal ligament as their primary tenets of hernia repair.[8]

Figure 7-2 illustrates the basic steps in the Shouldice repair. After suitable exposure and isolation of the cord, a pair of scissors is passed posterior to the transversalis fascia beginning at the medial pillar of the internal ring and extending inferomedially to the pubic tubercle. In this way, the transversalis fascia is separated from the preperitoneal fat plane. Care must be taken at this stage to preserve the inferior epigastric vessels that reside in the preperitoneal space. The transversalis fascia is then opened with scissors along the entire inguinal floor from internal ring to pubic tubercle, and the posterior surface of the transversalis is cleaned of its preperitoneal attachments. As the first layer of the repair, the free edge of the lower transversalis flap is sutured in a continuous, imbricated fashion behind the upper flap to the posterior surface of the upper transversalis fascia and the lateral component of the posterior rectus sheath. This running suture layer is started medially at the pubic tubercle and carried up to and through the internal ring, thereby tightening the transversalis fascia around the cord at its entrance to the inguinal canal. The first layer is not tied but continued in a running fashion from lateral to medial as a second layer closing the upper transversalis flap to the base of the lower edge as well as the inguinal ligament. This second layer progresses medially to the pubic tubercle where it is tied to the original tail that started the first layer. The third layer of continuous suture starts at the tightened internal ring and brings together the conjoined tendon (the internal oblique and transversus abdominis aponeuroses)

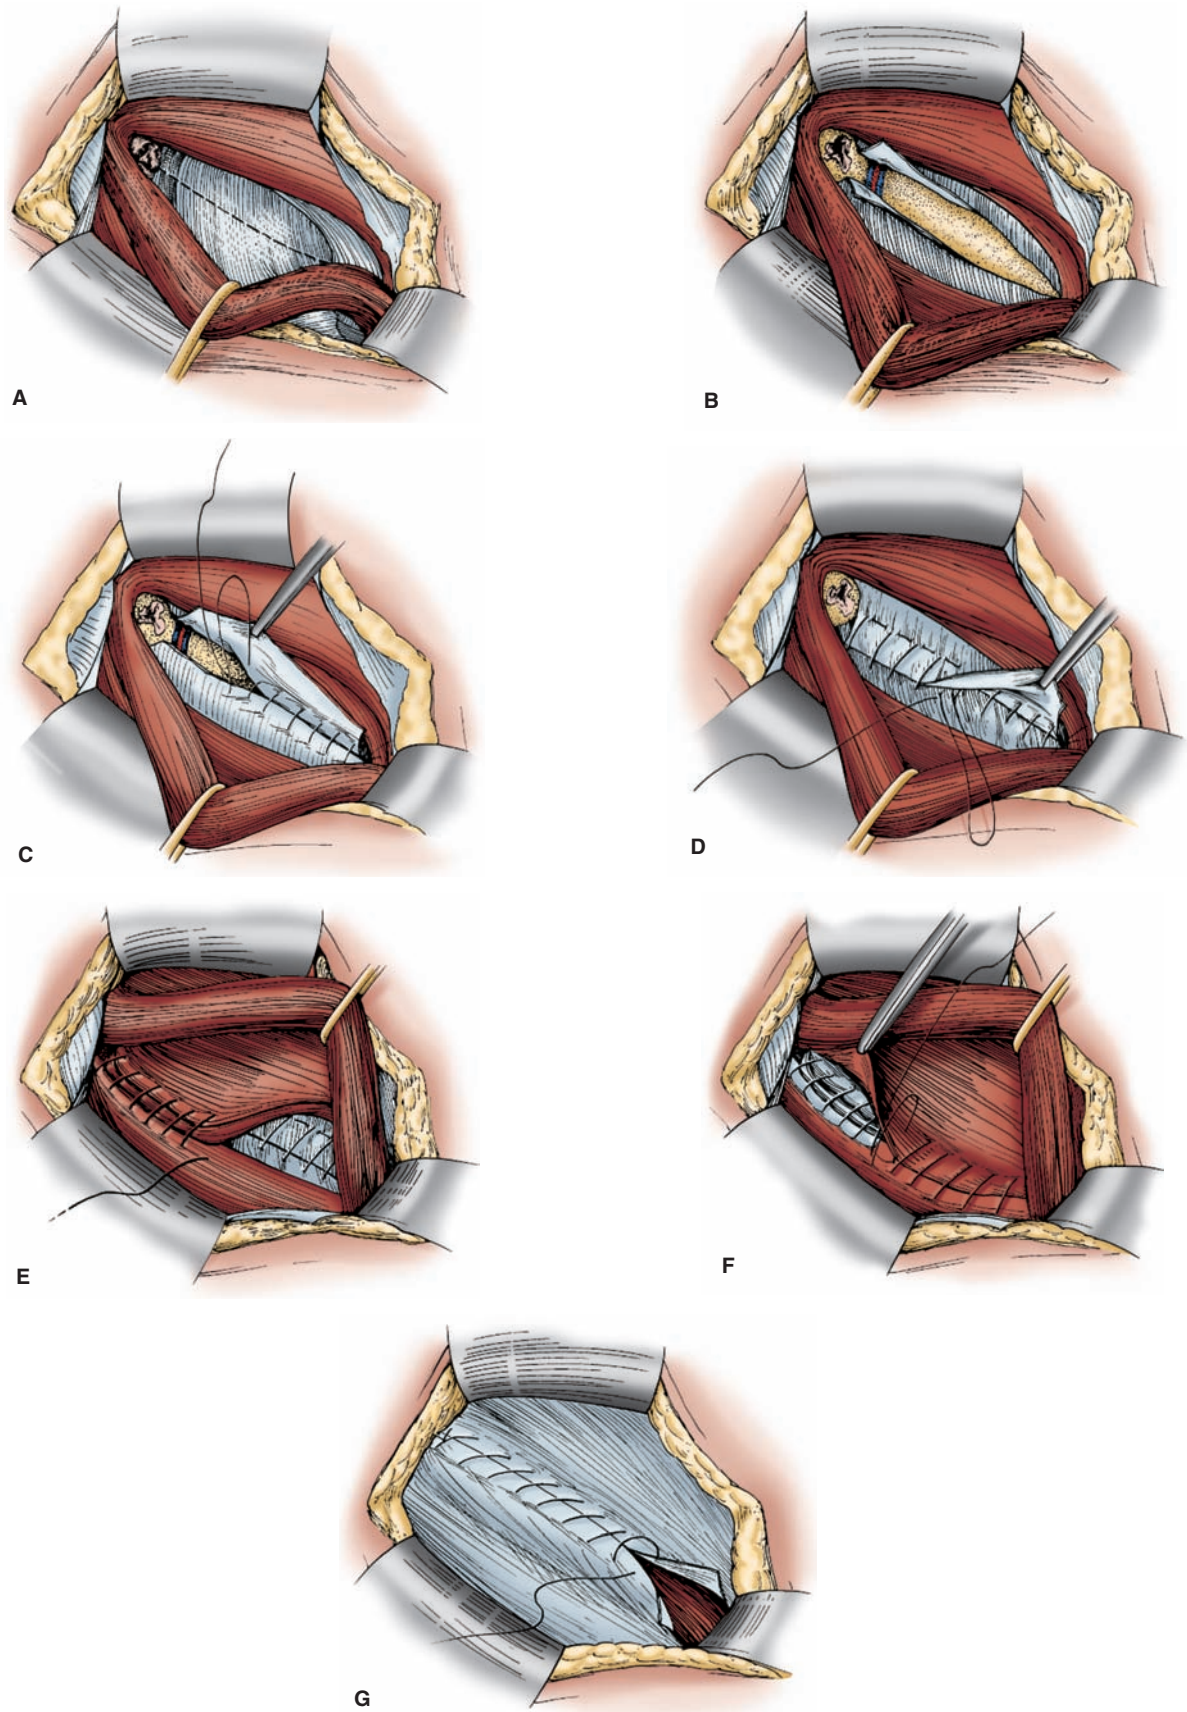

FIGURE 7-2 The Shouldice operation. **A.** The transversalis fascia is being incised. **B.** The upper and lower flaps of the transversalis fascia have been dissected free and elevated to expose the extraperitoneal fat and the inferior epigastric vessels. **C.** The first layer of the Shouldice operation. **D.** The second layer. **E.** The third layer. **F.** The fourth layer. **G.** The external oblique aponeurosis has been repaired anterior to the spermatic cord.

medially with the inguinal ligament laterally. This layer is run down to the pubic tubercle, and returns to the internal ring as the fourth layer including the anterior rectus sheath medially with the posterior aspect of the external oblique aponeurosis laterally. The cord can now be relaxed gently on the new inguinal floor, and the external oblique aponeurosis is closed in one to two additional continuous layers extending down to the external ring to reapproximate this structure. The original descriptions of the operation by Shouldice used continuous stainless steel wire suture for all four layers of repair, although surgeons commonly use permanent synthetic suture today.

The Shouldice Hospital reports excellent long-term outcomes from their operation with recurrence rates less than 1% in selected patients.[9,10] These results have not been achieved with any other pure tissue technique. The operation is well tolerated by most patients using local anesthesia only. From the multiple, overlapping, continuous suture lines, Shouldice proponents argue that any tension brought about in this type of closure is dispersed throughout the entire inguinal canal. The dissection is complicated, however, and requires excellent surgical technique and anatomic awareness. Moreover, other surgeons utilizing the Shouldice method have not achieved recurrence rates this low. Thus, the low rate of recurrence associated with the Shouldice technique likely depends on the level of surgical expertise and the patient selection. In one report of 183 inguinal hernia repairs using the Shouldice technique under local anesthesia, the recurrence rates for beginners versus more experienced surgeons were 9.4% versus 2.5%, respectively.[11]

A recent meta-analysis conducted by the Cochrane Collaboration compared the Shouldice technique with other open techniques for inguinal hernia repair.[12] The analysis incorporated results from 16 different randomized or quasi-randomized studies and compared 2566 hernias repaired via the Shouldice technique with 1121 hernias repaired with mesh and 1608 hernias repaired with other nonmesh techniques. The recurrence rate for the Shouldice repair was significantly higher than mesh repair (odds ratio 3.8), but significantly lower than nonmesh repair (Odds Ratio 0.62). There were no significant differences between the groups with respect to complications, length of stay, or chronic pain following herniorraphy.[12] Thus, the Shouldice technique is associated with a higher recurrence rate than mesh repairs, but appears to be the repair of choice in situations where mesh cannot be implanted.

THE COOPER LIGAMENT REPAIR

The Cooper ligament repair is the only technique that definitively repairs both the inguinal and femoral hernia defects in the groin. The operation is often named after Chester McVay, who popularized the operation in the 1940s and introduced the concept of the relaxing incision to decrease the tension from the repair. The repair is also a primary tissue repair in that no mesh is utilized.

The Cooper ligament repair begins similar to the Shouldice procedure, and exposure and isolation of the cord is performed. The transversalis fascia is then opened and cleaned posteriorly. At this time, Cooper's ligament is identified and dissected free of its fibrous and fatty attachments. The defects are repaired by using interrupted suture to affix the upper border of the transversalis fascia to Cooper's ligament beginning medially at the pubic tubercle and continuing until the femoral sheath is reached. At this point, the femoral canal is closed by carefully suturing Cooper's ligament to the femoral sheath. The repair is continued with interrupted sutures between the transversalis fascia and the iliopubic tract laterally until the entrance point of the cord is reached. In this way, the closure creates a new, and tighter, internal inguinal ring around the cord.

The Cooper ligament repair requires a relaxing incision because this pure tissue repair is associated with significant tension in closing all three groin hernia defects. After the transversalis fascia has been mobilized, and prior to the closure of the fascia to Cooper's ligament, a 2–4 cm vertical incision is made at the lateral border of the anterior rectus sheath beginning at the pubic tubercle and extending superiorly. The relaxing incision can be left open since the rectus muscle should protect against any herniation; alternatively, some surgeons argue for placement of a mesh over the relaxing incision since hernia formation can occur at this site.

The Cooper ligament repair is an outstanding technique for a femoral hernia and is associated with excellent long-term results in experienced hands. Disadvantages of the repair include a longer operating time, a more extensive dissection, the potential for vascular injury and thromboembolic complications from the femoral vessels, and a longer postoperative recovery phase.

Prosthetic Repairs

Polypropylene mesh is the most common prosthetic used today in mesh repairs of the inguinal hernia. The two most common prosthetic repairs are the Lichtenstein[13] and the "plug and patch" repair as described by Gilbert[14] and popularized by Rutkow and Robbins.[15]

The type of mesh to be used during prosthetic inguinal hernia repairs deserves a brief discussion. The most common and preferred mesh for groin hernia repair is a polypropylene woven mesh marketed under a variety of names. Polypropylene is preferred because it allows for a fibrotic reaction to occur between the inguinal floor and the posterior surface of the mesh, thereby forming scar and strengthening the closure of the hernia defect. This fibrotic reaction is not seen to the same extent with other varieties of prosthetic, namely expanded polytetrafluoroethylene (PTFE) mesh. PTFE is often used for repair of ventral or incision hernias in which the fibrotic reaction with the underlying serosal surface of the bowel is best avoided.

There are limited prospective, randomized data comparing the recurrence rate of open prosthetic repairs versus open nonprosthetic repairs. An attempted meta-analysis concluded that mesh repair was associated with fewer overall recurrences, although the authors report that formal analysis was limited

by the lack of available study data.[16] A review of 26,000 inguinal hernia repairs from Denmark found that mesh repairs had a lower reoperation rate than conventional open repairs.[17] The majority of groin hernia repairs performed in the United States in the modern era utilize mesh placement.

THE LICHTENSTEIN TECHNIQUE

The Lichtenstein inguinal hernia repair was the first pure prosthetic, tension-free repair to achieve consistently low recurrence rates in long-term outcomes analysis. This operation begins with the incision of the external oblique aponeurosis, and the isolation of the cord structures. Any indirect hernia sac is mobilized off the cord to the level of the internal ring. At this point, a large mesh tailored to fit along the inguinal canal floor is placed so that the curved end lies directly on top of the pubic tubercle. The mesh patch extends underneath the cord until the spermatic cord and the tails of the mesh patch meet laterally. Here, an incision is made in the mesh, and the cord is inserted between the tails of the mesh, thereby creating a new, tighter, and more medial internal ring. The tails are sutured together with one nonabsorbable stitch just proximal to the attachment of the cord. The mesh is then sutured in a continuous or interrupted fashion to the pubic tubercle inferiorly, the conjoined tendon medially, and the inguinal ligament laterally.

Rutkow and Robbins have reported interesting and effective advances in the Lichtenstein technique. The "plug and patch" repair, as illustrated in Fig. 7-3, represents a tension-free herniorraphy and can even be performed without sutures. In this technique, the patch is placed in a similar fashion to the modern Lichtenstein repair as it lies along the inguinal canal from the pubic tubercle medially to beyond the cord laterally. In addition, a mesh plug in the form of an umbrella or cone is snugly fit up and into the internal ring. In this way, the repair goes beyond just a tightening of the internal ring, but serves to close the ring around the spermatic cord. Modifications of this operation exist and are practiced commonly by general surgeons. The patch and plug can be sutured to the surrounding inguinal canal tissue in an interrupted or continuous fashion. Alternatively, both prostheses can be placed in appropriate position with no suture affixment. In this way, the body's natural scarring mechanism will hold both pieces of mesh in place over time. Wide internal ring defects, often caused by large or chronic indirect sacs, may require one or two sutures to tack the plug in place to avoid slippage into the canal anteriorly or the retroperitoneal space posteriorly.

THE PREPERITONEAL APPROACH

The preperitoneal space is found between the transversalis fascia and the peritoneum itself. The actual groin hernia defect is located anterior to this space, whether the defect exists in the internal ring (indirect inguinal hernia) or through the transversalis floor of the inguinal canal (direct inguinal hernia). Several authors, including Rives, Nyhus, Stoppa, and Kugel, advocate the use of a preperitoneal or posterior approach to repair the inguinal hernia. They argue that this approach is more effective than the traditional anterior herniorraphy because a repair in the preperitoneal plane fixes the hernia defect in the space between the hernia contents and the hernia defect. In contrast, the anterior approach does not keep the hernia contents from contact with the defect, but rather fixes the hernia defect anterior to the defective anatomy. The operation is also advocated for difficult inguinal hernia recurrences, since the posterior approach will usually remain open and without scar following a previous anterior hernia repair. The original operation as described by Nyhus repairs the hernia primarily with suture, although more recent modifications incorporate a mesh patch posterior to the floor of the inguinal canal. As described later in this chapter, the standard laparoscopic technique for inguinal hernia repair is based entirely on the preperitoneal hernia repair.

Figures 7-4 and 7-5 illustrate the preperitoneal repair as described by Rives.[18] In the preperitoneal hernia repair, the incision is usually made transversely in the lower quadrant 2–3 cm cephalad to the inguinal ligament. The incision is made slightly more medial than the anterior approach so that the lateral border of the rectus muscle can be exposed after incising the anterior rectus sheath. Once the muscle is exposed, retraction of the rectus muscle medially allows for careful opening of the posterior rectus sheath and entry into the preperitoneal space. The inferior epigastric vessels and the cord can be visualized in this space. The cord usually does not require extensive manipulation or dissection since the usual cord attachments (lipoma and cremaster fibers) are found in the anterior layers of the inguinal canal. In this way, the approach also avoids exposure to the sensory nerves of the inguinal canal.

Once the preperitoneal space has been entered and exposed, the specific repair to be performed depends on hernia anatomy. For direct defects, the sac is inverted back into the peritoneal cavity but does not need to be excised. The transversalis fascia is then reapproximated over the inverted sac using interrupted sutures; in this way, the upper border of the transversalis fascia is affixed to the lower border composed of the iliopubic tract. For indirect defects, the sac is reduced off of the cord and a high ligation of the sac is performed at the sac neck; ironically, with this approach, the "high ligation" is actually a "posterior" ligation, since the surgeon ideally should transect the sac just above the preperitoneal fat, which is situated along the inferior border of the exposed field. Once the sac has been ligated, the defect in the internal ring is repaired from the posterior plane using interrupted suture to affix the ring leaflets of the transversalis fascia to the iliopubic tract, thereby tightening the ring itself.

Modifications of this approach using the prosthetic mesh patch are relatively straightforward. The mesh patch is placed underneath the transversalis fascia and directly on the preperitoneal fat. This patch, if placed completely over the inguinal region, covers any peritoneum that could potentially form a hernia sac through a direct or indirect fascial defect.

Laparoscopic Repair

Laparoscopic groin hernia repair was first performed by Ger in 1979, although it was only within the past decade and a half that laparoscopic hernia repair became more accepted. The laparoscopic approach to hernia repair has since evolved into a common and effective procedure. Today, the laparoscopic approach comprises approximately 20–25% of groin hernia operations and 80,000–100,000 laparoscopic hernia repairs are performed annually in the United States. The most important difference between the laparoscopic and open approaches for inguinal hernia repair is anatomical: the laparoscopic approach uses mesh to repair the hernia defect in a plane posterior to the defect (either in the preperitoneal space or from within the peritoneal cavity), whereas the open approaches repair the hernia anterior to the defect.

Three different techniques exist for laparoscopic repair of groin hernias. The transabdominal preperitoneal (TAP) repair involves standard laparoscopy with access into the peritoneal cavity and placement of a large mesh along the anterior abdominal wall, thereby repairing the hernia posterior to the defect. This technique was the first laparoscopic hernia repair to be performed. Ports are generally placed

through the umbilicus and then laterally on either side of the rectus muscle. The hernia defect is usually well visualized from within the peritoneal cavity. After both inguinal regions have been inspected and laparoscopic adhesiolysis performed if necessary, the median umbilical ligament (the urachal remnant), the medial umbilical ligament (the remnant of the umbilical artery), and the lateral umbilical fold (the reflection of peritoneum over the inferior epigastric vessels) are identified. The parietal layer of peritoneum is then incised superior to the hernia defect and reflected inferiorly, thereby exposing the hernia defect, the epigastric vessels, Cooper's ligament, the pubic tubercle, and the iliopubic tract. The cord structures are then dissected free of their peritoneal attachments. In a direct hernia, the peritoneal sac is pulled back within the peritoneal cavity with gentle traction to separate the thin peritoneal layer from the equally thin layer of transversalis fascia anterior to it. In an indirect hernia, the peritoneal sac is retracted off of the cord structures and pulled back within the peritoneal cavity. Alternatively, in the setting of a large chronic indirect hernia, the sac can be divided distal to the internal ring so that only the proximal portion of the sac needs to be mobilized for the repair. A large polypropylene mesh patch is then placed between the peritoneum and the transversalis fascia that covers the inguinal floor, internal ring, and the femoral canal. The mesh is stapled or tacked to the pubic tubercle medially, Cooper's ligament inferiorly, and the anterior superior iliac spine laterally. The incised peritoneal flap is then closed over the mesh.

While the TAP repair has been shown to be effective, there is a risk that the prosthetic mesh will be in direct content with the bowel, and significant concern has been raised about the potential for intra-abdominal adhesions postoperatively.[19] Enthusiasm for this technique has waned in recent years with the advent of extraperitoneal laparoscopic approaches to inguinal hernia repair.

The total extraperitoneal (TEP) approach to laparoscopic inguinal hernia repair is currently the most popular laparoscopic technique. This repair is performed entirely within the preperitoneal space and does not involve the peritoneal cavity when performed correctly. In this technique, the surgeon carefully develops a plane between the peritoneum posteriorly and the abdominal wall tissues anteriorly, and thus insufflates the preperitoneal space. An incision is made inferior to the umbilicus, and the anterior rectus sheath on the ipsilateral side is incised. The rectus muscle is retracted laterally, and the preperitoneal space is bluntly dissected to allow placement of a balloon port to facilitate insufflation. Once the space has been insufflated, two additional ports are placed in the midline between the umbilicus and the pubic symphysis. In experienced hands, this approach provides for excellent visualization of the groin anatomy, and the dissection proceeds in a similar fashion to the TAP. The TEP repair allows a large prosthetic mesh to be placed through a laparoscopic port into the preperitoneal space, and it is then positioned deep to the hernia defect to repair the hernia from a posterior approach.[20]

The intraperitoneal onlay mesh technique (IPOM) was developed as a simplified version of the TAP repair. In this technique, laparoscopic exposure is obtained directly into the peritoneal cavity as in the TAP. However, this technique does not require an extensive mobilization of the peritoneal flap and dissection of the preperitoneal space. Rather, a large mesh is simply stapled or sutured directly posterior to the peritoneum to repair the hernia. In theory, once the peritoneum scars to the mesh after allowing for connective tissue in-growth, the peritoneum will not be mobile enough to herniate through the actual defect and intra-abdominal pressure will keep the abdominal contents posterior to the mesh patch. The disadvantage of this procedure is that there is direct exposure of mesh to the intra-abdominal contents and therefore a high risk of adhesion formation and possible erosion of the mesh into bowel contents. Another potential disadvantage of the IPOM is the fact that in large inguinal hernias, the mesh and peritoneum may herniate through the defect together, thereby negating any protective effect imparted by the mesh patch. Therefore, at the present time, this procedure is thought to be experimental only.

There are few prospective, randomized data available to adequately judge short- and long-term results of the different laparoscopic inguinal hernia techniques. A systematic review by the Cochrane Collaboration in 2005 found that among the several nonrandomized trials, TAP was associated with an increased rate of port site herniation and visceral organ injury. This review concluded that there are insufficient data from prospective, randomized trials to make firm conclusions about the relative effectiveness of the TEP and TAP procedures.[21]

There are emerging data comparing laparoscopic techniques to open inguinal hernia repair, although the evidence is far from definitive. While there are multiple meta-analyses in the literature, only two truly compare the laparoscopic hernia technique with a tension-free open repair. A meta-analysis of 29 randomized trials in 2003 found that laparoscopic hernia repair was associated with earlier discharge from the hospital, quicker return to normal activity and work, and fewer postoperative complications than open repair.[22] However, in these data there was a trend toward an increase in the risk of recurrence after laparoscopic repair. A separate meta-analysis reviewing 41 published randomized trials found no significant difference in risk of recurrence between the two approaches.[23] Laparoscopic repair was associated with a quicker return to function and less postoperative pain, but also was found to have a higher risk of visceral and vascular injuries. A more recent multicenter, randomized trial that analyzed long-term hernia results in over 2000 patients in 14 Veterans Affairs hospitals found that laparoscopic hernia repair was associated with a higher recurrence rate among primary hernias, but was equivalent to open repair in recurrent hernias.[24] In all of these studies, the laparoscopic repair was noted to take more time in the operating room. Proper laparoscopic technique also appears to play a significant role in recurrence rates. In a randomized, multicenter trial comparing 665 TEP versus 705 Lichtenstein repairs with 5-year

follow-up, authors initially found that the recurrence rate following TEP (3.5%) was significantly higher (p = 0.008) than that following Lichtenstein (1.2%).[25] However, when they removed a single surgeon who was responsible for 33% of all the recurrences in the TEP group, the cumulative recurrence rate for TEP was lowered to 2.4% and was not statistically different from the Lichtenstein group. Finally, a recent study has reported a significant learning curve inherent in the laparoscopic approach.[26] Clearly, more definitive multicenter data from surgeons experienced in both procedures are needed to reach formal conclusions about the utility of both hernia approaches.

A separate issue that deserves further study in laparoscopic hernia repair is the anatomical disturbance of the space of Retzius. This area, first described by Retzius in the 19th century, is the prevesical space located anterior and lateral to the bladder. Suprapubic prostatectomy is performed with dissection through this space, and this operation may be made more difficult following laparoscopic hernia repair.

SURGICAL COMPLICATIONS OF GROIN HERNIA

Although groin hernia repair is associated with excellent short- and long-term outcomes, complications of the procedure exist and must be recognized.

Recurrence

Recurrence of the hernia in the early postoperative setting is rare. When this does occur, it is often secondary to deep infection, undue tension on the repair, or tissue ischemia. Clearly, all of these etiologies raise the concern for a technical complication on the part of the surgeon, either in the handling of the groin tissues or the placement of mesh or suture. The patient who is overactive in the immediate postoperative setting may also be at risk for early hernia recurrence. In this way, it is thought that early exercise is performed before the suture or mesh in the repair has had an opportunity to hold tissue in place and promote scar tissue formation. In the initial postoperative setting, patients may also develop seromas along the planes of dissection as well as fluid in the obliterated hernia sac. These benign consequences of surgery must be differentiated from the more worrisome early recurrence.

Tension is an important, if not the primary, etiology of hernia recurrence. Tissues repaired under undue tension will tend to pull apart, even if sutures or mesh has been affixed to them. In addition, tension at the site of suture may lead to ischemia at the point where the suture pulls against the tissue, thereby further weakening the hernia repair. Sutures can also cut out or fall apart, especially if placed in a continuous fashion, when tensile force predominates. The role of excessive tissue tension in promotion of hernia recurrence is the basic rationale behind the modern, tension-free, and increasingly suture-free hernia repairs advocated by hernia experts such as Lichtenstein and Rutkow.

The size of the hernia defect is proportional to the risk of hernia recurrence. Larger hernias have an increased rate of recurrence postoperatively. This is most likely due to the nature of the surrounding fascial tissues that are critical to the strength and reliability of the repair. As large hernias stretch and attenuate the surrounding fascial planes, these tissues are correspondingly weaker when repaired with suture or mesh. The weakened tissue may also be relatively ischemic at the time of hernia repair, although this has not been adequately studied.

An emergency operation for strangulated or incarcerated hernia may increase the risk of postoperative recurrence. It is likely that the strangulated hernia, with its inherent inflammation, tissue ischemia, and fascial edema, provides an environment in which the hernia repair is placed either at increased tension or through unhealthy tissue.

A hernia that is overlooked in the operating room represents a potential etiology of hernia recurrence, although this should not be a major concern for the modern hernia surgeon. Most of the repairs in the current era emphasize the repair of both an indirect and a direct defect through strengthening of the internal ring and inguinal canal floor, respectively.

A final etiology of hernia recurrence pertains to tobacco use and smoking. The relationship between smoking and hernia formation as well as recurrence was first reported in 1981 and further research has identified proteolytic enzymes that may degrade the connective tissue components.[27]

Infection

Infection of the hernia wound or mesh is an uncommon postoperative complication but represents another etiology of hernia recurrence. In specialized hernia practices, the incidence of wound infection following inguinal hernia operation is 1% or less. When an infection does occur, skin flora is the most likely etiology, and appropriate gram-positive antibiotics should be initiated. Patients who undergo mesh placement during groin herniorraphy are at a slightly higher risk of postoperative wound infection. It is often difficult to determine whether the mesh itself is infected or if just the skin or soft tissue anterior to the layer of mesh is infected. However, even if mesh is present, most postoperative groin hernia infections can be treated with aggressive use of antibiotics after the incision is opened and drained expeditiously.[28] Mesh removal in this setting is rarely indicated; when this is mandated, primary closure or redo herniorraphy with a synthetic tissue substitute may be warranted and a preperitoneal approach may be necessary.

Seromas and hematomas are frequent complications in the postoperative setting. Seromas form in the dead space remaining from a wide dissection during the hernia repair or when fluid fills the distal remnant of the hernia sac.

While the sac is often ligated or excised during open herniorraphy, it remains in place following laparoscopic repair, and the filling of the remnant sac with seroma-type fluid has been termed a pseudohernia. This must be differentiated from the more concerning complication of the early recurrent hernia. Defined fluid collections infrequently require drainage or aspiration, as most will reabsorb or drain through the incision on their own.

Hematoma formation must be assiduously avoided during groin hernia repair. This is especially true in the anticoagulated patient, and therefore it is recommended that patients temporarily stop taking aspirin and clopidogrel at least 1 week prior to their operation. Hematoma formation may be minor and lead only to ecchymoses and wound drainage. The ecchymosis often spreads inferiorly into the scrotal plane in a dependent fashion. The hematoma usually resolves in days to weeks following repair and supportive management for pain control including scrotal elevation and warm packs is all that is required. A large volume of hematoma is concerning, as it may serve as a nidus for infection deep in the hernia wound and may risk secondary infection of the prosthetic mesh. Therefore, hemostasis at the end of a groin hernia repair is paramount to achieve effective wound healing.

Neuralgia

Postoperative groin pain, or neuralgia, is common to varying degrees following groin herniorrhaphy.[29] Often, the neuralgia will follow the known distribution of the regional nerves, including the ilioinguinal, iliohypogastric, genital branch of the genitofemoral nerve, and the lateral femorocutaneous nerves. During open hernia repair, the ilioinguinal, iliohypogastric, and the genitofemoral nerves are most commonly injured, while the lateral femorocutaneous nerve is more commonly injured during laparoscopic herniorraphy. Nerve injury is usually due to entrapment of a portion of the nerve in the mesh or suture line placed in one of the soft tissue layers.

Neuralgias can be prevented by meticulously avoiding overt manipulation of the nerves during operative dissection. The ilioinguinal and iliohypogastric nerves are generally injured during elevation of the external oblique fascial flaps, while the genitofemoral nerve is most likely to be injured during the isolation of the cord and stripping of the cremaster muscle fibers. Often, once the nerve branches are identified, they are encircled with a vessel loop and retracted out of the operative field to avoid injury. The nerves can also be intentionally sacrificed at time of surgery. The result of this maneuver is a region of sensory deprivation in the distributions of these nerve structures, namely on the inner upper thigh and the hemiscrotum. However, the sensory deprivation is thought to be better tolerated by the patient than the chronic and persistent pain attributed to nerve entrapment in scar or mesh. In laparoscopic repair, nerve injury can be prevented by avoiding tack or staple placement below the iliopubic tract.

Neuralgia should first be managed conservatively, with attempts at local anesthetic injection in the affected groin. When local anesthesia is injected along the known course of a nerve, this modality may serve as both a diagnostic and a therapeutic maneuver. In some cases, temporary control of the chronic pain with local anesthesia may reduce or altogether eliminate the sequelae of chronic groin pain. When this conservative approach does not succeed, groin re-exploration can be performed to ligate or excise affected nerve branches. This is clearly not the preferred first option, since the groin wound has abundant scar and previously undamaged nerve structures may be placed at additional risk. Occasionally, patients will present with postoperative neuralgia that does not match the distribution of any known inguinal nerve. Groin re-exploration should be avoided in this case since it is unlikely to ameliorate the pain and may damage additional structures.

Nerve injury during laparoscopic repair can occur during the tacking of the mesh to the anterior abdominal wall. Tacks should be avoided in the known areas of nerve structures. Some surgeons prefer to not place any tacking staples at all when performing laparoscopic herniorraphy to avoid this complication altogether.

Bladder Injury

The urinary bladder may be inadvertently injured during dissection of a direct inguinal hernia sac, but only rarely during repair of an indirect defect. The bladder can also participate in a sliding hernia so that a portion of the bladder wall is adherent to the sac in a direct defect. Because of the potential for this complication, direct sacs should be inverted into the peritoneal cavity so that excessive dissection can be avoided. If bladder injury takes place, the sac should be opened, and the bladder injury repaired in two layers of an absorbable suture. In general, a urethral catheter is placed for a minimum of 7–14 days.

Testicular Injury

Testicular swelling and atrophy is seen after inguinal hernia repair. Edema of the scrotum or testis may be secondary to edema or hematoma of the inguinal canal that tracks inferomedially to the scrotum in a dependent fashion. Alternatively, a tender testicle or an atrophic testicle may be secondary to injury to the blood supply to the genitals during dissection and isolation of the cord. In most cases, this is not an emergency in the adult patient, and the testes will atrophy without significant infectious complications so that orchiectomy is rarely necessary. A testicle that is tender on examination may require ultrasonographic imaging to rule out testicular torsion or a corresponding abscess. Necrosis of the

testes, a very rare complication of groin hernia repair, usually requires orchiectomy to avoid infectious complications.

In the pediatric patient, traction on the cord in the cephalad direction can cause the testes to migrate into the inguinal canal and out of the scrotum. For this reason, the scrotum is often prepped sterilely in the pediatric inguinal hernia operation, and the testes are confirmed to be in appropriate position by palpation at the end of the hernia repair. If the testes remain in the inguinal canal following herniorraphy, this may require manipulation of the testes further down the canal and into the scrotum using a long atraumatic forceps or a choker instrument.

Vas Deferens Injury

Injury to the vas deferens is a rare complication of groin hernia surgery in the male patient. Transection of the vas is the most serious form of this injury; this requires urologic consultation and likely immediate reanastomosis in the child or young adult, but may only require ligation of both ends in the older adult patient. Minor injuries to the vas can be avoided by using gentle, atraumatic traction only and by avoiding complete grasping or squeezing of the vas. The most worrisome sequela of vas deferens obstruction or transection is formation of antisperm antibodies in the serum, leading to infertility.

THE STRANGULATED GROIN HERNIA

The strangulation of a groin hernia is a complication of the hernia itself rather than of a hernia repair. This pathophysiologic process is associated with a high rate of mortality and morbidity, especially in the elderly population with multiple comorbidities. The risk of strangulation is highest in the first months to years after the initial presentation of a reducible hernia. Gallegos and associates estimated the probability of inguinal hernia strangulation over time to be 2.8% over 3 months and 4.5% at 2 years.[30] It is likely that with time, the hernia contents weaken the hernia defect and widen the hernia neck so that the sac is no longer compressed as tightly, thereby decreasing the opportunity for incarceration and strangulation to take place.

The mortality from a strangulated hernia is related to the duration of the strangulation and the age of the patient. A longer duration of strangulation leads to a greater degree of tissue edema, ischemia, and risk of outright necrosis. Therefore, a strangulated hernia clearly represents a surgical emergency. The incarcerated hernia without overt signs of strangulation on examination and laboratory analysis should undergo attempts at reduction, often requiring conscious sedation to minimize discomfort. After the hernia is reduced, the repair can take place 1–2 days later, usually during the same inpatient hospitalization, to minimize risk of recurrent incarceration leading to strangulation.

Surgery for an incarcerated inguinal hernia is most often performed under general anesthesia given the high likelihood that bowel resection will need to be performed. Epidural or spinal anesthesia may suffice in select cases, but local anesthesia should not be employed. The location of the incision depends on the diagnosis and clinical assessment. In those patients who are unlikely to have ischemic bowel present within the hernia sac, an inguinal incision will likely be successful in both reducing the hernia contents and repairing the hernia defect. If nonviable bowel is found on exploration of the inguinal canal, the resection and anastomosis can take place deep to the transversalis fascia in the preperitoneal space or a midline incision can be made. If the initial physical examination yields signs of ischemic bowel that may necessitate resection, a midline laparotomy can be performed and the hernia repaired in the inguinal canal using a tissue repair after the laparotomy is closed. A helpful alternative is the preperitoneal hernia repair, which can be used to evaluate the bowel and repair the hernia defect; yet it can also be easily converted to an intraperitoneal exposure if extensive bowel resection and anastomosis is required. Placement of prosthetic mesh should be avoided when possible in strangulated hernia repair given the increased risk of bacterial translocation and wound infection.

FEMORAL HERNIA

The femoral hernia is the second most common abdominal wall hernia, although it makes up only 5–10% of all hernias. The femoral hernia is more common in females than in males, by a ratio of approximately 4:1.

Anatomy and Etiology

Figure 7-6 illustrates the anatomy of the femoral hernia. The defect through which a femoral hernia occurs is in the medial femoral canal. The anterior boundary of this defect is the inguinal ligament, the lateral boundary the femoral vein, the posterior boundary the pubic ramus and Cooper's ligament, and the medial boundary the lacunar portion of the inguinal ligament. This space is obviously tight and does not have room to expand when hernia contents fill the sac since the boundaries are either ligamentous, bony, or the fibrous femoral sheath and its vessels. Therefore, femoral hernias have a high propensity for incarceration and strangulation. Gallegos and associates reported the cumulative probability of femoral hernia strangulation to be 22% in the first 3 months following diagnosis and 45% at nearly 2 years.[30] Therefore, repair of a known femoral hernia is mandatory to avoid this highly morbid complication.

In contrast to the inguinal hernia, the femoral hernia is unlikely to be of congenital etiology. The incidence of femoral hernia in infancy and childhood is exceedingly low, in the range of 0.5%. In addition, there is no embryologic mechanism for a preexisting sac of peritoneum in the femoral canal. The hernia defect most often presents in middle-aged

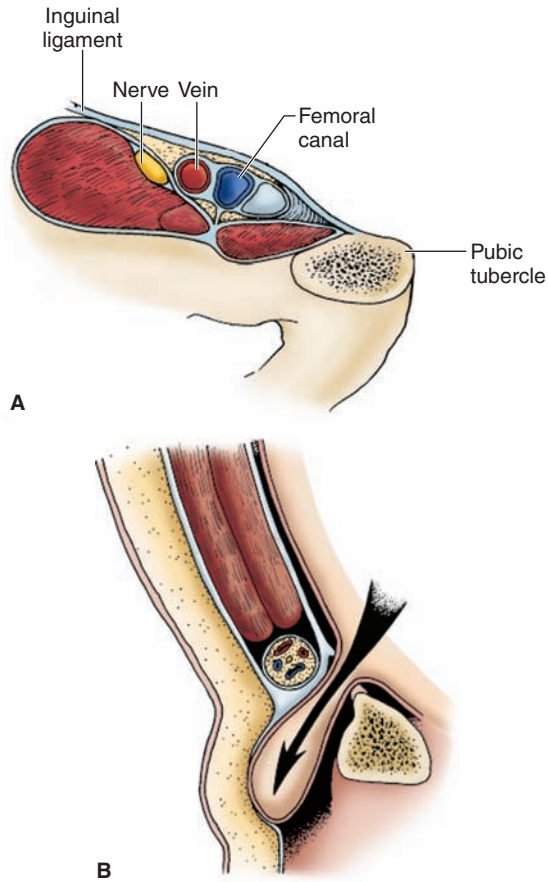

FIGURE 7-6 The anatomy of the femoral hernia. **A.** The structures posterior to the inguinal ligament. **B.** The femoral hernia passing through the femoral canal and bulging in the groin below the inguinal ligament.

to older women, suggesting that the natural loss of tissue strength and elasticity is a primary etiology.

Clinical Presentation

The femoral hernia often presents as a small bulge just below the medial groin crease. It is often difficult to reduce on initial presentation.[31] The hernia usually extends caudad as the sac increases in size with abdominal contents but may extend up and over the inguinal ligament anteriorly. Not uncommonly, the femoral hernia presents acutely with strangulation given its anatomic limitations. The differential diagnosis for a femoral hernia includes femoral lymphadenopathy, groin lipoma, or a soft tissue mass of benign or rarely malignant nature.

Treatment

The operative approach to repairing the reducible femoral hernia differs from inguinal hernia repair in several ways. The incision is usually centered transversely just below the inguinal ligament, although a standard groin hernia incision may still afford exposure to the defect. The simplest approach is anterior to the inguinal ligament. Here, the sac can often be found, dissected, and reduced into the peritoneal cavity. Repair of the defect can be performed using a Cooper ligament repair as described above, by affixing the transversalis fascia to the Cooper's ligament medially and the iliopubic tract laterally up to the internal ring. Alternatively, a simple suture repair can be performed by tacking the inguinal ligament anteriorly to Cooper's ligament posteromedially to close the defect. A third option is a purse-string suture placed first anteriorly into the inguinal ligament, then through the lacunar ligament medially, the pectineal ligament posteriorly, and finally through the fascia medial to the femoral vein and back to the inguinal ligament. All of these techniques can successfully close the femoral hernia defect.

However, a unique complication from suture repair of the femoral hernia defect is bleeding from an aberrant obturator artery. This vessel originates from the inferior epigastric rather than the internal iliac artery and traverses a space medial to the femoral hernia defect adjacent to the pubic ramus. The medial suture placed in femoral hernia repair can injure an aberrant obturator artery if present. A simple and possibly safer way to repair the femoral defect is a mesh plug placed from cephalad to caudad to obstruct the defect and promote scar tissue formation. This technique, shown in Fig. 7-7, has been reported by Lichtenstein with excellent results and low rates of recurrence.[32]

If the femoral hernia sac is large and filled with voluminous intra-abdominal contents, a preperitoneal repair should be considered. In this way, the transversalis fascia is opened and the preperitoneal plane is entered. This approach is particularly useful during repair of a strangulated hernia since there is more space to allow for inspection of the bowel to ensure viability. Bowel resection, if needed, can also take place in the preperitoneal space prior to full reduction of the hernia contents.

UMBILICAL HERNIA

The umbilicus represents a midline opening in the linea alba. Umbilical hernia occurs when the umbilical scar closes incompletely in the child or fails and stretches in later years in the adult patient. The hernia becomes readily apparent once the abdominal contents move through the umbilical opening given the relative lack of soft tissue in the anterior body wall at the site of the umbilicus.

History

Umbilical hernias have been documented throughout history with the first references dating back to the ancient Egyptians with the first known record of a surgical repair by Celsus in the first century AD. Mayo in 1901 reported the first series of patients to undergo the classic overlapping fascia operation through a transverse umbilical incision using nonabsorbable suture.[33]

Incidence

Estimates of umbilical hernia present at birth have a wide range. In Caucasian babies, the incidence has been reported at 10–30%, although for unknown reasons it may be several times greater in African-American children. Umbilical hernia is even more common in premature infants of all races and there is a tendency for familial inheritance.

The majority of congenital pediatric umbilical hernias are known to close over time, as the infant becomes a child. In this way, by school age, only 10% of umbilical hernias remain open on physical examination. Umbilical hernia repair in the child is therefore rarely performed electively before the age of 2 years, and incarceration in the child is rare. Current recommendations in the pediatric surgical literature advise the delay of umbilical hernia repair until at least 2–3 years of age given the likelihood that most umbilical hernias will spontaneously close in the young child.

The incidence of umbilical hernia in the adult is largely unknown but most cases are thought to be acquired rather than congenital. It is known to occur more commonly in adult females with a female:male ratio of 3:1. Umbilical hernia is also more commonly found in association with processes that increase intra-abdominal pressure, such as pregnancy, obesity, ascites, persistent or repetitive abdominal distention in bowel obstruction, or peritoneal dialysis. The etiology of umbilical hernia in the adult may be multifactorial, with increased intra-abdominal pressure working against a weak or incomplete umbilical scar.

Embryology and Anatomy

The fascial margins that make up the umbilical defect are formed by the third week of gestation, and the umbilical cord takes shape in the fifth week of gestation. In the sixth week, the intestinal tract migrates through the umbilicus and outside the coelom as intestinal growth outpaces the size of the abdominal cavity. The intestinal tract returns to the abdominal cavity through the umbilical defect as the midgut undergoes rotation at the tenth week of gestation, and subsequent to this, the four folds of the somatopleure begin to fuse inward. This, in turn, forms the tight umbilical defect, which allows only the passage of the umbilical vessels. At birth, when the umbilical cord is manually ligated, the umbilical arteries and vein thrombose and the umbilical aperture close. Any defect in the process of umbilical closure will result in an umbilical hernia through which omentum or bowel can herniate.

Clinical Manifestations

The diagnosis of umbilical hernia is not difficult to make. The condition presents with a soft bulge located anterior or adjacent to the umbilicus. In most cases, the bulge will be readily reducible so that the actual fascial defect can be easily defined by palpation. The patient may provide a history of vague abdominal pain associated with herniation and reduction. The list of differential diagnoses is short and includes abdominal wall varices associated with advanced cirrhosis, umbilical granulomas, and metastatic tumor implants in the umbilical soft tissue (Sister Joseph's node). In clinical practice, there is usually little doubt as to the diagnosis of umbilical hernia on physical examination.

While the majority of umbilical hernias will close spontaneously in the infant, the clinical spectrum varies widely in the adult. The hernia in the adult is often symptomatic and does not show a tendency to close without intervention. As the hernia contents increase in size, the overlying umbilical skin may become thin and ultimately ulcerated by pressure necrosis. The umbilical hernia with incarcerated omentum may present with significant tenderness on examination, despite the fact that bowel integrity is not at risk. Alternatively, an umbilical hernia may be found incidentally in the adult on physical examination. This hernia is usually small and any hernia contents are usually readily reducible. The small, asymptomatic, reducible hernia in the adult can be observed without the need for immediate intervention.

Patients with umbilical hernia secondary to chronic, massive ascites require special consideration. The repair of such hernias is associated with significantly increased morbidity and mortality. Fluid shifts leading to hemodynamic instability, infection, electrolyte imbalance, and blood loss are all considerable risks for the patient in this clinical scenario. Umbilical hernia recurrence is also common in this setting given the persistently increased intra-abdominal pressure. Thus, hernia repair in this population should be reserved for those with progressively symptomatic or incarcerated umbilical hernias.

Treatment

In the pediatric patient with a small umbilical hernia, a short curvilinear (smile) incision is made just inferior to the umbilicus in the typical skin crease. A skin flap is then raised cephalad using blunt dissection and low-level electrocautery. Dissection is carried through the subcutaneous tissues and down to the fascial level. The neck of the sac is then encircled with a hemostat. After the sac is dissected free of its umbilical attachments, it can be reduced or inverted completely into the peritoneal cavity or incised to explore the contents of the hernia sac. In this way, the redundant portion of the sac can be excised using electrocautery. The fascial defect is then closed transversely with interrupted sutures in a horizontal mattress fashion, and the skin of the umbilicus is tacked to the fascia layer using a single suture. This operation is usually performed under general anesthesia as a day-surgery procedure.

In the adult patient, most small umbilical hernia repairs are performed using local anesthesia with the possible addition of intravenous sedation. The approach is also through a curvilinear incision, placed transversely on the inferior border of the umbilicus or vertically on one curved edge of the umbilicus (Fig. 7-8). A skin flap is raised to elevate the umbilicus off the hernia sac. The sac is again dissected free of its fascial attachments to isolate the sac for complete reduction and to allow for an adequate width of fascia for suture closure. The sac contents are then reduced into the abdominal cavity and any excess sac can be excised. The defect is then closed with a strong, nonabsorbable suture (such as 0 polypropylene or nylon), usually in an interrupted fashion. The fascial edges are approximated through this technique. The traditional "vest-over-pants" technique originated by Mayo is less commonly utilized since overlapping fascial closures have been shown to weaken the overall wound strength in hernia repair.

In large defects that may close only with a significant degree of tension, a cone of polypropylene mesh can be fitted to fill the umbilical defect in place of a tissue repair. The mesh is then sutured circumferentially to the surrounding umbilical fascia to prevent migration. Newer mesh products contain polypropylene mesh or polyester mesh in combination with a bioabsorbable layer so that they can be placed in contact with the bowel without the formation of significant adhesions. These products can be very useful in the treatment of umbilical and other ventral hernias where mesh adherence to bowel is a concern.

EPIGASTRIC HERNIA

An epigastric hernia is a defect in the abdominal wall in the midline junction of the aponeuroses of the abdominal wall musculature from the xiphoid process superiorly to the umbilicus inferiorly. The region of this midline raphe is termed the linea alba, and the rectus muscles are situated just lateral to the linea alba. In this area, there is no muscle layer to protect

against herniation of intra-abdominal contents through defects in the midline fascia. A paraumbilical hernia is an epigastric hernia that borders on the umbilicus.

History

The epigastric hernia was first described by Villeneuve in 1285, but the term "epigastric hernia" was only first used to describe this condition in 1812 by Leville. The first successful repair of an epigastric hernia was reported in 1802 by Maunior.

Incidence

Estimates of the frequency of epigastric hernia in the general population range from 3% to 5%. It is most commonly diagnosed in middle age, and congenital epigastric hernias are uncommon. The condition is more common in males by a ratio of 3:1. Twenty percent of epigastric hernias may be multiple, although most are associated with one dominant defect.

Anatomy and Etiology

The cause of epigastric hernia is largely unknown. Since the condition does not predominate in children, it is unlikely that the defect is entirely congenital in origin. Rather, the hernia is likely the result of multiple factors, such as a congenitally weakened linea alba from a lack of decussating midline fibers and subsequent increase in intra-abdominal pressure, surrounding muscle weakness, or chronic abdominal wall strain.

The midline defect is usually elliptical in nature, with the long axis oriented transversely. The width of the defect is generally a few millimeters to several centimeters, and larger defects are rare. In most cases, the hernia is filled by a small amount of preperitoneal fat only and no peritoneal sac is present. The hernia will often not be seen on laparoscopy owing to the lack of peritoneal involvement through the hernia defect. Epigastric hernias that involve a peritoneal sac usually contain only omentum and rarely small intestine.

Clinical Manifestations

Epigastric hernia is often asymptomatic and represents a chance finding on physical examination. Patients with symptomatic hernias complain of vague abdominal pain above the umbilicus that is exacerbated with standing or coughing and relieved in the supine position. Severe pain may be secondary to incarceration or strangulation of preperitoneal fat or omentum. Bowel strangulation in epigastric hernias is a rare finding.

On examination, the hernia is diagnosed by palpating a small, soft, reducible mass in the midline superior to the umbilicus. The mass may protrude with a Valsalva maneuver or with standing. Palpation can be especially difficult in the obese patient. Rarely, imaging is needed to confirm the diagnosis, and computed tomography of the abdomen is the preferred technique.

Treatment

As illustrated in Fig. 7-9, operative repair of the epigastric hernia can most often be performed as a day-surgery procedure under local anesthesia. General anesthesia should be reserved for the complicated patient, a very large hernia, or the pediatric population. The herniated contents are exposed through a small midline vertical or transverse incision. The defect in the linea alba and the surrounding fascia are cleared of subcutaneous fat. Effort is made to identify a peritoneal sac protruding through the defect. If identified, a small sac can be simply inverted back within the abdominal cavity. Alternatively, a larger sac can be opened, its contents reduced, and any excess peritoneum excised. It is usually not necessary to perform formal closure of the peritoneal sac. The defect is then closed transversely with a few interrupted sutures of polypropylene or nylon, taking generous bites of surrounding fascia.

This repair usually suffices with minimal recurrence. In general, it is not necessary to reconstruct the linea alba for a single epigastric hernia. Most patients will not develop a subsequent epigastric hernia at a separate site, and repair of an epigastric hernia is a minor ambulatory procedure that can be repeated easily if necessary.

OBTURATOR HERNIA

An obturator hernia is one of the rarest forms of hernia, and most surgeons will see few in an entire career. An obturator hernia occurs when there is protrusion of intra-abdominal contents through the obturator foramen in the pelvis.

Incidence

The true incidence of obturator hernia is unknown. The largest reported series includes only 43 patients diagnosed with obturator hernia over a 30-year period.[34] It is thought that less than 1% of mechanical bowel obstructions arise from strangulated obturator hernias. The hernia is much more common in females, with a female:male ratio of 6:1. The gender discrepancy is often explained by differences in female pelvic anatomy, including a broader pelvis, a wide obturator canal, and the increase in pelvic diameter brought about by pregnancy. Most cases of obturator hernia present in the seventh and eighth decades, and this condition is clearly

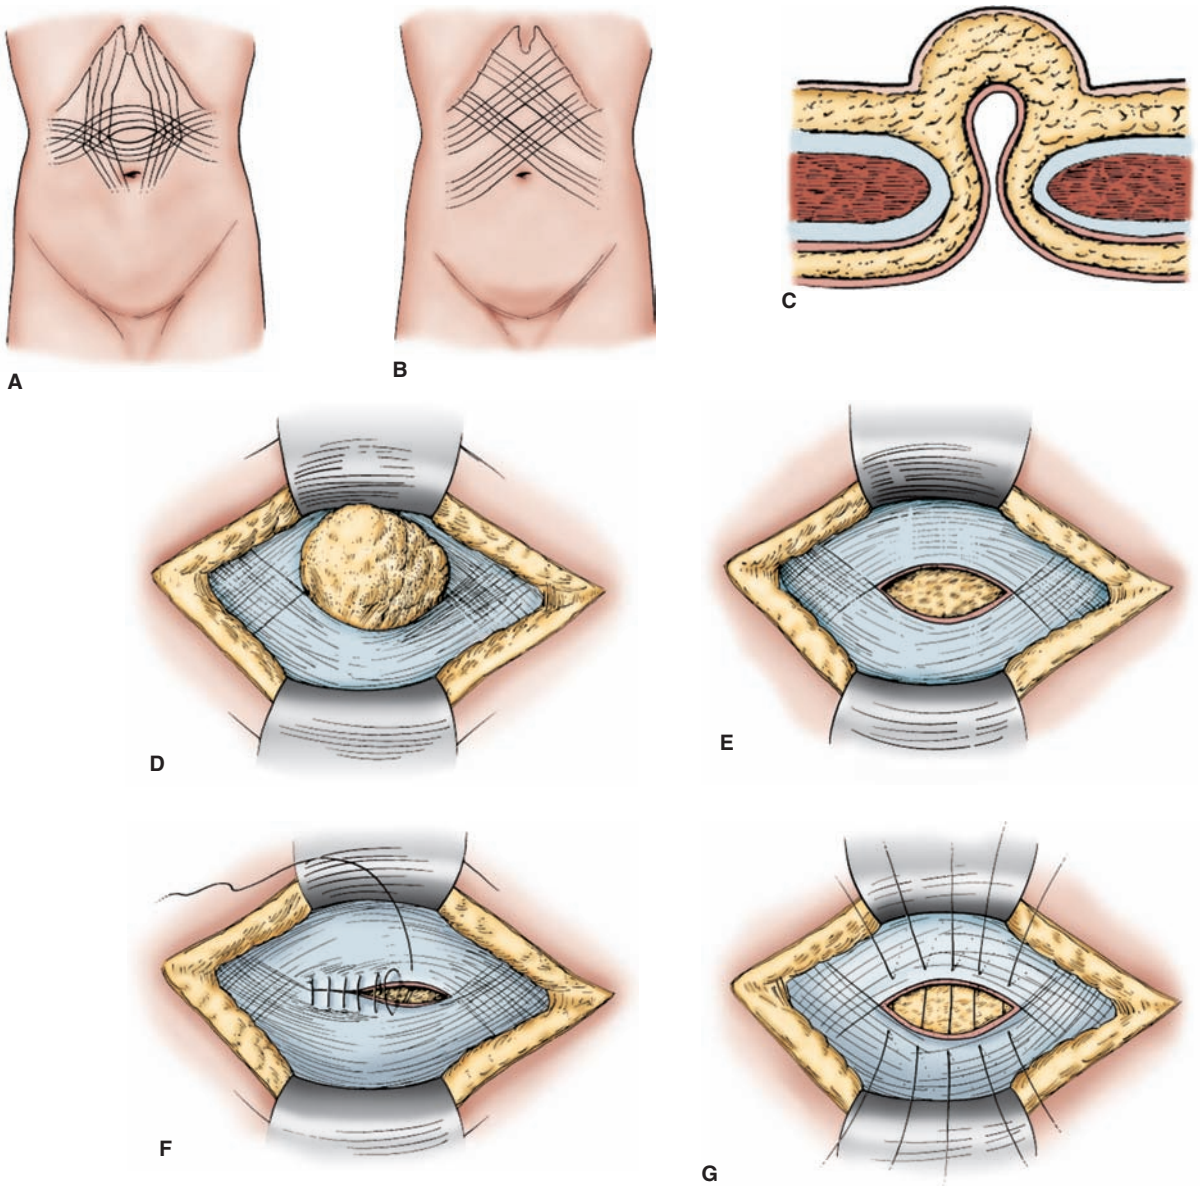

FIGURE 7-9 Repair of the epigastric hernia. **A.** The elliptical opening. **B.** The diamond-shaped opening. **C.** The small empty sac. **D.** Herniated fat exposed during dissection. **E.** Herniated fat and the sac have been excised. **F.** Repair of continuous suture technique. **G.** Repair using interrupted sutures.

associated with advanced age. Bilateral obturator hernias have been reported in 6% of cases.

Anatomy

The obturator foramen is formed by the ischial and pubic rami (Fig. 7-10). The obturator membrane covers the majority of the foramen space, except for a small portion through which the obturator vessels and nerve pass. These vessels traverse the canal to leave the abdominal cavity and enter the medial aspect of the thigh. The boundaries of the obturator canal are the obturator groove on the superior pubic ramus superiorly and the upper edge of the obturator membrane inferiorly. The canal is approximately 3 cm in length, and the obturator vessels and nerve lie posterolateral to the hernia sac in the canal. The hernia sac usually takes the shape of the canal so that it is long and narrow before ballooning in the upper thigh. The hernia lies deep to the pectineus muscle and therefore is difficult to palpate on examination. Small bowel is the most likely intra-abdominal organ to be found in an obturator hernia, although rare cases have been reported of the appendix, Meckel's diverticulum, omentum, bladder, and ovary incarcerated in the hernia.

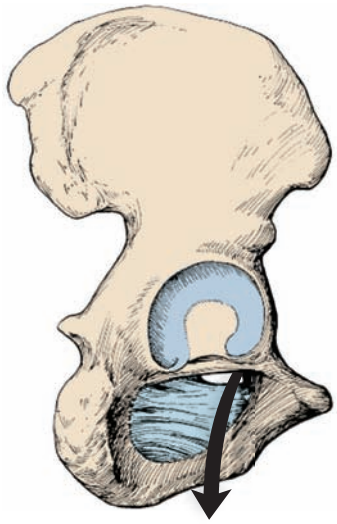

FIGURE 7-10 The direction of the obturator hernia through the obturator canal.

Clinical Manifestations

Obturator hernia is associated with four cardinal findings that assist in the difficult diagnosis. Rarely do all four physical findings occur together. The most common clinical manifestation is intestinal obstruction, which occurs in over 80% of patients. This is often in the form of acute obstruction secondary to hernia strangulation.[35] The second most common finding is the Howship–Romberg sign, seen in about one-half of patients with obturator hernia. With this sign, patients characteristically complain of pain along the medial surface of the thigh that may radiate to the knee and hip joints. The finding is likely associated with compression of the obturator nerve between the canal and the hernia sac. The adductor reflex in the thigh may also be weakened or lost secondary to motor dysfunction from an entrapped obturator nerve. The third finding, observed in 30% of patients, is a history of repeated episodes of bowel obstruction that pass quickly and without intervention. This is likely due to periodic incarceration of the hernia sac in the obturator canal. Finally, a fourth finding is a palpable mass in the proximal medial aspect of the thigh at the origin of the adductor muscles. The palpable mass is only found in an estimated 20% of patients with obturator hernia. The mass is best palpated with the thigh flexed, abducted, and rotated outward.

In rare cases, ecchymoses may be noted in the upper medial thigh due to effusion from the strangulated hernia contents. The obturator hernia mass may also be palpated laterally on a vaginal examination.

Treatment

The only treatment for obturator hernia is surgical repair. All obturator hernias should be operated on soon after diagnosis given the high risk for bowel incarceration and strangulation. There is no role for conservative management given the location of the hernia and the fact that the strangulated obturator hernia is difficult to diagnose. A preoperative diagnosis of obturator hernia is rare indeed, and a diagnosis prior to presentation with bowel obstruction is even more uncommon. The typical case of obturator hernia presents as an acute small bowel obstruction with evidence of ischemic bowel on examination, laboratory analyses, or imaging. Therefore, obturator hernia repair is often performed as a surgical emergency via a midline laparotomy.

There are three general operative approaches for obturator hernia repair: the lower midline transperitoneal approach, the lower midline extraperitoneal approach, and the anterior thigh exposure.

The lower midline transperitoneal approach is the most common method for repair of obturator hernias since most cases are encountered unexpectedly during exploratory laparotomy for small bowel obstruction of unknown etiology. Following laparotomy, the dilated small bowel is run deep into the pelvis where it is found to enter the obturator canal alongside the obturator vessels and nerve. A careful attempt should be made to reduce the incarcerated bowel with gentle traction. This maneuver may be augmented by palpation on the medial inner thigh to push the hernia sac into the abdominal cavity from the outside. This is difficult to perform without assistance since the thigh is rarely sterilely prepared for the exploratory laparotomy unless a preoperative diagnosis of obturator hernia has been made. The pelvic side of the obturator canal has a rigid opening that cannot be digitally dilated, making reduction of the hernia sac more difficult. If traction alone does not allow reduction of the bowel, the obturator membrane can be carefully incised from anterior to posterior to facilitate exposure. Care should be taken to avoid injury to both the incarcerated bowel and the obturator vessels. If these maneuvers are unsuccessful, a counter incision can be made in the medial groin to facilitate reduction from both sides of the canal. Once the hernia has been reduced, the intestine is assessed for viability and resected as needed. The hernia opening is then closed around the obturator vessels with a running layer of polypropylene or nylon suture applied in the thin layer of fascia that encircles the inner circumference of the canal. Alternatively, in a clean case without bowel contamination, a piece of mesh can be placed over the obturator foramen. Some hernia surgeons suture the mesh to Cooper's ligament to avoid migration.

The midline extraperitoneal approach is used when the diagnosis of obturator hernia has been made preoperatively. It allows complete exposure of the opening of the obturator canal. The incision is made in the midline from the umbilicus to the pubis. The preperitoneal plane is entered deep to the rectus muscle, and the bladder is peeled from the peritoneum. The space is opened so that the superior pubic ramus and the obturator internus muscle are exposed. The hernia sac is seen as a projection of peritoneum passing inferiorly into the obturator canal. The sac is incised at the base, the contents are reduced, and the neck of the sac is transected. Any remaining distal sac in the canal is extracted by traction or

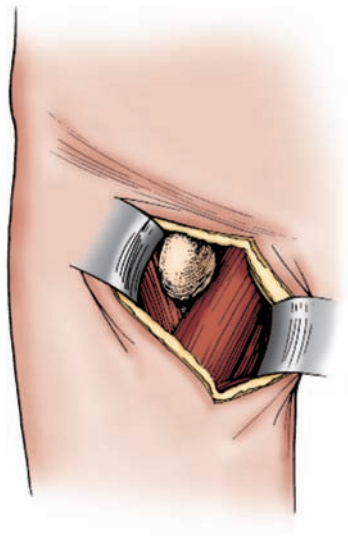

FIGURE 7-11 The thigh approach for repair of the obturator hernia.

with long forceps. The internal opening to the obturator canal is closed with a continuous suture as described above. The bites of tissue should include the periosteum of the superior pubic ramus and the fascia on the internal obturator muscle. Care must be exercised at all times to avoid injury to the obturator vessels and nerve that run alongside the hernia defect. In addition to or in place of the suture closure of the obturator defect, preperitoneal mesh placement has been described to cover the defect.

The thigh approach begins with a vertical incision in the upper medial thigh placed along the adductor longus muscle (Fig. 7-11). The muscle is retracted medially to expose the pectineus muscle, which is cut across its width to expose the sac. The sac is carefully incised, the contents inspected and reduced if viable, and the sac is excised. The hernial opening is closed with a continuous suture layer. If the bowel contents within the hernia sac do not appear viable, it is difficult to perform an adequate small bowel resection through the thigh incision and therefore midline laparotomy is usually performed.

Laparoscopic transperitoneal and extraperitoneal approaches have been recently described for obturator hernia repair with placement of prosthetic mesh to close the obturator opening.[36]

Results

Mortality after obturator hernia repair has been much higher than with other hernias because it is associated with acute bowel obstruction in an elderly population with multiple comorbidities. Recent data show a mortality of less than 5% and a 25% incidence of small bowel resection during obturator hernia repair.[34] These reports emphasize the benefit in accuracy in the modern era afforded by computed tomographic imaging techniques. Recurrence rates are low in published series, although long-term follow-up has proved difficult in this patient population.

PERINEAL HERNIAS

Hernias of the perineum are rare and composed of protrusions of the intra-abdominal contents through a weakened pelvic floor. They may also be termed pelvic hernias, ischiorectal hernias, pudendal hernias, subpubic hernias, or hernias of the pouch of Douglas. Perineal hernias should be differentiated from the more common rectocele or cystocele, which are related to pelvic floor relaxation, most often from childbirth, and do not represent true hernias.

Primary perineal hernias are extremely rare. The first reported case was by Scarpa in 1821. Secondary, or postoperative, perineal hernias are more commonly seen and occur in patients status postabdominoperineal resection in which the pelvic musculature is dissected to resect the distal rectum.

Etiology

Primary perineal hernias occur in the older population, usually between the fifth and seventh decades of life. They are at least five times more common in women than in men, and this is thought to be associated with the broader pelvic floor in the female and long-term effects of pregnancy and childbirth. Factors that may predispose to a primary perineal hernia include a deep or elongated pouch of Douglas, obesity, chronic ascites, history of pelvic infection, and obstetric trauma.

Postoperative perineal hernia may occur in patients who have undergone abdominoperineal resection or pelvic exenteration. It is thought to form as a result of excision of the levator ani musculature and its surrounding fascia with incomplete repair of the pelvic floor. An excision of the coccyx is thought to be an additional aggravating factor in hernia formation. As in primary perineal hernias, women are affected more often than men. The condition, while more common than the primary perineal hernia, remains rare.

Anatomy

The pelvic floor is formed by the levator ani and iliococcygeus muscles and their fascia. The pelvic outlet is bounded by the pubic symphysis and the subpubic ligament anteriorly, the pubic rami and ischial tuberosities laterally, and the coccyx and sacrotuberous ligaments posteriorly. The outlet is divided into anterior and posterior divisions by the superficial transversus perinei muscles. The anterior space is termed the urogenital triangle, and the posterior space is termed the ischiorectal fossa. Anterior and posterior perineal hernias are named according to the location of the hernia defect and subsequent sac protrusion, as shown in Fig. 7-12.

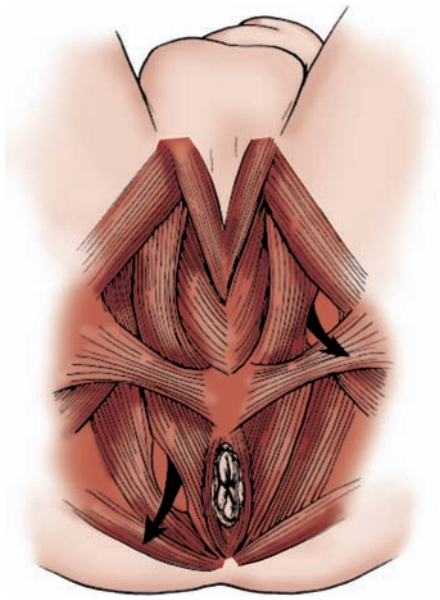

FIGURE 7-12 The anatomy of the perineal hernia showing the location of both anterior and posterior defects.

The anterior perineal hernia occurs almost exclusively in women. The sac enters in front of the broad ligament and lateral to the bladder, emerging anterior to the transversus perinei musculature. The sac may pass between the ischiopubic bone and the vagina, thereby producing a swelling in the posterior portion of the labia majus. Posterior perineal hernias are found in both genders but remain more common in women. In men, the hernia sac emerges between the bladder and the rectum to present as a bulge in the perineum. In women, the hernia enters between the rectum and the uterus to pass posteriorly to the broad ligament. In this space, the hernia can push forward to present as a bulge in the posterior vagina or emerge posteriorly into the rectum. The hernia can pass through the levator ani muscle or between it and the iliococcygeus muscle. A lateral pelvic hernia may occur through the hiatus of Schwalbe when the levator ani muscle is not firmly attached to the internal obturator fascia. This type of perineal hernia can present anteriorly in the labium majus or posteriorly in the ischiorectal fossa.

Clinical Manifestations

The patient with a perineal hernia most often complains of a soft protuberance that is reduced in the recumbent position. In cases of anterior perineal hernia, minor urinary retention or discomfort may be reported. A soft bulge may be noted in the posterior vagina or the labia, thereby interfering with labor or intercourse. In posterior perineal hernias, the patient may describe a mass protruding between the gluteus muscles, thereby making sitting difficult after the hernia has emerged in a standing position. The patient may rarely complain of constipation or the feeling of incomplete defecation.

In general, symptoms from a perineal hernia are mild, and strangulation is rare since the hernia defect in the pelvic floor is large and surrounded by soft tissue and atrophied musculature. Rectal prolapse may be confused with a posterior perineal hernia, although the two can exist concomitantly. The perineal hernia, even when the defect involves the posterior pelvic floor, will present as a bulge anterior to the prolapsed rectum.

Treatment

Three options for repair of the perineal hernia exist including the transperitoneal, perineal, and the combined approaches. The transperitoneal approach is the preferred method for complete repair. In this technique, a lower midline abdominal incision is performed and the bowel retracted out of the pelvis with the patient in the Trendelenburg position. A defect in the muscular lining of the pelvic floor will be noted, and any remaining bowel in the defect can usually be easily reduced. The sac is everted and excess sac tissue can be excised. While small defects in the pelvic floor can be closed with interrupted sutures of nylon or polypropylene, this is usually not an adequate repair given the poor strength of the atrophied tissue that often surrounds the hernia defect. Therefore, a repair with a large piece of nonabsorbable mesh is preferred and is usually tacked down to the pelvic floor tissues with interrupted nonabsorbable monofilament sutures.

The perineal approach to hernia repair is more direct and avoids a laparotomy but suffers from inadequate exposure of the actual hernia defect. In this technique, a transverse or longitudinal incision is made directly over the site of the hernia bulge. The sac is identified and dissected free of its attachments to the surrounding pelvic musculature and fascia. The sac is then excised and its contents are reduced within the abdominal cavity. The defect is repaired with interrupted nonabsorbable suture, as the exposure is usually not wide enough for proper placement of mesh. While this approach may be suitable for a small hernia defect in an unhealthy patient, the risk of recurrence is high.

In extraordinary cases in which the hernia contents cannot be reduced during a transperitoneal repair, a combined approach with dissection from the perineum can be considered. The actual repair of the hernia defect should take place from within the abdomen to obtain optimal exposure and facilitate placement of mesh to reinforce the closure.

Postoperative perineal hernia repairs may also be repaired by either a transperitoneal or perineal approach. However, the transperitoneal approach is preferred in this scenario, as the hernia contents may be difficult to completely reduce secondary to postoperative adhesion formation. In addition, given the previous operative dissection, the pelvic floor is already weakened and mesh placement is often necessary to achieve an adequate, tension-free closure of the defect.

SPIGELIAN HERNIA

A spigelian hernia occurs along the semilunar line, which traverses a vertical space along the lateral rectus border from the costal margin to the pubic symphysis. Adriaan van der Spieghel (1578–1625), a pupil of Fabricius of Padua and a professor of anatomy and surgery, was the first to accurately describe the semilunar line. He described the spigelian fascia as the aponeurotic structure between the transversus abdominis muscle laterally and the posterior rectus sheath medially. This fascia is what makes up the semilunar line, and it is through this fascial layer that a spigelian hernia forms.

Spigelian hernia is well described, and almost 1000 cases have been reported in the medical literature. It is likely that more of these hernias will be diagnosed, as the spigelian hernia is readily seen on computed tomography scans as well as laparoscopic views of the anterior abdominal wall.

Anatomy

In practice, the semilunar line is taken as the lateral border of the rectus sheath. Spieghel originally intended this structure to represent the line of transition from the muscular fibers of the transversus abdominis muscle to the posterior aponeurosis of the rectus. The semilunar line runs from the ninth rib cartilage superiorly to the pubic tubercle inferiorly. The spigelian fascia varies in width along the semilunar line, and it gets wider as it approaches the umbilicus. The widest portion of the spigelian fascia is the area where the semilunar line intersects the arcuate line of Douglas (the linea semicircularis; Fig. 7-13). It is in this region, between the umbilicus and the arcuate line, where more than 90% of spigelian hernias are found.[37] It is thought that since the spigelian fascia is widest at this point, it is also weakest in this region. Below the arcuate line, all of the transversus abdominis aponeurotic fibers pass anterior to the rectus muscle to contribute to the anterior rectus sheath, and there is no posterior component of the rectus sheath. The rearrangement of muscle and fascial fibers at the intersection of the arcuate and semilunar lines is thought to cause an area of functional weakness that is predisposed to hernia formation. Hernias at the upper extremes of the semilunar line are rare and usually not true spigelian hernias since there is little spigelian fascia in these regions.

As the hernia develops, preperitoneal fat emerges through the defect in the spigelian fascia bringing an extension of the peritoneum with it (Fig. 7-14). The hernia usually meets resistance from the external oblique aponeurosis, which is intact and does not undergo rearrangement of

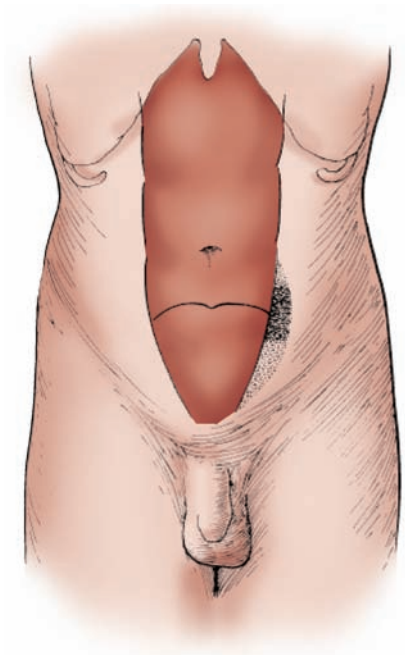

FIGURE 7-13 Anatomy of the spigelian hernia and the sites of most common occurrence.

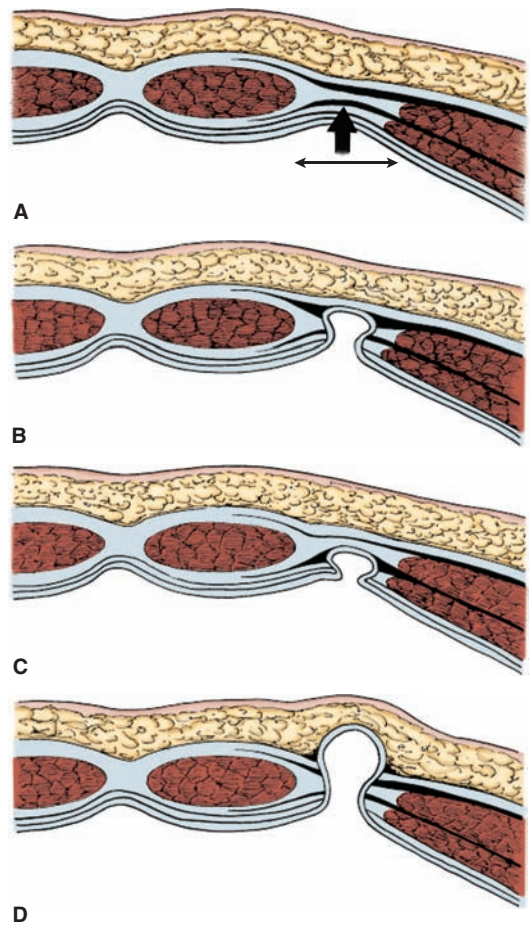

FIGURE 7-14 The spigelian hernia. **A.** Breaching the spigelian fascia. **B.** The most common type has passed through the transversus abdominis and the internal oblique aponeuroses and is spreading out in the interstitial layer posterior to the external oblique aponeurosis. **C.** The less common type in the interstitial layer between the transversus abdominis aponeurosis and the internal oblique muscle. **D.** The least common subcutaneous type.

its aponeurotic fibers at the arcuate line. For this reason, almost all spigelian hernias are interparietal in nature, and only rarely will the hernia sac lie in the subcutaneous tissues anterior to the external oblique fascia. This fact makes the accurate diagnosis of spigelian hernias more challenging. The hernia also cannot develop medially due to resistance from the intact rectus muscle and sheath. Therefore, a large spigelian hernia is most often found lateral and inferior to its defect in the space directly posterior to the external oblique muscle.

Clinical Manifestations

The patient most often presents with a swelling in the middle to lower abdomen just lateral to the rectus muscle. The patient may complain of a sharp pain or tenderness at this site. The hernia is usually reducible in the supine position. However, up to 20% of spigelian hernias will present incarcerated, and for this reason operative repair is mandatory once the hernia is confirmed on diagnosis. The reducible mass may be palpable, even if it sits below the external oblique musculature.

When the diagnosis is unclear, radiologic imaging may be necessary. Ultrasound examination has been shown to be the most reliable and easiest method to assist in the diagnostic workup. Testa and colleagues found that abdominal wall ultrasonography was accurate in 86% of cases of spigelian hernia.[38] If the hernia is fully reduced during examination and no mass is palpable, ultrasound evaluation can show a break in the echogenic shadow of the semilunar line associated with the fascial defect. Ultrasound can also identify the nonreduced hernia sac passing through the defect in the spigelian fascia. Computed tomographic scanning of the abdomen will also confirm the presence of a spigelian hernia. As described above, the anatomy of the spigelian hernia should make it readily apparent on laparoscopic evaluation of the anterior abdominal wall.

Treatment

The treatment for spigelian hernia is operative repair once the diagnosis has been confirmed, given the risk for incarceration. This is usually performed under general anesthesia given the need for splitting of the external oblique muscle. A transverse incision is made directly over the palpable mass or fascial defect. A hernia in the subcutaneous space will reveal itself immediately, and an interparietal hernia will require further dissection. In this way, the external oblique fascia is incised and the external oblique muscle is split to identify the sac posterior to the muscle. The sac is freed from its surrounding attachments until the neck is isolated. The sac is opened, the intra-abdominal contents reduced, and the sac is either excised if sizable or simply inverted into the intra-abdominal cavity. Suturing the medial and lateral edges of the internal oblique and transversus abdominis aponeuroses closes the fascial defect. Essentially, this approximates the internal oblique and transversus fascia laterally to the rectus sheath medially. Prosthetic mesh is not required for this repair, although the use of mesh plugs to close the hernia defect has been described.[38] Recurrence is uncommon and the operation is usually well tolerated.

LUMBAR HERNIA

The lumbar region is bordered by the twelfth rib superiorly, the iliac crest inferiorly, the erector spinae muscles of the back posteriorly, and a vertical line between the anterior tip of the twelfth rib and the iliac crest anteriorly. The region contains two anatomic triangles, through which the rare lumbar hernia can form. The inferior lumbar triangle of Petit is the more common of the two. Its anterior border is the posterior edge of the external oblique muscle, the posterior border is the anterior extent of the latissimus dorsi muscle, and the inferior border is the iliac crest (Fig. 7-15). The anterior floor of the canal formed by this triangle is the lumbar fascia. Occasionally, the lower border of the latissimus dorsi muscle overlaps the external oblique muscle, and in this setting the triangle is absent. The superior lumbar triangle of Grynfeltt (see Fig. 7-15) is deeper and is bounded by the twelfth rib and the serratus posterior inferior muscle, the posterior border of the internal oblique muscle, and by the quadratus lumborum and erector spinae muscles posteriorly. The floor of the superior triangle is composed of transversalis fascia and the entire triangular space is covered posteriorly by the latissimus dorsi muscle.

Congenital lumbar hernias are rare, but case reports can be found in the literature. Lumbar hernias most commonly present in adults older than 50 years of age. Two-thirds of the cases are reported in males, and left-sided hernias are thought to be more common. Bilateral lumbar hernias have been reported. Acquired lumbar hernias have been associated with

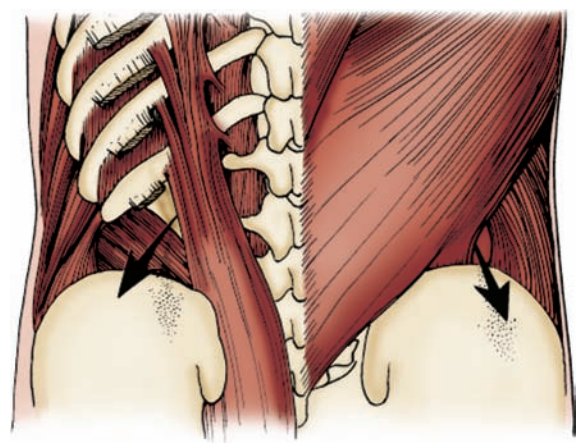

FIGURE 7-15 The anatomy of the lumbar hernia illustrating the superior and inferior lumbar triangles.

back or flank trauma, poliomyelitis, back surgery, and the use of the iliac crest as a donor site for bone grafts.

Strangulation is rare in lumbar hernias since at least two of the three boundaries for the hernia defect are soft and muscular in origin. The hernia tends to increase in size over time and may assume large proportions and overhang the iliac crest. Symptoms range from a vague dullness in the flank or lower back to focal pain associated with movement over the site of the defect. On physical examination, a soft swelling in the lower posterior abdomen will be found that is usually reducible without difficulty. The hernia will increase in size with straining or a standard Valsalva maneuver. Ultrasonographic or computed tomographic imaging is usually obtained in the patient with a suspected lumbar hernia to confirm the diagnosis.

Operative repair of the lumbar hernia is performed with the patient under general anesthesia and in a modified lateral decubitus position. A kidney rest can be used to widen the lumbar space between the twelfth rib and iliac crest. An oblique skin incision is made in the region of the hernia and the sac is identified. The dissection may require takedown of the latissimus dorsi muscle to reach the deeper superior lumbar triangle. Once the sac is identified, it is opened and the contents are carefully reduced. The empty sac can then be inverted or simply excised. While complicated procedures for lumbar hernia closure utilizing muscle flaps and grafts have been described, a small defect surrounded by healthy tissue can usually be closed primarily with an interrupted or continuous layer of nylon or polypropylene suture. If a large defect is found or the tissues appear weak, the hernia may be repaired with a large sheet of prosthetic nonabsorbable mesh placed between the peritoneal layer and the abdominal wall musculature. To prevent migration, the mesh is usually fixed to the peripheral tissues by a series of interrupted nonabsorbable sutures.

Recently, minimally invasive approaches to repair of lumbar hernias have been reported. These involve either intraperitoneal laparoscopy necessitating takedown of the lateral peritoneal reflection of the colon to facilitate exposure of the hernia defect,[39] or retroperitoneoscopy in which the lateral retroperitoneal space is entered and insufflated.[40] Initial results with the minimally invasive approaches are encouraging, although these case series contain small numbers of subjects.

SCIATIC HERNIA

A sciatic hernia is defined as a protrusion of peritoneum and intra-abdominal contents through the greater or lesser sciatic notch (Fig. 7-16). The greater sciatic notch is traversed by the piriformis muscle, and hernia sacs can protrude either superior or inferior to this muscle. There are classically three variants of the sciatic hernia that are defined by their anatomic site of exit from the pelvis. The suprapiriform defect is by far the most common and is thought to represent 60% of cases of sciatic hernia. Infrapiriform hernias are found in approximately 30% of cases, and subspinous hernias (through the lesser sciatic foramen) occur in 10% of cases.

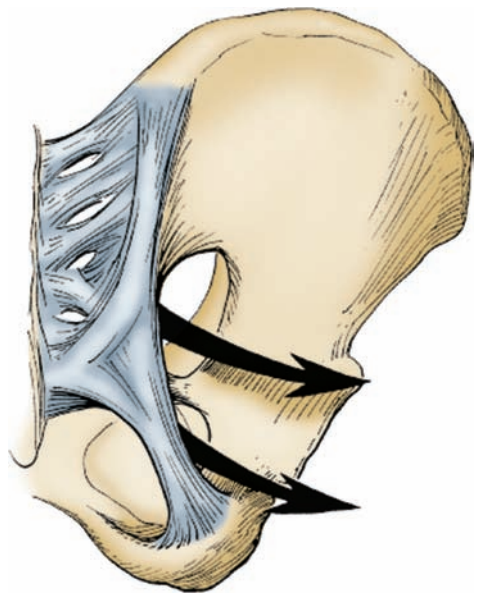

FIGURE 7-16 The superior and inferior sciatic foramina and the direction of sciatic hernias.

The hernia sac passes laterally, inferiorly, and ultimately posteriorly to lie deep to the gluteus maximus muscle. While case reports of this rare hernia exist in the pediatric age group, the majority of sciatic hernias are found in the adult population. The patient complains of pain deep in the buttock that may radiate down the leg in the sciatic nerve distribution. Alternatively, the patient may report a lump in the buttock or infragluteal area that is painful and tender. Rarely, ureteral obstruction occurs because the ipsilateral ureter is contained within the hernia contents. Physical examination often reveals a reducible mass deep to the gluteus maximus, although the actual hernia defect is rarely palpable given the anatomic depth and the thickness of the buttock musculature. Incarceration of the hernia can occur, and sciatic hernia has been known to present with bowel obstruction.

The treatment of a sciatic hernia is surgical. Both transperitoneal and transgluteal approaches have been described in depth, and the transperitoneal technique is preferred in the setting of bowel obstruction or incarceration. Rarely, a combined approach will be necessary to fully reduce the hernia contents. Even in the setting of incarceration, the bowel can usually be reduced from within the hernia with gentle traction. When necessary with the transperitoneal approach, the defect can be dilated with manual manipulation or the piriformis muscle may be partially incised. Full visualization of the structures is necessary and great care must be taken to avoid injury to the many nerves and vessels found in this region. After the sac has been excised, the defect is repaired using interrupted nonabsorbable suture or a prosthetic mesh plug or patch for larger hernia defects.

The posterior or transgluteal technique can be utilized for uncomplicated, reducible sciatic hernias diagnosed preoperatively. With this method the patient is placed in the prone position.

The gluteus maximus muscle is approached through a gluteal incision starting at the posterior edge of the greater trochanter and is detached at its origin to expose the hernia defect. This exposure allows visualization of the piriformis muscle, the gluteal vessels and nerve, and the sciatic nerve. The sac is then isolated and opened. Following reduction of the hernia contents, the defect can be sutured closed using large nonabsorbable suture or repaired with a prosthetic mesh.

POSTOPERATIVE VENTRAL WALL (INCISIONAL) HERNIA

A postoperative ventral abdominal wall hernia, more commonly termed incisional hernia, is the result of a failure of fascial tissues to heal and close following laparotomy. Such hernias can occur after any type of abdominal wall incision, although the highest incidence is seen with midline and transverse incisions.[41] Postoperative ventral hernias following paramedian, subcostal, McBurney, Pfannenstiel, and flank incisions have also been described in the literature. Laparoscopic port sites may also develop hernia defects in the abdominal wall fascia.

As the approximated fascial tissue separates, the bowel and omentum herniate through the opening, covered by a peritoneal sac. These hernias can increase in size to enormous proportions, and giant ventral hernias can contain a significant amount of small or large bowel. At the extreme end of the ventral hernia spectrum is the giant incisional hernia that leads to loss of the abdominal domain, which occurs when the intra-abdominal contents can no longer lie within the abdominal cavity.

Incidence and Etiology

Incisional hernias have been reported in up to 20% of patients undergoing laparotomy. Modern rates of incisional hernia range from 2% to 11%.[42–44] It is estimated that approximately 100,000 ventral incisional hernia repairs are performed each year in the United States alone. The incidence seems to be lower in smaller incisions so that laparoscopic port site hernias are much less common than hernias following large midline abdominal incisions. While it was once believed that the majority of incisional hernias presented within the first 12 months following laparotomy, longer-term data indicate that at least one-third of these hernias will present 5–10 years postoperatively.

Multiple risk factors exist for the development of an incisional hernia. Some of these risks are under the control of the surgeon at the initial operation, while many others are patient specific or related to postoperative complications. Patient-specific risks for postoperative ventral hernia include advanced age, malnutrition, presence of ascites, corticosteroid use, diabetes mellitus, cigarette smoking, and obesity.[41,45–47] Emergency surgery is known to increase the risk of incisional hernia formation. Wound infection is believed to be one of the most significant prognostic risk factors for development of an incisional hernia.[41,48] It is for this reason that many surgeons advocate aggressive and early opening of the skin closure to drain any potential infection at the fascial level. Postoperative sepsis has also been identified as a risk for subsequent incisional hernia.

Technical aspects of wound closure likely contribute to incisional hernia formation. Wounds closed under excessive tension are prone to fascial closure disturbance. Therefore, a continuous closure is advocated to disperse the tension throughout the length of the wound. In this way, 1 cm bites of fascia on either side of the incision are taken with each pass of the suture and the suture is advanced 1 cm at a time along the length of the incision. The type of incision may affect hernia formation. Studies have shown that transverse incisions are associated with a reduced incidence of incisional hernia compared to midline vertical laparotomies, although the data are far from conclusive.[46,49]

Clinical Manifestations

The patient with an incisional hernia will complain of a bulge in the abdominal wall originating deep to the skin scar. The bulge may cause varying degrees of discomfort or may present as a cosmetic concern. Symptoms will usually be aggravated by coughing or straining as the hernia contents protrude through the abdominal wall defect. In large ventral hernias, the skin may present with ischemic or pressure necrosis leading to frank ulceration. Presentation of the incisional hernia with incarceration causing bowel obstruction is not uncommon. This may be associated with a history of repeated mild attacks of colicky dull abdominal pain and nausea consistent with incomplete bowel obstruction.

On examination the hernia is usually easy to identify and the edges of the fascial defect can often be defined by palpation. The entire abdominal wall along the length of the incision should be inspected and palpated carefully, as multiple hernias are often present in the setting of an incisional hernia. In the obese patient with a suspected incisional hernia that cannot be confirmed on examination, computed tomography of the abdomen is the best way to visualize intra-abdominal contents within the hernia sac. In extreme instances, laparoscopy may be required to diagnose a hernia defect that only intermittently contains intra-abdominal contents.

Treatment

The treatment of ventral incisional hernia is operative repair, and three general classes of operative repair have emerged in the modern era. These techniques include primary suture repair of the hernia, open repair of the hernia with prosthetic mesh, and laparoscopic incisional hernia repair. The major sequela from operative repair of the incisional hernia is hernia

recurrence, and there are convincing data that placement of mesh to repair the hernia defect has decreased the high recurrence rate historically associated with primary suture repair to less than 25%.[50,51] Many advocates of the operation believe that laparoscopic incisional hernia repair will have the lowest rate of hernia recurrence and definitive studies are underway to assess this question.

In general, primary repair of incisional hernias can be performed for hernia defects less than 4 cm in diameter with strong, viable surrounding tissue. For larger hernias or hernias associated with multiple small defects, mesh repair is indicated. Even with mesh repair, hernia recurrence remains a significant complication. In one multicenter trial, for example, 200 patients were randomly assigned to suture or mesh repair of a primary hernia or a first recurrence of hernia at the site of a vertical midline incision.[52] The 3-year cumulative rates of recurrence among patients who had suture or mesh for repair of a primary hernia were 43% and 24%, respectively. The rates of second recurrence were 58% and 20%, respectively.

PRIMARY SUTURE REPAIR

The operation is best performed with the patient under general anesthesia to achieve full relaxation of the abdominal wall musculature. The skin is opened through the previous incision and dissection is performed through the subcutaneous tissues. Care should be taken as the level of the anterior rectus sheath is approached since portions of the sac and its contents may lie at this level. The sac is identified and cleared of its attachments to the fascia using electrocautery. In this way, any peritoneal attachments to the anterior abdominal wall in the vicinity of the hernia are taken down and the sac is fully reduced into the abdominal cavity. The fascia is then cleared of soft tissue both anteriorly and posteriorly for at least a 3–4 cm margin. This allows for a margin of healthy fascia to bring together in the midline with suture closure.

The fascia is then closed using an interrupted layer of nonabsorbable suture by taking large bites of the clean fascia on both sides of the defect. The sutures are usually placed sequentially and then tied after the entire layer of suture has been placed. The fascia is then inspected to confirm that no additional defects are present and that the repair sutures are not pulling through the tissue due to excessive tension. The skin is closed over the fascia using either staples or a running subcuticular layer. If the hernia contents have created a large pocket in the soft tissue above the anterior fascia, placement of a closed suction drain for evacuation of early seroma fluid can be considered.

If there is tension upon attempted closure of the abdominal wall, a separation of components can be performed in order to mobilize the fascia toward the midline (Fig. 7-17). This technique begins with the mobilization of the skin and soft tissue off of the underlying fascia. The fascia of the external oblique is then incised lateral to the rectus abdominis and the external oblique is dissected free from the internal oblique in a relatively avascular plane. This alone allows for significant mobilization of the abdominal wall toward the midline. Should additional mobilization be required, the posterior rectus sheath can be incised in a longitudinal fashion to allow the overlying rectus abdominis and anterior rectus sheath to slide even further toward the midline.[53] This technique allows for closure of complex or infected abdominal wounds without the need for implantation of any foreign material.

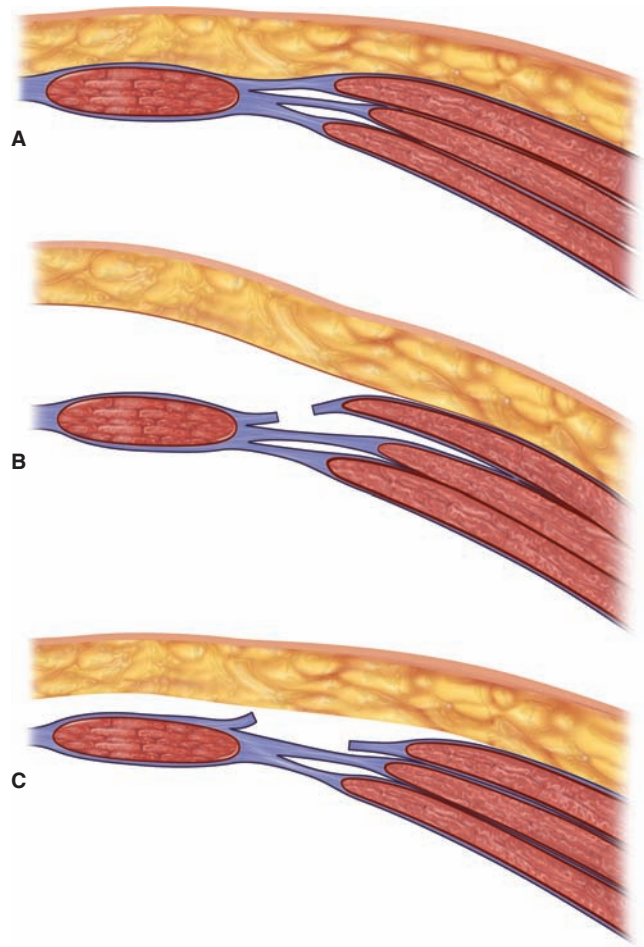

FIGURE 7-17 Separation of components of the abdominal wall to mobilize the fascia toward the midline.

Over the last 10–15 years, the introduction of component separation as a method for repairing ventral hernias has gained increasing popularity due to its conceptual purity and its overwhelming success. Recent series including those by Ko[54] has reported his experience in 200 patients who underwent this procedure over the course of slightly over 1 decade. The overall recurrence rate was 21%. Supportive polypropylene mesh was employed to cover the defect. In the process of performing this procedure, bilateral releases of the external oblique muscle are performed and the fascia is mobilized, thereby allowing medial movement of the rectus muscle. This brings the rectus muscle closer to the midline and achieves a muscular closure of the midline which can be reinforced or strengthened by the placement of either biologic or

manufactured mesh. Mesh is not a necessary portion of the component separation technique although it is frequently used. The variety of different types of mesh includes polypropylene, polyester, and other both biologic and nonbiologic materials. Primary repair using no mesh but using the component separation technique had a 22.5% recurrence rate, while recurrence rates using cadaveric biomesh were 33.3%. Those in whom low-weight polypropylene was used had a 0% recurrence rate. Part of the study looked at demographic factors and noted that elevated body mass had a significant risk of recurrence. This was true at less than a p value of 0.005 and also notable most commonly in patients with a BMI of greater than 25.

MESH REPAIR

The use of sheets of nonabsorbable prosthetic mesh placed across the incisional hernia defect and sutured to the abdominal wall is routinely employed in the modern era. It is associated with a low incidence of perioperative complications and lower rates of recurrence than open, nonmesh repairs.

Many variations of mesh repair for the incisional hernia have been described (Fig. 7-18). The mesh is cut to the shape of the hernia defect with a margin added circumferentially around the mesh to suture to healthy surrounding fascia. The mesh is sutured to the fascial layer either deep to the peritoneum or between the peritoneum and the abdominal wall. Alternative techniques have been described that suture pieces of mesh to fascia from both intra- and extraperitoneal planes.

The operation is performed under general anesthesia. The old scar is incised and the soft tissue dissected down to the level of the anterior rectus sheath. Here the defect is identified and the fascia is cleared of surrounding soft tissue attachments to allow a 3–4 cm rim of healthy fascia circumferentially. The sac is then freed from the fascia in order to reduce the hernia contents and prevent recurrence. This portion of the operation is often technically challenging, as significant adhesion formation may have occurred following the initial operation. It is often impossible to stay in an extraperitoneal plane in this situation, and dissection within the abdominal cavity may be necessary to fully excise the sac and reduce its contents. The mesh can now be placed either anterior to the fascia or posterior from within the intra-abdominal cavity. Effort should be made to protect the bowel from direct contact with the mesh patch, and a layer of omentum can often be placed between them. The mesh is sutured in an interrupted fashion in multiple sites throughout the entire circumference of the patch to ensure that any tension is distributed throughout the entire area of the repair. Large, nonabsorbable suture is used to affix the mesh to the fascia layer.

There are currently a variety of mesh products readily available for use in the repair of ventral incisional hernias. In general, these products can be grouped into those that are composed of synthetic materials and those that are composed of biologic materials. The synthetic meshes frequently incorporate either polypropylene or expanded polyfluorotetraethylene (ePTFE) in combination with some form of barrier to prevent adhesions to the bowel. While both polypropylene and ePTFE are used in the treatment of ventral hernias, they have significantly different properties. Polypropylene meshes are macroporous and allow for ingrowth of native tissue into the mesh, leading to incorporation. Conversely, ePTFE meshes are more microporous and do not promote as much ingrowth. This leads to less adhesions to ePTFE meshes, but also requires that there is adequate fixation in order to prevent disruption and thus recurrence. Biologic meshes are based on acellular dermal matrices from human, porcine, and fetal bovine sources. While the long-term outcomes for these meshes are currently being studied, the biologic meshes have been shown to be more resistant to infection than their synthetic predecessors and are more appropriate for use in infected or contaminated fields.[55]

Biologic grafts derive from two basic materials. The first is human tissue and the second is animal tissue. Their use in hernias is confined primarily to dirty or contaminated fields in which placement of a prosthetic mesh might increase the chance of infection. It is well recognized that primary closure of incisional hernias carries a high recurrence rate and that removal of prosthetic mesh in an infected field and attempts to primarily close these defects will invariably lead to recurrence. As a result, enthusiasm has recently grown for the use of biologic grafts that may enhance the repair, decrease the chances of infection, and provide a bridge to a clean wound. If recurrence subsequently develops, it can be managed with a prosthetic material. The biologic grafts have different characteristics depending on the tissue of origin. Grafts can be based on dermis, either human or porcine, or on submucosa. The dermis-based grafts are prepared in such a way as to allow collagen and elastin to remain within the matrix. Although these materials have excellent resistance to infection, they do have the distinct disadvantage of weakening over time because of elastin breakdown. This can lead to eventration, recurrence, or the possibility of pseudorecurrence, which can occur as a result of the weakening of the elastin, increased compliance, and softening of the graft. Methods that are utilized to improve the durability of these grafts are the use of glutaraldehyde and hexamethylene diisocyanate, cross-linking agents which make the material, whether it is human or porcine, more resistant to breakdown by enzymatic degradation. This leads not only to greater durability but also to increasing the susceptibility of these grafts to microbiologic attack. Cross-linking limits the ability of the host to incorporate the graft and make it essentially a part of the native tissue.

LAPAROSCOPIC REPAIR

The evolution of ventral hernia repair has advanced from open mesh repair to the application of mesh repair to the laparoscopic approach. In this technique, the defect is repaired posteriorly and no dissection within the scarred layer of anterior fascia is required. The laparoscopic approach may also allow for identification of additional hernia defects in the anterior abdominal wall during the repair.

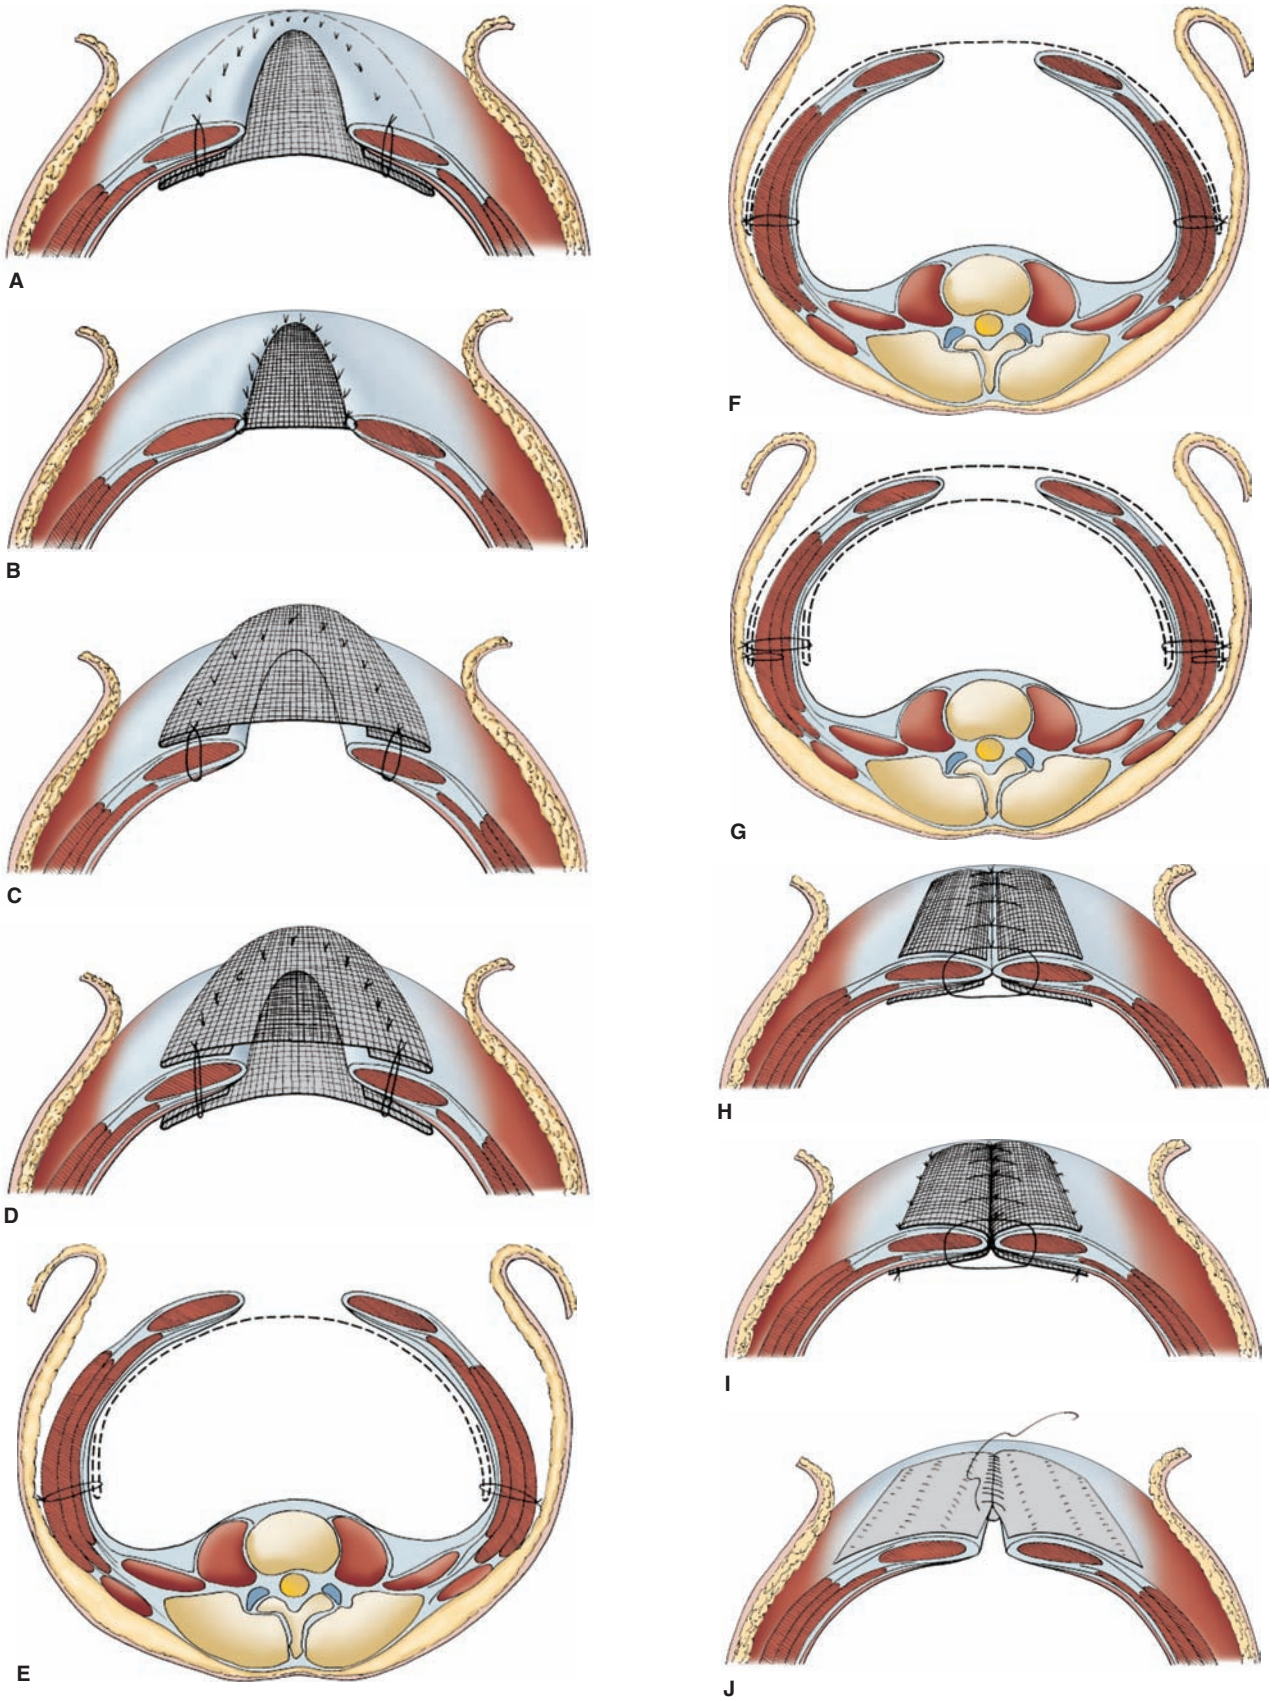

FIGURE 7-18 Variations of prosthetic mesh repair for incisional hernia. **A.** Underlay graft. **B.** Inlay graft. **C.** Overlay graft. **D.** Combined overlay and underlay grafts. **E.** Large underlay graft. **F.** Large overlay graft. **G.** Combined large overlay and underlay grafts. **H.** Reinforcing onlay and underlay strips of mesh. **I.** Wrap-around mesh reinforcement of wound edges. **J.** Two sheets of mesh sutured to abdominal wall, then sutured to each other to draw together the edges of the wound.

One of the challenging aspects of laparoscopic repair is port access into a peritoneal cavity that has been previously operated upon. In general, access can be obtained for needle insufflation via the left upper quadrant, placing the port along the anterior axillary line to avoid injury to the more laterally positioned spleen. Once insufflation has been achieved and instruments have been inserted, the next challenge is the extensive laparoscopic lysis of adhesions that is often necessary to gain exposure to the entire hernia defect. The goal of the adhesiolysis is to provide a 3–4 cm circumferential area of overlap for the mesh patch beyond the edge of the ventral hernia defect.

After the appropriate adhesions have been taken down and the fascial edges of the defect confirmed, the sac is retracted and excised from within the hernia. The outline of the defect is then drawn on the anterior abdominal wall. Edges of the defect at the skin level can be confirmed from within the abdominal cavity using the laparoscope. The mesh is then cut to fit this defect with a margin of 3–4 cm on each side to provide adequate coverage and to minimize tension. Nonabsorbable sutures are placed around the circumference of the mesh and tied, but not cut. The mesh is rolled so that the anterior surface lies inside the roll, and the mesh is inserted into the abdomen through a large 10- or 12-mm port.

Once inside the abdominal cavity, the mesh is unrolled and positioned. A transfascial suture passer can be introduced through small stab incisions placed around the marked border of the defect. The suture passer retrieves the long ends of the suture that has been previously placed in the mesh, and the ends are tied at the skin level at 4–6 points around the repair and buried with the subcutaneous tissue in the stab incision. This affixes the mesh patch to the fascia layers around the circumference of the patch. After all sutures have been tied and cut, laparoscopically placed tacks or staples can be used to further fasten the mesh to the anterior abdominal wall. Whether the strength of the repair is imparted by the transfascial sutures or the tacks or both remains controversial.

Complications

The major complication from open, nonmesh incisional hernia repair is recurrence. Rates of recurrence in this type of repair have approached 30–50% in some series. The risk of recurrence is likely related to the tension placed on the repair in large hernias, and for this reason, incisional hernias with a diameter greater than 4 cm should be repaired with mesh.

Open incisional hernia repairs using mesh can also suffer from hernia recurrence, although the risk is far less than that of the nonmesh technique. Several studies have shown that the risk of recurrence in incisional hernia repair with mesh is approximately 10%. Recurrence in this setting is usually secondary to the appearance of an additional, unrecognized hernia site or an improperly placed prosthesis that pulls away from the fascia edge of the repair. Hematoma or seroma formation may occur in the cavity left behind following a hernia repair. For this reason, closed suction drains may be placed if a large amount of dead space remains following the repair. The drains should be managed judiciously, however, since they may be placed in proximity to the prosthetic mesh, thereby increasing the chance of secondary infection. Wound infection and infection of the mesh can be grave complications, often necessitating removal of the mesh and application of an allogenic tissue graft. Wound infection in open mesh repairs is thought to approximate 5%.

The laparoscopic approach to incisional hernia repair shares the general complications of laparoscopy, including the potential for port-site herniation, vascular injury from trocar placement, and inadvertent bowel injury during laparoscopic adhesiolysis. The mesh placed during laparoscopic repair can also be prone to infection, although the incidence of mesh infection appears to be lower in laparoscopic than open mesh techniques. This may be related to the extensive tissue dissection required to place the mesh in the open procedure. Several nonrandomized studies have shown that the laparoscopic approach is associated with a low incidence of hernia recurrence, in the range of 0–11%.[56] Seroma formation in the retained sac above the mesh may occur but usually resolves spontaneously.

There are numerous prospective studies that provide data for the individual techniques, but data are scarce in the comparison between open and laparoscopic mesh repairs for incisional hernia. Nonrandomized, retrospective studies have provided ample evidence that the laparoscopic approach is associated with fewer postoperative complications, a lower incidence of wound and mesh infections, a lower rate of recurrence in long-term follow-up, and shorter in-hospital stays.[57] A recent meta-analysis pooled results from five separate randomized controlled trials comparing laparoscopic and open incisional hernia repairs.[58] The authors found no significant differences in recurrence rates between the two groups, but the open repair was associated with significantly longer length of stay and postoperative complications compared to the laparoscopic group. Clearly, more studies are required to definitively determine which procedure is optimal; however, at this time both open and laparoscopic techniques appear to be safe and effective in the treatment of incisional hernias.

PERSPECTIVE ON HERNIAS: LAPAROSCOPIC INCISIONAL HERNIA

Alex Escalona • David W. Rattner

INTRODUCTION

Incisional hernias are an all too frequent complication of laparotomies and surgeons spend a significant part of their practice repairing such defects. Leblanc and Booth published the first report of laparoscopic incisional hernia repair in 1993.[1] Over the course of time, this approach has gained popularity with patients who seek a "minimally invasive" solution to their hernia problem and with surgeons who believe that the laparoscopic approach offers advantages over traditional repairs.

After nearly two decades of experience with laparoscopic incisional hernia repair, there is a surprising paucity of good data clearly proving the benefits of this technique over standard open surgery. In this chapter, we will review the published experience, technical factors needed for successful laparoscopic repairs, the costs, and long-term results of laparoscopic ventral hernia repair (LVH). Since most ventral hernias are small and easy to repair primarily, we will focus on incisional hernias and use the term LVH to cover both types of defect.

RATIONALE FOR LAPAROSCOPIC VENTRAL HERNIA REPAIR

Although the pioneers of LVH felt that this approach would be less invasive and therefore less painful than traditional surgery, many other advantages became apparent as the procedure was developed. Traditional incisional hernia repairs—even when performed with mesh—have a relatively high failure rate. Some of the failures are due to patient-related factors such as obesity, steroid use, tobacco abuse, or abdominal stressors such as chronic cough. However, one of the most common technical causes of failure is failure to identify all fascial defects. Many incisional hernias have multiple components, some of which are not apparent on physical examination. If a surgeon fails to repair all the defects, failure (occasionally described as a new hernia defect in proximity to the prior repair) is almost certain to occur. LVH offers a superior view of the fascial defect and hence reduces the likelihood that a surgeon will fail to identify the extent of the problem that needs to be fixed. This is particularly helpful when the fascia is attenuated. An additional advantage is gained in patients who have undergone surgery for abdominal neoplasms in that peritoneoscopy may occasionally discover signs of recurrent disease. Finally, in patients whose incisions are deeply scarred, approaching the defect transperitoneally can avoid a tedious dissection of the subcutaneous layers. Likewise, if a patient has had a prior wound infection, the transperitoneal approach delivers the mesh prosthesis through a clean field and may reduce the risk of recurrent infection.

There are disadvantages of LVH that need to be considered when recommending treatment to a patient. Since very little is done to the subcutaneous tissue, LVH often leaves a large dead space that can result in a seroma. Even if seroma formation is prevented, excess skin and fat can lead to a poor cosmetic outcome following repair of large defects. Some patients in whom LVH is attempted may have severe adhesions necessitating a tedious and occasionally hazardous adhesiolysis. Inadvertent bowel injury is probably the leading cause of mesh infection in LVH and can be a devastating complication if it is not recognized and repaired promptly. Lastly, some locations in the abdomen preclude transfascial fixation of the mesh and hence may be more prone to failure of the repair than when the defect is centrally located (Table 8A-1).

TECHNIQUE

It is well established that the use of prosthetic mesh reduces the rate of long-term recurrence in open incisional hernia repairs compared with suture repair alone.[2,3] Although suture hernioplasty has been described in laparoscopic surgery, it is technically more difficult than mesh hernia repair and violates

TABLE 8A-1: PROS AND CONS OF LAPAROSCOPIC VENTRAL HERNIA REPAIR

Pros
Accurately identifies all fascial defects
May identify unsuspected intraperitoneal pathology
Approaches fascia through a "clean field"
Cons
Not possible to revise contour of abdominal wall
Adhesiolysis may be difficult with increase potential for enterotomy
Hard to get good fixation for defects at margins of abdominal cavity

the principle of a tension-free technique.[4] Therefore, laparoscopic hernia repair is almost uniformly performed with a mesh prosthesis.

In LVH, the mesh is placed in direct contact with the viscera. As in open inlay repairs, this carries the risk of development of chronic inflammation, fistula, infection, and mesh migration.[5] To minimize these risks, dual-sided mesh prostheses have been developed and should be utilized in LVH. These implants are coated with materials designed to prevent adhesion formation on the side exposed to the viscera. Animal studies have demonstrated good short-term results; nevertheless, there are few human studies evaluating long-term results that compare different types of mesh.[6,7]

Both open repair and LVH require clear identification of the hernia defect to place and fix the mesh properly. LVH replaces a large incision and an extensive dissection of the subcutaneous tissue with adhesiolysis, peritoneal dissection, and intra-abdominal reduction of the contents of the hernia sac. Paradoxically this minimally invasive approach may be more invasive than an open repair because of the extent of peritoneal and visceral trauma. This paradox may explain in part the limited advantage (if any) of LVH in reducing postoperative pain.[8,9] Indeed, in most of the randomized controlled trials (RCTs) and meta-analyses where postoperative pain and/or quality of life were evaluated, no significant differences between open repair and LVH were identified.[10,11] Different techniques of laparoscopic mesh fixation have also been evaluated with no significant differences in postoperative pain or quality of life.[12]

When extensive intra-abdominal dissection is required in the laparoscopic approach to access and/or identify the defect and place the mesh, it almost certainly accounts for the higher number of bowel injuries observed in laparoscopic technique compared with open surgery.[8,10,13,14] In LeBlanc's 2007 review article, the overall incidence of enterotomy secondary to incisional and ventral hernia repairs was 1.78% (72 out of 3925 patients). Patients who sustained this complication had an increase in mortality rate compared with those who did not have an enterotomy from 0.05% to 2.8%.[15]

As with any new procedure, the learning curve needs to be surmounted. A common mistake a novice surgeon is apt to make is failure to get adequate overlap of the mesh with normal tissue in covering the defect. While adhesiolysis can be performed at typical pneumoperitoneum pressures of 15 mm Hg, sizing the mesh should be done with the abdomen nearly deflated. If the mesh is measured with the abdomen fully distended, it will be lax once the pneumoperitoneum is released and patients may feel as if their hernia was never fixed! As Brooks et al point out in their chapter, transfascial fixation sutures are a vital component for good mesh fixation. The larger the mesh, the more sutures are needed in our opinion. Tacks should be placed between the fixation sutures to prevent herniation of viscera between sutures. Postoperatively, patients should be instructed to wear abdominal binders—particularly if a large defect has been repaired—in an effort to obliterate dead space and prevent seroma formation.

POSTOPERATIVE RESULTS

In contrast to many other laparoscopic procedures, LVH may not always reduce postoperative pain. As was previously discussed, immediate postoperative pain and quality of life appear to be similar after laparoscopic and open ventral hernia repair. Nevertheless, there are other postoperative outcomes where LVH offers advantages.

Most of the RCTs, meta-analyses, and comparative studies show a significantly lower rate of short-term postoperative complications after LVH compared with open surgery.[9,11,13,16,17] Detailed analysis of postoperative complications shows that this reduction is primarily due to fewer wound-related complications. In the article published by Itani and colleagues, postoperative complications were observed in 31.5% of a laparoscopic group and 47.9% of an open group of patients with an incidence of wound infection of 2.8% and 21.9% in laparoscopic and open hernia repair, respectively.[13] This is an important outcome because surgical site infection may require mesh removal. In the meta-analysis published by Forbes et al, the rate of mesh removal secondary to infection was 0.7% in LVH and 3.5% in open surgery.[17]

It is interesting that although postoperative pain is similar, hospital stay is shorter for patients undergoing LVH in most, but not all, the randomized controlled studies.[17] Some studies, such as the one published by Itani and colleagues that did not find a reduction in hospital stay (4.0 vs 3.9 in laparoscopic vs open surgery, respectively), did however find that LVH patients returned to work more rapidly than those undergoing open repairs (23 vs 28 days).

In summary, the overall incidence of postoperative complications is reduced after laparoscopic hernia repair mainly due to a lower incidence of wound-related complications. While short-term pain and quality of life appear to be similar, hospital stay and return to work appear to be shorter in LVH compared with open surgery.

LONG-TERM FOLLOW-UP

The most important outcome in hernia repair surgery is recurrence. The introduction of mesh in open hernia repair was a major advance that substantially reduced the recurrence rate.[2,3] Burger et al reported a 10-year cumulative rate of recurrence of 63% and 32% for suture and mesh hernia repair, respectively. Based on the data currently available, the rate of hernia recurrence after open and laparoscopic hernia repair is at least similar.[9,10,13,18] Unfortunately, most of the trials comparing LVH and traditional repairs were designed to evaluate postoperative complications, not long-term recurrence. Hence, there is little, if any, published follow-up beyond 3 years. A meta-analysis published in 2009 that analyzed eight RCTs found no significant difference in the risk of hernia recurrence between both techniques at short term of follow-up (3.4% and 3.6% in laparoscopic and open repair, respectively).[17] Similar findings were recently published by Itani and colleagues.[13] In this RCT, the recurrence rate at 2 years of follow-up was 12.5% for the laparoscopic repair group and 8.2% for the open technique group ($p = 0.44$). In open hernia repairs, the recurrence rate is lower when the procedure is performed by experienced surgeons.[19] It is logical to expect that the same relationship exists between LVH and surgeon volume.

COST-BENEFIT

The laparoscopic technique of hernia repair involves the use of laparoscopic instruments and potentially new, expensive mesh prostheses that must be added to the standard cost of operating room use and hospital stay. In open hernia repair, the use of mesh has been shown to be a cost-effective alternative to suture repair when one accounts for postoperative complications, recurrence rate, and long-term follow-up.[20] There is little data available for LVH. This is an issue that should be incorporated in future trials. It is impossible to compare the cost/benefit ratio of LVH to standard repairs without this information.

CONCLUSION

LVH is a well-established technique for treating abdominal wall hernias. It is hard to make a blanket statement that LVH is a superior approach to traditional mesh repairs. However, understanding the unique features of the approach allows well-trained surgeons to utilize it where it is most likely to be beneficial and likewise opt for a traditional mesh repair when LVH is unlikely to offer any advantage. The modern surgeon treating abdominal wall hernias should be facile with both techniques.

PERSPECTIVE ON HERNIAS: LAPAROSCOPIC INGUINAL HERNIA REPAIR

Lokesh Bathla • Robert J. Fitzgibbons, Jr

The transabdominal preperitoneal (TAPP) and the totally extraperitoneal repair (TEP) are the two most commonly performed types of laparoscopic inguinal hernia repairs. The intraperitoneal onlay mesh (IPOM) repair, the only truly minimally invasive laparoscopic hernia repair (because a radical dissection of the preperitoneal space is avoided), is rarely performed. Over the last decade, surgeons have become proficient in these procedures and an increasing number of laparoscopic repairs are being performed. Long-term follow-up data is now available, which shows that laparoscopic hernia repair has similar success rate as the conventional repair, with early return to work and possibly decreased overall cost.

Laparoscopic inguinal hernia repair requires that the surgeon appreciate the anatomy of the myopectineal orifice from a perspective opposite to that of the conventional anterior repair. Consequently, a detailed understanding of the anatomy of the deep inguinal region and the posterior aspect of the anterior abdominal wall is necessary to perform a laparoscopic inguinal hernia repair. The major nerves (five in number) in the region of the myopectineal orifice are all located lateral to the deep inguinal ring. The nerves, from lateral to medial, include the lateral femoral cutaneous nerve, anterior femoral cutaneous nerve, femoral nerve, femoral branch of the genitofemoral nerve, and the genital branch of the genitofemoral nerve. These nerve branches may be quite variable in their course and lie in the so-called *triangle of pain*, bordered medially by the gonadal vessels, anteriorly and inferiorly by the iliopubic tract, and laterally by the iliac crest.

On the other hand, the important vascular structures are located infero-medial to the deep ring. In some individuals, a vessel or vessels, which are usually referred to as "aberrant," arise from the inferior epigastric system, arching over Cooper's ligament to join the normal obturator vessels, thereby completing a vascular ring. This is referred to as the *corona mortis*. Bleeding can be quite significant from it if attention is not paid during the dissection in this region. The internal spermatic vessels and the ductus deferens approach the deep inguinal ring from different directions, forming the apex of the *triangle of doom*, so called because the external iliac vessels, deep circumflex iliac vein, genital branch of the genitofemoral nerve, and the femoral nerve lie in this region.[1]

A tension-free open mesh repair is still the gold standard for the treatment of inguinal hernia and is usually performed under local anesthesia with sedation. Compared with this, the laparoscopic approach requires general anesthesia, is associated with higher in-hospital costs, and has a long learning curve. More importantly, the laparoscopic approach has the remote potential for a fatal complication such as major vascular or bowel injury.

Certain hernia types are better served by the laparoscopic approach. These include, bilateral hernias because both sides can be repaired from the same access ports, thereby pushing the risk/benefit ratio in favor of laparoscopy; recurrent hernias assuming the preperitoneal space has not been previously dissected and hernias in women because of higher incidence of femoral recurrence with the usual anterior prosthetic repairs.[2] Many laparoscopic surgeons believe that sliding hernias especially when reducible are more effectively approached laparoscopically than conventionally. Previous surgery in the retropubic space, intra-abdominal adhesions, scrotal hernia, incarcerated inguino-scrotal hernia, and the presence of ascites constitute relative contraindications.

Brooks and his colleagues have nicely described the basics of the surgical technique in the previous section. We would like to emphasize a few additional points. For the TAPP operation, it is important to dissect the entire symphysis pubis to the contralateral pubic tubercle for adequate coverage of the myopectineal orifice to prevent the all too common pubic tubercle recurrence. Additionally, it is very important to adequately mobilize the inferior peritoneal flap because the prosthesis tends to roll up in the limited space and may be a cause for recurrence. A large inguinal scrotal sac does not need to be removed in its entirety and can be divided at a convenient point along the cord structures with the proximal side ligated and the distal side left widely opened. This avoids an excessive incidence of hydrocele and the vascular disruption

in the distal cord, which can lead to various testicular complications. Slitting the mesh to wrap around the spermatic cord is optional, and if done, care should be taken to adequately repair the mesh around the spermatic cord. Prosthesis fixation methods continue to be controversial with some authors in fact questioning the need to do so. Several methods of prosthetic fixation, including absorbable tacks and biologic tissue adhesives, have been evaluated in recent studies.[3,4] Additionally, it has been hypothesized that if there is enough overlap of the myopectineal orifice, fixation should not be required. Nevertheless, we continue to fix the mesh and avoid placing tacks inferior to the iliopubic tract and lateral to the internal spermatic vessels as they have been implicated in posthernia repair groin pain, which can be debilitating.

The choice between TEP and TAPP repair is largely determined by the surgeon's training, experience, and personal preference. The literature generally favors TEP over TAP because of the avoidance of complications associated with entering the peritoneal cavity including visceral injury, vascular injury, adhesion formation, and trocar site hernias. In addition, peritoneal closure does not have to be performed since the dissection is extraperitoneal. However, these advantages are not universally embraced and in fact the largest series of laparoscopic inguinal hernia repairs in the world were largely TAPP repair.[5]

A large number of randomized control trials and meta-analyses have shown that patients who undergo laparoscopic hernia repair experience less pain in the early postoperative period, and have lower analgesic and narcotic requirements, better cosmesis, and early return to normal activities. Most comparative studies have shown equivalent complication rates between the tension-free repair and the laparoscopic approach. It is important to note here that most of these outcomes have been reported from specialized centers and may not be truly reflective of outcomes in the community. This was suggested by the often-quoted Veterans Administration (VA) cooperative trial comparing a laparoscopic preperitoneal inguinal herniorrhaphy (mostly TEP) with a standardized Lichtenstein approach.[6] Recurrences were more common in the laparoscopic group (87 of 862 patients or 10.1%) than in the open group (41 of 834 patients or 4.9%) and this was statistically significant. The surgeons participating in this trial were well trained but did not have a specialty interest in hernia surgery. Thus, the selection of open versus laparoscopic has to be based on the expertise of the surgeon. Both the patient and the surgeon should weigh the risks and benefits of this approach before pursuing laparoscopic inguinal hernia repair. Although several studies in the past have tried to define the learning curve for laparoscopic hernia repair, the number of procedures recommended to gain proficiency continues to be variable.

The overall incidence of morbidity after laparoscopic inguinal hernia repair has been quite variable. Fortunately, serious complications are rare. These complications may be related to laparoscopy per se, the patient, the hernia, or the prosthesis. Over three quarters of the major vascular injuries occur during the insertion of the Veress needle or trocars. The risk of major vascular injury requiring operative repair is relatively low, around 0.8%.[7] Despite the low prevalence, these injuries are associated with mortality up to 17%.[8] Prompt repair of such injuries with formal laparotomy should be considered, as the true magnitude of the injury may not be truly appreciated laparoscopically. Occasionally, bowel or bladder injury occurs during the access phase of laparoscopy. Such injuries should be promptly repaired either laparoscopically or with laparotomy, depending on the experience and skills of the surgeon.

With improvement in laparoscopic skills and increased surgeon experience, the recurrence rates of laparoscopic hernia repair have become almost equivalent to those reported for conventional hernia repair. Chronic pain after hernia repair is an important adverse outcome and has been extensively discussed in the literature. Unfortunately, there is poor understanding of the pre-, intra-, and postoperative factors that cause the various pain syndromes. These pain syndromes could be somatic or visceral in nature (depending on the underlying cause) and can be difficult to treat. Initial treatment of all these pain syndromes is initially conservative with reassurance, anti-inflammatory medication, cryotherapy, and local nerve blocks. In case conservative measures fail to relieve patient's symptoms and other underlying causes have been excluded, groin exploration may be required. When exploring the groin in this situation, the surgeon must be prepared for possible mesh removal, which may be difficult because of the dense adhesions. Neurectomy, neurolysis, or neuroma excision should be reserved as a last resort. Occasionally, patients may develop infertility or the dysejaculation syndrome. These could be due to underlying injury to the vas deferens or extensive cicatrization around the vas deferens due to mesh-induced inflammation. These conditions, although rare, can be difficult to treat and usually have less than satisfactory outcomes.

The hospital cost for laparoscopic hernia repair is significantly higher than that for conventional hernia repair. However, when both direct and indirect costs are assessed in follow-up, there does not appear to be a significant cost difference. The direct operative costs appear to be compensated by the higher productivity attributable to earlier return to work.

In conclusion, laparoscopic inguinal hernia repair is an excellent alternative to conventional repair for the properly trained surgeon. Although appropriate for uncomplicated unilateral hernias, one must consider the risk/benefit ratio carefully because of the need for general anesthesia and the slight possibility of a disastrous laparoscopic accident that can be avoided with the conventional procedure. There is wide agreement that the risk/benefit ratio favors laparoscopy for patients with bilateral or recurrent inguinal hernias where the conventional space has been violated.

INTESTINAL STOMAS

Ira J. Kodner • Thomas E. Read • Donna L. Loehner

An intestinal stoma is an opening of the intestinal or urinary tract onto the abdominal wall, constructed surgically or appearing inadvertently. A colostomy is a connection of the colon to the skin of the abdominal wall. An ileostomy involves exteriorization of the ileum on the abdominal skin. In rare instances, the proximal small bowel may be exteriorized as a jejunostomy. A urinary conduit involves a stoma on the abdominal wall that serves to convey urine to an appliance placed on the skin. The conduit may consist of an intestinal segment, or in some cases a direct implantation of the ureter, or even the bladder, on the abdominal wall.

Information about the types and numbers of stomas constructed, complications of stomas, and resultant impairment of an individual's life has been limited because the diseases for which stomas are constructed are not mandated as reportable in the United States. Therefore, the United Ostomy Association of America (UOAA, www.uoaa.org), formerly the United Ostomy Association, a voluntary group of 40,000 members with stomas of various types, undertook the mission of collecting data from patients in the United States and Canada who have an intestinal stoma. A review of 15,000 such entries shows the peak incidence for ileostomy construction owing to ulcerative colitis to occur in persons between 20 and 40 years of age, with a lower peak but in the same age range for patients with Crohn's disease. The second largest peak represents colostomies constructed because of colorectal cancer, and this peak is in patients 60–80 years of age. When complications were analyzed according to original indication for surgery, we found that many patients knew that they had complications but were not aware of the exact nature of the complication. Postoperative intestinal obstruction occurred in all categories of disease, as did retraction of the stoma and abscess formation. There was a preponderance of hernia formation in patients who had surgery for colorectal cancer, whereas abscess, fistula, and stricture formation were the major complications in the patients with Crohn's disease. As new surgical procedures are devised, a justification for their utilization is often the reduction of the level of handicap that exists among patients who have had construction of a conventional ostomy. The UOA survey revealed that patients resumed household activities 90% of the time, vocational activities 73% of the time, social activities 92% of the time, and sexual activities 70% of the time. It is taken into account that patients who have proctectomy for cancer frequently lose their sexual function because of autonomic denervation and not because of the presence of a stoma.

Changes that have improved the quality of life of the patient with a stoma include the development and availability of improved stoma equipment. Specialized surgical techniques, some of which are described in this chapter, have been developed that facilitate the subsequent maintenance of an ostomy. In addition, specialized nursing techniques applied both preoperatively and postoperatively have enhanced the care of the patient with a stoma. The involvement of a Certified Wound Ostomy Continence Nurse (CWOCN) in the care of patients with stomas is critical.

The overall incidence of stoma construction appears to be decreasing and will probably continue to do so. There are now fewer abdominoperineal resections for cancer because of the advent of new surgical techniques, especially the use of stapling devices, as well as an increased use of local treatment for selected rectal tumors. The incidence of permanent ileostomies is decreasing because of the popularization of sphincter-saving procedures for patients with ulcerative colitis and familial polyposis. The surgical procedures that eliminate permanent stomas, however, have resulted in an increasing use of temporary loop ileostomies.

Each type of stoma is associated with a particular spectrum of complications, but some problems are common to all intestinal stomas. The specific ones are dealt with under each category of stoma. A common complication, regardless of the stoma type, is destruction of the peristomal skin, which is usually caused by poor location or construction of the stoma. In addition to the acute maceration and inflammation of the skin, pseudoepitheliomatous hyperplasia may arise at the mucocutaneous border of stomas subjected to chronic malfitting appliances. Appearance of a fistula adjacent to a stoma usually indicates recurrence of Crohn's disease. One of the difficult complications to handle, especially in an obese patient, is improper location of the stoma, which prohibits maintenance of the seal of an appliance. A stoma buried in a skin fold, or a flush stoma, can create devastating peristomal skin problems. A special problem arises in the patient who

has portal hypertension because the construction of a stoma results in the creation of a portosystemic shunt, and varices can form in the peristomal skin.

Other common problems include the need for precautions with medications, especially time-released enteric medications, which may pass through a shortened intestinal tract unabsorbed. Laxatives also can be devastating to patients with no colon or with a proximal colostomy. In some cases, the ostomy patient has chronic difficulty maintaining proper fluid and electrolyte balance, and diuretics in these patients can be especially difficult to manage. The usual intestinal preparations prior to diagnostic testing should be altered for the patient with an intestinal stoma.

Many potential stoma complications can be avoided by proper preoperative marking and counseling. The stoma location should be chosen and marked preoperatively, even if there is only a remote possibility of the need for an intestinal stoma during the operative procedure. Surgeons who perform intestinal stomas should be well versed in stoma care and management of stoma complications. The value of collaboration with an enterostomal therapist (CWOCN) cannot be overstated. Patients should meet with the CWOCN preoperatively, and the surgeon and CWOCN should discuss the selection of potential stoma sites together prior to operation.

COLOSTOMY

The most common indication for fashioning a colostomy is cancer of the rectum. Since a colostomy is an opening of the large intestine with no sphincteric control, its location would obviously be better on the abdominal wall than in the perineum, where an appliance cannot be maintained. A distal colorectal anastomosis in an elderly patient with a poorly functioning anal sphincter may result in what is essentially a "perineal colostomy." In these cases, it often behooves the surgeon to construct a good colostomy rather than to restore intestinal continuity to an incontinent anus. Colostomies are also constructed as treatment for obstructing lesions of the distal large intestine and for actual or potential perforations.

Type by Anatomic Location

Traditionally, the type of colostomy has been categorized by the part of the colon used in its construction. The most common type has been called an "end-sigmoid" colostomy. However, if the origin of the inferior mesenteric artery is transected during an operation for cancer of the rectum, the blood supply to the sigmoid colon is no longer dependable, and it should not be used for stoma construction. Therefore, an "end-descending" colostomy is usually preferable to an end-sigmoid colostomy. Other types of colonic stomas include the transverse colostomy and cecostomy. The physiology of the colon should be taken into account when considering stoma construction. The right side of the colon absorbs water and has irregular peristaltic contractions. Stomas made from the proximal half of the colon usually expel a liquid content. The left colon serves as a conduit and reservoir and has a few mass peristaltic motions per day. The content is more solid, and in many cases the stoma output can be regulated by irrigation. Proximal colostomies should be avoided, as they will combine the worst features of both a colostomy and an ileostomy: liquid, high-volume, foul-smelling effluent. The left colon should be used for a colostomy if possible; the distal transverse colon is also a reasonable choice.

Determination of Colostomy Location

The location of the colostomy must be carefully selected preoperatively. It should avoid any deep folds of fat, scars, and bony prominences of the abdominal wall. The site is chosen by evaluating the patient in the standing, sitting, and supine positions. Often abdominal skin and fat folds are only noted with the patient in the sitting position. A stoma faceplate is applied to the abdominal wall with its medial margin at the midline; care is taken to not overlay any fold, scar, or prominence; and the stoma site is marked. The inguinal fold and waistline fold should be avoided. If a sigmoid or descending colostomy is contemplated, the most desirable position is usually in the left lower quadrant of the abdomen. However, if the patient is obese, it may be preferable to site the colostomy in the left upper quadrant so that it is visible to the patient and not trapped on the undersurface of a panniculus. If a distal transverse colostomy is planned, the left upper quadrant is usually the preferable site. Please refer to the section on determination of the ileostomy location for more details regarding stoma site selection.

Type by Function

More important than the anatomy of the colon is the function that the colostomy is intended to perform. There are two considerations: (1) to provide decompression of the large intestine, and (2) to provide diversion of the feces.

DECOMPRESSING COLOSTOMY

A decompressing colostomy is most often constructed for distal obstructing lesions causing dilation of the proximal colon without ischemic necrosis, severe sigmoid diverticulitis with phlegmon, and for select patients with toxic megacolon. Alternative treatments exist for these conditions: total abdominal colectomy with ileostomy or ileorectal anastomosis; segmental colectomy with construction of end colostomy; segmental colectomy with primary anastomosis; and segmental colectomy with intraoperative colonic lavage and primary anastomosis with temporary diverting loop ileostomy. However, temporary decompressing stomas are still useful and safe. The procedure acts as a bridge to definitive operation for toxic patients with benign disease and those with malignant distal obstruction. The disadvantages of a decompressing stoma is that it does not provide definitive management of the disease process and thus the patient often requires subsequent operation, and it does not necessarily

provide complete fecal diversion and thus carries the risk of potentially fatal sepsis if there is distal perforation.

Types of Decompressing Stomas. There are three types of decompressing colostomies: (1) the so-called "blow-hole" decompressing colostomy constructed in the cecum or transverse colon, (2) tube cecostomy, and (3) loop colostomy.

Cecostomy and "Blow-Hole" Colostomy. A cecostomy should be constructed only rarely because it is difficult to manage postoperatively. It should be reserved for the severely, acutely ill patient with massive distention and impending perforation of the colon. This is seen most often with distal obstructing cancer or in some of the pseudo-obstruction syndromes seen in elderly or immuno-compromised patients. Because these operations are done on an urgent basis and the abdomen is usually distorted by intestinal dilation, the choice of site for an incision is over the dilated cecum. The location of this incision or of an intended decompressing transverse colostomy can be selected by placing a marker on the umbilicus when an abdominal film is obtained.

The construction of a blow-hole cecostomy or transverse colostomy (Fig. 9-1) is carried out by making a 4–6 cm transverse incision over the most dilated part of intestine and then placing a series of interrupted, seromuscular, absorbable sutures between the peritoneum and the seromuscular layer of the bowel to be decompressed. This should be done through an incision sufficient to allow subsequent incision of the intestine and suturing of the intestine to the skin. The bowel wall will be very thin, and it is not unusual to have leakage of gas as the sutures are being placed. A disadvantage of a cecostomy or loop colostomy done through a small incision is that one cannot evaluate other parts of the colon for potential ischemic necrosis due to massive dilation.

Once the first layer of sutures has been placed and the intestine is sealed from the remainder of the abdominal cavity, needle decompression of the gas-distended viscus is performed to reduce the tension on the intestinal wall. When this procedure is completed, a second layer of absorbable sutures is placed between the seromuscular layer of the intestine and the fascia of the abdominal wall. Subsequently, the colon is incised, usually with release of a large amount of liquid and gas. The full thickness of intestine then is sutured to the full thickness of skin, again with absorbable sutures, and an appliance is placed over the stoma. Postoperatively, it is not unusual for there to be significant inflammation in the abdominal wall around such a stoma, and after a period of weeks, significant prolapse may occur. Therefore, these stomas should be used for short periods of time, with definitive resection performed as soon as possible.

A tube cecostomy (Fig. 9-2) is constructed by making an incision similar to that used for a "blow hole" colostomy, by formal laparotomy, or by laparoscopy. A purse-string suture is placed in the cecal wall, and a large mushroom-tipped or Malecot catheter is placed in the cecum. The purse-string suture secures the catheter. Usually a second purse-string suture is placed, and the tube is brought through a right lower quadrant incision. The cecum then is sutured to the peritoneum of the abdominal wall. The advantage of this stoma is that there is less chance of prolapse. The major disadvantage is that the tubes usually become blocked with feces, drain poorly, and sometimes leak stool adjacent to the drain. Because of all their disadvantages, tube cecostomy and blow-hole colostomies are rarely performed at present.

Loop-Transverse Colostomy. A loop colostomy using the transverse colon (Fig. 9-3) or left colon can be used as a decompressive stoma, although it will usually completely divert the flow of stool away from the distal colon and can thus be considered a diverting stoma. Occasionally, the posterior wall of the stoma recesses far enough below the wall of the abdomen so that stool can enter the distal loop, although this is uncommon. These stomas are constructed for reasons similar to those described for the blow-hole type stoma and to provide temporary diversion for protection of complicated distal anastomoses. The other advantage is that when properly constructed, a loop colostomy can serve as a long-term stoma. The incidence of prolapse is not prohibitive. Parastomal hernias can occur if the fascia is not closed tightly enough, and these stomas usually cannot be regulated by irrigation techniques.

The site can be chosen for this stoma in an emergency situation as previously described, but it should be marked electively on the abdominal wall in preparation for potential construction in patients who are to have low colorectal anastomoses or in those in whom it is anticipated that an inflammatory reaction will be encountered and will require temporary diversion of intestinal contents as a safeguard against contamination from a leaking anastomosis. This occurs occasionally in patients with severe diverticulitis. In an elective situation, the stoma can be placed through the rectus muscle either on the right or left side, depending on later intentions of closing or resecting the colostomy site in continuity with a cancer operation, or it can be brought through the midline (Fig. 9-3A). If performed in conjunction with a midline incision, a midline colostomy site may be suboptimal because of difficulty with placing the ostomy appliance over the fresh incision.

Construction of loop colostomy requires the colon to be mobile enough to be brought to the level of the abdominal wall (Fig. 9-3B). If this cannot be done or if the colon is so massively dilated that loop colostomy is not safe, one should resort to the use of a blow-hole colostomy as previously described, in which only one wall of the intestine is utilized and tension on the mesentery is avoided. A transverse loop colostomy can be constructed by placing a tracheostomy tape or soft latex drain around the colon at the site chosen for the colostomy. The transverse colon at this site is usually dissected free of the overlying omentum in the embryonic peritoneal fusion planes. The tracheostomy tape and colon are brought through an avascular window in the omentum to allow better sealing between the colon and the abdominal wall (Figs. 9-3B and 9-3C). The fascia is then closed on either side of the loop of colon tightly enough to allow snug passage of one fingertip (Fig. 9-3D).

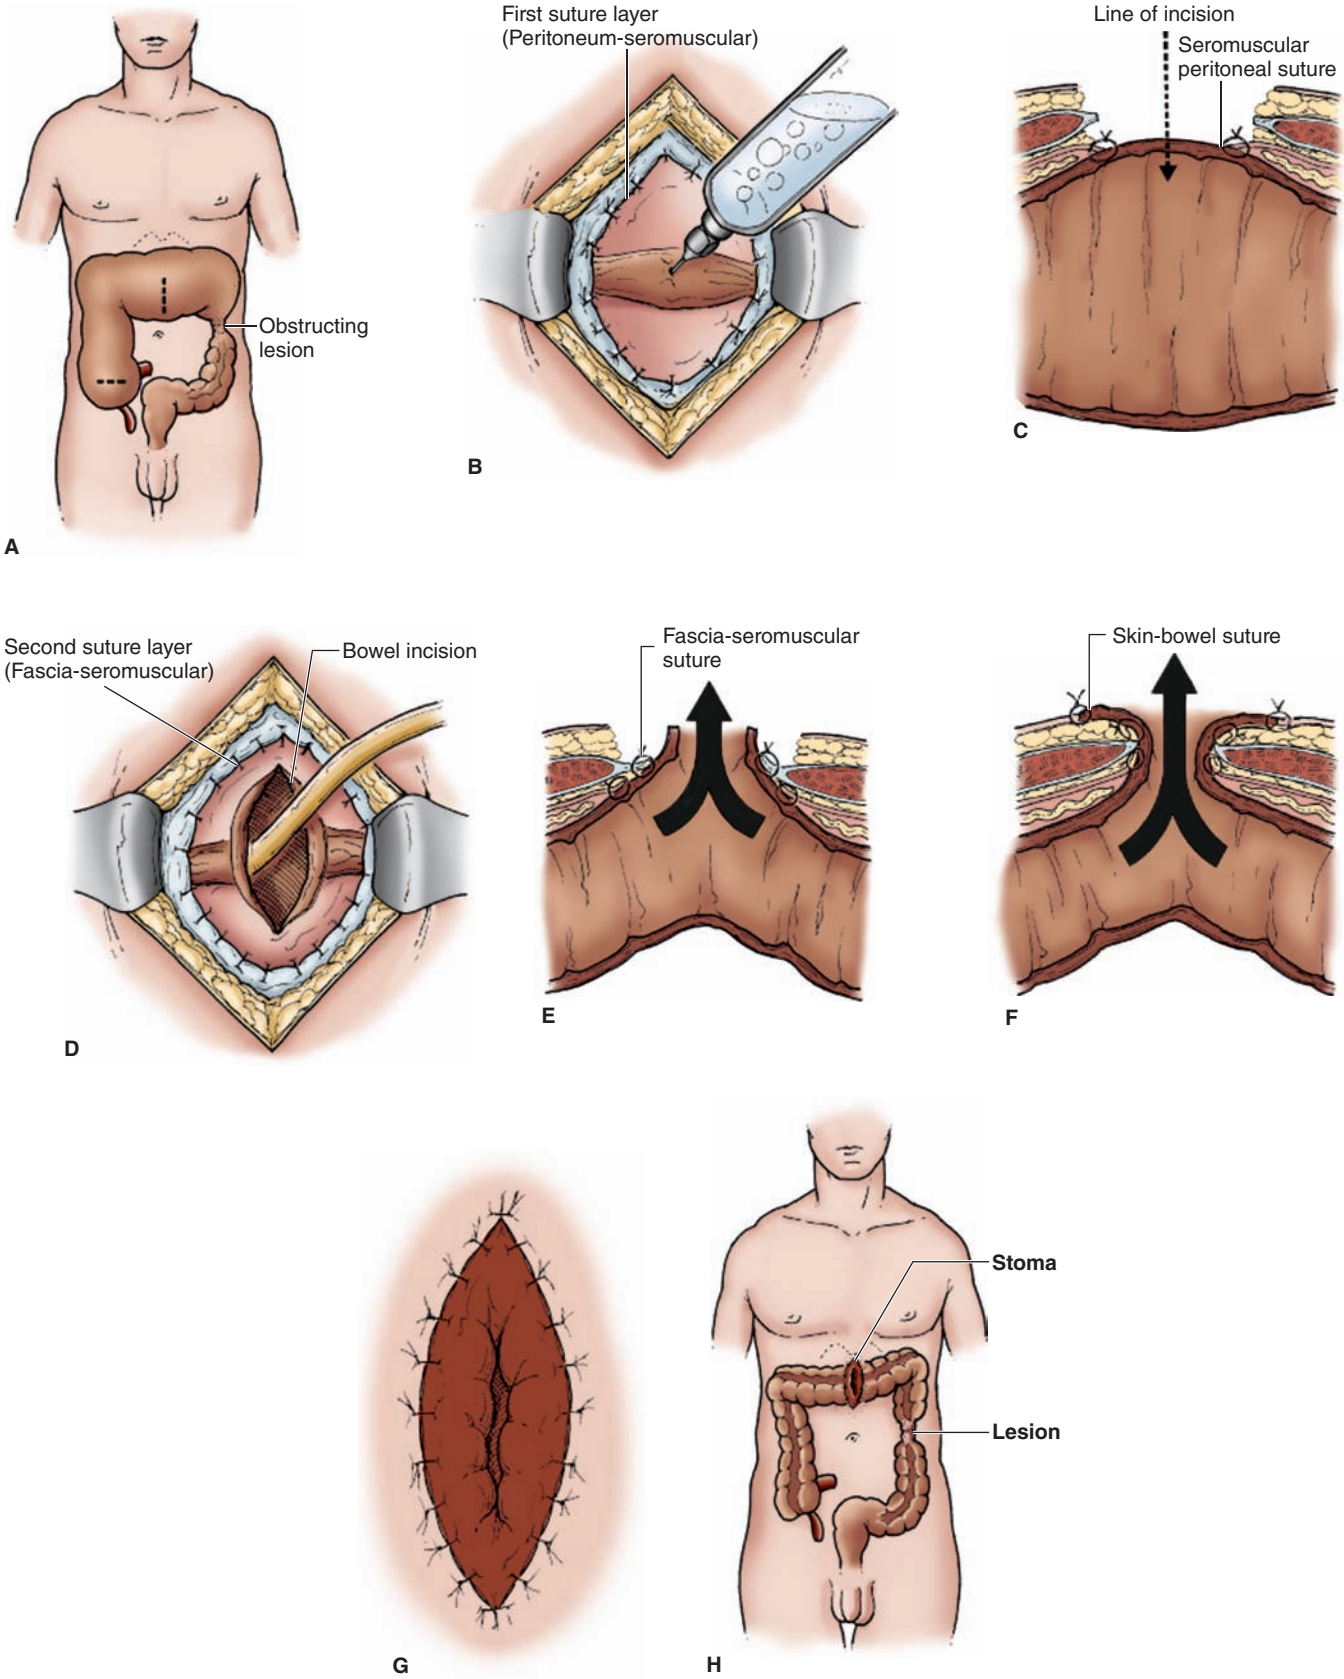

FIGURE 9-1 Construction of blow-hole cecostomy or colostomy. **A.** The incision is located over the most dilated aspect of the intestine. **B.** After the peritoneum is quarantined, gas is allowed to escape, decompressing the bowel. **C.** Placement of the quarantine sutures. **D.** The colon is opened, and more adequate aspiration is effected. **E.** Details of the second level of quarantine sutures between the fascia and seromuscular layer of the colonic wall (this should be completed before the bowel is opened). **F, G.** The stoma is completed by placement of sutures between skin and colonic wall. **H.** Completed blow-hole stoma.

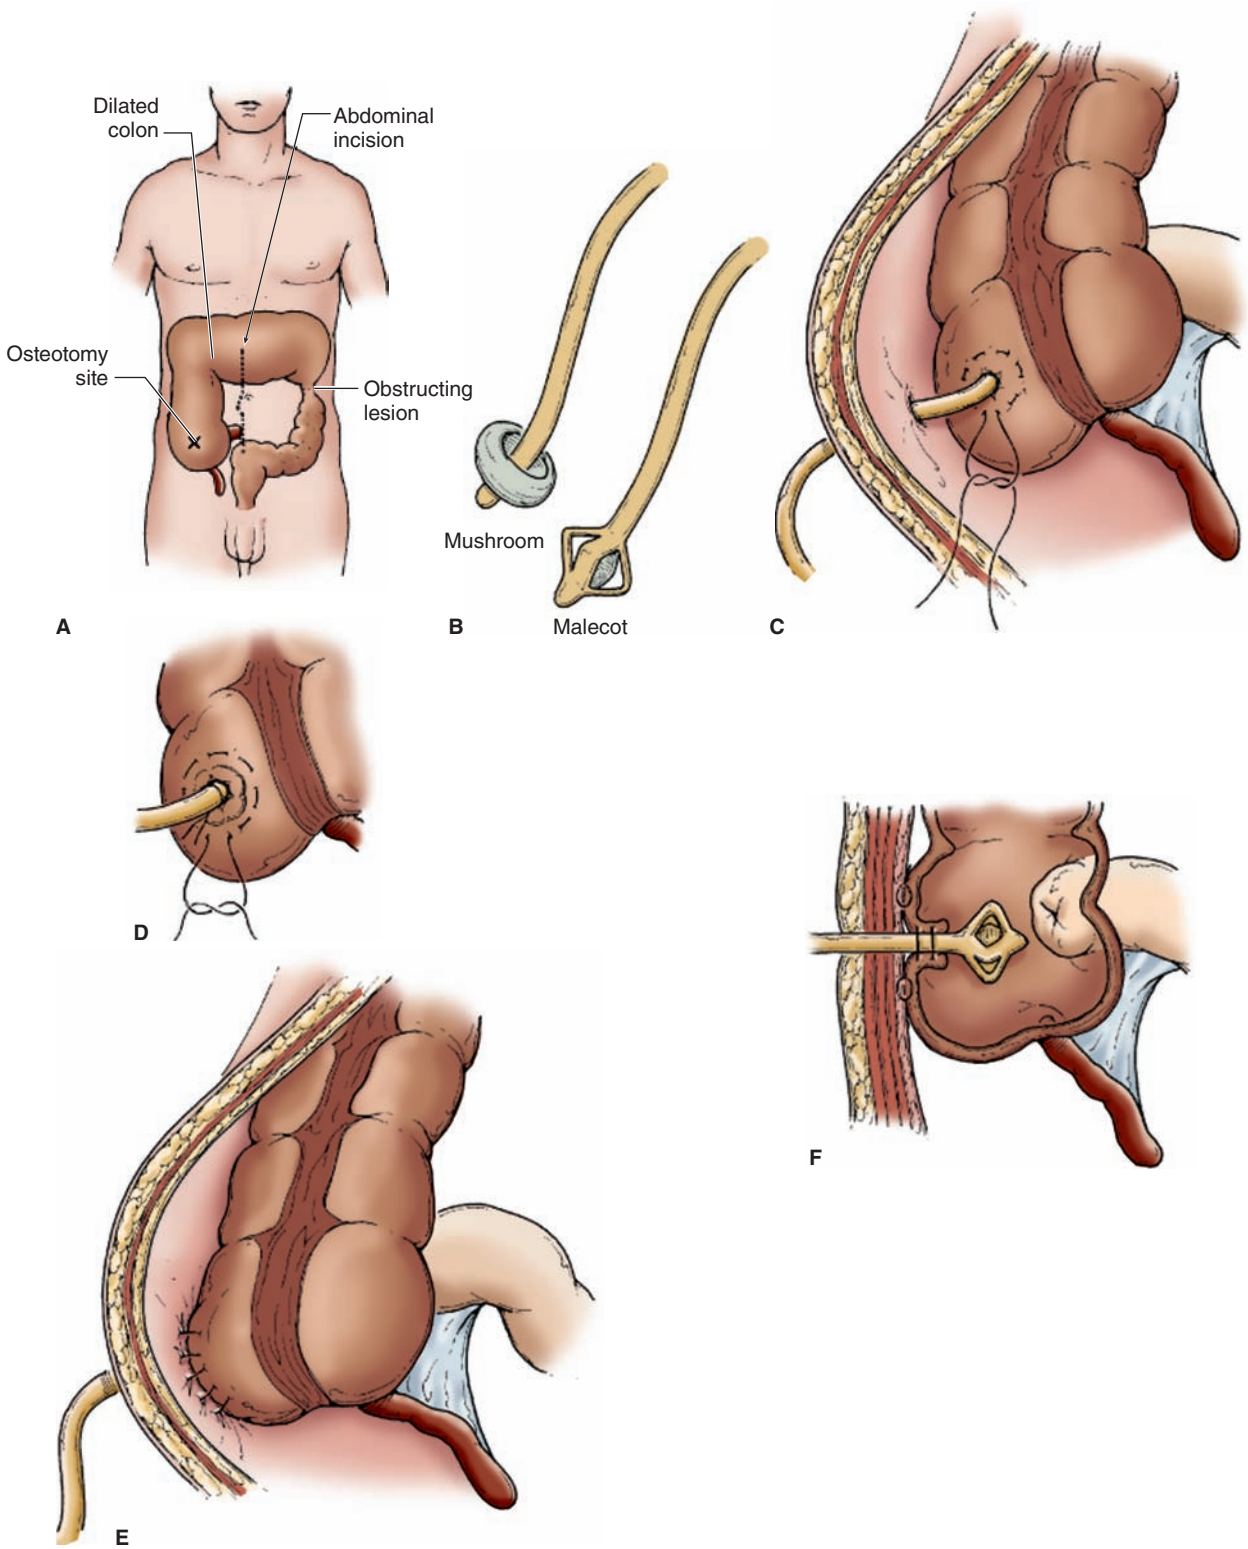

FIGURE 9-2 Construction of a tube cecostomy. **A.** The cecostomy is constructed over the most dilated aspect of the cecum. **B.** A very large Malecot or mushroom-tipped catheter is used. **C, D.** The catheter is secured within the cecum by two purse-string sutures. **E.** The cecum is sutured to the abdominal wall at the entry site of the catheter. **F.** Cross section of the completed tube cecostomy.

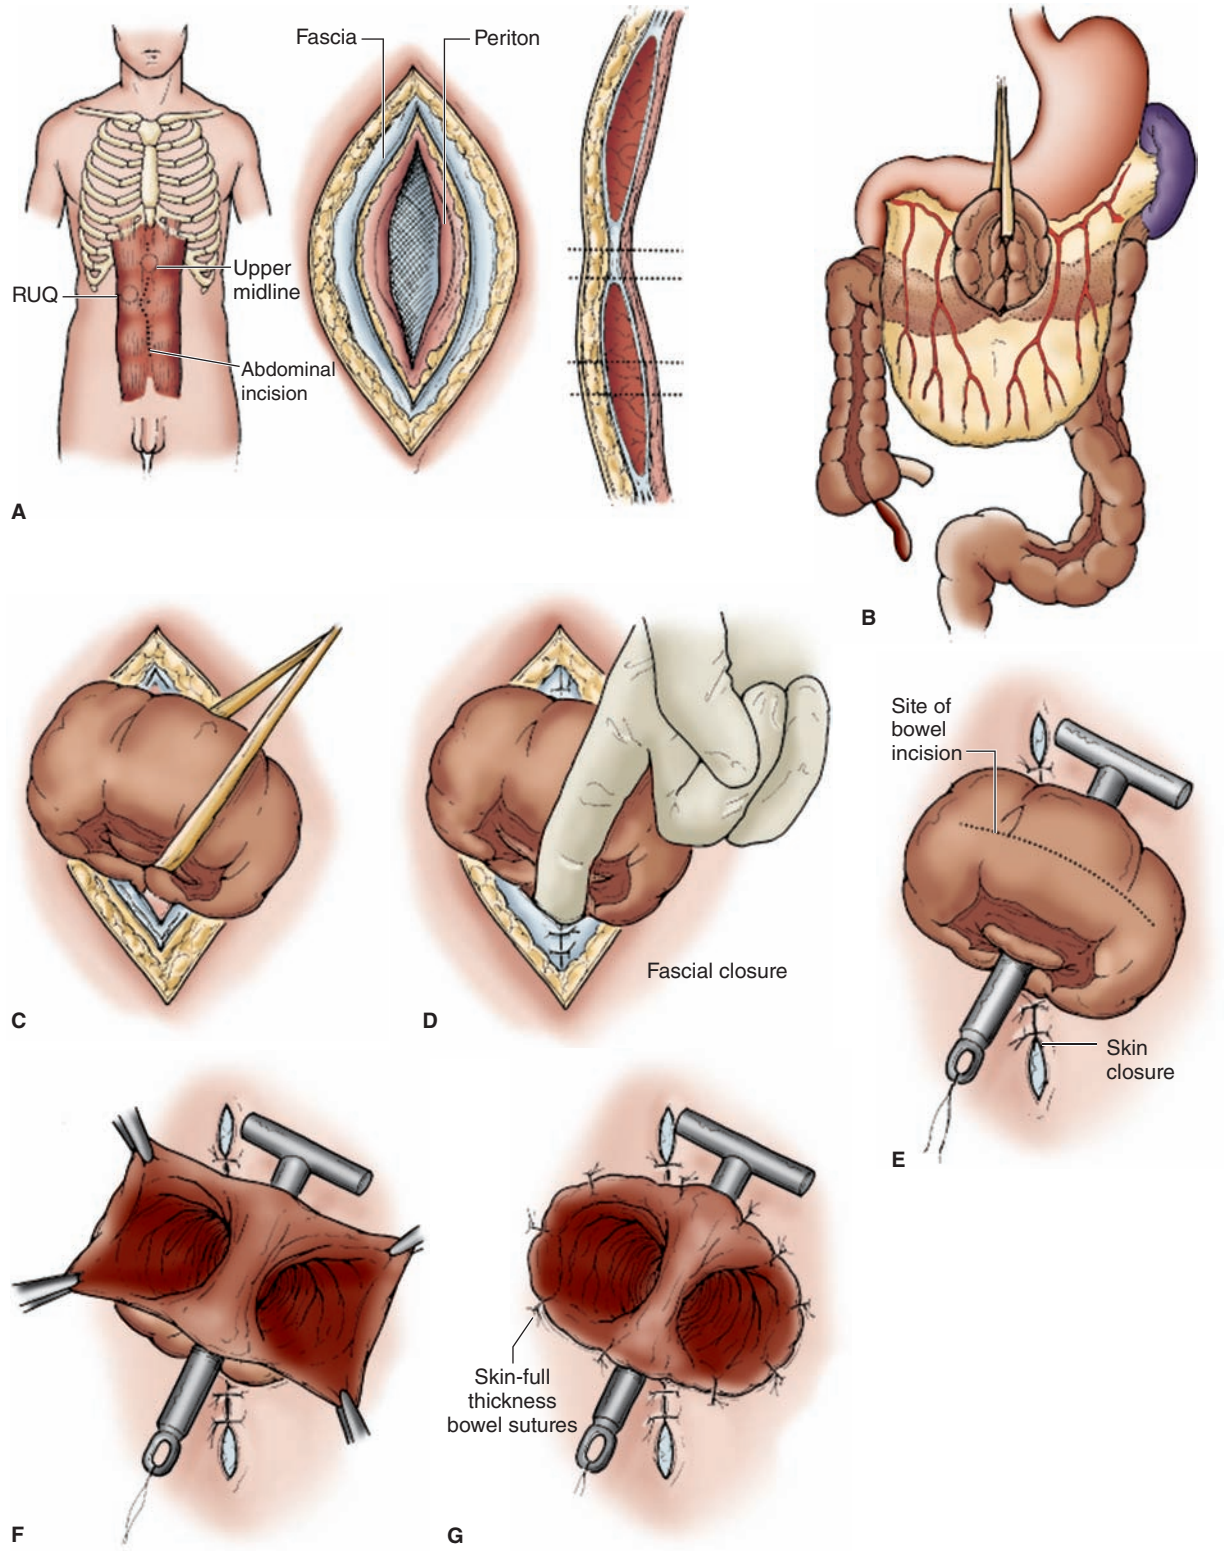

FIGURE 9-3 Construction of a loop-transverse colostomy. **A.** Choice of stomal location. **B, C.** Tracheostomy tape is used to pull the loop of colon through the incision. **D.** The fascia is closed tightly around the loop of intestine. **E, F, G.** The loop of colon is opened over a supporting rod and is sutured to the skin of the abdominal wall.

The skin is then snugly closed, on either side of the loop of colon. The tracheostomy tape is replaced by a plastic rod that frequently has a suture through each end so that it can be easily repositioned should it be displaced (Fig. 9-3E). The wound is protected, and attention is directed to the protruding loop of colon, which is incised either longitudinally or transversely to allow the best separation of the edges of the colon (Fig. 9-3F). Full thickness of intestine is then sutured to full thickness of skin with absorbable suture material (Fig. 9-3G). If this stoma is properly constructed, the posterior wall will bulge upward, providing the desired diversion as well as decompression. An appliance is applied either over the rod or beneath the rod, depending on the tension of the stoma.

If there is a possibility that the colostomy may become permanent, it may be advantageous to divide the colon with a stapler and create a "divided end-loop" stoma in the manner of Prasad and Abcarian. The proximal colon is matured as an end colostomy, and a corner of the distal limb opened and matured as a mucus fistula in the same stoma incision to vent the distal colon (see Fig. 9-9, construction of separated [divided end-loop] ileostomy). The stoma size is typically smaller than a loop colostomy and the tendencies to prolapse or retract may be lessened.

In the postoperative period, the appliance is emptied or changed as necessary, and the wound is kept clean. The rod is usually left in place for several days and then is easily removed. The colostomy appliance is fashioned as necessary as the contour of the stoma and skin opening change. Patients with this type of stoma usually are not taught to irrigate, because irrigation is infrequently successful. After the immediate postoperative period, the patient usually is instructed to empty the appliance as necessary and to change the entire appliance every 3 to 4 days, depending on the condition of the skin and the ability to maintain an adequate seal of the appliance to the skin.

Closure of a Temporary Colostomy. The most important consideration in dealing with closure of a temporary colostomy is deciding when it is safe to restore intestinal continuity. Distal integrity and adequacy of sphincter muscle function must be carefully evaluated before closure of the stoma is undertaken. The reason for constructing the stoma initially must be taken into account, and contrast studies and endoscopy should demonstrate clearly that the original reason for fecal diversion no longer exists.

Adequate function of the anal sphincter must be demonstrated before the temporary colostomy is closed. This can be done by formal manometric and electromyographic studies or by giving the patient a 500-mL enema and asking him or her to hold it until he or she can comfortably walk to a toilet and expel the enema. If the sphincter does not work and cannot be repaired, the patient will be better off with a properly constructed end colostomy than with attempts to preserve a nonfunctional sphincter. Once it is decided that it is safe to close the colostomy, the procedure should be undertaken with the same skill and precaution as that required for a colon anastomosis (Fig. 9-4). The complication rate following colostomy closure is not insignificant, and is cited by some authors as a reason to avoid diverting colostomy construction at all costs. However, as with all issues in medicine, careful consideration of the potential risks and benefits of the procedure in the individual patient should be made prior to deciding on whether or not fecal diversion is indicated.

The closure is begun by making a circumferential incision around the stoma, including a small rim of skin (Fig. 9-4A). If the stoma has been placed in the midline, the midline incision may be opened on either side of it to allow adequate mobilization. The circumferential incision is deepened until the peritoneal cavity is entered and the colon and surrounding omentum can be separated from the abdominal wall. The colon is then brought through the incision, and the serosal surface is clearly defined circumferentially (Figs. 9-4B and 9-4C). This involves resecting omentum and fibrofatty tissue from the serosal surface. Once this step is completed, the stoma is ready for closure, which can be accomplished by a linear stapling device (Figs. 9-4D and 9-4E), by a hand-sutured closure (Figs. 9-4F and 9-4G), or if the bowel has been compromised in any way, by complete transection of the colon and construction of a formal end-to-end anastomosis. Caution must be taken to ensure that no small intestine has been injured and that no significant bleeding has been left unattended. Once this has been accomplished, the colon is returned to the abdominal cavity and the abdomen is closed. Usually the skin itself is left open for delayed primary closure.

DIVERTING COLOSTOMY

A diverting colostomy is constructed to provide diversion of intestinal content. It is performed because the distal segment of bowel has been completely resected (as during abdominoperineal resection), because of known or suspected perforation or obstruction of the distal bowel (eg, obstructing carcinoma, diverticulitis, leaking anastomosis, or trauma), or because of destruction or infection of the distal colon, rectum, or anus (eg, Crohn's disease or failed anal sphincter reconstruction).

Choices for Construction. Although a completely diverting colostomy can be made only by complete transection of the colon, a well-constructed loop-transverse or sigmoid colostomy may provide near complete fecal diversion. Stool and flatus will move preferentially toward the low-pressure side of any pressure gradient, and this usually means that it will flow into the stoma appliance, which is at atmospheric pressure, rather than into the distal bowel. However, patients who have loop stomas must be counseled that if the stoma appliance becomes full, stool and flatus can be forced distally because the pressure gradient now favors passage of intestinal contents into the distal limb of intestine. This discussion should take place prior to discharge from the hospital, as this phenomenon usually occurs late

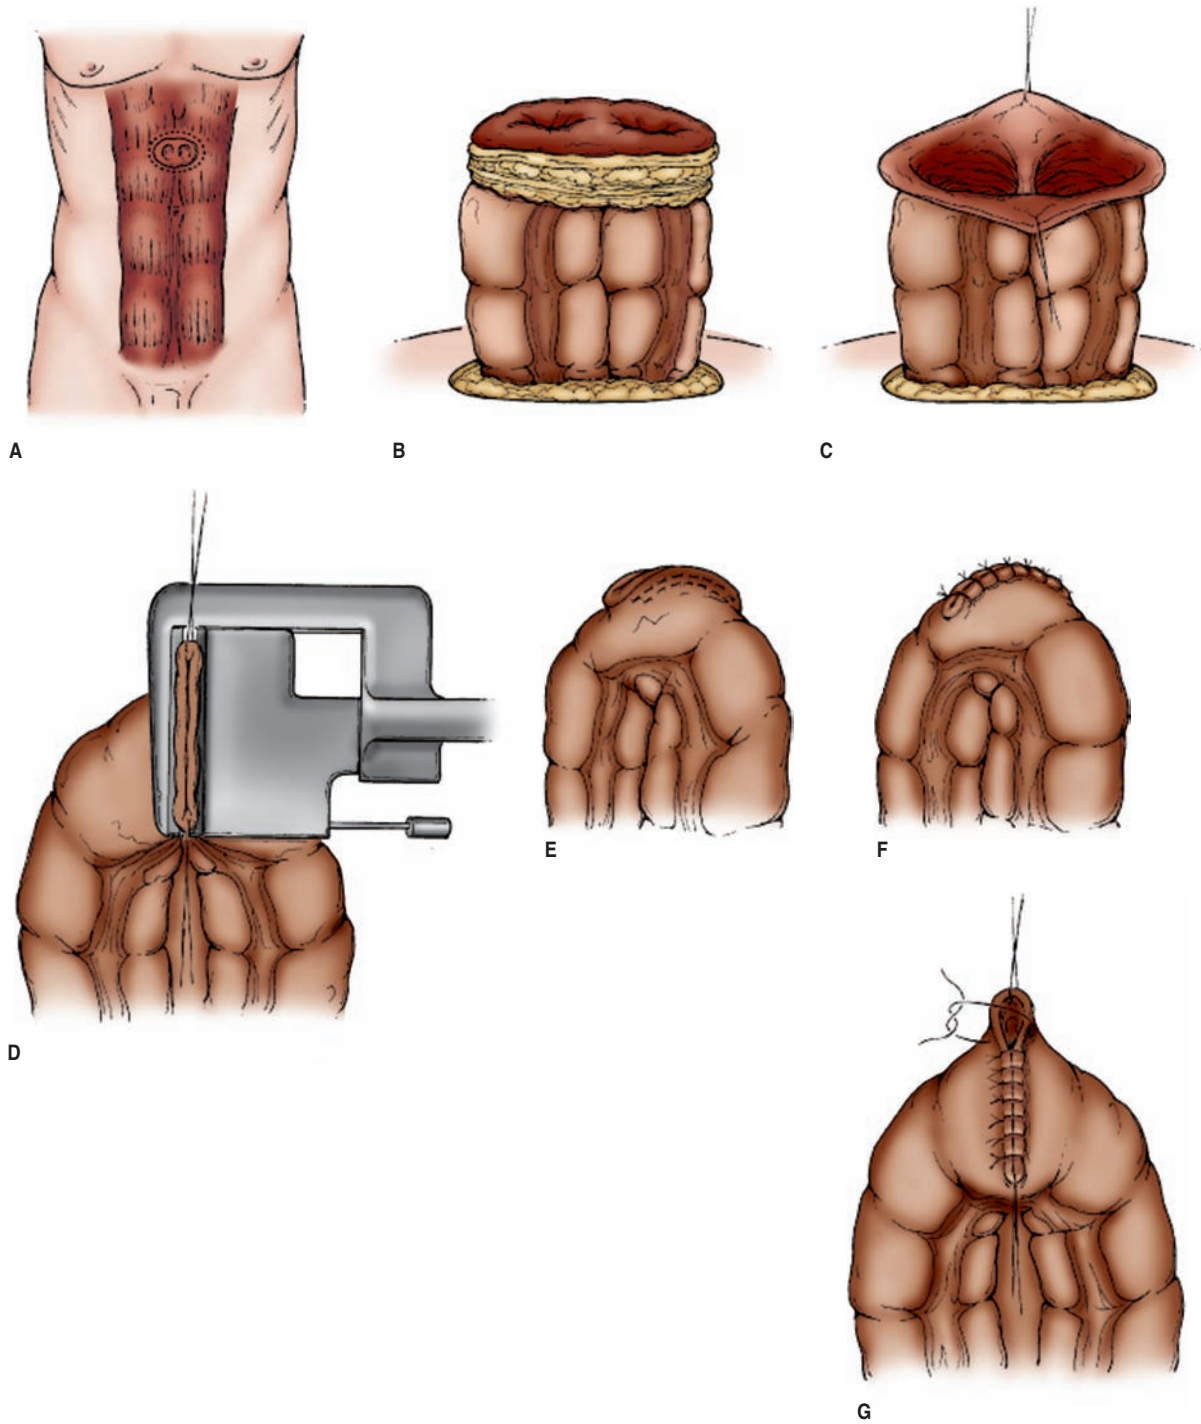

FIGURE 9-4 Closure of a loop-transverse colostomy. **A.** A circumferential incision is made around the stoma, with reopening of the midline incision if needed. **B, C.** The colon is mobilized adequately. **D, E.** Staple closure of the colostomy. **F, G.** Suture closure of the colostomy.

at night after the patient has slept and not emptied their appliance. The first passage of flatus or stool per anus in a patient who was under the impression that their fecal stream was completely diverted can be sufficiently alarming as to prompt an emergent call to the surgeon, usually in the wee hours of the morning.

There are some situations in which the diverting loop colostomy fails to divert the flow of stool because the stoma retracts into the abdomen and stool flows into the distal colon. Patients who are profoundly malnourished may be at increased risk of this complication. In addition, stomas that are constructed under tension may also be prone to retraction.

If a colostomy is being performed proximal to an obstructing lesion, to decompress the colon and divert the flow of stool, it is critical that the distal limb of the colostomy be vented to the atmosphere and not closed. If the distal limb is closed and there is a complete obstruction distal to the colostomy, this will create a closed loop obstruction, and there is a substantial risk of distention and perforation.

If the rectum and anus have been completely resected, an end colostomy is created. If a partial colectomy/proctectomy has been performed, and an anastomosis is not constructed, an end colostomy is created and the distal bowel is closed (as in a Hartmann resection) or brought to the skin as a mucus fistula. The decision about whether to create a mucus fistula or to close the distal segment will hinge on whether there is concern regarding distal obstruction, the length of the distal segment, and the integrity of the distal segment. For example, in a patient undergoing sigmoid colectomy and colostomy for complicated diverticulitis, it is reasonable to close the rectal stump providing that proctoscopy reveals a normal rectum. Conversely, in a patient undergoing abdominal colectomy and ileostomy for toxic colitis, it may be preferable to bring the distal sigmoid to the skin level as a mucus fistula to avoid rectal stump blowout. A mucus fistula may be constructed as a separate stoma, opening just a corner of the closed end as a small vent. Alternatively, the mucus fistula can be constructed so that the small vent is matured ("mature" means that the colonic wall is sutured primarily to the skin) in a corner of the abdominal wall opening used to create the proximal stoma in the manner of Prasad and Abcarian (the "divided end-loop" stoma). This facilitates care in that the patient has only one stoma appliance, and facilitates stoma closure because both limbs of the bowel are located adjacent to one another. The old operation of the so-called Divine double-barreled colostomy should be abandoned because the adjacent full-diameter stomas make application of an appliance very difficult.

Construction of an End Colostomy (Fig. 9-5). An end, completely diverting, colostomy usually is located in the left lower quadrant, where the site is chosen preoperatively by placing a vertical line through the umbilicus and another line transversely through the inferior margin of the umbilicus and by affixing a disk, the size of a stoma faceplate to designate the stoma opening through the rectus muscle and on the summit of the infraumbilical fan fold (Fig. 9-5A).

Once a site is chosen, the patient should be evaluated in multiple body configurations to verify the adequacy of the stoma site. A common mistake is to choose the site with the patient supine and then find when the patient rises to a standing or sitting position that the chosen site is completely obscured by fat folds, scar tissue, or a protruding skeletal structure. The location should be adjusted up or down, even considering the use of upper quadrants of the abdomen if necessary, to allow proper fixation of an appliance and easy access by the patient. The site usually is marked with ink in the patient's room and then is scratched into the skin with a needle in the operating room after induction of anesthesia. This is totally painless for the patient and does not leave a permanent tattoo should colostomy not be needed.

An end colostomy most often is constructed after removal of the rectum for low-lying malignancy (see Chap. 40). The entire left colon is mobilized on its mesentery, and depending on mobility of the colon and thickness of the abdominal wall, may require mobilization of the splenic flexure (Fig. 9-5B). If the patient has received neoadjuvant pelvic radiotherapy and/or the inferior mesenteric artery is transected at its origin at the aorta, the entire sigmoid colon should be removed because of concerns regarding ischemia and a descending colostomy created.

If the colostomy is to be brought through the left lower quadrant, an opening in the abdominal wall is made at the previously marked site by excising a 3 cm disk of skin. The undesirable oval configuration of a stoma is avoided by placing traction clamps in the dermis, the fascia, and the peritoneum. These clamps are held in alignment when the opening is made through the abdominal wall. This duplicates the configuration of the abdominal wall when the abdomen is closed and should allow construction of a desirable circular stoma.

The fat, fascia, muscle, and posterior peritoneum are incised longitudinally (Fig. 9-5A). The opening is then dilated, and the closed end of the colon is pulled through the abdominal wall (Fig. 9-5C). The mesentery of the colon can be sutured to the lateral abdominal wall with a running suture, although the complication of small bowel obstruction due to torsion of the small bowel mesentery around the colon mesentery has not been proven to be reduced by this maneuver. After the wound is closed and protected, attention is directed to completing the colostomy (Figs. 9-5C, 9-5D, and 9-5E). The stoma is completed by excising the staple or suture line and by placing chromic catgut sutures between the full thickness of colon and skin. If the stoma is constructed because of inflammatory bowel disease or radiated bowel, a spigot configuration is utilized by applying principles similar to those for ileostomy construction. This facilitates a good appliance seal for anticipated high-volume, liquid effluents.

Once the stoma construction is complete, an appliance is applied in the operating room. The simplest is a one-piece appliance with a skin barrier that can be cut to the appropriate size of the stoma. This same appliance can be used for colostomy and ileostomy. The appliance, which need not be sterile, is held in place with the skin adhesive of the appliance. Tincture of benzoin or other similar adhesives should never be used to maintain adhesion of an appliance to the skin because it has a high risk of initiating contact dermatitis. If colostomy function does not begin within 4 or 5 days, the stoma can be irrigated with small volumes (250 mL) of normal saline to initiate stoma function. The stoma nurses are involved early in the care of the stoma and in teaching the patient and family to provide long-term care of the colostomy. In some cases, the patient is taught the technique of stoma irrigation, and then each individual decides in the

more distant postoperative course if she or he wishes to irrigate the stoma or not.

Long-Term Colostomy Management

The patient with a properly constructed, well-functioning colostomy may elect to irrigate once a day or every other day and to wear only minimal appliance over the stoma or simply cover it with a gauze in the intervening period, although the patient should be instructed to always carry an appliance should episodes of diarrhea occur. Simple appliances exist to allow absorption of mucus and deodorized passage of gas during the period between irrigations, if the patient elects to irrigate.

IRRIGATION

The advantages of irrigating the colostomy include the absence of need for wearing an appliance at all times, the provision of a more regulated lifestyle, the reduced passage of uncontrolled gas, less leakage of stool between irrigations, and the general feeling of comfort that some people experience after irrigating the colostomy. The disadvantages are that it is a time-consuming ritual and that some people feel discomfort when the bowel is distended during irrigation. Irrigation carries a minimal risk of perforation. Absorption of water during the irrigation process can be significant, and the patient with an irritable bowel syndrome will usually not achieve adequate control by irrigation and may be frustrated by attempting to do so. The principle of irrigation is based on the fact that the distal colon displays a few mass peristaltic motions each day and that these can be stimulated by distention of the intestine. It has been shown that 80% of people who irrigate daily can depend on the discharge from the colostomy being one or two movements per day. Poor results from irrigation can be anticipated if the patient has irritable bowel syndrome, a peristomal hernia, irradiated bowel, inflammatory bowel disease, poor eyesight, reduced manual dexterity, or simply fear of dealing with the intestine at the abdominal wall. A preoperative history of irritable bowel syndrome is most important because these patients must never be promised regular function of their colostomies.

The technique of irrigation, usually performed in the morning, uses a cone tip that fits into the stoma only enough to provide a seal and to allow the instillation of 500–1000 mL of water. It is not necessary to dilate the stoma, and a finger is inserted only periodically to determine the direction for placement of the cone tip. Once the water has been instilled, a drainage bag is applied, and the individual can proceed with morning chores while the colostomy empties in response to the stimulation. Between irrigations the patient usually wears a security pouch, which permits passage of gas through a charcoal filter and provides a small pad to absorb any mucus normally secreted by the colonic mucosa.

Ischemia or infection causing partial loss of the intestinal wall or separation of the stoma from the skin can result in stricture of the colostomy. A tight stricture makes irrigation impossible and frequently causes the patient significant discomfort because of the resulting partial obstruction. Because the stricture is always at skin level, its correction is simple and no patient should suffer because of a colostomy stricture.

Colostomy Complications

GENERAL CONSIDERATIONS

A common problem experienced by the patient with a colostomy is irregularity of function, which most often is related to irritable bowel syndrome or irradiation of the intestine. Many problems are related to improper location of the stoma, which allows seepage of mucus and maceration of the skin because an appliance seal cannot be adequately maintained. Parastomal hernia formation is common, and prolapse less so. Patients experience episodes of diarrhea and constipation depending on their underlying disease, dietary habits, and episodic infections. Patients with colostomies can be troubled with gas and odor problems because there is no sphincter around the stoma and gas can be passed uncontrollably. However, most appliances today are odor-proof, making odor only an issue during changing or emptying the appliance. This problem is usually regulated by diet, and in some cases by administering mild antidiarrheal agents when social activity dictates. Minimal bleeding around a stoma is common because the mucosa is exposed to environmental trauma. Of course, prolonged bleeding should be evaluated to be sure that there is not a recurrence of the primary disease process. The same is true of cramps and diarrhea. These can be acceptable occasionally, but anything of a prolonged or severe nature must be evaluated.

Evaluation of the UOA data registry shows that hernia formation is the most common complication of end colostomy, with obstruction, abscess, and fistula presenting less frequently. Of all the complications that occur, few require surgical correction. Fecal impaction can occur with a colostomy and can be managed by irrigation and laxatives. Digital disimpaction is rarely required.

STOMA STRICTURE

In the past, it was believed unsafe to open the colon and suture the edges to the skin at the time of initial operation and stomas were thus opened in a delayed fashion. Serositis developed because the serosal surface of the exposed colon was irritated by exposure to air. After the exposed end of the colon was opened, it would take some time for the mucosa to eventually anneal to the epidermis. This process was called “maturation” of the colostomy. Strictures were common because the inflammation associated with serositis often led to fibrosis. Surgeons eventually learned to open stomas immediately at the time of initial operation and suture the intestinal wall to the skin. For historical reasons,

this maneuver is still referred to as immediate "maturation" of the stoma.

Another cause of colostomy stricture is ischemia, usually as a result of resection of too much mesentery during construction of the stoma, or from inadequate mobilization and tension. Repair may require a simple local procedure if the stricture is focal at the skin level, or revision of the stoma via a transabdominal approach if the stricture involves a longer segment.

COLOSTOMY NECROSIS

Ischemia or necrosis of the colostomy results from excessive resection of colonic mesentery, excessive tension on the mesentery leading to the stoma, creation of a fascial opening too small to accommodate the bowel and its mesentery, or poor perfusion due to low-flow states. The blood supply to an end colostomy is unidirectional, without collaterals; therefore, it will be most sensitive to changes in visceral perfusion. If the necrosis is limited to the area of the stoma anterior to the fascia, it may be observed carefully, and stoma revision performed electively at a later date, if necessary. If the necrosis extends into the peritoneal cavity, the abdomen should be explored and the stoma recreated. In some cases it is difficult to ascertain the extent of necrosis. Gentle flexible endoscopy via the stoma is an accurate method to determine the level of necrosis. Occasionally it may be possible to use a glass test tube and light to make this determination, but endoscopy is more reliable.

PARACOLOSTOMY HERNIA

Paracolostomy hernia is a frequent complication of colostomy creation, even when all is done according to acceptable surgical principles. The creation of an abnormal opening in the abdominal wall that is then subjected on a daily basis to the pressures of Valsalva maneuvers may predispose the patient to suffer a gradual enlargement of the fascial opening. The relative weakness of the posterior rectus sheath in the inferior abdominal wall, with the potential space that exists alongside the rectus muscle, may also predispose the patient to develop a peritonealized sac in the rectus sheath without a large fascial defect. Although it is surgical dogma to create stomas in the rectus sheath to lessen the development of parastomal hernias, there are no definitive data to support this contention.

Asymptomatic parastomal hernias should be observed because the rate of recurrence after repair or relocation of the stoma is high. Patients should be counseled to seek immediate medical attention if they develop symptoms or signs of intestinal incarceration in the hernia. Symptomatic hernias may be relocated or repaired, although no technique has proven to be reliably successful. Local suture repair often fails, and although broad fascial mesh repair appears to be a more rigorous method of repair, there is still a substantial risk of recurrence and the added concern of mesh infection. Laparoscopic repair with intraperitoneal mesh is being used more frequently, although it would appear to offer no advantage over open mesh repair other than a potential reduction in wound complications and short-term postoperative recovery. Some surgeons are placing mesh in the abdominal wall at the time of permanent stoma creation as prophylaxis against hernia formation, but the experience is too preliminary to make definitive assessments of the safety and efficacy of this technique.

COLOSTOMY PROLAPSE

Prolapse of the colostomy is seen most often with the transverse loop colostomy. This is probably the result of several factors, most prominent being the lack of fixation of the transverse mesocolon to the retroperitoneum, and the size of the fascial opening necessary to bring both limbs of the colon and the mesocolon to the skin level. If the transverse loop colostomy is constructed to decompress a dilated colon, the fascial opening may need to be large initially, and then be excessive once the colon decompresses and thus predispose the colostomy to prolapse later. The surgical treatment of transverse loop colostomy prolapse is difficult, and the best treatment is to rid the patient of the primary disease and restore intestinal continuity. If this is not possible, the loop colostomy should be converted to an end colostomy with mucous fistula, or a divided end-loop colostomy, with concurrent tightening of the fascial defect.

Prolapse of an end colostomy can be managed by a local procedure in which the mucocutaneous junction is disconnected, the redundant colon resected, and the mucocutaneous junction recreated. Concurrent hernia repair can be performed as indicated.

COLOSTOMY PERFORATION

Perforation of the colon just proximal to the stoma most often occurs during careless irrigation with a catheter or during contrast x-ray studies when a catheter is placed in the colostomy and a balloon is inflated. This occurrence represents a surgical emergency and must be dealt with by laparotomy and reconstruction of the colostomy with adequate drainage, if there is significant fecal or barium contamination. Cases of mild inflammation with extravasation of air can only be managed with antibiotics and localized drainage, and surgery can be avoided.

ILEOSTOMY

An ileostomy is an opening constructed between the small intestine and the abdominal wall, usually by using distal ileum, but sometimes more proximal small intestine. The stoma is constructed on a permanent basis for patients who require removal of the entire colon, and usually the rectum, for inflammatory bowel disease, either Crohn's disease or ulcerative colitis. The use of a loop ileostomy is becoming more frequent because of the complex sphincter-preserving operations being

performed for ulcerative colitis, familial polyposis, and rectal cancer. For these operations, it is necessary to have complete diversion of intestinal flow while the distal anastomosis and neorectum are allowed to heal and adapt. The loop ileostomy is also useful in cases where multiple or complex anastomoses must be performed distally, usually for Crohn's disease or diverticulitis. As sphincter-preserving operations are used more often, diminishing numbers of permanent ileostomies will be constructed, but similar principles and techniques will be utilized in constructing the temporary loop ileostomies. The same principles used in constructing an ileostomy can be applied to the construction of a urinary conduit.

The surgical construction of an ileostomy must be more precise than that for a colostomy because the content is liquid, high volume, and corrosive to the peristomal skin. Therefore, the stoma must be accurately located preoperatively, and it must have a spigot configuration to allow an appliance to seal effectively and precisely around the stoma.

Various types of ileostomies can be constructed. The most common has been the end ileostomy, using a technique popularized by Brooke and Turnbull. The loop ileostomy is used, as described, to divert stool away from diseased areas or surgical anastomoses distally. The loop-end ileostomy is a stoma that uses the principles of a loop ileostomy but is constructed as a permanent stoma when the mesentery and its blood supply need special protection. The continent ileostomy, a technique devised by the Swedish surgeon, Nils Kock, is an internal pouch that does not require the wearing of an external appliance. The urinary conduit is a stoma constructed of small intestine to provide a conduit to the outside for the urinary tract.

Determination of Ileostomy Location

The location of the ileostomy must be carefully chosen before surgery (Fig. 9-6). It should avoid any deep folds of fat, scars, bony prominences of the abdominal wall, the inguinal folds, and the waistline crease. The site is chosen by drawing a vertical line through the umbilicus and a transverse line through the inferior margin of the umbilicus and applying a disk the size of a stoma faceplate (approximately 8 cm in diameter) to determine the location. The disk is allowed to abut on both of the lines in the right lower quadrant, and the site is marked with ink. The patient is then brought to an exaggerated sitting position and allowed to turn in various directions to be sure the site is adequate in all positions, and there are no creases or skin folds created by changes of position. If so, the location should be adjusted to bring the stoma to the summit of the infraumbilical fat fold to be sure that there is clearance for fitting of an appliance. When the patient is in the operating room and anesthesia has been administered, the chosen site is scratched with a fine needle before preparation of the abdominal skin is carried out. The majority of complications arising from ileostomies can be avoided by taking these precautions in marking the site for the stoma preoperatively. Even in cases in which the use of a stoma seems remote, the precaution of marking the site preoperatively should be taken. In addition, whenever possible, patients should be seen by a CWOCN and an ostomy visitor so that they can be given information about the stoma and its care. The visit from an ostomate (someone who has done well with a similar stoma) is helpful because it allows the patient to know that the surgery can be survived and that life can be continued productively and normally with the presence of a stoma. The discussion should avoid excessive details about types of equipment and types of stoma problems during the postoperative period, as this information can be overwhelming to a patient facing complex surgery, often life-threatening disease processes, and the concept of having a stoma.

When an ileostomy is anticipated, the choice of abdominal incision is a left paramedian skin incision, slanting the incision to the midline fascia (Fig. 9-6A). This gives the advantage of opening the fascia through the midline to provide a simple, effective closure and at the same time preserve all the right lower quadrant peristomal skin for maintenance of the appliance seal.

End Ileostomy

The construction of the ileostomy begins early in the operative procedure. When the colon is mobilized for colectomy, as is the usual case when an ileostomy is to be constructed, full mobilization of the mesentery of the distal ileum should be carried out (Fig. 9-6D). This is an important and often neglected part of the procedure. There is an embryonic fusion plane of the mesentery of the small intestine to the right posterior abdominal wall. The ileum can be elevated on this mesentery up to the duodenum, allowing extreme mobility of the terminal ileum. The ileocolic artery is then transected as part of the colectomy, and the remaining blood supply to the small intestine is preserved (Fig. 9-6C). It is important to preserve the most distal arcade of vessels and mesenteric tissue on the ileum at the segment of the intended ileostomy. This blood supply is prepared early in the operative procedure so that if there is any question about the vascularity of the distal ileum, it will be known long before the abdomen is closed. The preservation of this distal bit of mesentery and fat on the ileum sometimes appears to cause excess bulk around the ileostomy, but this fat soon atrophies, allowing a well-vascularized stoma of appropriate size. The intestine is transected with a linear-cutting type of stapling instrument so that the end of the ileum can be easily pulled through the abdominal wall without increased risk of contamination. This can, of course, also be accomplished by suturing the end of the ileum.

When the intestinal resection has been completed, an opening is prepared in the right lower quadrant of the abdominal wall at the previously marked site (Fig. 9-6B). It is important to return the abdominal fascia to its natural position prior to making the stoma opening so that the fascia does not impinge upon the stoma when closed. This is of significant concern during situations when a Pfannensteil incision is used to accomplish the colectomy, as is common with hand-assisted laparoscopic colectomy. The round configuration of the stoma

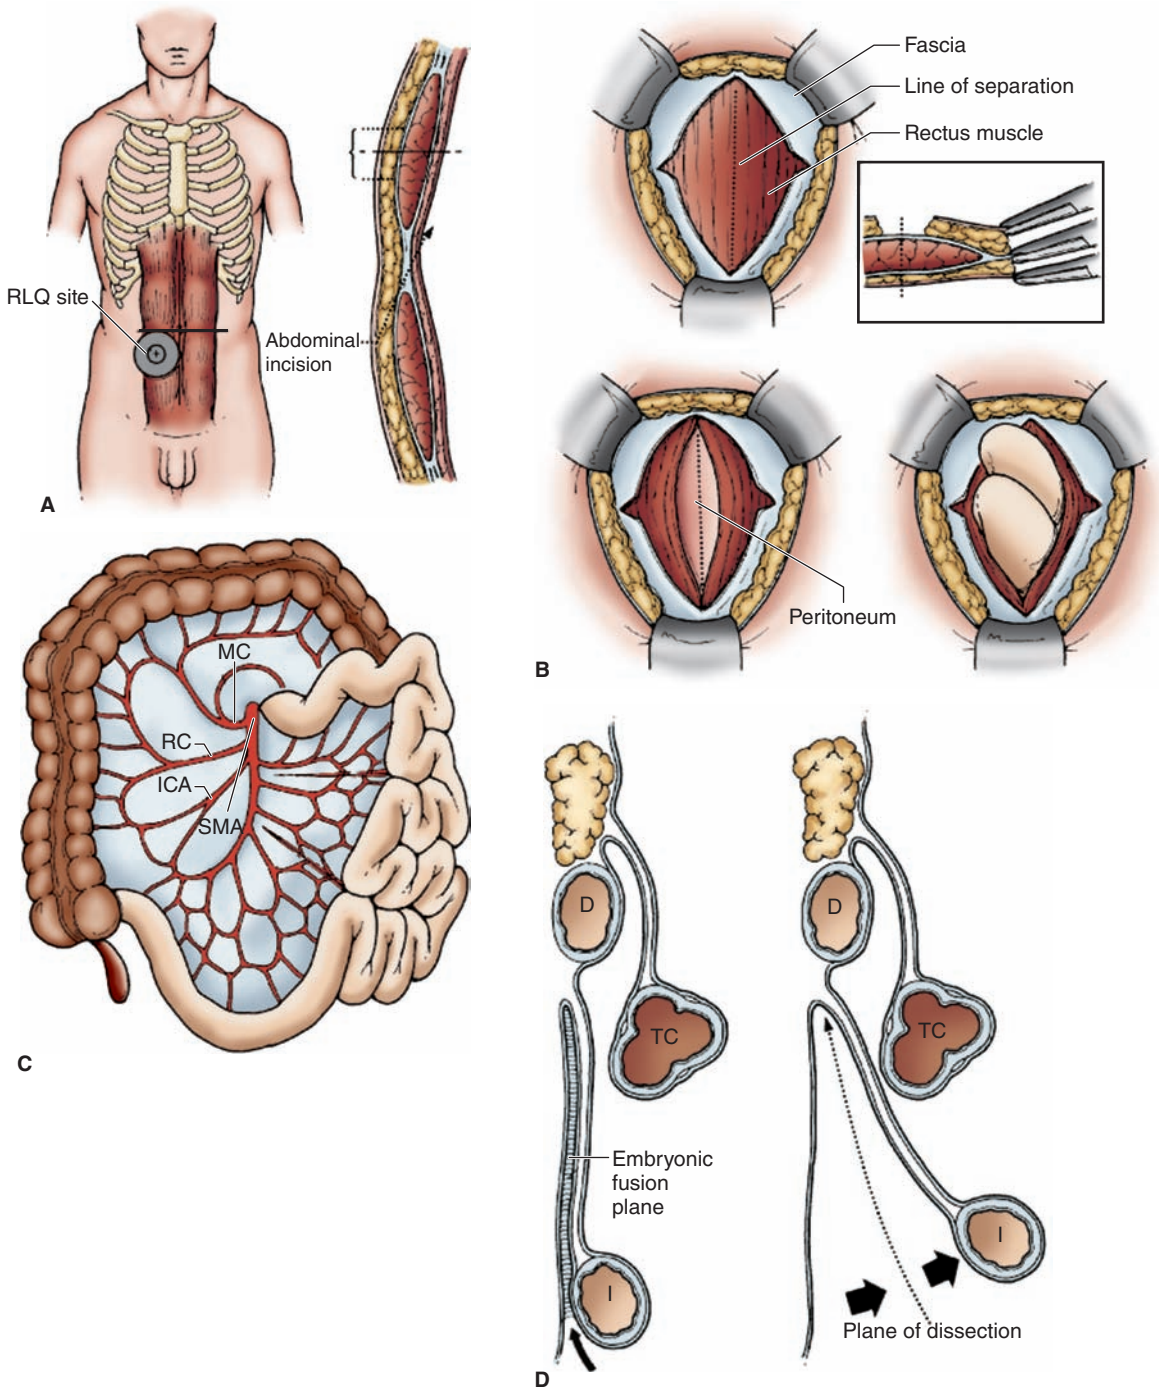

FIGURE 9-6 General considerations in construction of an ileostomy. **A.** Locating the ileostomy site and the use of a paramedian skin incision that slants to the midline fascia, allowing preservation of the peristomal skin. **B.** Technique for making the abdominal wall opening. **C.** Vascular supply of the distal ileum, which must be used to maintain viability of the ileostomy. (MC, middle colic artery; RC, right colic artery; ICA, ileocolic artery; SMA, superior mesenteric artery.) **D.** Plane of mobilization of the distal ileum to allow construction of an ileostomy without tension. (P, pancreas; D, duodenum; TC, transverse colon; I, ileum.)

is maintained by placing traction clamps on the dermis, fascia, and peritoneum. A 3 cm disk of skin is excised, and a longitudinal incision approximately 3–4 cm long is made through all layers, with each layer being retracted with small retractors as the incision is deepened. If the patient is obese, some fat can be excised, although this is not mandatory. The fascia is incised longitudinally as well, and frequently a small lateral notch is placed on each side. The muscle is separated, and any vessels are coagulated. The posterior fascia and peritoneum are then incised.

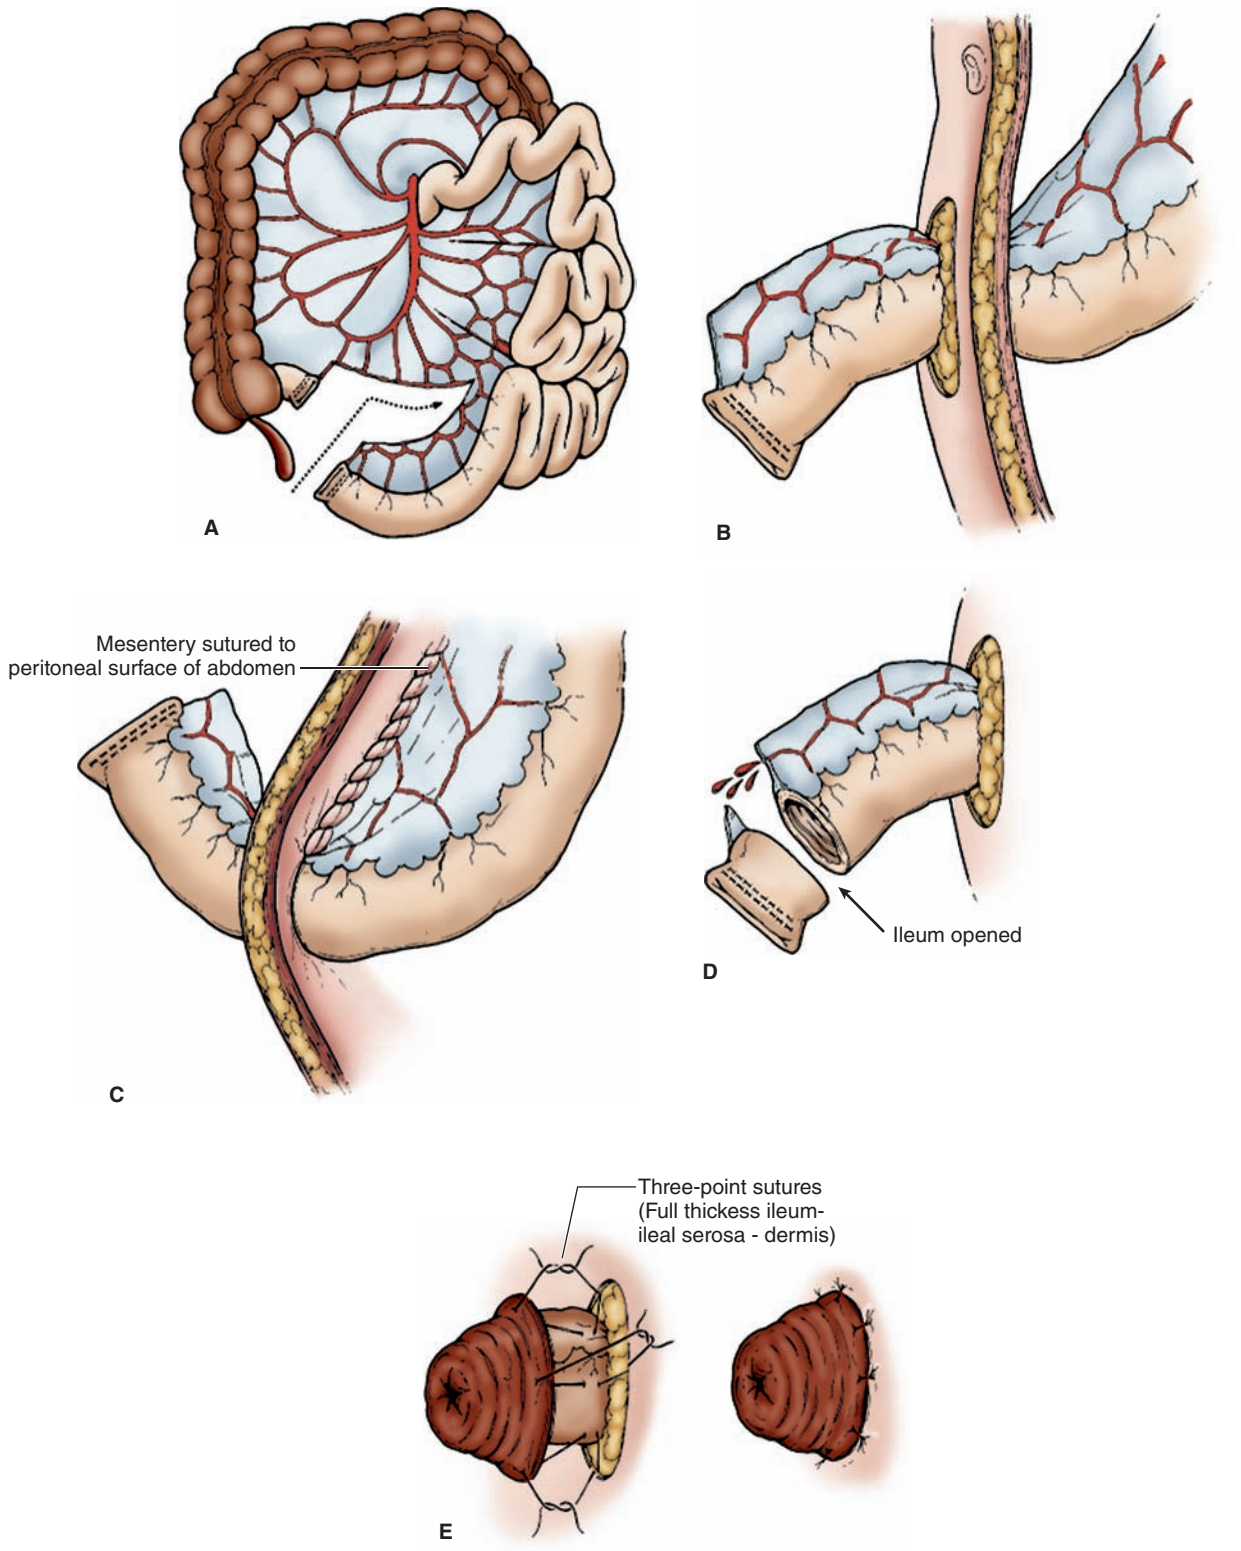

FIGURE 9-7 Construction of an end ileostomy. **A.** The distal arcade of vessels and some mesentery are preserved on the segment to be used for ileostomy construction. **B.** The closed ileum is pulled through the abdominal wall to a length of 6 cm. **C.** The mesentery of the ileum is fixed to the abdominal wall. **D.** The adequacy of the blood supply is verified. **E.** The spigot configuration is achieved by placing sutures to include full thickness of intestine, the seromuscular layer at the base of the stoma, and the dermis.

The size of the stoma opening should be approximated based on estimates of the diameter of the intestine and mesentery to be brought through, and the thickness of the abdominal wall. The geometric shape of the stoma opening should also be determined by these factors. If the abdominal wall is thin, the opening in the abdominal wall can be cylindrical. If the abdominal wall is thick, the shape of the incision should be pyramidal, with the fascial opening larger than the skin opening to accommodate the amount of mesentery that will be brought through at the fascial level. The oft-used "two finger" rule to gauge the size of the stoma opening is usually not adequate to account for all of the above considerations.

The ileum is brought through the abdominal wall to the intended length, usually about 6 cm (Fig. 9-7B). If the abdominal wall is thick, this maneuver may be difficult to accomplish. It may be helpful to use a small plastic wound protector/retractor through the stoma to facilitate passage of the intestine through the abdominal wall. Alternatively, the fat and skin can be raised off of the fascia as a flap, the intestine brought through the muscle and fascia first, and then subsequently brought through the fat to skin level. The mesentery of the distal ileum may be sutured to the right lateral abdominal wall, although there are no data to prove that this maneuver reduces the incidence of intestinal obstruction, stoma prolapse, or stoma retraction.

The abdomen is then closed. The incision is protected, and attention is directed to the ileostomy where the staple line or suture line is excised, verifying the adequacy of blood supply. If the blood supply of the stoma is questioned, more of the ileum should be resected.

The next objective is to make a protruding, everting stoma. This is accomplished by placing 3-0 chromic catgut sutures through the full thickness of intestine, the seromuscular area of the ileum at the base of the stoma, and the dermis (Fig. 9-7E). Sutures through the skin should be avoided, because any stellate scarring will prevent the maintenance of the required seal of the appliance. Eight of these sutures should be placed, one in and one between each quadrant; and as traction is applied after they are all placed, the stoma should evert nicely.

After the stoma is completed, an ileostomy appliance is applied. A simple appliance in which the skin barrier can be cut to the size of the stoma is best. In the immediate postoperative period, if there is any question about leakage around the appliance or malfitting of the appliance, it should be changed and the skin cleaned immediately. It is important to preserve the integrity of the peristomal skin, and all the nursing staff should be aware of the importance of this. The leaking appliance should not be left for changing by the next shift or for the CWOCN the next morning, because the skin can be damaged during this waiting period.

Loop Ileostomy

The loop ileostomy stoma is constructed when both diversion of the intestinal flow and decompression of the distal intestine are required. The location is chosen exactly as one would choose the site for an end ileostomy. The construction can then follow one of two techniques. The technique popularized by Turnbull at the Cleveland Clinic involves choosing the site in the intestine for the intended loop ileostomy and then placing orienting sutures proximally and distally (Fig. 9-8A). A loose suture with one knot can be placed proximally and

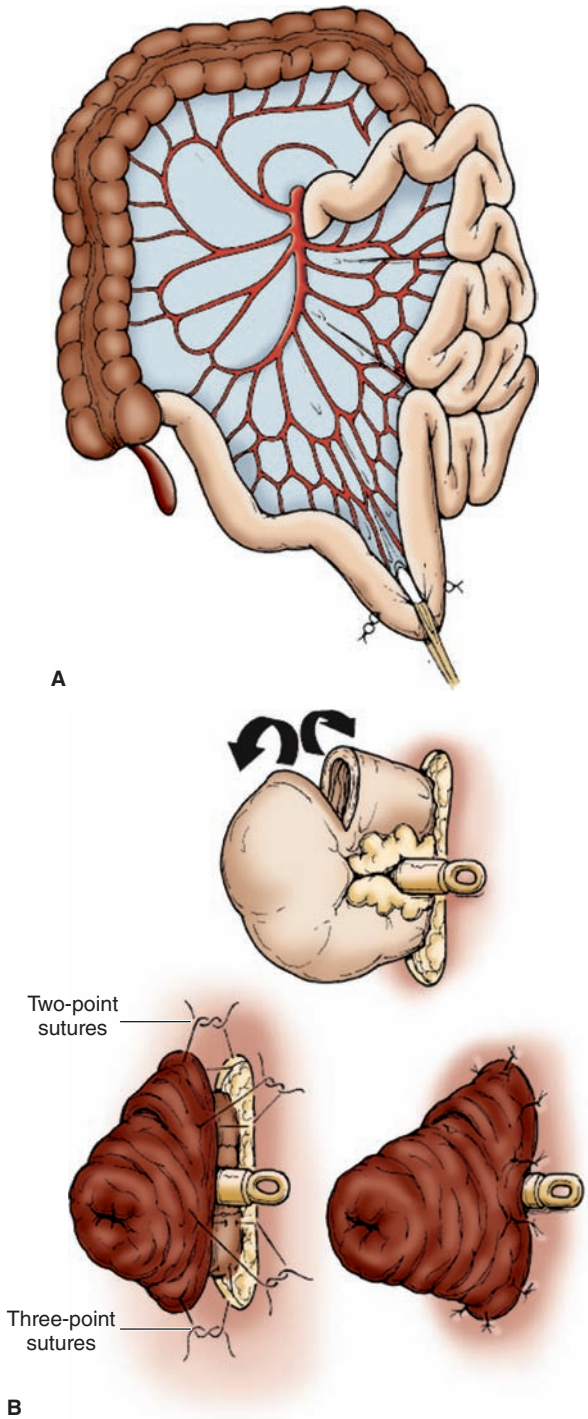

FIGURE 9-8 Construction of a loop ileostomy. **A.** A tracheostomy tape is placed at the segment for the intended ileostomy with sutures to identify proximal and distal limbs. **B.** The loop is pulled through the abdominal wall while its proper orientation is maintained. The tape is replaced by a plastic rod, and the spigot configuration is completed.

one with two groups of knots distally. It is important to maintain this orientation as the stoma is constructed.

The opening in the abdominal wall is made the same as for an end ileostomy (Fig. 9-6B), but the loop of intestine is drawn through this abdominal opening by a tape placed through the mesentery and around the intestine (Fig. 9-8A). Some surgeons recommend orienting the proximal functioning loop in the inferior position, placing a partial twist on the loop of intestine. Although this may help configure the spout of the ileostomy so that ileal effluent is less likely to undermine the appliance, this maneuver may be associated with a higher rate of intestinal obstruction. In massively obese patients with a shortened mesentery, it is necessary to make a pyramidal configuration of the opening in the abdominal wall, with the internal opening being much larger than the external opening at the skin. If this maneuver is used, it is best to place a row of tacking sutures between the peritoneum and the loop of intestine to maintain position and orientation. Once the loop is drawn through the abdominal wall, the abdomen is closed, maintaining the orientation of the loop. It is usually not necessary to fix the mesentery of the ileum to the abdominal wall when constructing a loop ileostomy. The wound is then protected, and attention is directed to the stoma.

The tape is replaced by a small plastic rod, which is commercially available (Fig. 9-8B). It is not sutured to the peristomal skin, but it often has a heavy suture tied around each side so that should the rod dislodge, it can be drawn back through the mesentery rather than being pushed through, with risk of injuring the mesentery. The loop of intestine is opened by making a four-fifths circumferential incision at the distal aspect of the loop, allowing 1 cm of ileum above the skin level in the superior aspect (Fig. 9-8B). The recessive limb thus is formed distally, and sutures are placed between the full thickness of ileum and dermis at this level. As the proximal aspect of the stoma is constructed, sutures are placed as previously described between the full thickness of ileum, the seromuscular area at the base of the stoma, and the dermis. As these sutures are tied, the stoma should assume a spigot configuration supported by the rod. The ileostomy appliance may be placed beneath the rod or over the rod, depending on the tension of the mesentery. The rod is left in place for 1 week, and the same ileostomy care is provided as previously described.

Another technique for constructing a completely diverting ileostomy is to use the divided end-loop method popularized by Abcarian and Prasad (Fig. 9-9). This technique involves transecting the ileum with a linear-cutting stapling instrument. No compromise of the mesentery is involved. The opening in the abdominal wall is made in identical fashion to that previously described, but when the intestine is pulled through, the proximal component is excised, and the stoma is constructed as previously described for an end ileostomy. The recessive limb at the base of the stoma has one corner of the staple line excised, and the full thickness of ileum is sutured to the dermis at the superior aspect of the stoma. This allows a small recessive limb that serves to decompress the distal intestine.

If a loop ileostomy cannot be brought to skin level because of obesity and/or tension on the mesentery (a situation most often encountered following restorative proctocolectomy), it may be helpful to create a divided end ileostomy to achieve more length. The ileum at the site chosen for ileostomy is divided and the proximal end brought out as an end stoma. The distal end is left closed in the peritoneal cavity or abdominal wall. This maneuver will sometimes result in formal laparotomy being required to close the stoma, but is a better alternative than a flush ileostomy.

CLOSURE OF LOOP ILEOSTOMY

When endoscopic procedures and contrast studies have shown that the pouch is intact or that the distal anastomoses have healed securely, consideration can be given to closing the loop ileostomy. If the primary procedure has involved the anal sphincter mechanism, careful physical examination and manometric studies should verify the adequacy of sphincter function before intestinal continuity is restored.

For closure of the loop ileostomy (Fig. 9-10), a circumferential dissection is carried out, with a minimal rim of skin included, until the peritoneal cavity is entered and clean peritoneal surface of abdominal wall can be palpated circumferentially. Once this is accomplished, the loop of intestine can usually be brought easily through the circular incision in the abdominal wall. Closure is completed by excising the rim of fibrous tissue, with care being taken to preserve as much of the viable intestinal wall as possible (Figs. 9-10B and 9-10C). The choice of closure then varies between hand-sutured transverse closure (Figs. 9-10D and 9-10E), stapled transverse closure (Figs. 9-10F and 9-10G), or formal construction of an anastomosis.

For closure of the separated (divided end-loop) ileostomy (Fig. 9-11), the mobilization is carried out in similar fashion, and a functional end-to-end closure is performed. A linear-cutting stapler is applied and removed, and the enterotomy is closed transversely. The intestine should be rotated so that antimesenteric surfaces are used for the staple line.

After intestinal continuity is restored, the abdominal wall is closed. Because of the risk of skin infection, many surgeons are reluctant to close the skin primarily. Rather, the skin defect can be handled by a number of alternative methods: closure over a drain; partial closure in linear fashion; or partial purse-string closure.

LOOP-END ILEOSTOMY

A loop-end ileostomy should be constructed in the rare circumstances in which it is unsafe to resect the mesentery of the distal ileum or when there is tension created on the mesentery as the ileum is brought to the abdominal wall for construction of the ileostomy. This occurs in the patient with a thickened mesentery or a very obese abdominal wall, or in a patient who has had multiple surgical procedures that altered the mesentery. These conditions preclude dealing with the usually

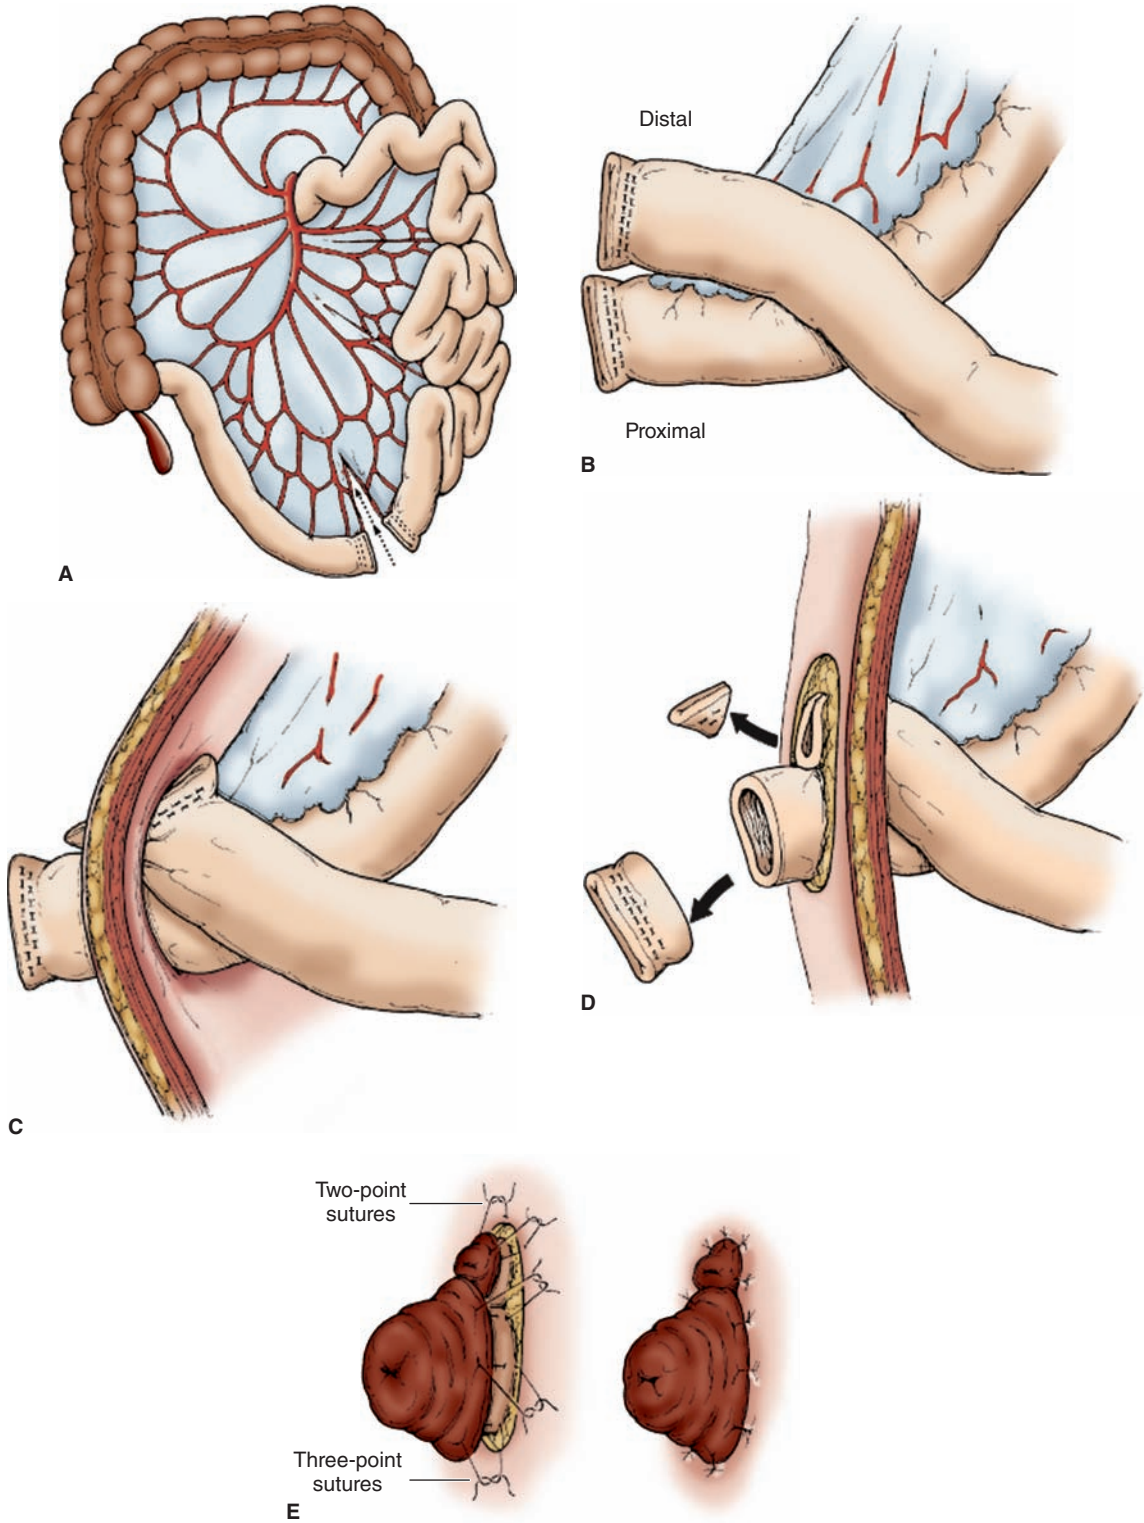

FIGURE 9-9 Construction of a separated (divided end-loop) ileostomy. **A.** The distal ileum, but very little of the mesentery, is transected, using a linear-cutting staple device, in preparation for constructing the ileostomy. **B, C.** The proximal, functioning component is brought through for spigot construction, whereas only the corner of the distal component is brought through. **D.** The entire staple line of the proximal component and a corner of the distal component are excised. **E.** The functioning spigot and nonfunctioning recessive opening are completed.

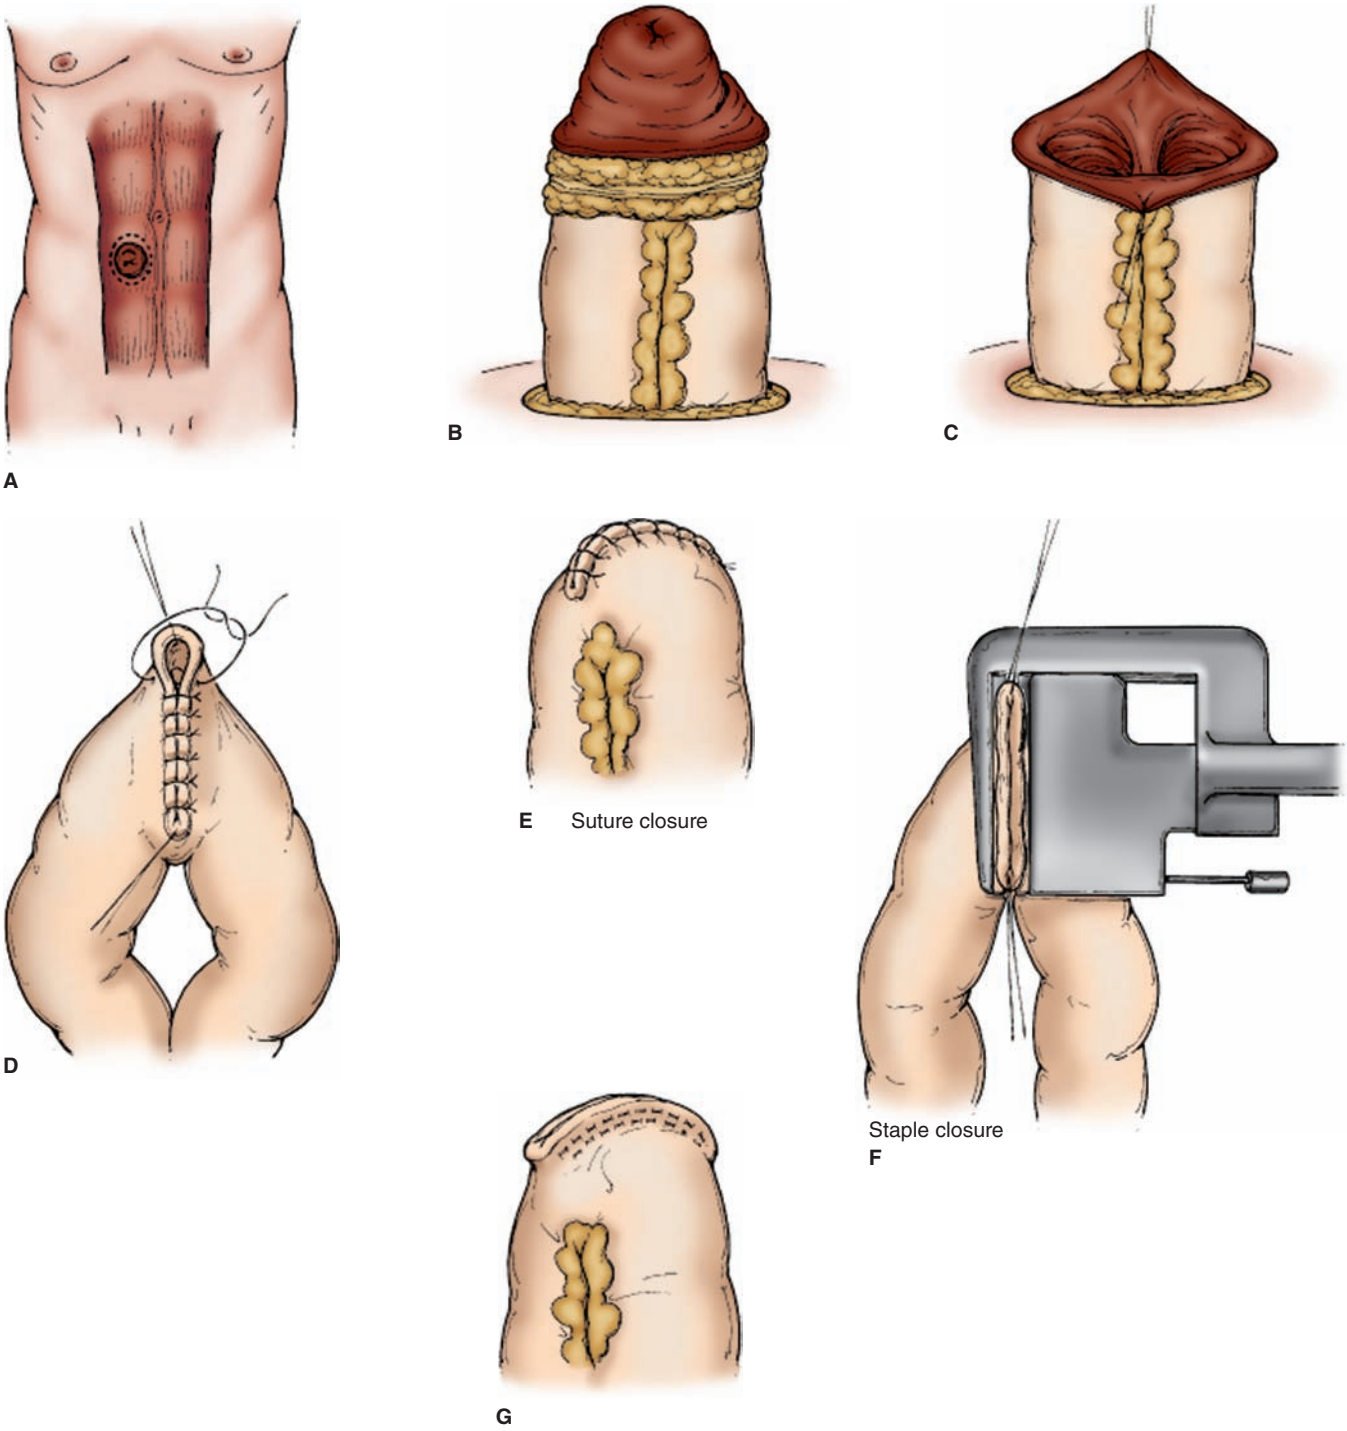

FIGURE 9-10 Closure of a loop ileostomy. **A.** A circumferential incision is made and carried into the peritoneal cavity. **B.** The loop of intestine is completely mobilized. **C.** The fibrofatty tissue is completely excised, preserving all the intestine. **D, E.** A suture closure can be performed, or a transverse stapled closure (**F, G**) can be performed.

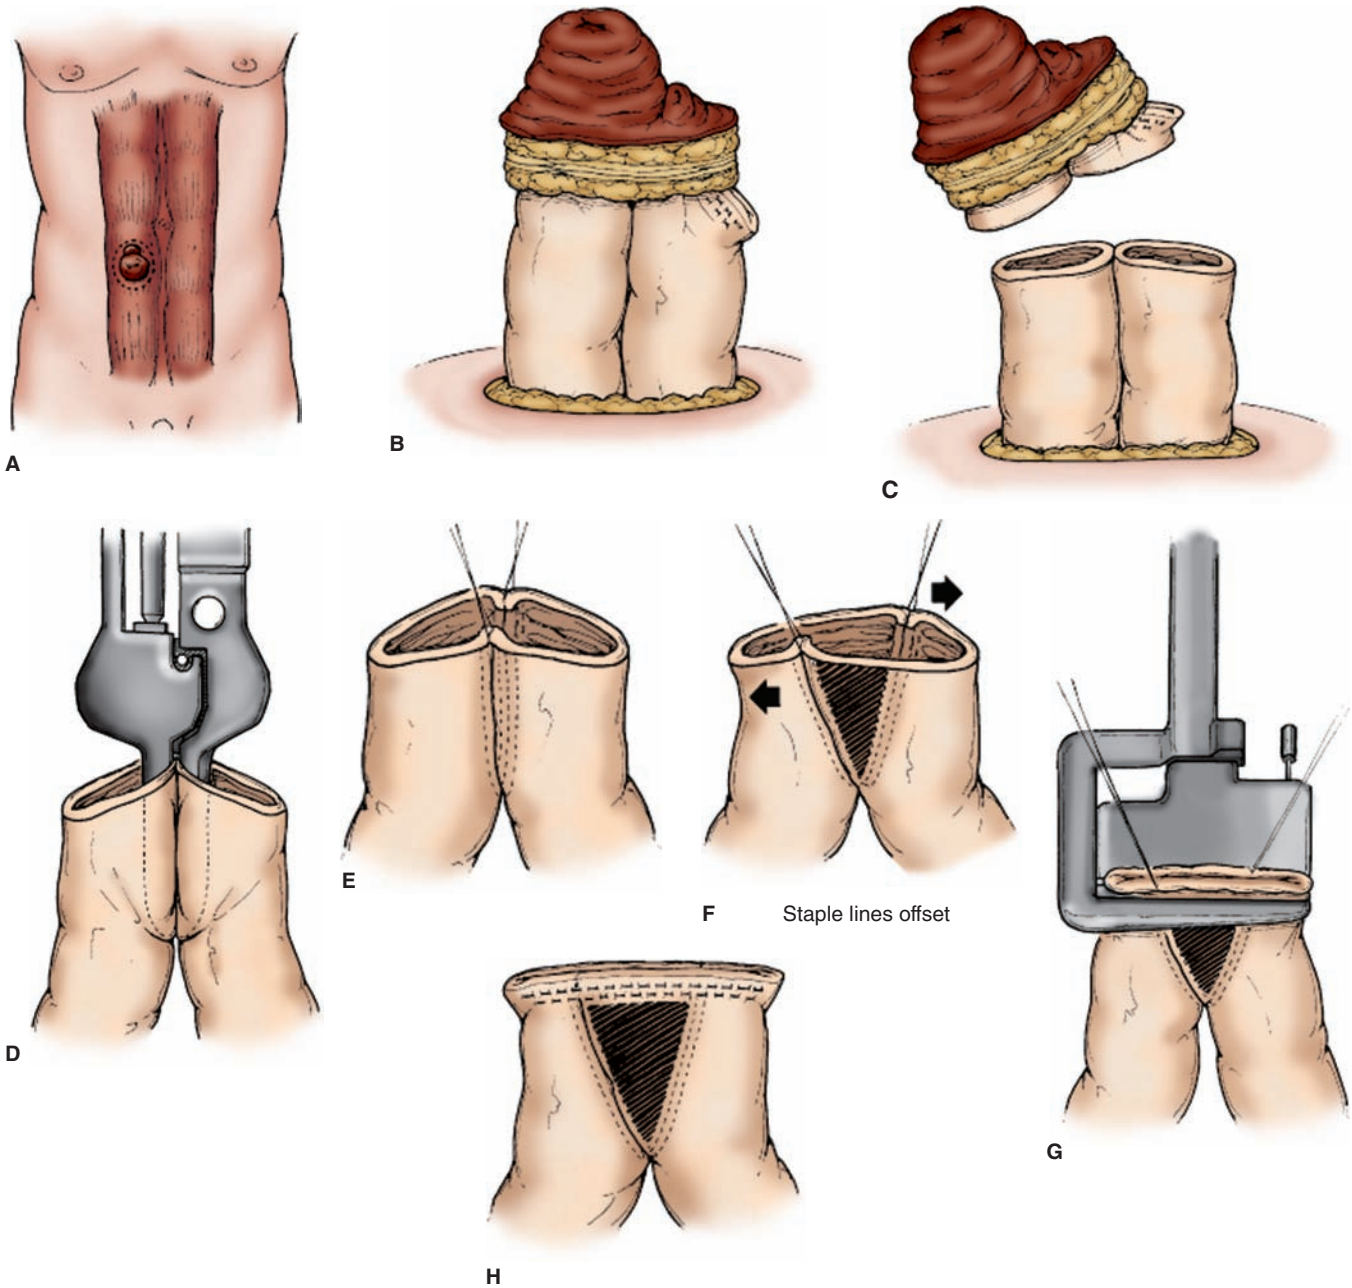

FIGURE 9-11 Closure of a separated (divided end-loop) ileostomy. **A.** A circumferential incision is made and carried into the peritoneal cavity. **B, C.** The stoma site and residual staples are excised. **D.** A linear-cutting stapler is applied to the antimesenteric side of the intestine. **E, F.** The components of the staple line are offset. **G, H.** The functional end-to-end closure is completed with a linear stapling instrument.

pliable mobile tissue. This technique is especially useful in the obese patient who requires construction of a urinary conduit after cystectomy and radiation. The technique is especially helpful because a supporting rod can be placed beneath the stoma for 1 week to help avoid retraction through a thick abdominal wall (Fig. 9-12).

Constructing a loop-end ileostomy involves transecting the ileum as previously described, but the closed end will remain closed (Fig. 9-12A). The staple line is inverted with seromuscular sutures, or if it is to be used for a urinary conduit, only absorbable sutures are used to close the end of the ileum, because stone formation has been reported around staples (Fig. 9-12B). The orienting sutures are then placed as described for construction of a loop ileostomy, and a tracheostomy tape is placed so that when the loop of ileum is pulled through the abdominal wall, the closed recessive end will be superior and just within the abdominal cavity (Fig. 9-12C). The construction of the loop-end stoma then proceeds exactly

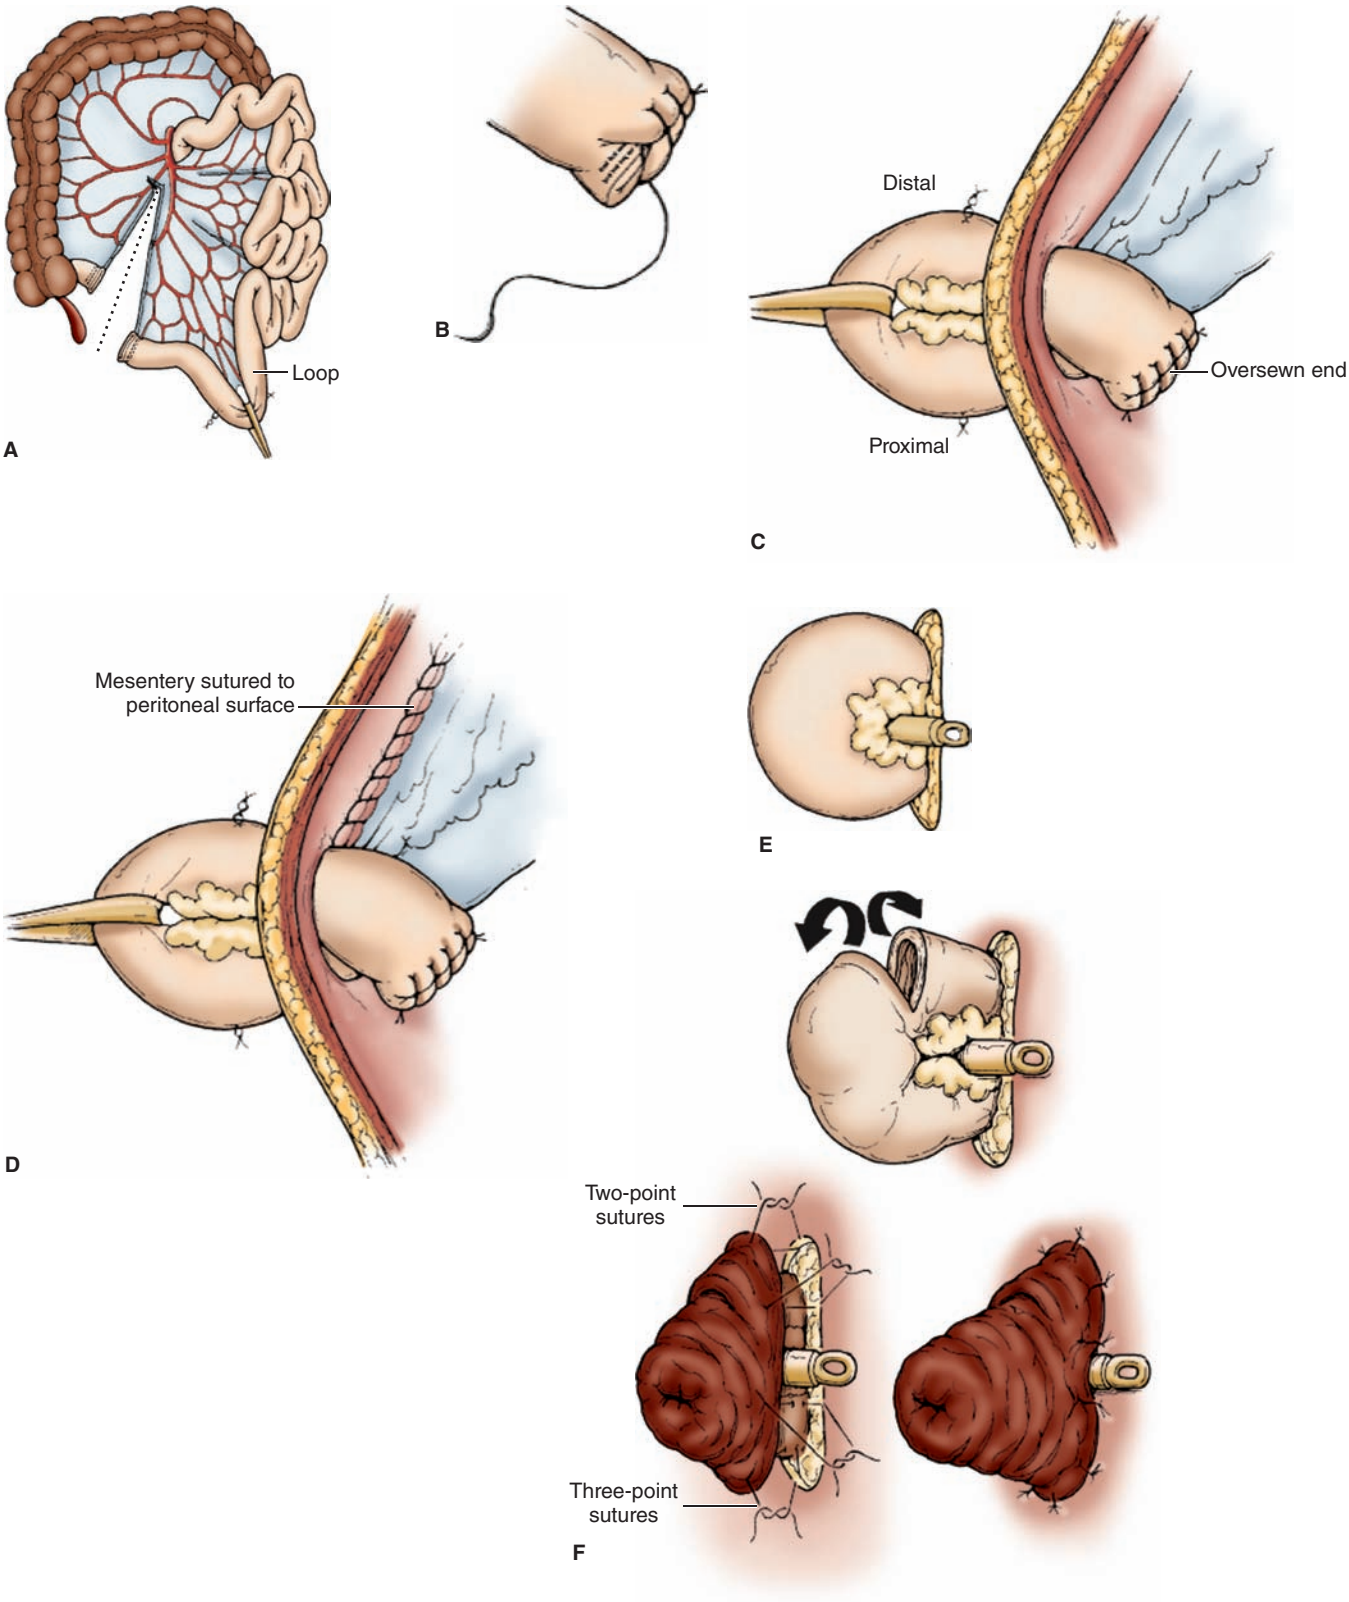

FIGURE 9-12 Construction of a loop-end ileostomy. **A.** A tracheostomy tape is placed around the loop of intestine, with the mesentery mobilized but completely preserved. **B.** The end of the ileum is inverted. **C.** The intestine is pulled through the abdominal wall so that the functional limb will be in the inferior position, and the closed end is allowed to reside just within the abdominal cavity. **D.** The mesentery of the ileum is fixed to the abdominal wall because this is meant to be a permanent stoma. **E.** The tracheostomy tape is replaced with a small plastic rod. **F.** The stoma construction is completed exactly the same as described for a loop ileostomy.

as that described for the loop ileostomy (Figs. 9-12D, 9-12E, and 9-12F). However, in the case in which the stoma will be permanent, the mesentery of the distal ileum is fixed to the abdominal wall (Fig. 9-12D). If the stoma will be used as a urinary conduit, the loop of the conduit should be brought through the abdominal wall before the ureteral anastomoses have been carried out. It is a disconcerting problem to have the ureters fixed and then find there is an inadequate length of ileum to bring through the abdominal wall. It is also easier to place the ureteral stents when the construction is done in this fashion.

A special problem has been found in patients with a loop-end ileostomy in that there continues to be mucus secretion from the recessive limb, and after a period of several months, this secretion may interfere with the perfect seal of the ileostomy appliance. If interference does occur, it may be necessary to resect the distal limb and convert the stoma to a proper end ileostomy. This is a small price to pay, however, because it is an easy operation to remove the recessive limb, and it can be done without opening the abdominal cavity. Of more importance is the fact that the loop configuration during the initial procedure has allowed maintenance of blood supply and a protruding configuration under circumstances in which this otherwise may have been impossible, and that would have resulted in major complications.

POSTOPERATIVE CARE OF ILEOSTOMIES

The components of an ileostomy appliance are a skin barrier with a faceplate, and a drainable pouch. Most ileostomy appliances are now commercially available as one-piece or semi-disposable two-piece units. The one in common use has a skin barrier with a fixed plastic flange (ring) so that the stoma opening can be cut precisely, the skin barrier applied, and the pouch snapped directly onto the plastic flange, thus allowing easy drainage and disposal of the pouch part of the appliance. The skin barrier component should need changing only every 4–5 days in a patient with a properly protruding and located stoma. A well-constructed ileostomy should allow the patient to display normal physical vigor, to eat a well-balanced palatable diet, and to engage in normal recreational and sexual activity. There should be no prolapse or retraction, the skin should remain normal, and the appliance should not leak. When first constructed, ileostomy output typically averages 1500 mL per day of liquid effluent, but after adaptation occurs, between 500 mL and 800 mL of thick liquid content should be passed per day.

ILEOSTOMY COMPLICATIONS

Before the concept of stoma eversion was conceived, in approximately 1960, the majority of patients who underwent construction of an ileostomy had serious postoperative complications, usually related to serositis, which caused a partial obstruction at the stoma itself. These patients suffered massive fluid and electrolyte imbalance and often death, which were related to the enormous sequestration of fluid secondary to the small bowel obstruction. This condition was called "ileostomy dysfunction" and was anticipated after the construction of each stoma. This devastating problem essentially has been eliminated, since stomas have been opened and everted immediately at the time of construction. The output of an ileostomy should thus not be excessive, even in the immediate postoperative period.

Patients with ileostomies do have problems, most often related to maintenance of the seal of the appliance because of poor location or defective configuration of the stoma. In some cases, it is necessary either to revise the stoma locally to bring it into a spigot configuration, or to relocate it so an appliance can be securely applied. The most common problem experienced by ileostomy patients is chemical dermatitis. This can be prevented by proper stoma construction techniques, and by obtaining a pouching system that is properly sized and adherent. If the patient has a poorly constructed stoma, or a poorly fitting appliance, destruction of the peristomal skin can be so severe as to require split-thickness skin graft for definitive management. In these cases and in others in which the skin is injured around the stoma, a special ileostomy appliance may be utilized. It is based on maintenance of the seal to the mucosa of the ileum rather than to the peristomal skin. This appliance is used infrequently, when it is the only solution to complicated peristomal skin problems. Its use requires wearing supportive belts to maintain the appliance in place, but the skin can be treated with medicated pads during this period.

Another potential complication of ileostomy is dehydration. In patients with newly constructed ileostomies, the output of intestinal contents is frequently high enough that patients will require intravenous fluid administration until the stoma output decreases and the patient can compensate with adequate oral intake of fluids and electrolytes. One of the early symptoms associated with dehydration is nausea, which further exacerbates the problem as patients are loath to drink fluids. This problem not infrequently results in readmission to the hospital following major intestinal surgery accompanied by ileostomy formation. Patients should be counseled prior to discharge regarding the signs and symptoms of dehydration, and to intervene early with increased oral intake of fluids. Patients with long-term ileostomies are also at risk of becoming dehydrated, which occurs in hot weather and during strenuous physical activity. The individuals should be instructed to maintain adequate intake of fluids and electrolytes. They should routinely have medications on hand for simple diarrhea so that control can be achieved before dehydration occurs.

Some patients with ileostomies will present with acute blockage of the stoma, which is usually related to food indiscretion creating a "food bolus obstruction" just proximal to the level where the intestine exits the abdominal wall. This complication is most common in patients with newly constructed stomas, as there is some residual edema in the tissues which creates a relative narrowing of the ileum as it crosses the abdominal wall. Typically, patients will have ingested some fibrous food with a high residual component and will present with crampy abdominal pain, reduced stoma output,

dehydration, and vomiting. These patients should be admitted to the hospital and started on intravenous fluid replacement. The stoma can then be irrigated in an attempt to release the presumed food bolus blockage. A Foley or similar catheter is placed into the stoma, and the stoma is then irrigated gently with warm saline. If food particles are returned from the initial irrigation, the irrigation can be continued until stoma function returns and the blockage is eliminated. If the return is clear, it suggests a more proximal obstruction or an adhesive obstruction, and a water-soluble contrast study should be done for evaluation. If the problem is food blockage, the instillation of the hyperosmolar contrast medium often will prove therapeutic. If there is no evidence of food blockage, it should be dealt with as an adhesive small intestinal obstruction. Figure 9-13 is an algorithm for the alleviation of ileostomy blockage.

Some patients develop a high ileostomy output because of dietary indiscretion, infectious disease, short bowel syndrome, or recurrence of inflammatory bowel disease. The cause must be determined and each problem dealt with individually. It is important to maintain fluid and electrolyte balance as these problems are being resolved. Special care must be provided for the patient with short bowel syndrome to maintain electrolyte balance and to compensate for the vitamin B_{12}, calcium, and fat malabsorption that occurs with absence of the distal ileum.

Another special problem that may occur with an ileostomy is the formation of a paraileostomy fistula. This usually represents recurrence of Crohn's disease and should be dealt with based on the extent of the Crohn's disease. While evaluation and treatment are being carried out, the appliance should be modified so that the fistula is allowed to drain into the appliance, and no attempt should be made to cover the fistula opening. This is usually achieved by modification of the configuration of the skin barrier component of the appliance.

Patients and those individuals aiding in the care of the ileostomy should be in the habit of observing the ileostomy for injury. There are no pain fibers in the ileum, and it is not unusual for a patient to lacerate the stoma with a malfitting appliance without noticing the injury, especially on the inferior aspect of the stoma.

Review of the UOA data registry overall shows a low incidence of complications from ileostomy and an even lower incidence of need for corrective surgery. The vast majority of patients with conventional ileostomies lead normal lives and rarely have a restricted lifestyle because of the stoma. Most patients spend less than 1 hour a day dealing with their stomas.

CONTINENT ILEOSTOMY

The continent ileostomy, or Kock pouch, has been used as an alternative to a conventional ileostomy for selected patients with ulcerative colitis or familial polyposis. It involves construction of an internal pouch with a continent nipple valve. The continent ileostomy allows placement of the stoma in an inconspicuous location and avoids the need for wearing an appliance permanently. It does require multiple intubations of the pouch daily to allow emptying. The complication rate for construction of this continent ileostomy has been high because of the difficulty in maintaining continence of the nipple valve and position of the pouch so that intubation can be easily accomplished. This operation should probably be done only in centers where it is performed frequently and where the complications are managed by an experienced team. The continent ileostomy can be constructed as a primary procedure for patients with ulcerative colitis. It may also be considered for patients who have an existing ileostomy that malfunctions, is poorly located, or causes severe injury to the peristomal skin because of allergic reaction to the ostomy equipment. However, the Kock pouch has been used infrequently as primary treatment for patients with familial polyposis and ulcerative colitis since the advent of the restorative proctocolectomy with ileal pouch-anal anastomosis. Most surgeons agree that the continent ileostomy is contraindicated for patients with Crohn's disease because of the significant risk of recurrent disease and the potential for loss of substantial length of intestine should the patient require pouch excision. It is also not to be recommended for patients who have a well-functioning end ileostomy.

The advantages of continent ileostomy are that a patient need not wear an appliance, the patient is continent between intubations, and she or he may experience a better quality of life than if they had a conventional ileostomy. The disadvantages are that not all patients are continent, it does require multiple intubations during the day, there can be difficulty in intubation, and the surgery is prolonged and carries a substantial risk of complications. If the procedure fails, the individual will lose a significant amount of small intestine. Also, psychological factors may have been involved in the original motivation for choosing the internal ileostomy that are not alleviated by the more complicated surgical procedure.

Construction of Continent Ileostomy

The construction of an intestinal reservoir for feces was first described in 1967 by Nils Kock. His original description of a U-shaped pouch was based on the theory that interruption of coordinated peristalsis would enhance capacity. Since then, J- and S-shaped pouches have been used with similar results. An S-shaped pouch is described here.

The construction of a continent ileostomy, or Kock pouch, can be broken into four components: (1) the creation of a pouch, (2) the creation of a nipple valve, which provides continence, (3) the suspension of the pouch from the abdominal wall in such a way as to prevent slippage of the nipple valve, and (4) the creation of a stoma.

The terminal ileum should be transected as close to the cecum as possible (Fig. 9-14A). The S-shaped reservoir is fashioned from a 30 to 45 cm segment of distal ileum, starting 15 cm from the cut end (Fig. 9-14B). The last 15 cm is used for the outlet (5 cm) and nipple valve (10 cm). The intestine is tacked in place in the shape of an S, using interrupted seromuscular sutures of 2-0 polyglycolic acid placed at the edge of the mesentery. Each limb of the S should be 10–15 cm long. The intestine is opened along the entire portion of the S, with the surgeon taking care to incise close to the mesenteric border on the outer limbs of the S and exactly at the antimesenteric surface of the central limb. A single-layer continuous suture line of 2-0 synthetic absorbable suture is first placed between the two walls of the central limb and the inner walls of the two outer limbs (Fig. 9-14C). The sutures that begin on the posterior wall continue onto the anterior wall as the suture line reaches the outer wall of each of the two outer limbs of the S. The anterior wall is completed by continuing the suture from each direction, using an inverting full-thickness technique (either "baseball" or Connell) until the sutures meet in the middle. Before the pouch is closed, the nipple valve must be constructed.

The 15 cm of ileum distal to the pouch will become the nipple valve and stoma. Prior to the completion of the anterior wall suture, with the pouch mostly open, the nipple valve is made by intussuscepting the ileum into the pouch (Figs. 9-14D and 9-14E). A Babcock clamp is passed into the distal ileum from within the pouch and is closed onto the full thickness of the bowel at a point 5 cm from the pouch. The clamp is drawn into the pouch, intussuscepting the bowel on itself to form the nipple valve. The valve is maintained in this position by placing a line of staples on either side of the mesentery and a third row of staples on the antimesenteric aspect (Fig. 9-14F). Occasionally it is possible to place four staple lines equidistant around the circumference of the nipple valve (Fig. 9-14G). A linear-cutting stapling instrument with the cutting blade removed is used to place the staple lines. One arm of the instrument is inserted into the lumen of the nipple from within the pouch before closing and firing the instrument. These staple lines make a serosa-to-serosa fixation of the nipple valve and prevent its unfolding. The anterior wall of the pouch is then completed as previously described (Fig. 9-15A). A 5 cm outlet of distal ileum remains that will pass through the abdominal wall and allow construction of a flush stoma.

The right lower quadrant stoma site is created as described earlier in this chapter, with the opening placed below the belt line and within the rectus muscle. Before the outlet is passed through the abdominal wall opening, a sling of soft synthetic mesh (1 × 10 cm) is passed through a window made in the mesentery of both the pouch and nipple valve under the major vessels as they fold into the nipple valve mesentery (Figs. 9-15B and 9-15C). The strip of mesh maintains the nipple configuration and helps secure the pouch to the abdominal wall. Seromuscular absorbable sutures are used to fix the mesh to the base of the outlet (Fig. 9-15D). The two ends of the sling are left long because they are sutured together at the antimesenteric surface of the outlet. This facilitates delivery of the outlet through the stoma site and allows a securing suture of nonabsorbable material to be placed through the sling into the anterior fascia. As the outlet is readied to be drawn through the abdominal wall, a row of three untied seromuscular sutures is placed on the shoulders of the pouch medial and lateral to the outlet (Fig. 9-15E). These sutures, incorporating the posterior fascia and peritoneum, are used to fix the pouch to the anterior abdominal wall. The outlet is delivered through the stoma site and the pouch is drawn toward the abdominal wall. The sutures are then tied, first laterally and then medially (Fig. 9-15F). A permanent securing suture is placed through the tails of the sling and the anterior fascia, and the ends of the mesh are trimmed.

If possible, the cut edge of the small intestine's mesentery is sutured to the anterior abdominal wall (Fig. 9-15F). A continuous suture is placed from the outlet of the pouch to the falciform ligament. The pouch in its final position should rest at the right pelvic brim, with the antimesenteric surface (anterior wall) of the pouch directed inferiorly.

The terminal ileum at the outlet should be excised at skin level (Fig. 9-15G). The stoma is finally completed by absorbable sutures between the subcuticular layer of the skin and the full thickness of the intestinal wall (Fig. 9-15H). A Medina catheter is passed through the stoma into the pouch and is secured to the skin to prevent slippage of the tube into or out of the pouch (Fig. 9-15I). There should be minimal resistance and no deviation from a straight passage. The pouch should be drained in this manner for 2 weeks before intermittent clamping is begun during the third week. Finally, the pouch should be extubated and reintubated every 4 hours until the intervals gradually increase to 6 or 8 hours.

The nipple valve provides increasing continence as pressure rises in the pouch. Should the nipple valve lose its configuration and prolapse or should it slip through the mesenteric aspect of the pouch (the weakest point), either incontinence or obstruction will result. These two problems, along with "pouchitis," are the most common complications following the continent ileostomy procedure. As a result, many variations of pouch construction have been used in attempts to prevent or correct these problems.

If a fistula should form from the nipple valve or if the nipple valve should slip, it may be possible to preserve the pouch and construct a new nipple valve (Fig. 9-16). The technique involves resecting the pouch outlet, including the nipple valve, after fully mobilizing the pouch from the

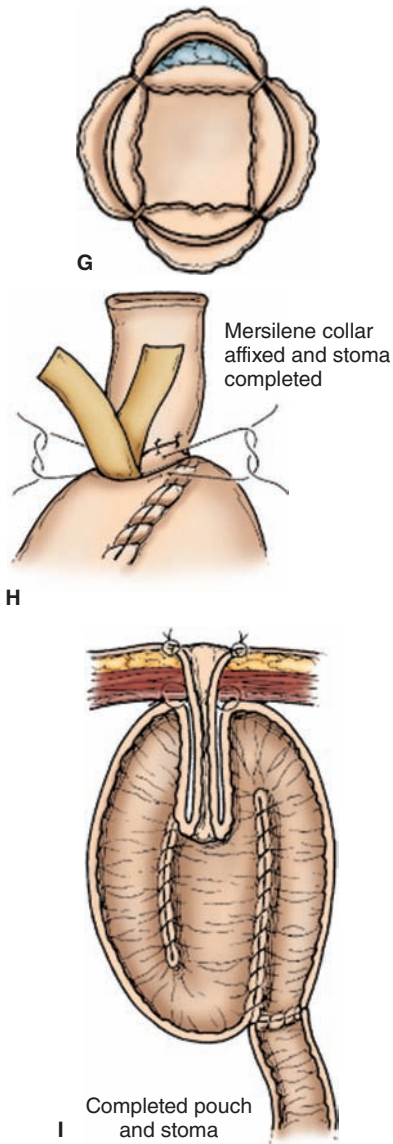

FIGURE 9-16 *Continued*—**H, I.** The pouch is fixed to the abdominal wall, and the stoma is completed.

abdominal wall and pelvis (Fig. 9-16B). The terminal ileum is transected 15 cm proximal to the pouch (Fig. 9-16C). The pouch is then rotated 180 degrees on its mesentery (Fig. 9-16D). A new nipple valve is created as previously described by intussuscepting the new outlet on itself and placing staple lines along the valve to secure the fold (Figs. 9-16E, 9-16F, and 9-16G). The opening in the pouch wall created when the old outlet was resected serves as the entry to the pouch to perform this maneuver. The proximal ileum's cut edge is then anastomosed to the pouch through a second enterotomy in a position that allows the pouch to lie comfortably in the right lower quadrant as before (Fig. 9-16D). If at all possible, the existing stoma site should be preserved and reused. The pouch then is resuspended by using a mesh sling as described above, and the stoma is constructed (Figs. 9-16H and 9-16I). The pouch should be protected by constant drainage through an indwelling Medina catheter for at least 1 week. Because the pouch will not require expansion and the patient will not need education, the prolonged period of progressive clamping should not be necessary.

URINARY CONDUIT

The urinary conduit is constructed of a segment of intestine with well-maintained vascularity so that it can be connected to the urinary tract to allow egress of urine through the abdominal wall via a stoma constructed exactly like an ileostomy. It is not intended to have any type of reservoir capacity but merely to provide an open conduit. This urinary conduit is constructed most often after removal of the urinary bladder for invasive cancer. It is also used for management of severe obstructive uropathy, the congenital abnormalities of spina bifida, meningomyelocele, or bladder exstrophy, and for trauma to the spinal cord resulting in a severely neurogenic bladder. The incidence of this surgery for congenital and traumatic disorders is decreasing as other means of emptying the bladder are devised. The cystectomy, construction of the urinary conduit, and ureterointestinal anastomosis are most often carried out by urologists, but the construction of the stoma, as well as restoration of intestinal continuity, may be done by a surgeon more experienced in intestinal and stoma surgery.

The basic principles of construction of the conduit and stoma involve isolation of a segment of intestine, with maintenance of the mesenteric blood supply and enough mobility to allow the distal end to be used as a stoma and the proximal end to serve as the site for ureteral implantation. It is most important to maintain the isoperistaltic direction of the intestine, especially if the conduit is constructed of sigmoid colon. The conduit must not be made of irradiated bowel, even if this requires using either colonic or proximal small intestinal conduits. If the stoma is improperly constructed, there may be a stasis of urine, resulting in reflux and damage to the proximal tract.

The surgical technique consists of choosing a long enough segment of small intestine to allow the stoma to be constructed at the level of the abdominal wall and still allow the proximal end to reach close enough to the retroperitoneum to preclude tension on the ureterointestinal anastomoses (Fig. 9-17). Usually, 18–20 cm of intestine is enough, but this must be modified if there is a shortened mesentery or a massively obese abdominal wall. It is in these latter situations that the loop-end stoma, supported over a small rod, can be advantageous. After the segment of intestine is chosen, the mesentery at the distal point is incised to allow enough mobility for reaching the abdominal wall. The mesentery at the proximal site of transection is incised only in a limited fashion, and care must be taken to preserve a generous blood supply (Fig. 9-17A). Intestinal continuity is restored, with the intended conduit positioned posterior to the restored intestine

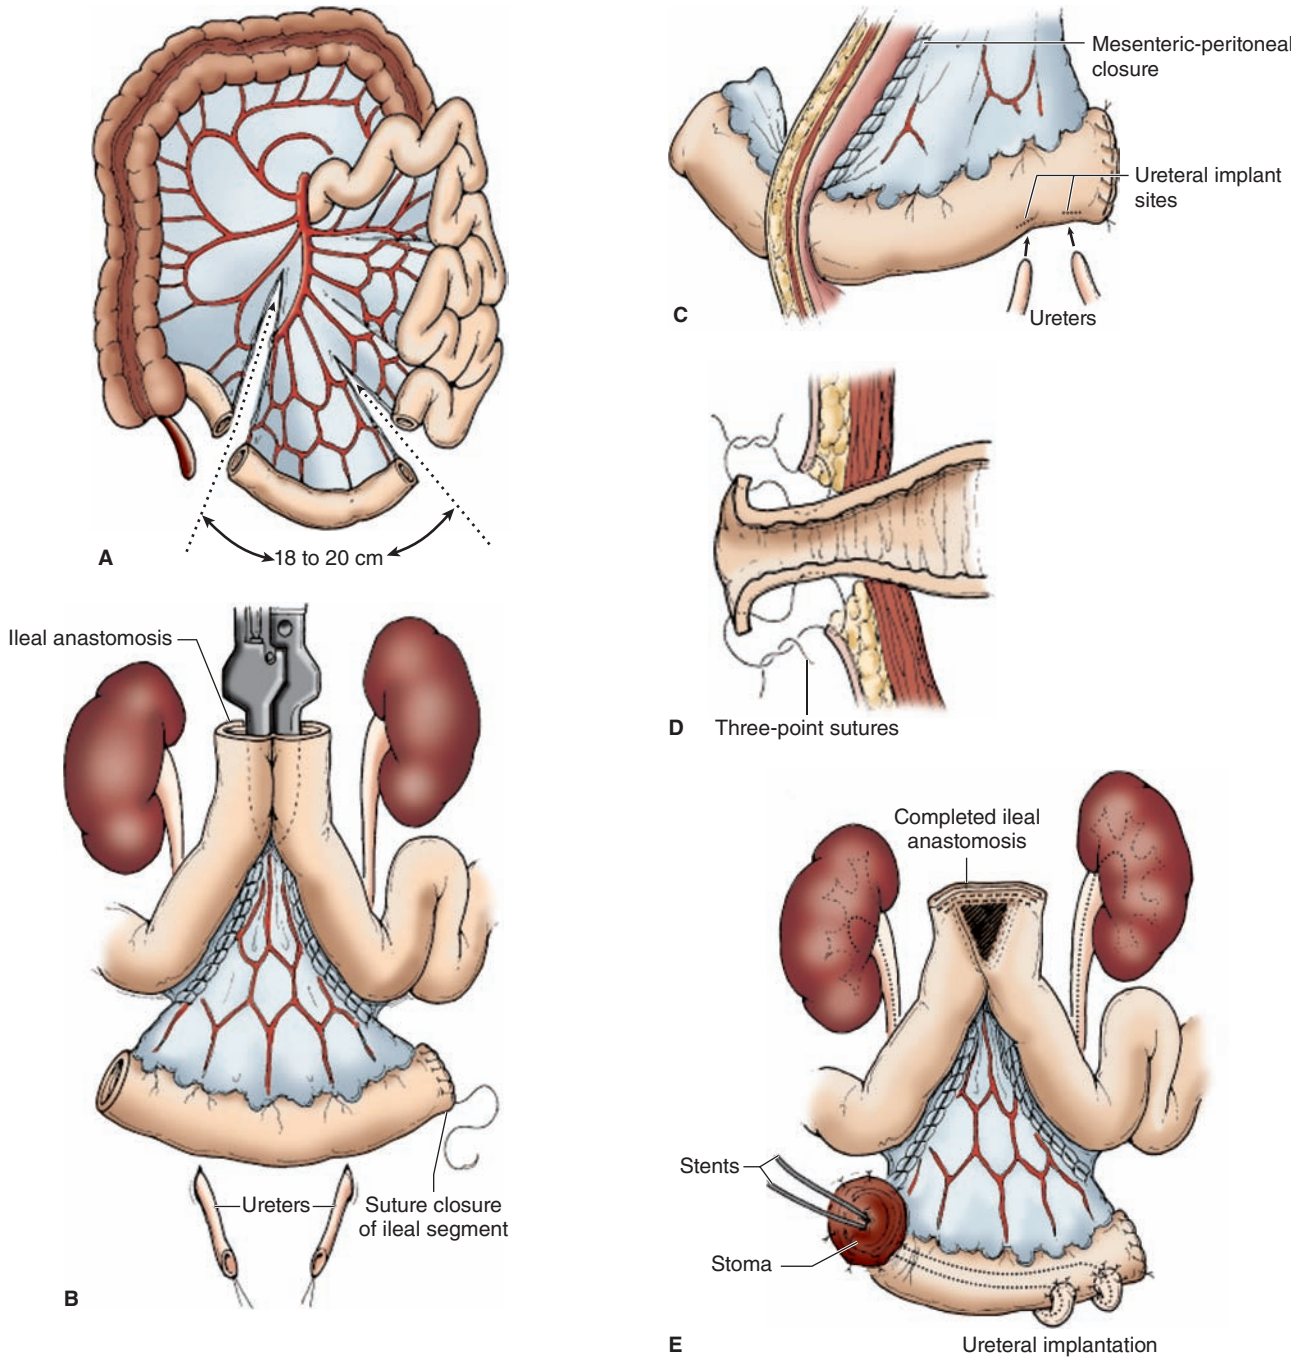

FIGURE 9-17 Construction of a urinary conduit. **A.** An 18 to 20 cm segment of distal ileum is taken out of continuity, and the blood supply is carefully preserved. **B.** Intestinal continuity is restored, and the intended conduit located posterior to the restored intestine. **C.** The ureteral conduit anastomoses are completed. **D.** The stoma is constructed with a spigot configuration. **E.** Stents are placed through the completed ureteral anastomoses.

(Fig. 9-17B). The ileoileal anastomosis may be completed in any fashion that uses sutures or staples. The conduit is then cleaned of intestinal content, and the proximal end is closed. Closure must be done with absorbable sutures, because staples can lead to stone formation. It is then preferable to make the opening in the abdominal wall to construct the stoma as previously described for an ileostomy (Figs. 9-17C and 9-17D). This procedure ensures that the ureteral anastomosis will be completed with the conduit in its final position and without the need for applying tension to bring the intestine through

the abdominal wall. The ureteral anastomoses are performed, and stents are placed (Fig. 9-17E). All aspects of the stoma construction are the same as those for an ileostomy except that the appliance must contain a valve to allow emptying since the volume of urine is high and its weight may tend to pull the appliance off. This problem is avoided by the patient emptying the appliance frequently and by sleeping attached to a night drainage system.

Complications of the Urinary Conduit

The most common complication of a urinary conduit is a leaking appliance because of improper placement or construction of a flush rather than a protruding stoma. Although some urologists believe that a flush stoma is less susceptible to injury, most surgeons disagree with this concept and believe that a spigot configuration is best. Sometimes sutures are placed in the skin rather than in the dermis during stoma construction. This leads to a circumferential series of radial scars that preclude maintenance of the seal of the appliance. Because the stoma effluent is thin liquid, the appliance seal must be precise to avoid injury to the peristomal skin. If there is stasis in the conduit, an odor will develop and become the cause of great concern to the patient. Odor, increased mucus production, flank pain, and fever can indicate a urinary tract infection. In order to obtain an accurate urine sample for culture, it is necessary to intubate the stoma rather than sending urine collected from the appliance. It is not unusual to have to revise and sometimes relocate flush urinary conduit stomas. If this is done, care must be taken to ensure that the length of the conduit is adequate. If it is not, it is possible to add a segment of small intestine so that a proper stoma can be constructed without having to revise the ureterointestinal anastomoses.

The patient who does not maintain adequate personal hygiene and acidification of the urine may develop stone formation, with crystal formation around the stoma itself. This development can be alleviated by acidifying the urine or by cleaning and soaking the pouch with white vinegar. The use of Collyseal (Torbot Co.) can also be used to maintain an acidic environment and thus minimize crystal formation at the stoma. If the stoma has been constructed within the field of radiation, the radiation can break down the skin around the stoma. This requires relocation of the stoma to a nonirradiated location on the abdominal wall. Relocation should be done even if the upper quadrants need to be used. Recent advances have employed the principles of Kock pouch construction, previously described, to allow construction of a continent urinary diversion.

INTESTINAL FISTULA

The formation of an intestinal fistula is not planned by the surgeon. Therefore, it must be dealt with as it occurs. Applying modern principles of stoma care to maintain the integrity of the peristomal skin until definitive treatment of the fistula can be carried out should prevent damage to the skin from primitive means of preventing severe destruction of the skin and abdominal wall. These stomal care techniques, coupled with intravenous nutritional supplementation, should alleviate uncontrolled intestinal drainage from abdominal wounds.

LAPAROSCOPIC CREATION OF INTESTINAL STOMAS

The most appealing operation early on in the laparoscopic colorectal surgery experience was creation of a diverting intestinal stoma. Laparoscopic loop stoma creation does not require division of the bowel or anastomosis, and the only incision larger than 5 mm required is at the stoma site. Thus, the full benefits of the totally laparoscopic approach can be realized. Surgeons inexperienced in laparoscopic approaches to colorectal disease may find that creation of intestinal stomas is a relatively straightforward and rewarding method to begin their laparoscopic colorectal experience.

Laparoscopic creation of intestinal stomas was reported in the early 1990s and the technique was quickly adopted by many surgeons. Several case series demonstrating the safety and efficacy of the procedure have been reported in the literature. Although there has not been a prospective, randomized trial of laparoscopic versus open stoma creation, case-controlled series have demonstrated reduced duration of postoperative ileus and reduced length of hospital stay with the laparoscopic approach. The benefits of the laparoscopic approach to stoma creation became immediately obvious to surgeons, and thus, it is unlikely that a prospective, randomized trial will ever be performed comparing outcomes of stomas created using laparoscopy versus laparotomy.

Laparoscopic ileostomy and colostomy creation have been performed for a plethora of indications, including obstructing rectal adenocarcinoma, rectal obstruction from extrarectal malignancies, fecal incontinence, penetrating rectal trauma, sacral pressure ulceration, obstructed defecation, perineal Crohn's disease, pelvic fracture, and lumbosacral burns. Virtually any disease process that is an indication for fecal diversion is an indication for consideration of the laparoscopic approach. Laparoscopic creation of diverting loop colostomy is particularly appropriate for patients suffering from symptomatic near-obstructing rectal carcinoma. The technique allows the surgeon to evaluate the liver and peritoneum for the presence of metastases that may be undetected on preoperative imaging studies, and institute fecal diversion without creating adhesions in the abdomen and pelvis that may increase toxicity of neoadjuvant radiotherapy and make future proctectomy more difficult. The absence of a laparotomy incision allows patients to recover rapidly, and allows them to begin neoadjuvant radiotherapy treatments almost immediately.

Some authors have argued that trephine stoma creation is an easier, quicker, and less expensive method of stoma creation than the laparoscopic technique. For the thin patient

with a virgin abdomen who will not benefit from abdominal exploration, the trephine method does offer those advantages. However, for patients who are obese, those who have had multiple prior laparotomies, those who would benefit from abdominal exploration, or those who require mobilization of the intestine from its retroperitoneal attachments, the laparoscopic approach offers significant advantages.

In order to save time and expense in the operating room, we have developed an approach to the patient requiring fecal diversion that combines the advantages of both trephine and laparoscopic stoma creation. If the patient is thin and would not necessarily benefit from laparoscopic exploration of the peritoneal cavity, the patient is approached initially with the intention of creating a trephine stoma, with the laparoscopic approach held in reserve. The patient is positioned for a laparoscopic procedure, but the laparoscopic equipment is kept unopened in the operating room. The stoma incision is made, and if the bowel can be delivered in correct orientation to the skin level, the stoma is created and the laparoscopic equipment remains unopened. However, if trephine creation of the stoma is impossible, a Hasson trocar is placed through the stoma incision and the procedure proceeds laparoscopically.

Technique of Laparoscopic Stoma Creation

Patients undergoing diverting colostomy should be placed in the dorsal lithotomy or split leg position in order to have access to the anorectum; patients undergoing ileostomy may be placed in the supine position. The preselected stoma site is opened, a purse-string suture is placed in the posterior rectus sheath, and a Hasson trocar is placed. A 5 mm trocar is placed in the contralateral abdomen and the peritoneal cavity explored. If the bowel to be used for the stoma is sufficiently mobile, no other trocars need to be placed. If mobilization is required, additional 5 mm trocars can be placed to facilitate the dissection. Mobility is usually adequate when the bowel will reach to the peritoneal surface at the stoma site, as the distance to the skin level will decrease when pneumoperitoneum is released. A 5 mm camera is then placed through one of the 5 mm port sites, and the bowel grasped in the correct orientation using an instrument placed through the Hasson trocar at the stoma site. It is occasionally useful to mark the bowel for orientation of the proximal and distal limbs with sutures or clips prior to delivery through the stoma site—this is especially true when creating an ileostomy. The pneumoperitoneum is then released and the posterior rectus sheath opened over the trocar, allowing the bowel to be delivered through the stoma opening.

If the bowel is to be divided and an end stoma fashioned, it is critical that orientation be confirmed. Left-sided colostomy orientation can be confirmed by insufflation of air through a proctoscope, instillation of povidone iodine or dye through a small opening in the distal limb of the stoma with confirmation of dye passage to the rectum via a proctoscope, or passage of a flexible sigmoidoscope to the stoma site. Alternatively, the colon can be divided with a linear-cutting stapler, the distal end is allowed to retract into the peritoneal cavity, and direct visualization with a 5 mm laparoscope is performed to ensure that the distal bowel can be traced in continuity to the rectum.

The rapidity with which postoperative ileus resolves following laparoscopic creation of intestinal stomas may allow patients to return home within 1–2 days. This may create a problem for the patient and the CWOCN, who has little time to perform in-hospital stoma care training. Therefore, it is imperative that the patient meet with the CWOCN preoperatively, not only for stoma site marking, but for stoma care teaching as well.

Laparoscopic Stoma Closure

Laparoscopic techniques are most applicable to patients who have undergone colectomy with construction of a proximal colostomy. Although laparoscopic adhesiolysis is occasionally a beneficial adjunct to loop stoma closure, this is rarely required, as most loop stomas can be closed via a peristomal incision. The most common indication for a laparoscopic approach to the restoration of intestinal continuity is colostomy takedown and construction of coloproctostomy following sigmoid colectomy for complicated diverticular disease ("Hartmann reversal"). This procedure can either be straightforward or complicated, depending on the number and severity of intraperitoneal adhesions and the degree of pelvic fibrosis.

Several methods can be used to perform laparoscopic Hartmann reversal. Some surgeons establish laparoscopic access initially, perform adhesiolysis, mobilize the colon and rectum, take down the colostomy and insert the anvil of the end-to-end stapling device, re-establish pneumoperitoneum, and perform the anastomosis. A more cost-effective method is to take down the colostomy initially, perform as much of the procedure as possible through the colostomy opening, and then decide whether a laparoscopic technique is feasible. A substantial amount of adhesiolysis and mobilization can often be performed through the stoma incision, especially if there is a parastomal hernia present that has enlarged the fascial opening. The proximal colon can be prepared for anastomosis and the anvil of a circular stapling device inserted. If a determination of laparoscopic feasibility can be made prior to establishing pneumoperitoneum, it avoids the need to open any laparoscopic instruments or struggle with fruitless attempts at laparoscopic dissection prior to conversion. However, if it appears that laparoscopic techniques are likely to be successful, pneumoperitoneum is then established, either by closure of the fascia around a port or by insertion of a hand-assist device. The size of the fascial defect will determine which method is more advantageous for the patient and surgeon. The operation is then completed laparoscopically.

Prior to embarking on a laparoscopic reversal of a Hartmann procedure performed for diverticular disease, the surgeon should consider that it may be necessary to resect retained

sigmoid colon and mobilize the splenic flexure to allow soft descending colon to reach easily into the pelvis for a colorectal anastomosis. Preoperative evaluation of the proximal colon and distal rectal stump with endoscopy and/or contrast enema will help the surgeon plan the operative procedure and exclude alternative diagnoses.

It is also possible to perform laparoscopic restoration of intestinal continuity following total abdominal or subtotal colectomy and ileostomy. The ileostomy can be taken down, and an end-to-end anastomosis performed laparoscopically using a surgical stapling device.

ABDOMINAL ABSCESS AND ENTERIC FISTULAE

Patrick S. Tawadros • Jory Simpson • Josef E. Fischer • Ori D. Rotstein

ABDOMINAL ABSCESS

Definition and Etiology

Abscesses are well-defined collections of infected purulent material that are walled off from the rest of the peritoneal cavity by inflammatory adhesions, loops of intestine and their mesentery, the greater omentum, or other abdominal viscera. Abscesses may occur in the peritoneal cavity, either within or outside of abdominal viscera (extravisceral), as well as in the retroperitoneum.[1] Most relevant to the surgeon are extravisceral abscesses that usually arise in one of two situations: (1) after resolution of diffuse peritonitis in which a loculated area of infection persists and evolves into an abscess and (2) after perforation of a viscus or an anastomotic breakdown that is successfully walled off by peritoneal defense mechanisms. More than 80% of intra-abdominal abscesses occur in the postoperative period, the majority of which occur after pancreaticobiliary or colorectal surgery and are usually related to anastomotic dehiscence.[2,3] Occasionally, postsurgical abscesses result from infection of an intraperitoneal hematoma that develops following surgery. Less frequently, intra-abdominal abscesses are unassociated with previous surgery and are usually attributable to spontaneous inflammatory processes associated with a small, localized perforation, such as in appendicitis, diverticulitis, and Crohn's disease.[3,4] Visceral abscesses are most commonly caused by hematogenous or lymphatic spread of bacteria to the organ. Retroperitoneal abscesses may be caused by several mechanisms, including perforation of the gastrointestinal (GI) tract into the retroperitoneum and hematogenous or lymphatic spread of bacteria to retroperitoneal organs, particularly the inflamed pancreas.

Pathophysiology of Abscess Formation

After bacterial contamination of the peritoneal cavity, a complex series of events is initiated that, under ideal circumstances, effects complete eradication of invading bacteria. The three major defense mechanisms in the peritoneal cavity are (1) mechanical clearance of bacteria via the diaphragmatic lymphatics, (2) phagocytosis and destruction of suspended or adherent bacteria by phagocytic cells, and (3) sequestration and walling off of bacteria coupled with delayed clearance by phagocytic cells.[5] The first two mechanisms act rapidly, usually within hours. Egress of bacteria from the peritoneal cavity via the lymphatics is responsible for the early septic response due to bacteremia and initiation of the innate immune response to infection.

The initial peritoneal response to bacterial contamination is characterized by hyperemia, exudation of protein-rich fluid into the peritoneal cavity, and a marked influx of phagocytic cells. Resident peritoneal macrophages predominate early in the infection, but the rapid influx of neutrophils after a 2- to 4-hour delay makes them the predominant phagocytic cell in the peritoneal cavity for the first 48–72 hours.[6] The combination of resident peritoneal cells plus the influxing into the peritoneum serves to propagate the initiation of the innate immune response, including the elaboration of inflammatory cytokines and the procoagulant response. In humans with severe intra-abdominal infection, peritoneal levels of tumor necrosis factor-alpha (TNF-α), interleukin (IL)-1, and IL-6 are higher than levels measured simultaneously in plasma.[7,8] Haecker and colleagues reported that TNF-α and IL-10 levels are increased and reach 100- to 1000-fold that is observed in the plasma following appendiceal perforation. In adult patients, a correlation between the magnitude of the cytokine response and outcome in infected patients has been demonstrated in several clinical studies.[9] Higher levels of circulating TNF-α and IL-6 have been recorded in patients who later die with intra-abdominal infection.[7] Interestingly, elevated peritoneal persist even after systemic inflammatory response has abated. This suggests that during resolving peritonitis, there is compartmentalization of the response with local cytokine elaboration, thereby promoting local resolution of infection. Other cell types are likely important in the initiation of the local peritoneal response. Peritoneal mast cells and

mesothelial lining cells have also been shown to be potent producers of a range of cytokines and procoagulants. Fibrin deposition appears to play an important role in this compartmentalization of infection, not only by incorporating large numbers of bacteria within its interstices[10] but also by causing loops of intestine to adhere to each other and the omentum, thereby creating a physical barrier against dissemination. Fibrin deposition is initiated after the exudation of protein-rich fluid containing fibrinogen into the peritoneal cavity. The conversion of fibrinogen to fibrin is promoted by the elaboration of tissue factor by both mesothelial cells and stimulated peritoneal macrophages.[11] In addition, generation of other inflammatory mediator molecules and components of the complement cascade (eg, C3a and C5a) further promotes the development of local inflammation. The net effect of these responses is the localization of the bacterial infection in the peritoneal cavity, wherein ultimate resolution can occur. However, a number of local factors thwart complete resolution and presumably establish the local environment for persistent infection and hence abscess formation. These include regional fibrin deposition that impedes phagocytic cell migration, factors that inhibit phagocytic cell function such as hemoglobin, particulate stool, low pH, and hypoxia. On the microbial side, polymicrobial flora of these infections as well as the near ubiquitous presence of *Bacteroides fragilis* and its unique capsular polysaccharide have been implicated in persistence of infection and abscess formation. Considered together, while the process of abscess formation represents a successful outcome of the peritoneal response to bacterial contamination of the peritoneal cavity, one is left with a residual infection that carries with it morbidity and potential mortality and must be actively managed.

Clinical Presentation and Diagnosis

CLINICAL PRESENTATION

Diagnosis of an intra-abdominal abscess is based on clinical suspicion complemented by radiologic confirmation of the presence of the abscess. High spiking fevers, chills, tachycardia, tachypnea, and leukocytosis, associated with localized abdominal pain, anorexia, and delay in return of bowel function in the postoperative patient are the classic signs and symptoms associated with the presence of an intra-abdominal abscess. The presence of a well-localized tender mass on clinical examination is consistent with the presence of an abscess. However, there may be considerable variability in the clinical appearance of the patient with this infection, ranging from a relatively mild picture where the patient appears generally well but is "slow to recover" from his surgical procedure to those who manifest evidence of profound systemic inflammation. There may be no mass palpable on clinical examination. A number of factors may contribute to this variability, including patient factors such as age, immunocompetence, and concurrent use of antimicrobials, as well as abscess factors such location and size of the abscess and how well walled off the abscess is. For example, subphrenic abscesses can present with vague upper quadrant abdominal pain, referred shoulder pain, and occasionally hiccoughs but with no localized abdominal tenderness or palpable mass. By contrast, paracolic abscesses present with localized tenderness and may manifest as a palpable mass on abdominal examination. Pelvic abscesses may also cause local irritation of the urinary bladder causing frequency, or of the rectum resulting in diarrhea and tenesmus. Retroperitoneal collections, particularly psoas abscesses, can manifest as leg and back pain with muscular spasm and flexion deformity of the hip. In reality, with the ready availability of computed tomography (CT) scanning in most institutions, almost any deviation from the normal recovery trajectory in the postoperative period will prompt a CT scan and possible early detection of the abscess.

DIAGNOSTIC TESTS

Imaging provides the definitive evidence of the presence of an intra-abdominal abscess. Abdominal plain films can be helpful in identifying air-fluid levels in the upright or decubitus positions, extraluminal gas, or a soft tissue mass displacing the bowel. In the postoperative patient, however, extraluminal gas may be present for up to 7 days. Overall, plain radiography may suggest the presence of an abscess, but other imaging modalities have essentially replaced plain films in the evaluation of intra-abdominal abscesses.

CT scanning has emerged as the radiological investigation of choice in the diagnosis of intra-abdominal abscess.[12] With its ready availability, it has essentially supplanted abdominal ultrasound (US) as the main diagnostic tool in this setting, mainly because of its accuracy, but also because its functionality is not impaired in the setting of ileus, wound dressings, stomas, and the open abdomen. The accuracy of the scan is improved if contrast is used. IV contrast increases the accuracy of defining the presence of an abscess, while GI tract contrast helps to distinguish fluid-filled bowel loops from an abscess and in addition may detect the presence of an anastomotic leak. In a retrospective study that compared US and CT in diagnosing intra-abdominal abscesses, the sensitivity of US in 123 patients was 82% compared to 97% in 74 patients by CT, and the overall accuracy of US was found to be 90% versus 96% for CT.[13] Criteria for identification of an abscess by CT have been well described and include identification of an area of low CT attenuation in an extraluminal location or within the parenchyma of solid abdominal organs. The density of abscesses usually falls between that of water and solid tissue.[14] Other radiological signs of an abscess are mass effect that replaces or displaces normal anatomic structures, a lucent center that is not enhanced after the intravenous administration of a contrast medium, enhancing rim around the lucent center after IV contrast administration, and gas in the fluid collection. One of the major advantages of CT over US is the ability to detect abscesses in the retroperitoneum and pancreatic area. There are also some disadvantages

to CT scanning. In the absence of contrast rim enhancement, gas or visible septations, CT cannot distinguish between sterile and infected fluid collections. Occasionally, there may be a solid-appearing collection that is really an abscess with a high leukocyte and protein content. Septations and other signs of loculated abscesses can often be better visualized with US than CT. Finally, CT scanning is sometimes unable to differentiate between subphrenic and pulmonic fluid, a relatively common situation in abdominal surgery.[15] In these limited circumstances, US may be considered as a complement to CT imaging.

Other modalities include magnetic resonance imaging (MRI). While MRI can sometimes better delineate the extent of an abscess, particularly in relation to adjacent soft tissue structures such as muscles and major blood vessels, it does not clearly have advantages over CT scanning and its practicality may be limited in the sick surgical patient.[16] One area where US and MRI may be relevant is in the investigation of the pregnant patient with abdominal pain.[17] US is particularly useful when appendicitis/appendiceal abscess is suspected, and MRI may be useful when localization is less clear. The roles of radiolabelled compounds in the diagnosis of abdominal abscesses are limited at present.[18]

Management

The basic principles underlying the successful treatment of intra-abdominal abscesses are threefold:

1. Adequate resuscitation and support
2. Antimicrobial therapy
3. Source control/abscess drainage

RESUSCITATION AND SUPPORT

In keeping with the variable presentation of patients with intra-abdominal abscesses, the initial approach to resuscitation and support will vary considerably. Attention to the ABCs (airway, breathing, circulation) while individualizing the intervention for each patient according to his/her deviation from normal physiology is appropriate. Particularly in the postsurgical patient, nutritional support should be considered. When feasible, oral nutrition should be given in preference to total parenteral nutrition. Some patients are able to ingest food and/or supplements by mouth, while others might require an enteral feeding tube, due to anorexia, precluding adequate ingestion of nutrients. Systematic review of the literature suggests that infectious complications and cost are reduced in critically ill patients receiving enteral nutrition compared to parenteral nutrition.[19] One can presumably extrapolate to patients with intra-abdominal infection. When abscess formation occurs due to an anastomotic leak, there is a sense that this might preclude use of enteral nutrition. This concern is likely unfounded, unless there is profound ileus associated with the infection.

ANTIMICROBIAL THERAPY

Considerations regarding antimicrobial use are based on the microbial flora recovered from the infections. Over the past decade, there has been increasing appreciation that there is an evolution of the flora with increasing severity of abdominal infection.[20] For example, Table 10-1 shows the bacteriology of peritonitis in patients with community-acquired peritonitis and those with postoperative peritonitis. The major pathogens in community-acquired intra-abdominal infections are coliforms (esp. *Escherichia coli*) and anaerobes (esp. *B. fragilis*). As illustrated, while both are polymicrobial, postoperative peritonitis has a higher incidence of more resistant microbes. Aside from patients with postoperative peritonitis, other factors predict this shift in microbiology, including advanced age, severe physiologic derangement, immunosuppression, previous use of antibiotics, and residence in a health care institution in hospitals and nursing homes, etc. Guidelines have been developed recently by the Surgical Infection Society and the Infectious Diseases Society of America regarding the use of antimicrobial therapy in intra-abdominal infection.[21] These authors have risk-stratified patients into three categories and provided recommendations for empiric antimicrobial regimens according to category. The three categories are (1) community-acquired infections of mild to moderate severity; (2) high-risk or severe community-acquired infections; and (3) health care–associated infections. Factors that dictate conversion from mild-to-moderate severity to high severity include severe physiologic derangement (eg, high Acute Physiology and Chronic Health Evaluation II [APACHE II] score), advanced

TABLE 10-1: MICROBIOLOGY OF COMMUNITY-ACQUIRED PERITONITIS COMPARED TO HEALTH CARE–ASSOCIATED PERITONITIS

TABLE 10-2: RECOMMENDATIONS FOR ANTIMICROBIAL THERAPY IN THE COMMUNITY-ACQUIRED SETTING

Regimen	Community-Acquired Infection in Pediatric Patients	Community-Acquired Infection in Adults: Mild-to-Moderate Severity: Perforated or Abscessed Appendicitis and Other Infections of Mild-to-Moderate Severity	Community-Acquired Infection in Adults: High Risk or Severity: Severe Physiologic Disturbance, Advanced Age, or Immunocompromised State
Single agent	Ertapenem, meropenem, imipenem-cilastatin, ticarcillin-clavulanate, and piperacillin-tazobactam	Cefoxitin, ertapenem, moxifloxacin, tigecycline, and ticarcillin-clavulanic acid	Imipenem-cilastatin, meropenem, doripenem, and piperacillin-tazobactam
Combination	Ceftriaxone, cefotaxime, cefepime, or ceftazidime, each in combination with metronidazole; gentamicin or tobramycin, each in combination with metronidazole or clindamycin, and with or without ampicillin	Cefazolin, cefuroxime, ceftriaxone, cefotaxime, ciprofloxacin, or levoflox acin, each in combination with metronidazole[a]	Cefepime, ceftazidime, ciprofloxacin, or levofloxacin, each in combination with metronidazole[a]

[a] Because of increasing resistance of *Escherichia coli* to fluoroquinolonoes, local population susceptibility profiles and, if available, isolate susceptibility should be reviewed.
From Solomkin JS, Mazuski JE, Bradley JS, et al. Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America. *Clin Infect Dis*. 2010;50:133, with permission.

age, or immunocompromised state. Table 10-2 shows the recommended agents according to this stratification. These guidelines are therefore readily applicable to decision making regarding patients coming into the hospital with abscesses, including processes such as appendiceal abscess or peridiverticular abscess. It is noteworthy that while enterococcus is frequently recovered in isolates in these infections, the evidence demonstrates no additional benefit to treating this microbe as part of empiric therapy. When possible, switchover to oral agents is appropriate. The duration of antibiotics should be 4–7 days, anticipating resolution of the clinical signs and symptoms during this period. Should there be no resolution by this time, reevaluation of the patient for the presence of persistent infection in the abdomen and elsewhere is appropriate.

Patients who present in the postsurgical period fall into the category of patients with health care–associated infection. In these patients, empiric therapy should include agents with expanded spectra against gram-negative aerobic and facultative bacilli, including meropenem, imipenem-cilastatin, doripenem, piperacillin-tazobactam, or ceftazidime or cefepime in combination with metronidazole. Table 10-3 shows the considerations regarding selection depending on local institutional microbial isolates. Empiric anti-enterococcal treatment should be given. Treatment of *Candida* with fluconazole when recovered from cultures and treatment of methicillin-resistant *Staphylococcus aureus* with vancomycin should be followed if the patient is colonized with the microbe.

SOURCE CONTROL

Source control is a term used to include all physical measures taken to control a focus of infection. Here we focus our discussion to abscess drainage, but adequate source control may also include debridement of necrotic tissue, surgical repair, resection, and/or exteriorization of the anatomic defect causing peritoneal contamination.[22]

Over the past two decades, percutaneous drainage of abscesses has become an established technique and a safe alternative to surgery. This evolution of care has not been based on a series of strong randomized trials showing equivalence or superiority of this approach. Rather, observational studies from a number of centers have shown it to be a safe effective alternative to surgical intervention, with equivalent success rates, comparable mortality (10–20%) and morbidity (~25%).[23–25] Combined with other advantages of percutaneous approaches including avoidance of general anesthesia, lower costs, and the potential for fewer complications, it has now become the default approach to abscess management. Prerequisites for catheter drainage include an anatomically safe route to the abscess, a well-defined unilocular abscess cavity, concurring surgical and radiologic evaluation, and surgical backup for technical failure. Multiple abscesses, abscesses with enteric connections as seen with enterocutaneous fistulas, and the need to traverse solid viscera are not contraindications. Indeed, as the technique has evolved over several decades, the barriers to accessing unusually positioned collections have disappeared with the use of unconventional routes (transgluteal, transvaginal, transrectal) and the advent of new technologies including endoscopic US.[26,27] Even the presence of septations and loculations has not precluded at least an attempt to use percutaneous drainage.[28]

Percutaneous drainage can be performed with US or CT guidance. CT provides for more precise identification of organs and bowel loops and is more accurate for planning of drainage route.[15]

TABLE 10-3: RECOMMENDATIONS FOR ALTERATIONS IN ANTIMICROBIAL THERAPY IN THE HEALTH CARE–ASSOCIATED SETTING

Organisms Seen in Health Care–associated Infection at the Local Institution	Regimen				
	Carbapenem[a]	Piperacillin-Tazobactam	Ceftazidime or Cefepime, Each With Metronidazole	Aminoglycoside	Vancomycin
<20% Resistant *Pseudomonas aeruginosa*, ESBL-producing Enterobacteriaceae, *Acneobacter*, or other MDR GNB	Recommended	Recommended	Recommemded	Not recommended	Not recommended
ESBL-producing Entorobacteriaceae	Recommended	Recommended	Not recommended	Recommended	Not recommended
P. aeruginosa >20% resistant to ceftazidime	Recommended	Recommended	Not recommended	Recommended	Not recommended
MRSA	Not recommended	Not recommended	Not recommended	Not recommended	Recommended

ESBL, extended-spectrum β-1actamase; GNB, gram-negative bacilli: MDR, multidrug resistant; MRSA, methicillin-resistant *Staophylococcus aureus*.
NOTE. "Recommended" indicates that the listed agent or class is recommended for empiric use, before culture and susceptibility data are available, at institutions that encounter these isolates from other health care–associated infections. These may be unit-or hospital-specific.

Once the abscess is identified, initial diagnostic aspiration should be sent for Gram's stain and microbiological culture. The catheter used for drainage should be as small as possible for safety, yet large enough so that the tubing does not become obstructed. Most commonly used catheters range in size from 8 to 12F. With appropriate catheter placement, the abscess cavity typically decompresses and collapses. Irrigation of the catheter should be done once daily to ensure tube patency. As catheter drainage decreases, repeat CT scanning can be performed to evaluate for residual contents. If drainage increases over time or continues at a steady rate, the development of an enteric fistula must be suspected. This may not have been unexpected when the catheter was initially placed near a perianastomotic abscess or an abscess adjacent to some underlying pathological process. Potential complications of catheter placement include bacteremia, sepsis, vascular injury, enteric puncture, cutaneous fistula, or transpleural catheter placement.

Catheters should be maintained on closed drainage systems. There does not appear to be benefit to the use of suction or irrigation of these catheters, although flushing once per day with saline ensures patency. Patients should respond with defervesce of symptoms within 48 hours of catheter insertion. If they do so, a repeat CT scan is done at approximately 5–7 days to ensure shrinkage of the abscess. Criteria for removal of the drain include (1) clinical resolution of septic parameters, including patient well-being, normal temperature, and leukocyte count; (2) minimal drainage from the catheter; and (3) CT evidence of the resolution of the absence.

As noted previously, studies comparing outcomes of surgical and percutaneous drainage of intra-abdominal abscesses demonstrate comparable efficacy. In one study, patients were matched for age, abscess location, and etiology, and had similar APACHE II scores. There were no differences between percutaneous and surgical drainage in patient morbidity, mortality, or duration of hospital stay.[24] Furthermore, initial percutaneous drainage of abscesses in the context of diverticular disease allowed for subsequent definitive operative resection and primary anastomosis in one rather than two operations. Another group retrospectively examined postoperative intra-abdominal abscesses after laparotomy. This study similarly demonstrated that use of either form of drainage resulted in similar cure rates for postoperative intra-abdominal abscesses.[25]

With clear demonstration of its efficacy when compared to surgical drainage, percutaneous drainage should be considered the preferred approach in source control of abscesses. Table 10-4 shows outcome of percutaneous drainage according to underlying pathological processes. In general, one should predict a successful outcome in patients with a single, well-defined abscess with no enteric communication. The presence of enteric communication per se does not reduce the likelihood of success as it is defined by the resolution of the infection. In a postoperative abscess, following drainage of the infection, the underlying anastomotic defect will usually close. In other settings, there may be a requirement for subsequent surgery to manage the underlying disease process such as diverticular disease or Crohn's disease. For example, in one study, approximately 75% of patients with large peridiverticular abscesses were drained percutaneously and then they went on to a single-stage sigmoid colectomy.[28] Other circumstances such as fungal abscesses, infected

TABLE 10-4: DETERMINANTS OF OUTCOME FOLLOWING PERCUTANEOUS DRAINAGE OF ABSCESSES

Clinical Condition	Successfully Treats Abscess	Comment
Single, well-defined bacterial abscess with no enteric communication	Yes	
Abscess with enteric communication (eg, diverticular abscess or Crohn's disease abscess)		May require subsequent surgery to treat pathological process or residual fistula
Interloop abscess or other difficult-to-access abscesses (eg, deep pelvic)	Usually	Requires alternative approaches to access successfully, eg, transrectal, transvaginal, transgluteal, etc
Early postoperative diffuse peritonitis (eg, caused by anastomotic dehiscence or bile peritonitis)	Low	Inappropriate—needs surgery
Infected tumor mass Fungal abscess Infected hematoma Pancreatic necrosis	Low	Inadequate drainage
Small abscess (<4 cm in diameter)	Low	Difficult to drain; antibiotics alone may be suitable

hematomas, peripancreatic necrosis, or necrotic-infected tumor have a lower success rate for percutaneous drainage and early consideration for surgical intervention.[29] CT features such as the presence of a "rind," a sharp exterior margin, air-fluid levels, and septations do not predict outcome and therefore should not be determinants as to whether or not initial percutaneous drainage should be used.[30] Finally, one should use clinical judgment as to the need for percutaneous drainage for small abscess (<5 cm diameter) such as those that might occur associated with acute diverticulitis, Crohn's disease, and interloop collections. These may well respond to antibiotics alone, and the use of percutaneous drainage may be meddlesome and potentially morbid.[31]

There are circumstances where percutaneous drainage should be considered contraindicated. Most important among these is the circumstance where peritoneal infection is not localized, such as in the early postsurgical period where an anastomotic leak leads to diffuse peritonitis. Abdominal CT scans performed in this scenario may demonstrate one or more discrete fluid collections. When there is diffuse peritoneal irritation on clinical examination, fluid collections distant from the anastomosis, or the presence of massive intraperitoneal air, surgical intervention is clearly indicated. Attempts to manage such situations with percutaneous interventions invariably lead to delayed definitive surgical management and adverse outcome.

SURGICAL DRAINAGE

As stated previously, percutaneous drainage is the procedure of choice for the majority of intra-abdominal abscesses, with the caveats being those indicated. Specifically, when the infection is diffuse rather than localized, surgical intervention is clearly indicated. Second, when the content of the abscess is too thick for percutaneous drainage, an initial percutaneous attempt may be reasonable, but conversion to surgery early in the course is reasonable. Finally, when access is impossible, surgery is indicated. This last circumstance is increasingly rare.

The transperitoneal approach allows for examination of the entire abdominal cavity and allows for the drainage of multiple abscesses. Subphrenic abscesses and right subhepatic abscesses may also be approached by lateral abdominal incisions. Once abscess cavities are identified, they are entered and drained quickly to minimize spillage and contamination of the rest of the peritoneal cavity. The abscess cavity should then be widely opened. Specimens should be sent for Gram's stain and culture. Copious warm irrigation must be used at the end of the operation to properly cleanse the abdominal cavity. Closed-suction drains should be placed in dependent positions to reduce the risk of reaccumulation. In extremely contaminated cases, the incision may be left open and packed to prevent wound infection.

ENTERIC FISTULAS

Introduction

A *fistula* is defined as an abnormal communication between two epithelial surfaces. Enteric fistulas may arise in a number of settings: (1) diseased bowel extending to

surrounding epithelialized structures; (2) extraintestinal disease eroding into otherwise normal bowel; (3) surgical trauma to normal bowel including inadvertent or missed enterotomies; or (4) anastomotic disruption following surgery for a variety of conditions. The first two generally occur spontaneously, while the latter two occur following surgical procedures. For the surgeon, the latter two are generally more problematic, in part because they are iatrogenic complications of surgery, but also because their early management often requires treatment of the critically ill patient with sepsis.

While this chapter overviews general considerations regarding the pathophysiology and management of enteric fistulas, it focuses on postsurgical enteric fistulas, particularly fistulas to the skin, that is, enterocutaneous fistulas. In this particular patient population, the mortality rate remains high, between 3 and 22% in series dating back six decades, largely due to the frequent complications of sepsis and malnutrition (Table 10-5). Successful outcome requires a multidisciplinary team of health care workers, including surgeons, infectious disease specialists, intensivists, radiologists, nurses, enterostomal therapists, and nutrition specialists. Management of these patients must also take into account the psychosocial and emotional needs of the patient and his/her family through a prolonged and often complex treatment course.

One of the challenges in attempting to discern optimal management of these patients relates to the quality of the medical literature. Most reports are retrospective reviews of large case series emanating from referral institutions. Notwithstanding this shortcoming, these series provide general approaches to therapy, which help to guide treatment.

Classification

Fistulas involving the alimentary tract have traditionally been classified in three distinct ways: by the *etiology* responsible for their formation, that is, spontaneous versus postoperative, by the *anatomy* of the structures involved, and finally by the *amount and composition of drainage from the fistula*. Such distinctions may provide important prognostic information about the physiologic impact of fistulas and the likelihood that they will close without surgical intervention.

SPONTANEOUS VERSUS POSTOPERATIVE

Enterocutaneous fistulas may be classified as either spontaneous or postoperative. Approximately three-quarters of fistulas occur in the postoperative setting, most commonly subsequent to procedures performed for malignancy, inflammatory bowel disease (IBD), or adhesive bowel obstruction.[32] These fistulas become evident to the surgeon in a number of different ways: (1) They may occur in the early postoperative period as a septic complication of surgery, sometimes with catastrophic physiological deterioration. This is usually a result of uncontrolled diffuse intra-abdominal infection caused by anastomotic leakage, breakdown of enterotomy closure, or a missed enterotomy. (2) They may occur in a more delayed manner, following treatment of a postsurgical infection with percutaneous drainage of a deep abscess or opening of a superficial wound infection may reveal that an underlying connection to the GI tract as a cause. (3) They may occur very late after the surgery due to unanticipated injury to the GI tract. The development of a wound infection following use of mesh for hernia repair would fall into this category either through erosion of mesh into bowel or due

to iatrogenic injury to the bowel as one attempts to debride infected mesh. Overly aggressive management of an open abdominal wound can also lead to intestinal injury and fistula formation. This complication has been reported to occur in up to 25% of patients during treatment with an open abdomen for abdominal sepsis.[42]

The remaining 25% of fistulas occur spontaneously, that is, without an antecedent surgical intervention. These fistulas often develop in the setting of cancer or inflammatory conditions. Fistulas occurring in the setting of malignancy or irradiation are unlikely to close without operative intervention. Inflammatory conditions such as IBD, diverticular disease, perforated ulcer disease, or ischemic bowel can result in fistula development.[43] Of these, fistulas in patients with IBD are most common; these fistulas may close following a prolonged period of parenteral nutrition, only to reopen when enteral nutrition resumes.[33]

ANATOMIC CLASSIFICATION

Fistulas may communicate with the skin (external fistulas: entero- or colocutaneous fistulas) or other intra-abdominal or intrathoracic organs (internal fistulas). Internal fistulas that bypass only short segments of bowel may not be symptomatic; however, internal fistulas of bowel that bypass significant length of bowel or that communicate with either the bladder or vagina typically cause symptoms and become clinically evident. Identification of the anatomic site of origin of external fistulas may provide further information on the etiology and management of the fistula.

Oral, Pharyngeal, and Esophageal Fistulas. Radical resections and reconstructions for head and neck malignancy may be complicated by postoperative fistulas in 5–25% of cases.[44] Alcohol and tobacco use, poor nutrition, and preoperative chemoradiation therapy all contribute to poor wound healing and increase the risk of fistula formation. Failure of closure of the pharyngeal defect at the base of the tongue most commonly leads to fistula formation, and free microvascular flaps are the preferred method for closure. Brown and colleagues reported a significantly decreased postoperative fistula rate in patients who underwent free flap closure versus those with pedicled pectoralis flap closure, 4.5 versus 21%, respectively.[45] Most esophagocutaneous fistulas result from either breakdown of the cervical anastomosis following resection of esophageal malignancy or following esophageal trauma. Less common causes of oropharyngeocutaneous or esophagocutaneous fistula include tuberculosis, laryngeal or thoracic surgery, trauma, congenital neck cysts, anterior cervical spine fusion, and foreign body perforations.[46–48]

Gastric Fistulas. The most commonly reported procedure associated with gastrocutaneous fistula formation is the removal of a gastrostomy feeding tube, particularly in children. The duration of gastrostomy tube placement appears to be related to the likelihood of development of a fistula after tube removal, with nearly 90% of children developing a fistula when the tube had been in situ for more than 9 months.[49] The rate of gastrocutaneous fistula following operations for nonmalignant processes such as ulcer disease, reflux disease, and obesity is between 0.5 and 3.9%.[50] The recent rapid increase in the number of bariatric surgical procedures was anticipated to lead to an increase in the incidence of gastrocutaneous fistula following surgery for benign disease, as the rate of anastomotic leakage after gastric bypass surgery is 2–5%. One study has reported that approximately 10% of patients with staple line leaks go on to form chronic fistulas, making the overall rate less than 0.5%.[51] Fistula formation following resection for gastric cancer remains a dreaded complication with significant mortality rates. Spontaneous gastrocutaneous fistulas are uncommon but can result from inflammation, ischemia, cancer, and radiation.

Duodenal Fistulas. The majority of duodenocutaneous fistulas develop after distal or total gastric resections or surgery involving the duodenum or pancreas. Inadvertent injury to or intentional excision of a portion of the duodenum during surgery of the colon, aorta, kidney, or biliary tract may also result in fistula formation. Spontaneous cases resulting from trauma, malignancy, Crohn's disease, and ulcer disease account for the remaining duodenal fistulas.[52,53] Prognostically, duodenal fistulas segregate into two groups: lateral duodenal fistulas and duodenal stump fistulas. Some authors have reported a decreased spontaneous closure rate with lateral duodenal fistulas when compared to that with duodenal stump fistulas.[32,54]

Small Bowel Fistulas. Fistulas arising in the small bowel account for the majority of gastrointestinal-cutaneous fistulas, the majority of which (70–90%) occur in the postoperative period.[33,34,55] Postoperative small bowel fistulas result from either disruption of anastomoses (either small bowel anastomoses or small bowel to colon anastomoses) or inadvertent and unrecognized injury to the bowel during dissection or closure of the abdomen. Operations for cancer, IBD, and adhesiolysis for bowel obstruction are the most common procedures antecedent to small bowel fistula formation. As noted previously, spontaneous small bowel fistulas arise from IBD, cancer, peptic ulcer disease, or pancreatitis. Crohn's disease is the most common cause of spontaneous small bowel fistula. The transmural inflammation underlying Crohn's disease may lead to adhesion of the small bowel to the abdominal wall or other abdominal structures. Microperforation may then cause abscess formation and erosion into adjacent structures or the skin. Approximately half of Crohn's fistulas are internal and half are external.[56–58] Crohn's fistulas typically follow one of two courses. The first type represents fistulas that present in the early postoperative period following resection of a segment of diseased bowel. These fistulas arise in otherwise healthy bowel and follow a course similar to non-Crohn's fistulas with a significant likelihood of spontaneous closure. The other group of Crohn's fistulas arises in diseased bowel and has a low rate of spontaneous closure.

Appendiceal Fistulas. Fistulas of appendiceal origin may result from drainage of an appendiceal abscess or post-appendectomy in a patient either without or with Crohn's disease.[59,60] In the latter case, the fistula often originates from the terminal ileum, not the cecum. The inflamed ileum adheres to the abdominal wall closure and subsequently results in fistula formation.

Colonic Fistulas. While spontaneous fistulas of the colon may result from inflammatory conditions such as diverticulitis, appendicitis and IBD, or from advanced malignancy, the majority of colocutaneous fistulas are postsurgical, usually secondary to anastomotic breakdown following colonic resection for one of these conditions. Preoperative radiation therapy reduces the risk of local recurrence and death from advanced rectal cancer and is an accepted practice.[61] However, radiation therapy contributes to both spontaneous and postoperative colocutaneous fistulas. Russell and Welch authors reported a 31% incidence of breakdown of primary anastomoses performed in irradiated tissues with resulting sepsis or fistula formation.[62]

PHYSIOLOGIC CLASSIFICATION

Traditionally, fistulas have been classified into high-output (>500 mL/d), moderate-output (200–500 mL/d), and low-output (<200 mL/d) groups. Enterocutaneous fistulas cause the loss of fluid, minerals, trace elements, and protein, and, when improperly managed, they can result in profound irritation of the skin and subcutaneous tissues. Depending on the origin of the fistula and its anatomy, the amount of output and nature of the effluent may be estimated (Table 10-6). However, direct measurement of these parameters for an individual fistula allows for accurate replacement and an understanding of the physiologic and metabolic challenges to the patient. Classification of enterocutaneous fistulas by the volume of daily output provides information regarding mortality and has been used to predict spontaneous closure and patient outcome.[32,63–65] In the classic series of Edmunds and associates, patients with high-output fistulas had a mortality rate of 54%, compared to a 16% mortality rate in the low-output group.[32] More recently, Levy and colleagues reported a 50% mortality rate in patients with high-output fistulas, while those with low-output fistulas had a 26% mortality.[63] Soeters and coworkers reported no association between fistula output and rate of spontaneous closure,[33] while multivariate analysis by Campos and associates suggested that patients with low-output fistulas were three times more likely to achieve closure without operative intervention.[65] The reason for these different closure rates most likely relates to the nature of the particular fistula, rather than the volume of output per se. If the fistula totally diverts flow, for example a pouting small bowel opening in the center of an open abdomen, it will be both high output and unlikely to close, without these two factors being causally related. By contrast, a defect at a small bowel anastomotic site with a long fistula tract and no local infection will likely be walled off by surrounding tissues and close spontaneously. These fistulas, while initially high output, will often close because of favorable local conditions. In essence, prediction of closure should be based on the local conditions, and particularly the nature of the fistula rather than the output. To the extent that the output often reflects the nature of the fistula, it will then be predictive.

TABLE 10-6: PREDICTED OUTPUT AND ELECTROLYTE COMPOSITION OF FISTULAS ACCORDING TO LOCATION

Source	Volume (mL/d)	pH	Na	K	HCO_3^-	Cl
Gastric	2000–2500	<4	60	10	—	90
		>4	100	10	—	100
Pancreatic	1000		140	5	90–110	30–45
Bile	1500		140	5	35	100

Predicting Closure of Enterocutaneous Fistulas

Spontaneous closure of enterocutaneous fistulas without the need for major surgical intervention is clearly a desirable outcome for these patients. The precise probability of spontaneous closure is somewhat difficult to assess since the large series reporting management of fistulas are usually derived from specialty centers for fistula management and thus not only represent a biased sample but also reflect differences in referral practice. Thus, spontaneous closure has been reported to occur in 10–75% of patients.[36,39,40,66,67] Nevertheless, a number of factors have been suggested to be predictive of failure of spontaneous closure of fistulas (Table 10-7). Some of these factors are modifiable, for example nutritional status, presence of local infection, and foreign bodies, while many do not include location, presence of an open wound, and the presence of distal obstruction. Knowledge of these factors should prove to be helpful in discussion of outcome with the patient and family members, as well as with the multidisciplinary team.

Risk Factors and Prevention of Enterocutaneous Fistulas

The majority of enterocutaneous fistulas arise in the postoperative period, often related to leakage of small bowel/colonic anastomoses or enterotomy closure. A number of factors have been associated with postsurgical enteric leaks. These can be divided into patient factors such as old age,

TABLE 10-7: FACTORS THAT PREDICT FAILURE OF SPONTANEOUS FISTULA CLOSURE

immunosuppression, malnutrition, emergency surgery, and peritoneal contamination, and surgical factors such as emergency surgery, level of anastomosis, preoperative radiation, duration of surgery, blood loss, tension on anastomosis, inadequate blood supply to anastomosis, and technical error in suturing or stapling. Use of mechanical bowel preparation, anastomotic technique (stapled vs hand-sewn; single vs double layer), and omentoplasty has not been shown to influence anastomotic integrity. A recent meta-analysis in 2008 of 13 trials and 4601 patients showed no difference in the anastomotic leak rate when a mechanical bowel preparation was used compared to when it was not used in elective colon resection.[68]

Clearly, optimization of modifiable factors will serve to reduce anastomotic leak. In the elective setting, operations may be delayed to allow for normalization of nutritional parameters, thus optimizing wound healing and immune function. In emergency operations, the luxury of optimizing nutritional status preoperatively is not possible. Instead, emphasis should be on adequate resuscitation and restoration of circulating volume, normalization of hemodynamics, and use of appropriate antibiotic therapy.

Once a patient has been optimized preoperatively, attention is then turned to operative techniques to minimize the development of a fistula. Performance of anastomoses in healthy, well-perfused bowel without tension provides the best chance for healing. Testing of the rectal and sigmoid anastomoses with intraoperative air insufflations has been shown to reduce "radiologic" leak rate through guiding placement of additional sutures as needed.[69] Careful hemostasis to avoid postoperative hematoma formation will decrease the risk of abscess, while inadvertent enterotomies and serosal injuries should be identified and repaired. A recent meta-analysis based on three randomized trials showed that omentoplasty to buttress a colonic anastomosis did not reduce the rate of postoperative radiological leaks, alter mortality or change the need for reoperation.[70] However, while omentoplasty per se does not reduce the probability of anastomotic leakage, interposition of an omental flap to separate the anastomosis from the abdominal incision may lessen the probability of injuring the bowel during closure or of an enterocutaneous fistula should anastomotic leakage occur. A recent study pooling the data from five European randomized clinical trials studying rectal cancer care demonstrated that diverting stomas reduced the rate of symptomatic anastomotic leaks and improved overall survival but had no effect on cancer-specific survival.[71] The differential survival was primarily attributable to early postoperative mortality. Proximal diverting colostomy or ileostomy may allow sufficient anastomotic healing prior to suture-line challenge by luminal contents.

Approach to Management

An organized treatment approach is of paramount importance to ensuring the optimal patient outcome. Table 10-4 lists overall mortality of patients presenting with enterocutaneous fistulas from a number of reports dating back six decades. Overall, the more recent studies appear to be associated with a lesser mortality rate, presumably a result of improvements in imaging, fluid resuscitation, antibiotic management, and intensive care support. However, the ultimate goals in treating patients with enterocutaneous fistulas are closure of the fistula with abdominal wall closure and return to baseline functioning level. Evenson and Fischer[72] outlined five distinct phases of management that can be used to guide care of this patient population. These phases are discussed in detail and also summarized in Table 10-8.

PHASE 1: RECOGNITION AND STABILIZATION

Identification and Resuscitation. As noted in the Introduction, the clinical presentation of patients with enterocutaneous fistulas depends on the underlying pathophysiological process. Invariably, the patient who develops a postoperative enterocutaneous fistula will do well clinically for the first few days after operation. Within the first week, however, the patient may suffer delayed return of bowel function, as well as fever and leukocytosis, together suggestive of intra-abdominal infection. This setting will usually prompt a request for an abdominal CT scan that demonstrates a perianastomotic abscess. Percutaneous drainage for therapeutic management of the abscess will serve to confirm anastomotic disruption, either immediately or a few days later when there is evidence of enteric content. Occasionally, erythema of the wound develops and opening the wound reveals purulent drainage that is soon followed by enteric contents. In both these circumstances, the peritoneal host defenses have successfully walled off and contained infection. By contrast, in some patients, diffuse peritoneal contamination arising from a leaking anastomosis or enterotomy causes profound and

TABLE 10-8: APPROACH TO MANAGEMENT OF ENTEROCUTANEOUS FISTULAS

Phase	Goals	Time Course
Recognition/stabilization	Resuscitation with crystalloid, colloid, or blood Control of sepsis with percutaneous or open drainage and antibiotics Electrolyte repletion Provision of nutrition Control of fistula drainage Commencement of local skin care and protection	24–48 h
Investigation	Fistulogram to define anatomy and characteristics of fistula Other GI studies CT scan to define pathology Operative notes from prior surgery	7–10 d
Decision	Evaluate the likelihood of spontaneous closure Decide duration of trial of nonoperative management	10 d–6 wk When closure, unlikely or after 4–6 wk
Definitive management	Plan operative approach Refunctionalization of entire bowel Resection of fistula with end-to-end anastomosis Secure abdominal closure Gastrostomy and jejunostomy	Surgical intervention at 3–6 mo after patient stabilized
Postsurgical	Usual postoperative protocol Psychological and emotional support	Ensure access to ICU for management of potential complication Team approach to management facilitates recovery

CT, computed tomography; GI, gastrointestinal; ICU, intensive care unit.

rapid deterioration of the patient with diffuse abdominal tenderness, evidence of organ dysfunction, and hemodynamic instability. Usually, these patients exhibit signs of organ dysfunction in the days prior to their catastrophic deterioration, including reduced level of consciousness, tachycardia, and mild renal impairment. The diagnosis then becomes clear and management shifts from routine postoperative care to the management of a potentially critically ill patient. As with all critically ill patients, attention should turn to management of the ABCs. The patient with a localized collection or one that has necessitated into the wound can usually be managed on the ward, while the patient with a more significant septic response may require transfer to an intensive care unit (ICU) setting. In both scenarios, restoration of intravascular volume usually crystalloid is appropriate with or without inotropic support as determined by physiologic monitoring. A recent *Cochrane Database Systematic Review* showed no difference in outcome in critically ill patients managed with crystalloid versus colloid and therefore recommended crystalloid as the preferable resuscitation fluid.[73] The initiation of broad-spectrum antibiotic therapy should occur early and be directed toward the most likely pathogens involved. Patients with postoperative peritonitis have increased probability of having multiresistant microorganisms and should receive broader-spectrum antibiotics. The consensus guidelines published by the Surgical Infection Society/Infectious Diseases Society of America address antimicrobial options for these severe health care–associated infections[21] (see Tables 10-2 and 10-3).

Control of Sepsis. Uncontrolled infection with the development of a septic response and the concomitant fluid imbalance and malnutrition are the leading causes of mortality in modern series of enterocutaneous fistulas. The leakage of enteric contents outside of the bowel lumen may lead to a localized abscess or to generalized peritonitis. Percutaneous management of localized abscesses accompanied by appropriate antibiotic therapy and supportive measure is usually sufficient to resolve infection in this subgroup. Diffuse peritoneal infection represents a much greater management challenge. In general, the generalized nature of the infection precludes successful therapy with percutaneous drainage and therefore an operative approach is indicated. Particularly in the early postoperative period, the surgeon should be wary of attempting to treat multiple intra-abdominal fluid collections observed on CT scan with percutaneous drains, when surgical intervention is required for definitive management.

Surgical Approach. The goals of operative management of peritonitis are to eliminate the source of contamination, reduce the bacterial inoculum, and prevent recurrent or persistent infection. The operative technique used to control contamination depends on the location and the nature of the pathological condition in the GI tract.[43] For patients progressing to diffuse peritonitis in the early postoperative period, the abdomen is usually reentered through the previous incision with the discovery of pus and enteric content. After aspiration of the fluid, an exploration to find the source

of contamination is warranted. Anastomotic dehiscence/enterotomy should generally be managed by exteriorization of the affected bowel. Whether this is performed via a single stoma site or with separate stomas (ie, end stoma plus mucous fistula) depends on the specific scenario. Obviously, if one is able to exteriorize the intestinal defect, the likelihood of a postoperative enteric fistula is markedly reduced. It is attractive to hope that a surgically repaired enterotomy or leaking enterotomy might heal primarily, given the obvious simplicity of the procedure. However, this is rarely successful in the setting of diffuse peritoneal infection, and therefore this approach is not recommended. Reoperation after this misjudgment is fraught with potential difficulty, in that the surgeon is faced with the need to reoperate on the patient in the early postoperative period. This laparotomy is invariably more difficult, often associated with bleeding, further enterotomies, and a bowel that is extremely difficult to exteriorize. Under these circumstances, there should be consideration of a proximal defunctioning stoma if technically feasible. These cases are frequently the ones associated with inability to close the abdominal wall.

A number of anatomical circumstances may also preclude exteriorization of a leaking anastomosis. The principle of "defunction and drain" is appropriately applied in this setting. Most important among these is the rectal or sigmoid anastomosis where the distal end can be neither exteriorized nor closed. Unless the anastomosis is greater than 50% disrupted, it is reasonable to defunction with an ileostomy or a colostomy upstream and drain the site of the hookup. This approach is preferred as it increases the probability of future restoration of the GI tract. This is particularly true of leaks below the peritoneal reflection.[74] If the anastomosis is almost completely disrupted, the surgeon is obliged to perform an end stoma and drain the pelvis, as the preserved anastomosis would stricture and preclude later stoma closure.

Control of Fistula Drainage and Skin Care. Concurrent with drainage of sepsis, a plan to control fistula drainage and provide local skin care will prevent continued irritation of the surrounding skin and abdominal wall structures. Obviously, fistulas created following percutaneous drainage of abscesses are usually well managed by the drain itself. Indeed, the drainage of a local infection is frequently sufficient to permit closure of the fistula. For small low-output fistulas, dry dressing may suffice. In less controlled circumstances, particularly in the setting of the open abdomen, control of the effluent is not straightforward and must be managed aggressively. A skilled enterostomal therapist can often provide useful insight into these issues and should work in concert with a dedicated nursing team.[75] The goals of therapy are to protect the skin, accurately monitor output, and minimize patient anxiety over effluent control. Use of a drainable wound pouch that is tailored to the size of the open wound is effective. This is often combined with some of colloid paste to protect skin and have an improved base on which to secure the stoma. Vacuum-assisted closure devices have been reported to aid in the care of these complicated wounds, including the promotion of closure. For example, Wainstein and coauthors reported promising results after reviewing their 10-year experience with it. In this study, fistula output was profoundly suppressed soon after commencing use of the device and spontaneous closure was achieved in 46% of patients. The use of a vacuum-assisted device was also found to reduce the frequency of wound dressing changes and improve dermatitis in all cases.[76] These findings are consistent with most surgeons' anecdotal experience with vacuum treatment. Some authors have reported a small number of patients developing new enteric fistulas with the vacuum device. Therefore, some judgment is required in patient selection; presumably stabilized patients with some granulation overlying the exposed bowel may be appropriate.[77,78]

Reduction in Fistula Output. While fistula output does not correlate with the rate of spontaneous closure, reduction in fistula drainage may facilitate wound management and decrease the time to closure. Further, reduced output enhances the ease of fluid and electrolyte management and may make local wound care easier. In the absence of obstruction, prolonged nasogastric drainage is not indicated and may even contribute to morbidity in the form of patient discomfort, impaired pulmonary toilet, alar necrosis, sinusitis or otitis media, and late esophageal stricture. Measures to decrease the volume of enteric secretions include administration of histamine antagonists or proton pump inhibitors. Reduction in acid secretion will also aid in the prevention of gastric and duodenal ulceration as well as decrease the stimulation of pancreatic secretion. Antimotility agents such as loperamide and codeine may also be effective.

As inhibitors of the secretion of many GI hormones, somatostatin, and octreotide were postulated to promote nonoperative closure of enterocutaneous fistulas. As recently reviewed, these agents did not accomplish this, although the data suggest that fistula output is reduced and time to spontaneous closure is lessened.[79] This effect is more pronounced with somatostatin infusion than with its longer-acting analogue, octreotide. Infliximab, a monoclonal antibody to TNF-α, has been shown to be beneficial in inflammatory and fistulizing IBD.[80] In a randomized trial of patients with chronic fistulas (duration >3 months), administration of infliximab resulted in a significantly increased rate of closure of all fistulas when compared to placebo.[80] Some evidence suggests a role for infliximab in treatment of fistulas complicating IBD and its use has been reported to promote healing of persistent fistulae even in non-IBD patients.[81] A number of other approaches to managing fistula output and promoting closure have been reported. These include endoscopic injection of fibrin glue into identified fistula openings,[82] radiologically guided percutaneous Gelfoam embolization of the enteric opening,[83] and the insertion of an absorbable fistula plug using a combination of percutaneous and endoscopic approaches.[84] All three involve the "plugging" of the opening with a biological material, presumably with the expectation of tipping the local conditions toward healing. These low-morbidity techniques may therefore be considered as adjuvant considerations for fistula management.

One would speculate that their greatest efficacy would be in the setting of a long tract, without epithelialization and with low output. Recently, endoscopic insertion of a silicone-covered stent across the fistula opening related to gastrojejunal leak following gastric bypass surgery has been described as a means of allowing early feeding and promoting fistula closure.[51] One well-documented and potentially morbid complication of the stent use is its downstream migration with obstruction and erosion of the intestine. Clearly, no consensus regarding use of this approach has been achieved, given the small patient numbers described.

Nutritional Support. Provision of nutritional support and time may be all that are necessary for spontaneous healing of enterocutaneous fistulas. Alternatively, should operative intervention be required, normalization of nutritional parameters will optimize patients in preparation for their surgery. Malnutrition, identified by Edmunds in 1960 as a major contributor to mortality in these patients, may be present in 55–90% of patients with enterocutaneous fistulas.[33] Patients with postoperative enterocutaneous fistulas are often malnourished due to a combination of poor enteral intake, the hypercatabolic septic state, and the loss of protein-rich enteral contents through the fistula and via the open abdominal wall. The optimal route of nutrition in the management of enterocutaneous fistulas has not been critically studied. Parenteral nutrition has long been the cornerstone of support for patients with enterocutaneous fistulas.[33,85–87] This, in part, is related to the fear that early enteral feeds will exacerbate the fistula through increasing output and also that enteral feeds may not be an adequate form of nutritional support. Parenteral nutrition can be commenced once sepsis has been controlled and appropriate intravenous access has been established. Transition to partial or total enteral nutrition has been advocated in recent reports to prevent atrophy of GI mucosa as well as support the immunologic and hormonal functions of the gut and liver. Additionally, parenteral nutrition is expensive and requires dedicated nursing care to prevent undue morbidity and mortality from line insertion, catheter sepsis, and metabolic complications. Thus, attempting enteral feeding is appropriate in most fistula patients. As achieving goal rates of enteral feeding may take several days, patients are often maintained on parenteral nutrition as tube feedings are advanced. Enteral feeding may occur per os or via feeding tubes placed nasogastrically or nasoenterically. Enteral support typically requires 4 ft of small intestine and is contraindicated in the presence of distal obstruction. Drainage from the fistula may be expected to increase with the commencement of enteral feeding, although this does not uniformly occur and is often dependent on fistula location and size of the fistula defect; however, spontaneous closure may still occur, often preceded by a decrease in fistula output. When parenteral and enteral nutrition are both options, the latter is preferred. It is far less expensive, safer, and is easier to administer (particularly if the intent is to manage the patient as an outpatient). A meta-analysis by Gramlich et al[19] indicated that ICU patients receiving enteral feeds have a lesser infection rate than those receiving parenteral feeds.

In patients with high-output proximal fistulas, it has been suggested to provide enteral nutrition by a technique called *fistuloclysis*. In fistuloclysis, an enteral feeding tube is placed directly into the matured high-output fistula.[88] Teubner et al reported on their experience using fistuloclysis in 12 patients before reconstructive surgery.[89] Eleven of twelve patients were able to discontinue parenteral support and nutritional status was maintained until surgery in nine patients (19–422 days) and for at least 9 months in the two patients who did not undergo operative intervention.[89] Of note, surgeons in this study also reported improved bowel caliber, thickness, and ability to hold sutures in patients who had received enteral nutrition.[89] Other measures such as the use of recombinant human growth hormone (rGH) on fistula patients have been examined. While able to promote intestinal mucosal epithelial cell proliferation; increase levels of total proteins, albumin, fibronectin, and prealbumin; and transfer and reduce nitrogen excretion, its clinical role has not been clearly defined.[90]

Psychological Support. Patients who develop postoperative enterocutaneous fistulas require considerable psychological support. They have sustained a major complication of surgery and are frequently faced with prolonged postoperative stay, excessive abdominal discomfort, and potentially one or more additional surgical interventions. In aggregate, all of these factors lead to psychological distress for patient and their families and should be addressed once the acute disease is dealt with.

PHASE 2: INVESTIGATION

Once the patient has been stabilized with control of sepsis and commencement of nutritional support, early radiological investigation may be of value. Abdominal CT scanning with GI contrast with help to discern whether there is residual local infection that requires drainage, to localize the level of the fistula and the amount of contrast flowing beyond the defect, and occasionally whether there is distal obstruction. Fistulograms down drainage tracts will elucidate the length, course, and relationships of the fistula tract. If the fistula is spontaneous, the nature of the local pathological process from which the fistula arises may be determined. In the setting where the mucosal bud of the fistula is readily observed in the center of an open abdomen, aside from a CT scan to rule out distant infection, little further early imaging is required. Because patients with enterocutaneous fistulas are frequently referred to larger centers for management, it is essential that all notes, particularly operative notes, be obtained from the referring hospital. Personal communication with the surgeon may further elucidate other factors in the patient's disease that are not readily evident from the notes.

PHASE 3: DECISION

Spontaneous closure of fistulas restores intestinal continuity and allows resumption of oral nutrition. As noted previously, the rate of spontaneous closure varies considerably from series to series, with an average of approximately one-third

of patients. This wide range likely represents patient selection in the various series, and in particular whether the series emanates from a referral center where the patient population tends to be more complex. A number of factors predict spontaneous closure. These are listed in Table 10-7. One might consider two case scenarios to illustrate these points. A long, narrow fistula tract originating from a small leak in a colonic anastomosis with no evidence of distal obstruction and a well-drained perianastomotic abscess is almost certain to close spontaneously. By contrast, a small bowel defect revealing itself as a mucosal bud in the middle of an open abdomen is unlikely to heal as the tract is short and epithelialized, in essence mimicking a stoma. Fistulas associated with IBD often close with nonoperative management only to reopen upon resumption of enteral nutrition. These fistulas should be formally resected once closed to prevent recurrence. Fistulas in the setting of malignancy or irradiated bowel are particularly resistant to closure and would suggest the need for earlier operative intervention.

Most authors agree that once resuscitation, wound care, and nutritional support are established, 90–95% of fistulas that will spontaneously close typically do so within 4–8 weeks of the original operation.[25,85] In the absence of closure, there should be consideration of surgical closure. Like any surgical procedure, weighing of the risk and benefits of surgical intervention is critical prior to proceeding to operation. This is particularly relevant in this patient population where the surgical procedure is a major one and has a finite risk of recurrence. Some patients are perfectly well, are tolerating a regular diet, and have fistula effluent that is trivial in volume and requires only coverage with dry gauze. The potential risks of a major operation in this type of patient might outweigh the ultimate benefit. The timing of elective operative intervention for fistulas that are unlikely to or fail to close is extremely important. Early operation is only indicated to control sepsis not amenable to percutaneous intervention. These early procedures are typically limited to drainage of infected fluid collections and drainage, defunctioning, or exteriorization of the defect.

There is some controversy in the literature as to how long one should wait before attempting definitive elective closure of enterocutaneous fistulae. Very early closure appears to be contraindicated because the patient condition is generally not optimized. Further, from a technical standpoint, adhesions tend to be dense and vascular, therefore rendering the procedure difficult. In one retrospective study, Keck et al observed that operative difficulty and denser adhesions leading to inadvertent enteromies were more common when patients were taken to surgery for reversal of a Hartmann's procedure before 15 weeks compared to after.[91] Poor outcome when surgery is performed in the 2-week to 3-month window has been report by several groups.[38,92] At least two reports suggest that a very long delay before definitive surgery (>36 weeks) might adversely affect outcome.[41,93] It is generally recommended that definitive surgery be considered in the window of 3–6 months after the patient is stabilized from the initial recovery from the procedure that lead to the fistula formation. Various factors will influence where, in this interval, surgery is performed. Patient factors such as nutritional status, ease of managing the fistula, and family support may influence decision making. Some authors talk about the "soft" abdomen and prolapse of the fistula as being a valuable clinical signs that peritoneal conditions are reasonable to proceed with surgery.[37] On occasion, there is intense pressure from the patient and family to reoperate and "fix" the fistula during this early period. This approach should be resisted.

PHASE 4: DEFINITIVE MANAGEMENT

Operations repairing enterocutaneous fistulas may be complex and often lengthy. In addition to repairing the fistula, many of these patients require complex abdominal wall closures. Before definitive management, the patient should have achieved optimal nutritional parameters and be free of all signs of sepsis. Through careful management of fistula drainage, a well-healed abdominal wall without inflammation should be present.

Consent. As for all operations, the patient should be fully apprised of the nature of the procedure and its potential for complications. Connolly and colleagues reported a very high incidence of complications following intestinal reconstructive surgery (82.5% of procedures) when one considered postoperative nosocomial infections including surgical site infections, respiratory infections, and central line sepsis together with postsurgical myocardial dysfunction, GI bleeding, and deep vein thrombosis.[94] In discussions with patients and their families, the unique difficulty of these procedures should be raised, pointing out the potential for adhesions and therefore inadvertent injury and excessive bleeding. The fistula recurrence rate is also significant with reported rates up to 33% (see Table 10-5), depending on the individual circumstance. The patient and relevant family members should know that the procedure may be prolonged and may require an ICU stay in the postoperative period. Some of the anxiety of the patient may be related to mistrust of physicians in general following a previously complicated operation. Clearly, the sensitive nature of reoperation for prior complications requires a strong physician-patient relationship to minimize patient anxiety prior to the planned procedure.

Patient Preparation. It is critically important for the operating surgeon to fully understand the nature of the prior surgeries. Reviewing the previous operative notes as well as speaking with the original surgeon will consolidate one's knowledge of the initial pathological process and the precise anatomy to be corrected in the reoperative setting. One should also be very liberal about using preoperative contrast imaging or endoscopy to completely define the anatomy. In the hypothetical case of reoperation after a colonic anastomotic dehiscence, the need for definition of the anatomy varies according to the initial source control procedure. A prior operation consisting of exteriorization of an end colostomy with nearby mucus fistula or exteriorization of the disrupted anastomosis

is a circumstance where investigation is probably unnecessary. In preparation for closure of a Hartmann's procedure, the rectal stump should be routinely investigated by endoscopy. This may help with planning of the operation as well as locating the stump at surgery. Closure of a defunctioning ileostomy or colostomy should also be preceded by investigation of the downstream anastomosis. This is intended to rule out the presence of a stricture or persistent defect at that site, both of which would alter surgical approach. Finally, contrast studies are essential when complex fistulas exist and are to be treated by reoperative surgery.

The general principles related to preparation for any surgery should be applied to reoperation. These would include optimization of the general medical status of the patient, administration of subcutaneous heparin and/or other antithrombotic strategies, and initiation of measures aimed at reducing postoperative infectious complications. Orthograde intestinal lavage by mouth as well as distally via the defunctioned limb has been recommended for mechanical preparation of the bowel. However, the evidence underlying this recommendation is limited and, in fact, recent studies show that mechanical bowel preparation for elective colon surgeon does not improve outcome and may have some deleterious effects.[69] Our practice is to forego the use of mechanical prep unless reconstruction involves passage of stapling device transanally. Clearance of inspissated mucus in the rectal stump with an enema may facilitate advancement of the stapler proximally. Finally, prophylactic intravenous antibiotics with broad-spectrum coverage of both facultative gram-negative enterics as well as anaerobic bacteria are indicated. Consideration of coverage of resistant microbes should be made.[21]

Operative Intervention. Patients should be positioned to permit optimal exposure to the field of surgery, to take into account potential requirements for extension of the operative field, and to facilitate optimal reconstruction of the GI tract and/or drainage of the operative field. In the majority of situations, the supine position is adequate. Concomitant lithotomy positioning is often helpful, particularly when reconstruction involves the left colon or rectum, where transanal access for endoscopy or stapling may be useful. When reoperation involves the upper GI tract, left lateral decubitus positioning will allow an initial thoracoabdominal incision or extension of an abdominal incision into the chest.

Careful planning of the location and type of incision are mandatory prior to making the initial incision. It is preferable to enter the peritoneal cavity through a previously unoperated area of the abdominal wall, thereby avoiding the areas where the most intense adhesions would be expected, that is, beneath the previous abdominal wall incision and in the region of the abdomen where the inflammation might have been the most severe. Inadvertent enterotomy is relatively common during reoperation, occurring in approximately 20% of patients, and is associated with a higher rate of postoperative complication and a longer postoperative hospital stay.[95] In addition, it is a frustrating beginning to an often long and tedious operation.

The use of the midline incision, beginning with entry either cephalad or caudad to this initial incision through an unoperated field is the most common approach to reentering the abdomen. This approach provides broad access to the peritoneal cavity with opportunity for extension and is also readily closed. Other approaches may include unilateral or bilateral subcostal incisions, transverse incisions, flank incisions, or thoracoabdominal incisions. In general, these should be considered when a specific area of the abdomen is operated on, because they generally afford less access to the overall peritoneal cavity. When placing new incisions, care should be taken not to render intervening tissue bridges ischemic. This might occur when a midline incision is placed adjacent to a previous paramedian incision. It is preferable to use the previous paramedian incision with extension into the midline above or below. When the fistula opening is in the center of a reepithelialized section of the abdomen with no underlying fascia/muscle, one should preferably enter the abdomen as described above, either cephalad and caudad to the previously operated area. When this is not possible, one should consider placing the initial incision along the line of the fascial edge, rather than though the reepithelialized portion. In the latter operative field, the skin may be very adherent to the underlying bowel, therefore increasing the chance of bowel injury. This is particularly true when there is retained mesh, which may have contributed to fistula formation in the first place.

Upon entering the peritoneal cavity, adhesions between the anterior abdominal wall and the underlying omentum and bowel must be released. By 3–6 months following the initial surgery, adhesions are generally relatively filmy and readily divided using scissor or cautery dissection. Gentle traction on the bowel with countertraction on the abdominal wall will facilitate exposure of the appropriate tissue plane for division. A similar approach is appropriate for dense adhesions, with some surgeons preferring knife dissection. During this dissection, it may be necessary to leave patches of abdominal wall (peritoneum with or without fascia) or even mesh adherent to bowel to avoid enterotomy. It is also noteworthy that enterotomies may be caused by traction on the bowel due to retraction on the abdominal wall. Clearance of the fascial edges along both sides of the entire incision is necessary to achieve adequate and safe closure of the abdominal wall.

Having successfully entered the abdominal cavity, one faces varying degrees of interloop adhesions. The degree to which these must be lysed depends on the particular operation to be performed. When one is operating on the colon for the purpose of stoma closure or reestablishment of colonic continuity, there is generally little need to exhaustively take down small bowel adhesions. The fact that the patient has been tolerating a normal diet preoperatively provides ample evidence that the small bowel adhesions are not of physiological significance. While not having to lyse all adhesions, it is necessary, however, to free small bowel loops from their attachments to the colon so that the latter might be adequately mobilized to permit easy closure or anastomosis. When operating to close a small bowel stoma or to correct an enterocutaneous fistula, when possible, one should consider more comprehensive lysis of adhesions,

along the entire length of the small bowel, but in particular the distal small bowel. The presence of a stoma or fistula may serve to defunction a distal small bowel adhesive obstruction prior to surgery and may therefore preclude its recognition. The presence of a distal obstruction following upstream anastomosis could prove catastrophic in the postoperative period.

Adhesiolysis varies considerably in its degree of difficulty. Even when the reoperation is appropriately delayed from the initial operative procedure and vascularized adhesions are no longer present, the number and density of residual fibrous adhesions may still be significant and represent a significant technical challenge. As described for opening the peritoneal cavity, good lighting of the operative field, excellent surgical assistance, and a dose of patience are absolute requirements for this part of the operation. Two experienced surgeons working together facilitates adhesiolysis. During lysis of adhesions, one should also be wary of encountering previous anastomoses. Adhesions may be particularly tenacious in these areas, particularly when the prior anastomosis was performed using a stapled technique. For side-to-side functional end-to-end stapled anastomoses, the crotch of the anastomosis may be mistaken for intense adhesions. Failure to recognize this may result in inadvertent enterotomy and the attendant increased morbidity.

When surgery has been timed appropriately, one usually finds that the dissection distant from the fistula to be reasonably straightforward. As one approaches the fistula site, it becomes increasingly tedious with multiple adherent loops of bowel. We recommend that the fistula be addressed relatively late in the dissection, after most of the small bowel has been mobilized. This minimizes inadvertent injury to loops of bowel uninvolved in the fistula.

Several of the large case reviews address surgical technique and risk of recurrence.[37,38,40,41] In general, it appears to be preferable to locally resect the segment of small bowel bearing the fistula rather than simply closing the intestinal opening. This may represent a biased finding since the instances where simple closure was used correlated with the finding of an abdomen with impossibly dense adhesions, therefore precluding mobilization and resection. Under these latter circumstances, one might consider the addition of a temporary proximal defunctioning stoma.

In the elective surgical setting, stapled anastomoses have been shown to be equivalent to hand-sewn anastomoses in terms of anastomotic dehiscence.[96] By contrast, for closure of enterocutaneous fistulas, hand-sewn appears to be the preferred approach to performing the anastomosis following resection. Whether single layer versus two layers of sutures or running versus interrupted stitching should be used has not been systematically addressed. Frequently, the chronically defunctioned bowel is atrophic, line-walled, and stiff. Under these circumstances, the stapling devices are unable to accommodate the pathological nature of this bowel, where hand sewing can better accommodate differences in size, thickness, and compliance of the intestine.

Wrapping of the anastomosis with omentum has been examined as a means of preventing anastomotic leakage but has not proven to be effective.[71] However, placement of a flap of omentum between the fresh anastomosis and the abdominal wall closure may minimize recurrence of fistulization. Some have advocated the placement of a decompressive gastrostomy and/or the placement of a feeding jejunostomy, both of which may aid in the postoperative care of patients undergoing procedures of this scale.

As the cumulative experience with complex laparoscopic procedures has increased, several groups have reported laparoscopic approaches to enteric and enterocutaneous fistulas.[97–102] The largest of these series reported 73 procedures in 72 patients, 20% of which were enterocutaneous fistulas.[101] The authors reported a mean operative time of 199 minutes with a 4.1% conversion rate.[101] Because surgical procedures for the management of enteric fistulas are generally complex ones, a laparoscopic approach would seem appropriate only in the hands of a skilled and experienced laparoscopic surgeon and only in selected circumstances.

Abdominal Wall Closure. After the fistula has been appropriately managed, one is left with closure of the abdominal wall. The complexity of this aspect of the operation varies depending on the preoperative state of the abdominal wall. Closure may be straightforward when the enterocutaneous fistula is along a previous drain tract or through necessitation of an abscess through an abdominal wound. By contrast, when the prior patient management involved an open abdomen approach with the fistula draining from the center of the wound, patients may present with large ventral hernias that are not amenable to simple fascial closure. In advance of surgery, it is essential that the surgeon consider management of abdominal wall a significant part of the procedure and reflect upon the various surgical options. Included in these preoperative deliberations should be the proactive involvement of a plastic surgeon to aid in the assessment of options and to potentially prepare him/her for involvement in the operation. Table 10-9 outlines the various approaches. Prior to beginning abdominal wall closure,

TABLE 10-9: MANAGEMENT OF ABDOMINAL WALL FOLLOWING ELECTIVE CLOSURE OF GASTROINTESTINAL FISTULA

No Preoperative Fascial Defect
- Primary closure with or without some fascial relaxation

Preoperative Fascial Defect
- Small defect (<5 cm)
  - Primary fascial closure with or without some fascial relaxation
- Large defect
  - Primary fascial closure using component separation technique
    - If very large, may be combined with prosthetic material
  - Coverage with vascularized flap
  - Use of prosthetic material
    - Nonabsorbable
    - Absorbable
      - Nonbiological
      - Biological

it is desirable to debride/remove any residual infected foci, including chronically infected suture material and previously placed infected mesh. One should also attempt to position the intestinal anastomosis away from the closure and, if possible, to interpose omentum between the anastomosis and the abdominal wall. Finally, it is generally considered that, in the setting of GI surgery where there is contamination of the surgical field, the use of nonabsorbable permanent mesh is contraindicated as it is associated with an increased risk of infection and refistulization.[103]

When no defect or a small defect in the fascia exists, primary closure is usually achievable although there may be some mild tension on the closure. This is, in part, related to the stiffness of the abdominal wall attendant with repeated abdominal surgery. In these circumstances, relaxing incisions placed in the aponeurosis of the external oblique muscle approximately 2 cm lateral to the edge of the rectus muscle may minimize any tension. Polydioxanone, a slowly absorbable monofilament suture material, appears preferable as it is equivalent to nonabsorbable monofilament suture in terms of recurrent hernias but has less wound pain and sinus formation.[104] Various closure techniques have been proposed when primary fascial closure is not possible.[103,105–107] There has been increasing enthusiasm regarding the use of the component separation technique as a means of achieving abdominal wall closure without prosthetic material.[105–107] In brief, this approach involves the separation of the external oblique and internal oblique muscles bilaterally plus division of the posterior rectus fascia. Together, these accomplish approximately 12-, 22-, and 10-cm advancement of the upper, middle, and lower thirds of the abdomen, respectively.[105] This approach has been reported for abdominal wall closure after trauma surgery, in patients with sepsis managed with the open abdomen and in patients with enterocutaneous fistulas.

Wind and colleagues examined the application of this technique in the presence of a contaminated abdominal wall defect, including during closure of an enterocutaneous fistula and/or stoma.[106] This study reported the feasibility of this approach in terms of achieving abdominal wall closure but noted considerable morbidity, including wound seromas, wound infections, and hematomas as well as recurrent abdominal wall hernias in approximately 22% of patients. Recurrence of the enterocutaneous fistula occurred in 25% of patients. In a small percentage of patients, the use of absorbable mesh was combined with the component separation technique, because the advancement of the abdominal wall alone was not sufficient to cover the defect.

Finally, absorbable prosthetics may be considered for management of the defect. Synthetic meshes such as polyglactin effect good initial coverage but have the anticipated long-term consequence of incisional hernia formation.[94] As an alternative, biological prostheses including porcine collagen mesh and acellular dermal matrix have been suggested with the potential advantage of increased resistance to infection and reduced late incisional hernias. These outcomes have not been uniformly achieved when used in the treatment of fascial defects following repair of enterocutaneous fistulas.[94,108]

In summary, management of the abdominal wall following reoperative surgery in these patients may be a considerable challenge. The major objective is to prevent recurrent fistula formation and minimize postoperative infection. Prevention of late ventral hernia formation is a secondary goal. Involvement of a surgical team with expertise in the options, including the use of the component separation technique, would appear to broaden the clinical options for the patient.

PHASE 5: POSTSURGICAL PHASE

The postoperative period can be divided into two parts: the early postsurgical recovery period and the later rehabilitation and convalescence phase. The former of these periods can be somewhat complex as postoperative complications are frequent, with up to 80% of patients having one or more complications.[94] In particular, these patients have a significant incidence of postoperative infection, both at the surgical site and at distant sites including lung and central venous lines. As shown in Table 10-5, the incidence of recurrent fistulization following surgery is considerable and is associated with prolonged hospital stays and repeat admissions to the ICU as well as repeat interventions. Brenner et al reported that recurrence of the enterocutaneous fistula in the postoperative period was the strongest predictor of mortality, invariably due to the development of overwhelming sepsis and organ failure.[41] Mortality is related to the presence of preoperative comorbidities.[109] Short of death, the recurrence of enterocutaneous fistula following surgery represents a major complication. Among those who survive this recurrence, only 50–66% go on to further surgery and successful closure, while the remainder live with a chronic fistula.[38,41] A number of factors predict recurrence (Table 10-10).

By the time their fistulas have been surgically closed, these patients have often been undergoing medical care, usually both as inpatients and outpatients for several

TABLE 10-10: FACTORS PREDICTING RECURRENCE AFTER ELECTIVE REPAIR OF ENTEROCUTANEOUS FISTULA

Patient Factors	
Open abdomen	
Origin of fistula (small bowel > large bowel)	
Underlying inflammatory bowel disease	
"Frozen abdomen" or residual intra-abdominal infection	
Surgical Factors	
Timing of surgery (<4 weeks, >36 weeks)	
Multiple inadvertent enterotomies at reoperation	
Oversewing of enteric defect, rather than resection and anastomosis	
Use of stapled anastomosis, compared to hand-sewn anastomosis	
Need to perform mesh closure of abdominal wall	

months following the initial development of their enterocutaneous fistulas. By the end of this period, which may have included prolonged in-hospital stays, multiple surgical and radiological interventions, frequent visits to health care facilities as outpatients, and an overriding focus on their medical disability, patients are invariably physically deconditioned and emotionally fatigued. The impact on the long-term quality of life, as measured by objective questionnaires, even in those treated, continues to be lower than matched controls especially if there is a concurrent medical illness.[110] Physical and occupational therapists play a role throughout each patient's hospitalization, but their efforts become even more important during the healing phase as the focus shifts to reintroducing the patient to normal activities of daily living. Involvement of case management staff early in the patient's course will identify obstacles to the patient's successful reintroduction to an active lifestyle, while use of psychiatric consultation-liaison services will identify and address issues of depression and adaptive disorders. Finally, active involvement by the senior surgeon responsible for the patient's care to ensure clear communication to the patient and the family during what is invariably a prolonged convalescence and rehabilitation period is essential. Optimally, this physician-patient relationship would have begun early in the patient's illness and would continue through till complete recovery occurs.

Conclusion

Enteric fistulas, occurring spontaneously or in the postsurgical period, represent a significant management challenge. This chapter has focused predominantly on the postsurgical enterocutaneous fistulas, which may result in both morbidity and occasionally mortality for the patient. The care in these patients may be complex and has led to the establishment of specialized intestinal failure units, aimed at optimizing outcome. General principles of care include (1) early recognition and stabilization of patients with fistulas combined with control of sepsis and provision of nutritional support; (2) investigation of the anatomic and etiological characteristics of each fistula, thus providing information about the likelihood of spontaneous closure or need for operative management; (3) decision making regarding the approach to management, including the involvement of a multidisciplinary team, will provide the best possibility of resolution of the fistula; (4) definitive surgical therapy in a controlled setting; and (5) postoperative care including physical rehabilitation and emotional support, which together help the patient return to their premorbid condition.

GASTROINTESTINAL BLEEDING

Anita Balakrishnan • Ali Tavakkoli • Stanley W. Ashley

OVERVIEW

Acute gastrointestinal (GI) hemorrhage is a significant cause of morbidity and mortality in the emergency setting. The source of GI bleeding can range from the esophagus through to the colon and is classified into upper or lower GI bleeding depending on the site of bleeding relative to the ligament of Treitz. Upper GI hemorrhage occurs from sites proximal to the ligament of Treitz frequently due to peptic ulcer disease and variceal hemorrhage and accounts for more than 80% of acute bleeding.[1] The majority of lower GI bleeding originates from the colon from pathologies such as diverticular disease and angiodysplasias. The small intestine is the site of hemorrhage in fewer than 5% of patients.[1] Hemorrhage persisting or recurring after negative endoscopy is termed *obscure bleeding*. Occasionally patients present with *occult bleeding*, where there are no signs of overt bleeding, but the presenting symptoms are due to chronic blood loss and anemia. In all cases, thorough investigation to localize the source of bleeding allows rapid and often definitive management.

Incidence of Acute GI Hemorrhage

The annual incidence of acute upper GI hemorrhage is estimated at 170 cases per 100,000 adults, with an increasing incidence with age. The majority of cases are due to upper GI bleeding, with lower GI bleeding having an annual incidence of only 20.5 per 100,000 adults.[2,3] There are geographical variations in the incidence, with reported rates varying from 45 per 100,000 in the Netherlands to 172 per 100,000 in Scotland. This difference is likely related to differences in population demographics and prevalence of various etiological factors between the countries.[4–10]

Morbidity and Mortality

Despite advances in medical and endoscopic therapies, the mortality from upper GI bleeding remains unchanged at 5–14%,[4,5,7–11] and is particularly high in the elderly and hospitalized.[12] In fact, recent reports from the United Kingdom highlight an increase in the mortality rates of patients with upper GI bleeding, in part due to the aging population.

Economic Effects

Acute GI bleeding exerts a massive drain on health care resources. Rectal bleeding was the 6th most common symptom and melena the 11th most common symptom requiring an outpatient clinic appointment in 2002,[13] while colonic diverticular disease with hemorrhage was the 11th most common cause of inpatient admissions in 2002.[13] Approximately 5% of surgery for diverticular disease was necessitated by massive bleeding.[14] Diverticular bleeding has been estimated to cost over US $1.3 billion[15] while upper GI bleeding exerts an even higher burden on health care systems, costing an estimated US $2.5 billion annually in the United States.[16] Variceal bleeding incurred particularly high costs, with an estimated cost of $23,207 per admission for complicated variceal bleeding compared to $5632 for complicated nonvariceal upper GI bleeding. Uncomplicated cases cost $3402 per admission (nonvariceal upper GI bleeding) and $6612 per admission (variceal upper GI bleeding).[17]

INITIAL ASSESSMENT AND RESUSCITATION

A structured approach is recommended in the initial evaluation and management of the patient with acute GI bleeding

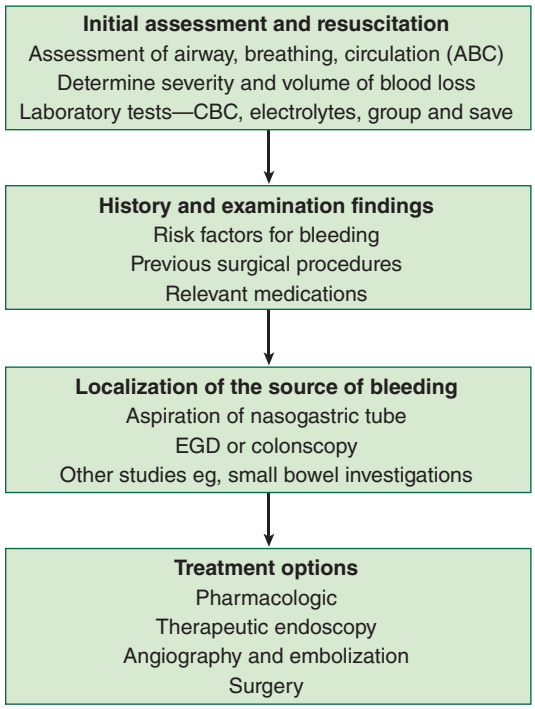

FIGURE 11-1 A brief overview of the management of gastrointestinal bleeding. ABC, airway, breathing, and circulation; CBC, complete blood count; EDG, esophagogastroduodenoscopy. (Adapted from Fig. 46-1, *Sabiston Textbook of Surgery*, 18th ed, Townsend, Beauchamp, Evers, and Mattox, Elsevier.)

(Fig. 11-1). Early resuscitation with the aim of restoring hemodynamic stability is of paramount importance, followed by a careful history and physical examination to identify the etiology and source of bleeding. Particular attention should be paid to comorbidities and the drug history as this may further complicate management. Diagnostic tests are subsequently performed to confirm the site of bleeding, and therapeutic interventions commenced to control active bleeding and prevent future recurrent hemorrhage.

Initial Assessment

Management of resuscitation should follow the principles of the ABCs (airway, breathing, and circulation). Once airway and breathing have been managed, adequate hemodynamic resuscitation is of the highest priority. In particular, the clinician needs to assess the amount of blood lost and the extent of ongoing hemorrhage. Initial evaluation should focus on rapid assessment of the magnitude of both the preexisting deficits and of ongoing hemorrhage. This can be determined by history and examination of the presenting symptoms, which may range from occult bleeding to life-threatening hematemesis and melena. In the majority of cases, a wealth of information can be obtained from simple clinical parameters such as conscious level, blood pressure, and heart rate (Table 11-1), and further facilitated by measurement of urine output as a marker of end-organ perfusion. Depending on the hemodynamic status of the patient and existing comorbidities, more invasive forms of monitoring such as central venous pressure measurements may be of use. Measurement of postural changes (drop in systolic blood pressure >10 mm Hg or increased pulse by >20 beats/min after sitting the patient up for approximately 5 minutes) will identify otherwise undetectable changes in circulating volume in patients with less than 20% circulating volume loss. Tachycardia (>100 beats/min) and a reduced pulse pressure suggest loss of 20–30% of circulating volume. Loss of greater than 40% of circulating volume produces impairment of conscious level (obtundation/agitation), cool, clammy peripheries, and drops the systolic blood pressure to less than 90 mm Hg. Note however that not all patients will demonstrate a tachycardic response to bleeding—occasionally severe blood loss may cause vagal-mediated bradycardia. Similarly, signs of hypotension are less reliable in the elderly and in those on beta-blockers.

While initial blood tests including full blood count and a group and save are essential, a normal hematocrit in the early stages of bleeding may be falsely reassuring, as the hematocrit will only decrease following dilution of the blood volume after resuscitation is commenced.

Resuscitation

The importance of adequate resuscitation cannot be overemphasized. The most important contributor to morbidity and mortality in acute GI bleeding is fulminant multiorgan failure resulting from insufficient resuscitation. The extent of resuscitation necessary will depend on the amount of blood lost and severity of ongoing bleeding. The critical care team

TABLE 11-1: LEVELS OF SHOCK

Class	Blood Loss (mL)	Blood Loss (%)	Heart Rate (beats/min)	Blood Pressure	CNS Symptoms
I	<750	<15	<100	Normal	Normal
II	750–1500	15–30	>100	Orthostatic	Anxious
III	1500–2000	30–40	>120	Hypotension	Confused
IV	>2000	>40	>140	Severe hypotension	Obtunded

CNS, central nervous system.

should be involved early in the resuscitation process, as early intubation and ventilation will reduce the complications of any respiratory compromise. Large-bore venous access is crucial in the hemodynamically unstable, particularly in those still actively bleeding. Fluid resuscitation in unstable patients should be commenced with a 2-L bolus of crystalloid solution of similar electrolyte composition to whole blood, such as lactated Ringer's. Success of fluid resuscitation should be monitored using simple clinical parameters such as heart rate, blood pressure, and urine output. Urine output is an excellent marker of end-organ perfusion and all hemodynamically unstable patients should be catheterized to allow hourly urine output measurement. A central venous catheter will allow accurate measurement of the preload in those with cardiac, pulmonary, or renal comorbidities, thereby facilitating more sensitive assessment of fluid balance and staving off fluid overload. Supplemental oxygen will maximize oxygen delivery to tissues. The basic blood tests of complete blood count, routine chemistries, and liver function tests should be performed. In addition, in this group of patients a coagulation profile and type and cross-match are essential.

Transfusion

Several factors need to be considered when deciding whether a blood transfusion is required. Of these, the most important are the presence and extent of ongoing bleeding and the response of the patient to fluid resuscitation. Other factors include the age of the patient (young patients are more able to tolerate blood loss than the elderly) and the presence of cardiopulmonary comorbidities that might produce preexisting compromise of tissue perfusion. The hematocrit (which can take 12–24 hours to equilibrate) is not a reliable first indicator of acute blood loss, but a hematocrit below 30% in the elderly and 20% in the young can be used as an index for the requirement for transfusion. The suspected likelihood of rebleeding should also be taken into account; for instance, in cases of upper GI bleeding, a transfusion is more likely to be required for pathology such as esophageal varices that have a high propensity for profuse rebleeding. While whole blood may be used in cases of massive blood loss, packed red cells are the optimal form of transfusion but are defective in clotting factors, calcium, and platelets. Patients requiring massive transfusion (>10 units of blood) must therefore also receive fresh frozen plasma, platelets, and calcium.

Risk Stratification

The development of risk stratification scores has greatly facilitated prediction of mortality and rebleeding as well as decision making regarding the need for hospital admission, intensive care unit (ICU) admission, or urgent investigation in patients with GI bleeding. This allows consistent differentiation of patients requiring only outpatient investigation (eg, in patients with transient rectal bleeding) from urgent therapeutic endoscopy in patients with ongoing upper GI bleeding. The BLEED study identified ongoing *b*leeding, *l*ow blood pressure (systolic blood pressure <100 mm Hg), *e*levated prothrombin time (>1.2 times control), *e*rratic mental status, and unstable comorbid *d*isease as risk factors for significantly higher rates of surgery, and increased recurrent bleeding and mortality in patients with GI bleeding.[18] Other studies have identified hepatic cirrhosis, high Acute Physiologic and Chronic Health Evaluation II (APACHE II) scores, active GI bleeding, hypotension, and end-organ dysfunction as independent predictors for the aforementioned outcomes.[19] These studies highlight the importance of comorbidities in determining outcome of GI bleeding. A further study confirmed this by identifying a mortality rate of nearly 30% in patients with significant renal disease and of 65% in patients with acute renal failure.[20] At present most of these scoring systems are predominantly used in research studies. There is little consensus on a uniform scoring system for use in the clinical domain, and these scoring systems should be applied with appropriate clinical judgment.

HISTORY AND EXAMINATION

A thorough history and examination will not only assist in diagnosing the cause of the bleeding but will also identify any comorbidity likely to influence outcome.

Important Characteristics of GI Bleeding

Time of onset, volume, and frequency of bleeding are key aspects of the history in determining amount of blood loss. The character of bleeding is also extremely important. *Hematemesis* is defined as the vomiting of blood, and it usually represents upper GI bleeding (rarely bleeding from the nasopharynx or oropharynx). Hematemesis may be bright red when fresh, but older blood will resemble coffee grounds. *Melena* is defined as the passage of offensive, black, tarry stool, again usually due to upper GI bleeding. The appearance of the stool is a result of gastric acid degradation (which converts hemoglobin to hematin), as well as the effects of intestinal enzymes and bacteria. Rarely, in cases of slow intestinal transit, blood loss from distal small bowel or the right colon may also present as melena. A guaiac test will allow differentiation of the tarry black stool of melena from the dark green stool of patients on iron supplementation (melena will test positive). Rectal bleeding is called hematochezia—this may represent blood on the tissue paper, blood around the stool, or blood mixed in with the stool, all important features to elicit on history taking. Hematochezia usually results from bleeding from the left side of the colon, usually sigmoid colon or rectum, but may manifest in massive upper GI bleeds with rapid transit through the intestine. Occasionally blood loss is occult, resulting in patients presenting with anemia. In these cases, history taking will identify end-organ symptoms suggestive of reduced oxygen delivery such as syncope, angina, or myocardial infarction.

Other Essential Features in the History

Other useful features to elicit in the history include antecedent vomiting (suggesting a Mallory-Weiss tear), recent weight loss or loss of appetite (suggesting malignancy), recent epigastric pain (possibility of peptic ulceration), and alcohol intake or liver disease (likelihood of variceal bleeding). Demographic data such as age will also assist in narrowing down the cause of bleeding—diverticulitis, angiodysplasias, malignancy, and ischemic colitis are likely culprits in the elderly. In contrast, younger patients are more likely to bleed from peptic ulceration, Meckel's diverticula, hemorrhoids, or esophageal varices. Previous abdominal surgery may be of relevance—previous aortic surgery in particular raises suspicion of aortoenteric fistula. Drug history is especially relevant in upper GI bleeding. Nonsteroidal anti-inflammatory drugs (NSAIDs) are a common cause of peptic ulceration, and similarly salicylates and selective serotonin reuptake inhibitors (SSRIs) are also associated with upper GI bleeding.[21,22] Use of anticoagulants may require administration of fresh frozen plasma to correct the clotting but is not in itself a predisposing factor for GI bleeding.[23]

PHYSICAL EXAMINATION

Although bleeding is likely to occur from the esophagus or more distal sites, bleeding from the nasopharynx and oropharynx may occasionally present as GI bleeding and so these sites should be routinely examined. Pigmented lesions in the oral mucosa suggest Peutz-Jeghers disease—a rare cause of GI bleeding. The abdomen should be examined to identify any masses or hepatosplenomegaly. A tender epigastrium is a nonspecific indication of possible peptic ulceration. The neck and groins should be examined for lymphadenopathy suggestive of malignancy. The examination should include inspection for stigmata of liver disease. The jaundiced patient with ascites, caput medusae, and palmar erythema may present with GI bleeding secondary to varices. Rectal examination and anoscopy are essential aspects of the examination to exclude rectal cancer or, more frequently, hemorrhoids.

IDENTIFYING THE SOURCE OF BLEEDING

Insertion of a nasogastric (NG) tube and aspiration may assist in identifying the source of the bleeding. An aspirate positive for blood (either fresh blood or coffee grounds) confirms upper GI bleeding, assesses the rate of bleeding, and allows removal of blood from the stomach to ensure good views of the gastric mucosa during esophagogastroduodenoscopy (EGD).

A negative aspiration of the stomach, however, does not rule out bleeding from the duodenum, as a competent pylorus will prevent reflux of bile, or blood from a bleeding duodenal ulcer, into the stomach. A blood-free bilious aspirate strongly suggests a lower GI source for the bleeding; however, a recent study showed that 20% of patients had a blood-free aspirate from the duodenum despite a diagnosis of upper GI bleeding.[24]

The Use of Endoscopy in the Management of Upper GI Bleeding

EGD remains the gold standard investigation for the diagnosis and management of upper GI bleeding, as it facilitates identification of the source of bleeding, determining the underlying etiology, achieving hemostasis, and providing prognostic information for risk stratification.[25] The timing of the endoscopic assessment in patients with GI bleeding remains controversial. Although there is little doubt that early endoscopy in hemodynamically unstable patients is necessary, the ideal timing for endoscopic intervention in stable patients remains less clear. A recent review of the studies examining the utility of early endoscopic intervention in upper GI bleeding concluded that while endoscopy within 24 hours of presentation was of benefit in terms of aiding risk assessment and reduced length of hospital stay, earlier endoscopies (within 12 hours) offered no additional benefit. Indeed, endoscopy within 12 hours of presentation was associated with unnecessarily increased use of therapeutic endoscopy without any benefit in terms of rate of rebleeding or survival. Overall, these studies suggested that endoscopy should be performed within 24 hours of presentation, and in hospitals without a 24-hour endoscopy service this should be offered to patients the following day.[26] Several issues need to be considered regarding the use of EGD in acute GI bleeding—first, the sensitivity of EGD may be reduced in the presence of active bleeding as mucosal visibility is impaired, and second, the rate of complications from EGD (perforation and aspiration) increases in the emergency setting. Airway protection and early intubation in the event of aspiration is therefore essential. Similarly, endoscopy in a patient with a low blood count can exacerbate the effects of sedative medications, causing hypotension and hypoxemia; hence resuscitative measures should not be delayed or paused for the endoscopic procedure. All patients undergoing urgent endoscopy should be continuously monitored using electrocardiogram (ECG) and noninvasive measurement of oxygen saturations.

The Use of Endoscopy in the Management of Lower GI Bleeding

FLEXIBLE SIGMOIDOSCOPY VERSUS COLONOSCOPY

Colonoscopy is recommended over flexible sigmoidoscopy in most cases of lower GI bleeding with few exceptions. Colonoscopy has been deemed the most appropriate investigation in patients older than 50 years with hematochezia

or iron deficiency anemia. In younger patients colonoscopy is unnecessary if a convincing benign source of bleeding has been demonstrated with flexible sigmoidoscopy but is necessary in the presence of repeated episodes of bleeding.[27]

EFFECTIVENESS IN IDENTIFYING THE SOURCE OF ACUTE LOWER GI BLEEDING

Colonoscopy has a diagnostic yield of 89–97% in the setting of acute GI bleeding.[28,29] Bowel preparation using polyethylene glycol with a prokinetic such as metoclopramide has been recommended to improve endoscopic visualization and thus diagnostic yield.[27,30] This step may have to be omitted in patients with severe ongoing GI bleeding, where there is insufficient time for a formal bowel preparation routine.

Capsule Enteroscopy and Deep Enteroscopy

Lesions of the small bowel causing bleeding are rare and account for only 5% of all GI bleeding. In the United States and Europe, angiodysplastic lesions account for 30–40% of such bleeding; the remaining sources are ulceration, Dieulafoy's lesions, and small bowel neoplasms in 1–3% of patients. Several factors make endoscopic access to the small bowel difficult, including the length of the small bowel, the intraperitoneal location, contractility, and overlying loops. Capsule enteroscopy has emerged as a suitable new option for small bowel imaging and is now the third diagnostic test in patients with obscure bleeding following EGD and colonoscopy.[31] The capsules measure 11 × 26 mm and contain a lens, white light-emitting diodes for illumination, silver oxide batteries, and an ultra high frequency (UHF) band radio telemetry transmitter. A capsule delivery device is available for patients with dysphagia, dysmotility disorders, and pediatric patients to deliver the capsule directly to the duodenum. Capsule enteroscopy has a much better yield than push enteroscopy or small bowel series, and an equivalent yield to intraoperative enteroscopy without the attendant morbidity and mortality of the operative procedure.[32,33] It must, however, be noted that capsule enteroscopy is unsuitable for imaging of the proximal duodenum because it provides poor visualization of the periampullary region, and the success of capsule enteroscopy is dependent on the experience of the reader.[34,35]

More recently, newer techniques for imaging of the small bowel ("deep enteroscopy") have been developed, specifically double-balloon enteroscopy, single-balloon enteroscopy, and spiral enteroscopy. The first two techniques use a balloon to grip the intestinal wall, allowing advancement of the endoscope forward through the intestine. Spiral enteroscopy uses a special overtube with helices at the distal end to pleat the small bowel onto the overtube, again allowing advancement of the endoscope through the intestine. Comparative trials are required to determine the advantages of each system in terms of insertion depth and procedure times. The advantage of these enteroscopic systems over capsule enteroscopy is their ability to perform biopsies of lesions, treat bleeding, and execute therapeutic measures such as stent insertion or stricture dilation.[36] The most significant disadvantage of deep enteroscopy over capsule enteroscopy is the relatively high rates of perforation (0.3–3.4%), particularly in patients with inflammatory bowel disease, malignancy, and bowel anastomosis.[35,37–40]

Angiography

Visceral angiography is a relatively insensitive investigation and able to detect bleeding only at a rate of 0.5–1 mL/min.[41,42] Although the specificity is 100%, the sensitivity varies from 47% with acute lower GI bleeding to 30% with recurrent bleeding.[43] Angiography has a role in patients with massive lower GI bleeding precluding colonoscopies or in patients with negative endoscopies.

Red Cell Labeling (Nuclear Scintigraphy)

Red cell labeling has been found to play a limited role in the diagnosis of GI bleeding and may be useful after other methods have failed. While sensitive (this method can detect GI bleeding at a rate of 0.1 mL/min), the site of bleeding is only localized to an area of the abdomen, and intestinal motility shifts intraluminal blood away from the site of bleeding, resulting in a relatively nonspecific investigation. Specificity is improved when scans are positive within 2 hours after injection of labeled erythrocytes as less motility will have occurred, resulting in correct localization in 95–100% of cases. This decreases to 57–67% when scans are positive more than 2 hours after injection.[44] Red cell scans are therefore more often used to identify a potential role for angiography—in red cell scans only positive after 2 hours, angiography is unlikely to be sufficiently sensitive to detect bleeding.

THERAPEUTIC OPTIONS

Pharmacologic Management

Pharmacologic management is unlikely to halt active bleeding but instead is aimed at preventing recurrence of bleeding by management of the underlying etiology, such as triple therapy for *Helicobacter pylori* infection or proton pump inhibitors (PPIs) to prevent recurrence of gastric ulceration and bleeding.

Endoscopic Treatment

Endoscopy remains the mainstay of investigation and often therapy for most causes of upper and lower GI bleeding. Techniques used for control of hemorrhage include thermal coagulation, injection therapy, and the use of mechanical

devices such as metallic clips and band ligation. Thermal coagulation probes include bipolar, monopolar, and heat probes, with an overall perforation rate of up to 2.5%, particularly frequent in the thin-walled right hemicolon.[45] Argon plasma coagulation (APC) is a means of noncontact coagulation with an almost nonexistent risk of perforation in the colon.[46] Laser-mediated coagulation (such as with the Nd:YAG laser) uses high-energy laser light to vaporize the tissue, producing deeper penetration than APC but with a higher perforation rate.

Injection of a 1:10,000 dilution of epinephrine is an effective and inexpensive method of endoscopic treatment, causing vasoconstriction and physical compression of the vessel. Metallic clips, both in reusable and disposable forms, are also suitable for arrest of hemorrhage endoscopically. Rubber band ligation is frequently employed in lower GI bleeding due to hemorrhoids or rectal varices.

Interventional Angiography

While initial attempts of embolization led to high rates of bowel infarction due to the use of large-bore catheters for cannulation, the more recent approach using microcatheters has circumvented this and produces success rates of 70–90% without significant complications and recurrent hemorrhage rates of only 15%.[47] Embolization material includes microcoils, Gelfoam (gelatin sponge), and polyvinyl alcohol particles. Selective angiographic embolization has been shown to arrest life-threatening bleeding from gastroduodenal ulcers, with a low rate of early rebleeding and no late rebleeding, obviating the need for emergency surgery in high-operative-risk patients.[48]

Early bleeding recurrence is associated with coagulation disorders, longer time to angiography, higher preprocedural blood transfusion volume, two or more comorbidities, and the use of coils as the only embolic agent.[49] Embolization has also been shown to be of value in patients with diverticular lower GI bleeding, with an 85% success rate, and particularly successful in the left colon compared to the right colon and caecum. Less success was noted in nondiverticular lower GI bleeding, such as from arteriovenous dysplastic lesions, with a greater than 40% rate of rebleeding.[50]

Angiography may also be coupled with selective infusion of a vasoconstrictor such as vasopressin or the longer-acting analogue terlipressin; however, this is associated with a 50% rate of rebleeding after cessation of the infusion.[51] The side effects of vasopressin and terlipressin, including abdominal pain and cardiac complications, have meant that this technique is now only rarely used.

Surgery

Surgery is rarely used as a means of controlling hemorrhage except when a clear bleeding point has been identified, but all other modalities of hemorrhage control have failed. However, surgery remains the treatment of choice in patients with neoplasia and may be used as a last resort in patients with recurrent bleeding without a defined bleeding point or in fulminant hemorrhage. Blind segmental colectomy is associated with unacceptably high rates of rebleeding (up to 75%) and mortality (up to 50%); hence intraoperative endoscopy should be used to aid in determination of the source of bleeding, resulting in a more conservative directed segmental colectomy (6% rebleeding and 4% mortality).[52,53]

UPPER GI HEMORRHAGE

Causes of Upper GI Hemorrhage

Causes of upper GI hemorrhage can be divided into variceal and nonvariceal bleeding (Table 11-2), of which the latter is more common. Nonvariceal bleeding is also more common than variceal bleeding in patients with portal hypertension; however, the higher morbidity and mortality of variceal bleeding means that this should be excluded before bleeding is attributed to any other source.

NONVARICEAL BLEEDING

Peptic Ulcer Disease and Bleeding. Numerous studies demonstrated a worldwide reduction in the incidence of peptic ulcers between 1958 and 1999, attributable to the introduction of *H. pylori* eradication therapy and PPIs. A reduction was also noted in the rate of operation and mortality from peptic ulcer disease; however, the overall incidence of peptic ulcer bleeding

TABLE 11-2: CAUSES OF UPPER GI BLEEDING

	Causes	Frequency (%)
Nonvariceal upper GI bleeding (80%)	Peptic ulcer disease	40
	Mallory-Weiss tears	15–20
	Gastritis/duodenitis	10–15
	Esophagitis	5–10
	Dieulafoy's lesions	1.5
	GAVE	4
	Malignancy	2
	Others:	7.5
	Aortoenteric fistula	
	Hemobilia	
	Hemosuccus pancreaticus	
	Iatrogenic bleeding	
Portal hypertensive upper GI bleeding (20%)	Gastroesophageal varices	>90
	Gastric varices	Rare
	Portal hypertensive gastropathy	Rare

GAVE, gastric antral vascular ectasia; GI, gastrointestinal.

did not show a significant decrease over the same period.[12] Peptic ulcer bleeding still carries a mortality rate of 5–10%,[11,54] and in-hospital care costs more than $2 billion annually in the United States.[55]

Nonvariceal bleeding accounts for 80–90% of acute upper GI bleeding, the majority of which is due to gastroduodenal peptic ulceration,[11] which accounts for 40% of all nonvariceal upper GI bleeding.[24] A large proportion of this is associated with use of aspirin and NSAIDs, and the majority of cases occur in the elderly (68% of patients are >60 years of age and 27% >80 years of age).[56] At some point during the course of the disease, 10–15% of ulcers will bleed. Patients with bleeding ulcers commonly present with hematemesis and/or melena, and require early and aggressive fluid resuscitation to replace any existing losses. History, examination, and investigations should proceed as outlined previously (Fig. 11-2). Both duodenal and gastric ulcers can bleed profusely; however, this predilection is higher in gastric compared to the more common duodenal ulcers. Bleeding is most significant when involving an artery such as branches of the gastroduodenal or left gastric arteries.

Several risk stratification scores have been developed to assist in identification of patients who require close monitoring and are at risk of rebleeding. The two most commonly used tools are the Rockall score and the lesser used Blatchford score (Table 11-3). The Rockall score utilizes clinical as well as endoscopic findings to risk-stratify patients. The score ranges from 0 to 11; a higher score is associated with greater risk of rebleeding or death.[57] The Blatchford score uses hemoglobin, blood urea nitrogen, systolic blood pressure, pulse, melena, syncope, hepatic disease, or cardiac failure to produce a maximum score of 23; again higher scores indicate higher likelihood of rebleeding or death.[58]

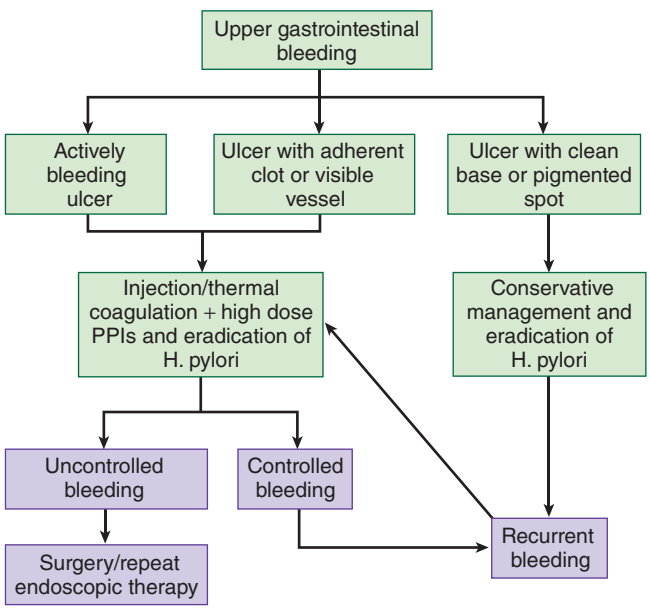

FIGURE 11-2 An algorithm for the management of peptic ulcer bleeding.

TABLE 11-3: COMPARISON OF THE BLATCHFORD AND ROCKALL SCORES

Criteria of the Blatchford Score	Criteria of the Rockall Score
Systolic blood pressure	Age
Blood urea nitrogen	Shock
Hemoglobin	Coexisting illness
Pulse	Endoscopic diagnosis
Melena	Endoscopic stigmata of recent hemorrhage
Syncope	
Hepatic disease	
Cardiac failure	

The endoscopic appearance of a bleeding ulcer alone can also be used to stratify the risk of rebleeding using the Forrest criteria (Table 11-4).[59] High-grade lesions are those that are actively spurting or oozing blood, or have a nonbleeding visible vessel or adherent clot.

Medical Management

Stop Any Causes (eg, Drugs). All ulcerogenic medication such as salicylates, NSAIDs, and SSRIs should be stopped and nonulcerogenic alternatives prescribed. Cyclooxygenase-2 (COX-2) inhibitors, which initially showed promise as a gastroprotective alternative to NSAIDs have recently been shown to demonstrate cardiotoxicity without significant benefit on gastric mucosal protection and are therefore infrequently used.[60]

Eradication of *H. pylori* and Long-Term Acid Suppression. The association of bleeding with *H. pylori* infection is not as strong as the association reported for perforated ulcers, with *H. pylori* infection reported in only 60–70% of bleeding ulcers. However, recent data show that treating patients positive for *H. pylori* with eradication therapy reduces the risk of rebleeding and obviates the need for long-term acid suppression[61]; hence *H. pylori* eradication is recommended in all bleeders infected with *H. pylori*.

TABLE 11-4: FORREST CLASSIFICATION FOR ENDOSCOPIC FINDINGS AND RISK OF REBLEEDING IN PEPTIC ULCER DISEASE

Classification (Grade)	Endoscopic Finding	Risk of Rebleeding
Ia	Active, pulsatile bleeding	High
Ib	Active, nonpulsatile bleeding	High
IIa	Nonbleeding visible vessel	High
IIb	Adherent clot	Intermediate
IIc	Ulcer with flat, pigmented spot	Low
III	Clean, nonbleeding ulcer bed	Low

Gastric acid has been shown to impair clot formation, promote platelet disaggregation, and increase fibrinolysis. In keeping with this, PPIs have been shown to significantly reduce the risk of ulcer rebleeding, the need for urgent surgery, and, in patients with high-risk stigmata who have undergone endoscopic therapy, mortality.[62,63]

Endoscopic Management. Patients with high-risk stigmata on endoscopy (active bleeding or nonbleeding visible vessel) require haemostatic intervention, such as injection, and thermal or mechanical therapy such as clips (Fig. 11-3). Addition of any one of these to adrenaline injection further reduces rebleeding rates, the need for surgery, and mortality.[64–66]

Several factors are predictors of failure of endoscopic therapy for peptic ulcer bleeding, including previous ulcer bleeding, shock and presentation, active bleeding during endoscopy, ulcers greater than 2 cm in diameter, a large underlying bleeding vessel greater *than* 2 mm in diameter, and ulcers on the lesser curve of the stomach or the posterior or superior duodenal bulb.[67] Recent studies suggest that second-look endoscopy (within 24 hours of the initial endoscopic therapy) provides only a small reduction in the rate of rebleeding, is not cost-effective in the presence of acid-suppressing medication, and is overall not recommended.[25,68,69] Repeat endoscopy should only be considered in cases of recurrent hemorrhage or unsuccessful first treatment.

Surgical Management. Meta-analysis and surgical registry data show the rate of surgical intervention for bleeding peptic ulcers has decreased to 6.5–7.5%. An improved understanding of peptic ulcer disease as well as the development of newer pharmacologic and endoscopic treatments has meant that surgery is now employed not as first-line or curative treatment, but instead only when other modalities have failed.

There are no consensus guidelines on the appropriate indications for surgery; however in general, persistent blood loss with failure of endoscopic therapy and a blood transfusion requirement in excess of 6 units are often considered an indication for surgical intervention (Table 11-5). Similarly, hypovolemic shock associated with recurrent hemorrhage or a slow continuous blood loss requiring transfusion of more than 3 units per day is also considered indicative. Shock on admission, an elderly patient, severe comorbidity, a rare blood type, refusal of transfusion, and bleeding chronic gastric ulcer with a suspicion of malignancy are considered relative indications for surgery.

TABLE 11-5: POSSIBLE INDICATIONS FOR SURGICAL INTERVENTION FOR PEPTIC ULCER BLEEDING

Possible Indications for Surgery in Peptic Ulcer Bleeding	
Absolute indications	Persistent blood loss refractory to endoscopic therapy
	Shock with recurrent hemorrhage
	Slow blood loss requiring >3 units blood
Relative indications	Shock on admission
	Transfusion in excess of 6 units
	Elderly patient
	Severe comorbidity
	Rare blood type/refusal of transfusion
	Suspicion of malignancy in a gastric ulcer

In stable patients with evidence of rebleeding, a second attempt at endoscopic hemostasis is often as effective as surgery with fewer complications and is the recommended management.[70] The aim of surgery in both gastric and duodenal ulcers is to arrest hemorrhage and perform an acid-reducing procedure if deemed necessary.

FIGURE 11-3 Metallic clips to arrest bleeding from a duodenal ulcer. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

Operative Procedure for Duodenal Ulcers. A longitudinal duodenotomy or duodenopyloromyotomy provides good exposure of bleeding sites in the duodenal bulb, the most common site of duodenal ulcers. Direct pressure provides temporary arrest of the bleeding, and it should be followed by suture ligation with a nonabsorbable suture such as Prolene. Four-quadrant suture ligation will achieve hemostasis in anterior ulcers. Posterior ulcers, particularly if involving the pancreaticoduodenal or gastroduodenal artery, will require suture ligation of the artery both proximal and distal to the ulcer for adequate control of hemorrhage, as well as placement of a U-stitch underneath the ulcer to control the pancreatic branches (Fig. 11-4).

The use of an acid-reducing procedure in duodenal ulcers remains a topic of debate, as theoretically arrest of hemorrhage and *H. pylori* eradication is likely to be sufficient management. In the absence of trials and convincing data, however, it is hard to make any firm recommendations, and the decision is best left to the surgeon taking into account each patient's condition and their experience with such operations. Surgical

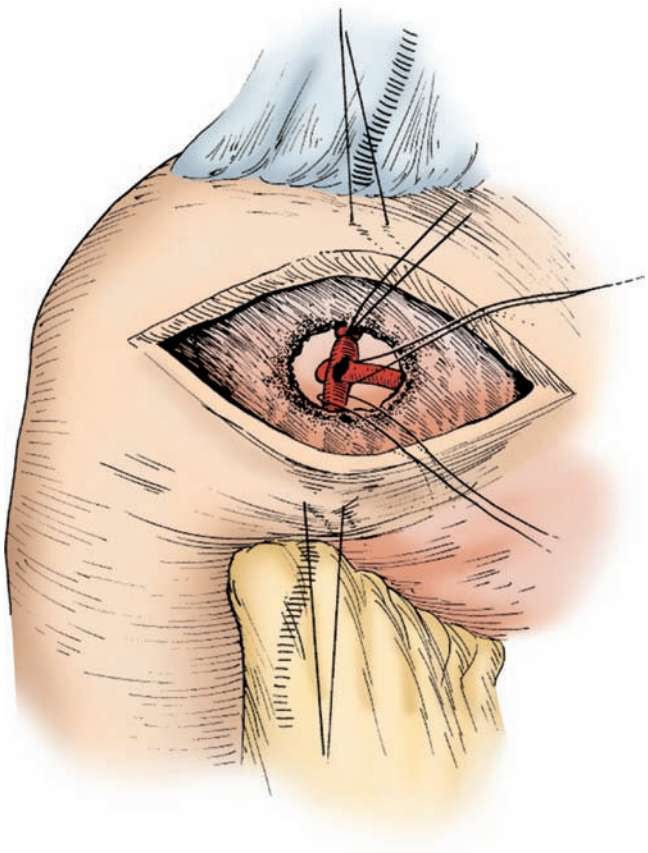

FIGURE 11-4 Suture control of bleeding duodenal ulcers. A longitudinal pyloric incision is made and figure-of-eight sutures are placed at the cephalad and caudad aspects of the ulcer to occlude the gastroduodenal artery.

options for acid reduction in bleeding duodenal ulcer management include pyloroplasty with truncal vagotomy, parietal cell vagotomy, or antrectomy with truncal vagotomy. The former is the most frequently used as it is facilitated by the longitudinal approach to the pylorus for arrest of hemorrhage. Parietal cell vagotomy is limited by surgeon inexperience. Antrectomy with truncal vagotomy may be suitable in patients refractory to conservative surgery but is a complex procedure that is unsuitable in the shocked patient. Ulcer surgery is covered in greater detail in Chap. 26.

Operative Procedure for Gastric Ulcers. Management of the bleeding gastric ulcer also prioritizes arrest of the bleeding. However, because of the risk of rebleeding and the 10% risk of malignancy in gastric ulcers, gastrotomy and suture ligation are insufficient in these patients. Resection of the ulcer alone is associated with a 20% rebleeding rate; hence a distal gastrectomy is recommended for ulcers in the antrum and distal stomach. In patients who may be unfit for a distal gastrectomy, resection of the ulcer itself combined with an acid-reducing procedure in the form of a vagotomy and pyloroplasty may be an option. Management of bleeding ulcers at the cardioesophageal junction and the proximal stomach is more challenging. While optimal resection would involve a proximal or near-total gastrectomy, this results in increased morbidity and mortality in patients acutely bleeding. More conservative options may suffice, such as distal gastrectomy with resection of a tongue of proximal stomach to ensure excision of the ulcer, or a wedge resection of the ulcer or simple oversewing with a vagotomy and pyloroplasty.

Mallory-Weiss Tears. The sensation of nausea is accompanied by closure of the pylorus, gastric distension, and retrograde propulsion of gastric contents toward the cardia. When this is followed by vomiting, the diaphragm moves abruptly upward, associated with rapid increase in intra-abdominal pressure that pushes the gastric cardia into the thorax through the diaphragmatic hiatus. With sufficient force, a longitudinal laceration of the esophagus or stomach can result.[71] Hiatus hernias coexist in more than 75% of patients with Mallory-Weiss tears, and the amount of herniated stomach determines the point of maximal dilation (law of Laplace) and therefore the position of the tear.[72,73] Large hiatus hernias are associated with more distal tears, while in patients with small or absent hiatus hernias, tears occur at or below the gastroesophageal junction. The majority of tears are situated within 2 cm of the gastroesophageal junction on the lesser curvature.

The highest incidence of Mallory-Weiss tears occurs in patients between 30 and 50 years of age and in men more than women. Some 40–75% of patients have a history of alcohol use[74] and 30% a history of aspirin use.[75] Patients typically present with a history of several episodes of vomiting or retching followed by hematemesis with fresh red blood. Ten percent of patients may present with only melena.

EGD usually identifies a single tear on the lesser curve of the cardia, or occasionally on the greater curvature of the cardia. Retroflexion during the endoscopic examination is an important maneuver in these patients to ensure the distal gastroesophageal junction and cardia are visualized. The majority of lesions heal spontaneously; hence management is largely supportive, with emphasis on antiemesis and acid suppression. Patients with persistent bleeding may require endoscopic injection or thermocoagulation, or angiographic embolization. Surgery may be required should these options prove unsuccessful, and hemorrhage can be arrested operatively by a high gastrotomy and suture of the mucosal laceration.

Stress-Related Mucosal Bleeding. Critically ill patients are at risk for the development of diffuse mucosal injury of the stomach, resulting in upper GI bleeding with significant morbidity and mortality. This phenomenon, termed "stress-related mucosal bleeding" or occasionally "stress gastritis," is a result of a combination of mucosal ischemia and reperfusion injury and impairment of host cytoprotective defenses, and ultimately results in a prolonged ICU stay in a vulnerable population of patients.[65] While this phenomenon was previously common, the incidence of clinically significant

bleeding in the critically ill population has now decreased to less than 3.5% with the use of prophylaxis.[76]

The most important risk factors for stress-related mucosal bleeding are prolonged mechanical ventilation (>48 hours) and coagulopathy. Other factors include shock, severe sepsis, neurologic injury/neurosurgery, greater than 30% burns, and multiorgan failure. Patients with these risk factors require prophylaxis with antacids, H_2-receptor blockers, PPIs, or Carafate.

Acid suppression is often sufficient to control hemorrhage in stress-related mucosal bleeding. For persistent bleeding, options include selective infusion of octreotide or vasopressin via the left gastric artery, endoscopic measures, or angiographic embolization. Surgery is now rarely performed but, if necessary, involves vagotomy and pyloroplasty with oversewing of discrete regions of hemorrhage or subtotal gastrectomy.

Esophagitis. In rare cases bleeding may originate in the esophagus and is then often due to esophagitis. Gastroesophageal reflux disease (GERD) repeatedly exposes the mucosa to irritant acidic gastric content, causing chronic inflammation and blood loss (Fig. 11-5). Occasionally ulceration may follow, presenting as occult bleeding with anemia or guaiac-positive stool. While GERD is the most common cause, other causes include Crohn's disease, certain drugs, and radiotherapy. Immunocompromised patients may have esophagitis of an infective etiology; causes most commonly include herpes simplex, *Candida*, and cytomegalovirus (CMV), but esophagitis can occasionally be due to ulceration directly induced by human immunodeficiency virus (HIV) or Epstein-Barr virus, or secondary involvement of the esophagus in mycobacterial infection of adjacent lymph nodes.[77] Infective esophagitis is uncommon but may lead to torrential hemorrhage.

Management, particularly of GERD-induced esophagitis, hinges on acid-suppressive therapy, occasionally requiring therapeutic endoscopy to arrest the bleeding. Treatment of the infective cause is often successful at managing the bleeding in immunocompromised infected patients.

Dieulafoy's Lesion. Dieulafoy's lesions are an arterial vascular anomaly featuring abnormally large ("caliber persistent") submucosal end arteries, likely congenital in origin, and with the potential for massive, potentially life-threatening hemorrhage upon erosion of the overlying gastric mucosa. These lesions are most commonly located in the stomach within 5–7 cm of the cardia but may present in small bowel, duodenum, and colon. These account for 1.5% of upper GI bleeding and are more commonly encountered in men.[78]

Dieulafoy's lesions appear as reddish-brown protrusions on endoscopy with no ulceration. Endoscopic therapy is often successful provided good visualization of the lesion is obtained; mechanical methods such as clipping or banding have been shown to work better than injections for control of hemorrhage.[79,80] Angiographic embolization or surgery may be employed for endoscopic failures. Surgical intervention may require prior endoscopic tattooing to facilitate identification of the site, followed by wedge resection of the lesion.[78]

Gastric Antral Vascular Ectasia (GAVE). GAVE, or "watermelon stomach," is so named for the dilated, tortuous mucosal capillaries and veins present in the antrum, converging onto the pylorus, and resembling the surface of a watermelon (Fig. 11-6). This condition is more common in women than in men and often presents with occult blood loss and iron

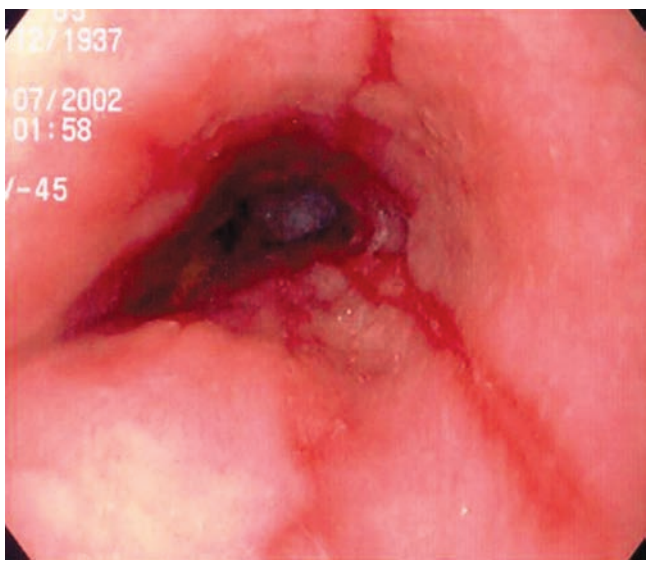

FIGURE 11-5 Gastroesophageal reflux disease (GERD) viewed on endoscopy.

deficiency anemia. APC is the treatment of choice for GAVE; treatment may need to be repeated for recurrences, and PPI cover is recommended for 1 month following treatment.[78,81] Patients refractory to APC should be considered for surgical intervention in the form of an antrectomy.

Malignancy. Malignant upper GI lesions rarely present with overt significant hemorrhage and instead are more likely to present with hemoccult-positive stool or iron deficiency anemia. Endoscopy occasionally reveals a recurrent bleeding ulcer, a common feature of GI stromal tumors, which characteristically appear as a submucosal tumor with central umbilication and ulceration (discussed further in Chap. 24), and on occasion leiomyomas and lymphomas (Fig. 11-7). Surgery is necessary as the rate of rebleeding in these malignant lesions is high, and may involve full curative resections or in unfit patients, palliative wedge resections for hemorrhage control.

Aortoenteric Fistula. Aortoenteric fistula is an important clinical condition, often presenting with torrential GI hemorrhage. Primary fistulae are rare; most commonly fistulation occurs following a previous abdominal aortic aneurysm (AAA) repair and is seen in approximately 1% of these cases. The pathophysiology behind this is likely to be infective in origin, leading to the development of a pseudoaneurysm at the proximal suture line, resulting in fistulization into the duodenum (Fig. 11-8).

Early diagnosis of this problem is critical but can be difficult. A high index of suspicion is required in all patients presenting with GI hemorrhage with known aortic aneurysms or a history of previous aortic aneurysm repair. Often, patients present with several smaller, self-limiting episodes of GI hemorrhage ("sentinel bleeds"). Urgent endoscopy at this stage is essential to preempt a subsequent torrential, often fatal bleed, and usually reveals bleeding at the third or fourth part of the duodenum (Fig. 11-9). CT with IV contrast is a useful adjunct in these patients, often demonstrating air within the aortic thrombus or around the graft (particularly in the context of an infected graft), and rarely a pseudoaneurysm or contrast within the duodenal lumen.

Surgical repair involves extra-anatomic bypass grafting and aortic ligation for primary aortoenteric fistula. For secondary aortoenteric fistula, surgery involves excision of the graft with extra-anatomic bypass or in situ aortic reconstruction. By necessity these procedures are often performed in critically ill,

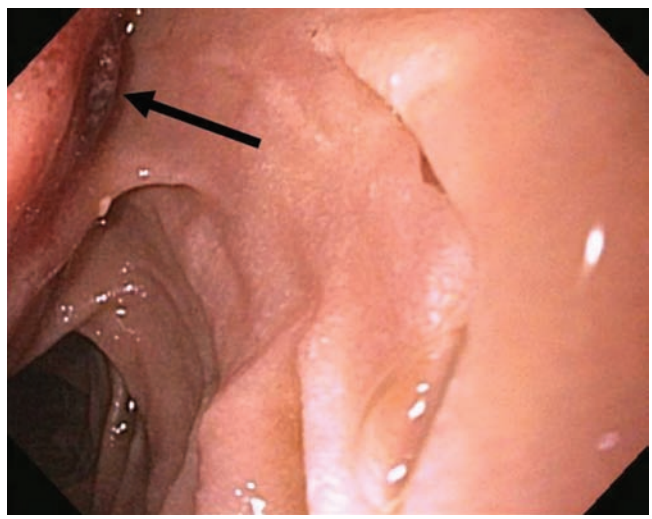

FIGURE 11-9 Endoscopic view of the aortoenteric fistula on EGD showing the fistulous track (*black arrow*) into the aneurysmal sac from the third part of the duodenum. (Used with permission from Neal Barshes, MD, MPH, Brigham and Women's Hospital, Boston, MA.)

severely exsanguinated, and septic patients and hence associated with high morbidity and mortality.

With the advent of endovascular stenting for primary AAA repair, various studies have been performed to determine the effectiveness of endovascular stenting for aortoenteric fistula. This has been associated with a high incidence of recurrent bleeding and infection, particularly in the presence of preprocedural infection.[82]

Hemobilia. Hemobilia is a rare cause of GI bleeding. Causes include trauma, hepatic neoplasms, instrumentation of the biliary tree, percutaneous radiofrequency liver ablation, and following liver transplant. A high index of suspicion is required in patients with these risk factors, as the classic presentation of hemorrhage, right upper quadrant pain, and jaundice is only seen in a minority of patients. Endoscopy may reveal blood at the ampulla, but angiography and embolization remain the diagnostic and therapeutic modality of choice.

Hemosuccus Pancreaticus. Bleeding from the pancreatic duct (hemosuccus pancreaticus) is another rare cause of upper GI bleeding, due to fistulation of a pancreatic pseudocyst into the splenic or other peripancreatic artery.[83] A presentation of abdominal pain, hematemesis, and melena in patients with a previous history of pancreatitis should raise suspicion of hemosuccus pancreaticus. Angiography is again both diagnostic and therapeutic, although in some cases distal pancreatectomy may be employed.

Iatrogenic Bleeding. Upper GI endoscopy or surgery is another cause of bleeding. Percutaneous gastrostomy is often necessary as a means of nutritional support in certain conditions but is accompanied by a 3% rate of GI hemorrhage. Bleeding may have tracked into the stomach from the incision site but may also be from the stomach mucosa; both causes can be managed endoscopically.

Endoscopic sphincterotomy is increasingly common as a means of accessing the biliary tree during an endoscopic retrograde cholangiopancreatography and facilitates endoscopic clearance of the common bile duct, but it is associated with a 2% risk of bleeding. Bleeding may occur after 48 hours but can often be arrested by local injection of epinephrine, rarely requiring surgical intervention. Bleeding following upper GI surgery may occur from suture or staple lines. This can occasionally be treated endoscopically, with minimal insufflation to avoid disruption of the anastomosis.

VARICEAL BLEEDING AND PORTAL HYPERTENSION

Portal hypertension is a serious cause of upper GI bleeding, often the result of cirrhosis that is the end stage of chronic liver disease. The pathophysiology of portal hypertension is discussed further in Chap. 47 and hence is not covered here. Approximately 50% of patients with cirrhosis will develop gastroesophageal varices as a result of portal hypertension.[84] Variceal bleeding occurs in 30% of patients and is one of the most important complications of hepatic cirrhosis. Variceal bleeding is associated with increased risk of rebleeding and transfusion requirement, greater length of hospital stay, and higher morbidity and mortality compared with nonvariceal bleeding.[17,84]

Gastroesophageal varices represent one site of portosystemic anastomosis, which is dilated as the portal circulation tries to decompress to the systemic circulation. Other sites of portosystemic collaterals are the stomach, the umbilical region (collateral formation leads to formation of caput medusae), and the distal rectum.

Factors that determine variceal bleeding include high variceal wall tension (determined by vessel diameter) and variceal pressure, in turn related to hepatic venous pressure gradient (HPVG). Patients with a HPVG of less than 12 mm Hg are unlikely to develop variceal bleeding.[85]

Isolated gastric varices (IGV) can occur in the absence of esophageal varices and are located along the gastric fundus (IGV1), or along the body, antrum, or pylorus (IGV2).[84] Risk factors for gastric variceal bleeding include variceal size and the presence of a cherry-red spot (localized reddish mucosal area or spots on the mucosal surface of a varix).[86]

In addition to varices, portal hypertension can also cause the development of portal hypertensive gastropathy, diffuse dilation of the mucosal, and submucosal venous plexus of the stomach with overlying gastritis. The stomach develops a snake-skin appearance with cherry-red spots on endoscopy, and rarely may be the site of major hemorrhage (Fig. 11-10).

The management of variceal upper GI bleeding follows the same principles as those of nonvariceal upper GI bleeding, with

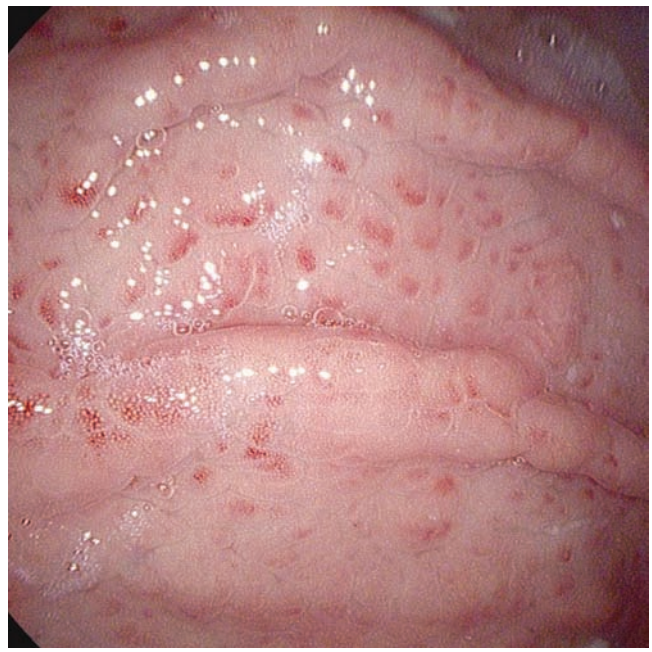

FIGURE 11-10 Endoscopic view of portal hypertensive gastropathy. Note the snake-skin appearance of the stomach and the associated cherry-red spots. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

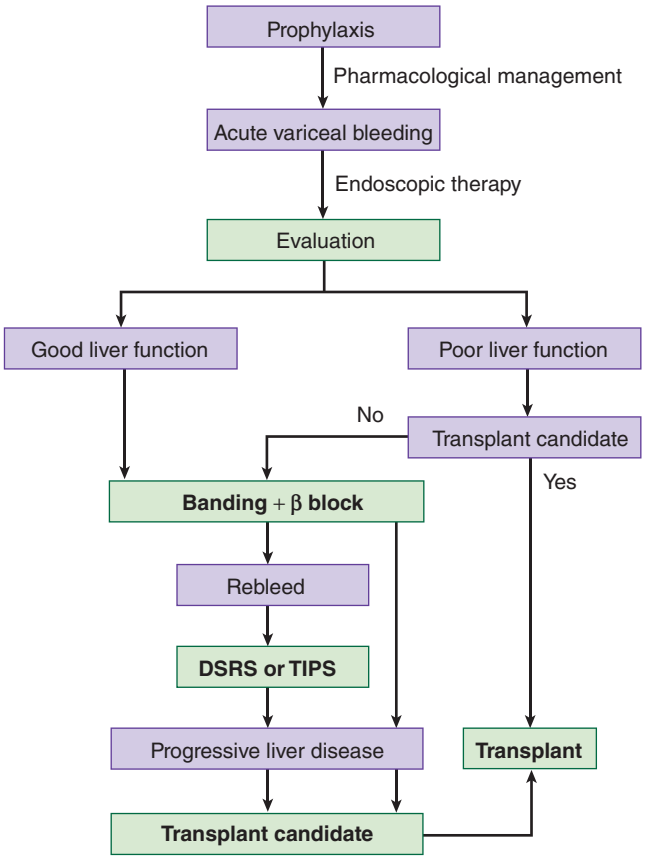

FIGURE 11-11 An algorithm for the management of variceal bleeding. DSRS, distal splenorenal shunt; TIPS, transjugular intrahepatic portosystemic shunt.

emphasis on urgent resuscitation and therapeutic endoscopy because of the higher morbidity and mortality associated with variceal bleeds (Fig. 11-11).

EGD remains the gold standard for diagnosing variceal bleeding. The diagnosis of variceal hemorrhage is based on meeting one of the following criteria: active bleeding from a varix, a "white nipple" overlying a varix, clots overlying a varix, or varices with no other potential source of bleeding.[87]

Management. Treatment of variceal bleeding requires a combination of medical and endoscopic management.

Medical. Somatostatin or its analogues octreotide or terlipressin should be administered as a bolus immediately in cases where there is a high index of suspicion, and continued for 3–5 days after endoscopic confirmation of diagnosis.[84] Fluids and blood products should be administered judiciously to maintain a hemoglobin level of greater than 8 g/dL. Current recommendations are that any patients with cirrhosis and GI bleeding should be given up to 7 days of antibiotic prophylaxis, specifically a fluoroquinolone such as norfloxacin or ciprofloxacin.

Endoscopic. Variceal bleeding should be diagnosed and treated by EGD, either with variceal ligation or sclerotherapy.[84] In patients with variceal bleeding, endoscopy should be performed as soon as possible (within 12 hours of admission).[88,89] This is of particular importance in patients with hemodynamic instability or features of cirrhosis. Early endoscopy also excludes nonvariceal causes of bleeding, which occur in 15% of patients with varices.[90] Variceal ligation is the endoscopic treatment of choice as it has been shown to have lower rates of complications compared to sclerotherapy, which can cause perforation, mediastinitis, and stricture formation. Variceal ligation involves the placement of rubber bands on the varices to completely interrupt blood flow into the ligated varix and arrest hemorrhage acutely. The mucosa and submucosa develop ischemic necrosis and granulation and sloughing of the rubber rings, and necrotic tissue results in replacement of varices by scar tissue. Sequential treatments may be required, as many as three treatments over 24 hours, but will achieve control of hemorrhage in up to 90% of patients.

Mechanical tamponade devices may be useful in temporarily controlling bleeding from esophageal varices where endoscopy and medical management have failed. One example is the Sengstaken-Blakemore tube, which consists of a gastric tube with gastric and esophageal balloons. Inflation of the gastric and esophageal balloons compresses the esophagogastric venous plexus, arresting bleeding, but at the risk of ischemic necrosis and perforation. Deflation of the tube can be associated with recurrent bleeding in 50% of patients; hence this technique is reserved as a temporizing measure in massive hemorrhage before more definitive intervention is commenced.

Gastric varices should be managed initially by pharmacotherapy. Endoscopic therapy is not as successful in gastric varices because of the diffuse nature of portal hypertensive gastropathy. Patients with refractory bleeding should be referred early for decompressive therapy such as TIPS (transjugular intrahepatic portosystemic shunt) or shunting.

IGVs, without associated portal hypertension, can occur in the setting of splenic vein thrombosis, often associated with pancreatitis. Varices occur in the presence of normal central portal pressures due to left-sided hypertension, rerouted from the spleen to the short gastric vessels. Splenectomy may relieve the hypertension, but the risk of variceal bleeding in these patients is low and hence splenectomy should not be routinely undertaken.[91]

Prevention of Rebleeding. Prevention of rebleeding is of the utmost importance in this patient population. Rebleeding may occur in up to 70% of patients within 2 months without further definitive therapy.[92] The highest risk of rebleeding is in the first few days following the initial episode. A combination of nonselective beta-blockers with isosorbide mononitrate has been shown to be more effective than beta-blockers alone in preventing rebleeding.[93] The addition of prophylactic endoscopic band ligation to combination pharmacotherapy did not reduce the risk of rebleeding but instead was associated with more adverse events in a recent randomized controlled trial.[94]

Radiologic or Surgical Portal Decompression. In approximately 10% of cases of variceal bleeding, endoscopic management is unsuccessful, necessitating urgent decompression of the portal system. A TIPS procedure involves the creation of an artificial anastomosis between the hepatic and portal veins under fluoroscopic guidance with the use of a covered stent, shunting blood away from the hepatic sinusoids and relieving portal pressure.[95] TIPS is, however, associated with a 30-day mortality of up to 30% in the emergency setting, usually a result of hepatic encephalopathy from diversion of blood away from the liver parenchyma.[96] Rebleeding may occur in 20% of patients and is often due to occlusion of the anastomosis. Surgery is another therapeutic option for decompression of the portal system. Surgical shunts, such as the selective distal splenorenal shunt (DSRS), have lower rates of rebleeding compared to endoscopic therapy but do not demonstrate any difference in survival.[97] DSRS patients have an in-hospital mortality of approximately 5%, a 5–8% rate of rebleeding, and a 75–80% 3-year survival.[97] A recent randomized controlled trial comparing TIPS with DSRS in patients with failed medical or endoscopic therapy showed no significant difference in the rate of rebleeding, hepatic encephalopathy, or overall survival, but identified a need for close follow-up and a greater need for reintervention in patients subjected to TIPS, suggesting that in patients with relatively limited access to health care facilities, DSRS may be a more suitable therapeutic option.[98] Further details on surgical decompression for portal hypertension are covered in Chap. 47.

LOWER GI HEMORRHAGE

Lower GI bleeding can occur from any site distal to the ligament of Treitz, most commonly from the colon. Occasionally bleeding can also occur from the small bowel. Difficulty in diagnosis of lower GI bleeding stems from the large surface area of colon and small intestine, intermittent bleeding, occasional lack of visible mucosal lesions, and difficulties in endoscopic visualization as lesions are obscured by forward movement of blood. The majority of patients with lower GI bleeding experience self-limiting episodes; only 10–20% of patients present with massive unremitting lower GI bleeding. Patients with self-limited bleeding can usually be managed with initial resuscitation, exclusion of an upper GI source, and further investigation using colonoscopy and, if necessary, angiography or nuclear scintigraphy. Younger patients with suspected hemorrhoidal bleeding should be followed up and the hemorrhoids managed appropriately, while older patients should be investigated for malignancy before bleeding is attributed to a benign pathology. Bleeding from the anus or rectum can be identified by digital rectal examination (DRE) and proctoscopy and may on occasion require sigmoidoscopy. Upper GI bleeding can be effectively excluded in the presence of a blood-free bilious NG aspirate; however, an EGD is required for definitive exclusion.

Management of Lower GI Hemorrhage

Lower GI bleeding is often less severe than upper GI bleeding; however, the same principles for resuscitation should be followed (Fig. 11-12), guided by the hemodynamic stability of the patient. Accurate identification of the source of bleeding can be difficult in patients with lower GI bleeding—more than one source for bleeding is found in 40% of patients and in up to 25% of patients no source is identified. A management algorithm is outlined in Fig. 11-13. Patients with hematochezia who are hemodynamically stable should undergo colonoscopy in the first instance to identify a cause for the bleeding. If a bleeding site is identified, endoscopic therapy should be attempted to control the bleeding. If no bleeding site is identified, an EGD should be performed, followed by capsule or deep enteroscopy if this is unsuccessful. Hemodynamically unstable patients should undergo EGD in the first instance as severe upper GI bleeding may often present as hematochezia.

Patients with bleeding refractory to endoscopic management or those with significant hemodynamic instability may require urgent operative intervention. In these patients an exploratory laparotomy is required, and attempts made to determine the location of blood within the GI tract. Although this is relatively nonspecific, it may assist in broadly localizing the origin of bleeding; for instance if blood is only present beyond the ileocecal valve, bleeding is likely to be colonic in origin. The GI tract should be thoroughly examined to exclude bleeding from small bowel tumors or Meckel's diverticulum. A segmental bowel resection is appropriate in localized bleeding, and in relatively fit patients this may be combined with a primary anastomosis. In unfit patients with preexisting hemodynamic instability or severe malnutrition, a mucous fistula and end stoma is a more appropriate option. Segmental colectomies should not be performed as "blind" procedures without localization of the bleeding source, as these have been associated with unacceptably high mortality rates and rebleeding rates between 20 and 50%.[99] A better alternative in patients without localization of the bleeding source is a "blind" subtotal colectomy, with a primary ileorectal anastomosis, associated with a less than 10% mortality rate and less than 10% rebleeding rate with the benefit of normal postoperative bowel control. This procedure further allows irrigation of the rectal segment with repeat proctoscopy to rule out rectal bleeding.

On-table lavage may allow identification of a bleeding source, facilitating segmental colectomy, but is best attempted in stable patients who may not retain acceptable bowel function after a total or subtotal colectomy and not advised in the unstable patient.

Causes of Lower GI Hemorrhage

OVERT LOWER GI BLEEDING

The majority of lower GI bleeding originates from the colon as a result of common pathologies such as diverticular disease

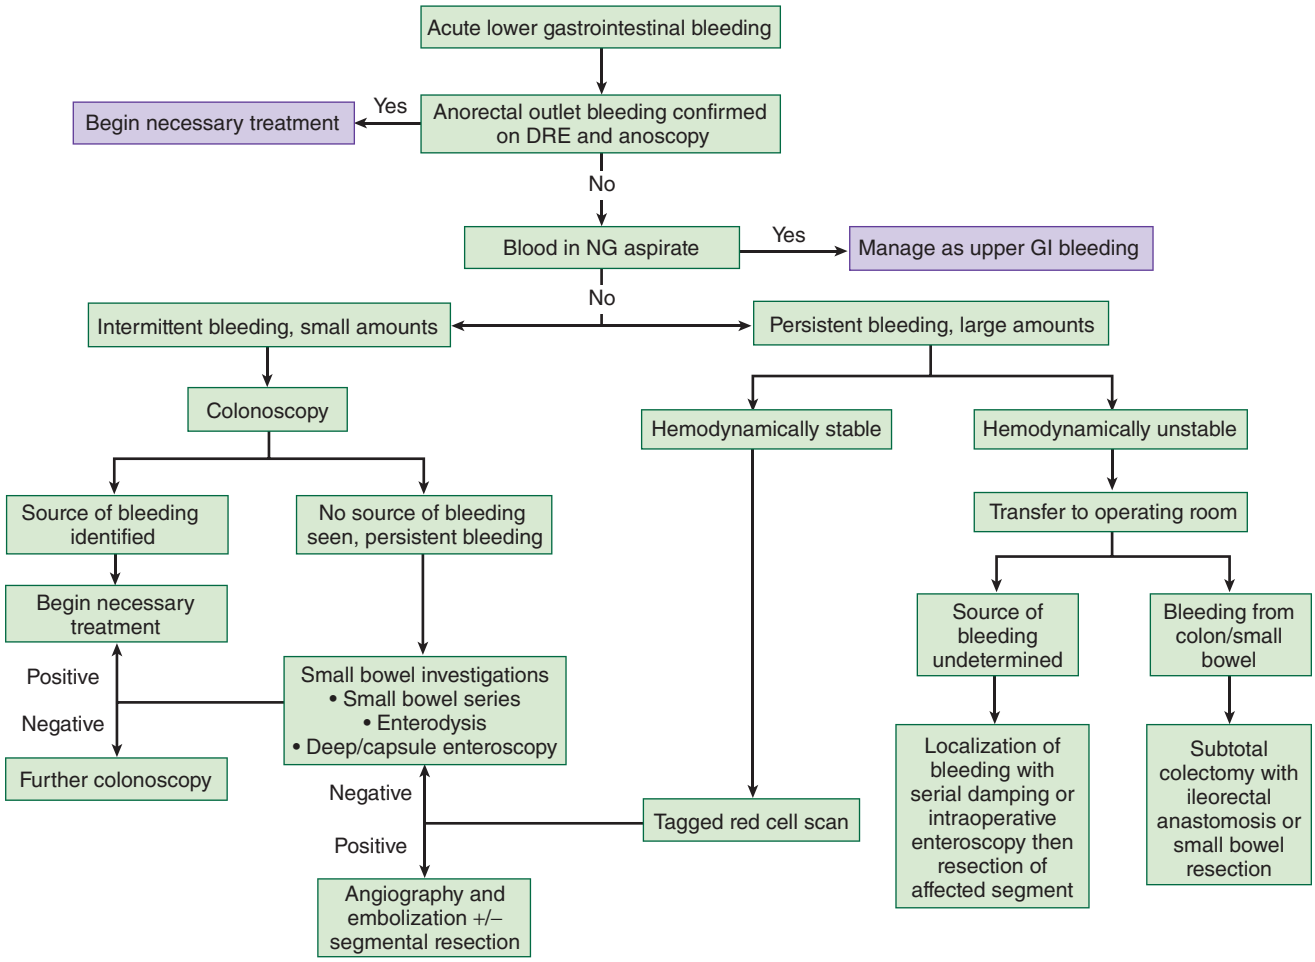

FIGURE 11-12 An algorithm for the management of lower gastrointestinal bleeding. DRE, digital rectal examination; GI, gastrointestinal; NG, nasogastric. (Adapted from Fig. 46-12, *Sabiston Textbook of Surgery*, 18th ed. Townsend, Beauchamp, Evers, and Mattox, Elsevier.)

and neoplasia (Table 11-6). Early identification of the cause of bleeding is essential to initiate appropriate management, in particular for cases of malignancy.

Diverticular Disease. Diverticular disease is an extremely prevalent and often asymptomatic disease of Western countries. The incidence increases with age; up to 60% of patients older than 80 years have diverticulae.[100] In Western countries, 95% of diverticula are in the sigmoid and left colon; however, in Asian countries 70% of cases are in the right colon.[101,102] Colonic diverticular are usually pulsion-type pseudodiverticula—outpouchings of the mucosa and submucosa through the muscular layer of the bowel at the sites of penetration of the vasa recta—resulting from high intraluminal pressure and bowel segmentation. Only 4–17% of patients with diverticular disease develop symptoms of bleeding[103]; however, the frequency of diverticular disease means that diverticular bleeding accounts for 30–40% of lower GI bleeding.[104] Eighty percent of diverticular bleeds stop spontaneously, but a small minority will require hemostatic intervention. Ten percent of patients will rebleed within a year and 50% within 10 years.[104]

TABLE 11-6: CAUSES OF LOWER GI BLEEDING

	Causes	Frequency (%)
Colonic bleeding (95%)	Diverticular disease	30–40
	Angiodysplasia	40
	Ischemia	6–18
	Anorectal disease	6–16
	Neoplasia	3–11
	Infectious colitis	3–29
	Polyps	5–13
	Inflammatory bowel disease	2–4
	Radiation proctitis	1–3
	Other	1–9
	Unknown	6–23
Small intestinal bleeding (5%)	Angiodysplasias	
	Neoplasia	
	Meckel's diverticulum	
	Erosions/ulcers	
	Crohn's disease	
	Radiation	

Colonoscopy remains the most useful diagnostic and therapeutic investigation for diverticular bleeding (Fig. 11-13), and can be combined with adrenaline injection, mechanical clipping, or thermal or electrical coagulation to achieve hemostasis. A recent meta-analysis showed embolization to be successful at arresting diverticular bleeding in 85% of patients.[50] Surgery is indicated in refractory bleeding, and a limited resection may also be considered as a management option in patients with multiple episodes of self-limiting bleeding.

Angiodysplasia. Angiodysplastic lesions in the intestine are degenerative vascular lesions that develop as a result of progressive dilation of submucosal vessels. Bleeding from these lesions can account for up to 40% of lower GI bleeds.[104] Angiodysplastic lesions are frequently found in the elderly and associated with aortic stenosis and renal failure. The majority of cases present with anemia and cease bleeding spontaneously; however, 50% will rebleed in 5 years. Massive bleeding may occur in up to 15% of cases.

In the colon, angiodysplastic lesions are predominantly located in the cecum and ascending colon, particularly in elderly patients. Colonoscopy reveals red stellate lesions with a rim of pale mucosa, while angiographic criteria include early prolonged filling of the draining vein, clusters of small arteries, and a visible vascular tuft (Fig. 11-14). First-line treatment options include injection with intra-arterial vasopressin, selective Gelfoam embolization, endoscopic electrocoagulation, or injection with sclerosing agents. Bleeding refractory to these treatments requires a segmental colectomy, usually in the form of a right hemicolectomy.

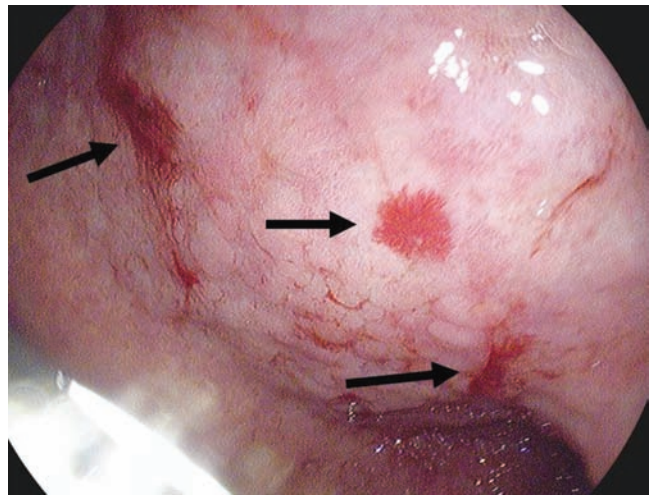

FIGURE 11-14 Telangiectatic lesions (*black arrows*) characteristic of colonic angiodysplasia, seen on colonoscopy. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

Neoplasia. Neoplasia is a rare cause of lower GI bleeding, accounting for only 2–9% of all hematochezia, but is significant due to the relatively high incidence of colorectal cancer in developed countries.[53] Neoplasia-induced hemorrhage presents as chronic painless bleeding, usually associated with iron deficiency anemia.[53] This is particularly frequent in tumors of the right side of the colon, while tumors of the left side often present with obstructive symptoms and occasionally ulcerate to produce bright red bleeding (Fig. 11-15). Colonic polyps are the cause of bleeding in 5–11% of patients and of anemia in 3–7% of patients; however, this is most often the case in polyps exceeding 1 cm in diameter (Fig. 11-16).[105]

A common cause of lower GI bleeding is postpolypectomy bleeding, where the site may bleed for up to 14 days

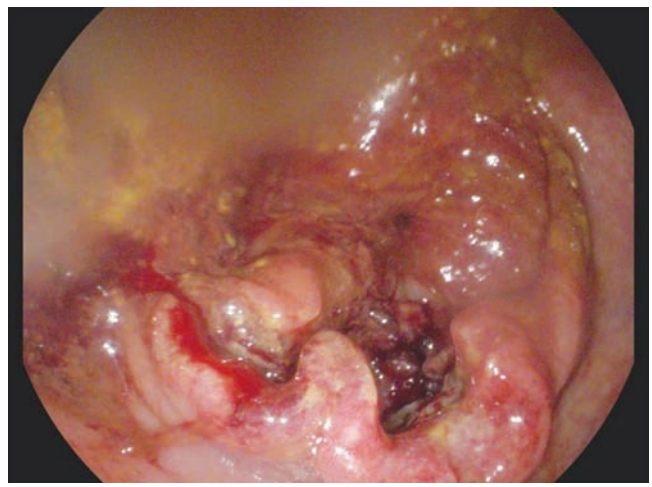

FIGURE 11-15 Colonoscopic views of a large ulcerated neoplastic lesion. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

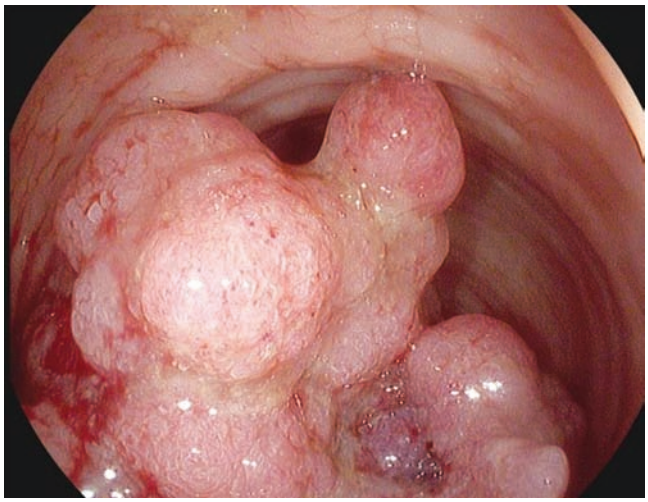

FIGURE 11-16 Colonoscopic view of a large pedunculated polyp with associated bleeding. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

following polypectomy (Fig. 11-17). Several factors influence the risk of postpolypectomy bleeding, including size of polyp, inadequate electrocautery, comorbidity, bowel preparation, and experience of the endoscopist.[106] Delayed postpolypectomy bleeding in particular was more likely in large polyps and in polyps in the right side of the colon, and in patients in whom anticoagulant therapy had been resumed within 1 week of polypectomy.[107] Colonic polyps and neoplasia are covered in more detail in Chap. 36.

Anorectal Disease. Anorectal pathology that can cause lower GI bleeding includes anal fissures, hemorrhoids, and colorectal neoplasia. Fissures are associated with significant pain on defecation and examination but rarely cause large amounts of blood loss. Inspection of the anal margin is usually diagnostic and can be made painless following injection of local anesthetic. Bleeding from fissures usually ceases spontaneously. Conservative management includes the use of stool bulking agents, stool softeners, increased fluid intake, and topical nitroglycerin or diltiazem, which facilitate healing of the fissure by reducing sphincter spasm.

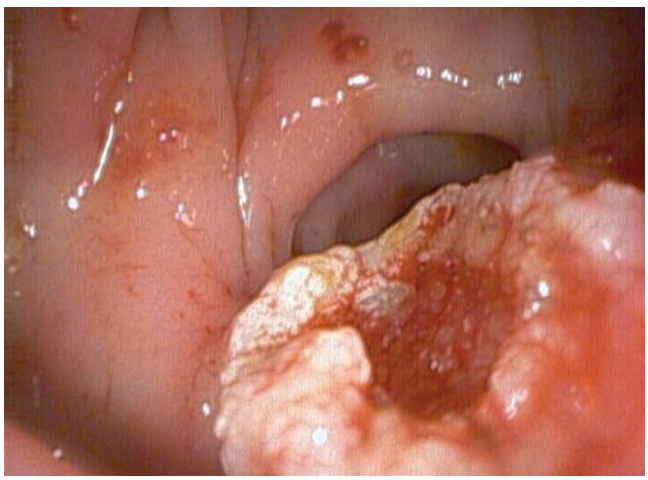

FIGURE 11-17 Colonoscopic views of bleeding from the base of a polyp postpolypectomy. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

Hemorrhoids account for lower GI bleeding in 2–9% of patients.[105] Fresh red blood is seen on the tissue paper, in the bowl, and around the stool, and is usually painless in nature. Bleeding usually derives from painless internal hemorrhoids and is associated with prolapse of these hemorrhoids, often requiring manual reduction. Management includes stool-bulking agents and increased consumption of fibre and water. Rubber band ligation, injection sclerotherapy, and infrared coagulation may also be employed, and in refractory cases surgical hemorrhoidectomy can be performed.

Other rarer anorectal causes of lower GI bleeding include solitary rectal ulcers and anorectal varices. Solitary rectal ulcers are postulated to arise as a result of local ischemia, due to internal rectal prolapsed or lack of inhibition of the puborectalis muscle on straining. Bleeding is rare with solitary rectal ulcers but in contrast can be severe with anorectal varices. These arise in patients with portal hypertension and can bleed in 18% of those patients.[108]

An important point to note is that anorectal causes of bleeding such as fissures and hemorrhoids are relatively common incidental findings and should not be considered the only source of bleeding until more proximal colonic neoplasia has been excluded, particularly in the elderly. Benign anorectal conditions are discussed further in Chap. 39.

Colitis. Bleeding associated with colitis may be multifactorial in origin.

Bleeding From Inflammatory Bowel Disease. Bleeding from colonic inflammation may be a feature of inflammatory bowel disease. Lower GI hemorrhage has been reported in the majority of patients with ulcerative colitis and in up to a third of patients with Crohn's disease.[109] Most bleeding stops spontaneously, but 35% of patients experience rebleeding.[110] Both ulcerative colitis and Crohn's disease are associated with abdominal pain and increased bowel movements. While ulcerative colitis predominantly involves the mucosal layer and begins at the rectum then spreads proximally, Crohn's disease is associated with transmural thickening of the bowel wall, skip lesions, and strictures, and classically involves the terminal ileum (Fig. 11-18). Both Crohn's disease and ulcerative colitis are diagnosed on endoscopy and managed with 5-aminosalicylic acid (5-ASA) compounds, immunomodulatory agents, steroids, and antibiotics as needed. Surgical therapy for ulcerative colitis is needed if the rare complication of toxic megacolon develops or in the event of refractory life-threatening hemorrhage. Surgery is avoided as much as possible in Crohn's disease because of the natural relapsing and remitting nature of the disease and the tendency of the lesions to affect any region of the GI tract.

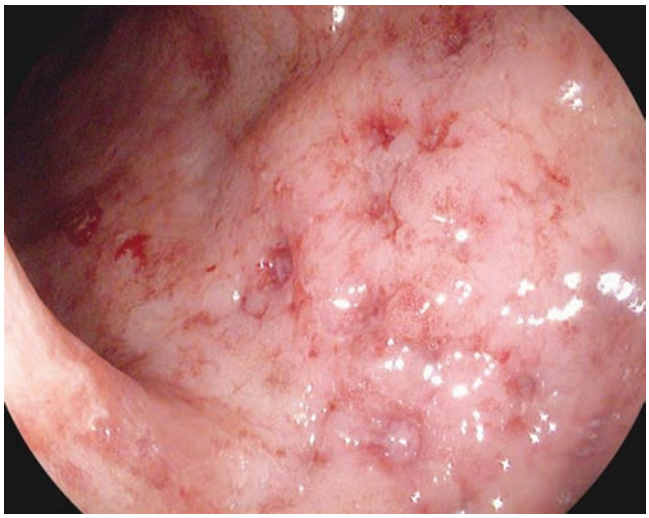

FIGURE 11-18 Colonoscopic view of Crohn's colitis. Note the cobblestone appearance of the mucosa and the associated edema and erythema. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

FIGURE 11-19 Colonoscopic view of radiation-induced proctitis, with the characteristic appearance of multiple telangiectasia on a background of otherwise pale mucosa. (Used with permission from Dr Nicola Simmonds, Luton and Dunstable Hospital, UK.)

Crohn's disease and ulcerative colitis are discussed further in Chaps. 33 and 34.

Infectious Colitis. Causes of infectious colitis that may cause bloody diarrhea include CMV colitis, *Escherichia coli*, *Shigella*, *Salmonella*, and *Campylobacter*. Patients with infectious colitis typically present with bloody diarrhea with positive stool cultures. CMV colitis typically affects the immunocompromised.

Patients with HIV are particularly at risk of GI bleeding and, because of the immune deficiency, are particularly at risk from opportunistic organisms. Causes of GI bleeding in the colon of HIV-positive patients include CMV colitis, lymphoma, colonic histoplasmosis, Kaposi's sarcoma of the colon, and bacterial colitis, with an overall average mortality of 14%.[111] Colonoscopy and biopsy confirms the diagnosis, and treatment should be commenced as appropriate.

NSAID-Associated Lower GI Bleeding. NSAIDs are also able to induce and exacerbate lower GI bleeding. NSAIDs can themselves induce mucosa damage and colonic inflammation, erosions, and ulcers. In addition, they can exacerbate existing colitis and increase the tendency of preexisting lesions such as polyps or angiodysplasia to bleed. NSAID-induced lesions appear as flat, irregularly shaped erosions and ulcerations with otherwise normal mucosa.[53]

Radiation Proctitis. Radiation therapy in the pelvic region is another cause of lower GI bleeding, producing a chronic radiation proctopathy due to the neovascularization resulting from radiation-induced endarteritis obliterans. Bleeding occurs in 4–13% of patients receiving radiation therapy for prostatic carcinoma.[112] Patients typically present with bloody diarrhea, cramping pelvic pain, and tenesmus. Endoscopy reveals multiple telangiectasias on an otherwise pale mucosa and can be coupled with argon plasma coagulation for treatment (Fig. 11-19). Other treatment options include antidiarrheals and hydrocortisone enemas. Ablation with 4% formalin solution may be considered for refractory bleeding.[113]

Mesenteric Ischemia. Mesenteric ischemia, or ischemic colitis, results from a sudden reduction in blood flow to the intestine due to either reduced blood pressure or vasoconstriction. This is particularly frequent in elderly patients with a background of cardiovascular disease; other risk factors include recent abdominal vascular surgery, hypercoagulable states, and vasculitis. Patients on inotropes and vasoconstrictors are particularly prone to mesenteric ischemia due to splanchnic vasoconstriction. The splenic flexure of the colon and the rectosigmoid junction are vascular watershed areas and are especially susceptible to ischemia. Patients present with abdominal pain and bloody diarrhoea. The diagnosis is suspected with the identification of a thickened bowel wall on CT and is confirmed on endoscopy showing bleeding, edematous mucosa with a demarcation between ischemic, and normal bowel (Fig. 11-20). Ulcerations may appear on endoscopy in the later stages of disease progression. Despite the self-limiting nature of the disease in most patients, mesenteric ischemia is associated with a high morbidity and mortality.[114] Conservative management is usually employed, with bowel rest, intravenous antibiotics, and cardiovascular support and normalization of the hemodynamic state. In 15% of patients, ischemia is followed by gangrene and perforation, the patient develops sepsis, acidosis, and peritonitis, and requires urgent laparotomy with resection of ischemic bowel and the creation of an end colostomy.[115]

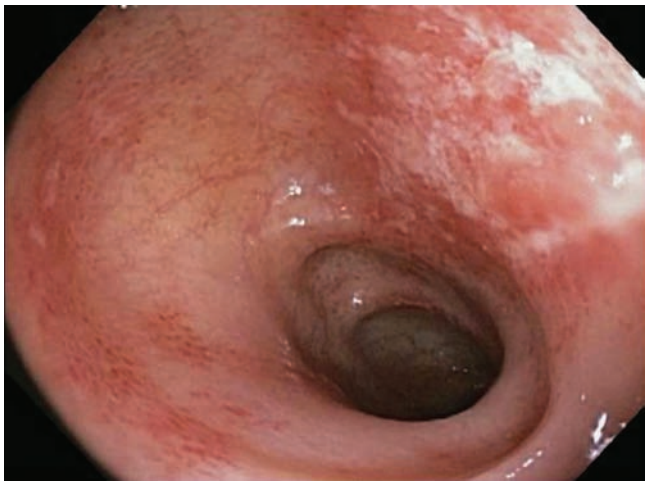

FIGURE 11-20 Ischemic colitis as viewed on colonoscopy, with evidence of ulceration and submucosal hemorrhage. (Used with permission from Dr Frederick Makrauer MD, Brigham and Women's Hospital, Boston, MA.)

FIGURE 11-21 Meckel's diverticulum seen intraoperatively. Meckel's diverticulum (*black arrow*) can be seen on the antimesenteric border of the ileum.

OBSCURE LOWER GI BLEEDING

Bleeding persisting or recurring after negative esophagogastroscopy and colonoscopy occurs in approximately 5% of cases is termed *obscure bleeding*, often the result of angiodysplastic lesions, Meckel's diverticula, Dieulafoy's lesions, and small bowel neoplasms.[116] Bleeding in these cases may be visible (termed obscure-overt bleeding) or only detected by the presence of guaiac-positive stools (obscure-occult bleeding). Further investigation in the form of capsule enteroscopy, deep enteroscopy, angiography, or red cell labeling is often necessary in these cases.

Angiodysplasia. Angiodysplasia is the most common cause of small bowel hemorrhage, accounting for up to 40% of cases in elderly patients and 10% of cases in younger patients. The jejunum is the most common site for these lesions. While angiodysplasias of the small intestine often present with obscure bleeding, patients with bleeding angiodysplastic lesions may also present with occult bleeding and iron deficiency anemia. Unlike colonic angiodysplasia, angiography is rarely helpful in small intestinal angiodysplasia, and deep enteroscopy or capsule enteroscopy are the investigative modalities of choice. Optimal management involves on-table endoscopy with segmental resection of the affected length of small bowel; however, it is important to note that a significant number of patients may spontaneously cease bleeding.[117]

Meckel's and Other Small Intestinal Diverticula. A Meckel's diverticulum is the incomplete obliteration of the remnant of the embryonic vitelline duct, the communication between the yolk sac and the fetal gut, and occurs in approximately 2% of the population. Meckel's diverticulum is usually found within 100 cm of the ileocecal valve and usually ranges from 1 to 10 cm in length (Fig. 11-21).[118] Up to 60% of Meckel's diverticula contain heterotopic mucosa, usually of gastric or pancreatic origin. Hemorrhage is a common complication of a Meckel's diverticulum in both adults and children, occurring in 38% of adults and 31% of children, and results from ulceration of the normal mucosa adjacent to the acid-producing heterotopic mucosa.[119] Radionuclide scans may assist in the diagnosis of Meckel's diverticulum but is much less accurate in the adult population compared to the pediatric population. The use of cimetidine, which decreases peptic acid secretion without affecting radionuclide uptake, slows the release of the pertechnetate into the lumen and increases the sensitivity of the scan to 95%.[120] Laparoscopy may be used for the diagnosis as well as the treatment of Meckel's diverticulum. Operative management hinges on removal of the Meckel's diverticulum and associated bands as well as resection of the adjacent affected bowel.

The incidence of nonmeckelian intestinal diverticulosis is low, ranging from 0.06 to 4.6% on autopsy studies.[121] These are particularly common in the elderly but may present in any age group. The pathophysiology of small bowel diverticula is similar to that of colonic diverticula—these are pseudodiverticula involving only mucosa and submucosa, unlike a Meckel's diverticulum that is a true diverticulum. The majority of small intestinal diverticula occur in the jejunum, corresponding with the greatest frequency of vasa rectae in the small intestine. Upper GI contrast series or CT scans may reveal diverticula as contrast-filled sacculations; however, these lack sensitivity. Enteroclysis is a double-contrast radiographic modality involving the use of duodenojejunal intubation and intraluminal distension, allowing even small diverticula to be filled. The lack of cost-effectiveness, however, makes this modality

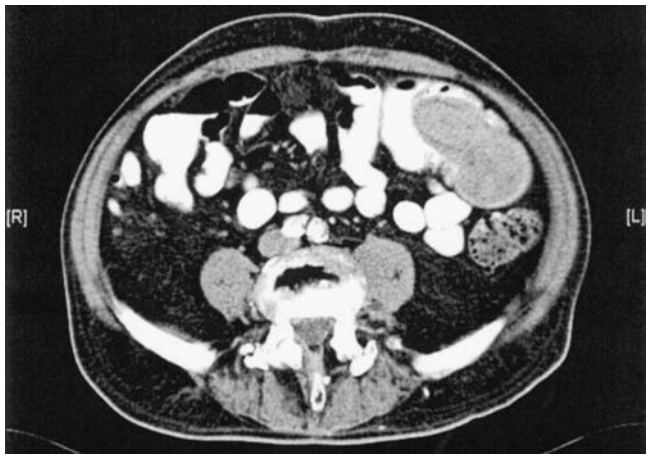

FIGURE 11-22 CT image of an ileal adenocarcinoma, obvious as a mass in the left midabdomen.

only appropriate if standard radiographic modalities have proved unsuccessful. The incidence of bleeding from jejunal diverticulosis ranges from 5 to 33%.[121] Enteroscopy (particularly deep enteroscopy) is suitable for diagnosis of diverticula complicated by bleeding, inflammation, or obstruction, but laparotomy remains the gold standard for diagnosis and management, particularly in the unstable patient. Operative management involves resection of the affected segment of small bowel with a primary end-to-end anastomosis. Rarely a large proportion of the bowel is involved (panjejunoileal diverticulosis), and conservative management may be tried to avoid massive small bowel resection and resultant short bowel syndrome. Selective mesenteric angiography and embolization may assist in the control of hemorrhage in these cases.

Neoplasia. Although small bowel tumors account for only 5% of all GI tumors, they are the second most common cause of small intestinal bleeding.[122] Patients may present either with melena or with fecal occult blood. Leiomyomas and leiomyosarcomas are the most common tumors to bleed and may bleed briskly due to tumor necrosis and mucosal ulceration. These are highly vascular tumors, and hence angiography has an 86% rate of detection for these lesions. Other tumors in the small intestine include adenocarcinoma, carcinoid, and lymphoma. Tumors can be diagnosed on enteroscopy, small bowel contrast series, or CT (Fig. 11-22), and treatment involves surgical resection of the tumor.

MANAGEMENT OF ABDOMINAL TRAUMA

L. D. Britt • Robert A. Maxwell

MANAGEMENT OF PENETRATING ABDOMINAL TRAUMA

Introduction

The management of penetrating abdominal trauma parallels the evolution of diagnostic modalities. In the 19th century, expectant (observation) management was the approach of choice worldwide. In 1880, Paule Reclese, a French surgeon, advocated supportive care only for penetrating abdominal injuries. Sir William McCormick, chief Army Surgeon during this same period, coined the McCormick aphorism regarding the management of gunshot wounds to the abdomen that stated "if a man undergoes surgery after being shot he dies and lives if left in peace." Even with a mortality rate that was exceedingly high, such dogma was the standard of care during this era for any penetrating abdominal trauma. This management approach was, unfortunately, applied when President James A. Garfield sustained a gunshot wound to the abdomen. The observational management, called the "Garfield Death Watch," by the President's medical team resulted in the demise of President Garfield. There were very few voices that challenged this surgical dogma of nonoperative management, with Dr Marion Simms, a prominent Southern surgeon who became president of the American Medical Association, being the most vocal.[1] With predictably overwhelming morbidity/mortality associated with these injuries, it became apparent that a more aggressive, interventional approach was needed for penetrating injuries to the abdomen, and, as a result, mandatory exploration, or celiotomy, became the prevailing management option of choice and essentially the standard of care.

Shafton and Nance's landmark articles, which emphasized surgical judgment in the management of penetrating wounds of the abdomen, changed the approach to penetrating abdominal injuries from mandatory celiotomy to a more selective management.[2,3] Enhanced diagnostic imaging has greatly assisted in making the nonoperative/selective management a more reliable and acceptable treatment option in penetrating abdominal trauma.

Initial Trauma Management

Before focusing on the specific anatomical region where there is an obvious traumatic injury, an initial assessment of the entire patient is imperative. The concept of initial assessment includes the following components: (1) rapid primary survey, (2) resuscitation, (3) detailed secondary survey (evaluation), and (4) reevaluation. Such an assessment is the cornerstone of the Advanced Trauma Life Support (ATLS) program.[4] Integrated into primary and secondary surveys are specific adjuncts. Such adjuncts include the application of electrocardiographic monitoring and the utilization of other monitoring modalities such as arterial blood gas determination, pulse oximetry, the measurement of ventilatory rate and blood pressure, insertion of urinary and/or gastric catheters, and incorporating necessary x-rays and other diagnostic studies, when applicable, such as focused abdominal sonography for trauma (FAST) examination, other diagnostic studies (plain radiography of the spine/chest/pelvis and computed tomography [CT]), and diagnostic peritoneal lavage (DPL). Determining the right diagnostic study depends on the mechanism of injury and the hemodynamic status of the patient.

The focus of the primary survey is to both identify and expeditiously address immediate life-threatening injuries. Only after the primary survey is completed (including the initiation of resuscitation) and hemodynamic stability is addressed, should the secondary survey be conducted, which entails a head-to-toe (and back-to-front) physical examination, along with a more detailed history.

PRIMARY SURVEY

Only the emergency care disciplines of medicine have a two-tier approach to their initial assessment of the patient, with primary and secondary surveys being integral components. As highlighted previously, the primary survey is designed to quickly detect life-threatening injuries.

Therefore, a universal approach has been established with the following prioritization:

- Airway maintenance (with protection of the cervical spine)
- Breathing (ventilation)
- Circulation (including hemorrhage control)
- Disability (neurologic status)
- Exposure/environmental control

Such a systematic and methodical approach (better known as the ABCDEs of the initial assessment) greatly assists the surgical/medical team in the timely management of those injuries that could result in a poor outcome.

A. **Airway assessment management (along with cervical spine protection):** Because loss of a secure airway could be lethal within 4 minutes, airway assessment/management always has the highest priority during the primary survey of the initial assessment of any injured patient, irrespective of the mechanism of injury or the anatomical wound. The chin lift and jaw thrust maneuvers are occasionally helpful in attempting to secure a patient airway. However, in the trauma setting, the airway management of choice is often translaryngeal, endotracheal intubation. If this cannot be achieved due to an upper airway obstruction or some technical difficulty, a surgical airway (needle or surgical cricothyroidectomy) should be the alternative approach. No other management can take precedence over obtaining an appropriate airway control. Until adequate and sustained oxygenation can be documented, administration of 100% oxygen is required.

B. **Breathing (ventilation assessment):** An airway can be adequately established and optimal ventilation still not be achieved. For example, such is the case when there is an associated tension pneumothorax (other examples include a tension hemothorax, open pneumothorax, or a large flail chest wall segment). Worsening oxygenation and an adverse outcome would ensue unless such problems are expeditiously addressed. Therefore, assessment of breathing is imperative, even when there is an established and secure airway. A patent airway but poor gas exchange will still result in a poor outcome. Tachypnea, absent breath sounds, percussion hyperresonance, distended neck veins, and/or tracheal deviation are all consistent with inadequate gas exchange. Decompression of the pleural space with a needle/chest tube insertion should be the initial intervention for a pneumo-/hemothorax. A large flail chest, with underlying pulmonary contusion, will likely require endotracheal intubation and the administration of positive-pressure ventilation.

C. **Circulation assessment (adequacy of perfusion management):** The most important initial step in determining adequacy of circulatory perfusion is to quickly identify and control any active source of bleeding, along with restoration of the patient's blood volume with crystalloid fluid resuscitation and blood products, if required. Decreased levels of consciousness, pale skin color, slow (or nonexistent) capillary refill, cool body temperature, tachycardia, or diminished urinary output are all suggestive of inadequate tissue perfusion. Optimal resuscitation requires the insertion of two large-bore intravenous lines and infusion of crystalloid fluids (warmed). Adult patients who are severely compromised will require a fluid bolus (2 L of Ringer's lactate or saline solution). Children should receive a 20 mL/kg fluid bolus. Blood and blood products are administered as required. Along with the initiation of fluid resuscitation, emphasis needs to remain on identifying the source of active bleeding and stopping the hemorrhage. For a patient in hemorrhagic shock, the source of blood loss will be an open wound with profuse bleeding, or within the thoracic or abdominal cavity, or from an associated pelvic fracture with venous or arterial injuries. Disposition (operating room, angiography suite, etc) of the patient depends on the site of bleeding. For example, a FAST assessment that documents substantial blood loss in the abdominal cavity in a patient who is hemodynamically labile dictates an emergency celiotomy. However, if the quick diagnostic workup of a hemodynamically unstable patient who has sustained blunt trauma demonstrates no blood loss in the abdomen or chest, the source of hemorrhage could be from a pelvic injury that would likely necessitate angiography/embolization if external stabilization (eg, a commercial wrap or binder) of the pelvic fracture fails to stop the bleeding. Profuse bleeding from open wounds can usually be addressed by application of direct pressure or occasionally ligating torn arterial vessels that can easily be identified and isolated.

D. **Disability assessment/management:** Only a baseline neurologic examination is required when performing the primary survey in order to determine neurologic function deterioration that might necessitate surgical intervention. It is inappropriate to attempt a detailed neurologic examination initially. Such a comprehensive examination should be done during the secondary survey or evaluation. This baseline neurologic assessment could be the determination of the Glasgow coma scale (GCS), with an emphasis on the best motor or verbal response, and eye opening. An alternative approach for a rapid neurologic evaluation would be the assessment of the pupillary size and reaction, along with establishing the patient's level of consciousness (alert, responds to visual stimuli, responds only to painful stimuli or unresponsive to all stimuli). The caveat that must be highlighted is the fact that neurologic deterioration can occur rapidly and that a patient with a devastating injury can have a lucid interval (eg, epidural hematoma). Because the leading causes of secondary brain injury are hypoxia and hypotension, adequate cerebral oxygenation and perfusion are essential in the management of a patient with neurologic injury.

E. **Exposure/environmental control:** In order to perform a thorough examination of a patient, he/she must be completely undressed. This often requires cutting off the garments to safely expedite such exposure. However, care must be taken to keep the patient from becoming hypothermic. Adjusting the room temperature and infusing warmed intravenous fluids can help establish an optimal environment for the patient.

SECONDARY SURVEY

The secondary survey should not be done until the primary survey has been completed and resuscitation initiated, with some evidence of normalization of vital signs. It is imperative that this head-to-toe evaluation be performed in a detailed manner in order to detect less obvious or occult injuries. This is particularly important in the unevaluable (eg, head injury or severely intoxicated) patient. The physical examination should include a detailed assessment of every anatomical region, including the following:

- Head
- Maxillofacial
- Neck (including cervical spine)
- Chest
- Abdomen
- Perineum (including the rectum and genital organs)
- Back (including the remaining spinal column)
- Extremities (musculoskeletal)

A full neurologic examination needs to be performed, along with an estimate of the GCS score if one was not done during the primary survey. The secondary survey and the utilization (when applicable) of the armamentarium of diagnostic adjuncts, previously mentioned, will allow detection of more occult or subtle injuries that could, if not found, account for significant morbidity and mortality. When possible, the secondary survey should include a history of the mechanism of injury, along with vital information regarding allergies, medications, past illnesses, recent food intake, and pertinent events related to the injury.

It cannot be overemphasized that frequent reevaluation of the injured patient is necessary in order to detect any deterioration in the patient status. This sometimes requires repeating both the primary and secondary surveys.

Topography and Clinical Anatomy

The *abdomen* is often defined as a component of the torso that has for its superior boundary the left and right hemidiaphragm, which can ascend to the level of the nipples (fourth intercostal space) on the frontal aspect and to the tip of the scapula in the back. The inferior boundary of the abdomen is the pelvic floor. For clinical purposes, it is helpful to further divide the abdomen into four areas: (1) anterior abdomen (below the anterior costal margins to above the inguinal ligaments and anterior to the anterior axillary lines), (2) intrathoracic abdomen (from the nipple or the tips of the scapula to the inferior costal margins), (3) flank (inferior scapular tip to the iliac crest and between the posterior and anterior axillary lines), and (4) back (below the tips of the scapula to the iliac crest and between the posterior axillary lines). The majority of the digestive system and urinary tract, along with a substantial network of vasculature and nerves, are contained with the abdominal cavity. A viscera-rich region, the abdomen can often be the harbinger for occult injuries as a result of penetrating wounds, particularly in the unevaluable abdomen as the result of a patient's compromised sensorium.

Mechanism of Injury

In addition to the hemodynamic status of the patient, important variables in the decision making regarding management of penetrating abdominal injuries are both the mechanism and location of injury (see Physical Examination). The kinetic energy generated by hand-driven weapons, such as knives and sharp objects, is substantially less than what is caused by firearms. Although not always evident, it is important to know the length and width of the wound along with the depth of penetration of the weapon or device that caused the stab injury. For example, a stab injury usually results in a long, more shallow wound that does not penetrate the peritoneum. Local wound management is the primary focus for these injuries with no concern for any potential intra-abdominal injury.[5] Although there are some stab wounds that do not penetrate the peritoneal cavity, such cannot be assumed without some formal determination or serial abdominal examinations to assess for worsening abdominal tenderness or the development of peritoneal signs.

There is notable variability among the full spectrum of firearms in the civilian setting, with this arsenal, including mostly handguns, rifles, shotguns, and air guns. The kinetic energy, which correlates with the wounding potential, is dependant on mass and velocity ($KE = 1/2\ mr^2$). Therefore, the higher the velocity, the greater the wounding potential.[6] Because the barrel is longer in a rifle than a handgun, the bullet has more time to accelerate—generating a much higher velocity. A high-velocity missile is propelled at 2500 ft/s or greater. Air guns usually fire pellets (eg, BBs) and are associated with a lower velocity and wounding potential. Shotguns fire a cluster of metal pellets, called a shot. The pellets separate after leaving the barrel, with a rapidly decreasing velocity. At a distance, the wounding potential is diminished. However, at close range (<15 ft), because of the increase in aggregate mass, the tissue destruction is similar to a high-velocity missile injury.

Although each injury should be handled on an individual basis, there are general principles that will provide some guidance in the management of penetrating injuries based on mechanism of injury. Regarding stab wounds, approximately one-third of the wounds do not penetrate the peritoneum and only half of those that do penetrate require

operative intervention. The number of organs injured and the intra-abdominal sepsis complication rate are significantly less than wounds caused by gunshots.[7,8]

Physical Examination

A complete and thorough physical examination of the entire body is essential in the management of penetrating abdominal injury. There are some findings (Table 12-1) on physical examination that are absolute indications for operative intervention. The components of the physical examination should include careful inspection, palpation, and auscultation.

In addition to being able to determine the location, extent, and the number of wounds, inspection can sometimes determine the trajectory of the missile or other wounding agent and, consequently, guide management decisions. For example, a patient with a documented, superficial tangential gunshot wound (low-velocity), with no other remarkable physical findings, would likely be managed expectantly (observation). However, if a penetrating abdominal injury results in a patient presenting with an evisceration, exploratory laparotomy would be the management option of choice. Palpation will enable the examiner to elicit abdominal tenderness or frank peritoneal signs, along with being able to detect abdominal distention and rigidity. On occasion, missiles can be palpated lodged in the soft tissue. Unless in a controlled and sterile setting such as the operative theatre, probing of a wound should be avoided. Auscultation is also an important component of the physical examination. It can help determine diminished or absent bowel sounds that could be suggestive of evolving peritonitis. Also, auscultation could detect a trauma-induced bruit, suggestive of a vascular injury.

The examiner has to be keenly aware of the fact that there are situations in which the abdominal examination will be unreliable due to possible spinal cord injury or a patient's altered mental state.

Diagnostic Studies

Even with penetrating injuries, the abdomen is notorious for hiding its secrets—occult injuries. Access to an extensive diagnostic armamentarium is imperative in the optimal management of these injuries. Strongly advocated by some for abdominal stab wounds, local wound exploration has the advantage of allowing the patient to be discharged from the trauma bay or emergency department, if surgical exploration of the wound fails to demonstrate penetration of the posterior fascia and peritoneum. However, if the patient has to go to the operating room for other injuries, the local wound exploration should be done in the surgical suite that will have better lighting and a more sterile environment. A positive finding during local wound exploration dictates a formal laparotomy or laparoscopy. However, even with local wound exploration as a guide, the nontherapeutic laparotomy rate can be high, given that only a third of the patients with stab wounds to the anterior abdomen require therapeutic laparotomies.[9,10] In the patient who has an evaluable abdomen, serial abdominal examinations would be an acceptable alternative to local wound exploration, in order to determine the need for operative intervention. Local wound exploration should only be done for stab wounds to the anterior abdomen. Such an approach is potentially too hazardous for thoracoabdominal penetrating injuries and back/flank wounds. Plain radiography (abdomen/pelvis/chest) can be pivotal in documenting the presence of missiles and other foreign bodies and determining the trajectory of the injury tract, particularly for wounds from firearms. Also, the presence of free air might be confirmed by plain radiography. Unless there is concern about a retained broken blade, there is little utility for plain radiography for stab injuries.[11] The DPL developed by David Root in 1965, was a major advance in the care of the hemodynamically labile patient who sustained blunt trauma.[12] With the advent of FAST and rapid CT, DPL has very limited utility. DPL has never had a broad appeal in the diagnostic evaluation of penetrating abdominal wounds. Although some have advocated its use with tangential wounds of the abdominal wall, the technique has failed to receive widespread support.[13] Its reliability in detecting clinically significant injuries sustained as a result of penetrating abdominal injuries has been a prevailing concern.[14–16] The reported sensitivity and specificity of DPL for abdominal stab wounds are 59–96% and 78–98%, respectively.[17] Also, DPL is a poor diagnostic modality for detecting diaphragmatic and retroperitoneal injuries.

Diagnostic imaging has had the greatest impact in changing the face of trauma management with CT taking the lead in this area. Its ubiquitous presence in the management of blunt abdominal trauma is well established. However, it is becoming an important diagnostic study in the evaluation of penetrating abdominal injuries. In addition to its excellent sensitivity in detecting a pneumoperitoneum, free fluid, and abdominal wall/peritoneal penetration, CT is helpful in identifying the tract of the penetrating agent. Hauser et al recommended the use of "triple contrast" CT in the assessment of penetrating back and flank injuries.[18] CT scan evaluation is an essential diagnostic tool in the increasing advocacy for selective management of abdominal gunshot wounds obviating the need for mandatory surgical exploration.[19] However, there still remain two major limitations of

TABLE 12-1: ABSOLUTE INDICATIONS FOR EXPLORATORY LAPAROTOMY IN PENETRATING ABDOMINAL INJURIES

CT: detection of an intestinal perforation and a diaphragmatic injury.

Unless the injury is confined to the solid organ of the abdomen, such as the liver or spleen, the matrix of intestinal gas patterns makes detection of penetrating injuries difficult. Kristensen et al were one of the first teams to introduce the role of ultrasonic scanning as part of the diagnostic armamentarium in trauma management.[20] Kimura and Otsuka endorsed using ultrasonography in the emergency room for evaluation of hemoperitoneum.[21] FAST does not have the same broad application in the evaluation of penetrating trauma as it does in blunt trauma assessment. Rozycki et al reported on the expanded role of ultrasonography as the "primary adjuvant modality" for the injured patient assessment.[22] Rozycki et al also reported that FAST examination was the most accurate for detecting fluid within the pericardial sac. Such a finding would be confirmatory for a cardiac injury and possible cardiac tamponade, given a mechanism of injury that could result in an injury to the heart.

As a diagnostic modality, laparoscopy is not a new innovation. Other specialists have been utilizing this operative intervention for several decades. However, it was formally introduced as a possible diagnostic procedure of choice for specific torso wounds when Ivatury et al did a critical evaluation of laparoscopy on penetrating abdominal trauma.[23] Fabian et al also reported on the efficacy of diagnostic laparoscopy in a prospective analysis.[24] With there being no conventional diagnostic tool that can conclusively rule out a diaphragmatic laceration or rent, diagnostic laparoscopy becomes the study of choice for penetrating thoracoabdominal injuries, particular left thoracoabdominal wounds (Fig. 12-1). Laparoscopy can also be used to determine peritoneal entry from a tangential penetrating injury.

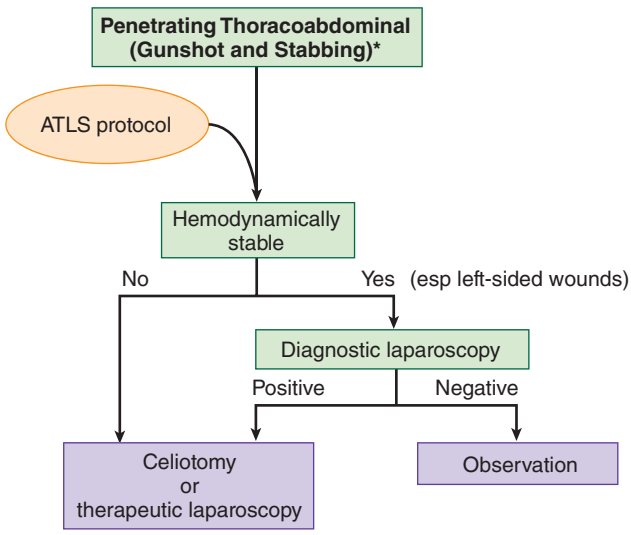

FIGURE 12-1 Management algorithm for penetrating thoracoabdominal injuries.

Penetrating Abdominal Injuries and the Hemodynamically Stable and Unstable Patient

As highlighted previously, the management principles in patients who sustain penetrating abdominal injuries and remain hemodynamically stable depend on the mechanism and location of injury, along with the hemodynamic status of the patient. Irrespective of the patient's hemodynamic parameters, the ATLS protocol should be strictly followed upon arrival of the patient to the trauma bay.[25] Figures 12-2 through 12-5 are management algorithms for the patient with penetrating thoracoabdominal, penetrating anterior abdominal, penetrating abdominal, or penetrating back or flank injuries.

Trauma Laparotomy

The operative theater should be large enough to accommodate more than one surgical team, in the event the patient might require simultaneous procedures to be performed. In addition, the room should have the capability of maintaining room temperatures in order to avoid having a hypothermic patient. Also, there should be a rapid transfusion device in the room in order to facilitate the delivery of large fluid volume and ensure that the fluid administration is appropriately warm.

Abdominal exploration for trauma has basically four imperatives: (1) hemorrhage control, (2) contamination control, (3) identification of the specific injury(ies), and (4) repair/reconstruction. The abdomen is prepared with a topical

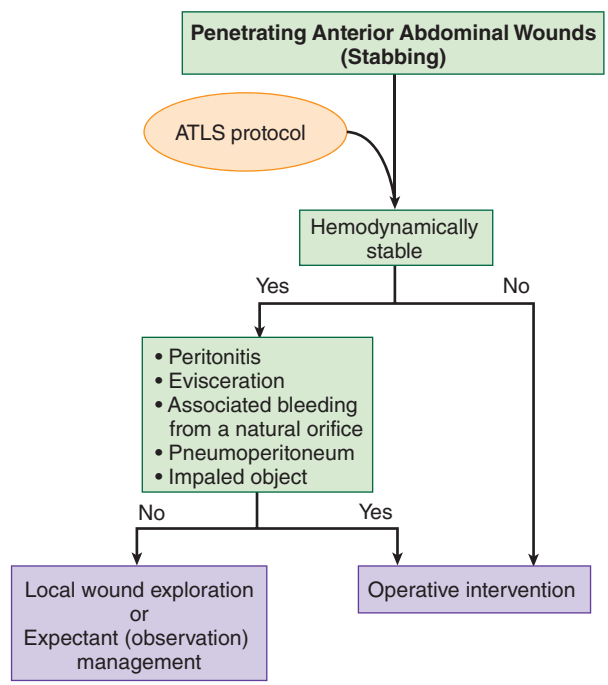

FIGURE 12-2 Management algorithm for penetrating anterior abdominal injuries.

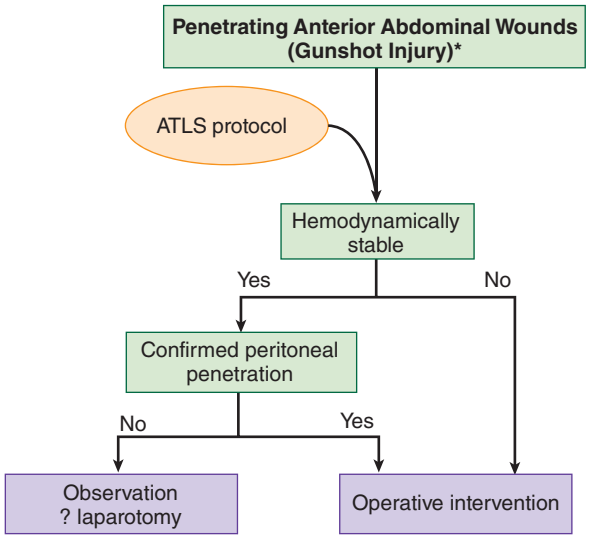

FIGURE 12-3 Management algorithm for penetrating abdominal injuries.

antimicrobial from sternal notch to bilateral midthighs and extending the prep laterally to the side of the operating room table, followed by widely draping the patient. Such preparation allows for expeditious entry into the thorax if needed and possible vascular access or harvesting. Exploration is initiated with a midline vertical incision that should extend from the xyphoid to the symphysis pubis in order to achieve optimal exposure.

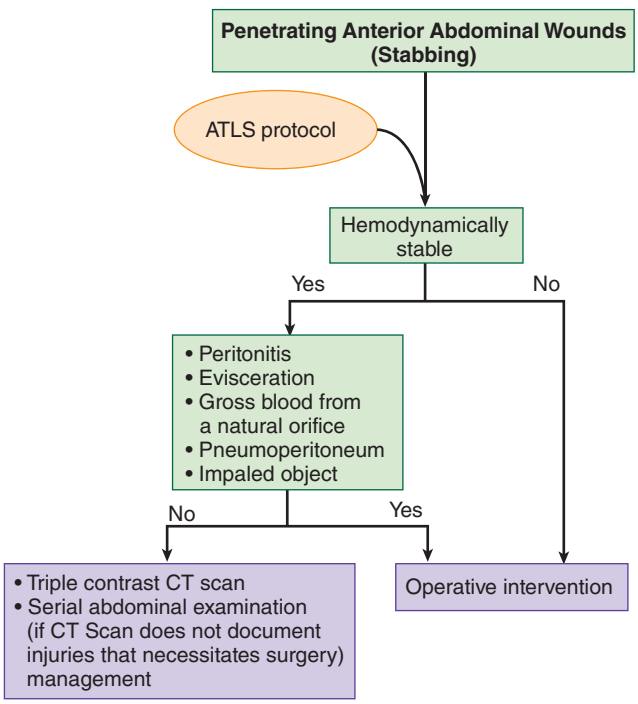

FIGURE 12-4 Management algorithm for penetrating abdominal injuries.

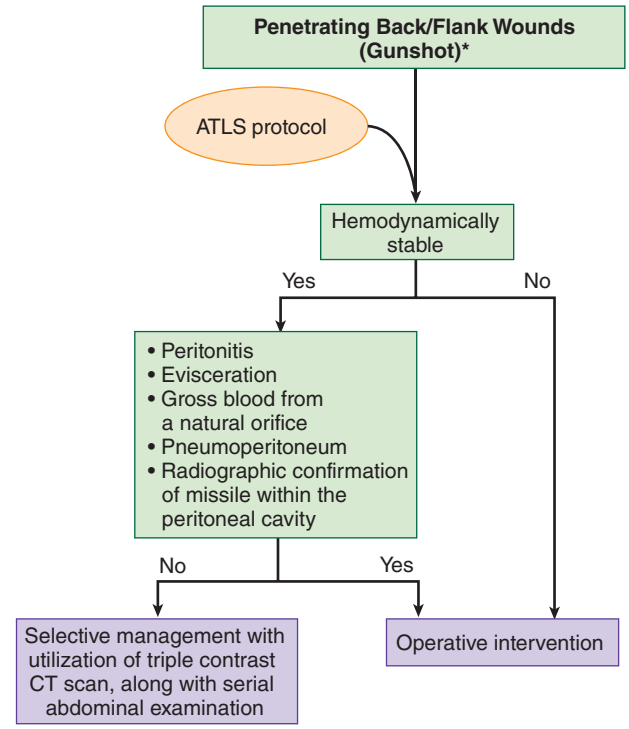

FIGURE 12-5 Management algorithm for penetrating back/flank injuries.

The first priority upon entering the abdomen is control of exsanguinating hemorrhage. Such control can usually be achieved by direct control of the lacerated site or obtaining proximal vascular control. After major hemorrhage is controlled, blood and blood clots are removed. Abdominal packs (radiologically labeled) are used to tamponade any bleeding and allow for identification of any injury bleeding. The preferred approach to packing is to divide the falciform ligament and retract the anterior abdominal wall. This will allow manual placement of the packs above the liver. Abdominal packs should also be placed below the liver. This arrangement of the packs on the liver creates a compressive tamponade effect. After manually eviscerating the small bowel out of the cavity, packs should be placed on the remaining three quadrants, with care taken to avoid an iatrogenic injury to the spleen. During the packing phase after ongoing hemorrhage has been controlled, the surgeon should communicate with the anesthesia team that major hemorrhage has been controlled and that this would be an optimal time to establish a resuscitative advantage with fluid/blood product administration.

The next priority should be control or containment of gross contamination. This begins with the removal of the packs from each quadrant—one quadrant at a time. Packs should be removed from the quadrants that you least suspect to be the source for blood loss, followed by removal of the packs from the final quadrant—the one that you believe is the area of concern.

After control of major hemorrhage has been achieved, any evidence of gross contamination must be addressed immediately. Obvious leakage from intestinal injury can be initially controlled with clamps (eg, Babcock clamp), staples, or sutures. The entire abdominal gastrointestinal tract needs to be inspected, including the mesenteric and antimesenteric border of the small and large bowel, along with the entire mesentery. Rents in the diaphragm should also be closed to prevent contamination of the thoracic cavity.

Further identification of any and all intra-abdominal injuries should be initiated. Depending on the mechanism of injury and the estimated trajectory of the wounding agent, a thorough and meticulous abdominal exploration should be performed, including entering the lesser sac to better inspect the pancreas and the associated vasculature. In addition, mobilization of the C-loop of the duodenum (Kocher maneuver) might be required, along with medial rotation of the left and/or right colon for exposure of vital retroperitoneal structures.

The final component of a trauma laparotomy is definitive repair, if possible, of specific injuries. As will be highlighted later in the chapter, the status of the patient dictates whether each of the components of a trauma laparotomy can be achieved at the index operation. A staged celiotomy ("damage-control" laparotomy) might be necessary if the patient becomes acidotic, hypothermic, coagulopathic, or hemodynamically compromised.

Definitive Management of Specific Injuries

SMALL INTESTINES

Isolated small bowel enterotomies can be closed primarily with nonabsorbable sutures for a one-layer closure. If the edges of the enterotomy appear nonviable, they should be gently debrided prior to primary closure. However, multiple contiguous small bowel holes or an intestinal injury on the mesenteric border with associated mesenteric hematoma will likely necessitate segmental resection and anastomosis of the remaining viable segments of the small bowel. The operative goal is always the reestablishment of intestinal continuity without substantial narrowing of the intestinal lumen, along with closure of any associated mesenteric defect. Application of noncrushing bowel clasps can contain ongoing contamination while the repair is being performed. Although a hand-sewn or stapler-assisted anastomosis is operator dependant, trauma laparotomies are time-sensitive interventions and expeditious management is imperative.

COLON

The segment of injured bowel should be thoroughly inspected, particularly missile injuries that are most common, for through-and-through enterotomies. This requires adequate mobilization of the colon in order to visualize the entire circumference of the bowel wall. Initially controversial, an enterotomy (right- or left-sided injuries) of the colon can be closed primarily, irrespective of contamination or transient shock state.[26] If the colon injury is so extensive that primary repair is not possible or would severely compromise the lumen, a segmental resection should be performed. Depending on the setting, the remaining proximal segment can be anastomosed to the distal segment or a proximal ostomy and Hartmann's procedure can be performed. If the distal segment is long enough, a mucous fistula should be established. Documented rectal injuries, below the peritoneal reflection should necessitate a diverting colostomy and presacral drainage (exiting from the perineum). Such drainage is, however, not universally endorsed.

STOMACH/DUODENUM

With respect to penetrating wounds of the stomach, the anterior and posterior aspects of the stomach need to be meticulously inspected for accompanying through-and-through injuries. Penetrating injuries of the stomach should be repaired primarily after debridement of nonviable edges. The primary repair can either be performed in a single layer with nonabsorbable suture or as a double layer closure with an absorbable suture (eg, Vicryl) for the first layer and the second layer being closed with unabsorbable sutures (eg, silk). There are very few penetrating injuries of the stomach that would compromise the gastric lumen. Also, it is unlikely that primary repair of a through-and-through stomach injury would compromise the gastric lumen. Duodenal injuries can be repaired primarily in a one- or two-layered fashion if the penetration is less than half the circumference of the duodenum. However, for more complex duodenal injuries, an operative procedure is needed to divert gastric contents away from the site (where closure of the wound has been attempted). Performing a pyloric exclusion with the establishment of a gastrojejunostomy is such a procedure.[27–29]

PANCREAS

Superficial or tangential penetrating wounds of the pancreas, in which there is not an injury to the main pancreatic duct, can be externally drained. However, a penetrating injury that transects the pancreas, including the main pancreatic duct, requires extirpation of the distal pancreas (distal pancreatectomy), particularly if the transection site is to the left of the superior mesenteric vessels. A more proximal penetrating injury that involves the main pancreatic duct, with associated complex duodenal injury (eg, injury to the ampulla), would likely necessitate a pancreatoduodenectomy. Unfortunately, because of the rich vascular network surrounding the pancreas, penetrating pancreatic wounds can be lethal injuries.

SPLEEN

Most penetrating splenic injuries, particularly gunshot wounds, require a splenectomy. In order to visualize the entire spleen, it should be mobilized to the midline by dividing its ligamentous attachments. Superficial penetrating injuries of the spleen can sometimes be managed by either splenorrhaphy or application of a topical hemostatic agent. Splenorrhaphy can be

done by a pledgeted repair or an omental buttress. However, complex repair of the spleen is not a prudent approach in the always time-sensitive trauma setting.

GALLBLADDER AND LIVER

Penetrating injuries to the gallbladder dictate the need for extirpation. There is no role for primary repair of a penetrating wound to the gallbladder.

Liver injuries are common in both blunt and penetrating trauma. The majority of injuries are superficial or minor and require no surgical repair. Simple application of pressure and/or a hemostatic agent or fibrin glue will constitute definitive management of the majority of these injuries. The argon beam coagulator, also a helpful adjunct in superficial hepatic injuries with persistent oozing, generates ionizing energy through an argon gas stream that causes rapid coagulation. The operative armamentarium for complex penetrating hepatic injuries is highlighted in Table 12-2.

GENITOURINARY SYSTEM

Fewer than 10% of patients with penetrating abdominal wounds sustain genitourinary tract injuries. The majority of the injuries are renal. Penetrating injuries that result in a grade IV (cortical/calyceal injury and associated vascular injury with contained hemorrhage) or grade V (shattered kidney and vascular avulsion) invariably necessitate a nephrectomy, particularly if there is a viable contralateral kidney. Lacerations or more superficial wounds of the kidney might require renorrhaphy, with approximation of the disrupted capsule with pledgeted sutures or a prosthetic (mesh) wrap. Absorbable interrupted suture should be used and all repairs should be drained. The injury pattern might dictate the need for a partial nephrectomy. Ureteral injuries can be extremely difficult to identify in penetrating wounds with an accompanying retroperitoneal hematoma. When possible, the ureter should be repaired primarily with interrupted absorbable suture over a double J-stent. A complete transection of the ureter requires debridement of the nonviable edges and the ends being spatulated, with and primary repair over a stent. All repair sites should be adequately drained. If the anastomosis cannot be performed in a tension-free fashion, a bladder flap (Boari) could be surgically constructed, with implantation of the proximal segment of the transected ureter into the flap. A psoas "hitch" might be required if there is any tension on the flap and the tunneled ureter.

Penetrating injury to the intraperitoneal bladder requires surgical repair. After no involvement of the trigone is confirmed, the bladder should be closed with a two-layer closure with absorbable suture (the second layer incorporates Lembert sutures to imbricate the first layer). Suprapubic drainage should only be done selectively; however, a Foley catheter should be left in place.

- Abdominal packing

Retroperitoneal Hematomas

The retroperitoneum, an organ-rich region, has several vital structures that can be injured when its boundaries are penetrated. It can be a major potential site for hemorrhage in patients sustaining either penetrating or blunt trauma due to the substantial vascularity along with bleeding that can occur from an associated solid organ wound (eg, kidney). In the central region (zone 1) of the retroperitoneum reside the abdominal aorta; celiac axis; and the superior mesenteric artery, vena cava, and proximal renal vasculature. The lateral retroperitoneum (zone 2) encompasses the proximal genitourinary system and its vasculature. The pelvic retroperitoneum (zone 3) contains the iliac arteries, veins, and tributaries of veins. In addition to the vasculature and the kidneys (plus ureters) highlighted above, the retroperitoneum contains the second, third, and fourth portions of the duodenum, along with the pancreas, the adrenals, and the intrapelvic portion of the colon and rectum. Table 12-3 underscores the management principles of trauma-related retroperitoneal hematomas. Ideally, proximal (and when applicable, distal) control need to be achieved before exploring any retroperitoneal hematoma. For retroperitoneal hematomas in zone 1, mandatory exploration is required irrespective of a penetrating or blunt mechanism. Also, retroperitoneal hematoma in any of the three zones requires exploration for all penetrating injuries. For zone 2 retroperitoneal hematomas resulting from blunt trauma, all pulsatile or expanding hematomas should undergo exploration. Gross extravasation of urine also necessitates exploration. Zone 3 (pelvic retroperitoneum) hematomas should be explored only for penetrating injuries to determine if there is a specific intrapelvic colorectal, ureteral, or vascular injury. However, such an approach should not be taken for blunt trauma, for the injury would likely be venous and application of an external compression device would be the

preferred intervention. An arterial injury could be addressed by arteriography/embolization.

Intra-abdominal Packing and "Damage-Control" Strategy

"Damage-control" strategy, popularized by Rotondo et al, is a staged celiotomy strategy that was initially made operational by Mattox and Feliciano and was labeled the "Bogota bag" approach. Although Mattox and Feliciano did not actually develop this approach, they certainly popularized the technique and made it acceptable for use in the United States.[30–34] Irrespective of the name given to this strategy of surgically managing only immediate life-threatening injuries (along with intra-abdominal packing and rapid temporary closure of the abdominal cavity), the goal is the same—avoiding the potential irreversibility of sustained acidosis, hypothermia, coagulopathy, and hemodynamic lability by delaying definitive operative management until the patient can be stabilized in the intensive care unit. Although "damage control" is most frequently used in association with severe hepatic wounds, other organ injuries, including vascular wounds, can necessitate this staged celiotomy approach with hepatic packing and a rapid, creative abdominal closure.

MANAGEMENT OF BLUNT ABDOMINAL TRAUMA

Introduction

Management of blunt abdominal trauma has undergone significant change over the past two decades, evolving from a primary operative scheme to more nonoperative management. The workup has shifted largely from the use of physical examination, plain x-ray, laboratory findings, and DPL to the extensive use of CT and ultrasonography. Treatment for visceral injury has traditionally been surgical, but many forms of solid-organ injury can now be managed nonoperatively or with minimally invasive and interventional radiology techniques. Management of the multiply injured trauma patient at level I trauma centers with state-of-the-art techniques has now conclusively shown significantly improved patient outcomes and survival.[35]

Diagnostic and Imaging Techniques

DIAGNOSTIC PERITONEAL LAVAGE

Originally described by Root in 1965, diagnostic peritoneal lavage (DPL) has been a mainstay in the management of blunt abdominal trauma for over four decades.[36] Before the era of routine CT scanning, it was used as a screening tool to evaluate patients having blunt or penetrating abdominal trauma with an accuracy rate reported between 92 and 98%.[37–42] Because of its invasive nature, DPL has largely been supplanted by CT scans and FAST. However, it remains an excellent tool for further workup of occult bowel injury or in unstable patients when FAST is not available or has questionable findings. In the workup for occult bowel injury, traditional parameters (Table 12-4) should be used to guide therapy. In unstable patients, a diagnostic tap is usually all that is necessary, and exploration indicated for greater than 10 mL of gross blood.

TABLE 12-4: DIAGNOSTIC CRITERIA FOR A POSITIVE DPL

Any Viscus	Bowel
10 mL gross blood	Bacteria
>100,000 red blood cell/mm^3	Bile
>500 white blood cell/mm^3	Food particles
>75 IU/L amylase	

The pitfalls of DPL are a relatively high false-positive rate, risk of creating visceral injury, and poor sensitivity for detecting injury to retroperitoneal structures such as the pancreas and duodenum.[43–45] Iatrogenic events are minimized if a Foley catheter and nasogastric tube are placed prior to the procedure. Patients with pelvic fractures and suspected retroperitoneal hematoma or pregnant females should undergo a supraumbilical approach. Visceral injury is less likely with an open approach but more time consuming and invasive.[46–49] Checking amylase or lipase in lavagate, concomitant use of CT scan, and a high index of suspicion are necessary to avoid missed retroperitoneal injury.

FOCUSED ABDOMINAL SONOGRAPHY FOR TRAUMA

One of the most recent advances in the workup of the acutely injured patient is the use of bedside ultrasonography for detection of cardiac and intra-abdominal injury. Known as focused abdominal sonography for trauma (FAST), this technique's noninvasive nature allows the operator to perform an examination simultaneously during the initial resuscitation and stabilization of a multiply injured trauma patient. The technique may thereby provide evidence of significant hemorrhage early in the course of an evaluation. An ultrasound probe is used to examine four key windows for fluid: the subxyphoid area permits visualization of the pericardium, the left subcostal area visualization of the splenorenal recess, right subcostal area visualization of Morison's pouch, and the suprapubic area visualization of the pelvic cul-de-sac (Fig. 12-6). The presence of fluid may indicate then presence of cardiac tamponade, intra-abdominal hemorrhage, hollow viscus perforation, hemoperitoneum, or ascites. False-positive results secondary to preexisting ascites or false negatives due to operator error and/or body habitus are the main limitations. Scanning the supra pubic area with distension of the

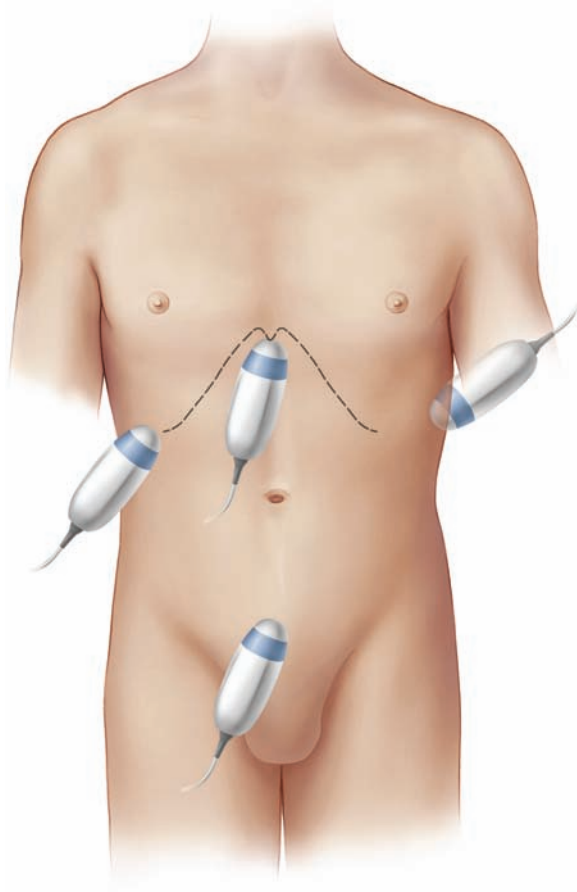

FIGURE 12-6 Schematic showing sonographic windows for (1) subxyphoid, (2) left subcostal, (3) right subcostal and suprapubic areas. Distension of the urinary bladder either prior to Foley catheter placement or by installation of 150–200 mL normal saline will enhance sensitivity. (Redrawn from Rozycki GS, Ochsner MG, Schmidt JA, et al. A prospective study of surgeon-performed ultrasound as the primary adjuvant modality for injured patient assessment. *J Trauma*. 1995;39:492–498; discussion 498–500.)

urinary bladder will enhance the sensitivity of the examination for the detection of pelvic fluid. A threshold of at least 200 mL of fluid in the abdominal cavity is necessary for detection, and intra-abdominal injuries must be associated with the presence of this much free fluid for a positive finding.[50] Reported sensitivities range between 73 and 88% and specificity between 98 and 100%.[51] Accuracy rates range from 96 to 98%. FAST is an inexpensive, rapid, portable, noninvasive technique that can be performed in serial fashion if there is a change in patient stability.[52–54] Additionally, it obviates the risk of exposing pregnant females to radiation. Positive findings in stable patients can be further evaluated with CT or DPL while unstable patients with a positive finding may be taken to the operating room for emergent exploration. Workup of a patient with a reliable abdominal examination may be complete with a negative FAST in the absence of abdominal signs or symptoms.

COMPUTED TOMOGRAPHY

Technological advances in CT have revolutionized the initial management of trauma patients over the past two decades. Multidetector scanners have dramatically improved resolution and accuracy of these imaging studies. Negative predictive values as high as 99.63% have been reported for patients sustaining significant mechanisms of blunt trauma allowing the use of CT as a reliable and noninvasive tool for screening patients with blunt abdominal trauma.[55] In light of modern-day CT capabilities, prospective data have demonstrated that patients with a signinficant mechanism and a benign abdomen can be released from the emergency department if a CT scan of the abdomen shows no evidence of visceral injury provided that there are no other reasons for hospitalization.[55]

CT reliably identifies injuries in solid organs such as the spleen, liver, and kidney because of their vascular nature demonstrating disruption of normal architecture, associated free fluid, and the so-called vascular blush.[56] Grading scales have been developed to allow for accurate classification and determination of management plan (Tables 12-5 through 12-7).[56,57]

TABLE 12-5: SPLEEN INJURY SCALE OF THE AMERICAN ASSOCIATION FOR THE SURGERY OF TRAUMA, 1994 REVISION

	Grade[a]	Injury Description	ICD-9[b]	AIS-90[c]
I	Hematoma	Subcapsular, <10% surface area	865.01 865.11	2
	Laceration	Capsular tear, <1 cm parenchymal depth	865.02 865.12	2
II	Hematoma	Subcapsular, 10–50% surface area; intraparenchymal, <5 cm in diameter	865.01 865.11	2
	Laceration	1–3 cm parenchymal depth that does not involve a trabecular vessel	865.02 865.12	2
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma		3
		Intraparenchymal hematoma	865.03	
	Laceration	>5 cm or expanding >3 cm parenchymal depth or involving trabecular vessels	865.13	3
IV	Laceration	Laceration involving segmental or hilar vessels producing major devascularization (>25% of spleen)		4
V	Laceration	Completely shattered spleen	865.04	5
	Vascular	Hilar vascular injury that devascularizes spleen	865.14	5

TABLE 12-6: LIVER INJURY SCALE OF THE AMERICAN ASSOCIATION FOR THE SURGERY OF TRAUMA, 1994 REVISION

	Grade[a]	Injury Description	ICD-9[b]	AIS-90[c]
I	Hematoma	Subcapsular, <10% surface area	864.01 864.11	2
	Laceration	Capsular tear, > 1 cm parenchymal depth	864.02 864.12	2
II	Hematoma	Subcapsular, 10–50% surface area; intraparenchymal, <10 cm in diameter	864.01 864.11	2
	Laceration	1–3 cm parenchymal depth, <10 cm in length	864.03 864.13	2
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma Intraparenchymal hematoma >10 cm or expanding >3 cm parenchymal depth		3
	Laceration		864.04 864.14	3
IV	Laceration	Parenchymal disruption involving 25–75% of hepatic lobe or 1–3 Couinaud's segments within a single lobe	864.04 864.14	4
V	Laceration	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud's segments within a single lobe		5
	Vascular	Juxtahepatic venous injuries; ie, retrohepatic vena cava/central major hepatic veins		5
VI	Vascular	Hepatic avulsion		6

[a] Advance one grade for multiple injuries, up to grade III.
[b] ICD, International Classification of Diseases, 9th Revision
[c] AIS, Abbreviated injury score.

TABLE 12-7: KIDNEY INJURY SCALE OF THE AMERICAN ASSOCIATION FOR THE SURGERY OF TRAUMA

	Grade[a]	Injury Description	ICD-9[b]	AIS-90[c]
I	Contusion	Microscopic or gross hematuria, urologic studies normal	866.00 866.02	2
	Hematoma	Subcapsular, nonexpanding without parenchymal laceration	866.11	2
II	Hematoma	Nonexpanding perirenal hematoma confined to renal retroperitoneum	866.01	2
	Laceration	Parenchymal depth of renal cortex (>1.0 cm) without urinary extravasation	866.11	2
III	Laceration	Parenchymal depth of renal cortex (>1.0 cm) without collecting system rupture or urinary extravasation	866.02 866.12	3
IV	Laceration	Parenchymal laceration extending through the renal cortex, medulla, and collecting system	866.02 866.12	4
	Vascular	Main renal artery or vein injury with contained hemorrhage		4
V	Laceration	Completely shattered kidney	866.03	5
	Vascular	Avulsion of renal hilum which devascularizes kidney	866.13	5

[a] Advance one grade for bilateral injuries up to grad III.

Detection of bowel injury via CT scan in patients who are intoxicated, intubated, or have associated closed-head injury or other distracting injuries can present a diagnostic challenge in the absence of a reliable abdominal exam. The incidence of blunt bowel injury varies from series to series but is generally reported in the 1–5% range in all blunt trauma patients admitted to level I trauma centers.[58,59] A high index of suspicion is predicated on mechanism of injury and physical examination findings such as abdominal wall tattooing and/or the seat belt sign. CT findings may be direct such as extravasation of oral contrast or pneumoperitoneum or more commonly indirect such as bowel wall thickening, stranding of the mesentery, or free fluid in the absence of solid organ injury. Indirect findings may be fairly nonspecific and secondary to bowel edema from resuscitation or preexisting ascites. Reproductive age females may have a small amount of normal or "physiologic" pelvic fluid present sometimes adding to the complexity of the evaluation. Patients on positive pressure ventilation or with significant barotrauma may develop mediastinal or subcutaneous emphysema that can tract through the peritoneum or retroperitoneum and give the appearance of free air. Great care in the radiologic interpretation and close clinical correlation are necessary in such cases. The liberal use of DPL may prevent nontherapeutic laparotomy. Obviously, when significant doubt remains, abdominal exploration may be necessary to confirm an injury.

The role of oral contrast in the evaluation of the acutely injured patient has recently come under question. Little time

is usually available in the emergent setting to permit adequate opacification of the small bowel. Patients are further at risk for aspiration of the contrast media, and administration often requires placement of a nasogastric tube. A number of reports now have shown that elimination of oral contrast media does not lead to an increased incident of missed bowel injury.[58–60] Many centers have now safely eliminated the use of oral contrast media from their routine trauma protocols expediting management and ease of patient care. Resuscitation edema may cause a hazy appearance around the head of the pancreas and duodenal c-loop raising the question of a pancreas or duodenal injury. Further clarification in this situation can be obtained, when it occasionally occurs, via repeat CT scan with the administration of oral contrast and the injection of 300- to 500-cc bolus of air down the nasogastric tube and may make the pneumoperitoneum obvious.

CT may also be of great importance in identifying patients with arterial hemorrhage related to pelvic fracture. CT imaging may demonstrate an arterial blush or large hematoma in the vicinity of a pelvic fracture indicating the need for pelvic arteriography or pelvic external fixation. A "CT cystogram" may also be helpful and eliminate redundancy of x-ray evaluation. The Foley catheter is clamped after placement in the trauma bay. Real-time interpretation, as the CT scan is performed by the evaluating physician, may dictate further delayed images or a formal three-view (anterior/posterior, lateral, and postvoid views) cystogram.

Specific Organ Injury

THE SPLEEN

The spleen is the most commonly injured intra-abdominal organ followed by the liver and small bowel in blunt trauma patients. The spleen's location in the left upper quadrant lends susceptibility to injury from broken ribs, deceleration, and blunt percussion forces. Clinically, patients with splenic injury may present with hypotension, left upper quadrant pain, or tenderness to palpation or diffuse peritonitis from extravasated blood. Referred pain to the left shoulder on deep inspiration, in face of splenic hematoma, is known as *Kehr's sign*.

Nonoperative Management. Most series indicate that approximately 60–80% of patients presenting with blunt splenic injury can be managed nonoperatively at level I or II trauma centers.[61–65] Facilities without the resources and experience of a bona fide trauma team may not safely meet the demands of nonoperative management and should consider patient transfer.[66] Patients selected for nonoperative management must have stable vital signs, be free of peritoneal signs or other concern for hollow viscus injury, and have no evidence of free extravasation of IV contrast from the splenic parenchyma.

Considerable debate remains regarding risk factors for failure of nonoperative management. Higher splenic injury grade, age greater than 55 years, moderate to large hemoperitoneum, subcapsular hematoma, and portal hypertension have all been suggested to increase the risk of failure. Early reports in the evolution of nonoperative management regarding ASST grade did not demonstrate higher failure rates for higher-grade injury. More recent reports using high-resolution multidetector CT scanners allow better assessment of injury grade. The data from these studies show patients with injury grades III–V to be at increased risk for nonoperative failure.[61,63] Age continues to be controversial subject matter in the literature with numerous reports claiming that age greater than 55 years *is* or *is not* a risk factor for failure.[61,63,67] Documentation of a moderate or large hemoperitoneum is suggestive of a major injury and should be considered a significant factor in individual patient assessment.

Patients with splenic subcapsular hematoma or history of portal hypertension are specific subgroups of patients who deserve special consideration. Patients with subcapsular hematoma in our experience tend to ooze from the raw parenchymal surface and further disrupt the capsule leading to more raw surface area to bleed. These patients are at increased risk for delayed rupture 6 to 8 days following injury and may already be discharged from the hospital if they have isolated injury. Furthermore, splenic embolization is not a very effective treatment of this condition because it usually necessitates coiling of the main splenic artery that can lead to significant pain and abscess formation. A history of portal hypertension or cirrhosis, while not absolute contraindications to nonoperative management, certainly should raise concerns. The general risks of laparotomy in a Childs B or C cirrhotic need to be carefully weighed against the risk of ensuing and worsening coagulopathy. This scenario may, indeed, call for main splenic artery embolization. None of these risk factors alone should dictate the decision to proceed immediately to operative intervention. Nonoperative management does reduce hospital length of stay and transfusion requirement; however, the morbidity of splenectomy should remain low in any surgeon's hands. Overall, the patient's condition, including comorbidities, coagulopathy, and other problems (such as traumatic brain injury, aortic injury and suspicion for concomitant hollow viscus injury) factor into the decision making process. No one should ever succumb to splenic hemorrhage that was undergoing nonoperative management.

Management of Blunt Splenic Injury. Approximately 20% of patients initially undergoing nonoperative management of blunt splenic injury require further intervention. Failure has been associated with the presence of a contrast blush in up to two-thirds of these patients.[68] The presence of a contained contrast blush within the parenchyma of the spleen represents pseudoaneurysm formation of a branch of the splenic artery. Angioembolization is now commonly used to selectively occlude the arterial branches containing these injuries.[61,62,65,69,70] Implementation of this salvage technique at centers that routinely screen for the presence of pseudoaneurysm has increased the success of nonoperative management to 90% or greater.

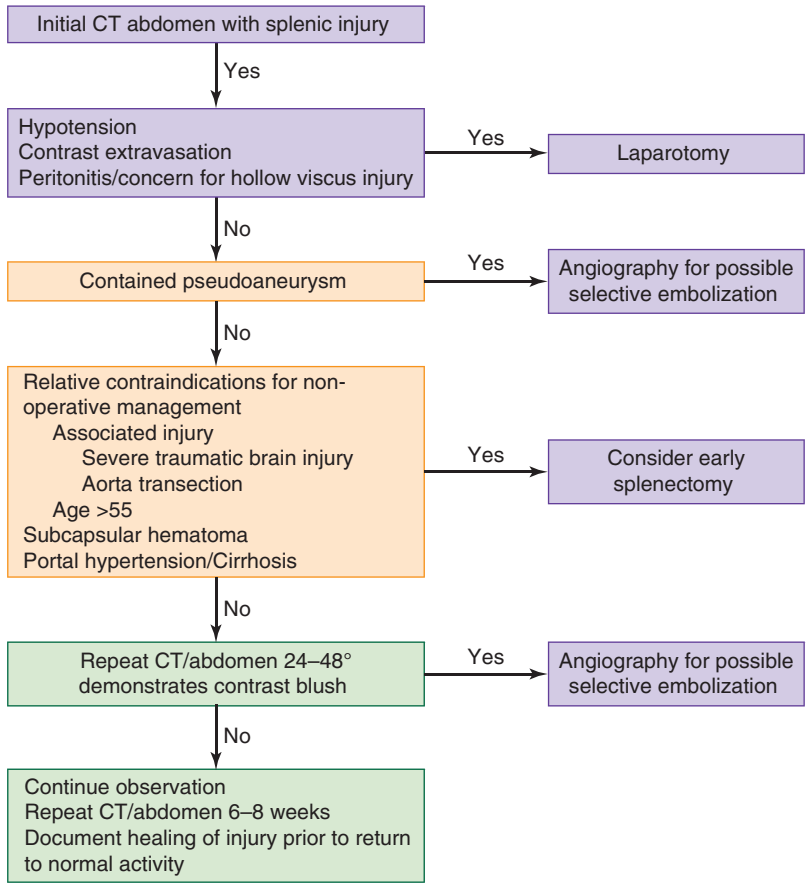

FIGURE 12-7 Management algorithm for blunt splenic injury.

Pseudoaneurysm formation has been observed in even grades I and II injuries and may not be present on the initial imaging.[61,64,70] Therefore, follow-up CT scan is recommended on all patients with splenic trauma within 24–48 hours after injury. If these images show stable injuries without pseudoaneurysm formation, expectant management may ensue. Figure 12-7 is a management algorithm for the patient with blunt splenic injury.

Long-term data are unavailable concerning the risk of outpatient or delayed rupture, but the incidence is low and has been reported to be about 1.4%.[71] The average date to readmission for delayed splenectomy after discharge was 8 days in this study. Lower-grade (I, II) injuries tend to heal more quickly and most all injuries are healed by 5–6 weeks.[72] However, approximately 20% of blunt splenic injuries will not show complete healing and may be at risk for pseudocyst formation. A CT scan should be repeated in 6 weeks for grades I and II injuries and 10–12 weeks in grades III–V before reinstating normal activity.

Splenectomy. Patients requiring urgent or emergent intervention for splenic hemorrhage may develop hypothermia, coagulopathy, and visceral edema. The most expeditious and safest course of action under these conditions is removal of the spleen. The general assumption of abdominal exploration for trauma is that there are known and, possibly, unknown injuries. The operative approach is via a midline vertical incision that allows the best exposure and facilitates temporary abdominal closure should visceral edema or damage-control measures be necessary. Standard operating procedure is similar to that previously highlighted in the section, Management of Penetrating Abdominal Trauma.

With respect to performing a splenectomy, a Buckwalter retractor is used to expose the left upper quadrant. The spleen is retracted medially with some downward compression, and the posterior attachments can be taken with the cautery. Once these attachments are freed, the spleen can be mobilized medially for optimal exposure. The assistant stands on the left side of the table and supports the spleen while the surgeon ligates short gastric and hilar vessels. Being careful to avoid the tail of the pancreas, a large clip, placed on the specimen side of the splenic hilum, will reduce back-bleeding and expedite the procedure. Once the spleen has been removed, the splenic fossa is inspected for further bleeding with a rolled laparotomy pad.

Splenorrhaphy. Hemodynamically stable patients found to have small to moderate amounts of parenchymal hemorrhage at laparotomy may be candidates for splenic preservation.

The spleen is mobilized into the wound using the same technique as for splenectomy. The injury to the spleen is assessed and decision is made whether to resect a portion if the parenchymal injury extends into the hilum or if arterial bleeding is coming from within the splenic laceration itself. If the decision is made to resect the upper or lower pole, the parenchyma is divided with the cautery, and the associated hilar vessels are taken with clamps and ties. Any arterial bleeding from the parenchyma is controlled with suture ligature and the cautery is used to control oozing from the parenchyma. A tongue of omentum is then sutured into the laceration or to the raw surface of the remaining spleen in the case of resection. Approximately 50% of the spleen is required to preserve adequate phagocytic and immunologic function. If this cannot be achieved, a splenectomy is probably the best option.

Overwhelming Postsplenectomy Infection. The incidence of overwhelming postsplenectomy infection (OPSI) following trauma is not well understood because it may not be appreciated when it occurs and it is not routinely reported. However, the reported incidence of OPSI in adult patients undergoing splenectomy for all causes is 0.9% with a mortality of 0.8%.[73] The risk of OPSI in adults following trauma is felt to be lower than the incidence seen after splenectomy for hematological disorders such as idiopathic thrombocytopenic purpura (ITP), lymphoma, and thalassemia. Children are at greater risk for OPSI and should receive prophylactic penicillin V 125 mg twice daily until age 3 and then 250 mg twice daily until age 5. Currently, anyone older than 2 years should receive the 23 valent pneumococcal vaccine and a one-time dose of the *Haemophilus influenzae* and meningococcal vaccine. A one-time booster dose of the pneumococcal vaccine is recommended 5 years after the original vaccine.[74]

The Liver

The liver is susceptible to the same blunt force mechanisms as the spleen making it the second most frequently injured intra-abdominal organ. Similar to the spleen, nonoperative management of blunt liver injury has greatly reduced transfusion requirements, hospital length of stay, and mortality.[75–78] Angiographic embolization of arterial injury has also greatly reduced the morbidity and mortality of liver trauma. Complications of nonoperative management such as biloma and liver abscess can usually be managed with minimally invasive techniques as well. What is imperative in the management scheme is the knowledge of when to take the patient immediately to the operating room for active hemorrhage versus attempting nonoperative management with angioembolization. The liver is obviously not as expendable an organ as the spleen, and there is no substitute for an in-depth knowledge and experience handling hepatic injuries.

NONOPERATIVE MANAGEMENT

Similar to the experience with blunt splenic trauma, routine use of CT scans has revolutionized the management of blunt hepatic trauma. The most recent data show that 70–85% of all patients presenting with blunt liver trauma can be managed nonoperatively.[75,76,79,80] Patients must be hemodynamically stable, free of peritoneal signs or other evidence of bowel injury, and have absence of contrast extravasation. Worsening grade of injury makes nonoperative management less likely, but injury grade alone should *not* dictate the decision to intervene.[78,81] Patients should have a stable systolic blood pressure greater than 90 mm Hg with a heart rate less than 100 beats/min after controlling other possible sources of extra-abdominal blood loss, such as orthopedic and soft tissue injuries. Failure from subsequent liver hemorrhage occurs in 0.4–5% of patients and failure due to missed injury of other intra-abdominal organs, such as the kidney, spleen, pancreas, and bowel, occurs in 0.5–15% of patients.[75,76,79,81,82] These data are summarized in Table 12-8. It is difficult to tell the specific cause of immediate surgery in the earlier reports because laparotomies for *all* causes, such as associated splenic hemorrhage, were included. Christmas et al and Velmahos et al

TABLE 12-8: FAILURE RATES FOR NONOPERATIVE MANAGEMENT OF LIVER TRAUMA

Study (year)	Number of Patients	Immediate Surgery (%)	Overall Failure Rate (%)	Liver Failure Rate (%)	Other Failure Rate (%)
Meredith et al[81] (1994)	116	48	3	3	0
Croce[75] (1995)	136	18	11	5	6
Pacther et al[82] (1996)	404	53	1.2	0.7	0.5
Malhotra[76] (2000)	661	15	7	3	4
Velmahos et al[79] (2003)	78	29[a]	15	0	15
Christmas et al[78] (2005)	561	32[b]	1.8	0.4	1.4

Other failure refers to failure due to injuries from other intra-abdominal organs such as the spleen, kidney, pancreas, or bowel.
[a] 15% for liver bleeding.
[b] 13% for liver bleeding.

report that rates of immediate operative intervention for liver hemorrhage are 15 and 13%, respectively.[78,79]

Angiographic embolization is a useful adjunct in the management of blunt hepatic trauma both in nonoperative patients and those who have undergone damage-control laparotomy in a number of small series.[78,79,83–89] Intravenous contrast extravasating from the liver parenchyma into the peritoneal cavity and contrast contained within the parenchyma of the liver associated with a large amount of intraperitoneal blood on initial CT scan are emergent situations mandating angiographic embolization or surgery.[90] If bleeding appears to originate from the retrohepatic vena cava or hepatic veins and is ongoing, emergent exploration is the only choice because arterial embolization is ineffective in these scenarios. Patients with labile blood pressure and parenchymal injury may be better served with emergent exploration depending on the time necessary to assemble the angiography team. However, if angiography is readily available, favorable results have been obtained transporting patients to the angiography suite with ongoing resuscitation for arterial bleeding.[86,91] Patients requiring significant resuscitation during a successful embolization procedure may still be at risk for abdominal compartment syndrome and should have bladder pressures monitored if they receive greater than 10 units of blood products.[79,92]

Patients with contrast extravasation contained within the liver parenchyma without significant associated hemoperitoneum are less worrisome but should probably undergo arteriogram for further assessment.[90] A perceived contrast blush on CT scan is associated with bleeding identified at angiography in approximately 60% of patients.[87] Arteriography in the absence of contrast extravasation will likely be a low-yield study. Patients requiring operative exploration of their liver wounds that have arterial bleeding from deep within the liver parenchyma may benefit from hepatic packing with radiolucent laparotomy pads and direct transportation to the angiography suite.[83,84,88]

Several complications can occur in the management of liver trauma, including biloma, hepatic necrosis, liver abscess, and gallbladder necrosis.[85] Minimally invasive techniques can be successfully used to handle the majority of these complications. Biloma can occur after significant damage to the biliary tree. Patients may present with an ileus, abdominal pain, distention, or an abscess often with some degree of hyperbilirubinemia. Percutaneous drainage for localized collections will often control the leak and immediate symptomatology.[87,88] Persistent bile leak will usually require an endoscopic retrograde cholangiopancreatography (ERCP) with biliary stent placement. Patients with hepatic duct or common bile duct injury may require hepatectomy or hepaticojejunostomy. Patients with generalized ascites may benefit from laparoscopic washout and placement of perihepatic drains followed by ERCP for persistent leak.[78,88]

Simple abscess can usually be managed with percutaneous drainage, unless significant hepatic necrosis simultaneously exists.[88] Sterile liver necrosis may eventually resolve with expectant management but usually requires hepatic debridement when associated with infection. Patients who undergo embolization without surgery have approximately a 20% chance of developing infected necrosis, while patients who undergo laparotomy followed by hepatic artery embolization have an incidence of hepatic necrosis of over 80% in one series.[85] Gallbladder necrosis occurs in approximately 20% of grades IV and V injury following nonselective embolization of the right hepatic artery.[87] These patients usually present several days after injury with leukocytosis, hyperbilirubinemia, and abdominal pain. HIDA (hepatobiliary iminodiacetic acid) scan and a high index of suspicion may be necessary to differentiate this diagnosis from the others listed.

OPERATIVE MANAGEMENT

Bleeding from minor liver injuries (grades I and II) usually stops spontaneously, and surgical intervention is rarely required.[75,81,93] Occasionally, patients may require exploration for other injuries after abdominal trauma in the presence of minor liver trauma. Nonbleeding liver injuries should be left alone. In the face of coagulopathy or hypothermia, minor hepatic injuries may present with persistent oozing. In such cases, topical hemostatic agents, with or without perihepatic packing, may be all that is necessary to stop the bleeding if the patient is being adequately resuscitated.

Major liver injuries (grades III–V) are more likely to bleed and require surgical intervention. Because grades IV and V liver injuries can present formidable technical challenges even in the hands of the most capable individuals, a variety of surgical techniques have been developed for their management.

Large liver wounds should be quickly inspected to get some idea about the degree of hemorrhage and then packed off initially. Anesthesia should be notified about anticipated blood loss and blood availability checked. Vital signs and resuscitation status should be reviewed. Bleeding should be contained with packing and direct pressure until anesthesia has had time to "catch up." Remaining focused and well organized, as well as replenishing intravascular volume, is invaluable in the management of any trauma patient.

The most direct approach at this point is to remove the packing and visually inspect for bleeding vessels which can be individually ligated. Debridement of devitalized tissue using finger fracture technique will expose additional bleeding vessels which may have retracted into the surrounding parenchyma. If bleeding prevents adequate visualization of the surgical field, the next step should be vascular control of the portal triad (ie, the Pringle maneuver).[93] This maneuver is easiest to perform for the person standing on the left of the patient. This individual places the fingers of the left hand into the foramen of Winslow and uses the thumb to palpate for the cord of tissue running into the caudal surface of the liver. Once this structure is suspected, its identity can generally be confirmed by appreciating the pulse in the hepatic artery. A hole is then created in the hepatoduodenal ligament using blunt finger dissection. A noncrushing vascular clamp can be applied or a ½-in. Penrose drain can be doubled, looped around the porta and cinched down with a Kelly clamp. We prefer the latter technique because it seems to be less obtrusive

to further manipulation of the liver and may be less traumatic to the structures of the porta.

If a Pringle maneuver does not adequately decrease liver bleeding, concern for hepatic vein or retrohepatic caval injury should be entertained. Obtaining adequate exposure in deep liver wounds or in juxtahepatic caval injuries is of utmost importance. The falciform ligament is taken off the diaphragm posteriorly to the bare area. The right and left triangular ligaments are dissected with the cautery extension to the corresponding coronary ligaments. Further dissection of the coronary ligaments to the bare area will allow vigorous mobilization of the liver into the surgical field. Careful dissection of the bare area will allow access to the suprahepatic inferior vena cava. If the plane in the bare area is difficult to develop, a transverse incision in the diaphragm here will gain access to the pericardium and intrapericardial control of the inferior vena cava can be achieved.[94] Total hepatic isolation can be achieved with a Pringle maneuver and vascular control of the infrahepatic, suprarenal inferior vena cava, and the suprahepatic intra-abdominal or intrapericardial inferior vena cava. The final step in this procedure is occluding inflow to the intra-abdominal aorta at the diaphragm while cardiac return from the lower body is eliminated. The physiologic stress of this technique may not be well tolerated in patients with severe shock and clamp times less than 20–30 minutes should be maintained.

Vascular shunts of the liver, otherwise known as atriocaval shunts, have been devised to circumvent impeding cardiac return when vascular isolation of the liver is desired.[95] In this procedure, early recognition of juxtahepatic venous injury is essential and liver bleeding is temporarily contained with packing and direct pressure.[96] A two-team approach is best; a median sternotomy is performed simultaneously while gaining vascular control of the infrahepatic suprarenal vena cava with a Rumel tourniquet. A Rumel tourniquet is also necessary around the intrapericardial inferior vena cava. A purse-string suture is placed in the right atrial appendage, and an opening is created in this structure. A 32F chest tube can then be directed from the atrium into the inferior vena cava. The Rumel tourniquets are applied. Before inserting the chest tube, an additional fenestration should be created approximately 3 in from the tapered proximal end. This opening will allow egress of the blood from the chest tube returning from the lower half of the body back into the heart. The proximal end of the chest tube protrudes from the right atrial appendage that is secured with the purse-string suture. The end of the chest tube is clamped or can be accessed with a Christmas tree adapter and used as a large-bore resuscitation line. Exploration of the retrohepatic cava is now possible. A number of institution-specific variations of this technique have been described, but we are unaware of any technique that has demonstrated improved results over Schrock's original description.[97–99]

The alternative to shunting grade V injuries is termed "direct exposure" popularized by Pachter and others.[100–102] This technique consists of four basic principles: (1) manual compression and packing of the liver with vigorous resuscitation, (2) portal triad occlusion, (3) wide mobilization of the hepatic ligaments allowing for medial rotation of the liver and exposure of the retro hepatic cava, and (4) extensive finger fracture including normal liver parenchyma for direct vascular control of the injury.[102] In one analysis of over 142 patients sustaining juxtahepatic venous injuries, 35 (24.6%) were managed without a shunt, resulting in a survival rate of 49%. The patients managed with a shunt had a survival rate of 19%.[102] Suffice it to stay, unless there is a significant institutional experience with the shunt, direct exposure or total hepatic isolation alone may provide the best chance for patient survival for the occasional patient presenting with a grade V injury.

Lobar hepatic resection offers exposure of the involved hepatic veins and retrohepatic vena cava in grade V injuries but has largely fallen out of favor because of high associated mortality rates.[96,103–106] The only current recommendation for this procedure is when the majority of the lobectomy occurred at the time of injury and the disrupted portion or lobe of liver has questionable viability. Selective hepatic artery ligation is another technique that has been employed to control arterial bleeding deep within the liver that cannot be easily identified or controlled through the liver wound.[107–110] In this situation, if a Pringle maneuver greatly reduces the arterial bleeding, the artery to the respective lobe should be dissected out and occluded. If this maneuver maintains hemostasis, the vessel may be taken. A more recent option is to pack the patient with radiolucent laparotomy pads and take him/her for an arteriogram and possible embolization.[83,84,88]

Once patients with operative liver trauma sustain surgical hemostasis, they may become hypothermic and coagulopathic with bleeding occurring from nonsurgical sources, in particular the raw liver parenchyma. At this point, the liver and other sources of nonsurgical bleeding may be packed with laparotomy pads and a temporary abdominal closure performed.[106,111–116] Patients can then be transported to the intensive care unit where they may be further resuscitated and warmed. Take back for removal of the packing, and debridement of devitalized liver may generally be undertaken safely in 24–48 hours. Omental packing of the liver defect originally described by Stone may reduce the incidence of bile leak and abscess formation.[117]

The Bowel

There is yet no place for nonoperative management of hollow viscus injury, and the nemesis of nonoperative management of blunt abdominal trauma is therefore the missed bowel injury and all its catastrophic consequences. Otherwise, most management is straightforward—debridement and primary repair for nondestructive injuries and resection with primary repair versus stomal formation for destructive injuries.

RADIOGRAPHIC FINDINGS OF BLUNT BOWEL INJURY

There are two basic types of findings of bowel injury on CT scan: direct and indirect. Direct findings are usually

TABLE 12-9: CT SCAN FINDINGS OF BLUNT BOWEL INJURY

Direct	Indirect
Oral contrast extravasation	Mesenteric hematoma
Free air	Mesenteric blush
	Bowel wall edema
	Unexplained ascites
	Fat streaking
	Unopacified (vascular contrast media) bowel loops

straightforward *if* present and amount to extravasation of oral contrast (if administered) and free air, which have been reported to occur in 4 and 28% of the time, respectively. Little else can explain the first of these two entities, while free air from other sources such as extensive subcutaneous emphysema tracking through a diaphragmatic hiatus is unusual.[118–120] Indirect findings may be subtle and can vary in presentation depending on the quality of the scan. Indirect findings include mesenteric hematoma or contrast blush, bowel wall edema, unexplained free fluid, "fat streaking" and bowel loops that don't opacify with intravenous contrast (Table 12-9).

Mesenteric hematoma is nonspecific and can occur from associated injuries, such as pelvic fractures or renal injuries with hematomas from these structures tracking into the bowel mesentery. However, a vascular blush in the leaves of the mesentery is indicative of active hemorrhage until proven otherwise and, generally, a determinant for immediate operative exploration. Bowel wall edema and ascites are common in blunt trauma patients, can occur from resuscitation of other injuries, and don't necessarily connote bowel injury. Free fluid in the absence of solid organ injury can be further evaluated with DPL if the abdominal examination is unreliable. Fat streaking can occur with mesenteric contusion and does not necessarily portend an operative indication. Unopacified bowel loops can indicate vascular disruption of the mesentery or simply be due to poor contrast timing in an under-resuscitated patient. In review of 8112 CT scans, Malhotra showed that at least one of these findings was present in 88.3% of patients with blunt bowel or mesenteric injury and that the likelihood of finding an injury at exploration increased when there was an increasing number of these findings.

OPERATIVE MANAGEMENT

Appreciation of the AAST organ injury grading scale is helpful in describing wounds of the bowel.[121] Grade I injuries are contusions and partial-thickness lacerations of the bowel wall without perforation. Grade II injuries are full-thickness wounds involving less than 50% of the bowel wall circumference. Grade III are lacerations comprising greater than 50% of the bowel wall circumference without complete transaction. Grades IV and V injuries represent complete transection of the bowel wall and transection with segmental tissue loss and/or devascularization of the mesentery respectively. The terms destructive and nondestructive simplify the terminology; nondestructive wounds are those injuries that can be managed with debridement and primary suture enterorrhaphy and comprise grades I–III.[122] Destructive wounds require resection of an entire segment of the bowel due to loss of colonic integrity or devascularization of the mesentery and encompass grades IV and V (Tables 12-10 and 12-11).

The distinction between destructive and nondestructive wounds is important in terms of the prescribed management. Nondestructive wounds of the large or small bowel can generally be repaired without further consideration. Most small bowel destructive injuries should be resected and reconstituted unless damage-control conditions prevail.

In contrast to the small bowel, the management of colon injuries has received great scrutiny. Ushering in the dawn of modern-day trauma surgery, the WWII military experience dictated that *all* colon wounds, destructive or not, be managed by colostomy. This philosophy remained surgical dogma until the 1980s.[123,124] In a comprehensive review of the literature since 1979, primary repair of the colon for nondestructive wounds had been shown to have a leak rate of 1.6%.[122] Compared to patients receiving colostomy for similar types of wounds, the incidence of intra-abdominal abscess was 4.9% for primary repair and 12% for colostomy, and overall complication rate was 14% for primary repair and 30% for colostomy. Mortality rates were similar at 0.11% for primary

TABLE 12-10: AAST SMALL BOWEL INJURY SCALE

Grade[a]	Type of Injury	Description of Injury	ICD-9[b]	AIS-90[c]
I	Hematoma	Contusion or hematoma without devascularization	863.20–863.31	2
	Laceration	Partial thickness, no perforation		2
II	Laceration	Laceration <50% of circumference	863.20–863.31	3
III	Laceration	Laceration ≥50% of circumference without transection		3
IV	Laceration	Transection of the small bowel	863.20–863.31	4
V	Laceration	Transection of the small bowel with segmental tissue loss	863.20–863.31	4
	Vascular	Devascularized segment		4

TABLE 12-11: AAST COLON INJURY SCALE

Grade[a]	Type of Injury	Description of Injury	ICD-9[b]	AIS-90[c]
I	Hematoma	Contusion or hematoma without devascularization	863.40 863.44	2
	Laceration	Partial thickness, no perforation	863.40 863.44	2
II	Laceration	Laceration ≤50% of circumference	863.50 863.54	3
III	Laceration	Laceration >50% of circumference	863.50 863.54	
IV	Laceration	Transection of the colon	863.50 863.54	4
V	Laceration	Transection of the colon with segmental tissue loss	863.50 863.54	4

ICD-9:4, .51 = ascending; 42, .52 = transverse; 43, .53 = descending; .44, .54 = rectum.
[a] Advance one grade for multiple injuries, up to grade III.
[b] ICD, International Classification of Diseases.
[c] AIS, abbreviated injury score.

repair and 0.14% for colostomy. These findings clearly show the superiority of primary repair for nondestructive wounds of the colon.

Several risk factors for anastomotic failure pertaining to destructive colon injury have been addressed in the literature: hypotension, shock, interval from injury to operation, amount of fecal contamination, associated organ injury, transfusion requirement, and comorbid disease.[125] No data have conclusively shown that any of these risk factors increase the likelihood of anastomotic failure with certain caveats. Patients with massive blood loss or shock may be better served by undergoing a damage-control procedure, with definitive repair delayed.[126] Interval from injury to repair greater than 12 hours can be a relative contraindication, if there is wide-spread (greater than one quadrant) fecal contamination. Greater than one- or two-organ system injury has been a concern, but this may just be a marker for degree of shock and overall physiologic derangement. Comorbidities such as AIDS and cirrhosis deserve special consideration, and these patients may be better off with diversion.[127,128] Aside from suture line failure, patients with any of these risk factors have a higher incidence of intra-abdominal abscess and overall complications rates.[122]

Not withstanding the risk factors for colon trauma, most series regard resection and primary anastomosis for destructive colon wounds in a favorable light. In a collective review of 207 patients reported in the literature, management of destructive bowel injury with resection and primary anastomosis had a reported leak rate of 7.2% with a mortality of 1.7% attributable to the colon wound.[122] In the largest single institution experience, Murray showed a leak rate of 11% in 112 patients undergoing resection and primary anastomosis for destructive colon wounds with two deaths related to leaks.[129]

In a multi-institutional trial, Demetriades reported 297 patients with destructive colon wounds in which 197 underwent resection and anastomosis and 100 underwent diversion.[127] The choice of operation was left to the discretion of the attending surgeon at the time of exploration. Not surprisingly, the patients with diversion were significantly more injured and ill than those being reconstituted. The anastomotic leak rate was 6.6%, with one leak from the stump of a Hartmann's pouch in the diverted group and four deaths related to anastomotic failure. Multivariate analysis showed no significant difference in mortality or abdominal complications between diversion and primary anastomosis groups. The authors concluded that "patients can be managed by primary repair regardless of risk factors." This study certainly demonstrates a liberal use of resection and primary anastomosis in a relatively sick and injured cohort of patients. However, the ultimate decision for the choice of operation was up to the discretion of the surgeon at the time of operation, for which there is no substitute.

At laparotomy, the bowel should be examined in its entirety after all other sources of major bleeding are controlled. Small injuries should be noted and tagged with an identifiable suture for easy reference. Larger wounds contributing to ongoing soiling can be temporarily controlled with a "whip stitch" (quick running suture) or Babcock clamps. Mesenteric injuries are identified and active bleeding controlled appropriately. Attention should be directed to the location of the superior mesenteric artery for injuries encroaching on the root of the mesentery. Mesenteric hematomas should be explored with ligation of injured vessels and mesenteric defects closed by careful reapproximation of the peritoneal edges so as not to compromise any feeding vessels. Bowel viability should be noted in relation to any mesenteric injury. Clusters of grade I through III injuries may be resected or individually repaired depending on the particular injury pattern. In blunt trauma, there is usually only one or two grade II or III wounds that can be repaired primarily or one or more devitalized segments that require resection.

Small, superficial grade I injuries can be left alone while deeper, longer grade I injuries can be closed with a simple running suture or interrupted Lembert sutures. Grades II and III wounds should be debrided back to healthy, viable bowel and closed transversely preventing narrowing of the lumen of the bowel. Single layer running or interrupted closure is generally sufficient for repair of the small bowel. When there is significant bowel wall edema, peritonitis or soiling, a two-layer closure with a running inner layer and interrupted Lembert outer layer may be preferential. Grades I and II colon wounds may be managed with single layer closure, but we usually close grade III colon wounds in two layers for added protection.

The leak rate associated with stapled versus hand-sewn anastomosis for destructive wounds of the bowel has been an area of controversy. In two retrospective studies totaling 284 patients undergoing stapled versus hand-sewn anastomosis, Brundage et al showed that hand-sewn procedures

had lower leak rates.[130,131] Two other retrospective studies totaling 484 patients showed no difference in the leak rate of stapled versus hand-sewn procedures.[132,133] Brundage's two studies included 78 colon wounds while the other studies were confined only to the small bowel. Stapled procedures may be a little quicker, particularly if there is more than one anastomosis. In general, the technique chosen according to the literature can be a matter of personal preference. With edematous bowel, the hand-sewn technique is a more prudent approach.

SUMMARY

In addition to the management of abdominal trauma that has been underscored throughout the chapter for both penetrating and blunt trauma, there are several proposed treatment paradigms for many of the injuries sustained in trauma. However, the standard-of-care management for an individual is heavily dependent on the resources and personnel available, along with transport options, if any. There are resource-rich trauma systems throughout the country, with highly qualified personnel. However, these systems are not uniform throughout the nation, and the concept of regionalization has not been perfected for all the regions in the country. The overarching goal remains the same: optimal management for everyone, irrespective of where the patient receives trauma care.

ABDOMINAL VASCULAR EMERGENCIES

John J. Ricotta • Cameron M. Akbari

INTRODUCTION

Among the many acute abdominal conditions that confront the general surgeon, disorders involving the vascular system are in the minority. Yet these conditions are often highly lethal if undiagnosed or inappropriately treated. Because operations involving vascular exposure, control, and repair are uncommon in the practice of most abdominal surgeons, a straightforward plan to identify and manage these conditions is required for optimal success. This chapter concerns itself with the general diagnosis of acute vascular abdominal conditions, principles of vascular control and repair, and a discussion of the management of the three most common types of vascular emergency: mesenteric ischemia, ruptured abdominal aneurysm, and abdominal vascular trauma. Whenever possible, emphasis is placed on general principles that can be applied to a variety of conditions. Acute pathology of the gastrointestinal tract that results in hemorrhage (eg, bleeding ulcer, esophageal varices, bleeding diverticula) is not considered within this chapter.

GENERAL DIAGNOSTIC CONSIDERATIONS

Acute vascular conditions can be divided into those associated with hemorrhage and those accompanied by vascular thrombosis. The presentation within each of these two broad categories is generally distinct. Conditions associated with hemorrhage present with evidence of blood loss including shock. Hemodynamic alterations, for example hypotension and tachycardia, predominate over physical findings. Signs of an "acute abdomen," specifically peritoneal irritation, are often absent. While abdominal pain is usually present, it is often focal and may be associated with a palpable abdominal mass. Signs of shock in the absence of generalized peritonitis or visceral perforation should prompt the consideration of a vascular emergency. In contrast, vascular thrombosis leads to intestinal ischemia and perforation. The clinical presentation of vascular thrombosis is often identical to that of other acute nonvascular abdominal conditions that cause an acute abdomen. Stigmata of cardiovascular disease, for example peripheral vascular occlusions, history of cardiac disease, atrial fibrillation, vascular bruits, and advanced age, should all increase the clinical suspicion of a vascular event as the underlying cause of symptoms. Nevertheless, thrombotic vascular complications often remain undiagnosed until the time of laparotomy.

While physical examination may help to identify patients with intra-abdominal or retroperitoneal bleeding (signs of hemorrhagic shock, absence of peritonitis), routine laboratory evaluations are less helpful. Acute hemorrhage may not result in changes in hemoglobin in its early stages. Laboratory studies are generally useful in excluding other acute inflammatory states such as pancreatitis, and acute processes of the biliary tree or intestine. Plain films of the abdomen may reveal vascular calcifications or suggest hemorrhage (loss of psoas shadow) but are often nondiagnostic. Computed tomography (CT) scanning, when available, is the most useful preoperative diagnostic study (Fig. 13-1). With the addition of intravenous contrast, CT angiography (CTA) can identify vascular calcifications, aneurysms, and pseudoaneurysms; localize and quantify blood loss; and often identify thrombosis of major arterial and venous structures. Refinements in CTA, such as three-dimensional (3D) reconstructions, have markedly reduced the need for diagnostic angiography and streamlined the evaluation of all patients with acute abdominal problems. In addition to visualizing vascular structures, nonvascular findings on CT scan may raise the suspicion of an acute vascular emergency.[1,2] Thickening of the bowel wall and pneumatosis intestinalis may be present without an identifiable lesion in the mesenteric arterial or venous system. Evidence of visceral embolization, particularly in the spleen or liver, should suggest a proximal embolic source, most often from endocarditis. Evidence of a shrunken kidney is a sign of visceral atherosclerosis and, while a nonspecific finding, should increase suspicion of disease in other visceral beds.

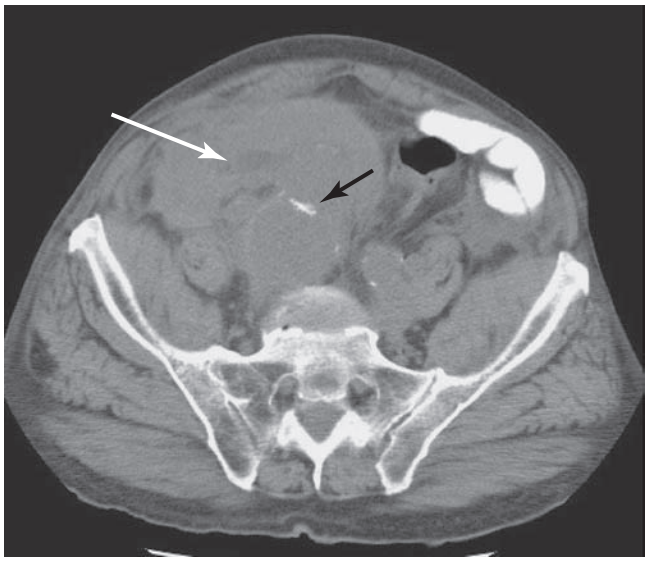

FIGURE 13-1 Noncontrast CT scan demonstrating calcium in the wall of the aorta (*dark arrow*) and retroperitoneal hematoma with fresh blood (*white arrow*) diagnostic of ruptured abdominal aortic aneurysm (AAA).

CT scanning cannot identify all acute vascular conditions, particularly when intravenous contrast is not administered, and scans may not be performed before laparotomy in a number of emergent cases. Under these circumstances, the diagnosis of an acute vascular emergency is made at the time of laparotomy. Most often this diagnosis is obvious on clinical grounds, identification of a mesenteric or retroperitoneal hematoma, presence of free blood in the abdomen, or the presence of infarcted bowel without evidence of internal hernia.

VASCULAR EXPOSURE AND CONTROL

Expeditious vascular exposure and control is essential for optimal management of vascular emergencies. The principles of operative vascular control are well established: proximal and distal control in a relatively normal area of the vessel. Proximal control should always be established before the lesion is addressed. When attempts to establish distal control would result in excessive dissection or cause damage to adjacent tissues and organs, the vessel is opened after proximal control is established and distal control established intraluminally by placing balloon catheters to control back bleeding. Increasingly, intraluminal techniques are being used for establishing proximal arterial control from remote access sites. *Antegrade* intravascular balloon control can be established without concern for balloon migration from arterial pulsation. A good example of this is placement of an arterial occlusion balloon in the suprarenal abdominal aorta through the arm vessels.[3] When the balloon catheter is placed from a site distal to the artery (retrograde control), the balloon must be buttressed to avoid migration as a result of the repetitive force of arterial pressure.[4] This can be done by supporting the catheter and balloon by a rigid sheath on which the balloon can rest. Balloon catheters can be used to tamponade proximal collateral bleeding if the main arterial inflow has otherwise been controlled. The most common example of this is the combination of supraceliac clamping coupled with placement of a Foley catheter to control collateral visceral back bleeding during repair of a ruptured aortic aneurysm.

In cases of active hemorrhage or when dissection is difficult, initial venous control is usually obtained by external pressure. Extensive venous dissection is usually avoided to reduce iatrogenic venous damage. Circumferential venous dissection must be meticulous because of the many venous tributaries and the fragility of the vein wall. Intraluminal balloons can be combined with external compression for both proximal and distal control in cases of venous injury, because this is a low-pressure system and catheter dislodgement is not a problem.

Endovascular techniques have been applied across all aspects of vascular surgery, and management of abdominal vascular emergencies is no exception. However, the application of most of these techniques requires angiographic capabilities in the operating room and significant endovascular experience. In routine practice, the most expeditious way to achieve control remains open exposure. Endovascular techniques remain most useful when they replace extensive or dangerous open dissection. While endovascular options will be discussed within the context of each disease process, these approaches will not be described in detail within this chapter. What follows is a description of the open surgical approach to control of the major abdominal vessels.

Exposure of the Aorta

SUPRACELIAC EXPOSURE

Expeditious supraceliac control of the abdominal aorta is the most important and versatile technique in the management of abdominal vascular emergencies. While suprarenal, intrarenal, and occasionally supramesenteric controls of the aorta are all possible, there is no evidence that these prove superior to supraceliac aortic control as long as visceral ischemia is limited to 45 minutes or less. Supraceliac aortic control can be achieved rapidly with very little risk of damage to adjacent organs such as the intestines, pancreas, or vena cava or the visceral vessels. Finally, the supraceliac aorta is most likely to be free of either aneurysmal or atherosclerotic vascular disease. For this reason, exposure and control of the aorta at that level is easier and safer than control between the visceral vessels.[5] Supraceliac control of the aorta through a left retroperitoneal approach has been well described[6] but is not germane in this situation, because it precludes evaluation of the abdominal viscera. Therefore, only the transabdominal exposure of the supraceliac aorta is described.

The supraceliac aorta is approached through the gastrohepatic ligament, which is divided between clamps (Fig. 13-2A). The left lobe of the liver is mobilized by dividing its diaphragmatic attachments if necessary. Division of the gastrohepatic ligament brings one directly down on to the esophagus and aorta as they course through the diaphragmatic hiatus. The aorta lies to the right of the esophagus and should be easily palpable. In the event that the two organs are not easily distinguishable, a nasogastric or orogastric tube may be placed in the esophagus to aid in distinguishing, but this is rarely required in our experience. Once the aorta has been identified, the key to obtaining control is complete division of the fibers of the left crus of the diaphragm as they cross the anterior aspect of the aorta (Fig. 13-2B). This can be done by placing either the index finger or a large-angled clamp between the aorta and the crural fibers as they cross over its anterior aspect. The fibers are divided, slightly to the left of the midline ("2 o'clock" position) to avoid bleeding, either with scissors or electrocautery. The phrenic arteries are identified and either clipped or, preferentially, spared. One cannot overemphasize the importance of completely dividing these fibers and clearing the anterior, medial, and lateral aspects of the aorta prior to applying the vascular clamp. If this is not done, any aortic clamp will slip anteriorly, resulting in loss of aortic control with disastrous results. Once the crura are divided, the aorta is encircled between the thumb and index

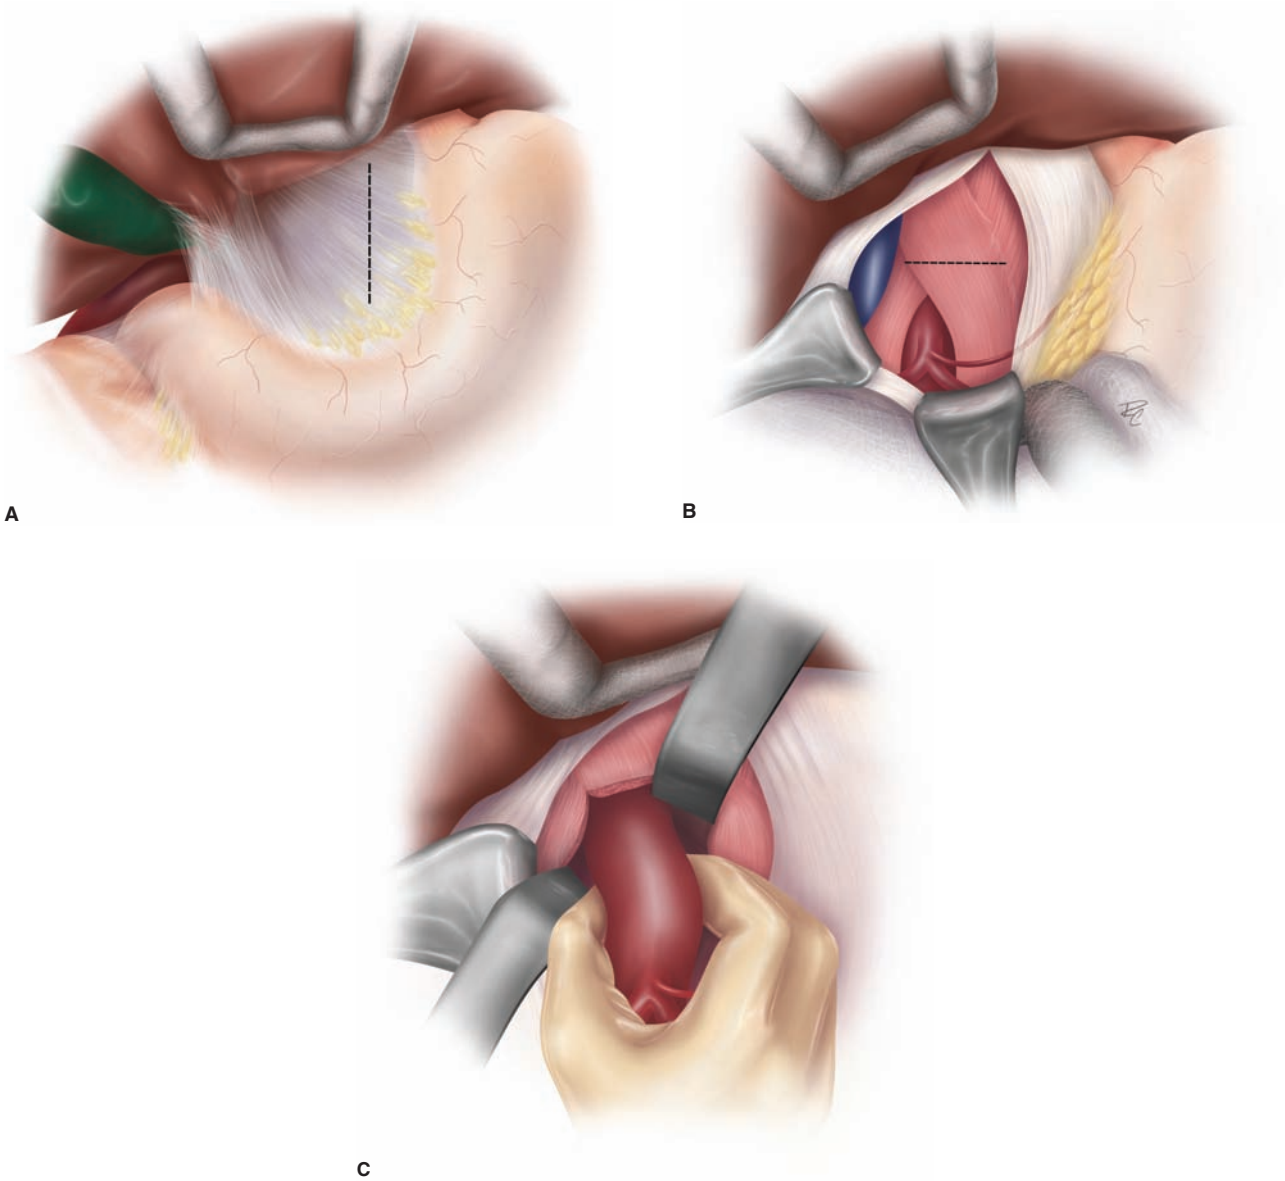

FIGURE 13-2 Exposure of supraceliac aorta. **A.** Division of gastrohepatic ligament. **B.** Line of incision in left crus of diaphragm to expose aorta. This is facilitated by placing a finger or a clamp between aorta and crural fibers. **C.** The aorta is then encircled bluntly using finger dissection.

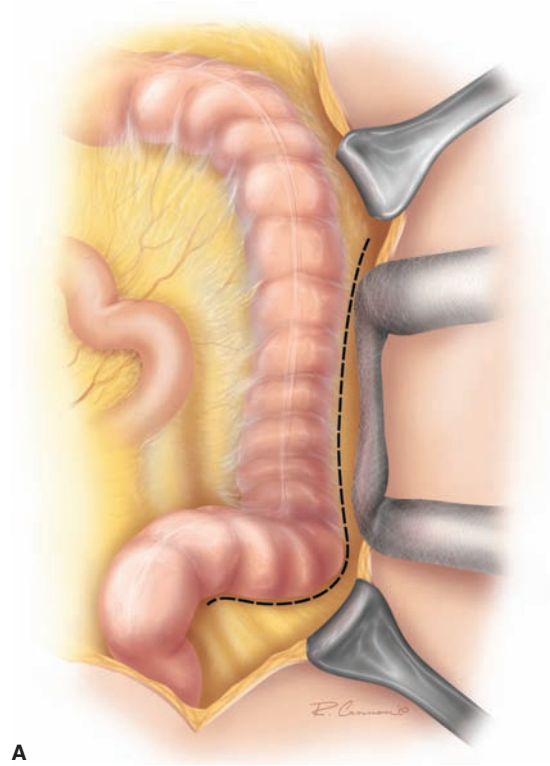
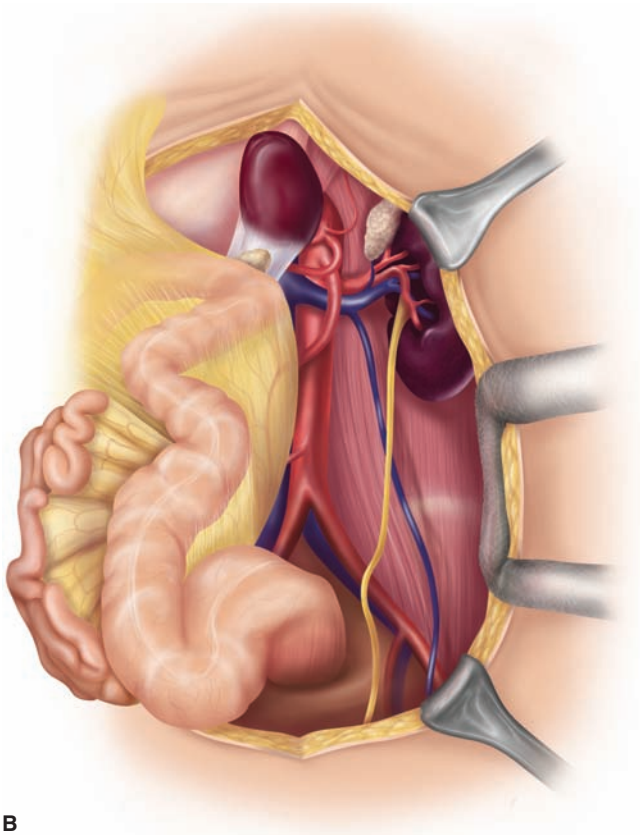
finger of the operating surgeon's right hand (Fig. 13-2C). The aorta is then lifted gently off the spine to be sure that it has been completely mobilized. A clamp can then be reliably placed across the aorta. More extensive dissection of the aorta is not required and we avoid passing angled clamps and loops under the aorta to minimize damage to intercostal vessels. Use of the index finger and a straight aortic clamp are all that is required.

EXPOSURE OF THE VISCERAL AORTA

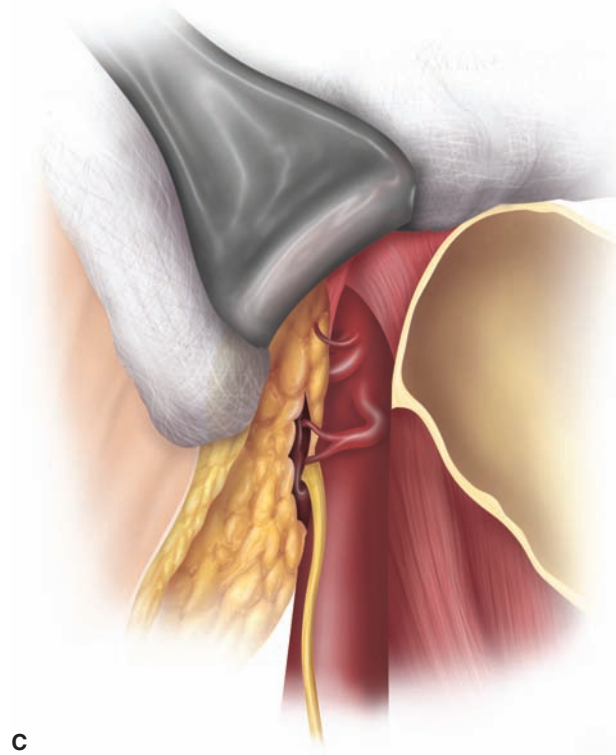
This area of the aorta will rarely need to be exposed for acute vascular emergencies. Transperitoneal control of the visceral aorta requires a left medial visceral rotation.[7] The left colon is mobilized along Toldt's line (Fig. 13-3A), the retroperitoneal and phrenic attachments of the spleen are divided, and the spleen, colon, and tail of the pancreas are reflected medially, leaving the left kidney down (Fig. 13-3B). This results in exposure of the anterior aspect of the aorta, and the origins of the renal, celiac, and superior mesenteric arteries (SMAs). If exposure of the posterior aspect of the aorta is required, the left kidney is elevated with the other viscera (Fig. 13-3C). Exposure of the visceral vessels more distally is described as follows.



A



B



C

FIGURE 13-3 Left medial visceral rotation. **A.** Mobilization of the left colon along Toldt's line. The spleen and pancreas are also mobilized. **B.** With reflection of the spleen, pancreas, and colon anteriorly toward the midline, the anterior aspect of the aorta is exposed along with the origins of the left renal, superior mesenteric, and celiac arteries. The aortic hiatus may need to be incised to provide additional cephalad exposure. **C.** If access to the posterior aspect of the aorta is required, the left kidney is mobilized outside Gerota's fascia, along with the other viscera.

INFRARENAL AORTIC EXPOSURE

This technique is familiar to most surgeons and involves incision of the ligament of Treitz and mobilization of the fourth portion of the duodenum superiorly and to the right (Fig. 13-4). When encountered, the inferior mesenteric vein may be divided between clamps. This sometimes improves exposure and is preferable to leaving an intact vein under tension with the risk of avulsion. The left renal vein serves as a reference to identify the superior extent of dissection. This vein almost never requires division. Should additional mobilization be required, the gonadal and lumbar veins can be divided for superior mobility and the adrenal vein is divided if the vein is to be retracted inferiorly. If these collaterals are divided and the renal vein is subsequently sacrificed, it must be repaired, either primarily or with an interposition graft. If the left renal vein is *not* encountered during this dissection, one must consider the possibility of an aberrant renal vein coursing posterior to the aorta, which occurs in 1% of patients.[8] In that case, the vein is at risk for damage during aortic cross clamping.

Lymphatic and areolar tissue anterior to the aorta is cauterized or divided and ligated between clamps. It is better to ligate large lymphatics to prevent chyle leak postoperatively. As with the suprarenal aorta, the vessel is encircled using the thumb and index finger and lumbar vessels usually do not require division. We are more inclined to place a tape around the aorta in the infrarenal location, because visualization is optimal, but this is not required. As described previously, the aorta is circumferentially mobilized digitally, raised off the spine, and an aortic cross clamp is placed under direct vision.

Exposure of the Iliac Arteries

The common and external iliac arteries are controlled after entering the retroperitoneum. For proximal iliac control, the small bowel mesentery is reflected to the right and the aortic bifurcation is exposed. For more distal control, particularly of the external iliac arteries, the right or left colon is mobilized along Toldt's line and reflected toward the midline (Fig. 13-5). It is important to be mindful of the ureter as it crosses over the iliac bifurcation. Control of the iliac arteries at the aortic bifurcation can be dangerous because of the confluence of the iliac veins behind the right iliac artery. This is one of the most common sites of iatrogenic vascular injury during aortoiliac surgery. The venous structures are gently separated from the arteries by use of blunt dissection

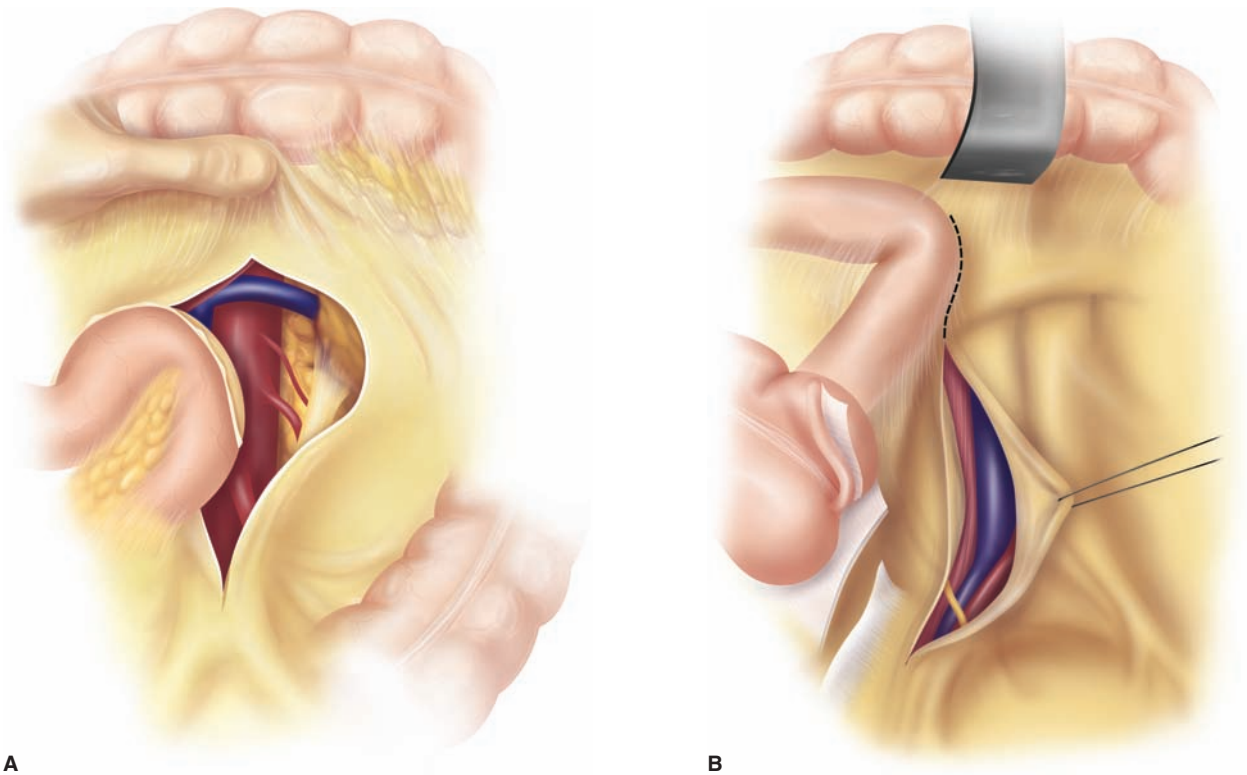


FIGURE 13-4 **A.** Exposure of the infrarenal aorta. The ligament of Treitz is divided and third and forth portion of the duodenum are mobilized. The left renal vein is used to identify the superior extent of dissection. The inferior mesenteric vein may be divided. The more distal superior mesenteric artery (SMA) can also be exposed in this manner, although the origin of the vessel will not be reached (see Fig. 13-3). **B.** Exposure of the iliac vessels. The common iliac vessels and much of the right external iliac artery are exposed by continuing the mobilization of the small bowel and cecum medially and superiorly.

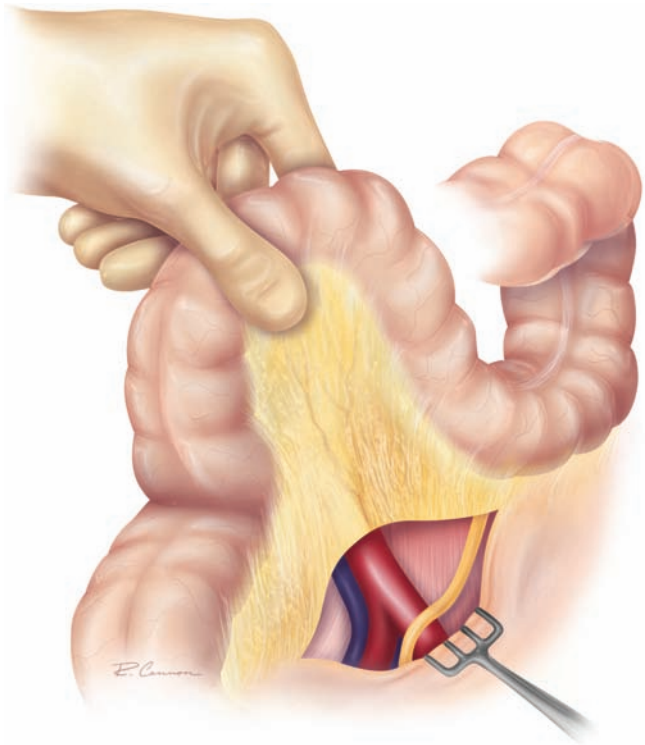

FIGURE 13-5 Exposure of the distal iliac vessels is performed by incising the lateral attachments of the sigmoid or cecum and retracting the bowel medially. Note the ureter as it crosses the iliac bifurcation.

(sponge on stick, kitner dissector or digital dissection). We avoid use of clamps to dissect around the iliac vessels whenever possible. Once the vessels are separated from the adjacent venous structures, they can be encircled with vessel loops and clamped. Relatively blind clamping of the iliac arteries without dissection away from surrounding veins is discouraged as venous injury may result with disastrous consequences.

The hypogastric arteries and distal external iliac arteries can be difficult to expose, particularly in a deep pelvis. The hypogastric artery in particular may present challenges with the risk of injury to deep pelvic veins. This artery can usually be controlled by retrograde balloon tamponade and oversewn. The very distal external iliac artery can be controlled with an intravascular balloon and, if necessary, oversewn. Vascular continuity can be restored by a bypass to the common femoral artery.

EXPOSURE OF THE CELIAC ARTERY AND ITS BRANCHES

Exposure of the proximal celiac artery can be obtained through the gastrohepatic ligament, as described for the suprarenal aorta, or by left medial visceral rotation. We prefer the former approach whenever possible. The celiac artery is identified as it originates from the aorta at the diaphragmatic hiatus. Division of diaphragmatic fibers facilitates proximal exposure. More distal control is achieved by careful dissection along the anterior aspect of the vessel with caudal traction on the stomach and superior border of the pancreas. The tissue surrounding the vessel is carefully divided and ligated.

By opening the gastrohepatic ligament along the lesser curvature of the stomach, one can trace and isolate the common hepatic artery superior to the pancreas. The proper hepatic artery courses in the portal triad anterior and medial to the portal vein. The standard techniques for exposure of the porta hepatis will serve to identify and isolate this structure. The splenic artery is exposed by entering the lesser sac and reflecting the pancreas inferiorly and anteriorly. The multiple branches of this vessel that supply the pancreas must be ligated for adequate exposure. The distal splenic artery is best exposed by mobilizing the spleen as for splenectomy.

EXPOSURE OF THE SUPERIOR MESENTERIC ARTERY

Transabdominal control of the superior mesenteric artery (SMA) at its origin requires medial visceral rotation of the left colon, spleen, and tail of the pancreas.[7] Exposure of the more distal SMA can be done through the base of the small bowel mesentery or by approaching the vessel on its posteromedial aspect after reflecting the small bowel mesentery to the right (as in standard aortic exposure). In the former approach, the transverse colon is elevated and the middle colic vessel is traced down to the SMA in the small bowel mesentery (Fig. 13-6). The anterior aspect of the vessel is cleared, taking care not to injure the adjacent vein. In the latter approach, the vessel is palpated in the root of the small bowel mesentery and dissection proceeds on the lateral aspect of the vessel (see Fig. 13-4A). In either case, dissection requires meticulous division and ligature of small venous, arterial and lymphatic branches, and the preservation of as many major arterial and venous branches as possible.

EXPOSURE OF THE RENAL ARTERIES

Transperitoneal control of the renal arteries can be achieved in a variety of ways, depending on the area of the artery to be controlled. The left renal artery is exposed in the same manner as the infrarenal aorta. The artery is usually superior and posterior to the left renal vein. The renal vein may require mobilization, including division of its lumbar, gonadal, or adrenal tributaries. Occasionally, the retroperitoneal attachments at the inferior border of the pancreas must be incised so the pancreas can be retracted in a cephalad fashion. The renal artery can be traced distally from its origin at the aorta. If the distal renal artery, near the hilum of the kidney, requires exposure, this is most easily done by mobilizing the left colon toward the midline. This may require mobilization of the splenic flexure and occasionally the tail of the pancreas, although this is not always the case. The proximal right renal artery can be exposed for a short segment between the aorta and inferior

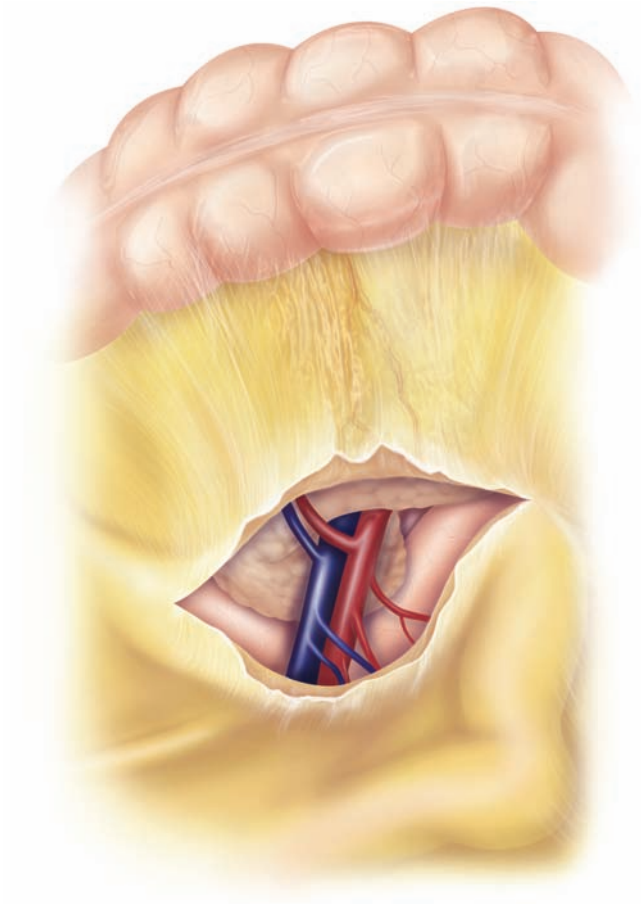

FIGURE 13-6 Exposure of the superior mesenteric artery (SMA) through the mesocolon. The colon is lifted cephalad and the small bowel mesentery pulled caudally. The middle colic artery is identified and followed down to the SMA. Alternative SMA exposure is shown in Fig. 13-4A.

vena cava (IVC). The first part of the exposure is similar to that for the infrarenal aorta. Because the right renal artery runs *behind* the IVC, significant proximal exposure of this vessel requires mobilization of the vena cava and retracting it to the right. This requires careful division of one and often two sets of lumbar veins. Even with this maneuver, only the most proximal portion of the renal artery is exposed. As a result, the right renal artery is most often exposed by an extended Kocher maneuver; which reflects the duodenum, ascending colon and hepatic flexure toward the midline.[9] The artery again lies posterior and inferior to the renal vein, which often requires mobilization.

EXPOSURE OF THE VENOUS STRUCTURES

The visceral veins are exposed by the same approaches as their corresponding arteries. Exposure of the vena cava and iliac veins requires some discussion. In general, these vessels are not involved in acute abdominal vascular emergencies outside the trauma setting. However, the vena cava is the vascular structure most commonly involved in penetrating abdominal trauma.[10] The IVC and confluence of the iliac veins are generally exposed by a right medial visceral rotation (Fig. 13-7). This involves mobilization of the right colon along with an extended Kocher maneuver rotating the duodenum and head of the pancreas when more proximal venous exposure is required. When exposing venous structures, one must be exceedingly cautious of the fragility of the vessel and, in particular, disrupting small, posterior, lumbar vessels. As a consequence and because the venous system is a "low-pressure" system, compression plays a greater role in control of the vena cava and iliac veins than it does in exposure and control of the corresponding arterial segments. Circumferential mobilization of the veins is avoided if possible, as is the application of clamps. The use of blunt instruments such as sponge sticks can usually provide adequate hemostasis (Fig. 13-8). Fine clamps, such as Allis clamps, can be used to coapt cut ends of vessels and facilitate either suture or control by applying partial occlusion clamps. Whenever possible, only the anterior segments of the vein are exposed to avoid dissection around the lumbar vessels. Exposure of isolated posterior injuries involves significant mobilization and rotation of the vena cava and often requires ligation of multiple tributaries. Ligation is liberally applied in cases of extensive venous injury.

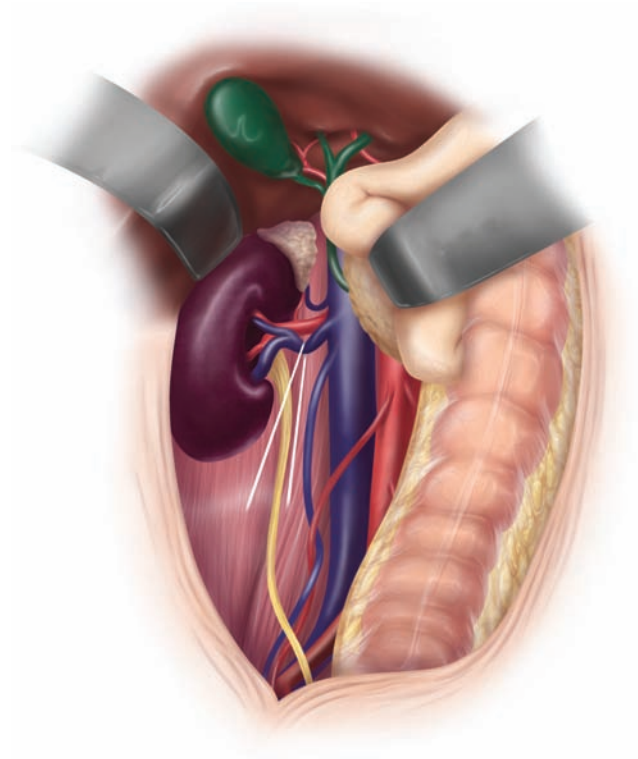

FIGURE 13-7 Right medial visceral rotation. The right colon, duodenum, and head of the pancreas are mobilized to expose the vena cava, the iliac veins, and the right renal artery and vein. The renal artery is exposed by retracting the vein either cephalad or caudad.

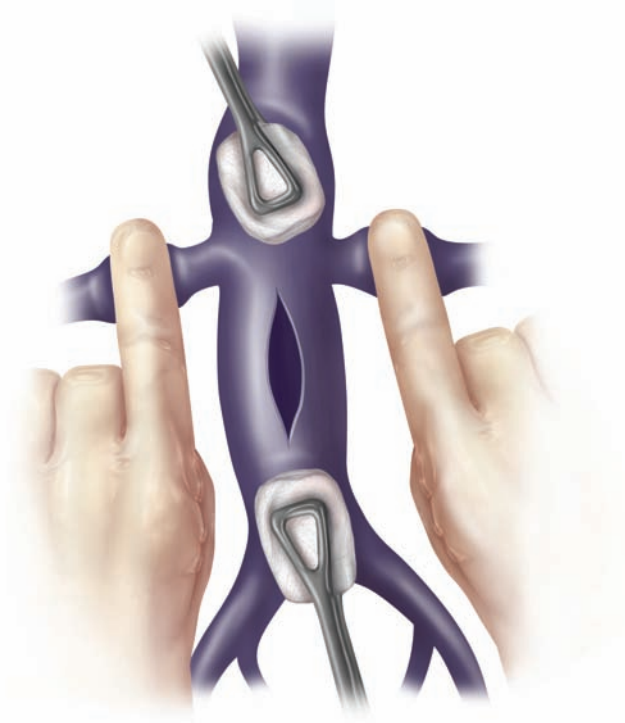

FIGURE 13-8 Control of vena cava. Pressure using digital compression or sponge sticks should be sufficient to control most venous injuries and avoids circumferential dissection.

PRINCIPLES OF ARTERIAL REPAIR

Several factors dictate the approach to emergency arterial repair, including the extent of contamination, size of the arterial defect, and the adequacy of collateral circulation. The following are principles that should guide the choice of procedure:

1. When possible, primary repair is indicated. While most circumstances do not lend themselves to this approach, lateral repair or primary end-to-end anastomosis, or even arterial reimplantation, is associated with good long-term results and avoids use of a conduit.
2. When adequate collateral circulation exists, ligation without repair is indicated. This is the case with most splenic artery aneurysms and selected aneurysms of the hepatic and superior mesenteric arteries.
3. In the absence of contamination, prosthetic conduits provide the best choice for bypass of major intra-abdominal arteries. The high flow in the aorta and major visceral arteries along with their relatively large diameters is associated with good long-term patency of prosthetic bypass. Prosthetic conduits have the advantage of adequate diameter and ready availability, which makes them preferable to saphenous vein in the absence of any contraindication. Occasionally when reconstruction of a small to medium diameter (<6 mm) vessel is required, saphenous vein may be the preferred conduit.
4. In the presence of anything in excess of minor contamination, autogenous material should be used when vascular reconstruction is required. The risk of prosthetic graft infection with rupture argues against its routine use. For small- to medium-sized vessels (<6 mm), or when a patch closure is feasible, saphenous vein is usually adequate. For larger vessels, deep veins (femoral, popliteal, or jugular) should be considered. Short segment arterial repairs (eg, visceral and renal vessels) can be performed with hypogastric artery. Aortoiliac repair in the face of contamination should be performed with either deep leg veins, or more often arterial ligation and extra-anatomic bypass to restore perfusion.

MANAGEMENT OF VASCULAR EMERGENCIES

Acute Mesenteric Insufficiency

PRESENTATION

Patients with acute mesenteric insufficiency generally present with abdominal pain out of proportion to their physical findings. However, if undiagnosed, acute ischemia will progress to intestinal infarction with the attendant signs of peritonitis. Laboratory investigations include complete blood count, electrolytes, lactic acid, liver panel, amylase, and lipase. In general, findings are nonspecific early in the course of the disease and consist of a leukocytosis and perhaps some evidence of hemoconcentration. Liver panel, amylase, and lipase are most useful to exclude other acute abdominal conditions. Elevated lactic acid is usually a late sign and associated with a poor prognosis. Plain radiographs are nonspecific. An ileus may be present and occasionally edema of the bowel wall ("thumb printing") may be present. CT, with intravenous contrast, has emerged as the most useful imaging modality. CT scans can identify abrupt arterial cutoffs, particularly when 3D reconstructions are available. In addition, late-phase CT angiography is the most reliable means to identify mesenteric vein thrombosis. Occasionally, angiography may be required, particularly when nonocclusive mesenteric ischemia (NOMI) is suspected. In these cases, angiography may be both diagnostic and therapeutic.

Mesenteric ischemia results from a variety of conditions; the most common is arterial embolism, followed by arterial thrombosis, low-flow states, and mesenteric venous occlusion.[11–15] Mortality is highest in low-flow (nonocclusive) ischemia and lowest in mesenteric venous thrombosis. Mortality of ischemia resulting from acute arterial occlusion remains 30–40%. Diagnosis is delayed in up to two-thirds of patients with mesenteric ischemia. Outcomes in acute mesenteric ischemia are related to the time to diagnosis,[11,15] and therefore effective treatment relies on prompt diagnosis and initiation of therapy before extensive bowel infarction occurs. This is dependent on a high index of suspicion. Prompt

effective fluid resuscitation is important in all cases of mesenteric ischemia, along with the initiation of broad-spectrum antibiotics. Patients with signs of an acute abdomen should be taken to the operating room as soon as they have been adequately resuscitated. Beyond this, however, the specific management of each type of mesenteric ischemia differs somewhat according to the etiology. Therefore, they are discussed separately.

Acute mesenteric embolization presents with the sudden onset of severe abdominal pain in the setting of a relatively normal abdominal examination. Most emboli are of cardiac origin and the patient may have an irregular pulse, cardiac murmur, or a history of prior myocardial infarction. Many patients may have a history of atrial fibrillation and/or prior embolic events. Because of the flow characteristics of the visceral vessels, most emboli preferentially go to the SMA. While some emboli lodge at the origin of this vessel, most end up distal to the first jejunal braches. An abrupt cutoff of flow in the SMA distal to the first jejunal branches on catheter angiography or CT angiogram is diagnostic of this condition (Figs. 13-9 and 13-10). Treatment is generally laparotomy and embolectomy. Characteristically, the most proximal jejunum is viable in the case of SMA embolus, because the occlusion occurs distal to the first jejunal branches. This is a helpful, but not foolproof, way to differentiate mesenteric embolization from mesenteric thrombosis.

As described earlier in this chapter, the SMA is exposed. The artery is usually soft and the site of the embolus is readily apparent. While a transverse arteriotomy with primary repair can be done, we prefer a longitudinal arteriotomy, and patch closure in most circumstances. The longitudinal arteriotomy can be extended if necessary and will allow thorough examination of the vessel and meticulous closure. It also facilitates bypass should this be required. Once the artery is opened, 3F and 4F embolectomy catheters are passed both proximally and distally to reestablish flow. If necessary, papaverine, 1 mg/kg, or 100 µg of nitroglycerine can be instilled in the distal vessels to reduce vasospasm. When there is concern about residual distal thrombus, 250 mg of urokinase or 1–3 mg of tissue plasminogen activator (TPA) in 50-cc saline can be instilled in the distal vascular bed.[16] If there is clinical evidence of atherosclerosis in the artery, a longitudinal arteriotomy and patch closure are mandatory. If bowel resection is required, proximal saphenous vein should be used for arterial reconstruction.

In unusual circumstances catheter-directed thrombolysis can be used as an alternative to open embolectomy.[17] The patient should have no signs of peritonitis and angiography should demonstrate distal emboli (not easily retrieved by an embolectomy catheter) or a partially occluding proximal embolus that permits distal flow to continue during thrombolysis. In these rare circumstances, an infusion of

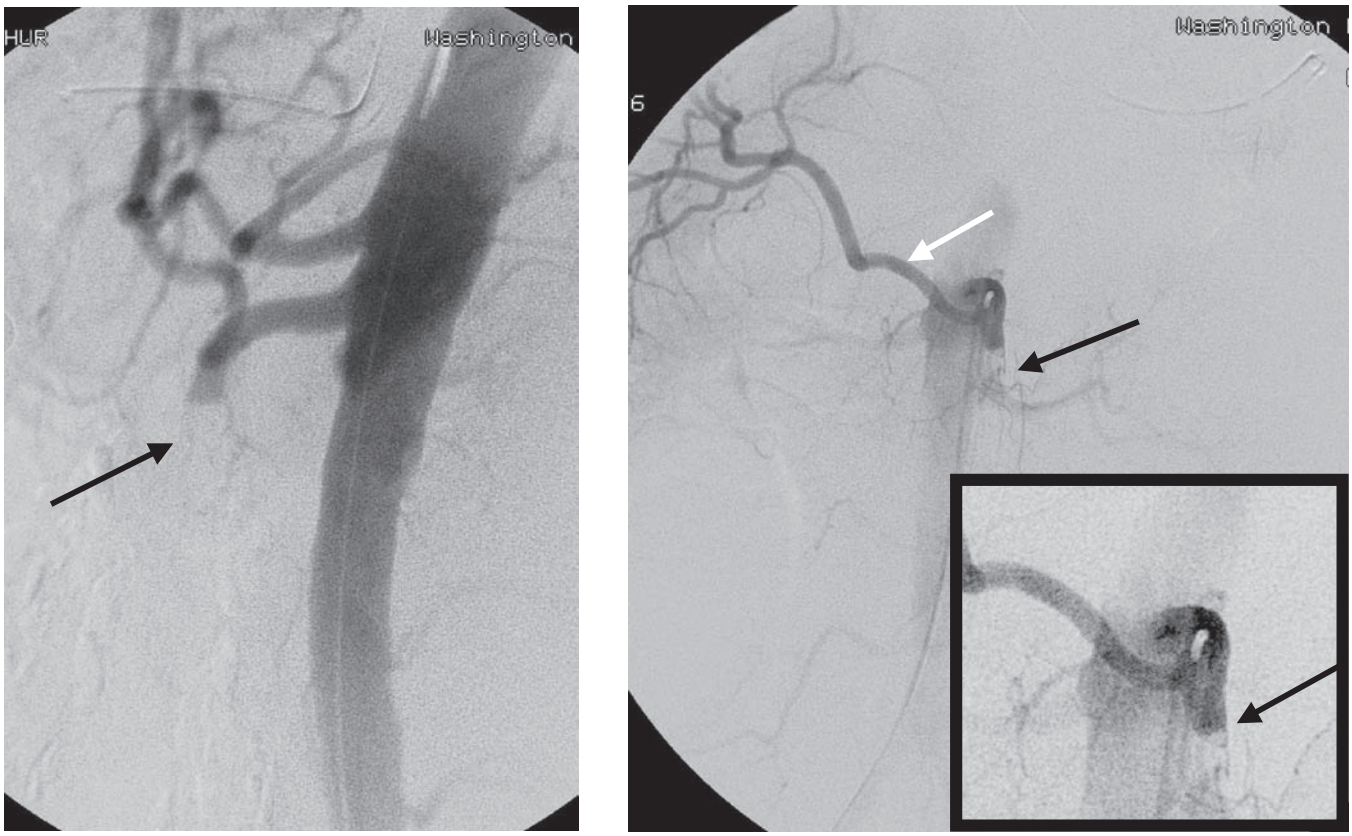

FIGURE 13-9 Angiogram of superior mesenteric artery (SMA) embolus demonstrating an abrupt cutoff distal to a branch point.

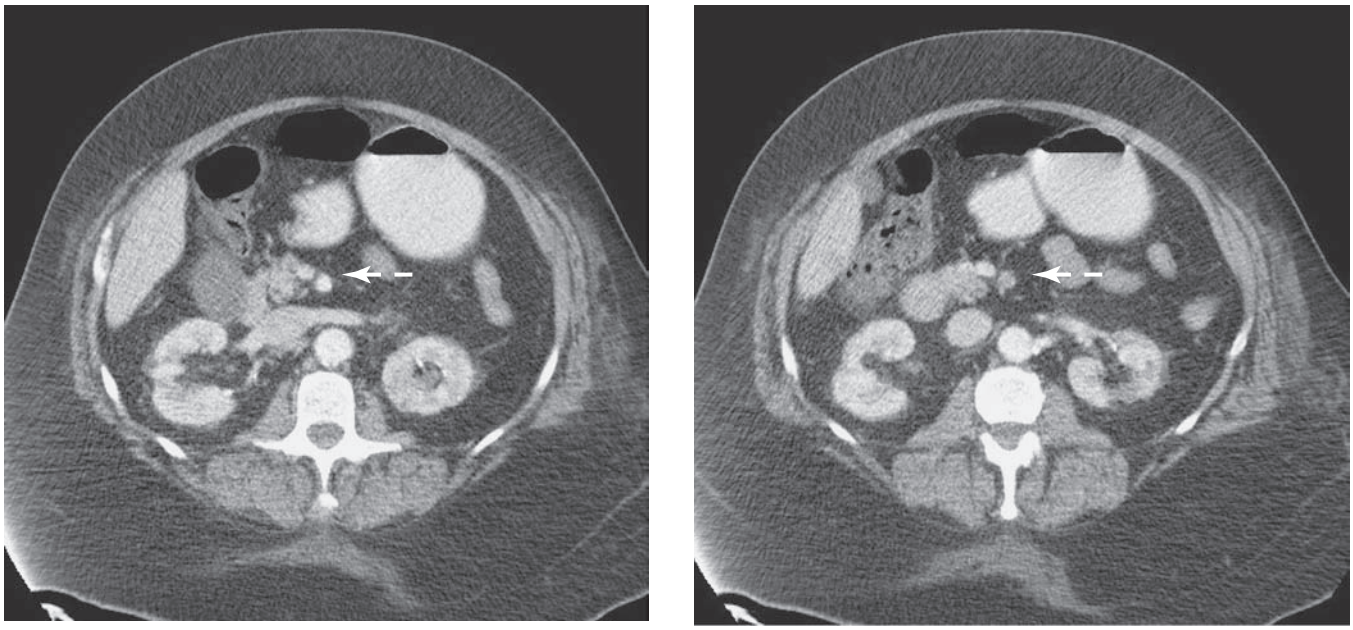

FIGURE 13-10 CT Scan of superior mesenteric artery (SMA) embolus showing patent SMA (*right*) with more distal thrombosis (*left*).

TPA directly into the SMA can be attempted. Mechanical thrombolysis should not be attempted because of the danger of distal embolization. The patient must be observed carefully during lysis for signs of deterioration and any concern over bowel viability will promote laparotomy. Best results are seen when symptoms show some resolution within 1 hour.[18]

The clinical signs of *acute mesenteric thrombosis* are indistinguishable from those of acute embolic occlusion; however, there are often differences in the history and some physical findings. History of arterial occlusive disease (stroke, claudication, myocardial infarction) is common, and atrial fibrillation or prior embolic episodes are unusual. Careful questioning may elicit a history of chronic postprandial pain and weight loss, characteristics of chronic mesenteric ischemia. Physical examination often reveals stigmata of atherosclerosis, for example absent pulses and vascular bruits. Angiographic findings usually reveal diffuse atherosclerosis of the aorta and visceral vessels with multivessel involvement. When vascular occlusion occurs, it is usually at the origin of the mesenteric vessels (Fig. 13-11).[14]

The operative approach to acute mesenteric ischemia from thrombosis differs from that of embolic occlusion. Mesenteric flow cannot be restored by a simple embolectomy and alternatives are required. The most common procedure required is bypass of the SMA usually from the infrarenal aorta or from one of the iliac arteries. While suprarenal bypass is preferred in elective surgery for chronic ischemia, an infrarenal origin of the bypass is more expeditious in the acutely ischemic patient and avoids the acute hemodynamic consequences of suprarenal clamping in a patient already acutely ill and often hemodynamically compromised. Because bowel resection is usually required, autogenous saphenous vein is the preferred conduit and should

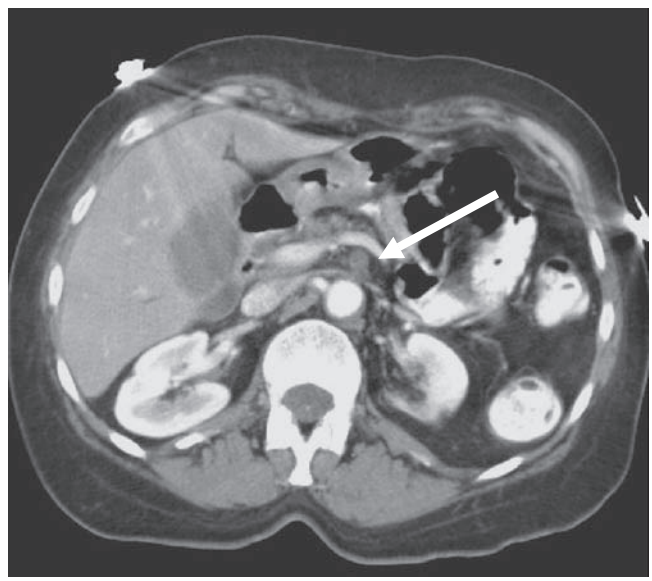

FIGURE 13-11 CT scan of superior mesenteric artery (SMA) thrombosis at the origin of the vessel. This is usually due to underlying atherosclerosis. Emboli lodge at the origin of the SMA in about 30% or fewer of cases.

be harvested from the proximal thigh. When the bypass is performed, there should be sufficient redundancy to allow a "lazy C" loop, traveling from right to left in the abdomen to avoid sharp kinking (Fig. 13-12). The bypass is usually performed on the lateral side of the SMA slightly posterior, so that it can lie without compromise when the viscera are returned to the abdomen. While it is tempting to use very short bypasses, these may be prone to kinking and perioperative thrombosis. In the acute setting, revascularization is usually restricted to the SMA alone.

When there is no suggestion of intestinal necrosis and angiography reveals high-grade stenosis rather than vascular occlusion, an endovascular approach may be attempted.[19,20] Endovascular recanalization is more dangerous when vessels are completely occluded because of the possibility of causing distal embolization. While the target lesion remains the SMA, it is reasonable to perform angioplasty of multiple visceral arteries if the patient remains stable. The visceral vessels may be engaged either transfemorally, or more often via a transbrachial approach. The latter facilitates access to the origin of the vessel and passage of angioplasty balloons and stents as required. If there is any indication of intravascular thrombus, lytic infusion should be performed prior to any attempt at angioplasty to avoid the possibility of distal embolization. Once the possibility of thrombus is excluded, angioplasty with the placement of a balloon expandable nitinol stent is then performed. Use of a short (15–20 mm) 5- to 6-mm-diameter balloon-expandable stent allows precise deployment. The stent should completely traverse the area of narrowing and extend a few mms out into the aorta. This is important because the lesion in this case usually has its origin in the aorta. Selecting an endovascular approach does not mean that laparotomy is avoided, because bowel ischemia may be present. Any signs of peritonitis require prompt laparotomy and inspection of the bowel for viability.

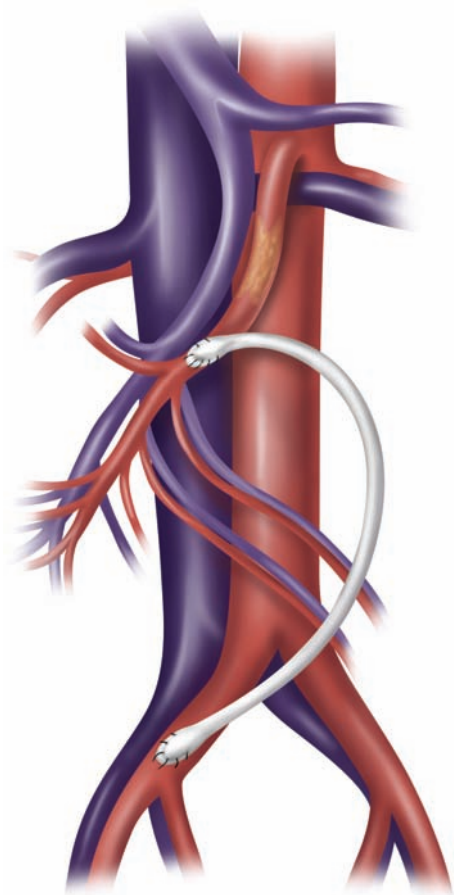

FIGURE 13-12 Retrograde bypass of superior mesenteric artery (SMA) occlusion. This can originate from the aorta or the right iliac artery. The "lazy C" loop reduces the chance of graft kinking. The SMA anastomosis is on the posterolateral aspect of the vessel.

Retrograde endovascular recanalization of a proximal SMA lesion has been reported at the time of celiotomy.[21] This technique involves a longitudinal arteriotomy made in the SMA and a wire is passed retrograde into the aorta under fluoroscopic guidance. Balloon angioplasty of the proximal lesion is performed as an alternative to bypass, and the arteriotomy is closed with a patch. While reports are anecdotal, this procedure is of interest because it avoids the possibility of distal embolization and may be performed more expeditiously than a vein bypass.

Nonocclusive mesenteric ischemia (NOMI) may occur as the result of low flow, without evidence of acute arterial thrombosis or embolization. In one form of this condition, the colon, in whole or in part, is involved. The arterial supply of the colon is less robust than that of the small bowel and, in elderly patients particularly, the inferior mesenteric artery (IMA) may be diseased or occluded. Systemic illness with reduced visceral blood flow, or abrupt interruption of the IMA, such as with aortic resection, may precipitate infarction of marginally perfused areas of the colon. This is most common in the sigmoid colon and the splenic flexure. The rectum is often spared in this process, because of its dual supply through the hemorrhoidal vessels. The small bowel is also usually spared. In these situations, resection of the infarcted colon, with exteriorization and diversion as necessary, is all that is required. The SMA and celiac arteries are usually normal, and no attempt at revascularization of the IMA is indicated.

Mesenteric ischemia without an underlying visceral lesion may also involve the SMA and celiac distribution. This has been called "nonocclusive mesenteric ischemia" (NOMI) and is associated with severe systemic illness, hypotension, and spasm of the mesenteric vessels without evidence of an obstructive lesion.[22] Patients with NOMI are often already in an intensive care unit (ICU) and have had a cardiac event requiring vasoactive drug infusions. Some patients may have been on digitalis preparations that themselves are known to reduce visceral blood flow. There have been some recent reports of NOMI following dialysis in patients with end-stage renal disease.[23] Angiography, when performed, shows "pruning" of the mesenteric vessels without discrete

obstruction. Management of these patients is directed at overall cardiovascular support, treatment of the underlying acute condition(s), and broad-spectrum antibiotics. Intra-arterial papaverine may be administered to relieve vascular spasm, although this is not always effective and may be complicated by systemic hypotension. NOMI usually portends a bad outcome in general, which is related as much to the underlying illness as to mesenteric compromise. Laparotomy should be reserved for patients in whom intestinal infarction is suspected and often will not influence the outcome in this disease.

Mesenteric venous thrombosis may result in acute intestinal ischemia, although this accounts for only about 5% of all cases. Patients are a distinct subgroup, being younger (30–50 years) and predominantly female.[24–27] Associated hypercoagulable state can be identified in more than three quarters of patients and a history of prior venous thrombosis is not uncommon. Common inherited states include deficiencies of protein C, protein S, and antithrombin III; activated protein C resistance; factor V Leiden mutation; and methylenetetrahydrofolate mutations.[27] Acquired prothrombotic states include profound dehydration, polycythemia, cancer, pelvic or abdominal inflammation, and hormone use. Mesenteric venous occlusion is most readily diagnosed by venous-phase CT angiography, which can demonstrate thrombus in the superior mesenteric vein and portal system (Fig. 13-13). Operative findings suggestive of this condition are edematous beefy red bowel with thrombus in veins of the mesentery. The primary mode of therapy is anticoagulation, operative intervention is rarely indicated. Most patients can be managed supportively, although significant volume resuscitation may be required. There are anecdotal reports of mesenteric and portal vein thrombectomy and thrombolysis,[28–30] but these do not reflect the standard of care for most patients.

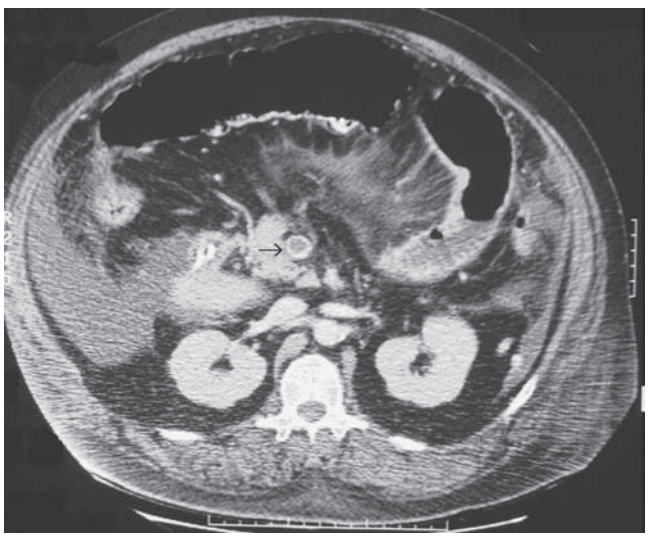

FIGURE 13-13 CT scan demonstrating thrombus in the superior mesenteric vein. CT scan is the most accurate diagnostic study in this condition.

DETERMINING INTESTINAL VIABILITY: THE ROLE OF "SECOND-LOOK" SURGERY

A major challenge in managing patients with intestinal ischemia is assessing the need for, and extent of, intestinal resection. Preoperatively, colonoscopy can be used to assess the viability of the large intestine in questionable situations. Friable red mucosa suggests viability and a grey mucosa that readily sloughs indicates the need for resection. Viability of the large bowel is difficult to judge from external appearance at the time of laparotomy and in general it is preferable to err on the side of resection in questionable circumstances, because maintaining large bowel length is not an absolute requirement for survival. Primary repair should not be undertaken after large bowel resection, as diversion with secondary reconstruction is preferred.

When the small intestine is involved, the problem becomes more complex.[31–33] Every effort should be made to preserve as much small bowel as possible. Clearly necrotic segments of bowel and areas of perforation are resected or excluded immediately to prevent contamination during vascular reconstruction. Evaluation of the remainder of the small bowel is done after blood flow to the intestine is restored. The bowel is usually observed for 15–20 minutes after revascularization and warm lap pads are applied to the intestines to reduce any vasospasm. External inspection, with attention to color and peristalsis, is more helpful than in the large bowel. Doppler interrogation of the antimesenteric border for arterial flow is useful when positive. Use of fluorescein (1 ampule given intravenously) followed by inspection with a Wood's lamp, is the most sensitive means of determining perfusion. Viable bowel will be fluorescent yellow while nonperfused bowel will appear dark purple. When the extent of resection is minimal and the remaining bowel is clearly viable, anastomosis and abdominal closure is appropriate. When there are large areas of questionable bowel that might mandate extensive resection, an alternative approach is undertaken. Under these conditions, marginal segments of bowel are left in situ and their ends are simply closed over and returned to the abdomen. Plans for a second operation are made. Stomas are not performed at this stage to preserve intestinal length. Fluorescein is not used at this time but reserved for the second procedure. The abdomen is temporarily closed using a "Bogotá bag," polytetrafluoroethylene (PTFE) patch, or other temporary appliance (to minimize the chance of abdominal compartment syndrome) and the patient is returned to the ICU where resuscitation continues. A subsequent laparotomy is performed at 18–24 hours after the patient has been stabilized. At this point fluorescein is injected and nonviable bowel is resected. Intestinal continuity is restored unless it is unsafe to do so. The abdomen often cannot be closed primarily at this point because of the danger of compartmental hypertension, and an "open abdomen" approach with delayed closure may be needed. Any deterioration in the patient's subsequent

hospital course should suggest breakdown of an anastomosis and prompt the appropriate therapy.

Despite increased clinical awareness and advances in diagnostic modalities and perioperative care, management of intestinal ischemia remains a significant challenge to the most experienced surgeon with continued high mortality and morbidity.

Management of Abdominal Vascular Trauma

Vascular injuries occur in 10–15% of cases of blunt and penetrating trauma.[34–38] Associated nonvascular injuries are seen in over 90% of patients with vascular trauma, most commonly small bowel, colon, and liver.[37] Vascular injuries can be highly lethal when they occur and remain the most common cause of death following penetrating abdominal trauma. Arterial and venous injuries occur with equal frequency. The pattern of injury differs between blunt and penetrating injuries. In penetrating injuries, the most commonly injured vessels are the vena cava, followed by the aorta, iliac arteries and veins, and the SMA, and vein and multiple vascular injuries are common.[10] Vessels of the mesentery are the most commonly involved in blunt trauma. This section provides principles for management of injuries to the major arteries and veins of the abdomen and retroperitoneum. The reader is referred to the prior sections on vascular exposure for a description of how to obtain control of these vessels. The discussion here centers on management of specific injuries.

Overall, principles of trauma management including initial resuscitation of the patient, rapid evaluation and triage, and expeditious operation when indicated should prevail. Stable patients, particularly those with blunt trauma, may undergo one or more diagnostic tests, including peritoneal lavage, "FAST" ultrasound examination, and, with increasing frequency, CT scan.[39] Many patients with penetrating trauma are taken directly to the operating room without further diagnostic evaluation. Consequently, in a significant proportion of cases, the extent of vascular trauma is not known preoperatively and must be assessed by the surgeon in the operating room.

Intraperitoneal hemorrhage is easily recognized and should be expeditiously controlled, by application of external pressure, vascular clamps, or intravascular balloon occlusion catheters. Once active hemorrhage is controlled, any visceral perforation is controlled by exclusion to prevent ongoing peritoneal contamination and any remaining solid-organ injuries (ie, liver, spleen, and pancreas) should be stabilized by packing. Definitive treatment of the vascular injuries should then receive priority over definitive visceral repair. The adaptation of a "damage control" approach to abdominal trauma has improved outcomes in abdominal trauma.[40,41] Vascular "damage control" involves the control of major venous injuries by ligation or packing and placement of temporary shunts to restore arterial continuity when arterial ligation will not be tolerated.[42,43] Shunts are most often used to temporarily restore flow to the extremities but are used less often in management of visceral injuries. In general, visceral vessels are either repaired or ligated during the initial operation. The end organ will either tolerate ligation because of collateral circulation or be sacrificed. The "damage control" concept combined with endovascular techniques may be of particular use when open vascular repair is exceedingly complex and associated with significant morality. This is particularly true of contained retroperitoneal or hepatic injuries. Definitive treatment can be deferred at initial laparotomy in these cases and attempted in an imaging suite using endovascular techniques after the patient is stabilized. Examples of this include embolization of intrahepatic arterial injury and treatment of some contained retroperitoneal hematomas. This approach is in evolution and holds significant promise.

There are a number of situations in which the surgeon must make a decision about whether to explore a contained hematoma. In these cases, the risk of missing a major vascular injury is balanced against the morbidity of operative exploration. Classic trauma training requires exploration of all contained hematomas that result from penetrating injury. In the case of blunt trauma, central hematomas (zone 1) are explored because of the risk of injury to the aorta or vena cava, while lateral and pelvic hematomas are explored only if there is active bleeding or expansion under observation.[36] If exploration occurs, it is important to obtain proximal and, whenever possible distal, arterial control outside the area of hematoma before proceeding. Venous control above and below the area of injury is desirable but may not always be obtainable. Approaches to vascular control, including endovascular techniques in various locations, have already been described. Intravascular occlusion catheters should be readily available for additional control as needed. Only after every attempt to control the arterial and venous ingress and egress to the hematoma has been made should it be entered.

The advent of endovascular techniques may be changing the classic paradigm of managing contained hematoma from either blunt or penetrating cause. The rationale for exploring nonexpanding hematomas of any type was based on the concern for occult vascular or visceral injury. The advent of CT angiography and the existence of sophisticated intravascular imagining in the operating room can facilitate evaluation of nonexpanding hematomas from both penetrating and blunt trauma without the need for operative exposure and its attendant blood loss. Furthermore, endovascular techniques such as covered stents or coil embolization will allow treatment of many vascular injuries from remote access with reduced risk of blood loss.[44,45] Such treatments are in fact preferred for trauma to branch vessels in the visceral, renal, or pelvic circulations. This potential change in paradigm suggests that the surgeon consider a form of vascular "damage control" in the case of contained hemorrhage, by considering an "endovascular first" approach for diagnosis and treatment of contained hematomas regardless of location. This area is currently evolving, and there is no consensus on the role endovascular techniques should and will eventually

play. With these general comments in mind, a discussion of specific vascular injuries and their management follows.

INJURIES TO THE SUPRARENAL AORTA AND VENA CAVA

These injuries as a group are highly lethal and management is difficult. They should be suspected in any patient with a central hematoma from either blunt or penetrating trauma. In the stable patient, CT scan with intravenous contrast can help to identify the area of injury. If CT scan is not possible preoperatively, a clear plan of exposure and management is crucial before commencing any attempt at repair. Because of the advances made in endovascular techniques, patients should be treated in an operating room that has the capability of intraoperative fluoroscopic imaging and angiography whenever possible. If an injury to the aorta or vena cava is suspected and the patient is not exsanguinating, the surgeon should consider intraoperative angiography through the femoral artery or vein as appropriate to evaluate the location and extent of vascular injury and consider intravascular control. Following this, proximal and distal control should be established. Open exposure of the aorta at the diaphragmatic hiatus or endoluminal balloon control,[3,4] both described previously, can be performed. Injuries to the vena cava can initially be controlled by balloon tamponade, although this may reduce venous return to the right side of the heart. Open control of the vena cava is described in the following text.

OPEN REPAIR OF THE SUPRARENAL AORTA

The visceral aorta is exposed by a left medial visceral rotation described previously. If access to the posterior aspect of the aorta is required, the left kidney should be elevated along with the other viscera; if access to the anterior aorta is needed, the kidney is left in its bed. Direct suture repair is undertaken whenever possible. Direct repair that does not narrow the lumen of the aorta more than 50% or impinge on a visceral vessel is well tolerated. Larger defects may require patch angioplasty using prosthetic material, arterial autograft, or arterial homograft. In the absence of significant contamination, prosthetic material provides a readily available, strong, and durable material for repair. In the presence of gross fecal contamination, biologic materials should be used if possible. Arterial homograft provides the most expeditious alternative both for size and durability, if available. Saphenous vein is inappropriate in this circumstance due to concerns about strength and durability; deep veins of the leg have proven reliable substitutes for in situ aortic reconstruction in infected fields.[46] If appropriate, the aortic repair can be buttressed by an apron of omentum of some paraspinous muscle, to separate the suture line from any visceral vessels. This should be done in the presence of associated visceral injury, particularly injury to the pancreas. Drainage is established as needed. If the damage involves the origins of one or more of the visceral vessels, these are ligated. Revascularization of these vessels can be performed as described in the following text. Damage control of the suprarenal aorta is not possible because of the mesenteric ischemia that would attend any such attempt.

ENDOVASCULAR REPAIR OF THE AORTA

This emerging alternative should be considered in selected circumstances. In a stable patient with a contained injury, placement of a suitable covered stent can be combined with extra-anatomic debranching of one or two visceral vessels, as has been described for treatment of thoracoabdominal aneurysms.[47] This is most suitable when a single mesenteric vessel is involved, because the bowel will tolerate more prolonged ischemia than the kidney. Modification of the stent graft ("fenestrations"), to allow continued visceral perfusion, is possible.[48] This is most feasible when the aortic defect is posterior and relatively remote from the visceral orifices. More precise fenestrations, as required in suprarenal aortic repair, are currently beyond the capability of most surgeons in an acute setting. If a stent graft is selected, its diameter should be 110–115% of the normal aorta to allow for secure fixation. A variety of off-the-shelf aortic cuffs are available and their successful use has been reported in conjunction with thoracic aortic transection.

OPEN REPAIR OF THE SUPRARENAL INFERIOR VENA CAVA

Open repair of injuries to the suprarenal vena cava is one of the most difficult of all abdominal vascular operations. Exposure of the infrahepatic suprarenal IVC is achieved by an extended Kocher maneuver and right medial visceral rotation. One cannot overemphasize the utility of intravascular balloon control in these cases to avoid hemorrhage. Balloon control can be combined with external pressure and the application of partial occlusion clamps to provide hemostasis. Fine Allis clamps are useful in coapting and controlling the cut ends of the IVC and are preferable to more traumatic attempts at control. Wounds of the infrahepatic suprarenal IVC are usually managed by lateral venorrhaphy with running vascular suture. Narrowing the IVC 50–60% is often acceptable. If lateral venorrhaphy is not possible, patch repair using prosthetic or biologic material is acceptable. The use of anticoagulation in these circumstances is unsettled and is likely to remain individualized. Ligation of the suprarenal IVC should be avoided. Injuries to the retrohepatic vena cava, especially those that accompany blunt trauma, usually involve avulsion of the hepatic veins. Such injuries are highly lethal. Exposure of the retrohepatic IVC involves mobilization of the liver and anterior medial rotation of the right lobe.[49–51] Repair of retrohepatic venous injuries may require hepatic isolation (control of the aorta at the hiatus as well as the vena cava above and below the injury and occlusion of the portal triad), placement of an intraluminal shunt between the right atrium and infrarenal IVC or veno venous bypass with hepatic isolation. These techniques are only used in desperate circumstances when bleeding persists despite adequate perihepatic packing. In general, injuries in this area should initially be treated by

packing, nonexpanding hematomas should not be opened, and the extent of injury should be defined and definitive repair planned after the patient has been stabilized.

ENDOVASCULAR TECHNIQUES IN THE SUPRARENAL IVC

At this point, any endovascular approach would be considered experimental. The complexities of and poor results with open surgery in this area make an endovascular approach to suprarenal IVC injuries an attractive potential alternative. Remote access and control, facilitating exposure, along with limited occlusion of the IVC, are all points in favor of an endovascular approach. The size and distensibility of the IVC complicate the selection of an appropriate diameter endovascular graft. Patients with caval injury are often in shock and there may be external pressure on the vessel, both factors that cloud the estimation of caval diameter. No stent grafts have been made for caval use, and it is likely that aortic cuffs or short segment of grafts used for thoracic aortic repair would be most useful. Inadvertent coverage of the renal or hepatic veins represents a further potential complicating factor. There have been no reports of endovascular treatment of hepatic vein injuries. Nonetheless, the potential treatment of these injuries by remote rather than direct access is appealing enough that it will undoubtedly be investigated in the future.

REPAIR OF THE INFRARENAL AORTA AND ILIAC ARTERIES

Injuries to the infrarenal aorta and iliac arteries can be managed by a combination of open and endovascular techniques. Use of an endovascular balloon to achieve proximal arterial control, described for ruptured aortic aneurysm, should be considered as a part of management. These techniques require access to intraoperative fluoroscopy and familiarity with endovascular techniques. The balloon should be placed in the operating room before celiotomy if possible, either through the femoral artery with a supporting sheath or the left brachial artery, as previously described.[3,4] The balloon does not need to be inflated if the patient remains stable. Because concurrent visceral injury is common, laparotomy is almost universally required. After "damage control" of any gross intestinal spillage, attention is turned to the arterial injuries. Exposure of the aorta and iliac arteries has been described. When there is minimal enteric spillage, irrigation and repair with an in situ prosthetic bypass of appropriate diameter is the most expeditious approach. The repair should be wrapped in omentum if possible to separate it from the viscera. In the presence of significant contamination, the infrarenal aorta and/or iliac vessels should either be repaired primarily, ligated, or a temporary shunt inserted as part of a "damage control "strategy."[42] If ligation is required, extra-anatomic (eg, axillofemoral or femoral) bypass with prosthetic material can be used to restore perfusion to the lower extremities. If the aortic bifurcation is preserved, a unifemoral bypass is possible. In cases where the aortic bifurcation is not salvageable, primary end-to-end anastomosis of the proximal ends of the common iliac arteries can be performed, followed by axillo-unifemoral bypass. If this is not possible, axillo-bifemoral bypass may be required.

Unilateral common iliac artery injuries may be ligated with subsequent cross femoral reconstruction using a prosthetic graft. Isolated external iliac artery injuries can be repaired in most cases with saphenous vein interposition. Internal iliac artery injuries should be ligated. In the absence of significant contamination, interposition graft replacement of the damaged vessel with a prosthetic graft is preferred. There are advocates of in situ prosthetic bypass, even in the face of more significant contamination.[52] We prefer not to do this unless the situation is life threatening and prefer temporary placement of a shunt.

Endovascular repair of injured aorta and iliac vessels can be performed using techniques applied for repair of endovascular infrarenal aortic aneurysm repair. One must remember, however, that many of these patients are young and the durability of these repairs is unknown. In addition most patients will require laparotomy for associated injuries. These two factors suggest a limited role for stent grafts in the treatment of traumatic lesions of the aortoiliac system. Endovascular repair has been used in treatment of traumatic dissection of the aorta or iliac arteries.[53] As previously noted, endovascular balloon tamponade is a valuable technique and endovascular coil embolization of difficult-to-access hypogastric artery branches can be employed with great success.

INFRARENAL IVC AND ILIAC VEIN

The principles of controlling venous injuries, including use of balloon tamponade and external pressure, have been previously described. The infrarenal IVC, iliac confluence, and right iliac vein are exposed through a right medial visceral rotation (see Fig. 13-7). The confluence of the iliac veins is obscured by the aortic bifurcation and right common iliac artery. If the aortic bifurcation cannot be sufficiently mobilized to provide exposure, the right common iliac artery should be mobilized or even transected for additional exposure. This is often required in any event because concomitant arterial injury is common. The more distal left iliac vein is approached on either side of the descending/sigmoid colon depending on the location of the injury.

As with the suprarenal IVC, lateral venorrhaphy is the preferred approach, with autogenous vein patch or ligation as alternatives. If needed, the infrarenal IVC and iliac veins can be ligated, due to the rather extensive collateral network that can develop within hours. While this may cause fluid sequestration in the lower legs, it is usually tolerated in the short term and is preferable to an attempt at repair in an unstable patient. In the rare case that ligation results in extreme distal venous hypertension, a bypass graft is indicated. In patients who have been stabilized, we prefer venous repair, either with a vein patch or, when an

interposition graft is required, a ringed prosthetic conduit. Successful venous repair must use a conduit of equal or slightly greater diameter than the native vein and should avoid any tension. Saphenous vein is of insufficient diameter for replacement of the iliac vessels and must be modified to be useful ("panel" grafts"). We find such panel grafts excessively time consuming to construct in these critically ill patients and prefer externally supported PTFE of suitable diameter and length. This is usually done in situ but may be performed using an extra anatomic route. When short segments of prosthesis are used in the presence of distal venous hypertension, flow is usually sufficient to maintain patency without the need for anticoagulation or an adjunctive fistula. In our experience, when thrombosis of a prosthetic vein graft does occur, adequate collateral venous flow has been invariably present. The indication for caval filters in patients with venous injury is not clearly established and remains a manner of individual clinical judgment.

TREATMENT OF TRAUMATIC ARTERIOVENOUS FISTULA

Fistula between the major arteries and veins can occur at any level, because the vessels are in close proximity throughout their course. It is important to realize that, while this may occur acutely, such a fistula rarely represents a true vascular emergency. Exsanguinating hemorrhage does not occur, because the arterial blood is decompressed into the venous system. Most of these patients present months to years after their initial injury. These patients may present with a continuous bruit, signs of lower extremity edema, and high-output cardiac failure.[54] Management depends on an accurate history of trauma, including prior surgery (particularly lumbar disc surgery) or endovascular manipulation. Detailed vascular imaging is essential. These patients are rarely in extremis, and an effort to delineate the problem and develop a careful plan of correction is time well spent. Repair can usually be delayed until the patient is stabilized and other acute problems are corrected.

Treatment is directed at repair of both the arterial and venous defect.[54,55] This is most often done by primary suture closure, although patch closure is sometimes required. Proximal and distal arterial control is essential and is obtained using open or endovascular techniques as described previously. Proximal and distal venous control should be obtained when possible before opening the fistula. This can be done by external dissection, compression, or an intraluminal balloon. Central venous occlusion is important to prevent air embolization when the vein is opened. We generally avoid extensive venous dissection in close proximity to the fistula. On occasion, venous control can be obtained by placing a balloon catheter *through* the fistula from within the artery and then closing the communication with interrupted or running sutures (Fig. 13-14). In the acute circumstance, the artery and vein may be separated, but this is more difficult in the case of a more chronic fistula and closure of the communication, by primary suture or patch, can be done from within the vessel. If this approach is chosen, it is important to be sure that the communication has been completely interrupted at the end of the procedure by use of intraoperative ultrasound or angiography. Appropriate flushing of both the arterial and venous sides is important to avoid embolization of debris or air into the central venous circulation.

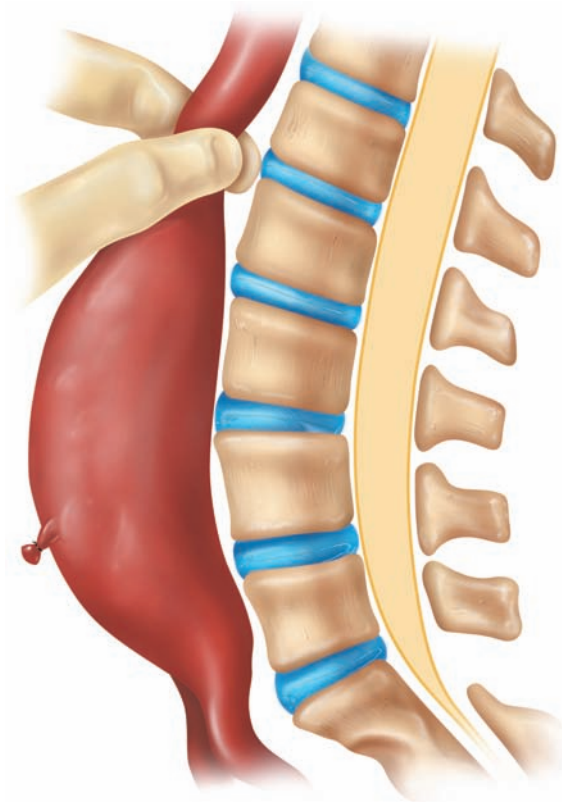

FIGURE 13-14 Control of the aorta by finger dissection. The aortic neck can be elevated off the spine and a clamp applied.

Arterial-venous communications can also be approached endovascularly using covered stents.[56] The stent can be placed only on the arterial side of the defect if the site of injury is in a main artery and can be accurately identified. However, it is important to remember that the arterial injury may be in a branch of one of the iliac vessels, in which case placement of a stent graft in the main artery will not correct the abnormality. Detailed description of repair of these branch fistulae is complex and beyond the scope of this chapter. Suffice it to say that coil embolization can be particularly dangerous in these cases due to the high flow in the venous system and chance of central venous embolization. A variety of techniques can be employed to reduce this possibility. Endovascular treatment of these lesions should only be undertaken by those with significant experience in endovascular techniques. As with open repair, it is important to be sure that complete interruption of the fistulous communications has occurred using completion angiography.

TRAUMA TO THE MESENTERIC ARTERIES AND VEINS

The origin of the celiac axis is exposed through the gastrohepatic ligament or by a left medical visceral rotation as described earlier. While a short bypass from the aorta to the bifurcation of the splenic and hepatic arteries can be performed, the origin of the celiac artery can be ligated safely, if necessary, in most cases. This is preferable to attempting repair in a relatively confined space in an unstable patient. Collaterals through the pancreaticoduodenal and gastroduodenal are usually sufficient to preserve foregut flow. If there is any doubt, a bypass can be performed from the aorta to the common hepatic artery. The splenic artery can be ligated, as can the splenic vein. In the case of proximal injuries to these vessels, the short gastric vessels provide adequate collateral flow. When the splenic vessels are injured close to the hilum, a splenectomy is usually the best approach. Injuries to the common hepatic artery may be ligated because of collateral circulation, while injuries to the proper hepatic artery are more likely to require repair. In order of preference, techniques are primary repair, interposition vein graft, and aortomesenteric graft using either saphenous vein or prosthetic. Two-thirds or more of hepatic flow is supplied by the portal vein, and, if this is intact, proper hepatic artery ligation is an acceptable option. Intrahepatic arterial lesions are generally treated with angiographically directed coil embolization unless massive exsanguination requires resection of the damaged area of the liver.

Injuries to the main trunk of the SMA should be repaired because significant loss of small bowel may result from sacrifice of the vessel. Ligation of proximal SMA aneurysms can be performed with acceptable results, due to the presence of collaterals from the celiac and inferior mesenteric arteries. However, in the trauma setting, integrity of collateral pathways from the pancreaticoduodenal and middle colic vessels is not easily ascertained and repair should be performed. Lesions at the origin of the vessel are best exposed by left medial visceral rotation and repaired with a short bypass originating from the aorta. More distal lesions are exposed through the base of the small bowel mesentery and can be repaired by patch angioplasty, interposition graft using saphenous vein, or proximal ligation and distal bypass arising from the aorta. In the trauma setting, the infrarenal aorta is preferred as inflow for the more distal SMA because supraceliac exposure and control is best avoided in patients who may be unstable and have multiple injuries. Saphenous vein is the preferred conduit. The details of SMA bypass have been described, including the need for proper length and orientation to prevent kinking. Trauma to the branches of the SMA is usually treated by vessel ligation and any nonviable bowel is resected. Attempts to repair distal arterial and venous injuries in the mesentery are not rewarding. Mesenteric hematomas that are not expanding and are not associated with compromised bowel should be observed initially with angiography as necessary to identify vascular lesions. Attempts to explore stable mesenteric hematomas can lead to excessive blood loss and vascular compromise, resulting in more bowel ischemia.

Injuries to the splenic vein are treated by ligation, with or without splenectomy. There is often an accompanying injury to the splenic artery. In the rare instance of isolated splenic vein injury, consideration should be given to concomitant splenic artery ligation or splenectomy. Acute ligation of the splenic vein alone may result in sequestration of significant amounts of blood within the spleen and left-sided portal hypertension. This can be ameliorated by ligating the main arterial inflow to the spleen. Injuries to the main trunk of superior mesenteric vein should be repaired to avoid bowel ischemia secondary to mesenteric venous obstruction. If the vein cannot be repaired using a patch angioplasty or short interposition graft, a bypass from the superior mesenteric vein to the portal vein should be performed. This probably will require a large (6- to 8-mm) conduit of either reinforced PTFE or deep vein (jugular or femoral). Injuries to the portal vein should be repaired if possible, by lateral venorrhaphy, patch angioplasty, or interposition grafting, if the patient is stable enough to undergo repair. The retropancreatic portal vein is best exposed by transection of the pancreas (Fig. 13-15). Isolated injuries of the portal vein, with an intact hepatic artery, may be ligated if necessary to save the life of the patient, although significant hepatic dysfunction and acute massive bowel edema can be anticipated. This leads to significant fluid sequestration and may even result in bowel necrosis. Lesions of the hepatic artery

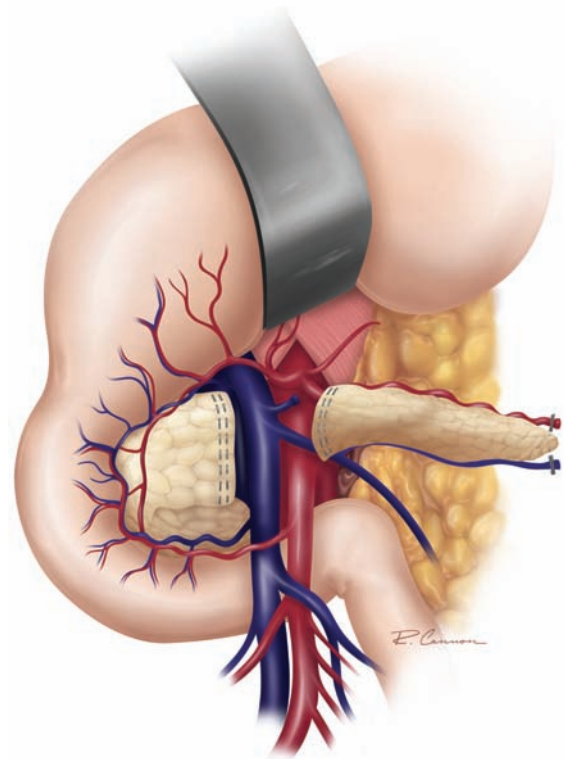

FIGURE 13-15 Exposure of the retropancreatic portal vein by division of the pancreas.

and portal vein that are not immediately lethal should be repaired if possible.

Injuries to the inferior mesenteric artery can usually be ligated, because adequate collaterals will exist from the arc of Riolan, the marginal artery of Drummond, and the hemorrhoidal vessels. If it appears that ligation will not be tolerated, reimplantation or a short bypass with saphenous vein is indicated.

INJURIES TO THE RENAL ARTERY AND VEIN

Management of renal artery lesions is dictated by the overall status of the patient, duration of ischemia, and presence or absence of a contralateral kidney. It is important to remember that after 60 minutes of warm ischemia time, most of the kidney's excretory function is lost. While some authors advocate renal vascular repair within the first 3–6 hours after injury, preservation of long-term renal function in these cases has been poor.[57,58] Therefore, situations in which there is nonvisualization of one kidney on a preoperative CTA or intravenous pyelogram (IVP) suggests that renal function will not be salvaged by revascularization. In most cases of arterial transection, ligation with nephrectomy is indicated. In cases of blunt trauma observation is usually indicated. In circumstances where the status of the kidney is unknown or when there is not a contralateral kidney, attempts at revascularization should be undertaken. The most expeditious approach is aortorenal bypass for lesions of the main renal artery, using saphenous vein with PTFE as a second choice. Lesions of the more distal renal artery, at or beyond branch points, are best ligated in the acute situation, unless they can be repaired with a simple vein patch, or if the injury is to a solitary functioning kidney. If there is doubt about contralateral renal function, the ipsilateral (damaged kidney) ureter can be clamped and indigo carmine administered intravenously. Appearance of dye in the urine confirms contralateral kidney function. Renal artery thrombosis due to blunt trauma, diagnosed as lack of perfusion on CT scan, can be treated by endovascular placement of a stent[59] if the patient is otherwise stable. However, salvage of a renal vessel in a patient with a contralateral functioning kidney remains a secondary priority in the trauma patient's overall management.

Lesions of the proximal renal veins may be ligated, as long as collateral flow through the gonadal, adrenal, and hypogastric veins is preserved. This works best on the left side. While it is known that some transitory renal dysfunction will occur after renal vein ligation, it is generally well tolerated. If inadequate venous collaterals exist or have been damaged during the course of the injury, a short bypass between the renal vein and the vena cava with 8- to 10-mm PTFE can be performed, although ligation and nephrectomy is appropriate if the patient is unstable. Under rare circumstances of injuries to the renal hilum, for example with a solitary kidney, nephrectomy with ex vivo repair and autotransplantation may be indicated. This extensive reconstructive surgery, however, is unwise in an unstable patient with a contralateral functioning kidney.

TREATMENT OF RUPTURED ABDOMINAL AND VISCERAL ANEURYSMS

In the patient presenting with abdominal pain, pathology of the abdominal aorta and its branches should always be included within the differential diagnosis. Because of their rapidly catastrophic potential, prompt diagnosis and timely treatment for ruptured abdominal aneurysms are mandatory for patient survival and a successful outcome. While the most common aneurysms of the abdomen involve the abdominal aorta and iliac arteries, aneurysms of the visceral vessels may also rupture and present as abdominal emergencies.

Ruptured Aneurysms of the Aorta and Iliac Arteries

Although historically called *atherosclerotic* aneurysms, the etiology of abdominal aortic aneurysms (AAAs) has come to be recognized as multifactorial.[60] This complex interplay, which includes elastin degradation, increased proteolytic activity, inflammation, matrix metalloproteinases, and other factors, leads to the ultimate development of aortic expansion and degeneration.[61–63] It is for this reason that the term *degenerative* aneurysm better describes the pathophysiology of AAAs. Familial[64] and sex-linked[65] factors also likely contribute: the incidence is several times higher in men, and the relative risk for development of AAA among first-degree relatives of affected individuals is increased 11-fold. The infrarenal aorta is the most common intra-abdominal location for aneurysmal degeneration; aneurysmal degeneration of the suprarenal aorta is much less common.

Despite advances in treatment and early diagnosis, AAAs continue to be a significant cause of death. In the United States, AAAs are the 15th cause of death overall and the 10th leading cause among men older than 55 years.[66] With improvements in the operative and perioperative management of *elective* AAAs, coupled with the introduction and refinement of endovascular techniques, *ruptured* AAAs overwhelmingly account for most of these deaths. Even among specialized centers, the operative mortality for ruptured AAAs is at least 40%, a number that has remained constant over the past three decades.[67] When one also considers the proportion of patients who die without reaching the hospital, the mortality rate approaches 75%.[68] Accordingly, and because AAAs are notoriously asymptomatic until ruptured, much clinical research has centered on the natural history of the disease, specifically focused toward identifiable risk factors for rupture.

The absolute diameter of the aneurysm is the principal determinant of rupture risk. As the diameter increases, the risk of rupture increases nonlinearly, such that larger aneurysms have a significantly higher rupture rate. For example, AAAs 5–5.5 cm have an annual rupture risk of less than 5%, whereas those 6–7 cm in diameter have a 10–15% annual risk of rupture.[69] These "hinge points," in which the

rupture risk rises dramatically, are the basis for recommending elective repair for asymptomatic AAAs based on size alone (in general, >5.5 cm in average risk patients).[70] Several other factors also independently predict rupture risk. The strongest risk factors are hypertension, chronic obstructive pulmonary disease (COPD), and family history of AAA.[71,72] Other possible risk factors include rapid expansion (>0.4 cm annually),[73] female gender,[74] and current smoking history.[75]

The classic presentation for ruptured AAA is abdominal or back pain, pulsatile mass, and hypotension; however, this complete triad is present in only a minority of patients. A large pannus or abdominal girth may preclude appreciation for a pulsatile mass; similarly, a blood pressure of 100 mm Hg systolic in an otherwise hypertensive individual may be mistakenly interpreted as "normotensive." Pain is almost always a presenting symptom, and may include abdominal or back pain, groin pain, testicular pain, or flank pain. Less commonly, a patient with a large ruptured AAA may be obtunded and can present with hypotension only. The diagnosis of ruptured AAA must be included among the differential in every patient older than 50 years presenting with abdominal pain, abdominal pain and hypotension, or hypotension alone. When a pulsatile mass is also appreciated, the diagnosis of ruptured AAA is almost certain.

Much less commonly, an aortocaval fistula may arise from rupture into the adjacent IVC; signs and symptoms may include a bruit, distended veins, and acute heart failure. In general, these patients may be hypotensive but can usually be resuscitated. Because their treatment is different from that of a ruptured aneurysm, careful examination of the abdomen, with an effort to identify a thrill or bruit, will help in diagnosis.

DIAGNOSTIC IMAGING

Ultimately, the role of imaging should depend on the patient's hemodynamic stability. In the patient with abdominal pain and hypotension and a pulsatile abdominal mass, immediate transport to the operating room without imaging is indicated. In the more stable patient, in whom the diagnosis is in question, abdominal ultrasound may be performed rapidly in the emergency room to identify AAAs. When performed expeditiously by an experienced ultrasonographer, the diagnosis of ruptured AAA may be rapidly confirmed. However, the technique is operator-dependent and accuracy may be limited by excessive bowel gas and obesity.

CT scanning is the most accurate and useful radiographic method in the evaluation of ruptured AAA (Fig. 13-16). The most common findings are retroperitoneal hematoma, an aneurysmal aorta, and retroperitoneal stranding of blood. With 100% specificity and a very high sensitivity,[76] CT can reliably confirm or rule out the diagnosis of ruptured AAA as well as identify alternative nonvascular causes of the patient's symptoms. It also yields important anatomical information about adjacent structures (such as a retroaortic left renal vein, horseshoe kidney, or concomitant iliac aneurysms) and about the aneurysm itself (such as an inflammatory AAA). CT scanning is particularly important if endovascular repair is contemplated. The newer-generation multislice scanners allow for complete chest and abdominal imaging to be completed in less than 5 minutes. Although intravenous contrast is very helpful in the planning for elective AAA repair, it is not required for diagnosis in the patient with suspected rupture and may exacerbate postoperative renal dysfunction. Even with an endovascular approach, thin slice (2 mm) noncontrast CT can provide sufficient information for repair.

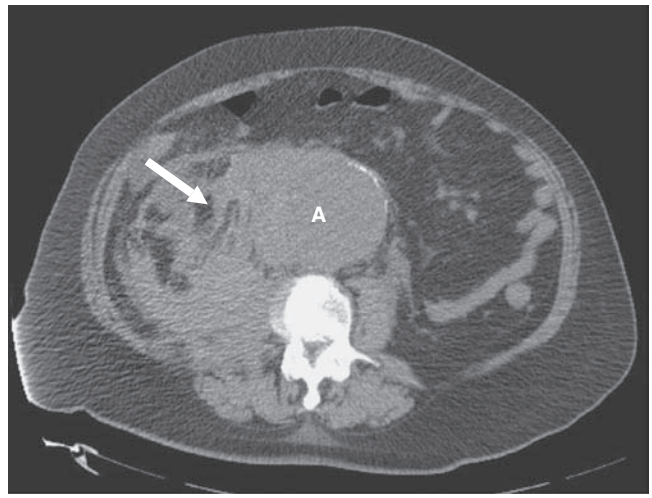

FIGURE 13-16 CT scan of ruptured abdominal aortic aneurysm (AAA) with retroperitoneal hematoma.

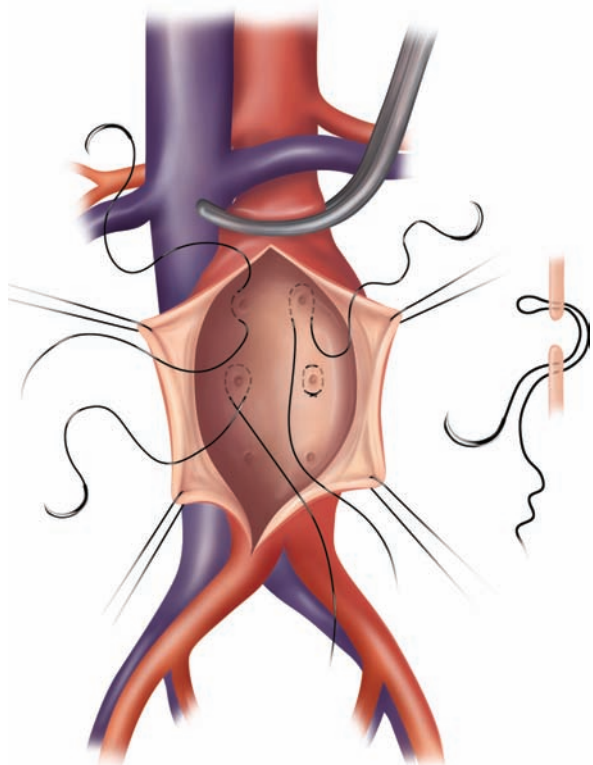

FIGURE 13-17 Control of lumbar vessels from within the aneurysm using mattress sutures to encircle the vessel.

PREOPERATIVE MANAGEMENT

Once the diagnosis of ruptured AAA is made, either by clinical presentation or radiographically, the patient should be taken immediately to the operating room. Large-bore intravenous access in the upper extremities (or central venous access), indwelling urinary catheter, type and crossmatch for at least 6 units of packed cells, and chemistry and coagulation studies should all be performed. Because elevated blood pressure may lead to frank rupture of an otherwise contained leak, a strategy of permissive preoperative hypotension with minimal fluid resuscitation has been recommended. Although no rigid blood pressure parameter exists, most vascular surgeons would favor a minimum systolic pressure to maintain consciousness (usually around 80 mm Hg systolic).

OPEN REPAIR

Open repair remains the most common and versatile approach to ruptured AAA. Because general anesthesia will lead to both generalized vasodilatation and relaxation of the abdominal musculature, both of which can produce abrupt hypotension; the patient must be prepped and draped ("nipples to knees") and the surgical team scrubbed prior to induction. A cell saver device should be set up and used when possible. A midline incision is performed for rapid access to the supraceliac aorta. After induction, the abdomen is opened from xiphoid to pubis. The abdomen and retroperitoneum are inspected. If a small or moderate retroperitoneal hematoma is found without intraperitoneal blood, the supraceliac aorta is controlled, as described earlier, but the artery is not clamped. If the juxtarenal aorta is spared of hematoma, this area may be dissected and a clamp applied directly below the renal arteries. Should bleeding develop during the course of this dissection, the supraceliac clamp is applied.

If intraperitoneal blood is present, rapid supraceliac aortic control is obtained, usually by manual compression at the diaphragmatic hiatus while the anesthesiologist rapidly continues resuscitation. The supraceliac aorta is then exposed as previously described and occluded with a vascular clamp. Once the cross clamp is placed, the distal aorta is palpated to confirm obliteration of the pulse and attention is turned to the aneurysm. In patients with massive rupture, bleeding, or hypothermia, in which coagulopathy is almost certainly present, heparin is not given. In such cases, thrombectomy of the distal vessels and vigorous flushing of the graft are necessary prior to restoring flow. In all other cases, we give a small dose of heparin, 40–50 U/kg.

There is an increasing tendency to obtain intravascular supraceliac balloon control of the aorta prior to celiotomy.[77] This is performed by passing a wire and then a balloon into the supraceliac aorta via either a retrograde transfemoral or a prograde transbrachial approach, as described earlier in the chapter, before induction of anesthesia. This requires intraoperative fluoroscopic capabilities and catheter/guidewire skills. This approach provides less invasive and more rapid control of the supraceliac aorta and can facilitate resuscitation of the patient in circumstances of profound shock.

The aneurysm is approached by evisceration of the transverse colon and omentum cephalad and the small bowel to the right. Care is taken not to injure the IVC or the inferior mesenteric, gonadal, or left renal veins. In most cases, the retroperitoneal hematoma facilitates the dissection. Efforts are made to identify an infrarenal neck of the aneurysm and place a clamp at this level. When there is a free rupture of the aorta, the surgeon can pass the fingers of one hand through the rupture into the aorta (after application of the supraceliac clamp) to help locate the proximal neck of the aneurysm. Bimanual palpation can facilitate the placement of a clamp above the aneurysm without extensive dissection. Once the aortic neck is controlled, the iliac vessels are dissected to allow for clamping and control. Because the iliac veins often adhere to the artery, circumferential dissection around the iliac arteries should be avoided to prevent vein injury. In most cases, the iliac arteries may be readily clamped with minimal dissection. However, if the dissection is difficult, as with a large distal hematoma, endoluminal control may be obtained using a number 5 occlusion balloon, placed in each iliac artery after opening the sac. Once the aneurysm has been isolated proximally and distally, the sac is opened longitudinally and thrombus evacuated. Bleeding from the lumbar vessels is controlled with direct suture ligation using a mattress suture (Fig. 13-17). Venous bleeding encountered inside the sac suggests an aorto caval fistula. In those cases the patient should be placed in mild Trendelenburg's position to reduce the chance of air embolus and the venous bleeding controlled by pressure. The defect is oversewn from within the aneurysm sac, with gentle digital or spongestick compression of the cava proximally and distally (Fig. 13-18). No attempt is made to clamp or mobilize the cava.

Because of the significant risk of colon ischemia following ruptured AAA repair, reimplantation of the IMA should be considered in cases of ruptured AAA.[77] Brisk back bleeding suggests adequate SMA collaterals and implantation is not required. If the IMA is *patent* and back bleeding is absent or sluggish, reimplantation of the IMA should be planned after aortic repair. In these cases, the IMA is controlled just outside the aneurysm sac with a small bulldog clamp, and after the aortic repair the IMA is reimplanted on the aortic graft using a Carrel spatulated patch. An IMA that is obviously occluded at its origin is not reimplanted.

With the aneurysm opened and bleeding controlled, the graft may be sewn in place. When possible, this is done with an infrarenal clamp in place. It is absolutely mandatory that the proximal anastomosis be sewn meticulously into relatively healthy (nonaneurysmal) aorta. Poorly placed sutures in friable aorta will lead to proximal suture line bleeding once clamps are removed. If a secure anastomosis cannot be performed with an infrarenal clamp, the proximal anastomosis should be done with a suprarenal clamp in place. Tamponade of visceral back bleeding may be required while this is performed by placing an inflated balloon catheter through the aneurysm neck into the visceral aorta. Sutures

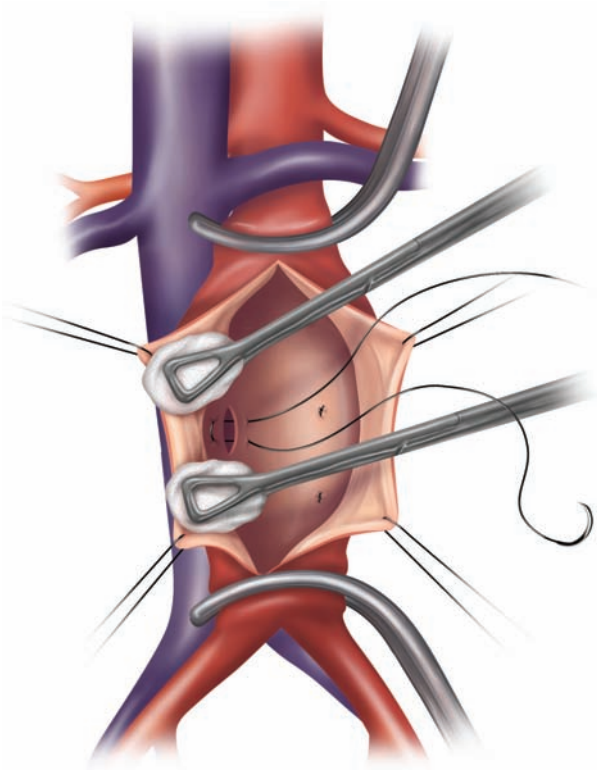

FIGURE 13-18 Repair of an aortocaval fistula from within the aneurysm. Venous back bleeding is controlled with sponge sticks. This avoids dangerous dissection of the vena cava.

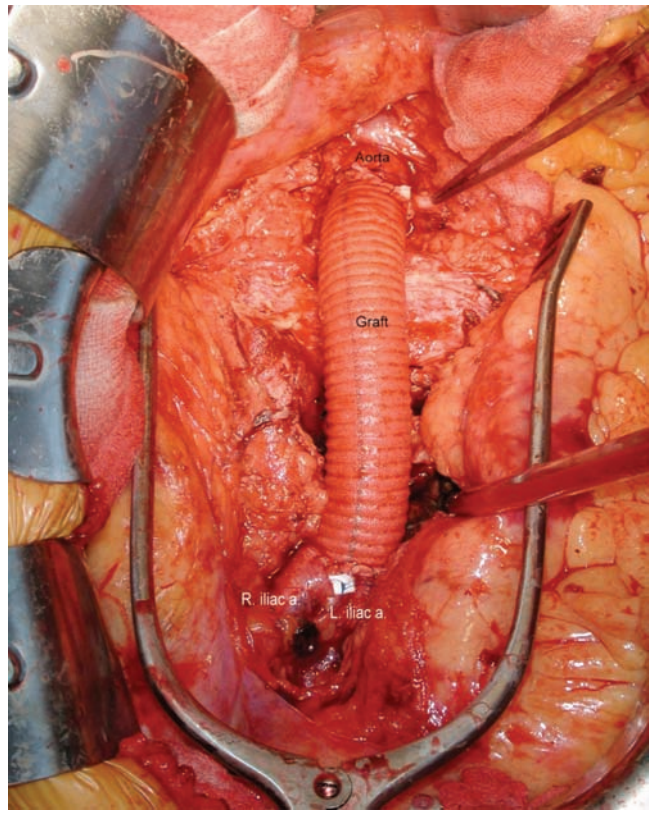

FIGURE 13-19 Aortic tube graft in place for treatment of aortic aneurysm.

must be placed in the aorta precisely and without tension or torsion of the needle. The proximal anastomosis may be reinforced with a Teflon felt pledget. Once the proximal anastomosis is completed and judged to be satisfactory, heparinized saline (5000 U/1000 mL saline) is flushed into the graft and the graft clamped. The distal anastomosis is then performed in a similar fashion. If heparin had not been given, a number 4 balloon thrombectomy catheter is gently passed down each iliac artery to extract thrombus. The graft should also be flushed to ensure adequate forward flow and the anastomosis is then completed (Fig. 13-19).

The anesthesiologist should be notified before release of the distal clamps. One leg should be perfused gradually, once the pressure has stabilized, the contralateral leg may be perfused. Pulses are checked at the femoral level and should be palpable; if not, thrombus or emboli are likely present and should be treated with thromboembolectomy. With the blood pressure stabilized and following a period of adequate perfusion, both feet should be assessed. Although palpable pulses may not be present, the feet should appear viable with reasonable capillary refill with Doppler flow.

Once adequate perfusion to the lower extremities has been achieved, the colon should be assessed. The colon should appear pink and Doppler flow should be present ideally at the antimesenteric border. If the colon appears ischemic, IMA reimplantation should be performed if not already done.

Hemostasis should be assured as best as possible prior to closure, and this may require infusion of additional clotting factors and protamine if heparin were given. The aneurysm sac is closed snugly around the graft with a running suture to obliterate the dead space and provide some hemostasis. The intestines should be excluded from contact with the graft as best as possible, usually by closing the proximal retroperitoneum or occasionally with a mobilized segment of omentum.

If the abdomen can be closed without tension, the linea alba is approximated and closed with a running suture. However, in many cases, the substantial hematoma precludes closure, and to prevent the development of abdominal compartment syndrome, the abdomen is left open with subsequent delayed closure several days later.

ENDOVASCULAR REPAIR

The rationale for endovascular repair (EVAR) for ruptured AAAs is extrapolated from data showing less blood loss and improved outcomes in patients undergoing elective endovascular AAA repair[78] and from direct data from specialized centers demonstrating encouraging results with ruptured AAAs.[79,80] EVAR requires accurate assessment of aneurysm geometry using either CT scan or intraoperative calibrated angiography. Accepted anatomic criteria for EVAR include (1) aortic neck diameter between 18 and

32 mm; (2) aortic neck length of 10 mm or greater; (3) proximal aortic neck angulation 60 degrees or less; (4) iliac artery fixation diameter of 8–22 mm; (5) distal iliac artery fixation length of 10 mm or greater (preferably >15 mm); (6) access vessel diameter of 7.5 mm or greater. Other considerations include the degree of iliac tortuosity, circumferential thrombus or calcification, and the aortic length.

Successful application of EVAR technology in treatment of ruptured AAAs requires an experienced surgical team; adequate endovascular imaging capabilities; and an adequate supply of grafts, sheaths, guidewires, and balloons.[80] The single most important consideration is the ability to expeditiously proceed with endovascular aortic control and suitable repair in the patient with a ruptured AAA before irreversible shock occurs. Multiple centers have described their techniques and operative strategy, and some variation exists; however, the fundamental principles are identical to our center's technique. The preoperative management and anesthetic considerations are the same as for open repair. Either local or general anesthesia is utilized; the advantage of the former being that the fall in blood pressure with induction is avoided. This is most advantageous while balloon control is being obtained. In most cases the repair is completed under general anesthesia to facilitate control of the patient's airway and minimize motion.

Access is obtained through both femoral arteries simultaneously. One artery may be accessed percutaneously with placement of a closure device. Once access is obtained by a Seldinger technique, bilateral 6F sheaths are placed over floppy wires and subsequently exchanged for a stiff wire over a guiding catheter to the level of the proximal descending aorta. Contralateral to the side proposed for deploying the main body of the graft, the sheath is exchanged for a large sheath and a compliant 45-mm aortic balloon is introduced to the level of T12. Although a 12F sheath is the minimum size for the compliant aortic balloon, we prefer larger sheaths to allow for simultaneous pigtail catheter placement. If the patient is hemodynamically stable, the procedure can proceed with the balloon in place but not inflated. A marking pigtail catheter is introduced over a second floppy wire, aortogram is performed, and the position of the renal arteries marked. The main body graft is then introduced through the opposite femoral artery over the stiff wire and placed in appropriate position (Fig. 13-20). The deflated aortic balloon and its sheath are pulled back and the graft is deployed as is normally done for an elective EVAR. The contralateral gate of the graft is then cannulated, and the contralateral limb is introduced and deployed. If the patient becomes unstable, the aortic occlusion balloon may be reintroduced through the sheath of the contralateral limb and inflated in the suprarenal aorta.

The ipsilateral limb deployment is then completed and any ipsilateral limb extensions (if needed) are introduced and deployed. Once the endografting has been performed, all fixation sites are molded with the compliant balloon and a completion aortogram performed to document absence of endoleak (Fig. 13-21). A type I (attachment or perigraft leak) or type III endoleak (modular disconnection) warrants further repair before leaving the operating room, whereas a type

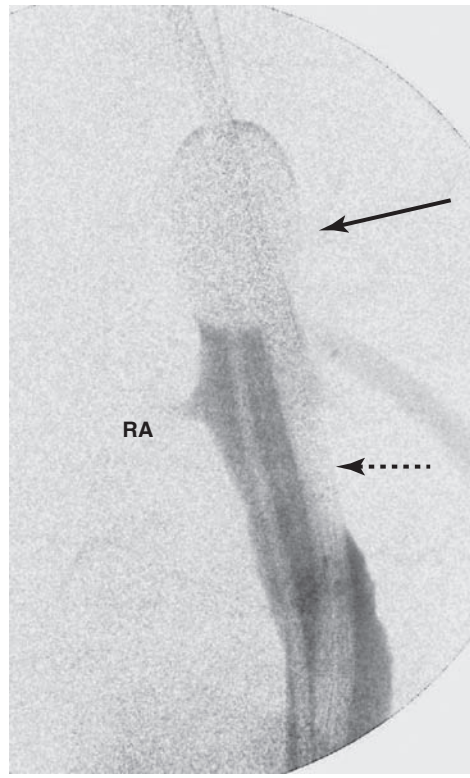

FIGURE 13-20 Intraoperative angiogram showing suprarenal occlusion balloon in place (*arrow*) and sheathed stent graft in position for deployment (*dotted arrow*).

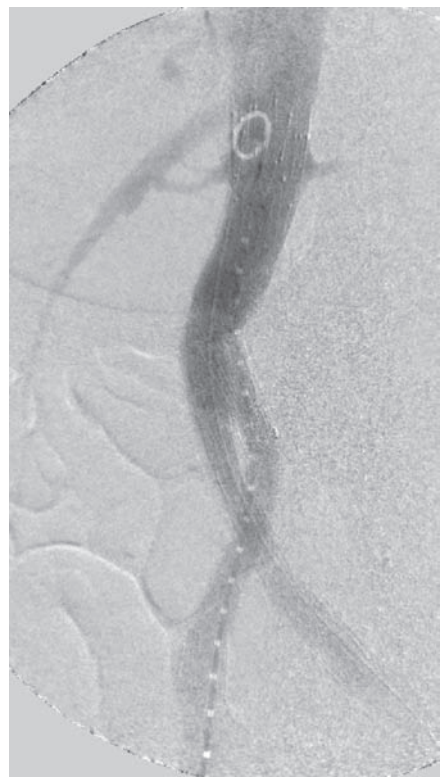

FIGURE 13-21 Completed endograft for ruptured abdominal aortic aneurysm (AAA) showing complete exclusion of the aneurysm.

II (branch endoleak) or type IV (graft porosity) endoleak may be followed conservatively.

The femoral arteries are then closed primarily. If heparin had not been administered, inflow and back bleeding should be assessed prior to closure, and, if judged to be poor, a thrombectomy catheter may be passed gently to retrieve thrombus.

Although the above describes one approach for ruptured EVAR, multiple options exist, and the surgeon should be well acquainted with the options based on anatomic criteria should an endovascular approach be undertaken. These may include conversion to an aortouniiliac device with a femoral-femoral crossover graft or a proximal aortic extension in the case of a type I endoleak. It is anticipated that the future generation of endografts, along with greater surgeon experience, will lead to greater use of EVAR for ruptured AAA.

Results

Although some variation exists among individual series, pooled data suggest an overall perioperative mortality of approximately 50% after open repair for ruptured AAA.[81] Attempts have been made to correlate both pre- and postoperative variables with the probability of survival. Poor prognostic preoperative predictors include hypotension on induction (systolic blood pressure <90); age over 80 years, preoperative cardiac arrest, and low hematocrit.[82] Similar logistic regression analysis has identified postoperative myocardial infarction, respiratory failure, coagulopathy, and renal dysfunction as strong predictors of postoperative mortality; the probability of survival decreases dramatically with two or more complications or with the need for dialysis.[83]

Studies suggest that 40–60% of patients with ruptured AAA may be treated by endovascular means. Encouraging survival results have been reported following EVAR for ruptured AAA, with perioperative mortality of less than 20% and decreased renal, cardiac, and respiratory complications when compared to historical (open repair) controls.[79] Analyses of institutional algorithms and larger databases suggest that endovascular repair of AAA is increasing and mortality is significantly lower than with open repair.[80,84,85] EVAR for ruptured AAA can be complicated by the development of compartment syndrome requiring decompressive laparotomy in a significant number of patients, and this must remain a consideration when this approach is undertaken.[86] While these admirable results cannot be applied universally, given the small number of specialized centers routinely performing ruptured EVAR, there is hope that increased dissemination of EVAR technology and its application in ruptured AAA will lead to a global decrease in the mortality of ruptured AAA.

Visceral Artery Aneurysms

Aneurysms of the visceral arteries are uncommon, seen in 0.01–0.02% of autopsy studies.[87] However, the increased utilization of routine body imaging has resulted in greater recognition and discovery of asymptomatic visceral artery aneurysms, and thus their true prevalence is likely higher. The elective treatment of visceral aneurysms is outside the scope of this chapter. The major complications of these aneurysms are rupture or distal embolization and prevention of these complications is the rationale for elective treatment. Table 13-1 summarizes the relative frequency of these aneurysms, their estimated risk of rupture, and recommended treatment. Approximately 25–30% of splanchnic artery aneurysms are ruptured at the time of presentation[88] and about one-third are associated with aneurysms elsewhere in the arterial tree.[89]

TBLE 13-1: VISCERAL ARTERY ANEURYSMS

Location	Frequency (%)	Risk of Rupture	Indications for Surgery	Type of Repair
Splenic	60	Low	Symptomatic; pregnant or childbearing age	Ligation; splenectomy; transcatheter embolization
Hepatic	20	High	Symptomatic; asymptomatic >2 cm (or all)	Ligation (common hepatic); endoaneurysmorrhaphy with arterial reconstruction; endovascular stent graft or transcatheter embolization
SMA	6	High	All	Ligation (with revascularization if compromised bowel)
Celiac	4	High	All	Ligation; resection with revascularization; aneurysmorrhaphy
Gastric/Gastroepiploic	4	Very high	All	Ligation
Peripancreatic	Rare	High	All	Transcatheter embolization

This chapter does not concern itself with the elective management of visceral aneurysms, but rather the proper surgical approach once rupture has occurred.

Splenic Artery Aneurysms

Splenic artery aneurysms are the most frequent visceral aneurysms (60%), are the only aneurysms with a female predominance (3:1), and have the lowest risk of rupture. Splenic artery aneurysms have the lowest risk of rupture, perhaps no more than 10% overall and less than 2% in low-risk patients. However, the risk of rupture rises dramatically among pregnant patients, with maternal and fetal mortality rates of over 70%, and after liver transplantation,[90] which is the rationale for recommending repair of asymptomatic aneurysms in these groups.[91] Both arterial medial dysplasia (more common in females) and the underlying vascular effects of multiple pregnancies (both hormonal and hemodynamic) have been proposed as contributing factors.[92] Other possible etiologies include portal hypertension and splenomegaly, pancreatitis or pseudocyst-associated local inflammation, and trauma. Ruptured splenic artery aneurysm initially presents with abdominal pain referable to hemorrhage in the lesser sac without abdominal distention or shock. These signs may become apparent later after continued hemorrhage spills into the peritoneal cavity through the foramen of Winslow ("double rupture").

In most cases, ruptured splenic artery aneurysms are treated by laparotomy and ligation. Restoration of arterial continuity is rarely necessary because of the collateral supply to the spleen, and therefore either open or endovascular obliteration of the aneurysmal segment is appropriate. Operative repair of proximal and midsplenic artery aneurysms entails exposure through the lesser sac, proximal and distal control, and simple ligation of the aneurysm without arterial reconstruction. It is important to ligate all feeding vessels; this may require opening the aneurysm and ligation from within the sac. Aneurysms of the splenic hilum require mobilization of the spleen and may be treated by ligation of all branches or splenectomy, if necessary. As in trauma, early control of the proximal splenic artery is important for the treatment of hilar aneurysms. While laparoscopic techniques have been reported for the elective resection of splenic aneurysms,[93] they have no place in the acute setting. Endovascular approaches are generally reserved for patients at high operative risk such as those whose aneurysms are associated with pancreatitis, advanced portal hypertension, or liver transplantation. In these cases, if the patient is stable, vascular access to the splenic artery is obtained through the celiac artery from a femoral or brachial approach. Using guiding sheaths and microcatheters, the splenic artery is engaged and coils are placed distal to the aneurysm, in the aneurysm sac and then proximal to the aneurysm. There is a 10–15% risk of rebleeding[94] using endovascular techniques, as well as a risk of splenic infarction when hilar aneurysms are treated. However, the difficulties of open surgery in patients with pancreatitis or advanced liver disease justify attempts at endovascular treatment as a first effort. Endovascular stent graft placement has also been described[95] and may be particularly useful in certain subsets, such as patients in whom preservation of splenic blood flow need be maintained (as for portal-systemic shunts) or in high-risk patients with pancreatitis-associated aneurysms and severe inflammation.

Hepatic Artery Aneurysms

Hepatic artery aneurysms, unlike splenic artery aneurysms, occur more frequently in men. There is some evidence that posttraumatic hepatic artery aneurysms are increasing in frequency. Etiologies include medial degeneration, atherosclerosis, trauma (up to 20% of cases), infection (usually secondary to illicit drug use), vasculitis, and as a consequence of orthotopic liver transplantation.[96] Hepatic artery aneurysms have a rupture risk of no less than 14%[96] and possibly higher.[97] About half the ruptured hepatic artery aneurysms present with signs and symptoms of intraperitoneal hemorrhage, while the other half will rupture into the biliary tract, manifesting as either hemobilia or gastrointestinal hemorrhage.

A variety of treatment options exist for hepatic artery aneurysms, including ligation, excision, repair with arterial grafting and reconstruction, hepatic resection, and endovascular approaches.[87,96–98] Treatment of ruptured hepatic artery aneurysms generally depends on their location and the status of hepatic blood flow. When feasible, preoperative arteriography is helpful in planning the operative approach. Arteriography can provide information on the collateral flow to the liver, demonstrate anomalies such as a replaced right or left hepatic artery, and identify multiple aneurysms, especially in the case of intrahepatic lesions.

Ruptured common hepatic artery aneurysms are treated by simple ligation and exclusion, unless the liver appears ischemic after clamping. Collaterals from the right gastric and gastroduodenal arteries will maintain hepatic artery flow in most cases. Arterial reconstruction is indicated for most aneurysms of the proper hepatic artery and its extra hepatic branches unless the patient is too unstable to tolerate attempts at bypass. In most instances, this requires interposition grafting (preferably with autologous saphenous vein) aneurysmectomy, or endoaneurysmorrhaphy. Because of their proximity to the bile duct and portal vein, dissection of the more distal hepatic or extrahepatic branch arterial aneurysmal segments may be tedious, and proximal and distal control may be easier from within the aneurysm itself. Ruptured aneurysms may require concomitant control at the supraceliac aorta level. If an interposition graft is not possible (as with distal common or proximal proper hepatic artery aneurysms), an aortohepatic bypass can be performed by exposing the right anterolateral border of the aorta through an extended Kocher maneuver and medial visceral rotation. The aortic anastomosis is performed first; the graft is tunneled retroduodenal to the porta hepatis and anastomosed to the hepatic artery after opening the aneurysm. If the patient is unstable, ligation of the hepatic artery, at any level, is acceptable as long as the portal vein is

patent; the risk of hepatic infarction is low and is less than that of an extended procedure in a compromised patient.

Intrahepatic aneurysms are best treated by catheter-based embolization unless they are large. Options for endovascular treatment of hepatic artery aneurysms include both coil embolization and stent graft placement. Embolization has been most useful for small, saccular intrahepatic pseudoaneurysms, as may be seen following trauma or percutaneous biliary procedures with iatrogenic arterial injury. Large intrahepatic aneurysms may require liver resection. Endovascular approaches have also been described for extrahepatic aneurysms, including both coil embolization and the placement of endovascular covered stents.[94]

Superior Mesenteric Artery Aneurysms

Superior mesenteric artery (SMA) aneurysms have been associated with an infectious etiology, dating back to DeBakey and Cooley's 1953 report of successful resection of a mycotic aneurysm,[99] and systemic infection (usually associated with endocarditis) continues to be a significant factor in their development. Other less common causes of SMA aneurysms include atherosclerosis, connective tissue disorders, vasculitis, and trauma. The risk of rupture of SMA aneurysms is in the range of 40–50%. The majority of SMA aneurysms occur in the proximal 5 cm of the vessel. SMA aneurysms are usually symptomatic, presenting with abdominal pain and sometimes signs of intestinal angina. Treatment of ruptured SMA aneurysms is complicated by their frequent infectious etiology and difficulty with arterial reconstruction. Unlike the situation with trauma to the SMA, resection and reconstruction of aneurysms is often more difficult because the lesion is more extensive. While early teaching mandated proximal SMA reconstruction, larger, contemporary series suggest that ligation without revascularization can be considered in most patients.[100] In these cases, test occlusion of the vessel to assess the extent of intestinal ischemia is critical prior to a decision on the need for reconstruction. When collateral circulation from the celiac and inferior mesenteric arteries, through the pancreaticoduodenal and middle colic vessels, respectively, is sufficient to maintain intestinal viability after test occlusion of the SMA, ligation can be performed. If extensive intestinal ischemia is present after test occlusion, bypass grafting is required. This is usually performed as an interposition graft or a bypass from the infrarenal aorta, using autogenous vein. More distal aneurysms of the SMA can often be treated by ligation with resection of the compromised small bowel as needed. Access to the origin of the SMA is obtained by left medial visceral rotation. The more distal segments of the SMA are exposed by elevating the mesocolon and dissecting through the small bowel mesentery, using the middle colic artery as a guide.

Transcatheter embolization is usually reserved for multiple small bleeding aneurysms in a hemodynamically stable patient. Assessment of bowel viability by angiographic determination of collateral flow and celiotomy is mandatory after the procedure is completed.

Celiac Artery Aneurysms

Medial degeneration is the most common etiology of celiac artery aneurysms. This is particularly true in those cases associated with anatomic anomalies such as a common celiomesenteric trunk.[101] On occasion, aneurysmal dilation occurs distal to compression by the median arcuate ligament, although the incidence of rupture in these cases is unknown. Atherosclerosis is also associated with celiac aneurysms. Ruptured celiac artery aneurysms are usually treated by ligation, which is generally well tolerated. In saccular or very focal aneurysms, aneurysmectomy, and arterial reconstruction may be considered.[102] In the patient with preexisting liver disease or evidence of portal hypertension, reconstruction is indicated to maximally preserve hepatic nutrient flow. When necessary, arterial continuity may be established using either an aortoceliac bypass, originating from the supraceliac aorta or, less commonly, with an interposition graft. In some cases, the aneurysm may be confined to a portion of arterial wall; aneurysmorrhaphy may be accomplished with excision of that portion of aneurysmal wall provided the remaining wall is healthy. Exposure and control of the celiac artery is best obtained through a transabdominal incision and medial visceral rotation, allowing for visualization and subsequent division of the crura and median arcuate ligament. Alternatively, a direct approach through the lesser sac may be used.

Gastric, Gastroepiploic, Gastroduodenal, Pancreatic, and Pancreaticoduodenal Aneurysms

Gastric and gastroepiploic aneurysms represent 4% of splanchnic aneurysms, the majority of which are solitary and involve the gastric artery. The etiology is undefined but likely results from either medial degeneration or an associated inflammatory process. These aneurysms have a very high incidence of rupture, either into the peritoneum or the gastrointestinal tract and 70% present with gastrointestinal bleeding. These aneurysms are best treated by ligation, including resection of involved organs as necessary. The excellent collateral supply of the stomach and the urgent nature of the operation make reconstruction inadvisable.

Aneurysms of the gastroduodenal, pancreatic, and pancreaticoduodenal arteries are usually associated with either acute or chronic pancreatitis.[103] Occasionally these aneurysms are seen after liver transplantation or pancreaticoduodenectomy, particularly when complicated by postoperative pancreatic fistula. Most are symptomatic; rupture and gastrointestinal hemorrhage are common occurrences. Because of their association with pancreatic inflammation, gastroduodenal and pancreaticoduodenal aneurysms are best managed with transcatheter embolization and obliteration, especially in the setting of active hemorrhage.

Aneurysms of Mesenteric Branches and the Inferior Mesenteric Artery

Jejunal, ileal, and colic branch aneurysms are usually small and often solitary.[103] These aneurysms are often identified during angiography to investigate gastrointestinal bleeding or on CT scans for evaluation of abdominal pain. The presence of multiple mesenteric aneurysms suggests a systemic pathology such as polyarteritis nodosa, septic emboli from bacterial endocarditis, or a connective tissue disorder. Rupture is most commonly seen in aneurysms involving colonic branches. Rupture most often occurs into the mesentery, although free intraperitoneal rupture can occur. Management is operative ligation, with resection of involved bowel as necessary. Transcatheter embolization has a very limited role, because laparotomy is required in any case to assess intestinal viability.

Aneurysms of the inferior mesenteric artery are exceedingly rare and little is known about their etiology or natural history. These aneurysms can usually be managed by ligation, with revascularization using autogenous vein if collateral circulation is inadequate.

COMPLICATIONS AFTER RUPTURED ABDOMINAL ANEURYSMS

Local and systemic complications are frequent after rupture of an abdominal aortic or visceral aneurysm. A high index of suspicion, prompt recognition, with early treatment of complications is mandatory for survival. Mortality rates range from 10–60% for ruptured visceral artery aneurysm and 40–75% ruptured aortoiliac aneurysms. Postoperative bleeding may occur as the result of ongoing coagulopathy ("medical bleeding") or from a technical defect ("surgical bleeding"). Correction of hypothermia and coagulopathy (using blood component therapy) should be prompt, and abdominal reexploration, if bleeding continues, is mandatory. In the face of extensive blood loss and resuscitation, abdominal compartment syndrome may occur and should be promptly recognized. Abdominal compartment syndrome results in increased peak airway pressures, progressive hypoxemia, renal dysfunction and visceral ischemia from direct compression of mesenteric and hepatic capillary flow and venous compression, reduced cardiac output, and increased intracranial pressure.[104] The diagnosis is suspected on clinical grounds and confirmed by bladder manometry. Bladder pressures that exceed 20 mm Hg should be treated with decompressive celiotomy. Once the edema has resolved (usually within 7 days), the abdomen is closed, either primarily or with mesh.

Residual visceral ischemia may occur after resection of aortic or visceral aneurysms. Patients who have persistent fever, leukocytosis, or ileus after surgery should be evaluated for residual visceral ischemia, pancreatitis, or intra-abdominal abscess. This is particularly true when resection of abdominal organs has been performed. Colon ischemia occurs in up to 30% of patients after ruptured AAA repair, with an associated mortality of more than 50%.[105] It occurs unpredictably, and can present with a range of signs and symptoms. Diarrhea, which may or may not be bloody, that occurs within 24 hours of AAA resection should raise suspicion of colonic ischemia; flexible sigmoidoscopy should be promptly performed in questionable cases. If the diagnosis of colonic ischemia is confirmed, differentiation between transmural and mucosal ischemia may be difficult, and the decision between nonoperative treatment (with broad spectrum antibiotics, fluids, and bowel rest and repeat colonoscopy) or celiotomy and resection should be based on the patient's clinical course. In questionable cases, it is better to err on the side of operative intervention and colon resection.

Rupture of the aorta or a major visceral vessel often results in shock and multisystem organ failure. Cardiac (myocardial infarction, heart failure, arrhythmias) and respiratory (respiratory failure, adult respiratory distress syndrome) problems predominate. Renal dysfunction occurs in about one-third of patients undergoing ruptured AAA repair; the need for dialysis portends a poor prognosis, with mortality rates of greater than 75%.[106] Gastrointestinal and infectious complications may also occur, usually in the later stages of protracted convalescence. Finally, the culmination of these manifests as multisystem organ failure, which is the most common cause of death beyond 48 hours in patients with ruptured AAA.

Limb ischemia may be seen in patients after resection of ruptured AAA and is caused by distal embolization of aortic debris. If femoral or popliteal pulses are absent at the conclusion of surgery, prompt vascular exploration, usually by a groin incision, is indicated. In most cases the offending thrombus can be removed with an embolectomy catheter. If femoral and popliteal pulses are present, but pedal Doppler signals are diminished or absent, more distal embolization has occurred. This sometimes manifests as "blue toes" and may be associated with microembolization of atherosclerotic debris to the buttocks, spinal cord, and sometimes abdominal and pelvic viscera. Treatment of this condition is generally supportive, because retrieval of microemboli is not feasible. Outcome depends on the severity and location of embolization and attendant ischemia and may range from full recovery to amputation and death.

BENIGN ESOPHAGEAL DISORDERS

Saurabh Khandelwal • Brant K. Oelschlager

The esophagus is a muscular tube whose function is to transport ingested material from the pharynx to the stomach. Its function is the result of a complex symphony of neuromuscular coordination. The esophagus is subject to a variety of disorders, both congenital and acquired. This chapter deals with the most common benign disorders encountered by the surgeon. These include paraesophageal hernias (PEHs), esophageal diverticula, and motility disorders. Our goal is to provide a logical and efficient approach to the evaluation and management of these disorders. Esophageal malignancy and gastroesophageal reflux disease (GERD) are addressed elsewhere in this book.

PARAESOPHAGEAL HERNIA

Paraesophageal hernias (PEHs) result from a defect at the diaphragmatic hiatus. Upward displacement of abdominal contents into the mediastinum occurs due to widening of the hiatal aperture between the right and left crura. The negative pressure of the chest creates a downward pressure gradient from the abdomen further facilitating this shift. Herniation may result from congenital anatomic causes, or it may be a result of trauma or iatrogenic causes. Prior surgery involving the gastroesophageal junction (GEJ), including esophageal mobilization, crural repair, or fundoplication, can result in PEH formation. The stomach is the organ most frequently involved; other organs including the colon, omentum, spleen, liver, and pancreas may also be associated.

Etiology And Anatomic Classification

Hiatal hernias are classified according to the location of the GEJ in relation to the diaphragmatic hiatus and also by the contents of the hernia sac. Type I hiatal hernias are by far most common and are characterized by cephalad displacement of the GEJ above the hiatus into the mediastinum (Fig. 14-1). Type I hiatal hernias are often referred to as sliding hiatal hernias and are typically reducible. Patients with type I hiatal hernias often suffer from gastroesophageal reflux (GER) as a consequence of the altered anatomy and mechanical function of the lower esophageal sphincter (LES) and hiatal complex. Loss of intra-abdominal esophageal length and alteration of the angle of His contribute to this. If type I hiatal hernias enlarge significantly, they may become fixed above the hiatus.

Type II hiatal hernias are considered true paraesophageal hernias and result from cephalad displacement of the fundus of the stomach into the mediastinum. The GEJ itself remains in its normal intra-abdominal location (Fig. 14-2). Dysphagia is a common symptom associated with a type II hiatal hernia, usually due to compression of the esophagus by the stomach. These types of hernia are also referred to as "rolling" hernias. Herniated portions of the stomach are typically found in the posterior mediastinum. These are the least common type of hiatal hernia.

Type III hiatal hernias are also true paraesophageal hernias and are best thought of as a combination of types I and II whereby both the GEJ and a portion of the stomach have herniated above the diaphragmatic hiatus (Fig. 14-3). These can become quite large and may involve complete herniation of the stomach into the thorax. The anchoring attachments of the stomach such as the gastrosplenic ligament and phrenogastric ligaments can become quite attenuated and stretched. This type of hernia can result in partial or complete outlet obstruction as well as in volvulus. Both organoaxial volvulus, where the stomach twists along its longitudinal axis, and mesoaxial volvulus, where the stomach flips anteriorly along its transverse axis, can occur. Organoaxial volvulus is more common. Patients will typically complain of reflux, dysphagia, regurgitation, and respiratory symptoms, all resulting from the displacement and altered mechanics of both the GEJ and the stomach.

Type IV hiatal hernias are distinguished by herniation of other abdominal viscera or omentum above the diaphragm. This can occur in association with either a type II or III PEH. The transverse colon and omentum are frequently involved, but other organs such as the spleen, liver, and pancreas may also be involved. Presenting symptoms can vary with particular organ involvement.

Clinical Presentation

Presentation of patients with PEH can vary widely from an incidental finding to an emergent presentation involving strangulation. Symptoms are often nonspecific and can include nausea, dysphagia, dyspnea, heartburn, regurgitation, bloating, chest pain, abdominal pain, early satiety, and aspiration leading to pneumonia. Severe pain is an ominous sign and usually indicates volvulus or incarceration evolving to strangulation. Symptoms can also be vague and intermittent with patients experiencing relief of their symptoms with shifting of their hernia contents or with relief of visceral torsion.

Iron deficiency anemia resulting from gastrointestinal (GI) bleeding due to mucosal ischemia is a common presenting finding in patients with PEH, affecting over one-third of patients with this condition.[1] This results from mucosal

irritation and ischemia occurring at the neck of the hernia sac where the crura are extrinsically compressing and rubbing against the gastric fundus, resulting in the linear gastric erosions known as *Cameron's ulcers*.[1–3] It is usually not until after exhaustive workup for other causes of anemia that the diagnosis of PEH as the offending agent is obtained. Surgical correction of the hernia results in resolution of the anemia.[4]

While the natural history of paraesophageal hernias is not clearly known, it is known that many of these hernias are incidental findings. They are commonly discovered on chest x-rays, CT scans, or during upper endoscopies being performed for other reasons. This is revealing as it tells us that the true incidence remains unclear.

Diagnosis and Evaluation

The physical examination is frequently unimpressive and nonspecific in these patients. Abdominal examination is usually unremarkable. Chest examination with auscultation may reveal decreased breath sounds on the affected side or the presence of bowel sounds within the chest. It is not uncommon for patients to undergo extensive workup for noncardiac chest or abdominal pain, ultimately arriving at upper GI (UGI) evaluation with which the diagnosis is made. Upper GI endoscopy and imaging studies are the mainstays of diagnosis and evaluation.

Imaging Studies

Chest x-rays, whether obtained for entirely unrelated reasons or not, can give the diagnosis of PEH. Common findings on chest films include a retrocardiac air-fluid level, resulting from an intrathoracic stomach (Fig. 14-4). Coiling of a nasogastric tube above the diaphragm is another classic finding.

The upper GI barium swallow/esophagogram is an essential part of the workup for these patients and often gives the most accurate information regarding the hernia's anatomy and position, as well as the location of the gastroesophageal junction. It can also offer some functional information regarding esophageal peristalsis and reflux, though it is not the best test to evaluate esophageal function (Fig. 14-5).

Computed tomography (CT) is not typically used in the workup of PEH. Its frequent use in patient workup for other reasons often leads to diagnosis of PEH when present. CT is a good modality to differentiate from other hernias of the diaphragm such as Morgagni's hernia or to evaluate hernia contents in a type IV hiatal hernia.

Endoscopy

Flexible esophagogastroduodenoscopy (EGD) is an extremely useful diagnostic test and one that is necessary as part of the workup for PEH. EGD allows the operator to evaluate the gastroesophageal junction and the size of the hernia, which

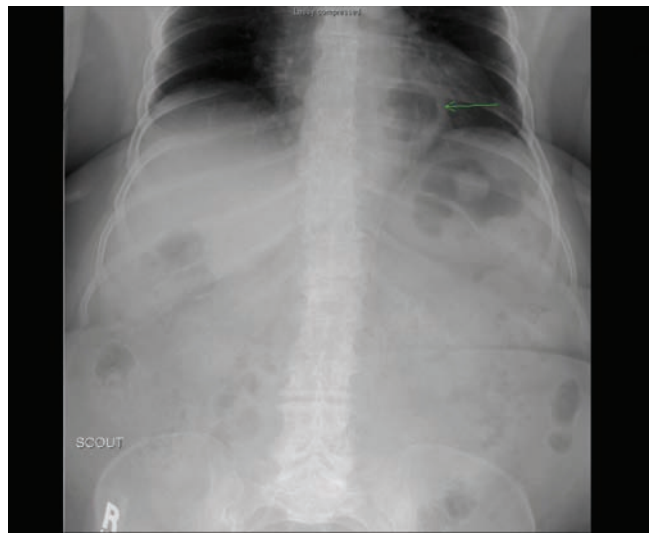

FIGURE 14-4 Chest x-ray—retrocardiac air-fluid level (*arrow*) resulting from intrathoracic stomach with paraesophageal hernia. (Used with permission from Saurabh Khandelwal, MD, University of Washington.)

are both seen best on retroflexion. Navigating the anatomy can be a challenge as displacement and extrinsic compression of the esophageal lumen or stomach alter anatomic landmarks. An important part of the endoscopic evaluation is to screen for Barrett's esophagus and malignancy. The presence of either of these can alter therapy.

Manometry and pH Testing

Ambulatory pH testing and esophageal manometry may be useful adjuncts in the workup of PEH. They can be technically

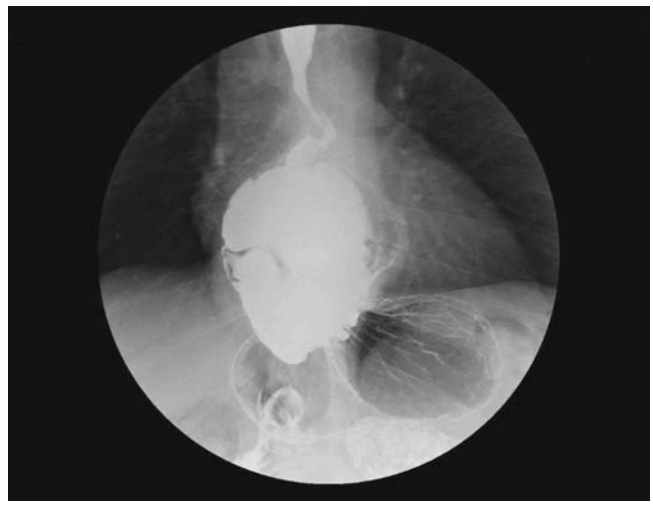

FIGURE 14-5 Upper gastrointestinal (GI) barium study. Type III hiatal hernia demonstrated. (Used with permission from Saurabh Khandelwal, MD, University of Washington.)

hard to perform, as intubation of the LES may be impossible to achieve due to anatomic distortion. Clarifying esophageal function in these patients with manometry, while useful, very rarely changes our operative plan. Only under circumstances of complete aperistalsis of the esophagus do we deviate from performing a routine Nissen fundoplication as part of the PEH repair. In these circumstances, either the fundoplication is omitted, or a partial fundoplication (Dor or Toupet) is performed. Because of the difficulty in successfully performing the test and because reflux is addressed surgically in our standard PEH repair with Nissen fundoplication, we do not mandate 24-hour pH testing. For those who perform fundoplication selectively, it may make even more sense to pursue 24-hour pH studies. That said, preoperative pH studies are probably a poor predictor of GERD after repair if a fundoplication is not done, because the hernia itself stretches the phrenoesophageal membrane and the other natural antireflux anatomy. In other words, even if patients do not have GERD before repair, most will develop GERD if a fundoplication is not employed. For patients whose symptoms are primarily related to suspected GERD, pH monitoring should be done to confirm the reason for surgical intervention.

Indications For Treatment

The indications for operating on patients with PEH continue to evolve over time. Earlier surgical tenets deemed the diagnosis of PEH an indication for surgical correction. This was largely in part due to retrospective observations, published by Skinner, Belsey, and Hill in the late 1960s and early 1970s and from other small case series or reports in which a high incidence of complications and mortality associated with observation or emergent operation was observed. Skinner followed 21 asymptomatic patients, of which 6 (29%) developed complications of bleeding, perforation, or strangulation with observation. This, in addition to an observed pooled mortality rate of 17% with emergent operation but a 1% mortality rate with elective repair, led to the recommendation that all patients fit for surgery should undergo repair of PEH.[5–7] We now know that these hernias are not always symptomatic, often discovered incidentally, less likely than previously thought to present with acute complications, and may not necessarily require repair.

Recently, Stylopoulos and colleagues performed a population-based study showing that mortality rates associated with observation to be lower than previously reported, and the mortality associated with emergent operation to be 5.4% rather than 17%. Their study used a population-based decision model to estimate the risk of watchful waiting versus repair in a cohort of 5 million patients, using available data from the 1997 Nationwide Inpatient Sample (NIS) on PEHs. They estimated that the perioperative mortality rate of those undergoing elective repair to be 1.4% and the annual risk of complications associated with watchful waiting to be 1%. As a result, they concluded that watchful waiting in an asymptomatic or minimally symptomatic population is a reasonable strategy.[8] We believe that this is a reasonable approach, especially in elderly patients with multiple comorbidities and asymptomatic hernias. We have found their data to be consistent with our clinical experience. Young (<65 years) and fit patients, even if not symptomatic, should probably be considered candidates for repair because they have many years to become symptomatic or develop an acute volvulus. Obviously, patients who are symptomatic or who have demonstrated progression of their symptoms should be evaluated and taken for elective repair if their medical condition allows.

Therapeutic Controversies

Widely differing opinions exist regarding the aspects of surgical management for paraesophageal hernias. They center on the ideal approach, the use of mesh, management of the shortened esophagus, and the use of fundoplication. As one develops an operative strategy, it is important to keep in mind the fundamental steps that are considered universal in PEH repair: reduction of the stomach into the abdomen without tension, excision of the hernia sac, reapproximation of the crura, and anchoring of the stomach.

OPERATIVE APPROACH

Laparoscopic, open laparotomy, and transthoracic approaches have been described for PEH repair. Each has advantages and disadvantages. Thoracotomy offers excellent visualization and it is easier to perform gastroplasty for esophageal lengthening from this approach. Performing a fundoplication from the chest, however, is difficult to accomplish. This approach confers the most morbidity, with longer hospital stays, need for single-lung ventilation, and postoperative chest-tube drainage. Open laparotomy approach is familiar to most surgeons, avoids a chest incision and its associated morbidity, and may result in decreased operative time. Visualization of the mediastinal structures and exposure of the hiatus, however, are difficult with this approach.

The laparoscopic approach overcomes many of the drawbacks of the two conventional open approaches. It provides good visualization of the hiatus and mediastinal structures, and allows for easier creation of a fundoplication. High mobilization of the esophagus into the mediastinum is possible. Avoiding the chest as an open operative field eliminates the need for single-lung ventilation, chest tubes, and the postoperative pain associated with thoracotomy. Since the introduction of laparoscopic techniques, many studies have confirmed its feasibility, safety, quicker recovery, and shorter length of stay.[9,10] While our approach is laparoscopic, we cannot overemphasize that these are complex operations to perform laparoscopically, even for those with advanced laparoscopic foregut experience. They should be left in the hands of experienced laparoscopic foregut surgeons. No randomized clinical trials have been performed comparing the various approaches.

CRURAL REPAIR

As recurrence is a major outcome measure with any hernia repair, it is important to examine the crural repair component of PEH repair. Crural repair and its longevity, as with any hernia repair, depends on a tension-free closure. Many strategies have been employed to overcome the tendency toward recurrence and improve the chances of healing at the hiatus. These have included the use of pledgets, relaxing incisions, and various types of prosthetic mesh. Two randomized trials comparing hiatal closure with and without mesh were performed by Frantzides et al and Carlson et al.[11,12] Carlson's study randomized patients with PEH to simple suture cruroplasty or cruroplasty with polytetrafluoroethylene (PTFE) and all patients had a Nissen fundoplication. They showed a reduction in hiatal hernia recurrence in patients who received a mesh closure (18.8% recurrence with simple cruroplasty vs 0% recurrence with PTFE-reinforced cruroplasty). Frantzides performed a study that included patients with all types of hiatal hernia (type I–IV) in which patients with hernia defects of greater than 8 cm were randomized to simple suture cruroplasty or cruroplasty with PTFE mesh. At a median follow-up of 2.5 years, a 22% recurrence rate with simple cruroplasty was observed and no recurrences with mesh repair.

Initial enthusiasm and results, mostly from small series, have been tempered with increasing reports of complications at the hiatus because of prosthetic mesh placement, including migration, infection, dysphagia, and erosion into the esophagus. Polypropylene exhibits significant shrinkage due to hydrolysis and adhesions, and we do not recommend its use at the hiatus. PTFE produces fewer adhesions, but erosion into the esophagus can occur.[13] Erosion into the esophagus is a serious complication that usually requires esophagogastrectomy for treatment and is a matter of high consequence.

Our preference has been to use a biologic mesh product to reinforce the primary closure. Biologic meshes act as a collagen-based absorbable bioscaffold into which native tissue ingrowth occurs. These materials potentially address the concerns of erosion, infection, and dysphagia associated with permanent prosthetic mesh placement at the hiatus.[14] To test this approach, we conducted a multicenter randomized trial in which patients were randomized to primary repair (n = 57) or primary repair buttressed with a biologic prosthesis (n = 51, small intestinal submucosa [SIS]). The primary outcome measure was recurrence seen on UGI. Upon completion of our study, we observed a reduction in hernia recurrence rate from 24% down to 9% in 95 patients at 6 months.[15] While our results only represent a 6-month follow-up, Jacobs and colleagues demonstrated excellent results with SIS mesh cruroplasty at a median follow-up of 28 months without complications and with similarly low recurrence rates.[16] Desai and colleagues performed a histologic analysis at 1-year follow-up in a canine model in which SIS mesh was used to repair hiatal defects. They demonstrated that good tissue ingrowth occurred and that SIS mesh cruroplasty did not result in erosions or strictures.[17] Problems with stenosis and fibrosis at the hiatus have been reported with biologic mesh, but not erosion. A recent review of mesh-related complications by Stadlhuber and colleagues summarizes the current literature in this regard.[18] Like most surgical complications, we feel that the true incidence is likely underreported. At this time, we feel that biologic mesh offers the best efficacy and safety profile of the available hiatal mesh prostheses, and do recommend its use during PEH repair.

ROUTINE FUNDOPLICATION

Routine partial or total fundoplication should be performed at the time of PEH repair for several reasons. First, there is a significant incidence of postoperative abnormal acid exposure as seen on 24-hour pH testing.[19,20] In addition to the already abnormal gastroesophageal junction anatomy associated with PEH, further dissection at the time of surgery likely disrupts this natural barrier even more, eliminating its contribution to the natural antireflux mechanism of the hiatus. Second, the creation of a fundoplication acts as a gastropexy mechanism anchoring the stomach below the diaphragm, likely reducing recurrence rates. Total fundoplication (360 degrees) has not been associated with increased rates of dysphagia in patients with impaired peristalsis.[21,22] In cases of complete aperistalsis, a partial fundoplication is a reasonable option.

Operative Technique: Laparoscopic Paraesophageal Hernia Repair

POSITIONING AND PORTS

The patient is positioned in the low lithotomy position, using a beanbag and gel pad to form a padded mold for support. The operation is performed in the steep reverse Trendelenburg's position (Fig. 14-6).

Access and insufflation are obtained per the surgeon's preference. We gain access at the left upper quadrant, immediately below the costal margin, using a Veress needle and an optical bladed trocar. Our ports are placed in what we refer to as our standard esophageal operating position (Fig. 14-7).

DISSECTION

The surgeon begins by gently reducing the stomach into the abdomen. The short gastric vessels are then divided using an appropriate energy source. These vessels are usually long and attenuated due to the fundus' displacement into the chest, and they will lead to the base of the left crus. We use a left crus approach as our group previously described.[23] The hernia sac is sharply entered using electrocautery at the base of the left crus. It is important to stay in the correct plane and divide the entire hernia sac. Great care must be taken to avoid injuring the crural pillars, which are usually thin and attenuated. The dissection between the sac and the mediastinal structures is carried up and to the right, proceeding circumferentially

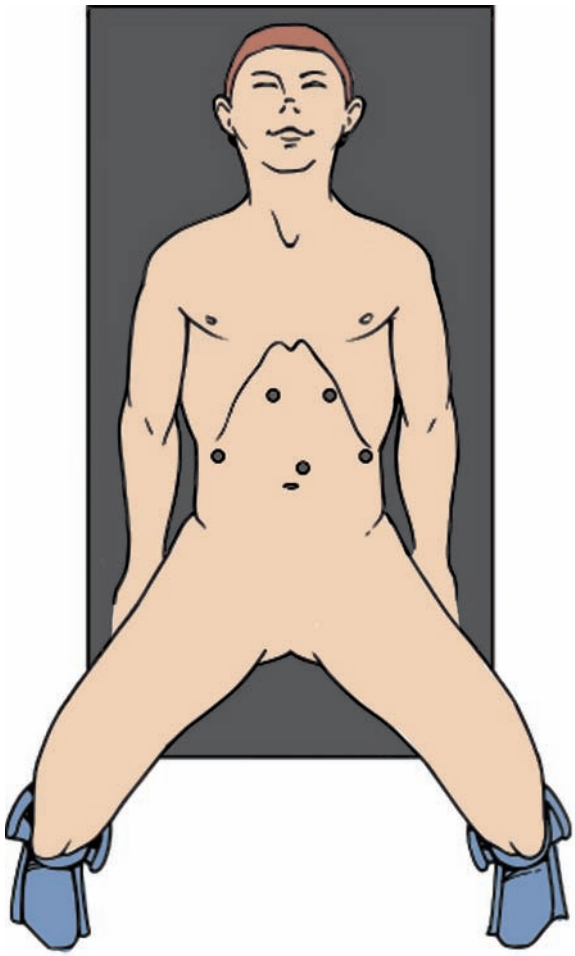

FIGURE 14-6 Patient in low lithotomy position for optimal access and exposure for the hiatus.

around the hiatus. The anterior vagus nerve (as it is often displaced away from the esophagus by the sac and is easily divided) and the esophagus must be clearly identified. The esophagus is distorted, and identification is aided by the careful passage of a lighted bougie placed in the esophagus. The bougie should be pulled back once the esophagus is identified, as traction against it can lead to perforation.

If an aberrant left hepatic artery is encountered, all attempts should be made to preserve it. The sac is then dissected off the right crus, taking care to identify and not injure the posterior vagus nerve. Great caution must be taken to identify and avoid injuring the left gastric artery and vein as they may be stretched and entering the mediastinum. Once the hernia sac is released and reduced from the mediastinum, ½-in Penrose drain is placed around the esophagus at the gastroesophageal junction and used to provide traction. The assistant, through the left flank port, grasps the drain to manipulate the esophagus in order to provide exposure.

All of the hernia sac should be reduced, after which mediastinal dissection is carried out to free up the esophagus and gain length. Dissection of the esophagus is routinely carried up to the level of the pulmonary veins and can be taken higher if needed. The goal is to dissect enough so that the gastroesophageal junction lies easily and without tension within the abdomen. Once the sac is reduced and the esophagus mobilized, the sac is resected en bloc, beginning to the left of the anterior vagus nerve. We feel this aides with the creation of the fundoplication by keeping this extra tissue out of the wrap.

CRURAL REPAIR

Posterior crural reapproximation is the next step after mobilization of the esophagus is completed. Either intracorporeal suturing with free needles or a laparoscopic suturing device can be used. We begin inferiorly just above the median arcuate ligament and proceed up the pillars with our sutures. Depending on the size of the defect, three to eight no. 0 or 1 braided, nonabsorbable sutures are placed in interrupted fashion. The 52F bougie can be advanced into the stomach at this time to gauge the cruroplasty. The tip of a blunt instrument should pass in the space between the bougie-filled esophagus and the reapproximated crura. On rare occasions, the final posterior crural sutures, if placed, can cause excessive anterior

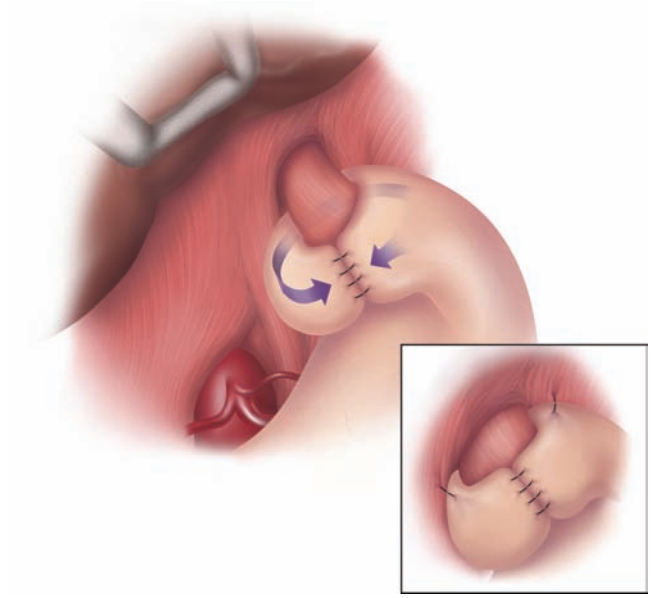

FIGURE 14-9 Construction of Nissen fundoplication after paraesophageal hernia (PEH) repair. (Oelschlager B, Eubanks T, Pellegrini C. *Sabiston Textbook of Surgery*, 18th ed, Chapter 42.)

angulation of the esophagus. In this case, we omit them and place anterior crural sutures using the same technique.

A biologic mesh is next used to buttress the crural repair. A U-shaped mesh is fashioned, using six-ply mesh, and affixed to the apex of the right and left crura with suture, then secured posteriorly with fibrin glue (Fig. 14-8).

FUNDOPLICATION

Fundoplication is then performed over a bougie to ensure appropriate sizing. To ensure correct geometry and positioning of the fundoplication, we first place a marking suture posteriorly on the fundus 3 cm below the gastroesophageal junction and 2 cm from the greater curve. This is brought to the patient's right side posteriorly through the retroesophageal window, at which point this suture is grasped. A mirror image is created with the anterior fundus, and they are brought together at the 10 o'clock position at the hiatus. A "shoeshine" maneuver is performed, bringing the posterior fundus back through the retroesophageal space to the left side, checking to see that an equal length of fundus is used on either side of the greater curve, as marked by the ligated short gastric vessels. This ensures that, when constructed, the sutures on the wrap should be 180 degrees opposite the greater curve.

Four sutures are placed, 1 cm apart, to create a 3-cm wrap. This is done over a 52F bougie. Three additional coronal sutures are placed. The first two are placed on the left and right sides respectively, through the top of the fundoplication, taking a good bite of the esophageal muscle, and finally through that respective right or left crus. The last suture is placed posteriorly where the fundoplication lies naturally against the now closed hiatus (Fig. 14-9).

For the open technique, essentially the same steps are taken but through a midline incision.

MOTILITY DISORDERS

Spastic Motility Disorders

Primary esophageal motility disorders (PEMDs) encompass both spastic disorders and achalasia. Spastic disorders include nutcracker esophagus, diffuse esophageal spasm (DES), and hypertensive lower esophageal sphincter (HLES). These rare disorders can present with variable or nonspecific symptoms and can be difficult to diagnose and treat. Symptoms frequently include chest pain, GERD, regurgitation, and less commonly dysphagia. The clinician must pay careful attention to presenting complaints and beware of what symptoms typically respond to treatments and which do not. It is important to distinguish between the primary motility disorders just mentioned and those symptoms secondary to GERD. GERD is a significant cause of esophageal dysmotility and should be evaluated for its presence. Its successful treatment, medically or surgically, often mitigates the symptoms suffered by many patients. These patients may be initially diagnosed with esophageal motility disorders but in actuality have a significant reflux component to their problem.[24–27] Secondary causes of esophageal motility disorders can include diabetes mellitus, Chagas' disease, collagen vascular diseases, and multiple sclerosis. If such conditions exist, their severity and prognosis should be taken into consideration when forming a diagnosis and prior to embarking on any therapy.

PATIENT PRESENTATION AND EVALUATION

Prior to investigation of the esophagus as the cause of symptoms, a cardiopulmonary evaluation should be performed to rule out the heart or lungs as the cause. The evaluation of motility disorders should include a careful history taking. This may help clarify the diagnosis and should allow the examiner to pick up on any confounding psychiatric illness or disorder that may be responsible, such as rumination syndrome. A systematic workup should include endoscopy and UGI barium swallow to evaluate the anatomy and rule out malignancy or other lesions as a cause. Esophageal manometry is an essential component of the workup, and 24-hour pH study should be performed to evaluate for reflux (Fig. 14-10).

DIFFUSE ESOPHAGEAL SPASM

Diffuse esophageal spasm (DES) was first described by Osgood in 1889.[28] Typically, patients affected by DES will complain of chest pain and dysphagia, and may present with functional obstructive symptoms. Symptoms of DES can be difficult to distinguish from GERD; both pH and manometry should be performed as part of the workup to evaluate the patient. If abnormal reflux is found on testing, the first treatment strategy should be to control GERD with antisecretory therapy. The defining characteristics of DES on manometry include greater than 10% (but <100%) of wet swallows that are followed by simultaneous esophageal contractions of amplitude 30 mm Hg or greater (Fig. 14-11).[29,30] LES dysfunction, manifested by improper relaxation and/or hypertensive state, is seen in over half of patients diagnosed with DES.[31] Intermittent peristalsis and prolonged contractions are also findings seen on manometry. DES is a rare true finding and is estimated to be found only in 3–5% of patients evaluated for an esophageal motility disorder.[32] Whereas previously there was thought to be little role for surgical treatment in DES, more recent reports of small series have shown good results for relief of dysphagia after esophageal myotomy in up to 80% of highly selected patients, while chest pain is more difficult to cure.[24,31,33] A careful, thorough workup and exclusion of GERD as a confounding factor should be done before attempting to diagnose and surgically treat DES. Medical management is an appropriate initial approach.

NUTCRACKER ESOPHAGUS

Nutcracker esophagus (NE) was first described by Brand and associates[34] in 1977 and named as such by Castell several years later.[35] Typical presenting symptoms of patients with NE include chest pain and less frequently dysphagia. Its defining characteristics on manometry include hypertensive esophageal contractions of greater than 180 mm Hg (Fig. 14-12). Patti and colleagues performed myotomy for these patients and observed that dysphagia was controlled in 80% of patients, but that chest pain persisted in 50% of them.[31] Interestingly, in the patients with recurrent pain, they *developed* dysphagia postoperatively, possibly because of weakening of peristalsis by performing the myotomy. Most patients with this manometric finding consistent with NE and presenting with chest pain do not need an operation, and consideration for surgery should rather be carefully given to patients with dysphagia as the presenting symptom. The best candidates may be a small subgroup in which manometry demonstrates a hypertensive LES in addition to NE findings as well as a functional obstruction on UGI. As with DES, one must evaluate for GERD and treat if present. GERD, when present in conjunction with hypertensive esophageal contractions, can be an inciting factor causing further esophageal irritation in a hypersensitive esophagus. Therapy aimed at correcting abnormal acid exposure and irritation can lead to significant improvement in symptoms. The mainstay of treatment is medical therapy. Calcium channel blockers have shown benefit in symptom improvement.[36] Tricyclic antidepressants may also provide symptom relief and benefit to patients.

HYPERTENSIVE LOWER ESOPHAGEAL SPHINCTER

Hypertensive lower esophageal sphincter (HLES) is a condition defined as having a resting LES pressure of greater than 45 mm Hg with intact, normal peristalsis (Fig. 14-13). Incomplete relaxation of the LES may also be a feature. The condition was first described in 1960.[37] Patients with HLES can be a heterogeneous group and can present with symptoms of chest pain and/or dysphagia. They may also have symptoms of a functional obstruction at the LES. Presentation can be with isolated symptoms or in association with GERD. Careful history taking and a thorough workup with manometry and pH testing are essential to clearly define the symptoms and the primary problem in terms of esophageal function. Therapy should be tailored to the presenting symptoms. Medical management to reduce LES pressures with calcium channel blockers, botulinum toxin, and phosphodiesterase inhibitors is typically the first-line approach in management. These drugs can have significant side effects and decreasing efficacy with time. In patients with GERD and manometric findings of HLES, Nissen fundoplication has shown good results in improvement of dysphagia and chest pain.[38,39] This suggests that reflux disease may be the etiology in these patients. Patients with dysphagia or chest pain as their predominant symptom and workup findings of only isolated HLES without GERD are more likely to benefit from myotomy and partial fundoplication for symptom relief, suggesting a primary sphincter dysfunction as the etiology of their symptoms. Good results have been reported by several groups that have used myotomy and partial fundoplication to treat this subset of patients, with relief of symptoms persisting as far as 3 years out.[31,38,40] While medical management is usually a reasonable first-line, conservative approach to treatment of HLES, in carefully selected and thoroughly worked up patients surgical treatment with either Nissen fundoplication or myotomy and partial fundoplication (depending on manometric and pH test findings) can produce good results. As HLES is a rare disease with heterogeneous presentation, the importance of carefully and thoroughly working

up affected patients before embarking on therapy cannot be overemphasized.

Summary

Spastic PEMDs (NE, HLES, DES) represent a diagnostic and therapeutic challenge to the clinician. Careful attention to presenting symptoms and thorough workup of esophageal function are of utmost importance for both diagnosis and discussion with patients regarding treatment options. Overlap with these disorders and GERD is frequent, and GERD can significantly contribute to and exacerbate presenting symptoms. Medical and surgical therapies have been tried in the past, most of which share the goal of relieving functional obstruction at the GEJ to allow for improved esophageal clearance. In most cases, a less invasive therapeutic approach with smooth muscle relaxing agents is a prudent first line of therapy. Surgery may be offered to carefully selected patients in whom an operation can address a discrete etiology such as abnormal GERD or isolated LES dysfunction.

Achalasia

Idiopathic achalasia is a primary motor disorder affecting the esophagus. Achalasia, which is typified by complete aperistalsis of the esophagus, is the most frequently encountered motility disorder seen by surgeons. It is a rare condition, with an incidence of 1–3 per 100,000 population in the Western world.[41] It is, however, of all the previously mentioned motility disorders, the most common PEMD. The histopathologic hallmark of the disease remains near complete or total loss of the myenteric plexus ganglion cells as a result of injury and fibrosis of these cells and myenteric nerves. Recent inquiries into the cause suggest an autoimmune disorder, as evidenced by CD3/CD8 lymphocyte markers seen on immunohistochemical analysis of the inflammatory infiltrate.[42–44] The inciting event or trigger may relate to cytotoxic T-cell activation by latent herpes simplex virus 1 (HSV-1) antigen exposure.[45,46] In addition, nitric oxide (NO) synthesis, a mediator of LES relaxation, is often impaired in the face of preserved cholinergic neuronal function.[47–49] These two insults result in loss of peristalsis and impaired relaxation of the LES, which in turn lead to the pathophysiologic findings of impaired esophageal emptying, aperistalsis, and a nonrelaxing LES.

PATIENT PRESENTATION

Achalasia can occur in patients of all ages but typically presents in patients in the second to fifth decades of life. It does not show a predilection toward either sex. Typical symptoms include dysphagia, regurgitation of indigested food, and complaints of food "sticking" in the chest. Symptoms often worsen after lying supine, with regurgitation occurring even the next day of the previous day's meal. Cold liquids frequently exacerbate symptoms, with inability to ingest cold water being a common complaint. Patients may give a history of various maneuvers they employ in attempts to allow passage of food through their nonrelaxing LES. These include raising their arms over their head, swallowing liquids to try to "wash down" food, or remaining upright for extended periods of time. It is only after overcoming the LES pressure with a column of food and liquid that exerts a greater hydrostatic pressure that the patient is able to swallow. Prior to severe progression of their disease, these maneuvers may work for them. As the disease progresses and the esophagus dilates, in effect acting like a stomach reservoir, one finds that regurgitation of the prior day's food contents becomes more common. Symptoms such as these can lead to avoidance of social situations by patients in which they fear regurgitating food in front of others. In addition, frequent regurgitation and aspiration can lead to pulmonary complications. Weight loss can occur with achalasia and tends to correlate with disease severity. However, in older patients (>60 years), recent onset of symptoms (<6 months) and significant weight loss (>10–20 lb) should stimulate concern for neoplastic causes otherwise known as *pseudoachalasia*. In such cases, patients should be worked up with a CT of the chest and abdomen and/or endoscopic ultrasound before therapy.

EVALUATION

Patients should be worked up in a systematic, methodical fashion. The workup has several components. An upper GI esophagram should first be performed to assess the anatomy. This is a common element used early in the workup of dysphagia and is a good screening tool. Particular attention to the morphology of the esophagus (ie, is a sigmoid esophagus present?) and anatomic location of the LES should be given attention. Classic findings on barium esophagram include distal tapering to the GE junction, resulting in a "bird's beak" appearance. Air fluid levels are often seen (Figs. 14-14 and 14-15). While radiologic reports often will comment on the peristaltic quality of the esophagus, we reserve such categorization for manometry.

Manometry is used to confirm the diagnosis of achalasia. Aperistalsis of the esophageal body and impaired relaxation of the LES are the hallmark findings on manometry, with aperistalsis being a requisite finding. Waveforms are typically low amplitude and simultaneous (Fig. 14-16). Vigorous achalasia, a variant in which high-amplitude waveforms are present can be encountered, and it is usually found in patients with earlier stages of the disease before complete destruction of the myenteric ganglion cells ensues.

Endoscopy is an essential part of the workup for achalasia patients. This offers the chance to directly inspect the mucosa and evaluate the GE junction. Any abnormalities should be biopsied to rule out causes of pseudoachalasia, as well as evaluated with CT and/or endoscopic ultrasound.

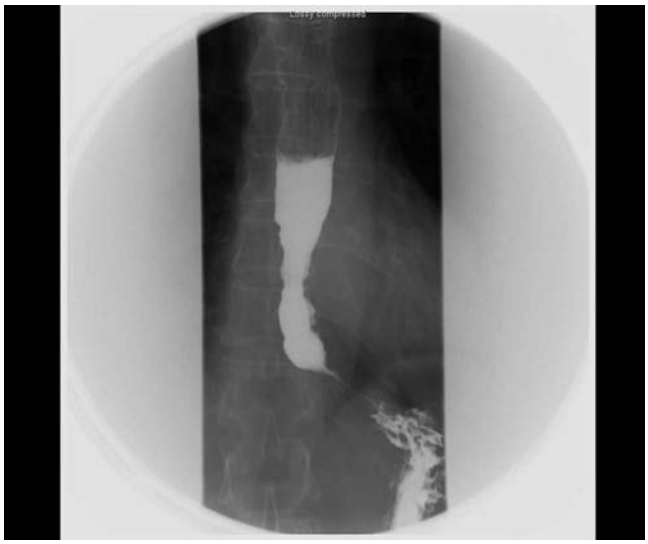

FIGURE 14-14 UGI demonstrates distal tapering and "bird's-beak" appearance in achalasia. (Used with permission from Saurabh Khandelwal, MD, University of Washington.)

We do not routinely perform 24-hour ambulatory pH monitoring on these patients, as it does not usually add to the clinical picture. False-positive results can occur as a result of fermentation of food within the esophagus.

TREATMENT

Therapy for achalasia is palliative in nature and may involve pharmacologic, endoscopic, and surgical therapies. It must be emphasized to the patient that therapies do not cure or address the pathophysiologic abnormality, but instead they are designed to relieve symptoms of obstruction and impaired esophageal emptying by relaxing or disrupting the muscle fibers of the LES.

FIGURE 14-15 Sigmoid esophagus seen with long-standing achalasia. (Used with permission from Saurabh Khandelwal, MD, University of Washington.)

Medical therapy has focused on drugs that relax smooth muscle and decrease LES pressure. Nitrates and calcium channel blockers are used. Because of their limited effectiveness and inconsistent absorption, their use is limited. Impaired esophageal emptying can affect their ingestion and absorption. In randomized controlled trials, calcium channel blockers have not shown significant success in improving clinical symptoms, despite lowering LES pressures.[50,51] Sildenafil, a phosphodiesterase inhibitor, has been shown to have potent relaxing effects on the LES,[52] but its clinical use is limited by poor tolerance and side effects. Nitrates, which can be used in sublingual formulation to overcome poor absorption, tend to work better than calcium channel blockers for symptom relief.[53] Their use, however, can lead to undesired side effects such as hypotension and headache and, like all medical therapies, their efficacy decreases with time. Pharmacologic therapy should be pursued only in patients who, for medical reasons, are unable to undergo other therapies.

Endoscopic therapies include balloon dilation and botulinum toxin injection. Botulinum toxin injection works by inhibiting acetylcholine release at cholinergic nerve endings, thereby decreasing LES pressure. A recent meta-analysis of therapies for achalasia, by Campos et al, reviewed 315 patients in 9 studies who underwent botulinum toxin injection and found initial symptom relief of 78.7% at 1 month postprocedure. This steadily declined over time to 40.6% at 12 months, with 46.6% of patients requiring repeat injection.[54] While botulinum toxin injection therapy may offer temporary relief of symptoms, its effects are not durable as with surgery and repeat treatments are often needed. Moreover, when compared with myotomy, the results for botulinum toxin seem inferior. Zaninotto et al, in a randomized trial comparing botulinum toxin injection with laparoscopic Heller myotomy with fundoplication, observed at 1 year 60% remained asymptomatic in the botulinum injection arm compared with 87% of patients in the surgical arm being symptom free. At 2 years, only 34% of patients in the botulinum injection arm remained without symptoms, while 87% in the surgical arm remained symptom free.[55] Multiple injections can further complicate future surgical therapy due to the submucosal fibrosis that can result, making myotomy more difficult and increasing the risk of perforation.[56] Endoscopic botulinum toxin injection may offer an alternative to those unwilling or unable to undergo more invasive procedures but has a limited role in the treatment of the disease.

Endoscopic balloon dilation, which creates a controlled tear in the LES muscle, is another endoscopic therapy that has been used to treat achalasia and is probably the main alternative to surgery. Different types of dilations have been used in the past, including fixed diameter dilators, mercury-weighted balloons, and water-filled balloons. The most controlled and consistent results are seen with the use of noncompliant pneumatic balloon dilators, such as the Rigiflex balloon dilator (Boston Scientific, Boston, MA).[57] Campos et al, in their meta-analysis, evaluated 15 studies involving 1065 patients

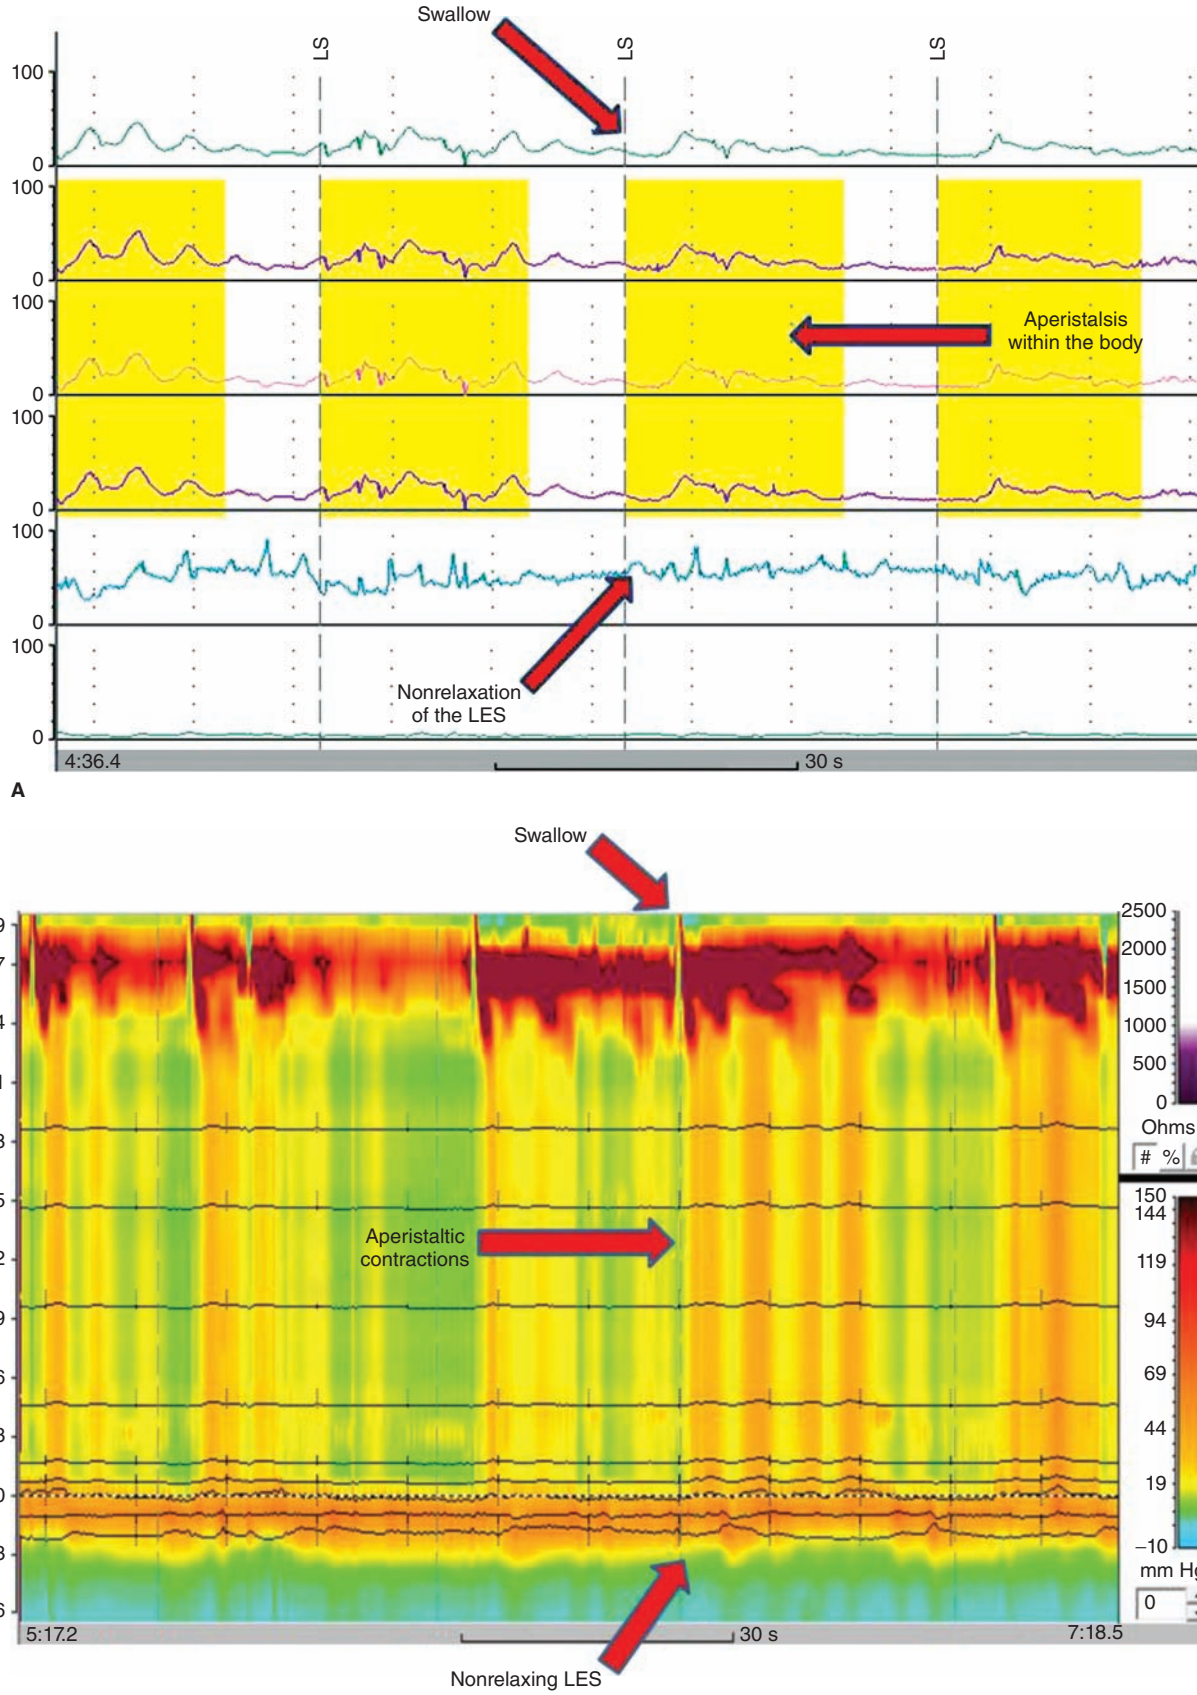

FIGURE 14-16 Achalasia as demonstrated by conventional and high-resolution manometry (HRM). LES, lower esophageal sphincter. (Used with permission from Roger P. Tatum, MD, Director, University of Washington Esophageal Motility Laboratory.)

using new generation pneumatic dilators, and observed symptom relief rates of 84.8% at 1 month postprocedure, 73.8% at 6 months, and 68.2% at 12 months. After 36 months, the symptoms relief rate declined to 58.4%. One quarter of all patients required repeat endoscopic balloon dilation therapy.[54] Balloon dilation has more long-term efficacy than botulinum toxin injection but still shows significant rates of symptom recurrence and the need for repeat therapy. It does carry more risk than botulinum toxin injection due to the risk of perforation, which is nearly 2% with pneumatic dilation methods.[54] This risk increases with the presence of significant esophageal dilation, hiatal hernia, and epiphrenic diverticula (ED). These should be considered relative contraindications to pneumatic dilation. Between the endoscopic therapies mentioned, pneumatic balloon dilation is a more efficacious procedure but has greater risk of perforation compared to botulinum toxin injection.

Surgical myotomy was first described by Ernst Heller in 1913.[58] His original description involved performing both an anterior and posterior myotomy. This has evolved in most centers to performing an anterior myotomy only. Esophageal myotomy for achalasia is associated with good long-term results and relief from dysphagia. Long-term follow-up studies have demonstrated symptom relief in nearly 75% of patients at 20 years out. Shorter-term follow-up studies demonstrate that nearly 90% of patients are symptom free approximately 3 years postprocedure.[41,54,59] Prior hesitancy for referring patients for Heller myotomy was partially due to the invasive nature of the procedure, which in the past was performed via laparotomy or thoracotomy, as well as a long hospital stay and long recovery. These approaches eventually evolved to the minimally invasive approaches via thoracoscopy or laparoscopy. Shimi et al reported the first laparoscopic Heller myotomy in 1991, while Pellegrini et al reported the first thoracoscopic approach in 1992.[60,61] Drawbacks to this thoracoscopic approach included the need for single-lung ventilation, postoperative chest tubes, and being unable to perform an antireflux procedure. The minimally invasive approach has moved predominantly to the laparoscopic myotomy approach that has eliminated these drawbacks of the thoracoscopic approach. Laparoscopy offers excellent visualization of the hiatus and the mediastinal structures, does not require single-lung ventilation or postoperative chest tube drainage, and makes creation of an antireflux technically straightforward. In addition, the laparoscopic performance of myotomy, when compared with the thoracoscopic technique, has shown better symptomatic improvement (89.3 vs 77.6%) and a lower incidence of reflux symptoms when combined with a partial fundoplication (14.9 vs 28.3%).[54]

The two main debates surrounding surgical myotomy have centered on whether or not to include an antireflux procedure (and if so which one) and what the optimal length and extent of myotomy are that should be performed. GER symptoms and esophagitis represent common causes of treatment failure after myotomy if a fundoplication is not added. Addition of an antireflux procedure to a standard Heller myotomy has been thought to reduce these symptoms and improve outcomes. This issue has been studied in a prospective, randomized trial by Richards et al, comparing Heller myotomy with Heller myotomy plus Dor (anterior) fundoplication. They demonstrated that the pathologic occurrence of GER, as defined by distal esophageal acid exposure of greater than 4.2% on 24-hour pH monitoring at 6 months postoperatively, was reduced from 47.6 to 9.1% with creation of a Dor fundoplication.[62] Some surgeons have advocated in the past for inclusion of a floppy Nissen fundoplication, rather than partial fundoplication, to prevent GER. Concern for postoperative dysphagia due to poor esophageal clearance and weak or absent propulsive force is clearly warranted in this instance. Rebecchi et al recently published the results of their study in which patients were randomized to Heller myotomy plus Dor fundoplication or Heller myotomy plus floppy-Nissen fundoplication. At 60 months of follow-up, no statistically significant difference in GER symptoms between the two groups were seen; the rate of dysphagia, however, was found to be significantly higher in the floppy-Nissen fundoplication group when compared to the Dor fundoplication group (15 vs 2.8%). They concluded that both antireflux procedures offered adequate protection from GER, but that recurrence of dysphagia was significantly higher when Nissen fundoplication was performed.[63] Toupet and Dor fundoplications with EM are being compared in a randomized, multicenter trial at this time, and the hope is that the data will help answer which is a superior antireflux procedure. Until the data can conclusively demonstrate superiority of one technique over the other, surgeon's preference and experience should guide which one is performed in conjunction with myotomy.

The length and extent of myotomy is another area of debate. Most surgeons agree that the proximal extent of the myotomy should extend 6–7 cm above the GE junction. This is carried out in a safe manner with appropriate dissection of the anterior esophagus. Distally, a standard myotomy has typically been performed and carried 0.5–1.5 cm below the GE junction. This length was chosen with the intent of being long enough to relieve the functional obstruction to the esophagus, while in an effort to preserve an antireflux barrier.[64] The result proved to fall short on both counts, with dysphagia and/or GERD being fairly common. In 1998, based on observations that reoperations for thoracoscopically performed myotomies that extended the myotomy onto the stomach resulted in improvement of dysphagia, we changed our practice to carry out the myotomy a full 3 cm below the GE junction (an extended myotomy) completely obliterating the LES fibers. We compared our extended myotomy/Toupet patients with standard myotomy/Dor patients and observed that patients who underwent extended myotomy had lower LES pressures (9.5 vs 15.8 mm Hg), less frequent and less severe dysphagia, and lower rates of recurrent severe dysphagia requiring interventions (3 vs 17%).[65] We continued to follow and then compared a cohort of 52 of these patients at a median follow-up of 46 months. No significant differences in heartburn frequency, esophageal acid exposure, or LES pressure were observed. However, dysphagia severity was reduced, and relief was improved in the EM and Toupet fundoplication group. Only 5% of patients who underwent EM/Toupet required reintervention (dilation)

versus 18% of SM/Dor patients (10% required endoscopic treatment, 8% required reoperation).[66] We feel that the Toupet is a better antireflux operation in combination with extended myotomy. Reasons for its superior efficacy may stem from its more physiologic angulation of the GE junction with its construction and its ability to stent open the myotomy and prevent reapproximation of muscle fibers and symptom recurrence. Our study compared two different operations (SM and Dor vs EM and Toupet), and we cannot answer which wrap is superior. At this time, we recommend performing either anterior or posterior fundoplication with extended myotomy. We continue to routinely perform extended myotomy and have seen excellent results and low rates of dysphagia. Rarely do we need to consider dilation, and we have essentially eliminated the need for reoperation with this approach. Because of this more complete obliteration of the LES, this should be used in conjunction with an antireflux procedure. We feel that extended myotomy of 3 cm below the GE junction should be a routine practice when performing a Heller myotomy.

OPERATIVE TECHNIQUE

Laparoscopic Heller Myotomy. The setup is the same as previously described in this chapter for PEH repair, utilizing our standard esophageal operating position regarding patient positioning and trocar placement. We use a 10-mm, 30-degree laparoscope to ensure the best possible image for performing the myotomy. This is especially important during the creation of a myotomy. In contrast, we use 5-mm, 30-degree laparoscopes for PEH repairs and first-time Nissen fundoplications. Patients are instructed to remain on a liquid diet for 2 days prior to surgery to minimize the amount of retained food within the esophagus and decrease the risk of aspiration at the time of surgery.

We begin by dividing the phrenogastric ligament sharply and then divide the short gastric vessels with ultrasonic shears. A left crus approach is employed as previously described, and left, right, and anterior mediastinal dissection of the esophagus is performed. It is not necessary to significantly dissect the posterior attachments of the esophagus, except to provide enough intra-abdominal esophagus to perform a good fundoplication. The main goal is to gain as much length as possible anteriorly to later perform the myotomy. It is important to identify and preserve the anterior (left) vagus nerve. This nerve and GEJ fat pad are carefully dissected away from the esophageal body and preserved so that a continuous myotomy can be performed, starting below on the stomach and extending above the vagus as it crosses from left to right on the anterior aspect of the GEJ. The anterior GEJ fat pad to the left of the anterior vagus nerve is resected. This allows for accurate identification of the GEJ at the time of myotomy.

At this time, a 50F lighted bougie is passed into the body of the stomach. The transillumination provided aids in identification of the submucosal plane. A laparoscopic Babcock clamp, first applied partially opened over the bougie, is used to gently drag the tissue over and around the bougie to provide tension and exposure. The myotomy is started on the anterior stomach 3 cm below the GEJ. We prefer an L-shaped hook to perform the myotomy, but other devices can be used as well. We employ gentle use of cautery to start the myotomy and then use the L-shaped hook to gently tease the muscle fibers apart, exposing the submucosa. Entering the correct plane takes patience and careful dissection. The submucosa of the stomach contains a rich plexus of vessels that can be used as a visual identifier. Once the appropriate plane is identified, the myotomy is carried cephalad. Only minimal electrocautery is used during performance of the myotomy (Fig. 14-17).

The correct plane may be difficult to identify on the stomach, as the sling fibers of the cardia cross in variable directions and the mucosa tends to be thin. Once the GEJ is reached, the plane becomes easier to identify due to the organized outer, longitudinal, and inner circular muscle fibers of the esophagus. We first divide the outer longitudinal muscle fibers and then the inner circular layer. The myotomy is carefully extended and taken above the level of the anterior vagus nerve as it crosses from left to right over the esophagus. The extent of the myotomy is to take it as proximally as is safe. Typically, one can get 6–8 cm above the GE junction. The assistant repositions the Babcock clamp as needed to continually provide exposure and tension on the tissues over the bougie. As the myotomy is carried cephalad, the assistant can switch over to using an atraumatic grasper to hold the left side of the divided muscle fibers on tension, with the surgeon's left hand holding the right-sided fibers. In this fashion, the myotomy is completed.

Bleeding from submucosal vessels that are mistaken for muscle fibers occasionally occurs but is self-limited; gentle pressure is usually adequate to control and stop it. One must be very cautious in applying electrocautery as an unrecognized injury may result leading to delayed perforation, and thus should be avoided. If mucosal perforation occurs during the dissection, it is usually evident as saliva or gastric secretions or the light from the bougie will be seen

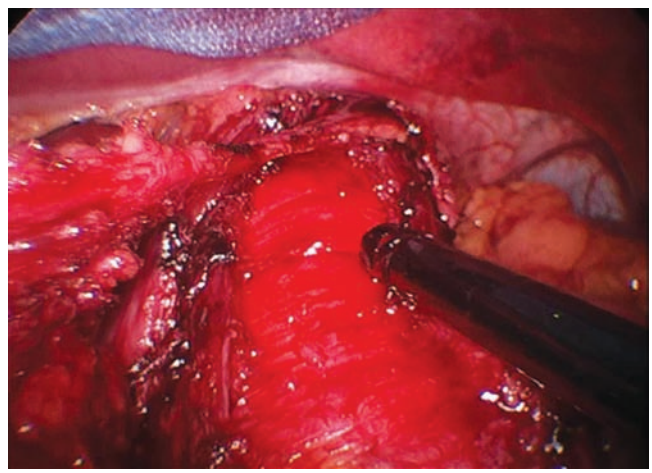

FIGURE 14-17 Myotomy performed over 52F lighted bougie. (Used with permission from Saurabh Khandelwal, MD, University of Washington.)

coming forth. Intraoperative endoscopy can be used to confirm injury as well as evaluate it after it has been repaired. Mucosal injuries should be repaired immediately with 4-0 absorbable suture, and consideration given to performing an anterior, buttressing fundoplication.

Intraoperative endoscopy is carefully performed to evaluate for the completeness of myotomy and to evaluate for injury. If all muscle fibers have been correctly divided, an open GE junction will clearly be visible on endoscopy, without indentations from undivided fibers. In addition, with gentle insufflation, injury to the mucosa can be seen both endoscopically and laparoscopically.

A Toupet (posterior) fundoplication is performed for the antireflux procedure as the final part of the operation. A suture is placed on the posterior portion of the fundus, 3 cm below the GE junction and 2 cm away from the line of the divided short gastric vessels. This is used as a reference point to ensure a symmetric posterior wrap. The fundus is brought posteriorly behind the GE junction, and the reference suture is grasped and brought up to the edge of the myotomy. The fundus is sutured to the right crus to alleviate tension, using 2-0 silk suture. The edge of the wrap is then sutured to the myotomized edge with three sutures. In similar fashion, the left component of the wrap is sutured to the edge of the myotomy and the left crus (Figs. 14-18 and 14-19).

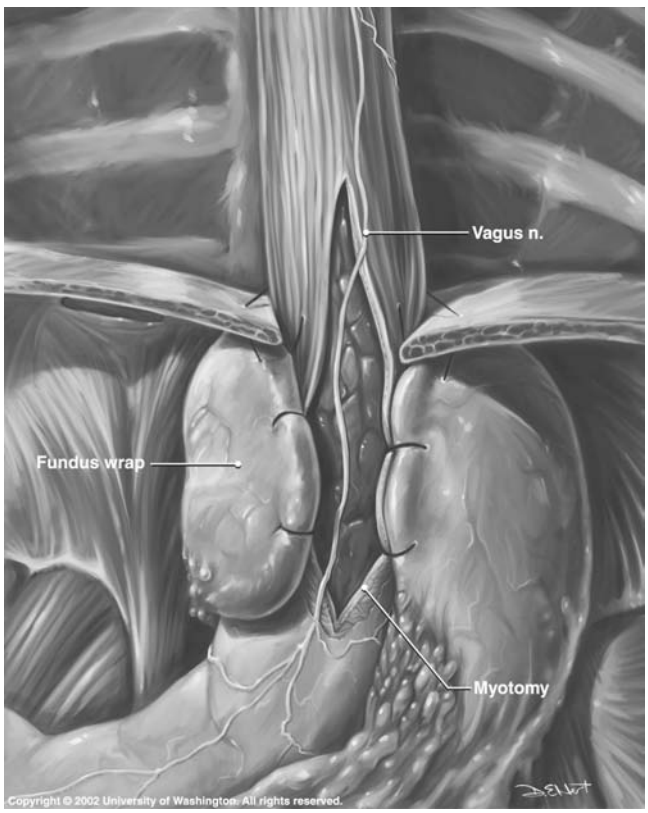

FIGURE 14-18 Diagram of completed Heller myotomy with Toupet fundoplication. (Woltman TA, Pellegrini CA, Oelschlager BK. Achalasia. *Surg Clin North Am.* 2005;85(3):483–493.)

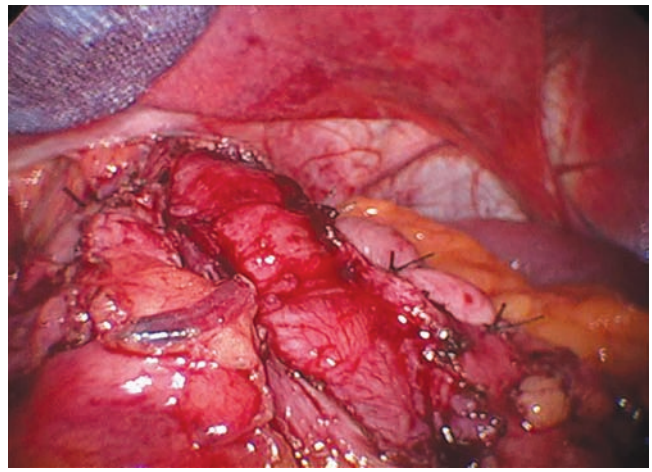

FIGURE 14-19 Intraoperative picture of completed Heller myotomy with Toupet fundoplication. (Used with permission from Saurabh Khandelwal, MD, University of Washington.)

After completing the wrap, the ports and liver retractor are removed and the port sites are closed, concluding the case.

A Dor fundoplication is an acceptable antireflux procedure and is technically easier to perform than the Toupet, as it requires less dissection, especially of the posterior stomach (Fig. 14-20). The Toupet does a better job of stenting open the divided muscle fibers and with this mechanism may lead to lower rates of recurrence and dysphagia. For this reason, we prefer this posterior fundoplication. Figure 14-21 depicts the construction and geometry of full and partial fundoplications. In patients with a very tortuous or sigmoid shaped esophagus, we omit the antireflux portion of the procedure because of the high incidence of postoperative dysphagia we have observed when performing fundoplication in these patients.

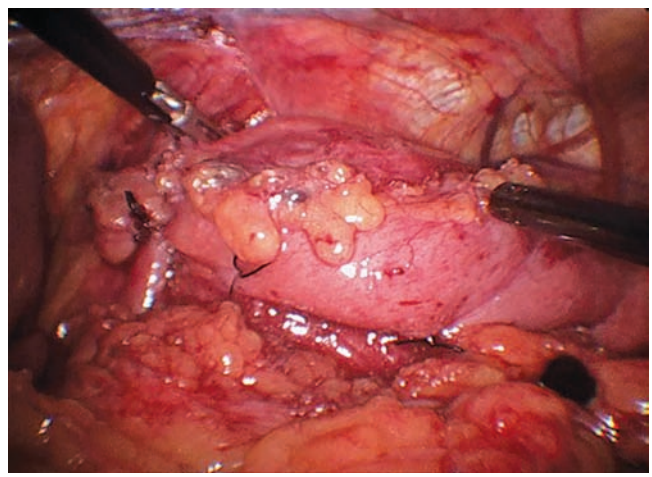

FIGURE 14-20 Completed anterior (Dor) fundoplication. (Used with permission from Saurabh Khandelwal, MD, University of Washington.)

Postoperatively, patients are started on a clear liquid diet and advanced slowly. We do not use nasogastric tubes. Nausea is controlled aggressively to prevent retching or emesis. Patients are typically discharged home on postoperative day 1. On routine follow-up, we assess for symptoms of reflux and dysphagia. At 4–6 months postoperatively, we request patients to repeat manometry and obtain 24-hour pH testing to evaluate acid exposure. If abnormal acid exposure is present or the patient has symptoms of GER, a proton pump inhibitor (PPI) is started to ameliorate symptoms and to reduce the risk of peptic stricture formation.

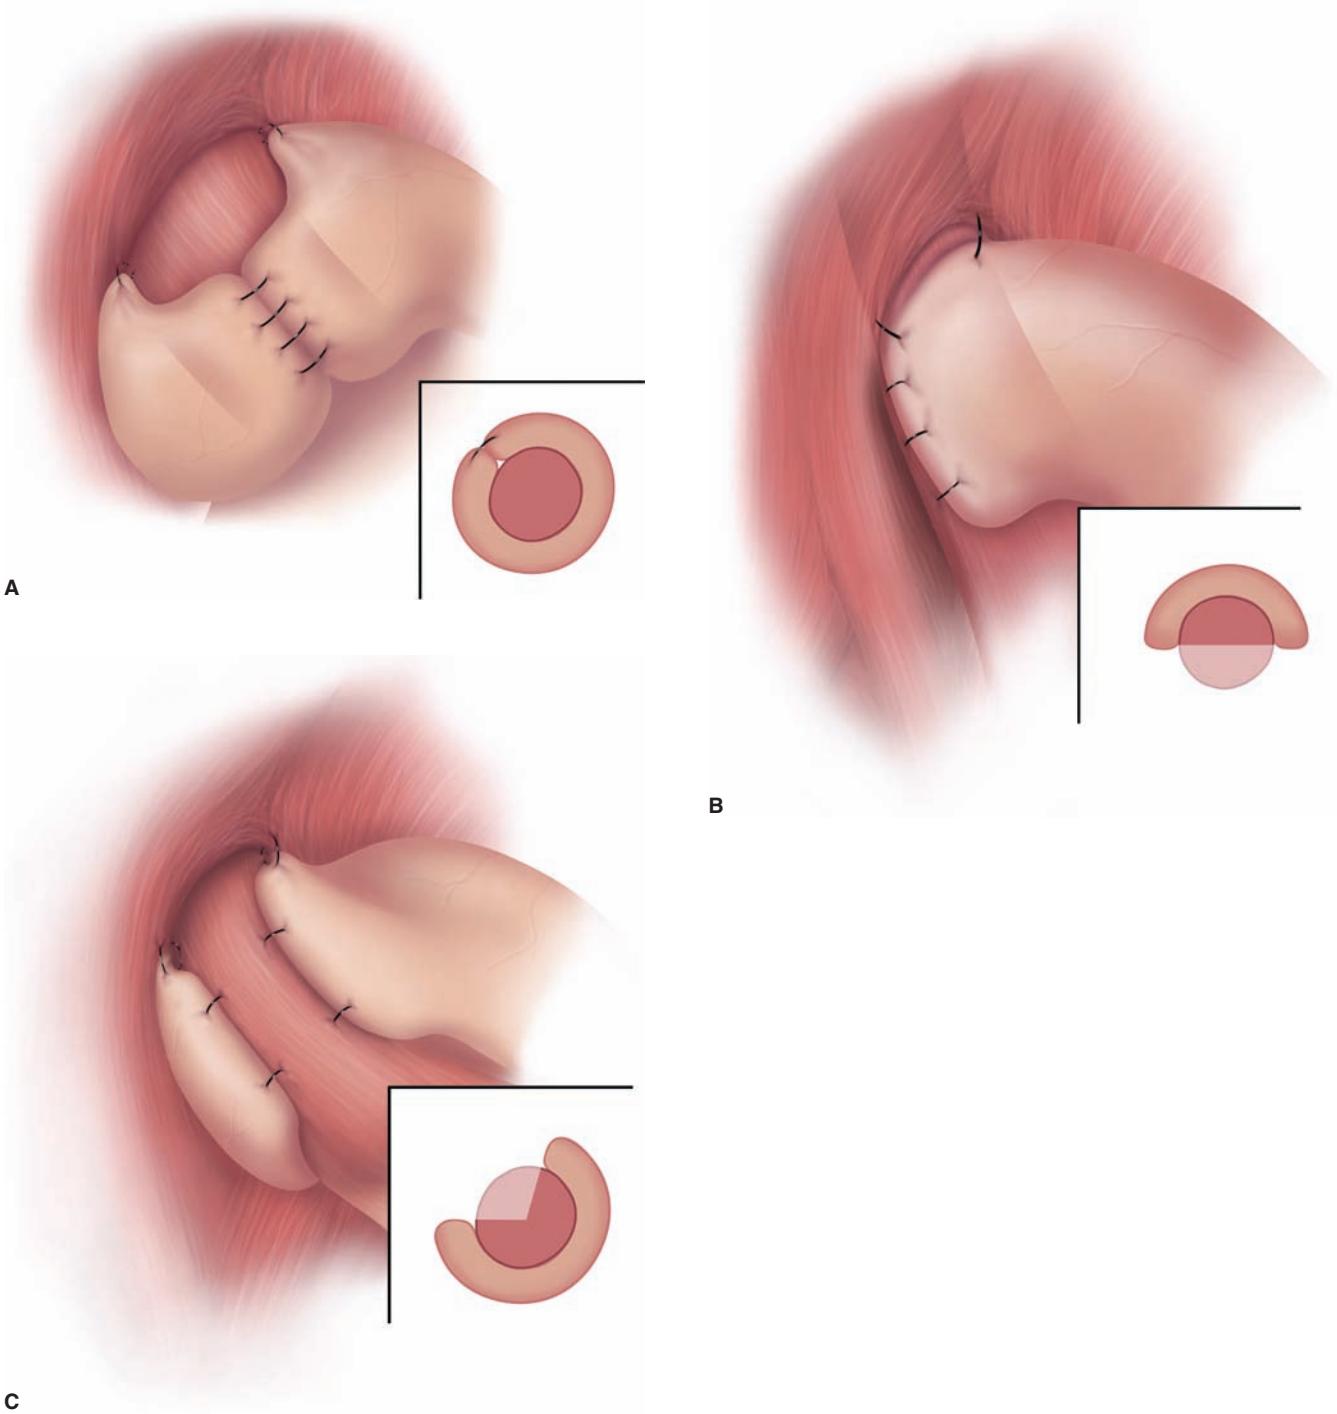

FIGURE 14-21 Different fundoplication wraps. **A.** Complete; **B.** anterior (Dor); **C.** posterior (Toupet). (Oelschlager B, Eubanks T, Pellegrini C. *Sabiston Textbook of Surgery*, 18th ed, Chapter 42.)

Summary

Motility disorders of the esophagus share the hallmark symptom of dysphagia. Careful history taking, in conjunction with physiologic testing with pH and manometry, and appropriate imaging lead to the diagnosis. With the exception of achalasia, many of these disorders can be managed medically, especially after careful evaluation and control of GER. Achalasia is a disease best treated surgically with laparoscopically performed extended myotomy and partial fundoplication. Though endoscopic therapies exist, they have inferior outcomes and durability, and should be reserved for patients unwilling or unable to undergo surgery. Minimally invasive techniques have shown great promise in treating achalasia both in terms of patient recovery and long-term outcomes.

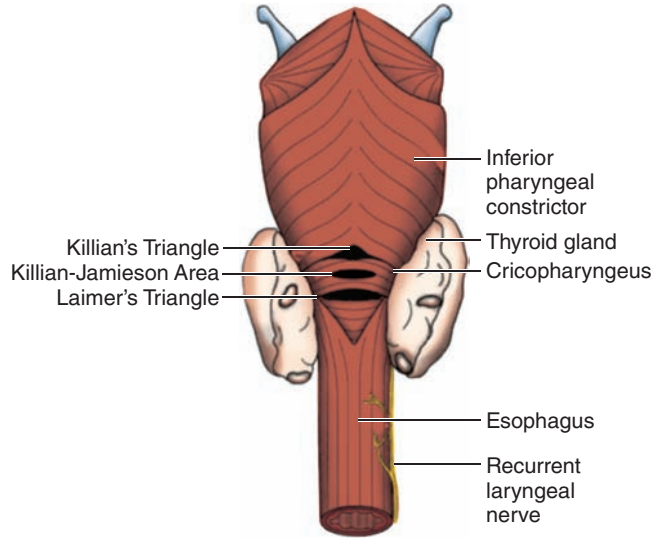

FIGURE 14-22 Schematic drawing of the posterior aspect of the pharyngoesophageal junction with areas of weakness identified.

ESOPHAGEAL DIVERTICULA

Diverticula of the esophagus are relatively uncommon. They are classified based upon their location: proximal or pharyngoesophageal, midesophageal, and distal or epiphrenic, with the latter being located within 10 cm of the GE junction. Midesophageal diverticula, which are usually traction diverticula and thus are true diverticula, are rare and usually do not require surgical treatment. They result from an extrinsic "pulling" inflammatory process and in the past were often associated with tubercular or granulomatous disease. Proximal and distal diverticula are more common and are false, or pulsion-type diverticula, as they are not composed of all layers of the esophageal wall but rather are outpouchings of mucosa. This chapter focuses on these types, specifically Zenker's diverticulum (ZD) and epiphrenic diverticulum (ED), and their management.

Zenker's Diverticulum

Originally described by Ludlow in 1769,[67] this proximal esophageal diverticula was named by German pathologist Friedrich Albert Von Zenker, who, more than 100 years later in 1877, described their etiology as being that resulting from increased pharyngeal pressure leading to formation.[68] The anatomic location of this lesion is proximal to the upper esophageal sphincter (UES) and in the posterior hypopharynx. The area in the posterior wall of the pharynx between the cricopharyngeus muscle and the inferior constrictor muscles is known as *Killian's triangle*. The weakest point in this space is the area between the two muscles, and it is here that herniation or outpouching of the mucosa and submucosa occurs, resulting in a Zenker diverticulum (ZD) formation (Fig. 14-22). In addition to a weak posterior wall, inelasticity and higher resting tone from fibrosis of the cricopharyngeus muscle are thought to contribute to the dysfunction of the pharyngoesophageal segment, leading to ZD formation.[69,70] A complete understanding of the causes for ZD formation does not exist, despite decades of research.

ZD usually presents in the seventh to eighth decades of life. It is not uncommon for significant lengths of time to elapse between the start of symptoms and presentation to a surgeon, because the symptoms are often vague, innocuous, with a lot of overlap with other benign conditions. Its incidence is difficult to estimate as the number of patients with ZD who are asymptomatic is unknown. Estimates in the United Kingdom place its incidence at 2 per 100,000 population per year.[71] Common symptoms include dysphagia, globus sensation, halitosis, aspiration, and regurgitation of undigested food. Physical examination findings are largely absent but may infrequently reveal a palpable mass, most often located in the left side of the neck.

Workup for ZD consists of barium swallow to delineate size, as measured in the craniocaudal dimension, and position. Only after this has been done, should endoscopy be attempted as perforation by blind intubation of the false lumen can lead to significant morbidity. Endoscopy largely serves to exclude other diagnoses, including tumors, mucosal abnormalities, synchronous esophageal lesions, malignant neoplasia within the diverticulum, and GERD. Manometry has not shown specific findings associated with ZD, though UES dysfunction may be present.

TREATMENT

Therapeutic options have evolved over the last century from open diverticulectomy and myotomy or diverticulopexy toward perioral endoscopic methods, including mucomyotomy with staplers, CO_2 laser, argon plasma coagulation (APC), and needle-knife. No randomized trials have been conducted comparing the methods. Most methods have

comparable symptomatic improvement ranging near or above 90% and with low morbidity and mortality. Choice of therapy is often a matter of patient and physician choice. Trends in therapy, following the European experience, seem to be shifting toward endoscopic management due to its low morbidity and mortality, avoidance of an open surgical procedure, and good outcomes.[69,72] Despite trends toward endoscopic therapy, there are patients for when the standard open surgical approach should be used, including those with narrow mandibles or small oral cavities, those in which the diverticulum cannot accommodate the scope, and instances in which the diverticulum is not posterior, for example Killian-Jamieson diverticula.[73] The instances in which open surgical resection should always be sought are with diverticula in which mucosal neoplastic changes are known to exist and those very large diverticula that cannot be approached safely with a perioral technique.

OPERATIVE TECHNIQUE

Open Cervical Diverticulectomy. Patients with ZD are placed on a liquid diet for 2 days prior to surgery, to minimize the risk of retained food and aspiration. The patient is placed supine with the neck fully extended and the head turned to the right, exposing the left neck. The left cervical approach is used as the majority of diverticula occur posteriorly and on the left. In addition, the esophagus is most accessible here as the trachea has a natural slight rightward shift. An oblique cervical incision, overlying the anterior border of the sternocleidomastoid muscle (SCM) is made. The SCM is retracted laterally as is the carotid sheath, while the thyroid gland is retracted medially. Ligation of the middle thyroid vein and omohyoid muscle is necessary to gain medial retraction of the thyroid and exposure of the tracheoesophageal groove and esophagus. The left recurrent laryngeal nerve should be identified and preserved. A left-sided approach is also more desirable from this aspect as the recurrent laryngeal nerve on this side has better exposure and more consistent anatomy compared to the right.

Dissection is carried distally and cephalad. A true ZD will be encountered in the posterior midline at Killian's triangle; it is grasped and its neck is dissected free. Next, a 50F bougie is placed under palpation and direct vision of the surgeon into the distal esophagus. A myotomy is performed, which must include the cricopharyngeus muscle and come down several centimeters onto the esophagus, which can be identified by its outer longitudinal and inner circular muscle fibers. The diverticulum is excised using a reticulating linear stapler (Fig. 14-23A–C). Resection of the diverticulum should be performed with the bougie in place to avoid narrowing of the esophagus. A drain may be placed at the discretion of the surgeon. The platysma is closed and the wound is closed in layers. If the patient is doing well clinically, he or she is started on a liquid diet the next day and can be discharged within 48 hours.

Surgical open diverticulectomy and myotomy are associated with excellent relief from symptoms in up 82–94% of patients and low recurrence rates of 3.6–7%.[69] Mild to severe complications, including staple-line leak, fistula formation, stenosis, recurrent laryngeal nerve palsy, mediastinitis, pneumonia, and hemorrhage have an occurrence rate of up to 25%. Mortality associated with the surgical approach ranges between 1.2 and 3.4%.[69,74–78]

Endoscopic Treatment. Endoscopic treatment of ZD was first described by Mosher[79] in 1917 and lost favor, because of complications, until revived by Dohlman and Mattsson in 1960.[80] They reintroduced the concept with use of electrocoagulation techniques. Collard et al in 1993 described the endoscopic stapled diverticulectomy (ESD) that is the predominant endoscopic method of treatment today.[81] Endoluminal treatments for ZD are the least invasive methods of treatment and the various forms all share the common principle of performing mucomyotomy by dividing the septum between the diverticulum and the esophageal lumen. CO_2 laser, electrocautery, needle-knife, clips, and staplers have been described and used.[80–83] The stapled diverticulectomy offers the additional advantage over these other methods of wound closure with the staples after division of the septum is completed. This is thought to decrease the risk of bleeding and possible perforation. Both rigid and flexible endoscopy platforms can be used. Rigid endoscopy is usually performed in the operating room by ENT (ear, nose, and throat) surgeons, and it incorporates the use of the stapler and a diverticuloscope, which can intubate both the esophageal lumen and diverticulum simultaneously (Fig. 14-24). Flexible endoscopic techniques employ various methods of cautery, cutting or clipping, or laser to divide the septum. Flexible endoscopy offers some advantages over the rigid method in that it can be done with sedation and analgesia, avoiding a general anesthetic, and can be performed in an outpatient setting with reduced stay and potential cost savings. It is associated with higher recurrence rate when compared to rigid endoscopy and ESD (up to 35% in some series vs up to 15.4% for ESD and rigid endoscopy). Head-to-head randomized trials comparing the differing endoluminal approaches have not been performed.

Endoluminal therapies demonstrate excellent symptom improvement in 80–96% of patients. Mild complications such as subcutaneous emphysema or mild hemorrhage are seen in up to 23% of patients; severe complications occur less frequently when compared to surgical treatment, ranging from 0 to 3.8%.[69,84] The most feared of these are esophageal or pharyngeal perforation. Mortality rates are low (0–0.4%) and no mortalities have been reported with the flexible endoscopic methods. Recurrence rates, however, are significantly higher than with surgical therapy and range between 3.3 and 35%.[69] Between the methods, the flexible platform has the highest recurrence rates; this can often be addressed with repeat therapy. While this is a drawback, the overall safety and lower-risk profile of endoluminal therapies may be a desirable factor when treating elderly patients, in which ZD most commonly presents. All patients are not candidates for endoluminal treatment of ZD, such as those with small oral cavities, large osteophytes, and small diverticula (<3 cm).[73]

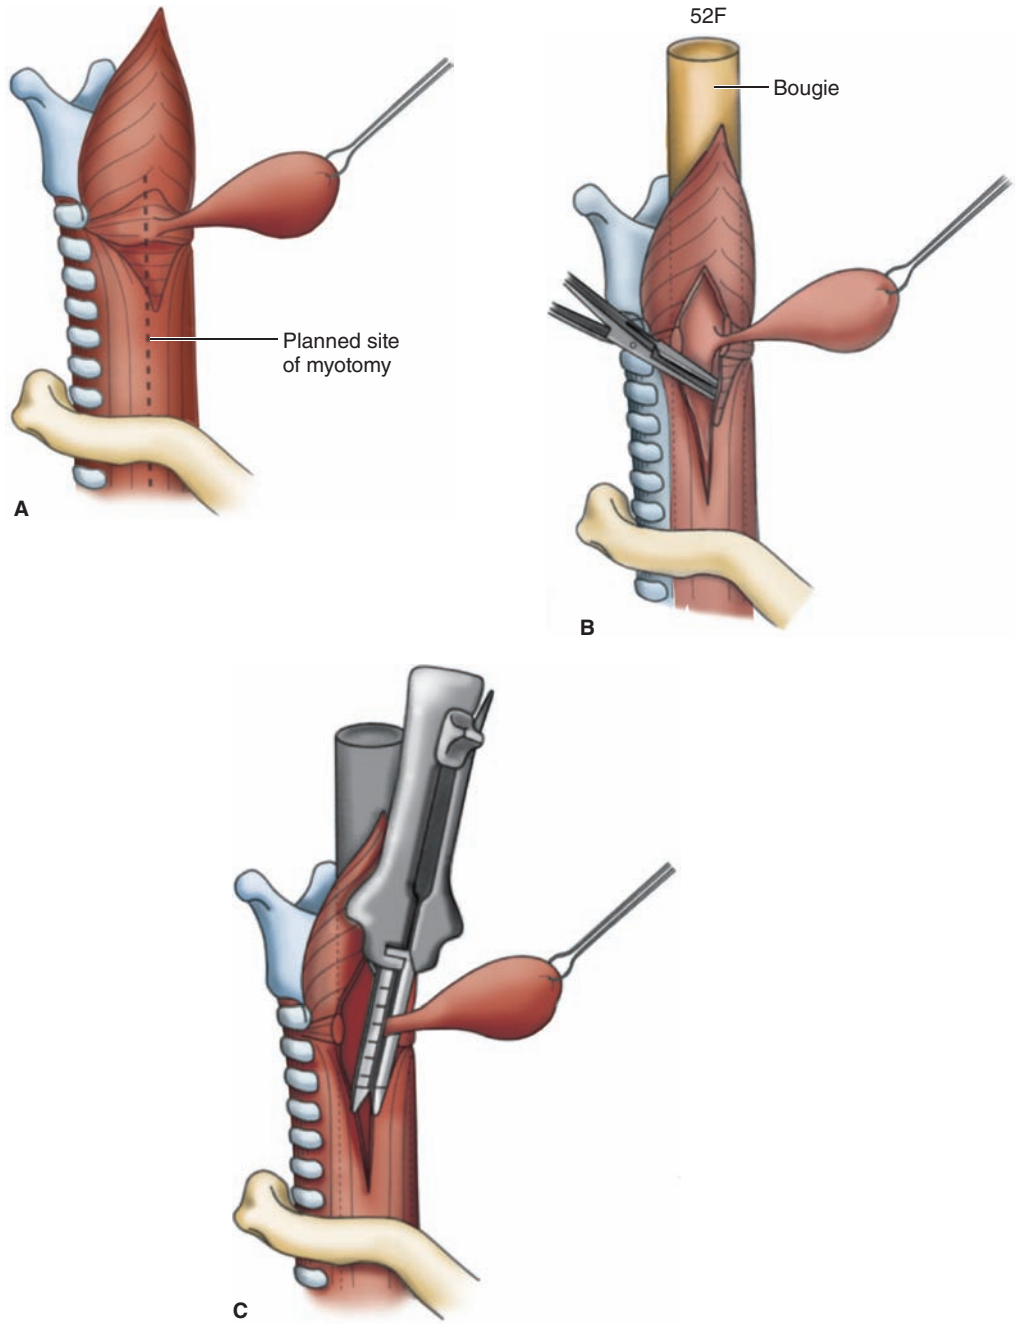

FIGURE 14-23 **A.** Zenker's diverticulum, dashed line indicates proposed site of myotomy. **B.** Isolation of Zenker's diverticulum, with myotomy. **C.** Resection of Zenker's diverticulum with gastrointestinal anastomosis (GIA) stapler.

Small diverticula are difficult to engage with the stapling device and diverticuloscope.

Summary

ZD is a rare disorder in which a pulsion-type diverticulum occurs in the posterior pharyngoesophageal region. Both surgical and endoscopic treatments (using rigid or flexible endoscopy) are employed. All therapies are associated with greater than 90% symptom relief. Endoscopic therapies are associated with shorter length of stay, can be performed as outpatient procedures, and may avoid general anesthetic administration. However, they are associated with higher recurrence rates, which can often be addressed with repeat endoscopic treatment. These are important factors to consider as ZD usually presents in elderly patients who are more likely to be infirm. Both open surgical technique and perioral

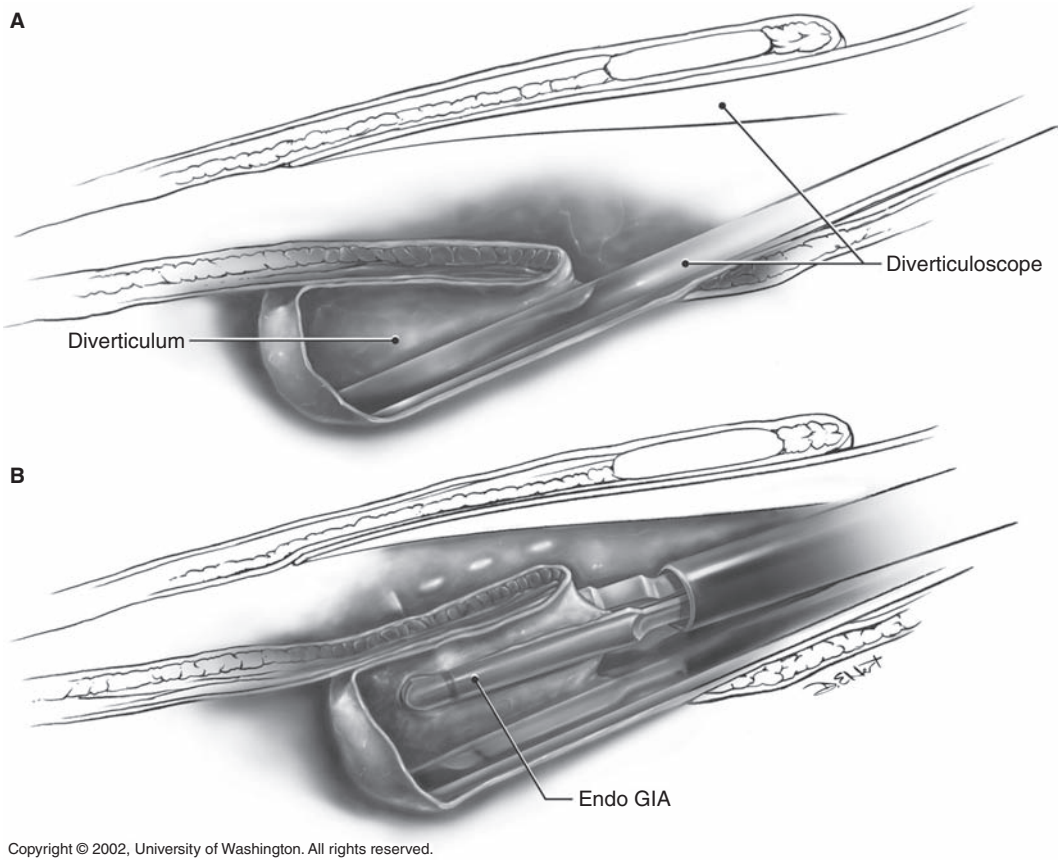

FIGURE 14-24 Zenker's diverticulectomy using diverticuloscope and stapler to perform mucomyotomy.

endoscopic methods are valid treatment methods and the choice of which to pursue should be based upon anatomic considerations, available expertise, and patient comorbidities.

Epiphrenic Diverticula

Diverticula present in the distal third of the esophagus, usually within 10 cm of the GE junction, are referred to as *epiphrenic diverticula* (ED). It is a rare condition, and its true incidence remains unclear as the number of patients with asymptomatic diverticula is not known. These are pulsion-type false diverticula, similar to ZD, as they are only outpouchings of mucosa and submucosa through the muscular wall of the esophagus. The pathophysiology underlying the disease, first recognized by Mondiere in 1833,[85] is assumed to be elevated esophageal intraluminal pressures, as a result of an underlying esophageal motility disorder, in conjunction with functional distal obstruction. With the advent of esophageal manometric testing, it is clear that EDs are commonly associated with a heterogeneous group of motility disorders and LES dysfunction, including achalasia, DES, Nutcracker esophagus, hypertensive LES, as well as nonspecific esophageal motility disorders (NSMD),[86,87] although often there is no detectable underlying motility disorder. As such, these patients may present with symptoms similar to the aforementioned motility disorders, most commonly to include dysphagia, chest pain, heartburn, and regurgitation. Intermittent nocturnal aspiration is frequently seen and occurs in nearly 45% of patients.[88,89] The workup of these patients should include a complete history and examination, upper GI barium swallow, esophageal manometry and pH testing, and endoscopy (Fig. 14-25). Some controversy exists regarding who should be treated surgically. Those with mild symptoms and small-size diverticula, or those to whom surgery presents significant risk, can be safely observed. If symptoms of GERD are present, they may be controlled with medications. These patients should be followed for progression of their symptoms.[90] Those with severe symptoms who are candidates for surgery should be treated surgically.

Treatment

Surgical treatment focuses on the concepts of resection of the diverticulum and treatment of the underlying esophageal motility disorder to relieve the functional obstruction, typically with long esophagogastric myotomy. Historically,

this was performed through a left thoracotomy to provide optimal exposure to the distal esophagus, GE junction, and cardia.[91] This was associated with excellent symptom relief in 76–94% of patients, but with mortality rates of up to 15% and complication rates of nearly 40%. Leak rates of 6–18% were observed.[92–94] Just as with treatment of achalasia and other benign esophageal disorders, the dominant operative technique has now shifted to the minimally invasive approach. Both the video-assisted thoracoscopic surgery (VATS) and laparoscopic approach have been described[95,96]; neither these nor the open approach have been compared in a randomized prospective fashion. When compared to thoracotomy approach, both minimally invasive techniques (VATS and laparoscopy) are associated with lower perioperative mortality rates (0–7.7%), shorter length of stay, and lower leak rates (14% cumulative rate); morbidity still ranges as high as 50%.[94,97,98] With the minimally invasive approaches, excellent relief of symptoms is seen in 83–100% of patients.[94] The laparoscopic approach, which has been the minimally invasive technique predominantly reported, capitalizes on these advantages and avoids single-lung ventilation and postoperative chest tubes. In addition, performing fundoplication is technically easier with the laparoscopic approach compared to the VATS approach. The laparoscopic method is the one we have adopted, in which we perform stapled resection of the diverticulum, long myotomy, and Toupet fundoplication.

Operative Technique

LAPAROSCOPIC EPIPHRENIC DIVERTICULECTOMY

Patients are placed on a liquid diet for 48 hours prior to operation to minimize retained food in the diverticulum. At the time of operation, endoscopy is performed prior to commencing, while the patient is under general anesthetic, to remove any retained debris and avoid its incorporation into the eventual suture line. The standard esophageal operating position is used, as previously described in this chapter. A 10-mm, 30-degree laparoscope is used to obtain the best image, and a liver retractor is placed to visualize the hiatus. The short gastric vessels are ligated, and the left crus technique is used to begin the division and dissection of the phrenoesophageal membrane. A Penrose drain is placed around the esophagus to aid with retraction. The esophagus is circumferentially dissected up into the mediastinum. The diverticulum usually becomes apparent at this time. Most diverticula are encountered on the right side. The diverticulum is freed from surrounding structures and dissected using both blunt and sharp dissection, taking care to cleanly expose the neck. The least obvious, but most important aspect of this is separating the diverticulum from the surrounding esophagus by dividing adhesions connecting the two. This is often underappreciated and can lead to incomplete resection of the diverticulum. An appropriately sized bougie is carefully placed in the esophagus (50–60 F) ensuring it does not enter the mouth of the diverticulum. The diverticulum is resected using an articulating laparoscopic stapling device, keeping the stapler parallel to the esophagus and using the bougie for guidance and to help avoid narrowing (Figs. 14-26A–C). The laparoscopic approach typically affords better visualization and stapler alignment than either VATS or open thoracotomy. The stapled edge is inspected to make sure there is no bleeding or disruption. A myotomy is performed opposite the suture line in the same fashion as previously described for achalasia, with extension of 3 cm onto the cardia. The separation of muscle fibers from the myotomy allows the suture line to be oversewn in Lembert fashion using interrupted sutures placed in intracorporeal fashion to protect it. Finally, a Toupet fundoplication is then performed as previously described to complete the operation, which provides protection from GER and in most cases will buttress the staple line. Endoscopy is performed to evaluate for leak or narrowing. Patients are admitted and an UGI barium study is performed on postoperative day 2. If no leak or stricture is seen, the patient is started on liquids and discharged home.

Summary

Epiphrenic diverticula are a rare type of pulsion diverticula that occur in the distal third of the esophagus. Treatment should be offered to those with symptomatic diverticula who are medically fit for surgery. Therapy should include surgical resection of the diverticulum and address the motility disorder to provide relief of distal obstruction, typically with long myotomy. Minimally invasive methods with either VATS or laparoscopy have demonstrated excellent symptomatic relief and lower mortality and morbidity compared to the older approach with thoracotomy.

C

FIGURE 14-26 **A-C.** Epiphrenic diverticulum resection. (Used with permission from Saurabh Khandelwal, MD, University of Washington.)

The laparoscopic method offers excellent visualization of the distal esophagus and is a technically easier approach for performing myotomy and partial fundoplication. The technique chosen should be based on anatomic considerations and surgeon experience.

GASTROESOPHAGEAL REFLUX DISEASE AND HIATAL HERNIA (INCLUDING PARAESOPHAGEAL)

Toshitaka Hoppo • Shamus R. Carr • Blair A. Jobe

GERD—OVERVIEW

Definition

Gastroesophageal reflux disease (GERD) is a chronic disorder related to the retrograde flow of gastric contents into the esophagus, resulting in a spectrum of symptoms with or without tissue injury.[1] Classic GERD symptoms in the absence of esophageal mucosal complications are the hallmarks of nonerosive reflux disease (NERD). Patients with NERD account for up to 70% of those with GERD in the community.[2] Antireflux surgery is the only effective and long-term therapy. Although various endoscopic approaches to treat GERD have been introduced, none of them has been able to achieve an efficacy equivalent to antireflux surgery.[3,4]

Symptoms

Heartburn (ascending retrosternal burning) and regurgitation are typical GERD symptoms. Epidemiologic studies have demonstrated that heartburn occurs monthly in as many as 40–50% of the Western population. The occurrence of heartburn at night and its effect on quality of life have recently been highlighted by a Gallup poll conducted by the American Gastroenterologic Society (Table 15-1).[5] Regurgitation of gastric contents often occurs when the patient is supine or with increases in intra-abdominal pressure, and may result in atypical symptoms, including cough, globus sensation, hoarseness, throat clearing, asthma, aspiration pneumonia, and pulmonary fibrosis. Dysphagia is a typical symptom of GERD and can be divided into (1) an oropharyngeal etiology, which is characterized by difficulty transferring food out of the mouth into the esophagus, and (2) esophageal etiology, which is characterized by the sensation of food sticking in the lower chest. Dysphagia can be a sign of underlying malignancy and should be aggressively investigated with upper endoscopy. Chest pain can be caused by GERD; however, it is very important to exclude a cardiac etiology. DeMeester and colleagues reported that nearly 50% of patients with severe noncardiac chest pain had a positive 24-hour pH study implicating GERD as the underlying etiology.[6] Chest pain precipitated by meals, occurring at night while supine, nonradiating, responsive to antacid medication, or accompanied by other symptoms such as dysphagia and/or regurgitation should trigger an evaluation for an esophageal cause. Additionally, it should be noted that the distinction between heartburn and chest pain can be difficult to make, and the perception of these symptoms is highly variable between patients.[7,8]

PATHOPHYSIOLOGY OF GERD

The antireflux mechanism includes four important components: (1) lower esophageal sphincter (LES); (2) crural diaphragm; (3) esophageal peristalsis; and (4) stomach (the reservoir).

Lower Esophageal Sphincter

The *gastroesophageal junction* (GEJ) is a complex arrangement of specialized muscles composed of both intrinsic (LES) and extrinsic (crural diaphragm) contractile elements. The LES, which can be identified as a high-pressure zone located at the GEJ, creates the barrier between the esophagus and stomach that normally prevents reflux. LES relax-

TABLE 15-1: AMERICAN GASTROENTEROLOGIC ASSOCIATION GALLUP POLL ON NIGHTTIME GASTROESOPHAGEAL REFLUX DISEASE SYMPTOMS

- 50 million Americans have nighttime heartburn at least 1/wk
- 80% of heartburn sufferers had nocturnal symptoms—65% both day and night
- 63% report that it affects their ability to sleep and impacts their work the next day
- 72% are on prescription medications
- Nearly half (45%) report that current remedies do not relieve all symptoms

ation occurs in two situations: (1) immediately following a swallow, when it momentarily relaxes to allow passage of food into the stomach, and (2) when the fundus is distended with gas, it is eliminated to allow venting of the gas (a belch)—transient LES relaxation (TLESR). For an LES to be effective, it must possess three characteristics: an adequate (1) total length, (2) intra-abdominal length, and (3) resting pressure (Table 15-2).[9] Therefore, a defective LES is identified by one or more of the following characteristics: (1) a high-pressure zone with an average pressure of less than 6 mm Hg, (2) an average overall length of 2 cm or less, and (3) an average length exposed to the positive pressure environment of the abdomen (intra-abdominal length) of 1 cm or less. The most common cause of a permanently defective LES is an inadequate abdominal length, secondary to the high prevalence of a hiatal hernia in patients with GERD.[9] A TLESR is an LES relaxation that occurs *without* a swallow and accounts for the physiologic reflux and "venting" of the stomach, particularly in the postprandial state. Frequent and prolonged TLESR can be associated with the development of GERD, and this may explain the etiology of disease observed in the 40% of patients with a manometrically normal sphincter. A transient loss of the LES can also occur due to a functional problem of the gastric reservoir and delayed emptying.[10] In this setting, if excessive air and food are swallowed, there are gastric distention and an increase in intra-gastric pressure with shortening of the LES (Fig. 15-1). This process continues until a critical LES length is reached and eventually the pressure drops precipitously and reflux occurs. This "transient sphincter"

TABLE 15-2: NORMAL MANOMETRIC VALUES OF THE LOWER ESOPHAGEAL SPHINCTER, N = 50

Parameter	Median value	2.5th percentile	97.5th percentile
Pressure (mm Hg)	13	5.8	27.7
Overall length (cm)	3.6	2.1	5.6
Abdominal length (cm)	2	0.9	4.7

shortening occurs in the initial stages of GERD and is the mechanism for the early complaint of excessive postprandial reflux. This process is associated with the common complaints of belching and bloating in patients with GERD. To compound matters, there is an increased frequency of swallowing (air and saliva) observed in GERD patients because the ingestion of saliva (pH 7) serves to neutralize the acidic fluid (pH 1) in the esophagus.[11] Therefore, GERD may begin in the stomach, secondary to gastric distention due to overeating and a high-fat diet, which delays gastric emptying. Further, a close relationship between the geometry of the cardia and one's propensity to reflux in the face of a given intragastric pressure has been established.[10] Greater gastric distension, as reflected by an increasing intragastric pressure, is necessary to "open" the sphincter in patients with an intact angle of His compared to those with hiatal hernia (Fig. 15-2).[12] These data elucidate why the presence of a hiatal hernia is often associated with GERD and explain the loss of the flap valve mechanism (intragastric portion of LES). In addition, in the presence of a hiatal hernia the intrinsic portion of the LES is no longer aided by the crural diaphragm (extrinsic LES).

Esophageal Peristalsis

Esophageal peristalsis is an extremely important component of the antireflux mechanism and serves to clear physiologic reflux and thus reduces contact time between the esophageal epithelium and gastric fluid. Ineffective esophageal motility can result in an abnormal esophageal exposure to gastric juice even in individuals with a mechanically effective LES and normal gastric function.[13] However, ineffective motility is more often seen in patients with a mechanically defective LES, where distal esophageal body function deteriorates as a direct result of repetitive inflammation; this effect further prolongs the esophageal exposure to gastric juice, which creates a vicious cycle leading to more severe disease. Diener and colleagues reported that 40–50% of patients with GERD had abnormal esophageal peristalsis.[13] In these patients, esophageal clearance time was prolonged, and gastric fluid was in contact with the esophageal mucosa for a longer period of time and traveled more proximally when compared to GERD patients with intact esophageal motility. Therefore, these patients were prone to having more severe mucosal injury and extraesophageal symptoms such as cough.[14,15] To highlight these points, it is established that patients with mixed connective tissue diseases such as scleroderma commonly have an aperistaltic esophagus and absent LES, which results in the most severe form of GERD.[16]

Crural Diaphragm

The crural diaphragm provides an extrinsic component to the gastroesophageal barrier. Mittal and colleagues demonstrated a direct correlation between intraluminal pressure of the GEJ and integrated electrical activity of the crural

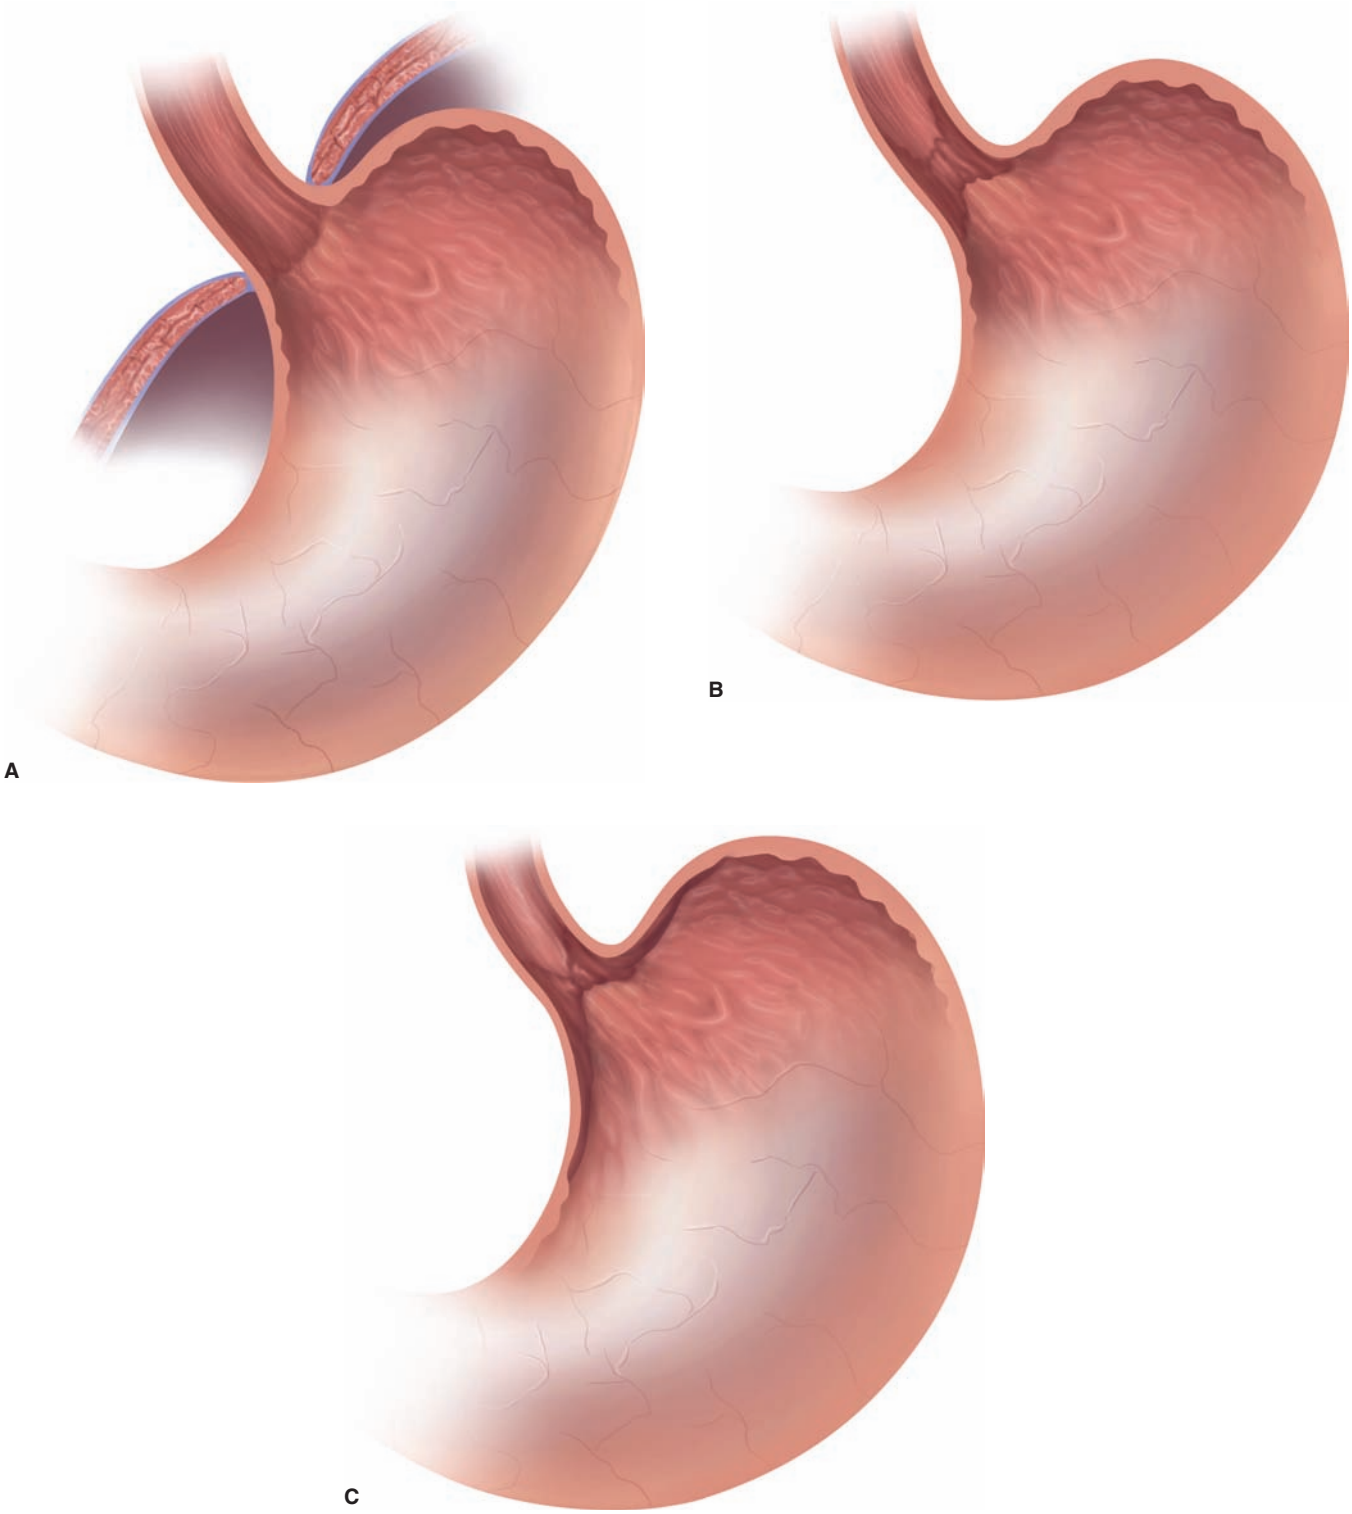

FIGURE 15-1 A graphic illustration of the shortening of the lower esophageal sphincter that occurs as the sphincter is "taken up" by the cardia as the stomach distends.

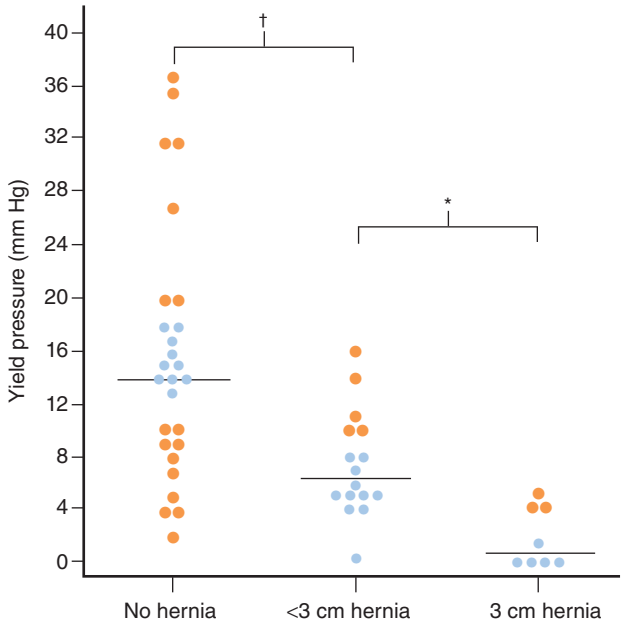

FIGURE 15-2 Yield pressure of the lower esophageal sphincter decreases as hiatal hernia size increases.

diaphragm.[17] Additionally, normal pressure of the GEJ from manometric tracings has been shown to range from 15 ± 11 mm Hg at the end of expiration to 40 ± 13 mm Hg at the end of inspiration mainly as a result of the diaphragmatic contribution.[18] This pinchcock action of the diaphragm is particularly important as a protection mechanism against reflux induced by sudden increases in intra-abdominal pressure.[19] This mechanism is obviously disrupted by the presence of a hiatal hernia where the intrinsic LES has "migrated" proximal to the diaphragmatic pinch.

Stomach

Impaired function of the stomach such as abnormal gastric emptying may contribute to GERD by increasing intragastric pressure, distension, and LES unrolling.[20] This may occur in patients with a large hiatal hernia, in which the herniated stomach in the chest does not empty appropriately, gastric outlet obstruction either from malignancy or peptic ulcer disease, and diabetic gastroparesis.

COMPLICATIONS OF GERD

The complications of GERD result from the damage inflicted by gastric juice on the esophageal mucosa, pharyngeal or respiratory epithelium, and the mucosal changes caused by their subsequent repair and fibrosis. These complications can be categorized into three groups: (1) mucosal complications such as esophagitis or stricture; (2) extraesophageal or respiratory complications such as laryngitis, pneumonia, asthma, and pulmonary fibrosis; and (3) metaplastic and neoplastic complications such as Barrett's esophagus and adenocarcinoma. The prevalence and severity of GERD-related complications are positively correlated with the degree of LES dysfunction and impaired esophageal motility (Table 15-3).[21]

TABLE 15-3: COMPLICATIONS OF GASTROESOPHAGEAL REFLUX DISEASE: 150 CONSECUTIVE CASES WITH PROVEN GASTROESOPHAGEAL REFLUX DISEASE (24-HOUR ESOPHAGEAL pH MONITORING, ENDOSCOPY, AND MOTILITY)

Mucosal Complications

Mucosal complications such as esophagitis and stricture can occur in the presence of two predisposing factors: (1) a mechanically defective LES and (2) an increased esophageal exposure to the gastric fluid with a pH less than 4 and greater than 7 (Fig. 15-3).[21] The components of the refluxed gastric fluid can include acid and pepsin as well as biliary and pancreatic secretions that travel from the duodenum into the stomach.[22,23] Although acid and activated pepsin are the key ingredients of the gastric juice that leads to esophagitis, it has been established that the most severe epithelial injury occurs during exposure to bile salts combined with acid and pepsin.[24] Previous experimental studies have shown that gastric or duodenal juice alone causes minimal or little damage to the esophageal mucosa, but the combination of duodenal juice and gastric juice is highly noxious. Previous study to directly measure esophageal bilirubin exposure as a marker of duodenogastroesophageal reflux has shown that 58% of patients with GERD have increased esophageal exposure to duodenal juice and that this exposure occurs most commonly when the esophageal pH is between 4 and 7 (Fig. 15-4).[25] Within this pH range, there is formation of nonpolarized, soluble bile acids, which can diffuse through the cell membrane and cause damage to the mucosal cells. Additionally, this type of exposure correlates with the development of Barrett's esophagus (Fig. 15-5).[25] The fact that the combination of

gastric and duodenal juice is more noxious to the esophageal mucosa than gastric juice alone may provide an explanation for the observation that 25% of patients with reflux esophagitis develop recurrent and/or progressive mucosal damage despite medical therapy.[21] Clinically, there is poor correlation between the symptom of heartburn and the endoscopic finding of esophagitis.[26] The reflux of acidic gastric juice combined with duodenal contents can irritate nerve endings close to the luminal surface and cause severe heartburn in the absence of endoscopically detectable erosions; bile salts inhibit pepsin and acid inactivates trypsin, and the patient exhibits little or no gross evidence of esophagitis. By contrast, the reflux of alkaline gastric juice may occur without symptoms because of the absence of hydrogen ions but cause endoscopically evident esophagitis secondary to bile-activated trypsin exposure to the esophageal epithelium. This is supported by recent clinical studies that demonstrated that the presence of alkaline reflux is associated with the development of mucosal injury.[25,27] In addition, several studies using either prolonged ambulatory aspiration techniques[28] or spectrophotometric bilirubin measurement[29] have shown that patients with GERD have more concentrated bile acid exposure to the esophageal mucosa than normal subjects, commonly in the supine position during sleep and in the upright position during the postprandial period. Furthermore, reflux of both acid and pancreaticobiliary juice is the most prevalent pattern of exposure and present in 100% of complicated Barrett's patients, 89% of uncomplicated Barrett's patients, 79% of patients with esophagitis, and 50% of patients with NERD.[30,31] These findings support that the reflux of duodenal juice containing bile acids is common in

patients with GERD and that proton pump inhibitor (PPI) therapy cannot prevent mucosal damage due to bile acids.

Esophageal stricture (circumferential scarring) formation and/or shortening (axial scarring) can be associated with severe esophagitis or Barrett's esophagus. Scarring occurs at the site of maximal inflammatory injury (ie, squamocolumnar junction). Thought by some to be a protective mechanism, the metaplastic columnar epithelium advances proximally into the area of inflammation leading to "protection" of that given length of esophagus; the proximal migration of the squamocolumnar junction leads to more proximal stricture formation within the esophagus. The presence of stricture can be an indicator of GERD even if there is no evidence of esophagitis or Barrett's esophagus. However, in patients with normal acid exposure, the stricture may be due to malignancy or a drug-induced chemical injury.[32] Biopsy should be obtained to exclude malignancy. A short esophagus should be suspected when there is a hiatal hernia of greater than 5 cm that does not reduce in the upright position on esophogram.

Extraesophageal or Pulmonary Complications

It has been increasingly recognized that a significant proportion of patients with GERD have laryngeal or respiratory symptoms such as cough, recurrent pneumonia, asthma, and progressive pulmonary fibrosis, sometimes in conjunction with typical GERD symptoms such as heartburn and regurgitation.[33] In addition, a strong association between GERD and the development of lung disease such as asthma and idiopathic pulmonary fibrosis has been established. Previous studies have demonstrated that up to 50% of asthmatics have either endoscopic evidence of esophagitis or increased esophageal acid exposure on 24-hour ambulatory pH monitoring,[34,35] and that 87% of patients with idiopathic pulmonary fibrosis[36] and 90.9% with cystic fibrosis[37] have documented GERD based on esophageal pH monitoring.

Two mechanisms have been proposed as the pathogenesis of reflux-induced respiratory symptoms: (1) aspiration of gastric contents and (2) vagally mediated bronchoconstriction. Recent clinical studies have demonstrated a strong correlation between idiopathic pulmonary fibrosis and hiatal hernia and a high association between GERD and pulmonary disease such as asthma.[33] Pathological acid exposure in the proximal esophagus is often identified in patients with respiratory symptoms and GERD. Scintigraphic studies have demonstrated aspiration of ingested radioisotope in patients with GERD and respiratory symptoms.[38] Simultaneous tracheal and esophageal pH monitoring has demonstrated the presence of concomitant acidification both in the trachea and the esophagus in patients with asthma.[39] Animal studies have shown an increased airway resistance after the instillation of hydrochloric acid into the trachea.[40] Additionally, it is well known that bronchoconstriction occurs following the acid exposure in the distal esophagus.[41] This can be explained by the common embryologic origin of the trachea and esophagus and their shared vagal innervation.

It is difficult to document that respiratory symptoms and/or injury are caused the underlining GERD as both are very prevalent. In a substantial number of patients with reflux-induced respiratory symptoms, GERD is often silent and is only uncovered when investigation is initiated. A high index of suspicion is required, especially in patients with poorly controlled adult-onset asthma in spite of appropriate bronchodilator therapy. Objective esophageal testing should be performed to document evidence of GERD and to attempt to correlate extraesophageal symptoms with reflux events. Upper endoscopy may reveal the presence of esophagitis or Barrett's esophagus. Manometry may demonstrate a hypotensive LES or some degree of impaired esophageal motility. Traditionally, the diagnosis of reflux-induced respiratory symptoms has been made using ambulatory dual probe pH monitoring; one probe is positioned within the distal esophagus and the other at a proximal location such as the trachea, pharynx, or proximal esophagus. Although ambulatory esophageal pH monitoring allows a direct correlation between esophageal acidification and respiratory symptoms, the chronological relationship between reflux events and bronchoconstriction is complex. The sensitivity of this approach is poor as much of the acid exposure is neutralized proximally after mixing with saliva. Multichannel intraluminal impedance-pH (MII-pH) has been introduced as a promising tool to evaluate the extension of reflux and its symptom correlation regardless of the composition of refluxate (liquid, gas, mixed, alkaline, acidic), especially in patients with atypical symptoms. Although several studies have shown that combined 24-hour MII-pH has a high yield for detection of GERD with atypical symptoms,[27] the clinical utility of MII-pH is still being investigated.

Once GERD is suspected or thought to be responsible for respiratory symptoms, the treatment options may be either the trial of high-dose PPI therapy (BID or TID dosing) or antireflux surgery. A 3–6 months trial of high-dose PPI therapy may suggest that GERD is partly or completely responsible for the development of respiratory symptoms. However, the persistence of symptoms despite the maximal PPI therapy does not necessarily rule out the possible contribution of GERD. The algorithm depicted in Fig. 15-6 is made based on the outcome of dual-probe 24-hour pH monitoring and esophageal manometry in patients with respiratory symptoms and does not include impedance. Previous studies have demonstrated that acid suppressive therapy with PPI improves asthma symptoms and/or peak expiratory flow rates in up to 73% of asthmatics with GERD, although fewer than 15% can be expected to have objective improvements in their pulmonary function parameters.[4,42,43] Most studies were conducted with a relatively short course of acid suppressive therapy (<3 months). This time period may have been sufficient for symptomatic improvement but insufficient for recovery of pulmonary function. Given the fact that acid suppressive therapy can only reduce the acidity of the gastric fluid but does not reduce the total number of reflux events, the conflicting results regarding medical therapy in

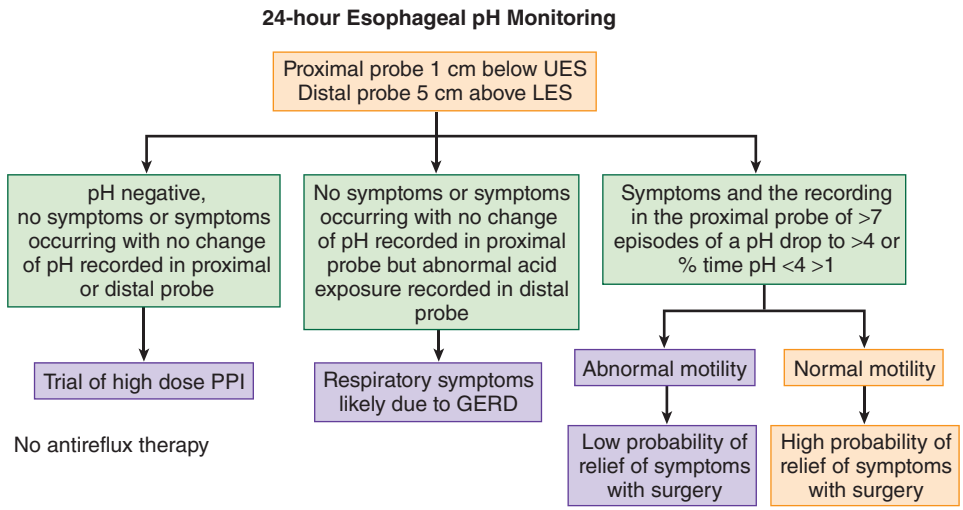

FIGURE 15-6 Correlation of symptoms with pH measurements predicts the likelihood that reflux symptoms are caused directly by acid reflux.

asthmatics may be secondary to the continued exposure of the aerodigestive tract by caustic nonacid gastric juice. This is supported by the literature indicating that antireflux surgery improves respiratory symptoms in nearly 90% of children and 70% of adults with asthma and GERD.[35,44] Additionally, improvements in pulmonary function were observed in around one-third of patients. A randomized controlled trial to compare surgical treatment with medical treatment for asthmatics with GERD demonstrated that fundoplication is the most effective approach to improve asthma symptoms and clinical course, although there was a minimal effect on pulmonary function, pulmonary medication requirement, or survival.[35] On the other hand, a potential benefit of antireflux surgery is to stabilize or delay the progression of end-stage lung disease such as idiopathic pulmonary fibrosis.[45]

Metaplastic (Barrett's esophagus) and Neoplastic (Adenocarcinoma) Complications

Barrett's esophagus (BE) is defined as a columnar lined segment of esophagus of any length visible on endoscopy with a biopsy showing intestinal metaplasia with the presence of goblet cells (Fig. 15-7). Despite this classification, it is common to make the distinction between short-segment BE (<3 cm) and long-segment BE (≥3cm). Both short- and long-segment BE are considered pathologic and premalignant. The prevalence of BE in the general population has been reported to be 1–25%.[46–50] BE represents an end-stage form of GERD and carries a 30- to 50-fold increased risk of developing esophageal adenocarcinoma via the metaplasia-dysplasia-carcinoma sequence compared to people without BE.[51] The incidence of esophageal adenocarcinoma in patient with known BE may be as high as 0.5% per year.[52–54] BE is currently classified into four broad categories: (1) BE without dysplasia, (2) indefinite for dysplasia, (3) low-grade dysplasia (LGD), and (4) high-grade dysphagia (HGD). Recent studies have identified a high prevalence of biopsy-proven intestinal metaplasia at an endoscopically normal appearing GEJ, which is termed *cardia intestinal metaplasia* (CIM). The significance and natural history of CIM remains unknown. However, CIM is currently considered a separate entity from BE, although the pathogenesis of CIM has been shown to be similar to reflux-induced BE.[55] Factors associated with the development of BE include abnormal bile reflux, hiatal hernia larger than 4 cm, a defective LES, and esophageal motility disorder.[56]

Pathophysiology of Barrett's Metaplasia

The pathogenesis of BE begins with injury to the squamous epithelium of the distal esophagus, secondary to the repeated distension of the stomach with large volume fatty meals that result in effacement of the LES and exposure of the distal esophageal squamous epithelium to caustic gastric juice.[10] Continuous inflammatory injury in this area of the lower esophagus can cause permanent loss of the musculature of the LES, resulting in a mechanically defective LES. With further loss of the gastroesophageal barrier function, esophageal exposure worsens with resultant injury to progressively greater lengths of the squamous mucosa. Endoscopically, this injury can be observed as erosive esophagitis. The resulting columnar metaplasia that develops in a previous squamous-lined esophagus appears as a layer of mucus secreting columnar cells termed *cardiac mucosa*, which is a highly specific mucosa that arises to replace injured squamous epithelium and is believed to be an adaptive response to better tolerate exposure to gastric juice.[57] Eventually, cardiac mucosa can remain without changing, form parietal cells, or develop goblet cells to become intestinalized cardiac mucosa in the divergent differentiation pathways.[58]

Screening and Surveillance

Although patients with the highest likelihood of BE are older (>50 years of age) Caucasian men with chronic reflux symptom,[59] screening for BE remains controversial because of the inability to predict who has BE prior to endoscopy, the lack of evidence-based criteria, the invasiveness and expense of standard sedated endoscopy, and the increasing documentation of a subgroup of patients with BE who lack reflux symptoms.[60] Surveillance endoscopy also remains controversial because of the lack of randomized trials supporting its value.[60] However, previous retrospective studies have demonstrated that survival is statistically enhanced if cancer is detected by endoscopic surveillance rather than presenting with symptoms of obstruction.[61,62] Surveillance endoscopy should be performed in patients with documented BE and those who have reflux symptoms controlled with antisecretory therapy or antireflux surgery. The Seattle Protocol (biopsies with jumbo forceps in four quadrants, along every centimeter of metaplastic epithelium with extra biopsies taken from suspicious areas) has been widely accepted. It should be noted that these surveillance biopsies sample only a small fraction of the esophageal epithelium (possibility for sampling error) but are the only method available for recognizing dysplasia.[63] In patients with BE without dysplasia, we perform surveillance endoscopy every 3 years. The finding of low-grade dysplasia (LGD) requires a follow-up endoscopy within 6 months to ensure that more advanced disease is not present. If the 6-month surveillance is negative for high-grade dysplasia (HGD) or adenocarcinoma, yearly endoscopy is performed until no dysplasia is present on two consecutive annual endoscopies. The presence of HGD in flat mucosa should be confirmed by two experienced gastrointestinal pathologists and a subsequent endoscopy is performed within 3 months to reduce the chances of sampling error. Nodules within a field of HGD should undergo endoscopic resection to rule out malignancy. Patients with confirmed HGD should be counseled regarding the treatment options, including intensive surveillance, ablation therapies, and esophagectomy. Because the risk for the development of invasive cancer is 50% within 3 years of diagnosis, HGD is considered the threshold for therapeutic intervention. Patients with LGD or no dysplasia can also be a candidate for therapeutic intervention if they have excessive fear of the development of cancer or a significant family history of BE and esophageal cancer. In our practice, patients with nondysplastic BE who undergo antireflux surgery are also offered ablation of the involved segment of the esophagus.

Management of Dysplastic BE

Given the fact that HGD has a high rate of progression to cancer and the prevalence of occult cancer in esophagectomy specimens of patients with a preoperative diagnosis of only HGD has been reported to be 38–73%,[64–66] esophagectomy has been recommended as a standard of care for HGD. However, esophagectomy is associated with significant mortality and morbidity even in experienced centers.[67–69] Additionally, esophagectomy may be unnecessary in the treatment of HGD because lymph node metastasis is unlikely (<5%).[70–72] In the recently updated guidelines by the American College of Gastroenterology, the authors state that "esophagectomy is no longer the necessary treatment response to HGD."[60] Several endoscopic ablation therapies such as photodynamic therapy,[73] radiofrequency

TABLE 15-4: RISK FACTORS TO CONSIDER WHEN USING ENDOSCOPIC MANAGEMENT OF ESOPHAGEAL NEOPLASIA (BARRETT'S ESOPHAGUS WITH DYSPLASIA AND T1A ESOPHAGEAL ADENOCARCINOMA)

Concurrent Cancer or Progression to Invasive Cancer	
Low-Risk	**High-Risk**
Unifocal (limited or focal), flat HGD	Multifocal HGD, HGD with nodules
Lymph Node Involvement	
Low-Risk	**High-Risk**
Type I, IIa <20 mm, IIb, IIc <10 mm	Type I, II >30 mm, type III
Well or moderately differentiated adenocarcinoma (grading G1/G2)	Poorly differentiated adenocarcinoma (grading G3), squamous cell carcinoma
Lesions limited to the mucosa (m)	Invasion into submucosal layer (sm)
No lymphovascular invasion	Presence of lymphovascular invasion

HGD, high-grade dysphagia.
Type I: polypoid type, II: flat type, IIa: flat, elevated, IIb: level with the mucosa, IIc: slightly depressed, III: ulcerated type.

ablation therapy,[74] and cryotherapy,[75,76] and endoscopic resection techniques such as endoscopic mucosal resection[77] and submucosal dissection[78] have been introduced. When considering these endoscopic therapies, the accurate clinical staging is critical to prevent an inappropriate endoscopic therapy on a patient with a high risk of invasive or metastatic disease (Table 15-4).[79] Currently, radiofrequency ablation therapy has been most commonly used since the results of a multicenter, sham-controlled trial was reported (Fig. 15-8).[80] In this trial, 127 patients with dysplastic BE were randomly assigned to treatment with radiofrequency ablation or a sham procedure. In patients with LGD, complete eradication of dysplasia occurred in 90.5% of those in the ablation group, as compared with 22.7% of those in the control group ($p < .001$). In patients with HGD, complete eradication occurred in 81.0% of those in the ablation group, as compared with 19% of those in the control group ($p < .001$). The rate of complications such as stricture and bleeding was 6%. This study demonstrated the safety and high efficacy of radiofrequency ablation therapy for dysplastic BE. Theoretically, antireflux surgery potentially prevents the progression to dysplasia and adenocarcinoma.[81] However, there have been no prospective randomized controlled studies documenting this supposition. Given the fact that BE results from GERD, antireflux surgery should be considered once BE is successfully treated.

PREOPERATIVE ASSESSMENT OF PATIENTS WITH GERD

The purpose of esophageal objective testing is to determine if the patients' symptoms are due to gastroesophageal reflux events and to define the severity of GERD and esophageal motility that will impact on the selection of the type of surgical therapy. The esophageal objective testing includes barium esophagram, upper endoscopy, esophageal manometry, esophageal pH monitoring, and MII-pH. Gastric emptying studies may be considered in patients with suspicious symptoms such as bloating and nausea.

Barium Esophagram

The *barium esophagram* is a test that is used to evaluate the entire anatomy of esophagus, including the esophageal body and both sphincters. This test is used to document the presence and size of a hiatal hernia, stricture severity and location, diverticula, esophageal emptying, and the presence of gastroesophageal reflux, both spontaneously and induced by provocative maneuvers. Esophageal motility can be assessed to some extent but is not the mainstay. Although the finding of reflux during the barium esophagram is thought by some to be a reliable indicator for GERD, the absence of roentgenographic evidence of reflux does not exclude disease.

Upper Endoscopy

Upper endoscopy is performed to examine the mucosa from the esophagus to the second portion of duodenum and biopsies can be obtained if necessary. Although only 40–60% of patients with GERD have endoscopic evidence of esophagitis, upper endoscopy has an excellent specificity for this diagnosis when erosions are present. Upper endoscopy may identify unexpected findings such as BE, malignancy, a large hiatal hernia, eosinophilic esophagitis, and Zenker's diverticulum. The location of the diaphragmatic crura, the anatomic GEJ, and the squamocolumnar junction should be recorded.

Esophagitis is one of indicators of the presence of GERD. The severity of esophagitis is most commonly described by the Los Angeles classification[82]; LA grade A is defined by the presence of one or more mucosal breaks that are less than or equal to 5 mm in length. LA grade B is defined by the presence of one or more mucosal breaks that are longer than 5 mm. LA grade C represents a more advanced stage where one or more mucosal breaks are continuous between the tops of two or more mucosal folds, but that involve less than 75% of the esophageal lumen circumference. LA grade D classifies one or more mucosal breaks bridging the tops of folds and involving at least 75% of the esophageal lumen circumference. Nonerosive esophagitis is difficult to reliably recognize endoscopically and its presence may be confirmed based on the microscopic findings of mucosal infiltration with polymorphonuclear leukocytes (PMNs), lymphocytes, eosinophils, and the recently described balloon cells.[83,84] The extension of the relatively high mucosal papillae and hyperplasia of the basal zone are further evidence of mucosal injury. However, these microscopic findings do not prove the presence of increased exposure to gastric juice as they can occur from other forms of injury.[85]

Barrett's esophagus is suspected endoscopically when the squamocolumnar junction is located proximal to the anatomic GEJ, and the characteristic appearance of a "salmon pink color" mucosa is encountered in the lower esophagus. Multiple random biopsies should be performed, and the diagnosis of BE must be confirmed by the microscopic findings of columnar epithelium with intestinalization. To standardize the endoscopic findings of BE, the Prague classification system of circumferential (C) and maximal length (M) has been proposed (Fig. 15-9).[86] This system identifies the landmarks of the squamocolumnar junction, the GEJ, the extent of circumferential columnar lining, and the most proximal extension of the columnar mucosa excluding islands to determine the length of BE. However, proximal islands of columnar lining and ultrashort BE (<1 cm) are not included in this system. The presence of BE is diagnostic of GERD. Particular attention must be paid to the squamocolumnar junction, where a mass, ulcer, nodularity, or inflammatory tissue should be considered suspicious for malignancy and requires biopsy. Nodules encountered in a field of BE should be removed with endoscopic resection for histologic examination and deep staging.

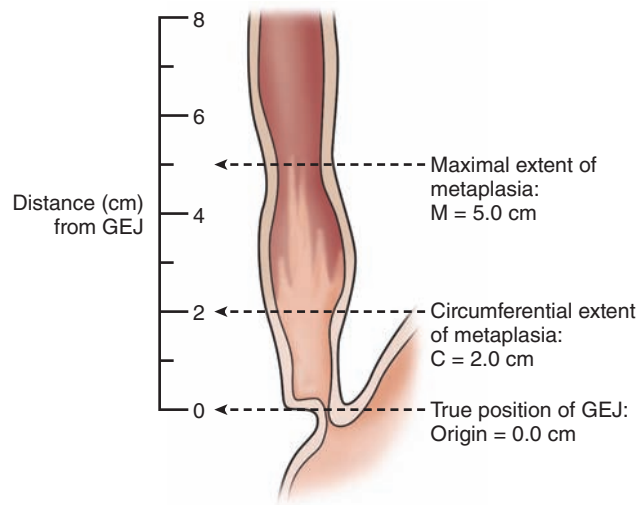

FIGURE 15-9 Prague classification system to standardize Barrett's esophagus (BE). Diagrammatic representation of endoscopic BE showing an area classified as C2M5. C: extent of circumferential metaplasia; M: maximal extent of the metaplasia (C plus a distal "tongue" of 3 cm). (Reproduced from Sharma P, Dent J, Armstrong D, et al. The development and validation of an endoscopic grading system for Barrett's esophagus: the Prague C & M criteria. *Gastroenterology*. 2006;131:1392–1399.)

Abnormalities of the gastroesophageal flap valve (gastric portion of the LES) can be visualized by retroflexion of the endoscope. Hill and colleagues graded the appearance of the gastroesophageal valve from I to IV according to the degree of unfolding or deterioration of the normal valve architecture (Fig. 15-10).[87] The appearance of the valve correlates with the presence of increased esophageal acid exposure, occurring predominantly in patients with grades III and IV valves. Grade IV valve is compatible with a hiatal hernia. A hiatal hernia is endoscopically confirmed by the finding of a pouch lined with gastric rugal folds residing 2 cm or more proximal to the margins of the diaphragmatic crura. The presence of hiatal hernia is often associated with an increased esophageal exposure to gastric juice. When a paraesophageal hernia (PEH) is found, a gastric ulcer (Cameron ulcer) or gastritis within the hernia should be excluded. Patients who present with anemia and a PEH with Cameron's ulcers should also have colonoscopy to rule out blood loss from a colon cancer.

Measurement of Gastroesophageal Reflux

AMBULATORY pH MONITORING

Fuchs and colleagues demonstrated that 24-hour esophageal pH monitoring had a very high sensitivity and specificity (96%), as well as positive and negative predictive values

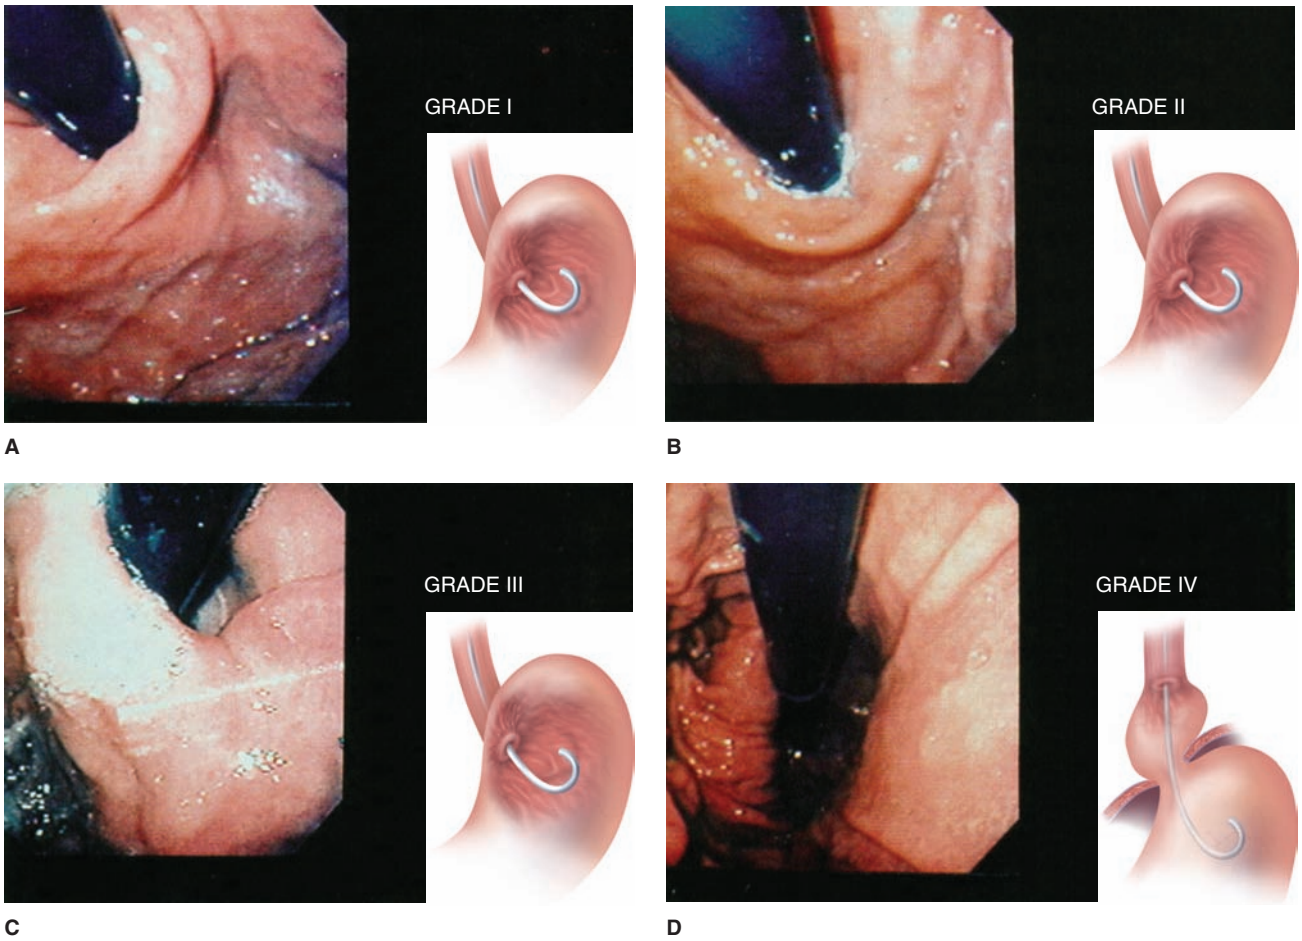

FIGURE 15-10 Hill classification. **A.** Grade I flap valve appearance. Note the ridge of tissue that is closely approximated to the shaft of the retroflexed endoscope. It extends 3–4 cm along the lesser curve. **B.** Grade II flap valve appearance. The ridge is slightly less well defined than in grade I and it opens rarely with respiration and closes promptly. **C.** Grade III flap valve appearance. The ridge is barely present, and there is often failure to close around the endoscope. It is nearly always accompanied by a hiatal hernia. **D.** Grade IV flap valve appearance. There is no muscular ridge at all. The gastroesophageal valve stays open all the time, and squamous epithelium can often be seen from the retroflexed position. A hiatal hernia is always present. (Reproduced from Hill LD, Kozarek RA, Kraemer SJ, et al. The gastroesophageal flap valve. In vitro and in vivo observations. *Gastrointest Endosc*. 1996;44:541.)

(96%), with an overall accuracy of 96%.[19] Since this study was reported, 24-hour esophageal pH monitoring has been a gold standard for the diagnosis of GERD. It is particularly important that preoperative pH testing be performed off medication in patients being considered for antireflux surgery to evaluate the symptom correlation with reflux events and the severity of the disease. Antisecretory medications should be discontinued 10–14 days prior to the study. An abnormal pH score with good symptom correlation has been shown to be the most important predictor of a successful outcome following antireflux surgery.

Despite being the most reliable technique for quantifying acid exposure in the distal esophagus, catheter-based 24-hour ambulatory pH monitoring has significant methodological limitations. The nasally passed pH electrode is uncomfortable and can lead patients to minimize or avoid reflux-provoking stimuli such as diet and physical activity, thus potentially resulting in a false-negative result. In addition, esophageal shortening during deglutition results in movement of the pH sensor closer to LES, thus potentially leading to a false-positive result.[6,88] In addition, patients with atrophic gastritis may be achlorhydric and have nonacid reflux that is not detected with pH testing. The recent development of a wireless pH capsule that can be implanted in the esophagus and transmit pH data to an external receiver has significantly changed patient tolerability and capability of performing extended recording periods of 2–4 days.[8,89] In addition, extended pH monitoring using wireless technology may improve the detection of reflux and increase the sensitivity of pH testing. Several studies have demonstrated that increasing the recording period from 24 to 48 hours results in an improvement in sensitivity of pH monitoring by 10–26%.[7,8] Several studies have also consistently demonstrated higher acid exposure values on day 2

compared to day 1 with the wireless pH capsule.[10] The pH probe should be correctly placed 5 cm (the capsule is placed 6 cm proximal to the LES or endoscopically measured anatomic GEJ) above the proximal border of the LES. This location minimizes potential noise from proximal stomach acid exposure, at the expense of decreased sensitivity.

Results of 24-hour pH monitoring are expressed in the form of a DeMeester score.[12] Six variables are measured and factored in to this composite score:

- The total number of reflux events
- The percentage of total time spent in an acid environment with a pH less than 4
- The percentage of upright time spent in an acid environment with a pH less than 4
- The percentage of supine time spent in an acid environment with a pH less than 4
- The duration of the longest reflux episode
- The number of reflux episodes lasting more than 5 minutes.

The first four of these factors evaluate the frequency and severity of reflux, and the last two assess the ability of the esophagus to clear acid. Normal values for these six components were determined from 50 asymptomatic control subjects. The mean values for esophageal acid exposure and 95th percentile results are shown in Table 15-5.[12]

COMBINED MULTICHANNEL INTRALUMINAL IMPEDANCE-pH MONITORING

Combined multichannel intraluminal impedance-pH (MII-pH) detects the intraesophageal bolus movement on the basis of a change in the resistance to electric current across adjacent electrode pairs positioned in a serial manner along a catheter. Multiple electrodes positioned along the axial length of the impedance catheter can determine the proximal extent of a reflux event. Air has a high impedance, whereas liquid has a greater conductivity and a lower impedance (Fig. 15-11). Based on this, it is capable of differentiating antegrade (swallow) from retrograde (reflux) bolus transit regardless of the composition of reflux (ie, liquid, gas, mixed) (Fig. 15-12). A pH monitor incorporated into the impedance catheter allows for simultaneous detection of both acid and nonacid contents. The configuration of impedance catheters can be modified depending on what type of reflux is targeted (ie, laryngopharyngeal reflux). MII-pH is a transnasal catheter-based system and the recording has been limited to 24 hours. As a result of the ability to detect, localize, and classify reflux events as acid, weakly acid, or nonacid, MII-pH has been posited as the future standard for reflux detection and monitoring, especially in patients with persistent typical and/or atypical GERD symptoms despite PPI therapy.[27,33] However, the clinical utility of MII-pH is still being investigated.[25]

TABLE 15-5: NORMAL VALUES FOR ESOPHAGEAL EXPOSURE TO pH <4 (N = 50)

Component	Mean	SD	95%
Total time	1.51	1.36	4.45
Upright time	2.34	2.34	8.42
Supine time	0.63	1.0	3.45

ASSESSMENT OF ESOPHAGEAL BODY AND LES FUNCTION

Esophageal Manometry

Esophageal manometry is the most accurate method to assess the coordination and pressure of the lower esophageal sphincter (LES) and the esophageal body. Patients with GERD may have manometric findings of a defective LES or impaired esophageal motility. Manometry is an important component in the preoperative workup of patients who are candidates for antireflux surgery. First, this form of testing excludes achalasia that may be occasionally misdiagnosed as GERD. Second, esophageal manometry characterizes the esophageal motility, and this information will be used to determine the surgical approach (Nissen or partial fundoplication). Finally, manometry enables measurement of the precise location of the LES for accurate pH probe placement.

Esophageal manometry used to be performed using water-perfused catheters with lateral side holes attached to transducers outside the body. Usually a train of five pressure transducers are bound together with the transducers placed at 5 cm intervals from the tip and oriented radially at 72 degrees from each other around the circumference of the catheter. The recent introduction and clinical application of high-resolution manometry (HRM) has made esophageal manometry simple, fast, and accurate. The basic concept of HRM is that by vastly increasing the number of pressure recording sensors and decreasing the spacing between them, one can monitor intraluminal pressure without spatial gaps between recording sites or temporal gaps between sampling times. Consequently, the morphology of the gastroesophageal junction pressure and esophageal peristalsis can be dynamically monitored in real time and a consistent fashion with normal respiration and with minimal movement-related artifact. HRM is performed using a solid-state manometric assembly with 36 circumferential sensors spaced at 1 cm intervals (O.D. 4.2 mm) (Sierra Scientific Instruments Inc., Los Angeles, CA). This catheter allows each of the 36 pressure sensing elements to detect pressure over a length of 2.5 mm in each of

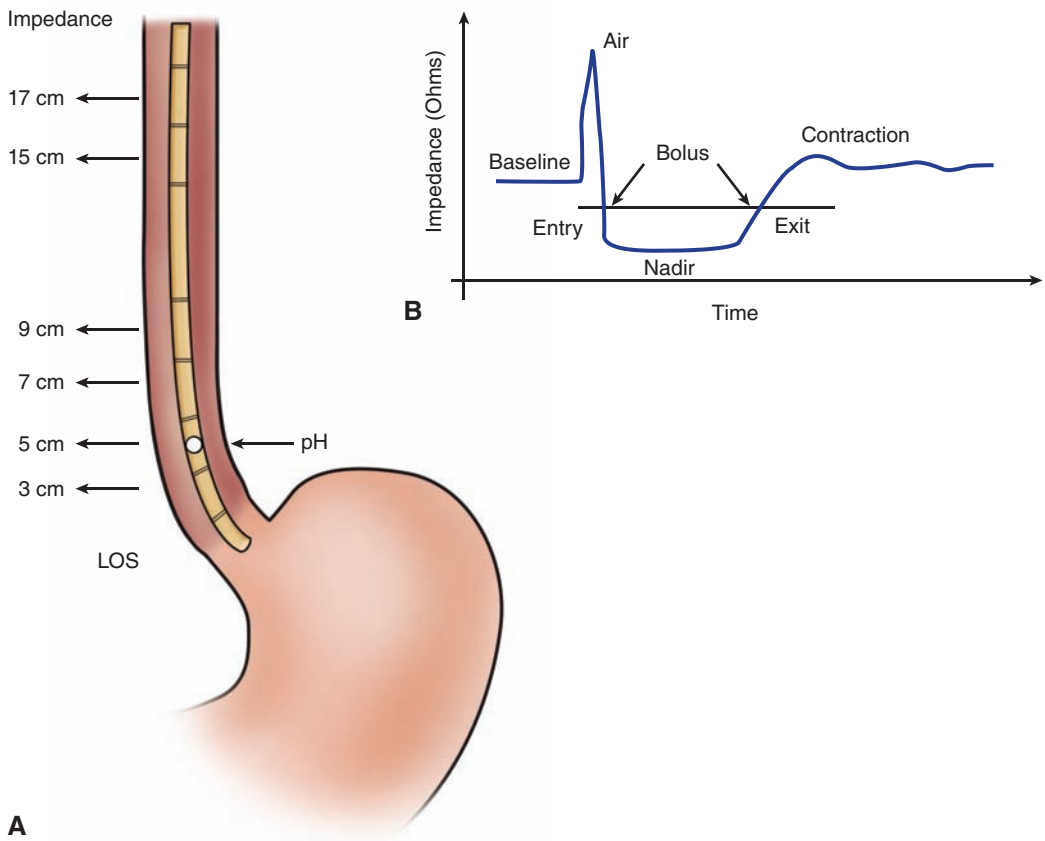

FIGURE 15-11 Combined multichannel intraluminal impedance-pH (MII-pH). **A**. Configuration of an impedance catheter. **B**. Structure of a typical appearance of a bolus. As a food bolus propagates down the esophagus, it pushes a pocket of air distally (small upward spike in impedance); as the bolus bridges the electrode pair, conductivity is increased and impedance drops; when the bolus passes the electrode pair, the resting impedance is restored.

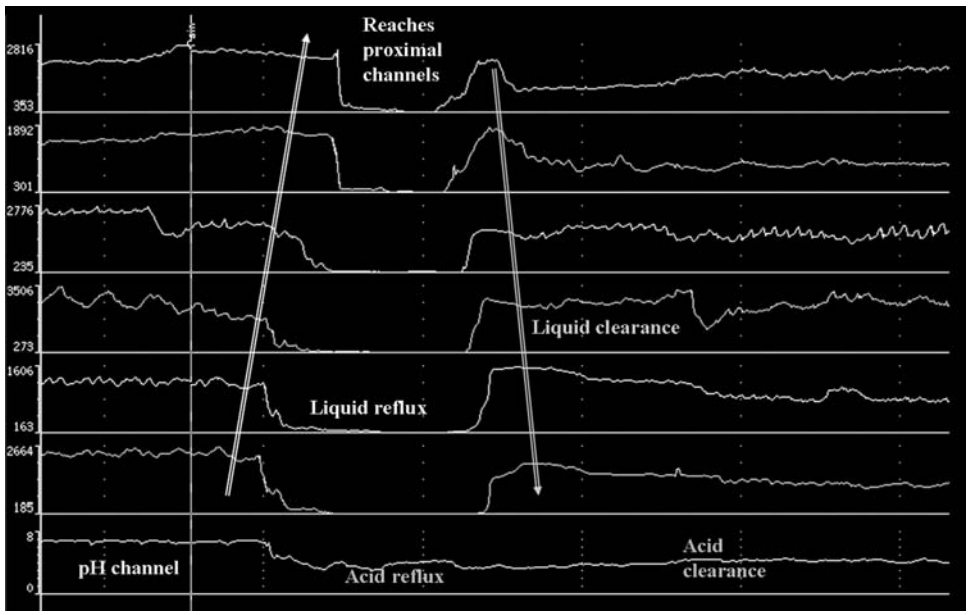

FIGURE 15-12 Typical tracing of a retrograde bolus movement (reflux) on multichannel intraluminal impedance (MII-pH). As the bolus bridges the electrode ring sets, the impedance decreases. The proximal extent of the bolus is traced as it crosses proximally located electrode pairs within the esophagus.

12 radially dispersed regions. The vast amount of data generated by these sensors is then processed and presented in traditional linear plots or as a visually enhanced spatiotemporal tracing that is readily interpreted. This enhanced spatial resolution allows real-time monitoring of contractile activity over the entire esophageal length and can be coupled with impedance measurement so as to determine whether pressure readings and bolus movement correlate (Fig. 15-13).

An incompetent LES is defined based on the comparison study between 50 healthy volunteers and patients with symptomatic GERD. An LES is considered defective by having one or more of the following characteristics: an average LES pressure of less than 6 mm Hg, an average length exposed to the positive-pressure environment in the abdomen (intra-abdominal length) of 1 cm or less, and an average overall sphincter length of 2 cm or less. *Achalasia* is defined by the manometric findings of a hypertensive, nonrelaxing LES with esophageal aperistalsis (100% failed or simultaneous contractions). *Ineffective esophageal motility* is defined by manometric findings of either failed peristalsis of greater than 30% or mean wave pressure of less than 30 mm Hg. *Nutcracker esophagus* is defined by peristaltic contractions that exceed 180 mm Hg within the smooth muscle portion of the esophagus. *Diffuse esophageal spasm* is defined by greater than 20% simultaneous contractions. Depending on the integrity of esophageal peristalsis, the antireflux procedure can be tailored to include either a "floppy" Nissen fundoplication or partial fundoplication. In our practice, patients with ineffective or failed peristalsis undergo a Dor partial fundoplication.

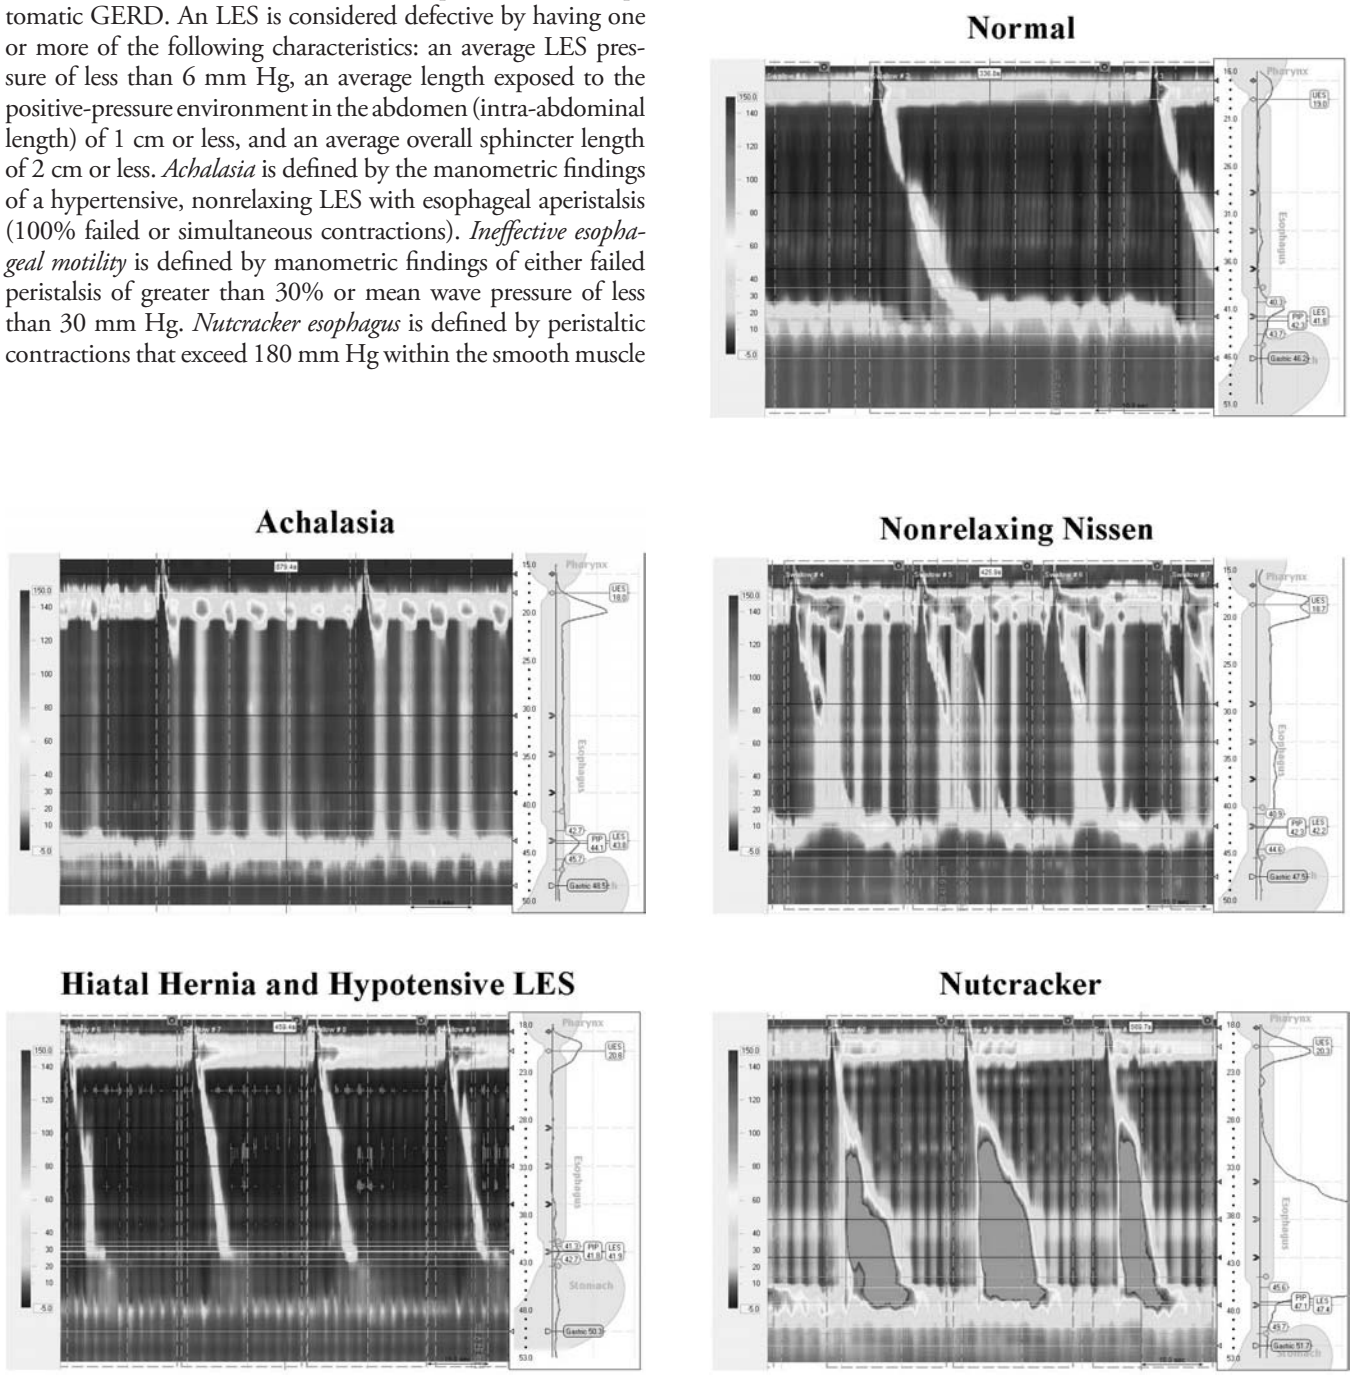

FIGURE 15-13 High-resolution manometry. Manometric appearances of normal peristalsis, achalasia, hiatal hernia and hypotensive lower esophageal sphincter (LES), nonrelaxing LES after Nissen, and nutcracker esophagus.

GASTRIC EMPTYING

Delayed gastric emptying causes bloating, dyspepsia, postprandial nausea, and abdominal distension. Previous studies have demonstrated that GERD is associated with delayed gastric emptying in approximately 40% of patients, but the precise role of gastric emptying in the pathogenesis of GERD is unclear.[90] It has been established that fundoplication improves gastric emptying by reducing the storage capacity of the fundus.[91–93] However, persistent delayed gastric emptying can cause an unsatisfactory outcome after antireflux surgery as fundoplication itself can lead to bloating. Therefore, a gastric emptying study should be considered for candidates of antireflux surgery with suspicious symptoms such as nausea, vomiting, and bloating. The gastric emptying study is performed with a radionuclide-labeled meal. Emptying of solids and liquid can be assessed simultaneously by having both phases marked with different tracers. After ingestion of a labeled standard meal, gamma counter images of the stomach are obtained at 5- to 15-minute intervals for 1.5–2 hours. After collection of decay, the counts in the gastric area are plotted as a percentage of the total counts at the beginning of the imaging. The *gastric emptying half-time* ($T_{1/2}$) is defined as the time required for 50% of the meal to exit the stomach. Patients with a $T_{1/2}$ more than 90 minutes are considered to have delayed gastric emptying. It has been suggested that patients with a $T_{1/2}$ of more than twice the upper limit of normal ($T_{1/2}$ >180 minutes) undergo pyloroplasty at the time of fundoplication.[91] However, the management of patients with a $T_{1/2}$ between the upper limit of normal and twice the upper limit of normal (90–180 minutes) remains controversial.[94] Postoperative bloating can be treated by reoperation and pyloroplasty, endoscopic dilation of the pylorus, or endoscopic botulinum toxin injection.

SURGICAL THERAPY FOR GERD

History of the Evolution of Antireflux Surgery

The first case of successful antireflux surgery was reported by Rudolph Nissen in 1956.[95] In this case, Nissen enveloped the lower esophagus with the gastric fundus over a large intraesophageal dilator. Subsequently, Nissen and Rossetti suggested that only the anterior wall of the stomach be wrapped around the lower esophagus.[96] Subsequently, the procedure has been modified in many ways. To avoid postoperative "gas bloat" syndrome, the partial anterior and posterior fundoplication techniques, in which the fundus encircles 270 degrees of the esophageal circumference, were developed and reported by Jacques Dor in 1962[41] and by Andre Toupet in 1963,[43] respectively. Donahue et al first described the "floppy" Nissen technique, in which the fundoplication was performed over a large-diameter esophageal dilator.[97] Then DeMeester et al further modified the operation by using a large dilator, limited the length of the fundoplication (2 cm), and completely mobilized the gastric fundus by division of the short gastric vessels.[98] Since the first description of successful laparoscopic Nissen fundoplication by Dallemagne et al in 1991, the laparoscopic approach has been widely accepted.[42] Several randomized trials have established that the laparoscopic approach achieves equivalent results with regard to subjective and objective resolution of GERD, with less postoperative pain, a shorter recovery period, and lower complication rate.[99]

Patient Selection for Surgery

Most patients have a relatively benign form of GERD that is responsive to life style and dietary modifications and medical therapy, and do not need surgical treatment. The mainstay of therapy for GERD is medical management. PPI therapy is highly effective, resulting in relief of symptoms and healing of esophagitis in more than 80% of patients.[44] However, most patients require lifelong treatment and discontinuation of therapy results in symptomatic relapse within 6 months in approximately 90% of patients with esophagitis and 75% of patients with NERD.[55] Additionally, it should be noted that PPI therapy does not reduce the esophageal injury associated with alkaline reflux and never addresses the mechanical incompetence of the barrier such as a defective LES and a hiatal hernia. A structurally defective LES is the most important factor predicting failure of medical therapy. Although the presence of a failed LES and esophagitis has been the primary indications for surgical treatment, antireflux surgery should be considered in any symptomatic patients with a documented GERD by pH testing or MII-pH regardless of presence of esophagitis and/or a defective LES. This is particularly true in patients who have PPI-responsive symptoms or persistent symptoms despite maximal PPI therapy. It is important to note that a good response to PPI therapy is a good indicator of the excellent outcome following antireflux surgery.

Young patients, especially women, with documented GERD are also excellent candidates for surgical treatment. They usually require lifelong medical therapy to control their GERD symptoms. The cost-effectiveness of surgical versus medical therapy in patients with GERD remains controversial.[51,59,100] Recent studies have suggested that long-term usage of PPI potentially causes impaired calcium absorption and osteoporosis, which may be associated with an increased risk of fractures.[57] This is particularly important for women.[82] Patients with esophageal stricture are excellent candidates for surgical treatment.[101,102] Esophageal stricture is often associated with a structurally defective LES and impaired esophageal contractility. Before proceeding with antireflux surgery, malignancy and a drug-related etiology of the stricture should be excluded, and the stricture should be dilated enough to resolve dysphagia. Esophageal manometry is then performed to evaluate the esophageal motility prior to laparoscopic fundoplication.

Patients with BE commonly have a severe structural defect of the LES and impaired esophageal motility.[56] The

presence of BE indicates the presence of GERD. In addition, BE may progress to adenocarcinoma. Antireflux surgery may prevent the development of adenocarcinoma, although there has been no prospective study performed that supports this supposition because of an extremely low incidence of adenocarcinoma arising from BE and the resultant inability to adequately power a comparison trial. BE should be first treated, followed by antireflux surgery. If BE with high-grade dysplasia and/or intramucosal carcinoma is found on biopsy specimens, an esophageal resection should be considered.

Patients with extraesophageal symptoms such as cough, aspiration, asthma, and progressive pulmonary fibrosis can also be good candidates for antireflux surgery. Before proceeding to surgical treatment, it is extremely important to document the correlation between reflux events and symptoms. Laryngopharyngeal reflux, a variant of GERD, may be associated with the development of extraesophageal symptoms.[83] Because the clinical presentation of laryngopharyngeal reflux is nonspecific and there has been no way to detect laryngeal events, it has been extremely difficult to demonstrate causality in the clinical setting. MII-pH could be an effective tool to make a diagnosis of laryngopharyngeal reflux.

Principles of Surgical Therapy

The primary goal of antireflux surgery is to safely restore the structurally defective gastroesophageal valve, to prevent its shortening with gastric distention while preserving the patient's ability to swallow normally. To achieve this goal, several principles regarding the reconstruction of the valve should be considered. First, the operation should restore the adequate pressure and length of the distal esophageal sphincter to prevent reflux from the stomach. The effect is to augment sphincter characteristics and prevent unfolding of the valve in response to gastric distention. In normal swallowing, a vagally mediated relaxation of the distal esophageal sphincter and the gastric fundus occurs.[85] To achieve adequate relaxation of the sphincter, only the gastric fundus should be used to create the fundoplication. The fundoplication should be placed around the distal esophagus and not the proximal stomach because it does not relax well with swallowing and has poor peristalsis. A deep groove on the surface of the fundoplication indicates that the repair is too tight and there should be no hesitation to take the repair down and begin over. Intraoperative injury to the vagal nerves should be avoided because it may cause the failure of sphincter relaxation with deglutition as well as delayed gastric emptying. Second, the fundoplication should not increase the resistance of the relaxed sphincter to a level that exceeds the peristaltic pressure of the esophageal body. Therefore, preoperative esophageal manometry is important to evaluate the esophageal motility. A Nissen fundoplication should be no longer than 3 cm and created over a 60F bougie. After a circumferential mediastinal esophageal mobilization resulting in 3 cm of tension-free intra-abdominal esophageal length, a posterior crural closure is performed to enable easy passage of the esophageal dilator. If adequate esophageal length cannot be achieved secondary to shortening of the esophagus, wedge gastroplasty as a lengthening procedure should be considered. Finally, an intraoperative endoscopic evaluation of the created valve is valuable to confirm the hallmarks of a successful fundoplication (Fig. 15-14). It should be noted that the initial fundoplication has the best chance to achieve the successful outcome.

Procedure Selection

A laparoscopic approach has been widely accepted, and the laparoscopic Nissen fundoplication is the procedure of choice for a primary antireflux surgery in the majority of patients with good esophageal motility and normal esophageal length. Previous prospective studies and randomized controlled studies have shown that the Nissen fundoplication is an effective antireflux surgery with minimal side effects, which provides long-lasting relief of reflux symptoms in over 90% of patients. Patients with a severe esophageal motility disorder defined by greater than 50% failed swallows, low peristaltic pressure, or an aperistaltic esophagus are best treated with a partial fundoplication to avoid the excessive outflow resistance.

PRIMARY ANTIREFLUX REPAIRS

Laparoscopic Nissen Fundoplication

The laparoscopic Nissen fundoplication is the most commonly performed antireflux procedure in the United States. The key points of this approach are the following:

- Preservation of both vagal nerves
- Complete mobilization of the gastric fundus by dividing the short gastric and posterior gastric vessels
- Extensive mediastinal dissection to obtain 3 cm length of tension-free intra-abdominal esophagus
- Creation of a large retroesophageal space
- Posterior crural closure
- Creation of a 2.5-cm "floppy" fundoplication around over a 60F bougie

The patient is placed supine and in a split-legged position, and the surgeon stands between the legs. A five-port technique is used: four 5-mm and one 12-mm ports are used. A 5-mm, 30-degree laparoscope is introduced through the 5-mm port placed in the left upper quadrant. All secondary ports should be placed under laparoscopic visualization. The second port (12 mm), which is used for the surgeon's right hand instruments, is placed 12 cm from the tip of the xiphoid process and 2 cm below the left costal margin. The third port (5 mm), which serves as the primary port site for the assistant, is placed

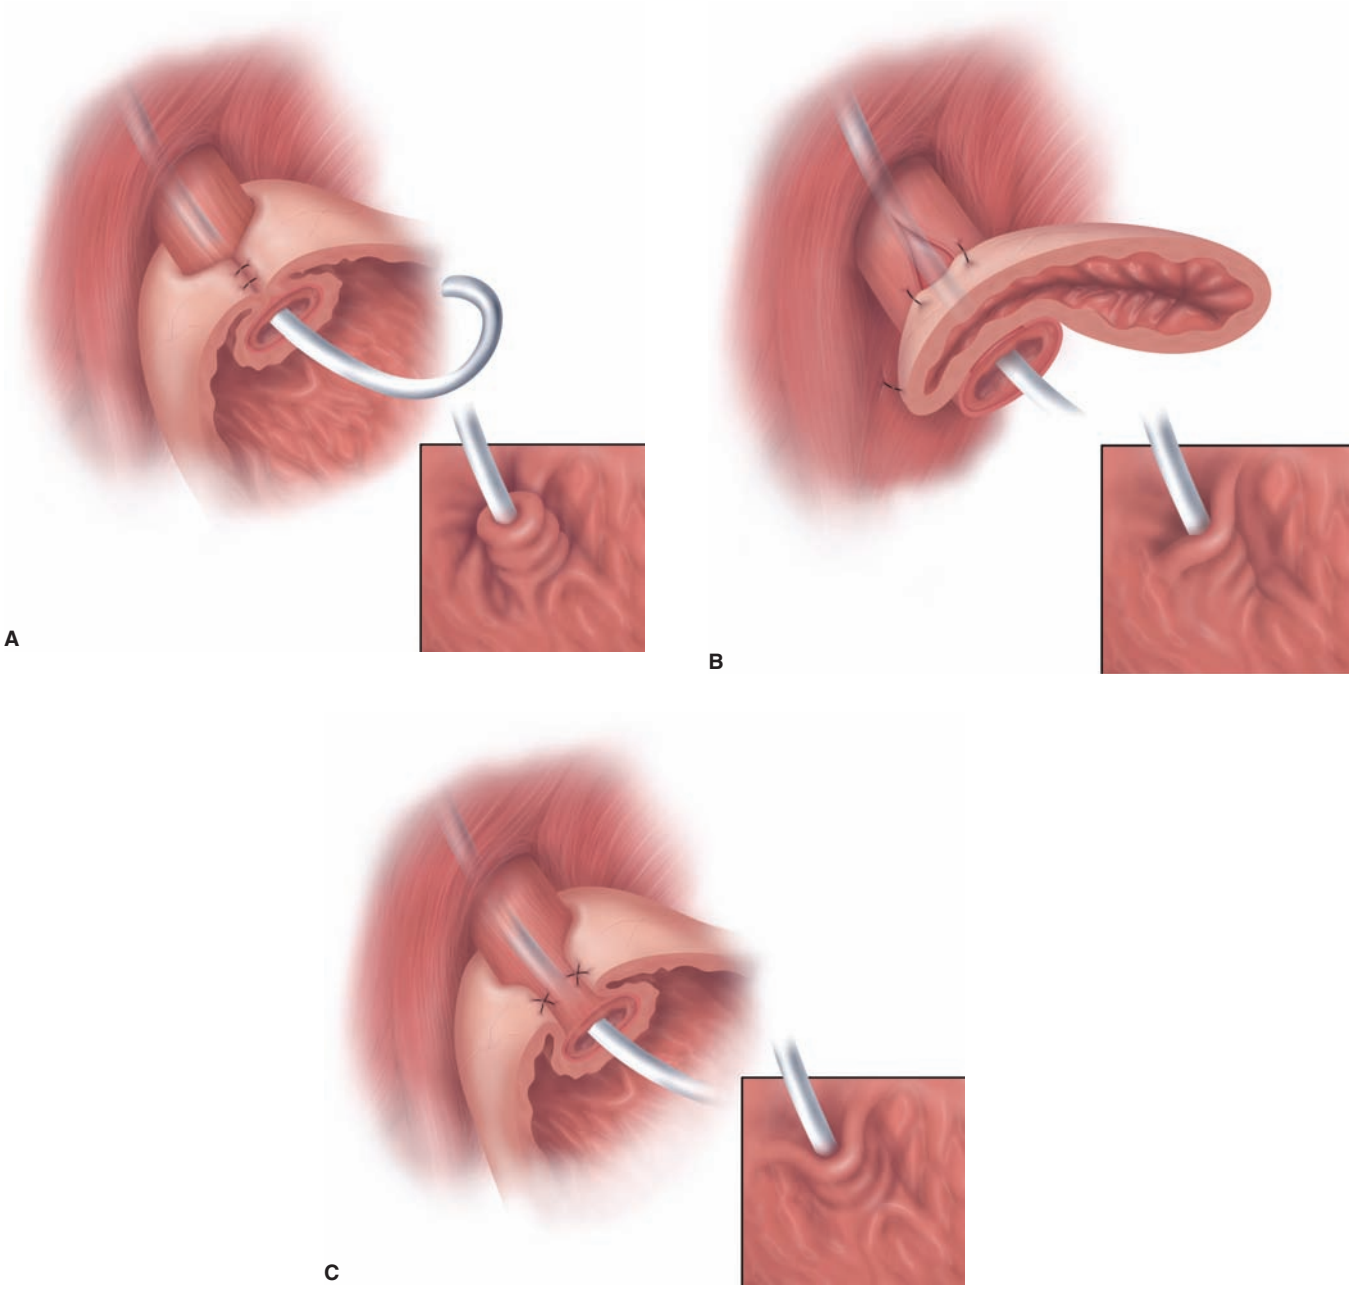

FIGURE 15-14 Endoscopic appearance of a re-created valve. **A.** Nissen fundoplication. **B.** Dor fundoplication. **C.** Toupet fundoplication. The left panels represent oblique section of each fundoplication. The right panels represent the endoscopic appearance of the corresponding valves. Endoscopy shows a "stacked coils" appearing nipple valve in Nissen fundoplication, "S"-shaped flap valve in Dor fundoplication, and an omega-shaped valve in Toupet fundoplication.

within the left anterior axillary line along the costal margin. The fourth port (5 mm) is created immediately to the left of the xiphoid process for placement of the Nathanson liver retractor (Cook Medical, Bloomington, IN) that is used to expose the hiatal opening and gastrohepatic omentum. The fifth port (5 mm), which is for the surgeon's left hand instruments, is placed inferior to the right costal margin immediately to the right of the falciform ligament (Fig. 15-15).

The first step in the hiatal dissection is opening the gastrohepatic omentum and then extending to the right and left crura to expose the esophagus circumferentially at the hiatus. In up to 12% of patients, an accessory left hepatic artery, originating from the left gastric artery, will accompany the hepatic vagal branch. This vessel should be preserved or, when necessary, divided between clips. The relationship between the division of hepatic vagal branch and the dysfunction of gallbladder

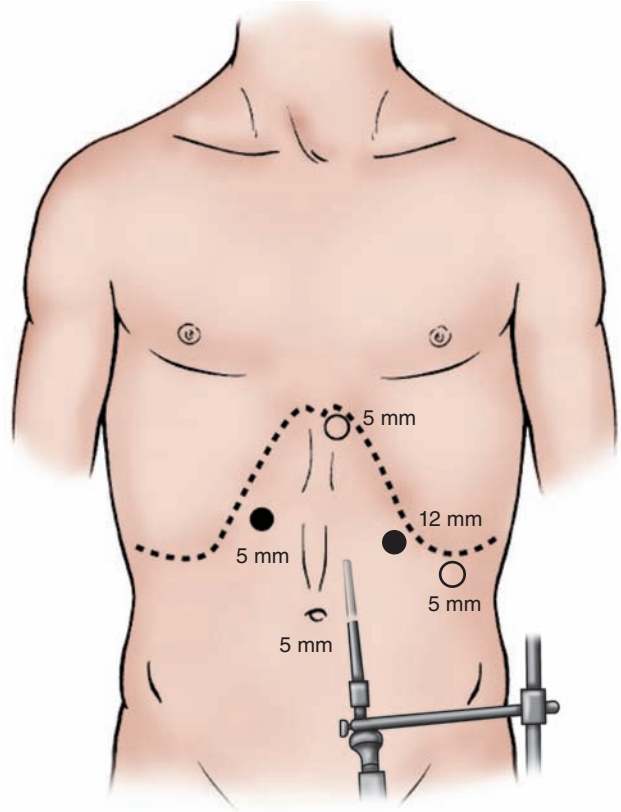

FIGURE 15-15 Patient position and port placement.

has been suggested. However, the benefit of preservation of the hepatic vagal branch remains controversial.[86,103] The gastrophrenic attachments over the anterior aspect of the left crus are divided, and this dissection is further extended so as to mobilize the angle of His and divide the highest short gastric vessels (Fig. 15-16). The phrenoesophageal ligament is then

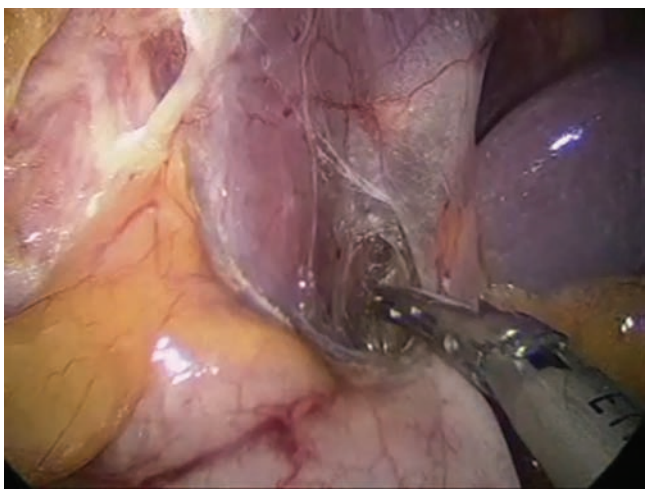

FIGURE 15-16 Division of the gastrophrenic attachments of the apex and pillar of the left crus anteriorly, angle of His, and highest short gastric vessels.

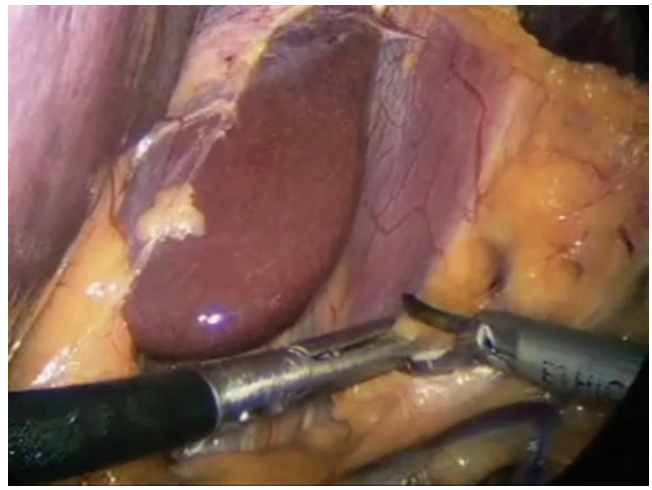

FIGURE 15-17 Dissection of the phrenoesophageal ligament.

opened at the right crus, and the dissection between the crus and esophagus is carried anteriorly (Fig. 15-17). During this maneuver, both anterior and posterior vagus nerves should be identified and preserved (Fig. 15-18). The hiatal dissection is then carried posteriorly until the union of the right and left crura is identified and the beginning of the posterior esophageal window is created (Fig. 15-19). Although the necessity of dividing the short gastric vessels remains controversial,[104,105] several studies have suggested that incomplete mobilization of the fundus can cause postoperative dysphagia.[106] Division of the short gastric vessels begins along the greater curvature of the stomach, at the level of the lower pole of the spleen (Fig. 15-20). After division of short gastric vessels, the posterior stomach is exposed, and the posterior pancreaticogastric fold and posterior gastric vessels are divided to achieve further mobilization of the fundus and expose the base of the left crus

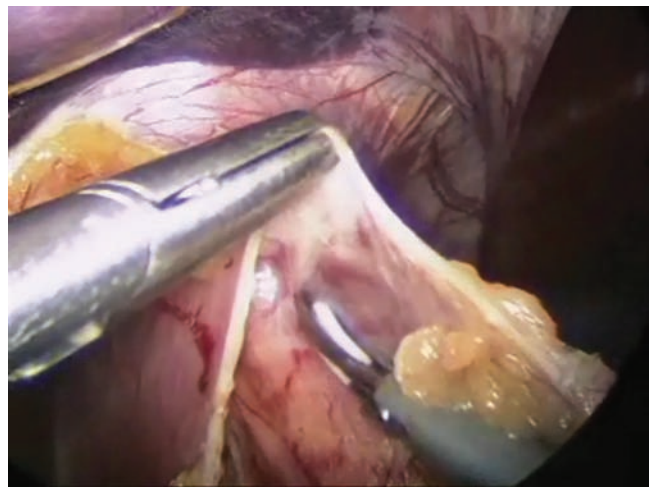

FIGURE 15-18 Identification of the anterior vagus nerve.

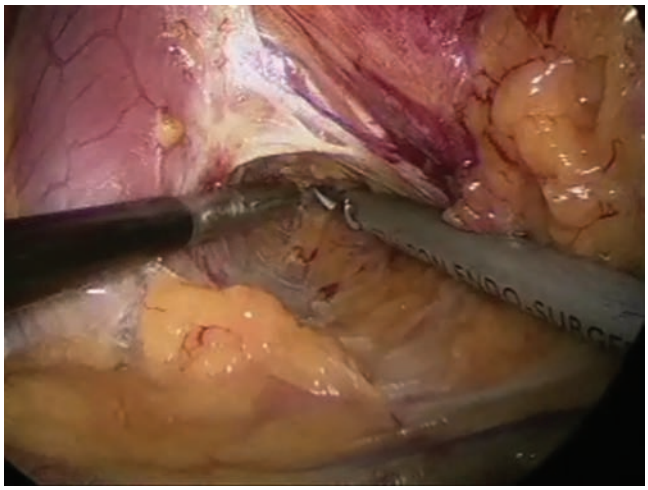

FIGURE 15-19 Beginning of the esophageal posterior window.

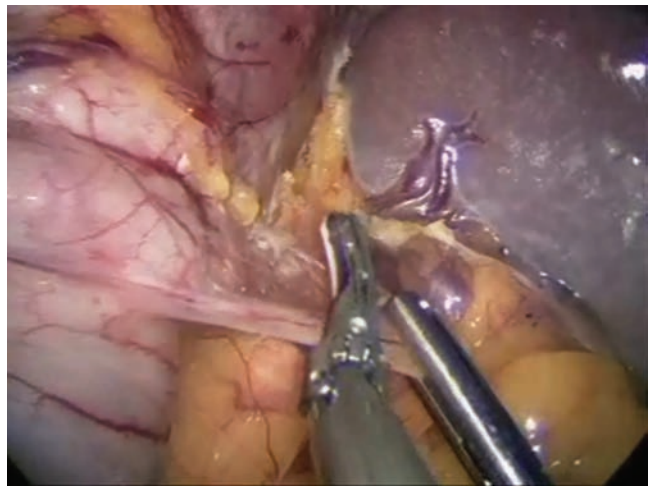

FIGURE 15-21 Division of the posterior gastric vessels.

(Fig. 15-21). A posterior esophageal window is then completely established from the right side, and a Penrose drain is inserted behind the esophagus and the ends secured together anterior to the esophagus with several clips. The Penrose drain facilitates retraction of the esophagus during the mediastinal dissection (Fig. 15-22).

An extensive mediastinal dissection of the esophagus is performed circumferentially until at least 3.0 cm of distal esophagus remains within the abdomen in a tension-free fashion (Fig. 15-23). Attention must be paid to preserve both vagus nerves. If an adequate length of intra-abdominal esophagus cannot be obtained even after extensive mediastinal dissection, a lengthening procedure such as a stapled-wedge Collis gastroplasty should be considered.[107] During the mediastinal dissection, attention should be paid to avoid injury of both vagus nerves and mediastinal pleura (Fig. 15-24). If the pleural cavity is accidentally opened, tension pneumothorax can be prevented by transabdominal insertion of a 14F red rubber catheter into the affected pleural space. At the end of the procedure, the pleural space is evacuated with a Valsalva maneuver and the catheter is removed. At the completion of mediastinal dissection, the diaphragmatic crura are approximated using interrupted 0 nonabsorbable suture. The closure should be snug, but not tight, around the esophagus and enable facile passage of the bougie (Fig. 15-25).

The fundus of the stomach is brought through the posterior esophageal window. By grasping the greater curvature of the fundus on either side of the esophagus, a "shoeshine maneuver" is performed to ensure that there is a proper orientation of the fundus without twisting or torsion (Fig. 15-26). At

FIGURE 15-20 Division of the short gastric vessels.

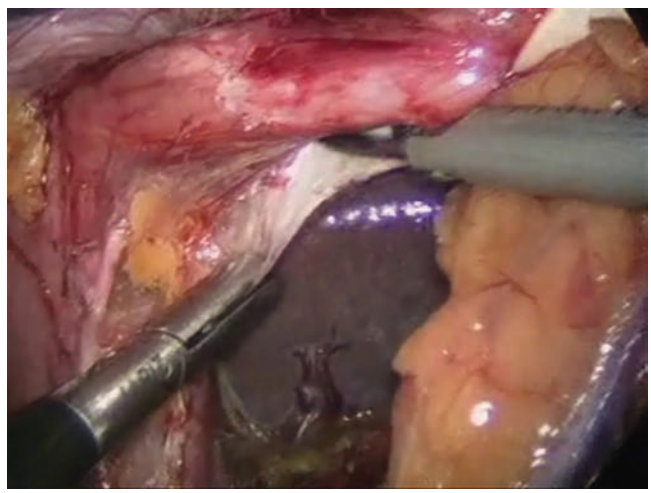

FIGURE 15-22 Creation of a large retroesophageal space.

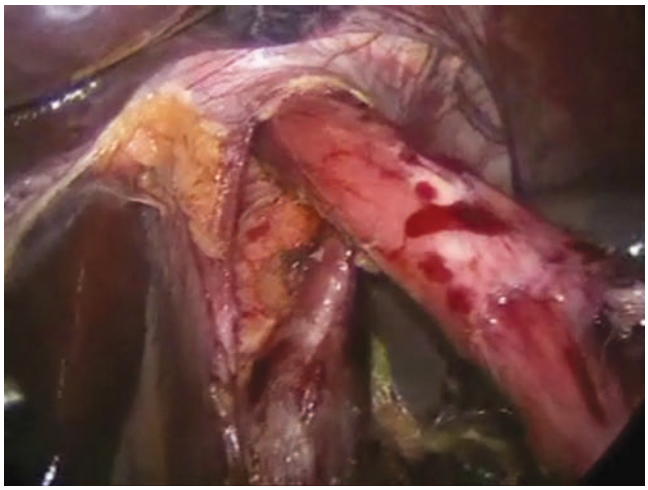

FIGURE 15-23 At the completion of extensive mediastinal dissection, an adequate tension-free intra-abdominal esophageal length was achieved.

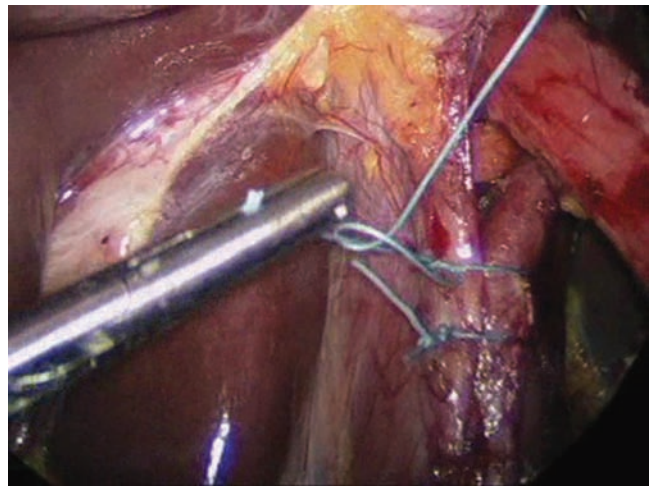

FIGURE 15-25 Completion of the approximation of diaphragmatic crura.

this point, an esophageal dilator (60F) is inserted and guided along the lesser curvature of the stomach under laparoscopic visualization. A 2.5-cm fundoplication is then performed around the end of esophagus with 0 nonabsorbable sutures that incorporate the right and left limbs of the fundoplication along the greater curvature. At this point, an instrument is advanced through the fundoplication toward the diaphragm to ensure the fundoplication is not too tight. Eventually, the fundoplication is secured with 3 nonabsorbable, unpledgeted sutures. Sutures should incorporate a full thickness of the stomach and partial thickness of the anterior esophageal wall, with care taken to avoid placement into the anterior vagus nerve (Fig. 15-27). The dilator is then removed and the intraoperative upper endoscopy is performed to confirm the proper orientation of the valve.

Laparoscopic Partial Fundoplication

Partial fundoplication is indicated in patients with impaired esophageal motility. The Dor and Toupet antireflux procedures consist of partial anterior and posterior fundoplication, respectively. Most of the key points are common with those listed for a Nissen fundoplication. The difference between a complete and a partial fundoplication is the structure of a newly created valve; a "nipple" valve in a complete fundoplication versus a "flap" valve in a partial fundoplication.

DOR FUNDOPLICATION

After mobilization of the distal esophagus and GEJ and hiatal closure, a 60F Bougie is placed as described in the section on Nissen

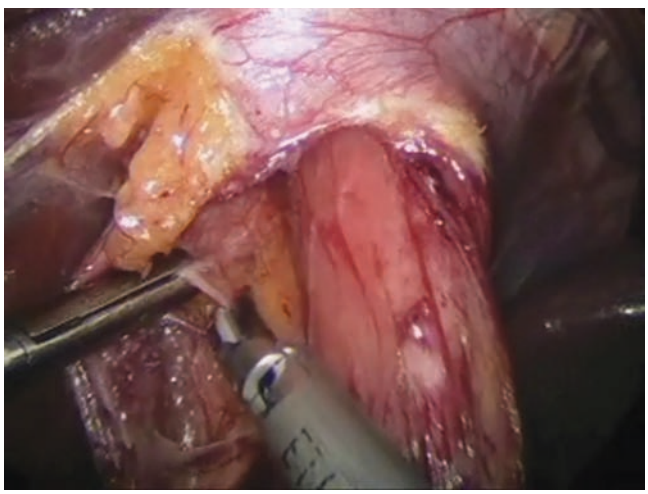

FIGURE 15-24 Mediastinal dissection. Attention must be paid to preserve the vagal trunks and prevent the injury to mediastinal pleura.

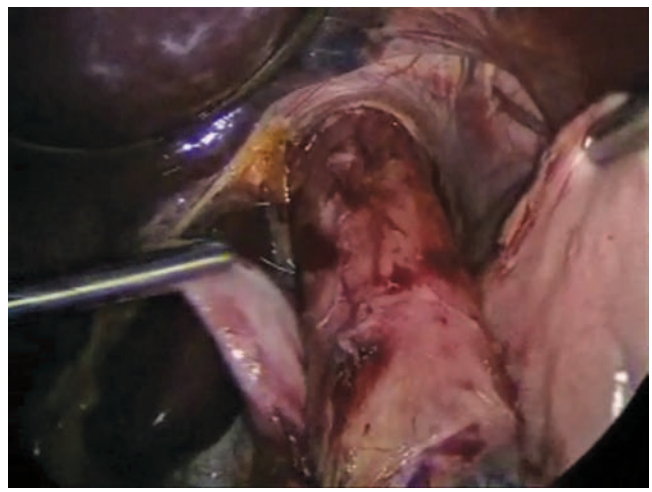

FIGURE 15-26 Shoeshine maneuver.

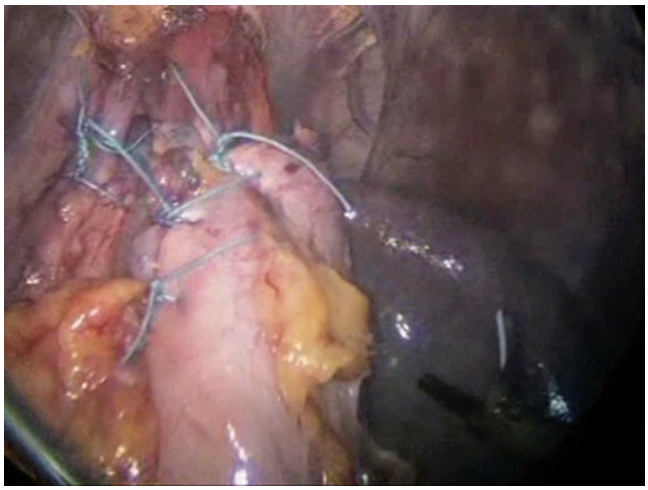

FIGURE 15-27 Completion of the fundoplication.

fundoplication. The initial suture of the Dor fundoplication incorporates the greater curvature side of the gastric fundus 2 cm distal to the GEJ, lateral wall of the esophagus 2 cm proximal to the GEJ, and base of the left crus to re-create the angle of His. Re-creation of the angle of His is an essential element of the Dor fundoplication. The greater curvature is then sutured to the arch of the diaphragm toward the apex of the crura, bringing the anterior fundus over the anterior wall of the distal esophagus with seven interrupted 0 nonabsorbable sutures. This repair is carried over to the right crus to the 9 o'clock position. At completion, the fundoplication should appear smooth without creases indicating the absence of tension.

TOUPET FUNDOPLICATION

In an identical fashion to the Nissen fundoplication, the gastric fundus is passed behind the esophagus through the retroesophageal space after hiatal closure and placement of an esophageal dilator. The right side of the fundus is sutured to the right margin of the esophagus with four nonabsorbable sutures, and the most distal suture is placed to the lesser curvature of the stomach immediately distal to the GEJ. The right posterior aspect of the fundus is sutured to the right side of the proximal preaortic fascia. A similar line of sutures secures the left limb of the fundoplication to the esophagus. The posterior aspect of the gastric fundus on left is sutured to the base of the left crus.

Outcome of Antireflux Surgery

The goal of surgical treatment for GERD is to relieve the symptoms by restoring a mechanically defective gastroesophageal barrier. This goal should be achieved without inducing postoperative complications such as dysphagia and gas bloat syndrome. Temporary dysphagia due to postoperative tissue edema of the wrap is common and generally resolves within 3 months without requiring any intervention such as dilation. However, persistent dysphagia beyond 3 months has been reported in up to 10% of patients. Bloating and hyperflatulence are also common after antireflux surgery because patients with GERD tend to swallow excessive air with saliva in order to neutralized acid refluxate. Scheduled administration of Simethicone is effective to reduce gas in the GI tract, improving the symptoms. In addition, it is important to prevent constipation so as to not worsen bloating. Another common side effect after antireflux surgery is the inability to vomit, but this is rarely clinically relevant. It is critical to control perioperative nausea so as to prevent retching with subsequent disruption of the repair.

Studies of long-term outcome following laparoscopic fundoplication have demonstrated relief of typical GERD symptoms such as heartburn, regurgitation, and dysphagia in more than 90% of patients at the follow-up interval of 2–3 years and 80–90% of patients at 5 years or more.[98,108–110] Laparoscopic fundoplication results in a significant increase in LES pressure and length, generally restoring these values to normal. Postoperative pH studies indicate that more than 90% of patients normalize acid exposure to the esophagus. A randomized study with 11-year follow-up demonstrated that the open and laparoscopic approaches for the Nissen fundoplication have similar long-term subjective symptomatic outcome despite the significantly higher incidence of incisional hernia and endoscopically defective valves in the open group; from these data, the authors defined the laparoscopic approach as the procedure of choice in surgical management of GERD.[111] There is a less predictable outcome of atypical symptoms such as cough, asthma, and laryngitis after antireflux surgery, being relieved in only two-thirds of patients probably because the documentation of correlation between reflux events and atypical symptoms has been difficult.[112–114] This could be addressed with the introduction of a reliable esophageal objective testing tool such as MII-pH.

Quality-of-life analyses have become an important part of surgical outcome assessment, especially for the surgical treatment of benign disease such as GERD. Currently, both global and disease-specific questionnaires have been used to quantify quality of life before and after surgical intervention.[115] Most studies have utilized the Short Form 36 (SF-36) instrument that is rapidly administered and well-validated. The GERD Health-Related Quality of Life Scale (GERD-HRQL), which is a disease-specific questionnaire, is also commonly used to address symptom severity in GERD. Fernando et al compared quality of life after antireflux surgery with that of nonoperative management for severe GERD, and showed that both SF 36 and GERD-HRQL were significantly superior in patients who underwent laparoscopic fundoplication compared with those who had medical treatment. They indicated that laparoscopic fundoplication should be considered for patients who are dissatisfied with medical treatment.[116]

Reoperation for Failed Antireflux Repairs

With the increased number of antireflux surgeries being performed, the reoperation for a failed repair has been more

frequent. Previous studies have shown that the failure rates for open fundoplication range from 9 to 30%,[98,117,118] whereas those for laparoscopic approach range from 2 to 17%.[119,120] Many patients with mild recurrent symptoms can be managed with nonoperative therapy. It has been estimated that between 3 and 6% of antireflux surgeries will require reoperation.[121] With the advance of minimally invasive surgical technique, more reoperations are being performed using a laparoscopic approach. However, the success rate for redo surgery does not equal to that of the initial antireflux surgery. Little et al reported that 84% of patients undergoing the first redo antireflux surgery achieved a satisfactory result, but only 42% of patients with three or more previous reoperations had a satisfactory result.[118] Although a recent systematic review of reoperations showed that recurrent reflux and dysphagia were the most frequent indications for redo antireflux surgery,[122] the etiology of recurrent symptoms varies considerably and patients with any persistent symptoms should be evaluated with objective testing. It is extremely important to identify the etiology of symptoms in order to choose an appropriate treatment option. Evaluation includes the repeat of esophageal objective testing such as upper endoscopy, barium swallow, manometry, pH monitoring, MII-pH, and gastric emptying. Based on radiographic findings, several patterns of recurrence have been reported (Fig. 15-28).[123] Herniation and disruption of the fundoplication were the most common causes of failure.[122] Additionally, inadequately treated short esophagus often contributed to repair herniation.[124]

There are several options for reconstructive antireflux surgery, including redo Nissen or partial fundoplication, Roux-en Y esophagojejunostomy, and esophagectomy. In redo fundoplication, it is essential to completely take down the previous repair in order to reestablish the normal anatomy, identify the "true" GEJ by medializing the gastroesophageal fat pat, preserve both vagus nerves, recognize a short esophagus, repair the crura, and re-create the proper fundoplication. The results of redo antireflux surgery are not as good as those of the primary antireflux surgery. However, good-to-excellent results can be achieved in more than 80% of patients using minimally invasive techniques at an experienced center.[125,126]

HIATAL HERNIA

History

In 1919, Soresi published the first report on the surgical treatment of hiatal hernia.[127] In 1950, Sweet described the transthoracic approach to hiatal hernia repair and 2 years later reported a series of 111 patients.[128] Allison established the relationship between hiatal hernia and gastroesophageal reflux and proposed surgical options to correct the defect, namely returning the stomach to the abdomen and repairing the diaphragmatic hiatus.[129] Subsequently, Barrett,[130] Hiebert and Sir Belsey,[131] and Hill et al[132] set the stage for the importance of reestablishing the cardiophrenic angle in correcting reflux symptoms. In 1967, Belsey and Skinner presented data on 1063 patients with hiatal hernia.[133] The work was the first to distinguish between a sliding hiatal hernia and a paraesophageal hernia (PEH). Since then, further evaluation and subclassification of hiatal hernias has occurred. From this work, the overriding consensus for the next several decades was that PEH required surgical repair so as to prevent strangulation, gastric necrosis, and patient death.

Categories of Hiatal Hernia

There are four types of hiatal hernia. Type I, sliding hiatal hernias, account for nearly 95% of all hiatal hernias.[134,135] The combination of hiatal enlargement, lengthening of the phrenoesophageal ligament, and increased intra-abdominal pressure allows the GEJ to become intrathoracic. Sliding hiatal hernias may be more likely to progress in patients who are obese, pregnant, or have a chronic cough. Because the GEJ is displaced from its normal anatomic position, there is concurrent dysfunction of the LES manifesting as decreased resting pressure. This causes a loss of the angle of His, thus distorting the esophageal flap valve.[87]

The other three types of hiatal hernias are broadly classified as paraesophageal. Compared with a type I hernia, which has no hernia sac, all PEHs are covered circumferentially by a layer of peritoneum that forms a true hernia sac. Type II PEH is the least common.[136] Type II hernias are characterized by preservation of the GEJ at its normal anatomic position within in the abdomen. The phrenoesophageal ligament is preserved, but the esophageal hiatus is enlarged and the fundus of the stomach is in the thoracic cavity. When there is proximal displacement of the GEJ and at least 30% of the stomach above the diaphragm, this is classified as a type III PEH, the most common type of PEH. When there is herniation of other organs into the thoracic cavity along with the stomach, this is termed a type IV PEH. Colon, small bowel, pancreas, spleen, omentum, and liver can migrate into the true anterior or posterior hernia sac. In addition to obstruction of the stomach, colon, or small bowel, there is the potential for compromised blood flow to the organs that are displaced intrathoracically.[137] The most common complaints associated with PEH are related to mechanical issues caused by the location of the fundus above the diaphragm while the GEJ is fixed in its proper anatomic position in the abdomen. These include chest pain or pressure, obstruction, incarceration, possible strangulation, and pulmonary dysfunction commonly associated with chronic aspiration. Additionally, about 40% of patients with a PEH have chronic anemia that may be the result of either mucosal venous engorgement or a Cameron ulcer.[138]

Hiatal hernias, including PEHs, occur most commonly in women. In the largest published series on treatment of PEH, 75% of patients were female.[139] About half of all patients presenting with PEH are older than 70, possibly because of loss of elasticity and muscle weakening. This loss of muscle tone around the diaphragmatic opening allows it to become dilated more easily. The gastric cardia then pushes into the opening and may or may not return to its normal anatomic position, thus further dilating the hiatus. Women may be affected more

frequently than men because of changes during pregnancy. Other etiologies that cause increases in intra-abdominal pressures (obesity, constipation, and abdominal ascites) are also implicated.

PEH and Short Esophagus

Short esophagus is defined as less than 2.5 cm of tension-free intra-abdominal esophagus. Three types of esophageal shortening have been identified.[140] The first is the apparent short esophagus, which is longitudinal compression of the esophagus in the mediastinum, but maintenance of normal esophageal length. The other two types are truly shortened esophagus and are classified as reducible and nonreducible. A reducible short esophagus is foreshortened, but with extensive mediastinal mobilization 2.5 cm of intra-abdominal esophagus can be obtained. In patients with a nonreducible short esophagus, extensive mediastinal mobilization fails to produce sufficient length and an esophageal lengthening

procedure must be considered. The ability to accurately identify a nonreducible short esophagus is critical to accomplish a tension-free PEH repair that results in a low risk of recurrence. The incidence of short esophagus in patients undergoing antireflux surgery is 3–10%, [140,141] while a higher incidence has been noted in patients with PEH, which is commonly identified as a risk factor for short esophagus.[142–144] Diagnosis of a short esophagus is made intraoperatively.

Preoperative Evaluation

At the time of evaluation, a detailed history and physical examination are important. While symptoms of reflux and dysphagia occur in 40–70% of patients, other symptoms are also commonly experienced. In the largest series to date, regurgitation, dyspnea, chest pain, or abdominal pain was also seen in 40–70% of patients.[139] If a patient presents with acute-onset, severe abdominal pain with vomiting, the physician needs to be mindful of the possibility of gastric volvulus, especially in patients with a known history of PEH. In these cases, urgency is essential as timely diagnosis and emergent operative intervention can mean the difference between reduction of the hernia and repair and subtotal gastrectomy or death.

ESOPHOGRAM

A barium esophogram will delineate how much stomach is herniated through the hiatus, and will determine whether there is organoaxial rotation of the stomach, which in conjunction with complaints of intermittent abdominal pain may be a harbinger of pending volvulus and either incarceration or strangulation necessitating elective repair on an urgent basis. Contrast examinations are also very important in the evaluation of recurrent PEH and may lend insight into the cause of the recurrence and assist in identifying complexities that may be encountered at the time of surgery.

ENDOSCOPY

Endoscopy enables examination of the mucosa to evaluate for esophagitis, BE, stricture, or malignancy. Endoscopy may also estimate the size of the hiatus. In cases where there is concern for incarceration or strangulation, flexible endoscopy is a valuable diagnostic test of mucosal viability and enables gastric decompression.

MANOMETRY AND pH TESTING

Most patients who have a PEH have poor esophageal motility. However, up to 80% may demonstrate improvement following surgical repair of the hiatal hernia.[145] The use of pH probe testing is not necessary; it can be difficult to get accurate results, and the results do not change the management algorithm. Esophageal manometry will determine whether there is normal esophageal body function and enable tailoring of the antireflux procedure.

GASTRIC EMPTYING STUDY

Gastric emptying studies are not obtained unless the patient is presenting with a recurrence of a PEH that will require reoperation. For patients who have previously undergone surgical repair of the PEH, a gastric emptying study is important to determine if the vagus nerves have been injured, as this may alter the surgical approach.

Operative Approach

Surgery for PEH is reconstructive in nature with two primary goals: restore the normal anatomy by returning the GEJ and stomach to the abdomen and correct the condition that contributed to the development of the anatomic problem, namely GERD. Surgeons can either choose a transthoracic, transabdominal, or laparoscopic approach to repair a PEH.[146–148] The best approach is a point of considerable debate and the different approaches to PEH repair have not been compared in a prospective, randomized trial. Laparoscopic repair significantly decreases postoperative complications and is the procedure of choice in most centers. The tenants of surgical repair include sac excision with complete reduction of the hernia from the mediastinum, establish tension-free esophageal length, repair the diaphragmatic crura, and perform an antireflux procedure.

TRANSTHORACIC APPROACH

A left posterolateral thoracotomy is performed with a planned entry at the seventh interspace. The inferior pulmonary ligament is incised to the level of the inferior pulmonary vein and the mediastinal pleura overlying the esophagus is opened. The esophagus is circumferentially mobilized from the carina toward the diaphragm. The hernia sac is then dissected free of surrounding structures until the crura are identified. The sac is then incised just above the crural fibers to avoid loss of the peritoneal covering of the crura. The esophagus and stomach are then dissected away from the crura. When the right crus is identified, the gastrohepatic ligament is divided to the level of the left gastric artery. The stomach is mobilized beginning with the highest short gastric vessels. Once the fundus is restored to its normal anatomic position, the crural approximation stitches are placed, but not tied. During mobilization of the anterior esophageal fat pad, the vagus nerves need to be identified and protected. Mobilization of the fat pad enables identification of GEJ to determine if there is appropriate intra-abdominal esophageal length. A fundoplication is then performed as described in section on Nissen fundoplication. The fundoplication is placed into the abdominal cavity and crural sutures are tied.

LAPAROSCOPIC APPROACH

The hernia sac is gently reduced. This is accomplished by grasping the sac just inside the diaphragmatic crura at the 12 o'clock position (Fig. 15-29). The sac is incised providing access to the fibroareolar plane within the posterior mediastinum. Dissection in the correct plane is generally free of hemorrhage and provides excellent visualization of the pleura, esophagus, and vagus nerves. The borders of the dissection are the pleura laterally, the pericardium anteriorly, and the aorta posteriorly. Circumferential mobilization facilitates reduction of the entire hernia sac into the abdomen, thus returning the stomach to its normal anatomic position. The gastrohepatic ligament is divided and this provides access to the posterior aspect of the sac from the right side. Short gastric vessels are completely divided and the gastroesophageal fat pad is fully mobilized to allow visualization of the GEJ (Fig. 15-30). Anterior and posterior vagus nerves are identified and preserved. The GEJ is evaluated to determine that there is an adequate length of intra-abdominal esophagus (Fig. 15-31). If aggressive esophageal mobilization fails to produce an appropriate length of esophagus, an esophageal lengthening procedure is performed using a stapled wedge gastroplasty.[149] (Fig. 15-32). An antireflux procedure is routinely performed (Fig. 15-33). The crura are reapproximated using nonabsorbable 0-suture. Bioprosthetic mesh is used selectively to buttress the hiatal closure.

OUTCOMES—TRANSTHORACIC APPROACH

The University of Michigan retrospectively reported their 25-year experience with open transthoracic repair of PEH.[146] In their series, 240 patients underwent PEH repair via a left thoracotomy, and 96% had a Collis-Nissen gastroplasty performed as part of the repair. At a median follow-up of 28 months, 86% of patients were satisfied with the results of the PEH repair, despite radiographic recurrence in 12% of patients. Maziak and colleagues followed 94 patients who underwent transthoracic PEH repair.[150] The majority of the patients underwent a Collis gastroplasty with a Belsey fundoplication. With a median follow-up of 72 months, anatomic recurrence was identified in 2%, postoperative morbidity in 19%, and mortality in 2%. More than 90% of the patients had good-to-excellent symptom resolution.

OUTCOMES—LAPAROSCOPIC APPROACH

Surgical repair of PEH is a complex operation and the minimally invasive approach requires advanced laparoscopic expertise. Very early experience of small, retrospective case reports was that these reports were able to demonstrate feasibility with good outcomes over a short follow-up.[151] The initial enthusiasm for laparoscopic repair of giant PEH waned as further reports were unable to reproduce the early results and were associated with high failure rates.[152–154] Recurrence rates as high as 40% with mortality

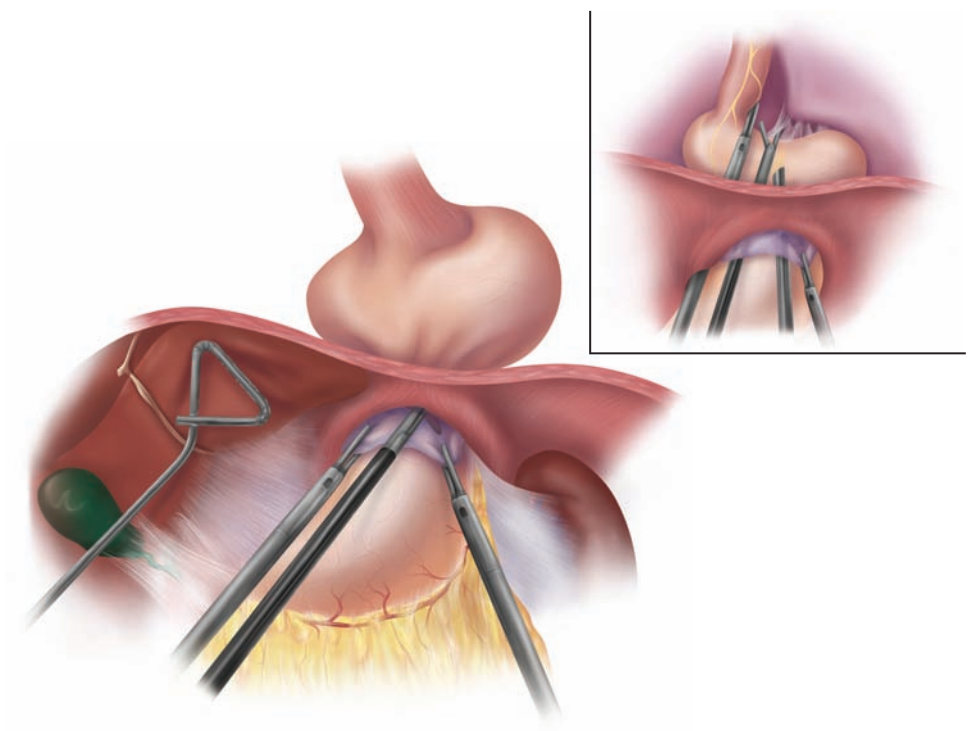

FIGURE 15-29 Beginning the hernia sac dissection. The sac is opened providing access to the space between the outside of the sac and posterior mediastinal structures.

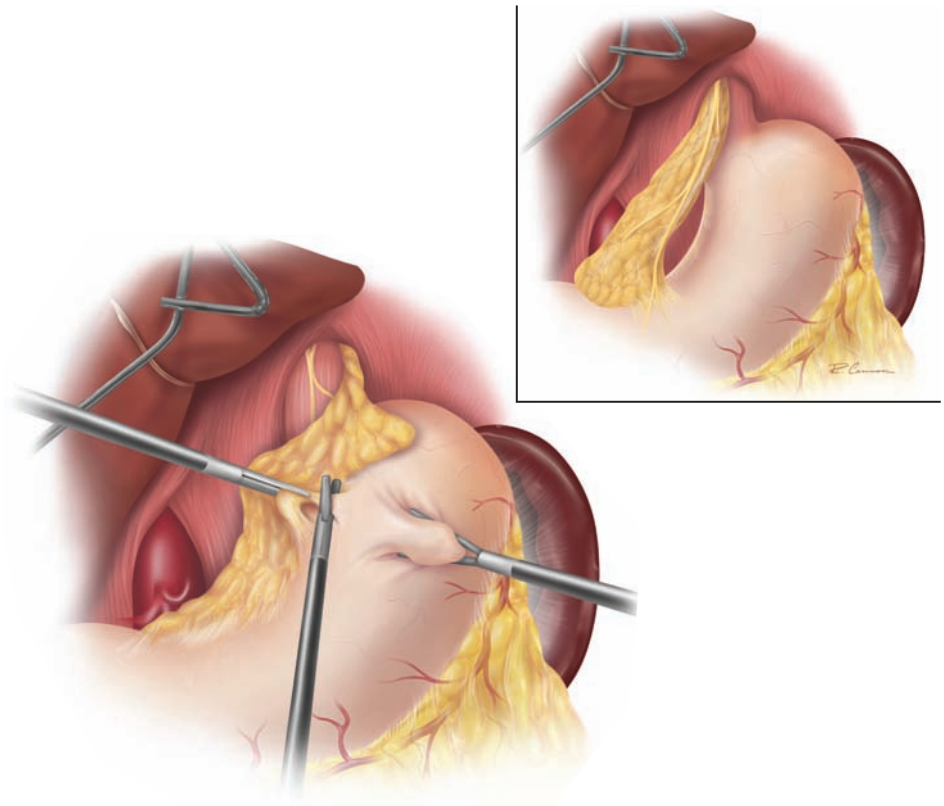

FIGURE 15-30 Medialization of the gastroesophageal fat pad so as to provide exposure of the anatomic gastroesophageal junction.

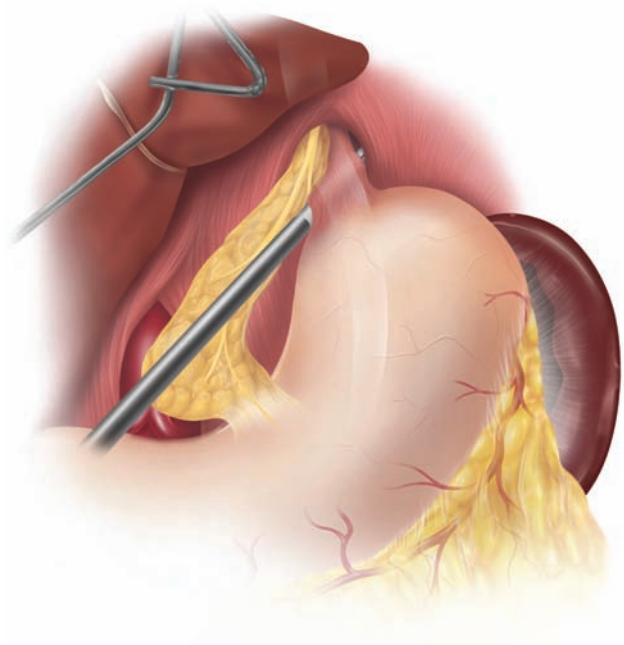

FIGURE 15-31 Evaluation of esophageal length. Dashed line indicates the planned wedge gastroplasty in patients with less than 3bcm of tension-free, intra-abdominal esophagus.

rates of up to 5%, both considerably higher than those for either open transthoracic or transabdominal repairs, were reported. However, over the past decade there has been a considerable evolution of the technique, and the feasibility and safety of the laparoscopic approach have been well established.[139,155] Operative mortality following laparoscopic PEH repair is now extremely low (0–2%) but is higher in patients older than 80 and in those requiring urgent repair.[139,156] Laparoscopic repair of PEH produces equivalent long-term outcomes to open approaches when all the surgical principles of the open technique are meticulously followed. At the University of Pittsburgh we have reported on 662 patients over the past 10 years who have undergone laparoscopic repair of PEH with low rates of radiographic recurrence (15.7%) and reoperations (3.2%). In the subset of these patients with a minimum follow-up of 5 years and a median of over 6 years, these results are durable and show unchanged rates of recurrence or reoperation.[157] Interestingly, we have found that radiographic recurrence was not associated with symptom recurrence and reflux-related quality-of-life scores indicated good-to-excellent results in 86.7% of patients. Additionally, laparoscopic repair significantly decreased postoperative complications, as well as length of intensive care unit

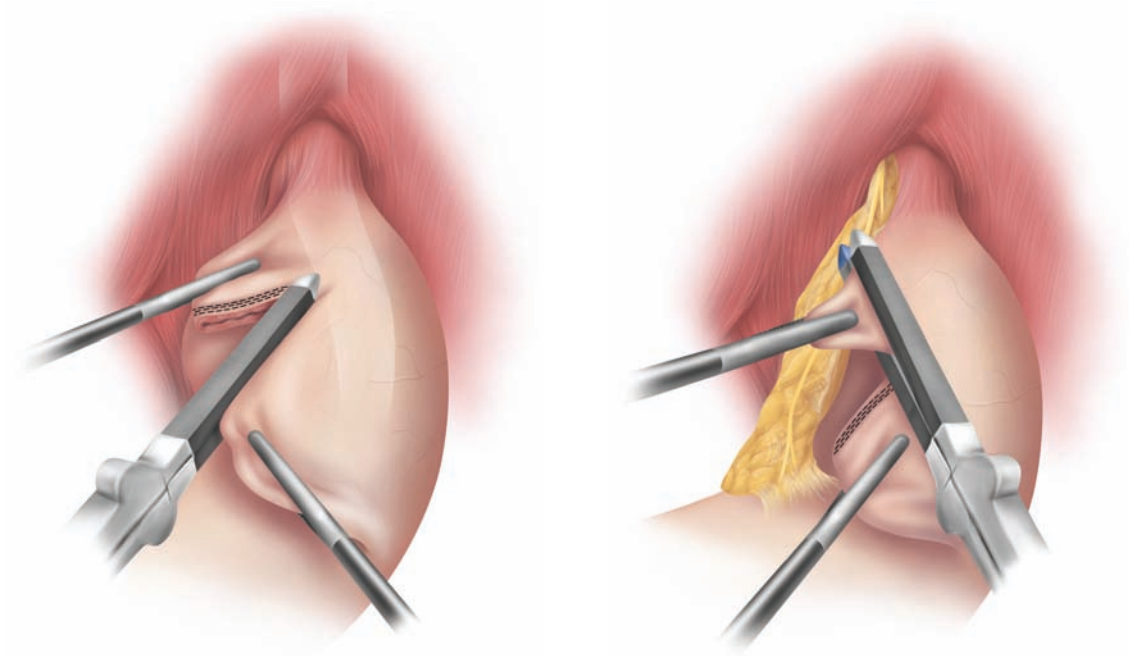

FIGURE 15-32 Wedge gastroplasty. A 48F bougie is placed and the surgeon left hand port is enlarged to accommodate a roticulating stapler.

stay, length of hospital stay, time to oral intake, and pain medication use.[158,159]

The routine use of mesh to reinforce the esophageal hiatus after laparoscopic repair decreases recurrence rates. In the only prospective randomized study on the use of mesh in laparoscopic repair of PEH, the recurrence rate in patients who did not have mesh was 42% as compared with a recurrence rate of only 9% when mesh was used, with only 6-month follow-up.[160] Furthermore, while a number of studies have shown safe and effective use of mesh,[161–163] reinforcement with mesh may increase the incidence of complications. A recent paper by Stadlhuber and associates reports that complications from mesh reinforcement of the esophageal hiatus may be underreported.[164]

Conclusion: PEH are most commonly diagnosed in people older than 70 years. With the population aging, surgical repair of PEH may become more common in the future. A detailed history is important because PEH produces either gastrointestinal or pulmonary symptoms, such as shortness of breath. Over 90% of people who undergo PEH repair have a significant improvement in symptoms that are long lasting. While open repairs using transthoracic and transabdominal approaches have resulted in low complication rates and mortality, the laparoscopic repair, in experienced hands, results in excellent outcomes and is safe.

PERSPECTIVE ON BENIGN ESOPHAGEAL DISEASE

John Hunter • Erin Gilbert

The preceding two chapters address benign diseases of the esophagus, including the diagnosis, evaluation, and management of hiatal hernia, motility disorders, and gastroesophageal reflux disease (GERD). In commenting on these entities, we follow the structure of these chapters.

THE GIANT (PARAESOPHAGEAL) HIATAL HERNIA

Hiatal hernia (HH), as common as it is, is truly idiopathic. While HH is rare in Asian and African populations, exact predisposing features are difficult to pin down. In a North American population, GERD is more common among middle-aged males,[1] and giant hiatal hernias (often called paraesophageal hernias) are more common among elderly women.[2] The predisposing conditions for development of these large hernias in elderly women include diaphragmatic stress during pregnancy (years earlier), loss of abdominal domain, kyphosis (as a result of degenerative spine disease),[3,4] and greater longevity than their male counterparts. There may also be collagen ultrastructural defects responsible for hiatal hernia development, but there is insufficient evidence yet to confirm this hypothesis.[5–8]

The natural history of hiatal hernia may explain the changing symptoms seen in these patients. Early, small "sliding" hiatal hernias (type 1) predispose to GERD by separating the lower esophageal sphincter (LES) from the crural diaphragm, effacing the angle of His, and placing the LES in the thorax where negative intrathoracic pressure contributes to a reduced resting pressure relative to intra-abdominal pressure.[9] Over the years, and as the hernia defect grows larger, type 1 hiatal hernia may evolve into type 3 (aka mixed paraesophageal hernia) where the gastric fundus again resumes a position cephalad to the GE junction. This progression will often re-create a GE junction flap valve, and the patients will notice that GERD markedly improves. Replacing the GERD symptoms are symptoms of early satiety, postprandial chest pain, and iron deficiency anemia (in 30%) as a result of visible or occult gastric bleeding by erosions or ulcers at the level of the diaphragm, known as *Cameron's ulcers or erosions*.[10,11] Because of this natural progression, it is understandable why type 2 HH, in which the GE junction remains below the diaphragm, is distinctly rare and probably only occurs when the GE junction is so tightly anchored to the preaortic fascia that the development of a hiatal hernia only results in an attenuation of the phrenoesophageal ligament and cephalad displacement of the gastric fundus. An even rarer event is the parahiatal hernia, where a diaphragmatic defect adjacent to the hiatus allows cephalad migration of the fundus. This is so rare that a true incidence has not been determined, but it presents as a type 2 HH and may be encountered once or twice in an esophageal surgeon's career.

Despite evolving support for the strategy of "watchful waiting" for the asymptomatic hiatal hernia, the incidental detection of a giant HH will warrant questioning about upper GI symptoms. Close questioning reveals that most patients with this defect are either symptomatic or anemic. In either situation, repair is warranted. Far and away the most common approach to repair in the 21st century is laparoscopic hiatal hernia repair. There are no known advantages to open repair.[12] Esophageal lengthening is as easily performed with laparoscopic access, the wedge Collis gastroplasty,[13] as it is with thoracic access. As well, the recurrence rate of open and laparoscopic repair appears similar, despite the lack of randomized trials.

The "Achilles heel" of giant hiatal hernia repair (usually type 3, mixed paraesophageal hernia) is hiatal hernia recurrence. It was a bit of a shock to most laparoscopic surgeons when they began to see frequent hiatal hernia recurrences with simple sutured repair (20–50%). The most common strategy to prevent recurrent HH is the placement of a large piece of bioprosthetic mesh in a U-shaped configuration, posterior to the esophagus. While early data suggested this technique to be much superior to sutured repair, late follow-up of a randomized controlled trial (RCT) demonstrated a disappointing greater than 50% recurrence rate with and without bioprosthesis.[14] Rather than abandoning the use of mesh, many surgeons are searching for a better bioprosthesis. New trials will better

tell us which bioprosthesis to use. Another strategy that appears to be of value is esophageal lengthening. When used selectively, in 20–40% of patients with giant hernias, HH recurrence rates seem to have decreased. Additionally, the symptomatic consequence of a small hiatal hernia recurrence is generally minimal, suggesting that it is a rare recurrence that will lead to reoperation.

The technique of repair described is little different from our approach, with a few exceptions. A split leg table is superior to low lithotomy stirrups, as the setup is simpler and the risk of lower extremity nerve compression and deep vein thrombosis (DVT) is decreased by the elimination of stirrup-related pressure points and knee flexion. We also use a mechanical scope holder, which increases operative efficiency and decreases surgeon fatigue, by maintaining a steady image. The pneumatic camera holder is attached to the right side of the bed, near the right hip.

Early in a surgeon's experience with laparoscopic giant HH repair, it was customary to recognize three problems: failure to identify the esophagus (leading to lighted dilator use), disorientation in the epiphrenic and lesser curvature fat, and bleeding from the lesser curvature vessels, including the left gastric artery. All of these problems may be solved by keeping the dissection focused on the diaphragmatic crura, detaching the hernia sac from the crura circumferentially and stripping the peritoneal sac from the lower posterior mediastinum. With this strategy, the esophagus becomes readily visible without the need for a lighted bougie, the fat is reduced by the reduction of the hernia sac, and the lesser curvature vessels are caudal to the field of dissection.

While the closure of a large defect may seem daunting, two strategies seem to allow closure of nearly all large hernias: (1) start posteriorly, as is described in this chapter, and (2) reduce the intra-abdominal pneumoperitoneum pressure to 5–8 mm Hg. With these steps it is almost never necessary to place anterior sutures, which are prone to tearing out because the diaphragm is often quite attenuated anteriorly, and the transverse orientation of the anterior crural arch makes closure technically difficult. Excessive anterior angulation of the distal esophagus is only a problem if the esophagus is not adequately mobilized off the aorta in the lower mediastinum.

ESOPHAGEAL MOTILITY DISORDERS

The most common (albeit quite rare) esophageal motility disorder of surgical concern is achalasia. The etiology of achalasia outside of the tropics is unknown, but the disease is remarkably democratic, affecting young and old, male and female, and all ethnicities nearly equally.[15,16] Such a pattern strongly suggests the current hypothesis that an immunologic response to viral exposure is responsible for the observed myenteric neural degeneration.[17,18] While herpes virus has been implicated as the most likely "culprit" by some, the evidence is far from convincing.

The treatment of achalasia with laparoscopic Heller myotomy and partial fundoplication has become the predominant primary therapy over the last 15 years. A recent randomized trial demonstrating equivalence of balloon dilation and Heller myotomy is unlikely to change our approach, as the balloon dilation strategy required intensive surveillance and frequent retreatment, as compared to laparoscopic Heller myotomy.[19] The only real "debate" in this field has been whether to fashion an anterior (Dor) or posterior (Toupet) fundoplication after dividing the LES. A recent randomized trial, closed due to lack of accrual, shows a slight, but not significant, advantage in diminished post-op reflux with the posterior fundoplication.[20] Nonetheless, worldwide, the anterior fundoplication is preferred as it requires less posterior dissection and it does not angle the GE junction anteriorly as the posterior fundoplication may do. The only "trap" of the Heller myotomy is carrying the myotomy too far above the diaphragm and inadequately on the stomach. If there is any esophageal outflow obstruction (from reflux stricture, angulation, or incomplete myotomy), the supradiaphragmatic myotomy site, lacking muscular support, may create an epiphrenic diverticulum, a result of the pressurized esophagus. Intraoperative endoscopy, immediately after the creation of the myotomy will identify easily if the myotomy extends to the dilated esophagus and onto the proximal stomach. A completely divided LES will open with air insufflations such that the endoscope "perched" in the distal esophagus can visualize the stomach through the previously spastic high-pressure zone, which will still appear as a waist.

Our performance of myotomy varies a bit from the technique described. Without a dilator in the esophagus (which may be hard to pass in the dilated esophagus), the anterior esophagus and upper 3 cm of stomach is cleared of all fat and neurovascular tissue such that the longitudinal muscle is clearly visible on the anterior wall of the esophagus (12 o'clock). We divide the epiphrenic fat pad with ultrasonic shears anteriorly, but we do not remove it as it makes a good handle for the first assistant. It is usually necessary to create a passage behind the anterior vagus nerve to remain on the anterior surface of the esophagus. When the esophagus and stomach are cleared off prior to myotomy, bleeding during the performance of myotomy is dramatically reduced. The submucosal plane is achieved just superior to the GE junction with Metzenbaum-type laparoscopic scissors. Firm lateral traction and countertraction by the surgeon's left hand pulling toward the liver and first assistant grasping a divided epiphrenic fat pad and pulling in the opposite direction will frequently disrupt the circular muscle with minimal sharp dissection. Once the submucosal plane is achieved, a blunt closed grasper can be run several centimeters up the esophagus in the submucosal plane, making subsequent division of the circular muscle quite easy with a pair of scissors. It is not necessary to use any thermal instruments (electrosurgery or ultrasonic dissector) near the mucosa. "Blanching" of the mucosa should be treated as a perforation in situ and should be oversewn as described in the text. The best strategy for dividing the proximal gastric portion of the LES is teasing distraction of the muscle fibers with two Hunter-type or Maryland-type graspers. It is critical that the mucosa be cleared of all circular smooth muscle, and blunt undermining

of the myotomy allows the cut edges of the muscle to retract out of sight behind the esophagus (frequently) just above the angle of His. Endoscopy is then performed as mentioned previously, and a "leak test" with air insufflation is then performed. Finally, a large (56–60F) Maloney dilator is passed by the surgeon or assistant to ensure that all circular muscle has been divided and undermining is adequate. Then, partial anterior (our favorite) or posterior fundoplication, as elegantly described in the previous chapter, is performed.

Failures of Heller myotomy are thankfully few, and the appropriate approach to failure has not been entirely defined. Some prefer balloon dilation, with a 3- to 3.5-cm balloon, but the same risk of perforation as with primary balloon dilation drives most surgeons to consider remyotomy. Esophagogastroduodenoscopy (EGD), to rule out cancer, ulcer, or stricture, should be complemented by video esophagram and high-resolution esophageal motility study. The appearance of a diverticulum at the supradiaphragmatic myotomy site should be addressed by an attempt at relieving the esophageal outflow obstruction. Rarely is diverticulectomy indicated and it will be ineffective at relieving recurrent dysphagia if the primary problem is not addressed. After complete LES myotomy, LES resting pressure should be less than 10 mm Hg. If the LES resting pressure is above 12–15, we usually recommend redo Heller myotomy. If the sphincter is already completely ablated (LES resting pressure <10), redo myotomy is unlikely to be successful. Under these circumstances, and especially with a mega or sigmoid esophagus, esophagectomy may be the best next step. The end-stage achalasic esophagus is amenable to minimally invasive surgery (MIS) esophagectomy techniques, but should not be treated with transhiatal esophagectomy or esophageal stripping, as the mediastinal blood vessels supplying a mega esophagus are much larger than normal and stripping may result in uncontrolled mediastinal bleeding.

The approach to other "named" esophageal motor disorders is a bit more controversial. As a general principle, nutcracker esophagus should not be treated with a long myotomy, (it won't help), and the dysphagia associated with diffuse esophageal spasm is best alleviated when the LES is divided. It may be unnecessary to take the myotomy as high as the top of the corkscrew appearance on contrast esophagram to achieve a successful outcome. In other words, the laparoscopic Heller myotomy and partial fundoplication may be the best operation for this condition. This is indeed a relief, as it may be difficult to tell vigorous achalasia from diffuse esophageal spam (DES) in many patients. The treatment of esophageal diverticula is well described in the prior chapter. Because of the propensity of distal esophageal diverticulectomy staple lines to leak (up to 30% in some early studies), we have taken the following three steps that seem to have solved the problem: (1) perform a Heller myotomy to decrease intraesophageal pressure, even in the absence of demonstrable LES hypertension, (2) sew the esophageal smooth muscle over the site of the staple line if possible and perform the myotomy 90 degrees away from the staple line and at least as far proximal as the proximal border of the diverticulum, and (3) leave the patient on a liquid diet for 7 days postoperatively to allow staple line healing before introducing solid foods. Occasionally, safe and complete diverticulectomy can only be performed with thoracoscopic access when laparoscopic access cannot safely expose the proximal extent of the diverticulum.

GASTROESOPHAGEAL REFLUX DISEASE

The diagnosis, evaluation, and management of gastroesophageal reflux disease (GERD) is extremely well covered in the text. I focus, in this commentary, on only four things: indications for surgery, proper use of the many tests available to assess the anatomy and pathophysiology of the esophagus and stomach, choice of an operation, and long-term effectiveness of laparoscopic antireflux surgery, especially as compared to treatment with proton pump inhibitor (PPI).

As has been pointed out, GERD is a very common condition, and a very small proportion of GERD patients elect to have antireflux surgery. While it is clear that the majority of patients are effectively managed with daily PPI, it is now recognized that as many as 40% of individuals will have persistent troublesome symptoms despite PPI treatment. Troublesome reflux is defined as mild GERD symptoms daily, or moderate to severe symptoms two to three times per week. Of all reflux symptoms, PPI therapy is most likely to control chest pain and heartburn. Only 17% of GERD patients will have regurgitation symptoms adequately controlled with PPI.[21] Therefore, we can define two populations poorly served with PPI for typical (esophageal) GERD symptoms, those with troublesome heartburn and chest pain despite adequately dosed PPI, and those with troublesome regurgitation that is unlikely to benefit from PPI. Both of these groups are ideally suited for laparoscopic antireflux surgery, as long as the diagnosis of GERD is secure, based on a standard evaluation.

The use of laparoscopic antireflux surgery for laryngopharyngeal reflux (LPR) may be equally effective, if used in the right patient. Because supraesophageal and/or laryngopharyngeal symptoms may be caused by so many common problems (eg, allergies, environmental factors, cigarette smoking, postnasal drip, infections), it is more difficult than it might appear to determine who truly has symptomatic LPR that would be improved by the elimination of all gastroesophageal reflux. While many technologies have been developed over the years to detect LPR, including dual-channel pH recording and nasopharyngeal pH recording, both these methods have proven difficult to validate. Two new promising methodologies, sputum pepsin measurement[22] and esophageal/nasopharyngeal impedance measurement, appear to be much more accurate for determining the presence of LPR and will probably become the test of choice in the near future to establish this diagnosis.

The preoperative evaluation of the patient with GERD is well described in the chapter outlined previously. Several years ago, we observed that all patients with heartburn responsive to PPI and erosive esophagitis, stricture, or Barrett's esophagus had an abnormal 24-hour pH study. Thus, we dropped routine pH testing in these patients as the diagnosis of GERD

was secure without pH testing in this population. Currently, we reserve pH testing for patients with no esophagitis, Barrett's esophagus or stricture, and for those with atypical symptoms. As mentioned previously, a pH study is not really needed prior to repair of the giant hiatal hernia, unless the patient's only symptom is heartburn and the EGD shows a pristine esophagus. This is rare indeed.

Operation choice for GERD is still a matter of some debate focused on the comparative long-term effectiveness of partial posterior (Toupet) fundoplication and total (Nissen) fundoplication. For many years the partial fundoplication was used in North America only for patients with ineffective or absent esophageal motility, as reflux control was less when a partial fundoplication was performed. When ineffective peristalsis is detected, it now appears that total and partial fundoplication create equivalent low levels of postoperative dysphagia. When peristalsis is completely absent (eg, achalasia or scleroderma), one should consider a partial fundoplication. Having said this, randomized data from Europe[23] suggest that the partial fundoplication provides equivalent reflux control in most GERD patients, regardless of motility pattern, while decreasing gas-related symptoms. Bottom line: either type of laparoscopic fundoplication may be performed. East of the Atlantic Ocean, perform a posterior partial fundoplication. On the west "bank" of the Atlantic Ocean, perform a total fundoplication.

Finally, there is great debate over the long-term effectiveness of laparoscopic Nissen fundoplication as compared to chronic PPI use. If one solely relies on the resumption of PPI as the indicator of fundoplication failure, the surgical failure rate may approach 30–40%, but physiologic assessment of these patients demonstrates that only 30% of this group will truly be refluxing, bringing the true failure rate (at 10 years) to about 10%.[24] Most patients who have had a good result from a first fundoplication will desire a redo fundoplication when the valve truly fails. The most common failure pattern is the recurrent HH, often a result of intra-abdominal stressors such as retching, straining, coughing, obesity, trauma, and excessive heavy lifting. The rate of reoperation following laparoscopic fundoplication performed by an expert is approximately 1%/year.

The comparative effectiveness of fundoplication to medical therapy has been tested in several randomized trials. When study entrance is restricted to those rendered asymptomatic on standard doses of PPI, surgery and medical therapy perform equivalently.[25] When the entrance criteria are broadened to include those with a partial response to PPI, fundoplication usually emerges as the most reliable and durable method for elimination of GERD symptoms.

CANCER OF THE ESOPHAGUS

Simon Law

HISTORICAL PERSPECTIVES

One of the earliest descriptions of esophageal cancer was in the second century AD, when Galen described a fleshy obstructing growth in the esophagus, which was responsible for the inability to swallow and led to emaciation and death. In early Chinese literature, a patient who had esophageal cancer was described as "one suffers in autumn, and does not live to see the coming summer." Improvement in treatment strategies has resulted in better outcome. However, most patients are still diagnosed at an advanced disease stage, with consequent poor prognosis. In 1877, Czerny was the first to successfully resect a cervical esophageal cancer and the patient lived for 15 months. Torek in 1913 performed the first successful transthoracic resection.[1] A 67-year-old woman had a squamous cell cancer of the midesophagus. Through a left thoracotomy, the esophagus was resected. The proximal cervical esophagus was brought out through an incision anterior to the sternocleidomastoid muscle and tunneled subcutaneously along the anterior chest wall, where a cutaneous esophagostomy was fashioned. The patient was fed via a rubber tube connecting the esophagostomy with a gastrostomy. The patient lived for 17 years.

The first successful resection of a thoracic esophageal cancer with reconstruction using the stomach was performed by Ohsawa, a Japanese surgeon in Kyoto, who reported the technique in 18 patients in 1933.[2] In 1946, Lewis described esophageal resection using a two-phase approach via a right thoracotomy and laparotomy.[3] Tanner independently also described the procedure in 1947.[4]

Although surgical resection has remained the mainstay treatment for esophageal cancer, recent years have seen a proliferation of treatment options especially with regards to different combinations of chemotherapeutic agents, radiotherapy and surgery. There has also been a divergence in the epidemiological pattern between Western and Eastern countries, which has made a major impact on the management of this disease.

EPIDEMIOLOGY

Esophageal cancer is the eighth most common cancer worldwide and the sixth most common cause of death from cancer.[5] There is marked geographic variation in the incidence of cancer of the esophagus and, to some extent, among different ethnic groups within a common area. The disease is especially common in countries of the so-called "Asian esophageal cancer belt," which stretches from eastern Turkey and east of the Caspian Sea through northern Iran, northern Afghanistan, and southern areas of the former Soviet Union, such as Turkmenistan, Uzbekistan, and Tajikistan, to northern China and India. High incidences are also found, in the Transkei province of South Africa and Kenya. In high-incidence areas, the occurrence of esophageal cancer is 50- to 100-fold higher than that in the rest of the world. It is the fourth most common cancer in China.[6] The age-standardized incidence rate of esophageal cancer in China is 27.4 per 100,000, compared to 10 in Japan, 7.9 in northern Europe and 7.6 in western Europe, 5.8 in North America, and 5.5 in Australia/New Zealand.[5] The provinces of Henan, Hebei, Shanxi in central/northern China, and areas within, such as Linxian and Cixian, have particularly high incidences.[7,8] The crude age-adjusted mortality is up to 140 per 100,000 and is the most common cause of cancer death.[8] Esophageal cancer most commonly presents in the sixth and seventh decades of life. In most countries it is a male-predominant disease, although in high-incidence areas, the male-to-female ratio approaches unity.

The most striking change in epidemiological pattern for esophageal cancer in the past three decades has been the shift from squamous cell cancers to adenocarcinomas of the lower esophagus and cardia in the Caucasian populations in Western countries. In the United States, squamous cell cancers predominate in African Americans, but the incidence of this cancer has seen a decline since the mid-1980s, while adenocarcinoma has been rising in incidence rapidly in the white population. The incidence of adenocarcinoma has surpassed squamous cell cancers since 1990.[9] Similar

changes have been observed in Europe and Australia. In Asia, however, esophageal cancers remain predominantly squamous cell in type and are mostly located in the mid-esophagus.[10]

Apart from squamous cell cancers and adenocarcinomas, other tumor types less commonly encountered include mucoepidermoid cancer,[11] adenosquamous cancer, small cell cancer,[12] basaloid squamous tumor,[13] sarcomatoid carcinoma, lymphoma, melanoma,[14] and various subtypes of stromal tumors.[15]

ETIOLOGIC FACTORS

Various factors associated with the development of esophageal cancer are shown in (Table 17-1). Smoking and drinking as independent contributing factors are shown by prospective studies of patients who drink but do not smoke and, conversely, of patients who smoke but do not drink.[16]

Genetic predisposition may be important in the pathogenesis of esophageal squamous cell cancer. Case-controlled studies have identified familial aggregation; suggesting that the cancer may be heritable.[17] Mitochondrial studies have proved historical population migrations from central/northern to south-eastern China, where another high-incidence area is found, again suggesting that hereditary factors may play a part.[18,19] Genetic polymorphism is important in individuals with chronic alcohol consumption.[20] Approximately 36% of East Asians show a physiologic response to drinking that includes facial flushing, nausea, and tachycardia. This facial flushing response is predominantly related to an inherited deficiency in the enzyme aldehyde dehydrogenase 2 (ALDH2). Alcohol is metabolized to acetaldehyde by alcohol dehydrogenase and the acetaldehyde is in turn metabolized by ALDH2 to acetate. Two main variants for ALDH2 exist, resulting from the replacement of glutamate with lysine at position 487. Only individuals homozygous with the glutamate allele have normal catalytic activity. Homozygotes with the lysine alleles have no detectable activity, while heterozygotes with Glu/Lys alleles have much reduced ALDH2 activity. The inability to fully metabolize acetaldehyde results in its accumulation in the body leading to the facial flushing and unpleasant side effects. Lys/Lys homozygotes could not tolerate much alcohol because of the intensity of the side effects, and so paradoxically they do not have increased risk because they simply would not consume significant amount of alcohol. Individuals who are glu/lys heterozygotes may become habitual drinkers because they could become tolerant to the side effects of alcohol and yet they had suboptimal catalytic activity and thus the acetaldehyde accumulates. These are the individuals most susceptible to the carcinogenic effects of alcohol consumption, which is related to acetaldehyde causing DNA damage and other cancer-promoting effects.[21] A simple questionnaire that elicits the history of a flushing response was shown to be useful in identifying at-risk individuals. They could be advised against drinking or to undergo screening endoscopy. The risk of developing cancer may be reduced or earlier diagnosis possible.[22,23]

TABLE 17-1: ETIOLOGIC FACTORS ASSOCIATED WITH PATHOGENESIS OF ESOPHAGEAL CANCER

Factor	Squamous Cell Cancer	Adenocarcinoma
Smoking	+++	+
Alcohol consumption	+++	–
Hot beverages	+	–
N-nitroso compounds, eg, pickled vegetables	+	–
Chewing betel nut	+	–
Maté drinking	+	–
Deficiencies of green vegetables, fruits, and vitamins	+	–
Low socioeconomic class	+	–
Fungal toxin or virus	+	–
History of radiation to mediastinum	+	+
Lye corrosive stricture	+	–
History of aerodigestive malignancy	+++	–
Plummer-Vinson syndrome	+	–
Achalasia	+	–
Obesity	–	++
Gastroesophageal reflux	–	+++
Barrett's esophagus	–	++++

For squamous cell cancer, in addition to drinking and smoking, dietary and environmental factors are important, especially in Asian countries. Nitrosamines and their precursors (nitrate, nitrite, and secondary amines), such as pickled vegetables, are incriminated.[24] Nutritional depletion of certain micronutrients, particularly vitamins A, C, E, niacin, riboflavin, molybdenum, manganese, zinc, magnesium, selenium, as well as fresh fruits and vegetables, together with an inadequate protein intake, predisposes the esophageal epithelium to neoplastic transformation.[25] Change in specific dietary habits, such as replacing traditional methods of food preservation and storage with refrigeration, together with consumption of vitamin-rich food, may have produced a drop in incidence rates in certain areas of China, especially in urban cities such as Shanghai.[26] Other dietary risk factors include consumption of hot beverages, opium smoking, chewing betel nuts, and maté drinking in South American countries.

The human papillomaviruses[27] and certain fungi belonging to the genera *Fusarium*, *Alternaria, Geotrichum*, *Aspergillus*, *Cladosporium*, and *Penicillium* are infective agents variably found to be associated with esophageal cancer.

Patients with other aerodigestive malignancies have a particularly high risk of developing squamous cell carcinoma (SCC) of the esophagus, presumably because of exposure

to similar environmental carcinogens and "field cancerization." Using esophageal cancer as the index tumor, multiple primary cancers were found in 9.5% of patients, of whom 70% were in the aerodigestive tract.[28] The overall incidence of synchronous or metachronous esophageal cancer in patients with primary head and neck cancer is estimated to be 3%.[29]

Diseases that are known to predispose to esophageal cancer are few. The risk from achalasia is estimated to be 7- to 33-fold, but symptoms of achalasia are present for an average of 15–20 years before the emergence of cancer.[30] Other diseases include lye corrosive strictures, Plummer-Vinson syndrome, tylosis, and celiac disease.

The reasons accounting for the dramatic rise in incidence of adenocarcinoma in Caucasian population is widely attributed to obesity, gastroesophageal reflux disease, and Barrett's esophagus,[31–33] which are uncommon in Asian populations.[34] Gastroesophageal reflux disease affects up to 44% of the general population in the United States, and approximately 5–8% will develop Barrett's esophagus,[35] with an estimated annual rate of neoplastic transformation of 0.5%.[36] Epidemiological data suggest a protective role of *Helicobacter pylori* against reflux. The high prevalence of *H. pylori* infection in Eastern populations may guard against reflux and Barrett's esophagus, and may account for the differences in cancer cell type.[37] However, this association remains controversial.

DIAGNOSIS

Screening, Surveillance, and Prevention for Early Cancer

SQUAMOUS CELL DYSPLASIA AND CANCER

Diagnosing esophageal cancer at its asymptomatic or early stage is crucial in improving prognosis, although at present this is only possible in the minority of patients. In high-incidence areas such as in China, abrasive cytology has been used for population screening. Two principal types of samplers have been used: an inflatable balloon developed in China[38] and an encapsulated sponge sampler developed in Japan.[39] When early-stage cancers are diagnosed by this method, excellent long-term results with 5-year survival rate approaching 90% and 25-year survival rate of 50% can be achieved, comparable to those of the normal population.[40]

Primary endoscopic screening with chromoendoscopy using Lugol's iodine as a useful adjunct is carried out in high-incidence areas in China (Fig. 17-1). It has been shown that dysplastic lesions seen in the esophagus have a quantifiable risk of malignant transformation.[41] Long-term endoscopic screening studies are ongoing, integrating with early treatment and chemoprevention programs.[42]

Nutritional intervention trials were undertaken in Linxian in China for the general population in the 1980s as a form of chemoprevention. The trial was tested in 29,584 participants. At the end of 5-year intervention, the group receiving selenium, β-carotene and vitamin E was found to have a statistically

significant reduction in all causes of mortality and cancer death. However, mortality reduction in combined esophageal/gastric cardia cancer was 10%, not reaching statistical significance.[43] To date, no conclusive evidence is available for chemopreventive strategies for squamous cell esophageal cancer.

BARRETT'S ESOPHAGUS AND ADENOCARCINOMA

For cancer due to Barrett's esophagus, screening and surveillance for early cancers have been controversial. Gastroesophageal reflux is prevalent; approximately 20% of adults have heartburn at least once per week, 5% of whom have Barrett's esophagus; thus a very substantial number of patients will require screening. However, the absolute risk of adenocarcinoma is low even in subgroups of patients with severe reflux symptoms. Moreover, 40% or more of patients with esophageal adenocarcinoma have no prior reflux symptoms and therefore would not be detected through screening programs targeted to those with such reflux symptoms.[32] Most patients with Barrett's esophagus also die from unrelated causes,[44] and the presence of Barrett's esophagus does not change life expectancy or overall survival.[45,46] These arguments, together with the high cost of endoscopy, mitigate against general population screening. Although retrospective studies have demonstrated survival benefits in patients with Barrett's esophagus undergoing surveillance,[47,48] these studies may have been biased because of selection, lead time, and length bias.[49] There is currently no confirmed evidence proving that screening or surveillance will lead to improved survival in patients with Barrett's esophagus.[50] Screening for Barrett's esophagus in the general population is not recommended. The use in selective populations at higher risk remains to be established.[48]

Despite the lack of clear evidence, individuals who are identified to have Barrett's esophagus should enter surveillance programs. Systemic four-quadrant, 2-cm biopsy protocol using large biopsy forceps is recommended.[48] Dysplasia is so far the only reliable indicator of risk development of invasive cancer. The recommendation given by the American College of Gastroenterology with regards to endoscopy interval and treatment is shown in Table 17-2. Endoscopy is performed every 3 years for those with no dysplasia and yearly for low-grade dysplasia. Diagnosis of high-grade dysplasia implies the need for intervention (by surgery or endoscopic means), or intensive surveillance at 3-month intervals. If the latter is preferred, a four-quadrant, 1-cm protocol is required for diagnosis of early invasive cancer.

Endoscopy and systemic biopsies remains the gold standard for diagnosis of Barrett's esophagus, dysplasia, and early cancer. Other modalities such as cytology with or without fluorescence in situ hybridization (FISH), autofluorescence imaging, narrow band imaging, optical coherence tomography, and confocal laser endomicroscopy are investigational techniques aimed at enhancing diagnostic capabilities.[51]

Chemoprevention can potentially prevent Barrett's esophagus from developing into invasive cancer. Proton pump inhibitors (PPIs) and nonsteroidal anti-inflammatory drugs (NSAIDs) have drawn the most attention in recent years. Currently there are no data that directly support the use of PPIs to prevent cancer, although retrospective studies have shown decrease in development of dysplasia in long-term users.[52] For NSAIDs, a meta-analysis of pooled studies found a protective association between aspirin/NSAIDs and esophageal cancer of both histologic types.[53] However, a randomized controlled trial showed that celecoxib, a COX-2 inhibitor, was not more effective than placebo in patients with Barrett's esophagus and dysplasia in changing the proportion of biopsies with dysplasia.[54] An ongoing phase III randomized trial in the United Kingdom (AspECT [Aspirin Esomeprazole Chemoprevention Trial] trail) aims at assessing whether intervention with aspirin results in decreased mortality or conversion rate from Barrett's metaplasia to adenocarcinoma or high-grade dysplasia.[55]

Advanced Cancer

For symptomatic patients, the spectrum of symptoms varies depending on the extent of disease. Elderly patients who complain of dysphagia must be assumed to have esophageal cancer until proven otherwise, especially in high-risk areas. Patients with chronic reflux symptoms who develop dysphagia must have the diagnosis of tumor entertained in addition to a reflux stricture. In advanced cases the most common presenting symptom is dysphagia (80–95%), which is progressive in

TABLE 17-2: DYSPLASIA GRADE AND SURVEILLANCE INTERVAL

Dysplasia	Documentation	Follow-up
None	Two EGDs with biopsy within 1 y	Endoscopy every 3 y
Low grade	• Highest grade on repeat EGD with biopsies within 6 mo • Expert pathologist confirmation	1-y interval until no dysplasia × 2
High grade	• Mucosal irregularity • Repeat EGD with biopsies to rule out invasive cancer within 3 mo • Expert pathologist confirmation	Endoscopic resection Continue 3-mo surveillance or intervention based on results and patient

TABLE 17-3: COMPARISONS OF PATIENTS WITH SCC AND ADENOCARCINOMAS OF THE ESOPHAGUS ASIDE FROM ETIOLOGY: ASIA VERSUS WEST

	Asia	West
Cell type	Squamous cell cancer	Adenocarcinoma
Location	Mid and lower esophagus	Lower esophagus/cardia
Comorbid diseases	• Pulmonary disease • Cirrhosis	Ischemic heart disease
Identifiable premalignant lesions	Dysplasia	Barrett's esophagus and dysplasia
Screening/surveillance	• Balloon cytology • Endoscopy with Lugol's iodine	Endoscopic surveillance for Barrett's esophagus and dysplasia
Surgical approaches	Predominantly transthoracic, two- and three-field lymphadenectomy Thoracoscopic ± laparoscopic surgery	Transthoracic/transhiatal, two-field or minimal lymphadenectomy Thoracoscopic ± laparoscopic *or* laparoscopic only
Prognosis	Worse?	Better?

SCC, squamous cell cancer.

severity. However, many patients delay seeking medical attention until severe dysphagia and weight loss have occurred. Regurgitation is common. In high-grade obstruction, this symptom may be worse at night when the patient lies supine. Fluid regurgitation can lead to bouts of coughing, aspiration, and even chest infection. Odynophagia (retrosternal pain associated with swallowing) is not uncommon. Hoarseness is the result of recurrent laryngeal nerve compression, either by the primary tumor or by metastatic lymph nodes.

The demographics of patients who suffer from squamous cell cancers and adenocarcinomas are different.[56] Patients with adenocarcinomas tend to be of higher socioeconomic class and have obesity-related chronic disease such as ischemic heart disease (Table 17-3). Examination of these patients therefore rarely reveals a wasted individual. Patients with squamous cell cancers are blue-collar workers, and general examination may show evidence of weight loss and muscle wasting. Chronic smoking and alcohol consumption leads to a higher prevalence of chronic lung disease and liver cirrhosis. The more proximal tumor location more easily predisposes to pneumonia from aspiration or the development of a tracheoesophageal fistula. Lymph nodes in the supraclavicular regions should be sought in all patients.

TUMOR STAGING

Staging System

Accurate staging serves to provide information for stage-directed therapies and is important for quality control for clinical trials.

The clinical staging system follows the American Joint Committee on Cancer (AJCC) staging or the International Union Against Cancer (UICC) TNM (tumor-node-metastasis) system, which are recently modified.[57] The definitions of TNM, tumor grade, level of tumors and nodal stations are shown in Tables 17-4 to 17-7 and Figs. 17-2 and 17-3.

TABLE 17-4: DEFINITIONS OF TNM FOR ESOPHAGEAL CANCER

T: Primary tumor

Tx	Tumor cannot be assessed
T0	No evidence of primary tumor
Tis	High-grade dysplasia
T1	Tumor invades lamina propria, muscularis mucosae, or submucosa
T1a	Tumor invades lamina propria or muscularis mucosae
T1b	Tumor invades submucosa
T2	Tumor invades into muscularis propria
T3	Tumor invades adventitia
T4	Tumor invades the adjacent structures
T4a	Resectable tumor invading pleura, pericardium, or diaphragm
T4b	Unresectable tumor invading other adjacent structures, such as aorta, vertebral body, trachea, etc

N: Regional lymph nodes[a]

NX	Regional nodal status cannot be assessed
N0	No regional lymph node involvement
N1	Regional lymph nodes metastases involving 1–2 nodes
N2	Regional lymph nodes metastases involving 3–6 nodes
N3	Regional lymph nodes metastases involving ≥7 nodes

M: Distant metastases

MX	Distant metastases cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

TNM, tumor-node-metastasis.
[a] Regional nodes extend from the neck to the celiac nodes.

TABLE 17-5: DEFINITIONS OF GRADE FOR ESOPHAGEAL CANCER

Histologic grade (G)[a]	
GX	Grade cannot be assessed—stage grouping as G1
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated
G4	Undifferentiated—stage grouping as G3 squamous

[a] Highest histologic grade on biopsy or resection specimen is used. If a tumor is mixed histologic type, it shall be recorded as squamous cell cancer. If grade is not available, it should be recorded as GX and stage grouped as a G1 cancer. G4, undifferentiated cancers, should be recorded as such and staged grouped similar to G3 squamous cell carcinoma.

This recently modified TNM system differs from the previous versions mainly on (1) the regional nodes encompass areas from the neck, through the mediastinum to the upper abdomen, including the celiac nodes; previously used M1a and M1b categories are deleted; (2) the separation of N1 to N3 depends on the number of nodes involved; (3) squamous cell cancers are stage-grouped differently to adenocarcinoma; and (4) location of tumor and grade of differentiation are also taken into consideration. Previously, it has been uncertain whether adenocarcinoma of the cardia should be staged as gastric or esophageal cancer. In this new edition, tumors whose epicenter is in the lower thoracic esophagus, gastroesophageal junction (GEJ), or within the proximal 5 cm of the stomach (cardia) that extend into the GEJ or esophagus are stage-grouped similar to adenocarcinoma of the esophagus and not that of the stomach. Cancers with their epicenter in the stomach greater than 5 cm distal to the GEJ, or those within 5 cm of the GEJ but not extending into the

Ae, abdominal esophagus; B, tracheal bifurcation; Ce, cervical esophagus; D, diaphragm; EGJ, esophagogastric junction; H, hiatus; Lt, lower third; Mt=middle third; O, esophagus; S, sternal notch; Te, thoracic esophagus; Ut, upper third.

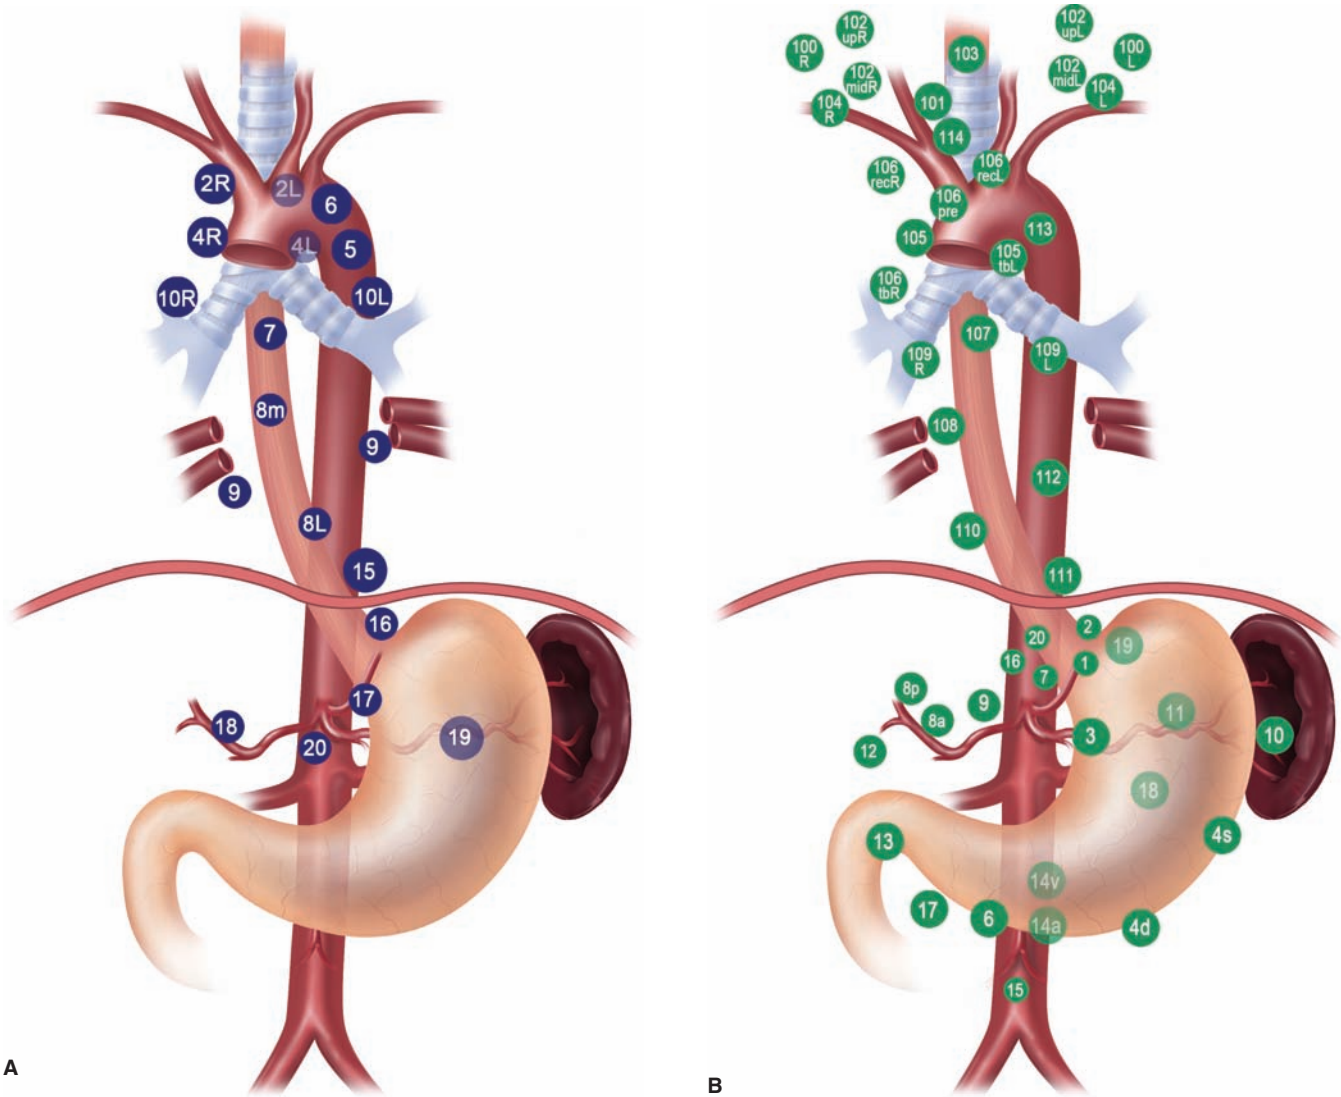

FIGURE 17-3 **A.** Lymph node stations according to the American Joint Committee on Cancer (AJCC) classification. **B.** Lymph node stations according to the Japan Esophageal Society.

GEJ or esophagus, are stage-grouped using the gastric cancer staging system.

Siewert's classification aims at classifying tumors that are located 5 cm proximal and distal to the GEJ into types I to III (esophageal, cardiac, and subcardiac), depending on the relative extent of involvement of either the esophagus or stomach (Fig. 17-4). The three types of cancers are different in patient demographics, possible etiology, histopathologic features, and prognosis.[58] This classification is useful clinically but is not considered in the new staging system.

The Japan Esophageal Society further classifies T1a/T1b tumors into finer categories; as there are important therapeutic implications (Table 17-8). This is discussed in later sections.

METHODS OF STAGING

Apart from physical examination and simple chest radiograph, specific methods in clinical staging include barium contrast studies, bronchoscopy, computed tomography (CT) scan, percutaneous ultrasound of cervical lymph nodes ± fine-needle aspiration (FNA) cytology, endoscopic ultrasound (EUS) ± FNA, 2-[^{18}F] fluoro-2-deoxy-D-glocose (FDG) positron emission tomography (PET) scan, and laparoscopy and/or thoracoscopy.

Barium Contrast Studies

Typical features on a contrast barium study include mucosal irregularity and shouldering, narrowing of the lumen and

There is no evidence of Barrett's esophagus.

TABLE 17-8: DIVISIONS OF T1 TUMORS ACCORDING TO THE JAPAN ESOPHAGEAL SOCIETY

TX	Depth of tumor invasion cannot be assessed
T0	No evidence of primary tumor
T1a	Tumor invades mucosa
T1a-EP	Carcinoma in situ (Tis)—formerly corresponds to M1
T1a-LPM	Tumor invades lamina propria mucosa (LPM)—formerly corresponds to M2
T1a-MM	Tumor invades muscularis mucosa (MM)—formerly corresponds to M3
T1b	Tumor invades submucosa
SM1	Tumor invades the upper third of the submucosal layer
SM2	Tumor invades the middle third of the submucosal layer
SM3	Tumor invades the lower third of the submucosal layer

In endoscopically resected specimens, because the full thickness of the submucosa extending into the muscularis propria is not available for examination, a tumor invading the submucosa to a depth of 200 μm is classified as SM1, while a tumor invading more than 200 μm is classified as SM2.

proximal dilation of the esophagus (Fig. 17-5). Tortuosity, angulation, axis deviation from the midline, sinus formation, and fistulization to the bronchial tree are signs indicative of advanced tumor that has traversed the adventitia and involved the neighboring fixed organs.[59] With the availability of other staging modalities, barium studies are becoming less essential.

Bronchoscopy

Use of the fiberoptic endoscope allows histologic confirmation of the cancer by biopsy or brush cytology. Flexible bronchoscopy is performed to assess tumor involvement of the tracheobronchial tree, especially for tumors in the middle and upper esophagus. Signs of involvement include a widened carina, external compression, tumor infiltration, and fistulization. The last two signs contraindicate resection.[60] Gross macroscopic bronchoscopic appearance may not be accurate, and biopsy and brush cytology is recommended.[61]

Computer Tomography Scan

The main value of CT scan in staging of esophageal cancer lies with its ability to detect distant disease, such as that in liver, lungs, bone, and kidneys. When metastasis to the liver is more than 2 cm, sensitivity is 70–80% although it drops to approximately 50% when it is less than 1 cm.[62] Solitary lung metastases are rare in patients presenting with esophageal carcinoma[63] and thus, when seen on CT, are more likely to be primary lung cancers or benign nodules and should be investigated as such.

FIGURE 17-5 Barium contrast study showing a stenotic tumor. Mucosal irregularities and proximal dilation with retention of contrast material is evident. A sinus often indicates infiltrative disease (*arrow*).

In the diagnosis of T4 disease, obliteration of the fat plane between the esophagus and the aorta, trachea and bronchi, and pericardium is suggestive of invasion, but the paucity of fat in cachectic patients makes this criterion unreliable. When the area of contact between the esophagus and the aorta extends for more than 90 degrees of the circumference, an 80% accuracy of infiltration was reported,[64] but this is by no means absolute and the accuracy is inferior to that of EUS.

The sensitivity of detecting mediastinal and abdominal nodal involvement is suboptimal with CT scans because only size alone can be used as diagnostic criterion. However, normal-sized lymph nodes may contain metastatic deposits and enlargement of lymph nodes may be due to reactive and inflammatory hyperplasia. Studies using high-resolution helical CT scanning have demonstrated sensitivities of 11–77% as well as specificities of 71–95% for detection of regional nodal disease.[65,66] CT scanning is nowadays commonly performed together with PET scanning; a composite picture is created in the same setting to correlate more accurate anatomy with metabolic uptake (Fig. 17-6). Experience with magnetic resonance imaging (MRI) has shown limitations similar to those of CT.[67]

Endoscopic Ultrasound and Percutaneous Ultrasound

Endoscopic ultrasound (EUS) is the only imaging modality able to distinguish the various layers of the esophageal wall, usually seen as five alternating hyper- and hypoechoic layers

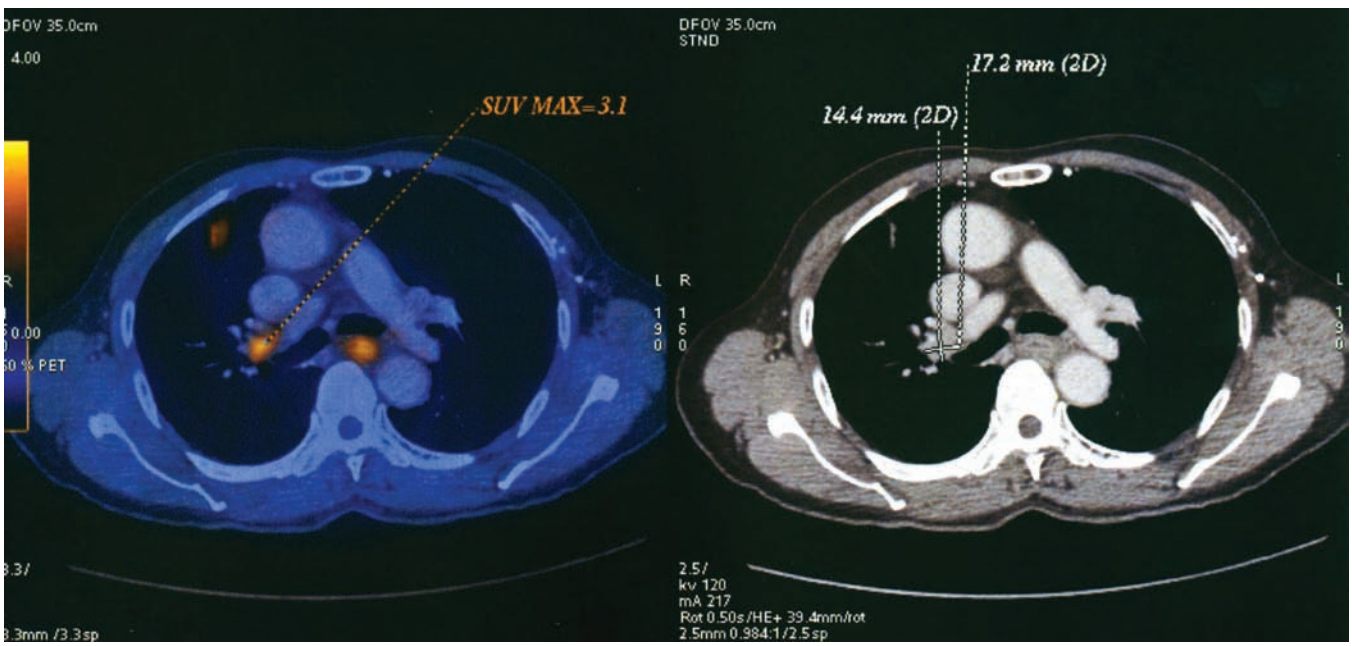

FIGURE 17-6 Combined PET and CT image: in addition to size of lymph nodes, the standard uptake value often will help to determine if the lymph node is involved by cancer. A right pulmonary hilar node identified with its corresponding PET image. Standard uptake value (SUV) uptake was 3.1.

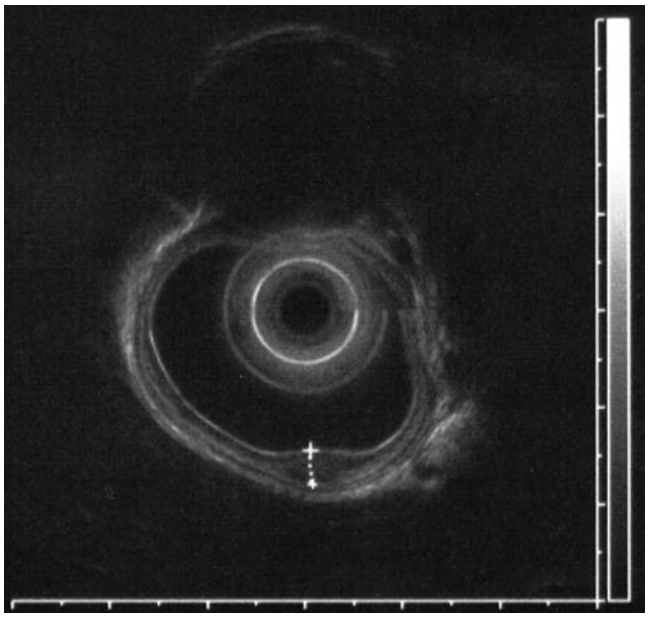

FIGURE 17-7 Endoscopic ultrasound (EUS) picture of an early tumor confined to the mucosa. Five layers of the esophagus could be seen; the two dark layers are the muscularis mucosae (inner layer) and muscularis propria (outer layer). In this tumor, the hyperechoic layer of the submucosa has not been reached. The tumor is at 6 o'clock. This lesion was removed with endoscopic submucosal dissection (ESD) technique.

(Fig. 17-7). The accuracy of EUS for tumor and nodal staging averages 85 and 75%, respectively, compared to 58 and 54% for CT scanning.[68] One problem with EUS is the nontraversable tumor stricture, which occurs in about one-third of patients.[69,70] Early studies showed that predilation may result in up to a 25% chance of perforation.[71,72] More recent results suggest that predilation is safe, and the success rate of complete examination depends on the size of dilation—36% for 11–12.8 mm, and 87% for 14–16 mm.[73] An alternative is to use miniaturized ultrasound catheter probes passed through the working channel of a conventional endoscope, which can achieve comparable accuracy to conventional EUS.[74]

Echo features of lymph nodes that suggest malignant involvement include echo-poor (hypoechoic) structure, sharply demarcated borders, rounded contour, and size greater than 10 mm, in increasing order of importance.[75] A collective review showed that the overall accuracy of staging nodal disease was 77%.[68] The accuracy of EUS may differ for different lymph node locations and is related to the depth of penetration of EUS (about 3 cm). It is best for detecting paraesophageal nodes, and sensitivity varies inversely with the axial distance of the nodes from the esophageal axis.[76] The ability to perform EUS-guided FNA cytology of suspicious nodes (such as celiac nodes) is another factor that makes EUS superior to CT scanning.[77]

Percutaneous ultrasound is particularly useful for obtaining FNA biopsies of cervical lymph nodes. In one large study in 519 patients, cervical lymph node metastasis was detected in 30.8% of patients (160/519). The sensitivity, specificity, and accuracy of US diagnosis in patients who underwent subsequent cervical lymphadenectomy were 74.5%, 94.1%, and 87.6%, respectively. In those who did not undergo neck dissection, the chance of cervical nodal recurrence was low, at less than 5%.[78]

Information gained by combining preoperative cervical ultrasound and EUS can be highly prognostic. In one study, when the number of metastatic nodes was stratified into subdivisions of 0, 1–3, 4–7, and 8 or more, the number of involved lymph nodes was prognostically similar to the eventual subdivisions as determined by histological diagnosis.[79] However, both percutaneous and EUS are highly operator-dependent, and their meticulous application is required to produce these results.

FDG-PET Scans

PET scan is gaining popularity in esophageal cancer staging (see Fig. 17-6).[80,81] For the detection of the primary tumor, the sensitivity of PET ranges from 78 to 95% with most false-negative tests occurring in patients with T1 or small T2 tumors.[65,82] Adenocarcinomas of the GEJ and proximal stomach sometimes show limited or absent FDG accumulation regardless of tumor volume (FDG nonavidity). Some investigators observed this phenomenon in as many as 20% of these patients, which seems to be related to the diffusely growing subtype and poorly differentiated tumors.[83]

PET does not provide definition of the esophageal wall and thus has no value in T stage. For locoregional nodal metastases, its spatial resolution is also insufficient to separate the primary tumor with juxtatumoral lymph nodes because of interference from the primary tumor, and thus most studies demonstrated poor sensitivity.[82,84] This is especially true for nodes in the middle and lower mediastinum, where most primary tumors are found. In one study, the sensitivities of PET for detecting cervical, upper thoracic, and abdominal nodes were 78%, 82%, and 60%, respectively, but was only 38 and 0% respectively for the mid- and lower mediastinum.[65] Specificity of PET in detecting regional nodes is usually much better, reaching 95–100% in some studies.[82,84] The low rate of false-positive findings is important in preoperative staging.

A meta-analysis of 12 publications on PET scanning in esophageal cancer showed that the pooled sensitivity and specificity for the detection of locoregional metastases were 0.51 (95% CI, 0.34–0.69) and 0.84 (95% CI, 0.76–0.91), respectively. For distant metastases, the corresponding figures were 0.67 and 0.97. When two studies (out of 11) that had particularly low sensitivities for detection of distant metastases were excluded (probably because they included more early tumors), the pooled sensitivity improved to 0.72 and specificity to 0.95.[85] This study highlights again that the accuracy of PET in locoregional nodes is only moderate. EUS-FNA is superior in this regard. PET is more useful for picking up distant metastases.

A multi-institutional trial with a primary objective to evaluate whether PET could detect metastatic disease that would preclude esophagectomy was recently published. Patients who had operable disease after conventional staging (including CT scan) were evaluated with PET scan. Of 189 patients, only 9 (4.8%) had M1b disease found and confirmed as true positives and were excluded from surgery. An additional 3.7% had unconfirmed M1b disease. However, apparent M1 findings by PET were also found in at least 3.7% of patients.[86] The true value of PET scan may therefore be limited and cost-effectiveness should be evaluated further.

Thoracoscopy and Laparoscopy

Thoracoscopy and laparoscopy have their advocates. Thoracoscopic staging usually involves a right-sided approach, with opening of the mediastinal pleura from below the subclavian vessels to the inferior pulmonary vein with lymph node sampling. Laparoscopic staging can include celiac lymph node biopsy and the use of laparoscopic ultrasound for detecting liver metastases. One multi-institutional study (CALGB 9380) reported results in 113 patients, and the strategy was feasible in 73% of patients. Thoracoscopy and laparoscopy identified nodes or metastatic disease missed by CT scan in 50% of patients, by MRI in 40%, and by EUS in 30%. Although no deaths or major complications occurred, it did involve a general anesthesia, one-lung anesthesia, a median operating time of 210 minutes, and a hospital stay of 3 days.[87] Laparoscopy could be used in diagnosing metastases (especially peritoneal spread) or identifying unsuspected cirrhosis, which may contraindicate resection, and it could be performed as a preliminary procedure during the time of planned esophagogastrectomy. Its main contribution would be in lower esophageal and cardial adenocarcinoma, while its value is expected to be minimal for more proximally located tumors.[88] Given their invasiveness, thoracoscopy and laparoscopy should be reserved for cases in whom positive confirmation of metastatic disease not otherwise obtainable is essential in deciding on treatment.

TREATMENT

Stage-Directed Therapy

In the past, esophageal cancer was treated by surgical resection alone, radiotherapy, or use of a plastic stent for palliation. Increasing choices and combinations of therapeutic options have made staging important; the treatment for early and advanced cancers should be individualized.

Treatment for Early Squamous Cell Cancers

Early tumors include T1a-EP, LMP, MM and T1b-SM1, SM2, and SM3 lesions as defined in Table 17-8. The distinction is important because of the risk of nodal metastases. The incidence of lymph node involvement in T1a-EP, T1a-LMP, and T1a-MM tumors are 0%, 3.3%, and 12.2%, respectively. For T1b-SM1, SM2, and SM3 lesions, the respective incidences of lymph node involvement are 26.5, 35.8, and 45.9%, respectively.[89] For mucosal cancers 5-year survival rates are 80–100% and for submucosal cancers 50–65%.

T1a-EP or LMP tumors are amenable to endoscopic resection because they carry a very small risk of nodal metastases and endoscopic resection is a sufficiently radical treatment. Because circumferential resection is likely to be associated with cicatricial stenosis, this procedure is indicated for lesions not exceeding two-thirds of the circumference. Lesions reaching T1a-MM or T1b-SM1 (200 μm deep from the muscularis mucosa) may be associated with nodal metastases, but endoscopic mucosal resection (EMR) is feasible for patients without clinical evidence of lymph node metastasis (relative indication). Lesions showing deep invasion (T1b-SM2 or SM3) are associated with metastasis at a frequency of about 30–50% and are treated in the same manner as advanced cancers. Recommendations by the Japan Esophageal Society with regards to endoscopic resection are shown in Fig. 17-8.[90] Other unfavorable features for endoscopic resection in addition to depth of infiltration and extent of involvement include poorly differentiated tumor and findings of lymphovascular infiltration in the resected specimen.

There are many techniques of EMR but the most commonly performed is perhaps EMR-cap EMR-C. Using a cap-fitted forward-viewing endoscope, saline is injected into the submucosal layer in order to raise the lesion from the deeper wall layer. The lesion is sucked into the cap and a snare wire that has been prelooped is used to snare the lesion. The strangulated mucosa is cut by blend-current electrocautery. In a series of 250 patients, 72% had absolute indications when EMR was performed for T1a-EP or LPM lesions. In these patients, no local or distant metastases occurred during follow-up. The 5-year survival rate was 95%. All those who died within 5 years died of non–cancer-related causes.[91]

Endoscopic submucosal dissection (ESD) techniques are now preferred by many endoscopists. In this method, the lesion's border is first marked, and like EMR, submucosal injection is carried out. Various types of fluid have been used for injection to delay dispersion, for example glycerol, hyaluronic acid, hypertonic saline, and mannitol. Through-the-scope "knives" such as hook, needle, flex, or insulated tip (with ceramic) knives are used to cut out the lesions. This technique is thus not limited by the size of the cap in EMR-C and can be used to remove large lesions of substantial length in one piece, thus achieving the aim of en bloc removal. The depth of resection can also be deeper and controlled, often revealing the underlying muscularis propria. Positive margins are less likely, and an en bloc specimen is more suitable for more complete pathological examination. The skill to perform ESD, however, is much more difficult to acquire compared to EMR. Complications common to both EMR and ESD include bleeding (which is usually minor), perforation (which can be prevented by adequate submucosal saline injection and can be treated sometimes with hemoclip), and stenosis (which tends to occur when the lesion is large).

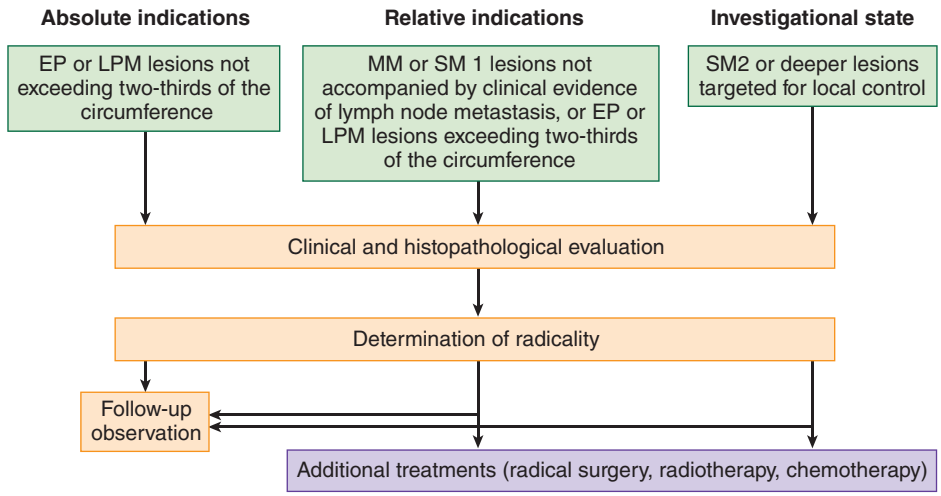

FIGURE 17-8 Recommendation by the Japan Esophageal Society for indications for endoscopic resection of esophageal cancer. Japan Esophageal Society. *Esophagus*. 2008;5:61–73, with kind permission from Springer Science + Business Media.)

Treatment for High-Grade Dysplasia and Early Adenocarcinoma

Barrett's high-grade dysplasia, synonymous with intraepithelial cancer, is the last preinvasive stage in the metaplasia-dysplasia-cancer sequence. Options of treatment include intensive surveillance, mucosal ablation, and esophagectomy.

INTENSIVE SURVEILLANCE

Proponents of endoscopic surveillance claim that such a strategy can diagnose invasive cancer at an early stage and treatment can be delayed until then without compromising prognosis. The high morbidity and mortality rate of esophagectomy is also thought by some to be a deterrent to immediate surgical resection. Opponents of surveillance observe that most patients with high-grade dysplasia will have an invasive adenocarcinoma identified during the following 5 to 10 years, in approximately 25% of patients at 1.5 years, 50% at 3 years, and up to 80% 8 years later.[31] High-grade dysplasia is currently the only reliable marker in preinvasive cancer detection, but interobserver concordance is suboptimal in distinguishing invasive and noninvasive lesions.[92] When esophagectomy is carried out in patients who have high-grade dysplasia, invasive cancer is identified in the surgical specimen in up to 42% of patients, even when patients have been recruited in surveillance programs.[93] More recent evidence, however, suggests that this figure is an overestimation; a meta-analysis of histologic findings after esophagectomy for high-grade dysplasia revealed invasive adenocarcinoma (at least submucosal cancer) in 12.7% and most of these had visible lesions at endoscopy, a known risk for invasive cancer.[94] In the absence of visible lesions, this figure is as low as 6.7%.[95] Most would regard the finding of high-grade dysplasia as a threshold for intervention. In patients who have visible lesions, such as raised nodules and not just a flat Barrett's mucosa, endoscopic resection is recommended to ensure no invasive cancer is present.[48] If surveillance is to be carried out, the American College of Gastroenterology recommends three-monthly surveillance.[48] The intensity that is required in surveillance of patients with high-grade dysplasia does make this an unattractive option.

ENDOSCOPIC THERAPIES

The rationale of endoscopic mucosal treatments is that the incidence of nodal metastases is low in high-grade dysplasia or T1a (intramucosal) cancers, and therefore treating the mucosal disease alone will result in cure. In T1a lesions, the rate of nodal metastases is low, reported as 0–6%. Once the submucosa is invaded (T1b lesions), this figure rises to around 20%.[96,97] EMR methods can be used to locally resect visible lesions in Barrett's esophagus. The largest series on the use of localized EMR was reported by Ell and colleagues. One hundred patients were treated; all had mucosal lesions of a diameter up to 20 mm, without lymphovascular invasion proven by histology of the resected specimen and histologic grades G1 and G2 arising in Barrett's metaplasia. Complete local remission was achieved in 99% of patients, 11% developed recurrence (6% locally and 5% at different locations), but successful repeated treatments were possible in all. Calculated 5-year survival rate was 98%.[98]

One problem about Barrett's metaplasia is multifocality of dysplasia and potential malignant transformation. Thus, in addition to localized resection of suspicious lesions, ablation of the whole Barrett's mucosa is desirable. Mucosal ablative therapies consist of various methods for ablating the metaplastic mucosa combined with high-dose acid-suppressive therapy so that normal squamous mucosa will replace the ablated metaplastic mucosa in a pH-neutral environment. Methods include circumferential EMR, bipolar electrocautery, argon beam coagulation, photodynamic therapy (PDT), and radiofrequency ablation.

If circumferential EMR is possible, more than one procedure is usually necessary to lessen the chance of stricture formation. In a series of 41 Barrett's patients who had high-grade dysplasia or early adenocarcinoma, circumferential EMR achieved complete removal of the Barrett's epithelium in 76% after a median follow-up of 32 months. Recurrent or metachronous early cancer was found in 12% of patients.[99] Recurrence is thus a significant problem with this type of EMR; this is not unexpected as resection is piecemeal and not en bloc. Barrett's epithelium could be missed and grow again. The advantage of EMR compared to other forms of mucosal ablative therapy is that specimens are available for histopathologic examination.

PDT has been demonstrated in a randomized trial to reduce the cancer risk in Barrett's esophagus. In this study, 208 patients with high-grade dysplasia were randomized comparing PDT using porfimer sodium plus a PPI against PPI only. High-grade dysplasia was eliminated in 77% of the PDT group, although 39% in the PPI group also lost high-grade dysplasia on subsequent biopsies. Barrett's epithelium elimination was achieved in 52% in the PDT compared to 7% in the PPI group. Adenocarcinoma developed in 15% of the PDT group compared with 29% in the PPI group, with a longer time to progression to cancer favoring PDT.[100] The problems with PDT treatment include the need for repeated sessions, photosensitivity, stricture formation (6% in the series just described), and the phenomenon of buried glands or pseudoregression; residual metaplastic mucosa beneath the regenerated squamous mucosa can be present, which makes continual surveillance necessary. This incidence can be as high as 51%.[101] Because PDT does not treat nodal disease and there is not specimen histological examination, accurate pretherapy diagnosis of noninvasiveness is necessary.

Recently a more promising ablative method is shown to be effective in treating both nondysplastic and dysplastic Barrett's esophagus. It is a balloon-based circumferential endoscopic radiofrequency device (HALO360); 60 tightly spaced bipolar electrodes that deliver radiofrequency are wrapped around the balloon. A sizing balloon is first introduced into the esophagus; an appropriately sized radiofrequency frequency balloon is then used to ablate the mucosa. Ablation is based on frictional heating of cellular water molecules. The advantages of the system are that it is easy to use, and, because of its controlled depth of injury up to 500–1000 μm (to the muscularis mucosae), stricture formation is uncommon. A more focal device (HALO90) mounted on the tip of a gastroscope is also available. The upper surface of the device is a 20-mm-long × 13-mm-wide articulated platform with an electrode array identical in pattern to the circumferential device. It is best used for ablating residual Barrett's mucosa after initial HALO360 treatment.

The Ablation Intestinal Metaplasia-II (AIM-II) trial examined the use of the HALO system in ablating nondyplastic Barrett's esophagus up to 6 cm in length. HALO360 treatment was performed at baseline and repeated at 4 months if there was residual intestinal metaplasia. Focal ablation with HALO90 was carried out after 12 months if needed. At 12 months complete remission of metaplasia was achieved in 48 of 69 patients (70%) and at 30 months 60 of 61 patients (98%). No stricture or buried glands were found.[102]

Another trial recently published examined the use of HALO system in ablating dysplastic Barrett's esophagus; 127 patients were randomly assigned in a 2:1 ratio to radiofrequency ablation or to a sham procedure. Randomization was stratified according to the grade of dysplasia and the length of Barrett's esophagus. Primary outcomes at 12 months included eradication rates of dysplasia and intestinal metaplasia. In the intention-to-treat analyses, among patients with low-grade dysplasia, complete eradication of dysplasia occurred in 90.5% of those in the ablation group as compared with 22.7% of those in the control group. Among patients with high-grade dysplasia, the respective figures were 81 and 19%. Overall, 77.4% of patients in the ablation group had complete eradication of intestinal metaplasia, compared with 2.3% in the control group. Patients in the ablation group had less disease progression (3.6 vs 16.3%) and fewer cancers (1.2 vs 9.3%). Stricture only developed in 6% of ablated patients.[103]

ESOPHAGECTOMY

Surgical resection is the only method to ensure complete eradication of the dysplastic mucosa, and the frequently undetected invasive cancer. Surgical resection was considered a standard treatment because of the high frequency of invasive cancers found in surgical specimens when resection was performed for high-grade dysplasia (up to 42%), though more recent evidence suggests that this figure is much lower at 13%.[94] The supposedly high morbidity and mortality rates of esophagectomy are also deterrents against surgical resection. However, in specialized centers, the mortality rate from esophagectomy, especially in this group of patients, is minimal. Minimally invasive surgical methods, including thoracoscopy, laparoscopy, or esophageal stripping, further reduce the trauma of surgical access. Excellent long-term survival with good quality of life is reported.[104,105]

Vagal-sparing esophagectomy leaves the vagi intact, is another approach aimed at preserving quality of life, and has been shown to result in much fewer postvagotomy symptoms.[106] In the Merendino procedure, limited surgical resection of the distal esophagus and GEJ, together with lymphadenectomy of the lower mediastinum and upper abdominal compartment, has also been advocated. An isoperistaltic jejunal interposition graft is used to restore intestinal continuity. This method combines the adequacy of nodal dissection and improved quality of life, as the jejunal loop prevents gastroesophageal reflux.[107]

In summary, in patients with high-grade dysplasia or early intramucosal cancer, there is a definite risk of progression to invasive cancer, treatment needs to be individualized. The choice between intensive surveillance, mucosal ablative therapies, and esophagectomy needs to be considered based on available expertise and patient's preference.

Treatment For Advanced Esophageal Cancer

SURGICAL RESECTION FOR ESOPHAGEAL CANCER

Surgical resection remains the mainstay treatment for patients with localized esophageal cancer. In dedicated high-volume centers, mortality rate from surgery of 2–3% can be achieved.[56,108–112] A volume-outcome relationship is evident.[111,113] Centralization of service to high-volume hospitals also improves outcome.[114]

Important aspects to enhance better outcome after esophagectomy are (1) selecting appropriate patients for resection, (2) choice of surgical techniques and their execution, and (3) enhancing perioperative care.

Patient Selection for Esophagectomy. How stringent one selects patients for esophagectomy will influence the resection rate. Selection depends on many factors, including (1) the referral pattern of individual centers, (2) the prevailing treatment philosophy, (3) the availability of alternative therapies, and (4) the possible mortality that the surgeon and patient are prepared to accept. Reported resection rates range from 21 to 70–80%.[110,115] This wide variation suggests probable prereferral bias or a high prevalence of early cancers in those with high resection rates.

In studies that report on improvement of surgical results over time, more stringent patient selection often comes into play, either by excluding high-risk patients or by treating advanced disease by nonoperative means.[116] Resection with a clear aim for palliation is becoming uncommon, and most would only operate on patients for potential cure.

Factors often cited as being predictive of morbidity and mortality after esophagectomy include advanced age,[112] poor performance status,[116] nutritional depletion[117] and weight loss, more proximally located tumor,[112] poor pulmonary function,[118] cirrhosis,[119] and abnormal cardiac evaluation.[116] Patients suffering from adenocarcinoma and squamous cell cancers also have different risk profiles. Patients with squamous cell cancers are more likely to be malnourished, have high alcohol intake, are smokers, and have more impairment of pulmonary and hepatic function. Patients with adenocarcinomas on the other hand are more likely to be overweight and are more at risk from cardiovascular diseases.[120]

Assessing a patient's fitness is often based on the surgeons' experience and intuition and is not an exact science. Objective scores can help assess operative risk and patient selection.[116,118,121] In one series of studies using a scoring system based on compromised general status and poor cardiac, hepatic, and respiratory function as independent predictors of postoperative death, 30% of patients with otherwise resectable tumors were excluded from surgery. When this was applied in prospective patient selection, it led to decrease in postoperative mortality rates from 9.4 to 1.6%[116]

It is uncertain if patient selection based on a strict mathematical scoring system is better than one based on surgeon and anesthesiologist assessments alone. They are more likely to be complementary to each other.

Choice of Surgical Approaches. There are many important variables in esophagectomy, such as surgical access, the extent of resection and lymphadenectomy, the type and the method of preparation of the esophageal substitute, the route of reconstruction, and the technique of esophageal anastomosis. Many of these variables are interrelated and could affect immediate morbidity and mortality rates, long-term quality of life, and survival. Tumor location and stage, patient's risk profile, and surgeon's preference and experience are important variables in deciding the surgical procedure. The surgeon should be versatile and well versed with the many different techniques to adapt to different clinical situations.

Cervical Esophageal Cancer. In 1960, Ong and Lee first described the procedure of pharyngolaryngoesophagectomy (PLE) as a one-stage, three-phase operation that involved cervical and abdominal incisions and a thoracotomy.[122] Tumors involving the hypopharyngeal and upper cervical esophageal region were resected together with the whole esophagus, and the stomach was delivered via the posterior mediastinum to the neck for pharyngogastric anastomosis. A terminal tracheostome was constructed. The thoracotomy was later replaced by transhiatal esophageal mobilization. Thoracoscopic esophageal mobilization has become another and our preferred alternative.[123] PLE is associated with significant morbidity and mortality, partly related to the fact that the procedure is often performed as a last resort for salvage when no other means of palliation exists.[123] So despite improvements in surgical care, results remain worse compared to patients with intrathoracic cancers. At the authors' institution, of 317 PLE performed from 1966 to 1995, mortality rate decreased from 31 to 9%.[124]

For tumors confined to the proximal portion of the cervical esophagus with sufficient distal margin, free jejunal interposition graft or deltopectoral or pectoralis major myocutaneous flaps are options for reconstruction after resection. The use of a free jejunal graft is advantageous because it avoids mediastinal dissection, though expertise in performing microvascular anastomosis is essential. Graft necrosis, fistula formation, and late graft strictures are specific problems. When compared with gastric pull-up, graft survival and leak rates are similar. Stricture was the most common late complication for free jejunal transfers, whereas reflux was most common in gastric pull-ups, both occurring in approximately 20% of patients.[125] Functional study showed a satisfactory swallowing mechanism in all patients.[126] The jejunal graft is also tolerant to postoperative radiotherapy.[127] The need to sacrifice the larynx does make surgical resection an unattractive option, and chemoradiation has been used up-front in many series, with surgery reserved for salvage.[128]

Intrathoracic Esophageal Cancer. For tumors in the upper thoracic esophagus, obtaining a sufficient proximal resection margin dictates an anastomosis placed in the neck.

For this reason, resection is best carried out by a three-phase esophagectomy or the McKeown approach.[129] In this procedure a right thoracotomy is first carried out to mobilize the thoracic esophagus together with lymphadenectomy; this is followed by abdominal and neck incisions for the mobilization of the esophageal substitute, placing the anastomosis in the neck. The split-sternum approach is an alternative, especially for tumors close to the thoracic inlet.[130,131]

The majority of intrathoracic cancers are squamous esophageal cancers located in the middle and lower esophagus, and Barrett's adenocarcinomas in the lower esophagus. The most widely used approach was that described independently by Lewis[3] and Tanner.[4] The operation begins with an abdominal phase, in which the stomach is prepared, followed by a right thoracotomy and resection of the tumor together with lymphadenectomy. The stomach is then brought up into the chest for anastomosis with the proximal esophagus at the apex of the pleural cavity.

An alternative approach involves a single left thoracotomy incision. Through a left thoracotomy and incision in the diaphragm, both the esophagus and stomach could be mobilized and resection carried out, and stomach delivered into the chest for anastomosis, either below or above the aortic arch. Proximally the aortic arch does hinder surgical access, making mobilization of the proximal esophagus and subsequent anastomosis difficult. The approach is therefore more suitable for cancer of the cardia or the distal esophagus where an adequate resection margin is obtained below the aortic arch.

A transhiatal approach, whereby the thoracic part of the esophagus is mobilized by blunt and often blind dissection through the enlarged esophageal hiatus, and the mobilized stomach is then delivered to the neck and anastomosed to the cervical esophagus This is advocated especially for distal esophageal tumor or early-stage tumors of other parts of the esophagus.

Abdominal Esophagus and Gastric Cardia Tumors. For cancers that are limited to the abdominal esophagus or gastric cardia cancers, an abdominal-right thoracic approach as in a Lewis-Tanner esophagectomy is one option, with the proximal stomach also resected in order to gain an adequate distal resection margin. A left thoracoabdominal incision through the seventh or eighth rib space also gives excellent exposure of the low mediastinum and upper abdomen. A single left thoracotomy with opening up of the diaphragm is also an option. This gives reasonable exposure of the upper abdomen. However, lymphadenectomy toward the hepatoduodenal ligament is hampered. When a thoracotomy is not desired, opening the hiatus widely by splitting the crura laterally and the diaphragm anteriorly can gain access to the low posterior mediastinum, and distal esophagectomy can be performed with the anastomosis performed from the abdomen without the need for a thoracic incision. The anastomosis is made easier with a mechanical stapler. Recently a stapler designed with a transoral placement of the anvil into the distal esophagus makes construction of a lower mediastinal anastomosis easier. When the proximal stomach is involved by tumor, a total gastrectomy with Roux-en-Y reconstruction is preferred by many.

Transthoracic Versus Transhiatal Resection. This continues to be controversial. Proponents of transhiatal resection believe that surgical resection for esophageal cancer is mostly palliative and a cure is a chance phenomenon for only those with very early tumors. More thorough lymphadenectomy through a thoracotomy merely improves staging but does not affect prognosis. The operating time is also shorter and postoperative morbidity is less with the transhiatal approach.[132] Conversely, surgeons who practice transthoracic esophagectomy (TTE) consider the open approach to be safer, with dissection under direct vision.[133] A more thorough lymphadenectomy leads to better staging and survival.

Population data from the Surveillance, Epidemiology, and End Results-Medicare linked database including 868 patients from 1992 to 2002 who underwent either transhiatal or transthoracic approach were studied in one recent study; 225 underwent transhiatal and 643 received TTE. Lower operative mortality rate was observed after a transhiatal than transthoracic approach (6.7 vs 13.1%). Survival was not different after adjusting for tumor stage, patient, and provider factor.[134] The largest randomized controlled trial comparing the two approaches studied 106 patients who underwent transhiatal esophagectomy and 114 patients who had the transthoracic approach for mid-lower third/cardia adenocarcinomas. Pulmonary complication rates were 27% in the former group compared to 57% in the later. Ventilation time, intensive care, and hospital stay were longer in the transthoracic group. There were, however, no significant differences in in-hospital mortality at 2 and 4%. Significantly more lymph nodes were dissected in the transthoracic group (16 vs 31). Overall 5-year survival was 34% (transhiatal) and 36% (transthoracic). Importantly, it showed that in individuals with limited nodal spread (one to eight positive lymph nodes), TTE imparted a survival advantage (64 vs 23%). Survival was not different in patients with no nodal metastases or in those with more nodal metastases.[135]

The location and stage of the primary tumor has bearing on which surgical approach is selected. From a purely safety point of view, transhiatal resection is not suitable for patients with advanced middle- or upper-third tumors, especially in patients with tumors closely related to the tracheobronchial tree and after neoadjuvant radiation therapy; tumor infiltration or fibrosis may obliterate tissue planes and make blind dissection unsafe. As such, its application is more suitable for lower esophageal tumors for which much of the mobilization can be performed under vision. From an oncological standpoint, the philosophy toward lymphadenectomy dictates the surgical approach.

Minimally Invasive Esophagectomy (MIE). Various combinations of minimally invasive approaches including thoracoscopy, laparoscopy, mediastinoscopy, hand-assisted laparoscopy, and open laparotomy and thoracotomy have been explored.[136] The myriad of surgical methods implies a lack of consensus on which is superior.

Large single-center series are few; some have experience of over 100 patients.[137–140] Several reviews on MIE have been published[136,141–144]; none could conclusively show that MIE is better or worse than that of the open approach,

and no randomized controlled trial has been undertaken. Conversion rate is approximately 5%, respiratory complications 13–22%, and a very low mortality rate of 3% is achieved.[142,143] Biere and colleagues examined 10 comparative studies comparing MIE with open esophagectomy, comprising 1061 patients. Three comparative groups were created for meta-analysis: (1) total MIE versus open TTE; (2) thoracoscopy and laparotomy versus open TTE; (3) laparoscopy versus open transhiatal esophagectomy. There was a trend toward less mortality with MIE in groups 1 and 2, and fewer anastomotic leaks with MIE in group 2 were found. Again, definitive conclusions could not be reached because of selection bias and the variety of techniques used.[144]

Potentially serious intraoperative complications can occur with MIE, such as bleeding from the azygous vein[145] and from intercostal vessels,[146] injury to the aorta,[147,148] tracheobronchial tree,[149–151] and recurrent laryngeal nerve,[152] but certainly they are not specific for these methods. The increased magnification and excellent visualization offered by thoracoscopy might help lessen complications.

Whether MIE could reduce morbidity and mortality rates remains controversial. This is partly because of the number of patients studied generally was too small to have enough statistical power to demonstrate a difference. There are also other reasons why benefits are difficult to confirm. With modern analgesic methods, such as epidural analgesia, postoperative pain control is less critical a problem.[153] The genesis of cardiopulmonary complications is multifactorial and does not depend solely on the size of the incisions. Surgical trauma from mediastinal dissection is independent of the incision size. The benefit of smaller port sites compared with open thoracotomy may be offset by the lengthened time of single-lung anesthesia. A learning curve obviously exists for such complicated procedures.[154,155] The duration of the thoracoscopic procedure, blood loss, and the incidence of postoperative pulmonary infection were all less, and the number of mediastinal nodes retrieved was more, in the latter half of a group of 80 patients who had thoracoscopic esophagectomy.[154] Thus, for most series, the full technical potential may not have been realized. The number of procedures that need to be performed before the learning curve is overcome is uncertain.

Patient selection is evident in many series, and in some studies most subjects had early-stage disease or high-grade dysplasia in Barrett's esophagus.[138,156] The most important test will be long-term survival by stage-by-stage comparison, but stage migration may be hard to eliminate. Most series do not report on survival data and, in those that do, there is no reported difference compared with historical controls. Existing data, however, do show that nodal harvesting can be equivalent to that of open surgery.[136] The place of MIE thus remains controversial without a well-conducted randomized controlled trial.

Extent of Resection: Axial and Lateral Margin. One of the most controversial aspects of treating gastrointestinal malignancies is the appropriate extent of resection, and this debate is exemplified by esophageal cancer.[157]

An R0 resection is consistently identified as the most important prognostic factor for long-term survival. An R0 resection results in total removal of the tumor mass (primary and lymph nodes) with clear proximal, distal, and lateral margins. The need to obtain clear axial and lateral margins is less controversial. The propensity of esophageal cancer to spread intramurally and to have multiple separate tumors in the esophagus is well recognized. The prevalence of intraepithelial, subepithelial, or intramural spread was as high as 46 and 54%,[158,159] and multiplicity of tumor was found in around 30% of patients.[159,160] The deeper the wall penetration of the primary tumor, the farther away such spread can take place.[158] It is clear that the chance of a histologically positive margin declines with increasing distance at which the esophagus is transected away from the tumor edge, and that the frequency of anastomotic recurrence is a function of the length of proximal resection margin attained. Taking into account shrinkage of the specimen after resection, as a guide to surgery, an in situ margin of 10 cm (fresh contracted specimen of approximately 5 cm) should be aimed at, to allow a less than 5% chance of anastomotic recurrence.[161] Intraoperative frozen section is one method to ensure a negative margin. However, a histologically involved resection margin does not necessarily lead to definite anastomotic recurrence, and a negative margin does not preclude anastomotic recurrence. The occurrence of skip lesions or submucosal spread can be missed even by a conscientious pathologist; hence margins may be falsely negative. Extramural recurrence with infiltration back to the anastomosis may also be indistinguishable from true anastomotic recurrence. Patients who have positive histologic margins are those likely to have more advanced disease, and early recurrences at more distant sites may make anastomotic recurrence less relevant. In our study, a positive histologic margin (diagnosed with definitive histology and not with frozen section) occurred in 7.5% of patients who had esophagectomy, which had an anastomotic recurrence rate of 10.3% compared to 4.9% in those with a negative margin. The difference, however, did not reach statistical significance.[161]

Microscopic involvement of the lateral margin (macroscopically clear) results in increased chance of local recurrence and worse survival.[162] Obtaining a clear lateral margin is difficult with esophageal cancer because of its anatomical position and adjacent indispensable structures. Neoadjuvant therapy may help achieve this. Some Western centers advocate the concept of "en bloc" resection, which aims at removing the primary tumor together with the pericardium, thoracic duct, azygous vein, intercostal vessels, and bilateral pleurae overlying the primary tumor and a surrounding cuff of crura (where the primary tumor is abutting) to enhance lateral clearance.[108,163] Obviously this type of resection is less suitable for upper esophageal cancers in close proximity to the trachea. The concept of "en bloc" resection is thus more applicable for Western patients, where most tumors are adenocarcinomas of the lower esophagus.

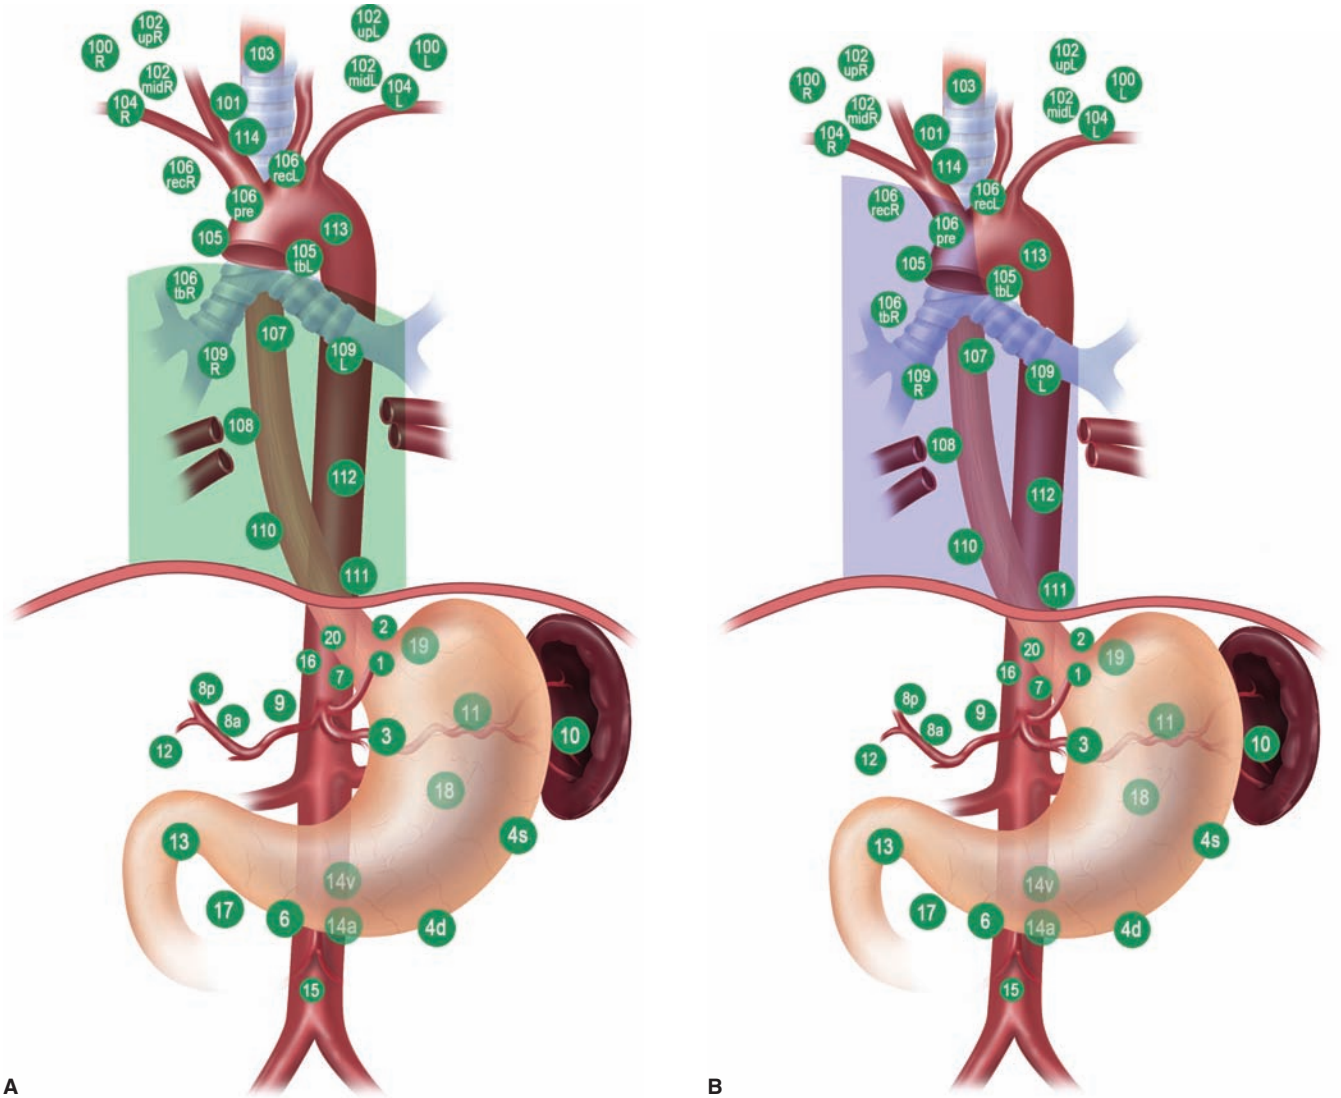

FIGURE 17-9 The extent of mediastinal lymphadenectomy: **A.** Standard mediastinal lymphadenectomy includes removing the paraesophageal nodes and subcarinal and right and left bronchial nodes below the tracheal bifurcation. **B.** Extended mediastinal lymphadenectomy involves standard lymphadenectomy plus right apical nodes, right recurrent laryngeal nerve nodes, and right paratracheal nodes.

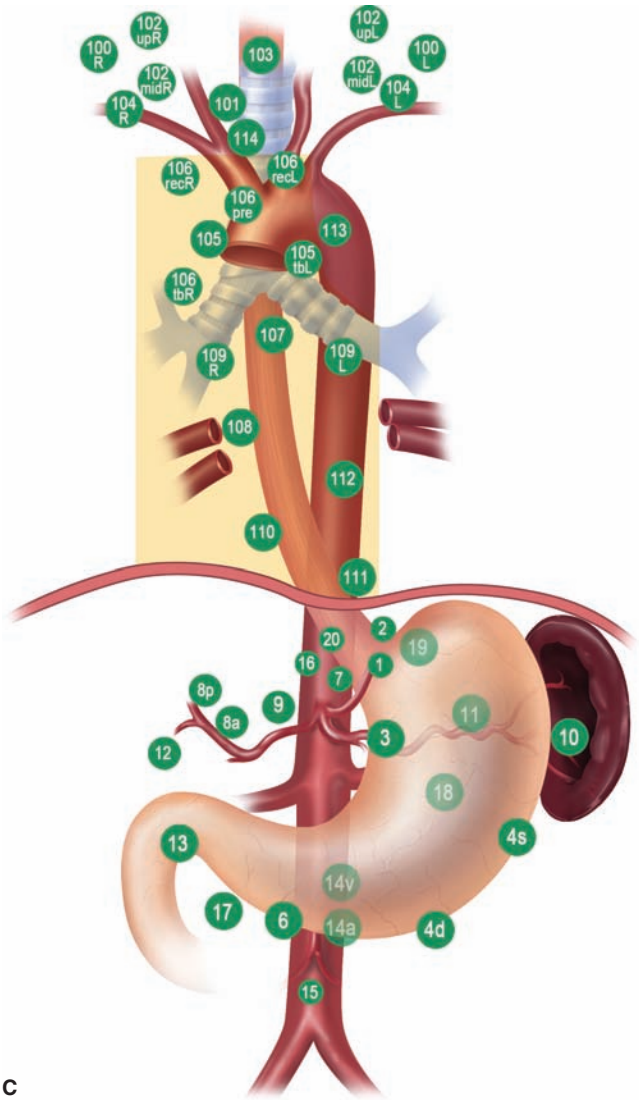
Extent of Lymphadenectomy: Squamous Cell Cancers. As discussed previously, the ability to perform lymphadenectomy is closely related to the surgical approach utilized, and an open transthoracic or thoracoscopic approach is necessary, unless only a limited lower mediastinal dissection is planned. In countries where squamous cell cancers are prevalent, transhiatal resection is uncommonly performed based on safety concerns, as well as because the value of lymphadenectomy is less questioned.

Conventional lymph node dissection for esophageal cancer usually involves a "standard two-field" lymphadenectomy, which entails removing the nodes and periesophageal tissue below the level of the carina, and the lymph node stations around the celiac trifurcation. When superior mediastinal lymph node dissection is performed, it is sometimes known as "extended two-field lymphadenectomy." "Three-field" lymphadenectomy involves additional bilateral cervical lymph node clearance (Figs. 17-9 to 17-14). For intrathoracic squamous cell cancers, detailed lymph node mapping of metastatic disease in Japan shows that lymph nodes can spread to the neck, mediastinum, and upper abdomen around the celiac trifurcation. The overall rate of cervical lymph node metastases is approximately 30%. In relation to the level of primary tumor, cervical lymph nodes are involved in 60, 20, and 12.5% of upper-, middle-, and lower-third tumors, respectively. When nodes along the recurrent laryngeal nerves from the superior mediastinum are considered together with the cervical nodes as one entity, this "cervicothoracic" group nodes are involved in up to 63.4% of proximal-third, 45.2% of middle-third, and 42.0% of lower-third cancers.[164] These data provide the rationale behind "three-field" lymphadenectomy, where the true value of extended lymphadenectomy



C

FIGURE 17-9 *Continued*—**C.** Total mediastinal lymphadenectomy includes an extended mediastinal lymphadenectomy plus the left recurrent laryngeal and paratracheal nodes.

does not lie with the addition of a cervical phase, but the completeness of the superior mediastinal dissection along the recurrent laryngeal nerves to the neck.

Three-field lymphadenectomy as practiced in Japan shows an overall hospital mortality rate of 4%. Although this very low mortality rate is achieved, most of these results come from experienced and specialized institutions and such extensive surgery is expected to carry with it a more unfavorable outcome if it were more widely and unselectively applied. In addition, morbidity rates are substantial; septic complications were the most common at 26.8%, followed by pulmonary ones at 21.3%.[165] Recurrent laryngeal nerve injury can occur in more than 50% of patients, which predisposes to pulmonary complications and impairs long-term quality of life.[166]

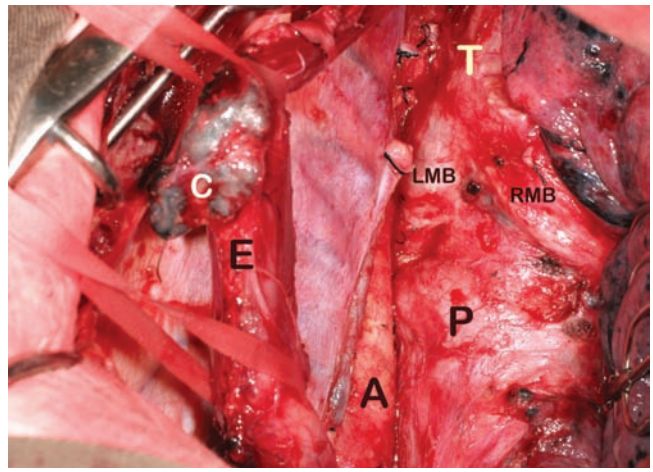


FIGURE 17-10 Infracarinal mediastinal dissection. A, aorta; C, carinal lymph node on esophagus; E, esophagus; LMB, left main bronchus; P, pericardium; RMB, right main bronchus; T, trachea.

Perhaps based on the realization that such an extensive operation carries with it substantial morbidity and that not all patients can benefit, the recent focus of research in this area is to further refine the indications for extended lymphadenectomy. A survival advantage was only evident for upper- and middle-third cancers in some studies.[164,167,168]

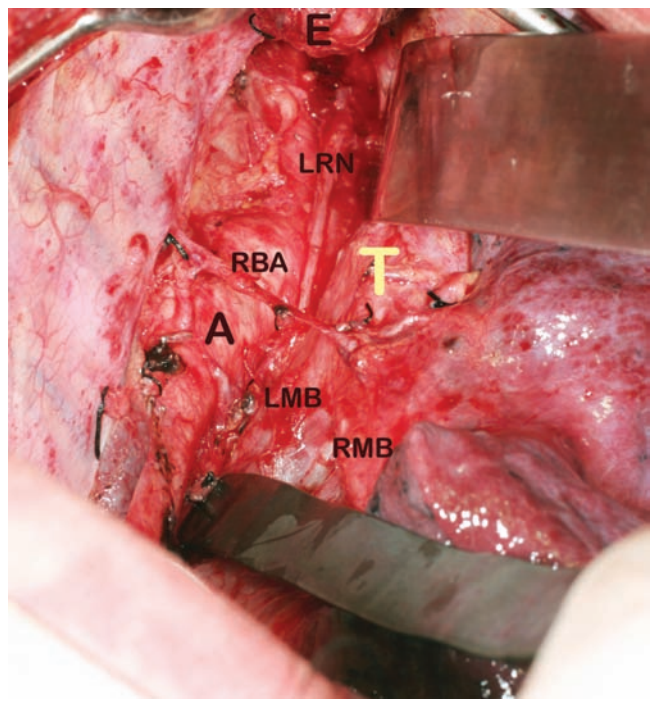

FIGURE 17-11 Superior mediastinal dissection. Large metal retractor retracting the trachea anteriorly to expose the left recurrent laryngeal nerve (LRN). A, aortic arch; E, esophagus; LMB, left main bronchus; RBA, right bronchial artery, which is preserved; RMB, right main bronchus; T, trachea.

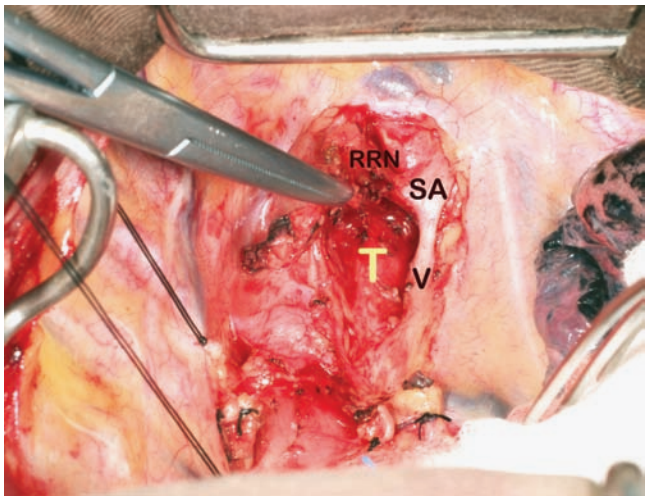

FIGURE 17-12 Right recurrent laryngeal nerve node dissection. RRN, right recurrent laryngeal nerve; SA, subclavian artery; T, trachea; V, vagus nerve.

Other poor prognostic factors include (1) when all three fields have metastatic nodes; (2) when a lower-third tumor has positive cervical nodes; and (3) when five or more lymph nodes are involved.[169] These situations suggest advanced metastatic disease and three-field lymphadenectomy may not be justified. Other suggested strategies include using intraoperative polymerase chain reaction to examine recurrent laryngeal nerve lymph nodes to predict the need for cervical dissection,[170] similar to the concept of sentinel lymph node metastasis,[171] and taking a two-stage operative approach to select patients suitable for cervical lymphadenectomy.[172] Replacing three-field lymphadenectomy by neoadjuvant, adjuvant, or intraoperative radiotherapy[173] are alternatives, but their roles remain controversial.

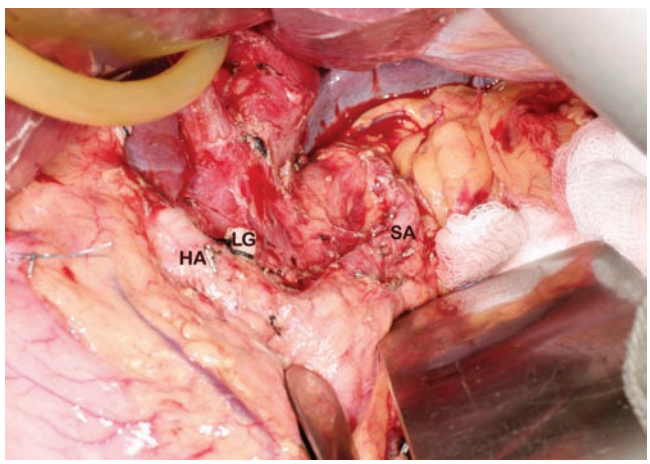

FIGURE 17-13 Abdominal lymphadenectomy involves dissection around the celiac trifurcation. HA, hepatic artery; LG, left gastric artery stump ligated; SA, splenic artery.

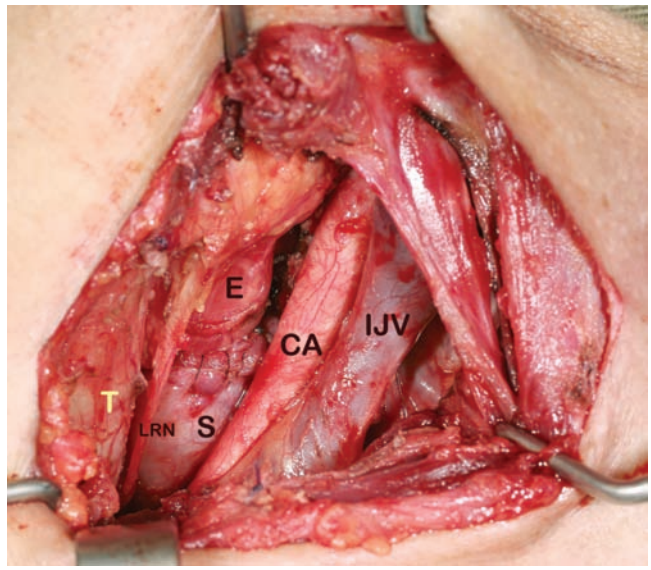

FIGURE 17-14 For cervical lymphadenectomy, the cranial landmark is the cricoid cartilage and the caudal border is the upper margin of the clavicle. The most important nodes are the paratracheal nodes along the recurrent laryngeal nerves. Left neck dissection. CA, carotid artery; E, esophagus; IJV, internal jugular vein; LRN, left recurrent laryngeal nerve; S, stomach; T, trachea. The esophagogastric anastomosis is seen, constructed with a one-layer continuous suturing technique.

Another major criticism of three-field dissection is that the prognostic superiority over conventional resection is only a result of stage migration. While retrospective studies provide evidence for benefits of three-field dissection,[174,175] the more robust evidence of a well-performed randomized controlled trial is lacking. Two small randomized trials could not demonstrate convincing survival advantage, and, in both, the patient groups appeared to be highly selected and not well-matched, and adjuvant therapies were not controlled for.[176,177]

Barrett's Adenocarcinoma and Gastric Cardia Cancers. For Barrett's adenocarcinomas of the lower esophagus and cancer of the gastric cardia, data suggest that nodal spread tends to occur later than for squamous cell cancers. Positive nodes are found in approximately 10% of patients with squamous cell cancers for T1a lesions, while in Barrett's cancer this is only 0–6%. In T1b cancers, the respective figures are 30–50% for squamous cell and 20% for adenocarcinomas. In addition, the pattern of lymphatic spread also differs; more than 85% of all positive nodes in early adenocarcinoma are located in close proximity to the primary tumor in contrast to fewer than 60% in squamous cell cancers.[178] Nodes are not commonly found in the superior mediastinum and, when present, probably indicate very widespread disease.[179] Thus lymphadenectomy is generally performed using a standard two-field approach. The advent of transhiatal esophagectomy came at a time when esophagectomy was a high-risk operation with high mortality rates, and this less invasive method

probably contributed to reducing overall death rates. With improvement in surgical techniques and perioperative care, it seems that, in most experienced centers, when selected appropriately, both procedures can be carried out safely and the margin of benefit in reducing morbidity for most patients with the transhiatal operation is not overwhelming. There is also increasing evidence of the benefits of radical lymphadenectomy in recent years.

The concept of en bloc resection has been discussed in a previous section; this enhances lateral margin clearance, results in a complete lymphadenectomy within a facial envelop surrounding the primary tumor,[108,163] and is especially advocated for adenocarcinoma of the lower esophagus. In dedicated centers, en bloc resection has a morbidity rate of 40%, a mortality rate of less than 5%, and a 5-year survival rate of 37–52%.[163,180,181] It has been suggested that local recurrence can be reduced to an impressive 5% within the field of dissection,[163,182–184] and nodal recurrences are mostly found outside the limits of dissection in the superior mediastinum or aortopulmonary window, in areas along the recurrent laryngeal nerves that are not routinely removed. Taking en bloc resection further, in selected centers in the United States and Europe, three-field lymphadenectomy has been tested and interestingly also yielded similar incidences of positive cervical lymph nodes of around 30%.[109,184] This type of resection, however, is not commonly performed in the West.

For tumor of the gastric cardia (Siewert types II and III tumors), most surgeons would perform a total gastrectomy with a Roux-en-Y jejunal loop reconstruction, though some would prefer to preserve the distal stomach for anastomosis. An upper abdominal compartment nodal dissection around the celiac axis seems routine for all, but complete lower mediastinal nodal dissection is somewhat controversial. Some argue that thorough lower mediastinal dissection is needed and this is only possible with the addition of a thoracotomy; others believe that this is unnecessary, and mediastinal nodal involvement could indicate advanced disease for which survival is poor regardless of the extent of lymphadenectomy. The Japanese Oncology Group trial 9502 addressed this question. Patients whose tumors were Siewert II or III adenocarcinomas and which have infiltrated into the esophagus for less than 3 cm were randomly assigned to a transabdominal (n = 82) or left thoracoabdominal approach (n = 85). A more thorough mediastinal dissection was deemed only possible with the later approach. The trial was closed prematurely after the first interim analysis, when the predicted probability of left thoracoabdominal approach having a significantly better overall survival than transabdominal route at the final analysis was only 3.65%. The morbidity rate was worse after the left thoracoabdominal approach. Thus a transabdominal approach seems adequate, though the surgeon must be prepared to add a thoracotomy when frozen section indicates a positive proximal resection margin.

Regardless of tumor histologic type, increasing evidence is emerging to show that extended lymphadenectomy is related to survival, from single and multi-institutional studies,[185,186] as well as from population data.[187,188] The number of nodes removed correlates significantly with long-term survival. One international multicenter study showed that the number of nodes removed was an independent prognostic factor, in addition to age, gender, cell type, presence of nodal metastases, number of nodes involved, and depth of tumor invasion.[186] The optimal number of nodes removed was identified as 23, though this number varies among studies. From a Worldwide Esophageal Cancer Collaboration including institutions from the United States, Europe, and Asia, the number of nodes that must be removed to maximize survival depends on the pT classification: for pT1, approximately 10 nodes must be resected; for pT2, 20 nodes; and for pT3 or pT4, 30 nodes or more.[189] Thus, one should resect as many regional nodes as possible, balancing the extent of lymphadenectomy with morbidity.

RECONSTRUCTION AFTER ESOPHAGECTOMY

The reconstruction phase of an esophagectomy determines to a significant extent the postoperative morbidity and long-term quality of life. The most commonly used conduit is the gastric tube, and of the many configurations, a tailored isoperistaltic tube based on the greater curvature with preservation of the right gastric and right gastroepiploic vessels is most reliable. A 4-cm gastric tube on the greater curvature gives the best blood supply.[190] The simplicity of preparation, adequate length, and robust blood supply makes it the first choice as the esophageal substitute (Fig. 17-15). Disadvantages of the gastric conduit include the fact that patients who have an intrathoracic stomach often experience postprandial discomfort and early satiety related to loss of normal gastric functions such as receptive relaxation. Patients can also suffer from acid reflux, possible gastric ulceration, and dysfunctional propulsion.[191] In addition, Barrett's esophagus has been reported to develop in the esophageal remnant,[192] although the clinical relevance of this finding is at present unknown. These are important considerations though, in our experience, serious problems are uncommon. The level of the esophagogastric anastomosis has a bearing on the severity of reflux. Patients who have a low intrathoracic anastomosis tend to have more severe reflux and esophagitis compared with the high intrathoracic or cervical anastomosis. Preserving a longer length of esophagus, on the other hand, theoretically may enhance swallowing function. Inadequate gastric emptying can be a problem. A pyloric drainage procedure is not universally practiced. In a randomized trial, 13% of patients who did not have a pyloroplasty had problems with gastric emptying.[193] A meta-analysis suggested that a drainage procedure lessens the chance of early postoperative gastric stasis, but long-term function is not affected.[194]

Many other factors contribute to emptying of the intrathoracic gastric conduit. A smaller stomach enhances postoperative emptying.[195] The straighter position of the stomach, when delivered to the neck via the posterior mediastinal or the retrosternal route, may make the stomach empty more efficiently compared to one placed in the right pleural cavity, where the angulation at the diaphragmatic hiatus as the stomach continues from the right paravertebral gutter into the

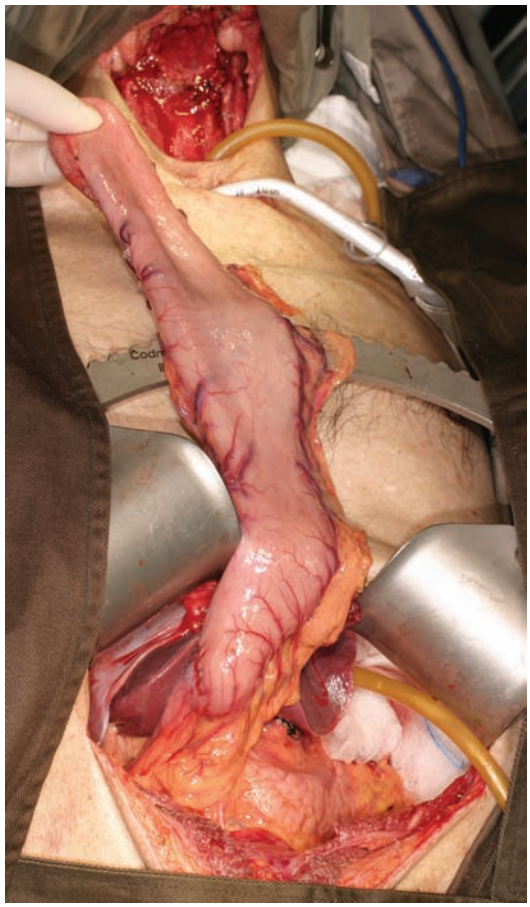

FIGURE 17-15 Gastric conduit prepared for transposition to the neck for pharyngoesophagostomy after pharyngolaryngoesophagectomy. Ample length is evident.

abdomen may produce relative obstruction. Rotation of the stomach at the hiatus should be avoided. With a gastric conduit, diet modifications and the use of acid suppressive and prokinetic drugs such as erythromycin may be useful.[196,197]

There are instances when the stomach cannot be used, such as after previous gastric resection, and tumor involvement of a substantial part of the stomach dictating its removal. In these situations the use of the colon is preferred. For most, colonic interposition remains an infrequently performed procedure and has the potential for more complications.[198] Mobilization of the colonic loop is more complex; its blood supply is less reliable than the gastric conduit; three anastomoses are required; when the colon becomes ischemic, the choice of alternative conduit is restricted. In our experience, use of a colon loop is associated with more blood loss, a longer operating time, and a higher anastomotic leak rate. Colon ischemia occurs in 1 of 42 patients (2.4%), which compares favorably to a rate of 3–10% reported in the literature.[199]

A colonic conduit provides good long-term swallowing function; it seems to have active peristalsis, and this is cited as an explanation for its superior function as an esophageal substitute when compared with a passive gastric conduit.[200,201] Although peristalsis can be demonstrated immediately following surgery,[202] long-term emptying likely relies on gravity.[203] When the distal stomach is retained in the abdomen after a colon interposition with a cologastric anastomosis, the latter provides additional reservoir function.[204]

The jejunum is used most frequently after distal esophagectomy and total gastrectomy for cancer of the lower esophagus and gastric cardia. A Roux-en-Y configuration seems best, as it prevents bile reflux to the esophagus. A jejunal loop used in a modified Merendino procedure to interpose between the esophagus and proximal stomach after limited resection of the distal esophagus and GEJ has also been advocated.[205] Excellent postoperative quality of life and function is claimed. A long jejunal loop is sometimes used to reach the neck, but preparation is tedious and the vasculature may not be reliable; a "supercharge" using a microvascular anastomosis to cervical vessels may be required.[206] A free jejunal graft is used for reconstructing the defect after resection of the pharyngoesophageal segment in the neck.[127]

The method of reconstruction is in part related to the surgical approach for resection. When a cervical anastomosis is chosen, one must decide whether to place the conduit via the orthotopic, retrosternal, or subcutaneous route. The subcutaneous route is rarely used because it is cosmetically unsightly. The retrosternal route has variably been shown to be associated with increased or similar cardiopulmonary morbidity and mortality rates.[207–209] The retrosternal route is 2–3 cm longer compared to the orthotopic route,[210] but this is rarely of relevance because the esophageal replacement conduit is usually of sufficient length. Some suggest that the tight space at the thoracic inlet in the neck could cause potential constriction on the conduit and recommend partial manubrial, clavicular head and first rib resection[211]; we have found this unnecessary. Functionally, although it was shown that there is a higher rate of gastric retention when the retrosternal route is used, quality of life is not adversely affected.[208,212]

When palliative resection is carried out for advanced tumor, recurrent tumor could infiltrate into the conduit placed in the posterior mediastinum. In a retrospective study of 209 patients who had undergone curative resection and orthotopic reconstruction, or 73 patients (35%) who had locoregional tumor recurrence, 46 (22%) had secondary dysphagia as a result. The authors concluded that in 27 patients (13%) dysphagia would likely have been prevented by using a retrosternal reconstruction route.[213] However, the site of the obstruction that produced dysphagia was not clearly stated. The stomach is usually spacious and tumor infiltration will not readily result in dysphagia. Only at the thoracic inlet and in the cervical region, where there is limited space, can tumor involvement lead to obstruction. Using the retrosternal route will eliminate tumor involvement in the posterior mediastinum, but infiltration from tumors in the neck cannot be avoided. The benefits of choosing the retrosternal route in reducing secondary dysphagia from recurrent tumor infiltration may be overemphasized. In our own study, only 4 out of 28 patients (14%) developed tumor infiltration into the gastric conduit in the posterior mediastinum. The main symptom was bleeding

in two patients and none had dysphagia.[214] It is our policy therefore to only use the retrosternal route for reconstruction when resection is palliative, especially when postoperative radiotherapy is planned, or when the reconstructive phase of the operation precedes tumor resection.

PERIOPERATIVE CARE AND POSTOPERATIVE MORBIDITY AND MORTALITY

With adequate preoperative workup, serious cardiac events like myocardial infarction should be rare. Atrial arrhythmia is common, affecting about 20% of patients. In itself, atrial fibrillation is benign; rather it serves as a marker for more serious underlying pulmonary and septic surgical complications.[215] Occurrence of atrial arrhythmia should prompt thorough search for a more ominous underlying cause.

Pulmonary complications remain the most common and serious postoperative morbidity. Major complications can affect 30% of patients; most series report a rate of about 20%.[216] Pneumonia and respiratory failure occurred in 15.9% of our patients and were responsible for 55% of hospital deaths. Predictive factors include advanced age, supracarinal tumor location (in part related to recurrent laryngeal nerve injury), and lengthy operating time. Neoadjuvant therapy did not lead to increased morbidity.[112] Measures to improve respiratory outcome include cessation of smoking preoperatively, chest physiotherapy, avoidance of recurrent laryngeal nerve injury, cautious fluid administration to avoid fluid overload, use of smaller chest tubes,[217] early ambulation, regular bronchoscopy, and early tracheostomy for sputum retention.[218] Epidural analgesia is invaluable in postoperative pain relief and has been shown to improve outcomes.[153]

The most common surgical complication after esophagectomy is still anastomotic leak and can reach 30%,[219] although in experienced centers leak rates of below 5% can be achieved. Most leaks are probably related to technical errors,[118,220] such as tension between the conduit and the esophageal stump, ischemia of the conduit because of rough handling and poor preparation, and suboptimal technique. The intrinsic vascular perfusion of the stomach can be enhanced by certain methods, such as "ischemic preconditioning," whereby partial mobilization of the gastric conduit is followed by a second stage-anastomosis later. The perfusion of the stomach could be shown to improve in the interim period.[221] Although an interesting concept and potentially useful, the existing wide range of reported leak rates (from 2–3 to 30%) suggests that much improvement is possible by other means, even without ischemic conditioning. It would be ideal if one could identify the right patients on whom to perform ischemic conditioning pre- or intraoperatively, so that such elaborate preparation can be selectively applied.

The actual method of anastomosis is perhaps less important than its proper application. Stapled anastomosis is popular for intrathoracic anastomosis while the hand-sewn technique is preferred in the neck. There is no evidence from randomized trials that leak rates differ between stapled and hand-sewn anastomoses, but the circular stapler may give rise to more strictures.[222] The linear stapler has also been advocated in the neck. One group reduced their cervical leak rate from 10 to 15% using a hand-sewn technique to 2.7% using linear staples with a side-to-side anastomosis.[223] With experience, however, the hand-sewn method is as safe, if not more so, and certainly less expensive.

As mentioned already, technical variables play an important role in the genesis of postoperative complications. Anastomotic leaks (largely technical) and recurrent laryngeal nerve injury, for instance, are related to higher incidences of postoperative pulmonary morbidities. At the author's center, pulmonary complications occurred in 10% of patients without technical complications, and in 38% of patients who developed such morbidities, and mortality rates were 3.3 and 9.2%, respectively.[224] Multivariate analyses also demonstrated that a long operating time was related to pulmonary complications, and increasing intraoperative blood loss was related to postoperative mortality.[112] In sum, the meticulous and expeditious execution of an esophagectomy and its subsequent reconstruction are of paramount importance in lessening complication and mortality rates.

Vigilant and aggressive treatment of complications is important for good outcomes. Management of complications has improved with time. At the author's unit, anastomotic leak rate was 16% in the 1960s to 1970s, 61% of whom died, resulting in a leak-related mortality of 9.8%.[225] In the 1980s the leak rate was 3.5%, of whom 35% died, a leak-related mortality of 1.2%,[220] while in the late 1990s leak occurred in 3.2% of patients and none died as a result.[226]

Other surgical complications like chylothorax and herniation of bowel through the diaphragmatic hiatus are rare but should be recognized early; both are corrected by surgical reexploration.

Combined Multimodal Treatment Strategies

The past two decades have seen a proliferation of additional treatments for esophageal cancer. The rationale is based on the suboptimal long-term results of surgery or radiotherapy. Both the spatial and synergistic actions of chemotherapeutic agents and radiotherapy are explored in multimodality treatments. How surgical resection and these new combinations should be integrated into treatment programs is an active area of research.

NEOADJUVANT RADIOTHERAPY

Trials of neoadjuvant radiotherapy have failed to show increased resection rate or improved survival compared with surgery alone.[227–232] The European Organization for Research and Treatment of Cancer (EORTC) study suggested improved local disease control but no better long-term outcome.[229] One study, which also involved chemotherapy, suggested a survival advantage imparted by preoperative radiotherapy but only in the pooled groups of patients receiving radiotherapy.[232] A Cochrane meta-analysis showed that if preoperative radiotherapy regimens do improve survival, the effect is likely to be modest with

an absolute survival benefit of 3% at 2 years and 4% at 5 years that was not statistically significant (p = .062).[233]

ADJUVANT RADIOTHERAPY

Postoperative radiotherapy was studied in three randomized trials[234–236]; all three demonstrated improved local disease control. The largest study randomized 495 patients with intrathoracic squamous cell cancers. Postoperative radiotherapy of 50–60 Gy was given in 220 patients to the entire mediastinum and bilateral supraclavicular fossae. Per protocol, analysis showed no overall difference in 5-year survival at 31.7% for the surgery alone group and 41.3% for the radiotherapy group. A benefit in the radiotherapy group was observed in stage III patients; 5-year survival rates were 13.1 and 35.1%, respectively. In patients with node-positive disease, the difference in survival was of borderline significance. The chance of mediastinal, cervical lymph node and anastomotic recurrence was also reduced.[236] Survival benefit was not demonstrated for the other trials. From these studies it seems reasonable to give postoperative radiotherapy to subgroups of patients, especially those who have palliative resections, to enhance local disease control.

NEOADJUVANT CHEMOTHERAPY

Eleven randomized trials studied the role of preoperative chemotherapy.[232,237–246] The two largest trials were the Intergroup (INT 0113) trial in the United States, and the Medical Research Council (MRC) trial in the United Kingdom (Table 17-9). The first study randomized patients to undergo surgery alone, or to have three cycles of cisplatin and 5-fluouracil before surgery, and in those who had stable or responsive disease, two additional postoperative courses.[245] Of 440 eligible patients, 213 were assigned to the neoadjuvant group. The median survival was 14.9 months for the chemotherapy group compared with 16.1 months for the surgery group. Two-year survival rates were no different at 35 and 37%, respectively. The MRC trial (OE02) involved 802 patients and similar preoperative regimens with two courses of cisplatin and 5-fluouracil.[246] Overall survival was better in the chemotherapy group. Median survival was 16.8 versus 13.3 months, and 2-year survival rates were 43 and 34%. Recently the long-term follow-up data were presented; with a median follow-up is of 6 years and 93% of patients followed to 5 years or death, 5-year survival rates were 23% in the chemotherapy group compared with 17% in surgery group. Benefits were evident for both squamous cell cancer and adenocarcinoma.[247]

Many differences between the two studies could explain the different outcomes, including the chemotherapy regimen, distribution of histologic cell types (66% adenocarcinoma in MRC and 54% in INT trials), number of patients who underwent resection, time to resection, type of surgery performed, and number of patients who also had radiotherapy. The larger sample size in the MRC trial also could have facilitated the detection of a small improvement with chemotherapy.

A Japanese study conducted by the Japanese Clinical Oncology Group (JCOG 9907) randomized 330 patients with stage II/III squamous cell cancers (excluding T4 disease) comparing two courses of preoperative cisplatin and 5-fluorouracil to a similar regimen given after esophagectomy. Overall 5-year survival was significantly better at 60% in the preoperative chemotherapy group compared to 38% in the postoperative group.[248] Although this trial did not specifically compare preoperative chemotherapy to surgical resection

alone, this has quickly become a standard-of-care treatment in Japan. In the United Kingdom, the MRC OE02 trial has also established preoperative chemotherapy as a widely practiced strategy. Another ongoing trial (OE05) compares the OE02 preoperative chemotherapy regimen with four courses of preoperative epirubicin, cisplatin, and capecitabine (ECX) in treating patients with adenocarcinoma of the esophagus and GEJ. Accrual was planned for 1300 patients.

The Medical Research Council Adjuvant Gastric Infusional Chemotherapy (MAGIC) trial, a randomized study, included 503 patients with adenocarcinoma of the stomach, GEJ, and the lower esophagus. Initially planned for gastric cancers, eligibility criteria were extended to include lower esophageal adenocarcinoma coinciding with termination of OE02. Thus 14% of patients had lower esophageal tumors, and another 12% had GEJ tumors. Three courses of epirubicin, cisplatin, and infused fluorouracil (ECF) were given to patients before surgery, and three courses were repeated afterward, comparing this to patients undergoing surgical resection alone. Both progressive-free and overall survival rates were improved in the chemotherapy group.[249]

A recent individual patient data-based meta-analysis on nine randomized trials (2102 patients) showed a statistically significant overall survival benefit in favor of preoperative chemotherapy translating into a 5-year absolute increase of 4% (from 16 to 20%). Disease-free survival and curative resection rates were also improved.[250] Similar benefits were demonstrated by another meta-analysis, with a 2-year absolute survival benefit of 7%. However, adenocarcinomas may benefit more than squamous cell cancers.[251]

ADJUVANT CHEMOTHERAPY

This is an area perhaps least well studied, and trials on pure postoperative chemotherapy are limited. JCOG 9907, mentioned in the previous section, was in fact a follow-up study on JCOG 9204, which randomized 242 patients comparing surgical resection with the addition of two courses of postoperative cisplatin and 5-fluouracil.[252] The 5-year disease-free survival rate was significantly different at 45% with surgery alone and 55% with surgery plus chemotherapy. The overall 5-year survival rates were not significantly different at 52 and 61%, respectively. The effect was more marked in the subgroup with lymph nodes metastases.[252] However, another small French study also using cisplatin and 5-fluouracil as adjuvant therapy did not show any advantage with chemotherapy.[253]

NEOADJUVANT CHEMORADIATION

Several groups have explored chemoradiation as neoadjuvant therapy (Table 17-10).[232,254–261] The radiation dose ranged from 20 to 45.6 Gy. In five trials, only squamous cell cancers were recruited[232,254,255,257,258]; three included mostly adenocarcinomas[259–261] and one treated adenocarcinomas only.[256] A survival advantage with neoadjuvant chemoradiation over surgery alone was demonstrated only in two trials.[256,260] The trial reported by Walsh and colleagues on adenocarcinomas only has been criticized because of inadequate preoperative staging, unclear surgical procedures, and the large number of protocol violations, and survival from the surgery group was exceptionally poor (3-year survival rates were 32 and 6% for the preoperative treatment group compared to surgery alone).[256] In CALGB 9781, 475 patients were planned, but the trial was terminated after 56 patients because of poor accrual. Nevertheless, a survival advantage was seen in the chemoradiation group; median survival was 4.5 versus 1.8 years and 5-year survival was 39 versus 16%.[260] However, the statistical analyses of the trial were much criticized.[262]

The results from these studies are conflicting and thus inconclusive. Several meta-analyses have addressed the role of neoadjuvant chemoradiation.[251,263–267] The latest published meta-analysis included the randomized trials comprehensively; 10 studies included 1209 patients. The hazard ratio for all-cause mortality with neoadjuvant chemoradiation versus surgery alone was 0.81 (95% CI 0.70–0.93; p = .002), corresponding to a 13% absolute difference in survival at 2 years, with similar results for different histological tumor types: 0.84 (0.71–0.99; p = .04) for SCC and 0.75 (0.59–0.95; p = .02) for adenocarcinoma.

Although it cannot be said conclusively that neoadjuvant chemoradiation therapy is superior to surgery alone in the treatment of localized esophageal cancer, it is widely practiced, especially in the United States. Neoadjuvant chemoradiation therapy does result in more pathological complete responses compared with chemotherapy (25–30% vs <10%). One recent trial compared preoperative chemotherapy with preoperative chemoradiation therapy in advanced adenocarcinoma of the lower esophagus and GEJ. More pathological complete responses were observed in the chemoradiation group (16 vs 2%), and more patients had negative nodal involvement (64 vs 38%). A trend toward improved median survival (32.8 vs 21.1 months) and 3-year survival (47.4 vs 27.7%) were also seen, though these did not reach statistical significance.[268]

DEFINITIVE CHEMORADIATION

The Radiation Therapy Oncology Group (RTOG 85-01) trial of chemoradiation versus radiotherapy provided convincing evidence of the superiority of chemoradiation.[269]. The 5-year survival rate reported for the combined therapy group was 26% compared to 0% following radiotherapy (median survival 14 vs 9 months). Data on recurrence patterns showed that both local and distant disease control were superior with combined treatment. Local persistence of disease and recurrence were 47% compared to 65%. Intensification of radiation dose to beyond 50.4 Gy, whether by external beam[270] or by brachytherapy,[271] did not yield further advantage but potentially added complications.

A Cochrane meta-analysis on 13 randomized trials that compared chemoradiation with radiation confirmed the superiority of chemoradiation. Concurrent chemoradiation provides a significant overall reduction in mortality at 1–2 years, an absolute

reduction in death rate by 7%, and a reduction in local persistence/recurrence rate by 12%. The downside is a 17% increase in grades 3–4 toxicities. Sequential chemoradiation provides no benefit, perhaps demonstrating the need to maximize the radiosensitizing properties of chemotherapy.[272]

THE ROLE OF SURGERY

The RTOG trial suggested that, in patients with T1-3 N0-1 M0 disease a 14–26% 5-year survival can be expected. It has been suggested that surgery may be of no additional value to chemoradiation and should be relegated to use as an adjuvant treatment.

Two clinical trials attempted to examine whether surgical resection was necessary after chemoradiation. A French study (FFCD 9102) treated 444 patients with both squamous cell cancers and adenocarcinomas of stage T3-4 N0-1 M0 with two cycles of 5-fluouracil, cisplatin, and concurrent radiation (46 Gy at 2 Gy/d or split course 15 Gy weeks 1 and 3). Only 259 patients who had at least a partial response were randomized to undergo immediate surgery or to have three more cycles of chemotherapy with 20 Gy at 2 Gy/d or split course 15 Gy. The death rate within 3 months after starting induction treatment was 9% for surgery group compared with 1% in the chemoradiation group. Two-year survival rates were not different at 34 and 40%, so were median survival at 17.7 and 19.3 months for surgical and nonsurgical groups, respectively. Patients in the surgical arm, however, required stenting less often (13 vs 27%) or dilations (22 vs 32%).[273] There was no difference in the long-term quality of life, but the surgery arm had transient deterioration in the immediate postoperative period.[274]

A German multicenter trial recruited 172 patients with squamous cell cancers (T3-4 N0-1 M0). Three cycles of

5-fluouracil/leucovorin/etoposide/cisplatin were given followed by chemoradiation (cisplatin/etoposide + 40 Gy). Resection was then performed. This was compared to a control group with the same chemotherapy, followed by definitive chemoradiation (cisplatin/etoposide + >60 Gy).[275] Long-term data from this trial were presented recently.[276] A nonsignificant trend toward better overall survival at 5 and 10 years was observed: 27.9 and 19.2% in the resection group, compared to 17.0 and 12.2% in the chemoradiation alone group. Local tumor control was significantly worse in the nonsurgical arm. Three-year survival rate was 35% in nonresponders undergoing complete tumor resection compared to 11% in nonresponders who did not undergo resection. Both the French and German studies concluded that surgical resection may not be necessary after chemoradiation therapy.

It may be premature to negate the value of surgical resection. First, chemoradiation is by no means harmless, and surgical resection may not be as morbid as described. Treatment duration of chemoradiation is often long and compliance is problematic. Only 68% of the patients in the RTOG-8501 trial could complete the planned treatment.[269] In the control arm of INT 0123, acute grades 3 and 4 toxicity affected 43 and 26%, respectively, and long-term grades 3 and 4 toxicity affected 24 and 13% of patients, respectively.[270] Treatment-related mortality was 5–9% as reported by the INT trials.[270,277] In studies that showed a benefit for chemoradiation or questioned the value of surgical resection, the results of the surgical arm were often suboptimal. In the FFCD 9102 trial, death rate within 3 months in the surgical arm was 9% compared to 1% in the nonsurgical arm[273]; in the German trial again the mortality rates were 10 and 3.5%, respectively.[276] The early surgical deaths likely biased the long-term survival results. Comparisons with nonoperative treatments will only be valid when better results from high-volume centers are integrated into clinical trials.

Second, local disease control with chemoradiation alone is less than satisfactory. It can be shown that with increasing extent of lymphadenectomy, better local control is achieved with surgery; by comparison, nonoperative chemoradiation has a much higher local persistence/recurrence rate of over 50%.[270] The relief of dysphagia, the main symptom requiring palliation, is much more certain with surgical resection; the need to treat dysphagia with a stent was twice in the nonsurgical group in the FFCD 9102 trial.[273]

Third, residual disease exists for the majority of patients treated by chemoradiation. The pathological complete response rate for most trials is in the region of 25%. Thus it is logical to assume that surgical resection would enhance cure at least in the remaining 75%, who did not completely respond. In the German trial, the 3-year survival of nonresponding patients who underwent resection was 35% compared with 11% in those who did not.[276] In the FFCD 9102 trial, 192 patients were not randomized primarily because of lack of objective response but also because of medical contraindications or patient refusal. Out of these, 112 patients had operations; among these 80 had R0 resection (42%). The median survival for the patients who underwent surgery was 17.3 versus 6.1 months for those who did not, and was comparable for those who were randomized. The data suggest that salvage surgery could benefit a subset of patients who do not respond to initial therapy.[278] Conversely, the role of surgery is less obvious in those with a complete response. However, ascertaining true complete response is difficult, whether by endoscopy, EUS, or CT scanning.[279,280] Recent studies using 18-FDG-PET scans show promise,[82,281] but, while PET scan can more reliably distinguish responders and nonresponders, it is not accurate enough to pinpoint the complete pathological responders.[282]

PREDICTION OF RESPONSE AND RESPONSE-DIRECTED THERAPY

Reliable predictors for response to chemoradiation would be useful, because multimodality treatments are toxic, time consuming, and costly. Various markers have been explored, such as simple histology,[283] proliferative cell nuclear antigen (PCNA), epithelial growth factor (EGFR), Ki-67, cyclin D1, thymidylate synthase, and microvessel density, both in tissue and serum. To date none have been proven to help clinical decision making.[284]

Metabolic imaging with PET scan has some promise. The degree of response detected by PET imaging has been shown by many studies to correlate with pathological response after chemotherapy or chemoradiation therapy (Fig. 17-16).[82,281]

The MUNICON (the Metabolic response evalUatioN for Individualization of neoadjuvant Chemotherapy in oesOphageal and oesophagogastric adeNocarcinoma) trial evaluated patients with locally advanced adenocarcinoma of the distal esophagus or type II cardia tumors undergoing neoadjuvant chemotherapy. Early metabolic response was defined as a reduction of 35% or more in the mean glucose standard uptake value (SUV) measured by serial PET scans at the beginning and at 2 weeks after commencement of treatment. Responders carried on chemotherapy for an additional 12 weeks before resection, while nonresponders went directly to immediate surgery. Out of 119 patients, 110 were evaluable for metabolic responses, of whom 54 (49%) were responders. Significantly improved R0 resection rate (96 vs 74%), major pathological response rate (defined as <10% residual tumor) (96 vs 0%), longer median event-free survival (29.7 vs 14.1 months), and median overall survival (median not reached versus 25.8 months) were found for metabolic responders versus nonresponders. More importantly, the outcomes for nonresponders were not different from previous results in such patients who completed 3 months of chemotherapy, indicating that such a strategy did not compromise these patients and could save them from suboptimal chemotherapy.[285]

The same investigators reported on their MUNICON-2 trial recently. Metabolic nonresponders as defined in MUNICON were switched to chemoradiotherapy (both chemotherapy and chemoradiotherapy were cisplatin-based). Out of 32 patients recruited, 13 (41%) were metabolic nonresponders. Subtotal histologic response (<10% residual tumor) following chemoradiotherapy was reported in three patients (23%), but no complete responses was observed. In contrast, complete histological response rate in metabolic responders were seen in 16%. Higher

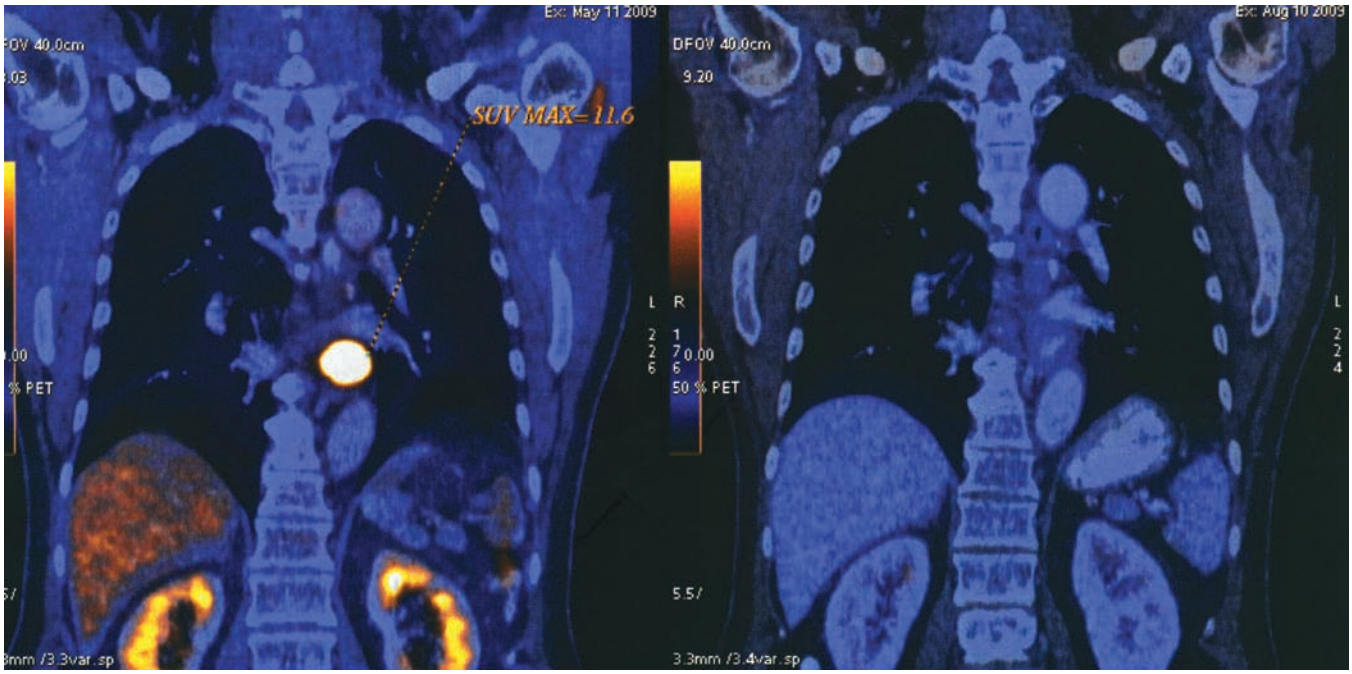

FIGURE 17-16 PET/CT before **(A)** and after **(B)** chemoradiation therapy; the tumor has become completely eumetabolic.

rates of R1/2 resections were also observed for nonresponders (31 vs 16%). One-year progressive-free survival was also inferior (46 vs 63%). The study suggested that merely adding radiotherapy to the same cisplatin-based chemotherapy in nonresponders was only marginally better.[286] Another strategy may be to switch to alternative, non–cross-resistant chemotherapy during radiation.

It seems that cisplatin and 5-fluouracil–based chemoradiation therapy has reached its therapeutic limit in treating esophageal cancer. More novel chemotherapeutic agents are being explored, including paclitaxel, docetaxel, the topoisomerase I inhibitor irinotecan (CPT-11), vinorelbine, gemcitabine, Herceptin (trastuzumab), oxaliplatin, and biomodulators such as interferon or targeted therapies with bevacizumab or cetuximab. This remains a very active area of research. In addition, advances in techniques in radiation delivery, such as intensity-modulated radiotherapy, may further reduce radiation toxicity.[287]

Endoscopic Palliation

Endoscopic palliative treatments for more advanced tumors include placement of an esophageal prosthesis, laser therapy, intralesional injection of various substances, and PDT. The most commonly employed technique is perhaps insertion of a prosthesis, especially self-expanding metallic stents (SEMS) (Fig. 17-17). The smaller diameter of the delivery mechanism makes aggressive dilation of the tumor before insertion unnecessary. These stents are more flexible than conventional plastic prostheses; membrane-covered versions

FIGURE 17-17 A self-expanding metallic stent (SEMS) in situ.

have been developed to seal esophagoairway fistulae and prevent tumor ingrowth. Three randomized trials were reported comparing the use of metallic stents with plastic prostheses. Perforation, pneumonia, bleeding, or migration rates were significantly less with metallic stents. Because of the lower morbidity, metallic stents were also more cost-effective despite their higher initial cost.[288–290] The choice of various metallic stents depends on their individual characteristics, in terms of flexibility, tensile force, and degree of shortening on deployment in relation to the site of placement. Compared with more conventional methods of palliation such as laser therapy, patients with SEMS spent less time in the hospital and required less frequent reinterventions.[291]

The main problems with SEMS are stent migration, tumor ingrowth or overgrowth, and, if placed across the GEJ, they allow acid reflux. Placing uncovered stents across the cardia lessens the chance of migration, and stents have been developed with a one-way flap valve to prevent reflux.[292] It has also been shown that "tumor" ingrowth is sometimes due to granulation tissue or hyperplastic reaction by the esophageal mucosa.[293] Patency can be achieved again by laser, argon beam application, or sometimes placement of a second stent within the first. One recent randomized trial compared the use of the Ultraflex stent (Boston Scientific, MA) with the Polyflex stent (Boston Scientific, MA), and the Niti-S double stent (Taewoong Medical, Seoul, Korea). The Polyflex stent is a silicone device with an encapsulated monofilament braid made of polyester. The silicone and polyester material is designed to lessen nontumoral tissue overgrowth, a problem common with SEMS. The Niti-S stent has an inner polyurethane layer over its entire length, and an outer uncovered nitinol wire tube to allow the mesh to embed itself in the esophageal wall. Success rates were similar for all three stents, but recurrent dysphagia was more common with the Ultraflex stent, because of tissue ingrowth and overgrowth, and, to lesser degree, the Niti-S stent. Polyflex stent had a higher chance of migration, not surprisingly, because the stent is also designed to be removable in benign esophageal stenosis.[294]

Another problem of stent insertion is for placement near to the upper esophageal sphincter. Foreign body sensation, pain, odynophagia, and airway compression can be troublesome and demand accurate placement. This is illustrated in the situation when recurrent disease is found at the anastomosis or in the esophageal remnant after subtotal esophagectomy. Placement of SEMS is still possible and achieves good palliation.[295]

SUMMARY AND FUTURE PERSPECTIVES

Advances have been made in the management of esophageal cancer; survival of patients has improved.[296] The key is to select the most appropriate combination for individual patients. Surgeons play a central role in directing management treatment of this disease by advising on how best to integrate surgical resection with nonoperative programs. Surgeons should aim at improving their results further, so that low mortality rates for resections are used to compare with seemingly safer therapies. The technique and extent of surgical resection may change when more information is made available, and should vary with patients and disease stage. MIE will be more widely practiced; it should achieve the same radicality of operation with less morbidity. Chemoradiation therapy has made a real impact on current management strategies,[296] but perhaps its overenthusiastic adoption and its presumed benefit have to be balanced against the lack of clear evidence of superiority over surgery.[297] Distant failure remains a major problem, and search for more effective systemic drugs as well as our ability to predict responders with precision must be therapeutic targets. Management strategies are going to evolve further, with improvements in molecular techniques, imaging methods, and introduction of more novel tumoricidal agents. The challenge for the future is for us to critically test our strategies in a scientific, unbiased manner, and to explore other innovative treatments.

SURGICAL PROCEDURES TO RESECT AND REPLACE THE ESOPHAGUS

Jon O. Wee • David J. Sugarbaker

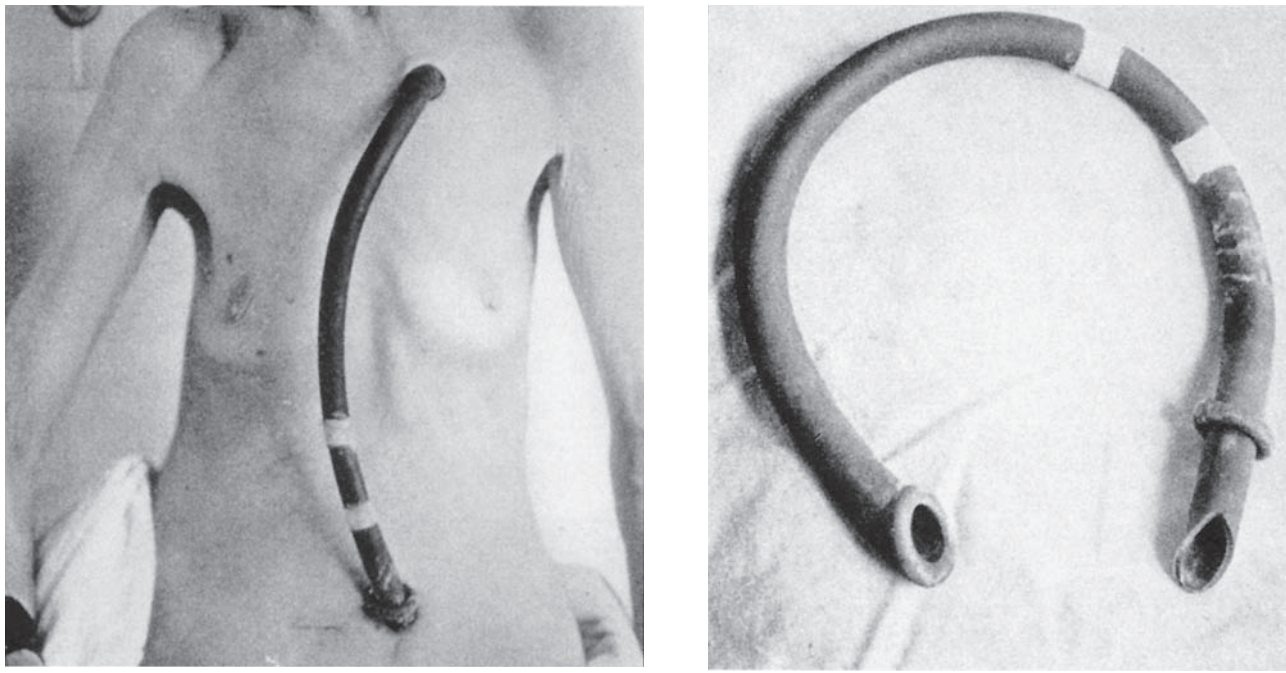
Billroth and Czerny described the first esophageal resections in the 1870s, and they consisted of resections of the cervical esophagus without reconstruction. Later, resection of gastroesophageal (GE) junction tumors was performed by laparotomy with gastroesophageal anastomosis to reestablish intestinal continuity. Because there were concerns over respiratory compromise, surgeons were hesitant to enter the chest to perform esophageal resection. In 1915, Torek described the first transthoracic esophageal resection.[1] He used a left thoracotomy to resect the esophagus but did not attempt reconstruction. Instead, a cervical esophagostomy and abdominal gastrostomy were performed. A 3-ft-long external rubber tube was used to connect the ostomies, and it allowed the patient to eat for 17 more years (Fig. 18-1). Turner performed the first transhiatal esophagectomy in 1933.[2] Oshawa reported the first transthoracic resection of the esophagus with esophagogastric anastomosis in 1933.[3] Knowledge of this procedure did not become widespread in the Western community until Adams and Phemister described the procedure in 1938.[4]

Ivor Lewis is credited with popularizing transthoracic resection of the esophagus. Initially, he performed the procedure in two stages: first, mobilizing the stomach via laparotomy and several days later resecting the intrathoracic esophagus and reconstructing with the stomach. The Ivor Lewis approach, which is an upper midline laparotomy for mobilization of the gastric conduit followed by right thoracotomy for resection and reconstruction, and the transhiatal approach are currently the two most commonly used techniques of esophageal resection. In 1962, McKeown described a tri-incisional approach. He used a right thoracotomy to mobilize the esophagus. The patient was then repositioned in the supine position, the gastric conduit was mobilized by laparotomy, and the anastomosis was performed in the neck.[5] Minimally invasive options for surgical resection have also become increasingly popular.[6,7] Combined thoracoscopic and laparoscopic techniques in some combination with open techniques have created a wider hybrid experience and are discussed in other chapters.

NEOADJUVANT TREATMENT

Historically, surgery has been the primary mode of treatment for localized esophageal cancer. Nonetheless, the long-term results of surgery alone for esophageal cancer are disappointing.[8] Preoperative chemoradiation has been proposed as a means of improving long-term survival. Eight randomized trials have been performed using preoperative chemoradiation. Although the two largest randomized trials comparing preoperative chemoradiation followed by surgery to surgery alone showed no difference in survival,[9,10] two smaller randomized trials have been used to support the use of preoperative chemoradiation. Urba and colleagues looked at 100 total patients randomized to preoperative chemoradiation or surgery alone.[11] Median survival was about 18 months in both groups, although there was a trend toward improved survival at 3 years (30 vs 16%; not statistically significant). Walsh and associates randomized 113 patients, and at 3 years 32% of those receiving preoperative chemoradiation were alive versus 6% of those undergoing surgery alone.[12] This study, however, has been heavily criticized for its lack of adequate pretreatment staging as well as a very poor survival in the surgical arm that is far below all other reported series. Hence, although there are no definitive data to support the use of chemotherapy and radiation in the neoadjuvant setting, it remains widely used.

CALGB 9781 (Cancer and Leukemia Group B 9781) was a prospective randomized intergroup trial that evaluated patients with stages 1–3 esophageal cancer. Patients were randomized to surgery alone or to preoperative cisplatin and 5-FU with concurrent radiation (50.4 Gy) followed by surgery. Poor accrual resulted in premature closure of the study with 56 patients, well short of its goal of 500 patients. Nonetheless, with median follow-up of 6 years, 5-year survival was 39% for the trimodality group versus 16% for the surgery-alone group. Median survival was 4.5 years for the trimodality group versus 1.8 years for the surgery-alone group (p = .02).[13] A meta-analysis by Urschel and Vasan in 2003



A B

FIGURE 18-1 **A.** Depiction of Torek's first patient after esophageal resection. The rubber tube connected the lower end of the esophagus with a gastrostomy. The patient lived 17 years after the surgery and died at age 80. **B.** Removable rubber tube conduit with beveled ends. (Reproduced, with permission, from Torek F. The operative treatment of carcinoma of the esophagus. *Ann Surg* 1915;61:385.)

combined the results of over 1100 patients from nine randomized controlled studies comparing neoadjuvant chemoradiotherapy followed by surgery versus surgery alone. This study did favor neoadjuvant chemoradiotherapy with surgery over surgery alone.[14]

There is substantial comparative evidence of the benefit of neoadjuvant chemotherapy for locally advanced esophageal cancer. The MRC (Medical Research Council) trial of 2002 demonstrated a statistically significant survival benefit (43 vs 34%) in those patients who received preoperative chemotherapy with an increase in median survival from 13.3 to 16.8 months.[15] This report was followed by the MAGIC (Medical Research Council Adjuvant Gastric Infusional Chemotherapy) trial in 2006, which further demonstrated an improved survival in patients with GE junction adenocarcinoma at 2 years (50 vs 41%) and at 5 years (36 vs 23%).[16] A head-to-head comparison of neoadjuvant chemotherapy versus neoadjuvant chemoradiotherapy by the German Esophageal Cancer Study Group did not demonstrate any improved ability to achieve R0 resection with the addition of x-ray therapy (XRT).[17] The study was underpowered, but there was a trend toward increased mortality in the radiation arm. Paradoxically, there also was a trend toward improved survival with the addition of radiation, although this finding was not statistically significant. Unfortunately, no clear determination was made regarding which method is better. The relatively low incidence of esophageal cancer, the variable response to treatment between squamous cell carcinoma and adenocarcinoma, and the regional practice patterns make a large, randomized study difficult to envision.

STAGING

It is important to recognize those patients with stage IV disease because the mean survival in these patients is 6–10 months. In the past, palliative esophagectomy was often thought necessary to restore swallowing and oral nutrition. With advances in photodynamic therapy, expandable endoscopic stents, and other endoluminal therapies, it is unusual for anyone to require esophageal replacement to reestablish swallowing ability. Hence, stage IV patients should be spared the perioperative mortality, morbidity, and recovery time associated with esophagectomy. The appropriate use of neoadjuvant treatment requires accurate staging. Patients with nodal involvement, invasion through the esophagus, or possibly even invasion into the muscularis often undergo preoperative chemoradiation, while patients with simple mucosal involvement generally proceed directly to surgery.

The main staging modalities available today are computed tomography (CT) scan, positron emission tomography (PET) scan, and endoscopic ultrasound (EUS). CT scans are used mainly for detecting distant metastases in the lungs, liver, or other remote sites, including the brain. CT scan may be useful for excluding T4 tumors if a fat plane can be demonstrated between the adjacent structure and the esophagus.

Such staging is often not possible if the patient is severely cachectic or if there are no natural fat planes, such as that between the trachea and esophagus. In regard to nodal status, CT is not as sensitive or as accurate as EUS.

PET scan is superior to CT scan for detecting distant metastatic disease. In a series of 91 patients, CT scan had a sensitivity of 46%, a specificity of 74%, and an overall accuracy of 73%. In contrast, PET scan had a sensitivity of 69%, specificity of 93%, and overall accuracy of 84%. All metastases that were missed by PET were less than 1 cm in size.[7] Other studies have shown similar results.[18,19] In addition, PET scan may aid in the diagnosis of primary tumor where it may be difficult to perform biopsy because of obstruction. Conversely, a certain percentage of nonbulky tumors of the esophagus may be PET-negative.

EUS gives detailed images of the esophageal wall and nearby structures (Fig. 18-2). Accurate identification of the layers of the esophageal wall is possible. Muscle layers tend to be hypoechoic with intervening hyperechoic mucosal layers. The first hyperechoic layer and second hypoechoic layer correspond to the mucosa and muscularis mucosa. The third hyperechoic layer is submucosa. The fourth hypoechoic layer is the muscularis propria, and the fifth hyperechoic layer is the outside of the esophagus. Tumor infiltration of the wall disrupts the normal-layered appearance, and extent of penetration is usually clearly visible. EUS has an overall accuracy of 80–90% in ascertaining T status. The differentiation between T1 and T2 is most difficult. In addition, biopsy of deeper layers of tumor not accessible by traditional grasping forceps is possible. It should be noted that EUS is not accurate in defining postneoadjuvant treatment T status because of fibrosis induced by the chemoradiation.

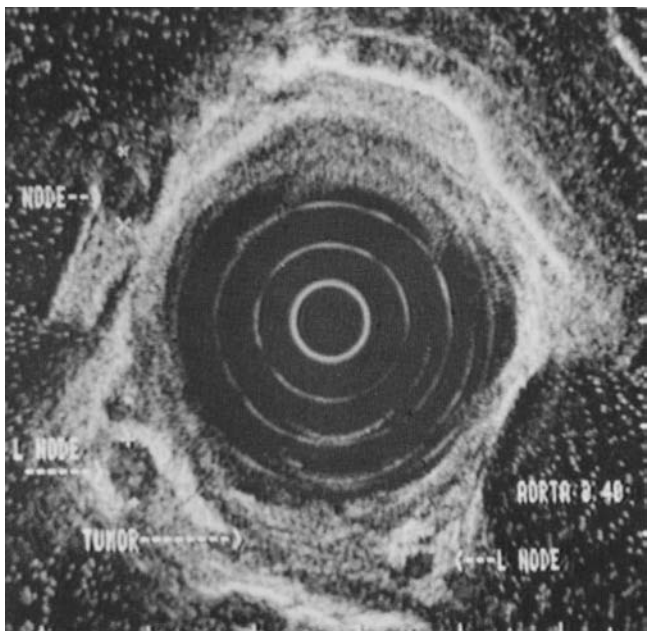


FIGURE 18-2 Endoesophageal ultrasound image of an adenocarcinoma of the esophagus (T3) and multiple lymph nodes suspicious for metastatic disease (N1). (Reproduced with permission from Van Dam J, Sivak MV, Catalano MF, et al. High-grade malignant stricture is predictive of esophageal tumor stage: risks of endosonographic evaluation. *Cancer*. 1993;May 15: 71(10):2910–2917.)

Nodal status is determined by examining four characteristics. Malignant nodes tend to be round and hypoechoic. They have discrete borders and are larger than 1 cm in size. Nodes that meet such criteria have a 90% chance of being malignant. Fine-needle aspiration (FNA) further increases the accuracy in determining nodal status. If the tumor is from a node, the cytopathologist should be able to identify lymphoid tissue in the specimen. False positives can result with FNA if the needle passes through the primary tumor. The accuracy of EUS in N-status staging is between 70 and 80%. EUS is 10–15% more accurate than CT scan.[20]

Developments in EUS and PET scanning have lessened the enthusiasm for pre-resection operative staging of esophageal cancer patients. Operative staging involving laparoscopy and thoracoscopy is more invasive but may be superior to EUS. Luketich and associates studied 26 patients and detected N1 disease in a considerable number of patients staged NO by EUS.[21] It should be noted, however, that the sensitivity of EUS in this series was only 60%, considerably lower than that described in other series. In addition, 15% of patients with no radiographic metastatic disease were found to have liver metastases by laparoscopic staging. The average cost of surgical staging was $20,000–$25,000 versus $2000 for EUS.

A common algorithm used in staging patients includes endoscopy for primary diagnosis, CT scanning with PET to evaluate for metastatic disease, and EUS if the patient is an operative candidate and neoadjuvant therapy is considered. In cases of esophageal obstruction, where EUS scanning is known to be less accurate, the incidence of lymph node metastasis is very high (90%) and neoadjuvant therapy should be considered.

APPROACH TO THE CERVICAL LESION

The treatment of a cancer of the cervical esophagus is challenging and requires a multidisciplinary approach involving an otorhinolaryngologist, a thoracic surgeon, and occasionally a plastic surgeon. Frequently, radiation will be required preoperatively to maximize margins and spare the larynx, if possible. The neck incision is made along the anterior border of the sternocleidomastoid muscle and can be extended across the midline if additional exposure is needed. If the tumor is fixed to the spine or neck vessels, the procedure is aborted and palliative radiotherapy is considered. If the larynx is involved, it is removed en bloc with the upper esophagus along with the upper paraesophageal nodes bilaterally. A radical neck dissection is not routinely performed. The dissection spares the jugular vein, sternocleidomastoid muscles, and spinal accessory nerves. The trachea is transected, leaving enough length to allow construction of a permanent end tracheostomy. The endotracheal tube is inserted into the distal trachea and the hypopharynx is divided sharply.

By this point, a separate midline abdominal incision will have been performed, and blunt dissection is begun on the esophagus from the abdomen. A two-team approach should be considered with one team at the neck, while the other prepares the gastric conduit. The gastric conduit is elevated to the neck with traction and the gastroesophageal junction is divided. The pharyngogastrostomy anastomosis is performed using a single-layer, interrupted hand-sewn anastomosis with a nonabsorbable suture. The cervical tracheostomy is performed above the sternal notch. If too much trachea has been resected to allow for this, manubrial resection will permit placement of the end tracheostomy lower in the midline.

STRATEGY FOR LESIONS BELOW THE THORACIC INLET

Lesions below the thoracic inlet can be divided according to their location in the upper esophagus (below the thoracic inlet but above the carina), midesophagus (between the carina and inferior pulmonary vein), or lower esophagus (below the inferior pulmonary vein). While we favor the tri-incisional approach for all malignant lesions (for reasons to be discussed later), lesions in the upper thoracic esophagus generally must be approached with this technique to ensure adequate proximal margins. If the lesion is in the midthoracic esophagus, either the tri-incisional approach or the Ivor Lewis approach may be adequate. Lower esophageal tumors can be resected with either of these two approaches, or additionally with a transhiatal approach or left thoracotomy and distal esophagectomy. With any resection, accommodation must be made for additional resection with reconstruction if frozen margins are involved with tumor.

Transhiatal Versus Transthoracic Techniques

Numerous retrospective analyses have been performed comparing the transhiatal to the transthoracic (mainly Ivor Lewis) approach. These are summarized in two meta-analyses. Rindani and associates reviewed 44 trials involving either Ivor Lewis or transhiatal esophagectomy that were published in the English language between 1986 and 1996.[22] Overall, the incidence of bleeding, cardiac complications, or pneumonia was no different between the two groups. Differences were seen in the anastomotic leak rate (16% transhiatal vs 10% Ivor Lewis), stricture rate (28% transhiatal vs 16% Ivor Lewis), and incidence of recurrent nerve injury (11% transhiatal vs 5% Ivor Lewis). Mortality was higher after the Ivor Lewis approach (9.5%) than the transhiatal approach (6.3%). Long-term survival was about 25% with either technique. Hulscher and colleagues also performed a meta-analysis of 50 studies published between 1990 and 1999 involving transthoracic and transhiatal resection.[23] Cardiac complications (20 vs 7%), anastomotic leakage (24 vs 7%), and vocal cord paralysis (10 vs 4%) were higher in the transhiatal group as opposed to the transthoracic group. Pulmonary complications (19 vs 13%), in-hospital mortality (9 vs 6%), and operative time (5 vs 4.2 hours) were higher in the transthoracic group. Overall long-term survival was similar between the two groups (23% for transthoracic and 21.7% for transhiatal resections). These reviews are retrospective and nonrandomized, and caution should therefore be used in applying these findings to individual institutions and patients.

Three prospective, randomized trials have been performed comparing transhiatal to transthoracic resection. The first was published in 1993 by Goldmine and associates.[24] Sixty-seven patients younger than 70 years with squamous cell cancer were randomized to Ivor Lewis resection or transhiatal resection. Operative time was longer (6 vs 4 hours) in the Ivor Lewis group. There was no difference in the incidence of pneumonia (20%), anastomotic leak, recurrent nerve injury, bleeding, perioperative mortality, or length of hospital stay. For those patients with nodal disease, however, none of the transhiatal patients was alive at 18 months, while 30% of the transthoracic patients were alive at 18 months.

Chu and coworkers randomized 39 patients with lower-third esophageal cancers to either Ivor Lewis or transhiatal resection.[25] Limitations of the study were small sample size, short follow-up (mean 15 months), and patient exclusions. Patients undergoing neoadjuvant therapy or those with forced expiratory volume in 1 second (FEV_1) less than 70% of expected were excluded. There were no perioperative deaths in either group. Intraoperative hypotension occurred in 60% of transhiatal patients but only in 5% of transthoracic patients. There was no difference in blood loss, pneumonia, or recurrent nerve injury. The mean proximal margin was 3 cm longer in the transhiatal group. No significant difference was seen in tumor recurrence or survival during the brief follow-up period.

A study comparing transhiatal resection to transthoracic, tri-incisional en bloc resection for distal adenocarcinoma of the esophagus or cardia was performed in the Netherlands. One hundred and six patients were randomized to transhiatal resection and 114 patients to transthoracic resection. In-hospital mortality was 2–4% in each group. Chyle leak was higher in the transthoracic resection group (10 vs 2%). Respiratory complications including atelectasis and pneumonia were higher in the transthoracic group (57 vs 27%). Although statistical significance was not reached, 39% of the transthoracic group was alive at 5 years, while only 29% of the transhiatal group survived 5 years.[26] Meta-analyses show that the incidence of bleeding, ischemic cardiac events, and length of stay are not necessarily different between the transthoracic and transhiatal approaches. Placement of the anastomosis in the cervical position appears to increase the risk of recurrent laryngeal nerve injury, anastomotic leak, and stricture. The mortality rate from an anastomotic leak, however, is less than that of a leak in the chest. The transthoracic approach increases operative time and in-hospital mortality.

An update of this study following with a full 5-year follow-up continued to show no statistically significant overall survival in either approach.[27] However, in a subgroup of patients who had one to eight positive lymph nodes in the resection specimen, the transthoracic approach (TTE) demonstrated improved overall survival compared with the transhiatal approach (THE) (39% TTE vs 19% THE, $p = .05$). Disease-free survival was similarly improved with the transthoracic approach (64% TTE vs 23% THE, $p = .02$).

The randomized trials show no statistically significant difference in survival, but they are small, and trends toward improved survival are observed in patients undergoing transthoracic dissection. No difference in mortality, blood loss, or incidence of pneumonia was detected. It should also be noted that unlike the meta-analyses, the randomized trials showed no difference in recurrent nerve injury or anastomotic leak. This is a testament to the importance of experience and volume in preventing these complications. Wong noted intraoperative hypotension in 60% of transhiatal dissections, but in only 5% of transthoracic dissections.[28] This finding confirms every surgeon's experience with transhiatal resection. While some may argue that transhiatal dissection may be less taxing on an elderly or debilitated patient (either because of shorter operative time or avoidance of a thoracotomy), the operation may be more taxing to a patient with severe cardiac valvular or atherosclerotic disease who cannot tolerate fluctuations in blood pressure. In these patients, transthoracic esophagectomy is safer.

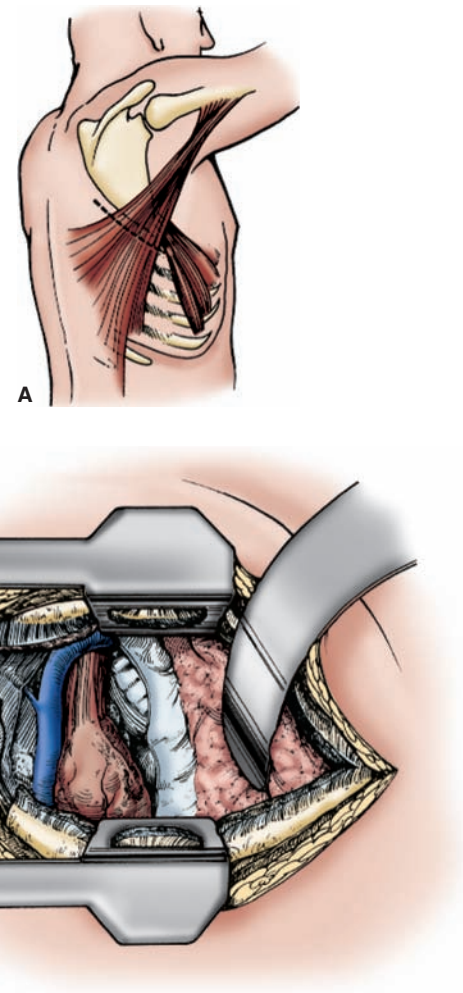

FIGURE 18-3 **A.** The right chest has been entered through the fifth interspace. A piece of the posterior sixth rib has been "shingled" to aid in exposure. The lung is retracted anteromedially, and the mediastinal pleura has been incised posteriorly to expose the esophageal tumor. *Inset*: The patient is placed in the left lateral decubitus position. The *dotted line* marks the skin incision for a right posterolateral thoracotomy. **B.** The latissimus muscle is divided as caudally as possible, and the serratus muscle is spared and reflected medially.

SURGICAL APPROACHES TO LESIONS BELOW THE THORACIC INLET

Tri-incisional Esophagectomy (McKeown Technique)

The tri-incisional technique of esophageal resection combines the most attractive aspects of the Ivor Lewis and transhiatal approaches. It allows for dissection of the intrathoracic esophagus under direct vision with complete nodal resection and brings the anastomosis to the neck, allowing for maximal proximal margins and minimizing the risk of an intrathoracic leak.

Under general anesthesia, bronchoscopy is performed to rule out tracheal or bronchial (most commonly left main bronchial) involvement with tumor. Esophagogastroduodenoscopy is performed to localize the tumor and rule out disease of the stomach or duodenum. The patient is then reintubated with a double-lumen endotracheal tube and placed in the left lateral decubitus position. A right posterolateral thoracotomy incision is made large enough, approximately 10 cm in length, to introduce the surgeon's hand (Fig. 18-3). The serratus muscle is spared. Division of the intercostal muscles anteriorly and posteriorly often permits adequate rib spreading without the need to remove a small portion, or shingle, a rib. The chest is entered through the fifth or sixth interspace depending on the location of the tumor. The inferior pulmonary ligament is divided using electrocautery, and the lung is retracted anteriorly.

Dissection of the esophagus begins at a point away from tumor and any associated scarring, and the esophagus is encircled with a Penrose drain. Traction on the Penrose drain allows for cautery dissection encompassing all adjacent nodes. Arterial branches directly off the aorta are clipped or ligated. The settings on the electrocautery should be low when cauterizing near the trachea. The azygos vein is typically divided, although this is not always necessary (Fig. 18-4). At this level, the vagus nerves are identified. Dissection cranial to this level involves the vagus nerves; the vagus nerves are peeled off and away from the esophagus to avoid injury to the recurrent vagus branches.

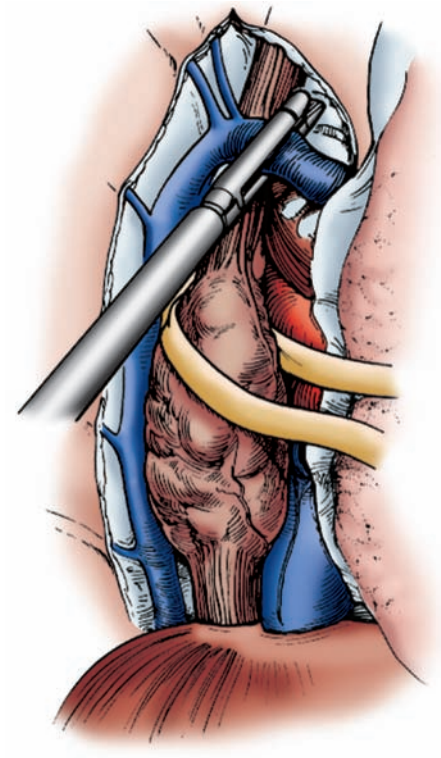

FIGURE 18-4 The esophagus has been isolated circumferentially at a point superior to the tumor and encircled with a Penrose drain. An endostapling device is used to divide the azygos vein near its caval connection.

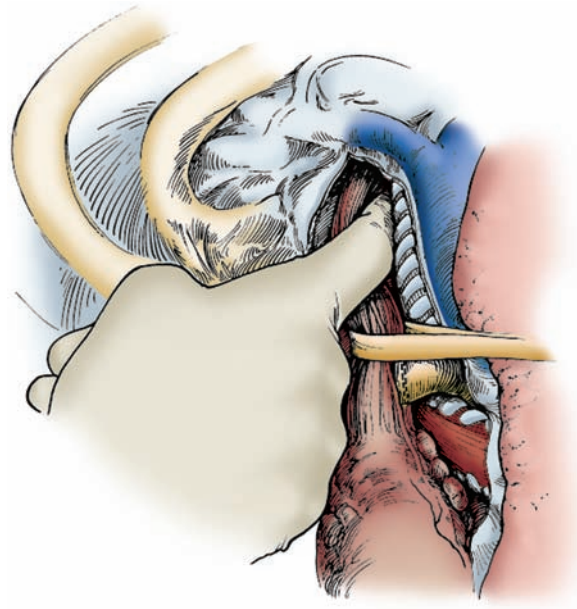

FIGURE 18-5 With countertraction applied to the Penrose drain encircling the esophagus above the tumor, blunt finger dissection is used to develop the tracheoesophageal plane to and above the thoracic inlet.

Dissection between the trachea and esophagus must be done with care and with low cautery dissection to avoid injury to the membranous trachea. Much of the dissection high in the chest can be done bluntly (Fig. 18-5). The cranial aspect of the dissection is complete when one's fingers reach easily above the first rib. The Penrose drain is knotted and passed into the lower neck with the knot against the vertebral body for later retrieval during the neck phase of the dissection (Fig. 18-6).

Another Penrose drain is used to gain traction on the lower esophagus and dissection continues caudally. All tissue between the pericardium, aorta, and azygos vein is dissected and incorporated into the specimen. No effort is made to resect the thoracic duct, although it is sometimes injured. For tumors near the gastroesophageal junction, a rim of diaphragm is incorporated into the specimen. The knotted Penrose drain is placed in the abdomen for later retrieval (Fig. 18-7). At this point, careful inspection is made for hemostasis and injury to the thoracic duct. Often, injury to the thoracic duct is evident when slightly cloudy or crystallized fluid is seen pooling in the region of the duct. If an injury to the duct is seen, it should be closed with a pledgeted fine suture such as 5-0 Prolene. Mass ligature of the duct, as it enters the chest, is then performed by encompassing all tissue between the spine, aorta, and azygos vein at the level of the hiatus with a 0 silk suture. A 28F straight chest tube is inserted via a separate stab incision and directed to the apex of the chest. An additional hole in the tube can be made to facilitate dependent fluid drainage. The ribs are reapproximated with 2-0 Vicryl sutures.

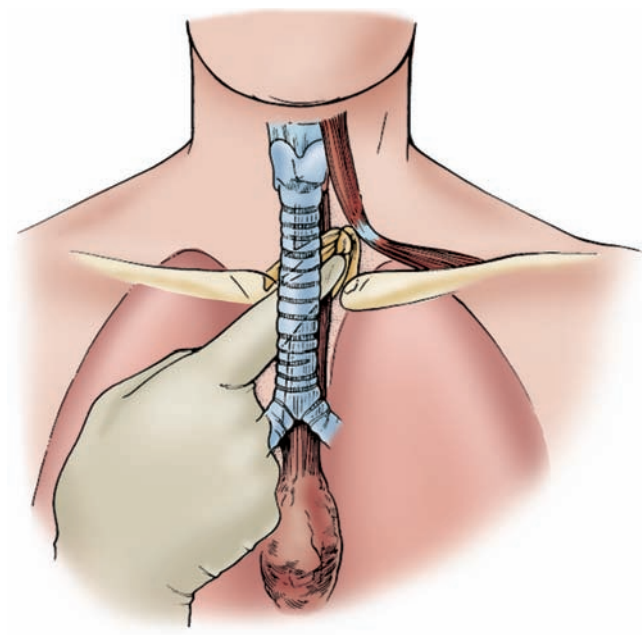

FIGURE 18-6 The knotted Penrose drain is pushed up through the thoracic inlet and left to lie beneath the omohyoid muscle on the left side of the neck.

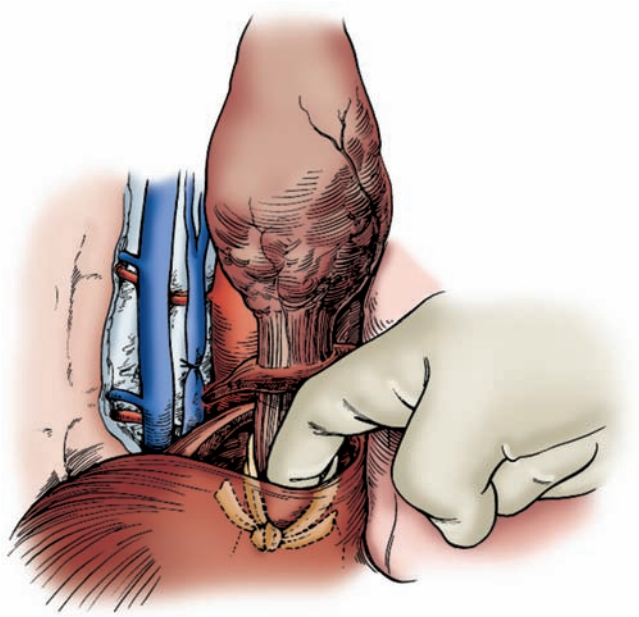

FIGURE 18-7 The lower Penrose drain is pushed down onto the gastroesophageal junction below the diaphragm. The thoracic duct is shown ligated, and a rim of the diaphragmatic hiatus encircles the lower esophagus.

The latissimus layer is closed using a running 0 Vicryl suture. A subdermal layer is closed with 2-0 Vicryl and the skin is closed in subcuticular fashion.

The patient is placed in the supine position and is reintubated with a single-lumen tube. A roll is placed under the back to permit neck extension, and the head is turned to the right. A midline laparotomy is performed from the umbilicus to the xiphoid. Exploration of the abdomen should include a careful palpation of the liver and inspection of the serosal surfaces for tumor implants. Palpation of the GE junction and proximal stomach should be performed to rule out gastric spread of tumor. The left lobe of the liver is mobilized and retracted to the right. The Penrose drain left from the chest dissection is used for retraction of the GE junction (Fig. 18-8). The gastroepiploic artery is identified and palpated. The pulse should be easily palpable provided the patient has a physiologic blood pressure. Staying at least 2 cm away from the gastroepiploic artery, the lesser sac is entered. Dissection continues cranially on the stomach along the greater curvature. Dissection may be performed by dividing tissue and ligating with 2-0 silk ties or by using an ultrasonic scalpel. The stomach is retracted medially and the omentum laterally. The artery itself should not be grasped or used for retraction. The gastroepiploic arcade ends near the point where the short gastric arteries begin. A pack placed behind the spleen often aids in exposure of the short gastric vessels (Fig. 18-9). The short gastric vessels can be ligated, double-clipped, or divided with an ultrasonic scalpel. Large vessels should be tied. Care should be taken not to incorporate stomach wall in the ligature, as this may result in delayed necrosis of stomach wall and a postoperative intrathoracic leak.

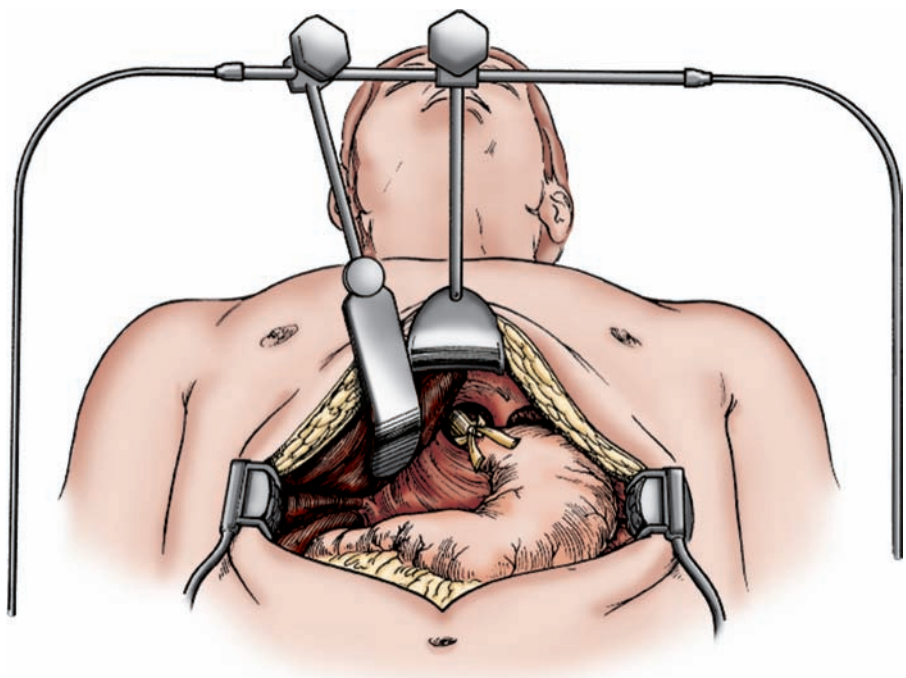

FIGURE 18-8 Exposure achieved by upper midline laparotomy. The large Balfour retractor is on the lateral abdominal walls, and the upper hand retractor reflects the liver to the right exposing the hiatus and lower Penrose drain around the GE junction.

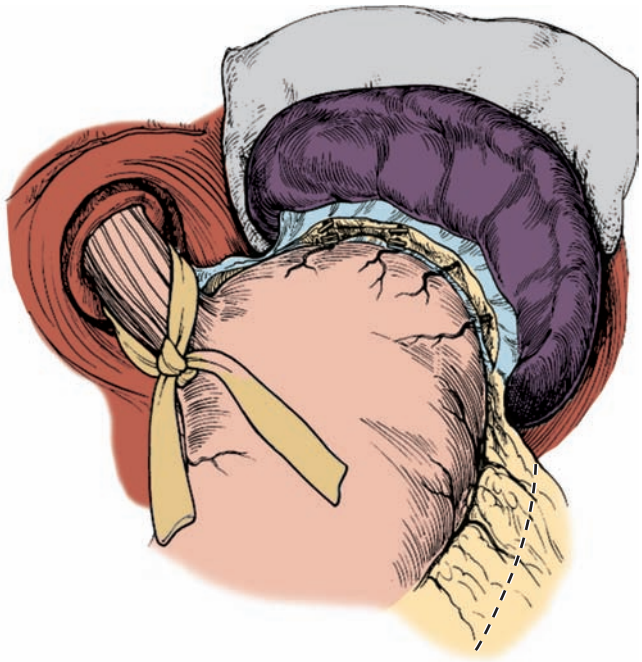

FIGURE 18-9 Gastric mobilization is begun at the superior greater curvature near the hiatus. A rolled Mikulicz pad is placed behind the spleen to aid in exposure. The short gastric vessels between the spleen and the stomach are divided, and the transition zone between the left and right gastroepiploic arteries is identified. Mobilization proceeds at least 2 cm away from the right gastroepiploic arcade (*dotted line*).

Dissection on the greater curvature proceeds to the hiatus and is complete when the Penrose drain is reached.

Proximal dissection on the greater curvature of the stomach proceeds in likewise fashion. The gastroepiploic artery migrates farther from the stomach as one dissects toward the pylorus, and care must be taken not to injure the vessel. The gastrohepatic ligament is divided with cautery up to the GE junction. The stomach is lifted anteriorly, and thin adhesions between the stomach and pancreas are divided with cautery. The left gastric vessels are approached from behind the stomach (Fig. 18-10). The vessels are skeletonized, and lymph nodes are swept up onto the specimen. The vessels are clamped with a vascular endoscopic 30-mm stapler. The gastroepiploic pulse should be palpated at this time to ensure that the celiac axis itself has not been clamped, and the stapler is then fired. The duodenum is then mobilized using a Kocher maneuver, bringing it to the midline (Fig. 18-11). A pyloromyotomy or pyloroplasty may be performed with equivalent efficacy in aiding gastric emptying. If a pyloroplasty is performed, it is best to close it in a single layer with interrupted (3-0 silk) sutures. A leak is exceedingly rare.

A neck incision is then made 6 cm in length along the anterior border of the left sternocleidomastoid muscle starting at the sternal notch. Deep to the platysma, dissection proceeds medial to the sternocleidomastoid muscle and carotid sheath and lateral to the thyroid. The omohyoid

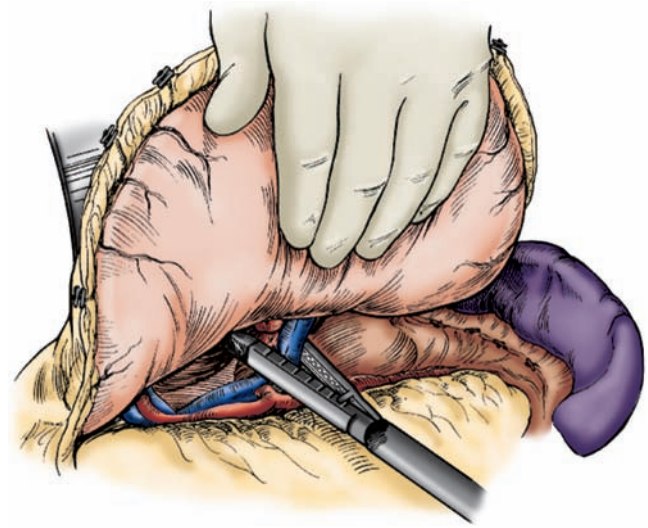

FIGURE 18-10 After the greater curvature is mobilized, the stomach is reflected superiorly and to the right, exposing the left gastric artery and coronary vein. These are ligated and divided with an endostapler, near their origin, from the celiac axis.

can be divided with cautery (Fig. 18-12). Blunt dissection is then used to approach the vertebral bodies (Fig. 18-13). Lying along the vertebral body, the Penrose drain is grasped and brought out into the neck wound with the encircled esophagus. Proximally, the esophagus can be gently mobilized. The nasogastric tube is removed, and the esophagus is divided with a GIA 75-mm stapler (Fig. 18-14). A 2 silk suture is attached to the proximal margin, and the specimen is drawn out into the abdomen (Fig. 18-15). The cervical end of this tie is fastened to a clamp.

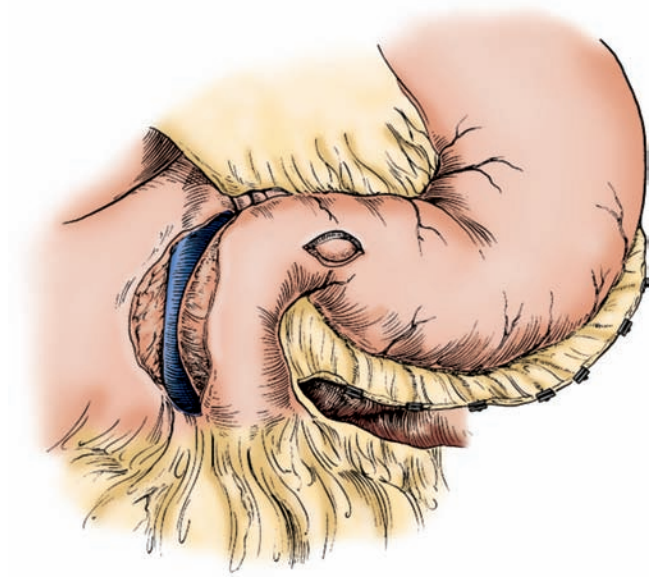

FIGURE 18-11 A Kocher maneuver to mobilize the duodenum and a pyloromyotomy are performed.

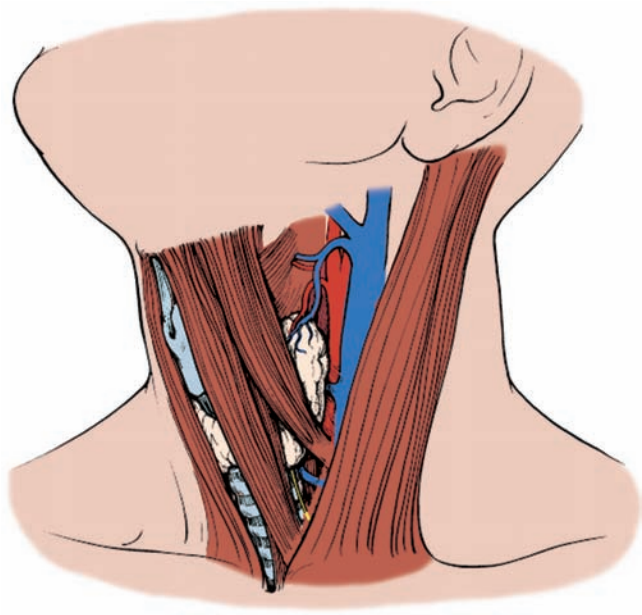

FIGURE 18-12 Anatomic structures of the left neck below platysma level. The incision line along the medial border of the sternocleidomastoid muscle is shown. Division of the omohyoid muscle along with ligation of the middle thyroid vein allows for exposure of the underlying esophagus.

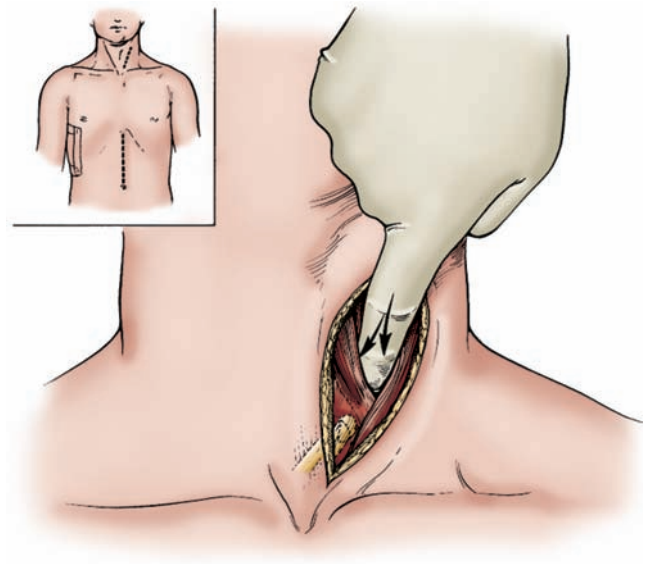

FIGURE 18-13 Left cervical incision with the sternocleidomastoid muscle reflected laterally. Finger dissection beneath the omohyoid muscle develops a plane to the knotted Penrose drain. *Inset*: The patient is placed supine for the neck and abdominal incisions (*outlined*).

The gastric tube is then constructed by resecting the GE junction and the lesser curvature of the stomach down to the crow's foot of veins with a series of thick tissue 75-mm gastrointestinal anastomosis (GIA) staplers (Fig. 18-16). A narrow gastric tube is believed to aid in emptying; however, a diameter of less than 5–6 cm may compromise conduit perfusion. The right gastric artery along the lesser curvature can be divided in order to allow elongation of the conduit (Fig. 18-17). The specimen is removed, and frozen sections are performed on the margins. Inspection for hemostasis is

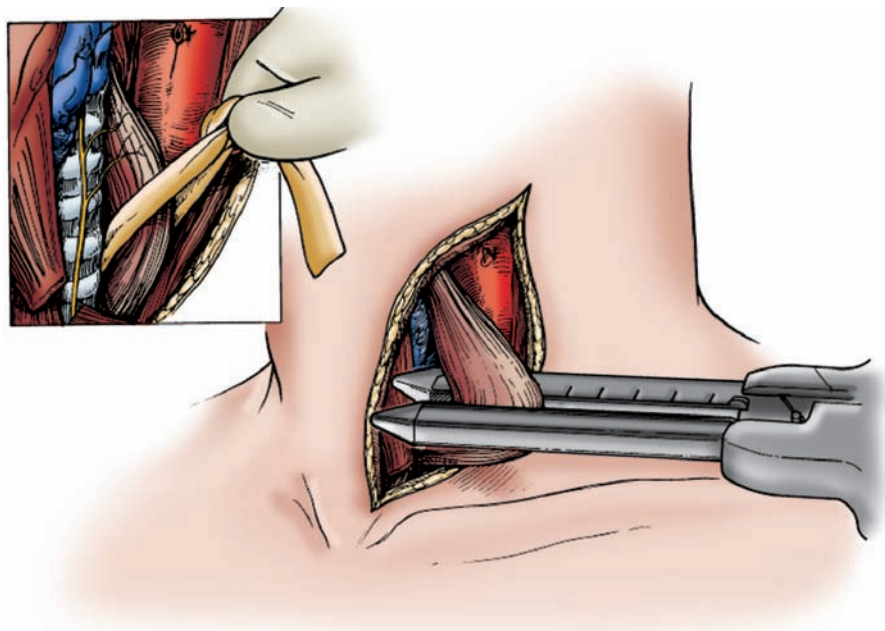

FIGURE 18-14 A GIA stapler is used to divide the cervical esophagus. Note the ligated middle thyroid vein and divided omohyoid muscle. *Inset*: Traction is placed on the Penrose drain around the cervical esophagus.

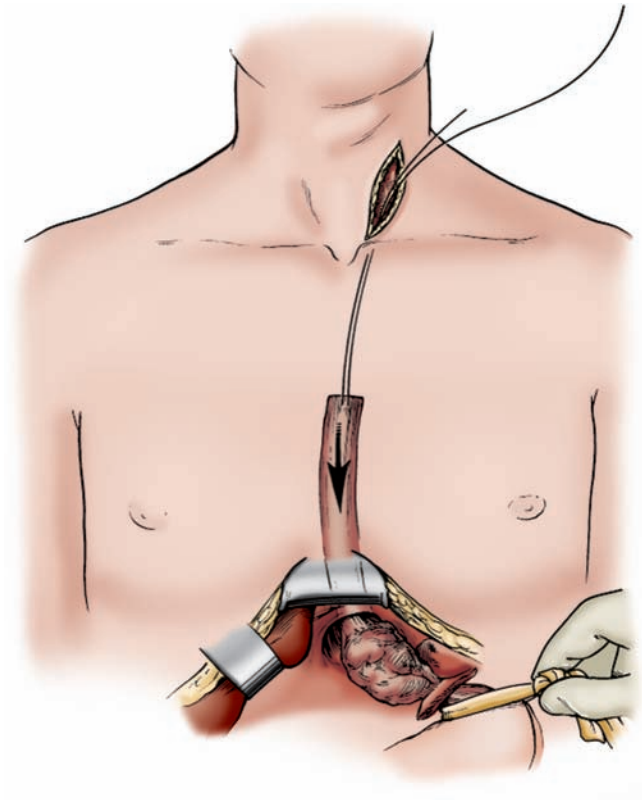

FIGURE 18-15 The specimen is removed through the abdominal incision with a long heavy silk suture attached to the end of the esophagus.

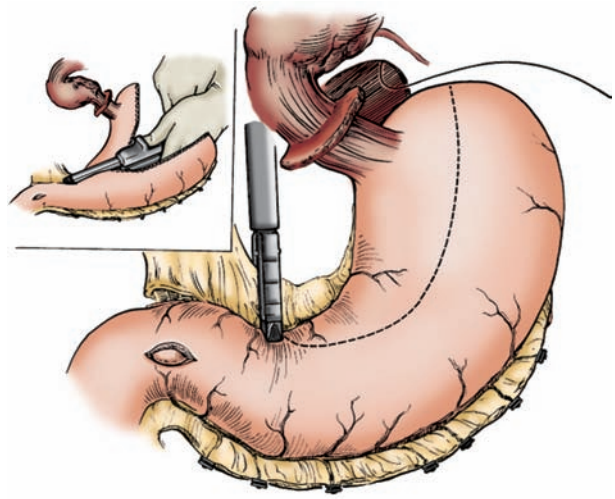

FIGURE 18-17 The right gastric artery and lesser omentum are divided with an endostapling device. *Inset*: A GIA stapler divides the stomach along the lesser curvature, creating the gastric conduit.

made of the gastric bed. The esophageal hiatus should admit four fingers. One ampule of IV glucagons is administered to ensure relaxation and lengthening of the gastric conduit. The silk tie that traverses the mediastinum is then attached to the valved end of a Foley catheter with a 30-cc balloon (Fig. 18-18). An endoscopic camera bag is secured around the 30-cc balloon (Fig. 18-19). The conduit is advanced into the bag, ensuring appropriate orientation. Suction is applied to the bag via the Foley catheter, and the conduit is drawn up into the neck incision (Fig. 18–20). The assistant must actively guide the conduit through the hiatus. At the end, the pylorus should sit at the hiatus.

The neck anastomosis can be hand-sewn using interrupted full-thickness 3-0 silk sutures (Fig. 18–21). The anastomosis may also be stapled in side-to-side, functional end-to-end fashion. A portion of the esophageal staple line is removed, an enterotomy is created on the posterior aspect of the gastric tube, and a linear GIA 75-mm stapler is inserted to create the anastomosis (Fig. 18–22). An additional fire of an endoscopic 30-mm stapler may be used to gain additional length on the anastomosis. The enterotomy is usually closed with a TA 30 or 60 stapler after guiding the nasogastric tube down toward the hiatus. Hybrid anastomosis has been described with the back wall of the anastomosis created using a 30-mm stapler and the anterior wall closed with sutures. A

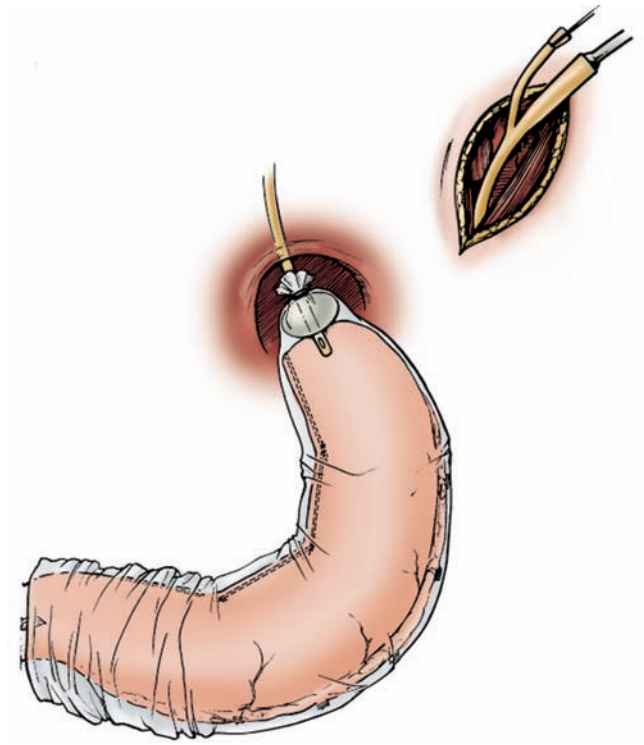

FIGURE 18-19 An arthroscopy camera bag is tied around the Foley catheter balloon and the gastric conduit is placed in the folded-up arthroscopy bag ensuring the proper axial orientation. *Inset*: A Yankauer suction is attached to the Foley catheter to collapse the bag around the neoesophagus.

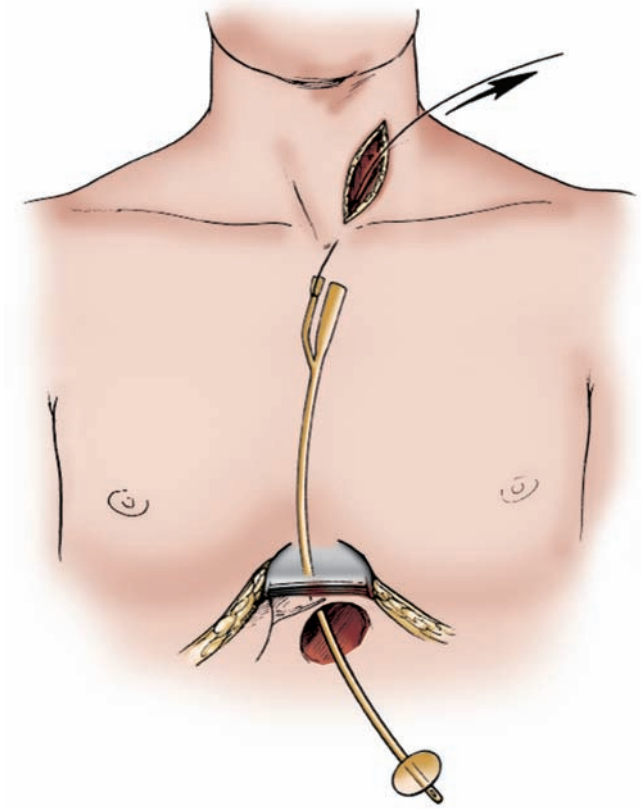

FIGURE 18-18 The heavy silk is tied to the port of a 30-cc balloon Foley catheter and is pulled up partially through the neck incision.

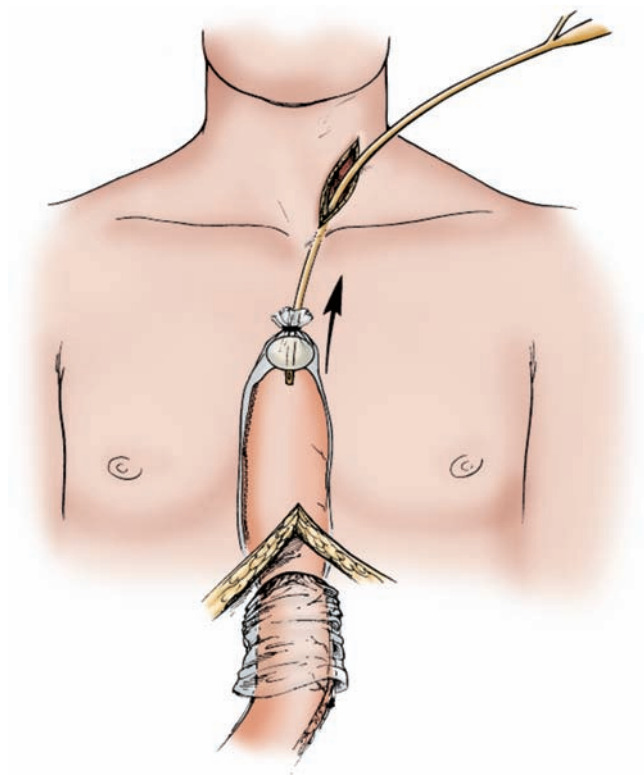

FIGURE 18-20 The gastric conduit is atraumatically pulled through the posterior mediastinum into the cervical wound.

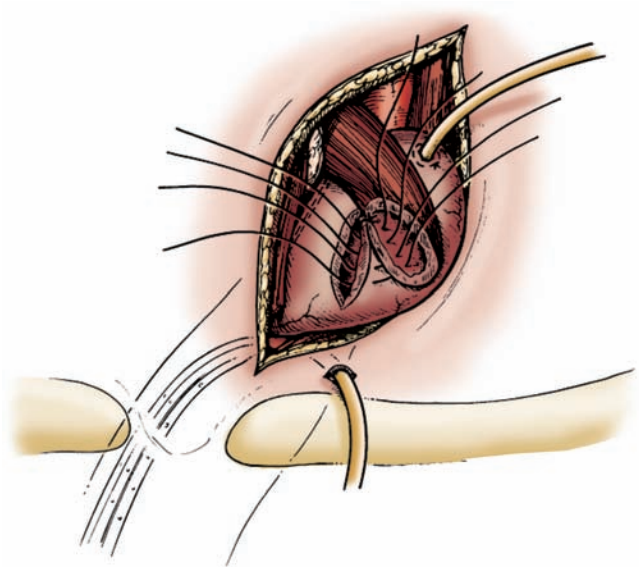

FIGURE 18-21 The esophagogastric anastomosis is performed with a single layer of full-thickness interrupted nonabsorbable sutures. The Silastic sump drain is shown emanating from the fundus of the gastric conduit. A Jackson-Pratt drain is shown positioned alongside the gastric conduit inferiorly and exiting from a separate stab wound above the clavicle.

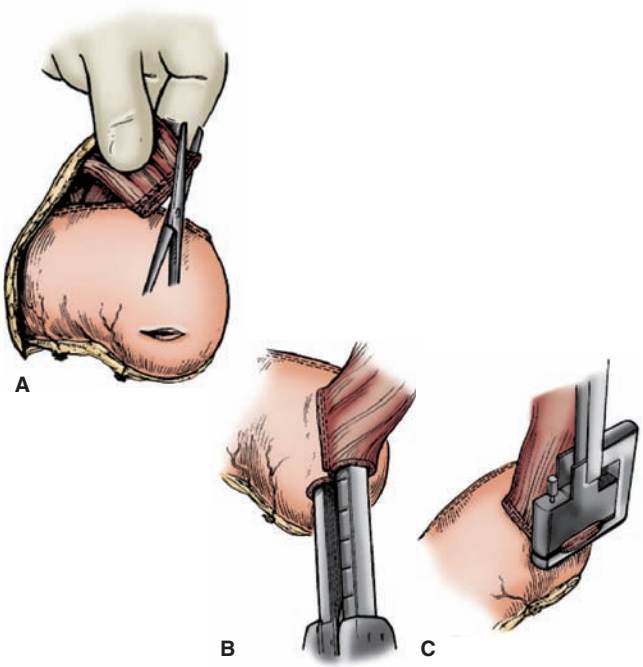

FIGURE 18-22 **A.** and **B.** The stapled functional end-to-end anastomosis is performed using the GIA stapler to approximate the side of the esophagus to the anterior wall of the stomach. **C.** The TA linear stapler is then used to close the defect between the two free walls.

soft drain should be placed posterior to the anastomosis and the platysma and skin are closed separately. It is wise to use an interrupted closure, as this will allow for reopening of a portion of the wound should a cervical leak develop. Before closing the abdomen, a J-tube should be inserted at a point approximately 40 cm distal to the ligament of Treitz. The fascia is closed using a #2 running monofilament suture and the skin is closed with staples.

Ivor Lewis Technique

The patient is placed in the supine position. Bronchoscopy to rule out tracheobronchial invasion and esophagoscopy to confirm the location of the tumor are performed. An upper midline incision is made from the umbilicus to the xiphoid. The abdominal phase of this operation is identical to the previously described tri-incisional technique. Enlargement of the hiatus and dissection of the lower esophagus are more easily performed through the abdomen than through a high thoracotomy incision. The GE junction and lesser curvature of the stomach are resected using a GIA stapler. The specimen is left attached to the esophagus to facilitate mobilization into the chest. A J-tube is placed before closing the abdomen.

A double-lumen endotracheal tube is placed and the patient is repositioned in the left lateral decubitus position. A right posterolateral thoracotomy is performed, and the chest is entered through the fourth or fifth interspace. The azygos vein is divided and the intrathoracic esophagus is dissected. All lymphatic tissue is included with the esophagus. Because a gross margin of 5 cm, and ideally 10 cm, is desired, the anastomosis is usually performed high in the chest at or above the level of the azygos vein. The proximal esophagus is dissected only several centimeters above the proposed level of transection to preserve its blood supply. The mobilized stomach is pulled up into the chest. The anastomosis can be constructed using an EEA stapler or hand-sewn technique. If a hand-sewn anastomosis is chosen, a double-layer technique is advisable (Fig. 18-23). In 1942, Churchill and Sweet described a method of double-layer anastomosis that is still often used today.[29,30] A point on the gastric tube at least 2 cm away from the staple line is chosen for the anastomosis. A circle of stomach serosa 2 cm in diameter is scored and the underlying gastric vessels are ligated with 4-0 silk sutures. The back outer layer of the anastomosis is constructed with interrupted 4-0 silk horizontal mattress sutures. These are placed 4 mm away from the serosal edge. Full-thickness stomach and esophageal wall are used. The esophagus is opened with a sharp instrument and the inner layer is constructed with interrupted suture incorporating esophageal mucosa and full-thickness stomach edge. The nasogastric tube is passed after completion of the posterior wall. A continuous Connell suture may also be used. The anterior outer layer anastomosis is constructed with 4-0 silk horizontal mattress sutures. The anastomosis should be wrapped or buttressed with omentum. At all times, atraumatic handling of mucosal edges and tying of sutures without crushing of tissues are advised. Some surgeons advise tacking

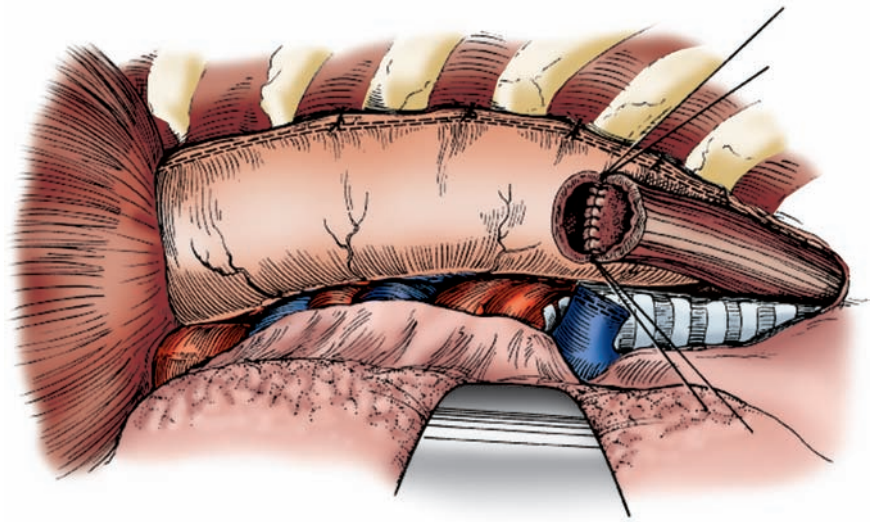

FIGURE 18-23 View through a right thoracotomy incision showing an esophagogastric end-to-side anastomosis in the apical right chest. Note the tacking sutures from stomach to the posterior chest wall to avoid torsion.

the edge of the stomach wall to mediastinal tissue or paravertebral fascia to decrease tension on the anastomosis, although it is not clear if this is necessary. A 28F straight chest tube is placed into the apex of the chest via a separate stab incision. The chest is closed with interrupted #2 Vicryl paracostal sutures, followed by a 0 Vicryl running latissimus layer, a 2-0 Vicryl running subdermal layer, and a 3-0 Vicryl subcuticular layer. Postoperative toilet bronchoscopy should be performed.

Transhiatal Technique

CONSIDERATIONS

We believe that a tri-incisional approach gives better exposure to the thoracic esophagus, allowing for a safer and wider resection and better lymphadenectomy. As discussed, there may be survival advantages to the radical resection permitted by the transthoracic technique, although trials to date have not shown a statistically significant survival advantage using this approach. In cases in which the thoracic esophagus is not involved with tumor (either high-grade dysplasia or a laryngeal tumor involving the proximal esophagus), the transhiatal technique may be performed with equivalent oncological efficacy.

TECHNIQUE

The patient is placed in the supine position with the head rotated 45 degrees to the right. The abdominal phase of the operation is performed in identical fashion to that described in the tri-incisional section above. An upper-hand retractor is useful in elevating the sternum and costal margin. The phrenoesophageal ligament is divided using cautery, and the lower esophagus is encircled with a 1 in wide Penrose drain. The phrenic vein must first be identified and ligated. This will also enlarge the window for dissection of the intrathoracic esophagus. The hiatus is dilated to allow entry of the surgeon's hand. Arterial branches from the aorta are clipped on the aortic side and divided using cautery. Thin handheld malleable retractors are used to retract either side of the pleura during the dissection. Dissection under direct vision is usually possible up to the level of the inferior pulmonary veins.

At this point, an incision is made in the left neck along the anterior border of the sternocleidomastoid muscle starting at the sternal notch and extending 6–8 cm. The platysma is divided. The sternocleidomastoid muscle and carotid sheath are retracted laterally. The omohyoid is often divided. The middle thyroid vein is ligated and divided. A retractor may be used but must not rest on the recurrent nerve in the tracheoesophageal groove. The esophagus is palpated anterior to the spine and posterior to the trachea. Sharp dissection is carried out immediately on the esophagus, separating the esophagus from the membranous trachea and recurrent nerve. The esophagus is looped with a 1-in Penrose drain.

Blunt dissection of the posterior plane of the esophagus is performed first. From the abdomen, the surgeon's hand is placed in between the spine and esophagus with the palmar aspect of the fingertips immediately against the esophagus (Fig. 18-24). This is performed in conjunction with raising the esophagus anteriorly with the aid of the Penrose drain. An identical maneuver is performed through the cervical incision. When sufficient dissection has been done from either side, both hands are introduced simultaneously and an attempt is made to touch fingertips. Intervening loose areolar tissue must then be torn, uniting the fingertips. If the surgeon's fingertips will not reach from the neck, a sponge stick can be used. While the surgeon's hand is behind the

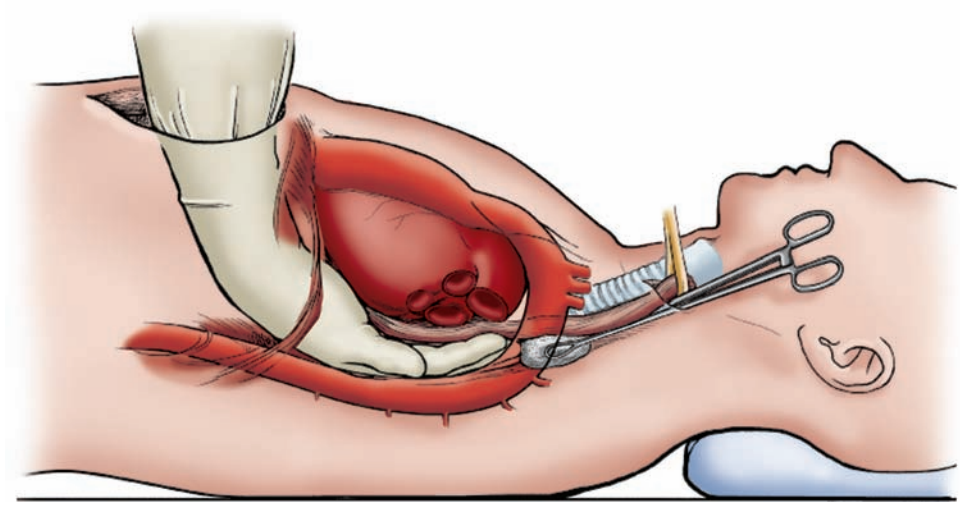

FIGURE 18-24 Lateral view of the blunt dissection posterior to the esophagus in the chest. A sponge stick is used, as it may be difficult to insert one's hand completely through the cervical incision. (Redrawn, with permission, from Orringer MB, Sloan H. Esophagectomy without thoracotomy. *J Thorac Cardiovasc Surg*. 1978;76:643.)

heart, there must be constant communication between the surgeon and the anesthesiologist. Hypotension often results from compression of the left atrium and impairment of left ventricular filling. It is wise to have the arterial line tracing and numbers in direct view of the surgeon; the surgeon's eyes should be on these numbers as he/she performs the blind dissection with his/her fingers.

Dissection anterior to the esophagus is then performed in nearly identical fashion. The palmar aspect of the hand is again kept directly against the esophagus (Fig. 18-25). As dissection approaches the carina from below, the surgeon will note an increase in the tenacity of the anterior attachments to the esophagus. Dissection must be gentler in this area. A gentle side-to-side motion of the fingertips will also separate the trachea from esophagus. Eventually the fingertips from both hands are united. Once the anterior and posterior dissection has been completed, the lateral attachments are then divided. From the neck incision, as much blunt dissection of the lateral attachments as possible is performed under direct vision. Next the surgeon's hand is introduced anterior to the esophagus with the palmar aspect of the hand facing the esophagus. The hand is inserted until the first and second fingers are above the level of dissection of the lateral attachments. These attachments are pressed against the spine, and using a raking motion the surgeon pulls his hand back toward the abdomen, releasing the lateral attachments (Fig. 18-26). Care must be taken in the region of the azygos vein and its branches.

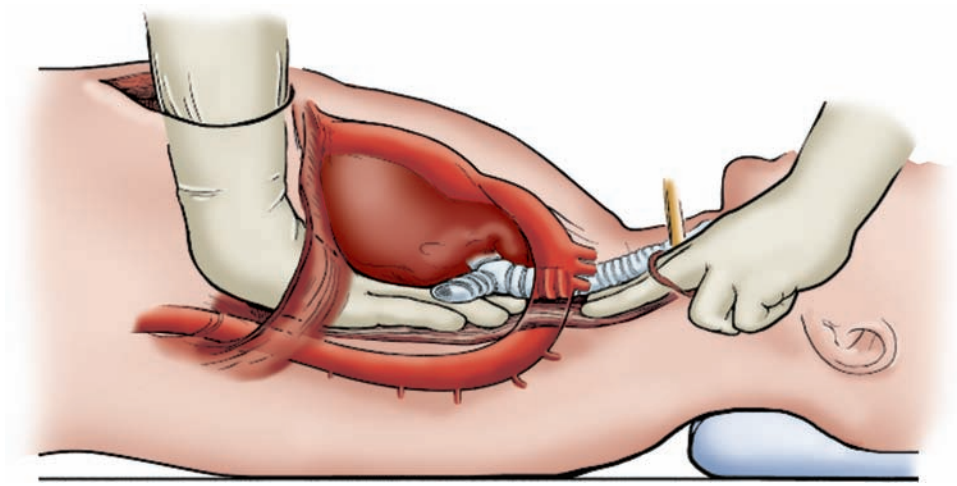

FIGURE 18-25 Anterior blunt dissection of the esophagus in the chest. Dissection must be gentle and deliberate around the level of the carina to avoid tracheal as well as azygos vein injury.

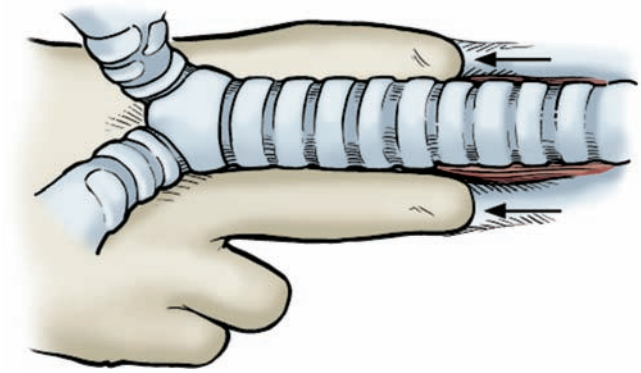

FIGURE 18-26 The esophagus has been freed from the trachea, and the lateral attachments are avulsed from a cranial to caudal direction.

The remainder of the operation, including the anastomosis, is identical to that of the tri-incisional technique. After removing the specimen, it is wise to pack the mediastinum with a lap pad (without compressing the heart) to facilitate hemostasis. Prior to drawing the conduit into the neck, a final inspection is made for hemostasis and for entry into either pleural space. If either pleural space is entered, a chest tube should be placed.

Left Thoracoabdominal Approach

CONSIDERATIONS

Limited resection of the distal esophagus via left thoracotomy is almost always a compromise procedure. Only the distal esophagus is readily accessible via the left chest, as the aortic arch obscures much of the upper esophagus. A tumor that extends more proximally than 30 cm should not be approached through the left, as a difficult dissection behind the aortic arch will be required. In addition, placement of the esophagogastric anastomosis low in the left chest can be associated with severe GE reflux. This approach is best reserved for a GE junction cancer that involves a significant portion of the proximal stomach and when there is concern that the residual stomach may be of insufficient length to reach the neck.

A variety of incisions or a combination of left thoracic and abdominal incisions can be used for this approach. An upper midline laparotomy can be extended across the costal margin. This is the least versatile approach and its use is limited to instances in which use of the esophagus is unexpected, as with proximal extension of a gastric tumor. A second approach involves placing the patient in full right lateral decubitus position and taking the diaphragm down in radial fashion 2–3 cm from the chest wall to gain exposure to the abdomen. This approach permits good exposure to the upper abdomen, although exposure to the pylorus and duodenum may be difficult.

TECHNIQUE

The most versatile thoracoabdominal approach involves positioning the patient in the right lateral decubitus position with the hips rotated posteriorly 45 degrees. A left sixth interspace thoracotomy is performed beginning at the tip of the scapula and extending across the costal margin toward the abdominal midline. The latissimus is divided and the serratus is spared. The costal margin is divided with a rib cutter. The left lung is deflated. The diaphragm is incised circumferentially 2–3 cm away from the chest wall (Fig. 18-27). Doing so avoids injury to the radial branches of the phrenic nerve. The abdomen is explored for metastatic disease. Cautery is used to divide the inferior pulmonary ligament. The mediastinal pleura overlying the esophagus is incised, and the esophagus is encircled in the lower chest including all tissue from the aorta to the pericardium. The esophagus is dissected proximally behind the inferior pulmonary vein. A proximal gross in situ margin of 10 cm is ideal, though lesser margins, if confirmed negative by frozen section, may be adequate. A point of division of the proximal esophagus is identified and mobilization above this point is minimized to preserve blood supply to the anastomosis. The thoracic duct can be located at this level and ligated if desired.

The incision permits excellent exposure of the short gastric vessels, which are ligated starting at the hiatus. Care is taken

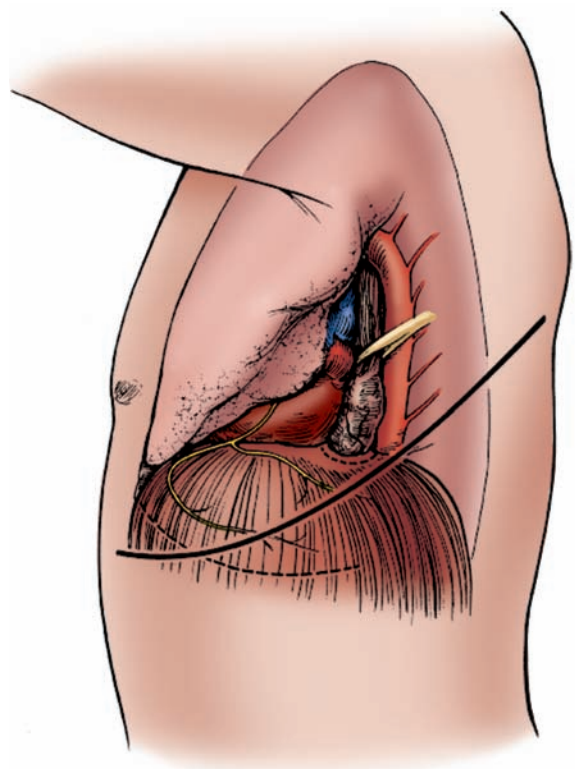

FIGURE 18-27 Left thoracoabdominal approach; *dotted lines* delineate the circumferential diaphragmatic incision as well as the hiatal margin incision. A Penrose drain encircles the esophagus above the tumor.

along the greater curvature, where the short gastric vessels end and the right gastroepiploic vessel begins. The right gastroepiploic artery is preserved. The gastrohepatic ligament is divided. The left gastric artery is identified and all celiac lymph nodes are swept up onto the specimen. The stomach is retracted anteriorly and the left gastric artery is divided with a vascular endoscopic stapler. The gastric tube is constructed by sequential fires of GIA staplers starting at the fundus and extending down to the crow's foot of veins. Six centimeters of distal margin is desirable. A Kocher maneuver and pyloroplasty or pyloromyotomy are performed, and the tube is passed through the enlarged hiatus into the chest. The anastomosis is typically constructed inferior to the aortic arch and may be hand-sewn as described in the previous section or stapled.

If needed, the dissection can be carried to the neck with this incision with some difficulty. The proximal esophagus can be dissected bluntly under the aortic arch, and provided the neck has been prepped into the field, a left cervical incision is made as in the tri-incisional technique and the conduit pulled into the neck. Closure begins with careful reapproximation of the diaphragm with interrupted horizontal mattress 0 silk sutures followed by solid reapproximation of the costal margin with figure-of-eight wire or heavy nonabsorbable suture such as no. 1 Prolene. Some surgeons prefer not to divide the costal margin and, instead, perform all intra-abdominal work through the divided diaphragm.

ALTERNATIVE METHODS OF RECONSTRUCTION: COLON AND JEJUNUM

Colonic Interposition

The stomach is the preferred organ for esophageal replacement because of its blood supply, the resistance of these vessels to atherosclerotic disease, the need for a single anastomosis, and the ability of the stomach to reach the neck without difficulty. Prior gastric surgery, scarring from peptic ulcer disease or involvement with tumor may preclude use of the stomach as a conduit. In this instance, colon interposition may be employed. The left colon is preferred over the right colon for several reasons. Its diameter more closely resembles that of the esophagus, its vascular supply has less variation, and greater length can be obtained. Unfortunately, atherosclerotic disease most commonly affects the inferior mesenteric artery, and the left colon is often more affected by diverticular disease than the right.

Preoperative preparation includes colonoscopy or barium enema to ensure normal anatomy and the absence of any intrinsic colonic disease. Patients older than 40 years or any patients with atherosclerotic risk factors should undergo mesenteric angiography. Significant vascular disease of the conduit vessel would preclude its use as a conduit. A complete bowel prep and oral antibiotics are necessary prior to operation.

LEFT COLON

After completion of the thoracic phase of the operation, the patient is placed in the supine position and a midline laparotomy is performed. After a careful search for metastatic disease, the left colon is mobilized by dividing the white line of Toldt and by dividing the attachments to the spleen and omentum. The colon is freed proximal to the hepatic flexure. A careful inspection is made of the vascular supply, including the marginal artery of Drummond (Fig. 18-28). A pulse should be palpable in the left colonic artery as well as the marginal artery. The middle colic artery supplying the hepatic flexure is clamped with a soft bulldog clamp and its perfusion is inspected for 10 minutes.

Prior to conduit isolation, the GE junction is isolated and the cardia and lesser curvature are dissected with division of the phrenoesophageal ligament and the gastrohepatic ligament. The stomach is divided using a GIA stapler. A pyloric drainage procedure is performed. The length of colon needed is estimated by placing an umbilical tie along the proposed route of colonic interposition. This tie is placed alongside the colon and the length of required colon is determined.

After ensuring adequate blood supply to the conduit, the marginal artery is ligated distal to both branches of the left colic artery. The middle colic artery is divided near its origin. The mesentery is scored and divided between clamps. The colon is divided with GIA staplers and the conduit is packed in moist gauze. The colocolonic anastomosis is most

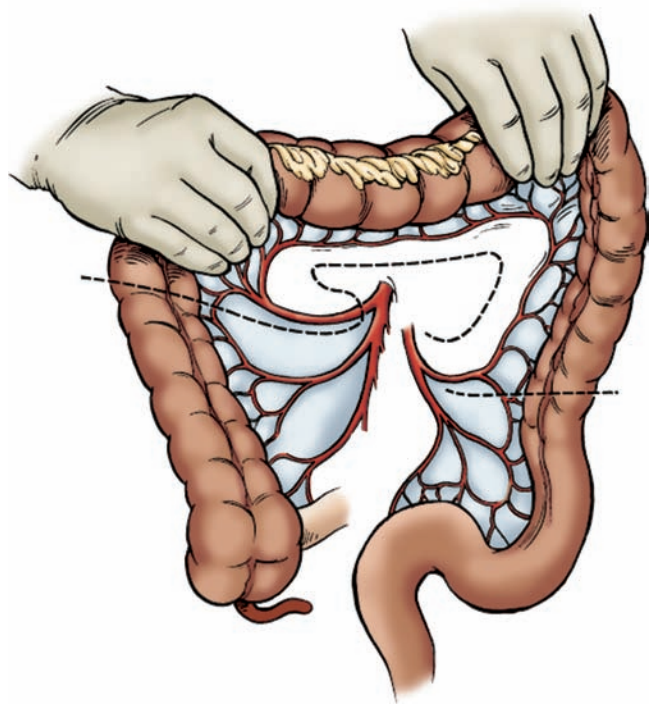

FIGURE 18-28 The mobilized colon is elevated, and the arterial supply and venous drainage are examined. The arterial and venous ligation sites and the mesenteric incision lines are illustrated for an isoperistaltic conduit based on a left colic artery supply.

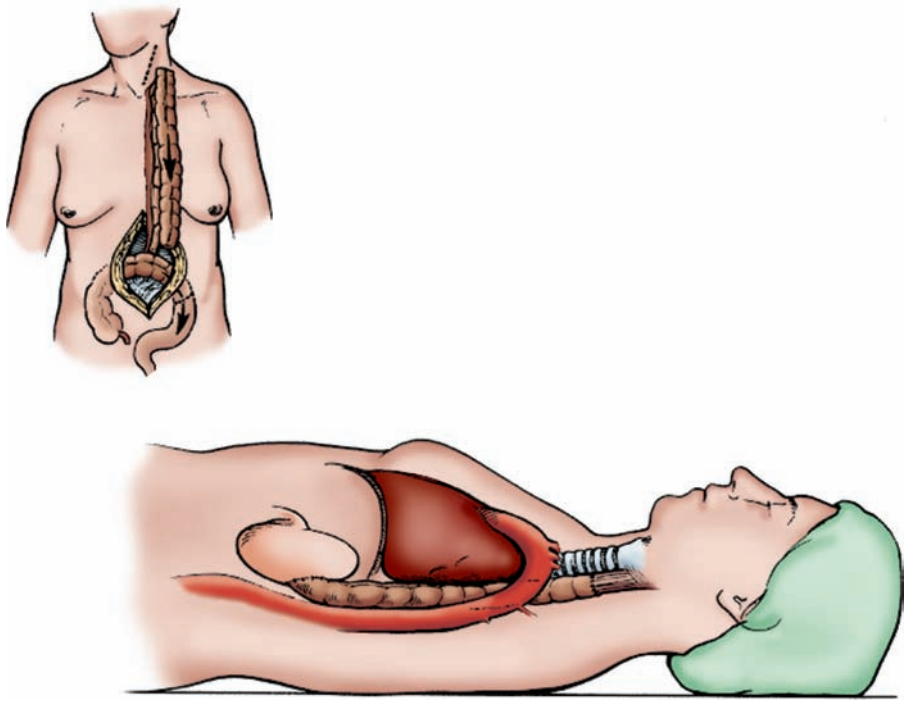

FIGURE 18-29 Lateral view of the colonic conduit in the posterior mediastinal esophageal bed. Cervical esophagocolonic and posterior cologastric anastomoses are shown. *Inset*: Neck incision marked and left colon conduit mobilized on the anterior chest wall, based on the marginal artery pedicle of left colonic artery and placed in isoperistaltic position.

easily stapled in side-to-side functional end-to-end fashion. The mesenteric defect is closed with a running suture to avoid internal herniation. The esophagus is identified in the neck and the esophagectomy is completed as previously described in the tri-incisional esophagectomy section.

The colon can be brought to the neck via either the anterior mediastinum (substernal) or the in situ route (bed of the resected esophagus). The in situ route is preferred, as it provides the shortest route to the neck (Fig. 18-29). In instances of prior infection or scarring (as seen with gastric conduit necrosis or leak), the in situ route may be scarred and unusable. The substernal route may then be used with resection of the manubrium required to prevent acute angulation and possible obstruction in the neck. The colon is oriented in isoperistaltic position and drawn to the neck in an endoscopic camera bag as described previously. The proximal anastomosis is most easily performed using a single-layer interrupted technique with fine 4-0 silk sutures. An EEA or functional end-to-end stapled anastomosis is also acceptable. The nasogastric tube is guided through prior to completion of the anastomosis. The cologastric anastomosis is then performed onto the posterior aspect of the stomach. The easiest method of anastomosis employs an EEA stapler. The handle is placed through an anterior gastrotomy and creates the anastomosis in the posterior wall of the stomach. The gastrotomy is then closed with a TA stapler. The nasogastric tube must be guided through the anastomosis into the stomach. Any excess length in the conduit should be pulled into the abdomen; if it remains in the chest, obstruction may result. The colon is sutured to the left crus of the diaphragm at the hiatus using seromuscular sutures in a two-third circumferential fashion in order to prevent herniation of abdominal contents into the chest.

RIGHT COLON

There are numerous conditions that may make the left colon unsuitable as a conduit, including extensive diverticular disease, stricture from ischemia or infection, atherosclerotic occlusion of the inferior mesenteric artery, or splenic vein thrombosis and thrombosis of the inferior mesenteric vein. In these instances the right colon may be used as a conduit to reach the neck. The right colon is mobilized by lysis of its retroperitoneal attachments. The length of colon needed is estimated with an umbilical tape as described previously. The greater omentum is removed from the hepatic flexure and proximal half of the transverse colon. Its mesentery is transilluminated revealing the ileocolic, right colic, middle colic, and marginal arteries. The ileocolic and right colic arteries are clamped in preparation for division of these vessels and mobilization of the conduit based on the middle colic artery. If perfusion appears adequate, these vessels are ligated. The peritoneum overlying the base of the mesentery is scored, and the remainder of the mesentery is divided between clamps and ligated. The proximal and distal ends of the conduit are divided with a linear cutting stapler. Some incorporate the

ileocecal valve and distal ileum in the conduit because the diameter of the ileum closely approximates that of the esophagus. Others prefer not to use distal ileum in the anastomosis, as the valve may contribute to dysphagia.

The colocolonic anastomosis is performed with staplers. The right colon conduit is then rotated in clockwise fashion (as the surgeon looks into the abdomen) in preparation for isoperistaltic transfer into the chest. As stated previously, the preferred route is via the esophageal bed. This route is often unavailable for use in colon transposition, as one of the most common indications is a failed gastric conduit placed in the esophageal bed. The retrosternal route is most often used. The diaphragm is bluntly detached from its inferior sternal attachments, and blunt dissection with the hand is performed to enlarge the tract. Division of cartilaginous attachments behind the manubrium is also necessary. The conduit is drawn into the neck via a plastic endoscopy bag as described previously. If the thoracic inlet is thought to be too constricting, the head of the clavicle, manubrium, and anterior aspect of the first rib may be resected. The proximal and distal anastomoses are performed as described for left colon conduits. The conduit may also be passed to the neck via the transpleural or subcutaneous route (with great cosmetic deformity).

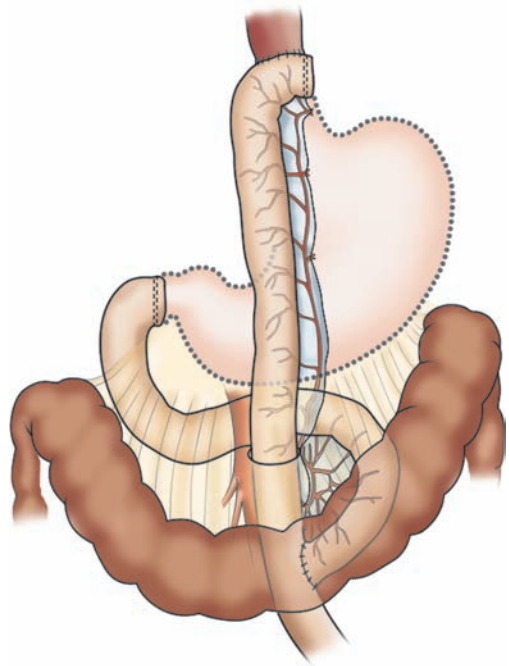

FIGURE 18-30 Roux-en-Y jejunal replacement of the distal esophagus.

Jejunal Interposition

Jejunal interposition may be applied as a free graft, pedicled graft, or Roux-en-Y replacement. Jejunum is often the third choice (after stomach and colon) for esophageal replacement, because it cannot replace the entire esophagus to the neck, but can be used to replace a portion of the distal or proximal esophagus. When distal esophagectomy is necessary for peptic stricture, jejunum or colon interposition is preferred, as both conduits are relatively resistant to reflux. The isoperistaltic conduits are believed to have a lower incidence of recurrent reflux than the simple gastric pull-up procedure. Free jejunal grafts are used in limited reconstructions of the cervical esophagus. Patients undergoing jejunal interposition should receive preoperative antibiotics. Although a mechanical bowel preparation is not needed, it should be used if it is possible that colon may be needed.

ROUX-EN-Y REPLACEMENT

Roux-en-Y replacement is most commonly used after total gastrectomy and distal esophagectomy (Fig. 18-30). Unlike stomach, it will not reliably reach to the cervical esophagus. The jejunum is divided approximately 20–30 cm beyond the ligament of Treitz. The jejunum and its mesentery are held up and its arcade is transilluminated. The proposed point of division is identified, as are the mesenteric vessels to be divided. The first few arcades are not divided to preserve blood flow to the native jejunum. Up to 60 cm of jejunum can be mobilized using this technique. The mesentery is scored and these vessels are clamped near their origin from the superior mesenteric artery with soft bulldog clamps. The conduit is observed for about 10 minutes for evidence of ischemia. The vessels are then ligated and divided. A hole is made in the transverse mesocolon to the left of the middle colic artery, just large enough to pass the jejunum and its mesentery. For replacement after total gastrectomy, the proximal anastomosis is made to the very distal esophagus in the upper abdomen. If resection of the distal esophagus is required, the incision is usually extended across the costal margin to the sixth or seventh interspace. If additional length is needed on the conduit, the next vessel in the arcade is identified, test-clamped, and then divided. The anastomosis can be performed by stapled or hand-sewn technique. The stapled anastomosis is most easily performed with an EEA stapler. The largest EEA stapler possible should be used for the anastomosis. The distal esophagus may first be dilated with a lubricated metal dilator. A full-thickness 2-0 Prolene suture is used to create a purse string in the distal esophagus. The shaft may be introduced by opening the stapled end of the jejunum. It can then be passed out the side of the jejunum and united with the anvil. Care must be taken not to occlude the ongoing lumen of the jejunum with the stapler. Two full-thickness anastomotic doughnuts should be verified. After removing the stapler, the jejunal end is closed with a TA 60 stapler. A hand-sewn anastomosis in one or two layers can also be performed. The jejunum is tacked to the hiatus at several points using interrupted silk sutures. This prevents herniation of abdominal contents into the chest and limits tension on the esophagojejunal anastomosis. Likewise, defects in the colonic mesentery should be closed to prevent an internal hernia. The distal anastomosis can be hand-sewn

or more rapidly performed with a side-to-side functional end-to-end stapled anastomosis.

PEDICLED JEJUNAL INTERPOSITION

Pedicled jejunal interposition is most often used to replace a strictured distal esophagus (Fig. 18-31). A left thoracoabdominal incision is employed with a left seventh interspace incision extended across the costal margin and rectus muscle. The jejunum is transilluminated and an appropriate length of jejunum is selected, beginning 20 cm beyond the ligament of Treitz. A single large vessel is chosen as the conduit feeder vessel. The jejunum is transected proximally and distally using a GIA stapler, and the mesentery is divided down each side toward the feeder vessel (Fig. 18-32A). The jejunum is reconnected using a side-to-side functional end-to-end stapled anastomosis (Fig. 18-32B). The pedicled jejunum is tunneled through the colonic mesocolon and brought up to the left chest through an enlarged hiatus. (Fig. 18-33) The proximal anastomosis can be constructed with an EEA stapler (usually 28 cm in size, but a larger anastomosis may be more resistant to postoperative stricture). The jejunogastric anastomosis is easily performed using an EEA stapler (inserting the handle through a separate gastrotomy). A two-layered hand-sewn anastomosis may also be used.

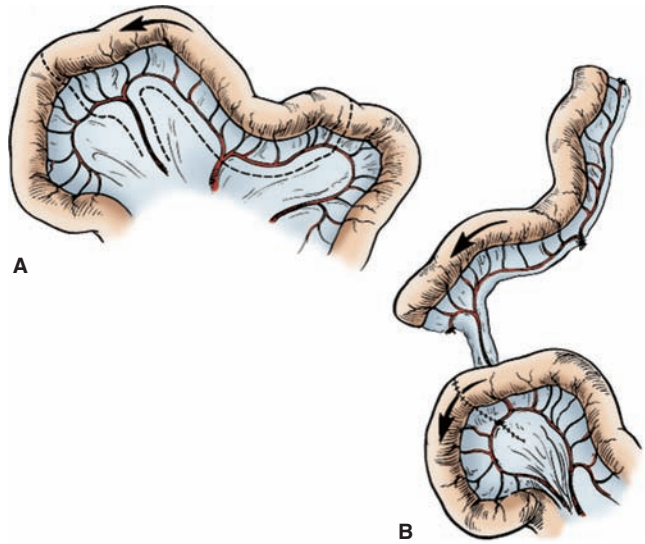

FIGURE 18-32 **A.** The jejunum is prepared in an isoperistaltic fashion (*arrows*) based on a distal mesenteric branch and proximal marginal arcade. The *dotted line* illustrates the line of resection of mesentery and the division of vessels. **B.** After dividing the mesentery and preserving the pedicle, jejunal continuity is restored and the mesenteric defect closed.

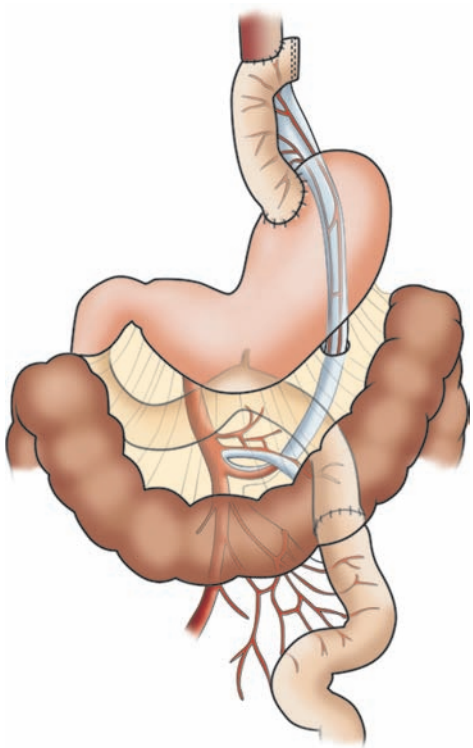

FIGURE 18-31 Pedicled jejunal replacement of the distal esophagus. The jejunum is brought through an incision in the transverse mesocolon.

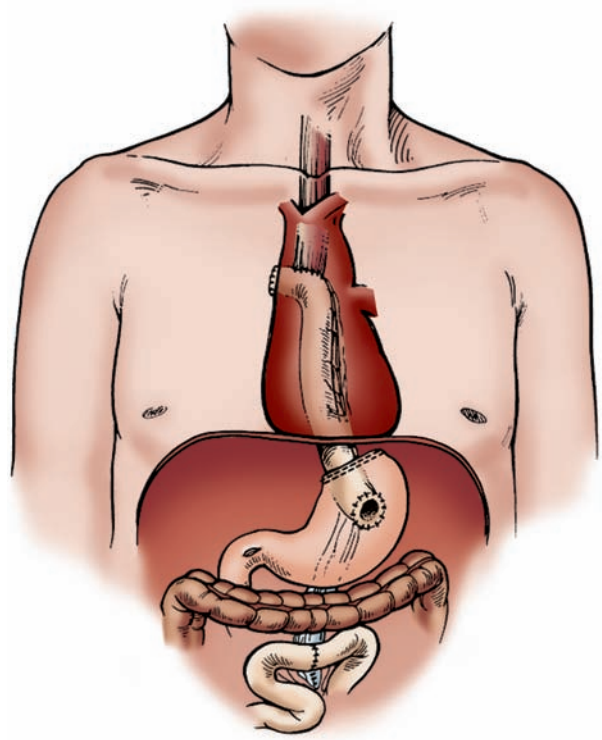

FIGURE 18-33 Jejunal interposition graft to reconstruct the lower esophagus. An end-to-side esophagojejunostomy is performed to avoid tension on the vascular pedicle. A posterior jejunogastric anastomosis avoids tortuosity of the conduit while an 8- to 12-cm segment of the jejunal graft situated below the hiatus aids in the control of reflux.

FREE JEJUNAL TRANSFER

Free jejunal transfer is needed if the pedicle is not of sufficient length, such as in replacement of a portion of the cervical esophagus for benign disease. It is not clear whether use of a free jejunal transfer is preferable to total esophagectomy and gastric pull-up. The use of jejunum does carry a lower incidence of postoperative reflux and avoids dissection of the thoracic esophagus; however, there is increased risk of graft ischemia and gangrene. Two anastomoses are required and there is an increased risk of anastomotic leak. As with a pedicled jejunal graft, a short segment of jejunum is chosen for harvest. A left cervical incision is made, and the esophagus as well as the carotid artery and jugular vein are isolated. A dominant feeder vessel in the jejunal segment is identified and divided with a scalpel. The artery and vein are flushed with heparinized saline. The proximal anastomosis is constructed first and is performed with a two-layer end-to-side hand-sewn anastomosis. An operating microscope is then used to perform the arterial and venous anastomosis to the carotid artery and jugular vein with 9-0 or 10-0 Prolene suture. The distal anastomosis is then performed in fashion identical to the proximal anastomosis (Fig. 18-34). Typically, a meshed skin graft is placed over the conduit for continuous postoperative monitoring. A feeding jejunostomy tube is placed as with every case of esophageal replacement.

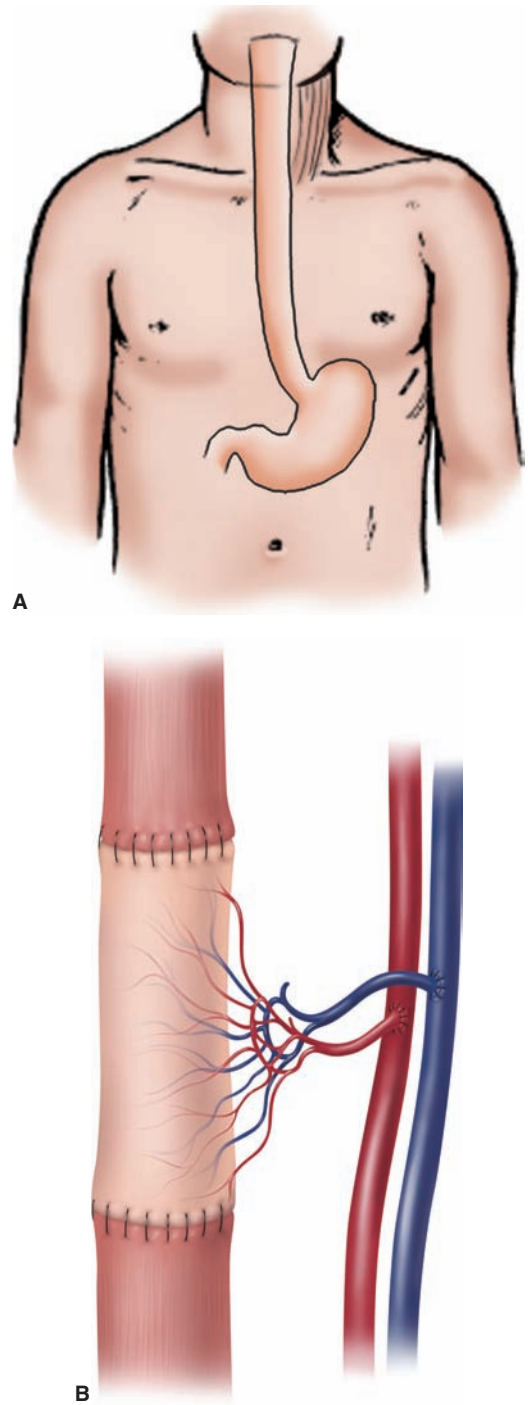

FIGURE 18-34 Free jejunal graft used as a cervical esophageal replacement. It is typically covered with a meshed skin graft so that conduit health can be observed postoperatively.

COMPLICATIONS AND HOW TO AVOID THEM

Anastomotic Leak

The incidence of anastomotic leak is higher following cervical anastomosis (10–15%) than intrathoracic anastomosis (5–10%).[22,30,31] The incidence of leak is believed to be higher in the cervical position for several reasons. First, increased length is needed and this may place increased tension on the anastomosis. The tip of the stomach, which is used in the cervical anastomosis, may have a more tenuous blood supply, as it is farther from the gastroepiploic artery. Additionally, venous engorgement due to a tight thoracic inlet may impair blood supply. An analysis of anastomotic leaks found that albumin level below 3 g/dL, positive margins, and cervical anastomosis were risk factors for anastomotic leak following esophagectomy.[32] A randomized comparison of hand-sewn versus stapled anastomosis in 102 patients undergoing Ivor Lewis esophagectomy did not show any significant difference in the incidence of anastomotic leak. The incidence was 5% after a single-layer monofilament anastomosis and 2% after a stapled anastomosis.[33] The incidence of leak following hand-sewn anastomosis is more operator-dependent, and those who perform few of these procedures may wish to use a stapled technique.

Anastomotic leak following Ivor Lewis esophagectomy is a feared complication that in the past was associated with a 50% mortality rate. Centers that routinely employ this technique have refined their techniques, resulting in very low leak rates in the 2% range. Early detection and aggressive management can reduce the high mortality rate usually associated with this complication. Unexplained fever, elevated white cell count, respiratory failure, delirium, hypotension, or low urine output may signal the onset of an intrathoracic leak. Confirmation is usually possible by Gastrografin swallow or instillation of

contrast through the nasogastric tube. Immediate intervention is required, and attempts at direct repair with muscle flap reinforcement and wide drainage are often successful. Patients who are unstable or severely ill should be diverted with a spit fistula, and either excluded at the hiatus, or have the conduit closed and returned to the abdomen. In rare instances, a clinically silent, small, contained leak that is not adjacent to vital structures such as the trachea or aorta may be observed and treated with strict NPO status and enteral feeds.

Although leak is more common following cervical anastomosis, it is rarely life-threatening. Occasionally a cervical anastomosis may leak into the chest and must be treated like an intrathoracic leak. Initially, mortality from a cervical leak was estimated at 20%, though recent series have shown that the mortality is much lower.[34] Cervical anastomotic leak is usually signaled by fever, erythema, and fluctuance in the neck incision. Opening of the neck incision and probing down to the prevertebral fascia (with placement of a drain) is usually all that is needed. Patients can be allowed clear liquids by mouth and may be fed via jejunostomy tube until the leak is sealed. Barium swallow following esophagectomy may miss 10% of cervical leaks. Giving patients purple grape juice to drink and observing the drain during swallow may detect leaks missed by barium swallow.

Anastomotic Stricture

The same risk factors that predispose to anastomotic leak also predispose one to stricture. Indeed, it is very common to present with stricture following treatment for an anastomotic leak. Retrospective meta-analyses have shown that the incidence of stricture is higher after cervical reconstruction (28%) than after Ivor Lewis reconstruction (16%).[22] The definition of stricture is not precise and is usually determined by the need for intervention (ie, dilation). As some surgeons are more aggressive than others with regard to dilation, this value may be misleading. A retrospective analysis of transhiatal esophagectomy patients revealed that the use of a stapled anastomosis, anastomotic leak, and the presence of cardiac disease were the only risk factors associated with the development of stricture.[35] Other studies have mentioned intraoperative blood loss and poor conduit vascularization as risk factors. A unifying theme in anastomotic stricture (other than mechanical stapler issues) is impaired blood supply to the region of anastomosis. In an effort to avoid ischemia, it is wise not to place the anastomosis too close to the tip of the gastric conduit. Careful handling of the gastroepiploic artery, ensuring systemic oxygen delivery, and avoidance of congestion all are important in avoiding anastomotic leak and stricture.

Mechanical factors may also contribute to development of stricture, especially when an EEA-stapled anastomosis is performed. In a randomized evaluation of the EEA stapler for Ivor Lewis anastomosis, the incidence of stricture was found to be 40% with a stapled anastomosis versus 9% with a hand-sewn anastomosis. When a small (25-mm) EEA stapler was used, the incidence of stricture was 43% as opposed to a 12.5% incidence with a 29-mm stapler, and no strictures was seen with a 33-mm stapler.[33]

Postoperative strictures may nearly always be managed by bougie dilation. Often, repeat dilations are needed. In the aforementioned study of strictures following Ivor Lewis esophagectomy, 53% of patients needed one dilation, 20% required two, 12% required three, and 8% required four. No patient was treated with reoperation. In Honkoop and associates' study of anastomotic stricture following transhiatal esophagectomy, the average patient required three dilations to achieve normal swallowing. Perforations occurred in 2 of the 519 patients requiring dilation.[35]

Recurrent Laryngeal Nerve Injury

The clearest risk factor for recurrent nerve injury is cervical anastomosis. In a retrospective analysis, the incidence of recurrent nerve injury with a cervical anastomosis was double (11%) that for intrathoracic anastomosis (5%).[22] The recurrent nerve can be injured at any point, from its "recurrence" from the vagus nerve (around the subclavian artery on the right and around the aortic arch on the left), to its course in the tracheoesophageal groove, to its insertion into the larynx. Although an Ivor Lewis resection should not touch the recurrent nerve, traction or cautery injury to the vagus nerve may cause injury to the recurrent nerve.

A left neck incision is often used to approach the cervical esophagus. The right recurrent nerve is farther from the esophagus than the left, and it is easier to avoid the right nerve from a left neck incision than it is to avoid the left nerve from a right neck incision. During neck dissection, it is important to stay immediately against the esophagus in order to avoid injury to the nerve. In a review of tri-incisional esophagectomy by Swanson and colleagues, refinements in technique resulted in a reduction of recurrent nerve injury from 14% to 7%.[36] In the Brigham and Women's Hospital technique, the vagus nerves are divided at the level of the azygos vein, and cranial dissection of the esophagus proceeds within the nerves. A Penrose drain is used to surround the esophagus and is positioned in the neck for later retrieval during the cervical phase of the operation to ensure isolation of the esophagus inside the recurrent nerves.

Early recognition and aggressive treatment is necessary to minimize respiratory complications from recurrent nerve injury. Recurrent nerve injury prevents cord apposition, making an effective cough impossible and interfering with protective reflexes involved in swallowing. Hoarseness is present with recurrent nerve injury but may be present after any intubation. Loss of effective cough is another hallmark of recurrent nerve injury but may not be present immediately following extubation, because there may be swelling of the cords after use of a double-lumen tube, a prolonged operation, and large fluid shifts. Effective cough may be lost between 24 and 48 hours after extubation as cord swelling decreases. Any patient with hoarseness and ineffective cough should undergo fiberoptic laryngoscopy. Immediate injection of the affected cord with gelfoam will allow an effective cough and clearance of secretions.

Respiratory Complications

In early series, anastomotic leak and infection were the most common cause of death following esophagectomy. In modern series, the most common cause of death is respiratory failure. The incidence of pneumonia following esophagectomy ranges from 2 to 57%.[26,31,37] The assumption that the incidence of pneumonia is higher with transthoracic esophagectomy than with transhiatal esophagectomy has not been definitively borne out by the literature. A large meta-analysis by Rindani and coworkers showed no difference in incidence of pneumonia between the two techniques.[22] Two randomized trials, one by Goldmine and associates and one by Chu and colleagues, also showed no difference in the incidence of pneumonia.[24,25] A larger randomized trial comparing tri-incisional, en bloc esophagectomy with transhiatal esophagectomy did show a higher incidence of combined atelectasis and pneumonia in the tri-incisional group (57%) versus the transhiatal group (27%). The unexpectedly high incidence of pulmonary complications in the transthoracic group should, however, be questioned, as reported rates are typically around 20–35%.[20,21]

A variety of modifications and maneuvers can be employed to limit the incidence of pulmonary complications. All efforts must be made to spare injury to the recurrent nerve, and, if injured, aggressive intervention including cord medialization is necessary. Efforts at limiting pain associated with thoracotomy, including a limited muscle-sparing thoracotomy, are helpful. The use of thoracic epidurals has been shown to decrease the incidence of pulmonary complications in thoracotomy patients. Early ambulation and aggressive pulmonary toilet are necessary.

Bleeding

Bleeding following esophagectomy occurs about 5% of the time regardless of the technique used. Meta-analyses have shown that estimates of blood loss are slightly higher with the transthoracic group as opposed to the transhiatal group.[23] Preoperatively, antiplatelet agents should be stopped well in advance of surgery. Low-lose subcutaneous heparin or low-dose low-molecular-weight heparin should not increase the incidence of perioperative bleeding. Intraoperatively, arterial branches from the aorta to the esophagus should be clipped whenever possible. If blunt dissection is used, staying immediately against the esophagus should help avoid larger arteries, as the esophageal arterioles tend to form a fine plexus of vessels approximately 1–2 cm away from the wall of the esophagus. A notorious site of bleeding during the transhiatal dissection is the azygos vein or one of its branches. This bleeding usually occurs at about the level of the carina, and, as always, extra care should be taken at this level. A common site of bleeding after any thoracotomy is the chest wall itself, including intercostal vessels; these should be inspected after removing the retractor.

Chyle Leak

The thoracic duct enters the chest through the aortic hiatus and lies between the spine, azygos vein, and aorta at the level of the diaphragm. At approximately the T6 level, it crosses to the left side and eventually empties into the left subclavian vein. The incidence of chyle leak following esophagectomy ranges from 2 to 10% and is at greatest risk during en bloc resection. If the thoracic duct is taken during en bloc dissection, the duct is ligated at the hiatus and inspected for leak. It is wise to inspect the area of the thoracic duct at the end of any transthoracic dissection of the esophagus. Often, clear fluid (in the unfed patient) can be seen welling up in the area and may lead one to a laceration of the thoracic duct. In such instances, the leak should be repaired directly with pledgeted 4-0 Prolene sutures. Prophylactic ligation of the thoracic duct following esophagectomy is sometimes performed. In this maneuver, all tissue between the aorta, spine, and azygos vein at the level of the hiatus is ligated with a large (0 or 1) ligature.

The diagnosis of a thoracic duct leak should be suspected if chest tube output remains high (>800 mL/d) in a patient despite a normal volume status. Definitive diagnosis may be difficult, because chyle is not milky unless the patient has been fed fats. Fluid should be sent for Gram's stain, triglyceride level, cell count, and cholesterol level. A triglyceride level greater than 1 mmol/L is strongly suggestive of a chyle leak, as is a lymphocyte count greater than 90%. If chylomicrons can be confirmed by electrophoresis, the diagnosis can also be established. A good bedside test involves feeding the patient cream enterally 200–300 mL over 2 hours and observing for a change in character of chest tube effluent, from serous to milky white.

Chyle leak following esophagectomy must be repaired. These patients are recovering from major surgery and most are malnourished. The loss of protein and lymphocytes associated with a chyle leak may be associated with infections and may interfere with healing. Once the diagnosis is confirmed, or even if it is strongly suspected, patients should be brought to the operating room and the thoracotomy incision reopened. The patient is given enteral cream 1 hour before the procedure to help locate the leak. The defect is repaired with a pledgeted 4-0 or 5-0 Prolene suture. A careful inspection for other leaks should be performed before closure, and mass ligation of the duct at the hiatus should be considered as well.

CT or MRI-guided noninvasive methods have been proposed for repairing chyle leaks. The cisterna chyli can sometimes be located under CT guidance, cannulated, and injected with either coils or glue. In a published trial of 42 patients (including 9 postesophagectomy patients), the thoracic duct could be embolized in 26 and 16 of these cases were cured.[38]

Impaired Conduit Emptying

Numerous factors affect conduit emptying postesophagectomy. These include vagotomy, drainage through the pylorus, width

of the conduit, redundancy and/or kinking of the conduit, and postoperative swelling. Studies objectively looking at conduit emptying following esophagectomy give conflicting results as to the effect of pyloroplasty on gastric conduit emptying time. A prospective trial studied 200 patients and randomized half to pyloroplasty and half to no pyloroplasty following Ivor Lewis esophagectomy.[39] The average daily postoperative nasogastric drainage was no different between the two groups. Thirteen patients who did not undergo pyloroplasty had symptoms from delayed gastric emptying, and two died of aspiration pneumonia. There were no complications from the pyloroplasty procedure. Six months after the procedure, gastric emptying was 6 minutes in the pyloroplasty group versus 24 minutes in the group without pyloroplasty. These patients had more symptoms attributable to delayed emptying as well. The same group conducted a randomized trial of pyloroplasty versus pyloromyotomy and found both to be equally effective and safe.

Width of the gastric conduit may also affect emptying. A thin gastric tube has been shown to have a lower incidence of symptoms related to poor gastric emptying (3%) than patients either with the whole stomach (38%) or distal two-third stomach (14%) acting as the conduit.[40] A conduit diameter of 5–6 cm is probably ideal. Excess conduit length or angulation may also impair emptying, and excess colon conduit length or angulation is known to cause immediate or delayed problems with emptying. However, a conduit that is too thin can lead to an increased anastomotic leak rate.[41]

CONCLUSION

Esophagectomy can be a technically challenging operation. Mortality rates can vary greatly with experience. Hospital volume and surgeon experience play significant roles. Analysis of the relationship between volume and mortality shows a large variance in mortality from almost 25% in low-volume and low-experience centers to as low as 2.5% in high-volume centers.[42,43] With improvements and increased penetration of minimally invasive techniques, mortality has been reported as low as 1.4 %.[41] Careful patient selection, preoperative preparation, and choice of operation, as well as meticulous surgical technique, excellent anesthetic and intensive care, and aggressive management of postoperative complications can limit the morbidity and mortality of this operation.

VIDEO-ASSISTED THORACIC SURGERY OF THE ESOPHAGUS

Ryan M. Levy • James D. Luketich

INTRODUCTION

Since the initial description of laparoscopic fundoplication in 1991,[1] there has been continued interest in minimally invasive approaches to esophageal disease. While proponents of minimally invasive surgery claim decreases in perioperative pain and length of stay, critics often express concerns over compromised outcomes, prolonged operating times, and increased cost. However, numerous reports have documented that for both gastroesophageal (GE) reflux and achalasia,[2,3] the laparoscopic approach offers equal efficacy and safety as well as decreased recovery times compared with traditional open surgery. These reports and the benefits of minimally invasive surgery perceived by the general public have increased referrals to surgeons who offer these approaches to esophageal disorders, even though alternative medical therapies are available.[4,5]

Although laparoscopic approaches for many benign conditions involving the distal esophagus and GE junction are now standard of care, this is not necessarily the case for minimally invasive approaches to the thoracic esophagus. This is particularly true for esophageal cancer. Concerns regarding the high degree of technical complexity, significant operator learning curves, reproducibility of outcomes in lower-volume centers, and equivalence of oncologic outcomes are at the forefront of the discussion. Despite evolving techniques and improvements in both the transhiatal and Ivor Lewis surgical approaches, esophagectomies are complex operations that are associated with significant morbidity and mortality. Furthermore, surgical candidates are often elderly patients with coexisting medical comorbidities, including respiratory and cardiovascular diseases. Nationwide, the mortality rates from esophagectomies range from 8% in high-volume centers to as high as 23% in low-volume centers.[6]

The application of minimally invasive surgery to complex cases may offer several potential benefits. First, open esophagectomy, even in experienced centers, continues to be associated with a significant morbidity, lengthy hospital stay, and delay in returning to preoperative activities.[7] This high complication rate along with the disappointing 25% 5-year survival rate after esophagectomy has led to ongoing concern over the role of surgery in the treatment of esophageal cancer. Consequently, for some patients, alternative approaches such as definitive chemoradiation alone, palliative photodynamic therapy, or stents may be chosen by health care providers. Minimally invasive approaches to esophagectomy that promise to decrease perioperative morbidity and allow for faster postoperative recovery are, therefore, appealing to patients and referring physicians. The caveat, however, is that the minimally invasive approach should not compromise operative technique or oncologic and functional outcomes.

There has been a significant evolution in technique since the initial descriptions of hybrid approaches to esophagectomy that employed thoracoscopic esophageal mobilization with a laparotomy.[8–10] Although no randomized studies of minimally invasive esophagectomy (MIE) have been performed, experience in our first 222 patients has suggested that MIE is associated with a complication rate and mortality lower than most reports of open esophagectomy.[11] In our experience, a minimally invasive approach reduces postoperative pain and pulmonary complications while comparing favorably to the best published open series with regard to morbidity, mortality, and oncologic outcomes. In addition, we and others have shown that minimally invasive staging of esophageal cancer patients is superior to conventional staging by computed tomography (CT) and endoscopic ultrasound (EUS)[12] and may allow for a better selection of patients to receive combined modality therapy. In this chapter, we review our experience with minimally invasive surgery for esophageal cancer, as well as detail surgical techniques for several other diseases of the thoracic esophagus, such as resection of benign esophageal tumors and thoracoscopic treatment of esophageal dysmotility. Laparoscopic approaches to other complex esophageal operations, including achalasia and paraesophageal hernia, are covered in Chapters 14 and 15.

ESOPHAGEAL CANCER

The optimal management of patients with potentially resectable esophageal cancer is still evolving. Although surgery remains the standard of care for early disease, several studies have suggested that definitive chemoradiation may be an acceptable alternative. This position is supported by the results of a randomized, prospective trial conducted by the Radiation Therapy Oncology Group (RTOG 8501), which compared definitive chemoradiation versus radiation therapy alone for patients with locally advanced esophageal cancer, who were not considered surgical candidates.[13] The study was closed after accrual of 121 patients, due to a clear survival benefit in the combined treatment group. The surprising finding in this study was that the 5-year survival in the chemoradiation group was 27%, a rate not appreciably different from the survival rates following esophagectomy alone.[14]

Additional support for the use of chemoradiation for esophageal cancer comes from the results of two, large prospective European studies. In these studies, chemoradiation followed by surgery was compared to chemoradiation alone.[15,16] In both studies, overall survival was equivalent between the two treatment arms. Chemoradiation with surgery decreased locoregional recurrence within 2 years of surgery. However, with chemoradiation alone, treatment-related mortality was decreased and hospital stays were shorter.[15,16]

These reports have led some clinicians to recommend nonoperative therapy for marginal surgical candidates, such as the elderly or those with multiple comorbidities. Indeed, the National Comprehensive Cancer Network now considers definitive chemoradiation to be an acceptable alternative to esophagectomy in their recent guidelines.[17] It is incumbent upon esophageal surgeons, therefore, to continue to refine the technique of esophagectomy, in order to offer therapy with either lower morbidity, improved survival, or both compared to traditional esophagectomy and other approaches.

Staging for Esophageal Cancer

Unlike lung cancer, in which mediastinoscopy is an accepted and proven staging technique, no invasive modality is considered standard for staging patients with esophageal cancer. However, to date none of the noninvasive staging techniques currently available, such as CT, EUS, or positron emission tomography (PET), has proven accurate enough to preclude the need for invasive staging. A recent evidence-based review concluded that there exists a benefit for laparoscopic staging of esophageal cancer based on level 2 evidence, showing a sensitivity of 71 and 78% for detection of peritoneal and nodal metastasis, respectively.[18] This compared favorably and exceeded sensitivities for endoscopic ultrasound and CT imaging.

The current noninvasive technology suffers from several, well-described limitations. CT, often the initial staging test performed for patients with esophageal cancer, is an appropriate tool to screen for distant disease, such as pulmonary or liver metastases. However, even in this role, occult metastatic disease is missed by CT scans in up to 15–20% of patients.[19] Furthermore, CT is clearly unable to provide sufficient anatomic detail to either accurately stage the depth of invasion of the esophageal wall or determine the presence of local nodal involvement. Indeed, the accuracy of CT scanning for nodal disease is only 45–60% in most series.[20,21]

PET scanning is a recently introduced technology that is based on imaging the differential uptake of radio-labeled glucose by malignant and normal cells. PET scanning has been extensively studied in the context of both lung and esophageal cancer. Indeed in some centers, PET scanning has become a routine component of the preoperative evaluation of lung cancer patients. This practice is justified by several meta-analyses that have demonstrated the superiority of PET over CT in staging nodal disease in the mediastinum.[22,23] However, equal efficacy for PET scanning has not been demonstrated for esophageal cancer patients. We have found the accuracy of PET scanning to assess locoregional lymph nodes in patients with esophageal cancer to be only about 50%.[24] The specificity is improved, compared to CT, but the sensitivity remains poor. In our experience PET scanning has been more useful in detecting distant metastatic disease. In a series of 100 consecutive patients with potentially resectable esophageal cancer staged at our institution by PET and CT, PET identified metastatic disease in 16% of patients missed by CT.[25] The false-negative rate for PET in this series was only 10% and usually occurred in cases of subcentimeter disease that was below the detection threshold of PET scans.

Another staging tool available in specialized centers is EUS. Although EUS is operator dependent, in experienced hands its accuracy for assessing T stage is greater than 90%, and it has an image resolution of 0.2 mm.[26] The accuracy of determining T stage increases with penetration of the esophageal wall: the accuracy for T1 tumors is 80%, T2 tumors 90%, and T3/4 tumors 95%.[27] However, the accuracy of EUS to determine nodal status is far lower than its ability to determine tumor depth and has been reported to be 65–86%.[12,28]

Technique of Minimally Invasive Surgical Staging

Currently, all patients at the University of Pittsburgh with a diagnosis of esophageal cancer undergo noninvasive staging with CT scans, PET scanning, and EUS. If any of these studies indicates metastatic disease or nodal involvement (in the case of EUS), a needle biopsy is performed. If distant metastatic disease is proven, palliative options are generally pursued. For patients without proven metastatic disease and GE junction tumors, we then, generally, proceed to laparoscopic staging. Laparoscopic staging is performed with the patient in a steep reverse Trendelenburg position with the surgeon standing on the patient's right side.

OPERATIVE STEPS OF MINIMALLY INVASIVE STAGING—LAPAROSCOPY

1. An initial 10-mm blunt trocar is placed via an open, cut-down technique in the right epigastrium. The location of this port is approximately 3 cm to the right of the junction between the lower and middle third of a line connecting the xiphoid and umbilicus. After the first port is placed, a visual assessment is made of the liver and peritoneal surfaces, and, if obvious metastatic disease is present, biopsy confirmation is obtained and the staging is complete. If no metastatic disease is seen on this initial survey, a more thorough staging is performed with placement of additional port sites. These are placed in the same locations utilized for MIE.
2. The five ports generally include one 10-mm blunt cut-down port just to the patient's right of midline, midway between the xiphoid and umbilicus (for the surgeon's right hand instruments), one 10-mm port at the same level to the left of midline for the laparoscope, two additional 5-mm ports along the right costal margin (for liver retraction and dissection), and one 5-mm port on the left costal margin for countertraction by the assistant (Fig. 19-1). The liver surfaces are carefully examined and any abnormalities biopsied. Ultrasound examination of the liver may then be performed, although in our experience, the yield of ultrasound examination in patients who do not have some visual evidence of liver metastases is low.[19]
3. The stomach is carefully assessed for gastric extension of the tumor to determine the suitability of the stomach for gastric pull-up.
4. Nodal assessment is initiated by incising the gastrohepatic ligament. The lesser sac is entered, and nodes along the lesser curve and at the base of the celiac artery are sampled.
5. We have been evaluating preoperative "conditioning" of the esophagus. This may be performed at the time of laparoscopic staging and includes lymph node dissection of the left gastric artery and vein and division with an Autosuture Endo GIA stapler (Covidien, Mansfield, MA) with a vascular load. We also divide the short gastric vessels from the left crus to the right gastroepiploic arcade.
6. At the conclusion of the staging procedure, a laparoscopic feeding tube may be placed. However, we have found that, in most cases, dysphagia will respond to chemotherapy, rendering a feeding tube unnecessary. If chemotherapy is planned, an Infusaport is placed at the time of staging.

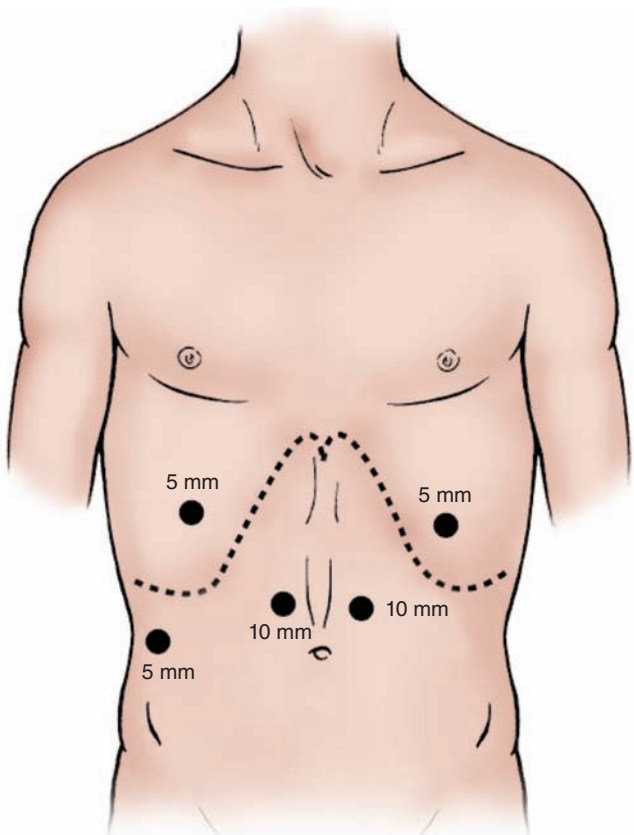

FIGURE 19-1 Abdominal port placement for staging laparoscopy and totally minimally invasive Ivor Lewis esophagectomy.

If the patient has no metastatic disease and minimal or no nodal disease is apparent on laparoscopy, we proceed to MIE. We have not found routine thoracoscopic staging to be very beneficial for most adenocarcinomas of the distal esophagus. Thoracoscopy is used selectively for tumors of the midthoracic esophagus, once laparoscopic staging has excluded gross intra-abdominal disease. This practice is based on our prospective series of 53 patients all of whom underwent both laparoscopic and thoracoscopic staging. Of the 36 patients with adenocarcinoma of the GE junction, those who were identified as node-positive using minimally invasive staging, 31 were identified by laparoscopy.[12] If thoracoscopy is indicated, the approach is normally through the right chest, although a left-sided approach may be appropriate if suspicious pulmonary lesions are identified on that side.

OPERATIVE STEPS OF MINIMALLY INVASIVE STAGING—THORACOSCOPY

1. Five ports are used for access and placed as depicted in Fig. 19-2.
2. The initial step is to mobilize the inferior pulmonary ligament and to sample the level 9 nodes.
3. Next, the pleura overlying the lower third of the esophagus is opened. Once this plane is developed, nodes from the periesophageal (level 8) and subcarinal stations (level 7) may be harvested. Lymph node dissection is continued until a positive node is found or an adequate sampling indicates benign nodes only.

Two large, prospective studies have investigated the benefits of minimally invasive staging for esophageal cancer. The first, from our institution, showed significant advantages

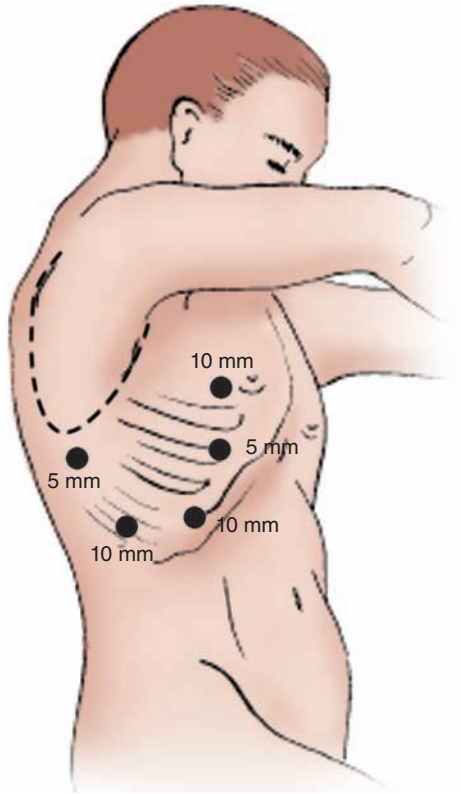

FIGURE 19-2 Thoracoscopic port placement for staging and totally minimally invasive Ivor Lewis esophagectomy.

for minimally invasive staging compared with more standard modalities.[12] All 53 patients in this report underwent CT and concurrent laparoscopy and thoracoscopy. Forty-seven patients also underwent endoscopic ultrasound. The sensitivities of CT and EUS to document nodal metastases were only 33 and 63%, respectively. Even when these two modalities were combined, inaccuracies in staging were seen in 32% of cases, compared with minimally invasive staging. Only two complications were seen in this series: a prolonged air leak and a port site hernia that was repaired on the first postoperative day.

The second study, comprising 134 patients, was a multi-institution, National Cancer Institute (NCI)–sponsored study designed to determine the feasibility of minimally invasive staging.[29] Successful minimally invasive staging was defined as documentation of T4 or M1 disease, the procurement of at least one abdominal and three thoracic lymph nodes, or one node that documented metastatic disease. Minimally invasive staging was successful in 73% of patients and was performed with no mortality and only minimal morbidity. Noninvasive tests, such as CT and EUS, failed to identify positive lymph nodes documented by minimally invasive staging in 20% of patients. Unfortunately, the true sensitivity of minimally invasive staging was not determined by this study because the majority of patients underwent induction chemotherapy prior to resection.

Ultimately the role of minimally invasive staging should be clarified by clinical trials that demonstrate a survival advantage for patients with node-positive disease who receive induction therapy. To date, most randomized trials have had significant limitations and demonstrated marginal benefits for preoperative chemoradiation.[30] However, the poor survival obtained after surgery alone ensures that the neoadjuvant approach will continue to be investigated. We believe that a significant limitation of the studies performed to date is that patients have not been accurately staged prior to undergoing combined modality therapy. Accurate staging may identify a subpopulation of patients who would benefit from such aggressive treatment, and studies not designed for subgroup analysis may report false-negative conclusions.

Molecular Staging of Esophageal Cancer

It is estimated that between 30 and 50% of patients who are staged as node-negative by routine histological evaluation following esophagectomy will develop a recurrence of their disease.[31] This suggests that these patients harbored micrometastatic disease that was undetected by routine histology. In an attempt to improve the staging of these patients, we have used minimally invasive staging to obtain lymph nodes that are evaluated with molecular biology techniques, such as reverse transcription polymerase chain reaction (RT-PCR), to determine the presence of micrometastases.[32] We evaluated nodes from 30 patients who were histologically staged as node-negative.[33] Of these 30 patients, 11 were identified by RT-PCR as harboring micrometastatic disease. Furthermore, the quantitative expression of carcinoembryonic antigen by RT-PCR was a powerful, independent predictor of disease recurrence and death. We believe that these techniques may identify patients with early-stage disease who have a high risk of recurrence and may benefit from additional therapy.

Minimally Invasive Esophagectomy

The technique of minimally invasive esophagectomy (MIE) that has evolved as our experience with other minimally invasive foregut procedures, such as laparoscopic Heller's myotomy, repair of giant paraesophageal hernia, and staging for esophageal cancer, has grown. At present, minimally invasive techniques for esophagectomy include laparoscopic transhiatal, laparoscopic-thoracoscopic three-hole (McKeown), and laparoscopic-thoracoscopic (Ivor Lewis) esophagectomy. Each of these can be performed with lymph node sampling or a more complete lymph node dissection. While the choice between approaches is to a large degree based on surgeon preference, the operative approach is at times dictated by anatomic location of the tumor margins.

Initial attempts at MIE were hybrid operations combining traditional open surgery with minimally invasive techniques. One of the first reports by Collard et al in 1993 included 12 patients who underwent thoracoscopic mobilization of the esophagus followed by laparotomy and preparation of the gastric conduit.[9] In that series, two patients required conversion to thoracotomy for bleeding. Several subsequent reports have demonstrated the feasibility of this approach; however no definitive benefit has been shown compared to open esophagectomy.[34–36]

A completely laparoscopic transhiatal esophagectomy has also been described. The largest series, published by DePaula et al in 1995,[37] described 48 patients who required esophagectomy predominantly for end-stage achalasia secondary to Chagas' disease. Only two patients required conversion to laparotomy. Early experience with MIE in the United States was reported in 1997, when Swanstrom and Hansen described a carefully selected group of nine patients with small tumors, benign strictures, and Barrett's disease.[38] Eight of these patients had a totally laparoscopic transhiatal esophagectomy, while one required the addition of a right video-assisted thoracoscopic surgery (VATS) procedure.

Similar to these early reports, our initial efforts at MIE were with the transhiatal approach. Advantages of a totally laparoscopic approach include single patient positioning and no need for single-lung ventilation. However, we found that the disadvantages of this approach were significant. The small working space through the hiatus allowed limited access to the middle and upper third of the esophagus and made any thoracic lymph node dissection extremely difficult. Because of this, we added a right VATS to mobilize the thoracic esophagus followed by laparoscopy to prepare the gastric tube. To date, we have performed over 1000 MIEs at the University of Pittsburgh Medical Center. For the majority of our initial experience, we utilized a three-hole laparoscopic-thoracoscopic approach. In our earlier publications with this technique, we demonstrated that MIE could be performed safely with equivalent stage-specific survival as compared to the larger open series in the existing literature.[11] Though technically demanding and associated with a significant operator learning curve, data from our series revealed a decrease in operative blood loss, length of stay, pulmonary complications, and narcotic requirements. In both our own experience and publications elsewhere, concerns arose regarding an increased incidence of technical complications associated with cervical esophagogastric anastomosis, including anastomotic leak, stricture, recurrent laryngeal nerve injury, and pharyngoesophageal swallowing dysfunction.[39–41] In light of these concerns and the dominance of GE junction cancers in our current referral pattern, our technique has evolved to a completely laparoscopic-thoracoscopic (Ivor Lewis) esophagectomy with complete lymph node dissection. Unless contraindicated by tumor location or previous thoracic surgery, we presently favor the totally minimally invasive Ivor Lewis approach.

The main criteria favoring the Ivor Lewis approach include the following: (1) The surgical margin afforded by the Ivor Lewis approach is adequate for almost all GE junction tumors. (2) The technical experience of most training programs in thoracic and general surgery residencies is in the abdomen and chest and not in the neck. (3) The morbidity of recurrent laryngeal nerve injury is as high as 20–30% with neck anastomosis. (4) The length of gastric conduit needed to reach the neck may be up to 10 cm longer than that needed for an intrathoracic esophagogastric anastomosis. (5) Although easier management of leaks through the neck incision may be considered an advantage of cervical anastomoses, leaks from the neck may still drain into the chest after laparoscopic-thoracoscopic three-hole (McKeown) techniques especially when a narrow gastric conduit is constructed.

Early in our experience, MIE was only offered to patients with Barrett's disease and early-stage tumors; however, we now offer MIE to patients with more advanced disease. Patients found to have bulky celiac nodal metastases by CT or staging laparoscopy are not felt to be immediate candidates for MIE, and consideration is given to an open operation, a neoadjuvant protocol, or definitive chemoradiation.

Operative Technique

As previously mentioned, our preferred approach has evolved to a totally minimally invasive laparoscopic-thoracoscopic (Ivor Lewis) esophagectomy. The patient is positioned supine on the operating room table with a foot board in place. A double-lumen endotracheal tube is placed for single-lung ventilation during the thoracoscopic portion of the procedure. The laparoscopic portion of the procedure is performed first.

LAPAROSCOPIC PHASE

1. The initial step of MIE is an on-table esophagogastroduodenoscopy (EGD) to confirm the precise location of the tumor, evaluate proximal and distal extent with careful attention to involvement of the cardia, and assess the suitability of the stomach as a conduit for reconstruction. It is important to minimize insufflation during the endoscopy as overdistention of the small bowel can complicate the laparoscopic phase of the procedure.
2. The laparoscopic portion of the procedure is then initiated. The surgeon stands on the right side and the assistant on the left. Five ports (three of 5 mm and two of 10 mm) are placed, similar to the staging procedure (see Fig. 19-1). Initially, we place the 10-mm port via a cut-down technique approximately 3 cm to the right of the junction between the lower and middle third of a line connecting the xiphoid and umbilicus. Carbon dioxide insufflation is utilized for pneumoperitoneum to a pressure of 15 mm Hg. The remaining ports are then placed: 5 cm to the left of the operating port (30-degree camera port), subcostal on the right and left midclavicular lines (tissue grasper ports), and in the right flank (liver retractor port). If clinically indicated, we then perform laparo-

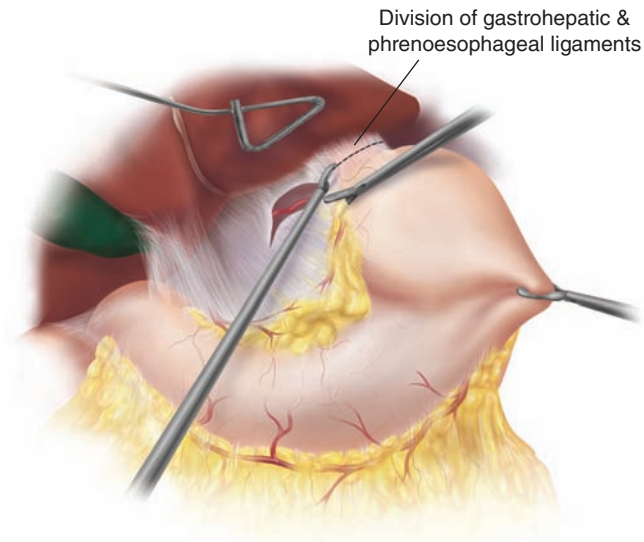

FIGURE 19-3 Initial dissection, division of gastrohepatic ligament and crura, hiatal mobilization.

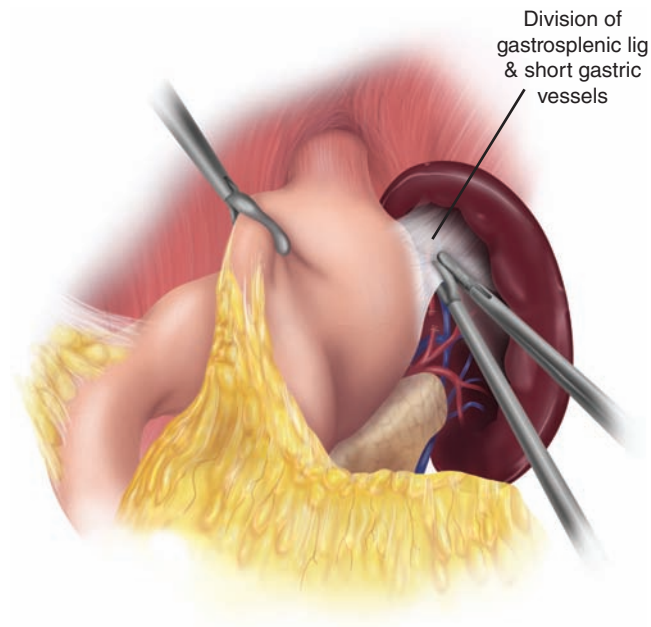

FIGURE 19-4 Gastric mobilization. (Modified from Tsai WS, Levy RM, Luketich JD. Technique of minimally invasive Ivor Lewis esophagectomy. *Op Techn Thorac Cardiovasc Surg*. 2009;14:176–192. Copyright 2009, with permission from Elsevier.)

scopic staging as described previously. This lower position of the ports may make the hiatal dissection somewhat difficult but greatly facilitates the mobilization of the gastric tube. This emphasizes the importance of completely mobilizing the esophagus and any hiatal hernia sac circumferentially during the thoracoscopic dissection.

3. The gastrohepatic ligament (lesser omentum) is first divided and the right and left crura of the diaphragm are dissected to mobilize the lateral wall of the esophagus (Fig. 19-3). Care is taken not to divide the phrenoesophageal membrane at this point so as to prevent loss of pneumoperitoneum into the chest cavity. The left gastric artery/vein pedicle is identified, and by tracing its course proximally the celiac lymph nodes are then examined. A complete lymph node dissection is carried out to include the celiac nodes, sweeping all nodal and fatty tissue with the specimen; the nodal dissection is later continued along the splenic artery and the superior border of the pancreas during gastric mobilization. This plane continues cephalad toward the right and left crus, continuous with the preaortic dissection plane into the lower thoracic cavity. All lymph nodes are removed, and any lymph nodes suspicious for metastatic involvement are dissected and sent for frozen-section analysis.
4. Gastric mobilization (Fig. 19-4). The dissection is then carried anteriorly and superiorly over the esophagus to finally expose the anterior hiatus. As the dissection is continued toward the left crus, the fundus of the stomach begins to be mobilized. The medial border of the right crus is dissected inferiorly until the decussation of the right and left crural fibers, thereby exposing a retroesophageal window and completing the mobilization of the superior portion of the lesser curvature and GE junction. The greater curvature of the stomach is then mobilized by first dividing the short gastric vessels, followed by division of the gastrocolic omentum while carefully preserving the right gastroepiploic arcade (see Fig. 19-4). We utilize either the ultrasonic shears such as Autosonix (Covidien, Mansfield, MA) or the LigaSure device (Valleylab, Boulder, CO). Occasionally, clips will be required during division of large-diameter, short gastric vessels. Recently, on the basis of published data[42] and personal communication (Dr Earl Wilkins), we have selectively utilized an omental pedicle wrap of the intrathoracic esophagogastric anastomosis. At this point in the operation, we mobilize a long, narrow tongue of omentum from the middle to upper third of the greater curvature. We attempt to base this omental pedicle off of two feeding vessels to ensure viability (Fig. 19-5). After the gastrocolic omentum is identified, the antrum of the stomach is retracted and a window is created in the greater omentum, thus allowing access to the lesser sac. Dissection is carried along the greater curve of the stomach until the end of the gastroepiploic arcade is reached. During this mobilization, it is important to be constantly mindful of the location of the right gastroepiploic vessel.
5. The mobilized stomach is retracted superiorly, and any remaining adhesions between the posterior wall of the stomach and the pancreas are divided as well. The left gastric vessels are then identified, dissected, and

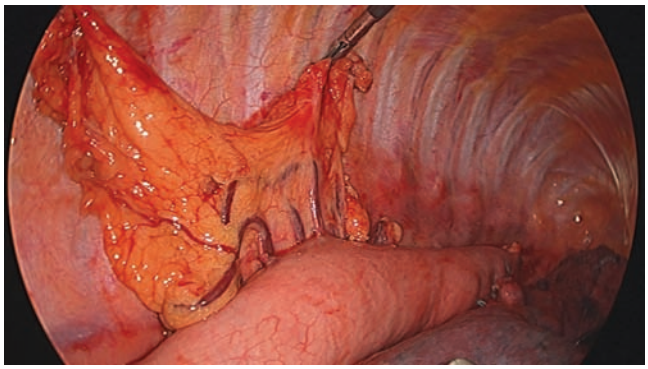

FIGURE 19-5 Creation of omental pedicle flap.

divided with a vascular load of the stapler. This is done by approaching the pedicle from the lesser curve. Prior to division, a complete celiac lymph node dissection is performed, continuing along the superior border of the splenic artery and pancreas toward the splenic hilum. Adherence to oncologic principles is important at this step, so the pedicle should be dissected completely clean with all celiac and left gastric nodes swept up into the specimen.

6. Attention is then turned to mobilization of the pyloric antral area and subsequent pyloroplasty (Fig. 19-6). There are often significant adhesions in the retroantral and periduodenal regions that also need to be dissected to allow for adequate mobilization of the inferior portion of the stomach. Particular attention to mobilization of the pyloric antral area is needed in patients who have had prior cholecystectomy. Adequate mobilization is evident when the pylorus can be gently lifted up to the level of the right crus in a tension-free manner. This may require a partial or complete Kocher maneuver. Two traction sutures are placed at the edges of the pylorus with the 2-0 Endo Stitch (US Surgical, Norwalk, CT). The pyloroplasty is performed by incising the pylorus longitudinally with the ultrasonic shears and closing it transversely with interrupted sutures using the Endo Stitch device in a Heineke-Mikulicz fashion. This usually requires four to five sutures. Prior to completing the abdominal portion of the procedure, a tongue of omentum is mobilized to fashion an omental patch that is sutured to the pyloroplasty site.
7. Creation of the gastric tube. All tubes previously in the stomach or esophagus are pulled back. A 4- to 5-cm-diameter gastric conduit is then constructed using multiple fires of the stapler (4.8 mm) beginning from the lesser curve antral area, just proximal to the pylorus and heading toward the angle of His (Figs. 19-7 and 19-8). It is essential to avoid excessive manipulation and resulting trauma to the gastric conduit during all steps. To facilitate exposure, staple alignment, and conduit

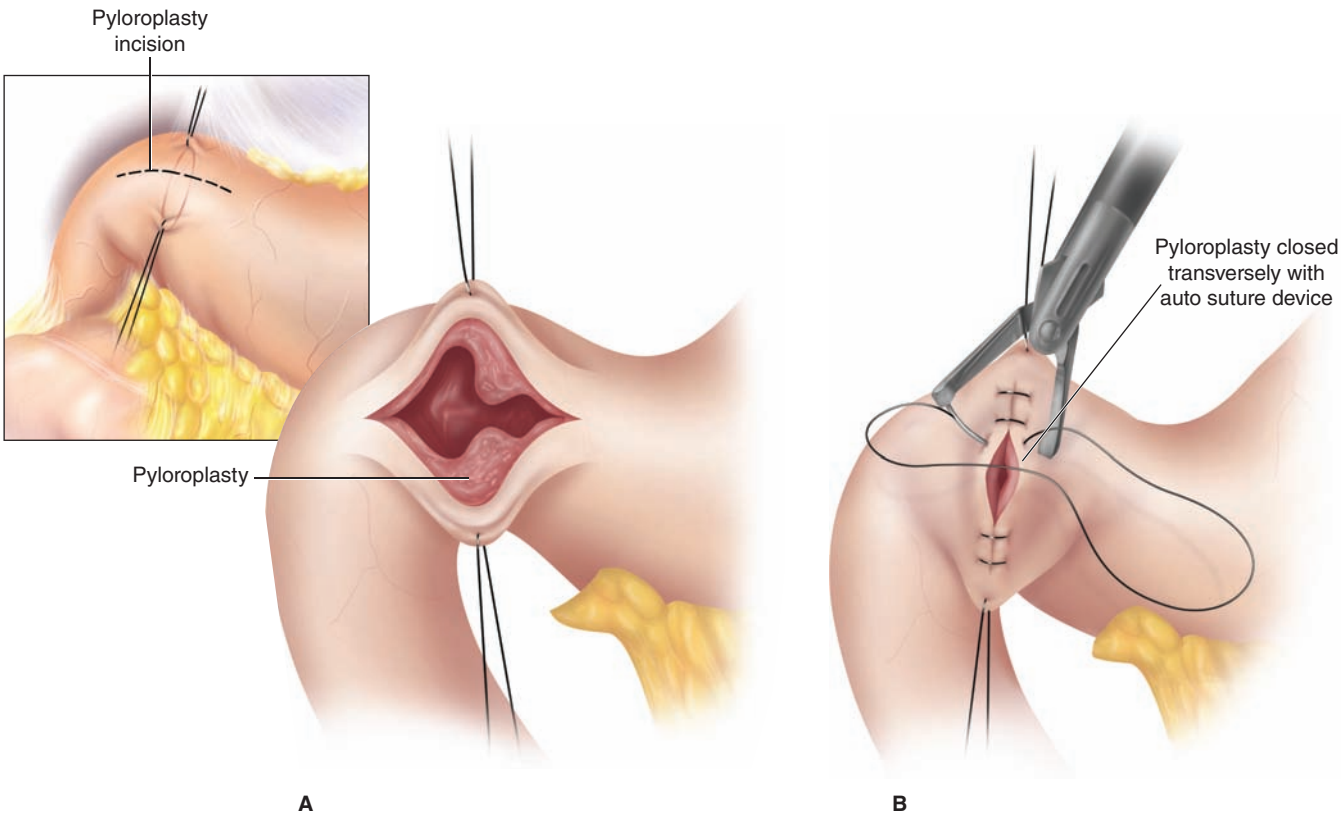

FIGURE 19-6 Creation of the laparoscopic pyloroplasty.

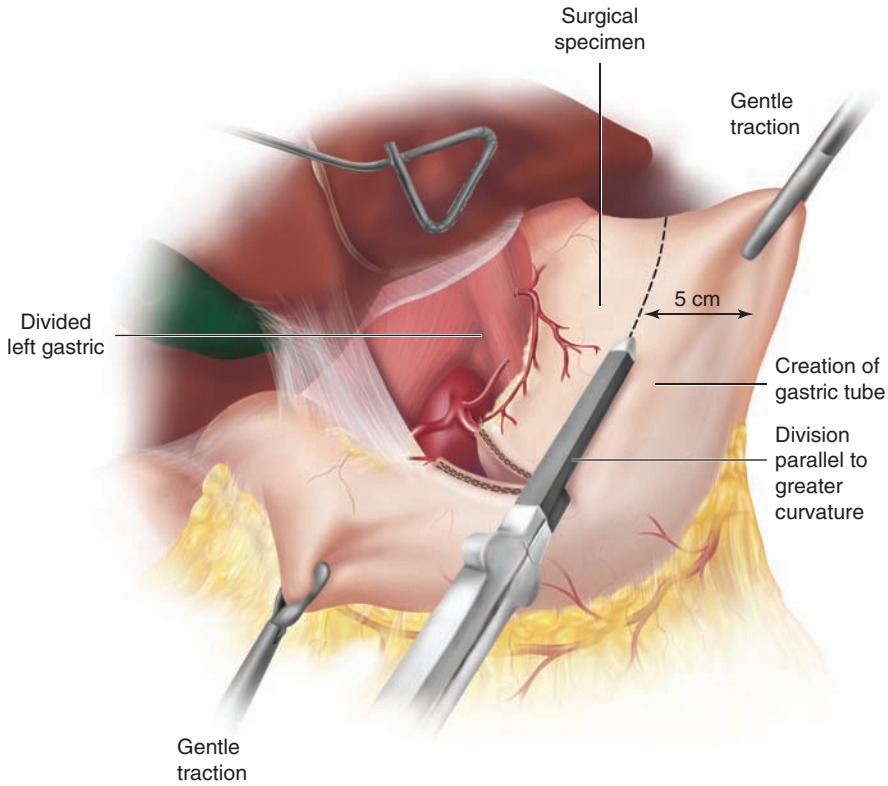

FIGURE 19-7 A vascular stapler is fired across the lesser curvature near the incisura to begin formation of the gastric tube.

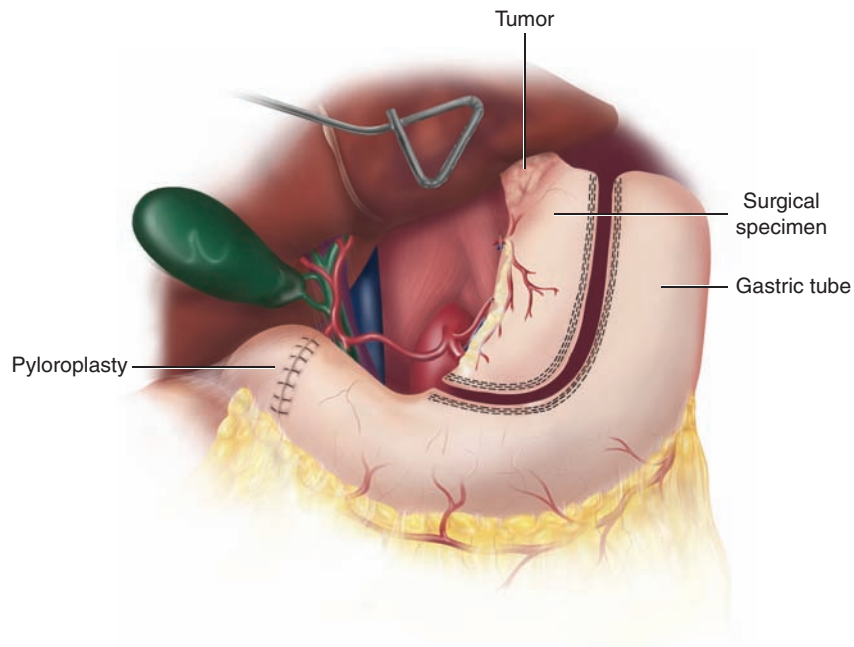

FIGURE 19-8 Completion of gastric tube construction.

length during this step, we have found it helpful to have the assistant gently lift the greater curve of the stomach, along the line of the proximal short gastric arteries and retract gently toward the spleen. Simultaneously, another assistant grasps the antrum and retracts inferiorly. This is accomplished through an additional 12-mm port placed in the right lower quadrant to assist with the creation of the gastric tube. This essentially elongates the entire stomach and provides the alignment necessary to construct a consistent diameter gastric conduit without spiraling. The first stapler used for this is a vascular load to control bleeding from the adipose tissue and vessels along the lesser curve. The stapler is placed just up to, but not onto, the gastric antrum as this tends to be thicker tissue. The initial 12-mm right midclavicular port is changed to a 15-mm port to allow for the placement of a 4.8-mm Endo GIA stapler. Creation of the gastric tube is then started by dividing the stomach at the lower end of the lesser curve near the incisura using a vascular load (2.5-mm) stapler, with care being taken to preserve the main right gastric vessels and one or two of the first branches entering the antral area. The stomach is first divided across the antrum with 4.8-mm staple loads. Because this region of the stomach is generally quite thick and muscular, larger staples are required to secure its closure. Early in our experience, we discovered that very narrow gastric conduits (2–3 cm in diameter) were associated with increased gastric tip necrosis and anastomotic leaks, and therefore we now construct wider conduits measuring about 4–5 cm in diameter. Once the thicker antrum has been divided, the operating port is changed back to an 11-mm port and the fundus is divided using a 3.5-mm stapler. As the fundus is divided, the graspers are readjusted to keep the stomach constantly stretched. If there is extension of tumor onto the gastric cardia, a wider margin is left in this region.

8. Feeding jejunostomy. Under direct vision, a jejunostomy catheter (10F) is then placed using the Seldinger technique as depicted in Fig. 19-9. The patient is placed in the Trendelenburg position with the transverse colon and greater omentum retracted cranially. The 12-mm, previously placed, right lower quadrant port is used as the operating port while the right upper quadrant epigastric port is used for the camera to facilitate this maneuver. The ligament of Treitz is identified, and approximately 30 cm distal to this point, a suitable limb of proximal jejunum is tacked to the lateral, anterior abdominal wall in the left midquadrant with a single 2-0 Endo Stitch. Under direct visualization, a jejunostomy catheter (Compat Biosystems, Minneapolis, MN) is then placed, with intraluminal position confirmed by distending the jejunum with 10 mL of air insufflated via the catheter. The jejunum is then securely tacked to the abdominal wall at the catheter entry site with a purse-string type circumferential tacking stitch using a 2-0 Surgidac Endo Stitch. A second simple 2-0 Surgidac Endo Stitch is placed 3 cm distal to the catheter insertion site so as to prevent torsion and possible strangulation around a single fixed point (see Fig. 19-9).
9. The tip of the gastric conduit is then secured to the specimen with 2-0 Endo Stitch (Fig 19-10). During this step, care is taken to maintain alignment so that subsequent retrieval of the specimen through the hiatus into the chest does not lead to any rotation and maintains perfect anatomic alignment of the gastric conduit with the short gastrics facing the direction of the spleen and the lesser curve staple line facing the right chest. With our recent use of omental pedicles, we have also started tacking the omental pedicle wrap to the proximal end of the conduit so as to

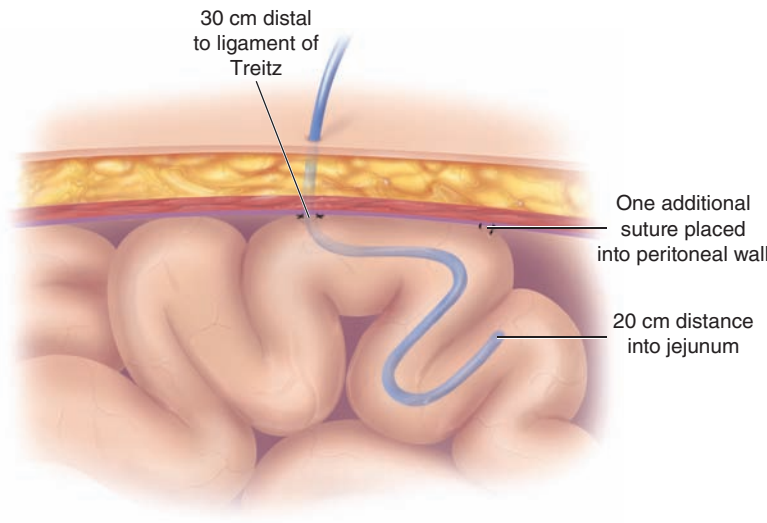

FIGURE 19-9 Feeding jejunostomy.

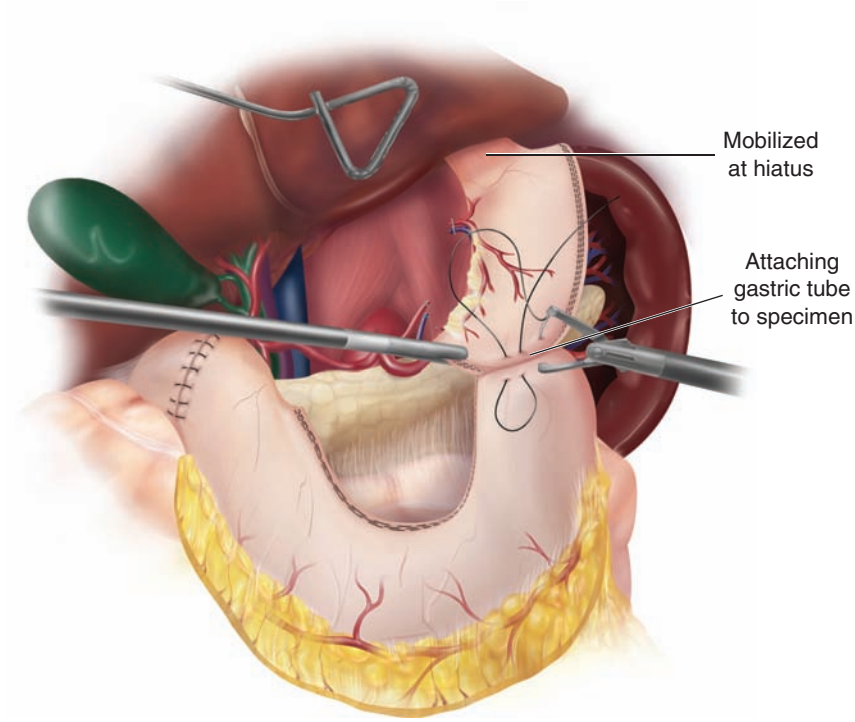

FIGURE 19-10 Completion of laparoscopic phase of minimally invasive Ivor Lewis esophagectomy.

facilitate bringing it through the hiatus without trauma to the omentum or the supplying vasculature.

10. If the hiatus appears wide, we add one or two 0 Surgidac sutures (Covidien, Mansfield, MA) to approximate the right and left crus to minimize the likelihood of a delayed herniation of the conduit into the chest. The pyloroplasty site is covered with an omental patch as described previously. The initial Hasson trocar site is closed with the Carter-Thompson suture passer with 0 Vicryl suture, the abdomen is desufflated, and the skin incisions are closed accordingly.

THORACOSCOPIC PHASE

1. The patient is placed in the left lateral decubitus position. The operating surgeon stands on the right side of the table (facing the patient's back) and the assistant on the left side of the table.

2. Five thoracoscopic ports are used (see Fig. 19-2; Fig. 19-11). A 10-mm camera port is placed in the seventh or eighth intercostal space, just anterior to the midaxillary line. The surgeon's working port is a 10-mm port that is placed at the eighth or ninth intercostal space, posterior to the posterior axillary line. Ultimately, this eighth posterior interspace port will be enlarged to 5 cm to enable passage of the end-to-end stapler (EEA, US Surgical, Norwalk, CT) and removal of the specimen. Another 10-mm port is placed in the anterior axillary line at the fourth intercostal space, through which a fan-shaped retractor aids in retracting the lung to expose the esophagus. A 5-mm port is placed just inferior to the tip of the scapula, and this is used by the surgeon's left hand for countertraction. A final port is placed at the sixth rib, at the anterior axillary line for suction, and is especially useful while fashioning the anastomosis.

3. An important initial step to aid in exposure is placement of a traction suture (0-Silk) through the central tendon of the diaphragm (Fig. 19-12), which is brought out through a 2-mm stab incision in the antero-lateral chest wall near the costophrenic angle using an Endo Close

FIGURE 19-11 Thoracoscopic (right VATS) port placement.

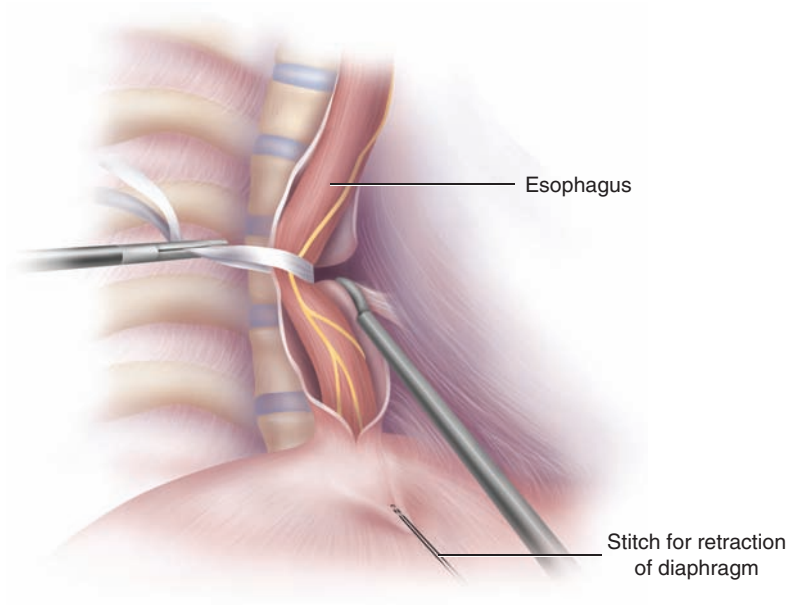

FIGURE 19-12 Thoracoscopic mobilization of esophagus.

device (Covidien, Mansfield, MA). This suture retracts the diaphragm inferiorly and allows excellent visualization of the lower one-third of the esophagus.

4. Thoracic esophageal mobilization (see Fig. 19-12). Mobilization of the esophagus is begun by dividing the inferior pulmonary ligament to the level of the inferior pulmonary vein and retracting the lung anterior. This facilitates incision of the mediastinal pleura over the esophagus. Dissection moves in a cranial direction from this point along the line of the mediastinal pleura. It should be noted that the dissection should be carried down to the pericardium as it is actually the medial boundary of the line of dissection. The deep boundary is the contralateral pleura. The esophagus and accompanying periesophageal tissue and level 7 lymph nodes are mobilized circumferentially en bloc toward the right mainstem bronchus and carina. Care is taken not to injure the posterior membranous wall of the right mainstem bronchus in this area. We use the ultrasonic shears for much of the dissection, as the sharp blade of this instrument is ideal for a precise dissection plane. Endoscopic clips are utilized for hemostasis on larger vessels. Because of the extensive lymphatics in this area and fragile vessels attached to the subcarinal nodes, careful use of endoclips also aids in minimizing oozing of chyle and blood. Lateral dissection is facilitated by opening the mediastinal pleura in the groove posterior to the esophagus. This should be done in a superficial dissection plane so as to avoid injury to the aorta and the thoracic duct. The azygous vein is mobilized and divided as it overlies the esophagus posteriorly with a vascular staple load. The vagus nerve is transected above the level of the divided azygous vein to prevent any traction injuries to the recurrent nerve during the mobilization of the esophagus. The esophagus is then mobilized circumferentially from the hiatus to near the thoracic inlet, the ultimate cephalad extent depending on the proximal extent of the tumor and/or Barrett's esophagus and the length and condition of the gastric conduit. Above the azygous vein, the plane of dissection should stay directly on the esophagus so as to prevent injury to the posterior membranous trachea and recurrent laryngeal nerve. We do not perform an aggressive lymph node dissection at level 2 or level 4 unless preoperative PET, CT, or EUS confirmed presence of malignant nodes at this level.
5. The distal esophagus and previously constructed gastric conduit are then brought up through the hiatus into the chest (Fig. 19-13). Maintaining proper orientation of the gastric conduit is critical to avoid spiraling or twisting of the conduit. The staple line should face the camera so as to avoid spiraling of the conduit. The stitch is cut between the specimen and the conduit, and the specimen are retracted anteriorly and superiorly. We carefully estimate the amount of conduit that will lie in the chest. It is a common mistake to bring an excess amount of stomach into the chest in an effort to minimize tension on the anastomosis. This excess conduit will often assume a sigmoid conformation above the diaphragm and may lead to significant problems with gastric emptying.
6. The proximal esophagus is then transected above the azygous vein with Endo Shears (Covidien, Mansfield, MA). Again, the precise location of this division and ultimate location of the anastomosis tends to be high, near the thoracic inlet. However, cutting the esophagus too proximal

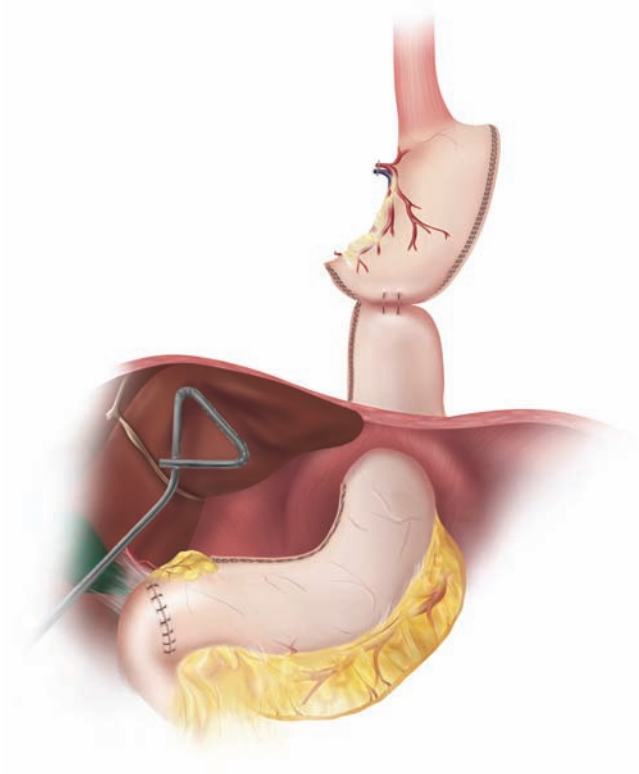

FIGURE 19-13 Specimen and gastric tube are carefully pulled to intrathoracic position.

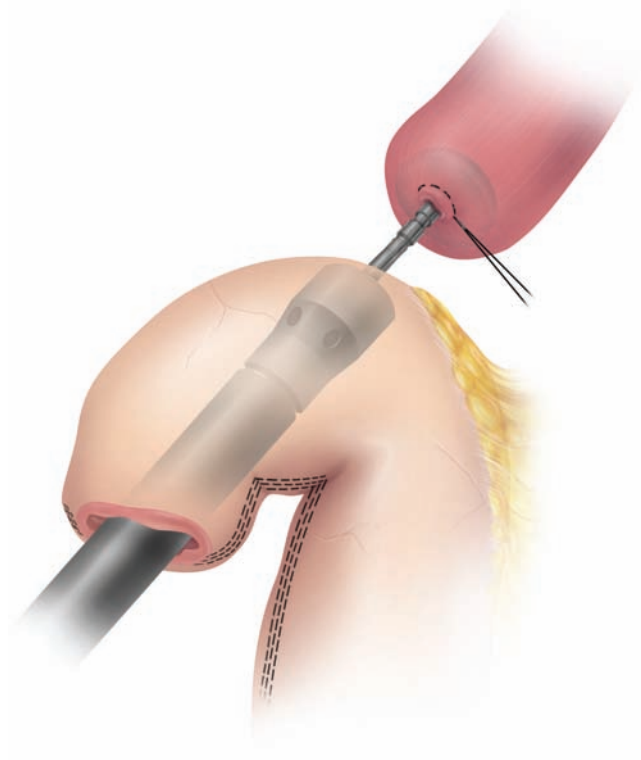

FIGURE 19-14 Creation of intrathoracic esophagogastric anastomosis.

may make the anastomosis technically difficult and should be avoided. In the case of concern over tumor margin, we may rescope at this point to precisely determine where to transect the esophagus.

7. The eighth interspace port site is enlarged, and an Alexis wound protector (Applied Medical, Rancho Santa Margarita, CA) is placed for specimen removal after cutting the previously placed sutures that secured the conduit to the specimen. The specimen is then sent for frozen-section analysis of the esophageal and gastric margins.
8. Creation of intrathoracic esophagogastric anastomosis (Figs. 19-14 and 19-15). The anvil of a 28-mm EEA stapler is placed in the proximal esophagus, and a 2-0 Endo Stitch purse-string suture is placed and tied (intracorporeal technique) to secure the anvil in position. It is technically challenging to make this first stitch perfect as the anvil has a tendency to migrate out of the open end of the proximal esophagus. For this reason, a second purse-string suture is placed to further secure the anvil and pull in any mucosal defects, thereby ensuring complete rings following EEA firing. Ultrasonic shears are used to open up the tip of the gastric conduit along the staple line. The EEA stapler is then introduced through the eighth interspace incision into the tip of the gastric conduit via the gastrotomy at the apex of the conduit. This is technically challenging for most trainees, and care must be taken to angle the gastric tube facing straight up to accept the tip of the EEA device aimed

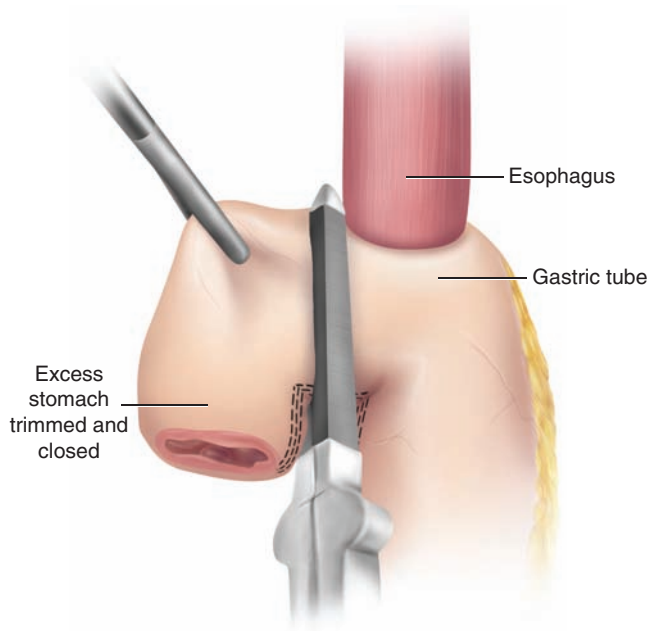

FIGURE 19-15 Resection of redundant gastric tube tip.

straight down, much the same way one angles the tip of your foot as you pull on your sock. The anvil is then docked into the stapler. A circular anastomosis is then created in an end- (proximal esophagus) to-side (gastric conduit) fashion above the level of the azygous vein. A reticulating Endo GIA stapler is used to close the gastrotomy closure and excise the redundant portion of the gastric conduit tip. Routine endoscopy is *not* performed.

9. As previously mentioned, we have recently starting selectively wrapping a tongue of omentum mobilized from the greater curve of the stomach around the anastomosis, securing in place with 2-0 Surgidac Endo Stitch at several points (Fig. 19-16). It is important to ensure that the conduit is not twisted in the process of wrapping the omentum around the anastomosis.
10. Under direct vision, a nasogastric tube is advanced beyond the anastomosis to just above the hiatus. The chest is drained with a 28F chest tube placed posteriorly but not on the anastomosis, and a number 10 Jackson Pratt drain placed directly posterior to the anastomosis, behind the gastric conduit, down to the diaphragmatic hiatus, across the dome of the diaphragm, and out through a small stab incision near the costophrenic angle. To prevent herniation, the conduit is tacked to the right crus with one or two interrupted 2-0 Endo Stitches.

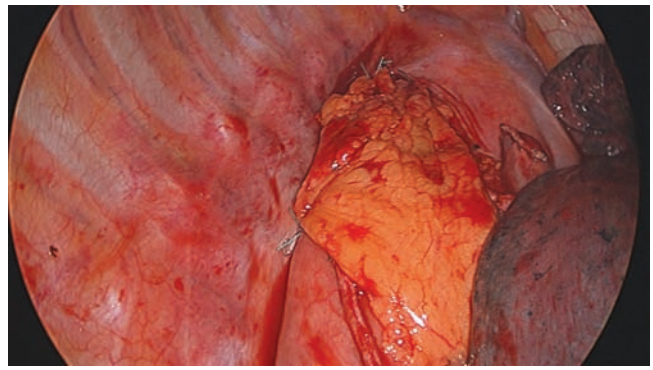

FIGURE 19-16 Completed anastomosis with omental pedicle wrap.

Outcomes and Complications Following MIE

In 2003, we published our series of 222 consecutive patients who had undergone McKeown or "three-hole" (laparoscopic-thoracoscopic with cervical anastomosis) MIE at the University of Pittsburgh.[11] To this date, the approximately half of our MIEs (>500 cases) was performed with this three-field technique. Indeed, the procedure was the mainstay of our initial experience in the first 10 years with reduced perioperative morbidity and mortality compared with many other open series. Although early in the series we selectively performed MIE on patients with smaller tumors and no previous therapy, 35% of the patients in the overall series had been treated with chemotherapy and 16% with radiation. In addition, 25% of patients had undergone prior open abdominal surgery.

MIE was completed as planned in 206 patients (93%). There were no emergent conversions to an open procedure. Of the 16 cases who required nonemergent conversion, 11 required a minithoracotomy for adhesions and, in one case, oversewing of an intercostal vessel that could not be controlled by VATS.

There were three deaths in the series (mortality 1.4%). These deaths were from postoperative pneumonia and multisystem organ failure in one patient, a myocardial infarction on postoperative day 5 in another, and pericardial tamponade that developed 3 days after MIE in the third patient. None of these deaths were in patients who developed an anastomotic leak or gastric tube necrosis. Presumably, traction injury to the pericardium during VATS was the mechanism for the development of postoperative tamponade in the third patient.[43] This very low mortality rate compares favorably with the largest series of open esophagectomy (Table 19-1).

The rate of anastomotic leak in this series was 11.7%. In our experience, this complication was frequently related to the diameter of the gastric tube. The leak rate associated with a 3-cm-diameter tube was 26% in 56 consecutive patients. In the latter half of the series, those patients who underwent creation of a larger diameter conduit had the leak rate of only 6%. Thus, there is invariably an operator learning curve.

Injury to the recurrent laryngeal nerve is a complication associated with significant morbidity. Mechanisms related to this complication include excessive traction on the nerve during the neck dissection or injury during dissection of the upper one-third of the esophagus. In our series, vocal cord palsy occurred in 3.6% of patients. This is lower than our open experience and is in part due to enhanced visualization of the upper thoracic esophagus during VATS. We believe early division of the vagus nerve and limiting lymph node dissection above the azygous vein are important technical details that contribute to lower rates of injury to the nerve in this area. However, as previously mentioned, in addition to recurrent nerve injury, a significant number of patients experience pharyngoesophageal swallowing dysfunction after cervical anastomosis. These are among the concerns that prompted our recent switch to a totally minimally invasive Ivor Lewis approach in the last several years.

Other complications seen after MIE, as well as open esophagectomy, include chylothorax, delayed gastric emptying, and airway injuries. All of these complications are potentially related to surgical technique. Inadequate control of small ductules that branch off of the thoracic duct or a gross tear of the main duct is typically the cause of a chylothorax. Seven patients (3%) developed this complication early in our series. Following this early experience, we have liberally applied clips to even small branches emanating from the thoracic duct along the right esophageal border during VATS, and this complication has fallen to less than 1%. Delayed gastric emptying is reported to occur in up to 10% of patients following esophagectomy. This

TABLE 19-1: MORTALITY AND MORBIDITY FOLLOWING MIE COMPARED TO OPEN ESOPHAGECTOMY

	Pittsburgh n = 222 (%)	Michigan n = 1085 (%)	VA n = 1777 (%)	Sloan-Kettering n = 510 (%)	Duke n = 379 (%)

may be due to a number of factors, including the vagotomy itself, the creation of a full-size gastric conduit that may empty poorly compared to a tubularized conduit, incomplete pyloromyotomy or pyloroplasty, spiraling of the gastric tube, excess stomach above the diaphragm leading to a sigmoid loop effect, and an inadequate crural opening. In our series, only 2% of patients developed delayed gastric emptying after MIE. The creation of a pyloroplasty rather than a pyloromyotomy and attention to all of the details listed previously have contributed to this low complication rate.
