The multimodal plan should be continued with suggestions for dose reductions as the acute pain episode resolves. In patients with a history of opioid abuse, consideration should be given to limiting the amount of opioid prescribed and providing for early and frequent follow-up. Referrals to pain medicine specialists or addiction specialists may be considered.

CHAPTER 55

Regional Anesthesia in Patients with Trauma

Jeff Gadsden, Emily Lin, and Alicia L. Warlick

INTRODUCTION

Trauma is the leading cause of death in those aged 1–44 years and the third leading cause of death for all age groups.[1] Trauma accounts for 30% of all life years lost in the United States—more than cancer, heart disease, and HIV combined.[1] The economic burden of trauma exceeds $400 billion in the United States annually. This chapter aims to discuss the role of regional anesthesia within the overall framework of pain management in trauma, explore several examples of where regional anesthesia may affect outcomes in specific injuries, and briefly address the issue of acute compartment syndrome in the context of neuraxial and peripheral nerve blockade.

MANAGEMENT OF ACUTE PAIN IN PATIENT WITH TRAUMA

The management of pain in the acutely injured patient can be challenging. Resuscitation and the assessment and treatment of life-threatening injuries are the first priorities in the trauma patient, and provision of adequate analgesia must frequently be delayed until the patient is stable. However, there is mounting evidence that the pain associated with injury is often undertreated (oligoanalgesia).[2] There are several barriers to effective analgesia for trauma patients. Physicians are often hesitant to administer pain medications (especially systemic opioids) to trauma patients for fear of causing hemodynamic instability or respiratory depression and airway compromise. Patients with head and/or spinal cord injury require frequent reassessments, which may be impaired or obscured with systemic opioids. Opioid-induced delirium is also a concern, particularly in the elderly population. Trauma patients are frequently unable to communicate their pain intensity due to the need for sedation and mechanical ventilation, among other considerations, which can impair adequate pain assessment.

Analgesia is often unjustifiably delayed, even in patients with injuries that are not life threatening. In a study of 36 Australian emergency departments, patients who presented with hip fracture (n = 645) were found to have a mean time to first treatment of their fracture-related pain of 126 minutes.[2] Reported barriers included confusion/dementia, comorbidities such as head injury or hypotension, patient refusal, and language or communication problems. Notably, only 7% of these patients received a femoral nerve block. Another study of patients presenting to the emergency department predominantly with injuries of the extremities showed that while 91% had pain on admission (mean numeric rating scale rating 5.9), 86% still had pain upon discharge (mean numeric rating scale rating 5.0), and pain actually *increased* in 17% at the time of discharge.[3] Of the 450 patients in this study, only 19% received any type of pharmacologic pain therapy.

Intravenous opioids are the most common approach to treating pain in trauma patients. While opioids are potent analgesics and a rational choice in patients with multiple injuries, they carry a significant burden of potential adverse effects, including the following:[4]

- Nausea and vomiting
- Constipation
- Delirium
- Vasodilation and hypotension (especially in hypovolemia)
- Respiratory depression
- Pruritus
- Immunosuppression
- Increased staffing requirements to monitor the patient (primarily due to the risk of respiratory depression)
- Increased length of stay in emergency department or recovery room

Rather than single-drug therapy with opioids, a multimodal approach is increasingly becoming a standard approach for treating pain in a wide variety of elective surgical patients, where it has been shown to lead to a reduction in both opioid requirements and opioid-related adverse effects.[5,6] Examples include nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, gabapentinoids, ketamine, and corticosteroids, as well as locoregional analgesia. One difference between the trauma and elective surgical populations is the frequent inability to utilize the oral route for medications in trauma patients due to sedation, neurologic impairment, or the presence of an airway device. Fortunately, many of the standard multimodal classes of drugs are available in parenteral form, including ketamine, acetaminophen, ketorolac, clonidine, and dexmedetomidine.

THE ROLE OF REGIONAL ANESTHESIA IN TRAUMA

Musculoskeletal injury is common in the trauma patient. While skeletal fractures and muscular injuries can occur anywhere on the body, the extremities are disproportionately affected. Approximately 60% of multiple-trauma patients with an injury severity score of ≥ 16 have an extremity injury of some type, and 18% have both lower and upper extremity injuries.[7] Over 30% of the same population will have 2 or more extremity fractures. Since the majority of regional anesthesia procedures involve the extremities, its role in analgesia for trauma patients is particularly well suited.

Mechanism of injury is an important epidemiologic factor—for example, those in motor vehicle crashes (MVCs) have a significantly higher prevalence of extremity injury; similarly, due to improvements in battlefield medicine and body armor, modern military combatants have a dramatically reduced rate of fatal torso injury. As a result, more trauma victims are surviving with higher rates of extremity injury. While patients with isolated extremity injuries tend to have favorable outcomes, it has been shown that orthopedic and general health outcomes are significantly poorer if the same injury is present in a polytrauma patient.[8]

Regional anesthetic techniques, and peripheral nerve blocks in particular, provide high-quality analgesia that is site specific and devoid of any systemic (especially opioid-related) side effects. Regional anesthesia may also confer several other advantages over systemic analgesic therapies for trauma patients, including decreased length of stay in the emergency department and critical care unit,[9,10] improved ability to perform neurologic assessments,[11] improved comfort and safety for transport,[11,12] and cost savings compared to procedural sedation.[13]

The persistence of pain well beyond the time of injury and the development of chronic pain is a significant problem following acute injury. Up to 77% of patients who incur severe musculoskeletal trauma will report posttraumatic chronic pain, defined as pain lasting greater than 3 months from the time of injury.[14] There are multiple risk factors that contribute to the likelihood of transitioning from acute to chronic pain. These include age, comorbid medical conditions, depression or anxiety states, and alcohol and tobacco consumption. The risk factor that appears to be most predictive of eventual chronic pain is the intensity of acute pain at the time of injury (odds ratio between 2.4 and 11.2).[15,16] Regional anesthesia has been shown to significantly reduce acute pain intensity in traumatic injury.[17] Despite this, the evidence supporting the preventive role of regional anesthesia in the development of chronic pain in trauma is very weak at present, and properly powered, randomized, controlled studies are needed.[14] Regardless, there are multiple other benefits in providing high-quality analgesia in the acute setting with regional anesthesia and analgesia.

Clinical Pearls

- Up to 77% of patients with severe musculoskeletal trauma may develop chronic posttraumatic pain.
- The severity of the acute pain is predictive of development of chronic pain after trauma.

CONTINUOUS PERIPHERAL NERVE BLOCKS IN PATIENTS WITH TRAUMA

Single-injection techniques with bupivacaine or ropivacaine can be expected to provide 16–24 hours of analgesia, whereas continuous peripheral nerve block (CPNB) techniques can significantly prolong the duration of analgesia. The pain intensity associated with trauma is often severe and longstanding, making CPNBs useful. Catheters can be left in for days to weeks. Patients with complex injuries that require repeated debridement, fracture fixation, and/or skin grafting may benefit from indwelling catheters (Figure 55–1). The pumps can be programmed to deliver a background infusion of a low-concentration, long-acting local anesthetic (eg, 0.1%–0.2% ropivacaine) while on the ward or intensive care unit. The catheters can be manually bolused with a higher-concentration solution upon return to the operating room to provide surgical anesthesia. Buckenmaier et al. described a series of 187 patients injured in combat who were treated with CPNBs for a median of

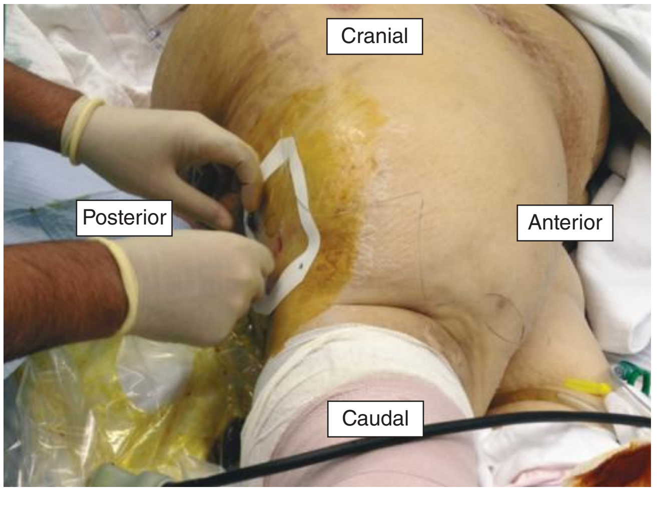

FIGURE 55–1. A popliteal catheter being placed for the management of pain following a traumatic amputation of the foot.

8 days (range 1–33 days); catheter-specific complications were rare (3.7%) and included kinking, dislodgement, and superficial infection.[18] It should be noted that these data reflect a specific patient population: healthy, fit, young soldiers. Catheter techniques in the elderly and unhealthy civilian trauma victims may have additional challenges, although there are limited data to suggest that these techniques have a lower safety profile in certain age or physical status subpopulations.

Colonization and infection of the catheter site is a concern when using an indwelling catheter in the trauma population, since these patients are at risk for bacteremia and sepsis, and procedures are often performed in less than ideal environments, such as the emergency room or intensive care unit (ICU). Capdevila et al. demonstrated that injured patients admitted to a trauma ICU were 5 times more likely to develop a CPNB catheter infection than elective surgical patients.[19] Other factors reported to increase the risk of catheter infection include duration of catheter use greater than 48 hours, the use of prophylactic antibiotics, insertion at the femoral or axillary location, and frequent dressing changes.[19–23] Catheter type may also play a role in the development of infection. Lai et al. reported a case series of 2 superficial and 4 deep infections, in which the deep infections requiring operative incision and drainage were associated with stimulating catheter use.[24] The authors hypothesized that repetitive movements of a catheter with an internal metal coil could result in microhematoma formation, providing a rich culture medium for hematogenously spread bacteria. Despite these data, the overall incidence is still low, with only 0%–3% of all catheters showing evidence of infection.

Approximately 20% of polytrauma patients have both upper and lower extremity injuries; thus, the opportunity to use multiple catheters arises frequently. Plunkett and Buckenmaier placed bilateral sciatic nerve catheters and a single femoral nerve catheter in a patient with bilateral leg injuries who was receiving treatment doses of enoxaparin that precluded epidural analgesia.[25] Care must be taken to consider the dose of local anesthetic that is being delivered in order to prevent toxic plasma levels; however, this is rarely an issue since the concentrations that are used clinically for catheters are low (eg, 0.1%–0.2% ropivacaine). One prospective study of 13 combat trauma patients receiving 0.2% ropivacaine infusions at 6–14 mL/h for a period of 4–25 days showed a median unbound plasma ropivacaine level over the duration of the study of 0.11 mg/L (range: undetectable–0.63 mg/L) with no reports of toxic events.[26] The toxic unbound plasma concentration of ropivacaine is approximately 0.6 mg/L.[27] However, two patients' plasma levels neared this threshold after a large dose (60 mL bolus of 0.5% ropivacaine) prior to the determination of the plasma level. Taken together, these data suggest that long-term infusions of ropivacaine at low concentrations are safe in the trauma population. Notwithstanding, polytrauma patients frequently have two catheters infusing simultaneously, which may increase the risk of toxic plasma levels of local anesthetic. Common strategies to mitigate this risk include lowering the concentration of the local anesthetic infusate (eg, ropivacaine 0.1% or 0.15% rather than 0.2%) and/or relying more on periodic intermittent boluses than on a high-rate continuous background infusion.

REGIONAL ANALGESIA IN THE EMERGENCY DEPARTMENT AND PREHOSPITAL SETTINGS

Regional anesthesia has been used effectively in the emergency department for injured patients requiring analgesia for a variety of indications, including hip fracture, as well as during procedures such as reductions of fractures or dislocated joints and repair of lacerations. Compared to procedural sedation, upper extremity blocks confer several advantages. Interscalene block for shoulder reduction has been shown to reduce emergency department length of stay and the requirement for one-to-one monitoring.[10] Patients with upper extremity fractures, dislocations, and/or abscesses who received supraclavicular block for their procedure experienced a shorter length of stay without any impact on patient safety or satisfaction.[9] Ultrasound-guided intercostal blocks have been effective for chest drain placement following traumatic pneumothorax.[28]

Clinical Pearl

- Peripheral nerve blocks improve clinical flow and decrease the length of stay in the ED compared to procedural sedation for selected procedures.

Anesthesiologists are typically the physicians most qualified to perform nerve blocks. However, due to work demands and time constraints, anesthesiologists may not be able to attend to patients in the emergency department or critical care unit in a prompt manner, leading to significant delays in providing quality analgesia. Randall et al. reported the results of a successful initiative to train orthopedic nurses in the performance of fascia iliaca blockade.[29] This creation of a "physician extender" improved patient access to effective pain control with the use of a simple and safe procedure that is easily taught. (The topic of regional and local anesthesia in the emergency department is covered in more detail in Chapter 60.)

It may also be safe and appropriate to provide regional analgesia in the field or during transport to hospital. This decision has to be made in the context of the skill and experience of the doctors or medics attending to the patient, as well as the nature and severity of the injuries. In North America, where emergency medical services (EMS) teams are largely staffed by paramedics, emergency medical technicians (EMTs), or firefighters as first responders, there is a limited set of interventions available. In some parts of the world, physicians (eg, anesthesiologists in western Europe) highly trained in resuscitative and trauma medicine are dispatched by ambulance and helicopter to perform retrievals; these tend to be systems that benefit most from on-scene triaging, evaluation, and intervention.

Several studies have shown the fascia iliaca block to significantly reduce pain associated with femoral shaft or neck fractures when performed at the scene of the accident or injury.[30–33] Advantages to the fascia iliaca block include minimal equipment required (a syringe and needle), a simple approach that does not rely on ultrasound or nerve stimulation, and a good safety profile with little chance of puncturing a vessel or nerve. Femoral block has also been reported to be effective in prehospital care, but its success depends more on the experience and skill level of the operator.

Additional block techniques that have been reported to successfully reduce pain intensity prior to arriving at hospital include sciatic nerve block,[34] interscalene nerve block,[35] multiple nerve blocks about the elbow,[36] and digital nerve block.[37]

SPECIFIC INJURIES: HIP FRACTURES

Fracture of the femur at the hip joint is a very common injury and is associated with significant morbidity and mortality. Patients with hip fracture tend to be older and have multiple medical comorbidities, placing them at higher risk for complications, especially chest infection, delirium, and heart failure.[38] Over 95% of hip fractures are fall related.[1] Falls are the leading cause of death in adults over 64 years of age, with hip fracture being the most serious and costly injury resulting from a fall.[39]

The reported pain intensity from a fractured hip can be moderate to severe. The pain resulting from these fractures is well suited to regional techniques due to the anatomical location of the fractures. In a systematic review of 83 studies addressing various analgesic options for hip fracture (including systemic analgesia, traction, multimodal pain management, and neurostimulation), the only intervention that was found to be effective at reducing acute pain was peripheral nerve blockade.[40]

An understanding of the osteotomal innervation of the femur and hip joint is important in block planning. (Figure 55–2). Several studies have demonstrated that a femoral nerve block reduces pain intensity following hip fracture and is a valuable adjunct in this population, allowing patients to sit up, move in bed, breathe deeply, and cough with reduced pain while awaiting surgery.[41–43] A Cochrane collaboration review of nerve blocks in patients with hip fracture concluded that femoral nerve block resulted in significant reductions in both pain intensity and opioid requirements both preoperatively and during surgery.[44]

Several studies have found that fascia iliaca block reduced pain scores and opioid requirements in patients with hip fracture. Fascia iliaca block aims to block the femoral and lateral femoral cutaneous nerve (and possibly the obturator nerve) with one injection. The technique is less technically demanding than femoral nerve block, but when compared to femoral block, fascia iliaca may not provide the same degree of pain relief.[43,45] This may be due to imprecise placement of the local anesthetic during what is traditionally a landmark technique, relying on the spread of a large (30–40 mL) volume for efficacy.[33,46] Ultrasound guidance increases the frequency of sensory loss of all three nerves compared to the landmark technique.[46] Obturator nerve block appears to also be an effective analgesic technique following hip fracture, which is not surprising given the proportion of the proximal femur and hip joint innervated by this nerve.[47] However, this technique is not as widely practiced as femoral blockade and even with ultrasound guidance is an intermediate-level technique, limiting its widespread use.

Patients with hip fracture benefit from regional analgesia immediately on admission to hospital, both to improve comfort and reduce the side effects of opioids. An increasing number of hospitals have a hip fracture clinical pathway that includes femoral nerve block placement in the emergency department. Catheter techniques are particularly valuable in this situation since patients with hip fracture may not receive their operative fixation for 48 hours or longer for various medical or logistical reasons. Pedersen et al. introduced a care pathway for hip fracture that replaced parenteral opioids with a continuous femoral nerve block in a retrospective cohort study; the nerve block group had a significantly reduced incidence of in-hospital complication (odds ratio 0.61, 95% CI 0.4–0.9, P = 0.002), as well as significantly reduced rates of confusion and pneumonia.[48] Mortality was also decreased from 23% to 12%, although this trend was not present in patients who were admitted from nursing homes.

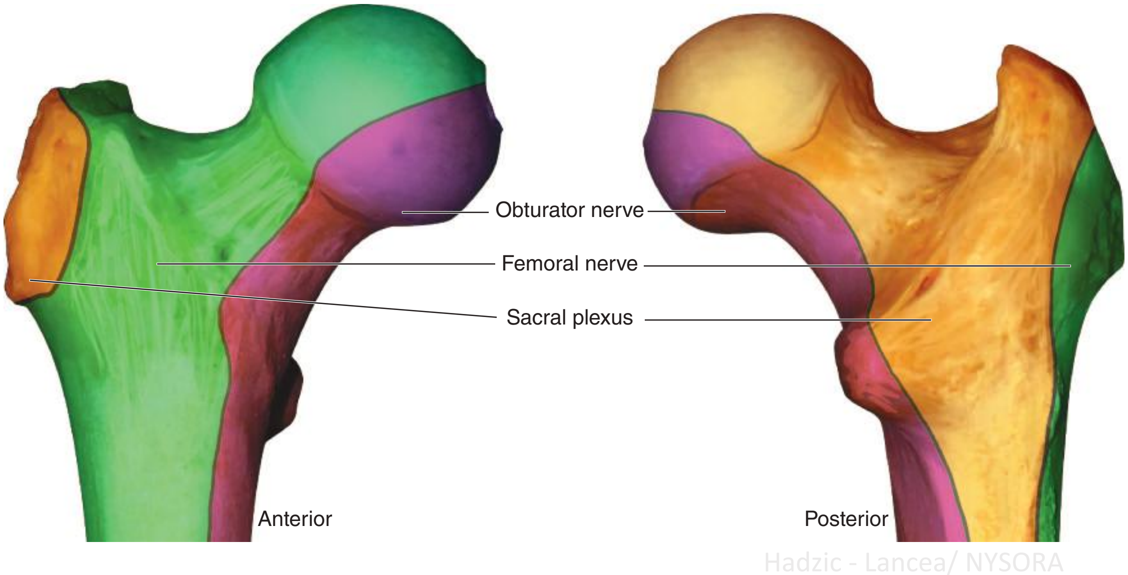

FIGURE 55–2. Osteotomal innervation of the proximal femur.

Confusion and delirium are common in the hospitalized elderly patient. Delirium is an independent risk factor for death, institutionalization, and dementia after hip fracture.[49] Two factors that are known to substantially increase the likelihood of delirium are moderate to severe pain and opioids, both of which can be minimized with regional techniques. The impact of regional analgesia on the risk for developing perioperative delirium is unclear, and the absence of effect in some studies likely relates to the complex pathophysiology of delirium. However, there may be specific subpopulations of hip fracture patients who benefit from nerve blocks. Mouzopolous et al. risk-stratified hip fracture patients for delirium on admission using a validated instrument and investigated the effect of daily fascia iliaca block on delirium in intermediate- and high-risk patients.[50] No difference was seen between high-risk patients who received the block with bupivacaine versus a sham block. However, intermediate-risk patients in the fascia iliaca block with bupivacaine group were significantly less likely (2%) to become delirious versus those in the sham block group (17%). Data from these studies support the idea that regional analgesic techniques should be initiated timely in hip fracture patients and continued until pain intensity is sufficiently low that oral nonopioid analgesics are all that are required for pain management.

Clinical Pearl

- A clinical pathway including a femoral nerve block and/or catheter may reduce the incidence of confusion, delirium, pneumonia and opioid requirements for patients with hip fracture.

The best choice of *anesthetic* technique for operative fixation of hip fracture is still a matter of some controversy. Several recent large studies have focused on this question. Luger and colleagues conducted a meta-analysis of 34 randomized, controlled trials, 14 observational studies, and 8 reviews/meta-analysis publications (n = 18,715) and demonstrated that neuraxial anesthesia was associated with significantly reduced early mortality, fewer incidents of deep venous thrombosis, less postoperative confusion, and fewer overall pulmonary complications, including postoperative hypoxia, pneumonia, and fatal pulmonary embolism.[51] There were no differences between groups in the rates of arrhythmias, myocardial events, congestive heart failure, intraoperative blood loss, renal failure, or stroke. Hypotension seemed to occur independent of anesthetic technique, although continuous spinal appeared to have an advantage over single-injection spinal in this regard. Geriatric patients are typically at low risk for postdural puncture headache, and the placement of a spinal catheter is usually free of side effects.

In 2012, Neuman and colleagues published a retrospective analysis of a prospectively collected database collected over 2 years from 126 New York State hospitals.[52] Over 18,000 patients admitted for hip fracture from 126 hospitals were identified and the association between type of anesthesia and patient outcomes tested. Regional anesthesia in this study reduced the risk of in-hospital mortality relative to general anesthesia by 29% and the risk of pulmonary complications by 25%. There was no difference between groups with regard to cardiovascular morbidity.

More recently, White et al. reported the results of an observational audit of over 65,000 patients from the National Hip Fracture Database in the United Kingdom.[53] The authors specifically looked at early mortality and found no difference between groups receiving general versus neuraxial anesthesia in terms of either 5-day or 30-day mortality. The authors suggest that with modern advances in pharmacotherapy and monitoring, as well as improved methods for optimizing patients prior to surgery, may have diminished any difference in this metric. They also suggest that our research efforts should now be focused on postoperative confusion, hypotension, pain, mobility, and respiratory complications.

On balance, it appears that data tend to show that there are morbidity advantages to regional anesthesia techniques, if not mortality advantages. Although regional anesthesia is not yet a standard of care, the burden of proof is increasingly on the anesthesia provider to demonstrate why it would be more appropriate to proceed with a general rather than regional anesthetic in this group of patients.

SPECIFIC INJURIES: FRACTURED RIBS

Rib fractures are the most common injury associated with chest trauma, with an incidence of 12% of all trauma admissions.[54] The number of rib fractures is directly related to the associated mortality: 5% for 1–2 ribs, 15% for 3–5 ribs, and 34% for 6 or more ribs fractured.[54] The cause of mortality is related primarily to pulmonary injury, such as lung contusion and pneumothorax, and delayed pulmonary processes, such as pneumonia and acute respiratory distress syndrome.[55] Fractured ribs are a marker of injury severity, especially in young patients with compliant ribs cages where this injury is associated with more impact energy.

Fractured ribs and significant pain may limit the patient's ability to breathe adequately. The lack of deep inspiratory sighs and shallow tidal breathing promote atelectasis, V/Q mismatching, and hypoxemia, increasing the risk of pneumonia and respiratory failure. Chest physiotherapy is usually either contraindicated or ineffective due to the chest wall pain. Effective analgesia for patients with rib fractures is the primary management goal for these patients, since operative fixation is not performed in most cases. There are several options available for pain management, and the management plan should be individualized, as there is no one best modality for all patients. The goal of therapy should be to minimize respiratory depression and optimize respiratory excursion, while minimizing the possible side effects and complications of the technical procedure, such as local anesthetic systemic toxicity (LAST) or iatrogenic pneumothorax.

Intravenous opioids are a common analgesic option but have the downside of causing sedation and respiratory depression; because of this, opioids may in fact promote respiratory complications at the same time that they reduce pain. NSAIDs can be effective for mild rib fracture pain but may potentiate bleeding in patients who have vascular injury or are taking anticoagulant medications. Acetaminophen is a fairly safe mild analgesic with few side effects, but its effect is limited in multiple rib fractures when pain intensity is high.

There are several regional analgesic options for relief of rib fracture pain. Thoracic epidural analgesia (TEA) is a very effective regional anesthetic technique for broken ribs, especially when injuries are bilateral. The Eastern Association for the Surgery of Trauma (EAST) has stated that epidural analgesia may improve clinically significant outcomes (Grade B recommendation) and that it should be considered the preferred analgesic modality (Grade A recommendation).[56] Several studies have evaluated the effect of TEA on outcomes. Bulger et al. randomized 46 patients with 3 or more rib fractures to receive either TEA with bupivacaine or intravenous opioid therapy.[57] Despite a higher severity of pulmonary injury in the epidural group, the incidence of pneumonia was significantly higher in the opioid group (38% vs. 18%). When adjusted for the presence of direct pulmonary injury, the relative risk of pneumonia in the opioid group was 6-fold higher. In addition, randomization to epidural analgesia decreased the number of days requiring mechanical ventilation by half. This reduction in ventilator-dependent days has also been shown in other randomized, controlled studies.[58,59] TEA also reduces the pain associated with coughing or deep breathing compared with intravenous opioids or intrapleural bupivacaine.[60–62] In contrast, a retrospective review of 64 patients with rib fractures demonstrated that while TEA provided superior analgesia to intravenous patient-controlled morphine, hospital or ICU length of stay and major morbidity were unaffected.[63] Furthermore, a meta-analysis of 8 studies (n = 232) also failed to show a difference in major outcomes such as mortality, hospital/ICU length of stay, and duration of mechanical ventilation with epidural analgesia, although the studies chosen were heterogeneous, with both lumbar and thoracic epidural sites included and various combinations of local anesthetic and/or epidural opioid in the infusate.[64]

Although TEA may be effective at reducing morbidity and other outcomes in the setting of rib fractures, it is not appropriate for all patients. Contraindications include hypovolemia and hypotension, coagulopathy, head or spinal injury, and sepsis, conditions that are all relatively common in the trauma population. Thoracic epidural analgesia is performed infrequently in patients who are heavily sedated or under general anesthesia because of the traditional belief that the absence of patient feedback may put the patient at risk for a needle-related spinal cord injury. For this reason, the actual impact of TEA on the reduction in ventilator-dependent days may be limited, since these patients are likely to be sedated and mechanically ventilated prior to consultation for pain management.

Paravertebral nerve block (PVB) is an alternative regional anesthetic procedure that provides excellent unilateral (or bilateral, if performed on both sides) analgesia.[65] A catheter technique is typically employed for fractured ribs, with the needle insertion at the midpoint of the rib levels. The block can then be manipulated to the desired level by the administration of increasing volumes of local anesthetic. In a randomized study of TEA versus thoracic PVB for unilateral multiple fractured ribs, both techniques were found to be equivalent with respect to pain relief, improvement in respiratory function, and incidence of pulmonary complications.[66] The risks of the technique are generally small and include contralateral spread via the epidural space (1%), pneumothorax (0.5%), hypotension (5%), and vascular puncture (4%).[67]

One unique advantage to PVB catheters over TEA is the ability to provide long-duration analgesia in the ambulatory setting. Murata and colleagues reported a case of a patient with multiple (T3–T8) unilateral rib fractures who was experiencing intense pain and respiratory distress.[68] A paravertebral catheter provided rapid and long-lasting (60 h) relief and facilitated discharge home from the critical care unit the day after the block. In another example, Buckley et al. reported that an anesthesiology resident who was experiencing debilitating pain from multiple fractured ribs was able to continue clinical work opioid-free while receiving an infusion of local anesthetic through a paravertebral catheter for a total of 18 days.[69]

Clinical Pearls

- Continuous paravertebral analgesia provides excellent relief from pain associated with rib fractures and facilitates improved respiratory mechanics.
- Selected patients can be safely discharged home with paravertebral catheters for days to weeks in order to prolong the high-quality analgesia.

Alternative regional techniques have been used but have not been shown to be as effective as either TEA or PVB. Intercostal blocks provide good initial relief but suffer from a limited duration of action and the need to repeat the procedure.[70] In addition, the risk of pneumothorax with each level attempted is additive and thus increases the risk of this complication. Intrapleural block with local anesthetic is similarly limited in efficacy and carries a high risk for rapid systemic absorption of local anesthetic.[71] Transdermal lidocaine patches placed over rib fracture sites have not been shown to significantly improve pain control in patients with traumatic rib fractures.[72]

SPECIFIC INJURIES: DIGITAL REPLANTATION

Long-term graft function after digital replantation (Figure 55–3) is contingent on the grafted digits receiving an optimal blood supply and the avoidance of vasospasm and thrombosis. Continuous nerve blocks of the limbs facilitate these goals first and foremost by providing sympathetic blockade, which interrupts injury-induced vasospasm and allows maximal vasodilation. The profound reduction in afferent input reduces the stress response, which both reduces the tendency toward hypercoagulability and potential thrombotic events and reduces circulating catecholamines, thereby promoting maximal vasodilation. Acral systolic blood pressure and flow are improved, and the muscle relaxation associated with a continuous nerve block

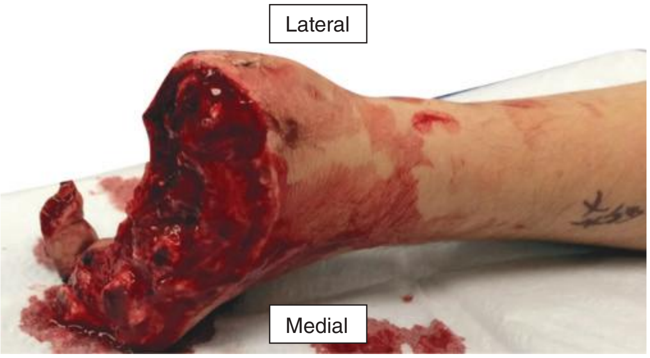

FIGURE 55–3. Multiple digital amputations resulting from an industrial accident. An infraclavicular catheter was placed preoperatively and local anesthetic infused for 6 days. All four fingers that were replanted survived with good function.

helps to prevent inadvertent movement-related mishaps with the delicate anastomoses.[73]

Improvements in outcomes with continuous brachial plexus blockade have been demonstrated in several studies. In one study that randomized patients to continuous supraclavicular block versus parenteral opioids for digit transfer and/or replantation, reoperation rates due to vascular insufficiency were 0% vs. 29%, respectively.[74] Skin temperature, a marker of tissue perfusion, is consistently elevated in patients with brachial plexus blocks.[75–77] Pain scores have also been shown to be improved, as well as the incidence of vasospasm.[74,77] On the other hand, one study failed to show a difference in overall graft survival at 6 months when continuous brachial plexus block was used.[78] However, the retrospective nature of this study limits the strength of its conclusions. Additional prospective, randomized studies are needed to clarify the extent of the impact of these techniques on outcomes.

REGIONAL ANESTHESIA FOR SHOULDER REDUCTION

Reduction of a dislocated shoulder is a common procedure performed in the emergency department. Intravenous procedural sedation using propofol, ketamine, or etomidate is commonly employed to produce sufficient muscle relaxation to reduce the joint.[79] However, procedural sedation is often not ideal for such short and limited procedures. Approximately 6 hours of fasting is required to reduce the risk of gastric aspiration, a condition not commonly met in trauma patients presenting to the emergency room. Hypotension and respiratory compromise are real risks, especially with the use of such potent cardiopulmonary depressive agents as propofol. These risks mandate close monitoring and one-on-one care in the emergency room that can occupy nursing resources.

Regional anesthesia, particularly interscalene brachial plexus block (ISB), offers an attractive alternative that eases the requirements for performing shoulder dislocation reduction. ISB provides profound shoulder girdle muscle relaxation by anesthetizing the superior trunk of the brachial plexus. ISB does not require sedation, and, although cardiorespiratory monitoring is still required, the risk of apnea or hypotension is virtually nonexistent. Blaivas et al. demonstrated that length of stay in the emergency department and the need for one-on-one care are reduced in patients receiving ISB versus procedural sedation for shoulder reduction.[10]

REGIONAL ANESTHESIA FOR BURNS

Early management of burn injuries should focus on (1) an airway with a low threshold for intubation; (2) breathing with the availability of high-flow 100% oxygen administration; and (3) aggressive fluid resuscitation. Standard protocols suggest 2-4 mL/kg of crystalloid for each 1% body surface area (BSA) affected. This applies to large burns only (ie >20% total BSA) given this population's increased vascular permeability and fluid requirement.[80]

Pain related to burn injuries can range from mild to debilitating, depending on the area involved and the depth of the burn. Skin nociceptors that are not destroyed transmit pain immediately after injury, and the perception of pain is complicated by both primary and secondary hyperalgesia, which occur at the wound and spinal level, respectively. Patients with extensive burns often experience more postoperative pain at the split-thickness skin donor site than in the grafted wound itself. Single-injection nerve blocks have provided much success in the harvesting of these donor sites.[81,82] Burn patients, however, commonly require repeated visits to the operating room and painful procedures such as physical therapy and dressing changes in the burn unit. This pattern of brief, intense painful procedures superimposed on moderate background pain makes effective analgesia challenging in these patients. Such procedures can occasionally be severe enough to require general anesthesia or deep sedation in the ICU or operating room. This is disadvantageous for a number of reasons, not least of which is the frequent interruption of enteral nutrition to keep patients fasted at a time when anything by mouth (*nil per os*, NPO) at a time when their metabolic demand is supranormal.

Therefore, the use of continuous peripheral or neuraxial catheter may be favored over single-injection techniques whenever appropriate.[83] Given the greater risk of infection from the loss of a protective barrier and altered immune response in burn patients, the decision to use catheters should be made carefully. Catheters should not be placed through burned skin. Burns result in a hypercoagulable state, and deep blocks or neuraxial analgesic techniques are generally safe, unless the patient develops coagulation abnormalities from sepsis or profound blood loss without factor replacement.

Multiple peripheral nerve catheters can aid in covering extensive burn injuries. While the principal concern with continuous infusions is systemic toxicity, evidence has shown this to be rare with clinically relevant dosing regimens and primarily a theoretical concern (see discussion above under heading "Continuous Peripheral Nerve Blockade in Patients with Trauma").[26] Moreover, plasma levels of alpha-1 acid glycoprotein (AAG), the plasma protein and acute phase reactant that binds local anesthetics, are known to be significantly elevated in burns (and trauma in general) for at least 20 days, which may help to provide an increased margin of safety in these patients.

CHAPTER 55

Much of the morbidity in burn patients is due to the significant stress response that results, with its attendant effects on metabolism, wound healing, and immune function. Neural blockade of a burned area can substantially reduce this profound stress response via its inhibition of nociceptive input to the central nervous system. It has been demonstrated that neural blockade reduces the incidence of hyperalgesia following thermal injury.[84] Moreover, regional anesthesia results in reduced vasospasm and local thrombosis during skin grafting procedures, effects that are detrimental to graft function.

ACUTE COMPARTMENT SYNDROME CONSIDERATIONS

Acute compartment syndrome (ACS) is a serious soft tissue injury of an extremity that can occur following trauma. This pathologic syndrome arises when the pressure within a closed compartment rises above a capillary perfusion pressure, compromising the circulation and tissue function within that space. This is typically the result of a high-energy injury to soft tissue but has also been reported with crush or reperfusion injury, exercise, arterial puncture, circumferential dressings, burns, and snake bites. Over one-third of all cases of ACS are associated with tibial fracture, particularly the proximal and middle thirds of the diaphysis (due to the bulkier muscle mass compared with the ankle). Fractures of the forearm are also common injuries that may lead to ACS.

Clinical Pearls

- ACS occurs in areas packed with muscles, such as the proximal leg or forearm.
- The risk of ACS is highest in proximal tibial fractures, occurring at a rate of approximately 6%–10%.

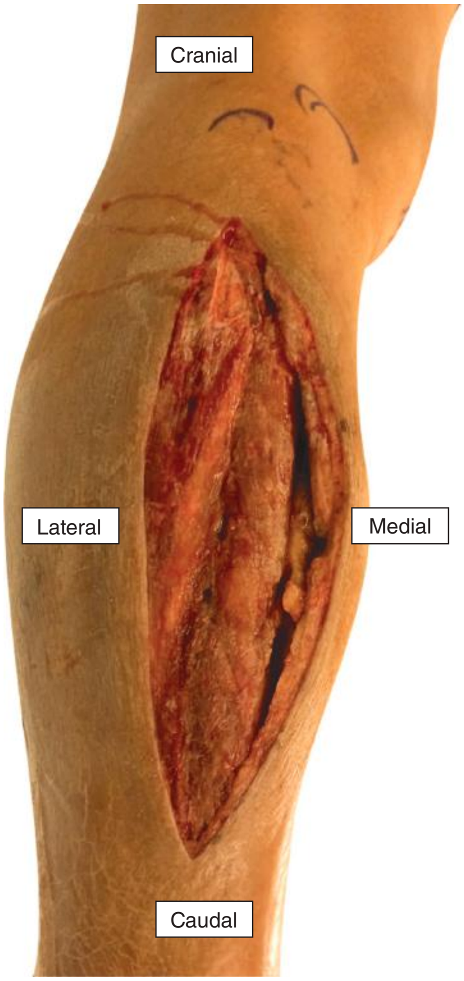

FIGURE 55–4. Fasciotomy of the anterior and lateral compartments of the leg to relieve acute compartment syndrome following a tibial fracture.

Following capillary collapse, flow into the venous system ceases, leading to tissue hypoxia and the release of vascular mediators. The resultant leakage of fluid through capillary and muscle membranes increases edema and worsens the intracompartmental pressure, leading to a vicious cycle of increased pressure → ischemia → leakage → increased pressure. Tissue pressure in muscular compartments is usually 0–10 mm Hg, and capillary filling pressure is equivalent to diastolic arterial pressure. When the gradient between tissue pressure and diastolic blood pressure falls to within 30 mm Hg, the risk for capillary collapse and the development of ACS rises significantly. Emergent fasciotomy is required to release the tense muscles from the inelastic osteofascial compartments (Figure 55–4); if not performed within 3–6 hours of the onset of ischemia, myonecrosis occurs, followed by rhabdomyolysis, myoglobinuria, acute tubular necrosis, and hyperkalemia. ACS can be a fatal complication.

Regional anesthesia and analgesia in the presence of injuries at high risk for ACS remain controversial. Many anesthesiologists and orthopedic surgeons agree to avoid regional techniques for fear that the neural blockade may mask the developing syndrome, since ACS is traditionally diagnosed on the basis of pain out of proportion to the injury (especially on passive stretch) and paresthesia.[85] However, these clinical signs and symptoms appear to have a sensitivity and positive predictive value of only 11%–19%, whereas the specificity and negative predictive value for lower leg injuries are 97%–98%.[86] In other words, the classic clinical findings are more likely to be present in an injured patient without ACS than in a patient with the syndrome. While the absence of clinical signs and symptoms appears to be a reassuring sign, it is unlikely that a patient who has a sufficiently serious injury to be at risk for ACS would be free of pain, therefore calling into question the utility of the high negative predictive value. In addition, these signs are probably even less useful in the sedated or neurologically impaired patient.

A handful of case reports have been published relating specifically to peripheral nerve blocks and ACS. However, in all but one of these cases, a nerve block actually *facilitated* the early detection and prompt treatment of the ischemic limb by the development of new-onset breakthrough pain, alerting the clinicians to a change in the status.[87–91] One case report did assert that a femoral block was responsible for a missed anterior compartment syndrome of the leg following intramedullary nailing.

However, the anterior compartment is supplied by the deep peroneal nerve, making femoral block a very unlikely contributing factor.[92] In contrast to peripheral nerve blockade, epidural analgesia has been implicated in at least 3 reports of ACS when dense motor block has been present.[85] This finding highlights the need to use dilute solutions of local anesthetics when placing peripheral nerve blocks in trauma patients. Catheter techniques are particularly effective and safe, as the concentration of the local anesthetic can be adjusted to match the intervention (surgical procedure vs. postoperative pain), and the infusion can be stopped entirely if required. Catheters can be placed at any time during the hospital course and left "dry" (or with a small infusion of saline to prevent clotting) and bolused when appropriate.

Clinical Pearl

- To date, there are no published cases of regional anesthesia delaying the diagnosis of ACS. In contrast, there are several reports of pain breaking through a block, which has facilitated the early diagnosis of a developing ACS.

Since randomized controlled trials are unlikely to be forthcoming due to ethical issues, hard data on the safety of nerve blocks is unavailable. Furthermore, it is possible that the diagnosis of ACS in the setting of peripheral nerve blocks is underreported or simply avoided in high-risk patients. Rather than focusing on whether or not to perform a PNB, our attention might better be directed toward careful monitoring of analgesic consumption and breakthrough pain and the use of compartment pressure monitoring for high-risk patients. Vigilance by both surgical and anesthetic teams involved in the patient's care is the key to the early detection of ACS. More information on the pathophysiology of acute compartment syndrome can be found in Chapter 51.

SUMMARY

Patients with acute trauma frequently require complex management, with coexisting, often competing, priorities. High-quality analgesia in this population must also be addressed. In addition to improving patient comfort, peripheral nerve and neuraxial blockade significantly reduce the requirement for systemic opioid analgesia and the adverse effects associated with opioid use. This is often critical in the multiply injured patient who suffers from neurologic, cardiovascular, and/or pulmonary impairment. In addition, the early use of regional anesthetic techniques in selected trauma patients appears to improve outcomes such as pulmonary morbidity, delirium, and mortality and facilitates reductions in length of stay in both the emergency room and hospital overall.

Additional research is required to clarify the impact of peripheral nerve blocks and neuraxial analgesia on outcomes such as the development of delirium, mobility, chronic posttraumatic pain and posttraumatic stress disorder. While peripheral nerve blocks may not delay the diagnosis of acute compartment syndrome, prudent use of regional techniques in trauma patients should be combined with a multidisciplinary approach, astute clinical judgment, and vigilance.

CHAPTER 56

Regional Anesthesia for Cardiac and Thoracic Anesthesia

Paul Kessler

REGIONAL ANESTHESIA FOR CARDIAC SURGERY

General anesthesia is the most commonly used anesthetic technique for cardiac surgery, both for valvular procedures and for coronary artery bypass grafting (CABG) performed either on pump or off pump. However, there are several reports from the 1970s and 1980s describing improved postoperative analgesia through the intrathecal and epidural application of opiates in cardiac surgery.[1,2] Faster extubation of patients is another benefit of the neuroaxial application of opiates.[3] Local anesthetics are also routinely applied as they suppress the stress hormone response in addition to having analgesic properties, resulting in improved outcomes.[4]

For intrathecal application, two procedures have been reported: opiates or the "high spinal technique," achieved with large doses of local anesthetic. In contrast to a single-shot intrathecal technique, epidural opiates and local anesthetics can be applied continuously. As a result, the intraoperative benefits of a neuraxial procedure can be continued beyond the postoperative phase. Intrathecal and epidural procedures are typically combined with a general anesthetic, although segmental pain elimination allows for cardiac procedures through the sole use of a high thoracic epidural anesthesia.[5]

Paravertebral blockade (PVB) is another reported regional anesthetic procedure in cardiac surgery (Table 56–1).[6] Varying techniques are used: single-shot or continuous application; unilateral for thoracotomy or bilateral for sternotomy.[6,7] Due to the limited number of published cases, the importance of PVB in cardiac surgery currently cannot be assessed.

Techniques

High Thoracic Epidural Anesthesia

Despite some beneficial effects of regional anesthesia, especially the neuraxial techniques, its use is not yet widely accepted in cardiac surgery. This is due to the ongoing discussion regarding the potential risks of epidural hematoma formation and subsequent adverse neurological sequelae related to perioperative anticoagulation, which thus discourages the use of epidurals in these patients by many anesthesiologists. There is a great deal of controversy in the cardiac literature concerning neuraxial techniques in cardiac surgery.[8,9]

Physiological Effects High thoracic epidural anesthesia (hTEA) results in excellent analgesia achieved throughout the epidural application of opiates and/or local anesthetics, allowing for faster recovery and extubation after surgery.[10.11] This is due to the superior analgesia of hTEA after CABG surgery, which may improve respiratory muscles strength.[12]

Beyond its analgesic properties, hTEA's beneficial effects on the postoperative neurohumoral stress response and cardiovascular pathophysiology have been demonstrated in both clinical and experimental investigations. hTEA results in a segmental thoracic sympathectomy; at a level between T1 and T5, this sympatholysis dilates the coronary arteries and the internal mammary arteries and thus improves perfusion of the respective vessels.[13–15] Heart rate is reduced,[16] cardiac arrhythmia is less frequent, and intraoperative hemodynamic stability can be significantly improved.[16–18] In addition, hTEA lowers the incidence of intraoperative myocardial ischemia,[18,19] reduces the endogenous stress response to surgical manipulation,[4,20] and decreases stress hyperglycemia and the need for insulin in cardiac surgery patients.[21] Reductions in both tachycardia and ischemic events have also been demonstrated with hTEA in the postoperative period. Improved pulmonary function without affecting the ventilation–perfusion ratio allows for earlier and smoother weaning of mechanical ventilation and a decreased incidence of postoperative pulmonary dysfunction.[12,16–19] There is also evidence of a reduction in postoperative neurologic complications when hTEA is used.[22]

TABLE 56–1. Techniques of regional anesthesia and analgesia for cardiac surgery.

Epidural
Spinal
Paravertebral

Clinical Pearls

- High thoracic epidural analgesia (hTEA) has beneficial effects on the postoperative neurohumoral stress response and cardiovascular pathophysiology.
- Addition of hTEA and general anesthesia may reduce postoperative morbidity (postoperative arrhythmias, pulmonary complications, renal failure) in addition to providing analgesia.

High Thoracic Epidural Anesthesia and General Anesthesia

In the past two decades, hTEA as an adjunct to general anesthesia has become more prevalent and has been demonstrated to be potentially beneficial in patients with coronary artery disease (Table 56–2).[17,23]

Case series regarding the use of hTEA in valvular surgery have been published.[24,25] hTEA has been shown to provide superior analgesia and to be associated with a lower incidence of pulmonary and cardiac events and a reduced median time on mechanical ventilation. A randomized, controlled study demonstrated that hTEA improves cardiac performance in low-to-moderate-risk patients undergoing elective coronary artery bypass graft surgery with or without aortic valve replacement. Time spent in the intensive care unit (ICU) and quality of recovery, however, remained unchanged.[26,27]

The combination of hTEA with general anesthesia remains controversial among cardiac anesthesiologists.[8,9,28] The results of the existing studies are contradictory: some studies show a reduction in postoperative morbidity (postoperative arrhythmias, pulmonary complications, renal failure) and an improvement in pain control, allowing for earlier extubation and hospital discharge.[17,29–31] Others have shown no improved outcome.[32,33]

There are also conflicting data from meta-analyses on this topic. Whereas one analysis suggested that epidural analgesia combined with general anesthesia reduces the incidence of perioperative acute renal failure and time on mechanical ventilation and improves outcomes on the composite endpoints of mortality and myocardial infarction in patients undergoing cardiac surgery,[34] other meta-analyses, including more than 1000 patients, have found no difference in mortality rate or incidence of myocardial infarction between general versus regional anesthetic techniques.[35,36] However, patients undergoing cardiac surgery with hTEA have a reduced risk of postoperative supraventricular arrhythmias and respiratory complications.[35,36] In addition, patients receiving regional analgesia seem to benefit from superior postoperative analgesia and shorter postoperative ventilation.[37] These are the main reasons why epidural anesthesia plays an integral part of fast-track anesthesia protocols in cardiac surgery that utilize hTEA. In addition to improvements in short-term recovery, hTEA may also have positive psychological effects.[38]

TABLE 56–2. Possible benefits of epidural anesthesia in cardiac surgery.

Decreased myocardial ischemia
Reduced cardiac arrhythmia
Improved ventricular function
Increased hemodynamic stability
Improved pulmonary function
Earlier extubation and ambulation, shorter ICU stay
Reduction in overall cost

ICU, intensive care unit.

Clinical Application

Patient Selection A concomitant hTEA can be used in different types of cardiac surgery: CABG with cardiopulmonary bypass (CPB), off-pump coronary artery bypass (OPCAB), and valve replacement.

In principle, hTEA can be used in all cardiac surgery procedures. Contraindications for hTEA should be taken into account, however, and include patient refusal, past surgery on the cervical or upper thoracic spine, infection at the local site of injection, and continued use of antithrombotic and antiplatelet drugs. According to the American Society of Anesthesiologists and European Society of Anaesthesiology guidelines, strict adherence to the recommended time intervals between the administration of anticoagulants, neuraxial blockade, and the removal of catheters is thought to improve patient safety.[39,40] Patients with abnormal coagulation (thromboplastin time < 80%, prothrombin time > 40 sec, platelets < 100/nL) or a bleeding disorder should be excluded.

Epidural Technique The question regarding the optimal time interval between placement of hTEA and surgery remains unanswered. In the early days, catheters for hTEA were placed a day before surgery to ensure safe timing from placement to intraoperative heparinization. This practice also ensured that surgery would not have to be postponed in case of a "bloody tap" (blood in the epidural catheter). Many centers now place the catheter on the day of surgery. This procedure offers organizational advantages and apparently does not increase the risk of epidural bleeding if a gap of less than 1 hour between catheter placement and application of heparin is avoided. Currently, there is no evidence-based guidance regarding the safe minimum time interval between catheter placement and heparinization.[39–41]

Catheter placement is performed while the patient is sitting or lying on his or her side with a midline approach and is usually located at T1–2 or T2–3. Using a 16- or 18 gauge Tuohy needle, the epidural space is identified either by loss of resistance or using the hanging drop technique. The catheter is advanced 2–3 centimeters beyond the needle tip, and correct placement is verified with a test dose of, for example, 2 mL of lidocaine 2%.[42]

The literature discusses many regimes concerning when and how the epidural catheter is used and which substances are applied. Most studies start with a loading dose before surgery and then use either a continuous application or intermittent boluses during the procedure.

The continuous administration of local anesthetic via TEA is preferable as it seems to provide very stable hemodynamic conditions compared to intermittent bolus application.

Local anesthetics, preferably bupivacaine, ropivacaine, or levobupivacaine, in concentrations from 0.2%–0.5% are used either exclusively or in combination with opiates (eg, fentanyl or sufentanil).[41,43–45] After surgery, local anesthetics in low concentrations from 0.1%–0.2%, with or without opiates, are administered continuously, intermittently, or via patient-controlled analgesia (PCA). Since the maximum pain after cardiac surgery occurs within the first 48 hours, hTEA is typically used for up to 3 days.[46]

Postoperative Management Removing the catheter requires exact synchronization with postoperative anticoagulation to reduce the risk of complications due to bleeding. The timing and type of anticoagulation is important and is discussed in more detail in Chapter 53. The safest route is to remove the epidural catheter prior to commencing anticoagulation.[39,40] Unfortunately, this complicates the management and decreases the utility of TEA, as the immediate use of anticoagulation post-surgery has become more common, making safe catheter removal without pausing the medication difficult. As an alternative, a single-shot technique, either spinal anesthesia or paravertebral blockade, can be used. Prior to removal of the catheter, current lab results with regard to clotting are mandatory.

Complications of High Thoracic Epidural Anesthesia

Transient Neurological Symptoms There are no reports in the literature of permanent neurological symptoms following hTEA in cardiac surgery. In a review publication, Ruppen et al. found 4 cases out of 4971 patients in 9 studies reporting neurological symptoms, and Jack and Scott reported on 12 cases out of 2837 patients.[17,44,47] All patients fully recovered. From these data, the reported incidence of transient neurological complications in patients undergoing cardiac surgery with TEA is 0.20%.

Severe Infectious Complications To date, no reports of epidural abscess or meningitis after hTEA in patients undergoing cardiac surgery have been published. The incidence of epidural abscess or meningitis after hTEA in patients in non-cardiac surgery patients varies from 0.04%–0.6%.[48]

Epidural Hematoma The risk of bleeding complications after hTEA is not known. Nevertheless, the possibility of developing an epidural hematoma is the main cause for concern regarding hTEA among cardiac anesthesiologists, and the risk–benefit ratio of hTEA in cardiac surgery remains controversial.[28,49] Under the conditions of an off-pump procedure, with considerably less heparinization in comparison to CPB, most anesthesiologists consider the associated risk to be reduced. However, there is no definitive evidence for this. The removal of the catheter and postoperative anticoagulation remain unresolved problems when considering hTEA for cardiac surgery. If the catheter must be removed, then, according to the guidelines, anticoagulation must be stopped.[39,40] This, however, introduces a risk of coronary ischemia or thromboembolic event (Table 56–3).[50]

TABLE 56–3. Epidural safety issues.

Strict adherence to the recommended time intervals of antiplatelet drugs
Insertion of the catheter the night before or at least 1 hour prior to heparinization
Normal clotting at the time of insertion
Antagonize heparin at the end of operation (ACT)
Removal of the catheter after coagulation is normalized
Withholding of heparin (s/c) prior to catheter removal

ACT, activated clotting time.

Until now, only very few epidural hematomas have been described in cardiac surgery patients in the context of hTEA, but all associated with intraoperative hepatinization or postoperative catheter issues.[51–54] Regardless, meticulous monitoring of cardiac patients with hTEA in the postoperative period is essential. It is also important to coordinate the postoperative course and drug therapy (particularly anticoagulant therapies) with the timing of catheter removal and monitor for new sensory and/or motor deficits for the entire postoperative period and at least 12 hours after catheter removal. If patients are not extubated in the operating room, close neurological surveillance is often delayed. Undetected cord compression reduces the chance of early hematoma evacuation and the chance of full neurological recovery.[55]

The first risk calculation of blockade-induced hematoma with a 95% confidence interval was from 1:150,000 to 1:1,500 for epidurals;[56] the most recently published risk estimation was 1:12,000.[45] The actual number of epidural hematomas is likely higher, but so is the actual number of performed, but unpublished, thoracic epidurals. The 1:12,000 incidence of hematoma is similar to that described with epidural in noncardiac surgery.

Summary

To this day, no randomized controlled trial or meta-analysis has demonstrated that hTEA decreases mortality after cardiac surgery. However, it is well-documented that hTEA reduces postoperative morbidity (postoperative arrhythmias and pulmonary complications) and improves pain control, allowing for earlier extubation and hospital discharge. The accepted benefits of hTEA in cardiac surgery need to be carefully weighed against the potentially catastrophic outcome of high thoracic epidural hematoma.

High Thoracic Epidural Anesthesia and Awake Cardiac Surgery

Awake cardiac surgery was first performed in 1998 as coronary artery graft surgery by the Turkish cardiac surgeon Karagoz.[5]

With thoracic epidural anesthesia as the sole anesthetic modality, the author reported that 5 patients successfully underwent OPCAB surgery.

Minimal surgical access (eg, partial lower sternotomy or thoracotomy) and operation techniques on the beating heart (OPCAB) avoiding CPB and full heparinization were the requirements for the first set of awake cardiac surgeries. The majority of published awake cardiac surgeries have been performed on OPCAB patients,[42,49,57–60] but there are also case reports of OPCAB technique for total revascularization via a full median sternotomy.[49,61] Recently, small case series including valve replacements with CPB on awake high-risk patients have been published.[62–66]

Clinical Application

Patient Selection Patients undergoing awake cardiac surgery need to be extensively and thoroughly informed about the anesthetic technique used, potential adverse events, and the pre- and intraoperative routines. An awake OPCAB procedure is not applicable to all kinds of coronary artery stenoses. Revascularization of the left circumflex artery requires Trendelenburg positioning and luxation of the heart and is therefore difficult to perform awake. In addition, patients with highly impaired left ventricular function dependent on a certain cardiac sympathetic tone should be excluded from this new technique. Further exclusion criteria arise from the common contraindications of epidural puncture, such as compromised coagulation, bleeding disorders, and the use of any antiplatelet drugs.

Anesthetic Technique The process of epidural puncture does not differ from the technique described earlier. Regarding intraoperative catheter use, various regimens have been described. Commonly, a loading dose of local anesthetic, with or without opiates, is given until the desired level is achieved after verification of correct positioning. Thereafter, the infusion rate is reduced to maintenance dosage. During wound closure, the epidural infusion is stopped and restarted with a lower concentration of local anesthetic, with or without opiates, for analgesia postsurgery (Table 56–4).[67]

After commencing the loading infusion, the level of anesthesia is checked every 5 minutes via pinprick and warm–cold discrimination. The motor blockade is estimated by observing intercostal breathing or arm movement. For full median sternotomy, the level of sensory and motor blockade must be at C7–C8; for partial or lower sternotomy and thoracotomy, the level is adjusted according to the required surgical access.[49,67] Extending regional anesthesia with other techniques (eg, femoral nerve block[58,68] or lumbar spinal anesthesia[59]) allows for additional removal of veins from the legs for grafting.[68] Furthermore, a case report has been published in which coronary artery bypass graft surgery with TEA was followed by disobliteration of the carotid artery using a cervical plexus block.[69]

After onset of sensorimotor blockade, cannulation of the radial artery and siting of the central venous catheter is performed. Patient monitoring includes arterial blood pressure, 5-lead electrocardiogram (ECG) with continuous ST-segment analysis, and saturation and ventilation via pulse oximetry and capnography. All patients receive oxygen continuously via mask. As long as the application of larger amounts of sedatives is avoided, appropriate ventilation and oxygenation of awake patients is guaranteed during surgery.[70] Additional intraoperative IV sedation is not mandatory since the epidural opioids result in a sedative effect. A low-dose infusion of propofol or midazolam boluses can be beneficial to allay anxiety.[70]

TABLE 56–4. Local anesthetics and opioids for high thoracic epidural anesthesia in awake cardiac surgeries.

Study	Drugs and Concentrations	Administered Dose
Karagoz et al.[5,71]	Bupivacaine 2 mg/mL Lidocaine 8 mg/mL Fentanyl 5 μg/mL	Initial bolus of 10 mL; additional boluses when necessary
Kessler et al.[67,70]	Ropivacaine 5 mg/mL Sufentanil 1.66 μg/mL	Initial bolus infusion of 10–12 mg over 15–20 min; maintenance with 2–5 mL/h
Lucchetti et al.[59]	Ropivacaine 5 mg/mL Clonidine 7.5 g/mL Fentanyl 5 μg/mL	Initial bolus of 12mL; maintenance with bolus of 4 mL
Hemmerling et al.[58]	Bupivacaine 5 mg/mL Sufentanil 2 μg/mL	Initial bolus of 12 mL over 25 min; maintenance with 4–7 mL/h
Gerosa et al.[69]	*Initial:* Ropivacaine 6 mg/mL Lidocaine 6 mg/mL Fentanyl 5 μg/mL *Maintenance:* Bupivacaine 2.5 mg/mL	Bolus of 10 mL; additional boluses when necessary
Noiseux et al.[68]	Bupivacaine 5 mg/mL Sufentanil 1.66 μg/mL	Initial bolus of 20 mL over 60 min; maintenance with 2–14 mL/h
Watanabe et al.[49]	Lidocaine 10 mg/mL Bupivacaine[a] Morphine 50 μg/mL	Maintenance with 20 mL/h

[a]Concentration not given in publication.

TABLE 56–5. Potential benefits of awake cardiac surgery.

Excellent postoperative pain relief
Bypass of ICU or short-term ICU stay
Avoidance of endotracheal intubation
No weaning
Faster mobilization
Shorter hospital stay
Decreased costs
High patient acceptance

ICU, intensive care unit.

TABLE 56–6. Side effects and disadvantages of awake cardiac surgery.

Insufficient analgesia
High motor block
Phrenic nerve palsy
Permanent neurologic symptoms resulting from the TEA
Hemodynamic changes
Unprotected airway
Inability to perform a TEE

TEA, thoracic epidural anesthesia; TEE, transesophageal echocardiography.

Awake Cardiac Surgery

The hypothetical benefits of awake cardiac surgery may result from the avoidance of endotracheal intubation and from the use of hTEA (Table 56–5). The following advantages of awake cardiac surgery with hTEA have been described: stable intraoperative hemodynamics;[70] faster mobilization (some activities of daily living may be performed) within a few hours after surgery;[67,71] shorter-term ICU stay or even complete avoidance of the ICU;[57,70] shorter hospitalization; and, overall, a modern fast-tracking technique for cardiac patients[57,71] with significant cost reduction potential and high patient acceptance.[70] Furthermore, case reports have demonstrated advantages for patients with significant pulmonary risk factors, such as chronic obstructive pulmonary disease (COPD) or post-tracheal reconstruction, due to the avoidance of endotracheal intubation and, consequently, potential weaning difficulties postoperatively.[72,73] In addition, awake CABG allows for verbal intraoperative monitoring of patients with compromised cerebrovascular function (eg, severe carotid artery stenosis) (Figure 56-1).[69]

Clinical Pearl

- Awake cardiac surgery is described primarily in coronary artery graft surgery on the beating heart (OPCAB).

FIGURE 56–1. Awake off-pump coronary artery bypass surgery.

Awake Cardiac Surgery Risks

The side effects and complications of awake cardiac surgery may result from the use of epidural anesthesia and from the avoidance of general anesthesia (Table 56–6). Uncontrolled spreading of epidural anesthesia toward the cranium can result in cardiovascular changes (hypotension, bradycardia), requiring a supportive increase of heart rate or the use of vasopressors.

A unilateral or bilateral paresis of the phrenic nerve and thus paralysis of the diaphragm is possible should the hTEA spread to C5/6, in which case the patient must be intubated and ventilated. Extubation is usually not a problem if the administration of local anesthetic is stopped toward the end of surgery.[70]

Accidental perforation of the pleura during surgery is no rare incident while preparing the internal thoracic artery but usually remains without clinical relevance in intubated and ventilated patients. However, if the patient is breathing spontaneously and mechanics are compromised due to other factors (eg, complete discontinuity of the bony thorax structure through sternotomy or loss of intercostal muscle function), a perforation can result in lung collapse and acute respiratory insufficiency requiring controlled ventilation.[70,71,74] While maintaining spontaneous breathing, it is possible to seal the lesion. This is followed by the insertion of a pleural drainage.[71]

Further reasons for conversion to general anesthesia include insufficiency of the hTEA and the surgical necessity to use CPB (Table 56–7).

Awake cardiac surgery may be associated with significant patient anxiety. However, to date, there has been no study focusing on the psychological impact of awake cardiac surgery on patients. In contrast to presumptions,[28] compared to general anesthesia, the patient's stress response does not seem to be increased in awake surgery, and postoperative surveys have shown very high levels of patient acceptance.[70,71,74] One report compared the experiences of patients who underwent awake surgery who had previously undergone cardiac surgery with general surgery; all of these patients reported preferring the experience of awake cardiac surgery.[75]

There are no differences between patients undergoing awake cardiac surgery and those undergoing such surgery with combined TEA and general anesthesia in terms of the risks of epidural bleeding, transient neurologic symptoms, or epidural infection.

Summary

For over 15 years, awake cardiac surgery has been performed and results have been published by a few specialist centers. This technique is used mainly in coronary artery graft surgery on the beating heart (OPCAB) based on the reduced heparinization and therefore the lower possible risk of epidural hematoma. Most of the published accounts of awake cardiac surgeries are case reports or observational studies that simply describe the feasibility of this method. Only a few studies have had control groups comparing awake cardiac surgery using hTEA alone with hTEA plus general anesthesia and cardiac surgery with general anesthesia only. These studies showed no advantage in the awake cardiac surgery group versus the hTEA with additional general anesthesia group.[49,70,76,77]

The future of hTEA and awake cardiac surgery is not known. There may be selected centers with experienced teams of anesthesiologists and cardiac surgeons with clearly defined perioperative protocols who will continue to use hTEA. However, many patients are now treated interventional by cardiologists, thus avoiding surgery altogether. Patients scheduled for bypass surgery these days are usually high-risk patients with compromised myocardial function or patients requiring additional valve surgery. In addition, intraoperative transesophageal echocardiography (TEE) is now a standard procedure and cannot be performed on the awake patient. Finally, the feasibility of performing cardiac surgery with hTEA in patients with coronary artery disease and the current anticoagulation strategy should always be considered in terms of the risk–benefit ratio.

Spinal Anesthesia

Indication

Spinal anesthesia (SPA) has been used in combination with general anesthesia for various cardiac surgery procedures for several decades, most frequently in patients undergoing CABG. The primary rationale for the use of SPA is to provide prolonged, profound postoperative analgesia. In most studies, intrathecal morphine was used.[78–80] Lipophilic opiates are of little use due to their short duration of action. Other benefits of SPA are reduced perioperative attenuation of sympathetic autonomic activity and the realization of so-called "fast-track" targets, such as rapid extubation and patient transfer. Although SPA has excellent analgesic properties, the technique is not in widespread use in cardiac surgery, at least partly due to risk of spinal hematoma as a result of systemic anticoagulation.

Clinical Application

The intrathecal application of morphine has been well studied with dosages of ranging from 0.25–4.0 mg;[81–84] most studies have reported improved postoperative analgesia with this technique as compared to an IV technique. However, the optimal dose for striking a balance between optimal analgesia and a minimal side effects remains undetermined. An increased dose of morphine improves and prolongs postoperative analgesia, although at the cost of increased levels of side effects (ie, pruritus, nausea, vomiting, and urine retention).[78] Additionally, higher doses of intrathecal morphine prevent early extubation after surgery.[46] On the other hand, the absence of local anesthetic infusion lacks the titratability of analgesia and significantly limits the benefits up to 24 hours postoperatively.

Of note, intrathecal opioids alone do not alter the sympathetic response to cardiac surgery and cardiopulmonary bypass; this benefit is seen only with local anesthetic.[85] Subsequent studies have investigated the sole application of high-dose intrathecal local anesthetic as a "high spinal" anesthesia or in combination with intrathecal opiates.[86,87] Both treatments efficiently suppress the stress response during surgery, although with a higher incidence of bradycardia and hypotension with increased amounts of vasoconstrictors required as compared to a technique without intrathecal application of local anesthetics and/or opioids.

Complications

Spinal analgesia has not acquired widespread acceptance in cardiac surgery; this is mainly because of the potentially increased risk of neuraxial hematoma in patients receiving heparin during surgery. The concerns are founded; many of these patients receive antiplatelet drugs, receive intraoperative high-dose heparin for CPB, and continue anticoagulation after valve surgery. However, there is still a lack of sufficient data and experience to determine if the risk of epidural hematoma is increased when combining neuraxial techniques with anticoagulation in cardiac surgery.

It is important to observe the relevant guidelines issued by the anesthesiology societies[39,40] regarding perioperative anticoagulation and neuraxial procedures. In addition to adhering to recommendations regarding the timing of the procedure and anticoagulation, postoperative monitoring of neurologic function and selection of a neuraxial procedure that minimizes postoperative sensory and motor block in order to facilitate the detection of new or progressive neurodeficits are required.

In contrast to TEA, thus far no case reports of hematoma-related permanent spinal cord damage after SPA in cardiac surgery patients have been reported. However, this may be because SPA is performed less frequently than TEA in cardiac surgery. The potentially lower risk of neuraxial hematoma with spinal anesthesia is probably due to the small-gauge needles used with spinal anesthesia and the avoidance of catheter insertion and removal. Based on reports, almost 50% of epidural hematomas occur after catheter removal.[88]

Outcomes Data

Reviews and meta-analyses have evaluated the existing studies of the use of SPA in cardiac surgery.[8,35,37,89] The critical question is whether spinal analgesia might influence patients' outcomes after cardiac surgery. The meta-analysis performed by Liu and colleagues on spinal analgesia in coronary artery bypass graft surgery including 17 randomized, controlled trials (RCTs) showed no improvement in major clinical endpoints.[35] Two observed benefits of spinal analgesia were modestly decreased systemic morphine use and pain scores.[25] A meta-analysis from Zangrillo et al. including 25 randomized studies on spinal analgesia confirmed no reduced perioperative mortality, myocardial infarction, or arrhythmia but an increased rate of postoperative pruritus.[89]

Summary

The intrathecal administration of opiates or local anesthetics can provide effective postoperative analgesia with decreased intravenous analgesic requirements. However, studies of intrathecal analgesia in cardiac surgery have not demonstrated a significant positive effect on morbidity and mortality.

Paravertebral Blockade

The effectiveness of thoracic paravertebral blockade (tPVB) in thoracic surgery has been well-documented.[90] For thoracic surgery, tPVB is considered equivalent in its analgesic properties to hTEA but with a more favorable side effect profile.[91] The application of local anesthetic into the paravertebral compartment generates an ipsilateral somatic and sympathetic nerve blockade across several thoracic dermatomes.[92]

The use of tPVB in cardiac surgery is limited to a few case series and individual case reports.[6,7,93–95] A tPVB with continuous application of local anesthetic has been used in minimally invasive procedures with thoracoscopic access[6] and was found to be as effective as hTEA for analgesia.[93] Other authors have reported the use of a bilateral tPVB using a bilateral single-shot or continuous-catheter technique for conventional cardiac surgery with complete sternotomy.[7,94] Side effects included hypotension, blood vessel puncture with an incidence of around 5%,[96] a failure rate of between 6.1% and 10.7%, and a rate of pneumothorax of between 0.4% for unilateral technique and 4% for bilateral technique.[97] As the location of puncture in tPVB is close to the spinal canal, which may cause complications if bleeding occurs, the same safety time intervals regarding application of anticoagulants as for neuraxial procedures are required for puncture and catheter removal.[39,40] The few data available concerning tPVB and cardiac surgery do not allow for a definitive recommendation.

REGIONAL ANESTHESIA FOR THORACIC SURGERY

Surgeries on the chest wall are among the most painful procedures performed[98] and carry a high risk of chronic pain.[99] Splinting of the wound or immobilization is near impossible, whereas postoperative pain reduces pulmonary function and impairs effective cough and clearing of secretions. Combined, these factors predispose patients for the development of atelectasis and pneumonia.[100] Surgical access (minimal vs. open) and incision technique (posterolateral vs. muscle sparing vs. sternotomy) have a significant effect on postoperative pain intensity. The increasingly used technique of video-assisted thoracoscopic surgery (VATS) results in less postoperative pain compared to open thoracotomies.[101]

Several clinical studies indicate that effective intra- and postoperative analgesia management reduces the number and severity of complications encountered after surgery, especially pulmonary complications.[100,102] Systemic analgesics (opiates and nonopiates) and regional analgesia procedures (intercostal, paravertebral, interpleural, and epidural blockades with local anesthesia and opiates) have all been used with success for pain management after thoracic surgery. Comparative studies, meta-analyses, and systemic reviews consistently demonstrate that regional analgesic techniques (TEA or PVB) are superior to systemic analgesia.[91,103–105] Used intraoperatively, regional anesthesia reduces the need for intraoperative opioids and their side effects.

Techniques

Thoracic Epidural Anesthesia

TEA is typically used in combination with general anesthesia, making use of its excellent analgesic properties. It is currently considered the gold standard in the treatment of thoracotomy pain.[103,105] In many comparative studies of the use of systemic opiates, TEA was proven superior.[106–107] TEA has also been used exclusively in selected surgical procedures.[108]

Physiological Effects

Along with the excellent analgesic properties of TEA, the sympathetic blockade of local anesthetics has significant beneficial effects on several organ systems: increased gastrointestinal motility and perfusion and decreased myocardial ischemia and systemic stress response. However, the effective analgesia must be balanced against the possible alteration of lung function

TABLE 56–8. Pulmonary effects of thoracic epidural anesthesia.[114,116,117]

Decreased bronchial reactivity as a result of systemic effect of local anesthetic
No increased airway resistance in patients with severe obstructive pulmonary disease
No influence on hypoxic pulmonary vasoconstriction (HPV)

through the epidural motor blockade of respiratory muscles and the potentially detrimental effects of sympathicolysis, leaving an unopposed vagal tone with a potentially increased bronchial tone and reactivity.

Data show that in healthy volunteers, TEA with sensory blockade up to the cervicothoracic region decreases vital capacity (VC) and forced expiratory volume in one second (FEV_1) significantly.[109] This is mainly due to a motor blockade of the intercostal muscles. The effect is more pronounced when local anesthetics in high concentrations are used. In patients undergoing thoracic or abdominal surgery with general anesthesia exclusively, though, TEA improves the reduced VC postsurgery.[110] Two effects of TEA contribute to this improvement: improved diaphragmatic function and better postoperative analgesia than systemic opioids. Higher values of functional residual capacity (FRC), FVC, and FEV_1 in patients treated with TEA show that the analgesic effect outweighs the potential negative effects on relaxation of the intercostal muscles.[111] Postoperative FEV_1 seems to be a useful predictor of postoperative outcome. A low predicted postoperative value of FEV_1 has been shown to correlate significantly with a complicated postoperative course and poor surgical outcome.[112] By increasing lung volume, TEA may help reduce the incidence of pulmonary complications post-thoracotomy.[113]

A further caveat against the use of TEA, especially in patients with COPD, however, stems from thoracic sympathicolysis and its effects on bronchial muscle and vascular tone.

Since the pulmonary vasculature is innervated by the autonomic nervous system, hypoxic pulmonary vasoconstriction (HPV) may be influenced by sympathetic neural blockade. Prospective clinical observations demonstrated that TEA in combination with general anesthesia did not affect arterial oxygenation or shunt fraction during one-lung ventilation. TEA therefore seems to be suitable for analgesia during thoracic surgery.[114,115] TEA does not increase airway obstruction in patients with COPD or severe obstructive pulmonary disease (Table 56–8).[116,117]

Thoracic Epidural Anesthesia and General Anesthesia

Several studies have shown a reduction in pulmonary complications when general anesthesia was combined with intra- and postoperative epidural anesthesia and analgesia. This reduction was a result of early extubation, better analgesia during mobilization and coughing, attenuation of bronchial reactivity, and improved diaphragmatic function.[107,111,118]

Meta-analyses of pulmonary outcomes have confirmed that TEA in combination with general anesthesia decreases the incidence of atelectasis, reduces the incidence of pulmonary infection, increases arterial oxygen tension, and decreases pulmonary complications overall.[119,120] TEA in combination with general anesthesia can also be recommended for patients with severe COPD and asthma undergoing lung resection surgery.[113,121,122]

Clinical Application

The epidural catheter should be inserted between level T3 and T8 in a midline or paramedian approach using the "loss of resistance" or "hanging drop" technique. Typically, a combination of dilute concentration of local anesthetic (bupivacaine or ropivacaine) with a lipophilic opiate (fentanyl or sufentanil) is used pre- and intraoperatively.[91,123] This combination allows for a reduced dose and side effects of both components.

The epidural application of bupivacaine 0.1% in addition to a concentration of fentanyl 5 μg/ml is a common mixture used with success by many.[124] Combinations of ropivacaine with sufentanil (ropivacaine 0.2%, 0.5–0.75 μg/mL sufentanil) are also common place.[125–127]

The TEA catheter usually remains in situ for 3–4 days after surgery and is usually discontinued after removal of the thorax drainage. During this period, the epidural medication is given in the same combination as during surgery: a low concentration of local anesthetic (0.5–1 mg/mL bupivacaine or 1–2 mg/mL ropivacaine) with a lipophilic opiate (5 μg/mL fentanyl or 0.5 μg/mL sufentanil).

Complications

TEA can be technically challenging and is associated with a failure rate of over 10%. It may cause hypotension or difficulty in voiding and poses a risk of epidural hematoma.[128] More considerations on this topic can be found in Chapter 48.

Thoracic Epidural Anesthesia and Awake Thoracic Surgery

Several case reports and small case series have been published regarding the successful use of TEA in awake cardiac surgery.[108,129,130] The overriding benefit of TEA, in addition to effective analgesia, is the avoidance of intubation and mechanical ventilation required with general anesthesia, as this carries a risk of complications in patients with decreased respiratory function and in patients with comorbidities undergoing cardiac surgery. A few examples of the risks involved with intubation and mechanical ventilation include delayed extubation, increased risk of pneumonia, impaired cardiac performance, neuromuscular problems due to neuromuscular blocking agents, airway pressure–induced injury (barotrauma), lung inflation–induced injury (volutrauma), and the release of a variety of proinflammatory mediators (biotrauma) (Table 56–9).[131]

Clinical Application

A wide variety of thoracic surgical procedures have been performed under TEA as the sole anesthetic modality: resection of pulmonary nodules[108] and solitary metastases,[132] management

TABLE 56–9. Adverse effects of general anesthesia with one-lung ventilation.

Difficult airway
Impaired cardiac performance
Pressure-induced lung injury (barotrauma)

of pneumothorax,[133,134] lung volume reduction surgery,[129] transsternal thymectomy,[135] and even major thoracic procedures such as thoracotomy and median sternotomy (Figure 56–2).[136]

Several randomized studies on awake thoracoscopic operations demonstrated beneficial effects in a wide variety of procedures, such as a lower incidence of postoperative respiratory complications, less nursing care required, shorter in-hospital stay, and higher patient satisfaction than with procedures performed under general anesthesia.[89,132,137–139] In addition, the perioperative surgical stress response may be attenuated in awake VATS as a result of reduced postoperative stress hormones (Table 56–10).[140]

FIGURE 56–2. Video-assisted thoracoscopic surgery in the awake patient.

TABLE 56–10. Potential advantages of awake thoracic surgery over conventional surgery.

Easier acceptance of surgery
Reduced need for high-dependency stay postoperatively
Better respiratory function in the early postoperative period
Reduced operative mortality
Reduced morbidity
Shorter hospital stay
Lower procedure-related costs
Attenuated stress hormone response
Attenuated impairment of immune response
Better survival in oncological surgery

Whether thoracic surgery can be performed on the awake patient under TEA depends on the planned surgery and patient-specific factors. The duration of surgery is a considerable criterion. In the majority of cases, patients considered for awake surgery are high-risk and have several comorbidities. Avoiding general anesthesia in these cases, theoretically at least, can be beneficial. The patient's acceptance, coordination, and close cooperation are mandatory prerequisites for awake procedures.

Contraindications for awake surgery are the same as those for TEA and procedures requiring lung isolation to protect the contralateral lung from contamination: pus, alveolar proteinosis, bronchopleural fistula, and massive bleeding.

Anesthetic Technique

Standard perioperative monitoring includes ECG, peripheral oxygen saturation, noninvasive blood pressure, and end-tidal carbon dioxide to monitor spontaneous ventilation. Invasive monitoring, such as direct arterial pressure and central venous pressure, should be based on the individual patient's general condition and the type of procedure.

TEA is usually performed at level T4–T6 using a median or paramedian access, allowing for a sensorimotor blockade from level T1–T9 depending on the surgical proceeding. Verification of successful puncture and adequate level is performed using warm–cold discrimination. Intraoperative medication via TEA consists of higher-concentrated local anesthetics (bupivacaine 0.5% or ropivacaine 0.75%, with or without opiates [fentanyl or sufentanil]). Sedation during surgery is not usually necessary but should be considered depending on the patient, as it may reduce anxiety and discomfort during awake procedures. However, sedation may also increase the risks of hypercapnia and hypoxemia. Low-dose propofol infusion or small boluses of midazolam have been used.

Clinical Pearl

- Available studies have demonstrated that TEA and PVB are superior to systemic analgesia in treatment of thoracotomy pain.

Side Effects and Complications of Awake Thoracic Surgery

The overall incidence of side effects and complications with awake thoracic surgery is low. Incomplete analgesia of TEA requires immediate conversion to general anesthesia. Spontaneous breathing may become difficult due to the open pneumothorax resulting in mediastinal shift and compression of the dependent lung. However, maintenance of diaphragmatic tone will tend to reduce compromised breathing. Therefore, in most cases, no additional management in awake patients with spontaneous ventilation and lung collapse is necessary.[129]

Nevertheless, hypoxemia and hypercapnia may occur during awake thoracic surgery, mainly due to increased intrapulmonary shunt and paradoxical respiration. Hypoxemia can be treated with oxygen. Hypercapnia may occur for several reasons. First, the sustained hypoventilation of the collapsed lung increases carbon dioxide levels in the respiratory system, which is rebreathed in the contralateral lung. Second, blocking of the intercostal muscles or the diaphragm may occur due to high TEA with phrenic nerve palsy (C3–C5). The conversion rate ranges from 0%–10%.[136,138,141]

Postoperative Management

Adequate postoperative analgesia is essential after thoracic surgery. Analgesia is necessary to allow effective chest physiotherapy, in addition to the administration of bronchodilators and early mobilization. Effective postoperative analgesia can be successfully implemented with TEA by continuously administering local anesthetics in low concentration with or without opioids, via intermittent boluses, or via PCA. As part of a multimodal pain management regimen, TEA should be combined with nonsteroidal anti-inflammatory drugs (NSAIDs).

Summary

Awake thoracic surgery under TEA is feasible, and several studies have demonstrated benefit, especially in thoracoscopic procedures. However, this technique is currently used only in a few specialized centers.

Paravertebral Blockade

In addition to TEA, tPVB plays a significant role in the treatment of intra- and postoperative pain in thoracic surgery (91). tPVB allows for unilateral, effective analgesia across several thoracic segments. It is applied as a single shot or as a continuous, intermittent or PCA infusion of local anesthetic via catheter. Adding adjuvants (eg, opiates) provides no additional benefit.[142] Bilateral use of tPVB has also been reported.[143] tPVB is typically combined with general anesthesia during surgery, though there are reports of tPVB being used exclusively on awake patients for VATS.[144]

Clinical Application and Anatomy

The paravertebral space lies on both sides of the spinal column. It is delimited ventrally by the pleura, medially by the vertebrae, and dorsally by the costotransversal processus. The spinal nerves are embedded in paravertebral adipose tissue and are not surrounded by a thick fascia. The thoracic paravertebral space continues laterally into the intercostal space and medially into the epidural space.

A local anesthetic is injected at the site where the spinal nerve emerges from the intervertebral foramen, resulting in a blockade of the anterior and posterior rami of the intercostal nerve, sympathetic chain, and rami communicantes. Placement of local anesthetic within the paravertebral space produces unilateral somatic and sympathetic block. Spreading of the local anesthetic occurs laterally along the intercostal nerve and medially through the intervertebral foramen. The craniocaudal spread occurs ipsilaterally and depends on the amount of anesthetic administered and the level of puncture.[145]

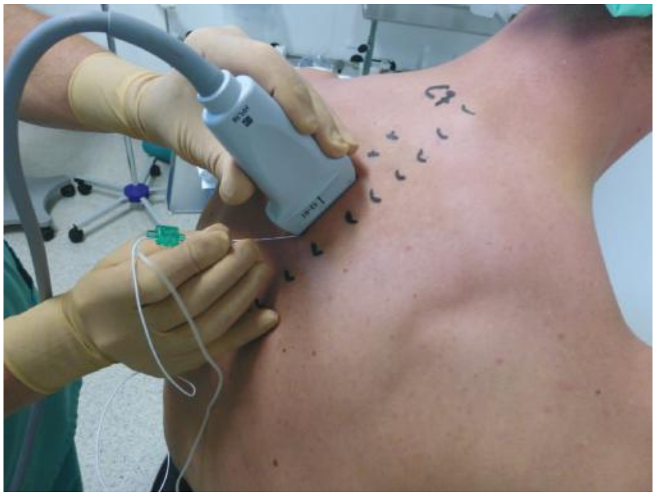
Technique

Standard techniques use surface landmarks and can be combined with either nerve stimulation or loss of resistance.[92,146] The patient is placed in the sitting or lateral position. At a position 2.5 centimeters lateral of the spinous processes, corresponding to the required level of block, a Touhy needle is advanced until the transverse process is located. The needle is then withdrawn and redirected superiorly or inferiorly to "walk off" 1–1.5 centimeters past the transverse process. For thoracic surgery, a block between T3 and T9 is required. A catheter may be placed but should not be advanced more than 2–3 centimeters past the cannula, as the catheter tip may be inadvertently placed in the pleura, epidural space, or prevertebral space (Figures 56–3 and 56–4).[147]

FIGURE 56–3. Surface landmark technique of tPVB. Skin puncture sites are 2.5 cm lateral to the spinous processes.

PART 7

A



B

FIGURE 56–4. Different ultrasound-guided approaches to perform tPVB. **A:** transversal approach; **B:** parasagittal approach.

As an alternative, paravertebral catheters can be inserted under direct vision by the surgeon during thoracotomy. The success rate is much higher if tears and incisions in the medial parietal pleura are sutured before closure. The insertion of paravertebral catheters during VATS has also been described.

In the last few years, tPVB has increasingly been successfully performed using ultrasound (US).[148] Various positions for probe alignment and angles of approach for needle insertion have been suggested (eg, parasagittal, transversal), but no approach has been described as superior to the others.[149,150] The available literature suggests that tPVB may be performed with a high probability of success using US guidance as an adjunct to traditional techniques. At this time, there is insufficient evidence to show that US guidance improves block success rates or reduces the risk of complications compared to traditional techniques for performing single-shot or continuous paravertebral blocks.[151]

Levobupivacaine and ropivacaine are the most widely used local anesthetic agents for tPVB in current practice. No reliable relationship between the extent of spread and the volume injected has yet been established. A single injection of 15 mL of local anesthetic produces a somatic block over a median of 3 dermatomes and a sympathetic block over 8 dermatomes.[92] For continuous local anesthetic infusions, a rate of 0.1 mL/kg per hour in adults is recommended.[92]

Contraindications

The contraindications for tPVB include infection at the site of puncture, tumor in the paravertebral space, and allergy to local anesthetic drugs. Coagulation disorders and anticoagulation are relative contraindications. Due to the paravertebral space being in close vicinity to the spinal column, the same recommendations that are used for neuraxial blockades, regarding safety intervals between puncture and thromboprophylaxis should be observed.[39,40] To date, no case concerning hematoma-related damage to the spinal column in association with a tPVB has been published.

Clinical Pearls

- A meta-analysis and 2 systemic reviews have shown that tPVB can be at least as effective as epidural analgesia with a better side effect profile and a reduced rate of complications versus epidural analgesia.
- Due to the paravertebral space being in close vicinity to the spinal column, the same recommendations regarding safety intervals between puncture and thromboprophylaxis should be observed.

Complications

The overall incidence of reported complications with tPVBs is low, between 2.6% and 5%.[152] The failure rate varies between 6.8% and 10%.[96] Other specific complications include hypotension (4.6%), vascular puncture (3.8%), pleural puncture (1.1%), pneumothorax (0.5%), epidural or intrathecal spread of anesthetic, and hemothorax or pneumothorax (Table 56–11).[151]

Comparison of TEA and tPVB

Several prospective randomized studies have compared the efficacy of tPVB versus TEA in thoracic surgery. The various studies were re-examined in a meta-analysis and 2 systemic reviews, which reached the conclusion that tPVB is at least as effective as epidural analgesia but has a better side effect profile and a

reduced rate of complications.[91,90,153] Experts rated both procedures equally in a treatment algorithm for pain management after thoracic surgery,[91] though there have been objections regarding these conclusions due to weaknesses in methodology in the comparative studies.[152] Optimally conducted epidural analgesia has not been compared with tPVB. The current literature indicates that tPVB may be an alternative for post-thoracotomy pain when TEA is not feasible. Severe coagulation abnormalities constitute a contraindication for both tPVB and TEA.[39,40] Higher concentrations of local anesthetics are needed to obtain intercostal nerve blocks and epidural analgesia with tPVB, thus introducing a risk of local anesthetic systemic toxicity (Figure 56–5).

Other Techniques

Intercostal Nerve Blockade

Intercostal nerve block (ICNB) seems to be the most frequently used technique worldwide for post-thoracotomy pain control.[153,154] It is easier, less time-consuming, and, perhaps, a safer technique when ICNB is performed by the surgeon under direct vision before closure of the thoracotomy.[155] ICNB can be performed as a single shot or continuously via catheter.[156] Due to the limited number of comparative studies available, an evaluation of whether US-guided ICNB is superior to the surface landmark technique is currently not possible. Perioperative ICNB reduces pain and the required opiates after thoracic surgery but has been found to be markedly inferior in terms of analgesia to TEA in comparative studies.[157–159] ICNB in combination with systemic analgesia remains an alternative if contraindications preclude the use of TEA or tPVB or if the puncture has been unsuccessful.

Clinical Pearl

- ICNB in combination with systemic analgesia remains an alternative if contraindications preclude the use of TEA or tPVB.

Intrathecal Opioids

The effectiveness of the intrathecal application of opiates for analgesia after thoracic surgery has been demonstrated in several clinical trials.[80,160,161] Its use decreased the amount of systemic morphine required, although this effect was limited to the first 24 hours postoperatively. Morphine (100–1000 μg) is used either exclusively or in combination with sufentanil as a single bolus before surgery.

One of the side effects of intrathecal opioids found during an investigation was an increased rate of urinary retention.[80] Additionally, depending on the dose, an increased incidence of postoperative respiratory complications was observed, and thus appropriate monitoring is required.[162]

Based on the available studies, a single preoperative bolus of intrathecal opioid is a recommended alternative if epidural analgesia or paravertebral block techniques cannot be used. The application of intrathecal opioids should be part of a multianalgesic regimen and preferred to intravenous opioids via PCA, based on this method's greater pain reduction for up to 24 hours. However, it is important to note that the intrathecal administration of an opioid as a single shot is insufficient for most thoracotomy patients, as it does not provide analgesia beyond 24 hours.[91]

SUMMARY

Several regional techniques can be used for analgesia after for thoracic surgery. Optimal analgesia in thoracic surgery should not be limited to a single technique or medication. It requires early application of a multimodal therapeutic regimen combining the systemic application of nonopiates with a central regional technique (TEA or tPVB) and intensive physiotherapy including mobilization of the patient.

TEA with continuous application of a local anesthetic and opioids is currently considered the standard by most experts. In addition to its analgesia effect, additional cardiovascular, gastrointestinal, and neuroendocrine system benefits may be attained, although the effect of TEA on postoperative mortality and severe morbidity is unclear. Reductions in morbidity postsurgery and in 30-day mortality could be demonstrated only in high-risk patients with obstructive pulmonary disease. Treatment with anticoagulants and antiplatelet drugs presents limitations for the use of TEA. tPVB is an effective analgesic alternative to TEA in thoracic surgery, and both should be considered standard analgesic modalities in thoracic surgical interventions.

CHAPTER 57

Regional Anesthesia in Austere Environment Medicine

Chester C. Buckenmaier III

INTRODUCTION

Regional anesthesia has played a pivotal role in the development of anesthesiology as a medical specialty since the discovery of the local anesthetic properties of cocaine by Carl Köller in 1884. In the decades since this landmark discovery, surgeons and anesthesia providers have appreciated the advantages of regional anesthesia in their patients, particularly in surgical situations complicated by limited resources and austere environmental conditions. War, more than any other human endeavor, has driven the need to provide effective anesthesia for surgery in austere environments. Indeed, the development of anesthesiology as a distinct specialty has been attributed to the medical experience obtained in World War II.[1] The physician-anesthetists of that era quickly recognized that regional anesthesia imparted the least physiologic insult to the wounded soldier and allowed a more awake patient to be returned to the recovery ward, thus reducing the burden on limited wartime medical resources.[1] As anesthesiology matured as a medical specialty and departments of anesthesiology began to break away from departments of surgery in academic centers, regional anesthesia continued to evolve. During the Vietnam War, the value of regional anesthesia in harsh medical conditions was reestablished. In one series of 1000 battle casualties, nerve block, spinal, or local anesthesia was used in 49% of cases: "This allowed increased anesthesia coverage of more surgical procedures at any one time as well as decreasing the demands on postoperative ward personnel in a multiple casualty situation."[2] The role of regional anesthesia in combat casualty care continues to expand in modern conflicts. Consequently, military medical planners are understandably interested in austere environment anesthesia due to the realities of military wartime missions. Civilian anesthesiologists are also interested in the advantages of regional anesthesia in austere environments for disasters, civil defense, and missions to medically underserved regions of the world.

In the last 20 years, regional anesthesia has undergone a renaissance. New equipment, such as peripheral nerve stimulators and ultrasound technology, has facilitated block placement and enhanced resident training in regional anesthesia. Continuous peripheral nerve block (CPNB) catheters and peripheral nerve infusion pumps have extended the benefits of regional block techniques beyond the immediate perioperative period to days after an operation and even into the home.[3] Additionally, the practice of regional anesthesia has evolved into an important subspecialty of anesthesiology termed *acute* or *perioperative pain medicine*. Acute pain services are now an integral component of quality healthcare in the United States.[4] In this chapter, the advantages and application of advanced regional anesthesia in austere environment medicine will be examined. The role of recent advances in regional anesthesia equipment and techniques for facilitating anesthesia in less-than-ideal conditions will also be discussed.

AUSTERE ENVIRONMENT ANESTHESIOLOGY

The practice of medicine in an austere environment requires a significantly different approach than that used for medicine practiced in major medical centers and in developed countries in general. This is especially true for the practice of anesthesiology. In developed countries, the anesthesiologist has a tremendous resource base that is readily available and largely transparent to the production of an anesthetic plan. The utilities, roads, computers, and other wonders of modern infrastructure common to developed nations are rarely noticed by anesthesiologists, but they impart a tremendous advantage in ensuring a successful anesthetic outcome. In contrast, the anesthesiologist practicing austere environment anesthesiology (AEA) becomes very aware of the effect limited resources can have on anesthetic decisions. In AEA, the anesthesiologist must factor

FIGURE 57–1. Twenty-first Combat Support Hospital, Balad, Iraq, 2003. The hospital is on the left with living quarters on the right.

local infrastructure and logistic realities into anesthetic plans. Anesthetic choices and plans that work well in state-of-the-art operating rooms can have disastrous consequences if applied to austere environments without due consideration of local resources and conditions. The available roads; electrical, sanitation, medical, and gas services; climatic conditions; and operating room facilities, among other issues, will greatly affect the anesthetic plan in AEA.

The influence of local environmental and weather conditions on AEA is a particularly important consideration, especially during medical missions following natural disasters. Temperature and terrain extremes, along with dangerous faunae and disease, must be included in any successful anesthetic plan in these environments. Temperature extremes can affect patient health directly and degrade equipment, medication, and anesthesiologist function. Rough terrain can affect practitioner and patient travel, impede communication, and limit resupply of consumable medical supplies. Finally, local geopolitics, in its most extreme form, war, can have a tremendous influence on AEA.

One approach to overcoming the realities of AEA is to surmount local resource limitations by transporting the modern anesthesia infrastructure to the AEA location, thus freeing the anesthesiologist from many if not all of these considerations. This approach is best illustrated by the U.S. military in caring for wounded soldiers on the battlefields of Iraq and Afghanistan through the fielding of combat support hospitals (CSHs) that have capabilities similar to civilian hospitals in developed countries (Figure 57–1). While the CSH is a successful approach to caring for injured patients anywhere in the world, the logistics required to place and support such a facility are well beyond the capability of most humanitarian medical mission planners or disaster medicine planners.

ADVANTAGES OF REGIONAL ANESTHESIA IN AUSTERE ENVIRONMENTS

Because of the logistical constraints and the environmental realities inherent to AEA, anesthesiologists involved in these types of missions must find anesthetic and analgesic techniques that require minimal logistical support, provide adequate surgical conditions, afford postoperative pain control, and result in a patient that is alert in the postoperative recovery room. Modern advanced regional anesthesia has many characteristics that make it an attractive choice for AEA missions (Table 57–1).

TABLE 57-1. Advantages of regional anesthesia in austere environmental conditions.

Excellent operating conditions
Profound perioperative analgesia
Stable hemodynamics
Limb-specific anesthesia
Reduced need for other anesthetics
Improved postoperative alertness
Minimal side effects
Rapid recovery from anesthesia
Simple, easily transported equipment needed

Compared with general anesthesia using a volatile anesthetic, regional anesthesia is particularly suited for AEA because of its small logistics footprint. The equipment for regional anesthesia (peripheral nerve stimulator and/or ultrasound machine, single-injection or continuous peripheral nerve block needle and tubing, local anesthetic, and infusion pump) is compact, lightweight, and easily transported. In contrast, the equipment used to deliver volatile anesthetics does not possess these attributes (Figure 57–2a). Though general anesthesia remains the gold standard for AEA, this capability must be planned for and surgical cases that demand general anesthesia carefully triaged. The availability of compressed oxygen can often dictate the number and types of cases that can be managed in austere environments. Many anesthetic ventilators are pneumatically driven and can consume significant quantities of compressed oxygen during a typical general anesthetic. Oxygen cylinders or oxygen generation equipment (eg, the portable oxygen generation system [POGS], shown in Figure 57–2b, which required 6 men to lift into place) can represent a significant logistics challenge to any AEA mission. Possible alternatives to pneumatically driven volatile anesthetics include draw-over anesthesia or total intravenous anesthesia (TIVA) using target-controlled infusion (TCI) pumps. These alternatives remain in development and may not be available to many anesthesiologists. Whenever possible, regional anesthesia is the preferred technique for most cases during an AEA mission because it allows conservation of resources that may be required for more complicated surgeries or emergencies.[5]

Regional anesthesia provides excellent operating conditions for the surgeon. With the establishment of a surgical block, motor, sensory, and sympathetic nerves to a body region are blocked. This provides muscle relaxation,[6] preemptive analgesia,[7]

reduced overall stress response to surgery,[8] a reduction in thromboembolic complications,[9] and reduced blood loss.[10,11] Because afferent nociceptive stimulation from the surgical site is greatly attenuated or eliminated during the operative procedure, stable hemodynamics are characteristic of regional anesthesia. In AEA, when monitoring capability is often constrained, intraoperative hemodynamic stability is important. Regional anesthetic techniques allow the procedure to be performed on an awake or lightly sedated patient who can communicate with the anesthesiologist, providing the best monitor of patient well-being.

Postoperatively, the advantages of regional anesthesia in AEA become even more apparent. Unlike general anesthesia, which provides for little to no postoperative analgesia, regional techniques with long-acting local anesthetics can provide analgesia for hours after surgery. If CPNB techniques are employed, analgesia can be extended for days postoperatively. Another important benefit of regional anesthesia in the postsurgical recovery area is the mental acuity and reduced nausea and vomiting associated with these techniques. In the modern ambulatory surgery setting, the increased incidence of postoperative nausea and vomiting, drowsiness, and pain are the most frequent causes of prolonged postoperative stay.[12,13] Although these issues have economic significance in developed countries, in the resource-limited practice of AEA, difficult recovery can have a profoundly negative effect on mission success. Recovery area personnel and monitoring capability are usually limited in AEA. Anesthesiologists working in this environment favor techniques, like regional anesthesia, that facilitate discharging alert patients, free of pain and nausea, who can be active proponents in their recovery despite limited resources. Rapid recovery of the patient's own airway protective reflexes is a significant advantage of regional compared with general anesthesia in AEA.

There is also a growing body of evidence that aggressive acute pain management can prevent "chronification," that is, the development of chronic pain following surgery or trauma.[14] Continuous peripheral nerve block procedures are particularly well suited for managing acute pain as part of a multimodal pain plan that is designed to reduce the patient's stress response to surgery and mitigate the unwanted cascade of events associated with poorly managed perioperative pain that leads to a risk of neuropathy, psychopathology, and eventual disability (Figure 57–3).

ACCEPTANCE OF ADVANCED REGIONAL ANESTHESIA IN AEA

Effective perioperative pain management is an important consideration following any operative procedure regardless of the location and conditions under which it is performed. Since Sertürner, a German pharmacist, first identified and isolated morphine from opium in 1803, morphine and other opioid drugs have played a major role in pain management in austere environments, especially in the military. Although the preeminence and success of opioid medications in pain management is well established, their use is not without significant side effects that are undesirable in the best medical environments but can be potentially devastating in AEA. International regulations concerning the transportation of opioids and limited monitoring capability can further complicate the use of these drugs in AEA. Studies have demonstrated a reduced requirement for opioid pain medication following surgery when regional anesthesia techniques are used.[3,15,16] Using CPNB techniques, pain relief can be extended for days, further reducing the need for opioid pain medications. The efficacy of CPNB infusions has been demonstrated in the ambulatory surgery setting, allowing anesthesiologists to extend the benefits of peripheral nerve block following surgery well into the patient's recovery at home.[17–20]

Despite the benefits of regional anesthesia techniques, information regarding the use of CPNB in AEA is limited.

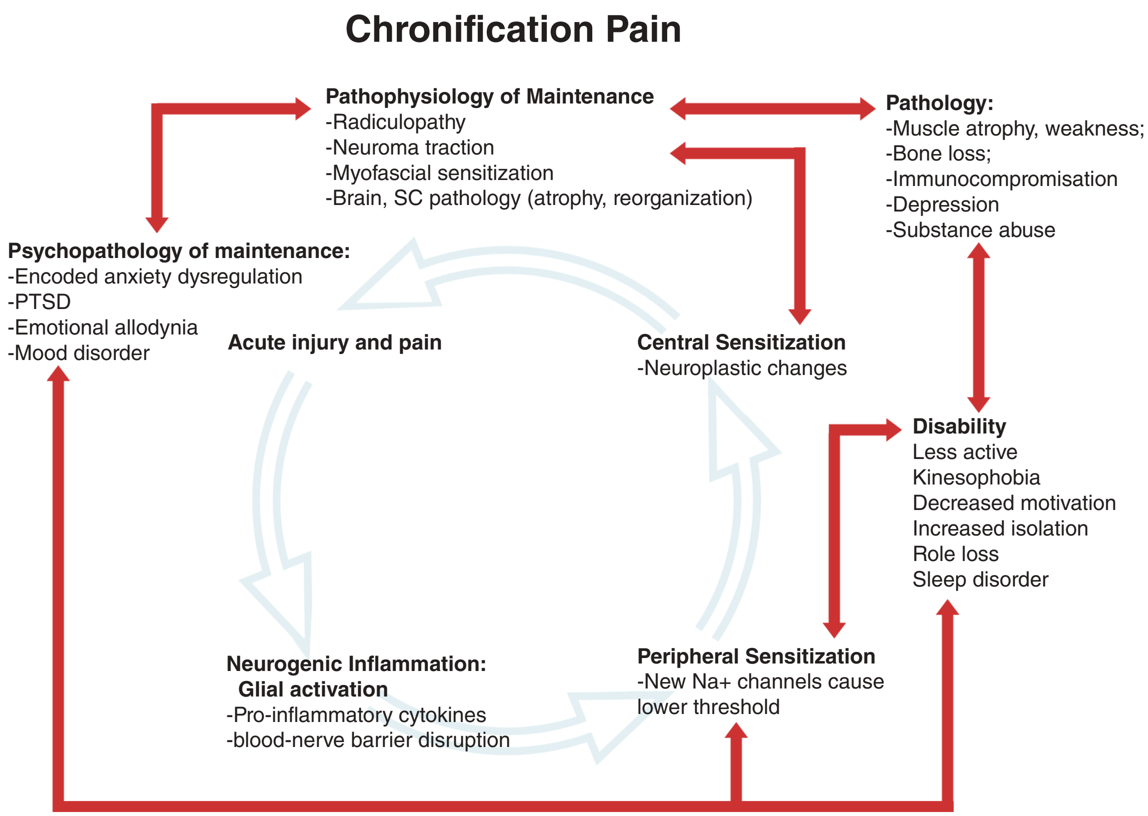

FIGURE 57–3. Chronification: The Chronic Pain Cycle. (Modified with permission from Ebert M and Kerns R: *Behavioral and Psychopharmacological Pain Management*. New York: Cambridge University Press; 2011.)

Recently, the use of CPNB for surgical anesthesia and analgesia on the modern battlefield and throughout the evacuation chain back to the United States has been demonstrated successfully.[21] Since this first success, CPNB catheters have been increasingly used to treat a number of patients within the Iraq combat theater. In 2009, the first deployment of an acute pain medicine service (APS) at a CSH occurred at Camp Bastion, Afghanistan. In general, the wounded treated by the APS had a significant decrease in pain scores immediately following wounding, and, overall, the perceived quality of pain control provided by the APS was high.[22] During this deployment, military healthcare providers at Camp Bastion were surveyed regarding their perceptions of the APS as part of the trauma team. The survey sample (n=70, of which 61.4% were male) included 50% nursing staff, 15.8% surgeons, and 10% anesthesiologists who completed the survey following the 3-month APS implementation period. Overall, the majority of providers surveyed indicated support for the APS within the CSH system and confirmed its contribution to improved trauma care.[23] This pilot project has led to formal military doctrine, the Joint Theater Trauma System Clinical Practice Guideline—Management of Pain, Anxiety, and Delirium in Injured Warfighters, that supports the establishment of APS assets within theater CSHs and military treatment facilities throughout the evacuation chain.

The application of regional anesthesia, CPNB in particular, has been one of the medical success stories from the military's experience in the Iraq war. Although the technology remains new to the modern battlefield and is far from being universally accepted, many soldiers have enjoyed the benefits of advanced regional anesthesia and CPNB in the management of their combat wounds in the austere battlefield environments of Iraq and Afghanistan. Advances in soldier body armor and improvised explosive devices have resulted in a preponderance of extremity wounds and traumatic amputations. The application of CPNB catheters in many of these patients has facilitated the multiple operative procedures that these patients often undergo, since reestablishment of a surgical block can be easily accomplished via the existing catheter(s). Additionally, the analgesic block provided by CPNB allows for far superior pain control on the long, evacuation flights to Germany and the United States compared with morphine alone, which until relatively recently was the only option for pain control on an evacuation aircraft.

Regardless of this initial success, the military has been slow to embrace advanced regional anesthesia as a viable battlefield medicine standard of care. The reasons are not easily defined but worth exploring since the military medical community's concerns over advanced regional anesthesia will also provide insight into why, despite its many advantages, advance regional anesthesia is not the predominate anesthetic for AEA. First, general anesthesia with volatile anesthetics is the "gold standard" anesthetic in developed countries. The safety and efficacy of general anesthesia has been established over the decades with countless successful applications. Anesthesiology training programs focus on general anesthesia techniques, and most practitioners are very comfortable with its use for all surgical indications. Unfortunately, the technology and personnel support needed to employ general anesthesia successfully can quickly exhaust the resources available during AEA as previously noted. In the U.S. military, a tremendous investment has been made in technology to safely provide general anesthesia to war casualties, regardless of the environment. Additional requirements on the military medical supply system, such as advanced regional anesthesia, are less attractive to medical logistical planners when so much effort has already been directed toward volatile-anesthetic-based general anesthesia. Although the capability to perform general anesthesia in AEA is vital, general anesthesia is not necessarily the best choice for every clinical situation encountered on the mission. The availability of other options is a key to AEA mission success.

Lack of training in advanced regional anesthesia has also hampered the development of this anesthetic in the AEA environment.[24,25] Advanced regional anesthesia training, at least in U.S. anesthesiology residency programs, is far from what it needs to be for these techniques to become ubiquitous within the anesthesia community and not just the domain of a select few regional anesthesia specialists. A considerable investment is required by the anesthesiologist to learn block techniques and detailed human anatomy before advanced regional anesthesia can become part of routine anesthesia practice. This investment includes system and facility enhancements, such as establishing an APS, that will allow full realization of the benefits of regional anesthesia when offered as part of a multimodal perioperative acute pain medicine plan. The increased availability of regional anesthesia courses, the development of acute pain medicine and regional anesthesia fellowship training programs, and the expansion of interest in the medical literature suggests that this will change in the near future. The Defense & Veterans Center for Integrative Pain Management (DVCIPM; www.dvcipm.org), a congressionally sponsored program established in 2003, has done much to establish advanced regional anesthesia and other modern pain management techniques on the modern battlefield.

With the resurgence of interest in regional anesthesia, there has been a number of advances in technology to support and enhance the practice of advanced regional anesthesia. The new technologies, such as peripheral nerve stimulators, stimulating catheters, portable infusion pumps, and ultrasound, to name just a few, have revolutionized the practice of regional anesthesia However, the plethora of equipment and the lack of consensus among regional anesthesiologists as to which technologies and practices are best for physician and patient alike often make standardization and training difficult. Stimulating versus nonstimulating catheters, ultrasound-guided versus stimulating needle placement, local anesthetic selection and adjuncts, needle sharpness and design, CPNB catheter infusion rates, and bolus parameters are just a few of the topics that often pervade regional anesthesia conference floor discussions. Unlike general anesthesia, modern regional anesthesia (particularly CPNB) does not have a track record of decades of standardized application and ubiquitous expertise. Considerable effort is needed to take the "art" out of regional anesthesia and establish its "science" before these techniques can become generally accepted.

Perhaps the most unusual reason for the slow acceptance of regional anesthesia in AEA and in the military is our professional and social attitudes toward pain. The science of understanding pain and its management is a relatively new. Before the advent of modern anesthesia practice, surgeons were instructed to not display excessive concern over a patient's discomfort during surgery and to operate fast, since a speedy surgery limited suffering.[26] Even after the development of anesthesiology as a medical specialty, pain has been, and still is, considered an unfortunate and unavoidable consequence of surgical intervention. In the AEA environment, expending limited medical resources on the management of pain can seem a luxury. As evidence mounts on the destructive aspects of pain, particularly as it contributes to the overall surgical stress response and postoperative morbidity, effective pain control is fast becoming less a luxury and more a necessary component of successful surgical care.[27,28] Though compassion and the relief of suffering are reason enough to provide good pain control, in the twenty-first century it an inherent aspect of good medicine.

PERIOPERATIVE MEDICINE & ACUTE PAIN CONTROL

The successful application of regional anesthesia in austere environments requires anesthesiologists to embrace their role as physicians of perioperative medicine. The anesthesia practitioners must accept responsibility for the patient's operative care before, during, and long after his or her surgical procedure. Although this extended role for the anesthesiologist beyond the operating room and recovery area is nontraditional, the anesthesiologist is uniquely trained to manage perioperative pain and enhance recovery using a multimodal approach that includes advanced regional anesthesia techniques and technologies. The anesthesiologist's perioperative role is enhanced through the establishment of an APS. The anesthesiologist working outside of the operating room in the APS facilitates the introduction of advanced regional anesthesia both in modern hospitals and in AEA. This location is equipped with regional anesthesia supplies and should have basic monitors, oxygen, suction, airway, and resuscitation equipment and medications in the event of an emergency. This investment in resources has advantages in the AEA environment. The regional anesthesia area facilitates patient preparation for surgery, and, if appropriate, blocks with long-acting local anesthetics or CPNB can be established before previous surgery patients are out of the operating room, thus improving efficiency. The APS practitioner is also available to serve as a perioperative medical consultant, critical care provider, and acute pain specialist for recovering patients. Additionally, the APS provides a framework for establishing an interdisciplinary acute pain management team of physicians, pain nurses, integrative medicine providers, and other specialists working with patients in a coordinated fashion.

The need for this expanded role of anesthesiologists in perioperative analgesia is exemplified by the austere military medical environment that currently exists in Afghanistan and existed in Iraq. In previous conflicts, wounded American soldiers often spent days recovering from combat wounds before they were deemed fit to be evacuated to higher levels of medical care outside the war theater. In the current conflicts, a soldier's evacuation from point of injury to a major medical facility outside the combat theater is often measured in hours. This aggressive evacuation policy has contributed significantly to the salvage of many soldiers who likely would have died in previous conflicts. Traditional opioid-based pain management techniques alone are not well suited to the challenging air evacuation environment that makes rapid removal of casualties to distant major medical facilities. Medical personnel on evacuation flights are often faced with a number of wounded patients in significant pain. In the low-light, high-noise, high-vibration, and difficult-monitoring environment of evacuation aircraft, the side effects associated with opioid-only pain control become magnified. The advantage of CPNB and modern peripheral nerve infusion pumps that allow patients to manage their own pain control is obvious. These catheters also facilitate repeated operations and dressing changes by allowing reestablishment of surgical blocks through bolus administration of local anesthetic via established CPNB catheters. Military anesthesiologists are actively pursuing this technology.

PEARLS & PITFALLS OF REGIONAL ANESTHESIA IN AN AUSTERE ENVIRONMENT

Patients receiving regional anesthesia as part of their care should be warned to avoid weight bearing on blocked extremities. They should also be advised to take special precautions to avoid further injury to the blocked region of the body since normal protective sensations and proprioception will be diminished or absent. Patients should also be cautioned about possible side effects that may be associated with specific block procedures. For example, patients receiving an interscalene block should be warned of the possibility of developing Horner syndrome and a hoarse voice. They should be reassured that these conditions are temporary and will resolve completely with resolution of the block. These warnings are especially important in AEA where cultural differences can heighten patient fears and negatively affect the patient's perception of their anesthetic care. Planning for adequate translator resources is vital for any medical mission in which language differences exist between caregivers and patients.

CPNB, can extend the benefits of regional anesthesia for days into a patient's recovery from surgery. This can have a profoundly positive influence on the care of patients who require evacuation over long distances or have injuries that necessitate frequent surgical interventions or dressing changes. Although this technique has important advantages in AEA, it also presents the medical team with unique management challenges that are best addressed by the APS anesthesiologist working outside the operating room. The decision to use CPNB on AEA patients must be individualized to each patient's clinical situation. During the clinical evaluation of the patient for anesthesia, the anesthesiologist will be able to ascertain if the patient is a suitable candidate for CPNB. Not all patients are willing or

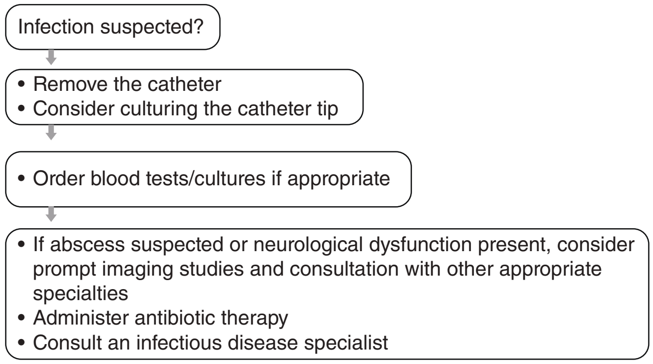

FIGURE 57–4. Algorithm for suspicion of infection at catheter site.

able to tolerate CPNB infusions despite the relative simplicity of the technology. If a patient remains resistant to CPNB therapy after thoughtful discussion with a physician, then the technique should be abandoned in favor of more traditional anesthetic and pain management techniques. Additionally, personnel resources must be available to monitor and appropriately manage any development of local anesthetic toxicity following a block. The anesthesiologist must also weigh the benefits of applying CPNB for each surgical situation against the risks of the technique. In the author's practice, all patients are warned, "The use of a block needle can result in injury or infection (Figure 57–4), and, because we are working near nerves, the possibility of nerve damage does exist, though these complications are rare." The least invasive intervention that can adequately control a patient's pain should always be sought for each clinical situation. In polytrauma situations, the patient is often unable to have a meaningful conversation about the risks and benefits of CPNB. Implied consent is often applied in trauma management to justify the use of invasive treatments that the trauma team has determined are in the patient's best interest. With the introduction of ultrasound technology to regional anesthesia in Afghanistan, CPNB catheters have been placed in anesthetized trauma patients when the surgical team determined the benefits of the catheter exceeded the risk of placement in an unconscious patient. The author, utilizing ultrasound guidance, performed over 50 CPNB catheters in anesthetized trauma patients with no complications. This practice should be reserved for serious trauma situations and only in consultation with the trauma team leader. Finally, the anesthesiologist must have an established plan for a follow-up of CPNB patients. Follow-up can be as simple as a telephone call, but CPNB patients and their catheters should be evaluated daily. Patients treated with CPNB catheters should also be educated on signs and symptoms of local anesthetic toxicity. The patient must have 24-hour access to an anesthesia provider should problems occur during the infusion. Fortunately, the answer for any CPNB infusion problem is the same: stop the infusion, resort to back-up pain medications or therapies, and seek medical help. The U.S. Air Force has developed a series of infusion pump labels to provide CPNB patients and their caregivers basic instructions during air evacuation to manage infusion problems when an anesthesiologist may not be immediately available (Figure 57–5). Email is also a valuable

FIGURE 57–5. Military and U.S. Air Force AeroEvacuation-specific labels for continuous peripheral nerve block infusions.

communication tool when physicians and nurses are required to treat CPNB patients that are being transferred to medical facilities separated by great distance. Email can often be accessed in the most remote areas where other forms of long-distance communication are unavailable. Although these CPNB management principles may seem burdensome to apply in the AEA environment, the advantages in pain relief for patients are clear and consistent with compassionate anesthetic care. With proper planning, CPNB works well in austere environments.

One of the frequent complaints concerning CPNB infusions is catheter dislodgement. Poorly secured catheters can migrate or fall out, reducing the effectiveness of the technique, especially when patients require evacuation to other medical facilities. Although many devices and procedures are available to secure catheters, in the military evacuation environment and in military hospitals, the following CPNB catheter-securing procedures seem to work best. After placement, all catheters are gently aspirated for blood and 5 mL of local anesthetic containing epinephrine 1:400,000 is injected to diagnose possible intravascular placement. Catheters are tunneled 3–5 cm under the skin in any CPNB patient who will be evacuated or is expected to maintain the catheter for more than 72 hours (this includes epidural catheters). Whether tunneled or not, all catheters are secured with cyanoacrylate glue at the skin puncture site,[29] followed by a medical spray adhesive. The catheter is looped at the puncture site and further secured with Steri-Strips and a transparent dressing. All catheters are labeled with the site of the block and the date and time of catheter placement.

A variety of excellent peripheral nerve infusion pumps are available. A discussion of infusion pump technology is beyond the scope of this chapter, but more information comparing and contrasting the devices can be found in Chapter 13.[30,31] The ambIT (Summit Medical products, Inc., Sandy, Utah) is a multiuse, adjustable electronic infusion pump that is currently being used throughout the casualty evacuation care continuum. These devices were selected because of their consistent infusion performance in temperature extremes and at altitude, light weight, simplicity of function, and patient-controlled bolus function, among other parameters. The device also has a unique shape and color (international orange) that distinguishes it from other infusion devices as a safety precaution.

A variety of local anesthetics are available for use in AEA regional anesthesia. Ropivacaine is the long-acting local anesthetic preferred by the author for single-injection blocks and CPNB catheter infusions. Compared with other long-acting local anesthetics such as bupivacaine and levobupivacaine, ropivacaine is the safest long-acting local anesthetic available.[32,33] Mepivacaine is the intermediate-acting local anesthetic often selected when a shorter-duration block is desirable or when catheters are bolused to reestablish a surgical-level block for dressing changes or surgery. Table 57–2 provides some examples of effective single-injection and CPNB infusion rates for a variety of regional anesthetic blocks.

SUMMARY

Regional anesthesia is uniquely suitable in AEA. The obvious advantages, such as improved postoperative alertness, pain control, and possibly enhanced recovery are apparent, these benefits are only realized through a significant investment by anesthesiologists in the education and increased effort to apply advanced regional anesthesia requires under difficult circumstances. Anesthesiologists who embrace the challenge of advanced regional anesthesia, particularly as part of an APS, become more versatile anesthesia providers whether their practice is in a modern, high-technology hospital or an isolated, austere tent. As recent events involving terrorism and natural disasters have demonstrated, the ability to provide safe anesthesia and effective analgesia regardless of environmental circumstances is a paramount skill in twenty-first century.

TABLE 57-2. Standard adult ropivacaine dosages for single-injection and continuous regional anesthesia at Walter Reed army medical center.[a]

Regional Anesthesia Technique	Adult Single-Injection Dose of Ropivacaine (mL 0.5% ropivacaine, except as noted)	Continuous Infusion of 0.2% Ropivacaine (mL)	Patient-Controlled Bolus Rate of 0.2% Ropivacaine[b] (mL bolus/20 min lockout)	Notes
Interscalene	20-30	8-10	2	Often supplemented with an intercostal brachial nerve block
Supraclavicular	20-30	8-10	2	Shortest-latency block of the brachial plexus
Infraclavicular	20-30	10-12	2	Catheter techniques less effective than supraclavicular catheters
Axillary	30	10-12	2	Catheter techniques less common
Paravertebral	3-5 per hadel blocked	8-10	2	Catheters effective in thoracic region only
Transversus abdominis plane (TAP)	10-20 per side	8-12	2	Alternative when epidural is not an option for abdominal analgesia
Lumbar plexus (posterior approach)	35-40	8-10	2	Epidural spread is a concern
Femoral	20-30	8-10	2	Catheter techniques less effective than lumbar plexus catheters
Sciatic (anterior or posterior approach)	20-30	8-10	2	Proximal approaches to the sciatic nerve preferable Not conducive to catheters
Sciatic (lateral or popliteal approach)	35-40	10-12	2	Catheter techniques less common
Lumbar plexus or femoral + sciatic	40-50 mL between both sites	5-10 for both catheters	2 mL on one catheter	Infusion rates divided between catheters based on distribution of patient's pain
Epidural	20-25	6-10	2	Opioids often added to infusions
Spinal	5-15 mg of 1.0% ropivacaine	N/A	N/A	Opioids often added to injections

[a]Information is based on the authors' experience with ropivacaine in a successful and busy regional anesthesia practice. Ultrasound guidance is assumed. Mepivacaine 1.5% can be used in place of ropivacaine at the volumes noted when a shorter-duration block is desirable.

[b]Occasionally, a 5 mL bolus/30-min lockout is used in selected patients. Generally, total infusions (continuous plus bolus) >20 mL/h are avoided.

CHAPTER 58

Anesthesia for Humanitarian Relief Operations

Andres Missair

INTRODUCTION

The World Health Organization (WHO) Centre for Research on the Epidemiology of Disasters (CRED) defines a disaster as "a situation or event which overwhelms local capacity, necessitating a request to a national or international level for external assistance; an unforeseen and often sudden event that causes great damage, destruction and human suffering." Specific criteria include the following:

- 10 or more people reported killed
- 100 or more people reported affected
- Declaration of a state of emergency
- Call for international assistance

While natural disasters are categorized according to causality (tectonic events, flood, plague, etc.), many share similar patterns of increasing frequency, severity, and humanitarian impact (Figure 58–1).[1] Whether this is a result of improved data reporting or growing population and increased urbanization in susceptible areas, the result is a growing need for rapid and effective strategies to provide anesthetic care for trauma victims treated during the emergency medical relief scenarios of a collapsed medical infrastructure.

Much of the published data from medical humanitarian relief efforts comes from seismic events. Over 500,000 earthquakes are documented yearly, of which 3000 are perceptible. In the last 30 years, an annual average of 21 major earthquakes has been reported. Since 2005, however, this average has increased to more than 30 major events.[2] Since 1975, over 1.2 million deaths have been reported due to seismic events as per the U.S. Geologic Survey (USGS), with nearly half of all fatalities occurring within the last 10 years as a result of growing urban population density.[3] According to the United Nations Environment Programme Global Resource Information Database (UNEP GRID), humanitarian disasters resulting from climatic and tectonic events demonstrate the greatest and most rapid impact on human health (Figure 58–2).[4] Consequently, anesthetic strategies designed for these specific scenarios are of utmost importance from a healthcare perspective.

ANESTHESIA FOR DISASTER RELIEF FOLLOWING MAJOR NATURAL DISASTERS: EARTHQUAKES

Patient Injury Patterns: Presentation

In order for anesthetic medical relief to be effective, it must address the needs of the predominant injury pattern of those patients who are considered "salvageable." Malish et al. conclude that the consideration of typical injury patterns helps establish early diagnosis and predict treatment requirements with the goal of stabilizing patients in the mass-casualty scenario.[5] Based on various studies, early disaster surgical intervention focuses on surviving patients with limb injuries. In the proceedings of the WHO Symposium on Earthquakes and People's Health,[6] a global incidence of 51.2% was reported for limb injury based on earthquake data from 11 separate epidemiologic studies. In another study by Missair et al., the average incidence of traumatic limb injury per seismic event was 63.01% for the 16 studies analyzed, totaling 30,822 patients. In those studies that identified upper versus lower extremity injury, lower limb involvement invariably exceeded 60% of cases. Conversely, cranial, thoracic, and abdominal injuries combined represented less than 36% of all cases across earthquake survivors (Figure 58–3).[7] Ganjouei et al. report strong intracluster correlations between skull, thorax, and spine fractures versus a weak link between lower extremity fracture and

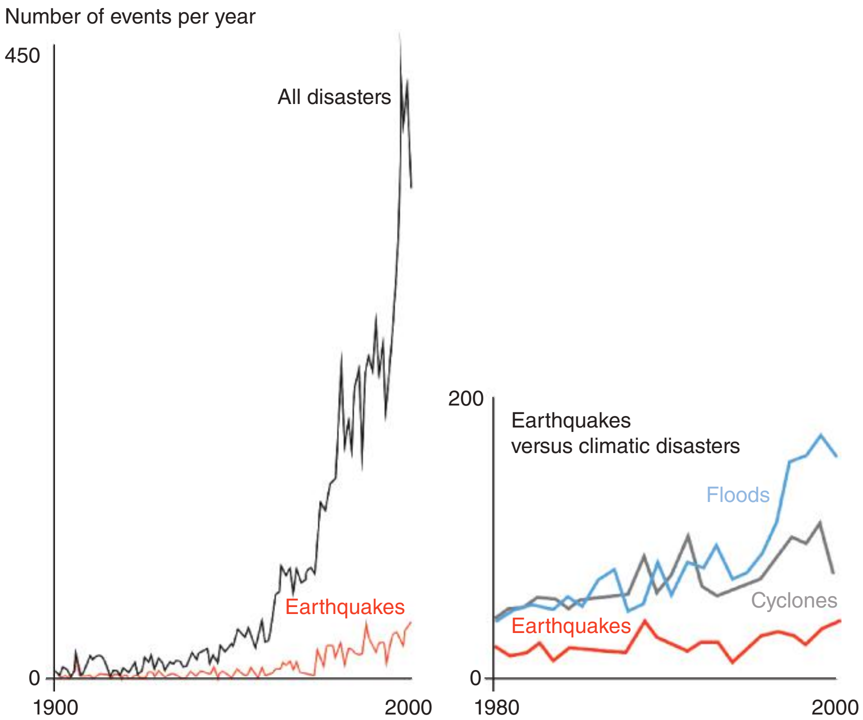

FIGURE 58–1. Natural disaster trends over time. United Nations Environmental Programme/GRID-Arendal.

any other fractures following the 2003 Bam earthquake in Iran that left more than 30,000 injured.[8] This finding supports recommendations regarding the focus of anesthetic management during the acute phase of earthquake medical relief on limb injury (Table 58–1) versus all other anatomic locations.

Patient Injury Patterns: Evolution

Anesthetic relief efforts must respond to the evolving needs of the overall medical disaster relief mission. Over the short course of a humanitarian aid operation, the acuity and chronicity of patient morbidity can change dramatically. Consequently, the phases of medical relief are divided as follows (Figure 58–4).

During the emergent phase, medical relief teams face complete infrastructure collapse: electrical power, clean water, telecommunications, and transportation are either critically limited or nonexistent. Hospitals and buildings have collapsed or are structurally unsafe for occupation. Aftershocks continue to destabilize the field, and victims and relief teams are exposed to the

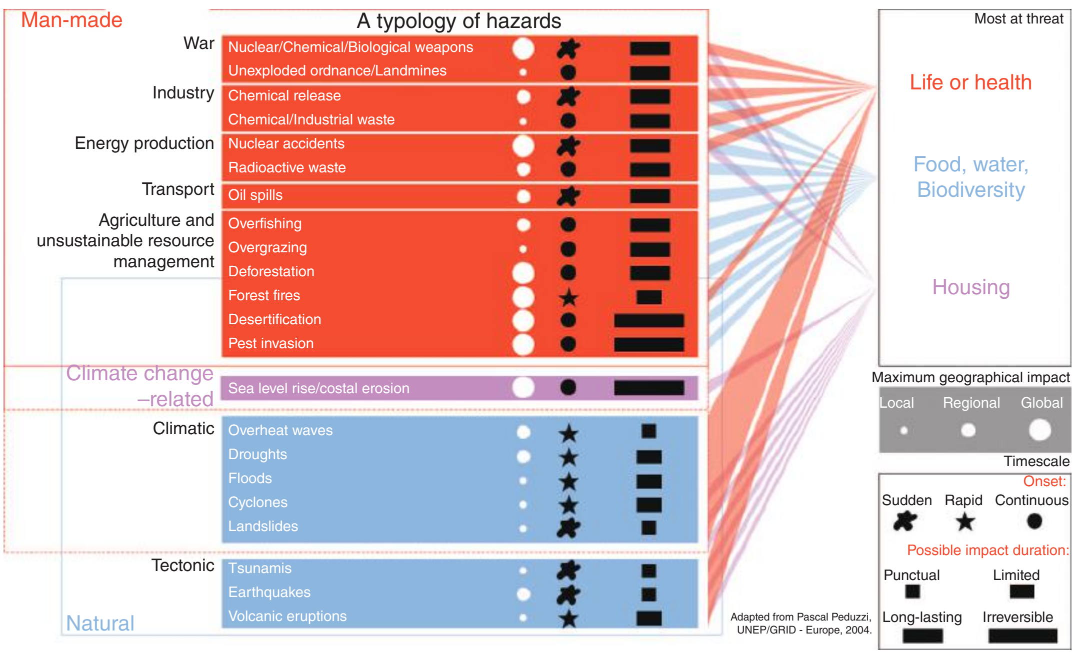

FIGURE 58–2. Epidemiology of disasters by type and impacted humanitarian area. United Nations Environmental Programme/GRID-Arendal.

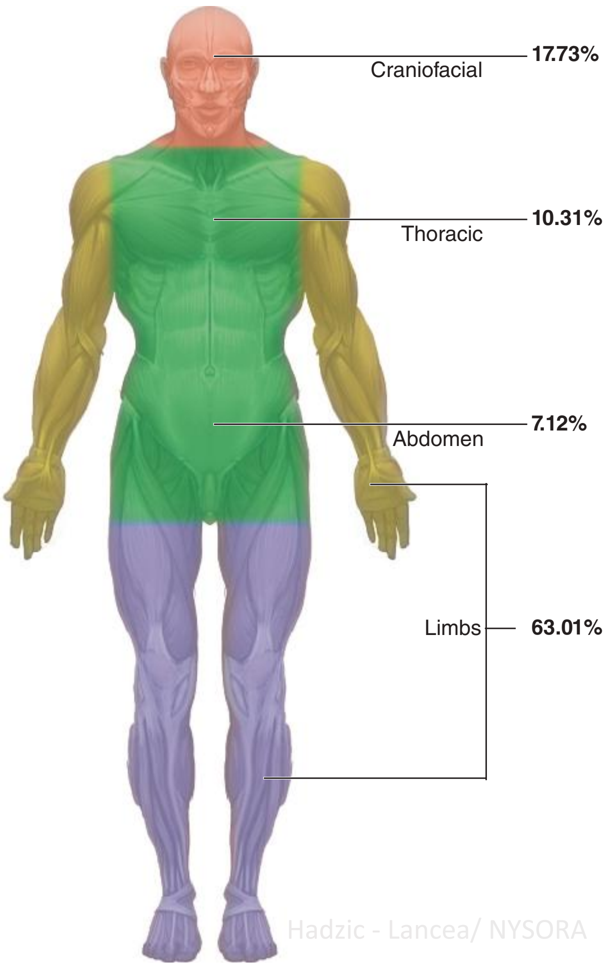

FIGURE 58–3. Anatomic distribution pattern of traumatic injuries immediately following major earthquakes.

elements. Local emergency services personnel are overwhelmed or absent. Access to the disaster zone can be extremely limited and only possible on foot or by helicopter (Figure 58–5).

During the acute phase, international disaster relief teams composed of medical volunteers and professional rescue personnel begin to appear in the field. Portable infrastructure support is established, such as tents, electricity generators, and basic supplies. Compressed gases are either critically limited or absent. The supply chain remains precarious and undependable such that extreme rationing continues. At this stage, patients who have sustained cranial or thoracic trauma have already expired, and those with salvageable injuries (predominantly limb and superficial soft tissue) are presented for emergency treatment. The majority of surgical interventions at this stage are for hemodynamic stabilization and infection mitigation. As a result, most surgical efforts focus on limb amputation and soft tissue incision and drainage. During the major earthquakes in Armenia (1988), Japan (1995), Pakistan (2003), and Haiti (2010), field hospitals could not be established for the first 4–14 days following the disaster despite intact local medical facilities, equipment, and personnel only 30–40 kilometers away.[9–11] Regardless of the socioeconomic status and geographic location of the affected region and population, field hospitals remain an unattainable goal during the emergency and acute phases of disaster medical relief (Figure 58–6).

TABLE 58–1. Typical limb injuries.

Long-bone fractures
Crush injury
Contusion
Laceration
Wound infection
Hemorrhage

During the chronic phase, field hospitals are created, and limited ancillary surgical services are available, such as ventilators, oxygen, suction, and electrical cautery. Supply chains are now established and largely dependable. Emergency transportation begins to improve, although other aspects of basic infrastructure remain collapsed. Patients from the emergent and acute phases are evacuated to intact neighboring medical facilities; those who remain may begin to present with medical complications such as infection, sepsis, phantom limb pain, pneumonia, and thromboembolic events. Surgical efforts begin to encompass a broader range of services, including open reduction internal fixations (ORIFs), cesarean sections, intra-abdominal procedures, and ongoing care of the critically ill (Figure 58–7). New patients now present with infectious disease, dehydration, malnutrition, and exacerbations of predisaster chronic ailments (eg, diabetes, hypertension).

Logistical Obstacles

After the 2010 Haiti earthquake that killed over 200,000 people, CNN reported the headline, "Expect Gettysburg: Civil War Anesthesia During the Haiti Earthquake."[12] Importantly, what we learned from this event was that time equals lives and that a surgical team staffed and equipped to provide regional anesthesia could be dispatched rapidly to serve as a bridge to more advanced field surgical care, which takes longer to deploy and set up (on average 2–3 weeks). During the emergent and acute phases of natural disasters, or on the battlefield, the ability to access an established medical infrastructure is often compromised, and complete operational autonomy is fundamental to ensure safe and effective anesthetic care by the first-response team. The numerous advantages of regional anesthesia in the modern battlefield include excellent operating conditions, profound perioperative analgesia, stable hemodynamics, minimal side effects, and simple portable equipment requirements.[13] These characteristics are paramount when anesthetic delivery faces the logistical obstacles of manmade and natural disasters resulting in the total collapse of medical infrastructure.

In order to design an effective anesthesia disaster response plan, certain goals and obstacles must be considered, as illustrated in Table 58–2.

Interestingly, certain obstacles encountered during field operations are created by the relief effort itself: medical provider nutrition, hydration, hygiene, and rotation must be addressed prior to deployment so that volunteers do not become victims

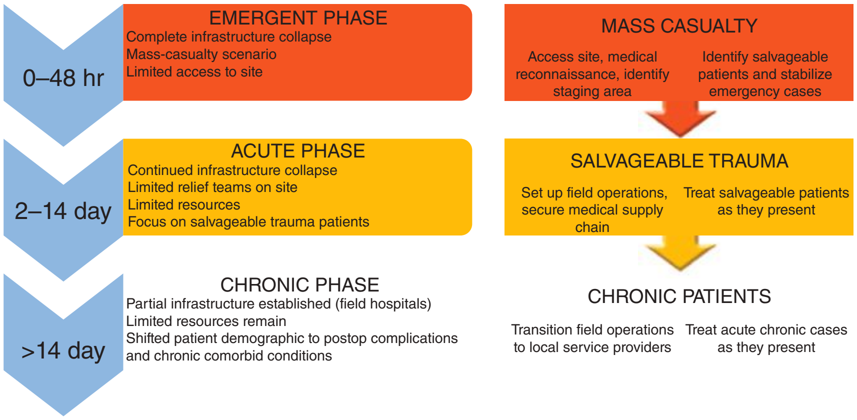

FIGURE 58–4. Phases of medical relief during humanitarian natural disasters.

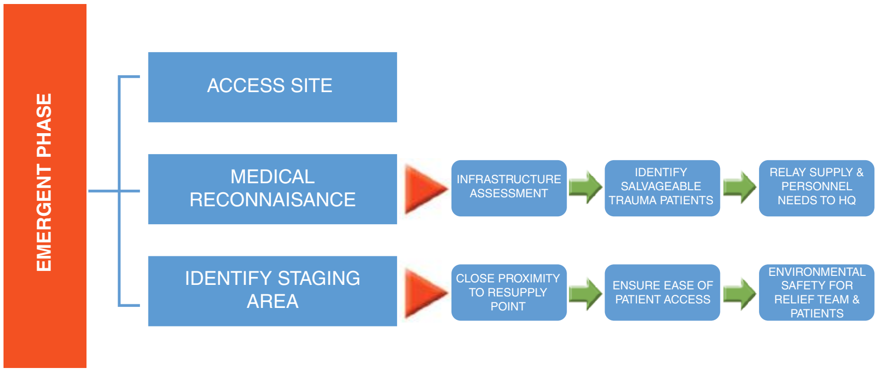

FIGURE 58–5. Anesthesia medical relief objectives during the emergent phase.

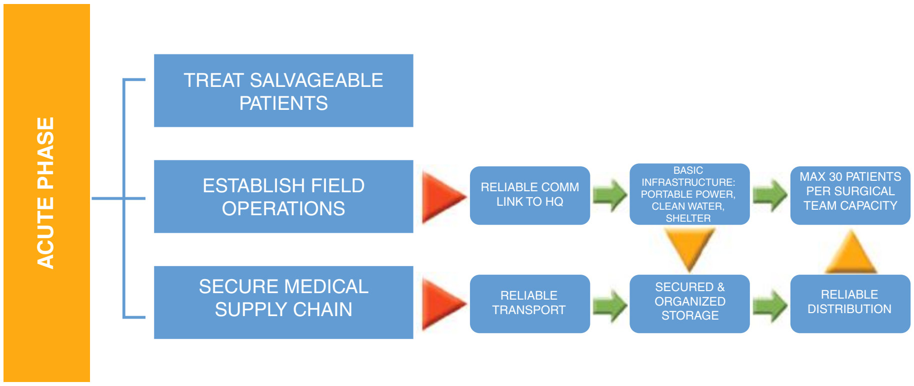

FIGURE 58–6. Anesthesia medical relief objectives during the acute phase.

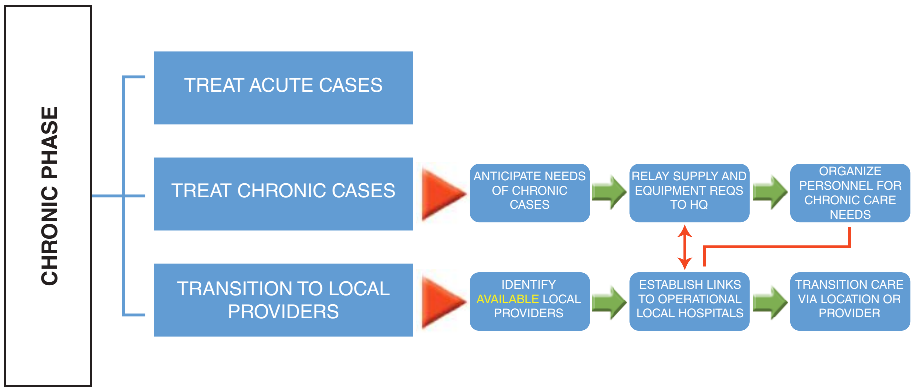

FIGURE 58–7. Anesthesia medical relief objectives during the chronic phase.

TABLE 58–2. Effective anesthesia disaster response plans: goals and obstacles.

Goals
- Rapid field deployment within 24 hours
- Complete autonomy
- Patient safety
- 30-patient capacity per day per provider
- Guaranteed communication link to headquarters
- Provider safety in the field
- Sustainability

Obstacles
- Limited access to field
- Absent medical infrastructure
- Austere, unstable environment
- Provider fatigue
- Supply chain integrity
- Mass-casualty scenario
- Evolving patient presentations
- Transition

themselves. Staff turnover can become a logistical nightmare in the context of compromised access to the field and can lead to complete operational collapse within 72 hours. For this reason, the WHO recommends that the majority of medical relief efforts be conducted locally or by neighboring countries with rapid access to the affected disaster zone.

Anesthetic Solutions

Ketamine Monitored Anesthesia Care/Local Anesthesia

There are both pros and cons to the use of ketamine in monitored anesthesia care (MAC), as shown in Table 58–3.

Ketamine MAC with unsecured airways has been used extensively during medical relief operations. The safety and efficacy of ketamine as the primary anesthetic drug under disaster conditions has been well described by Mulvey et al.[14,15]

TABLE 58–3. Pros and cons of ketamine monitored anesthesia care in disaster situations.

Pros
- Stable hemodynamics
- IV and IM routes
- Spontaneous ventilation maintained
- Anesthetic and analgesic
- Proven use in the mass-casualty scenario following earthquakes and tsunamis
- Inexpensive

Cons
- <5% incidence of nausea and vomiting reported
- Risk of intraoperative hallucinations

IM, intramuscular; IV, intravenous.

After the 2005 7.8-magnitude earthquake in Kashmir that resulted in 86,000 deaths and more than 80,000 severe injuries, the authors reported on the use of ketamine as the sole anesthetic for 149 patients (adult and pediatric) undergoing emergency surgery within a completely devastated hospital infrastructure. The conditions reported by the authors (absence of mechanical ventilation, vital sign monitors, and supplemental oxygen) are similar to those encountered during the 2010 Haiti earthquake, where Missair et al.[10] reported more than 500 surgeries performed with combined ketamine MAC anesthesia and single-shot peripheral nerve block. Both studies describe the use of ketamine with an unsecured airway and reported a rate of less than 5% complications following its use, comparable to results found by Paix et al.[16] during the 2004 Banda Aceh tsunami.

REGIONAL ANESTHESIA

The pros and cons of regional anesthesia in disaster scenarios are described in Table 58–4.

Regional anesthetic techniques can be divided into neuraxial approaches and peripheral nerve blocks. The intravascular volume status of the natural disaster patient population is typically compromised and must be considered before the use of neuraxial techniques in light of the induced sympathectomy and the potential for severe intraoperative hypotension. In fact, Jiang et al.[17] report significant hypotension requiring resuscitation after spinal anesthetics in 80% of patients treated in the field. It is prudent, therefore, to fluid resuscitate any patient before placing a neuraxial block under these conditions. The time required to safely accomplish this goal, however, is often limited by the emergent nature of surgery performed during mass casualties.

In our experience in the battlefield, peripheral nerve blocks provide "excellent operating conditions, profound perioperative analgesia, stable hemodynamics, minimal side effects, and simple portable equipment requirements."[13] These attributes have since been confirmed in the civilian scenario, following the 2010 Haiti earthquake medical relief effort by Project

TABLE 58–4. Pros and cons of regional anesthesia via single-shot nerve block in disaster situations.

Pros
- Stable hemodynamics
- Proven use in the battlefield and in disaster medical relief scenarios
- Minimal side effects
- Rapid establishment of surgical conditions
- Analgesic coverage extended to the postoperative period
- Minimal, portable equipment requirements
- No reliance on ventilator equipment, compressed gas, or electrical power

Cons
- Requires specialty training
- Limited anatomic coverage
- Specialized equipment requirements

TABLE 58–5. Pros and cons of continuous peripheral nerve blocks in disaster situations.

Pros

- Prolonged analgesia
- Simplified and rapid reestablishment of surgical conditions
- Decreased postoperative opioid consumption and associated side effects

Cons

- Increased risk of infection
- Increased equipment and supply requirements (especially if pumps are used)
- Increased personnel demands for care and monitoring

Medishare, where hundreds of patients received single-shot nerve blocks for emergency limb surgeries. Operating conditions are rapidly established with single-shot neural blockade, and postoperative analgesia is provided by the use of long-acting local anesthetic drugs.[7,13] The prolongation of analgesia may help reduce field post-anesthesia care unit (PACU) complications such as opioid-induced emesis and respiratory depression and decrease the burden on limited drug supplies and the already limited and overextended medical personnel caring for postoperative patients.

For the earthquake trauma patient in the austere medical environment, the placement of indwelling catheters such as epidurals or continuous peripheral nerve blocks has been reported in a few studies. For example, Buckenmaier et al. report on the safe use of continuous peripheral nerve blocks (CPNBs) during military field operations;[13] however, it must be emphasized that these patients were either rapidly evacuated to hospitals in military bases abroad or cared for in military field hospitals. In mass-casualty scenarios, such as earthquakes, the feasibility and necessary manpower for the subsequent care and monitoring of patients with indwelling catheters must be taken into consideration. In addition, the environmental conditions of the field hospital (if one exists) may present an infection risk for these particular anesthetic techniques. Finally, the additional equipment and supply requirements, such as infusion pumps, intravenous (IV) fluids, tubing, and available resuscitation drugs may preclude the safe and effective implementation of indwelling catheters for anesthesia and postoperative pain management. On the other hand, it can be argued that the benefits of prolonged analgesic coverage and the possibility of quickly reestablishing surgical conditions of the injured limb requiring serial wound debridements or procedures may justify the additional resources and risks inherent to the use of CPNBs in austere environments. In these scenarios, therefore, it might be prudent to consider using *bolus-only* catheter techniques without infusion pumps, thereby reducing demands on limited resources and personnel (Table 58–5).

Interestingly, no short-term complications specific to regional anesthetic management have been reported in the literature. Nevertheless, it is important to emphasize that patient safety must always be ensured, as per the WHO guidelines for disaster relief operations. This goal is easily achieved with minimal but specific portable ancillary monitoring equipment:

1. Manual manometer
2. Portable finger pulse oximeter (eg, Lifebox)
3. Injection pressure monitor (eg, B-Smart)

These three monitoring tools support the goal of autonomous and safe anesthetic delivery while minimizing energy requirements and being lightweight enough to be portable.

Rapid and streamlined deployment is crucial in order to respond during the first 24 hours. For this reason, portability is a critical design consideration when developing a regional anesthesia kit for disaster response. Access to the impact zone is often via helicopter, horseback, or on foot once relief personnel reach the nearest airport, seaport, or available mass-transit point. All relevant equipment and supplies must, therefore, be carried by hand via carry-on bags or backpacks (Figure 58–8).[7] In addition to size and weight restrictions, kits must ensure adequate protection of supplies and equipment from the elements since shelter from the environment is seldom guaranteed and often limited or structurally unsafe. During the initial 72 hours

of the Haiti earthquake, for example, the medical team from the University of Miami treated patients outdoors due to the danger of aftershocks causing subsequent collapse of remaining buildings.[10]

The emphasis for regional anesthesia kit supply should be placed on airway management, basic monitoring, IV access, resuscitation, and single-shot nerve-stimulated blockade (Table 58–6).[7] Due to space and weight limitations, a portable finger pulse oximeter and a manual manometer with stethoscope are the most relevant and appropriate equipment for perioperative monitoring. It must be emphasized that field conditions during the acute phase of perioperative medical care will preclude any capacity for mechanical ventilation during extended periods of time. As a result, any airway equipment selected for inclusion in these kits is based on the need for temporary intraoperative airway control only.

Disaster response kits should implement a modular design, maximizing resource efficiency by separating reusable supplies (eg, monitors, nerve stimulators) from single-use items and medications. Each kit should then be equipped with the capacity to treat 30 patients, which is the average surgical case load per anesthesiologist over 48 hours during disaster relief efforts. This model simplifies field logistics and prevents redundancy and waste, while providing a capacity that is both portable, in terms of weight and volume, and compatible with average resupply chain times (48 hours).

SUMMARY

In the context of predominant limb injury requiring urgent surgical intervention, all anesthesia techniques may be safe, but single-shot peripheral nerve blocks may provide the necessary safety, patient comfort, portability, and efficiency to support mass casualties in the face of a collapsed medical infrastructure.[7,8,10,18] Regardless of the socioeconomic status and geographic location of the affected region and population, field hospitals remain an unattainable goal during the emergent and acute phases of disaster medical relief. Based on study findings, a well-equipped portable nerve block kit (see Figure 58–8), designed to provide basic monitoring and ketamine MAC capabilities, can serve as the first critical step in effective and safe anesthetic care during the acute phase of medical relief and act as a bridge to the subsequent establishment of field hospitals.

The solution proposed herein to address the acute perioperative anesthetic needs of a displaced patient population without medical facilities is consistent with the recommendations of the WHO Interagency Emergency Health Kit (IEHK) manual which states, “In situations of war, earthquakes or epidemics, specialized teams with medicines and medical devices will be required.”[19] In fact, the WHO and its partner agencies intentionally excluded equipment for resuscitation and major surgery from the IEHK. Regional anesthesia, therefore, directly complements the primary care and first aid provided by the interagency IEHK and affords the emergency anesthetic capabilities required during the acute phase of medical relief.

PART 8

REGIONAL ANESTHESIA IN THE EMERGENCY DEPARTMENT

This page intentionally left blank

CHAPTER 59

Regional Anesthesia and Acute Pain Management in the Emergency Department

Andrew A. Herring, Sam Van Boxstael, Pascal Vanelderen, and Knox H. Todd

INTRODUCTION

Emergency physicians are called upon to provide care for a variety of acute and life threatening conditions. Often patients present with pain as the primary symptom of their illness or require diagnostic and/or therapeutic interventions that are inherently painful to perform. As a result, the management of pain in the emergency department (ED) is a critical skill and an important element in the overall care of patients in emergency settings. This chapter provides an overview of acute pain in the ED as well as potential therapies, including regional anesthetic techniques for the emergency physician.

EMERGENCY MULTIMODAL ANALGESIA

Systems-Based Multimodal Approach

The management of acute pain relies on providers and systems of care that are motivated, trained, organized, and equipped to rapidly treat acute pain. Without a clear organizational initiative and focus, pain treatment easily reverts to the low priority it has traditionally held in the emergency setting. Current understanding of the pathophysiology of pain suggests that opioids should preferentially be used only within a multimodal analgesic strategy tailored to the individual patient and his or her specific needs. Integrated use of complementary pharmacologic, interventional, and nonpharmacologic approaches enables the use of opioids that maximizes their beneficial properties while minimizing risk.

Nonpharmacologic Interventions

Effective treatment of the dislocated glenohumeral joint is prompt relocation. The underlying principle is that the ED should be organized so that simple, nonpharmacologic interventions such as elevation, icing, and immobilization of an acutely injured limb are prioritized from the point of triage. A humanistic approach with an outward expression of empathy and kindness can help to alleviate patient anxiety and fear.

Identify Injuries and Conditions Appropriate for Regional Anesthesia at Triage

Regional blocks should be placed as close to the time of initial injury as possible to maximize the potential of the block to limit the cascade of adverse physiologic events triggered by uncontrolled pain. Minimizing "door-to-block time" should be made a priority through collaborative systems development between emergency physicians and consultants.

Nonsteroidal Anti-inflammatory Drugs

Patients with severe acute pain should receive a nonsteroidal anti-inflammatory drug (NSAID) *and* acetaminophen unless contraindicated. Unfortunately, impaired platelet function and the risk of associated bleeding are of relative concern whereas nonselective NSAIDs should be avoided in the setting of acute trauma. An alternative strategy is the use of a selective cyclooxygenase-2 (COX-2) inhibitor such as celecoxib in combination with acetaminophen. Acetaminophen, although a relatively weak analgesic on its own, significantly enhances the analgesic effects of NSAIDs and opioids.

Avoid a "One Size Fits All" Individual

The dose response to opioids is notoriously variable. Rapid titration of relatively small doses every 10-15 minutes helps to both avoid overshooting the analgesic target and prevent oligoanalgesia.

Ketamine

Ketamine is an *N*-methyl-D-aspartate (NMDA) receptor antagonist that has a well-established track record in acute pain management and profound analgesic properties at low doses. Its stimulating cardiovascular and bronchodilatory activity has made it particularly popular in prehospital and austere settings. In the ED, ketamine is particularly useful to rapidly establish analgesia in the hypotensive severely injured trauma patient. Opioid-tolerant patients may particularly benefit from the addition of subdissociative-dose ketamine as a bolus or infusion. Finally, in our experience, the quality of multimodal analgesia incorporating is more profound and may help establish a degree of comfort with extremely painful injuries, such as an unstable fracture, that is not possible with opioids alone.

Anticonvulsants

Pregabalin and gabapentin are analgesic, anxiolytic, and antihyperalgesic agents that have been shown to reduce anxiety, improve pain control, and reduce opioid consumption in the perioperative setting. In the acute setting, a single oral dose of 600–1200 mg is preferred, and its primary side effect is somnolence without hemodynamic depression. Its role in acute injury has yet to be clearly established.

Adjuvant Analgesics

Alpha-antagonists, such as clonidine and dexmedetomidine, have analgesic properties. Clonidine can be administered intravenously, intramuscularly, intra-articularly, or as an adjuvant to peripheral nerve blocks. Dexmedetomidine has similar analgesic properties but is profoundly sedating. Tricyclic antidepressants, adenosine, droperidol, naloxone, corticosteroids, and magnesium have also all been used for acute pain management, but there is limited available evidence to clearly define their role in emergency pain medicine.

OLIGOANALGESIA IS A PROBLEM IN THE ED

Pain is the single most common reason patients seek care in the ED, and it accounts for up to 79% of visits.[1] Given the prevalence of pain as a presenting complaint, there is an increasing focus within emergency medicine to assign a high priority to analgesia. However, in the fast-paced, high acuity setting of the ED, pain can all-to-often be overlooked by providers of emergency medical care. The resulting inadequate use of methods to relieve pain was termed Oligoanalgesia by Wilson and Pendleton[2] in 1989. Several studies have established that oligoanalgesia is a common and complex problem in emergency medicine.[3] Notwithstanding the goal of providing compassionate care, pain that is not acknowledged and managed appropriately causes anxiety, depression, sleep disturbances, increased oxygen demands with the potential for end-organ ischemia, and decreased movement with an increased risk of venous thrombosis.[4,5] Failure to recognize and treat pain may also result in patients' dissatisfaction with medical care, unscheduled returns to the ED, delayed return to full function, and an increased risk of litigation (Table 59–1).[6]

TABLE 59–1. Adverse consequences of inadequate analgesia.

Patient Experience	• Decreased patient satisfaction, needless suffering
Physiologic	• Metabolic stress response • Hyperglycemia • Protein catabolism • Increased free fatty acids (decreased myocardial contractility, increased myocardial oxygen demand, impaired vasodilation) • Hypercoagulability • Thromboembolic events • Pulmonary complications • Immunosuppression • Delirium • Development of chronic pain states • Complex regional pain syndrome
Long-term psychologic	• Posttraumatic stress disorder • Insomnia
Logistic	• Increased duration of intensive care unit and hospital stay • Decreased participation in rehabilitation

Several studies have defined the prevalence of pain and oligoanalgesia in ED settings. For instance, Johnston and colleagues[7] investigated the incidence and severity of pain among patients presenting to noncritical treatment areas within the EDs of 2 urban hospitals in Canada. They found that 58% of adults and 47% of children reported pain on ED arrival. Approximately 50% of these patients described their pain as moderate to severe. At the time of discharge, one-third of both groups reported persistent pain of moderate to severe. In fact, 11% of children and adults in this study reported clinically significant increases in pain intensity during their stay in the ED.

Another prospective study showed that among adults treated at one Chicago ED, 78% presented with pain as a chief complaint.[8] Of all patients, 58% received analgesics or nonpharmacologic interventions, but only 15% received opioids, despite high levels of pain intensity. Guru and Dubinsky[9] found that 50% of patients who were treated for acutely painful conditions did not receive prescriptions for pain management at discharge. Data from a review of urban, university-based EDs revealed that 69% of patients with painful conditions, including thermal burns, long-bone fractures, and vaso-occlusive crises, received no pain medication at all and that 55% were discharged with no analgesic prescription.[10]

A study by Brown and colleagues[11] revealed that pain medications were frequently not part of ED treatment for fractures, even for patients with documented moderate or severe pain.

Yet, in spite of the tendency to undertreat pain in the ED, patients appear to expect better analgesia. As an example, Fosnocht and colleagues[12] used a 100-mm visual analog scale

(VAS) to gauge patients' expectations of pain relief in the ED (0 mm = no relief; 100 mm = complete relief). Patients with pain reported a mean expectation for pain relief of 72%, and 18% of patients expected complete relief of their pain. Interestingly, this value was seemingly independent of the initial pain severity, so that those with mild pain expected the same degree of relief as those with severe pain. Other studies have suggested that patients' expectations are very influential on both their experience of pain and satisfaction with their care.[13,14]

Several factors conspire to result in under treatment of pain in ED. Difficulty in accurately assessing pain is a well-known problem to providers of emergency medical care. Data from several studies indicated that caregivers underestimate pain when their assessment of pain is compared with those reported by the patients themselves.[9,15] The assessment may also be hindered by the limitations of commonly used verbal scales. For example, Rupp and Delaney[3] pointed out that asking a patient to describe his or her pain in relation to the "worst pain imaginable" obviously yields different answers, depending on the patient's particular frame of reference. Other factors leading to oligoanalgesia may include apprehension (on the part of both the patient and the physician) about opioid dependence,[16] concern regarding side effects such as respiratory depression,[17] the desire to withhold pain medication until informed consent for a procedure has been obtained, and concern about the risk of adequate pain management obscuring a diagnosis (eg, in patients with an acute abdomen). However, there is mounting evidence that adequate analgesia may actually diminish involuntary guarding as a confounding factor and allow for a more precise evaluation of localized sensitivity.[3,18–20] Suitable treatment of pain is not only a necessity from a ethical point of view; better analgesia can also prevent delayed complications of certain injuries. For instance, an intervention as simple as the early administration of ketorolac reduces the risk of pneumonia after rib fractures and increases intensive care unit- and ventilator- free days without increasing the risk for acute kidney injury, gastrointestinal hemorrhage, or non-union of the fractures.[21]

Some patient populations are at a higher risk of oligoanalgesia (Figure 59–1). For example, several studies have documented lower rates of analgesic administration for both young children and the elderly when compared with other patients in pain.[10,22,23] Kozlowski and colleagues[24] reported that in patients with isolated lower extremity injuries, those with fractures were twice as likely to receive pain medication as those without fractures, even when controlling for the severity of pain. Patients' gender does not appear to influence the quality of analgesia in ED, according to one prospective study.[25]

Patients' ethnicity is perhaps the best-studied risk factor for oligoanalgesia in the ED. In 1993, Todd and colleagues[26] examined the medical records of all patients with acute, isolated, long-bone fractures seen at the UCLA Emergency Medicine Center in 1991 and 1992. Hispanic patients in this study were twice as likely as non-Hispanic white patients to receive no pain medications during their ED stay (RR 2.1; 95% CI 1.4–3.3). This relative risk for Hispanic patients to receive no analgesia remained significant after controlling for covariates related to characteristics of the patient (gender, language, and insurance coverage), injury (open versus closed fracture, admittance versus discharge, and need for reduction), and physician (ethnicity, sex, and specialty). After multiple logistic regression analyses, patients' ethnicity remained the strongest predictor of ED analgesic administration. In a follow-up study at a large university-affiliated community ED in urban Atlanta, Todd and colleagues[27] found similar disparities in analgesic treatment between white and African American patients with isolated long-bone fractures despite similar documentation of pain complaints.

The solution to these disparities may involve more than simply addressing cultural biases, however. Research into the genomic basis of pain sensation is beginning to show that different individuals, as well as groups of individuals, process pain signals differently.[28] This may help guide providers of analgesia as to which individuals may be experiencing more intense pain from the same injury or illness. In addition, response to analgesics may also be attributable in part to gene expression, just as cytochrome P450 receptor differences determine a patient's ability to metabolize codeine.[29]

PAIN ASSESSMENT IN THE ED

Recognizing that pain is a major public health problem, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has placed a great deal of emphasis on the

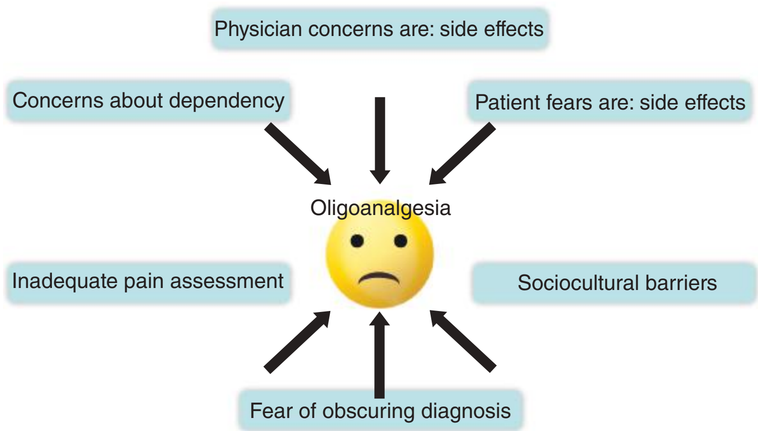

FIGURE 59–1. Factors leading to under treatment of pain.

Least Possible Pain ____ Worst Pain Imaginable

Indicate the severity of your pain by placing a single mark through the line above at the appropiate point.

FIGURE 59–2. Visual analog scale.

importance of pain management, in part by implementing standards that create new expectations for the assessment and management of pain.[30] These standards have been endorsed by the American Pain Society.

One of the key JCAHO's recommendations focuses on the use of standardized tools for frequent assessment of pain, documentation, and treatment. Indeed, many hospital EDs have begun to include pain as the "fifth vital sign" to encourage frequent and standardized reassessment.

Several pain assessment tools are available for use in the ED. One of the most common is the VAS, which is easy to use and convenient for statistical analysis. Patients are asked to make a mark on a horizontal line that corresponds to the intensity of their pain (Figure 59–2). This scale is attractive for acute care settings in which short-term changes in VAS scores can be used to guide the titration of analgesic therapy. Todd and colleagues[30] conducted serial interviews with patients reporting acute pain and concluded that a change of less than 13 mm in the VAS score is clinically insignificant. A similar tool is the 11-point numeric rating scale (NRS), which asks the patient to verbally rate his or her pain on a numerical scale, usually from 1 to 10. Both the VAS and NRS have been shown to be reliable and valid tools for assessing acute pain.[31–33] However, the numeric rating scale is becoming the pain scale of choice because of its ease of use, broader range of applications, and consistent results across a wide range of languages and cultures.[34,35] A reduction of 2 points or 30% in NRS was deamed clinically important by Farrar et al.[36] Moreover, the relationship between the percent change in NRS and the patiënt's global impression of change is more consistent regardless of baseline pain scores. Finally, mandated reporting of pain scores has been shown to result in improved frequency of analgesic administration for ED patients presenting with acute pain.[37]

MONITORING DURING SEDATION AND ANALGESIA

Urgent procedures in the ED are common and often require some level of sedation for optimal patient comfort. This may range from light sedation via a small dose of midazolam and fentanyl before the placement of a regional block to deep sedation via propofol for a complex abscess incision and drainage or etomidate for cardioversion. An overview of the many options for ED sedation is presented in Table 59–2. The recommendations regarding sedative use in the ED should be based on the indication and resulting sedation state, not the specific pharmacologic agent involved. Therefore, ED staff should apply monitoring standards solely on the basis of the anticipated depth of sedation. For example, low dose of midazolam or ketamine in

TABLE 59–2. Emergency sedation.

Drug	Emergency Dosing	Comments
Midazolam	1–2 mg IV titrated to effect; more than 5 mg IV cumulative should be avoided.	Sedative only with dose-dependent cardiovascular respiratory depression.
Propofol	0.5–1.0 mg/kg IV loading dose titrated to effect.	Sedative only with dose-dependent cardiovascular respiratory depression; very quick onset and rapid recovery.
Ketamine	Broad range from as low as 5 mg IV (<0.1 mg/kg) for analgesia to 150 mg IV (2–3 mg/kg) for dissociative anesthesia; rapid onset within 3–4 min allows rapid titration.	Powerful analgesic at low doses; at higher doses results in a surgical dissociative anesthesia; dose-dependent dissociative effects are bothersome to some patients. Addition of an opioid or benzodiazepine tends to increase patient tolerability of the dissociative effects.
"Ketofol" (1:1 mixture of ketamine and propofol combined in a single syringe)	0.5 mg/kg ketamine + 0.5 mg/kg propofol delivered together.	Potentially balancing side effect profile.
Etomidate	0.1–0.2 mg/kg slow IV push.	Myoclonus and adrenal suppression are considerations; clinically, most commonly used for cardioversion and endotracheal intubation.

Abbreviation: IV, intravenous.

young, healthy subjects may not always require full monitoring as such could lead to the underutilization of sedation and oligoanalgesia.

The classification of sedation proposed by the American Society of Anesthesiologists comprises 4 categories: minimal-moderate-deep sedation and general anesthesia with clear definitions of these categories in terms of responsiveness, airway, cardiovascular and spontaneous ventilation.[38] Any patient who is treated with moderate or deep sedation requires the presence of an physician at the bedside with appropriate nursing assistance to allow for continuous monitoring of cardiac function and oxygenation. Oxygen, suction, reversal agents, and advanced life support medications and airway equipment should be available. Continuous capnography may help in the early identification of hypoventilation.

PHARMACOLOGIC STRATEGIES FOR TREATING ACUTE PAIN

Analgesic protocols that involve standing orders for the nursing staff with mandatory and frequent pain assessments are particularly effective in the ED setting where the emergency physician may not be able remain at the bedside to titrate analgesia. The cornerstone analgesics are acetaminophen and NSAIDs. In general, patients should receive both in combination unless there are specific contraindications.

Clinical Pearls

Acetaminophen and NSAIDs are the foundation of emergency analgesia.

- Any patient considered for opioid analgesics should also be given acetaminophen in combination with an NSAID unless there are specific contraindications.
- Acetaminophen should be given in combination with an NSAID unless contraindicated.
- Trauma patients should receive a selective COX-2 NSAID (such as celecoxib) because non-selective NSAIDs are associated with increased bleeding risk.
- IV formulations of both acetaminophen and NSAIDs are available for patients who are unable to take medications by mouth.

Acetaminophen

Acetaminophen has both analgesic and antipyretic, but no anti-inflammatory, properties. Although acetaminophen's precise mechanism of action is unclear, it likely involves some inhibition of prostaglandin synthesis. It is an appropriate first-line analgesic option for mild to moderate pain, such as, musculoskeletal pain, headache, earache, and dysmenorrhea. The most serious adverse effect is hepatotoxicity, most commonly seen in the setting of accidental overdose with combined opioid–acetaminophen preparations. Another point of attention is the dose-dependent interaction between acetaminophen and vitamine K antagonists, leading to clinically relevant increases in INR of 0.17 per gram of ingested acetaminophen.[39] Because of its long safety record and low incidence of adverse effects, acetaminophen is the most frequently used analgesic in North America. In combination with NSAIDs it is the base on which to build a multimodal analgesic regimen. A parenteral formulation of acetaminophen is now available potentially increasing its applicability in the ED setting.[40,41] With regard to pain related to soft tissue injuries (sprain, strain or contusion of a joint, ligament, tendon or muscle), a recent Cochrane review could not identify superiority of acetaminophen or NSAID's when used in monotherapy. Similar conclusions applied to swelling and return to function. There was low-quality evidence of more gastrointestinal adverse effects with non-selective NSAID compared with acetamoniphen.[42] However, in the setting of postoperative pain relief, a combination of NSAID's and acetaminiphen was more proficient than either drug in monotherapy.[43]

NSAIDs

In addition to their analgesic and antipyretic properties, NSAIDs function by inhibiting cyclooxygenase (COX), an enzyme responsible for prostaglandin synthesis. This property renders NSAIDs useful for treating inflammatory and prostaglandin-related pain, such as rheumatoid arthritis and dysmenorrhea, as well as renal and biliary colic, headache, and musculoskeletal injuries. The inhibition of COX is also responsible for the side effects of NSAIDs, which include nephrotoxicity via decreased renal perfusion and an increased risk of gastroduodenal ulcer formation. These side effects are dose dependent and are more likely to occur in the elderly and those with preexisting renal or peptic ulcer disease.[44] Other adverse effects include hypersensitivity, platelet dysfunction, and asthmatic exacerbation in sensitive individuals.[45]

There are many NSAIDs to choose from, and they appear to be relatively interchangeable as a class. In other words, with the correct dosing, ibuprofen is as effective as indomethacin or diclofenac. Ketorolac is unique in that it may be used parenterally, thereby ensuring a rapid onset, which is an attractive attribute in the ED. Ketorolac has been used favorably in emergency medicine for various types of acute pain.[46] Topical NSAID's are effective for analgesia in patients with acute sprains, strains and overuse injuries, probably similar to that provided by oral formulations and with few systemic side effects.[47] Mainly gel formulations of diclofenac, ibuprofen, and ketoprofen provide the best results with NNT of 1.8, 3.9 and, 2.5, respectively for 50% pain relief. Selective COX-2 inhibitors are associated with adverse cardiovascular outcomes with long-term use; however, they have shown promise as part of a multimodal approach to patients with major trauma in whom non-selective NSAIDs, such as ketorolac, are contraindicated due to bleeding risk. (ref:48).

Opioids

Despite being a mainstay of acute pain management in the ED, opioids are often associated with widely divergent attitudes toward dosing and application in the ED. Both under-dosing for fear of opioid-associated adverse events resulting in under-treated pain and excessive dosing resulting in sedation, respiratory depression, nausea, and delirium are common in the ED. routine use of a multimodal approach—combining opioids with adjuvant analgesics whenever possible—with rapid titration can help avoid both of these undesirable outcomes (Table 59–3).[49–51]

Clinical Pearls

Protocolized, rapid titration of morphine to improve analgesia and reduce the incidence of adverse events.

- Opioids are often the best agent for acute severe pain in the ED.
- Potentially life-threatening adverse events attributable to opioids are largely preventable.
- Individual dose response is highly variable. Response cannot be accurately predicted based on pain score and weight alone.
- Relatively small doses can be surprisingly effective, just as large doses may not provide substantial relief.
- CNS concentrations of morphine peak within 20-30 minutes.
- Avoid large (ie > 0.15 mg/kg) single-dose orders without close observation of clinical effect.
- In opioid-naïve patients, start with a lower dose (eg, <0.1 mg/kg IV).
- Titrate rapidly with repeat doses every 10-20 minutes based on clinical response
- Instruct patients about safe use and opioid addiction whenever prescribing these drugs for out-of-hospital use.

Opioids however, carry a risk of dependency and addiction for both ED personnel and patients. A recent study showed that patients in the ED often have misconceptions about opioid addiction and under- as well as overestimate their personal risk for addiction.[52] As such, ED physicians should discuss opioid addiction with patients whenever they prescribe these drugs. A simple educational intervention consisting of verbal instructions and a one-page information sheath has shown to improve the patient's knowledge concerning safe use of opioids.[53] A realistic appreciation of this reality in a setting of nonjudgmental and empathetic care is warranted whenever opioids are used.[54] Additionally, chronic opioid use poses unique challenges for acute ED pain management such as opioid tolerance and opioid-induced hyperalgesia. In particular some opioid tolerance patients will demonstrate a very narrow therapeutic window, special care is often needed to avoid fluctuating between undertreated pain and opioid toxicity in these patients. The use of adjuvant acetaminophen, NSAIDs, and low-dose ketamine in conjunction with the rapid titration of an intravenous (IV) opioid is the best available strategy for this challenging clinical situation.[55]

In addition to morphine, a wide spectrum of opioids, such as fentanyl and sufentanil, are suitable because of their rapid onset and limited duration of action during procedural sedation and analgesia.[56] Other commonly used parenteral opioids are meperidine and hydromorphone, although the use of meperidine is declining owing to its neurotoxic and anticholinergic side effects. Major side effects common to all opioids include dose-dependent respiratory depression, nausea, constipation, pruritus, and urinary retention (Tables 59-3 and 59-4).

In Europe, tramadol is often used in the ED for its analgesic properties, particularly in children and the elderly. It poses less risk for of side effects of such as respiratory depression or altered consciousness. Another advantage of Tramadol is the spinal re-uptake inhibition of noradrenaline and serotonin, which makes the drug suitable for patients with neuropathic pain syndromes. It is administered typically in combination with an anti-emetic to reduce the risk of nausea and vomiting.

The use of opioids in combination with acetaminophen or an NSAID has increased dramatically in recent decades, and combinations of hydrocodone and acetaminophen are the most commonly prescribed medications in the United States by a large margin. There is little evidence to support such a large role for this class of medicine in moderate, non-malignant pain. Conversely, there is no high-quality evidence that this practice is harmful. As a result, community practice is widely divergent, as are expectations for ED-based opioid prescribing. A consistent approach coordinated with inpatient and outpatient services is ideal when possible.

Ketamine

Ketamine, an NMDA receptor antagonist, is a potent analgesic at low doses (0.1–0.3 mg/kg IV) and has a unique dissociative anesthetic effect at higher doses (1–2 mg/kg IV). Ketamine has several unique applications in emergency care.[57,58]

Clinical Pearls

Ketamine Analgesia in Emergency Care

Monitoring

- Ketamine at doses less than 0.3 mg/kg IV does not produce more than mild sedation, and additional monitoring beyond typical or IV opioids is not necessary.
- Reconsider the use or reduce the dose of ketamine in patients with suspected intracranialtraumatic brain injury hypertension because the effect of ketamine on intracranial pressure is still uncertain.[59] Care should also be taken or in patients with myocardial ischemia due to increases in myocardial oxygen consumption associated with ketamine.

Psychomimetic effects

- Ketamine can produce fleeting, difficult-to-describe alterations in perception and sensation that for most patients are not unpleasant. Is important to obtain informed consent and advise patients beforehand so these experiences do not come as a surprise.
- Emergence reactions do not occur at low doses. While not available in the USA, the racemic ketmaine (ketmaine-S) is uniquely suitable in the ED because of the substantially reduced psychotropic side-effects.

Important ED applications

- Ketamine is recommended for agitated, hypotensive trauma patients; brief, painful procedures such as the infiltration of local anesthetic around a laceration or abscess; opioid-dependent patients presenting with complex pain crises; and intractable cancer pain.

TABLE 59–3. Example of multimodal analgesia for an injured 70-kg opioid-naive patient.

1. Rapid identification of patients with acute pain and immediate intervention

Prompt relocation, proper splinting, wound protection, cooling, and positioning using a humanistic approach that maximizes the beneficial psychologic effects of provider attention, empathy, and kindness.

2. Evaluation for regional anesthesia

The preparation for regional anesthesia can begin in parallel with the other components of a multimodal approach.

3. Early initiation of anti-inflammatory regimen

+ an NSAID or selective COX-2 inhibitor should be administered.

Medication	Emergency Dose	Comments
Acetaminophen	15 mg/kg orally, rectally, or IV every 6 h 60 mg/kg maximum per day	Few contraindications which should not be overlooked, as it has potent effects when used in combination with other analgesics.
Celecoxib (selective COX-2 inhibitor)	400 mg oral loading dose then 200 mg daily, 4 mg/kg daily	
Consider risk/benefits ration of using ibuprofen, ketorolac, naproxen, and other nonselective COX inhibitors in the acute trauma setting because of bleeding risk or in patients with acute kidney injury and GI disease (eg, peptic ulcer).		
Ibuprofen	400–800 mg orally every 8 h (5-10 mg/kg oral every 4-8 h)	
Ketorolac	0.5 mg/kg IV every 6 h	May cause severe bronchospasm in asthmatic patients.

4. Rapid titration of IV opioid (fentanyl) every 3–5 minutes and transition to longer-acting opioids (morphine or hydromorphone) as needed

Medication	Emergency Dose for Acute Pain	Comments
Fentanyl	25–100 mcg every 5 min titrated at bedside (1-2 μ/kg)	Synthetic opioid; rapid action; relatively limited cardiovascular impact.
Hydromorphone	1–3 mg every 3–4 h IV (0.05-0.1 mg/kg)	Can titrate as quickly as every 5–10 min with caution.
Morphine	5–15 mg every 3–4 h IV (0.1-0.2 mg/kg)	Most commonly used opioid.

Protocolized pain assessment and drug administration may help achieve rapid titration. For prolonged stays in the ED, consider patient-controlled analgesia and /or the addition of long-acting oral opioids such as oxycodone, tramadol, or oral morphine.

5. Ketamine

Consider ketamine as a coanalgesic for intractable severe pain, opioid tolerance, or hypotension. Ketamine can also be used to rapidly establish deep analgesia or as rescue bolus followed by infusion for refractory pain and may be a first-line agent in patients with hypovolemia, hypotension and/or agitation. Where available, consider using racemic ketamine (S).

Drug	Emergency Dose	Comments
Ketamine	0.1–0.3 mg IV bolus every 5 min titrated at bedside; 10–30 mg/h IV continuous infusion	Rapid acting; can result in profound analgesia; unpleasant "drugged" feeling is decreased at lower doses; true dissociation uncommon at lower doses.

6. Consideration of a gabapentinoid

Drug	Emergency Dose	Comments
Gabapentin	300–600 mg orally every 8 h Initial dose as high as 1200 mg orally	Used routinely in the U.S. military for acutely injured; side effects include somnolence.
Pregabalin	75–150 mg orally every 12 h	Similar to gabapentin.

Abbreviations: COX-2, cyclooxygenase-2; ED:, emergency department; NSAID, nonsteroidal anti-inflammatory drug.

PART 8

TABLE 59–4. Limitations of opioid analgesics.

Acute side effects	Respiratory depression, nausea and vomiting, pruritus, vasodilation and hypotension, immunosuppression
Logistic	Most common source of dosing errors
	Prolonged recovery and increased duration of stay
	Resource-intensive monitoring at higher doses
Pharmacologic	Opioid-induced hyperalgesia and tolerance that limit effectiveness
	Risk for abuse and dependence that affects both patients and providers

The Agitated, Hypotensive Trauma Patient

Agonal patients in hypovolemic shock from hemorrhage can become confused and thrash wildly, delaying full evaluation and potentially life-saving administration of blood products. Small doses of ketamine (0.1–0.2 mg/kg IV) can have a profound calming and analgesic effect with a lower risk of hypotension than that associated with opioids (including fentanyl).

Brief, Painful Procedures

Examples of these procedures include infiltration of local anesthetic around a laceration or abscess, followed by suturing or evacuation, respectively. The patient should first receive an NSAID and acetaminophen. Next, an IV opioid is given, and then 5 minutes before the expected maximum intensity of pain, low-dose ketamine is administered (0.1–0.2 mg IV). We find that high-quality analgesia greater than that normally achieved with an opioid alone occurs rapidly with only a light sedative effect and mild psychomimetic effects that are not unpleasant.[57,58]

Clinical Pearls

Reducing the pain of local infiltration

- Use small needles (ie, 27- to 30-gauge).
- Inject the anesthetic slowly (1 mL over 30 s).
- Buffer local anesthetics with sodium bicarbonate.
- Inject anesthetics from within lacerations rather than through intact skin.
- Use some type of topical anesthesia beforehand.

Opioid-Dependent Patients Presenting with Complex Pain Crises

In this setting, NMDA receptor–mediated pro-nociceptive pathways may play a substantial role in the suffering of the patient. Small doses (0.1–0.2 mg IV or 0.2–0.4 mg intramuscularly) of ketamine can be very effective.[58] Intractable cancer pain is increasingly common in the ED setting. These patients are often receiving long-term opioid therapy and may benefit from the addition of a ketamine bolus (0.1–0.2 mg IV) followed by an infusion of 0.3 mg/kg IV per hour.[57,58,60]

Other Adjuvants

There is a wide variety of patients presenting with severe pain in ED that may respond favorably to additional adjuvants. This is an area in need of further study, and the role of agents such as gabapentin, clonidine, and lidocaine has not yet been clarified.

Topical Anesthetics

Topical anesthesia involves the application of a local anesthetic directly to a mucosal or skin surface. The application of a topical local anesthetic mixture before the injection of a local anesthetic can significantly reduce the severity of pain on injection for patients with lacerations or abscesses.[61,62]

Oropharyngeal anesthesia is most commonly used for peritonsillar abscess incision and drainage and endotracheal intubation in awake patients. Lidocaine 1–4% can be administered several different ways: viscous lidocaine jelly can be swished around the mouth; liquid lidocaine can be nebulized for anesthesia of the oropharynx and airway; and lidocaine-soaked pledgets can be applied directly to a mucosal area in the nose or oral cavity. Pretreatment with an antisialagogue such as glycopyrrolate (0.2 mg IV) 10 minutes before the application of lidocaine can promote better tissue penetration. Because relatively higher concentrations (eg, 4%) of lidocaine are used and system uptake from mucosal surfaces can be rapid, safe dosages should be calculated in advance and adhered to. Common options for topical anesthesia for venipuncture, wound repair, or use prior to local anesthetic injection are presented in Table 59–5.

Nitrous oxide

Nitrous oxide is mainly used for sedation of children that require minor surgical procedures or painful interventions in the ED. Appropriate equipment for airway management, intravenous access and hemodynamic and respiratory monitoring must be available in case of too deep sedation. Provisions for scavenging of gases must be present in the ED since N2O can have deleterious effect on the fetus and chronic exposure may lead to infertility, and adverse effects on bone marrow and the central nervous system.[63,64] In a prospective trial, the effect of a N2O/O2 (50:50 mixture) sedation was evaluated in 210 children (mean age 9y, range 2.7-16y).[65] In 137 cases nitrous oxide was used to facilitate administration of local anesthetic, other indications were skin sutures, reduction of fractures and dislocations, venapunctures, abcess and hemotoma drainage. The average duration of N2O administration was 10 min (range 5-30 min). Patients were calm and pain free in 73.8% of the procedures. Failure defined as any event necessitating the termination of N2O administration occurred in 1.4%. Compared to intravenous ketamine, nitrous oxide sedation allows for a more controlled depth of sedation with faster recovery times.[66] Frequently observed side effects with nitrous oxide sedation are nausea and vomiting, euphoria, dizziness which occur in 5 to 16% of patients. The odds of vomiting increase with concomitant administration of opioids or when clear fluids were

TABLE 59–5. Emergency topical anesthesia[a].

Agent	Action
Intact Skin	
Eutectic 1:1 mixture of 2.5% lidocaine and 2.5% prilocaine (EMLA)	Onset is 60 min; occlusive dressing is required; methemoglobinemia is a rare complication of prilocaine.
4% lidocaine cream in a liposomal matrix (LMX)	Onset 30 min, and no occlusive dressing is required.
Vapocoolant spray	Ethyl chloride is the most commonly used agent. Spray until skin blanches for up to 10 s 3–9 in. from skin surface; duration is approximately 1 min after blanching.
Nonintact Skin	
Lidocaine 4%, epinephrine 0.1%, and tetracaine 0.5% (LET)	Onset 30 min after direct application to open wound.

[a]Other techniques for delivering lidocaine topical anesthesia such as iontophoresis and needle-free jet delivery remain uncommon in the emergency department and are under study. Agents containing cocaine and benzocaine are less commonly used owing to concerns about systemic toxicity (cocaine) and methemoglobinemia (benzocaine).

ingested <2 h before N2O administration.[67] More serious complications consist of oxygen desaturation and generalized tonic-clonic seizures which are increasingly seen with N2O concentrations >50% and prolonged administration of N2O >15 min. The use of a face mask with a patient demand valve can be helpful to prevent oversedation. Recently, a case of laryngospasm, pulmonary aspiration and desaturation associated with nitrous oxide (70%) sedation was described in a 16 month old child which was fasted for 4 h. This case once more highlights the need for adequately monitoring in sedated patients and the presence of ED staff skilled in emergency airway management.

Overview

A wide variety of regional anesthetic techniques are used in the ED setting (Table 59–6). Nerve blocks placed as close to the time of injury as logistically feasible are one of the most important recent advances in emergency pain management. Widespread adoption of early regional anesthesia has proven revolutionary in the contemporary military trauma setting.[68] Nerve blocks have multiple important advantages. First, they reduce or eliminate the need for opioids. Moreover, by halting the nociception from of an acute injury, nerve blocks reduce central nervous system (CNS) sensitization or "wind-up." Finally, nerve blocks offer improved analgesia and a decreased metabolic stress response to acute injury (see Table 59-7).[68-71]

Traumatic injury results in a catabolic stress response that is directly proportional to the degree of tissue injury and may be attenuated by regional anesthesia, that blocks peripheral afferent noxious stimuli from reaching the CNS. The barrage of noxious stimuli to the CNS after traumatic injury triggers a cascade of metabolic, neurohormonal, and inflammatory events leading to detrimental physiologic changes such as hyperglycemia, hypercoagulability, and immunosuppression. Although, the stress response is an adaptive "fight or flight" mechanism to promote survival, but in the medical context, it may be associated with delayed recovery, delayed healing, and increased morbidity.[71]

Tailoring Multimodal Analgesia in ED

Mastery of emergency pain management requires matching the best agent or modality to the tremendous variety of individual clinical circumstances and patient types that present to a busy ED (see Table 59–6). For example, there is evidence to support preferentially using NSAIDs for ureteral colic and vascular headaches, whereas some anterior shoulder dislocations may be best treated with manual muscle massage.

TABLE 59–6. Types of emergency regional anesthesia.

Regional Anesthesia Technique	Comments
Tissue infiltration	Simple; but can be painful and anesthesia may be incomplete, particularly with fractures.
Field blocks	Can be very effective in select anatomic locations.
Intra-articular injection	Analgesia is limited to joint surface relatively of short duration.
Fracture hematoma injection	Can be rapidly placed once fracture is identified; limited duration and scope of analgesia.
Regional nerve block	Superior analgesia for extremity trauma.
Neuraxial and IV techniques	ED applications are currently limited; somewhat higher risk profile and unclear benefit compared with regional nerve blocks.

Abbreviations: ED, emergency department; IV, intravenous.

TABLE 59–7. Benefits of regional anesthesia.

- Targets effective analgesia to a specific anatomic area.
- Reduces the need for opioids and the incidence/severity of opioid-related side effects.
- Reduces the need for sedatives and the incidence/severity of sedative-related side effects.
- In hypovolemic patients, may reduce the incidence of hypotension compared with traditional sedation and analgesia.
- May reduce the stress response to injury.
- Improves the quality of pain control.
- Decreases the need for close medical supervision of awake and alert patients with well-controlled pain.

Low-dose ketamine may be a good analgesic choice for an elderly patient with cancer-related pain already taking opioids or for a heroin user undergoing procedural sedation with propofol. The skillful emergency physician will also recognize that pain is not simply nociceptive and is often accompanied by other unpleasant sensory and emotional experiences. The liberal use of adjunctive benzodiazepines and antiemetics is a well-established practice for maximizing patient comfort and satisfaction. Small details, such as the use of topical anesthesia prior to local anesthetic infiltration may have a large impact on the patient's satisfaction and overall pain experience (Table 59–7). Finally, organizational protocols and structures can have a significant impact on common ED barriers to quality pain management. Objective, protocolized, pain assessment that begins at triage and is linked to an immediate and simple analgesia protocol is likely the best approach ref 50. Perhaps above all, mastery of emergency pain management requires the accumulation of experience using the entire pain management armamentarium (see Table 68-6).

In summary, the best approach to acute ED pain management is generally one that (1) includes immediate pain assessment and treatment at the point of triage, followed by multimodal analgesia that is tailored to the patient and the diagnosis; (2) combines complementary analgesic agents; (3) incorporates loco-regional anesthesia when appropriate; and (4) addresses associated problems like nausea and anxiety.

PERIPHERAL NERVE BLOCKS IN ED

A wide variety of peripheral nerve blocks are applicable to emergency care (see Table 68-8).[72,73] ED staff are becoming increasingly more accustomed to performing loco-regional anesthesia procedures in a timely manner and provide close nursing observation. Optimizing the capacity of an ED to implement peripheral nerve blocks involves several steps: (1) patient selection and care coordination; (2) technique standardization; (3) local anesthetic toxicity (LAST); and (4) long-term complication management (Table 59-8).

TABLE 59–8. Nerve blocks suitable for use in ED.

Head and face
- Infraorbital
- Mental
- Supraorbital, supratrochlear, and infratrochlear
- Dorsal nasal nerve
- Zygomaticotemporal
- Zygomaticofacial
- Mandibular

Neck and upper extremity
- Superficial cervical plexus
- Suprascapular nerve
- Brachial plexus
- Cutaneous blocks of the forearm
- Peripheral radial, median, and ulnar nerves

Trunk
- Intercostal and paravertebral
- Abdominal wall

Lower extremity
- Femoral nerve block
- Lateral femoral cutaneous nerve
- Popliteal sciatic nerve
- Common peroneal nerve
- Posterior tibial nerve

Patient Selection and Care Coordination

Establishing close partnerships with consultants in orthopedic surgery, trauma, general surgery, and anesthesia services to develop consensus protocols that detail the specific use of peripheral nerve blocks in the emergency setting is necessary. Treatment protocols can be particularly effective in reducing delays and confusion about which injuries are appropriate for use of loco-regional anesthesia in the ED. Clear and logical protocols for block administration, documentation, and continued management of the block in the inpatient or outpatient setting are essential for safety and efficacy.

Standardization of Techniques

Safe and effective use of peripheral nerve blocks in the ED requires a well-developed staff training program and standardized techniques that maximize efficiency and consistency, and minimize the risk of complications such as LAST, nerve injury, and delayed diagnosis of compartment syndrome. Additionally, a well-organized and stocked "block cart" can promote the efficiency and standardization of the consenting process, materials used, and technical aspects of the procedures.[74]

Local Anesthetic Toxicity (Last)

Any ED where regional nerve blocks are performed should have guidelines for the recognition and treatment of LAST and should be equipped with readily available IV lipid infusions.

A recent study identified 67 reports of LAST over a 4 year period.[75] LAST most frequently occurred with single injections of LA (50/67 cases), followed by continuous infusions (8/67 cases) and topical administrations (7/67cases). Two reports concerned the unintentional injection of LA through an intravenous cannula. In the group of single injections associated with LAST, interscalene block (23%) is the most often reported technique followed by local field infiltration anesthesia (22%), epidural/caudal block (16%) and dorsal penile block (13%). 78% of LAST symptoms appear within the first 30 min with only 10% occurring after 60 min. Toxicity associated with topical LA mostly occurs in pediatric patients. LAST symptoms have a tendency to progress from central nervous system to cardiovascular manifestations in 83% of the patients. The most common sign of central nervous system toxicity was seizure (54%). Other symptoms included confusion, dizziness, tinnitus, dysgeusia, hallucinations, slurred speech, gait problems, limb twitching, extremity paresthesia, intention tremor, hypotonia, and facial sensorimotor and eye movement abnormalities. The most common cardiovascular expressions of LAST were bradycardia, hypotension and shock (41%) followed by tachycardia, hypertension, ventricular fibrillation (15%) and cardiac arrest (7%). Treatment of LAST is discussed in another chapter in this volume.

Long-Term Complication Management

All patients who receive a nerve block in the ED should have a developed pathway for the evaluation and management of delayed complications such as nerve injury that is coordinated with neurology and the chronic pain medicine service.

Ultrasound

Ultrasound has become an essential part of emergency care, and nearly all U.S. EDs have ready access to a modern ultrasound machine. Given the clear advantages of ultrasound guidance, we see few reasons not to use an ultrasound-guided technique for regional nerve blocks in the ED.

Matching the Peripheral Block to the Clinical Need

The most challenging aspect of administering emergency regional anesthesia is matching the correct peripheral nerve block to the clinical injury or procedure in the most site-specific and effective manner. Given the unpredictability of injuries in the ED, a well-established knowledge of the peripheral innervation patterns and a broad armamentarium of peripheral blocks is required (Table 59–9).

Emergency Regional Anesthesia by Area of Injury

Neck and Shoulder Girdle

The superficial cervical plexus block is a particularly useful block in the ED owing to its technical ease of implementation and relatively large area of innervation. The greater auricular nerve, although quite small, can frequently be found on the superficial surface of the sternocleidomastoid and blocked selectively (Table 59–10 and Figure 59–3). Clavicle fractures are common in the ED and generally excellent analgesia can be obtained with a low dose interscalane plexus block.[76]

Emergency Regional Anesthesia for the Shoulder

Shoulder dislocations are very common in the ED and are an excellent indication for a low-volume interscalene brachial plexus block. Compared with etomidate sedation, ultrasound guided interscalene block resulted in comparable pain scores and patient satisfaction. Reduction is possible in most patients.[77] In contrast, reduction was not possible in 4/30 patients after a interscalene block in a study by Underhill and colleagues.[78] The use of a surface landmark technique without the use of a nerve stimulator is probably the main reason for the 4 failed reductions in the latter study. The key component of a successful shoulder reduction is muscle relaxation, which is generally very consistently achieved with an interscalene brachial plexus block. A short-acting local anesthetic such as 3% 2-chloroprocaine or 1% lidocaine is ideal. A retrospective study with 224 patients in France reported a complication rate of 8% associated when with sedations for repositioning of shoulder dislocations mainly because standard guidelines concerning fasting and sedation are not followed. The authors reported no complications with the use of an was used for reposition of the shoulder dislocations versus no complications when interscalene block.[79] Moreover the use of regional anesthesia can significantly shorten the time care providers spend on monitoring patients as well as shorten the time patients spend in the ED and hereby allowing for a more efficient deployment ED resources k was used.[77,80]

Intra-articular lidocaine is a valuable alternative to interscalene block for the reduction of schoulder dislocation. In a recent meta-analysis of 9 randomized, controlled studies, intra-articular lidocaine was associated with equal success rates but less complications (vomiting, respiratory depression, thrombophlebitis) than intravenous sedation. Among injection drug users, deltoid abscesses are common, and brachial plexus blockade (interscalene or supraclavicular) or a selective axillary nerve block provides excellent anesthesia for incision and drainage in these cases (Table 59–11 and Figure 59–4).[81,82]

Emergency Regional Anesthesia for the Arm

Elbow dislocation is also common in the ED and can be well managed with a supraclavicular brachial plexus block (Figure 59–5). Although blockade of the C8–T1 innervation of the elbow may not always be complete, in most cases, anesthesia is sufficient to permit closed relocation.

Proximal humerus fractures are quite common in the elderly and notoriously painful. These fractures are generally very unstable and do not immobilize well with splinting. In this setting, developing a consensus plan with the orthopedic service is particularly important given the risk of a "double crush" nerve injury (Table 59–12).[83]

Below the elbow, superficial injuries of the forearm require blockade of the radial nerve and the lateral and medial

TABLE 59–9. Emergency peripheral nerve blocks: applications.

Block	Emergency Indication	Comments
Head and Face		
Infraorbital		
Mental	Facial lacerations	
Supraorbital, supratrochlea/infratrochlear		
Zygomaticotemporal		
Zygomaticofacial		
Greater auricular	Lacerations to the ear lobe	Blocked as part of the superficial cervical plexus or alone.
Greater occipital	Intractable migraine	
Dorsal nasal	Nasal laceration, abscess I&D	Normally combined with infraorbital block.
Neck		
Superficial cervical plexus	Ear lobe laceration repair, neck abscess I&D or laceration repair, IJ cannulation, clavicle fracture analgesia	Wide area of anesthesia from blockade of the supraclavicular, transverse cervical, lesser occipital, and greater auricular nerves.
Shoulder		
Suprascapular nerve	"Frozen shoulder"/adhesive capsulitis	Provides partial analgesia and relaxation to glenohumeral joint and can be used for shoulder reduction.
Axillary nerve	Deltoid abscess I&D Deltoid laceration repair	May provide significant analgesia for proximal humerus fractures if a full brachial plexus block is contraindicated.
Upper Extremity: Brachial Plexus		
Interscalene	Injury to the upper extremity above the mid-humerus	Typically misses the C8, T1 roots and elbow, wrist, and hand are incompletely blocked. Low volumes are effective for shoulder applications.
Supraclavicular	"Spinal of the arm" covers the entire arm	Most reliable block for anesthesia to elbow and distally.
Axillary and infraclavicular	Elbow, forearm, wrist, and hand injuries	Misses the medial antebrachial cutaneous nerve. Blocked with musculocutaneous nerve.
Radial nerve	Wrist, thumb, and hand injuries	Posterior interosseous nerve contributes to wrist.
Median nerve	Wrist and hand injuries	Anterior interosseous nerve contributes innervation to the wrist.
Ulnar nerve	Elbow, wrist, hand, and small finger injuries	An isolated boxer's fracture can usually be reduced with an ulnar block alone. However, significant injuries to the wrist and hand typically require blocking all three terminal nerves—radial, ulnar, and median.
Musculocutaneous nerve and its terminal branch nerve, the lateral antebrachial cutaneous	Lateral aspect of the skin of the forearm	Can be blocked in the upper arm with ultrasound guidance or as a cutaneous field block.
Medial antebrachial cutaneous nerves	Medial aspect of the skin of the forearm	Small cutaneous nerve; can be visualized and blocked with ultrasound or with field infiltration. When combined with blocks of the radial nerve and musculocutaneous nerve, a complete cutaneous forearm anesthesia results.

(*continued*)

TABLE 59–9. Emergency peripheral nerve blocks: applications. (*Continued*)

Block	Emergency Indication	Comments
Intra-artiuclar injection and fracture hematoma injection	Shoulder, elbow, and wrist fracture dislocations	Analgesia is somewhat unpredictable and short lived; however, can be placed rapidly at bedside as long-term analgesic plan is established.
Trunk		
Intercostal and paravertebral	Thoracic wall trauma such as rib fractures, lacerations, or placement of thoracostomy tubes.	The anesthesia includes the parietal pleura itself. Thoracostomy tubes can be placed painlessly with well-placed, posterior intercostal blocks. Area of high local anesthetic absorption and concomitant toxicity risk.
Rib fracture hematoma injection	Rib fractures can be visualized well with ultrasound.	Likely lower risk for pneumothorax and technically less challenging than paravertebral blocks; however, a shorter duration and less complete analgesia is found.
Anterior Abdomen		
Transversus abdominis plane block	Anterior abdominal wall injury or abscess I&D	Target a contiguous anatomic space and the interconnected plexus of nerves that innervate the anterior abdominal wall from the pubis symphysis to T8.
Rectus sheath		
Ilioinguinal and iliohypogastric nerves	Inguinal injury, abscess I&D, or hernia repair wound complications	
Superior cluneal nerves	Superficial buttock abscess I&D	The superior cluneal nerves innervate the skin overlying the superior buttocks but not the underlying muscle.
Lower Extremity		
Femoral nerve	Hip fracture, hip dislocation, femoral shaft fracture, tibial plateau fracture, patellar fractures, lacerations or abscess I&D to the anterior thigh	Effective for analgesia. Owing to mixed innervation, complete pain control for hip fracture requires both a sciatic and obturator blockade.
Saphenous nerve	Lacerations or abscess I&D to the medial lower leg, ankle fracture dislocations in combination with sciatic nerve blocks	Terminal branch of the femoral nerve.
Lateral femoral cutaneous nerve	Hip abscess I&D as is common among patients who "skin pop" heroin in this area.	Superficial nerve does not innervate the deep muscle layers.
Popliteal sciatic nerve	Ankle dislocation and fracture	Always consider more selective blocks. Combine with a saphenous block for ankle fracture reductions.
Common peroneal and sural nerves	Injury or abscess I&D to the dorsum of the foot	Deeper structures innervated by the posterior tibial nerve.
Posterior tibial nerve	Closed calcaneal fracture, foreign body removal, or laceration to the sole of the foot	When blocking for calcaneal fracture, always be vigilant for concomitant lumbar vertebral fractures.
Intra-articular hip injection	Acetabular fracture	Relatively brief duration of action; can be very effective in acute period to establish analgesia.

Abbreviations: ED, emergency department; I&D, incision and drainage; IJ

TABLE 59–10. Peripheral nerve blocks for the neck and shoulder girdle.

Emergency Indication	Regional Block
Laceration to the auricle of the ear including the helix, lobule, and antitragus. The antihelix, concha, tragus, and most superior portions of the helix are not blocked.	SCP, greater auricular nerve or selective greater auricular nerve
Laceration or abscess I&D on the neck from the submandibular region to shoulder "cape"	SCP, transverse cervical nerves, and supraclavicular nerves
Internal jugular cannulation	SCP, transverse cervical nerves
Clavicle fracture analgesia	SCP, supraclavicular nerves

Abbreviations: SCP, superficial cervical plexus; I&D, incision and drainage.

FIGURE 59–3. Large neck laceration repaired in the ED with anesthesia provided by a superficial cervical plexus block.

TABLE 59–11. Peripheral nerve blocks for the shoulder.

Emergency Indication	Regional Block
Acromioclavicular separation	Interscalene brachial plexus block or direct infiltration.
Shoulder dislocation	Interscalene brachial plexus block. We prefer a low volume of a short-acting local anesthetic such as 2-choloroprocaine. Provides analgesia and deep muscle relaxation. Intra-articular infiltration under ultrasound guidance is also successful in some patients, although the level of anesthesia and analgesia is far lower. Selective suprascapular block provides partial analgesia that is adequate for some patients.
Deltoid abscess	Common in drug abusers. A selective axillary nerve block if there is no overlying cellulitis is the most selective approach but can miss the most superior/proximal aspect of the shoulder (augment with local infiltration). The interscalene or supraclavicular approaches provide excellent anesthesia for even large abscesses. Premedication is particularly important in these patients who are often hyperesthetic and in opioid withdrawal.
"Frozen shoulder"	Suprascapular block. For some patients, pain relief is dramatic; corticosteroid is typically added. Low dose interscalene block.

FIGURE 59–4. Deltoid abscesses are common in patients who "skin pop" heroin. This abscess was drained in the ED after an interscalene brachial plexus block.

FIGURE 59–5. Elbow dislocation successfully reduced in the ED with a supraclavicular brachial plexus block.

TABLE 59–12. Peripheral nerve blocks for the upper arm.

Emergency Indication	Regional Block
Proximal humerus fracture	Interscalene or supraclavicular brachial plexus block.
Mid and distal humerus fracture	Supraclavicular or infraclavicular brachial plexus block.
Elbow fracture/dislocation	Supraclavicular or infraclavicular brachial plexus block.
Superficial lacerations or injury on lateral aspect of upper arm	The cutaneous innervation most superior aspect of the shoulder is primarily via the supraclavicular nerves. Moving distally, the deltoid (or "regimental patch") area is primarily axillary, and the area below the deltoid is innervated primarily by the radial nerve. Local infiltration or field block can be particularly suitable/effective.
Superficial lacerations on medial aspect of upper arm	Medial antebrachial cutaneous. Not a common area for injury. Blocked with a field block in the axilla.

antebrachial cutaneous nerves depending on the injury location (Figures 59–6 and 59–7).

Radial and ulnar fractures such as the common Colles' fracture are best treated with a supraclavicular brachial plexus block. Although some patients receive excellent anesthesia from a fracture hematoma block, the results are inconsistent (Table 59–13).[84]

Recently, proximal periosteal nerve blocks were advocated for distal ulna and radius fracture manipulations.[85] This technique consists of LA injection in and around the lateral (in case of the radius) or medial (in case of the ulna), ventral, and dorsal periosteum 6 cm proximal to the wrist via a skin entry on the radial and medial side. In a prospective study with 40 patients, this technique resulted in successful fracture relocation in 95%. The relocation was described as painless in 85% of the cases.

Emergency Regional Anesthesia for the Hand

The hand is well anesthetized with distal blocks of the radial, median, and ulnar nerves in combination or selectively depending on the injury. These superficial nerves are generally very well visualized with ultrasound (Table 59–14 and Figure 59–8).[86]

Emergency Regional Anesthesia for the Thorax and Abdominal Wall

Rib fractures are quite common in the ED and are associated with severe pain. The major issue that arises with ED

FIGURE 59–6. This volar forearm injury (A) was large but superficial and was repaired using anesthesia from a medial and lateral antebrachial field blocks placed just above the elbow.

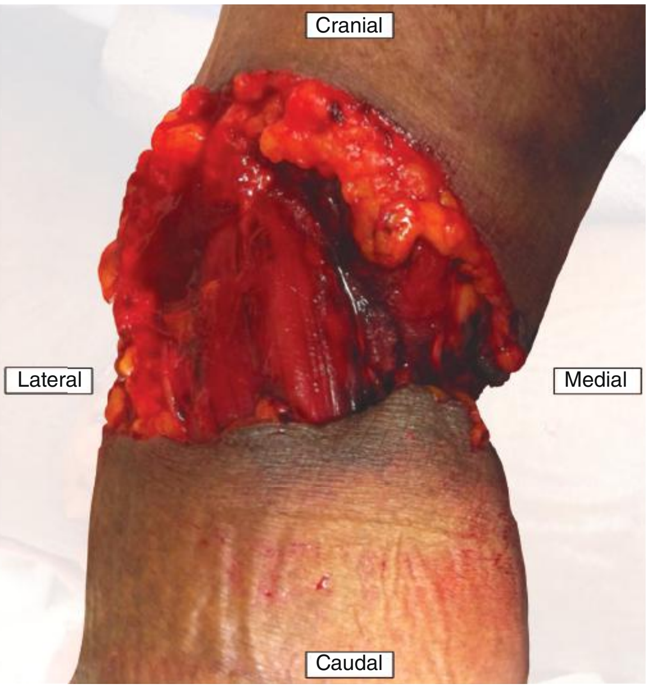

FIGURE 59–7. This forearm injury involved deeper structures and a supraclavicular brachial plexus block was used for anesthesia with excellent results.

TABLE 59–13. Peripheral nerve blocks for the forearm.

Emergency Indication	Regional Block
Forearm laceration or injury	The superficial innervation of the forearm is supplied by the lateral antebrachial cutaneous nerve (a terminal branch of the musculocutaneous nerve), the medial antebrachial cutaneous nerve, and branches of the radial nerve. The emergency provider has three options: (1) supraclavicular brachial plexus block, (2) selective ultrasound-guided block of the component nerves based on the injury location, and (3) landmark-based field blocks.
Anterior forearm	Medial and lateral antebrachial cutaneous nerves. (It is important to note the underlying muscle and bones of forearm have separate innervations.) These blocks can be accomplished either with a landmark-based skin wheal or selective blockade. The musculocutaneous nerve is quite easy to locate and block; the medial antebrachial cutaneous nerve is quite small and superficial, and the relative of advantage of ultrasound guidance is less clear.
Posterior forearm	Radial nerve and medial and lateral antebrachial cuntaneous nerves.
Forearm fractures	Supraclavicular or axillary brachial plexus block.
Wrist fracture or dislocation, distal ulna radius fractures, and carpal bone dislocations	Axillary, infraclavicular, or supraclavicular blocks. The wrist has a complex innervation that includes the radial, medial, ulnar, and musculocutaneous nerves. Distal radius fractures are very common, and the degree and pattern of pain associated with reduction is variable. For some patients, fracture hematoma injection may suffice, although rarely without some degree of discomfort, and is generally inferior to a brachial plexus block. Below-the-elbow radial, ulnar, and median blocks will not address innervation via the posterior interosseous, anterior interosseous, and musculocutaneous nerves.

placement of intercostal blocks is the time required to place the block at multiple levels. Particular vigilance for signs of LAST is needed given the high systemic intake of local anesthetic at this location. A paravertebral approach is less time consuming, as multiple levels can be blocked with a single injection, but requires more technical skill. Tube thoracostomy is often performed at the bedside in the ED, and the analgesia for the procedure can be accomplished by either intercostal or paravertebral block. A key strategy is to carefully identify the thoracic levels to match the injury with the appropriate block; one level above and one below the level of insertion is necessary (Table 59–15 and Figure 59–9). In patients with multiple level s or bilateral rib fractures, an epidural analgesia may provide more consistent, extendable analgesia with catheter placement and requires lower volumes of LA's. In a retrospective study with 64 patients sustaining rib fractures after motor vehicle accidents, Wu et al. found thoracic epidural analgesia to be superior to patient-controlled intravenous analgesia.[87] Epidural analgesia for thoracic trauma also proves to be superior with regard to mortality and mobidity. In an elderly population (mean age 70 y) with thoracic trauma, epidural analgesia with opioids reduced mortality and

TABLE–59-14. Peripheral nerve blocks for the hand.

Emergency Indication	Regional Block
Major hand injury	Radial, median, and ulnar blocks at the mid-forearm. Given the degree of overlap, any major injury should have all three nerves blocked. Radial block below the elbow avoids a wrist drop. Axillary and supraclavicular brachial plexus blocks are also options. In principle, choosing the most distal feasible block for a given injury is preferable.
Localized hand injuries	
Thumb and index finger	Radial and median nerve blocks at the forearm for any significant thumb injury.
Thumb cutaneous only	Dorsum blocked with a radial nerve block, palmar aspect with a median nerve block.
Superficial palm	Median and ulnar blocks at the forearm.
Superficial dorsum	Radial and ulnar blocks at the forearm.
Small finger	Ulnar block at the forearm.

FIGURE 59–8. Median and radial nerve blocks were used as anesthesia method for partial index finger amputation in ED.

FIGURE 59–9. Intercostal blocks can make thoracostomy tube placement in the ED much more comfortable procedure.

pulmonary complications compared with parenteral analgetics. There were no procedure related complications in the epidural group *vs.* 9% in patients that received intercostal nerve blocks (pneumothorax and intravascular injection).[88] Similar results were noted in a younger population (mean age 49 y) with ≥ 3 rib fractures: systemic opioid analgesia was associated with a 6-fold increase in the risk of pneumonia and a 2-fold increase in ventilator days compared with epidural analgesia notwithstanding the fact that patients in the epidural group tended to have more flail segments and lung contusions. The reported complication rate with epidural analgesia was higher than in the former study (27%) but consisted mainly of minor adverse events: pruritus, transient motor block, catheter site inflammation and allergic reaction.[89] Finally, epidural analgesia can favorably alter myocardial oxygen supply/demand, reduce thromboembolic complications, and shorten the duration of gastrointestinal ileus.[90] However, epidural analgesia is not suitable for all patients. Contraindications include hypotension, hypovolemia, coagulopathy, raised intracranial pressure, sepsis and aortic valve stenosis. Paravertebral nerve block may be an alternative for patients with contraindications for epidural analgesia and provides similar pain relief and improvements in respiratory function.[91] Abdominal wall abscesses can become large and require emergency incision and drainage for which abdominal fascial plane blocks can be quite effective.[92]

TABLE 59–15. Peripheral nerve blocks for the thorax.

Emergency Indication	Regional Block
Rib fracture or other thoracic wall trauma Thoracostomy tube insertion	Intercostal or paravertebral blocks. Isolated rib fractures can be treated with direct infiltration of local anesthetic into the fracture site.
Abdominal wall injuries and abscess I&D.	The rectus sheath, transversus abdominis plane, and ilioinguinal/iliohypogastric nerve blocks all target contiguous anatomic space that contains the arborized plexus of thoracic nerves innervating the anterior abdominal wall and parietal peritoneum.
• Central, periumbilical	Rectus sheath block.
• Periumbilical level to inguinal region	Transversus abdominis plane block.
• Inguinal region	Ilioinguinal/iliohypogastric block.

Clinical Pearl

- Meticulously marking the rib levels can help avoid inadvertently skipping a level when placing multiple blocks.

Emergency Regional Anesthesia for the Lower Extremity

Emergency regional anesthesia for the proximal lower extremity involves blockade of the femoral, lateral femoral cutaneous, and sciatic nerves. Hip fractures are common and painful injuries in the elderly that are associated with significant morbidity and mortality. Since the femoral nerve innervates a large part of the hip joint and the femur, targeting this nerve either individually with a femoral nerve block or combined with the lateral femoral and obturator nerve as with a fascia iliaca block (FIB) provides good pain relief. Femoral nerve blocks also provide adequate pain relief for diaphyseal or distal femur fractures.[93] A femoral nerve block for femoral fractures is the most widely used nerve block in emergency medicine.[94–97] Although administering this block is technically easy, the challenge lies in developing the capacity of the ED to consistently provide the block in a timely manner. A prospective study in 137 patients with hip fractures, showed a significant improvement of 3 points on a NRS in 77.4% of the patients 60min after a FIB with a surface landmark technique.[98] Compared to intravenous morfine, femoral nerve block significant shortened the time to lowest pain score and significantly reduced opioid consumption.[99] Surface landmark FIB has also proven to be useful in children

TABLE 59–16. Peripheral nerve blocks for the lower extremity.

Emergency Indication	Regional Block
Hip fracture or dislocation	Femoral or Fascia Iliaca block. There are obturator and sciatic nerve afferents to the hip joint that are not blocked by a femoral block, resulting in analgesia, but not surgical anesthesia.
Acetabular fracture	Intra-articular injection. Quick, rapid relief but short lived. Best for initial presentation to establish analgesia.
Femoral shaft fracture	Femoral nerve block. Very effective for mid and distal fractures.
Patellar fracture	Femoral nerve block.
Tibial plateau fracture	Given the concern for compartment syndrome, must establish a collaborative consensus with orthopedic surgeon.
Lateral thigh laceration or abscess I&D	Lateral femoral cutaneous block.
Anterior thigh laceration or abscess I&D	Femoral nerve block.
Patellar laceration or abscess I&D	Femoral nerve or femoral triangle block.
Medial calf laceration or abscess I&D	Saphenous nerve block at mid-thigh.
Tibia and fibula fractures	Popliteal sciatic block. The notorious vulnerability of traumatic tibial fractures to develop compartment syndrome demands a well-developed census plan with surgical services for patient selection and monitoring.
Lateral lower leg injury	Common peroneal block. The skin of the lateral lower leg is innervated via the peroneal nerve; medially it is supplied by the saphenous nerve.
Ankle fracture/dislocation	Popliteal sciatic and saphenous blocks. The majority of innervation is supplied via the sciatic nerve; however, there is potentially significant contribution to the joint from the femoral (via saphenous) nerve.
Calcaneal fracture	Posterior tibial block. Isolated calcaneal fractures respond very well to selective posterior tibial block. However, high-energy injuries with extensive soft-tissue injury or additional fractures will require a popliteal sciatic block.
Extensive foot injury	Popliteal sciatic block. Diabetic patients with large abscesses are a common ED presentation.
Dorsum of the foot	Common peroneal block.
Sole of the foot	Posterior tibial block. Very effective for foreign body removal as the deeper structures of the sole of the foot are well anesthetized, allowing for deep exploration.

Abbreviations: ED, emergency department; I&D, incision and drainage.

for analgesia of lower limb fractures. In a retrospective study, 158 pediatric patients that received a FIB were compared with 101 patients that received IV analgetics for femur fractures.[100] The FLACC and Bieri pain scores were 1.5 points lower in the FIB group. One patient in the FIB group developed seizures due to LA toxicity that required treatment with intravenous lipid emulsion. A prospective randomized controlled trial comparing FIB with IV morfine in comparable settings yielded similar findings.[101] In a prospective feasibility study, ultrasound guidance was used to perform FIB in 20 patients with hip fractures. The investigators reported significant reductions (over 50% improvement) in VAS scores up to 8 hours after an ultrasound guided FIB with 30ml of 0.25% bupivacaine.[102] However, a confounding factor in this study could be the administration of morfine 2h before the administration of the FIB. Since the observed pain relief lasted longer than the clinical effect of morfine, the authors attributed this analgesia to the FIB. Similar outcomes were noted after ultrasound guided femoral nerve block for patients with hip fractures.[103] The latter studies outline the important aspect that outcomes and safety of regional anesthetic techniques in the ED could be improved by the use of ultrasound guidance. These findings are confirmed in a randomized controlled trial that compared ultrasound guided femoral nerve block with a landmark technique.[104] Ultrasound guidance resulted in significant more complete blocks and shorter times to complete block than the landmark technique. Additionally, the role of the placement of continuous catheters in the ED is evolving and may have a significant role in the future.[87,88] Selective saphenous or lateral femoral cutaneous blocks can be an elegant way to provide anesthesia for large skin lacerations. The popliteal approach to the distal sciatic nerve combined with a saphenous nerve block is ideal for complex ankle fracture dislocations. Selective posterior tibial blocks are particularly useful for common ED presentations such as plantar foreign body removal and calcaneal fracture analgesia (Table 59–16 and Figure 59–10).[105] Regional anesthesia techniques must be used judiciously in injuries that lead to an acute compartment syndrome since early signs can be masked.

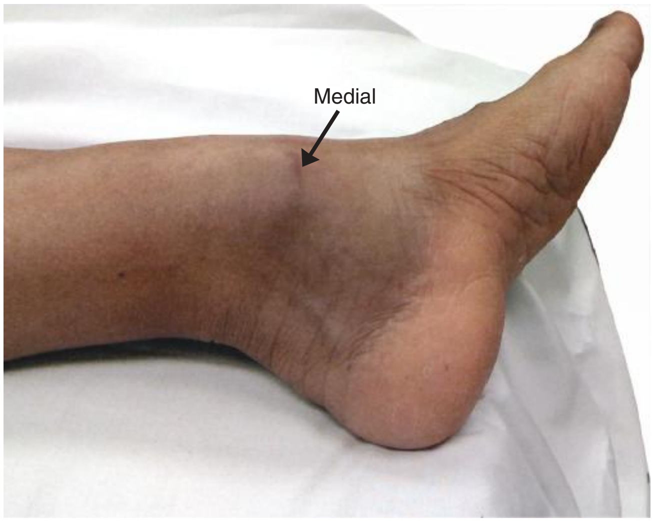

FIGURE 59–10. A popliteal sciatic block was used to reduce and splint this patients ankle fracture dislocation.

SUMMARY

Acute pain is well recognized as a problem in the ED. Emergency departments must develop an approach to caring for acutely ill patients that includes the assessment and treatment of pain as well as the treatment of the underlying illness. Multimodal analgesia with a combination of oral, parenteral, and nerve block techniques is the most effective way to provide quality pain relief in the ED while minimizing the risk of adverse effects. Regional anesthesia is a powerful adjunct to acute pain management that has been gaining popularity in the ED, particularly with the advent of the point-of-care ultrasound.

CHAPTER 60

Complications and Prevention of Neurologic Injury with Peripheral Nerve Blocks

Michael J. Barrington, Richard Brull, Miguel A. Reina, and Admir Hadzic

INTRODUCTION

This chapter reviews various factors that may contribute to neurologic complications after peripheral nerve blocks (PNBs) and suggests principles of practice and implications of monitoring modalities to mitigate the risk of neurologic complications.

ANATOMY CONSIDERATIONS OF PERIPHERAL NERVE BLOCK–RELATED NERVE INJURY

A nerve is a distinct organ comprising neural tissue, a specific connective tissue stroma, and a designated blood supply (Figure 60–1). Nerve cells, or neurons, are composed of a cell

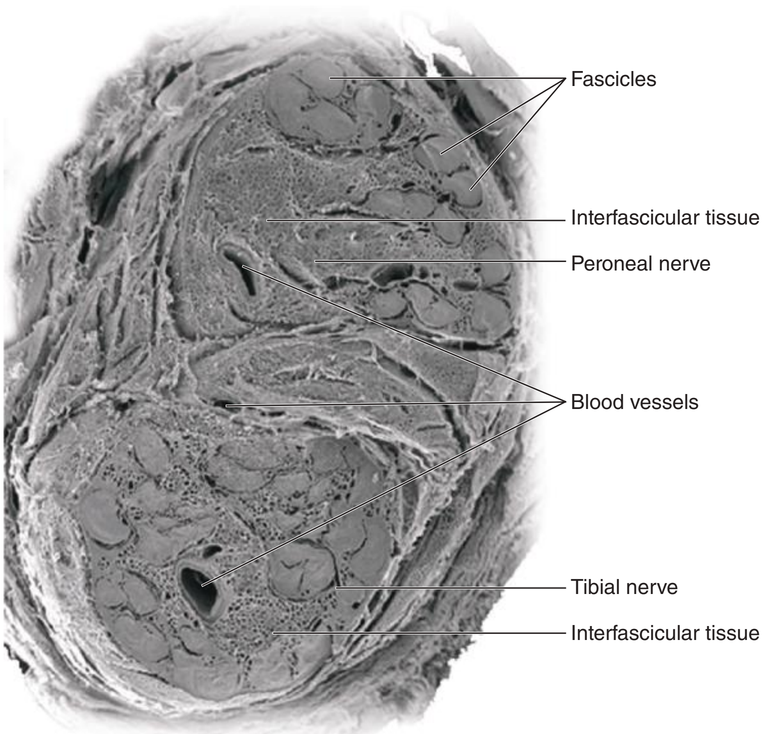

FIGURE 60–1. Human sciatic nerve. Scanning electron microscopy. (Reproduced with permission from Reina MA: *Atlas of Functional Anatomy for Regional Anesthesia and Pain Medicine*. Heidelberg: Springer; 2015.)

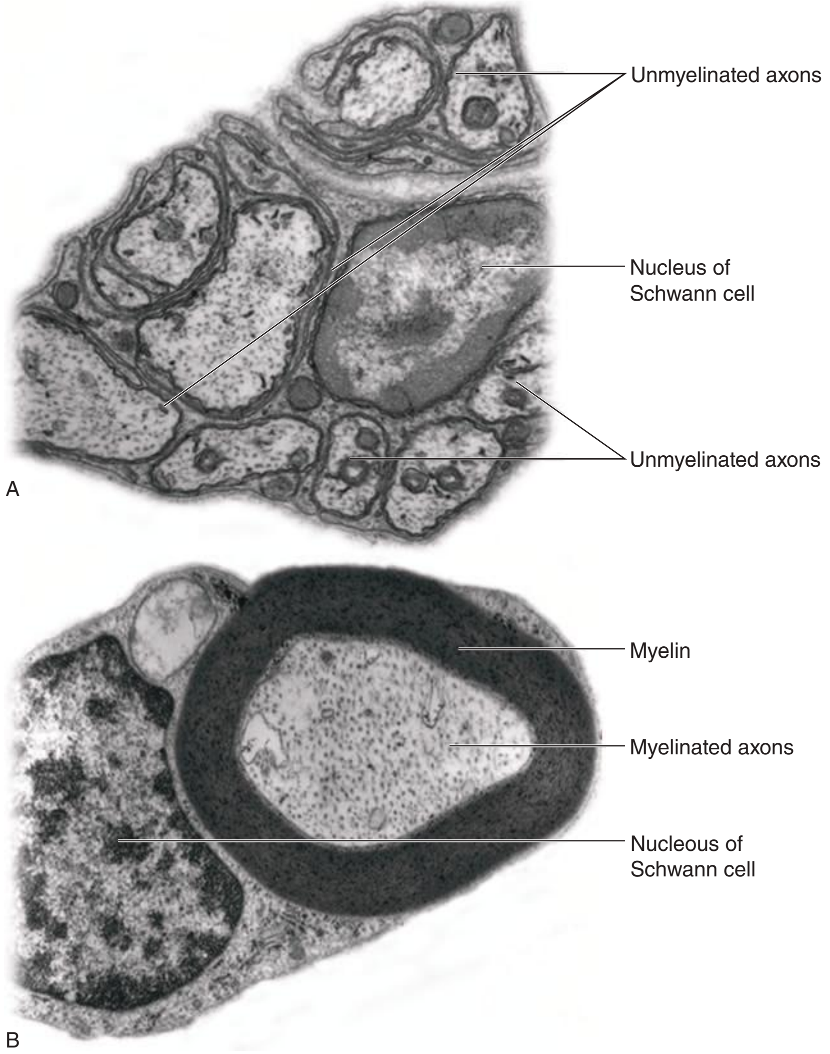

FIGURE 60–2. **A:** Unmyelinated axon of a human nerve rootlet. **B:** Myelinated axon of a human sciatic nerve. Transmission electron microscopy. (Reproduced with permission from Reina MA: *Atlas of Functional Anatomy for Regional Anesthesia and Pain Medicine*. Heidelberg: Springer; 2015.)

body, dendrites, and an axon. The axon is a cytoplasmic extension of the neuron that transmits electrical signals along its length from the cell body proximally to anywhere from just a few millimeters up to nearly 1 m distally. Most peripheral nerves can transmit both afferent motor and efferent sensory signals.

In the peripheral nervous system, the vast majority of axons are myelinated, characterized by a sheath of Schwann cells that encase the axon in a layer of myelin (Figure 60–2). The Schwann cells are interrupted at interposed spaces, known as the nodes of Ranvier, where the process of depolarization and repolarization occurs during the saltatory propagation of the action potential. Together with its myelin sheath, each axon is bound by a thin layer of connective tissue called an endoneurium (Figure 60–3) and then termed a nerve fiber.

Nerve fibers are organized into groups called fascicles (Figure 60–4). Within each fascicle, the nerve fibers form an intraneural plexus in which the axons take different positions along their path (Figure 60–5). In the vicinity of joints, the fascicles are thinner and more numerous and tend to be surrounded by a greater amount of connective tissue, which reduces the vulnerability of the fascicles to insults such as pressure and stretching.

Each fascicle is surrounded by perineurium consisting of continuous and concentric layers of 8 to 18 cells (Figure 60–6). The thickness of the perineurium is typically 7 to 20 μm. The layers of perineurial cells provide a barrier for diffusion of substances into and out of the fascicles. The space between perineurial cells is composed of fundamental amorphous substances, collagen fibers, and fibroblasts. These collagen fibers can be aligned in different directions, but predominantly along the longitudinal axis of the fascicle (Figure 60–6). The perineurium allows for some movement of axons within a fascicle and maintains intrafascicular pressure while serving as an effective physical barrier against mechanical and chemical injury. Likewise, the perineurium serves as an important diffusion barrier, preventing exposure of the axons to potentially noxious substances, such as local anesthetics.

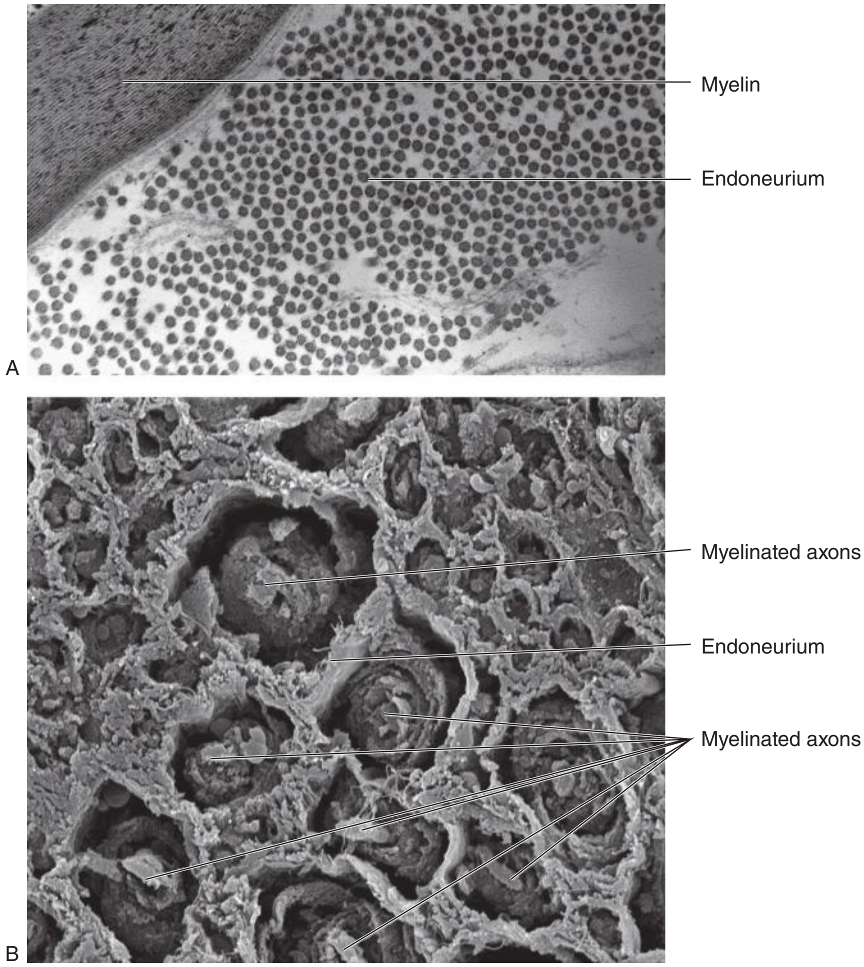

FIGURE 60–3. Endoneurium. Myelinated axons enveloped by endoneurium obtained from a human sciatic nerve. **A:** Transmission electron microscopy. Groups of fascicles are bound together by an epineurium, the thickest of the three connective tissue layers that encases groups of fascicles along with their interfascicular supporting tissue and adipocytes (Figure 60–1). The epineurium is composed mainly of collagen fibers and a small number of blood vessels (Figure 60–7). The collagen fibers of the epineurium are similar in size and appearance to collagen fibers of the dura or dural sleeves. The epineurium gives the nerve its characteristic external appearance on ultrasound imaging (ie, it appears as a discrete structure).

Peripheral nerves have two independent, yet interconnecting, vascular systems. The extrinsic system consists of arteries, arterioles, and veins that lie within the epineurium, while the intrinsic vascular system comprises a group of longitudinal capillaries that run within the fascicles and endoneurium (Figure 60–8). Anastomosis between the two vascular systems is formed by vessels (Figure 60–1) that originate in the epineurium and traverse the perineurium. Injury to these vessels can lead to a range of complications, from ischemia to inflammation due to hematoma.

Nerve roots have less tensile strength and elasticity compared to the axons and their supporting elements in peripheral nerve trunks.[1] Axons included within the spinal nerve roots are not surrounded by a perineurium or other structure with a barrier effect. More distally (eg, spinal nerves and plexus trunks/divisions), fascicles have their own protective perineurium[2] (Figures 60–9, 60–10, and 60–11) and have a plexiform arrangement that contributes to their tensile strength. Nerve trunks within tissue beds, fascicles within nerve trunks, and axons within fascicles have a slight undulating course, resulting in relative excess length. In addition, nerves are often attached loosely by their epineurium to adjacent structures. There is a nonspecialized network of areolar (deep fascial) connective tissue that fills the space between specialized structures such as nerves, muscles, and vessels (Figure 60–12). This tissue loosely connects these structures so that movement of one on another is permitted.[1] This movement is reduced when nerves are tethered by entering blood vessels, branches, or other landmarks.[2]

Clinical Pearl

- Loss of muscle tone, as occurs during anesthesia, theoretically exposes the neural elements to traction forces. However, there are also anatomical features protecting against lateral traction or stretch injury. For example, in the setting of interscalene brachial plexus blocks, the fourth, fifth, and sixth spinal nerve roots are lodged into the gutter of the transverse processes and are therefore relatively protected from these forces. The dorsal and ventral roots of spinal nerves are further protected from lateral traction by wedging of a cone of dura surrounding the nerve root–spinal nerve complex into the intervertebral foramen.

PATHOPHYSIOLOGY OF PERIPHERAL NERVE INJURY

Severity of Peripheral Nerve Injury

The primary determinants of prognosis of peripheral nerve injury (PNI) are the severity of the injury and the residual integrity of the axons. PNI severity is typically classified according to the relative degree of axonal disruption. Proximal axonal lesions (ie, close to the cell body) are traditionally believed to be more severe than distal axonal lesions (ie, closer to the innervation target) as the likelihood for reinnervation and recovery appears to vary indirectly with the distance between the location of the axonal lesion and the target tissue.

The two most commonly used anatomical classifications are the Seddon[3] and Sunderland[4] classifications (Table 60–1). The more commonly used classification in clinical practice is the three-tier Seddon classification, which includes (from mild to severe) neuropraxia, axonotmesis, and neurotmesis. *Neuropraxia* refers to damage to the myelin sheath typically associated with nerve stretching or compression where the axons and supporting elements (endoneurium, perineurium, and epineurium) remain intact. The prognosis for a neuropraxic injury is favorable, with complete recovery of function occurring within weeks to months.

Clinical Pearl

- Most postoperative neurological symptoms associated with regional anesthesia tend to follow a neuropraxic pattern of injury and recovery.[5]

Axonotmesis refers to axonal injury associated with fascicular impalement, nerve crush, or toxic injury, with damage to the endoneurium and possibly to the perineurium (Figure 60–13). Recovery following axonal loss may be prolonged and variable, depending on the extent (partial or complete) of disruption to the perineurium and on the distance from the injury site to the corresponding muscle.

Finally, *neurotmesis* refers to complete transection of the nerve, including the axons, endoneurium, perineurium, and epineurial connective tissue. It typically requires surgical intervention. The prognosis is often poor.

Mechanisms of Injury

The mechanism of PNI related to the use of PNBs falls into one of three broad categories: mechanical and injection injury (traumatic), vascular (ischemic), and chemical (neurotoxicity). Most information on peripheral nerve injection injury are obtained from experimental research in animal models. Because such research is not possible in humans, mechanisms of PNI are not fully understood.[6] This is because animal models significantly vary in species used, nerves injected, and study protocols, making it difficult to readily extrapolate such data to actual clinical practice.

Mechanical and Injection Injury

Mechanical or traumatic injury includes compression, stretch, laceration, or injection injury. Nerve compression or entrapment may produce a conduction block and, if prolonged, a focal demyelination of some axons. Needle trauma and other mechanical insults to nerves result in an increase in neuropeptide production and dorsal horn activity.[6,7] Needle-related nerve compression can result from forceful needle-nerve contact from

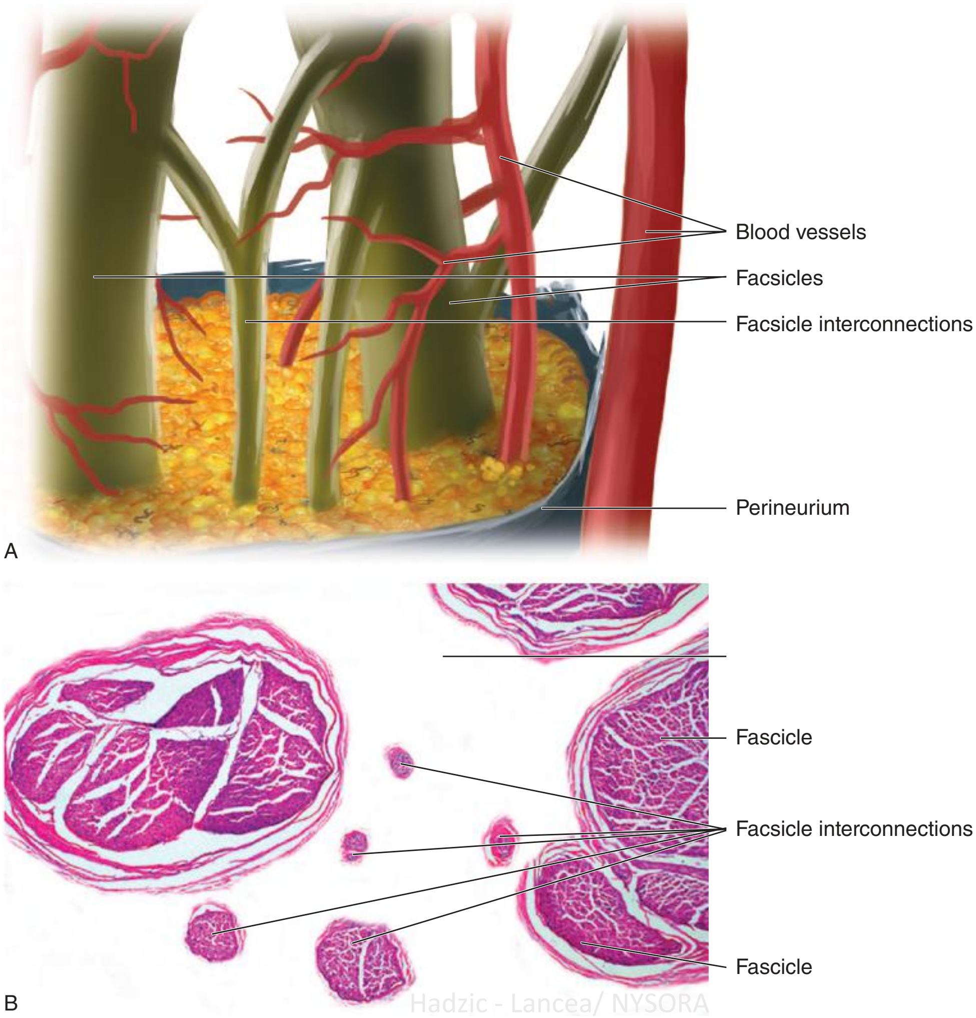

FIGURE 60–5. Intraneural plexus. **A:** Diagram. **B:** Fascicles and interconnection fascicles. (B, Reproduced with permission from Reina MA: *Atlas of Functional Anatomy for Regional Anesthesia and Pain Medicine*. Heidelberg: Springer; 2015.)

an approaching needle[8] or injection inside the nerve itself. It has been postulated that an intraneural injection may lead to sustained high intraneural pressure,[9] which, when exceeding capillary occlusion pressure, may lead to nerve ischemia and potentially injury. Inadvertent injections of antibiotics, steroids, bovine collagen, botulinum toxin, and local anesthetics into peripheral nerves have all been associated with deleterious neurologic deficits.[1,10–13] In a cadaveric model of deliberate intraneural injection of the sciatic nerve, the needle tip disrupted 3% of axons.[14] Although some degree of axonal injury may potentially occur even in the absence of injury to the perineurium, the actual anatomical site of injury (eg, injection) is critical prognostically.[15] One of the main causes of block-related PNI is injection of local anesthetic into a fascicle, causing direct needle and injection trauma, rupture of perineurium, and loss of the protective environment within the fascicle with consequent myelin and axonal degeneration.[6,11,15–18] Stretch injuries to the nerves may result when nerves or plexi are placed in a nonphysiologic or exaggerated physiologic position. Finally, mechanical injury from laceration results when the nerve is injured by a needle, with the potential for spontaneous recovery most unlikely following complete transection. Table 60–2 indicates the evidence-based recommendations to reduce the risk of block-related PNIs.

Vascular Injury

Damage to the nerve vasculature during nerve blocks can result in local or diffuse ischemia and occurs when there is direct vascular injury, acute occlusion of the arteries from which the vasa nervorum are derived, or from a hemorrhage within a nerve sheath. The epineurial circulation is a critical component of the overall neural circulation, and its removal reduces nerve blood supply by 50%.[19] In most circumstances, no single vessel dominates the pattern over an entire length of nerve; however,

the sciatic nerve is an exception to this rule, receiving its major arterial supply in the gluteal region from the arteria comitans nervi ischiadici.[1]

Clinical Pearl

- Vascular supply of the sciatic nerve is less abundant than the supply of most other peripheral nerves. This may explain the clinical observation regarding why addition of epinephrine to local anesthetic appears to prolong sciatic block significantly longer than for most other PNBs.

Nerves with an abundance of connective tissue may be less susceptible to compression because external forces are not transmitted directly to epineurial vessels. Local anesthetics and adjuncts potentially reduce neural blood flow in an agent- and concentration-dependent manner.[19,20] Epinephrine has the potential to cause local vasoconstriction, but its role in causing nerve ischemia and injury is controversial.[20] Trauma from injection may compromise blood flow further. Neural ischemia may also occur following disruption of the intrafascicular microvasculature, high injection pressures, tourniquets, and other compressive insults. Factors regarding inadvertent vessel puncture, resulting in the formation of an internal or external hematoma that can mechanically compress the fascicles from within or outside the nerve sheath and cause nerve inflammation, have been implicated in neurologic injury.[21,22]

Chemical Injury

Chemical nerve injury results from tissue toxicity of injected solutions (eg, local anesthetics, alcohol, or phenol) or its additives. The toxic solution may be injected directly into the nerve or into adjacent tissues, causing an acute inflammatory reaction or chronic fibrosis that indirectly involves the nerve. Much of the research on neurotoxicity of local anesthetics has been done in in vitro models, particularly with intrathecal application. There is evidence that nearly all local anesthetics can have myotoxic, neurotoxic, and cytotoxic effects in various tissues under certain conditions[23–33]; however, local anesthetics vary in their neurotoxic potential.[34–36] Several studies have demonstrated that local anesthetics can lead to fragmentation of DNA and disrupt the membrane potential in mitochondria, resulting in the uncoupling of oxidative phosphorylation, which may result in apoptosis.[37] There is also a direct correlation between concentration of the local anesthetic and duration of exposure to the nerve, with death of Schwann cells, infiltration with macrophages, and myelin damage.[34,38] Some local anesthetics have an intrinsic vasoconstrictive effect that can decrease blood flow to the nerves, potentially resulting in ischemia and injury.[39] However, the inherent difficulty in extrapolating these

laboratory studies to the clinical practice of modern PNBs is that there is a substantial decrease in the concentration of local anesthetics by the time it reaches the axons.

The site of local anesthetic application (extraneural, intraneural, interfascicular, intrafascicular) (Figures 60–12, 60–14, and 60–15) may be the primary determinant of whether neurotoxicity will occur, especially if the concentration is high and duration of exposure prolonged.[11] Most chemical substances, including all local anesthetics, injected intrafascicularly lead to severe fascicular injury, whereas the same substances injected intraneurally but interfascicularly cause less injury or no detectable injury at all.[40] Indeed, needle penetration of a nerve may result in minimal damage if it is not combined with local anesthetic injection within the nerve fascicle.[6,15]

In a rodent model, Whitlock demonstrated that intrafascicular injection of 0.75% ropivacaine resulted in severe histological abnormalities, including demyelination, axonal degeneration, and Wallerian degeneration.[11] However, extrafascicular injection of 0.75% ropivacaine also resulted in axonal injury, although reduced in severity.

Farber and colleagues recently reported that all commonly used local anesthetics (bupivacaine, lidocaine, and ropivacaine) produced nerve injury when injected intrafascicularly.[41] In their study, the degree of injury decreased with increasing distance from site of injection. Of note, even administration of saline intrafascicularly resulted in intermediate damage to nerves, indicating a baseline level of injury associated with injecting any agent into a nerve.

Clinical Pearl

- While the clinical importance of neurotoxicity remains controversial,[33] the location of the needle tip during injection of the local anesthetic plays a crucial role in determining the likelihood and severity of nerve injury.

Inflammatory Injury

Inflammatory mechanisms of PNI are being increasingly recognized as an important mechanism in post-PNBs neurologic deficit.[42,43] Nonspecific inflammatory responses targeting peripheral nerves can occur either remote from the site of surgery or within the operative limb, where it may be difficult to distinguish from other causes of PNI. Inflammatory mechanisms have been proposed as responsible for persistent phrenic nerve injury following interscalene block for shoulder surgery (Figure 60–12).

Kaufman and colleagues reported a series of 14 patients with chronic diaphragmatic paralysis following interscalene block.[44] During surgical exploration, adhesions, fascial thickening, vascular changes, and scar tissue (present in 10 of 14 patients) involving the phrenic nerve suggested chronic inflammation and were consistent with compression neuropathy. Recent research suggested that intrathecal and intraneural injection of ultrasound gel can also lead to inflammation in the subarachnoidal and peripheral nerves, respectively.[45,46]

ETIOLOGY OF NERVE INJURY FOLLOWING PERIPHERAL NERVE BLOCKADE

Anesthetic Factors

Several studies have reported that the type of anesthesia (regional vs general) does not appear to influence the incidence of PNI. The University of Michigan performed a retrospective analysis of PNI and did not identify PNB as an independent risk factor for PNI in their series.[47] Three epidemiologic studies from the Mayo Clinic reported that regional anesthesia does not increase the risk of PNI following total knee arthoplasty (TKA),[48] total hip arthroplasty (THA),[49] and total shoulder arthroplasty.[50] Recent surgical literature suggested that the risk of postoperative neurologic injury associated with PNB may be higher than that reported in anesthesia literature.[44,51–53] We discuss several technical factors related to PNB that may increase the risk of PNI.

Intraneural Injection

Avoidance of deliberate trauma to nerves, including intraneural injection, is probably a key safety principle of regional anesthesia.[54] However, intraneural injection may occur in clinical practice without resulting in overt signs of nerve injury.[55–57] In fact, unintentional intraneural (but probably extrafascicular) epineurial injection may be more common than previously recognized.[58] The presumed risks of intraneural injection have been challenged by Bigeleisen and colleagues,[56] who reported that nerve puncture and apparent intraneural injection during axillary brachial plexus block in healthy patients did not lead to neurologic injury. A larger study by Liu recruited 257 young, healthy patients having ultrasound-guided interscalene or supraclavicular block for shoulder surgery.[55] The incidence of unintentional intraneural injection was 17% without any occurrence of PNI. However, clinical experience is limited, and the sample sizes of current studies are inadequate to capture infrequent events, such as nerve injury. In contrast, in a case report by Cohen, PNI occurred following intraneural injection during ultrasound-guided interscalene block.[59]

Unfortunately, reports of intraneural injection do not inform us regarding sites of injection in relation to fascicles. Distinguishing the outer epineurium of a peripheral nerve

TABLE 60–1. Classification of nerve injury.

Seddon[3]	Sunderland[4]	Processes	Prognosis

	5	Complete nerve transection No conduction	

from surrounding tissues using ultrasound imaging is challenging. Orebaugh performed mock interscalene injections (albeit with small volumes) in a cadaver model.[60] Ultrasound imaging cannot differentiate extrafascicular and intrafascicular neural components over the range of locations that PNB is performed.[61] Furthermore, an injection adjacent to the outer epineurium may generate a halo similar in appearance to an intraneural injection, making it difficult to discern hazardous from nonhazardous needle placement. Importantly, only a small amount of local anesthetic (eg, 0.1–0.5 mL) is sufficient to rupture the fascicle and its perineurium.

Clinical Pearl

- Relying on observation of nerve swelling on ultrasound during PNBs as a monitoring method is inadequate for detection of intrafascicular injection and injury prevention. Most recent experimental and clinical data suggest that PNI from local anesthetic injection into the nerve occurs and remains a real clinical danger.[41] The sequelae from such an injury may be long lasting and require surgical intervention.[41,44]

Proximal Versus Distal PNBs and Risk of Neurologic Injury

The PNB injections at more proximal sites (ie, roots of brachial plexus vs peripheral nerves of the brachial plexus) (Figures 60–9, 60–10, and 60–11) may be at higher risk of nerve injury compared to distal sites of PNB. This is likely due to differences in neural architecture, primarily the ratio of neural versus nonneural (connective) tissue[62,63] (Figure 60–16). Clinically, intraneural injection into the extrafascicular connective tissue within the epineurium may not result in nerve injury.[62] This is consistent with experimental work that has correlated intrafascicular injection to peripheral nerve injection injury.[15]

The structural organization of the peripheral nerve provides insight into the relative risk for mechanical injury among different nerves or even at different locations within the same nerve (Figure 60–16). Because the epineurium is typically a tougher layer than the surrounding adipose tissue, nerves tend to be "pushed away" by an advancing needle, rather than penetrated.

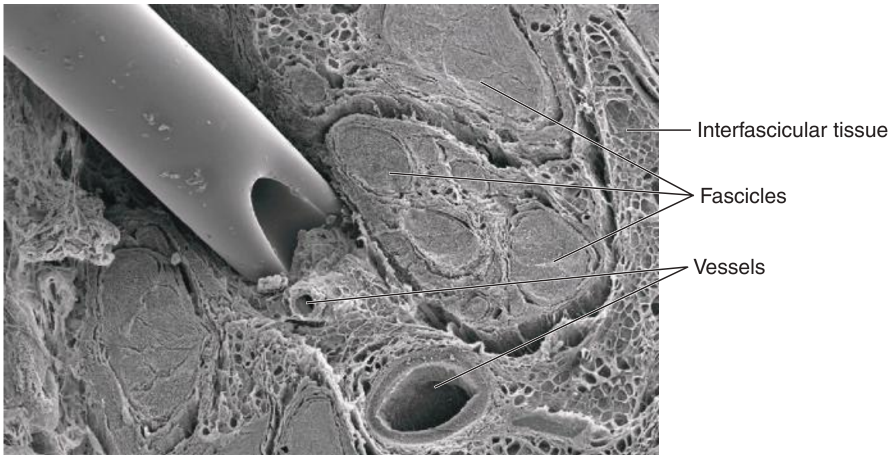

FIGURE 60–13. Human tibial nerve. In vitro puncture of nerve with neurostimulation needle. Scanning electron microscopy. (Reproduced with permission from Reina MA: *Atlas of Functional Anatomy for Regional Anesthesia and Pain Medicine*. Heidelberg: Springer; 2015.)

TABLE 60–2. Evidence-based recommendations to reduce the risk of block-related PNI.

- Intraneural needle insertion may not always lead to nerve injury.
- Intrafascicular needle placement and injection should be avoided.
- Neither the presence nor the absence of a paresthesia during needle advancement or on injection of local anesthetic is entirely predictive of nerve injury.
- Elicitation of severe pain during needle advancement or on injection of local anesthetic should prompt cessation of injection.
- Presence of an evoked motor response at a current of less than 0.5 (0.1 ms) indicates intimate needle-nerve relationship, needle-nerve contact, or intraneural needle placement. This information is useful in clinical decision-making.
- Injection pressure monitoring can detect injection into a poorly compliant tissue space, such as a nerve fascicle.
- Ultrasound can detect intraneural injection, although such detection may occur too late to prevent injury as a small quantity of injectate is sufficient to rupture the fascicle.
- Current ultrasound technology does not have adequate resolution to discern between an interfascicular and an intrafascicular injection.
- Adequate images of needle-nerve interface are not consistently obtained by all operators and in all patients.

Similarly, when the epineurium is penetrated by a needle, the needle tip and injection are much more likely to enter the interfascicular adipose tissue than the fascicles (Figure 60–15). The adipose tissue within the epineurium allows the fascicles to escape the advancing needle; however, this protection may be undermined by abrupt needle advancement needle or forceful needle-nerve contact.[8] The nerves characterized by tightly packed fascicles and high fascicular-to-connective tissue content may be at greater risk of mechanical nerve injury than those characterized by lower fascicular-to-connective tissue content.[62,63]

Relatively high incidences of transient neurologic sequelae are reported following interscalene block, where there is a 1:1 ratio of neural to nonneural tissue[62] (Figure 60–12). Several studies documented a rather high incidence of neurologic symptoms after brachial plexus block, but without severe sequelae.[64–66] In other studies, there were low absolute numbers of upper extremity PNB-related neurologic complications, rendering any comparison of outcomes at proximal sites with distal sites problematic.[67–69]

Injury rates following lower extremity PNB have been reported as 0.41% (95% confidence interval [CI], 0.02–9.96) in the gluteal region, compared with 0.24% (95% CI, 0.10–0.61) in the popliteal region,[5] indicating no significant difference. It is possible that many of the neurologic symptoms reported by the patients postoperatively after PNBs are inflammatory and due to needle-nerve contact or forceful injection, leading to intraneural inflammation, leading to symptoms, as demonstrated by Steinfeldt.[8,72] Therefore, the wisdom in Selander's teaching that "nerves should be handled with care" remains relevant.

Needle Type

Needle-tip characteristics influence the likelihood of fascicular penetration and nerve injury.[70] Long-bevel needles are more likely to puncture and enter the fascicle compared with short-bevel needles[14]; however, short-bevel needles appear to cause more damage in case of fascicular penetration[70] (Figure 60–17). The severity of nerve injury after needle-nerve perforation is also linked to the needle diameter[71]; however, no such difference exists with regard to extent of inflammation after needle-nerve trauma.[71,72]

The effect of needle design on the likelihood and severity of mechanical nerve injury has been extensively debated.[24,29,32] It is not surprising that mechanical needle trauma and intraneural injection are key mechanisms in iatrogenic nerve injury, such as with regional anesthesia. For example, in the setting for neuraxial anesthesia, the dural lesions produced by different needle types vary greatly in morphology; a Whitacre needle produces a more traumatic opening, with tearing and severe disruption of the collagen fibers, than a Quincke-style needle.[73] Similarly, the likelihood and extent of mechanical injury to nerve fascicles following intraneural injection during PNB also depend on needle-tip design. It seems intuitive that short-bevel needle types are less likely to penetrate the protective connective tissue layers of the peripheral nerves (epineurium, perineurium). Indeed, Selander and colleagues documented that a needle with a 45° bevel is much less likely to penetrate perineurium and inflict fascicular injury than a needle with a 15° bevel.[70,74,75] However, should a nerve fascicle become accidentally impaled during a nerve block procedure, the lesions induced by short-bevel needles may be more severe and take longer to repair than those induced by long-bevel needles.[23]

Surgical Factors

Surgical Positioning Requirements

Neurologic complications can occur following positioning for surgical requirements. Mechanisms of nerve injury related to surgery include traction, transection, compression, contusion, ischemia, and stretch. Regardless of mechanism, the final pathway of nerve injury may include the following factors: physical disruption of intraneural blood vessels causing patchy ischemia or hemorrhage; elevated intraneural venous pressures; endoneurial edema; impairment of axoplasmic flow; Schwann cell damage; myelin displacement; axonal degeneration; and Wallerian degeneration.[76] During surgery, patients are placed in positions they would not otherwise tolerate unless anesthetized. In addition, the physical forces required during surgery (eg, placement of prostheses) can be excessive, potentially stressing anatomical

PART 9

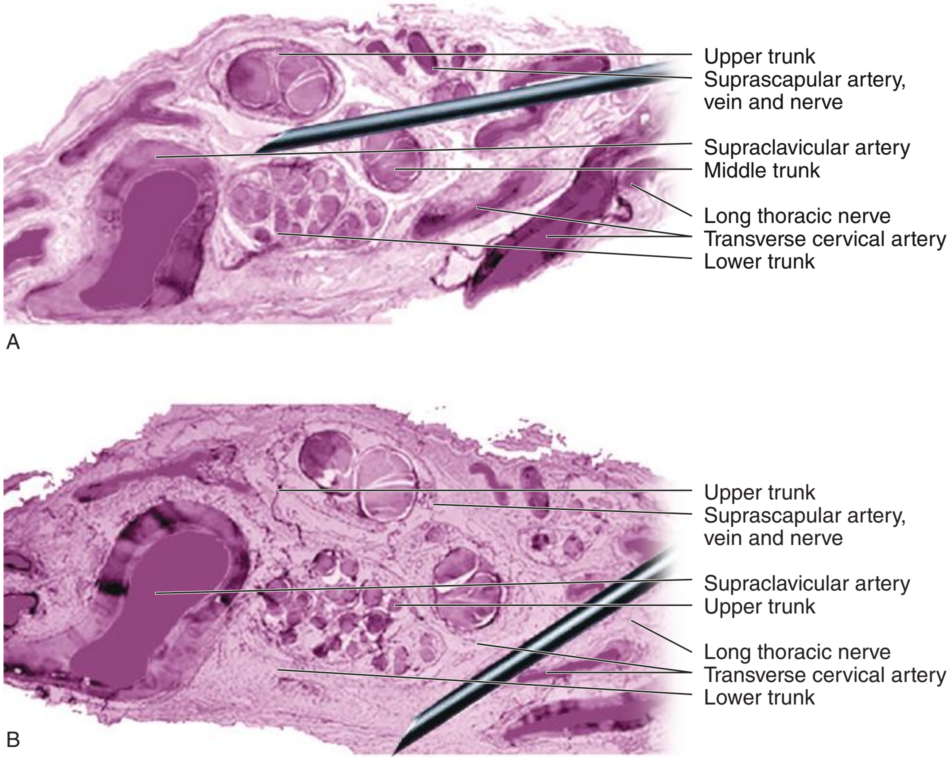

FIGURE 60–14. Overlap of the needle in the supraclavicular brachial plexus. If the neurostimulation needle pierces the nerve, as compared with the static images, the needle injures the fascicles. Different approaches are shown in **A.** and **B.** (Reproduced with permission from Reina MA: *Atlas of Functional Anatomy for Regional Anesthesia and Pain Medicine*. Heidelberg: Springer; 2015.)

structures remote from the surgical site, including the vertebral column. In a closed-claims analysis, 9 of 53 anesthetic-related brachial plexus injuries were related to intraoperative positioning (shoulder braces in the head-down position [three claims], patient's arm suspended on a bar [two claims], and other malpositions [four claims]). Only two claims were related to a regional anesthesia technique.[77]

Effects of the Pneumatic Tourniquet

Tourniquet inflation causes nerve damage by mechanical deformation or ischemia.[7,78,79] The main features of tourniquet neuropathy include weakness or paralysis, diminished touch, vibration and position sense, and preserved senses of heat, cold, and pain.[80] In an experimental model, tourniquet compression

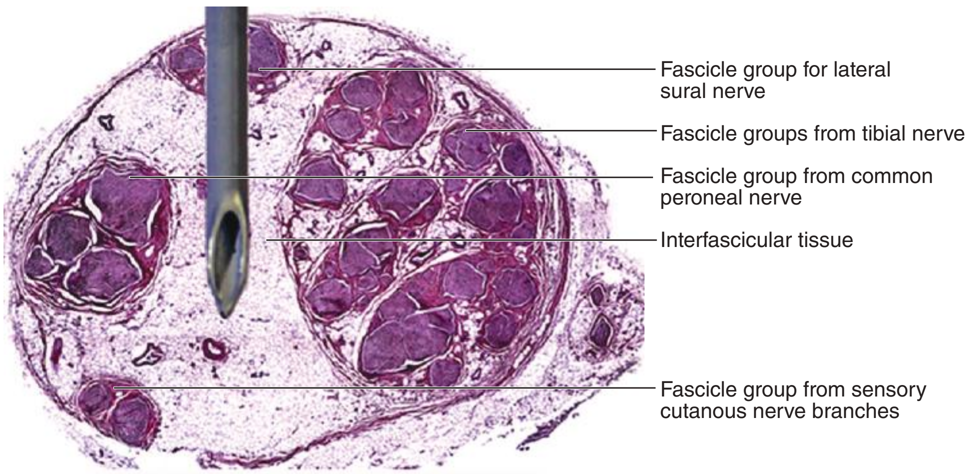

FIGURE 60–15. Overlap of the needle in the sciatic nerve, posterior approach. If the neurostimulation needle pierces the nerve, based on the static images, the needle injures the fascicles. Observe the difference in size between the needle and fascicles. If there is a large amount of interfascicular tissue, as occurs within the sciatic nerve, the risk of fascicular injury is reduced. resulted in increased vascular permeability, intraneural edema, and sciatic nerve degeneration.[82] For instance, tourniquet compression during meniscectomy surgery can lead to femoral nerve denervation and delayedfunctional recovery.[83,84] Wider tourniquets, using lower cuff pressures, and limiting the duration of inflation have been proposed as methods to prevent tourniquet neuropathy.[81]

Postsurgical Inflammatory Neuropathy

Patients with postsurgical inflammatory neuropathy typically present with a neuropathy that is delayed in onset and remote from the surgery. The neuropathies are focal and multifocal with pain and weakness. An inflammatory-immune mechanism is responsible, and there is evidence of axonal degeneration and lymphocytic-mediated inflammation.

Clinical Pearl

- Not all episodes of PNI are mechanical in origin.[43]

Patient Factors

Preexisting Neuropathy

A preoperative neurologic deficit or neural compromise, whether from nerve entrapment or metabolic, ischemic, toxic, hereditary, and demyelination reasons, may be present in patients presenting for surgery. Many of these preexisting neurologic conditions are subclinical, yet they may be associated with increased risk of PNI postoperatively.[85] For instance, often-overlooked, but common, cervical spondylosis may result in rough and irregular opening of the intervertebral foramen. The spinal nerve–nerve root complex becomes subject to repeated trauma, resulting in fibrosis reducing its mobility. The spinal nerve–nerve root complex is consequently at increased risk of traction injury during upper extremity movement and positioning.[1] The ulnar nerve may become entrapped in the cubital tunnel at the elbow or at the wrist. Risk factors for perioperative ulnar neuropathy include male gender, extremes of body habitus, and prolonged admission.[86,87]

Diabetic neuropathies are common and represent a wide range of clinical entities commonly resulting in distal symmetric sensory polyneuropathy. Asymmetric diabetic neuropathies comprise acute or subacute proximal motor neuropathy (often painful), cranial neuropathy, truncal or thoracoabdominal neuropathy (often painful), and entrapment neuropathy in the limbs.[88] Diabetic lumbar radiculopathy can present with pain radiating from the back to the lower limbs and mild weakness. There may be diffuse neuropathy with abnormal electromyography of paraspinal muscles and muscles innervated by the sacral plexus, gluteal, femoral, and sciatic nerves. Elderly patients with diabetes may have combined proximal and distal involvement, placing these patients at increased risk of PNI. Diabetic nerve fibers may be more susceptible to toxic effects of local anesthetics because of chronic ischemic hypoxia and because nerves are exposed to larger concentrations of local anesthetics related to decreased blood flow.[89] The occurrence of PNI following neuraxial blockade in patients with diabetic neuropathy has been reported as being higher (0.4%; 95% CI, 0.1%–1.3%) than the general population; however, its true clinical relevance is controversial as many of these patients are among the greatest beneficiaries of PNBs.[90]

Similarly, the actual risk of PNBs in the setting of severe peripheral vascular disease, vasculitis, cigarette smoking, and hypertension is not known.[47,91] Regardless, patients with these conditions could be more vulnerable to further ischemic insults during the perioperative period, similar to patients with alcohol-[92] and cisplatin-induced neuropathies.[93] Patients with multiple sclerosis and hereditary neuropathy may have subclinical preoperative neural compromise within the peripheral nervous system.[94]

Lumbar Spinal Canal Stenosis

Lumbar spinal canal stenosis may exaggerate a peripheral injury, adversely affecting physical recovery.[95] Spinal canal stenosis is a risk factor for common peroneal palsy following THA and may be significant in cases of paraplegia or cauda equina syndrome following epidural anesthesia.[96,97] Hebl documented new or progressive neurologic deficits following neuraxial anesthesia in patients with preexisting spinal canal stenosis or lumbar disk disease.[98] Overall, 10 (1.1%, 95% CI 0.5%–2.0%) patients developed new deficits or worsening of preexisting symptoms. The frequency of complications was higher in patients who had compressive radiculopathy or multiple central neuraxial diagnoses. However, it is likely that there were multiple etiological factors because deficits often correlated with the side of preexisting pathology or surgical procedure. A summary of anatomical, anesthetic, surgical, and patient factors contributing to PNI is listed in Table 60–3.

MONITORING NEEDLE-NERVE DISTANCE DURING PNBS AND PREVENTION OF COMPLICATIONS

While the risk of needle-nerve contact, intraneural needle placement, and intraneural injection has recently been questioned in small clinical series where overt injuries did not occur,[55–57,105] PNB-related nerve injuries continue to be reported. Susan MacKinnon's team has recently sternly warned against intentional intraneural injection based on their results of neurotoxicity following intrafascicular injections of local anesthetics.[36] This publication in one of the premier journals in the specialty (*Anesthesia and Analgesia*) specifically warned against the recent recommendations by some providers that intraneural injection is without risk and, in fact, can be beneficial for block quality.[106] It is important to note that MacKinnon's team's warning stems from decades of clinical practice of peripheral nerve repair surgery and over 350 scientific publications on the subject. Although the incidence of PNB-related nerve injuries is relatively uncommon, they are among the most common disabling complications related to administration of anesthesia and are likely underreported in the literature due to medicolegal and institutional reputation-related implications.[28] The potentially devastating impact of a severe nerve injury on the patient's quality of life mandates a systematic approach to mitigating the risk through standardization of injection techniques.

Mechanical Elicitation of Paresthesias

The association between the mechanical elicitation of paresthesias and consequent PNI has been the subject of debate for a long time.[17,57,107] While some large observational trials[17,108] have indeed implicated the elicitation of paresthesias as a risk factor for PNI, such an association has not been supported by others.[109–111] Moreover, the occurrence of paresthesias is not a sensitive sign of needle-nerve contact, as only 38% of patients experienced paresthesias during real-time visualization of needle-nerve contact.[112] Therefore, the absence of paresthesias during the performance of a nerve block does not reliably exclude needle-nerve contact, and nerve injury has been reported both in patients who have experienced severe paresthesias *and* in those experiencing no paresthesias during the PNB procedure. Regardless, a severe paresthesia, or pain on needle advancement or injection, may indicate intraneural needle placement and, when present, should prompt cessation of injection and needle repositioning.

If and how the use of deep sedation influences patients' perception and interpretation of the paresthesia as a symptom has not been studied. Likewise, ultrasound-guided PNBs often involved multiple injections of aliquots of local anesthetic in several different anatomical areas. It is not known how the spread of the local anesthetic during multiple-injection techniques and the incipient sensory blockade that occurs during the procedure may have an impact on the value of paresthesia as a safety monitor.

Peripheral Nerve Stimulation

Motor response to peripheral nerve stimulation relies on Coulomb's law, whereby a smaller current intensity (mA; or, more correctly, electrical energy) is required to elicit a motor or sensory response as the needle tip approaches the nerve.[113]

TABLE 60–3. Summary of anatomical, anesthetic, surgical, and patient factors contributing to perioperative nerve injury.

	Factor Potentially Contributing to or Relevant to PNI	Comment
Anatomical	Internal morphology of nerve, including connective tissue supporting fascicles and axons[1,63]	Epineurial tissue may offer protection from direct trauma and external compression
	Gross anatomical factors: location, course, relations, attachments, and relative mobility of nerves[1]	—
	Specific structures are at risk	Examples: ulnar nerve at elbow,[76,99] CPN [81,100,101]
Anesthetic	Type of anesthesia	EA and GA but not PNB were associated with PNI.[47] PNB not associated with PNI following TKA,[48] THA,[49] or TSA.[50]
	Insensate limb	Places nerves at risk from compression or stretching[76]
	Site of PNB: proximal at increased risk versus distal PNB	Not supported by clinical evidence
	Level of sedation during nerve blockade	Continues to be controversial. However, with objective monitoring of needle-nerve relationship and disposition of injectate (US, nerve stimulation, opening injection pressure monitoring), this issue is likely to become mute. For latest published recommendation, consult ASRA practice Advisory
	Mechanical trauma from needle, catheter, or injectate	—
	Direct local anesthetic toxicity	Time and concentration dependent; risk with intrafascicular greater than extrafascicular exposure[6,15]
	Neural ischemia	Secondary to compression,[76] vasoconstrictors,[19,20] intrafascicular injection,[54] tourniquet[82,103]
Surgical	Trauma: contusion, compression, retraction, traction, transection	
	Perioperative positioning[76]	
	Tourniquet: duration of inflation and pressure[81,104]	Associated with marked clinical deficits[80] and pathological changes on EMG[84]
	Swelling, plaster casts	
	Specific procedures have unique risk profile[95]	Risks of PNI following TKA,[48] THA,[49] and TSA[50] were 0.79%, 0.72%, and 2.2%, respectively
Patients	Preoperative neural compromise theoretically increases risk of PNI	Etiology includes entrapment, metabolic, ischemic, toxic,[93] hereditary, and demyelination causes[94]
	Lumbar canal stenosis	May be significant risk factor following neuraxial blockade[96,98]
Other	Inflammatory mechanism	Nonmechanical cause physically and temporally remote from PNB[43]

ASRA, American Society of Regional Anesthesia and Pain Medicine; CPN = common peroneal nerve; EA = epidural analgesia; EMG = electromyography; GA = general anesthesia; PNB = peripheral nerve block; PNI = peripheral nerve injury; THA = total hip arthroplasty; TKA = total knee arthroplasty; TSA = total shoulder arthroplasty.

The importance of avoiding injection when motor response is obtained by very low current intensity (<0.2 mA) and risk of nerve injury was first reported by Voelckel and colleagues.[114] Histological nerve injury occurred in 50% of the pigs when motor response was obtained at less than 0.2 mA, compared to no histological changes at 0.3–0.5 mA. Presence of motor response at less than 0.2 mA has been shown to be a specific but not sensitive indicator of intraneural needle placement in both animals[59,115,116] and humans.[55,117,118]

Peripheral nerve stimulation as a nerve localization technique is characterized by relatively low sensitivity but high specificity for predicting relative needle-nerve proximity, suggesting that such a response actually reflects needle-axon distance.[116] Both experimental data and clinical reports have shown that an evoked motor response may not be reliably elicited when the needle is placed in the immediate vicinity of the nerve or even intraneurally.[117,119] However, the same research indicated that when a motor response is elicited at low current intensity (eg,

< 0.5 mA, 0.1 ms), the needle tip is invariably positioned on the nerve or within the nerve. Importantly, peripheral nerve stimulation has withstood the test of time, as evidenced by the largest published data sets related to PNI,[67,68,108,120,121] all of which relied primarily on peripheral nerve stimulation to achieve safe and successful PNB.

Opening Injection Pressure Monitoring

The association between high injection pressures and intrafascicular injection was first described in 1979 by Selander[122] and subsequently studied in several animal models. In a dog model, an intentional intrafascicular injection was associated with both high opening injection pressure (≥25 psi) and corresponding clinical and histological nerve injury.[16] In contrast, extrafascicular injections were not associated with high injection pressures or with nerve injury. In another study in a dog model,[123] high injection pressure (≥20 psi) was also associated with intrafascicular injection as well as clinical and histological nerve injury, while intraneural but interfascicular injection was associated with low injection pressure (<10 psi) and no neurologic or histologic consequences.

During intraneural injection into the median nerves of pigs, Lupu and colleagues were unable to detect a significant correlation between the maximum pressure generated and clinical or histological nerve injury.[124] In this study, peak injection pressures were well below 25 psi, yet 7 of 10 nerve specimens had evidence of axonal damage on histological examination. In one case, axonal damage ensued following a maximum injection pressure of only 2.2 psi. Importantly, functional deficits measured up to 7 days postinsult were absent in all 10 pigs studied. More recently, in the first such study in human tissue, Orebaugh and colleagues reported that 100% of injections directly into the roots of the brachial plexus of fresh human cadavers resulted in high injection pressures (>30 psi), with one occurrence of injectate spread into the epidural space.[125] Importantly, analysis of the attained injection pressure curves indicated that all injections into the brachial plexus roots were associated with pressures greater than 15 psi.

Similar data on the injection pressure–nerve relationship were reported by Krol et al[126] in the peripheral nerves. In a study on pressure monitoring during injections for median, radial, and ulnar nerve PNBs in fresh human cadavers, the authors reported significant differences between intraneural and perineural injection pressures. Intraneural injection pressures showed low specificity but high sensitivity with intraneural needle placement.

Several studies have utilized injection pressure as a monitoring tool for intraneural (intraepineurial) injection during sciatic nerve block without complications.[117,127,128] Robards and colleagues studied 24 patients, who each received an injection inside their sciatic nerve at the level of the popliteal fossa. Injection pressures of less than 20 psi were recorded in 20 patients, while injection pressures greater than 20 psi were observed in the remaining 4 patients, prompting cessation of the injection; none of the patients suffered any neurologic dysfunction, suggesting that injections that occurred intraneurally were extrafascicular.[117]

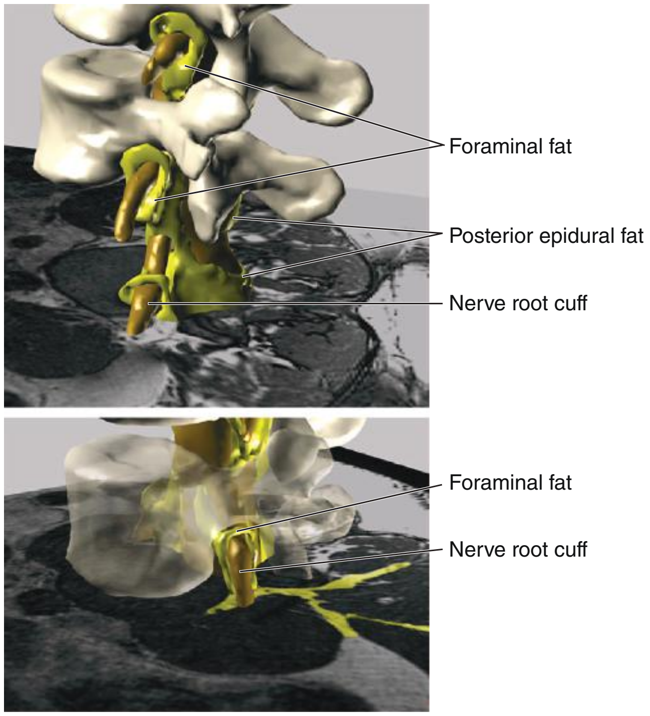

FIGURE 60–18. Three-dimensional reconstruction of MRI image of vertebrae, dural sac, epidural fat and foraminal adipose tissue. The yellow painted areas represent interconnections between the adipose tissues which can serve as potential paths for spread for injected solutions. (Used with permission from M.A. Reina.)

In a study of intraneural stimulation thresholds during ultrasound-guided supraclavicular brachial plexus blocks, Bigeleisen and colleagues reported a combination of high resistance to injection, low current stimulation, and pain on injection coincided in two patients with an intraneural needle placement that necessitated needle repositioning before completing the injection without complications.[57]

Beyond the risk of neurologic injury, high injection pressures can lead to several other unwanted effects or serious complications. For instance, Gadsden and colleagues reported that high injection pressure during lumbar plexus block carries a risk for epidural spread[129] (Figures 60–18 and 60–19). In this study, injection pressures greater than 20 psi during lumbar plexus block led to unacceptable risk of high-level epidural block, in some patients as high as the T3 level, necessitating early termination of the study for safety reasons.

More recently, Gautier et al reported that high injection pressure during interscalene injection can lead to substantial epidural spread of the injectate. Gautier's report offered an explanation for the precipitous respiratory and cardiovascular demise occasionally reported immediately following interscalane block, as well as suggested that injection force/pressure should be monitored during the injection process.

Assessment of injection pressure (resistance) during PNB is of increasing interest to clinicians and researchers.[130,131] This is not surprising, given that injection into densely packed nerve fascicles requires more force to initiate an injection (opening pressure) than perineural or intraneural-interfascicular injections into the loose perineural or perifascicular connective

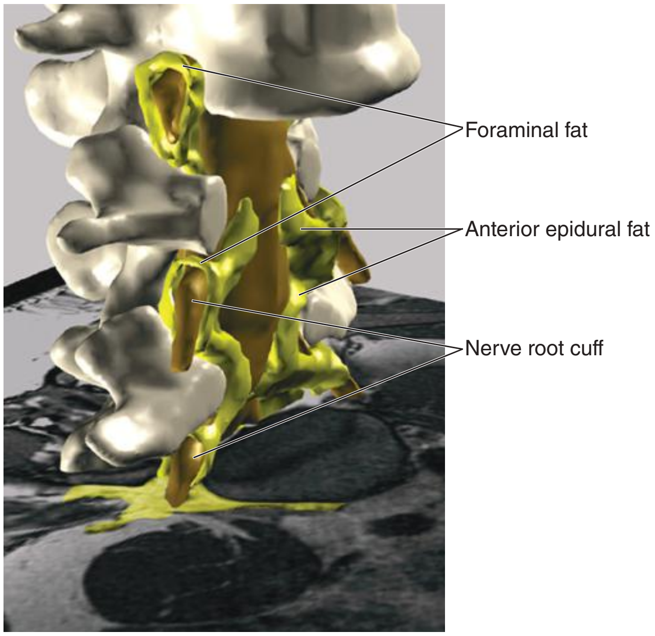

FIGURE 60–19. Three-dimensional reconstruction of vertebrae, dural sac, epidural fat, and foraminal fat from magnetic resonance images of a patient. We can see the potential pathway through the fat from epidural fat, foraminal fat, to other fat compartments, as the fat envelops the nerve roots outer the foraminal canal of the spine or the fat found among the muscular fascias. Two vertebral bodies were removed, allowing visualization of epidural fat in the anterior epidural space. (Used with permission from M.A. Reina.)

tissue (Figures 60–12, 60–14, and 60–15). In an attempt to standardize monitoring and documentation of nerve block procedures, a group of North American experts suggested documenting the resistance to injection as one of the elements of the standard clinical note.[132] However, two independent groups found that the clinician's accuracy in gauging injection pressure or the tissue being injected is limited when using a subjective, syringe feel technique, thus questioning the reliability of subjective assessments.[133,134] In the meantime, several means of monitoring injection pressures have been recommended.[131,135]

Taken together, the data to date suggest that high opening injection pressure can detect an intrafascicular injection, but not an intraneural interfascicular injection.[123,125] In the first study in patients, Gadsden and colleagues demonstrated that opening injection pressure with the needle tip at 1 mm away from the nerve roots of the interscalene brachial plexus was consistently lower than 15 psi (mean peak pressure 8.2 ± 2.4 psi). In contrast, opening injection pressure during needle-nerve contact was 15 psi or more (mean peak pressure 20.9 ± 3.7 psi) in 35 of 36 injections. In this study, aborting the injection when opening injection pressure reached 15 psi reliably prevented commencement of injection in 97% cases of needle-nerve contacts.[136] In addition, high opening injection may correlate well with other indices of needle-nerve contact, such as low current stimulation and paresthesia on injection.[57,117]

In a follow-up study, Gadsden et al used similar methodology to determine whether high opening pressure can also detect needle-nerve contact in peripheral nerves, such as the femoral nerve. The researchers reported that high opening injection pressure consistently detected (97%) needle-nerve contact and prevented an injection against the femoral nerve or fascicles. Moreover, their research suggested that high opening injection pressure can detect insertion of the needle into a wrong tissue plane. In this report, inability to inject local anesthetic with opening injection pressure below 15 psi detected 100% of instances of the needle placement on the wrong aspect of the fascia iliaca.

Further research is needed to determine the clinical benefits of routine injection pressure monitoring and actual "safe" opening injection pressure values for various nerve block procedures. Regardless, sufficient data exist to suggest that monitoring opening injection pressure during interscalene and femoral nerve blocks adds additional critical safety information that can influence clinical decision-making. Injection pressure monitoring may prove to be most useful for its negative predictive value for functional nerve injury, as no cases of clinically significant neuropathy have been reported in the literature with low injection pressures. Based on the available data, avoidance of high resistance and opening injection pressure greater than 15 psi appears to be a prudent strategy. At the very least, this is because during nerve block injections, the injections into the loose perineural connective tissue should never require more than 15 psi; therefore, when opening pressure of 15 psi is reached before injection actually occurs, the operator has an opportunity to reposition the needle away from the nerve before injection into possibly the wrong tissue space or vulnerable parts of the nerve (fascicles, needle-nerve contact).

Electrical Impedance

Electrical impedance monitoring measures the resistance to flow of an alternating current in an electrical circuit and could be added to the existing nerve stimulators. Electrical impedance is sensitive to changes in tissue composition, particularly water content. In a pig sciatic nerve model, Tsui and colleagues demonstrated that nerves have greater electrical impedance than the surrounding muscle and interstitial fluid due to their low water and high lipid content.[137] They found that the electrical impedance increased abruptly on entrance into the intraneural compartment relative to the extraneural compartment. The absolute value at which intraneural needle placement occurred could not be determined because of substantial variance within the data.

While electrical impedance monitoring appears promising to detect intraneural needle tip placement, it necessarily implies that nerve puncture must occur before a change in impedance is detected. There is also reasonably strong evidence that measurement of electrical impedance can differentiate intravascular from perineural placement of a needle when 5% dextrose in water is injected before performance of the block.[138] Based on the currently available data, impedance monitoring can differentiate between certain tissues, such as muscle and adipose/connective tissue. However, the variability of impedance measurements among different nerves or even the same nerves at different locations requires further research before any recommendations regarding the potential clinical applicability of this modality can be made.[139]

Ultrasound

Although ultrasound can detect intraneural injection, the widespread use of ultrasound guidance has not decreased the rate of PNI. In animals, ultrasound is sensitive enough to detect as little as 1 mL of injectate[61,115]; however, a much smaller amount of injectate is sufficient to injure the fascicles.[41] Regardless, no animal or human study to date has definitively demonstrated an association between real-time sonographic visualization of intraneural injection of local anesthetic and consequent functional (or otherwise clinically important) nerve injury.[56,57,105]

One reason may be that the resolution of the current ultrasound machines produced is not high enough to differentiate potentially hazardous intrafascicular injection from injection into the potentially more forgiving extrafascicular compartment. In addition, the ability to interpret such images is highly user dependent, and the ability to obtain high-definition, quality images varies among patients.[140] The use of ultrasound guidance has substantially facilitated the teaching and popularized the utilization of PNBs while decreasing the incidence of systemic toxicity of local anesthetics.[141] However, in studies to date, ultrasound has not decreased the incidence of PNI.[68,121,141] More information about ultrasound and monitoring is covered in Chapter 63.

Clinical Pearl

- The main mechanisms of PNB-mediated injury include mechanical trauma, ischemia, local anesthetic toxicity, and inflammation. The main source of PNB-mediated neurologic complications is likely mechanical fascicular injury or injection of local anesthetic into a fascicle, causing myelin and axonal degeneration.

SUMMARY

Neurological complications associated with PNB are multifactorial and associated with a range of perioperative processes and patient, anesthetic, and surgical factors, The anatomy of peripheral nerves is variable in location, structure, and susceptibility to injury. The main mechanisms of PNB-mediated injury include mechanical trauma, ischemia, local anesthetic toxicity, and inflammation. The main source of PNB-mediated neurologic complications is likely mechanical fascicular injury or injection of local anesthetic into a fascicle, causing myelin and axonal degeneration. The reported incidences of neurologic complications following PNB vary significantly, and interpreting the literature is difficult because of varied study methodologies, including differences in the neurological outcomes captured. Fortunately, most postoperative neurological deficits appear to resolve with time, and the incidence of serious long-term neurologic complications attributable to PNB is relatively uncommon.

Avoidance of deliberate trauma to nerves, including intraneural injection, is a key safety principle of regional anesthesia. At this time, there is evidence that objective monitoring of needle placement and injection, such as ultrasound, nerve stimulation, and opening injection pressure, can help detect needle-nerve contact and intraneural needle placement. Although, as with many other monitors in clinical practice (eg, pulse oximetry), there is no evidence these monitors can reduce incidence of neurologic complications, there are data suggesting that their combination should confer additional safety during PNBs. Careful patient selection, combined use of more than one nerve localization technique or monitor, avoiding injection with opening injection pressure, and limiting the number of needle passes and injections where appropriate will further decrease the risk and make the practice of PNBs less of an art than a science.

CHAPTER 61

Assessment of Neurologic Complications of Regional Anesthesia

James C. Watson

INTRODUCTION

Neurologic injury following regional anesthesia is an uncommon, but dreaded, complication that creates high levels of anxiety in the patient and anesthesiologist.[1–3] Most deficits will be sensory predominant and limited in duration and severity and can be handled with reassurance and appropriate follow-up. Discerning these cases from the rare complications that require emergent imaging, neurologic or neurosurgical consultation, or treatment is vital. This chapter focuses on recognition of postoperative neurologic complications, recognition of barriers to their recognition and evaluations, and an efficient, structured clinical approach to postanesthesia neurologic complications.

BARRIERS TO RECOGNITION OF POSTOPERATIVE NEUROLOGIC INJURY

Neurologic deficits in the postoperative setting may result from perioperative anesthetic procedures, surgical factors or iatrogenic injury, nerve compression occurring in the operative theater or during postoperative recuperation, or recognition of preexisting, but previously unappreciated, neurologic disease. While recognizing a neurologic complication immediately postoperatively would strongly implicate a perioperative complication (surgical, anesthetic, or positioning), there are many barriers to early recognition of perioperative neurologic complications. Postoperative sedation or analgesia may mask the complication.

Given expected neurologic symptoms postoperatively after regional anesthesia, patients and caregivers may presume that the patient's symptoms are block related. Patients therefore fail to complain of symptoms that may be unrelated to the block, and caregivers may fail to pursue reported symptoms because they presume they are block related, when in fact they may be distinct in distribution from the expected neurologic deficit. Patients also are unaware of what to expect postoperatively and may presume that postoperative symptoms are normal. Surgical dressings, drains, castings, and postoperative activity restrictions limit a patient's activity level postoperatively such that a postoperative neurologic deficit may be unrecognized until more normal activity levels can be resumed. Finally, patients often see the postoperative period as a single time epoch (the perioperative blur) instead of individual days where precise recognition of symptom onset would have been useful in fine-tuning the differential diagnosis regarding the cause of a postoperative neurologic complication. In a prospective study of postoperative ulnar neuropathy, some patients in follow-up reported that their symptoms were noted "immediately" following surgery, while the prospective evaluations had clearly documented an onset of signs and symptoms more than 48 hours after surgery, hence exonerating the surgical and anesthesia operative teams and implicating a postoperative convalescence complication.[4]

Given these barriers, only 77%–90% of sensorimotor and 20% of sensory nerve injury complications following total hip and knee arthroplasties were recorded during the procedural hospitalization.[5,6] Studies that only include early neurologic injury (less than 48 hours postoperatively) likely underestimate risk.[7]

Conversely, injuries recognized late often have (or perhaps more likely have) nonanesthetic/operative-related causes, including infection, postoperative inflammation, and consequences of immobilization or compression in the recovery period. The frequency of ulnar neuropathy in surgical cohorts more than 2 days postoperatively, for example, is similar to the frequency in medical patients hospitalized for the same duration.[8] These nonanesthetic/operative complications are often obvious as they occur in a distribution distinct from the surgical or anesthetic site, but when they do not, they further confuse the clinical picture.[5,6,9]

BARRIERS TO NEUROLOGIC EVALUATION OF A POSTOPERATIVE NEUROLOGIC COMPLICATION

Neurologic evaluation of an identified postoperative neurologic complication is limited by many of the same factors that interfere with recognition. Dressings, casting, drains, and activity restrictions limit the ability to perform a comprehensive neurologic examination and hence the ability to localize a nerve injury. Electrophysiologic testing has the same limitations in being able to adequately access muscles and nerves that may be discriminatory for localization. The operating room and specifically regional anesthetic and surgical approaches to various problems are generally foreign to most neurologists, and as such they may be unaware of which structures were most at risk or which mechanism of injury may be most probable from a given surgical or anesthetic technique. In many institutions, the anesthetic record may be unavailable to the consulting neurologist or when available formatted in a way that makes extracting usable information challenging for the nonanesthesiologist. Useful neurologic consultation is facilitated by direct and frank discussion between the anesthesia, surgical, and neurologic services.

Mechanisms of Injury

The potential mechanisms of anesthesia-related neurologic injury have been previously articulated[10]; however, the mechanism of injury is pertinent to workup and prognosis. Documentation and recognition of preexisting neurologic disease is important, as it may explain falsely localizing neurologic signs evident during the assessment of an apparent postoperative nerve injury. For example, hyperreflexia and a Babinski sign from preexisting cervical spinal stenosis may falsely suggest a central nervous system etiology in a patient with a peripheral nerve injury (PNI). Preexisting neurologic disease, while sometimes insufficient alone to cause clinical symptoms, limits the neurologic reserve of a nerve, meaning that it is more susceptible to developing clinical deficits from a second injury. This has been shown to be particularly relevant in postanesthesia nerve injuries, which are more common in at-risk nerves (the double-crush phenomenon).[11,12]

Similarly metabolic derangements that are frequently associated with peripheral neuropathy, such as diabetes mellitus, may have caused unrecognized PNI previously insufficient to have caused clinical symptoms, but sufficient to decrease the neurologic reserve and put a peripheral nerve at risk from a second hit. This likely explains the frequent association of diabetes as a risk factor for post–regional anesthesia neurologic complications. Preexisting systemic diseases associated with neurogenic impairment (diabetes with neuropathy, for example) likely also impair the potential for recovery following a PNI.

Vascular injuries are the most catastrophic of possible postanesthesia complications. Ischemic vascular injuries may be related to an embolic phenomenon, direct trauma, or vasoconstriction of the artery of Adamkiewicz causing an anterior spinal artery syndrome (ASAS) or from watershed ischemia related to hypotension or vasoconstriction. Notably, spinal cord blood flow is autoregulated, and hypotension would need to be extreme (mean arterial pressure < 50 mmHg) or occur in the setting of impaired autoregulation to cause a watershed spinal cord ischemic event.[10] Hematoma formation is critical to recognize, as it is treatable; it is devastating if unrecognized. Anticoagulation or a bleeding diathesis predispose to hematoma risk, and consensus recommendations exist for antiplatelet and anticoagulation use in the setting of regional anesthesia.[1]

Infectious processes can cause neurologic impairment from diffuse involvement (meningitis or a polyradiculopathy) or from abscess formation and compression (epidural abscess). Infectious processes are obviously treatable, but potentially devastating when unrecognized.

Direct neurogenic injury (spinal cord or peripheral nerve) from needle or catheter trauma, local anesthetic toxicity, or surgical trauma is variable in its severity and prognosis. Unfortunately, once it has occurred, there is little that can be done to intervene on or improve its natural history and likelihood of recovery.

Some peripheral nerve injuries are unrelated to the anesthetic or surgical intervention, although the anesthesiologist or surgeon are often erroneously blamed. For example, there would be appropriate concern for a neuraxial complication in a patient with an epidural catheter who awoke with a foot drop, but careful evaluation may show a simple peroneal compressive neuropathy at the fibular head unrelated to the epidural catheter. In addition, while compressive neuropathies can occur in the operative theater, they commonly occur during postoperative hospitalization and the period of convalescence.[4] Similarly, there has been increasing recognition that some postsurgical neuropathies are related to an inappropriate inflammatory response directed at the peripheral nervous system.[13] These are important to recognize as they are unrelated to a specific anesthetic or surgical intervention and are potentially treatable.

Neuraxial Complications

Neuraxial complications from anesthetic techniques include epidural hematoma (EH), spinal epidural abscess (SEA), ASAS, and direct cord trauma. Fortunately, these are very rare (EH, 2 per 100,000 to 1 per 140,000–220,000 neuraxial techniques[14–16]; SEA, 1 in 40,000 to 1 in 100,000 neuraxial anesthetics[2,3,17–19]), but they can be neurologically devastating if unrecognized. With all neuraxial complications, the longer it takes to diagnose and treat, the worse the prognosis is. As such, unless the neurologic deficit is distinctly limited to the distribution of a peripheral nerve susceptible to compression (ulnar or peroneal nerve), in the setting of a postoperative neurologic complication occurring following neuraxial anesthesia, the patient needs emergent advanced spine neuroimaging.

Magnetic resonance imaging (MRI) is the imaging modality of choice given its ability to localize the catheter (if an epidural catheter intervention), differentiate soft tissue structures, define neurogenic impingement of adjacent structures (cord or root[s]), and identify preexisting, but pertinent, comorbidities (such as spinal stenosis).[20–23] Computed tomography (CT) of the spine is sufficient to identify space-occupying lesions such as EHs or abscesses that require emergent neurosurgical intervention but lacks the soft tissue discriminatory sensitivity of MRI.[24] As such, CT would not be able to identify an intrinsic spinal cord injury such as ASAS or direct needle trauma. If MRI is not immediately available on recognition of a postanesthetic complication following neuraxial intervention, CT of the spine should be pursued. It will exclude a neurosurgical emergency (SEA or EH), but if the CT is negative without resolving neurologic deficits, MRI should be arranged as soon as possible to assess for an intrinsic cord process even if it requires transfer to a facility with more immediate resources.

Clinical Pearls

- In the setting of neuraxial anesthesia, any concern for spinal cord dysfunction requires emergent neuroimaging.
- MRI is the preferred imaging modality. However, imaging should not be delayed to arrange MRI or to obtain neurologic consultation. CT or CT myelography is acceptable as initial imaging to exclude a compressive lesion.

Epidural hematoma in the setting of neuraxial anesthesia generally presents more fulminantly (75% present with deficits maximizing over 24 hours) than when EH is related to anticoagulation or unknown causes.[25] However, 25% present with a slower evolution of symptoms, and, as such, the absence of a fulminant presentation should not reassure the anesthesia team. Emergent imaging should be pursued for any unexplained neurologic deficit following neuraxial intervention.

Typically, EH is heralded by localized spinal pain at the time of bleeding onset; however, anesthesia or analgesics frequently mask this. Patients progress from vague sensory symptoms below the site of the hematoma to a dense sensory loss below this level (a sensory level) that can be identified with cold (alcohol swab) or pinprick. A flaccid lower extremity paralysis develops concomitantly as the sensory deficits become more severe, and two-thirds of patients develop neurogenic bowel and bladder as a late complication.[25] Risk factors include anticoagulation (most common), antiplatelet usage, bleeding diathesis, an emergency operation, technically challenging epidural or spinal anesthesia, and older age.[14,25,26]

Spinal epidural abscess risk factors include diabetes, immunosuppression, systemic cancer, preexisting infection, intravenous drug abuse, alcoholism, trauma, and prolonged duration of epidural catheter maintenance.[27,28] Like EH, localized spinal pain is frequently the first sign for SEA, but this is often masked by postoperative analgesia. Fevers and elevated serologic inflammatory markers follow, but in patients who are immunosuppressed, these signs may not develop. The first neurologic sign is usually root irritation in a distinct radicular pain pattern. Neurologic deficits, including sensory level, paraparesis, and neurogenic bowel and bladder, develop below the level of the SEA with time, although a smaller percentage than with EH progress to frank paralysis before diagnosis.[29] SEA may also seed the leptomeninges, causing frank meningitis, with such patients showing signs of sedation, confusion, headache, nuchal rigidity, light sensitivity, and possibly seizure.

Anterior spinal artery syndrome results from a complication involving the anterior spinal artery causing ischemia to the anterior two-thirds of the spinal cord. This has been reported most commonly with neuraxial pain interventions, particularly transforaminal epidural steroid injections, but could conceivably occur with paravertebral procedures or neuraxial anesthetic procedures during which the needle is placed laterally in the interlaminar space. Mechanisms include embolization (particulate steroid, vertebroplasty cement, or atherosclerotic debris), dissection, vasospasm, or direct trauma to the artery of Adamkiewicz in the thoracolumbar spine or to the vertebral, ascending, or deep cervical arteries in the cervical spine.[10,30–35] Patients present fulminantly and progress rapidly to para- or tetraplegia, with a sensory level limited to pain and temperature modalities (spinothalamic tract dysfunction) with relative sparing of the posterior columns (proprioception). Hyperreflexia and spasticity will eventually develop, but in the hyperacute phase, spinal shock causes areflexia and a flaccid tone.

Direct needle trauma to the spinal cord with neuraxial anesthesia may be the most difficult of neuraxial complications to recognize. Needle insertion into the cord without injection may not cause pain. While pain would be expected with increased intramedullary pressure with injection into the cord, this may not be evident in a sedated patient. In addition, paresthesias are not uncommon with properly performed epidural anesthetics, so their presence alone does not indicate cord trauma.[36] ASA closed-claim data indicate these are most common in cervical spine procedures (including pain interventions) and are commonly associated with major morbidity or mortality.[37] The clinical manifestations and prognosis of direct needle trauma to the cord are variable depending on the site of injury and whether an injection was performed.

A diagnostic algorithm for the evaluation of postneuraxial anesthesia neurologic complications is presented in Figure 61–1.

TREATMENT AND PROGNOSIS OF NEUROLOGIC COMPLICATIONS OF NEURAXIAL PROCEDURES

The prognosis following a neurologic complication of neuraxial anesthesia can be dire: 5.5% of patients with EH and 15% with SEA die.[25,26,28,29,38] For EH and SEA, early recognition and intervention improve neurologic functional outcome. For EH, of those evacuated within 8–12 hours, 40%–66% make a complete recovery, whereas when evacuation occurs more than 12 hours after presentation more than half of patients are left with no improvement or severe residual neurologic deficits.[25,26,38] For SEA, functional recovery is significantly improved in those treated definitively before paralysis or in those with paralysis for less than 36 hours. Patients with paralysis for more than 48 hours at the time of

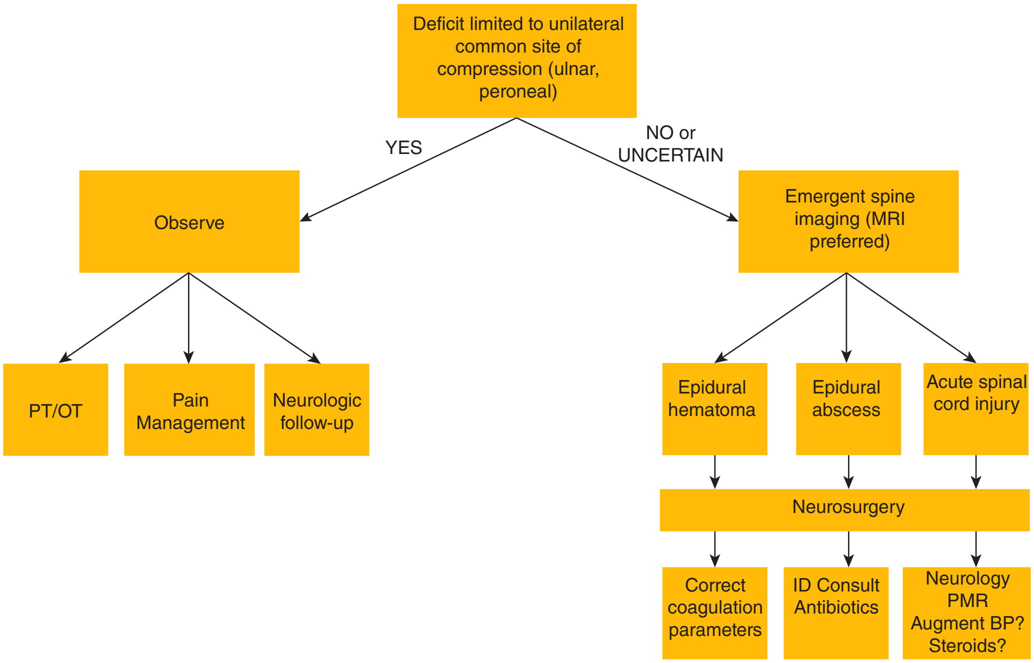

FIGURE 61–1. Diagnostic algorithm for neurologic deficit following neuraxial anesthesia. BP = blood pressure; MRI = magnetic resonance imaging; OT = occupational therapy; PT = physical therapy; ID = infectious disease, PMR = polymyalgia rheumatica.

evacuation are unlikely to recover.[28,29] Of all patients with SEA, almost one-third remain paralyzed.[29] The severity of the neurologic deficit at the time of evacuation predicts outcome, with more severe deficits at evacuation having a lower likelihood of a good recovery.[14,38] As such, for EH or SEA, the goal should be surgical evacuation as soon as possible after diagnosis, and neurosurgical consultation should be obtained immediately even if it requires transfer to a facility with more immediate access to neurosurgical services.

Clinical Pearls

- Diagnosis of a compressive lesion (EH or SEA) within or near the neuraxis demands emergent neurosurgical consultation for consideration of decompression.
- Outcomes for compressive lesions (EH or SEA) are dependent on the severity of neurologic impairment and the duration of symptoms at the time of neurosurgical decompression. Neurologic recovery is improved with early decompression (<8–12 hours from symptom onset in EH and < 36 hours from symptom onset for SEA) and with milder preoperative neurologic deficits.

Unlike EH and SEA, for which early intervention can improve neurologic outcome, there is no proven treatment for ASAS or for direct cord trauma. Almost two-thirds with ASAS do not improve, minimally improve, or die. Those that survive often require gait aides or a wheelchair for motor and sensory deficits and are left with neurogenic bowel and bladder functional deficits.[39–41]

Corticosteroids are frequently used in the setting of acute traumatic spinal cord injury. Treatment is with methylprednisolone at a dosage of 30 mg/kg over 15 minutes within 8 hours of the injury, followed by a maintenance infusion of 5.4 mg/kg/h for an additional 23 hours, having been shown in meta-analysis and Cochrane review to improve motor outcomes at 1 year postinjury.[42–44] Others have questioned the validity of this practice or the assertion that it has a benign side effect profile and thus concluded that the evidence is insufficient to recommend corticosteroids as a standard guideline to treat acute spinal cord injury.[45–48] Steroids are commonly empirically given intraoperatively with variable dosing in the setting of presumed neurologic injury. The role of corticosteroids in the setting of neuraxial complications of regional anesthesia is unknown. Considerations to their unproven use in this setting include that the postoperative neurologic complication may have been delayed in recognition, whereas the supportive data for traumatic spinal cord injury are in the hyperacute phase immediately following the injury. In addition, corticosteroids may increase the risk of postoperative infection or impaired wound healing.

Peripheral Nerve Injury

There are multiple risk factors for PNI in the setting of regional anesthesia (Table 61–1).[7,12,49–52] These include patient characteristics that make regional anesthetic procedures more challenging (body mass index) or lead to limited neurogenic reserve, putting nerves at risk from a second perioperative insult (double-crush syndrome), as well as perioperative factors.

There are three steps to evaluating a postanesthetic or operative peripheral nerve injury (PNI). (1) Is there an active process (hematoma or compartment syndrome) causing neurologic

TABLE 61-1. Risk factors associated with perioperative peripheral nerve injury.

Patient Characteristics	Perioperative Characteristics
- reexisting neurologic disease[a] - Diabetes[a] - Smoker - Body mass index (BMI) extremes - Elderly	- Paresthesia with needle placement - Pain with injection - Prolonged tourniquet time - Positioning: compression or stretch - Sedated patient during regional block - Prolonged hospitalization

[a]Double-crush syndrome.

impairment that can be treated? (2) Is the PNI surgically related? (3) Localize the neurologic deficit.

Similar to neuraxial complications, a bleeding complication (perineural or retroperitoneal hematoma) should be considered in patients whose perioperative interventions were performed or maintained while on anticoagulation or antiplatelet agents, in the setting of thrombocytopenia or bleeding diathesis, or if the procedure was performed in close proximity to vascular structures (particularly if the regional anesthetic was performed without ultrasound guidance). When considered, urgent imaging (CT or ultrasound) should be pursued. If identified, coagulation parameters should be corrected and, if severe, surgical evacuation to be considered.

The second issue to be considered is whether the deficit is iatrogenic, but surgically related. In a study of 1614 axillary blocks, surgical variables were thought responsible for 89% of the identified PNIs, most commonly related to direct trauma or stretch.[53] Of PNIs serious and lasting enough to require peripheral nerve exploration, 17% were for iatrogenically induced neuropathies, of which 94% of these were originally injured intraoperatively.[54] The surgical team would be aware of suspicious sutures, clips, or instrumentation placed intraoperatively, whether any nerve relevant to the patient's symptoms was directly at risk intraoperatively from direct trauma or transection, whether excessive traction was necessary, or whether there were intraoperative concerns raised regarding vascular structures, hemodynamics, or intraoperative monitoring. Cases with severe neurologic deficits and a concern for a potential surgical complication may require urgent surgical exploration. Patient care is facilitated by direct, nonincriminatory discussion between the anesthesia and surgical teams.

The final step in evaluation is localization and characterization of the PNI. This will help stratify which patients can be reassured and simply followed and which patients deserve early neurologic consultation and further workup. Localization is important as PNI is often in a distribution distinct from where the peripheral regional anesthetic was performed.[5,6,9] While this may exonerate the anesthesiologist, it still requires further assessment and arrangements for appropriate follow-up. If the clinical symptoms are sensory in nature (two-thirds of PNIs) and limited to the distribution in which the block or infusion was performed, the prognosis is excellent, and patients can be reassured that these symptoms should resolve over days to weeks.[12,55–57] Appropriate follow-up should be arranged to ensure symptom resolution. In the rare case where symptoms persist at follow-up several weeks after symptom onset, further neurologic and electrophysiologic assessment should be considered.

If symptoms are in a territory distinct from the distribution of the block, it should be determined if the clinical findings are limited to a nerve that is vulnerable to compression in the operative theater (most commonly, ulnar nerve at the elbow and peroneal nerve at the fibular head). If the symptoms are limited to this distribution, then the presumed mechanism of injury is neurapraxia, whereby there is localized myelin sheath dysfunction, usually from compression. Even if associated with weakness, these usually improve over a period of days to weeks and can be managed with reassurance and scheduled follow-up to direct further assessment if symptoms or deficits persist. Nerve conduction studies (NCSs) can identify conduction block indicating neurapraxia at a common site of compression in the acute postoperative period and can be useful to confirm compressive mononeuropathy if there is clinical uncertainty in the immediate postoperative period. Beyond this, electrophysiology is of limited utility in the immediate postoperative period (see the section on the role of electrophysiology).

If clinical signs and symptoms are limited to a single nerve distribution (mononeuropathy) but severe (defined as a neurologic deficit causing functional limitations), motor predominant, or progressing, then early (in-hospital) neurologic assessment is appropriate, as is consideration of active treatable causes (hematoma, compartment syndrome, inflammatory neuropathy) or of a surgical complication. If the PNI cannot be localized to an individual nerve territory and is diffuse or multifocal (or simply challenging to localize), then early neurologic assessment is appropriate, especially if associated with functional impairment or progressive signs and symptoms (Table 61–2).

TABLE 61-2. Indications for early neurologic consultation for PNI.

- Deficit(s) are
  - Severe
  - Functionally limiting
  - Progressive[a]
  - Multifocal of difficult to localize[a]
- Unexplained neurologic impairment outside the block region or region of common compression
- Associated severe pain (disproportionate to typical postoperative course)[a]
- Intervening return to neurologic baseline after surgery before development of PNI[a]

[a]These features may suggest an inflammatory cause of the postoperative nerve injury.

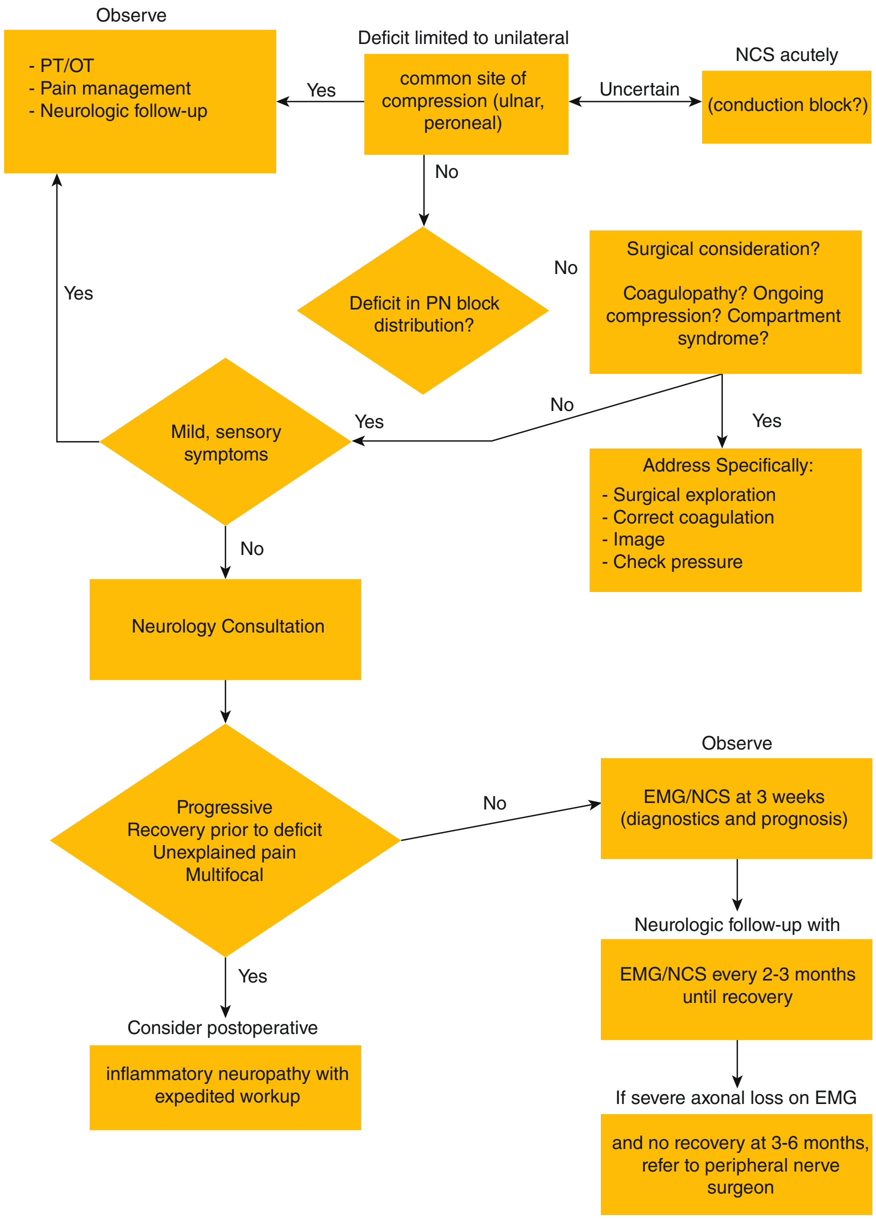

FIGURE 61–2. Diagnostic algorithm for peripheral nerve injury following regional anesthesia. EMG = electromyography; NCS = nerve conduction studies; OT = occupational therapy; PN = peripheral nerve; PT = physical therapy.

Clinical Pearl

- Once an active process that requires urgent intervention to remove something causing ongoing damage has been excluded, unfortunately there is nothing further that can be done that will materially affect the patient's neurologic functional outcome.

Figure 61–2 outlines an algorithmic approach to peripheral nerve injuries following regional anesthesia.

Postsurgical Inflammatory Neuropathies

There is an evolving literature on postoperative peripheral nerve deficits arising from an inflammatory-immune response triggered by the stressor of surgery or anesthesia that inappropriately targets the nerves of the peripheral nervous system.[13,58,59] Postsurgical inflammatory neuropathies are most often multifocal or diffuse within a limb, but mononeuropathies have been reported as well. Most commonly, they are recognized in a distribution distinct from the surgery or regional anesthetic, but they can occur within the same distribution, which makes discerning them from a direct surgical or regional anesthetic complication challenging. The temporal onset of the neurologic symptoms can be useful in distinguishing a postsurgical inflammatory neuropathy from other causes of PNI.

Classically, inflammatory neuropathies such as Parsonage-Turner syndrome (idiopathic brachial plexopathy),[60] diabetic or nondiabetic lumbosacral radiculoplexus neuropathy,[61] or postsurgical inflammatory neuropathies[13] have severe pain at their onset, developing hours to weeks after a stressor (surgery, anesthesia, vaccination, illness). The pain is usually poorly localized but often affects the proximal more than the distal limb. While it can be confused for a radiculopathy, back or neck pain is absent or limited and, in the context of a postoperative complication, mechanistically unlikely. Weakness will develop subsequently, although sometimes is not appreciated until pain has started to improve. The weakness is variable in distribution but usually multifocal within the limb. Sensory deficits accompany the motor weakness, but clinically the pain and weakness predominate the clinical picture, and there are notable functional limitations related to both.

In cases occurring during the postoperative hospitalization, perioperative analgesia and regional anesthesia (particularly infusion catheters) make recognition of the painful onset of an inflammatory neuropathy challenging. A contextual cue of an inflammatory cause of PNI in the immediate perioperative period would be unexplained, refractory severe postoperative pain distinct from that typically expected or a period of good pain control followed by the emergence of severe, unexplained limb pain. Similarly, severe pain in a region distinct from the surgery or regional anesthetic that progresses to neurologic deficits would suggest the possibility of an inflammatory postsurgical neuropathy, as would neurologic symptoms emerging, in a painful limb, after a period of documented return to baseline neurologic function postoperatively. When clinical features raise the possibility of an inflammatory postsurgical neuropathy, early neurologic consultation is appropriate (Table 61–2).

Clinical Pearl

- Clinical cues of a possible postoperative inflammatory neuropathy include atypical, unexplained, refractory postoperative pain; severe limb pain and emerging neurologic dysfunction after a period of documented return to baseline neurologic function postoperatively; and multifocal or difficult-to-localize, progressive postoperative neurologic deficits.

The cause of postsurgical inflammatory neuropathies is unknown, but biopsy of affected nerves in postoperative cases demonstrated perivascular lymphocytic inflammation consistent with a microvasculitis.[13] There is significant axonal loss with this form of PNI, and as such the recovery is protracted. The process is usually monophasic, and functional prognosis has been reported to be good (90% have good functional recovery within 3 years in Parsonage-Turner syndrome).[60] However, patients whose peak deficits are severe or located distally may have incomplete recovery. Given the pathologically proven inflammatory etiology, corticosteroids are mechanistically a rationale as a potential treatment (and often used in practice) but have not been evaluated in randomized controlled trials.

The Role of Electrophysiology in Evaluating Postoperative Nerve Injuries

Electrophysiologic studies consist of NCSs and electromyography (EMG). NCSs are electrophysiologic tests whereby a peripheral motor, sensory, or mixed sensorimotor nerve is stimulated and a recording made of the motor or sensory response. Normal values have been established using standard techniques to define abnormalities of the response amplitude (corresponding with axonal loss) and speed of transmission along a nerve (conduction velocity and distal latency, corresponding to demyelination). EMG is an electrophysiologic test whereby a small (commonly 26-gauge) concentric recording needle is placed into muscles innervated by different spinal roots, pathways through the plexus, and peripheral nerves to identify characteristic electrical changes of neurogenic, myopathic, or neuromuscular transmission disorders. Pertinent to PNI, by evaluating different muscles innervated by different peripheral nerves, EMG can help localize the site of a nerve injury as well as assess the severity of the injury and whether recovery is occurring. EMG and NCS are complementary to one another and are almost always performed together and in common practice are referred to collectively simply as EMG.

Nerve injury (from any source) can be categorized, and these categories are important prognostically (Table 61–3).[62] Most perioperative PNIs are related to compression or transient dysfunction of the myelin in a focal area of the nerve (neurapraxia)

TABLE 61-3. Classification of nerve injury.[62]

	Pathology	Electrophysiology	Prognosis
Neurapraxia	Localized myelin derangement - Axons intact Sensory > motor	Conduction block or focal slowing	Excellent
Axonotmesis	Axonal integrity and transport impaired → Wallerian degeneration - Endoneurial tube intact	NCS: low amplitude/absent motor and sensory responses EMG: denervation	Slow recovery
Neurotmesis	Axonal and connective tissue strata (neural tube) destroyed	Similar to axonotmesis, but no reinnervation on serial studies	No recovery

without any underlying damage to the nerve axon. Neurapraxia is evident on NCS, almost immediately after injury and symptom onset, as conduction block: There is normal nerve conduction distal to the site of injury and abnormal conduction proximal and through the site of injury. As such, NCS can be used in the acute perioperative period to identify patients with a common compression neuropathy (usually ulnar or peroneal) by identifying conduction block at a common site of compression. Because sensory fascicles of nerves are more susceptible to injury than motor fascicles, most perioperative compression neuropathies are sensory predominant. Patients with predominantly sensory symptoms or evidence of neurapraxia (conduction block) on NCS have an excellent prognosis, with expected complete recovery over days to a couple of months.

When the PNI results from more severe or longer duration compression, from direct trauma to the nerve (needle, scalpel, suture, staple, or cautery), or from ischemia, the injury affects not only the myelin sheath but also the axons within the nerve. When the axon is injured, axonoplasmic flow is disrupted such that the axon cannot be maintained and will degenerate (Wallerian degeneration). Because Wallerian degeneration occurs over a few weeks following axonal nerve injury, its effects on electrophysiologic testing are not evident in the acute perioperative period, and the extent (severity) of axonal injury cannot be determined acutely with electrodiagnostic testing. As such, in cases of functionally significant PNIs that are not purely sensory or localized to a single nerve territory, the role of electrophysiologic testing in the acute perioperative period is limited. It could be used to identify preexisting neurogenic injury, but the electrophysiologic effects of the acute axonal injury from the PNI will not be definitively identifiable until approximately 2 to 3 weeks following the injury.[63–65] Therefore, definitive electrophysiologic localization of a PNI and determination of injury severity cannot be determined electrophysiologically in the immediate perioperative period and can be done only 2 to 3 weeks postinjury. Importantly, while electrophysiologic testing localizes a lesion, defines its severity, and provides prognostic information, it does not elucidate the cause of the injury.

Clinical Pearls

- Electrodiagnostic studies (EMG and NCSs) may help confirm neurapraxia with conduction block or define preexisting disease when performed acutely.
- Axonal loss (prognostic) and the extent of a perioperative neurogenic injury will be better clarified by electrodiagnostic studies performed 3 weeks after injury.

The prognosis is much less favorable when there is significant axonal injury and degeneration compared to when there is only evidence of neurapraxia. Axonal injury can be classified depending on whether the injury is only to the axon (axonotmesis) or whether the connective tissue strata around the axon (the neural tube) has been damaged as well (neurotmesis), such as in transection.[62] Peripheral nerve axons will regenerate back through the neural tube to their original targets of innervation if the neural tube is intact (axonotmesis), but not in neurotmesis. A single EMG (here used collectively to refer to NCS and EMG) study cannot differentiate these categorizations of axonal injury (any other clinical or imaging test also cannot). However, in axonotmesis, serial studies performed every 2–3 months will show axonal regeneration and reinnervation into muscles adjacent to the area of injury initially and proceeding distally with time. Electrodiagnostic evidence of reinnervation and recovery will be evident before clinical recovery. In cases of more severe axonal injury (neurotmesis), no recovery will be seen on serial studies. When this occurs, patients should be referred to a peripheral nerve neurosurgeon for surgical options. Functional improvement is improved if surgical intervention occurs before 6 to 9 months following the time of injury.[54,63,66]

Clinical Pearl

- Nerve lesions that fail to resolve 3–5 months after initial neurologic evaluation should prompt consideration of consultation with a peripheral nerve neurosurgeon.

CONCLUSION

Perioperative central or peripheral nervous system injuries from anesthetic or surgical factors are fortunately rare, and most are sensory predominant and transient. Neurologic complications in the setting of neuraxial anesthesia require urgent evaluation as delay in the diagnosis of EH, epidural abscess, or spinal cord injury contributes to long-term morbidity. In the setting of peripheral nerve injuries, early neurologic evaluation should be considered when deficits are severe, progressive, or difficult to localize.

Unfortunately, once an active process has been excluded as the cause of a perioperative neurologic injury, there is nothing that can be done to improve the neurologic outcome. However, patient perceptions of a perioperative neurologic injury can be managed by providing adequate patient education, pain management, functional assistance through physical and occupational therapy, and scheduled follow-up with neurologic and electrophysiologic consultation if appropriate. All of these should be in place before dismissal for a patient with a significant perioperative nerve injury. For patients with only sensory symptoms, clinical follow-up to ensure symptom resolution should be arranged.

CHAPTER 62

Perioperative Nerve Injury Unrelated to Nerve Blockade

Steven L. Orebaugh

INTRODUCTION

Injury to the peripheral nerve is a relatively uncommon but potentially serious complication of regional anesthesia. The fear of neurologic injury with nerve blocks may influence some practitioners as well as patients to avoid peripheral nerve blocks. The mechanisms by which nerve blocks may cause neural injury, along with evaluation and management, are discussed in separate chapters. Instead, this chapter discusses other potential causes of nerve injury as a number of possible factors may result in neurologic symptoms in the perioperative period.

To understand how the perioperative period may adversely influence nerves in extremities, even in subtle ways, ulnar nerve injuries reported in the anesthesiology literature over a decade ago are discussed.[1,2] Injury to the ulnar nerve may be the most common nerve injury associated with general anesthesia and a significant source of litigation.[3] These injuries appear to occur in the absence of obvious trauma to the involved extremity and are often delayed in their clinical presentation. The compression, pressure, and stretch at the level of the elbow all likely play a role in the pathophysiology,[4,5] and preexisting neural compromise may also be a consideration.[6] The deleterious effects of stretching or pressure on the ulnar nerve in an anesthetized patient can be prevented by simple maneuvers; for example, placing the extended forearm in supination, rather than pronation, was found to protect an unconscious patient against ulnar nerve injury.[7]

However, when an extremity is itself the site of surgical intervention, many more additional factors may conspire to result in a nerve injury. Initially, the skin is subjected to harsh antimicrobial solutions after clipping or shaving. A pneumatic tourniquet is often placed for these surgeries, with resultant distal ischemia and high pressures on the nerves of the proximal extremity. The surgery itself offers potential for sharp, blunt, or thermal trauma, which could adversely affect nerves, both at the level of small, local cutaneous branches near the incisions and at the level of peripheral nerve trunks. Non-physiologic body position may occur and held for long periods, typically involving the surgical extremity, but sometimes the nonsurgical ones as well. In the postoperative phase, long periods of immobilization in nonphysiologic positions have the potential to cause nerve stretch or compression, as do the immobilizing devices, especially in the presence of unavoidable dependent, posttraumatic edema. Combined with the lack of perception due to general anesthesia or postoperative opioid analgesics, as well as any loss of sensation caused by local anesthetics, there is risk for neural dysfunction or injury or alterations in sensory function (Tables 62–1 and 62–2).

SURGICAL TOURNIQUETS

Use of the pneumatic tourniquet for extremity surgery has several benefits, including control of blood loss and improved operating conditions for surgeons (Figure 62–1). However, the pressure created by these devices may result in muscle or nerve injury, and recommendations for safe use (and safe technology) continue to evolve. The reported incidence of complications related to the use of a tourniquet in one report was as high as 0.15%.[8] However, other large databases have reported a lower risk of injury.[9,10] If electrophysiologic, subclinical abnormalities are used as a criterion for incidence of neurologic disturbances, incidence could be much higher, especially with high tourniquet pressures. For instance, Saunders et al noted electromyography (EMG) changes, lasting on average 51 days, in 62.5% of knee arthrotomy patients subjected to tourniquet pressures set at 350 to 450 mm Hg.[11] In a randomized, controlled study of 48 patients undergoing knee arthroscopy, Dobner et al noted denervation on EMG in 71% of cases with tourniquets, which

Positioning of extremities
Incision/sharp dissection
Retraction/stretch/pressure on nerves
Electrocautery thermal injury
Insertion of fixators or other sharp instrumentation
Limb/joint over-extension or malposition

had a mean cuff pressure of 393 mm Hg,[12] versus no such changes in the control group, which had no tourniquet for the surgery. These electrophysiologic abnormalities correlated with delayed return of function and lasted several months.

While ischemia may contribute to nerve injury with tourniquets, actual physical compression of tissue beneath the cuff may be the dominant insult.[13,14] In primate studies, the injury to the nerve was primarily found deep to, and at the edges of, the cuff. Such nerve injuries are characterized by microvascular injury, edema formation, disruption of myelin, and axonal degeneration.[14,15]

The inflation pressure, the duration of cuff inflation, and the shape and size of the cuff are all significant variables related to tissue trauma with pneumatic tourniquets.[16] Existing evidence is insufficient to establish exact recommendations for duration of inflation to ensure that no nerve damage will occur. In general, longer durations of inflation seem to predispose to a higher frequency of nerve injury; most animal studies suggested that 2 hours is a threshold beyond which cellular injury may become irreversible.[17–21] Beyond this time, periodic deflation and reinflation is recommended, although there is no clinical evidence linking this to improved outcomes.[22]

Tourniquet cuff pressures are frequently set at 150 mm Hg above systolic pressure for the lower extremity and 100 above systolic pressure for the upper extremity. However, absolute safe levels are difficult to determine. Simple prescriptions to inflate to 250 mm Hg for the lower extremity, with a somewhat lower level for the upper extremity, for up to 2 hours fail to take into account all of the potential hazards of these devices. If incorrectly incorrectly applied, inappropriate size, or utilization

TABLE 62–2. Potential postoperative causes of nerve injury.

Inflammatory changes/postsurgical inflammatory neuropathy

FIGURE 62–1. Application and use of a surgical tourniquet should take into account limb size, cuff size and shape, and arterial pressure. If possible, a limb occlusion pressure should be obtained, which allows for lower intraoperative cuff pressures while maintaining a bloodless field.

for prolonged duration are used, tourniquets can lead to neuropraxia.

The recognition that higher pressures cause more tissue damage and increase the risk of nerve injury[12,22,23] has led to a recommendation for use of lower tourniquet pressures in the past two decades, as well as an interest in finding ways to diminish blood flow to the surgical site while keeping cuff pressures low. Cessation of blood flow to an extremity is actually a function of the limb occlusion pressure (LOP), rather than simply of the systolic arterial pressure; the LOP is determined by the shape and size of the extremity and the site and conformation of the tourniquet, together with the arterial inflow pressure.[22] Interestingly, LOP does not vary directly with the arterial pressure. As such, it is unique for each patient and extremity, suggesting that it is difficult to prescribe universal recommendations for setting cuff pressure based on systolic blood pressure.

Existing pneumatic tourniquets may be modified to determine LOP.[24] Some newer tourniquet systems also feature an integrated means of determining LOP, as well as recommendations, based on this parameter, for setting the optimal tourniquet cuff pressure. Wider, contoured cuffs allow lower pressures as well, which may contribute to patient safety.[16,24]

While there are no specific guidelines suggested by orthopedic specialty societies for tourniquet management, other specialty societies have issued recommendations for safe use of these devices. Table 62–3 summarizes existing guidelines and recommendations from the literature. The Association of Surgical Technicians recommends that tourniquets on the lower extremity not be inflated higher than 100 mm Hg above the systolic arterial pressure for the lower extremity and 50 mm Hg above systolic pressure for the upper extremity—significantly lower than the prevailing wisdom might suggest.[25]

Some guidelines for tourniquet management rely specifically on the determination of the LOP. Setting the tourniquet at this level of pressure, with the addition of a safety factor (in case of

PART 9

TABLE 62–3. Recommendations for tourniquet inflation pressures.

AST[25]	UE: 50 mm Hg above the systolic pressure LE: 100 mm Hg above the systolic pressure
AORN[27]	Determine LOP; 40 mm Hg above LOP for an LOP less than 130 mm Hg, 60 mm Hg above LOP for LOP between 130 and 190 mm Hg, 80 mm Hg above LOP if LOP more than 190 mm Hg
Crenshaw[57]	50-75 mm Hg above systolic pressure for UE 100-150 mm Hg above systolic pressure for LE
Noordin[22]	Determine LOP; base the cuff pressure on level of LOP
Estersohn[58]	90-100 mm Hg above systolic pressure for LE

blood pressure elevation during the case), allows for an overall lower cuff pressure to control blood flow, with a potentially beneficial effect on patient safety. In one series, when LOP was utilized in patients undergoing anterior cruciate ligament reconstruction, tourniquet cuff pressures were dropped by over half compared to the use of standard inflation pressures based solely on systolic blood pressures.[26] The American Society of Operating Room Nurses (AORN) recommends determination of LOP, with addition of a variable degree of pressure, depending on the patient's systolic blood pressure (greater pressures are added for higher patient blood pressures).[27] Some authors in the orthopedic literature have suggested the use of LOPs as well to favorably affect patient outcomes[22] (Table 62–3).

Since transmission of pressure to deep tissues is related to the quantity of tissue located directly beneath the cuff,[28] the pressure/shearing effect of the tourniquet is mitigated by a greater thickness of tissue between the cuff and the nerve. This explains the need for higher cuff pressures in larger extremities to control blood flow into the surgical field and the recommendation for use of lower cuff pressures in the arm of adults (as compared to the leg) and in pediatric patients.[29] In general, the lowest pressures that are effective for control of blood flow, coupled with the shortest duration possible, are likely to be safest for the patient.[23] The use of LOPs, which take into account limb size and shape, as well as prevailing arterial inflow pressures, allows for this.

Tourniquet-related nerve injury due to the pressure imparted directly by the cuff on the underlying nerve (as opposed to the distal ischemic insult) frequently results in a greater degree of motor loss than sensory loss, hence the historic term *tourniquet paralysis*.[10] In the lower extremity, tourniquet injury most commonly affects the sciatic nerve, while in the arm, the radial nerve appears to be most vulnerable.[23] Fortunately, many of these injuries resolve over time,[30] and permanent injury is uncommon. It should also be noted that, while pneumatic tourniquet use has been the subject of much research, the combination of shear stress and ischemia from the tourniquet, coupled with temporary disruption of normal nerve physiology by local anesthetic administration, has not been sufficiently studied.

POSTSURGICAL INFLAMMATORY NEUROPATHY

Another potential cause of nerve injury that may occur in the wake of surgery, with no apparent relationship to peripheral nerve block, is postsurgical inflammatory neuropathy (PSIN). In this pathologic entity, surgical trauma with tissue damage results in immune stimulation, which is primarily expressed as inflammation of neural tissue.[31,32] This inflammatory nerve dysfunction may occur in the region of the surgery, at a distant site in the same extremity, or at a completely remote site in the body. PSIN may even develop diffusely at multiple sites. Affected nerves show evidence of edema, microvascular derangements, myelin injury and loss, and axonal injury, with influx of acute inflammatory cells.[31] Biopsy is required for definitive diagnosis of PSIN; however, magnetic resonance imaging is supportive of the diagnosis and, together with clinical evidence, may allow for presumptive diagnosis and therapy[31] (Figures 62–2 and 62–3). Treatment with corticosteroids is helpful in many cases, and while most episodes of PSIN improve gradually over time, permanent sequelae have been reported.[33]

In 2011, Staff et al. summarized the most extensive database of cases of PSIN to date.[31] A variety of different surgical types were involved, including orthopedic procedures, general surgery, and even dental cases. None of the 33 patients had received peripheral nerve blockade. The typical presentation was pain and weakness in the territory of the affected nerves; sensory changes were common as well. Twenty-one of the cases were confirmed by biopsy. The authors noted that nerve injuries may sometimes be inappropriately ascribed to mechanical causes during surgery, when immune mechanisms are actually the unsuspected cause, and that PSINs may underlie such symptoms of neural compromise much more commonly than is recognized.[31,32] Given this potential, serious nerve injuries should likely be evaluated, not only with EMG and nerve conduction studies, which are relatively nonspecific unless a level of injury can be clearly established, but also with magnetic resonance neurography, which may provide additional information regarding the severity, extent, and location of the neural insult(s).[34] If a diagnosis cannot be established, nerve biopsy should be considered.

SURGICAL CAUSES OF NERVE INJURY

Given the invasive nature of surgical procedures, unintended injuries to anatomic structures are not surprising. Injury to nerves from surgical trauma, whether by sharp dissection or insertion of surgical or fixation devices, is a potential risk of many types of procedures. For instance, in shoulder surgery, injuries may occur to the suprascapular, axillary, musculocutaneous, subscapular, or spinal accessory nerves from either open or arthroscopic procedures.[35–38] Femoral nerve injuries in the perioperative period are commonly related to ischemia from stretch or retraction occurring during abdominal or pelvic procedures.[39] During hip arthroscopy, sciatic nerve injury may occur and is

FIGURE 62–4. Hip arthroscopy surgery requires forceful distraction of the operative leg, which poses a risk for sciatic nerve injury.

most closely related to the force of distraction on the operative leg[40] (Figure 62–4). During hamstring tendon harvest for autograft anterior cruciate ligament reconstruction, injury to the infrapatellar or sartorial branch of the saphenous nerve, with consequent sensory deficits, occurs in as many as 74% of patients.[41] Fixation devices, such as K wires, may inadvertently cause trauma to nerves as well.[42,43] Aberrant anatomy may result in unpredictable positions of nerves, putting them at risk during otherwise-routine procedures.[44]

Positioning for Surgery

Surgical positioning in the operating room may play a crucial role in nerve injury and should be considered when new nerve symptoms are reported, especially when positions other than supine are utilized. Prone position, lithotomy, and severe degrees of Trendelenburg are all known to predispose to nerve injury.[45] In addition, the lateral position is more likely to result in brachial plexus nerve injury than beach-chair position for shoulder procedures[46] (Figure 62–5). In the sitting position, prolonged cases have resulted in neuropraxia to either or both sciatic nerves, including sensory loss and disabling motor weakness[47] (Figure 62–6). Lateral tilting of the head in the sitting position may result in stretch of the brachial plexus, with the potential for nerve compromise as well.[48,49]

FIGURE 62–5. Lateral position for shoulder surgery is associated with a higher incidence of nerve injury.

FIGURE 62–6. The beach-chair position, when adopted for prolonged periods, may result in sciatic nerve compression injury.

Postoperative Immobilization

The positioning of the extremity after an operation may also contribute to nerve compromise. While immobilization in a relatively neutral position at the hip, knee, and ankle is usual for lower extremity procedures, this is not the case for the upper extremity. In orthopedic procedures for hand, wrist, shoulder, and some elbow conditions, holding the extremity in flexion at the elbow for long periods, in a sling or shoulder immobilizer, helps to protect the injured extremity and reduce the severity of postoperative edema. However, prolonged immobilization in flexion, sometimes for weeks, may be deleterious to the ulnar nerve, which is placed in a degree of stretch[5] (Figure 62–7). The combination of this position with relative immobility and the inevitable postoperative edema that occurs may predispose to ulnar entrapment, compression, and sulcus ulnaris syndrome.[50]

Another concern in the postoperative period is the immobilizing device itself. Splints, casts, and braces, if applied without regard to underlying nerves, may present a hazard.[51] Even when placed with care for potential pressure or constriction, the unavoidable edema that occurs in the aftermath of surgical trauma, especially with dependency, may serve to make a comfortable device quite tight (Figure 62–8). Compartment syndrome may result when such appliances completely extinguish blood flow to the underlying tissues,[52] and this is discussed more fully in Chapter 50.

However, even in the absence of such severe circulatory embarrassment, pressure over a nerve, with resultant palsy, may occur.[51] One example is the potential for a knee brace, placed after anterior cruciate ligament reconstruction, to impinge on the peroneal nerve over the neck of the fibula, with resultant numbness over the top of the foot and weakness of dorsiflexion[53] (Figure 62–9). Shoulder immobilization devices, with snug

FIGURE 62–7. Shoulder surgeries and other upper extremity procedures usually require a prolonged period of immobilization in flexion at the elbow, in slings or other devices. This may result in ulnar nerve dysfunction or injury.

straps over the distal extremity or circular cutouts that lie at the base of the thumb, may lead to sensory changes in the tip of a digit, which typically resolve rapidly when this constriction is addressed, as experienced in my own practice.

Prolonged Skin Pressure

Pressure over a digital or more substantial nerve may lead to sensory or motor deficits in the territory of that nerve. However, prolonged contact with a patch of underlying skin caused by an immobilizing splint, brace, or cast may lead to sensory deficits in that region, simply as a result of long-term compression of sensory receptors in the skin.[54] Such abnormalities of sensation would not be expected to cause changes in either EMG or nerve conduction studies. While these effects on nerve function are not, of themselves, related to anesthesia interventions, the mere presence of a protracted period of sensory alteration due to peripheral nerve blockade (whether applied by the anesthesiologist or the surgeon) may make it difficult for the patient to perceive the pressure caused over skin or a subcutaneous nerve, contributing to the potential for injury or temporary dysfunction of these tiny nerves. Of particular concern is heel ischemia and ulceration after prolonged heel rest in patients who have received sciatic nerve block.[55] Thus, careful home-going instructions and follow-up of such patients is essential.

FIGURE 62–8. Postoperative casts or splints should be placed with care to avoid firm apposition against skin or pressure over bony prominences or superficial nerves, with consideration of likely edema of the affected extremity.

FIGURE 62–9. During placement of a knee brace after surgery, care should be taken to avoid a tight fit or pressure directly over the common peroneal nerve, which may result in sensory or motor loss in the foot.

Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS) after surgery is usually the result of the traumatic event itself, although it may also occur as a result of nerve injury, so called type 2 CRPS.[56] While this entity usually manifests with pain and limb dysfunction, sensory disturbances may be primary symptoms early in its course.[50] Severe cases may result in atrophy and weakness as well.[56] Distinguishing early CRPS from nerve injury can be accomplished with careful neurologic exam, quantitative sensory testing, the quantitative sudomotor axon reflex test (QSART), and appreciation of other changes that come with this disease. Sensory disturbances in CRPS will not likely be limited to the territory of a single peripheral nerve, as is expected with peripheral nerve injury.[57]

POSTOPERATIVE EVALUATION

Determining the etiology of a nerve injury requires integration of the physical examination, electrophysiology or imaging. When all diagnostic modalities are carefully scrutinized, the majority of postoperative nerve injuries in fact are caused by factors other than regional technique.[58] The utility of EMG as a test depends on both patient tolerance of the procedure and the skill and experience of the examiner.[59] Physical findings may add further specific information about the level of the actual nerve lesion.

For instance, in femoral nerve injury, the level of the lesion may be reliably determined to be above or below the inguinal ligament by assessing whether the hip flexor muscles (iliacus and psoas muscles), which are innervated high in the pelvis, are affected, along with the knee extensors, which are innervated in the thigh itself, below the level of arborization of the nerve.[60] A lesion that occurs proximally, in the pelvis—such as an inflammatory lumbar plexopathy[61]—with weakness of hip flexion as well as knee extension cannot be related to structural damage to the femoral nerve caused by a peripheral block at the level of the femoral crease. Similarly, a sciatic nerve injury with loss of hamstring innervation could not be attributable to trauma from a popliteal/sciatic block, which occurs at a significant distance below the release of branches to these muscles.

SUMMARY

There are numerous potential causes of neurologic injury or dysfunction in the perioperative period. Anesthesiologists should assume the leading role in establishing the cause of postoperative neurologic injury to guide therapy as well as for medicolegal reasons. This requires a multidisciplinary approach with detailed motor and sensory examination, neurology or physical medicine referral, appropriate electrophysiologic testing, as well as imaging, as detailed in Chapter 61.

Jeff Gadsden

INTRODUCTION

The incidence of complications from general anesthesia has diminished substantially in recent decades, largely due to advances in monitoring of the respiratory and cardiovascular function during administration of anesthesia.[1] The use of objective monitors such as pulse oximetry, capnography, electrocardiography, etc., allow practitioners to timely identify changing physiologic parameters, intervene rapidly and appropriately, and guide their therapeutic decisions.

The practice of regional anesthesia has traditionally suffered from a lack of objective monitors that aid the practitioner in more objectively monitoring the needle-nerve relationship and preventing neurologic injury. The practice of peripheral nerve blocks traditionally relied on subjective end points to gauge the potential risk to the patient. This is changing, however, with the introduction and adoption of standardized methods by which to safely perform peripheral nerve blocks with the minimal possible risk to the patient. For example, instead of relying on feeling "clicks," "pops," and "scratches" to identify needle-tip position, practitioners can now monitor the interaction at the needle–fascial layers using ultrasonography. Likewise, quantifying the minimal current intensity and resistance to injection can be used to gather additional data useful in clinical decision-making to minimize the risk of needle placement into an unwanted tissue plane, intravascularly, or into vulnerable anatomical structures intraneurally. Recent advances in monitoring therefore may reduce the three most feared complications of peripheral nerve blockade: nerve injury, local anesthetic toxicity, and inadvertent damage to adjacent structures ("needle misadventure").

Objective monitoring, and the rationale for its use, is discussed in the first part of this chapter. The latter section focuses on documentation of nerve block procedures, which is logical record keeping of the objective information obtained by the monitors. Objective and robust documentation of *how* a nerve block was performed has obvious medicolegal implications and provides a useful database to guide advances in safety and efficacy.

MONITORING

Available Means for Monitoring Needle-Nerve Relationships

Monitors, as used in the medical practice, are devices that assess a specific physiologic state and warn the clinician of impending harm. The monitors discussed in this chapter include those for nerve stimulation, ultrasonography, and monitoring injection pressure. Each of these has its own distinct set of both advantages and limitations and each is best used in an additive, complementary fashion (Figure 63–1) to minimize the potential for patient injury, rather than just relying on the information provided by one monitor alone. There is sufficient evidence-based information that the combination of all three monitors is likely to produce the safest possible process during the practice of peripheral nerve blocks.

Another, pharmacologic monitor, that many clinicians utilize regularly is the use of epinephrine in the local anesthetic. There is some evidence to support this practice as a means of improving safety for most patients during peripheral nerve blocks. First, it acts as a marker of intravascular absorption. Intravenous injection of 10 to 15 μg epinephrine reliably increases the systolic blood pressure more than 15 mm Hg, even in sedated patients or patients treated with β-blockers.[2,3] The recognition of this increase may allow for early detection of intravascular injection and permits the clinician to promptly halt the injection and sharpen vigilance for signs of systemic toxicity. Second, epinephrine decreases the peak plasma level of

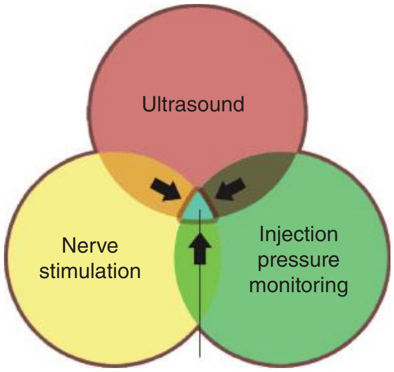

FIGURE 63–1. Three modes of monitoring peripheral nerve blocks for patient injury. The overlapping area of all three (blue area) represents the safest means of performing a block.

local anesthetic, resulting in a lower risk for systemic toxicity.[4,5] Concerns regarding the vascular effects of epinephrine, vasoconstriction and nerve ischemia have not been substantiated, and in fact concentrations of 2.5 µg/mL (1:400,000) have been associated with an increase in nerve blood flow, likely due to the predominance of the β-effect of the drug.[6] Therefore, epinephrine can enhance safety during administration of larger doses of local anesthetics without docummented risk of limb ischemia and neurologic demise.

Of note, the use of ultrasound guidance during peripheral nerve blocks has significantly decreased the risk of severe systemic toxicity of local anesthetics for several reasons. This is most likely because ultrasound guidance has allowed for decreased volume and dose of local anesthetic to accomplish most nerve block procedures by monitoring its spread. In addition, observation of the needle path on ultrasound, avoidance of intravascular placement, and confirmation of the spread of local anesthetic in the tissues all add to greater safety with ultrasound-guided regional anesthesia.[7]

Nerve Stimulation

Neurostimulation largely replaced paresthesia as the primary means of nerve localization in the 1980s. However, its utility as a method of precisely locating nerves has been recently challenged by data of several studies that demonstrated that evoked motor response (EMR) may be absent despite intimate needle-nerve contact as confirmed by ultrasonography. Indeed, in a number of needle-nerve contacts or even intraneural needle placement, unexpectedly high current intensity may be required to elicit an EMR.[8–10] For instance, in some instances an EMR could be obtained only with a relative current intensity of more than 1 mA even with intraneural needle placement as seen on ultrasound.

There are probably multiple factors that contribute to the explanation for this phenomenon. The most important factor is most likely the shunting of the electrical current alongside the path of least resistance (impedance). In other words, even when the needle is in the immediate vicinity of the nerve, the electrical current may not necessary chose to travel toward the nerve but rather travels alongside the path of least resistance to exit via the skin electrode. An additional factor may include the nonuniform distribution of motor and sensory fibers in the compound nerve.

This, however, does not mean that electrical stimulation of peripheral nerves is obsolete in an era of ultrasound guidance. For instance, data from several animal and human studies suggested that the presence of a motor response at a very low current (ie, < 0.2 mA) is associated with intraneural needle-tip placement and intraneural inflammation after an injection in this condition (Table 63–1). Voelckel et al. reported that when local anesthetic was injected at currents between 0.3 and 0.5 mA, the resulting nerve tissue showed no signs of an inflammatory process, whereas injections at less than 0.2 mA resulted in lymphocytic and granulocytic infiltration in 50% of the nerves.[11] Tsai et al. performed a similar study investigating the effect of distance to the nerve on current required; while a range of currents were recorded for a variety of distances, the only instances in which the motor response was obtained at less than 0.2 mA were when the needle tip was placed intraneurally.[12]

Bigeleisen et al. studied 55 patients scheduled for upper limb surgery who received ultrasound-guided supraclavicular brachial plexus blocks. The authors set out to determine the minimum current threshold for motor response both inside and outside the first trunk encountered.[13] They reported that the median minimum stimulation threshold was 0.60 mA outside the nerve and 0.3 mA inside the nerve. However, EMR was not observed with stimulation currents of 0.2 mA or less outside the nerve, whereas 36% of patients had an EMR twitch at currents less than 0.2 mA with the intraneural needle placement.

To further refine this relationship, Wiesmann and colleagues applied an electrical current to the brachial plexus of pigs at three different positions (intraneural, with the needle contacting the epineurium, and at 1 mm from the nerve) while varying the pulse duration (0.1, 0.3, and 1.0 ms).[14] The minimum threshold current to elicit a motor response was identical between the intraneural and needle-nerve contact positions, and both were significantly lower than the position 1 mm away. Pulse duration had no effect on the minimal threshold current. These authors concluded that a motor response at less than 0.2 mA (irrespective of pulse duration) indicated *either* intraneural or needle-nerve contact. This is important because it has been established that, even in the absence of puncture of the epineurium, even forceful needle-nerve (epineurium) contact results in inflammation and potential for nerve injury.[15,16]

Taken together, the available data suggest that the sensitivity of a "low current" to elicit an EMR in a potentially dangerous needle-nerve relationship (intraneural/epineurial placement) is about 75%.[17] However, the specificity of the EMR when present at less than 0.5 mA nears 100%. In other words, a motor response is elicited by a low-intensity stimulating current (eg, < 0.2 mA according to Voelckel et al[11]), the tip is always intraneural or intimately related to the epineurium. Therefore, the utility of the nerve stimulator is obvious: Unexpected appearance of an EMR at 0.5 mA indicates a dangerous needle-nerve relationship (eg, needle-nerve contact) and may allow the operator to stop the needle advancement before the needle enters the nerve.

TABLE 63-1. Summary of recent studies of nerve stimulation current and needle-tip position.

Study	Subject	Method	Findings
Voelckel et al (2005)[11]	Pigs (*n* = 10)	• Posterior sciatic nerve blocks performed bilaterally • Two groups - Injection after EMR at 0.3–0.5 mA - Injection after EMR at < 0.2 mA • 6 hours postinjection, sciatic nerves harvested for histologic analysis	• Normal, healthy appearance of nerves in high-current group • 50% of nerves in low-current group showed evidence of lymphocyte and polymorphic granulocyte sub-, peri-. and intraneurally • One specimen in low-current group showed gross disruption of perineurium and multiple nerve fibers
Tsai et al (2008)[12]	Pigs (*n* = 20)	• General anesthesia • Sciatic nerves exposed bilaterally • Current applied with needle at various distances from 2 cm away to intraneural • Two blinded observers agreed on minimal current required to obtain hoof twitch • 40 attempts at each distance	• Sciatic nerve twitches only obtainable 0.1 cm or closer • Wide range of currents required to elicit motor response • Only when intraneural did a motor response result from current < 0.2 mA
Bigeleisen et al (2009)[13]	Patients for hand/ wrist surgery (*n* = 55)	• Supraclavicular block • Minimum current (mA) recorded - With needle outside nerve trunk (but contacting nerve) - Inside trunk • "Intraneural" position sonographically confirmed with 5-mL injection of local anesthetic	• Median minimal current threshold outside nerve 0.60 mA ± 0.37 mA • Median minimal current threshold outside nerve was 0.30 ± 0.19 mA • No EMR observed at any time with < 0.2 mA when needle placed outside nerve
Wiesmann et al (2014)[14]	Pigs (*n* = 6)	• Open brachial plexus model • Stimulation at three positions: intraneural, needle-nerve contact, and 1 mm away from nerve • 3 pulse durations tested (0.1, 0.3, and 1 ms)	• Current intensity cannot distinguish between intraneural and needle-nerve contact • Motor response < 0.2 mA (irrespective of pulse duration) indicated intraneural or needle-nerve contact

It is universally accepted that injection of local anesthetic into the nerve carries a a risk factor for nerve injury; therefore, extraneural deposition of local anesthetic constitutes safer practice.[18,19] While unquestionably useful, ultrasonography is far from an infallible monitor of the needle-nerve relationship.[20] Because injection into a fascicle carries a high risk of injury,[21] addition of electrical monitoring of the needle-tip position is useful for safety, particularly in patients with challenging ultrasound anatomy when imaging proves to be difficult or the quality of an image is poor. If an EMR is elicited at currents below 0.5 mA, this indicates an intimate needle-nerve relationship that should prompt slight withdrawal of the needle and careful injection while avoiding an opening injection pressure greater than 15 psi. Overall, nerve stimulation adds little to the cost of a nerve block procedure, in terms of time or cost and can also serve as a useful functional confirmation of the anatomical image shown on the ultrasound screen (eg, "Is that the median or ulnar nerve?"). For these reasons, nerve stimulation should be used routinely in conjunction with ultrasound as a valuable additional monitor of the needle-tip position.

Ultrasonography

Ultrasound has revolutionized the practice of regional anesthesia and allowed a substantial evolution of the subspecialty from an art practiced by a few to a science that is more reproducible. The advantages are that ultrasound makes it possible to see the needle in real time and therefore quickly and more accurately guide the needle toward the target. Ultrasound also allows for additional injection when the first attempt is not adequate and accurately depositing the injectate into tissue spaces for reproducible nerve blockade. Also, ultrasound allows nerve blockade to be performed even in patients who are paralyzed, amputees who do not have a limb for an EMR, and so on.

Ultrasound has the potential to improve the safety of peripheral nerve blocks for a number of reasons. Adjacent structures of importance can be seen and avoided. The resurgence in popularity of the supraclavicular block is a testament to this. Prior to ultrasound, this highly effective block was relatively unpopular as a means of anesthetizing the brachial plexus for fear of causing a pneumothorax, due to the proximity of the plexus and sight of needle placement to the pleura and chest cavity. However, because the brachial plexus, and more importantly the rib, pleura, and subclavian artery can be identified on ultrasound, supraclavicular block has become commonplace in clinical practice. Regardless, ultrasound should not be thought of as fail-safe because complications, including pneumothorax, still do occur with ultrasound guidance.[22] Similarly, there are reports of intravascular and intraneural needle placement witnessed by (and despite the use of) ultrasound.[23–25]

An important advantage of ultrasound screening is the ability to determine the distance from skin to target. This, coupled with needles that have depth markings etched on the side, confers an additional safety margin by warning the clinician of a "stop distance," or a depth beyond which the clinician should stop advancing the needle to deeper tissue and reassess.

Another important advantage that ultrasound is the ability to see the local anesthetic distribution in real time. (Figure 63–2). If corresponding tissue expansion is not seen when injection begins, then the needle tip may not be *not* where it is thought to be, and the clinician can halt injection and reassess the location of the needle tip. This is particularly important in vascular areas, as the lack of local anesthetic spread can signal intravascular needle placement. On the other hand, ultrasound monitoring can be used to diagnose intra-arterial needle-tip placement when an echogenic "blush" is noted in the lumen of the artery, decreasing the risk of systemic toxicity.[26,27]

Ultrasonography appears to decrease the risk of local anesthetic systemic toxicity (LAST).[28,29] In one analysis of a large, multicenter registry of peripheral nerve blocks (>25,000 peripheral nerve blocks), the risk of LAST was reduced by greater than 65% with the use of ultrasound guidance.[28] The mechanism proposed by the authors was the ability to substantially reduce the volumes and doses of local anesthetic required to accomplish regional block. Indeed, decreasing the dose and volume of local anesthetic needed for success of regional anesthesia has been a consistent trend over the last decade. Numerous reports have documented substantial reductions in the volume required to effect an equivalent block as compared to pre-ultrasound–guided regional anesthesia techniques.[30,31] For instance, brachial plexus blocks can be performed with as little as less than 10 mL of local anesthetic, without sacrifice in effectiveness of anesthesia or analgesia.[32–34] Even if the entire volume of injectate is administered intravenously by accident, severe LAST resulting from, for example, a volume of 7 mL of 0.5% ropivacaine in an adult of average size is unlikely.

In contrast, the use of ultrasound guidance during peripheral nerve blocks has not decreased the risk or incidence of nerve injury. This disappointing observation was documented in several reports and is likely multifactorial. Ability to discern the needle-nerve relationship is user and anatomy dependent. In fact, studies have demonstrated that practitioners may miss approximately as much as one in six intraneural injections.[35–37] Second, the current resolution of the ultrasound machine may not be adequate to discern between an intra- versus

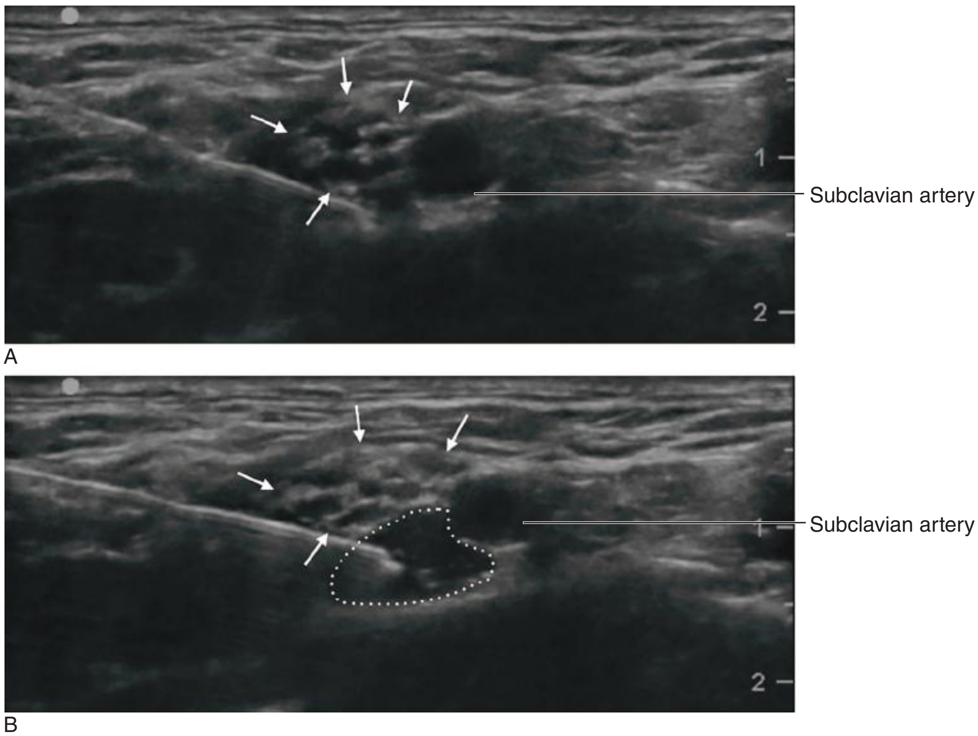

FIGURE 63–2. Supraclavicular brachial plexus block showing plexus (arrows) adjacent to subclavian artery (SA). **A** Before and **B** after deposition of 10 mL of local anesthetic (dotted outline).

extrafascicular needle-tip location. This difference is crucial, as an intraneural (but extrafascicular) injection is likely not associated with injury, whereas injection inside the fascicles themselves produces clinical and histological damage.[21,38] Importantly, one cannot rely on the nerve swelling as warning of an intraneural injection because once this is noted on ultrasound, it may be too late to prevent injury. This is because even a minuscule amount of local anesthetic will produce damage if injected into the fascicule, yet such small quantities of local anesthetic (eg, 0.1–0.5 mL) may not be detected by ultrasound.[39] Therefore, reliance on the visual confirmation of tissue expansion may result in damage before expansion is detected on the screen.

Injection Pressure Monitoring

An injection of lidocaine while the needle tip was in an intrafascicular position in canine sciatic nerves was associated with high opening pressure (>20 psi), followed by a return of injection pressure tracing to normal (ie, < 5 psi) after fascicular rupture. In contrast, perineural and intraneural extrafascicular injections yielded low opening and injection pressures.[21] The limbs in which sciatic nerve injections were associated high opening injection pressures experienced clinical signs of neuropathy (muscle wasting, weakness) as well as histological evidence of neurologic injury (inflammation, disruption of the nerve architecture). The implication is that injection into a low-compliance compartment, such as within perineurium-bound fascicles, requires high opening injection pressure before the injection can be initiated.

The intraneural needle-tip position is also associated with high opening injection pressures in human cadavers. Orebaugh et al placed needles into cadaveric cervical roots using ultrasound and quantified the pressure over the course of a 5-mL injection of ropivacaine and ink over 15 s.[40] In contrast to the control needles placed outside the roots (peak pressure < 20 psi), the intraneural injections resulted in a mean peak pressure of 49 psi (range 37–66 psi). Similarly, Krol et al performed ultrasound-guided injections intraneurally and perineurally in more distal nerves in fresh human cadavers (median, ulnar, and radial nerves) and also reported that the opening injection pressure was more than 15 psi intraneurally, while extraneural opening injection pressures were less than 10 psi.[41]

In a clinical study of 16 patients undergoing shoulder surgery, needle-nerve contact during interscalene brachial plexus block was associated with an opening injection greater than 15 psi.[42] In fact, at the needle-nerve contact and just before needle entry into the roots of the brachial plexus, the flow of injectate was not able to commence at pressures less than 15 psi. Halting an injection when the required opening injection pressure to commence an injection reached 15 psi allowed avoidance of injection in this hazardous position in 97% of subjects. In contrast, a needle position 1 mm away from the nerve was associated with the initiation of flow at opening pressures less than 15 psi. Therefore, as a monitor of needle-nerve contact, an opening injection pressure greater than 15 psi was far more sensitive than a minimum threshold current of either 0.5 or 0.2 mA or occurrence of paresthesia.

These data suggest that when the pressure in the system approaches 15 psi without the ability to commence flow of injectate, this high opening injection pressure may signal a dangerous needle-nerve relationship or needle placement in wrong tissue plane. Therefore, the injection should be halted and needle position reevaluated.

How should injection pressure be monitored? The use of "hand feel" to avoid high injection pressure is unfortunately not reliable. Studies of experienced practitioners blinded to the injection pressure and asked to perform a mock injection using standard equipment revealed wide variations in applied pressure, some grossly exceeding the established thresholds for safety.[43] Similarly, anesthesiologists performed poorly when asked to distinguish between intraneural injection and injection into other tissues, such as muscle or tendon, in an animal model.[44] Therefore, the only meaningful and reproducible monitoring is by using an objective and quantifiable method of monitoring opening injection pressure.

While the practice of injection pressure monitoring during peripheral nerve blocks is relatively new, there are several monitoring options. Tsui et al described a "compressed air injection technique" by which 10 mL of air is drawn into the syringe along with the local anesthetic.[45] Holding the syringe upright, a maximum threshold of 1 atm (or 14.7 psi) can be avoided by allowing only the gas portion of the syringe contents to compress to half of its original volume, or 5 mL (Figure 63–3). This is based on Boyle's law, which states that pressure × volume must be constant. A pressure of 20 psi or less is considered to be a safe threshold for initiating injection during peripheral nerve blocks. Boyle's law has also been employed in another simple apparatus using a four-way stopcock and a 1-mL syringe filled with air.[46] If, during the initiation of injection, the fluid meniscus reaches the halfway point in the 1-mL syringe (ie, 0.5 mL), this is indicative of doubling of the pressure in the system (ie, another atmosphere or 14.7 psi). These are both inexpensive and ubiquitously

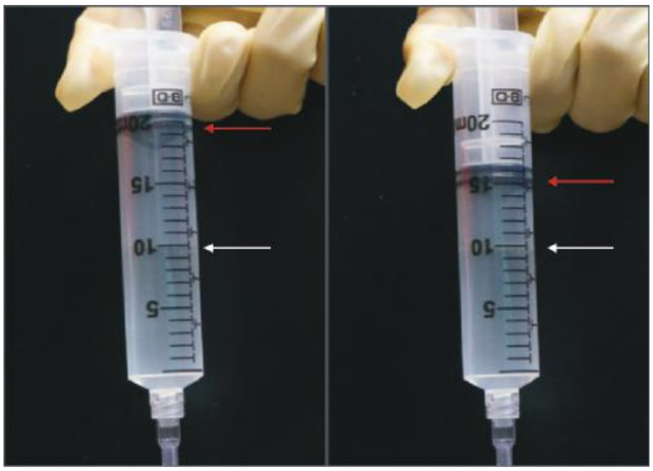

FIGURE 63–3. The compressed air injection technique. A 10-mL bubble of air is placed in the syringe of local anesthetic, which is then inverted. Compression of that bubble in a closed system to half of its original volume (ie, 5 mL) will increase the pressure in the system by 1 atm (14.7 psi).

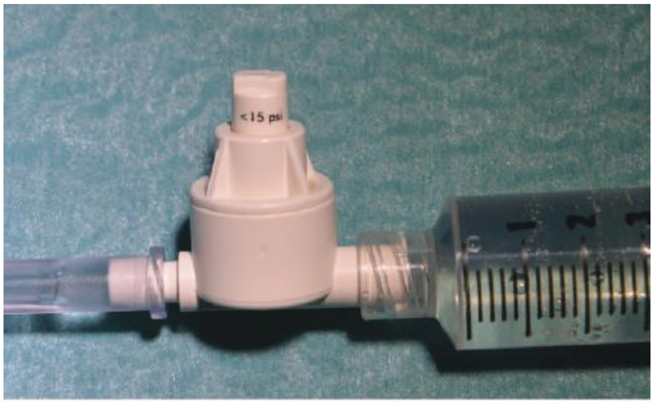
available ways to limit injection pressure during peripheral nerve blocks. Practical limitations include the need either to hold the syringe upright or to periodically turn the stopcock to the 1-mL syringe off when aspirating so air is not allowed to enter the injection tubing.

Another option to monitor injection pressure is the use of in-line, disposable pressure manometers specifically manufactured for this purpose. These devices bridge the syringe and needle tubing and, via a spring-loaded piston, allow the clinician to continuously monitoring the pressure in the syringe-tubing-needle system. On the shaft of the piston are markings delineating three different pressure thresholds: less than 15 psi, 15–20 psi, and more than 20 psi (Figure 63–4). An advantage of this method is the ease with which an assistant who is performing the injection can read and communicate the attained pressures. This method also allows objective documentation of the injection pressure during a peripheral nerve block procedure. Importantly, the opening pressure (pressure at which the flow begins) is independent of the size of the syringe, tubing, and needle or injection speed (Pascal's law) (Figure 63–5). While greater pressure can be generated by a smaller syringe and higher injection pressure can be attained by fast injection, the opening pressure at which the flow begins is the same and independent of these variables for common syringe-tubing-needle sizes (ie, 18–25 gauge). When the injection begins, however, these factors will influence the attained injection pressure. Therefore, a slow, steady injection speed is suggested with all nerve block procedures (10–15 mL/min). The opening injection pressure becomes relevant with every needle reposition and consequent injection.

Pressure monitoring may be a useful safety monitor in several other aspects of peripheral nerve blocks. In a study of patients receiving lumbar plexus blocks randomized to low (<15 psi) versus high (>20 psi) pressures, Gadsden et al demonstrated that 60% of patients in the high-pressure group experienced a bilateral epidural block.[47] Furthermore, 50% of the patients in the same group developed an epidural block in the thoracic distribution, whereas no patient in the low-pressure group experienced bilateral or epidural blockade. Similarly, Gautier et al demonstrated that when volunteers were randomized to low (<15 psi) versus high (>20 psi) pressures during interscalene brachial plexus block, cervical epidural spread occurred in 11% of high-pressure injections (vs 0% in the low-pressure group).[48] In addition, all subjects requested that the injection be halted in the high-pressure condition due to discomfort, but not during the low-pressure injection. These data suggest that monitoring opening injection pressure is important for several aspects of safety and patient comfort during the practice of peripheral nerve blocks.

Summary

Regional anesthesia has been making a transition from art to science, as more rigorous and precise means of locating nerves are developed. The same process should be expected for monitoring peripheral blockade. The use of neurostimulation, ultrasonography, and injection pressure monitoring



A

B

C

FIGURE 63–4. An example of a commercially available in-line pressure manometer (B-Smart, B. Braun Medical, Bethlehem, PA). As seen in **A–C**, respectively, the monitor displays pressure ranges in color on the movable piston: 0–15 psi (white), 15–20 psi (yellow), and more than 20 psi (orange). In clinical use, the exact opening injection pressure (OIP) is less important than prevention of exceeding the range of OIP associated with fascicular injury (>15 psi). Practically, this is avoided by aborting the injection with appearance of *any* color on the piston throughout the injection cycle (>15 psi). Importantly, opening pressure (pressure at which the flow begins) is independent of the size of the syringe, tubing, and needle or injection speed (Pascal's law).

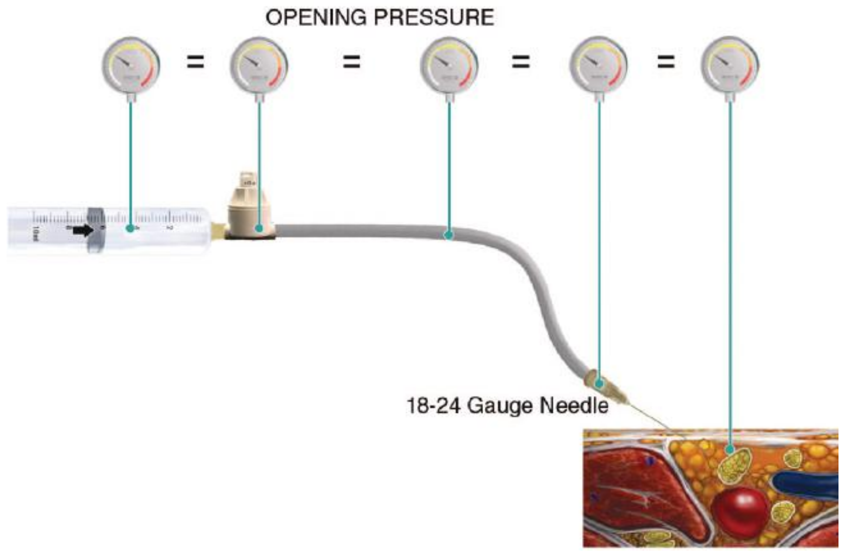


FIGURE 63–5. Opening injection pressure (pressure at which the flow begins) is independent of the size of the syringe, tubing, and needle or injection speed, and it is equal throughout the injection system (Pascal's law).

together provides a complementary package of objective data that can guide clinicians to perform the safest blocks possible.

Figure 63–6 is a flowchart outlining how these monitors are used in our practice.

DOCUMENTATION

Block Procedure Notes

Documentation of nerve block procedures has, lagged behind the documentation of general anesthesia, and it is often relegated to a few scribbled lines in the corner of the anesthetic record. Increasing pressure from legal, billing, and regulatory sources has provoked an effort to improve the documentation for peripheral nerve blocks. Samples of a peripheral nerve block documentation form that incorporates all of the monitoring elements mentioned previously in this chapter are shown in Figures 63–7 and 63–8. These can be adopted and modified to suit individual practices. The forms have a number of features that should be considered by institutions attempting to formulate their own procedure note. These include the following:

Paper records are increasingly being replaced with electronic medical record-keeping systems. Block documentation

Useful Features of a Peripheral Nerve Block Procedure Note	Example
Elements that guide the practitioner to meet a given standard of care	A space to indicate the use of epinephrine in the local anesthetic solution or if none was used, why not
A compromise between efficiency and ability to individualize	Information recorded using both tick boxes and blank line spaces
Documentation to safeguard against common medicolegal challenges	Practitioner must indicate patient's level of consciousness
Documentation of compliance with regulatory agencies (eg, Joint Commission)	Tick boxes indicate laterality
Elements to facilitate successful billing	Language required by many insurance companies indicating block specifically requested by surgeon
Documentation of clinicians involved and in what capacity	Was the attending the individual performing the block, or was he or she medically directing a resident?

is simple with computerized systems such as these, as the block variables can be selected quickly from a list by indicating relevant documentation items, whereas any narrative elements can be rapidly typed using a keyboard (Figure 63–8). Legibility and ability to correct errors are advantages to the e-block note.

Another useful aspect of peripheral nerve block documentation is the recording of an ultrasound image or video clip, to be stored either as a hard copy in the patient's chart or as a digital copy in the electronic health record (EHR) or separate secure hard drive. This not only is good practice from a medicolegal point of view but also is a required step that must be taken if the clinician wishes to bill for the use of ultrasound guidance. Any hard copies should have a patient identification sticker attached, the date recorded, and any pertinent findings highlighted with a marker, such as local anesthetic spreading around nerve. Additional examples of highly practical documentation of essential nerve block and spinal anesthesia procedures are shown in Figures 63–9 and 63–10, respectively.

Informed Consent

Documentation of informed consent is an important aspect of regional anesthesia practice. Practice patterns vary widely on this issue, and specific written consent for nerve block procedures is often not obtained. However, the written documentation of this process can be important for a number of reasons:

- Patients are often distracted and anxious on the day of surgery (when many consents are obtained) and may not remember the details of a discussion with their anesthesiologist. Studies have shown that a written record of the informed consent process improves patient recall of risks and benefits.[49]
- A written consent establishes that a discussion of risks and benefits occurred between the patient and the physician.
- A specific document for regional anesthesia can be tailored to include all the common and serious risks; this allows the physician to explain them to the patient as a matter of routine and reduce the chance of omitting important risks.

The following tips can be utilized to maximize the consent process:

Suggestions for improving the consent process.

Be brief. A simple, short explanation helps recall of the risks and benefits more than lengthy paragraphs.

Include not only serious and major risks but also benefits and expected results of the proposed regional anesthetic procedure. It is difficult for patients to make an informed choice if only risks are discussed.

Use the consent process as a means to educate the patient simultaneously.

Offer a copy of the form to the patient. This has been shown to aid in recall of consent-related information.

CHAPTER 64

Diagnosis and Management of Spinal and Peripheral Nerve Hematoma

Ariana Nelson, Honorio T. Benzon, and Rasha S. Jabri

INTRODUCTION

Spinal epidural hematoma (SEH) is an accumulation of blood in the loose areolar tissue between the vertebrae and the dura of the spinal canal. Typically, the hematoma is asymptomatic, but in rare cases it will compress the spinal cord, with potentially devastating neurological consequences. These symptoms include sensory disruption, bowel and bladder incontinence, motor weakness, or, in severe cases, complete paralysis of the affected limbs. This clinical entity was first described in the medical literature in 1682 as spinal hematoma with spinal apoplexy in the *Histoire de l'Academie Royale des Science* (Volume 2; G.J. Duverney).[1] Nearly 200 years later, in 1869, a report of the first clinical diagnosis of SEH was published in the *Lancet*.[2]

The SEHs can be spontaneous in nature or may occur in the setting of an invasive procedure, such as lumbar puncture, neuraxial anesthesia, or spine surgery. Hematoma is more likely to be symptomatic in the cervical and thoracic regions, given the constricted spinal canal in this area compared to the greater space available for volume compensation in the lumbar and particularly the cauda equina region.[3]

SPINAL EPIDURAL HEMATOMA

Incidence

Symptomatic SEH accounts for less than 1% of all spinal space-occupying lesions[4] and affects only 1 per 1 million people annually.[5,6] SEHs arise from myriad etiologies but most often from a procedure performed in or near the epidural space. For example, the presence of SEH can be found on postoperative imaging in 33% to 100% of patients after spinal surgery,[7] but patients will rarely show any neurologic deficit. A 2010 systematic review found an overall calculated incidence of symptomatic SEH after spine surgery of 0.2%, with individual study calculations ranging between 0% and 1.0%.[8] Therefore, the incidence of SEH is routinely quoted as the incidence of *symptomatic* SEH; henceforth in this chapter, the qualifying term *symptomatic* is implied.

The incidence of SEH after neuraxial anesthesia has historically been approximated to be less than 1 in 150,000 epidural placements and less than 1 in 220,000 spinal anesthetics.[9] However, according to recent epidemiologic studies, the incidence may be increasing.[10] This estimation was confirmed by a large-scale Swedish study that found an incidence of SEH after epidural blockade of 1:18,000, a figure that results from the average of an obstetric incidence of 1:200,000 and a remarkably high incidence of 1:3600 calculated in a population of elderly female patients undergoing knee arthroplasty.[11] Another study showed an overall SEH incidence of 1:4741 that increased to 1:1000 if the population assessed was narrowed to include only elderly women undergoing lower extremity surgery.[12] This large disparity can be attributed to the presence or absence of risk factors in these incongruent patient populations. Pregnancy induces a relatively hypercoagulable state and obstetric patients are also younger with a larger and more compliant epidural space than elderly patients.[13] The lower incidence of SEH in obstetric patients was confirmed in a recent study wherein there were no recognized cases of SEH in 709,837 patients evaluated in the peripartum period.[14] This study noted an incidence of 1:9000 (95% confidence interval [CI]: 1:20,189–1:4330) in patients who received perioperative epidural placements.

Risk Factors

Increasing age carries with it an increased risk of SEH. The reduction in the size of the epidural space with age was first reported in 1967 in a study of local anesthetic spread.[15] This can be extrapolated to account for the higher incidence of SEH in the elderly because an equivalent volume of blood will cause increased pressure in the smaller epidural space of an elderly patient compared to a younger counterpart. No racial predilection has been reported, but SEH is more frequent in females. This could potentially be explained by the higher prevalence of osteoporosis in female patients,[16] which causes vertebral deformities or fractures and enlargement of the vertebral bodies, resulting in narrowing of the spinal canal.[17] Osteoporotic narrowing of the epidural space therefore could account for both the gender and the age predilections of SEH and may contribute to the greater than 50-fold increased likelihood of SEH after epidural anesthesia for knee arthroplasty as compared to epidural labor analgesia. However, thromboprophylaxis is a necessity in the orthopedic surgical population, which also may contribute to their relatively higher incidence of SEH compared to obstetric patients, who do not require routine prophylaxis against deep vein thrombosis.[11]

Indeed, the most important risk factor for SEH is the presence of a physiologic or iatrogenic disorder of the coagulation system, such as liver disease, alcoholism, thrombocytopenia, or pharmacologic anticoagulation.[7] A recent retrospective study also identified a significant increase in SEH after spine surgery in patients with Rh^+ blood types, intraoperative blood loss greater than 1 L, hemoglobin level less than 10 g/dL, and an international normalized ratio greater than 2.0 in the first 48 hours.[18] Anticoagulant therapy in association with neuraxial analgesia as well as the length and intensity of anticoagulation have been identified as the most significant risk factors for epidural hematoma.[19] Approximately one-quarter to one-third of all SEH cases are associated with anticoagulation therapy.[20,21] In an extensive review of every case of SEH associated with neuraxial anesthesia, 87% of patients had either a hematologic abnormality or a procedure complicated by technical difficulty.[22] Cases of spontaneous hematoma are rare, but when they do occur are often associated with anticoagulation, thrombolysis, blood dyscrasias, coagulopathies, thrombocytopenia, neoplasms, vascular malformations, or vertebral hemangioma.[23,24]

Decreased patient weight, which may exaggerate the anticoagulant response, represents a theoretical concern for bleeding tendency and has been suggested as the explanation for the increased risk in women and the elderly. However, in Sweden, a gender-specific reduced dose of low molecular weight heparin for prophylaxis against deep vein thrombosis has not been shown to improve the well-described increased incidence of SEH in women.[11] Thrombolytic therapy imposes the greatest risk of bleeding complications, and neuraxial procedures should be diligently avoided in patients who have recently undergone thrombolysis.[25]

Clinical Pearl

- Recent studies on the incidence of the risk of spinal hematoma in patients without overt risk factors showed an increase to 1:18,000 after epidural and 1:3600, even 1:1000, in elderly patients undergoing lower extremity surgery.

Etiology and Location of Hematoma

The proposed factors that cause SEH include trauma, anticoagulation, thrombolysis, lumbar puncture, epidural or spinal anesthesia, interventional spine procedures or surgeries, coagulopathy or bleeding diathesis, hepatic disease with portal hypertension, vascular malformation, disk herniation, Paget disease of the vertebral bones, Valsalva maneuver, and hypertension.[26] The most important causes of spontaneous SEH are clotting disorders, which may be acquired (eg, anticoagulant therapy, malignancies) or congenital (eg, hemophilia).[27,28] Vascular malformations are rarely responsible for spontaneous epidural hematomas; only 4% in a series of 158 cases and 6.5% in a series of 199 cases were reported to be due to vascular malformation.[29,30] Less-common predisposing factors include systemic lupus erythematosus, ankylosing spondylitis, rheumatoid arthritis, Paget disease, disk herniation, and hypertension.[31–33]

The dorsal venous plexus is the most commonly implicated source of hemorrhage because this plexus lacks valves and permits reversal in blood flow during increased intravascular pressure from physical activity.[34,35] These veins lack protection as they are surrounded only by loose areolar tissue and are therefore vulnerable to sudden increases in intra-abdominal or intrathoracic pressure, leading to rupture and hemorrhage.[36,37] The epidural venous plexus is most prominent in the thoracic spine,[23] and spontaneous SEH most often occurs in the thoracic and cervicothoracic region, followed by the thoracolumbar area.[4,30,38,39] SEH is typically posterior or posterolateral to the thecal sac (Figure 64–1) because the firm adherence of the dural sac to the posterior longitudinal ligament in the ventral aspect of the spinal canal prevents the accumulation of hematoma. The dorsal aspect of the thoracic or lumbar region is commonly involved, and expansion is typically limited to only a few vertebral levels.

In pregnant women, it has been proposed that increased venous pressure due to uterine enlargement, in association with the hemodynamic changes of pregnancy, may predispose to rupture of a preexisting pathologic epidural venous plexus wall.[40,41] Although a venous source is the most widely accepted, debate continues regarding a potential arterial source of SEH, with proponents of this theory stating that venous blood pressure is less than intrathecal pressure; therefore, although forward flow is possible into the low-pressure epidural space, venous blood could not cause compression of the spinal cord.[42]

Clinical Pearls

- Hemorrhage into the spinal canal most commonly occurs in the epidural space because of the prominent epidural venous plexus.
- SEH may be spontaneous or may follow minor trauma, such as lumbar puncture or neuraxial anesthesia.
- SEH occurs primarily in anticoagulated or thrombocytopenic patients.

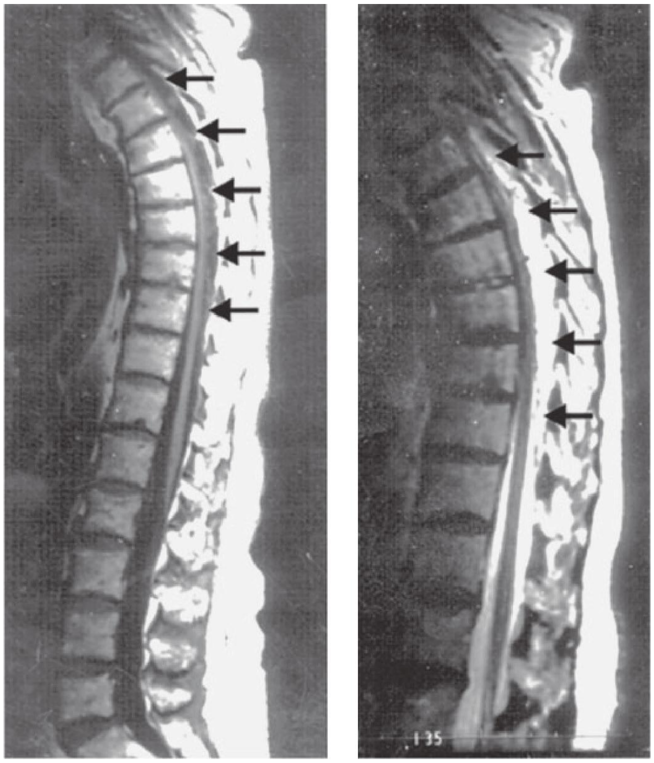

FIGURE 64–1. Sagittal magnetic resonance images of the thoracolumbar spine. A large complex epidural hematoma extending from T3 to T10 through T11 is seen with hypo- and isodense signal characteristics on a T1-weighted image (left; arrows) and hyperintense signal characteristics on a T2-weighted image (right; arrows). At the center of the hematoma, the spinal cord abuts the posterior aspect of the thoracic vertebral bodies (left). No signal abnormalities of the cord itself are seen. (Reproduced with permission from Schwarz SK, Wong CL, McDonald WN: Spontaneous recovery from a spinal epidural hematoma with atypical presentation in a nonagenarian. *Can J Anaesth*. 2004 Jun-Jul;51(6):557–561.)

History and Physical Examination

Classically, the presenting symptom of SEH is acute axial back pain that radiates to corresponding dermatomes and evolves to focal neurologic deficit with signs of nerve root or spinal cord compression.[43] The pain is generally described as a severe, localized constant back pain with or without a radicular component that may mimic disk herniation, especially in the lumbar spine. Back pain is amplified by percussion over the spine, as well as maneuvers that increase intraspinal pressure, such as coughing, sneezing, or straining. However, a 2010 analysis demonstrated that lower extremity weakness is the most common presenting sign, although back pain is still a common early symptom.[44] Associated symptoms may include numbness, weakness, and urinary or fecal incontinence.[38,45]

The onset of pain is occasionally related to minor strain, such as with lifting, coughing, sneezing, or Valsalva maneuvers, although in the majority of cases the onset of pain is spontaneous.[31,39] Depending on the level and the size of the hematoma, physical findings may include unilateral or bilateral weakness, sensory deficits with unilateral or bilateral radicular paresthesias, various alterations in deep tendon reflexes, and alterations of bladder or anal sphincter tone.[46] Signs of spinal cord and nerve root dysfunction appear rapidly and may progress to paraparesis or, in high thoracic or cervical locations, quadriparesis. In cases of SEH related to neuraxial anesthesia or lumbar puncture, the presence of new or progressive postoperative neurologic symptoms should alert the physician to a possible epidural hematoma.[47]

Clinical Pearls

- The patient may present with a severe, localized, constant back pain with or without a radicular component that may mimic disk herniation.
- Associated symptoms may include weakness, numbness, and urinary or fecal incontinence.
- Return of sensory or motor deficit several hours after spinal or epidural block has worn off (with or without back pain) is highly pathognomonic and should be considered and treated as spinal or epidural hematoma until proven otherwise.
- Neurologic recovery after conservative management has been reported in patients with back pain and leg weakness without paralysis.
- Neurologic recovery can occur if surgery and decompression is performed within 36 hours of a complete motor deficit and within 48 hours of a partial deficit.

Diagnosis

As noted previously, the clinical findings of SEH usually include back pain and motor/sensory deficits that may rapidly progress to paraplegia, quadriplegia, or autonomic dysfunction. An epidural hematoma ordinarily presents within the first 24–48 hours after a procedure. Any new or progressive neurologic symptoms warrant immediate clinical evaluation and diagnostic workup to rule out any space-occupying lesion, including epidural hematoma. A neurologic deficit occurring in the presence of epidural analgesia mandates immediate discontinuation of the infusion, with the catheter left in place, to rule out any contribution from the local anesthetic. If the epidural infusion is the cause of the neurologic manifestation, a return of sensory and motor function will be noted. Otherwise, an immediate workup and radiographic imaging studies should be obtained and a consultation with a spine surgeon sought to rule out an evolving epidural lesion.

In a patient presenting with acute axial back pain with progression of neurologic deficits, immediate assessment for the presence of pathologic entities associated with nerve root and spinal cord compression is required to differentiate miscellaneous lesions simulating SEH. The clinical presentation of a patient with suspected epidural hematoma may resemble presentation for epidural abscess, spinal cord disease, neoplasm, or acute disk herniation.[47] The differential diagnosis of new or progressive postoperative neurologic symptoms includes surgical neuropraxia, prolonged or exaggerated neuraxial block, anterior spinal artery syndrome, exacerbation of a preexisting neurologic disorder, and presentation of a previously undiagnosed neurologic condition.

A complete blood cell count with platelets should be ordered to assess the extent of bleeding and to determine the presence of infection. Prothrombin time and activated partial thromboplastin time determine the presence of bleeding diathesis.

Rapid radiologic evaluation is essential to minimize delay in treatment of SEH. Currently, magnetic resonance imaging (MRI) is the diagnostic imaging method of choice for spinal emergencies because it allows rapid, noninvasive evaluation of the vertebral column and the spinal cord in all planes. Spinal MRI may delineate the location of an epidural hematoma and identify an associated vascular malformation; it will also provide information regarding the extent of the hematoma as well as the degree of cord compression. MRI can also aid in assessment of the age of the hematoma (Figure 64–1).[31,48,49]

The chronologic characteristics of an MRI of SEH are similar to those seen with intracranial hemorrhage. In the hyperacute stage (first 6 hours), the SEH appears isointense compared to the spinal cord on T1-weighted images and mildly hyperintense and heterogeneous on T2-weighted images, as a result of the presence of intracellular oxyhemoglobin. In the acute stage (7–72 hours), the hematoma is still isointense on T1-weighted images and becomes hypointense on T2-weighted images.[49] This is due to the presence of intracellular deoxyhemoglobin, which causes T2 shortening. As the concentration of methemoglobin increases, the hematoma becomes hyperintense and homogeneous on T1- and T2-weighted images. Gadolinium-enhanced magnetic resonance arteriography (MRA) may further define the extent of an arteriovenous malformation.

Conventional computed tomography (CT) has the potential to diagnose an epidural hematoma but may give false-negative results if the hematoma is isodense to the thecal sac or spinal cord and the image quality is affected by artifacts often seen in the upper thoracic region.[49] Spinal CT scanning may be nondiagnostic in the thoracic spine, where resolution is poorer than in the lumbar and cervical spine because of the high contrast between the lung parenchyma and vertebral bone. Conventional angiography may be required to definitively demonstrate the presence of a vascular malformation.[31,37]

Myelography, and later CT myelography, were previously the main modalities for diagnosis of epidural hematoma.[50] Combined with spinal CT scanning, myelography will display SEH as an intraspinal biconvex and hyperdense lesion with a density equivalent to blood.[51] Although this may demonstrate an epidural lesion with partial or complete spinal block, the findings are not specific. Moreover, myelography is invasive and may worsen the patient's clinical status. In addition, although it can demonstrate signs of compression with visualization of nonspecific contrast blockade or extradural convex compression, myelography cannot determine the nature and the true extent of the lesion.[52] These techniques are now rarely used in the United States as MRI has become the gold standard diagnostic measure.[53]

Prevention, Treatment, and Prognosis

Lumbar puncture or epidural anesthesia should be avoided in individuals who are on anticoagulant therapy, have received thrombolytic therapy, or are suspected to have a bleeding diathesis. Anesthesiologists are urged to be up to date on their knowledge of anticoagulation protocols, new anticoagulant medications, and current guideline recommendations. The decision to perform neuraxial blockade and the timing of catheter removal in a patient receiving antithrombotic therapy should be made on an individual basis, weighing the risks of spinal hematoma with the benefits of regional anesthesia for a specific patient. The American Society of Regional Anesthesia and the European and Scandinavian Society of Anaesthesiologists have published consensus statements on neuraxial anesthesia and anticoagulation, which provide an up-to-date source for guidelines in the decision-making process in performing neuraxial anesthesia in a patient with risk factors (see Chapter 52, Neuraxial Anesthesia and Peripheral Nerve Blocks in Patients on Anticoagulants).[44,54,55]

In contrast, no guidelines exist regarding anticoagulation in surgical patients. Recent retrospective studies regarding the incidence of postoperative hematoma after spine surgery concluded that perhaps patients should receive deep vein thrombosis prophylaxis as this does not appear to have an impact on the likelihood of SEH formation.[8,18,56] However, further prospective studies are needed prior to widespread institution of thromboprophylaxis after spine surgery given the devastating consequences of SEH.

Case reports have described successful conservative management of epidural hematoma.[57,58] Nonoperative treatment with good outcome was mainly reported in hematomas localized at the cauda equina level and those with mild neurologic deficit.[20] It appears that complete recovery can occur with conservative management when the patient reports back pain and leg weakness or numbness but does not exhibit leg paralysis.[59,60] Reversal of clotting abnormalities, close observation of neurologic deficits, and, in rare cases, steroid administration may achieve a good outcome without surgery.[61,62] A practical approach to management of suspected epidural hematoma is displayed in Figure 64–2.

Urgent surgical decompression is the treatment of choice for SEH causing acute compromise of cord function. Laminectomy is followed by evacuation of the hematoma, coagulation of bleeding sites, and inspection of the dura. The dura is then tented to the bone, and, occasionally, epidural drains are employed for as long as 24 hours. Although historically the efficacy of drains has been controversial, recent data suggest that subfascial drains significantly decrease SEH formation.[63] Recovery after prolonged paralysis without surgery is rare, and surgical consultation for consideration of emergent decompressive laminectomy must be obtained as soon as possible. The overall mortality rate is 8%.[64]

Ultimately, the surgery team must decide to observe or operate on a case-by-case basis. The critical factors for recovery after SEH are the level of preoperative neurologic deficit and the operative interval.[27,65] Prognosis for neurologic recovery primarily depends on the patient's preoperative neurologic status and

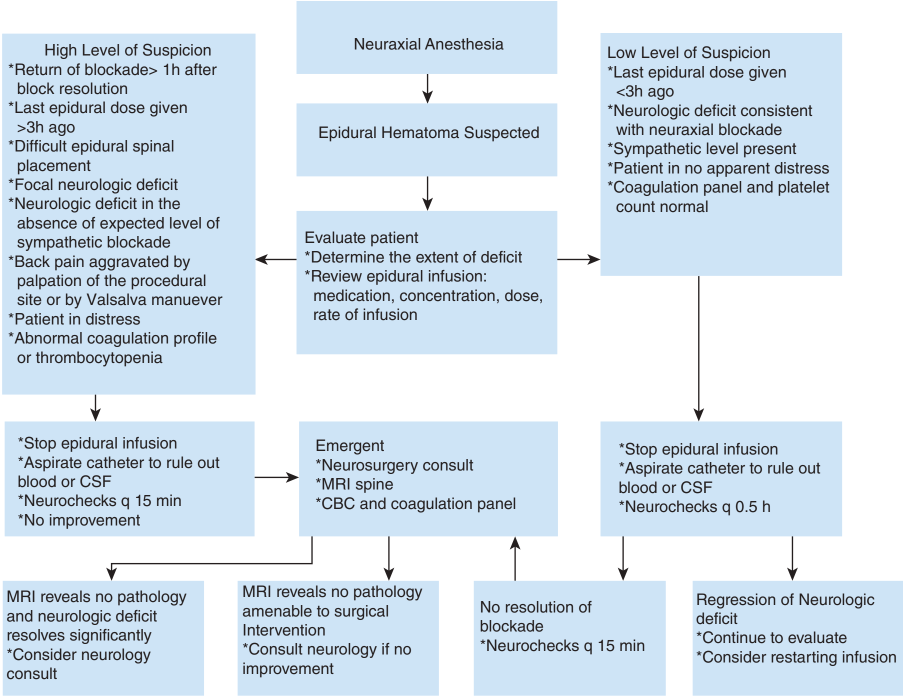

FIGURE 64–2. Practical approach to decision-making in workup and treatment of a patient with suspected epidural hematoma. CBC = complete blood cell count; CSF = cerebrospinal fluid; MRI = magnetic resonance imaging; q = every.

duration of neurologic dysfunction.[36,66] The prognosis is worse when there is a delay between the injury and surgical intervention. Previously, complete neurologic recovery was considered to be unlikely if more than 8 hours had elapsed between the development of paralysis and surgical intervention.[67] However, other authors have noted recovery when surgery is performed within 12 hours of paralysis.[48,68]

This recommended time frame for intervention has been further delineated by the recent finding that recovery can be achieved when surgery is performed within 48 hours of an incomplete motor deficit and within 36 hours of a complete motor deficit (Table 64–1).[69] It is interesting to note that functional recovery after 72 hours of symptoms has been reported.[70] While it is reassuring that functional recovery may occur after such intervals, appraisal of the patient's symptoms and emergency MRI take time. Therefore, consultation with a spine surgeon regarding potential emergent evacuation of the hematoma should be obtained as soon as possible.

TABLE 64-1. Neurologic recovery in relation to timing of surgery.

Author Interval between paralysis and recovery	
Wulf[68] 8 hours	36 hours of a complete motor deficit
Lawton et al[48] 12 hours	48 hours of an incomplete motor deficit

Spinal Epidural Hematoma: Summary

Spinal epidural hematoma is a rare source of neurologic deterioration and can result in autonomic, sensory, and motor disturbance of varying degrees depending on the location and size of the hemorrhage. SEH may be acute or chronic, spontaneous, post-traumatic, or iatrogenic. Known risk factors include technically difficult neuraxial procedure, presence of intrinsic or acquired coagulopathy, female gender, and advanced age. Potential risk factors as evidenced by inconsistent data in the literature include low hemoglobin level, presence of Rh^+ antibody, and anatomical abnormalities of the spinal cord.

Given that SEH is a rare but potentially reversible cause of spinal cord compression, it is essential that the diagnosis be made without delay to enable full recovery. Spinal hematoma may occur even in the absence of identifiable risk factors; therefore, health care providers must maintain a high index of suspicion and vigilance in monitoring for new neurologic symptoms. Although MRI cannot be conducted with the rapidity of a CT scan, it is the diagnostic modality of choice because it is both sensitive and specific. Swift detection of neurologic deterioration is critical to early diagnostic imaging and prompt intervention.

It is reassuring to note that recovery can occur without surgery in the absence of paralysis. When paralysis occurs, surgical decompression of the spinal cord and nerve roots can result in full functional recovery when accomplished within a reasonably rapid interval. If intervention is delayed, permanent sequelae of SEH can include sensory deficits, paraplegia, spasticity, neuropathic pain, and urinary or anal sphincter dysfunction.

PERIPHERAL HEMATOMA AFTER NERVE BLOCKS

Hematoma in the epidural space is certainly the most devastating hemorrhagic sequelae of neuraxial or peripheral regional anesthesia, but hematoma may also occur in the periphery after single-shot[71–75] or continuous nerve blocks.[76–79] The most common risk factors appear to be procedural difficulty and concomitant anticoagulation or antiplatelet therapy.[80] This complication is exceedingly rare, with fewer than 30 cases of hematoma after peripheral nerve block (PNB) reported in the literature to date,[44] and the consequences are also less dire as compared to SEH given that hemorrhage occurs in a compressible peripheral space.

In contrast to SEH, the presenting symptom of hematoma after PNB is rarely neurologic dysfunction but more typically visible bruising (Figure 64–3), local tenderness, decrease in hemoglobin/hematocrit, or relative hypotension due to blood loss. This is not to say that that the compliant nature of the peripheral space precludes significant morbidity and mortality, as there is one reported case of a patient fatality secondary to retroperitoneal hemorrhage after lumbar sympathetic block in the setting of antiplatelet therapy.[73] The patient was found on autopsy to have lost 3 L of blood in his retroperitoneal space, which speaks to the occult threat presented by the compliant periphery. Indeed, several other cases have been reported where patients suffered significant morbidity due to PNB hematoma, including lengthened hospital stay, requirement for transfusion, or acute renal failure.[54]

Given that in every case reported in the literature, the neurologic deficit, if present, had resolved by 1 year, it appears that the more concerning source of morbidity is blood loss into the

FIGURE 64–3. Neck hematoma in a patient in whom the external jugular vein was punctured with an 18-gauge Tuohy-style needle during insertion of a catheter in the interscalene groove. The hematoma shown was self-contained and was treated conservatively with local compression.

hematoma. However, due to the rare nature of this complication, it is difficult for experts to make recommendations regarding this procedure in the setting of anticoagulation. This difficulty is exacerbated by the existence of case reports wherein a hematoma occurred despite the practitioners following American Society of Regional Anesthesia and Pain Medicine (ASRA) guidelines.[71] In addition, there are reported cases of spontaneous hematomas that have occurred in patients on enoxaparin or thrice-daily heparin.[81–85] Taken together, these facts have led to somewhat-contrasting guidelines in different countries. For example, the German Society of Anaesthesiology and Intensive Care has issued recommendations regarding cessation of anticoagulation prior to PNB, but the Austrian Society states that distal PNBs, such as sciatic or axillary blocks, may be performed in an anticoagulated patient.[86]

The ASRA guidelines state that the recommendations regarding neuraxial techniques should be applied to deep plexus blocks and PNBs.[44] Therefore, patients receiving anticoagulation are not candidates for these anesthetic techniques, but some researchers suggested that with the advent of ultrasound guidance, these anticoagulated patients could safely undergo blockade of peripheral nerves.[75] In addition, studies showed not only a reduced incidence of vascular puncture with the use of ultrasound[87,88] but also a decreased rate of local anesthetic toxicity.[89–91] This option has the potential to improve patient safety, given that patients on anticoagulation often have risk factors for general anesthesia and would benefit from avoiding the resultant fluctuations in hemodynamics and fluid status.

A CT scan is currently the most common imaging technique for diagnosis of blood in peripheral tissues, especially the retroperitoneal space.[92] However, ultrasound has been used to demonstrate the presence of renal subcapsular hematoma[93] and could potentially be a more easily accessible diagnostic technique than CT in regions of the body amenable to this method of visualization. The increased use of ultrasound in initial placement of PNBs could facilitate diagnosis of suspected cases of post-block hematoma as the ultrasound equipment will be readily available.

Although timely diagnosis is ideal, subsequent treatment of hematoma after PNBs is typically expectant management. A surgical team is ordinarily consulted, blood transfusions are ordered as necessary, and surgical drainage is considered only in critical or rapidly deteriorating patients. Certain case reports of psoas hematoma have resolved without surgical evacuation of the hematoma,[71,93] and the patients regained their sensory and motor status a few days to 4 months after the diagnosis. As for hematoma concomitant with peripheral nerve catheter, these also are often self-limiting, but there are reports where surgical drainage was performed.[77]

Given the dearth of data available regarding hemorrhage after PNB or continuous nerve block, it may be difficult to accurately determine superiority of a certain anesthetic technique for a specific patient. Anesthesiologists should individualize their decision based on the suitability of PNBs in patients on anticoagulants and, as always, discuss in detail the risks and benefits of the block with the patient and the surgeon. If a block is performed, the patient should be observed closely in the perioperative period for signs and symptoms of peripheral hematoma.

PART 10

LAST: LOCAL ANESTHETIC SYSTEMIC TOXICITY

This page intentionally left blank

CHAPTER 65

Local Anesthetic Systemic Toxicity

Marina Gitman, Michael Fettiplace, and Guy Weinberg

INTRODUCTION

The introduction of cocaine as the first local anesthetic (LA) in the late nineteenth century was soon accompanied by reports of its systemic toxicity. The symptoms of toxicity were frequently described as seizures or respiratory failure, but some cases also included accounts of adverse cardiac effects. Often lethal, local anesthetic systemic toxicity (LAST) was treated with caffeine, ammonia, or even hypodermic ether.[1] The development of procaine in 1904 did not solve the problem of systemic toxicity, and the Committee for the Study of Toxic Effects of Local Anesthetics published a report of 43 fatal cases linked to the use of LAs.[2] Identification of contributing factors, emphasis on prevention and the almost-complete elimination of cocaine from clinical practice helped decrease the incidence of LAST for nearly 50 years.

However, the synthesis of long-acting, lipid-soluble LAs such as bupivacaine in the late 1950s with subsequent associated reports of LAST resulted in return of lethal LAST. These included multiple cases of fetal demise associated with paracervical blocks, ventricular fibrillation after an interscalene block, and what is considered to be the "sentinel" case of a young man who suffered a cardiac arrest after a caudal block.[1,3,4] The following several decades were plagued by isolated accounts describing a common problem: cardiovascular (CV) demise associated with LAST that was particularly resistant to available resuscitative measures, such as vasopressors (eg, epinephrine) and defibrillation.

MECHANISM OF LOCAL ANESTHETIC TOXICITY

Local anesthetics are generally safe and effective when limited to the site of therapy, such as tissue infiltration, near a nerve or a plexus of nerves. However, if large amount of LA reaches the systemic circulation, supratherapeutic blood and tissue levels can cause toxicity. This transit into the blood may be due to inadvertent intravascular injection or vascular uptake from local spread. At the target site, LAs reduce the sodium ion flux through voltage-gated sodium channels by a combination of an increased energy barrier and steric hindrance. This block occurs from the intracellular side and requires LAs to move across the lipid bilayer first.[5] LAs also block calcium channels and other channels at similar concentrations.[6] At lower concentrations, LAs block protein kinase signaling induced by tumor necrosis factor α.[7] At higher concentrations, LAs can inhibit other channels, enzymes, and receptors, including the carnitine-acylcarnitine translocase in mitochondria.[8]

Although there is no clear consensus, cardiac toxicity is likely caused by the combination of electrophysiologic and contractile dysfunction. Compared with other LAs *in common clinical use*, bupivacaine is more lipophilic and has a greater affinity for the voltage-gated sodium channels. These qualities may contribute to its cardiotoxic profile.[9–11] Of note, toxicity can occur at serum concentrations that are lower than expected because LAs accumulate in mitochondria[12] and cardiac tissue[13] at a ratio of about 6:1 (or greater) relative to plasma.

DIAGNOSIS AND CONTRIBUTING FACTORS

The typical presentation of LAST usually begins with prodromal symptoms and signs, such as perioral numbness, tinnitus, agitation, dysarthria, and confusion. These may be followed by more severe central nervous system (CNS) derangements such as seizures and coma. CV derangements can occur as well, initially presenting with hypertension and tachycardia, then bradycardia and hypotension, with progression to more serious complications, including ventricular arrhythmias and asystole. The majority of adverse events occur within 1 minute after injection of LA, but not all cases follow this pattern. Toxicity can have a delayed onset of greater than 1 hour after injection and can manifest as isolated CV dysfunction or as a combination of CNS and CV signs without the classical progression.[14]

Variables that increase the risk of toxicity include the type of LA and dose, site of injection, the patient's comorbidities, extremes of age, and small size or limited muscle mass. The lipophilicity of a LA is associated with toxicity. More lipophilic LAs like bupivacaine have an increased risk of toxicity relative to the less-lipophilic LAs like mepivacaine and lidocaine.

Higher total dose and the dose-to-weight ratio of the drug can potentially increase the possibility of LAST.[15,16] In particular, skeletal muscle acts as a depot for systemically absorbed LA,[13] which may account for the clinical risk of LAST in diminutive patients whose muscle mass is substantially less than normal. Accordingly, nerve blocks and epidural anesthetics that require larger doses carry an inherent risk for such patients. For example, bilateral transversus abdominus plane blocks performed with as much as 40 mL of 0.5% ropivacaine can result in an increased incidence of local toxicity.[17]

Last, but not least, the site of injection also contributes to the risk of vascular spread of the drug. The classical teaching that the vascular absorption of LAs is highest with intercostal blocks followed by epidural and brachial plexus injections corresponds to the clinical data demonstrating that the highest incidence of LAST occurs with paravertebral blocks, followed by upper extremity and trunk/lower extremity blocks.[16]

Patient-dependent risk factors include organ dysfunction, the serum level of the binding proteins, and age. Preexisting cardiac disease can make patients more prone to the arrhythmogenic and myocardial depressant effects of LAs. Extreme caution is advised for those with decompensated heart failure, severe valvular pathology, or depressed ventricular function. Hepatic or renal dysfunction can result in decreased metabolism and clearance and a higher level of circulating drug. In addition, liver/kidney failure, malnutrition, or any other disease process that results in a decreased serum level of albumin can indirectly increase the level of the free drug for a given dose.[18,19]

Patients at the extremes of age are more susceptible to toxicity, a finding that may be related to a number of factors. The elderly are more likely to have organ dysfunction, which will contribute to toxicity. Further, both elderly and pediatric patients may have diminished muscle mass and, as such, are more likely to receive a higher dose of drug for their weight. Most children are anesthetized when a block is placed, so the early symptoms will be missed, and more serious CNS/cardiac derangement could be the first sign of toxicity.[20]

OCCURRENCE OF TOXICITY

Neuraxial anesthesia and peripheral nerve blocks (PNBs) are the most commonly performed procedures requiring the use of LAs. The low volume of drug required for intrathecal dosing rarely poses a problem. However, the high volume required for epidural anesthesia and PNBs increases the risk of LAST. Currently available data indicate that the incidence of LAST associated with PNBs has decreased from 1.6–2/1000 in the 1990s to 0.08–0.98/1000 between 2003 and 2013.[16,21–25] In fact, one recent study observed no cases of LAST with more than 9000 PNBs over a period of 6 years.[26] Likewise, the incidence of LAST with epidural anesthesia decreased from 9.75/1000 in the early 1980s to 0.1–1.2/1000 in the 1990s and stayed at 0.1/1000 in 2003.[23,27,28]

While large population studies are mostly limited to epidurals and PNBs, there are numerous reports describing LAST with other types of local anesthesia. For example, with the recent popularity of a transversus abdominus plane block for abdominal procedures, there have been several cases of LAST after these blocks were performed for cesarean sections.[29,30] Neurologic toxicity has also been described after the topical use of LAs, which anesthesia providers frequently use prior to airway instrumentation for awake intubation.[31] This is likely underreported because the neurological symptoms may be mild (perioral numbness, tinnitus, agitation) and masked by preoperative sedation that precedes the induction of general anesthesia that immediately follows awake intubation.

Occasional causes of LAST outside the usual scope of an anesthesiologist include retrobulbar blocks for ophthalmologic surgery and inferior alveolar nerve blocks for dental procedures. Toxicity from a retrobulbar block is caused by subarachnoid spread of the anesthetic causing brainstem anesthesia; which can be manifest as altered mental status, apnea, and seizures.[32–34] Specific reports of LAST after inferior alveolar blocks are rare, but it is clearly a potential risk. The richly vascular area of the pterygomandibular space increases the risk for intravascular needle placement, which can be as high as 15.3% even among experienced oral surgeons.[35] Finally, there is a recent increase in utilization of regional blocks in emergency room settings[36] and corresponding reports of LAST in the emergency room,[37,38] but the scope of this problem is currently unknown.

TREATMENT

Presently, the three pillars of LAST treatment consist of seizure management, advanced cardiac life support (ACLS), and prompt administration of a 20% lipid emulsion. For hemodynamically stable patients with isolated seizure activity, intravenous benzodiazepines may be used. Small doses of propofol are considered by some an acceptable alternative for seizure control but can worsen cardiac dysfunction that may develop with LAST. Supplemental oxygen is appropriate for any patient exhibiting signs of LAST, but for patients with apnea, hemodynamically unstable arrhythmias, or cardiac arrest, immediate, more aggressive airway management or circulatory support is required. The goals are to maintain pulmonary ventilation and adequate organ perfusion with well oxygenated blood and to avoid further acidosis until initiation of lipid emulsion therapy.[39]

Before the introduction of lipid emulsion resuscitation, the treatment of severe cardiac toxicity was limited to ACLS and cardiopulmonary bypass. The use of vasopressors during resuscitation potentially worsened acidosis and arrhythmias. Cardiopulmonary bypass had been used in some cases; unfortunately, not all hospitals have that capability.[40] The idea that a lipid-rich substance has the potential to reverse the effects of certain drugs began in the 1960s, when several animal experiments demonstrated that intravenous administration of an oil emulsion decreased the duration of action of thiopental or decreased the free fraction of chlorpromazine in blood.[41,42] Serendipitously, in 1997, the case of LAST in a young woman with isovaleric acidemia and carnitine deficiency inspired a series of animal experiments. Carnitine is required for the transport of fatty acids into the mitochondria for β-oxidation, and accumulation of cytoplasmic acylcarnitines (eg, during myocardial ischemia) is associated with arrhythmias.[43] So, Weinberg et al hypothesized that overloading cells with exogenous fatty acids by infusing a lipid emulsion would exacerbate LA toxicity.[44] Surprisingly, the opposite was seen. Infusing a fat emulsion decreased and even reversed LA toxicity.[45]

In 2006, the first successful resuscitation of a human patient with a lipid emulsion was reported.[46] Since then, there have been many clinical reports describing effective reversal of LAST in adults and children.[47,48] Treatment of toxicity with an intravenous lipid emulsion has been termed *lipid resuscitation therapy* (LRT). The mechanism of LRT is multimodel in action, with lipid exerting both a scavenging effect (previously known as the "lipid sink") and a direct cardiotonic effect.[49,50] The scavenging effect is moderated by the lipid emulsion's ability to take up lipophilic moieties[51] and transfer them around the blood to sites of storage and detoxification. This provides a "lipid shuttle" effect. However, the scavenging effect is not sufficient to explain the rapid recovery.[52] A second effect occurs whereby in laboratory models infusing the lipid emulsion increases cardiac output through a combination of volume and direct cardiotonic effects to improve cardiac output once the cardiac concentration of drug drops below ion channel–blocking thresholds.[53,54] A 20% lipid emulsion is efficacious in the treatment of LAST caused by bupivacaine as well as other less-soluble LAs, such as ropivacaine, mepivacaine, and lidocaine.[55]

The lipid emulsion LD_{50} (median lethal dose) tested in a rat model was found to be much higher than the doses used for lipid rescue in humans.[56] Potential side effects include interference with clinical laboratory measurements (hemoglobin, methemoglobin, electrolytes, base excess); allergic reactions; nausea/emesis; dyspnea; and chest pain. Nonetheless, actual reported side effects are limited to bronchospasm, hyperamylasemia, and laboratory measurement interference. Transaminitis, hepatosplenomegaly, and bacterial contamination are typically associated with prolonged use of a lipid emulsion and do not play a role in the short-term administration for LAST. Although the use of high volumes of lipid emulsion (especially 30%) in premature and low birth weight neonates has been associated with death from fat accumulation in the lungs, there are case reports in neonates, toddlers, and older children of successful reversal of drug overdose (bupivacaine and non-LAs) using standard recommended regimes of 20% lipid.[55,57,58]

Last, as mentioned, one should exercise caution with the use of propofol in this setting: It is not a substitute for a lipid emulsion. There is insufficient lipid content in standard sedating or antiseizure doses of propofol to exert a benefit in the overdose setting; however, propofol can compromise CV stability.

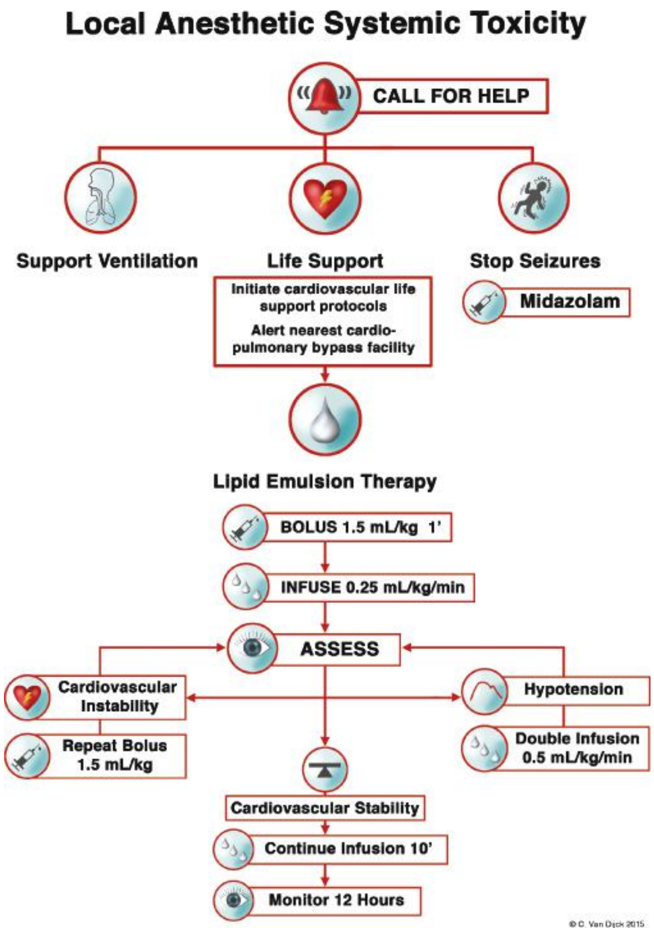

FIGURE 65–1. Checklist for management of local anesthetic systemic toxicity.

After numerous case reports validated the role of LRT as an effective treatment of LAST, the American Society of Regional Anesthesia and Pain Medicine (ASRA) issued a practice advisory in 2010 followed in 2012 by a checklist for managing LAST (Figure 65–1). The guidelines stress the importance of immediate cardiopulmonary resuscitation and provide a detailed algorithm for the dosing and administration of the lipid emulsion.[59,60] Timely use of the LRT, at the earliest signs of toxicity, can improve resuscitative efforts and decrease the amount of vasopressors used. As with any life-threatening emergency, securing intravenous access is essential; however, intraosseous administration of lipid emulsion is a possible alternative if intravenous access proves problematic.[61]

PREVENTION

As always, the best treatment is prevention. This is especially true for LAST. The efficacy and availability of LRT does not decrease the potential morbidity even in cases of successful treatment. The presence of a "silver bullet" does not remove the need for caution. For that reason, the use of ultrasound, intravascular markers, incremental injection with aspiration, less-toxic drugs, and the lowest effective dose is recommended.

Clinical Pearls

- There is a greater likelihood for LA systemic toxicity in petite patients (small muscle mass), those at the extremes of age, and patients with preexisting heart disease or carnitine deficiency.
- Roughly half the cases of LAST are atypical, with no seizures (other CNS symptoms), only CV toxicity or delayed onset.
- The incidence of toxicity increases with injections near richly vascular areas. It is highest with paravertebral injections, followed by upper and lower extremity PNBs.
- Prevention of LAST-related morbidity requires optimizing a complete system for regional anesthesia: patient selection, block choice, drug and dose, complete monitoring and use of USGRA when possible, and preparing for LAST by having a kit available and practicing with simulation.
- Prevention also includes raising awareness and educating our nonanesthesiology colleagues about proper use of LAs and risks, including management of LAST.

Ultrasound offers several potential advantages. It allows for direct visualization of injectable spread of drug, detection of unintended intravascular injection, and the use of smaller volumes of LAs.[26,62–64] Moreover, there is evidence that the use of ultrasound for PNBs can reduce the incidence of LAST.[16,25,26] An intravascular marker such as 10–15 μg of epinephrine has reasonable (albeit imperfect) sensitivity and positive predictive value and can be administered with a test dose. An increase in heart rate of 10 beats/minute or greater or an increase in systolic blood pressure of 15 mm Hg or greater suggests an intravascular injection. Incremental injection of LAs (usually 3–5 mL) and frequent aspiration have been regularly recommended and, together with the use of the test dose, may have contributed to the decrease in the incidence of LAST seen with epidurals. Finally, the use of the lowest effective dose provides an additional margin of safety.[65] It is also reasonable to adjust a dose downward for patients recognized to have a condition that could increase their susceptibility to LAST. This seems somewhat redundant if one always uses the least dose necessary for any block.

Prudence is the point. None of these measures is in itself precise or perfect; hence, it is vital not to rely on a single prevention step, but to incorporate several plus common sense to put patient safety first.[66]

AWARENESS AND EDUCATION

Anesthesiologists use LAs every day in various practice locations and for a wide variety of procedures. Thus, every site where LAs are used in potentially toxic doses should be equipped with basic resuscitation equipment and a 20% lipid emulsion. In addition, the ASRA checklist for the treatment of LAST can help guide the treatment process.[67] An electronic decision support tool was shown to improve adherence to guidelines during simulation of management of LAST and may be of benefit during actual cases.[68] Finally, education of nonanesthesia providers is crucial to raise their awareness of both the risk of LAST and its treatment. Patients could be saved if such very rare events are properly diagnosed and managed by nonanesthesiologists or others among the uninitiated who will otherwise remain ignorant of the risk. Education differs among institutions and departments, but there is suboptimal knowledge of LA dosing, safety precautions, and treatment of LAST among other specialties.[69] For that reason, the ASRA checklist and the electronic decision support tool can be invaluable for physicians in the event of LA toxicity.

CHAPTER 66

Pharmacoeconomics of Regional Anesthesia: Implications in Ambulatory Orthopedic Surgery, Hospital Admission, and Early Rehabilitation

Brian A. Williams, Patrick J. Hackett, Pulsar Li, and Andrew J. Gentilin

INTRODUCTION

The analysis of the relationship of pharmaceutical and device costs to health care systems has been termed *pharmacoeconomics*, and four types of analytical techniques are commonly used for this purpose: cost-minimization, cost-benefit, cost-effectiveness, and cost-utility analyses.[1] With changing payments from private and government-based health insurance programs worldwide, physicians and administrators are forced to focus attention toward cost containment to maintain a profitable (or at least "break-even") enterprise. Cost analysis is an emerging tool in health care economics that can help physicians and administrators meet these new challenges.

TYPES OF COST ANALYSES

Cost analysis examines health care expenditures, and the subtypes of cost analysis also examine factors that are inserted into a denominator of a cost equation. Such factors include monetary benefits (eg, cost-benefit analysis, or CBA), incremental changes of health status variables (eg, cost-effectiveness analysis, or CEA), and patient-reported quality of life (eg, cost-utility analysis, or CUA).[2] If outcomes are determined to be equivalent regardless of the treatment program implemented, then a basic cost-minimization analysis is all that is required because the denominators are equal and the only relevant comparison is between the cost numerators of the compared programs.[3]

Cost-effectiveness analysis is applicable when the effects of comparable health treatments or services share the same therapeutic goals but have different degrees of effectiveness.[4] With CEA, the analyst can compare alternative treatment strategies so that results can be expressed in identical effectiveness units. CEA accounts for the effect of a treatment plan on all clinical outcomes and its economic implications, rather than considering only the cost of devices, supplies, and pharmaceuticals.[4] Effectiveness indicators, such as the number of adverse effects avoided or hospital stay reductions, are useful for comparing the different therapeutic alternatives considered. For this reason, CEA is one way of comparing treatment plans with the same desired effect but different outcome profiles, thus producing results expressed in terms of the number of adverse effects avoided. This approach implies weighing all adverse effects alike or weighing the different adverse effects in the way deemed most suitable by the analyst.[4]

With respect to anesthesia selection, it is highly unlikely that comparing regional anesthesia (RA) with general anesthesia/volatile agent (GAVA) techniques would show equal benefits or equal effectiveness (ie, life-years gained, days of disability avoided). RA significantly differs from GAVA, and the relevant side-effect profiles and risks are quite different as well. In fact, in the past few years, it has become clear in ambulatory procedures, for example, that the choices of the anesthetic and postoperative analgesic techniques have significant consequences for both the length of hospital stay and the frequency of unplanned hospitalization[5,6] and, consequently, the overall cost of the surgery. As a result, comparisons between RA and GAVA would require a CBA, CUA, or CEA.

Clinical Pearls

The four types of analytical techniques used in pharmacoeconomics are
- Cost minimization
- Cost-benefit analysis
- Cost-effectiveness analysis
- Cost-utility analysis

As physicians caring for individual patients, it is important to note that basing a clinical practice strictly on cost analysis is not well advised because individual patients have individual needs. However, in the setting of identifiable patient and hospital benefits when RA is used instead of GAVA, proper patient education regarding the benefits of RA is a most necessary step before any patient or health system benefits can be enjoyed.

It is also important to note that the literature is not replete with conclusive evidence addressing the cost-effectiveness of RA versus GAVA for surgical procedures in which both options are viable alternatives for patient care. Limited studies available can be used to apply cost analysis estimations for other studies that did not specifically address costs, but such approaches must be interpreted with caution.

ANESTHESIOLOGY INTERVENTIONS APPLIED TO COST ANALYSES

Selection of Techniques, Drugs, and Agents

Rationale for Avoiding General Anesthesia With Volatile Agents in Outpatients

When considering invasive outpatient orthopedic surgery, the routine use of GAVA without peripheral nerve blocks (PNBs) as the centerpiece of a multimodal analgesic plan is commonly associated with the following costly outcomes:(1) postanesthesia care unit (PACU) admission; (2) multiple nursing interventions for pain and postoperative nausea or vomiting (PONV); (3) PACU and same-day surgery discharge delays; and (4) unplanned hospital admission.[7–11] However, most hospital pharmacy and therapeutics committees are primarily focused on the pharmacy budget. Six percent or less of all hospital costs related to surgical care are attributed to pharmacy drug costs,[12] and examining drug costs in isolation without regard to patient outcomes is ill advised. The "least-expensive" outpatient GAVA technique, from the standpoint of drug acquisition for line items used for anesthetic maintenance, would probably include volatile agents, opioids, and muscle relaxants.

Postoperative Nausea and Vomiting and Comprehensive Multimodal Analgesia in Outpatient Regional Anesthesia Practice

Clinical Pearls

- General anesthesia with volatile agents causes PONV.
- Opioids (including patient-controlled intravenous analgesia) cause PONV.
- Propofol and multimodal antiemetics prevent PONV.
- Multimodal analgesia minimizes opioid requirements.

A traditional GAVA plan (volatile agents, opioids, and muscle relaxants) is traditionally favored for these specific line-item budgets of the anesthesia department and the hospital pharmacy, but the technique is fraught with "downstream" expenses for the hospital and presents a common basis for patient dissatisfaction. It has been well documented that GA techniques that exclusively use propofol for induction ***and*** maintenance (or as an intravenous sedative technique combined with RA) has a significantly lower PONV rate than do GAVA techniques,[10,13,14] and volatile agents and opioids are considered to be the leading causes of PONV.[15] Exclusive use of propofol instead of volatile agents is considered to provide an important but incomplete method of prevention of PONV.[15]

Three antiemetics of differing mechanisms are required to prevent equivalent PONV outcomes in GAVA patients versus propofol total intravenous technique patients.[16] RA techniques (without GA) are historically considered to be protective against PONV,[17] but research has indicated that there can be significant differences in PONV incidence when differing RA techniques are compared for the same type of surgical procedure.[18] In fact, patients undergoing single-injection PNB techniques that are later prescribed intravenous patient-controlled analgesia (IVPCA) do not appear to have significant benefit of PONV prevention versus similar patients undergoing GAVA with IVPCA[17], whereas patients receiving sustained analgesia primarily with continuous PNBs obtain additional PONV prevention benefits.[17]

For simple knee arthroscopy (mean procedure time < 30 minutes), GA with desflurane was compared with ipsilateral hyperbaric bupivacaine spinal anesthesia (4 mg) to assess PONV and myriad other outcomes.[19] Desflurane patients received PONV prophylaxis with dexamethasone and ondansetron if at least two risk factors were present (female, nonsmoker, PONV history, or motion sickness). Despite PONV prophylaxis in at-risk desflurane patients, all desflurane patients encountered significantly more PONV (6/32, 19%) than did patients receiving selective spinal anesthesia (zero PONV, $P = .024$).[19] In addition, desflurane patients encountered significantly more pain in both phases of postoperative recovery and more "extreme tiredness" in phase II recovery than did patients receiving selective spinal anesthesia.[19]

Generally, the following hold for outpatient orthopedic anesthesia routinely incorporating RA techniques: (1) GAVA should be avoided; (2) opioids should be minimized; and (3) at least two, if not three, antiemetics of differing mechanisms of antiemetic prophylaxis should be used. Our suggested criteria for multimodal antiemetics in outpatient orthopedics is all inclusive, primarily because all patients are likely to have at least one dose of an opioid at some point perioperatively. In outpatient orthopedics, use of a volatile agent alone is a sufficient sole risk factor for routine multimodal antiemetic prophylaxis, regardless of other risk factors, and volatile agents are frankly most logically avoided in the presence of other options (such as propofol total intravenous anesthesia [TIVA]). We suggest (1)[1] oral perphenazine[18,20–22] (8 mg preoperatively, but avoided in patients with Parkinson disease or a history of adverse extrapyramidal reactions to phenothiazines); (2) dexamethasone[18,22–27] (4 mg intravenously, perhaps avoided in patients with diabetes); and (3) a serotonin receptor 5-HT_3 serotoninergic antagonist. The combination of dexamethasone and a 5-HT_3 antagonist is more effective in preventing nausea and vomiting after discharge than is a 5-HT_3 antagonist used alone.[28]

In addition to their emetogenic potential, it is now known that volatile anesthetics possess hyperalgesic properties.[29,30] In a recent prospective randomized clinical trial, Cheng and colleagues reported significantly less pain and less morphine use in women undergoing uterine surgery ($P < .01$ and $P < .01$) with propofol TIVA versus GAVA. This transient hyperalgesia is believed to be due to inhibition of neuronal nicotinic acetylcholine receptors.[31]

It should be understood that opioids are commonly going to be used for RA procedure premedication, intraoperative management of nerve block onset latency, and postoperative analgesic rescue of symptomatic pain not covered by the peripheral block's nerve distribution. In addition, multimodal analgesic techniques, such as low-dose intravenous ketamine,[32–35] pre- and postoperative inhibitors of the cyclooxygenase type 2 (COX-2) enzyme,[36,37] and intra-articular injections by the surgeon to cover myriad mechanisms of the acute pain inflammatory cascade, also have the potential to be useful.[38–44] While COX-2 inhibitors valdecoxib and rofecoxib have been previously withdrawn from the market due to their cardiac side effects, studies are reassuring that the single-dose preoperative use of celecoxib remains safe.[36]

Minimizing Anesthesia-Controlled Time in the Operating Room

The potential value of the RA induction room should not be underestimated from the pharmacoeconomic perspective. Performing PNB techniques before operating room (OR) entry has been shown to be associated with a time savings of approximately 4–9 minutes of OR time per case compared with using GAVA without blocks.[9,45] In general, when the patient enters the OR ready for surgical preparation and has a faster emergence (and exit) due to the use of sedation versus GAVA, an OR with five cases can save 20–45 minutes each day. If the cost of a minute of OR time is estimated to be $30, then 1 day of this amount of time savings for five cases carries a potential cost reduction of $600–$1350. A portion of this theoretical savings is likely "real" in centers operating at or above 80% capacity, in which forced overtime (of preoperative, intraoperative, and postoperative nursing/ancillary staff) is a major budgetary expenditure. The cost savings becomes even more significant when cases later in the day (eg, after 3 PM or 5 PM) are commonly "stacked" into fewer available staffed ORs, further lengthening already-long clinical days. Dexter and colleagues estimated that emergence that is 6 minutes faster than baseline likely translates to a per case overtime reduction ranging from 1.3 to 2.6 minutes.[46] In a 50-case surgical pavilion, this translates to 65 to 130 minutes of overtime saved.

How the reduction of anesthesia-controlled time influences OR staff retention is unknown. Repeated episodes of forced overtime for OR staff may lead to a loss of staff morale, which may translate to staff turnover. Staff turnover implies the replacement of departed, experienced staff with less-experienced staff, associated training, and possible surgical process inefficiencies until training is complete and posttraining experience is sufficient to resume an optimally efficient surgical process. Prolonged anesthesia-controlled time may also adversely affect staff morale in both phase I and phase II PACUs. While no studies to date have correlated reduced anesthesia-controlled time and perioperative nursing or OR staff retention, a recent study inferred an increase in several adverse events and errors with increased nursing work hours.[47]

Clinical Pearl

- Performing RA procedures in induction rooms decreases both induction time and emergence time in the OR.

Operating room time savings for outpatient shoulder surgery, via shorter induction time and emergence time values, has also been substantiated when interscalene nerve block was used alone without GAVA.[48] In this study, recovery room times and unplanned hospital admissions were also reduced in the patients treated with the interscalene block versus GAVA.[48]

Bypass of the Postanesthesia Care Unit in Ambulatory Surgery

In outpatient surgery, PACU bypass has been shown to be achievable in nearly 90% of patients receiving exclusively RA techniques (including neuraxial techniques if hemodynamic criteria are met).[10] To achieve PACU bypass in an institution where RA techniques are used in high volume, it is important to use tested criteria that incorporate both physiologic parameters and immediate symptomatic outcomes to determine PACU bypass eligibility and to use criteria that incorporate specific outcomes for both RA patients and GA patients.[49] The WAKE score[50] entails criteria that incorporate the original regional anesthesia PACU bypass criteria,[10] the traditional Modified Aldrete score,[51] the White-Song fast-tracking criteria,[52] and the Mayo Modified Discharge Scoring System[49,50] (Table 66–1).[49,53] Appropriately adjusting legacy criteria to the modern practice of ambulatory anesthesia and RA while incorporating "zero-tolerance criteria,"[50] which are applicable to all anesthetic types, appears to allow for "maximal return on investment" from the routine use of RA.

PART 11

TABLE 66–1. Parameter-scored and zero-tolerance criteria for phase I PACU bypass (outpatient surgery) or phase I PACU discharge (inpatient or outpatient surgery) and likely effects of anesthetic drug/technique selection on meeting the described criteria for fast-tracking purposes.

Movement (LE: Lower Extremity; UE: Upper Extremity)	Scores
Purposeful movement of (at least) 1 LE and 1 UE	2
Purposeful movement of at least 1 UE (and neither LE)	1
No purposeful movement	0

Clinical correlations:

1. An isobaric spinal anesthesia would decrease the likelihood of achieving a score of 2 compared to an ipsilateral hyperbaric spinal anesthesia.
2. Prolonged emergence time from GA with volatile anesthetic (± neuromuscular blocking drugs) would increase the likelihood of achieving a score of 0 as opposed to a 1 or 2.
3. Interscalene block patients with blocks designed to provide overnight anesthesia-analgesia would not achieve an Aldrete parameter score of 2 because only three of four extremities would achieve purposeful movement.

Blood Pressure (Sitting and Supine)	Scores
Within 20% of preoperative baseline, not orthostatic	2
Within 20%–40% of preoperative baseline, not orthostatic	1
Less than 40% of preoperative baseline and/or orthostatic	0

Clinical correlations:

4. Isobaric bilateral spinal would likely cause a greater sympathectomy and hypotension than would an ipsilateral hyperbaric spinal.
5. Vasodilatory effects of propofol sedation would likely dissipate equal to or faster than the vasodilatory effects of volatile anesthetics.
6. Low-dose ketamine sedation would not typically cause vasodilation and subsequent hypotension.

Level of Consciousness	Scores
Awake and/or easily aroused by single stimulus, follows commands	2
Arouses to repeated or continuous stimuli, protective reflexes, follows commands	1
Obtunded or persistently somnolent; ± protective reflexes	0

Clinical correlations:

7. Avoidance of airway instrumentation, mechanical ventilation, volatile agents, and systemic opioids allows faster emergence from anesthesia and return of a level of consciousness consistent with a score of 2.
8. Perphenazine, ondansetron, and dexamethasone are all off-patent nonsedating antiemetics.

Respiratory Effort	Scores
Coughs and deep breathes freely and/or on command	2
Involuntarily cough only; unsupported airway	1
Tachypnea, dyspnea, or apnea and/or requiring airway support	0

Clinical correlations:

9. Avoidance of airway instrumentation, mechanical ventilation, volatile agents, and neuromuscular blocking drugs all favor a more timely score of 2.

Oxygen Saturation	Scores
≥95% or (preoperative reading minus 2) without supplemental O_2	2
≥95% or (preoperative reading minus 2) with supplemental O_2	1
<95% or (preoperative reading minus 2) ± supplemental O_2	0

(*continued*)

TABLE 66–1. Parameter-scored and zero-tolerance criteria for phase I PACU bypass (outpatient surgery) or phase I PACU discharge (inpatient or outpatient surgery) and likely effects of anesthetic drug/technique selection on meeting the described criteria for fast-tracking purposes. (*Continued*)

Clinical correlations:

10. Systemic opioids and neuromuscular blocking drugs can cause hypoventilation-induced desaturation; ipsilateral hyperbaric spinal anesthesia and/or peripheral nerve blocks would be unlikely to do so.

A score of 8 or higher, along with meeting all the zero-tolerance criteria (see next section), is sufficient to qualify for phase I PACU bypass after outpatient surgery or to fast-track phase I PACU discharge when transfer to an inpatient nonmonitored bed is planned after surgery. For patients with diagnosed obstructive sleep apnea (OSA), a score of 9 is recommended, along with the same zero-tolerance criteria (next section), and after 30–60 minutes of no episodes of witnessed apnea in an otherwise-nonstimulating PACU environment. The authors will send OSA patients to a postoperative monitored bed (eg, continuous pulse oximetry with or without capnography) if these OSA-specific WAKE criteria are not met.

Zero-tolerance criteria for WAKE score PACU bypass (outpatient surgery) or fast-track PACU discharge (inpatient or outpatient surgery) and the likely effects of anesthetic drug/technique selection on meeting the described criteria for fast-tracking purposes.

(1) Pain as appropriately adjusted to patients' baseline pain scores (with movement) at the surgical site

Clinical correlations:

1. Multimodal analgesia is logically employed on a routine basis, emphasizing nonsedative analgesics such as acetaminophen, type 2 cyclooxygenase inhibitors or nonsteroidal anti-inflammatory drugs, and N-methyl-D-aspartate antagonists (low-dose intravenous ketamine, and/or perioperative oral dextromethorphan, and/or intravenous magnesium).
   - Preoperative PNBs render patients as more likely to meet this criterion than would postoperative systemic opioids for rescue analgesia.
   - If a patient has a preoperative baseline pain score with movement of 8 of 10, in the absence of a PNB, it is highly likely that the patient will meet PACU bypass/discharge criteria on all other parameters and be successfully discharged with a postoperative pain score with movement of 10 of 10, by the nature of the limited analog scale available to choose from given the high preoperative pain score. However, in the presence of PNBs covering all relevant nerve distributions (eg, femoral and sciatic for total knee replacement), this would seem much less likely.
2. Buprenorphine added to peripheral nerve blocks will likely carry much greater analgesic duration than would an equivalent systemic dose of morphine or other opioid.
3. Maintenance anesthesia with propofol avoids the hyperalgesic effects of volatile anesthetics.
4. Spinal/regional anesthesia is likely far less hyperalgesic than is anesthesia with volatile anesthetics and short-acting opioids.

(2) PONV as a "yes-no" assessment

Clinical correlations:

5. Preoperative oral perphenazine is less sedating than intraoperative prochlorperazine and is similarly nonsedating as ondansetron and dexamethasone.
6. Systemic clonidine (eg, as a nerve block adjuvant) may have antiemetic benefits.
7. Volatile anesthetics and systemic opioids are emetogenic.

(3) Shivering, pruritus, and/or orthostatic symptoms (light-headedness and/or hypotension in the sitting position)

Clinical correlations:

8. Ipsilateral hyperbaric spinal (comprising a lower overall total intrathecal dose than would an isobaric bilateral spinal) may be less likely to create light-headedness in the sitting position when compared with isobaric spinal anesthesia by the time surgery is finished.
9. Systemic clonidine (eg, added to peripheral nerve blocks) and phenylephrine infusions (commonly coadministered during spinal anesthesia) have favorable antishivering and/or thermoregulatory benefits.
10. Volatile anesthetics disrupt thermoregulation more so than does regional anesthesia.
11. Systemic opioids commonly cause pruritus.

GA = general anesthesia; PNBs = peripheral nerve blocks; PONV = postoperative nausea and vomiting.

Source: Modified with permission from Moore JG, Ross SM, Williams BA: Regional anesthesia and ambulatory surgery. *Curr Opin Anaesthesiol*. 2013 Dec;26(6):652–660.

In surgical pavilions with large caseloads (eg, 50 cases/day), an 80% PACU bypass rate (compared with no PACU bypass) can lead to a PACU nurse full-time-equivalent (FTE) staffing reduction of up to four FTEs if the PACU nurses are full-time employees or by 20 nursing hours if the PACU nurses are part-time employees.[46,54] When combined with forced overtime of OR staff and step-down (phase II) recovery staff, OR time savings and PACU bypass (documented to be achievable with exclusive use of RA) can present important cost-saving opportunities for the hospital. In addition, a reduction in medical errors from reduced mandatory nursing hours previously noted could lead to additional decreases in hospital costs, as well as improved patient outcomes.[47]

In a patient population undergoing anterior cruciate ligament (ACL) reconstruction, PACU bypass using criteria resembling the described WAKE score was associated with a $420 hospital cost reduction (in year 2000 inflation).[55] The cost-savings component from the initial amount of $420 per PACU bypass patient (which excluded savings associated with nurse staffing reductions highlighted by Dexter and colleagues detailed previously) were likely attributable to RA patients experiencing fewer symptoms than those receiving GAVA. Williams and coworkers also reported that throughout the multipavilion university hospital during peak use of PACU bypass (3000 outpatient orthopedics procedures per year), PACU nurse staffing requirements for 25,000 surgical patients per year (throughout all pavilions) consisted of 28 FTE PACU nurses.[55] When the main campus multipavilion hospital relocated outpatient orthopedics to another off-site hospital in the health system, PACU bypass was used on the main campus for monitored anesthesia care cases only. Soon after, PACU nurse staffing requirements increased to 36 FTE (from 28 FTE) for the same annual caseload.[55] When nerve blocks are routinely used, PACU bypass is a potentially powerful cost management tool in ambulatory orthopedic anesthesia not only from a staffing standpoint, but also with respect to overall symptom reduction and return to wakefulness during same-day recovery.

Successful Same-Day Discharge in Ambulatory Surgery

Woolhandler and Himmelstein estimated that the cost of hospital admission (for all types of diagnoses and procedures, in 1997 inflationary dollars) is $1050.[56] Williams and coworkers found that the hospital cost increment associated with an overnight admission after ACL reconstruction was $385.[55] The likely cost differences in the findings of Williams and coworkers versus those of Woolhandler and Himmelstein are likely related to the generally healthy status of outpatients presenting for ACL reconstruction. The key point is that it will always be less expensive to the hospital administrator for a patient to go home immediately after outpatient surgery than to be admitted overnight for observation.[57] That said, precautions are required to ensure that costs are not incurred later in the form of requiring hospital readmission for complications improperly managed during the initial admission, especially because these readmissions are often ineligible for third-party reimbursement. Indeed, refractory pain is the most common cause of hospital readmission after discharge, accounting for over one-third of such readmissions.[58]

Clinical Pearls

- Criteria exist (e.g., WAKE score[50]) to determine safe PACU bypass (ie, phase I recovery) after RA and GA procedures.
- PACU bypass with the WAKE score is achievable in up to 90% of RA patients.
- The implications for staffing in a high-volume PACU bypass program using the WAKE score are significant.

It is important to understand that the associated hospital cost reductions of $420 for PACU bypass and $385 for successful same-day discharge were calculated using standard econometric techniques of multivariate regression analysis.[55] These are not necessarily nursing cost reductions. Further detailed cost center study methodology would be required to determine if cost reductions were traced to nursing costs in particular, versus via another cost center. Thus, the associated cost savings captured in these values incorporate any and all expenditures related to OR time, additional RA equipment and medications used, prophylactic antiemetics, and postoperative parenteral nursing interventions required for symptoms. When specific time-resource and symptomatic outcomes were incorporated into the stated multivariate regression analysis, these covariates were not independent predictors of hospital costs; only PACU bypass and successful same-day discharge were independent predictors of hospital cost reductions. Thus, when deriving any cost analysis equation using these cost-saving values, it is important to use these values only for such analyses, pending the results of future, more detailed, economic studies. It would not be methodologically correct to simultaneously incorporate cost values from myriad other studies that calculate various itemized costs of events such as “minutes of PACU time,” “minutes of phase II recovery time,” or individual drug costs or labor costs. The use of cost estimate values from multiple studies is methodologically incorrect because “double counting” would occur, which may artificially elevate incremental differences in cost, cost-benefit, cost-effectiveness, and cost-utility analyses.

Successful Resource Management of Well-Trained RA Practitioners in the Ambulatory Surgery Setting

In ambulatory surgery, well-trained RA practitioners may be tempted to implement a comprehensive nerve block care algorithm for all surgical patients. This enthusiasm should be tempered by the consideration of the “opportunity cost” of providing labor-intensive nerve block anesthesia for patients who may not necessarily benefit from these procedures. For instance, in the study by Williams and colleagues,[11] 543 patients underwent “relatively noninvasive” outpatient knee surgery, while the remainder underwent “more invasive” knee surgery. Forty-seven percent (253/543) of the patients undergoing the noninvasive procedure received femoral (with or without sciatic) nerve blocks, but the use of nerve blocks (with local anesthetics) in these patients was not associated with a reduction in symptoms, nursing interventions, or unplanned hospital admissions.[11] As a result, these authors concluded that, based on this retrospective review of a significant clinical caseload of noninvasive knee surgery outpatients, nerve blocks with local anesthetics should be reserved for patients who have significant refractory postoperative pain or in other special situations, such as a complicated pain history or intolerance to traditional oral analgesic techniques. Whether future efforts of motor-sparing perineural analgesia with avoidance of motor block (via avoidance of local anesthetics in nerve blocks to avoid the risk of patient falls) have the potential of proving cost-benefit advantage or cost-effectiveness requires further study.

Clinical Pearls

- Hospital admission and readmission are costly.
- Additional material costs for an RA program for outpatients are likely offset by significant overall hospital cost savings when reliably achieving PACU bypass and same-day discharge.

In the same review of 1200 consecutive knee surgery outpatients, 657 underwent more invasive knee surgery, and 527 of these 657 (80%) received femoral with or without sciatic nerve blocks.[11] In these patients, nerve block anesthesia and analgesia were significantly associated with reduced pain symptoms during recovery (therefore, fewer nursing interventions for pain management) and fewer unplanned hospital admissions. It is important to note that the selection of nerve block anesthesia-analgesia appears to be necessary but not sufficient to comprehensively reduce postoperative nursing interventions and unplanned hospital admissions: Whenever GAVA was used (in the presence or the absence of nerve block anesthesia/analgesia), the odds ratio of more associated symptoms after GAVA was 2.1 ($P < .001$), whereas the odds ratio of more associated unplanned hospital admissions after GAVA was 3.3 ($P = .001$).[11] Thus, nerve block anesthesia and analgesia for indicated (more invasive) procedures (ideally in the setting of a comprehensive multimodal analgesic care plan) and the avoidance of GAVA (for all procedures) would likely provide the anesthesia care team (and the hospital) with the fewest possible side effects and the greatest facilitation of successful same-day discharge. However, routine sensorimotor blocks (ie, with local anesthetics) for non-invasive knee surgery may be an investment of RA practitioners' time (and risk) that may provide relatively little benefit and that takes away the opportunity for RA practitioners to engage in other value-adding activities. Such value-adding activity may include the placement of continuous nerve block (CNB) catheters for select patients, when time may have been only available previously to administer a single-injection nerve block (SINB).

Pain Risk Stratification

Clinical Pearls

- Routine use of PNBs in outpatient surgery is most efficient when patients are likely to encounter sufficient postoperative pain to justify their use.
- It is important to categorize surgery as "sufficiently non-invasive" versus "sufficiently invasive" to justify nerve block use on a per patient basis.

Upper Extremity Surgery

Shoulder For outpatient shoulder or upper extremity surgery, there have been few substantiated, comprehensive recommendations for allocating nerve blocks (single injection vs continuous infusion) based on anticipated postoperative pain, postoperative nursing interventions (with vs without), or unplanned hospital admissions.

In shoulder surgery, the comparison of single-injection blocks with GAVA has shown predictable findings. For arthroscopic acromioplasty of the shoulder performed under GAVA, Singelyn and colleagues showed that interscalene nerve block provided definitive recovery advantages over suprascapular nerve block, single-injection intra-articular local anesthetic, and controls.[59] For outpatient open surgery of the rotator cuff, Hadzic and coworkers reported that GAVA use (vs single-injection brachial plexus block with ropivacaine) led to increased PACU admissions (vs phase I recovery bypass), higher reports of postoperative pain, longer time to ambulation, longer time to same-day discharge, and higher risk of unplanned hospital admission.[60] In this study, no outcome differences occurred in follow-up from 24 hours to 2 weeks after surgery, but this study was underpowered.

In addition to the potential for cost savings mentioned, recent studies have shown data supportive for the use of RA with sedation (instead of GA) when the beach-chair position is used for shoulder surgery.[61] A recent study by Koh et al. found a significantly higher incidence of cerebral deoxygenation with GA versus interscalene block and monitored sedation, 56.7% versus 0%, respectively.[62]

Past literature has shown favorable analgesic outcomes with the use of intra-articular analgesic infusions for postoperative analgesia in less-invasive shoulder surgery.[63] But, many case reports have shown that this practice, especially continuous infusions of local anesthetic, can lead to chondrotoxicity. This devastating but rare complication can lead to irreversible cartilage breakdown, at times necessitating total joint arthroplasty.[64] While it seems likely that using only single injections with lower concentrations of local anesthetics in fact may attenuate chondrotoxicity risk, intra-articular anesthesia is no longer recommended.[65,66]

A review by Chelly and associates[67] provides an overview that may guide practitioners for categories of postoperative shoulder pain until more definitive evidence is available. In this review, shoulder procedures are clustered into a catheter-eligible category if the following procedures are involved: shoulder arthroplasty, rotator cuff repair, Bankart repair, and open reduction/internal fixation of the humerus.

The benefit of continuous interscalene catheters for shoulder arthroplasty and rotator cuff repair is well documented.[68–74] Although logic would indicate similar effectiveness for less-invasive procedures, there is little evidence at this time to indicate that interscalene brachial plexus catheters would be similarly useful for patients undergoing less-invasive shoulder operations (eg, shoulder stabilization procedures, distal clavicle resection or acromioplasty, subacromial decompression, biceps tenodesis or tenotomy, or even routine debridement inside the glenohumeral joint) when compared with SINBs and perioperative multimodal oral analgesia. Thus, studies are needed to show the benefit of CNBs (vs single injection) and single-injection blocks (vs no blocks) for a wide variety of shoulder procedures that produce an uncertain magnitude of postoperative pain.

Upper Extremity Distal to Shoulder For outpatient wrist and hand surgery, Hadzic and coworkers addressed this patient population comparing chloroprocaine infraclavicular nerve block against GAVA, showing that GAVA use led to more PACU admissions (vs phase I recovery bypass), higher reports of postoperative pain, longer time to ambulation, and longer time to same-day discharge.[75] However, there were no outcome differences in follow-up from 24 hours to 2 weeks after surgery. This last finding was underpowered and did not show statistical equivalence.[75]

Chan and associates prospectively studied nonrandomized hand surgery patients (n = 126) undergoing GAVA (n = 39), axillary block (n = 42), or Bier block (n = 45).[76] GAVA was associated with the most postoperative symptoms and nursing labor intensity, as well as the longest discharge times. Bier block patients not only had the fastest recovery times and lowest associated total perioperative costs but also were at small risk for conversion of the anesthesia plan (2/45) to GAVA due to tourniquet pain.

Gebhard and colleagues retrospectively studied hand surgery patients (n = 62) receiving GAVA (n = 20), Bier block (n = 21), or wrist block (n = 21).[77] They found that wrist block patients were discharged home soonest and encountered (1) less hypertension than did Bier block patients and (2) less hypotension than did GAVA patients.[77]

McCartney and coworkers prospectively studied 100 hand surgery outpatients randomized to receive GAVA (n = 50) or brachial plexus block with lidocaine (n = 50). These authors found essentially similar, if not identical, findings to those reported by Hadzic (prospectively) and Chan (retrospectively) as mentioned previously. McCartney and coworkers also concluded that there were no long-term (2-week) pain outcome differences, although the brachial plexus block group only received the short-acting local anesthetic lidocaine.[78]

For other (distal) upper extremity surgery, Chelly and associates stated that PNB catheters are likely indicated for implantation procedures after trauma, as well as for open reduction/internal fixation of the hand or digits,[67] although a prospective randomized trial to definitively verify this intuitive concept may be difficult to achieve. Ilfeld and colleagues have shown that a continuous infraclavicular brachial plexus catheter (vs placebo catheter infusion) resulted in less postoperative dynamic pain and opioid consumption and fewer sleep disturbances.[79]

Less-invasive upper extremity procedures (typically applicable to outpatients) have not been comprehensively studied with respect to the potential value of continuous catheters versus single-injection blocks. However, Rawal and coworkers[80] showed that an axillary CNB catheter with intermittent-bolus dosing provided excellent wrist and hand analgesia for patients undergoing surgical procedures that may have been somewhat less invasive than those described earlier by Ilfeld and colleagues.[79] Rawal and coworkers' study included 60 patients who received a mepivacaine axillary block bolus and concomitant nerve block catheter placement and were undergoing carpal tunnel release (n = 11), finger fracture repair (n = 11), tendon repair (n = 10), finger joint arthrodesis (n = 10), wrist arthroscopy (n = 8), and tumor resection or other procedures (n = 10). This study studied neither a control group of patients undergoing no nerve block nor a treatment group undergoing SINB only. In fact, 3 of the 60 patients studied did not use the bolus dose function postoperatively. However, almost every bolus treatment was prompted by patients achieving a verbal pain score of at least 5 (of 10), and bolus treatments returned pain scores to around 3 (of 10), thus providing clinically significant analgesia.[80] Patients in this study used all of their allotted boluses by the 12th hour after surgery; as such, the reader may speculate that patients may simply benefit from a long-acting, SINB designed to provide 18 hours or more of postoperative analgesia, instead of the technical complexity of a nerve block catheter.

While Rawal and coworkers found that the most common cause of patient dissatisfaction with the continuous-catheter, intermittent-bolus technique was hand numbness, a recent randomized-observer blinded study by Fredrickson et al showed that motor block related to a long-acting brachial plexus block did not appear to cause patient dissatisfaction.[80,81] Therefore, patient uncertainty and potential dissatisfaction associated with prominent numbness or motor block should likely be factored into the decision of which nerve block technique is selected when a single-injection versus a continuous-catheter technique is considered.

Recent literature has also pointed toward an increase in OR efficiency with the use of RA for upper extremity surgery. Mariano et al. (2009) showed reduced anesthesia-controlled time with both intravenous RA and RA for upper extremity procedures when a nerve block induction room was utilized preoperatively.[45] In this study, anesthesia-controlled time was reduced from an average of 32 minutes with GA to 28 and 25 minutes with PNB and intravenous RA, respectively.

Clinical Pearls

- Arthroscopic debridement and subacromial decompression of the shoulder are likely among the "least-invasive" procedures with respect to postoperative pain, but this does not translate to "no pain" after least-invasive shoulder surgery.
- Rotator cuff repair and arthroplasty of the shoulder are likely among the "most invasive" procedures with respect to postoperative pain.
- Wrist and hand surgery can generate significant postoperative pain; however, the pragmatic value of catheter techniques for these same-day discharge procedures requires further evaluation.

To summarize, outpatient hand surgery often results in significant postoperative pain, with patient pain scores often reaching or exceeding a 5 (of 10) on a visual analog scale.[82] Retrospective reviews and prospective studies have demonstrated uniformly that patients receiving PNBs have significantly improved outcomes on the day of surgery compared with patients receiving GAVA. For shoulder surgery, the use of continuous brachial plexus catheters is sufficiently substantiated to recommend their routine placement (by trained practitioners) for invasive shoulder surgery, pending other economic considerations (eg, reimbursement from third-party or government entities). Perineural catheters and associated CNBs provide incremental benefits, but not without higher technical difficulty of percutaneous catheter placement. Ambulatory CNBs have been shown to be effective with a relatively low complication rate in postoperative pain management.[83] Because of difficulty in follow-up and reimbursement as well as lack of incremental pay, it may be more beneficial to consider use of perineural adjuvant medication to prolong the patient-perceived effectiveness of a SINB.[84] These findings also encourage the routine use (by trained practitioners) of all peripheral/regional techniques for upper extremity surgery, although further research is needed to determine outcome benefits of continuous blocks versus SINBs in the days and weeks following mildly to moderately invasive shoulder and distal upper extremity surgery. The usefulness of intra-articular and incisional infusions after simple arthroscopic procedures of the shoulder has been documented, but due to the risk of chondrotoxicity, they are no longer recommended.

Knee Surgery

Recommendations for rational nerve block selection (SINB vs CNB vs none) in outpatient knee surgery have previously been suggested.[85] This guideline incorporates the resource management principles described previously and creates three major categories: (1) noninvasive, (2) more invasive, and (3) most invasive (Table 66–2). *Noninvasive* implies that routine use of nerve block analgesia is probably not necessary, as described previously.[11] *More invasive* implies that a routine femoral nerve block would be recommended, but that a sciatic nerve block is probably not necessary because the vast majority of the postoperative pain is likely attributable to femoral nerve distribution. *Most invasive* implies that the postoperative pain will likely be attributable to both femoral and sciatic nerve distributions, and both nerves would likely benefit from routine blockade. The more invasive and most invasive knee surgery categories are based on clustering moderate and severe into one category of surgical invasiveness.[11]

This algorithm[85] also describes when a single-injection block would likely be sufficient versus when a CNB catheter would likely be of greater benefit than a single injection. If multimodal perineural analgesia applied to SINB provides meaningful extensions of patient-perceived analgesic duration, this may lead to a significant paradigm shift away from the more labor-intensive CNB care plan.

Foot and Ankle Surgery

For outpatient foot and ankle surgery, few, if any, substantiated, comprehensive recommendations are available for allocating nerve blocks (single injection vs continuous infusion) based on anticipated postoperative pain, postoperative nursing interventions (with vs without), or unplanned hospital admissions. Interestingly, few studies compared SINBs against GAVA for surgery below the knee. In addition, few studies have categorized postoperative foot and ankle pain as sufficiently manageable with SINB versus CNB. Most studies evaluating the use of various approaches to the sciatic nerve block for foot and ankle surgery have simply evaluated block success rate (with no comparative treatment group), compared varying popliteal/sciatic nerve block approaches (sometimes with neuraxial techniques), or compared continuous-infusion strategies.

Singelyn and colleagues provided one of the first studies describing the efficacy of the popliteal fossa block placed with nerve stimulator guidance and reported a low 3% (15/507) rate of conversion to GAVA,[86] whereas Provenzano and coworkers reported an 18% conversion rate to GAVA (84/467).[87] In the same study, Provenzano and coworkers reported a significant reduction in postoperative opioid requirements in patients with a successful popliteal fossa block compared with 367 patients who did not receive the block.[87]

When neuraxial techniques are being considered, Curatolo and associates provides important insight that epidural anesthesia for foot and ankle procedures is associated with a high (4.4%, 7/160) conversion rate to GAVA, although epidural success was correlated with larger per-segment doses.[88] Several studies have compared the efficacy of spinal anesthesia with popliteal fossa block. All have shown the intraoperative efficacy of both techniques, although the in-hospital recovery after spinal anesthesia was more lengthy,[89,90] with an additional risk of urinary retention after spinal.[90] Protić and colleagues showed faster onset of time until surgical anesthesia was achieved with spinal, but with significantly shorter duration of analgesia.[91]

Generally, meaningful postoperative analgesia should not be expected after neuraxial techniques, and analgesia after popliteal fossa block will depend on the local anesthetic agent (and additives) used. In addition, when the analgesic duration of the popliteal sciatic block (with long-acting local anesthetics) is compared with the durations of ankle block, foot block, or subcutaneous infiltration, one should expect doubling or tripling the analgesic duration with a sciatic-specific depot injection.[92]

Continuous sciatic nerve catheters have gained popularity in recent years. After being introduced by Singelyn and colleagues, who described a complex Seldinger (catheter-over-guide-wire) technique for catheter placement (achieving a 92% success rate),[93] authors have repeatedly found that CNB techniques lead to excellent analgesic outcomes when compared with SINB techniques (or placebo catheters).[94–96] At this time, there are no definitive guidelines for the selection of SINB versus CNB techniques based on anticipated surgery, with the exception of recommendations implied by the myriad findings reported previously. Others have suggested that for hardware removal from the foot and ankle, a single-injection block is sufficient, whereas for most other foot-ankle procedures, CNB use may have additional benefits.[67]

A recent prospective randomized trial by Elliot and colleagues showed a significant difference in pain scores and oral opioid usage in postoperative days 2–3 after major ankle surgery when given a sciatic CNB local anesthetic bolus, with saline infusion or with bupivacaine infusion, for 3 days postoperatively. The authors, however, questioned the clinical

TABLE 66–2. Algorithm for recommended nerve block analgesia for knee surgery.

Category I (Noninvasive)
Types of Procedures: Knee arthroscopy with debridement, lateral release, meniscal surgery, simple meniscal repair, removal of superficial hardware, dropout cast application
Care Plan: No blocks unless unanticipated postoperative pain occurs
Category II (More Invasive)—Femoral Nerve-Distributed Pain
Category IIA: Less Painful Category II
Types of Procedures: Arthrotomy, deep hardware removal, microfracture, mosaicplasty/chondroplasty or cartilage transplant, complex meniscal surgery, ACL with single-bundle allograft
Care Plan: Single-injection femoral nerve block recommended: no sciatic block unless unanticipated pain refractory to femoral block
Category IIB: More Painful Category II
Types of Procedures: ACL with patellar tendon autograft or double-bundle allograft
Care Plan: Continuous catheter recommended: no sciatic block unless unanticipated pain refractory to femoral block
Category III (Most Invasive)—Femoral and Sciatic Nerve-Distributed Pain
Category IIIA: Least-Painful Category III
Types of Procedures: Distal patella realignment, some complex meniscal repairs involving the posterior knee
Care Plan: Single-injection femoral and sciatic nerve blocks
Category IIIB: More Painful Category III
Types of Procedures: ACL hamstring autograft, meniscal reconstruction, unicompartmental knee arthroplasty
Care Plan: Continuous femoral catheter and single-injection sciatic nerve block
Category IIIC: Most Painful Category III
Types of Procedures: Total knee replacement ACL double-bundle autograft, meniscal reconstruction, high tibial osteotomy, multiligament reconstruction (including PCL, LCL, MCL, POL), posterolateral corner reconstruction, management of knee trauma involving multiple incisions affecting anterior and posterior knee
Care Plan: Continuous femoral and sciatic nerve block catheters; caution with block of sciatic nerve via bolus or catheter infusion dose until dorsiflexion of the foot is documented postoperatively; consider perineural analgesics without local anesthetics (eg, clonidine-buprenorphine) until common peroneal nerve function is confirmed, before use of perisciatic local anesthetics

ACL = anterior cruciate ligament; LCL = lateral collateral ligament; MCL = medial collateral ligament; PCL = posterior cruciate ligament; POL = posterior oblique ligament.

significance of their study given the highest pain levels were 3.5/10, in addition to the added cost and inherent risks of CNB catheters in outpatients.[97]

The ultimate decision about the use of SINB versus sciatic CNB may depend on realistic expectations by the surgeon regarding return to weight-bearing status. In this situation, the surgeon may not have an accurate impression of weight-bearing success rates in the setting of uncontrolled pain, but full weight bearing in the setting of a partially anesthetized sciatic nerve (via a continuous sciatic catheter) may be ill advised. Evolving work with multimodal perineural anesthesia may lead to increasing analgesia with decreased risk of motor block.[98]

Summary Statement Regarding Nerve Block Technique Allocation

The rational use of SINB versus CNB in ambulatory surgery, that is, allocating the "scarce resource" of the well-trained RA practitioner and avoiding routine nerve blocks for patients who probably do not need them (or providing SINBs when a continuous catheter is not likely needed) will free time to perform catheter techniques for patients undergoing indicated procedures. Again, because of continued decreases in reimbursement and difficulties arranging follow-up for perineural catheters in the outpatient setting, SINB (perhaps with multimodal perineural analgesia, pending further study) with concomitant use of multimodal oral/systemic analgesics may be a reasonable and more cost-effective approach in the ambulatory surgery setting.[84] In OR settings that care for both outpatients and inpatients, this strategy allows the skilled RA practitioner to also dedicate time to CNB placement, where the incremental workload and cost would seem to be more beneficial.

EFFECTS OF PNB TECHNIQUES ON POSTOPERATIVE LENGTH-OF-STAY AND REHABILITATION OUTCOMES

The Need for Training and the Importance of Multimodal Analgesia

Despite the evolution of multimodal analgesia and nerve block analgesia, little progress has been made with respect to patient perceptions of quality improvements in analgesia care. This has been documented in two studies almost a decade apart, with Warfield and Kahn[99] and Apfelbaum and coworkers[100] using similar methodologies. Warfield and Kahn surveyed hospital patients from 300 hospitals (42% of which had acute pain management programs) and found that 77% of patients experienced pain after surgery, with 80% of these respondents categorizing their pain as moderate to severe. In the study by Apfelbaum and coworkers 8 years later, 80% of surveyed adults (n = 250) experienced pain after surgery, with 86% of these respondents characterizing the pain as moderate, severe, or extreme.[100] This latter study did not characterize the hospital-based acute pain management infrastructure where respondents underwent surgery.[100] Thus, the time between the first development in 1992 of federal recommendations for acute pain management[101] and pain management mandates in 2001 by the US Joint Commission[102] did not show perceptions of improvement in pain management after surgery in the general population.

Clinical Pearls

- Pain is often undermanaged in the opinion of the general public.
- Many health care professionals feel they need more training in understanding analgesic methods and means to implement them.

One approach to making significant progress toward improving postoperative pain management is to properly educate clinical staff. One study by Loder and colleagues described the surveying of the clinical staff of a rehabilitation hospital about their knowledge and attitudes regarding effective pain management.[103] This study showed that rehabilitation hospital staff held generally progressive attitudes toward the treatment of pain, but with a substantial degree of ambivalence about the use of opioids in that treatment.[103] The same staff rated their own lack of education about pain management as one of the chief barriers to effective pain management, and a large percentage reported feeling uncomfortable with various technical aspects of pain care.[103] As pain management techniques continue to increase in both effectiveness and complexity, detailed planning and education are required for all health care providers, patients, and families (surgical hospital, rehabilitation hospital, outpatient rehabilitation facilities, and outpatients at home) to help make meaningful analgesia a successful endeavor.

Opioid protocols have been successfully implemented in rehabilitation hospital settings. Cheville and associates reported on the successful implementation in a randomized controlled trial of the use of controlled-release oxycodone for rehabilitation inpatients after unilateral total knee replacement surgery.[104] In this study (n = 59), patients were randomized to receive controlled-release oxycodone versus placebo every 12 hours, with the opportunity to receive immediate-release oxycodone every 4 hours as needed for breakthrough pain. Patients in the treatment group had lower pain scores, significantly better range of motion of the knee, and improved quadriceps strength than did the placebo group.[104] In addition, treatment group patients were discharged home from the inpatient rehabilitation facility 2.3 days sooner than placebo patients.[104] To summarize, a straightforward treatment intervention of a regularly scheduled controlled-release oral opioid led to significant outcome improvements and lower use of health care resources compared with the likely typical care plan of analgesics only as needed. However, such an approach has kindled (or substantiated) fears of opioid dependence and diversion. In addition, escalating doses of oral opioids are well associated with increasing side effects.

Dose-dependent opioid-related side effects were well described in a study showing that the increase of daily opioid dosing by the equivalent of 4 mg of morphine was associated with one additional clinically meaningful opioid-related symptom or one additional patient-day with an opioid-related clinically meaningful event.[105] These symptoms and events specifically included nausea, vomiting, constipation, urinary difficulty, difficulty with concentration, drowsiness, light-headedness, confusion, fatigue or weakness, pruritus, dry mouth, and headache.[105]

Logic would dictate that using multimodal analgesia, with a PNB technique as an integral component, will likely help improve patient perceptions of pain relief after surgery, especially when the patients are no longer in a surgical hospital (eg, inpatient rehabilitation or discharged to home). Kehlet has reviewed important principles of multimodal analgesia on postsurgical physiology.[106] However, neuraxial (epidural) analgesic techniques are unlikely to be a meaningful contributor to postoperative analgesia out of the surgical hospital setting, for obvious reasons. PNB anesthesia, including CNB, may provide a useful component of multimodal analgesia outside the surgical hospital setting in the years to come, but these prospects will likely disappear in settings where such services had been reimbursed but are no longer reimbursed (as in the United States). Even though significant progress has been made with respect to infusion technology; dose-response curve derivation; and education of clinical staff, patients, and family members when an anesthesiologist is not in immediate attendance, it would be difficult to economically justify the continuation of this costly subspecialty service for outpatients in the absence of payment to offset the costs and risks of delivering this service.

Decreasing Role for Epidural Techniques

For many years, neuraxial anesthesia was highly recommended as a technique of first choice for patients undergoing lower extremity total joint replacement or hip fracture repair. Much of this enthusiasm was based on the classic meta-analysis by Sorenson and Pace, which reported that the use of neuraxial anesthesia versus GA was associated with a significant reduction in mortality (odds ratio = 0.67), and a 31% reduction in deep venous thrombosis, for the repair of fractures of the femoral head.[107] Years later, the meta-analysis of several types of surgery (including orthopedics) by Rodgers and coworkers reported significant reductions in mortality (odds ratio = 0.70), pulmonary embolism (odds ratio = 0.45), deep vein thrombosis (DVT; odds ratio = 0.56), myocardial infarction (odds ratio = 0.67), renal failure (odds ratio = 0.57), pneumonia (odds ratio = 0.61), respiratory depression (odds ratio = 0.41), and transfusion requirements (odds ratio = 0.45 to 0.50) when neuraxial anesthesia was used instead of GAVA with postoperative intravenous patient-controlled opioid analgesia.[108] As discussed in the next section, it is unlikely that neuraxial epidural anesthetic-analgesic techniques will be sustainable and practical, but there are no apparent restrictions to the ongoing preferential use of spinal anesthesia combined with PNBs as a routine replacement for GAVA/opioid techniques.

Regional Anesthesia Techniques in the Setting of Modern Anticoagulants

Although the aforementioned studies would logically serve as landmarks for change in clinical practice, enthusiasm for epidural techniques has significantly decreased with the introduction of more potent and effective anticoagulants in routine clinical practice. Guidelines for neuraxial anesthetic use in the setting of systemic anticoagulation have been well publicized,[109,110] and the risks have been more accurately defined.[111] However, it seems less likely that patients will have epidural anesthesia-analgesia available to them in these clinical settings in the near future, pending a long-term outcome study that describes the frequency of adverse events created (eg, hemorrhagic cerebral infarction[112]) versus adverse events prevented (eg, pulmonary embolism and death) by the use of newer antithrombotics and anticoagulant agents.

Clinical Pearls

- Regional anesthesia techniques have been traditionally associated with fewer thromboembolic complications.
- Newer anticoagulants have offset previous thromboembolic differences seen between RA and GA.
- Indwelling perineural catheters have emerged as a valuable anesthetic technique for postoperative analgesia, but have led to some theoretical concerns regarding bleeding complications in anticoagulated patients.

In a meta-analysis of outcomes after the use of fondaparinux versus enoxaparin,[113] fondaparinux was shown to reduce the odds of venous thromboembolism by 55% compared with enoxaparin. Although fondaparinux was associated with higher "major bleeding," this did not translate to a clinically adverse outcome, such as risk of reoperation or death. In addition, the use of fondaparinux appeared to offset any outcome benefits achieved by neuraxial anesthesia versus GAVA, specifically for the avoidance of venous thromboembolism. The likely loss of the availability of epidural techniques as surgeons focus on the prevention of venous thromboembolism, without regard for the other documented benefits of neuraxial anesthesia/analgesia (eg, on the cardiac, pulmonary, and renal organ systems), forces the well-trained RA practitioner to incorporate SINB or CNB to give patients any chance for meaningful postoperative analgesia after lower extremity joint replacement or fracture repair. Therefore, the RA practitioner should actively ensure that patients' doses of the described anticoagulants are stopped in advance appropriately to render spinal anesthesia as the routine anesthetic of choice, supplementing spinal instead with ipsilateral PNBs (acknowledging the limited usefulness of continuous epidurals in current care, as described).

Horlocker and colleagues have documented the popularity of PNBs due to improved surgical outcomes. However, they also cited or speculated regarding block-related morbidity and mortality from serious hemorrhagic complications occurring in blocks given to anticoagulated patients. This underscores the importance of a firm understanding about anticoagulation as its popularity continues to increase regardless of nerve block technique.[114] We forecast that single-injection spinal anesthesia and SINB (especially in the form of multimodal perineural analgesia) will dominate clinical practice in the near future as decreasing reimbursements and added inconveniences of coordinating catheter placement and removal render "coordinated care" impracticable.

Evolving Role for Continuous PNB in Lower Extremity Surgery

Clinical Pearls

- Knee surgery has two tiers of postoperative pain considerations.
  1. For least-invasive procedures, blocks are probably not required.
  2. For moderately invasive procedures, a femoral nerve block is likely required.
  3. For the most invasive procedures, femoral and sciatic blocks are likely required.
- The other tier is **likely pain duration**: short duration (likely manageable with SINBs) versus longer duration (manageable with continuous-infusion blocks).

The use of PNBs for joint replacement has been examined during the past 20 years. Early on, outcomes were equivocal, but many studies primarily focused on SINB techniques. One exception is a study by Hirst and colleagues, where patients receiving GA did not gain additional analgesic benefit from a femoral perineural infusion compared with patients who received a SINB, although both groups required less postoperative opioid analgesia than did controls who received no block.[115] A study by J. G. Allen and associates showed that patients receiving femoral-sciatic single-injection blocks had better short-term (24-hour) pain outcomes than did patients only receiving spinal.[116] Another single-injection block study for total knee replacement patients by H. W. Allen and colleagues showed that the addition of single-injection sciatic nerve block did not confer any additional benefit versus the use of femoral nerve block alone.[117] This latter finding has not been reproduced in any study with similar methodology.

The late 1990s produced two important studies from Europe examining rehabilitation outcomes after total knee replacement when a continuous femoral catheter was used (vs epidural catheter or active control IVPCA device). These studies were predicated on the notion that continuous femoral nerve block analgesia (vs IVPCA) leads not only to better pain relief but also to significantly better knee flexion, faster achievement of ambulation goals, and overall faster convalescence. Studies by Capdevila and coworkers[118] and Singelyn and associates[119] showed that patients for total knee replacement undergoing GA with either continuous epidural analgesia or continuous femoral nerve block analgesia made faster progress in meeting rehabilitation objectives and were discharged from the inpatient rehabilitation unit sooner than were patients receiving IVPCA. Patients receiving femoral nerve catheter infusions experienced fewer side effects than did patients receiving epidurals in both studies, and patients with a continuous femoral catheter were discharged home from inpatient rehabilitation units sooner by 20% (40 vs 50 days[118] and 17 vs 21 days[119] in the femoral catheter vs IVPCA groups, respectively).

In the United States, a similar anesthetic treatment method was applied by Chelly and colleagues to patients receiving total knee replacement.[120] All patients received GAVA and were randomized to receive IVPCA, epidural infusion, or single-injection femoral-sciatic blocks followed by a continuous femoral infusion. Patients with continuous femoral blocks (vs patients with IVPCA) had an associated reduction of postoperative bleeding by 72% ($P < .05$), achieved better performance on continuous passive motion, had a 90% decrease in serious complications (including less blood loss), ambulated sooner (2.5 vs 3.5 days), and had a 20% decrease in the length of hospitalization (4 vs 5.5 days).[120] Duration of hospitalization did not include postoperative long-term rehabilitation (which is usually done on an outpatient basis in the United States),[120] as did the two previously listed European studies,[118,119] although early postoperative rehabilitation was aggressive.

Additional studies have supported the findings of Chelly and colleagues associating femoral nerve blocks with less opioid requirement, superior range of motion, and shorter hospital stay.[121,122] However, none of the aforementioned reports examined the benefits of sciatic CPNB, given the concern for "foot drop" and loss of proprioception/weight bearing below the knee from L4–S3 nerve block by local anesthetics. Future research is needed to examine the use of multimodal perineural analgesia excluding local anesthetics in relation to analgesia in the L4–S3 distribution.

The question of the need for a continuous sciatic catheter after total knee replacement was addressed in a prospective pilot study by Ben-David and coworkers.[123] In this study, 12 consecutive patients had continuous femoral and sciatic catheters placed preoperatively, but only the femoral catheters were dosed to allow for postoperative evaluation of sciatic nerve function (specifically aiming to produce dorsiflexion). Sciatic catheters were dosed only if dorsiflexion was intact and postoperative knee pain was refractory to additional boluses through the femoral nerve catheter. Ten of these 12 patients required dosing of the sciatic catheters, with median pain scores of 7.5 (of 10) before dosing and 2.0 after dosing. This pilot study refutes the earlier finding by H. W. Allen and colleagues[117] with respect to the value of sciatic nerve block for total knee replacement.

For hip fracture surgery, there has been less-convincing evidence with respect to PNBs, pain management, and rehabilitation outcomes. From the Cochrane Database of Systematic Reviews in 2002, lacking an update since, Parker and associates reported that:

> Because of the small number of patients included in this review and the differing type of nerve blocks and timing of insertion, it is not possible to determine if nerve blocks confer any significant benefit when compared with other analgesic methods as part of the treatment of a hip fracture. They do reduce the degree of pain experienced by the patient from hip fracture and subsequent surgeries. Further trials with larger numbers of patients and full reporting of clinical outcomes would be justified (p. 2, verbatim from the abstract).[124]

However, this systematic review of hip fracture surgery would not have included subsequent studies that addressed either hip fractures or other hip procedures.

Fournier and coworkers reported that patients receiving single-injection femoral nerve block versus sham block had a 4-hour delay in requests for first parenteral analgesic after prosthetic hip surgery, although pain outcomes were no different at 24 and 48 hours.[125] Stevens and colleagues reported that patients undergoing total hip arthroplasty receiving lumbar plexus single-injection blocks had less pain for up to 6 hours after surgery and less blood loss during and for up to 48 hours after surgery.[126]

Naja and associates reported (retrospectively) that elderly patients with hip fracture receiving lumbar plexus and parasacral blocks (vs GAVA) (1) encountered significantly less hypotension during surgery, (2) were less likely to be admitted to the intensive care unit after surgery (0/30 vs 11/30), and (3) had a shorter length of hospital stay (7 vs 14 days).[127] De Visme and colleagues ($n = 15$)[128] and Buckenmaier and coworkers ($n = 10$)[129] provided the first two reports of lumbar plexus and parasacral plexus blocks as the sole anesthetic for hip surgery (ie, coadministered GAVA or spinal anesthesia were not deemed necessary).

Souron and associates found that patients receiving intrathecal morphine (0.1 mg) versus single-injection lumbar plexus block with ropivacaine had better overall analgesic outcomes with intrathecal morphine after primary hip arthroplasty, although patients receiving intrathecal morphine had a 37% incidence of urinary retention (vs 11% for lumbar plexus block; $P < .05$).[130] Biboulet and colleagues compared single-injection femoral and lumbar plexus blocks with intravenous opioid patient-controlled analgesia (PCA) for patients undergoing total hip arthroplasty and found that PCA was as efficient as the single-injection blocks used in overall outcome, even though the pain scores and opioid requirements were lowest in the lumbar plexus single-injection group during the first 4 hours after surgery.[131]

Kullenberg and coworkers prospectively studied 80 patients who underwent hip fracture repair and were randomized to receive single-injection femoral nerve block (n = 40, block placed postoperatively) or no block (n = 40).[132] This study found that patients receiving nerve block had 15 hours of meaningful pain relief and ambulated 13 hours sooner (23 vs 36 hours) than did patients who received no block.[132]

The aforementioned studies particularly addressed SINBs for hip surgery and did not address CNB catheters. The following three studies did specifically address perineural infusions for such patients: Singelyn and Gouverneur prospectively evaluated 1338 patients undergoing total hip arthroplasty who chose IVPCA, continuous femoral block, or patient-controlled epidural analgesia.[133] These authors reported that patients who received continuous femoral infusion had the highest satisfaction, fewest side effects, the lowest request rate for supplemental opioids, and the fewest technical problems, but pain scores themselves did not significantly differ.[133] In a randomized clinical trial, Turker and coworkers compared patients receiving continuous lumbar plexus catheter (n = 15) with others receiving epidural catheter (n = 15) for hip hemiarthroplasty under GAVA and found that patients with the lumbar plexus catheter (1) had less motor block, (2) ambulated sooner, and (3) had significantly fewer overall complications.[134]

However, there have also been data showing an association between CPNB for hip arthroplasty and patient falls. Ilfeld et al examined three previously published, randomized, placebo-controlled trials involving femoral CPNB, with one arm receiving saline (n = 86) and another ropivacaine 0.2% (n = 85). None of the patients in the saline group fell, while the ropivacaine group showed seven falls among six patients (7%; 95% confidence interval [CI] = 3%–15%; P = .013). They concluded by stating a causal association between femoral CPNB and a risk of falling, with the caveat that four of the seven falls occurred after hospital discharge, with these patients not properly using a knee immobilizer.[135]

Based on the available evidence, femoral or lumbar plexus single-injection blocks have the potential to improve immediate postoperative analgesic outcome and possibly reduce hospital resource utilization in patients having invasive hip surgery. Unlike single-injection femoral nerve blocks, single-injection lumbar plexus blocks can be associated with a risk of bilateral spread, which carries a risk of perioperative implications in a frail elderly patient with limited cardiovascular reserve. One theoretical strategy to avoid precipitous hypotension (from bilateral spread with a single-injection lumbar plexus block) is to provide slow incremental doses via a continuous lumbar plexus catheter. In this setting, the incremental doses can be stopped as soon as it appears that surgical anesthesia/analgesia seems to be in place, but still keeping the catheter injection port available to the anesthesia team during surgery in the event additional boluses are needed intraoperatively.

Other than bilateral spread, a potential concern for lumbar plexus blocks (specifically continuous catheters) is the risk of hematoma in an anticoagulated patient. Technically more challenging, continuous lumbar plexus blocks have been associated with hematoma-related complications in four patients documented in three case reports.[136–138] In one patient who was fully anticoagulated and receiving aspirin (325 mg daily), three serial single-injection lumbar plexus blocks were given, the last of which was considered "difficult," and a retroperitoneal hematoma was diagnosed a few days later.[137] A second patient developed a retroperitoneal hematoma in which significant vascular trauma was noted at the time the block was performed and the catheter placed.[136] A third patient developed a retroperitoneal hematoma 2 days after the single-injection psoas compartment block was placed, and this patient was rendered supratherapeutic on intravenous heparin throughout the 2 days after surgery.[136] The final patient had a history of factor 5 Leiden mutation treated with phenylindanedione; further details are described in the case report.[138] In each of these four cases, the clinical situations could not be reasonably considered routine, and all of these cases resolved without sequelae and without requiring surgical evacuation.

Other than these four cases, there have been no reports of hemorrhagic complications in patients receiving lumbar plexus catheters or fascia iliaca compartment blocks in the setting of modern anticoagulation practice.[139] There have been no published data regarding the estimated risk of retroperitoneal hematoma associated with lumbar plexus catheter removal in patients receiving effective postoperative anticoagulant therapy for the prevention of deep venous thrombosis. More cases are required to establish the safety of such a protocol. When considering the risk of bleeding associated with the removal of a lumbar plexus catheter in patients who are anticoagulated for the prevention of DVT, it is also important to acknowledge that the consequences of such bleeding are less serious than the bleeding that may result from the placement or removal of an epidural catheter. Epidural hematoma has been associated with serious neurologic complications in over 50% of cases, whereas no serious neurologic complications have been associated with the development of a retroperitoneal hematoma. Nevertheless, many clinicians who often utilize lumbar plexus and other CNB techniques tend not to address removal of CNB catheters with the same detailed scrutiny that has been deemed appropriate for epidural catheters.

Role of CNB Catheters and Effects on Rehabilitation in Upper Extremity Surgery

Data addressing physical therapy outcomes after major shoulder surgery performed with nerve block anesthesia are limited. Two studies addressed in more detail the recovery of motor function, comparing different CNB infusion drugs and concentrations. Borgeat and colleagues studied hand motor function and the presence of paresthesias in the fingers after open-shoulder surgery, when pain was managed via a brachial plexus CNB. Two infusion drugs were compared: bupivacaine 0.15% and ropivacaine 0.2%.[71] Infusions were run via an electronic device at 5 mL/h, with a 4-mL bolus available with a 20-minute lockout. Although both treatment groups' patients had equal analgesia and were equally satisfied, patients receiving bupivacaine CNB had more hand weakness at 24, 48, and

54 hours while reporting more finger paresthesias up to 48 hours after the initial nerve block than did patients receiving ropivacaine.[71]

Another study addressing motor function was conducted by Casati and coworkers.[140] Patients who underwent open-shoulder surgery were assigned to one of two CNB infusion drugs: ropivacaine 0.2% or levobupivacaine 0.125%. The infusion was run at 6 mL/h and allowed for a 2-mL bolus with a lockout of 15 minutes. There were no clinical differences in pain relief quality or motor function during the 24-hour infusion period. Thus, it appears that ropivacaine 0.2% and bupivacaine/levobupivacaine 0.125% are equipotent in providing CNB analgesia in the brachial plexus. The infusion rate of 5 to 6 mL/h while allowing for intermittent boluses of 2 to 4 mL with a 15- to 20-minute lockout provided an optimal balance of analgesia and preserved motor function.

One important safety feature to consider in the postoperative recovery of patients receiving continuous interscalene analgesia is adequate ventilatory function. It is generally accepted that most patients undergoing brachial plexus nerve blocks for shoulder surgery will encounter simultaneous block of the phrenic nerve, which is responsible for proper function of the diaphragm.[141–144] Borgeat and associates measured respiratory function during use of a CNB dosing technique that used both a continuous infusion (ropivacaine 0.2%, 5 mL/h) and a CNB bolus function (3–4 mL with a 20-minute lockout).[145] In this study, all patients received a preoperative bolus injection of ropivacaine 0.75%, 30 mL, and all patients underwent major shoulder surgery (rotator cuff repair, $n = 26$; arthroplasty, $n = 7$). The control group consisted of patients receiving IVPCA with opioids. Patients in the CNB group had better pain relief for up to 24 hours after surgery than the patients who were randomized to the opioid IVPCA. An important new finding was that overall respiratory function was better in the CNB group than in the IVPCA group. Forced respiration (ie, movement in the diaphragm on the nonoperative side) was better in the CNB group at 24 and 48 hours than in the IVPCA group. The rationale for this finding was that the pain control was better in the CNB group, and that there were fewer opioid-related side effects (eg, respiratory depression) in the CNB group, facilitating patients' forced respiratory efforts. Interestingly, forced diaphragmatic excursion on the side of surgery was not significantly different between the CNB and IVPCA groups at 24 and 48 hours after surgery. This study showed that forced respiratory effort was improved up to 48 hours after surgery in the CNB group, which when combined with better analgesia in the CNB group, provided an important safety validation in the evolution of same-day discharge of patients with CNB catheters and appropriate infusion devices after shoulder surgery.

Clinical Pearls

- More studies are needed to delineate define the severity of postoperative pain.
- Postoperative physical therapy and range-of-motion goals should be considered when deciding on the use of PNBs for postoperative pain management.

To date, there is limited research regarding the role of CNBs and the achievement of physical therapy milestones. One such study was performed by Ilfeld and colleagues, who retrospectively examined the charts of 50 patients having total shoulder arthroplasty (TSA), one-half who received an interscalene CNB with 0.2% ropivacaine infusing at a rate of at least 7 mL/h and the other half that did not receive a block. The cohort treatment arms were matched for age, gender, and type of TSA (primary vs revision). The results showed the CNB group achieved superior maximum shoulder elevation and external rotation. Ilfeld et al also showed median numeric pain scores for the CNB group of 2 versus 8.5 for the controls ($P < .001$).[146] These data imply improved physical therapy outcomes with interscalene CNB for TSA most likely from improved pain scores; however, more work is required, including more prospective, randomized trials to solidify the role of RA for upper extremity surgery.

Cost Analysis Illustrations Based on Available Data

Cost-Minimization Analysis

For this cost-minimization analysis, we compare three anesthesia treatments for a traumatic, closed patellar fracture in one patient. The mathematical formulas described here can be applied to actual incidences of compared outcomes using weighted-average techniques derived from larger surgical population data.[147] For the individual patient in this example, GAVA is compared with two spinal anesthesia techniques, one of which uses a single-injection femoral nerve block (two-needle technique), and the other that uses a femoral perineural catheter with single-injection sciatic nerve block (three-needle technique). Assumptions are as follows: (1) The patient receiving GAVA will encounter a routine recovery room stay, then hospital admission for 2 days (pain management, antiemesis, and resolution of somnolence); (2) the two-needle patient will encounter an unplanned hospital admission to "23-hour observation" after experiencing posterior knee pain treated with opioids and leading to PONV; and (3) the three-needle patient will be discharged home the same day with a disposable continuous-infusion device after successfully bypassing the PACU. Based on cost assumptions (Table 66–3) described in previous reports,[8,55] the sole task of cost minimization shows the incremental cost savings is roughly $800 for using the two-needle technique and an additional $200 when the added cost of equipment and medication for the three-needle technique is offset by the cost savings of PACU bypass and the avoided hospital admission.

Cost-Effectiveness Analysis

For a hypothetical CEA from the patient's (and the societal) perspective, we assume that patients are most interested in returning to nonstrenuous work as soon as possible, with sufficient cognitive function and pain control. In what should be interpreted as a strictly speculative illustration, the GAVA patient is assumed to require 10 days to return to work due to lingering effects of volatile agents, cumulative dose of opioids, and sedative effects of antiemetics. The two-needle patient

TABLE 66–3. Cost analysis illustration: ORIF patellar fracture.

	Anesthesia Care Plan for 3 Individual Patients					
	(1)	(2)	(3)			
Cost item	**GAVA**	**Spi-Fem ("2-Needle")**	**Spi-Fem Cath-Sci Single-Injection ("3-Needle")**			
Base	$50	$60	$90			
Infusion device and drug	0	0	$200			
PACU admission	$400	0	0	*Incremental Cost Savings*		
Hospital admission	$800 (2d)	$400 (23 hr)	0	*2 vs 1*	*3 vs 2*	*3 vs 1*
Total cost	$1250	$460	$290	$790	$170	$960
Effectiveness parameter: *lost workdays (nonstrenuous work)*	10	8	2	Incremental Workdays Preserved		
				2 vs 1 2	*3 vs 2* 6	*3 vs 1* 8
<u>Cost-effectiveness analysis:</u> ratio of incremental hospital costs to workdays preserved				790/2	170/6	960/8
Incremental cost-effectiveness ratios (hospital costs per day of work preserved for the patient)				$395: 1 day	$28: 1 day	$120: 1 day
Benefit parameter: *lost wages at $200/day (strenuous work)*	$2000	$1600	$400	Incremental Wages Preserved		
				2 vs 1	*3 vs 2*	*3 vs 1*
				$400	$1200	$1600
<u>Cost- benefit analysis</u>: ratio of incremental hospital costs to wages preserved				790 / 400	170 / 1200	960 / 1600
Incremental cost-benefit ratios (hospital costs per dollar of wage preserved for the patient)				1.98	0.14	0.6
Utility parameter: *Outcome units on QoR-40 anesthesia outcome survey on postoperative day 2 (maximum score = 200)*	170	175	180	Incremental Utility Units Preserved		
				2 vs 1 5	*3 vs 2* 5	*3 vs 1* 10
<u>Cost-utility analysis:</u> ratio of incremental hospital costs to patient utility units preserved				790/5	170/5	960/10
Incremental cost-utility ratios (hospital costs per preserved utility unit)				158	34	96

Cath = perineural catheter; GAVA = general anesthesia with volatile agents; ORIF = open reduction and internal fixation; QoR-40 = Quality of Recovery 40-item scale, as reported in 2000 by Myles et al[148]; Sci single-injection = single-injection sciatic nerve block; Spi-Fem = spinal anesthesia with single-injection femoral nerve block.

All values in dollars.

Base costs for GAVA and Spi-Fem based on Williams et al.[8]

PACU and hospital admission costs based on Williams et al.[55]

would probably have less cognitive dysfunction from (1) avoiding volatile agents and (2) encountering less cumulative effects of opioids and antiemetics, whereas the three-needle patient is pain free with the clearest cognition and is able to return to work on postoperative day 3 (with an infusing perineural catheter).

The increments of improvement in the return-to-work parameter are calculated by determining the difference in days to return to work from the reference value of 10 days (for the GAVA patient). Then, the incremental differences are inserted in the denominator, and the incremental hospital costs comprise the numerator. The ratio of incremental hospital cost savings to days of work saved for the patient (Table 66–3) was most cost effective (ie, the lowest cost-effectiveness ratio) when the decision was made to use a femoral catheter and sciatic single-injection block (three-needle technique) instead of just a femoral block (two-needle technique). It should be understood that an isolated cost-effectiveness ratio is only meaningful in the context of comparative methods being evaluated. In addition, hospital costs for each anesthetic technique do not clearly reflect the costs associated with anesthesiologist labor because the incremental workload is increased from GAVA, to the two-needle technique, to the three-needle technique, respectively. One would hope that well-trained RA practitioners recognize the value of their services and compassionately care for patients in such a way that gives the patient the best chance for immediate return to work in a health care system that is otherwise optimized.

With respect to using more population-based return-to-work data for a given procedure in an institution, certainly, Gaussian curves illustrating the 95% confidence intervals of actual return-to-work outcomes could be incorporated into the calculation, and similarly 95% confidence intervals of the cost-effectiveness ratio can be determined to evaluate the extent of overlap between techniques for the desired parameter of effectiveness. However, population-based return-to-work data after the wide variety of orthopedic procedures performed are scarce, and available population data are likely based currently only on a vast preponderance of cases being performed under GAVA without any PNB techniques.

Cost-Benefit Analysis

Using the design for the CEA example discussed, the effectiveness variable for CBA analysis now takes on a monetary value in the denominator. In this analysis, we assume the patient requires reasonable ambulation capabilities at work as a factory foreman paid an hourly wage who is not paid for time off for medical leave. The return-to-work benefit outcome takes the form of achieved wages. The return-to-work timeline remains the same as that described in the previous CEA example (Table 66–3).

In this example, the reference value for 10 days of lost wages is $2000 (after receiving GAVA with no blocks). Patients receiving spinal anesthesia with a femoral nerve block are assumed to return to work on postoperative day 8, incrementally reclaiming $400 of the lost $2000 in wages. Patients receiving spinal, femoral nerve block catheter, and single-injection sciatic block are assumed to return to work on postoperative day 3, thus reclaiming $1600 of the lost $2000 in wages. These reclaimed wages are inserted into the denominator of the incremental cost-benefit equations, with the respective hospital cost increments inserted into the numerator. The cost-benefit ratios (CBRs; Table 66–3) indicate that the selection of the three-needle technique provides a better (lower) CBR than does the two-needle technique when the reference GAVA technique is considered as the standard for comparison.

Cost-utility analysis involves the insertion of a patient-reported effectiveness variable into the denominator of the cost analysis. We use the QoR-40 of Myles and colleagues[148] as a measure of utility from the patient's perspective, again comparing the hospital costs of the GAVA patient ($1250 cost) versus $460 and $290 for spinal anesthesia patients receiving single-injection femoral nerve block versus continuous femoral and single-injection sciatic nerve blocks, respectively. The achieved utility scores based on the QoR-40 by Myles and colleagues (with possible highest score of 200) are assumed to be 170 (GAVA), 175 (two needle), and 180 (three needle), respectively. These QoR-40 scores were validated by our published data of 154 patients undergoing ACL reconstruction standardized with spinal anesthesia and then randomized to receive perineural catheter injection-infusion with either normal saline or 0.25% levobupivacaine.[149] The incremental cost-utility ratios would be described as "hospital costs per preserved QoR-40 score unit" (Table 66–3). The two-needle technique shows an incremental cost-utility ratio of 158:1 versus GAVA, and the three-needle technique cost-utility ratio is 96:1 versus GAVA.

In both the cost-benefit and cost-utility illustrations, as with the cost-effectiveness illustration, the decision to use the three-needle technique instead of the two-needle technique provided the most impressive incremental pharmacoeconomic benefit. For the CEA and CBA, the analyses showed that the selection of the three-needle technique versus the two-needle technique provided a magnitude of "patient/societal benefit" by a factor of 14 (in comparison with the selection of the two-needle technique vs GAVA), whereas for the cost-utility benefit, the magnitude of benefit was a factor of almost 5 when comparing the same increments per technique. Indeed, it is conceivable that a win-win anesthetic technique (eg, total RA incorporating select nerve block catheters) may provide much greater societal benefit than the patient may be able to recognize if using only symptom-specific patient satisfaction surveys.

Obviously, the examples provided are simplistic and do not account for the significant variability in the care of many patients. However, the core structure of the analyses, including multiple variables that are important contributors to costs and outcomes, can be analyzed using decision analysis trees and weighted-average techniques to provide meaningful comparisons of anesthesia care techniques.

SUMMARY AND CONCLUSION

In the pharmacoeconomic analysis of the value of RA, several considerations are important. The first is to distinguish the objectives of outpatient surgery from the objectives for inpatient care. The second is to recognize that almost every decision made by the anesthesiologist may have a crucial influence on patient outcome not only in the short term but also potentially in the long term. The third is for the skilled RA practitioner to rationally allocate his or her own labor-related resources to ensure that patient-specific and procedure-specific criteria are met for each and every patient being considered for RA techniques to minimize wasted effort on patients unlikely to benefit from these labor-intensive interventions. The fourth is that the anesthesiologist is likely the primary patient advocate with respect to analgesic outcome, due to less likelihood of expertise or even interest among surgical colleagues and other health care personnel with respect to subspecialized pain management and its cost-related patient-centered benefits. The fifth is that a coordinated effort is required to gain the surgeon's and patient's confidence in the anesthesia team while simultaneously guiding all other related health care personnel with education efforts to redefine policies and procedures. Finally, awareness of overall cost implications, to both the hospital and society at large, is required to justify the expansion of (and reimbursement for) RA services to hospital administrators (and third-party payers or legislative entities).

CHAPTER 67

Regional Anesthesia, Cost, Operating Room, and Personnel Management

John Laur and Franklin Dexter

INTRODUCTION

Whether in a private practice anesthesia group, academic institution, hospital organization, or some hybrid of these, understanding how regional anesthesia (RA) affects your budget and costs, as well as the perceptions and outcomes of patients, is important for planning and conducting economic discussions with health care administrators and surgeons. This chapter reviews the costs and economics of RA and describes the concepts that apply to anesthesia providers and groups across the globe. Billing is not included as each country chooses how it bills and is paid for RA procedures. Moreover, we focus on outpatient anesthesia, for which cost savings can be better defined. While facilities may benefit financially from RA applied in inpatient settings, such billing and cost issues are local. The economics of heterogeneity in bringing down costs for measured reductions in length of stay (LOS) were reviewed recently.[1–4] In brief, although RA can reduce patient LOS, Taheri et al demonstrated that for patients with an average LOS of 4 days or more, the majority of costs occur in the initial days of the hospital stay, and only 3% of costs are incurred in the concluding hospital days.[1]

Clinical Pearl

- Understanding how RA and analgesia affects budget and costs, as well as the perceptions and outcomes of patients, is important for planning and conducting economic discussions with health care administrators and surgeons.

OPERATING ROOM EFFICIENCY

Perhaps the most basic and important management decision is to increase the efficiency of use of operating room (OR) time. Maximizing OR efficiency is a major cost reduction strategy that is implemented by reducing the hours of over- and underutilized OR time. Allocated OR times are assigned by the institution to its surgical services. On days of the week that a service has allocated time, their cases are scheduled within the specified start and stop times of the service.[5–7]

Overutilized time is the positive difference between the total duration of cases (including all turnover times) and the allocated OR time interval, when the allocated time has been calculated as that which maximizes the efficiency of use of OR time. For example, cases and turnover times have a total duration of 10 hours, yet 8 hours of time are allocated—this yields 2 hours of overutilized time. Importantly, referring to time as overutilized implicitly assumes that the time allocated has been calculated to maximize the efficiency of use of OR time (ie, minimizing the weighted combination of overutilized and underutilized time).

Underutilized time is the positive difference between total case duration, including turnover time, and the time allocated for that day. An example would be having 8 hours allocated and cases completed in 6 hours, including all turnover time, resulting in 2 hours of underutilized time. If a surgical services committee sets the policy that all ORs are planned for 10 hours, then there are not 4 hours of underutilized time, just the 2 hours. That is because referring to time as underutilized implicitly assumes that the time allocated was calculated based on maximizing the efficiency of use of OR time.

Due to an improved side-effects profile and the excellent pain control provided by RA techniques compared to general anesthesia (GA) with volatile anesthetic agents and opioids, RA may reduce total OR case time (*case duration*, defined as patient in OR to patient out of OR), patient recovery duration, and time until discharge. However, to reduce the inefficiency of use of OR time, the technique has to help reduce the hours of overutilized OR time and/or the allocated hours of OR time (same amount of work done in less time).[8]

The cost of an hour of underutilized time is negligible relative to the cost of an hour of overutilized time. Consequently, the decision to use RA on the day of surgery will often have a negligible effect on OR efficiency. In other words, working faster generally does not increase OR efficiency; it is just "working faster." Because RA use is based on reducing undesirable side effects for patients, lowering incidence of unplanned admissions, and reducing patient and surgeon waiting times, appropriate OR allocation has a far greater impact on OR efficiency and economics than it does on RA use.[7]

The following narrative explains how use of RA can influence OR efficiency[5,6,9]:

> Today, the allocated times for OR5 and OR6 are from 7 AM to 7 PM and for OR7 from 7 AM to 3 PM. OR5 will complete its present case at 3:30 PM and begin its last case (of 2.5-hours duration) at 4 PM. *Case duration* here refers to the time period from patient in to patient out of the OR, not surgical time. OR6 is expected to finish its present case at 4:30 PM and begin its last case (of 1.5-hours duration) at 5 PM. OR7 is estimated to complete its last case at 2:30 PM.
>
> The same surgeon has requested a peripheral nerve block (PNB) for the last two cases in OR5 and OR6.
>
> - *Scenario 1*: For the cases to *start on time*, the medical director plans to ask the OR nurses and the anesthesiologist in OR7 to stay late to place the nerve blocks, monitor the patients, and make them ready for OR5 and OR6. Each PNB procedure requires 20 minutes to complete.
>
> If the staff from OR7 stay late and prepare the patient going to OR5, that patient will go into OR5 at 4 PM, incision can be made at 4:10 PM, and surgery will be finished at 6:30 PM. There would be no overutilized OR time in OR5. The patient scheduled to start next in OR6 would instead start in OR7 and would enter OR7 at 5 PM. Incision would be made by 5:10 PM, and the patient would be out by 6:30 PM. By 5:00 PM, the current OR6 case has exited, handoff can occur, and the team from OR7 can leave. *Alternatively*, the anesthesiologist out of OR7 could sequentially cover anesthesiologists in OR5 and OR6, allowing them to provide PNBs to their own patients while the OR7 nurse monitors them in a preoperative area (Figure 67–1). Either way, after those two nerve block procedures are completed and the last two patients for those rooms are brought to the respective ORs, the OR7 team who stayed late could go home. The net effect is 2 hours of overutilized time (from 3:00 to 5:00 PM with OR7).
>
> - *Scenario 2*: Suppose that the OR7 team leaves after OR7 work is completed (by 3:00 PM). The OR5 staff would then bring their patient to OR5 by 4 PM, perform the PNB, make incision at 4:30 PM (20 minutes to place the block, 10 minutes for positioning and preparation). The surgery then finishes by 6:50 PM (total duration 2.5 hours). The OR6 team escorts their patient to OR6 by 5 PM and proceeds with PNB placement. At 5:30 PM, incision is made, and surgery is finished by 6:50 PM. Both OR5 and OR6 end 20 minutes *later* than originally scheduled but still within the allocated OR time (7:00 PM). Thus, the OR7 surgery is finished before 3 PM, and OR5 and OR6 complete their cases by 7:00 PM (Figure 67–2). There is no overutilized OR time.

When OR time is *properly allocated*, RA use will have no effect on OR efficiency for the greater portion of management decisions made on the day of surgery. To help drive this home, the scenarios exaggerated the consequences that the day of surgery OR management decisions would have on OR efficiency. Still, the point remains that the most important factor influencing how RA affects OR efficiency is use of good statistical forecasting, done months in advance, to plan allocated OR time (also known as OR staffing).

Other opportunities for labor cost reduction are often limited. Dexter et al analyzed data obtained from the 2006 National Survey of Ambulatory Surgery for determining the amount of OR time used for sedation or monitored anesthesia care (MAC) alone after PNB. This data set sampled all ambulatory surgical procedures from all licensed freestanding ambulatory surgery centers and nonfederal hospitals performing ambulatory surgery within the United States in 2006. MAC with a PNB or PNB alone accounted for approximately one-third of ambulatory center OR time with an anesthesiologist or certified registered nurse anesthetist (CRNA). In short, PNB cases accounted for a large portion of total ambulatory care in the United States. The consequence is that, faced with economic constraints, payers may consider reducing payments for RA, and groups may want to prepare for the impact on their facilities.

For example, if there are two ORs on a given day with hand surgery cases and some are performed by RA only and others under GA, an OR manager may consider resequencing the cases so that one room (surgeon A) has GA cases for the first half of the day and another room (surgeon B) has GA cases during the second half of the day. A CRNA or anesthesiologist assistant (AA) could work one room at a time, performing all the GA cases, and a nurse, certified in moderate sedation, could provide light-to-moderate sedation for the RA cases. Managing such an OR schedule would require no overlap of cases needing a CRNA or AA. Certain statistical methods can be used to minimize the probability of overlap accounting for built-in

Scenario 1 Timeline					
Time		Pre-Op/Block Room	OR7	OR6	OR5
2:30			Last case out	2nd to last case out	2nd to last case out of OR5
3:00	OR7 Staff work 2 hours over utilized time (3 to 5 pm)	OR7 staff handoff patient in PACU, then stay to help prepare OR5 and OR6 cases	OR cleaned		
3:30		OR7 covers for OR5 staff in order to place nerve block and also monitor OR5 patient			
4:00					Turnover time
4:30		OR7 staff covers OR6 staff to place nerve block and also monitor OR6 patient			Last OR5 case (2.5-h duration) enters
5:00		OR7 staff handoff patient and leave for the day		Turnover time	
5:30				Last OR6 case in (1.5-h duration)	
6:00					
6:30				Last case out	Last case out

FIGURE 67–1. Graphical timeline of scenario 1.

uncertainty. If no time buffer was used, surgeons and patients could expect delays. Also, patient requests for or denial of RA would create delays and increase costs.[10]

Clinical Pearls

- Increasing the efficiency of use of OR time is implemented by reducing the hours of over- and underutilized OR time.
- Appropriate OR allocation has a far greater impact on OR efficiency and economics than RA use.
- The most important factor influencing how RA affects OR efficiency is use of good statistical to plan allocated OR time.

ON-TIME STARTS

In a prospective time-motion study on first cases of the day, Chelly et al described an academic setting with the use of an acute interventional pain service team consisting of two anesthesiologists, two nurses, and four anesthesia residents or fellows performing the procedures in a preoperative area. They succeeded in having only four to six patients receive their nerve blocks and enter the OR on time. During the study, up to nine patients were indicated to have PNBs placed preoperatively, indicating a mismatch of pain service personnel to demand. This conclusion was based in part on the amount of time required for an advanced trainee (postgraduate year 4 anesthesia resident or postgraduate year 5 regional anesthesia and acute pain medicine fellow) to place a nerve block (20–30 minutes) under constant supervision of the attending physician. The study included landmarks or nerve stimulator–based techniques; no ultrasound guidance was used.[11] Mean time to place a block was 21 minutes (95% confidence interval [CI], 20–22 minutes). Duration of the PNB procedure varied by block type, and placing two catheters required the most time (mean, 30 minutes; 95% CI, 28–33 minutes).[11]

Mean time from patient arrival until transfer to the OR was 11 minutes longer for PNB patients than for controls (2:03, 95% CI 1:59, 2:07 h:min vs 1:51, 95% CI 1:42, 2:01 h:min, respectively) (P = .0019). For controls, 49% left on time for the OR compared to 40% of those in the PNB group (P = .067 one sided). More than half of the delays transferring patients to the OR were caused by surgical issues (control group 52%, PNB group 54%). Of delays in the PNB group, 15% were related to performing the nerve blocks, with 13% of that time being due to a lack of personnel. In fact, there was an average of 5.4 patients in the PNB group compared with 4.2 patients in the

Scenario 2 Timeline

Time		OR7	OR6	OR5

control group (P = .0007). The specific values are likely sensitive to the characteristics of the facilities. The RA team should arrive on time and early enough based on prior data to place successful blocks so surgery is not delayed. In many hospitals policy states that the surgeons must arrive early enough to consent patients and mark the surgical site before a nerve block is allowed to be placed. Also, when possible, the team should first perform block procedures for patients in the ORs with expected hours of overutilized time. When feasible, the team should next perform block procedures for patients in rooms where there is a single surgeon and more than 8 hours of cases. Further, months in advance when staff scheduling is calculated, more anesthesia providers who perform PNB cases should be planned for those days of the week when more PNB cases are expected.[6,9]

Clinical Pearls

- When possible, the team should prioritize block procedures for patients in the ORs with expected hours of overutilized time. When feasible, the team should next perform block procedures for patients in rooms where there is a single surgeon and more than 8 hours of cases.
- Months in advance, when staff scheduling is calculated, plan for more anesthesia providers who perform PNB cases on days of the week when more PNB cases are expected.

BLOCK TEAM AND SURGEON PERCEPTION

The most common complaints among surgeons about implementing RA are delays in induction of anesthesia and unpredictability of success.[12,13] However, other factors can be involved. In a study by Eappen et al, the addition of an RA team with dedicated space to place blocks did not reduce anesthesia-controlled times (ACTs) or turnover times.[14] A "block team" was created to shorten turnover times in an institution that was experiencing long turnover times of greater than 60 minutes. The team identified potential RA patients, transported them to a block room about 1 hour before the intended start time, and placed the block while the OR was performing the preceding case. Nerve blocks consisted of PNBs and epidurals (spinal anesthetics were placed in the OR by the OR anesthesia team). Patients with nerve blocks placed in the block room were "ready for incision" as they entered the OR. Anesthetic care was handed over to the OR anesthesia team once the patient was brought to the OR. It was up to the discretion of the OR anesthesia team whether to use GA.

Anesthesia emergence time was reduced by 1 minute among cases where regional block was used. There were no improvements in other segments of total OR time. Of note, there were only 0.7 turnovers per day on average; hence, there were less than two cases per room per day on average. In this academic hospital setting, having an impact on turnover time or on other OR times would not have significant clinical or economic impact. These time-motion results were probably specific to that hospital. More important, 10 orthopedic surgeons who collectively performed 80% of the cases completed a survey as part of the Eappen et al study. The surgeons indicated that the block team was effective, had changed the quality of their day for the better, and should be available every day. The surgeons may have had a positive perception originating from actually seeing their patients' readiness to go to the OR. Later studies showed that surgeon perceptions of nonoperative times are based on a mental model of workflow, not on actual time to place PNBs.[15] Consequently, even though the time to place PNBs is the major source of criticism, it does not explain the use or nonuse of PNBs.[12,13]

Surgeons were surveyed whether they would choose a block for themselves if they were undergoing the same surgical procedure.[12,13] The concordance between surgeon choice of a nerve block and his or her recommendation for a patient was high.[12,13] The concordance rates between surgeons' wanting a block for themselves and what they preferred for their own patients were 89% for arthroscopic shoulder surgery, 87% for arthroscopic anterior cruciate ligament reconstruction, and 93% for total knee replacement (Cohen's κ, $P < .001$ for each). Surgeon perceptions of time to place the PNB ($P \geq .27$) and PNB success rate ($P \geq .30$) were not correlated with whether they would recommend PNBs to their patients.

It is important to define block team members and have a plan for expected tasks, required skills, training, and the costs and benefits of hiring block team personnel. This can be part of a business plan when bringing the concept of a block team to hospital or group administrators and decision-makers.[16] A block team model often includes some type of assistant for the practitioner performing the procedure. Literature describing the concept of a RA "block nurse" is available.[17,18] This team member assists with preparation, performs a time-out, confirms medication labeling, assists with injections, monitors the patients after the block, and can be certified in moderate sedation and other tasks. Some procedures can be done in the preoperative holding area or in a block/induction room, thereby reducing time spent completing these procedures in the OR.

Clinical Pearl

- The concordance is high between a surgeon's preference of a nerve block for him- or herself and the surgeon's recommendation of a nerve block for his or her patient. Concordance is not with perceptions of time to place the PNB and PNB success rate.

BLOCK ROOM MODEL

Armstrong et al described a block room model for which upper extremity plastics or orthopedic surgical procedures were performed by nine surgeons. The anesthetic method was chosen at the discretion of the attending anesthesiologist and included brachial plexus blocks.[19] Intravenous and local anesthetic infiltration methods were excluded. Brachial plexus blockade was performed in the block room or in the OR at the discretion of the anesthesiologist. There was no standardization of technique.

Placing a PNB in a block room significantly reduced presurgical OR time compared to GA alone or to PNB placed in the OR (mean 11.4 vs 17.8 vs 32.9 minutes, respectively; $P < .05$). Compared to GA alone, postsurgical OR time was significantly reduced using either PNB alone or combined with GA. ACT was longer when the PNB was performed in the OR than in a block room (mean 37.1 vs 15.1 minutes, respectively; $P < .05$). The surgical procedure time was shorter with PNB than with GA alone (mean 75.3 vs 99.4 minutes; $P < .05$).[19]

An editorial on the Armstrong-Cherry study noted that less than half of the PNBs were performed in a block room. This may be due to multiple factors involved in a busy practice environment, suggesting that perhaps the block room could be used more systematically.[20] Using the block room no more than twice a day would not make much sense from a cost-effectiveness perspective unless the area also doubled as a surveillance area.[17,20] In the Armstrong-Cherry study, the block room did, in fact, serve as a monitoring area for ophthalmology patients, whose nerve blocks were also placed there.

Findings such as the number of nerve blocks performed per day and additional uses of block areas imply that there is no single economic value to PNBs. Instead, the science shows which factors are important to the local business plan.[16]

SWING ROOM MODEL

The use of two ORs for performing hand and wrist surgeries under PNB alone was studied by Head et al. The anesthesia model consisted of one anesthesiologist and two AAs monitoring patients in the OR. The "swing-room" patients (RA-SR group) received a brachial plexus block, the non–swing-room control patients received GA (GA-OR).[21]

The RA-SR group had shorter turnover times than the GA-OR group.[21] The surgeon was able to proceed with the procedure on the next case in one room while an assistant closed and dressed the incision of the case just completed in another room. A "negative" turnover time was created for 10% of cases with that surgeon (not with the individual OR). This was not applicable in the GA-OR group because personnel were held to one room.[21] The swing-room system can be costly, and if an institution is considering this, it should be determined that more surgeries per OR per day will be performed using this dual-room model for one surgeon compared to a single-room model.

ANESTHESIA-CONTROLLED TIME

Williams et al demonstrated that ACT in the OR can be shortened by using RA instead of GA with volatile anesthetics.[22] Blocks for anterior cruciate ligament reconstruction procedures performed by one surgeon were placed in the preoperative holding area with an anesthesiologist and an RA resident. Patients were monitored by a preoperative nurse or an anesthesia resident. When the OR was available, the patient was brought into the OR, monitors were applied, and the patient was prepared and positioned. Patients with planned GA were prepared and positioned before GA was induced.[22]

Anesthesia-controlled time for RA patients was shifted from inside the OR (costly time) to the preoperative holding area (less-costly time). ACT was lowest when RA was performed in the holding area (mean, 11.4 ± 1.3 minutes, ± 2 SEM). Patients having GA combined with PNB also had shorter ACT (mean, 15.7 ± 1.0 minutes) than GA alone (mean, 20.3 ± 1.2 minutes).[22] In a stepwise regression model, using the preoperative holding area to induce RA predicted lower ACT than inducing GA in the OR. In-OR induction time (for GA) increased ACT when compared to RA performed in the preoperative holding area or local anesthetic infiltration/Bier block administered in the OR.[22]

Mariano et al demonstrated that upper extremity surgery ACT was significantly reduced by placing PNBs in the preoperative holding area or by performing a Bier block or certain local anesthetic infiltration procedures in the OR compared with GA. That is, the median ACT was 28 minutes (interquartile range, IQR [15]) compared to the median ACT of 32 minutes (IQR [12]) for RA versus GA, respectively (P = .039). Mean ACT in the nerve block group may have been 4.5 minutes shorter than in the GA group, although the difference did not reach statistical significance (95% CI, –9.4 to 0.4 minutes).[23]

The OR intervals (minutes) have been analyzed by Shuster et al.[24] Mean ACT was similar for GA and spinal anesthesia (mean, 30.4 ± 15.1 minutes and 31.7 ± 13.6 minutes, respectively). Mean ACT was statistically significantly greater for PNB and epidural anesthesia placed in the OR (mean, 44.8 ± 17.9 minutes and 46.4 ± 21.7 minutes, respectively) than compared to GA ($P < .05$).[20] RA care pathway patients had shorter OR duration (from surgery end until patient out of room) than patients with GA alone.[25]

INDUCTION AND SURGICAL TIME

Liu et al compared RA and GA in a meta-analysis of randomized controlled trials.[26] "Anesthesia induction time" described the interval from "beginning of induction until the patient was ready for surgery," that is, when the patient's level of anesthesia allowed the surgical procedure to begin. Central neuraxial block (odds ratio, 8.1; 95% CI, 4.1 to 12.1) and PNB (odds ratio, 8.1; 95% CI, 2.6 to 13.7) were both associated with an increased time until anesthesia ready compared to GA.

Dexter et al performed a meta-analysis of studies that used RA and compared nerve block methods with GA. The intent was to evaluate the effect of increased use of RA on overall performance of the surgical suite. Retrobulbar, local anesthetic infiltration (2 studies, 163 patients); spinal (10 studies, 812 patients); and epidural (11 studies, 702 patients) techniques were included. There were no significant differences in surgical times for the regional techniques compared with GA (mean difference, 1.7 minutes; 95% CI, –0.05 to 3.9 minutes).[27]

TURNOVER TIMES

Preoperative RA procedures and activation of anesthesia start times associated with the RA procedure significantly lengthened the time from anesthesia start to patient-in-room time compared to the GA care pathway group or to all historical controls.[25] However, turnover times were not significantly different between GA (median 24 minutes, IQR [12]) and either the nerve block (median 25 minutes, IQR [20]) (P = .88 vs GA) or local anesthetic infiltration (including Bier block) (median 21 minutes, IQR [20]) groups (P = .948 vs GA).[23]

Williams et al showed that nerve blocks often do not increase turnover time.[22] Instead, turnover time must be thought of as a product of a multidisciplinary team, not simply as part of an anesthesia-limited process. This finding adds more data that indicate turnover times are influenced by multiple factors and not solely by RA procedures.[11,22,28,29]

PACU COSTS

Compared with personnel costs, drugs and materials represent only a small (2%) portion of PACU charges. Dexter et al created simple simulations to quantify the degree to which three interventions can reduce postanesthesia care unit (PACU) costs: (1) use of short-acting anesthetic agents, (2) elimination of nausea and vomiting by any means, and (3) adjustments to OR scheduling practices. For a brief workday in their ambulatory surgery center, the number of admissions per hour rose linearly to a peak and then linearly declined to zero. This triangular distribution was used to determine how admission rates to the PACU would affect the peak PACU patient census by hour of the day. Changes in the peak patient admission rates were simulated. The OR schedule had far greater impact on the number of PACU nurses needed than eliminating nausea and vomiting entirely or using short-acting anesthetic agents only. The distribution of patient admissions to the PACU throughout the day was the main factor determining PACU costs.[30] Varying the time of day of the last patient admission to the PACU had a smaller effect than altering the arrival times.

Minor differences in patient PACU durations that have full-time nursing staff are unlikely to create lower labor costs. In contrast, depending on the number of patients admitted daily, the use of RA to increase the PACU bypass rate can decrease staff and associated labor expenses. Table 67–1 is a resource for managers wishing to estimate the number of PACU nurses that could be reduced by bypassing the PACU at various rates and at different quantities of patients per day. The top eight rows of the original table are reproduced here. The table is designed to be used as a screening tool for facilities to decide whether to perform their own detailed analyses.

For example, hypothetically every ambulatory surgery center patient is brought into the PACU by 4:00 PM at the latest. Care is provided for 40 patients per day on average (5 patients per OR with eight ORs), where there is an average of a 30-minute stay in the phase I PACU and 60 minutes in the second-stage recovery. An initial starting point is that 20% of MAC or RA patients bypass the phase I PACU. By increasing the PACU

TABLE 67–1. Example of what to reproduce from the original (the top eight rows).

Time in Phase II (minutes)	Time in Phase I (minutes)	Time of Last Admit (PM)	Mean Number of Patients Each Day	Full-Time PACU Nurses at Specified Phase I Bypass Rates						
				0%	20%	30%	40%	50%	60%	80%
60	30	2	20	7	6	6	6	6	5	5
60	30	2	30	9	8	8	8	7	7	6
60	30	2	40	11	10	10	9	9	8	8
60	30	2	50	12	12	11	11	11	10	9
60	30	4	20	6	5	5	5	5	5	4
60	30	4	30	7	7	7	7	6	6	6
60	30	4	40	9	9	8	8	8	7	7
60	30	4	50	11	10	10	9	9	8	8

Source: Adapted with permission from Dexter F, Macario A, Manberg PJ, et al: Computer simulation to determine how rapid anesthetic recovery protocols to decrease the time for emergence or increase the phase I postanesthesia care unit bypass rate affect staffing of an ambulatory surgery center. *Anesth Analg*. 1999 May;88(5):1053–1063.

bypass rate from 20% to 30%, a facility can reduce the need for one PACU nurse (from 9 to 8) and save on labor costs.[31]

Clinical Pearl

- The distribution of PACU admissions throughout the day is the main factor determining PACU costs. Altering this distribution by using RA to increase PACU bypass rates can reduce PACU labor costs.

PACU BYPASS

Using a multivariable linear regression model to predict the determinants of discharge times for patients following outpatient lower extremity surgery, Williams et al found that time to patient discharge can be reduced by using an RA PACU bypass criteria (RAPBC) scoring system. The anesthetic plans consisted of GA alone, an anesthetic lower extremity PNB alone, an analgesic PNB combined with either a GA or neuraxial anesthetic, or neuraxial anesthetic alone. GA was maintained with nitrous oxide and oxygen with either sevoflurane or desflurane. Anesthetic methods were categorized into "GA" versus "no GA," and "recommended blocks used" versus "not used." Surgical invasiveness was categorized into "mild" (e.g., arthroscopic knee meniscus repair), where short-term anesthetic blocks with or without GA or spinal, but no long-acting PNBs, were used; or "invasive" (eg, arthroscopic anterior cruciate ligament reconstruction), where long-lasting PNBs were provided based on the observed surgical pain patterns prior to the study.[32]

The RAPBC scoring system allowed an 87% PACU bypass rate. After mild surgery, the linear regression showed an 18% reduction in time until discharge for GA-alone cases and a 14% reduction when the PACU was bypassed. Invasive surgery showed an 18% reduction in discharge time when the PACU was bypassed. Any nursing interventions in the phase II recovery unit had a 45-minute (18%) or 47-minute (32%) increase in discharge time with mild or invasive surgery, respectively. Age, gender, GA, or the use of PNBs were not associated with mean differences in discharge times after invasive surgery.

The RAPBC was later modified and called the "WAKE© score," published in 2011 by Williams and Kentor.[33] This score targeted patients having MAC, GA, or RA, whereas prior scoring systems were focused on patients having GA. Some important differences in the WAKE (C) score from the RAPBC are the modification of the requirement to move a blocked limb, the measurement of blood pressure in a sitting or head-elevated position (checking orthostatic symptoms) before leaving the OR after any neuraxial blockade, and the addition of a "zero-tolerance criteria," which includes an adjustment of the patient's PACU pain score to their baseline pain score and inclusion of any postoperative nausea and vomiting symptoms.

As described by Armstrong and Cherry, the PACU bypass rate was 53% among patients with PNB only. Their PACU stay before going to phase II recovery was shorter than that of GA-only patients (mean difference = 26 minutes, $P = .02$). Phase II recovery times may also have been shorter in patients with PNB compared to patients with GA; the difference was not statistically significant.[19]

Patients who received only regional anesthetics were more likely to bypass the PACU than were patients who received GA with volatile anesthetics. RA patients bypassed the PACU at a greater rate than GA patients (86% vs 62%; odds ratio, 3.85; 95% CI 2.70 to 5.56; $P < .001$).[34] Given that PACU bypass can be achieved in 87% of RA patients, work by Dexter et al showed that with 50 cases/day, an institution can achieve staffing reductions of as many as 4 full-time equivalents in PACU staffing compared to *no* PACU bypass.[31] Thus, the appropriate PACU bypass criteria used in combination with RA can result in substantial savings.

Patients who bypassed the PACU exhibited no sequelae that necessitated nursing interventions at a PACU level of care. In the Williams et al study, the GA and RA historical control groups did not bypass the PACU, while the RA care pathway groups that had femoral nerve block or epidural anesthesia both experienced a 91% PACU bypass rate ($P < .001$). The historical control patient group and the GA care pathway group exhibited unexpected hospital admissions with a frequency of 20%, while the GA with femoral nerve block and epidural anesthesia care pathway groups had a 4% and 6% ($P = .002$) unexpected admissions rate, respectively.[25]

In the meta-analysis conducted by Liu et al, PACU bypass occurred with greater frequency using PNB (odds ratio, 14; 95% CI, 7.5 to 27.4) and was associated with shorter PACU time in minutes (odds ratio, −24.3; 95% CI, −36.3 to −12); decreased nausea (odds ratio, 0.17; 95% CI, 0.08 to 0.33); and increased patient satisfaction rating of excellent (odds ratio, 4.7; 95% CI, 1.8 to 12).[26] PACU bypass patients have been shown to have a reduced time until discharge.[32] Thus, the question remains regarding why the meta-analysis did *not* demonstrate shortened time until discharge with PNB. Possible explanations include the lack of discharge criteria (eg, the WAKE (C) score) during the time the studies were analyzed, the wait until a long-acting block has worn off until discharging patients, or other medical practice differences.

In the Head et al swing-room study for wrist and hand procedures, the RA group demonstrated shorter time for discharge (median 28 minutes and 95% CI 20–46 vs 156 minutes and 95% CI 118–215); shorter total time in facility (median 186 minutes and 95% CI 153–224 vs 345 minutes and 95% CI 290–430); fewer postoperative antiemetics (2% vs 17%; $P < .0001$); and less need for rescue opioids (0.6% vs 80%; $P < .0001$) compared to the GA-OR group.[21]

SUPPLIES, ULTRASOUND, BILLING, AND PAYMENTS

Liu and John performed a sensitivity analysis for the costs of using ultrasound during PNB.[35] If billed and revenue is obtained, ultrasound guidance can become profitable regardless of clinical setting (ie, ambulatory vs inpatient hospital). If billing procedures are not in place, then the clinical setting predominates. For example, in the ambulatory surgery center, nerve stimulator–guided nerve blocks would require a 96% success rate to compete with ultrasound guidance. The factors with the biggest cost impact for ultrasound were billing revenue (85% of variability), proportion of patients on whom the device is used (10% of variability), and success rate of the ultrasound-guided nerve block (2.6% of variability). In contrast, the factors with the biggest cost impact for the peripheral nerve stimulation model were block success rate (89% of variability) and liability paid out in a failed airway situation (9% of variability). Individual facilities should consider these factors when making important purchasing decisions.

Supplies, direct costs, and process time intervals were analyzed by Shuster et al according to anesthesia techniques used for trauma and orthopedic services, including spinal, brachial plexus, epidural anesthesia, and GA.[24] The study showed that 11% of costs were related to drugs and supplies, suggesting that opportunities for cost savings are small. However, as almost 78% of the costs were due to personnel, labor savings could make a significant economic impact.

A best-fit regression line of anesthesia-related costs estimated a statistically significant but small cost advantage of spinal over GA, which was shown to be 13% for a 50-minute case, 9% for a 100-minute case, and 5% for a 200-minute case.[24] Anesthesia-related costs of PNB using brachial plexus blocks were statistically significantly greater than GA costs but were still small. The cost difference for brachial plexus block over GA was much greater for shorter cases and estimated at 19%, 8%, and 1% higher for a 50-, 100-, and 200-minute cases, respectively. There was no difference in costs between GA and epidural anesthesia.

The publications that discussed supply costs and use of ultrasound consider a US perspective.[16,36,37] These concepts may apply to countries outside the United States that have similar private and governmental insurance billing payment structures, but the actual revenue quantities and ratios are likely to be different. Further, economic circumstances are known to change over time, and specific details may no longer apply. Payment source can affect patients' access to RA methods, and further research on the factors that affect patient access to RA is needed.[38]

Clinical Pearl

- Payment sources affect patient access to RA and analgesia methods, and further research on the factors that affect patient access to RA is needed.

SUMMARY

The majority of OR costs are due to personnel. The ability to reduce these costs often has limitations.[2] A large and important consideration in how RA influences OR economics lies in the use of statistical forecasting to plan allocated OR time months ahead of time. Consequently, on the day of surgery, the decision regarding whether to use RA methods will not affect OR economics by a large factor; instead, decisions should be made based on improved patient outcomes and reducing patient and surgeon waiting. Another consequence is that sequencing cases for blocks (eg, among first cases of the day) can have economic benefit.

Avoiding the side effects of GA can reduce unplanned admissions, reduce length of hospital stay, and shorten surgical unit stay when proper bypass and discharge criteria are implemented. RA has demonstrated the ability to allow patients to bypass the PACU and move directly to the second-stage recovery or "step-down" unit. PACU and recovery times can be affected by the use of RA techniques. PACU costs are less affected by reducing postoperative nausea and vomiting or using faster-acting anesthetic agents to speed anesthesia emergence. Rather, PACU costs can be determined to a large degree by the distribution of patient admissions to the PACU.

Practitioners should understand the literature and apply the findings to their own facilities or institutions in order to determine what specific cost savings could be realized. Science has demonstrated that RA procedures that are properly planned and executed do not increase OR time and can decrease PACU time, thereby potentially reducing costs.

CHAPTER 68

Regional Anesthesia and Perioperative Outcome

Ottokar Stundner, Suzuko Suzuki, and Stavros G. Memtsoudis

INTRODUCTION

The focus of anesthesiologists on patient safety has led to advancements in anesthetic techniques and perioperative pain management, as well as profoundly affected patient care in the entire perioperative period. However, studies of the contributions of anesthesia and advances in analgesic approaches as well as their effects on measurable outcomes have only recently gained momentum and widespread recognition. The increasing realization that anesthesia-related factors and choices made by anesthesiologists can influence perioperative events and patient safety has thus sparked interest in a variety of outcomes previously thought beyond our control.

As the patient population seeking surgical care presents with serious comorbidity more commonly, the perioperative challenges will demand that anesthetic considerations assumes a major part of the care plan for patients to ensure the best possible outcomes. Utilizing regional anesthesia provides a significant benefit in achieving this goal.

In the past, the scope of neuraxial anesthesia and peripheral nerve blocks has primarily encompassed their use for intraoperative anesthesia and postoperative analgesia, respectively. However, the choice of anesthesia may positively influence the risk of perioperative cardiopulmonary complications, infections, and mortality.[1,2] The pathophysiologic reasons for these findings remain incompletely understood. Attempts to explain these associations depend on a number of observations made in small clinical or preclinical studies. The effects seen, however, might feasibly represent a composite result of avoidance of general anesthesia on the one hand and intrinsic positive effects brought about by regional anesthesia on the other hand. General anesthesia, systemic analgesia, and mechanical ventilation often prove problematic in patients with comorbidity,[3] especially those with pulmonary pathologies. Regarding the latter, neuraxial anesthesia was associated with lower blood loss, shorter surgical time, and a lower incidence of thromboembolism,[4,5] possibly conferred by its sympatholytic action and beneficial effects on the coagulation system.[6] In orthopedic patients, earlier mobilization and discharge readiness may contribute to a lower complication incidence. Advances in perioperative pain control have also been associated with better medical and economic outcomes as well as improved patient satisfaction.[7,8] Moreover, recent research suggested that regional anesthesia may have long-term outcome benefits from reduction of cancer recurrence and prevention of chronic postsurgical pain.

However, there is little quantitative evidence on these beneficial effects of regional anesthesia, particularly for peripheral nerve blocks. Available studies are mostly limited by their small sample sizes and scope. Nonetheless, data gained from large-scale, population-based studies show promising results.

This chapter summarizes currently available data on outcomes pertaining to the use of regional anesthesia. The discussion focuses on its use in the context of specific surgical interventions. Regional anesthetic techniques and their impact on perioperative outcomes in selected types of surgeries, long-term medical outcomes, and finally economic outcomes and cost-effectiveness issues are reviewed.

SHORT-TERM OUTCOME: MORBIDITY AND MORTALITY

With the advent of advanced preoperative evaluation, perioperative monitoring, and treatment modalities, the incidence of many major perioperative complications, including mortality, has substantially declined over the last century. Anesthesia-related mortality was reported to be as low as 1.1 deaths for a population of 1 million per year.[9] Surgical mortality, on the other hand, largely depends on the type of surgery and associated patient demographics, with mortality rates ranging from 0.07% for low-risk breast surgery to almost one-fifth of patients undergoing liver transplantation.[10] Anesthesia has long been thought to play a secondary role with regard to major perioperative complications and mortality, not least because it has been difficult to reliably assess its impact in the setting of low-incidence outcomes. Only recently, advanced techniques for data aggregation were introduced, including pooling of studies in meta-analyses, database-driven population-based approaches, and assembly of dedicated, prospective adverse event registries.

Most available data on morbidity and mortality in the perioperative setting focuses on the differential impact of general and neuraxial anesthesia. For peripheral nerve blocks and other techniques of lower invasiveness (like local anesthetic wound instillation), conclusive data on perioperative outcome are still scarce.

General Noncardiac Surgery Populations

Rodgers and colleagues integrated 141 randomized controlled studies, including 9559 patients receiving neuraxial versus general anesthesia for noncardiac surgery into a meta-analysis.[1] The primary outcome was defined as differential mortality. The authors reported a reduction in overall mortality by 30% in patients receiving neuraxial blockade compared to general anesthesia (odds ratio [OR] = 0.70; confidence interval [CI], 0.54–0.90), along with reductions in complications, including deep vein thrombosis, pulmonary embolism, blood product transfusion, pneumonia, respiratory depression, myocardial infarction, and renal failure (Figures 68–1 and 68–2). However, in a subgroup analysis, no clear difference was apparent between different types of surgery. The authors conceded that the study was underpowered to reliably detect differences across surgical specialties. Another limitation of the meta-analysis approach is that individual studies with largely different research questions, protocols, and time of origin are pooled, representing the introduction of cofounders that cannot entirely be accounted for. Moreover, although individual randomized controlled trials are thought to be of high scientific validity, they may feasibly introduce bias by restricting the patient population to a tightly controlled academic environment.

Thus, for the purpose of risk assessment on a public health level, administrative or billing databases are increasingly

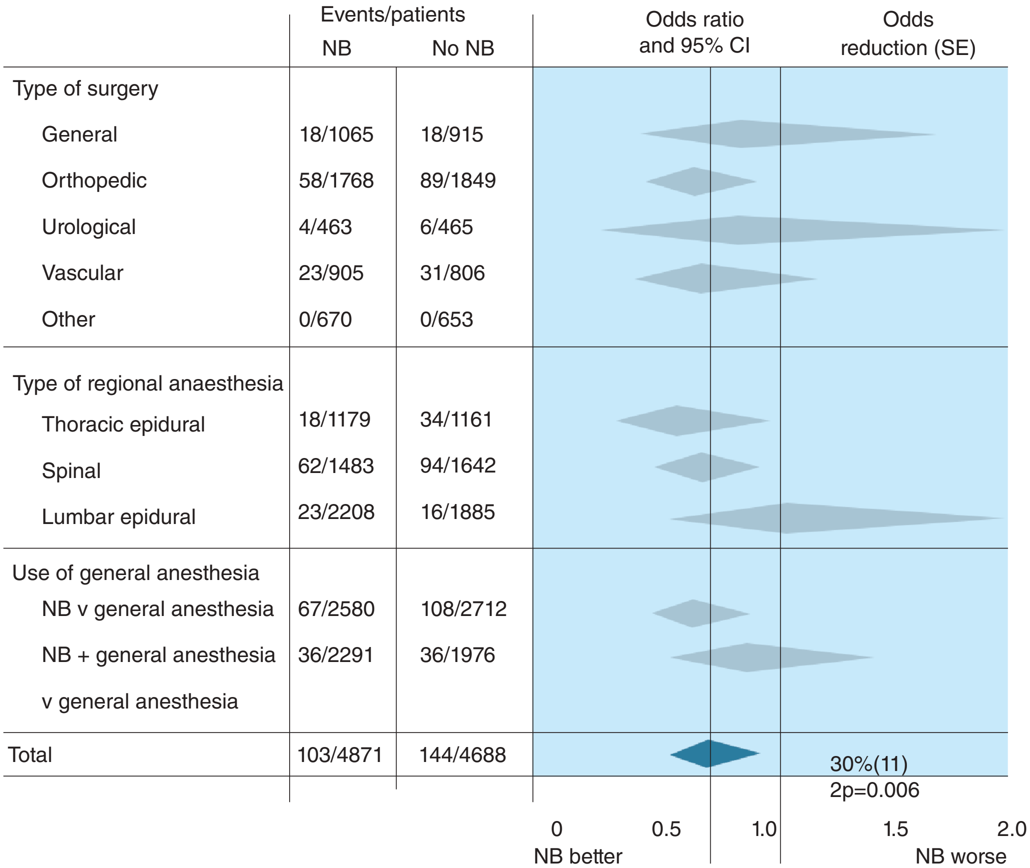

FIGURE 68–1. Effect of neuraxial blockade (NB) on postoperative mortality, by surgical group, type of neuraxial blockade, and use of general anesthesia. Obstetrics and gynecology trials are included with other surgery. One trial with unknown details of anesthesia was grouped with lumbar epidural and neuraxial blockade plus general anesthesia versus general anesthesia comparisons. Diamonds denote 95% confidence intervals for odds ratios of combined trial results. The left vertical line represents the overall pooled result. utilized for comparative effectiveness research. Wijeysundera and colleagues queried population-based administrative databases originating from Ontario, Canada.[11] They studied more than a quarter of a million patients aged 40 or older undergoing elective, medium- to high-risk noncardiac surgery during a 10-year period. Within a matched-pairs cohort generated using propensity scoring, 30-day mortality was compared between patients receiving epidural versus general anesthesia. The 22% of patients receiving epidural anesthesia had a slightly lower rate (1.7% vs 2.0%) and relative risk (RR) (0.89 [CI, 0.81–0.98], P = .02) of mortality than those undergoing surgery under general anesthesia (Figure 68–3). The effect was more pronounced in thoracic and orthopedic surgery compared to abdominal or vascular surgery. While the authors acknowledged that their findings were not as convincing in terms of mortality reduction as earlier results, they emphasized the relative safety of epidural anesthesia for indications other than reduction of mortality. However, it must be kept in mind that the data used here only represent a geographically restricted region and might not be fully applicable to other areas.

In contrast, Wu et al used a random sample from the Medicare database.[12] Differential outcomes of patients undergoing intermediate- to high-risk noncardiac surgery with or without epidural anesthesia were compared with regard to death within 7 or 30 days. Regression analysis controlling for race, gender, age, comorbidities, hospital size, hospital teaching status, and hospital technology status were performed. Epidural anesthesia was associated with lower adjusted odds ratios for mortality at 7 days (OR = 0.52 [CI, 0.38–0.73], P = .0001) and 30 days (OR = 0.74 [CI, 0.63–0.89], P = .0005), but no difference in major complications was apparent except for pneumonia, which was, oddly, higher in the epidural group.

Limitations of most database studies revolve around the reliability of the data source, in terms of adequate coding of events and the propensity to readily identify complications. For statistical adjustment, the granularity of available information on preexisting morbidity is important, as this is known to be a prime determinant of postoperative outcome. Finally, there is considerable heterogeneity not only within the individuals undergoing surgery, but also across various types of procedures. All previously discussed studies attempted to specify differences between surgical subspecialties from the overall cohort. However, their sample sizes were likely too small to provide adequate power to answer specific related questions.

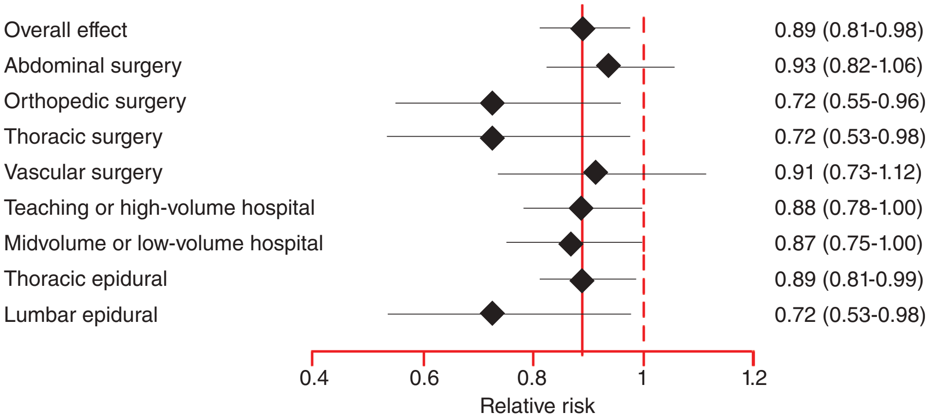

FIGURE 68–3. Association of epidural anesthesia or analgesia with 30-day mortality in the subgroup analyses. Diamonds represent relative risks for 30-day mortality within each subgroup. Error bars are 95% CI. The corresponding numerical values for these point estimates and confidence intervals are presented on the right. The solid vertical line represents the overall treatment effect (relative risk 0.89). The dashed vertical line represents a null effect (relative risk 1). (Reproduced with permission from Wijeysundera DN, Beattie WS, Austin PC, et al: Epidural anaesthesia and survival after intermediate-to-high risk non-cardiac surgery: a population-based cohort study. *Lancet*. 2008 Aug 16;372(9638):562–569.)

Orthopedics and Trauma Surgery

A number of studies have focused on orthopedics and trauma surgery, predominantly when utilized for lower extremity joint surgery. Regional anesthesia lends itself to the management of these procedures, as it does provide complete coverage of the entire operative field along with sustained analgesia, thus allowing for the avoidance of general anesthesia and mechanical ventilation. Pugely and colleagues queried the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) database for patients undergoing primary total knee arthroplasty between 2005 and 2010 and evaluated 30-day complication rates and mortality, according to type of anesthesia (spinal vs general anesthesia).[13] Of the 14,052 patients identified, 57.1% of surgeries were performed using spinal anesthesia. Compared to the group receiving general anesthesia, patients receiving regional anesthesia had lower unadjusted rates of overall complications, shorter duration of surgery, and shorter length of hospital stay. Adjustment for covariates yielded a significantly higher likelihood of complications in the general anesthesia group (OR, 1.129 [CI, 1.004–1.269]). Patients with a high comorbidity load were most likely to incur complications.

Unlike other large studies, a study by Memtsoudis et al managed to discriminate between the use of sole neuraxial anesthesia versus the addition of neuraxial to general anesthesia.[2] The authors utilized a commercial administrative discharge database containing data from approximately 400 US hospitals to examine the impact of the type of anesthesia in over half a million patients undergoing primary hip or knee arthroplasty between 2006 and 2010. Three groups were established: patients receiving neuraxial anesthesia alone (11%), general anesthesia alone (74.8%), or a combination of both (14.2%). The unadjusted incidence of 30-day mortality was significantly lower in the first two groups (0.10%, 0.10%), compared to the last (0.18%; $P < .0001$). After adjustment for demographic and health care–related variables, type of surgery, and preexisting comorbidities, the multivariate regression yielded 30-day mortality odds ratios of 1.83 (CI, 1.08–3.1; $P = .0211$) for general versus neuraxial anesthesia and 1.70 (CI, 1.06–2.74; $P = .0228$) for general versus combined general-neuraxial anesthesia and thus a substantially lower risk for the regional techniques. The same observation held true for numerous in-hospital complications, including cerebrovascular events, pulmonary compromise, cardiac complications, pneumonia, infectious complications, mechanical ventilation, and blood product transfusion, all of which exhibited higher odds ratios in the general-only group. Interestingly, the beneficial effects of neuraxial anesthesia appeared to be most pronounced when it was used as the sole anesthetic (Tables 68–1 and 68–2); in combination with general anesthesia, the odds ratios often ranged in between those of neuraxial and general anesthesia as the sole technique. The authors concluded from this finding that the benefits seen in this cohort not only might stem from avoidance of general anesthesia but also might imply a positive modifiable effect conferred by neuraxial anesthesia itself.

Very similar results to those gained in elective orthopedic surgery were recently published in the field of acute trauma surgery. A retrospective study of 18,158 patients undergoing surgery for hip fracture in 126 hospitals in the New York State area found no difference in unadjusted mortality whether neuraxial or general anesthesia was used.[14] However, after adjustment for covariates, regional anesthesia was associated with significantly lower odds of mortality (OR, 0.71 [CI, 0.54–0.93]; $P = .014$) and pulmonary complications (OR, 0.75 [CI, 0.64-0.89]; $P < .0001$) compared to general anesthesia. Patients with intertrochanteric fractures benefitted more than those with femoral neck fractures.

Thoracic and Cardiac Surgery

Pulmonary mechanics were reported to be better in patients receiving regional anesthesia, which is of particular importance for spontaneous ventilation and fast rehabilitation after intrathoracic procedures.[15] This improvement is likely associated with better pain relief achieved with regional anesthesia compared to systemic opioid administration.[16] Paravertebral block

was reported to be as effective as epidural anesthesia for intrathoracic surgery, with potentially lower risk of neuraxial bleeding complications but higher risk of pneumothorax.[17] In cardiac surgery, the addition of thoracic epidural anesthesia to general anesthesia was associated with improved coronary perfusion and myocardial oxygen supply as well as reduced incidence of arrhythmias, probably evoked by sympathicolysis at the thoracic level. Moreover, relief of sternotomy pain may allow for early tracheal extubation and faster initiation of respiratory therapy. However, epidural anesthesia for cardiac surgery is subject to intense controversy, as high-dose systemic anticoagulation necessary for cardiopulmonary bypass might increase the risk for epidural hematoma and its potentially devastating consequences. In addition, pronounced hypotension as a result of sympathicolysis may be problematic and difficult to counteract in these patients.

Svircevic and colleagues' recent meta-analysis including 2731 patients from 28 randomized controlled studies yielded a better risk profile for patients receiving epidural in addition to general anesthesia[18]: fewer respiratory complications (RR, 0.53 [CI, 0.40–0.69]); supraventricular arrhythmias (RR, 0.68 [CI, 0.50–0.093]); lower risk of mortality (RR, 0.81 [CI, 0.40–1.64]); perioperative myocardial infarction (RR, 0.80 [CI, 0.52–1.24]); and stroke (RR, 0.59 [CI, 0.24–1.46]). Given the potential risks, further research is necessary to clarify the potential of the use of regional anesthesia with regard to major morbidity and mortality outcomes, most of which did not reach statistical significance in this and earlier studies.

Abdominal Surgery

The scope of abdominal surgery ranges widely from ventral herniorrhaphy and appendectomy to liver resection and abdominal thoracic aneurysm repair. Despite the advent of laparoscopic procedures and minimally invasive surgical techniques, there continues to be a need for open and major abdominal surgeries. The ramifications of abdominal surgeries may include, but are not limited to, multiple-organ involvement, large fluid shifts and blood loss, need for blood transfusions, intensive care unit admissions, need for specialty consultations, pain control, infections, prolonged hospital stay, malnutrition, and deconditioning.

Regional anesthesia is frequently utilized in major abdominal surgeries, most commonly in the form of epidural anesthesia. The use of epidural anesthesia in addition to general anesthesia for abdominal surgeries is associated with a number of conceivably beneficial effects that could address many of the potential perioperative challenges.

First and foremost, epidural anesthesia can provide excellent analgesia for large abdominal incisions. Adequate pain control leads to reduced opioid consumption and its

TABLE 68–2. Multivariable regression analysis results for total knee arthroplasty.

associated side effects, earlier ambulation, and increased patient satisfaction. Thoracic epidural analgesia is also known to improve functional residual capacity (FRC) and vital capacity (VC) after abdominal surgeries,[19] possibly due to better pain control and prevention of atelectasis. In addition, the associated sympathectomy at the thoracic level may blunt the cascades of neuroendocrine responses to the surgical insults. The use of epidural blockade is shown to attenuate the rise of cortisol and proinflammatory cytokines in response to surgical stimulation.[20–22] Attenuation of the stress response and cardiovascular stability are obviously desirable and may lead to decreased perioperative cardiovascular complications, wound infection, and better healing. It also has been observed that thoracic epidural anesthesia increases the gastrointestinal and hepatic blood flow and improves tissue oxygenation during surgery.[23] Furthermore, postoperative ileus was significantly reduced by epidural analgesia, although the risk of postoperative nausea and vomiting was not shown to be affected.[24] The implication of these findings may include better nutritional support, reduced risk of infectious complications, earlier hospital discharge, and improved patient satisfaction.

Some of the effects mentioned may be reflected in the data from the study by Rodgers et al, which included abdominal surgeries.[1] In this study, the use of regional anesthesia was associated with a reduction in the risk of pulmonary embolism by 55%, pneumonia by 39%, myocardial infarction by 33%, bleeding by 50%, blood transfusion by 55%, renal failure by 43%, and 30-day mortality by 30%.

In conclusion, the available data on outcome measures and regional anesthesia in abdominal surgeries are positive but limited. Further and more definitive conclusions await additional studies and analysis.

Obstetrics

Owing to the reported benefits for mother and newborn, regional anesthesia is widely used in obstetrics for both cesarean section and vaginal delivery. For the former, general anesthesia is usually only chosen when contraindications for the regional technique prevail or in highly time-critical situations. For this reason, large-scale data on comparative perioperative outcomes and mortality in parturients are scarce. In a meta-analysis of 16 studies comparing neuraxial to general anesthesia for uncomplicated cesarean delivery, no significant difference was seen in the incidence of neonatal Apgar scores of 6 or less or 4 or less at 1 and 5 minutes, respectively, and the requirement of neonatal resuscitation.[25] The primary advantages of neuraxial anesthesia for cesarean section include avoidance of general anesthesia, airway manipulation, and systemic administration of anesthetic drugs. Induction of general anesthesia and intubation is associated with a considerably higher risk for the mother due to the possible presence of a difficult airway and higher risk of aspiration. Moreover, the fetus is only exposed to a very small dose of systemically absorbed local anesthetics when neuraxial anesthesia is used, thus reducing the direct impact of anesthesia on its physiology. However, spinal and epidural anesthesia can still affect the fetus through indirect effects, including pronounced maternal blood pressure drops evoked by sympathicolysis. While, untreated, this can have detrimental effects on the neonate's circulation and acid-base status, it can usually be readily counteracted with vasopressors.[26]

Low-dose ("walking") epidural anesthesia is often applied for pain relief in women during labor. While systemic administration of analgesics can be avoided with this approach, it was suspected to potentially delay the birthing process and increase rates of vaginal instrumentation and cesarean section. In a meta-analysis by Liu et al including seven trials of nulliparous women comparing epidural anesthesia to systemic opioid administration, epidural anesthesia was not associated with an increased risk of cesarean section (OR, 1.03 [CI, 0.71–1.48]) but with a nonsignificantly increased risk for instrumental vaginal delivery (OR, 2.11 [CI, 0.95–4.65]).[27]

Interest in the effects of anesthesia on long-term cognitive development is growing. Sprung et al reviewed medical and educational records of 5320 children in Minnesota who were delivered vaginally, via Cesarean section under general anesthesia, or under regional anesthesia.[28] The risk of learning disabilities was significantly lower in those receiving regional anesthesia for cesarean section compared to standard vaginal delivery (hazard ratio, 0.64 [CI, 0.44–0.92], $P = .017$).

LONG-TERM OUTCOME

The anesthesiologists' role as perioperative clinicians has been constantly redefined in the context of the rapid expansion of research. The fields of anesthesiology and perioperative medicine have started to have an impact beyond the traditional, acute perioperative period with the realization that what happens at and around the time of surgery may have measurable effects months and even years later.

Regional Anesthesia and Cancer Recurrence

The time of tumor resection is a critical period in cancer cell survival and proliferation. A growing body of literature has suggested that various aspects of anesthetic care may have significant effects on the rate of cancer metastasis and recurrence. Stress and surgical tumor resection have long been known to promote cancer metastasis.[29] The body's major defenses against such pathophysiology are the neuroendocrine and anti-inflammatory responses. In simplistic terms, factors that increase the stress and inflammatory response or conversely weaken the immune systems will likely promote cancer metastasis and growth. In theory, interventions opposing the stress response may therefore have beneficial effects. The choice of anesthetic types and medications may significantly influence this cascade.

General anesthesia is suggested to suppress the immune response by direct effects or by activation of the hypothalamic-pituitary-adrenal axis and the sympathetic nervous system.[30] Several anesthetic agents, including ketamine, thiopental, and volatile agents, have been shown to reduce the function of natural killer (NK) cells, which carry out the body's major antineoplastic activity. Opioids also suppress the immune system, and it has been suggested that morphine may promote angiogenesis. In addition, pain itself is known to suppress NK cell function.[31]

The use of regional anesthesia has been suggested to reduce cancer recurrence after prostatectomy and mastectomy. A retrospective study compared the use of epidural analgesia to opioid analgesia in addition to general anesthesia and suggested a 57% reduction in cancer recurrence rate,[32] while another showed reduced cancer progression after prostatectomy (hazard ratio, 0.45).[33] Exadaktylos et al. reported that postmastectomy recurrence- and metastasis-free survival was significantly higher in patients who received paravertebral catheter analgesia compared to those who received morphine patient-controlled anesthesia (94% vs 77% at 36 months).[34] In addition, the serum from patients who received propofol and a paravertebral block has been shown to inhibit cancer cell proliferation compared to that of patients who received sevoflorane and opioids. Furthermore, the use of spinal in addition to general anesthesia was associated with 70% reduction in metastatic progression of lung cancer after unrelated surgery (laparotomy) in a rat model.

The effect of regional anesthesia on cancer recurrence, if substantiated by further trials, is likely multifactorial and may include the prevention or blunting of neuroendocrine response to surgical insults, reduction of the dose of anesthetic agents and opioid consumption and their related effects, as well as the reduction of pain. In addition, local anesthetics themselves have been suggested to possess antineoplastic and even cytotoxic properties.[35]

Regional Anesthesia and Postsurgical Chronic Pain

Patients may undergo successful surgery and can still be burdened by lingering postsurgical pain many months or years after the operation. Certain types of surgeries have been associated with a higher incidence of postsurgical pain; these include thoracotomies, coronary artery bypass grafting (CABG), breast surgeries, and inguinal herniorrhaphies with an individual incidence of 30%–60%, 30%–50%, 20%–30%, and 10%, respectively (Table 68–3).[36] For instance, the rate of postthoracotomy pain was reported as 30%–60% but could be as high as 80%. In one study, 40% of patients with pain reported that the pain limited their daily activities and 46% thought that pain was their worst problem.[37]

The prevention of such postsurgical pain is of interest for anesthesiologists, and the possible influence of preemptive analgesia using regional anesthesia has been investigated. Although data are limited, positive influences on this outcome have been suggested. A meta-analysis based on a pool of 250 patients showed that epidural analgesia was associated with decreased rates of postthoracotomy pain at 6 months (OR, 0.33).[38] In the same analysis, 89 patients from two studies favored paravertebral block for the outcome of decreased postmastectomy pain at 5 to 6 months (OR, 0.37). Nonetheless, further studies are needed to draw any firm conclusions.

TABLE 68–3. Surgeries associated with higher incidence of postsurgical pain.

Surgery Type	Rate of Chronic Pain (%)	Rate of Chronic Severe Pain (VAS >5) (%)
Amputation	30–50	5–10
Thoracotomy	30–40	10
CABG	30–50	5–10
Breast surgery (mastectomy, lumpectomy)	20–30	5–10
Inguinal hernia repair	10	2–4

Source: Modified with permission from Kehlet H, Jensen TS, Woolf CJ: Persistent postsurgical pain: risk factors and prevention. *Lancet.* 2006 May 13;367(9522):1618–1625.

The mechanism of chronic postsurgical pain is complex and includes inflammatory and neuropathic components.[36] Therefore, the use of regional anesthesia for this purpose is likely most effective in combination with improved surgical techniques and optimization of multimodal analgesic approaches containing neuropathic pain medication such as ketamine, gabapentin, pregabalin, acetaminophen, cyclooxygenase (COX) inhibitors, and steroids.

ECONOMIC OUTCOMES

Performance of regional anesthetic procedures is frequently suspected to be more complex and time consuming than other modes of anesthesia and analgesia (eg, induction of general anesthesia or systemic opioid administration). In this context, regional anesthesia is sometimes thought to prolong turnover time. However, Mariano and colleagues recently reported that anesthesia-controlled time was in fact shorter when nerve blocks were applied for upper extremity surgery, compared to general anesthesia (28 minutes vs 32 minutes, P = .0392).[39] Turnover time did not differ between groups. When complex techniques (eg, multiple nerve blocks, thoracic epidural anesthesia) are applied, anesthesia-controlled time and turnover time might also be decreased by usage of dedicated block rooms or swing rooms.[40]

Moreover, numerous reports exist evidencing economic benefits of regional anesthesia in terms of shorter length of hospital stay and lower resource utilization.[41] The previously mentioned study by Memtsoudis et al found significant differences in the median number of days patients stayed in the hospital after major lower extremity joint replacement. The incidence of prolonged length of stay (exceeding the 75th percentile) was lower in the neuraxial and neuraxial plus general groups, compared to the general-only group (28.7%, 27.4%, and 35.4%, respectively; P < .001), as well as the adjusted odds ratios for this outcome. Similarly, odds ratios for mechanical ventilation and blood product transfusion, which considerably add to perioperative cost, were significantly higher in patients receiving general, compared to regional, anesthesia.[2]

These direct and indirect economic benefits could outweigh the increased amount of time and trained personnel required for the performance of regional anesthetic techniques. Additional benefits could arise from circumvention of complications and their treatment. However, because of vastly different settings, modes of compensation, and other costs associated with either technique, it is difficult to quantify the direct economic difference between regional and general anesthesia.

CONCLUSION

Regional anesthesia is increasingly recognized as anesthesia modality associated with improved perioperative outcomes beyond better pain management. As many interventions have been introduced over the last decades to reduce severe complications in patients undergoing surgery, it remains challenging to reliably identify new ways that are capable of further reducing the risk. Regional anesthesia may emerge as one such intervention. Large multiinstitutional registries with a high volume of granular data could help gain better insight into many outstanding questions on this topic.

CHAPTER 69

The Effects of Regional Anesthesia on Functional Outcome After Surgery

Arthur Atchabahian and Michael H. Andreae

INTRODUCTION

The goal of this chapter is to additionally discuss the benefits of regional anesthesia with beyond the immediate perioperative period. While there are several other outcomes of interest, such as morbidity and mortality or cancer recurrence, our focus is on three long-term outcomes after elective surgery because of their particular importance: (1) chronic pain, (2) joint function, and (3) cognitive outcomes.

These outcomes were selected because their importance is understandable and easy to communicate to surgical colleagues, patients or health consumers, hospital administrators, and lawmakers.

REGIONAL ANESTHESIA FOR THE PREVENTION OF CHRONIC PAIN AFTER SURGERY

Chronic or persistent pain (defined as pain beyond 6 months after surgery) is often severe and frequent, condition.[1] Table 69–1 details the risk of chronic pain after several common surgical procedures.[2] Because there are only a few effective treatments to date,[1] prevention wherever possible is paramount. Even mild chronic pain can significantly diminish quality of life and impair daily functioning.[3] Between 25% and 40% of patients undergoing thoracotomy, amputation, or breast surgery suffer from persistent pain lasting for months afterward.[4] Even for procedures with a low risk of persistent postsurgical pain, such as hernia repair or cesarean section, prevention is equally important.[5] Some 5% of patients suffer from persistent pain after minor surgery, and around 40% of patients do so after limb amputation or thoracotomy.[6] About 10% of patients will develop persistent pain following cesarean section.[5]

Mechanism

Figure 69–1 graphically represents how regional anesthesia, by interrupting the development of central sensitization, may prevent chronic pain from arising after surgery. In Figure 69–1A, pain impulses are transmitted from the primary nociceptor via a synapse in the dorsal horn of the spinal cord to the secondary neuron and from there to the brain. During surgery, the high nociceptive input from the surgical site may induce central sensitization—a permanent change in synaptic strength leading to perception of pain disproportionate to the stimulus (Figure 69–1B); this causes hyperalgesia (exaggerated perception of painful stimuli); allodynia (painful perception of nonpainful stimuli, such as touch); and persistent pain after surgery.[7] Regional anesthesia, by blocking nociceptive transmission, prevents sensitization and thus the development of chronic pain (Figure 69–1C).

Summary of the Evidence

A systematic review and meta-analysis for the Cochrane Collaboration included 23 randomized controlled trials (RCTs) investigating regional anesthesia or local anesthetics for the prevention of chronic pain after surgery.[8,9] Pooled data from 250 patients in four RCTs with contrasting outcomes at 6 months after thoracotomy strongly favored epidural anesthesia with an odds ratio (OR) of 0.34 and a 95% confidence interval (CI) of 0.19–0.60. Data from 89 participants in two RCTs with outcomes at 5 or 6 months favored paravertebral block after breast cancer surgery, with an OR of 0.37 and 95% CI of 0.14–0.94. Pooled results are shown in Figure 69–2 as forest plots. When studies of cosmetic breast surgery and a study using multimodal topical analgesia were added, the strength of the evidence was increased. However, the intermediate methodological quality of the included studies weakened the conclusions.

TABLE 69–1. Risk[a] for persistent postoperative pain (PPP) after various types of surgery, with estimated surgical volumes per year in the United States.[b]

Type of Surgery	Risk of Persistent Postoperative Pain (%)	Risk of Severe Persistent Postoperative Pain (%)	Approximate Number of Cases per Year in the United States in 2003
Amputation	40	10	130,000
Breast surgery	25	10	110,000
Thoracotomy	40	10	70,000
Hernia repair	10	4	250,000
Cesarean section	10	4	1,200,000

Although the risk may seem low for some interventions, the sheer number of cases leads to a significant number of previously healthy patients having severe, disabling pain after surgery.

[a]Risk values adapted from Kehlet et al.[1]

[b]Number of surgical cases adapted from Merrill and Elixhauser.[2]

The currently available evidence supports the use of epidural anesthesia to reduce the risk of persistent pain 6 months after surgery for patients undergoing thoracotomy and the use of paravertebral blocks for women undergoing breast cancer surgery, shown in Table 69–2. Persistent postsurgical pain may be devastating, yet possibly preventable in one of four patients by using an effective perioperative regional nerve blockade. The different RCTs, conducted in diverse settings,

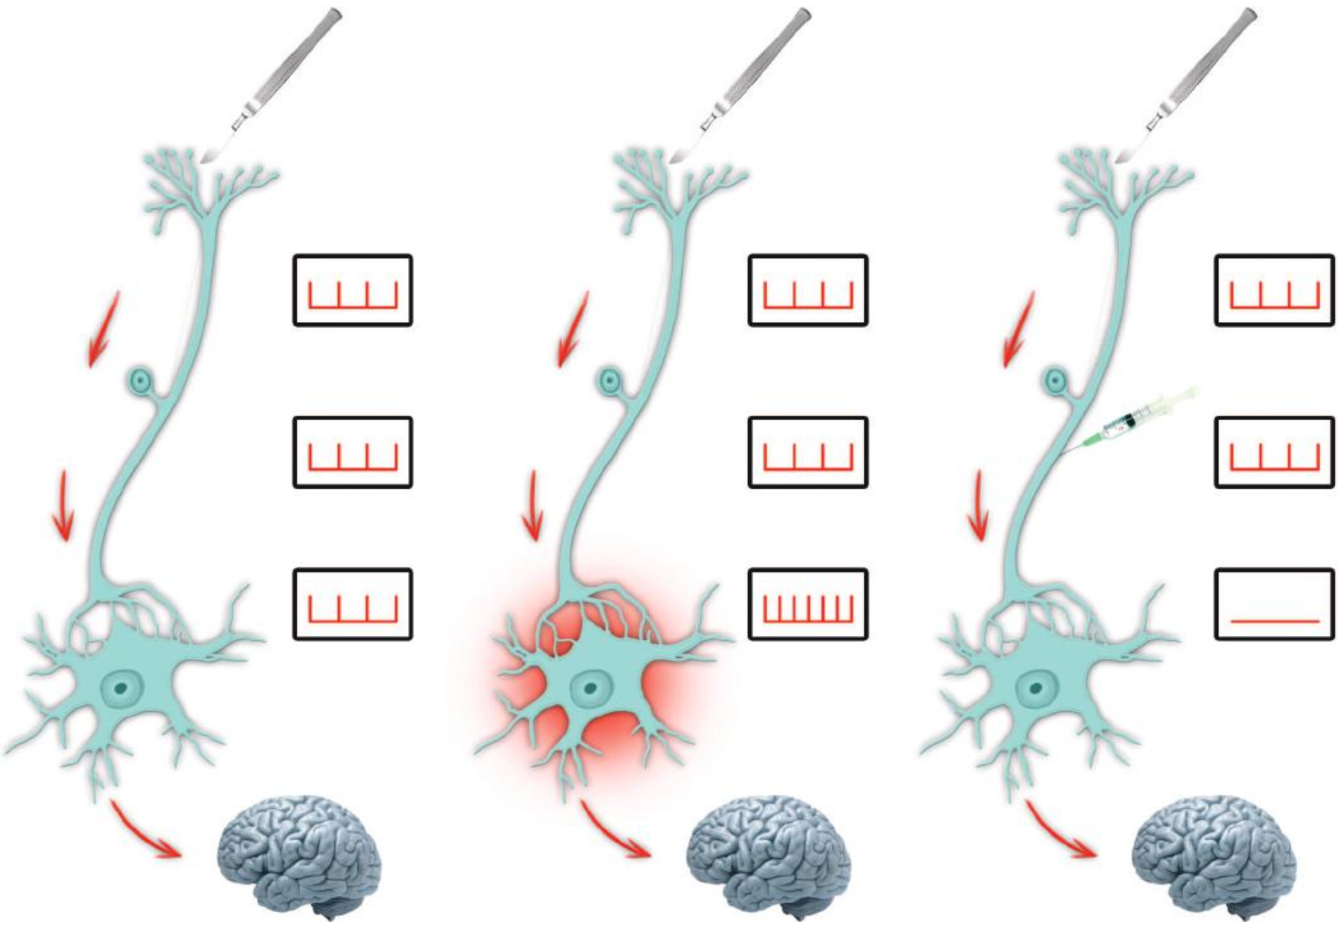

FIGURE 69–1. Site of action of local and regional anesthesia techniques in the signal pathway relevant to the development of chronic post-surgical pain.

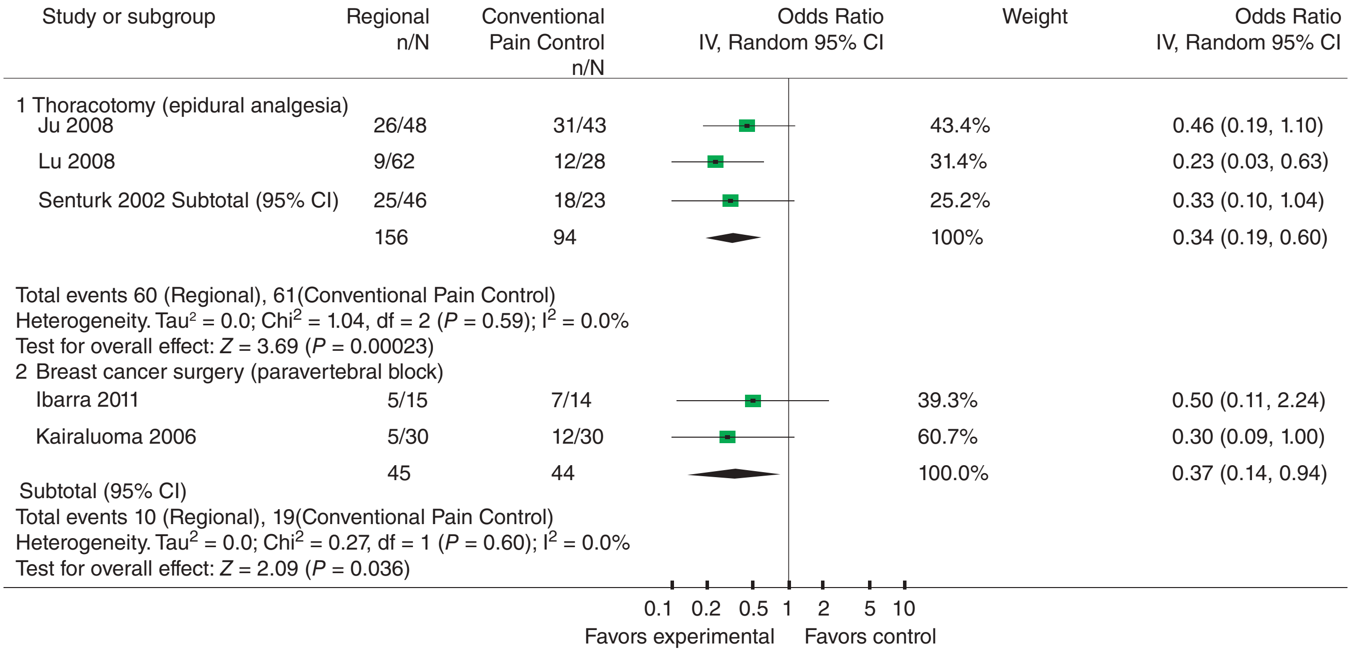

FIGURE 69–2. Pooled results for the Cochrane Collaboration included 23 randomized controlled trials (RCTs) investigating regional anesthesia or local anesthetics for the prevention of chronic pain after surgery.

were remarkably homogeneous and consistent in their estimates of the long-term effect. It is important to remember that effects of one specific block for one specific surgical intervention may not translate to other regional anesthesia techniques or surgical procedures.

Perioperative regional anesthesia and analgesia may reduce the risk of developing chronic pain after surgery. Outside the scope of this chapter, there is additional evidence suggesting that the avoidance of general anesthesia and opioids along with the use of regional anesthesia and analgesia could also reduce the risk of cancer recurrence.[19] These are compelling arguments in favor of the use of regional anesthesia and analgesia.

REGIONAL ANESTHESIA TO IMPROVE JOINT FUNCTION AFTER MAJOR JOINT REPLACEMENT

As the population in developed countries ages, severe arthritis has become more prevalent, leading to increased demand for total joint replacements (shoulder, hip, knee). Improved function over the long term, rather than immediately postoperatively, is the main outcome of these interventions. Improved functionality and mobility dictate the activity and independence of the patients and are linked to secondary comorbidities, such as diabetes mellitus, obesity, and possibly even cognitive decline.

Mechanism

Severe postoperative pain can hinder effective rehabilitation through reflex inhibition of muscle fibers, limiting strength and muscle building, as well as decreasing joint range of motion. Optimal pain control enables patients to participate more actively in physical therapy. Single injection, continuous administration through catheters, or sustained-release preparations of local anesthetics block the conduction of pain impulses from the operated joint to the central nervous system. They offer excellent analgesia, especially in combination with acetaminophen/paracetamol, nonsteroidal anti-inflammatory drugs (NSAIDs), gabapentinoids, and opioids. Better pain control may allow more effective rehabilitation.[20] Early mobilization and range-of-motion exercises are the key factors for optimal long-term joint function—the outcome of interest. Therapy facilitated by regional analgesia can increase passive joint range of motion, with sustained gains lasting for at least a few months after surgery.[21]

Summary of the Evidence

Reported findings are derived from a systematic review and meta-analysis for the Cochrane Collaboration.[22] In Table 69–3, eight RCTs reporting functional outcomes at or after 3 months following major joint replacement are listed. Results from the pooled data from 140 participants from three studies suggest no significant improvement in range of motion (improvement of 4° with 95% CI ranging from –2.23 to 10.21). Of note, two of the studies included in Table 69–3 were not included in the Cochrane review as they compared short-term (24-hour) versus longer-term (4-day) regional analgesia.

In the results from this meta-analysis, short-term improvements in function were not sustained in the long run. However, there are important limitations in the quality of evidence, starting with the heterogeneity of patients, interventions, and agents used. In addition, no study detailed the rehabilitation protocol used. No studies were found demonstrating long-term shoulder function, and only one study of patients following hip replacement was identified in this search.

An absence of evidence is not evidence of absence of effect; the jury is still out regarding whether regional anesthesia and analgesia lead to improved long-term function after total knee surgery. Although there is little evidence to support periarticular infiltration, many surgeons have been using it, often with extended-release local anesthetics. At this time, however, there is no convincing level 1 evidence of long-term benefits.

REGIONAL ANESTHESIA FOR IMPROVED COGNITIVE OUTCOMES AFTER NONCARDIAC SURGERY

Long-term cognitive outcomes are important to an aging surgical population; postoperative cognitive dysfunction (POCD) has a major impact on quality of life and independence of the elderly even after a successful surgical procedure.[30] Three months after surgery, POCD[31] is still present in 1 of 10 high-risk (elderly) patients.[32] POCD and delirium independently predict other adverse outcomes, such as increased morbidity and mortality, higher associated health care costs, long-term cognitive impairment, and further decline beyond 12 months.[33]

Mechanism

The pathophysiology of POCD after surgery is unclear.[30] Microemboli can reach the brain during orthopedic and cardiac surgery. Perioperative imbalances in neurotransmitters and inflammatory mediators have been implicated. Regional anesthesia may improve cognitive outcomes after surgery by attenuating the inflammatory response. Benzodiazepines,

opioids, and other psychoactive medications are associated with POCD and may trigger a vicious cycle of POCD, leading to more medication and therefore leading to more POCD. Regional anesthesia, by controlling pain and eliminating the need for opioids, may improve cognitive outcomes; however, it is unclear whether these mechanisms would lead to sustained improvement over conventional general anesthesia.

Summary of the Evidence

A meta-analysis[34] of 26 RCTs with over 1100 patients in each group combining both long-term and short-term studies failed to support the concern that general anesthesia contributed to long-term POCD in adults (standardized difference in means –0.08; 95% CI –0.17–0.01; P = .094). The weakness of this meta-analysis is in pooling heterogeneous cognitive outcome measurements and patient populations. Certain published systematic reviews of short-term cognitive dysfunction suggest a clear benefit of regional anesthesia in the elderly,[35] while others do not.[36,37]

The few clinical RCTs with long-term cognitive outcomes comparing a regional anesthesia intervention versus a conventional general anesthesia approach are tabulated in Table 69–4. These studies do not seem to support the hypothesis that regional anesthesia versus general anesthesia, or regional analgesia versus conventional analgesia, improves long-term cognitive function.

These conclusions are mostly based on older small studies (in Guay's review,[34] 18 of 26 studies were published in 1995 or earlier) with significant attrition, while most recent RCTs did not follow patients long enough to assess long-term cognitive outcomes. Many confounders can muddle the results. Patients with worse POCD may have selectively dropped out to avoid the embarrassment of failure in cognitive tests, biasing the studies toward the null hypothesis. Many patients in the regional anesthesia groups received midazolam, which may offset the potential benefit of regional anesthesia.[44] Most important, the focus of

these studies was on intraoperative management, not on extended postoperative regional analgesia, where opioid sparing might have the strongest effect in preventing cognitive dysfunction.

While there is evidence that short-term cognitive impairment might be more likely after general rather than regional anesthesia, long-term differential effects have not been demonstrated. Especially in elderly patients, preferring regional anesthesia when the procedure is amenable and there are no medical contraindications is reasonable and may avoid the confusion sometimes induced by opioids.

CONCLUSION

In the ever changing health care system, patients, payers, providers, and the public must be convinced that regional anesthesia is worth the investment. Pointing to its obvious benefits immediately after surgery may not be sufficient. Rather, sustained effects on long-term outcomes, among them chronic pain after surgery, long-term function after joint replacement, and sustained cognitive outcomes in the elderly, must be studied.

The effects of regional anesthesia on the prevention of persistent postsurgical pain are robust. They are supported by many RCTs and a Cochrane review and are based on a well-founded molecular mechanism. At this time, there is insufficient evidence for improvement of long-term function after major joint repair, but because the rationale is compelling, further studies are warranted. For long-term cognitive outcomes, the benefit of regional anesthesia is unclear at present.

More research is needed on the sustained benefits of patient-centered extended perioperative nociceptive blockade and its effects on the rehabilitation.

ACUTE PAIN MANAGEMENT

This page intentionally left blank

CHAPTER 70

Intravenous Patient-Controlled Analgesia

Marie N. Hanna, Omar Ahmed, and Sarah Hall

INTRODUCTION

Management of postoperative pain has improved in the last few decades. In 2000, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) officially recognized patients' rights in pain management and implemented standards for assessment, monitoring, and treatment of pain[1]; in 2004, the American Society of Anesthesiologists established the Pain Task Force and published clinical practice guidelines to promote standardization of procedures and the use of multimodal analgesia[2]; and in 2010, the Department of Health and Human Services and the Institute of Medicine agreed to promote the recognition of pain as a significant public health problem. Now, pain management has become a focus of the healthcare system and an important ethical responsibility of the medical profession. Opioids remain the primary analgesic agent for treating moderate and severe pain after surgery; however, opioid-related side effects may compromise quality of recovery.

Preventive analgesia is a method of attenuating the central sensitization that results from a painful insult and the inflammatory reaction that develops after the insult.[3] For effective prevention of central sensitization and reduction of postoperative and chronic pain,[4,5] aggressive multimodal analgesic interventions should be used during the perioperative period. Maximum benefit occurs when pain interventions are extended into the postoperative phase.[6]

Multimodal analgesia (Figure 70–1) involves the administration of two or more analgesic agents by one or more routes. The different agents should exert their effects via different analgesic mechanisms and ideally act synergistically at different sites in the nervous system, thereby providing superior analgesia with fewer side effects. Multimodal analgesia can include regional analgesia with local anesthetics, acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and opioids.[7] The combination of several nonopioid analgesics with opioids delivered by patient-controlled analgesia (PCA) offers advantages over opioids alone.[8,9] Multimodal pain-control strategies for certain procedures could become an integral part of clinical pathways to provide effective postoperative analgesia and rehabilitation.[8,9]

The broader concept of PCA is not restricted to intravenous opioid use. In fact, any analgesic delivered by any route (epidural, peripheral nerve catheter, subcutaneous, or transdermal) can be administered under patient control (with or without a continuous background infusion). This technique is based on delivering a preprogrammed dose of drug when the patient pushes a demand button through a microprocessor-controlled infusion pump.[10]

HISTORY OF INTRAVENOUS ANALGESIA

In 1963, Roe[11] was the first to demonstrate that postoperative narcotics are necessary and that small intravenous (IV) doses of opioids provide more effective pain relief than do conventional intramuscular (IM) injections. In 1968, Sechzer,[12] the true pioneer of PCA, evaluated the analgesic response to small IV doses of opioid administered by a nurse at the patient's request. In 1971, the first apparatus for delivering opioid on demand was introduced and marked the initial development of PCA technologies.[13] Forrest et al.[14] and Keeri-Szanto[15] initiated the concept of a demand mode. In 1976, the Cardiff Palliator, the first commercially available PCA pump, was developed at the Welsh National School of Medicine.[16] Since then, PCA devices have evolved in technologic sophistication.

In the 1970s, Marks and Sachar[17] started the revolution of pain management. Their study demonstrated that pain was undertreated in a large proportion of hospitalized patients, and that healthcare providers lack adequate experience and knowledge in the use of opioids.

In 1990, Ferrante and Covino[18] described the essential components of effective opioid analgesia that cannot be achieved

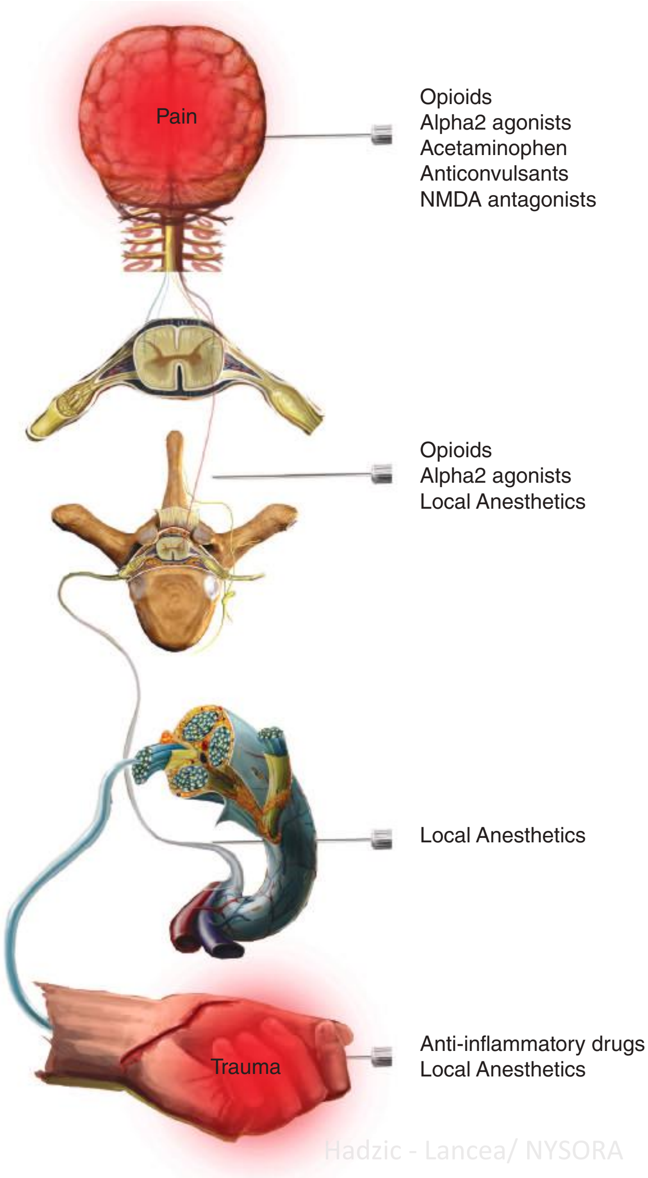

FIGURE 70–1. Possible sites for intervention.

with PRN (as needed) or scheduled IM injections. These essentials were mainly to maintain constant plasma opioid concentrations, avoid peaks and troughs, and titrate the opioid dose to achieve the most effective analgesia with the minimum effective analgesic concentration. In contrast, patients who receive IM bolus injections experience frequent periods of severe pain, as plasma opioid concentrations fall below their individual minimum effective analgesic concentration, followed by periods of "overshoot," when higher-than-optimal plasma concentrations cause excessive sedation, possible respiratory depression, and poor analgesia.

OPIOID ANALGESIA

Opium and its derivatives are the most commonly used medications for the treatment of acute and chronic pain. Although opioids have no analgesic ceiling effect, their main limitations stem from numerous and sometimes profound adverse effects.[19–21] These include somnolence, respiratory depression, hypotension, urinary retention, and emesis due to chemoreceptor trigger zone activation. Slowed gastrointestinal transmit often results in constipation and ileus as well. Opioids as a class have few absolute contraindications, aside from hypersensitivity to a specific opioid. Relative contraindications relate especially to metabolism. For instance, the half-lives of hydromorphone and morphine are prolonged in renal insufficiency.

The mechanism of action for opioids is via mu-receptors in the central nervous system, with some evidence of peripheral opioid receptor activity as well.[22] There are three classes of mu opioid–receptor binding: pure agonists, agonist-antagonists, and partial agonists.[23] The pure agonists are obviously the most useful for acute pain management because of their complete mu-receptor binding. In equianalgesic doses, all of the common parenteral opioids are equally effective for pain control and do not differ in side-effect profiles (Table 70–1). Patients receiving mu-agonists have a risk of acute withdrawal.

Agonist-antagonist opioids act as kappa-receptor agonists and mu-receptor antagonists. These drugs were marketed as having a better safety profile owing to the ceiling effect they have on respiratory depression. However, this effect also translates to having a ceiling effect on their analgesic properties, limiting their effective usage in acute pain control. Similarly, partial agonists have limited clinical application for pain control because they exhibit only partial mu- receptor binding.

Clinical Pearls

- Common opioid side effects include somnolence, respiratory depression, hypotension, urinary retention, emesis, and constipation.
- There are three classes of mu opioid–receptor binding: pure agonists, agonist-antagonists, and partial agonists.
- Agonist-antagonist opioids act as a kappa-receptor agonist and a mu-receptor antagonist.

TABLE 70–1. Opioid agonist equianalgesic dosing.

Drug	Parenteral IV/IM (mg)
Morphine	10
Hydromorphone	1.5-2.0
Fentanyl	0.1-0.2
Sufentanil	0.01-0.04
Remifentanil	0.05
Tramadol	100
Meperidine	75-100
Methadone	10

Abbreviations: IV, intravenous; IM, intramuscular.

ROLE OF IV ANALGESIA IN PAIN MANAGEMENT

Intravenous (IV) PCA is considered the “gold standard” by which systemic opioids are delivered postoperatively. Unlike traditional PRN analgesic regimens, IV PCA allows the clinician to compensate for several factors, including the wide interpatient and intrapatient variability in analgesic needs, variability in serum drug levels, and administrative delays, which might result in inadequate postoperative analgesia. When compared with traditional PRN analgesic regimens, use of IV PCA may be associated with improved patient outcomes, including superior postoperative analgesia, improved patient satisfaction,[22,23] and possibly decreased risk for pulmonary complications.[24,25] Although IV PCA provides no apparent decrease in cost or length of hospital stay, it does reduce demand on the nursing staff, who are required for delivery of IV or IM PRN analgesics. This reduced workload of the nursing staff may indeed have a cost benefit.[26]

The incidence of opioid-related side effects, including respiratory depression (0.5%), from IV PCA does not appear to differ significantly from that of other administration routes (e.g., IV, IM, or subcutaneous).[24,27–29] Similarly, all of the mu-agonists, when used in common IV-PCA dosages, have similar effects on gut motility.[30]

The occurrence of respiratory depression with IV PCA is relatively low. It is no higher than with PRN systemic or neuraxial administration.[31,32] Many factors could contribute to the occurrence of respiratory depression with IV PCA, including the use of a background infusion, concomitant use of a sedative or hypnotic agent, advanced age, and the presence of pulmonary disease or sleep apnea.[24,27,28,33]

Clinical studies have shown iontophoretic patient-controlled transdermal fentanyl to be superior to placebo and comparable to IV PCA with morphine for the treatment of acute postoperative pain.[34,35] Transdermal delivery of fentanyl, a continuous passive dose, is not indicated for the treatment of acute pain but could be an option for the treatment of chronic cancer pain; it could also be an alternative to oral opioids when patients cannot tolerate oral intake for an extended time. A recent technologic development has added the process of iontophoresis to substantially increase dermal penetration capacity and thereby allow in essence a “PCA fentanyl patch.”[36]

In general, there is no standard opioid that should be considered first-line. However, individual patient characteristics may steer the practitioner toward choosing one opioid over another. Variability in individual patient responses to specific opioids will ultimately guide practice.[21] A basic understanding of each specific IV-PCA opioid’s pharmacology is, therefore, necessary.

Clinical Pearls

- When compared with traditional PRN analgesic regimens, use of IV PCA may be associated with improved patient outcomes, including superior postoperative analgesia, and improved patient satisfaction.
- Factors that could contribute to the occurrence of respiratory depression with IV PCA, include the use of a background infusion, concomitant use of a sedative or hypnotic agent, advanced age, and the presence of pulmonary disease or sleep apnea.
- Transdermal fentanyl usage should be reserved for chronic cancer pain, or as an alternative for patients who are NPO.

DOSAGE PARAMETERS OF IV-CONTROLLED ANALGESIA

The programmable components of IV PCA include the demand dose, a lockout interval, background or basal infusions, and dosing limitations. Each of these variables allows for substantial versatility in delivering IV opioids. The flexibility of IV PCA helps account for the variability in individual patient pain-control requirements. The effectiveness of IV PCA does, however, require regular and frequent assessment of the patient’s needs by his or her healthcare provider.[37]

Demand Dose

The demand dose is the amount of drug that is delivered when the patient pushes the PCA delivery button. It may also be referred to as the incremental, PCA, or bolus dose. Ideally, the dose should produce noticeable pain relief without causing toxicity.[38] It should be noted that this bolus or demand dose is separate from the initial loading dose, which is used at the initiation of PCA usage.[23] The initial loading dose is used to titrate opioid to the minimum plasma concentration required for analgesia. Alternatively, large loading doses like this may be used for severe breakthrough pain.

Lockout Interval

The lockout interval is the minimum amount of time that must elapse before the PCA will deliver more drug on demand. This restriction will ignore demand attempts within a certain time and thereby prevents overdosage. The lockout time should account for the minimum amount of time for the drug to reach an effective plasma concentration (i.e., the opioid’s onset time). After the minimum effective analgesic concentration has been reached, onset times among common PCA opioids do not appear to differ greatly.[23,39]

The number of demand attempts during lockout intervals, hourly, and over 24 hours may be a valuable piece of information for practitioners who are assessing the patient’s opioid requirements. However, adjusting lockout times for variable patient pain may be less useful than initially thought. It has been suggested that decreasing the lockout time to allow for more than three demand doses per hour may be an ineffective way to improve pain relief.[28,40] Patients who require more than three demand doses per hour may in fact benefit more from an increase in the demand dose.

Basal Infusions

Basal, or background, infusions continuously deliver a low dose of drug to the patient regardless of demand attempts. Initially, background infusions were thought to help with patient pain satisfaction and sleep. However, numerous studies have shown that there is no improvement in pain or sleep scores, but a significant increase in respiratory depression.[41,42] A recent meta-analysis determined that use of continuous infusions with demand dosing was associated with a higher incidence of respiratory events in adult, but not pediatric, populations.[43] Generally, continuous infusions are not recommended for routine use with IV PCA, except for a few select patient populations and with appropriate monitoring.

Dosing Limits

Dose delivery can be restricted over a certain period as an added safety measure against overuse, most commonly over 1 or 4 hours. However, routine use of these dosing limits is controversial because of the unpredictable amount of opioid needed for analgesia or adverse effects.

Clinical Pearls

- IV PCA glossary: Demand dose is the amount of drug delivered when the patient pushes the PCA button.
- Lockout interval is the minimum time that must elapse before the next demand dose can be initiated.
- Basal infusions continuously deliver a low dose of drug.
- Dosing limits set a maximum dose delivery over a set period of time.

WAYS TO IMPROVE EFFICACY OF OPIOID IV PCA

IV PCA should not be considered the only therapy for postoperative pain management. Multimodal analgesia has been shown to decrease opioid consumption, sedation, and narcotic side effects.[44] Scheduled doses of NSAIDs clearly improve analgesia and reduce IV-PCA opioid requirements. Peripheral nerve blocks and continuous catheter techniques can all be used effectively in conjunction with IV PCA.

Several meta-analyses suggest that the use of NSAIDs, cyclooxygenase (COX)-2 inhibitors, or acetaminophen in combination with IV PCA produces an opioid-sparing effect. However, acetaminophen and COX-2 inhibitors do not appear to decrease the relative risk for opioid-related side effects (e.g., postoperative nausea and vomiting [PONV], sedation, pruritus, urinary retention) or adverse events (respiratory depression), whereas nonspecific NSAIDs appear to decrease the relative risk only for some opioid-related side effects (e.g., PONV, sedation).[44–46] In terms of pain control, the addition of NSAIDs (multiple dose or infusion only) and COX-2 inhibitors, but not acetaminophen or single-dose NSAIDs, produces significantly lower pain scores postoperatively.[44–46]

A systematic review revealed that perioperative administration of ketamine (vs control) resulted in lower pain scores and significantly decreased morphine consumption over a 24-hour period, with no difference in morphine-related adverse effects between the groups.[47] However, use of ketamine as an adjunct to IV PCA may not improve postoperative analgesia.[48] Low-dose ketamine infusions do not appear to cause hallucinations or cognitive impairment, and in patients undergoing general anesthesia, the incidence of hallucinations appears to be low and may be independent of benzodiazepine premedication.[47,49,50] A study that evaluated adding small doses of ketamine to morphine IV PCA[51] showed no differences in pain scores, morphine consumption, patient satisfaction, or nausea scores. The ketamine group had an increased incidence of side effects, including dysphoria, resulting in early withdrawal from the study.

Similar studies evaluated the addition of 16 mg IV lidocaine to IV-PCA morphine and concluded that adding lidocaine 10 or 20 mg/mL to morphine 1 mg/mL produced no differences in opioid use, pain levels, side effects, or speed of recovery.[52,53]

MONITORING PATIENTS ON IV PCA

One of the most concerning adverse effects of IV PCA is oversedation culminating in respiratory depression and cardiac arrest. Therefore, it is recommended that patients on IV PCA receive either continuous monitoring (possibly in an intensive care unit [ICU] setting) or periodic monitoring in a nonacute setting. The level of monitoring should be based on a patient's comorbidities and risk factors for respiratory depression (e.g., obstructive sleep apnea [OSA] or other pulmonary disease, advance age, morbid obesity, concomitant administration of sedative or hypnotics). Monitoring should be frequent in the early postoperative period and during times of opioid dose adjustments.

Usually, a respiratory rate of less than 10 breaths per minute is a sign of respiratory depression. However, this may be a late sign and is not a sensitive indicator when used alone.[54] Monitoring end-tidal carbon dioxide ($EtCO_2$) is a more effective way to detect respiratory depression than using standard monitors, such as pulse oximetry,[54,55] and respiratory rate. Technically advanced IV-PCA pumps have $EtCO_2$ modules that monitor a patient's $EtCO_2$ value and provide a capnograph.[56] The $EtCO_2$ module can be used in intubated and nonintubated patients and is. Therefore, not limited to an ICU setting. The Alaris Pump (CareFusion, San Diego, CA) also pauses the IV-PCA infusion if a patient's respiratory status falls below a set limit determined by the clinician. This added safety feature is especially beneficial for patients at risk for respiratory depression.

In addition to monitoring the patient, members of the acute pain service and nursing staff should also routinely check the PCA pump and its settings. Detrimental adverse events have occurred more commonly as a result of operator error than as a result of pump malfunction.[27,28]

CHOICE OF IV-PCA OPIOID

IV PCA with opioids is ideally used for acute postoperative pain, cancer pain, and sometimes chronic pain. The choice of a specific opioid for IV PCA depends on numerous factors, including patient characteristics, clinical setting, and

TABLE 70–2. Common dosing parameters for intravenous patient-controlled analgesia in adults.

Drug/Concentration	Demand Dose	Lockout Interval (min)	Background Infusion
Agonist			
Morphine	0.5-2.5 mg	5-10	0.5-2.5 mg/hr
Hydromorphone	0.05-0.25 mg	5-10	0.05-0.25 mg/hr
Fentanyl	10-20 mcg	4-10	20-100 mcg/hr
Sufentanil	2-5 mcg	4-10	2-5 mcg/hr
Remifentanil	0.2-0.7 mcg/kg/min	1-3	0.025-0.1 mcg/kg/min
Tramadol	10-20 mg	5-10	
Methadone	0.5-2.5 mg	8-20	0.5-2.5 mg/hr
Meperidine	5-25 mg	5-10	5-10 mg/hr
Agonist-Antagonist			
Nalbuphine	1-5 mg	5-15	
Buprenorphine	0.03-0.1 mg	8-20	
Pentazocine	5-30 mg	5-15	

practitioner preference.[40] In essence, nearly all of the most common opioids have been used effectively (Table 70–2).[57–59] Unless the patient is opioid tolerant, continuous settings should be avoided because their use can increase the risk of respiratory depression.[28]

Fentanyl PCA

Fentanyl's fast onset, owing to its lipophilicity, makes it a good choice for IV PCA. Common dosing parameters include a bolus of 10–40 mcg and a lockout of 4–10 minutes. When fentanyl is given in single doses, it can be considered to be 80–100 times as potent as morphine. However, because of its shorter duration of action, in a IV-PCA format, it is usually considered to be only 30–40 times as potent.[23,60]

When compared to morphine and hydromorphone, patients on fentanyl IV PCA may report less nausea/vomiting, pruritus, urinary retention, and sedation. However, the rate of respiratory depression does not differ significantly among these three agents when administered as IV PCA. In a multicenter, retrospective analysis, patients receiving fentanyl IV PCA had a lower median pain score on postoperative days 1 and 2 of orthopedic surgeries than did patients receiving morphine or hydromorphone IV PCA.[61]

Fentanyl undergoes hepatic metabolism via CYP3A4 and is a good choice for patients with renal failure. Furthermore, it has no active metabolites and a wider therapeutic index than morphine.[62] However, because of its rapid onset and rapid offset, patients on a fentanyl IV PCA may actually have higher requirements for the drug. There is also a marked increase in context-sensitive half-time with fentanyl, even after a few hours of infusion, owing to its high volume of distribution and long elimination half-life.[63]

Fentanyl Analogue PCA

Of the fentanyl analogues, sufentanil and remifentanil have been studied the most. Alfentanil has been used much less frequently and may have questionable or limited clinical applicability.[64]

Common dosing parameters for sufentanil are a bolus of 2–5 mcg with a lockout of 4–10 minutes. Sufentanil is generally considered to be 5–10 times more potent than fentanyl.[62] Biotransformation occurs mainly in the liver and small intestine. It has a relatively immediate onset of action, limited accumulation, and rapid elimination from body storage sites.

With the highest therapeutic index, sufentanil may be associated with less incidence of respiratory depression, less oxygen desaturation, and more effective analgesia.[65] Because of its extremely short-acting nature, a basal infusion may also be necessary. However, unlike fentanyl, sufentanil does not exhibit a dramatic increase in the context-sensitive half-time with prolonged infusions. Despite these characteristics, the rapid redistribution of this drug makes it an unpopular choice for IV PCA.

Remifentanil is considered an ultra–short-acting fentanyl analogue. Remifentanil has approximately double the potency of fentanyl and 100–200 times the potency of morphine. It undergoes hydrolysis of its ester linkage by nonspecific blood and tissue esterases to form inactive metabolites. Its analgesic effect occurs within 30–60 seconds, peaking at 2.5 minutes, and it has a half-life of 6 minutes.[66–68] In 1-minute infusions, patients may experience a dose-dependent drop in blood pressure and heart rate.

Remifentanil has been tried in situations where there is severe but brief pain, such as in labor.[69] In a recent study comparing remifentanil to fentanyl and meperidine PCA for labor analgesia, remifentanil was found to provide better pain control for patients, but only during the first hour of treatment.[70] Remifentanil also was noted to produce greater sedation scores and cause a greater decrease in oxygen saturation compared to meperidine and fentanyl. Despite these drawbacks, in this and previous studies, patients' overall satisfaction scores were best for remifentanil and worse for meperidine.[71,72]

The use of background infusions with ultra–short-acting opioids is controversial. It would seem intuitive that, owing to their inability to reach a steady-state plasma concentration, a continuous infusion would be necessary. However, studies have shown more frequent decreases in oxygen saturations with a background remifentanil infusion. Furthermore, when used in the correct setting, e.g., labor analgesia, remifentanil PCA without a background infusion has been shown to be more effective than with a background infusion.[73]

Hydromorphone PCA

Because of its alternate route of metabolism, hydromorphone is considered by many to be a reasonable alternative to morphine.[23] Extensively metabolized via glucuronidation in the liver, more than 95% of the dose will be metabolized to hydromorphone-3-glucuronide along with minor amounts of 6-hydroxy reduction metabolites.

Hydromorphone is approximately 5–6 times as potent as morphine. Common dosing parameters will, therefore, have a bolus range of 0.05 mg to upward of 0.5 mg, with a lockout of 5–10 minutes. This higher potency may have the added practical benefit of increasing the interval between reservoir refills, as most PCA concentrations are 0.5 mg/mL or 1.0 mg/mL. This characteristic may be helpful in the opioid-tolerant population.

The adverse-event profile is relatively similar to that of morphine. In a systematic review of common opioids and their associated adverse events, Wheeler et al.[19] found that hydromorphone was second only to meperidine in central nervous system side effects. While this was attributed. mainly to somnolence, hydromorphone's metabolites may also have an excitatory effect as well.[19,62] Interestingly, Wheeler et al.[19] found that hydromorphone caused more pruritus but less urinary retention than did morphine. However, a multicenter comparison of morphine and hydromorphone did not show a difference in any of the most common adverse reactions when used in IV-PCA form.[61]

Morphine PCA

As one of the oldest and most studied parenteral opioids, morphine is still one of the most common opioids used in IV PCA. Common dosing parameters include a bolus range of 0.5–2.5 mg and a lockout interval between 5 and 10 minutes.

Morphine is primarily metabolized in the liver, with approximately 87% of a dose being excreted in the urine within 72 hours. Although morphine itself undergoes glucuronidation, its metabolites are primarily excreted in the kidney. Morphine's active metabolites, morphine-3-glurcuronide (M3G) and morphine-6-glucuronide (M6G), have been shown also to produce analgesia, sedation, and respiratory depression.[74,75] These effects are especially evident and prolonged in patients with impaired renal function.[76,77]

Histamine is released after morphine administration and may produce flushing, tachycardia, hypotension, pruritus, and bronchospasm. Furthermore, IV-PCA morphine may cause higher rates of adverse side effects such as nausea, pruritus, and somnolence than does IV-PCA fentanyl.[61] Morphine's low therapeutic index also implies that it may not be the best postoperative analgesic for many patients.[62,78]

Sam et al.[79] recently measured mean plasma concentrations of morphine, M3G, and M6G in patients receiving IV-PCA morphine with and without increasing levels of background infusion. They found that background infusions up to 1 mg/hour did not offer any distinct advantages over PCA alone. Moreover, background infusions of 2 mg/hour conferred the greatest risk of respiratory depression. This evidence suggests that morphine, like other forms of IV PCA, should not routinely be used with a background infusion, both from an efficacy and safety perspective.

Tramadol PCA

Tramadol has been used safely in injectable and IV-PCA forms in a few European countries for many years, but in the United States, it has been used most commonly in oral form.[23] Tramadol is a racemic mixture and controls pain through both opioid and nonopioid centrally acting mechanisms. In addition to its weak mu-receptor activity, which is approximately 6000 times less potent than that of morphine, tramadol inhibits both serotonin and norepinephrine reuptake.[80] Tramadol is also known to have weak kappa and delta affinity.

Tramadol undergoes cytochrome P450 metabolism, and its metabolites are excreted in the kidney. One of its major active metabolites, O-desmethyltramadol, has a greater mu affinity and longer elimination half-life than does tramadol itself. This metabolite has been cited as one of the reasons for tramadol's effective analgesic properties. Seizures have also been reported when tramadol is used in high doses or with monoamine oxidase inhibitors, selective serotonin reuptake inhibitors, or tricyclic antidepressants.

Tramadol has been recommended in patients with poor cardiopulmonary function and when a pure nonopioid is contraindicated.[81] It also appears to cause less dependence than equipotent doses of stronger mu-agonists.

In equipotent doses, tramadol has been shown to have analgesic and sedative effects that are similar to those of morphine IV PCA. However, tramadol IV PCA may be associated with more gastrointestinal side effects, such as nausea and vomiting, which can lower overall patient satisfaction.[82–85] The usage of metoclopramide has been suggested not only to decrease the nausea and vomiting, but also to enhance the multimodal feature of tramadol.[86]

Methadone PCA

Methadone is rarely used in IV-PCA form, but it may be well suited for highly opioid-tolerant patients, such as those with cancer pain.[87] In addition to being a mu-opioid agonist, methadone also binds to the glutamatergic N-methyl-D-aspartate (NMDA) receptor, and thus acts as a glutamate receptor antagonist.[88] This NMDA antagonism is thought to aid in the reversal of morphine tolerance. Common IV-PCA dosing will have a bolus range of 0.5–2.5 mg and a lockout interval of 8–20 minutes.

Side effects of many of the common opioid agonists may limit their usage. When these side effects precede the analgesic effects of the opioid agonist, or when there is tolerance to a certain opioid agonist, patients may benefit from trials of other agonists.[87,89] Methadone has been cited in particular as an alternative to other opioids because of its NMDA antagonistic properties, which allow for incomplete cross-tolerance, reversal of tolerance, and possible reduction in dose requirements.[88,90]

Methadone is metabolized in the liver, but the rate of metabolism varies greatly among individuals. Compared to most other opioids, it has a large initial volume of distribution and high bioavailability. Generally speaking, it also has a longer, but inconsistent, elimination half-life than do other opioids, which could increase risk for toxicity secondary to accumulation.

When given IV, methadone has a faster onset of action than morphine.[91] This quick onset, coupled with its long elimination half-life, could be advantageous in IV-PCA format. The long elimination half-life can be useful in patients with chronic, intractable pain, such as those with cancer. However, the marked variability in elimination half-life makes routine use of methadone IV PCA challenging. Dosage should be titrated carefully and determined on an individual basis.

Meperidine PCA

Meperidine was historically one of the most commonly used opioids for IV PCA. However, it has largely fallen out of favor for routine use. Dosing parameters included a bolus size between 5 and 25 mg with a lockout of 5–10 minutes. Meperidine is approximately one-tenth as potent as morphine.

The Institute of Safe Medication Practices and the American Pain Society currently do not recommend meperidine for pain control.[92,93] In general, it should be avoided because of the accumulation of its toxic metabolite, normeperidine, and its central nervous system excitation effects, which include delirium, irritability, tremors, myoclonus, and generalized seizures.[94] These symptoms are to be considered irreversible and may actually be exacerbated by opioid antagonists. Overdose is usually handled with supportive treatment.

Because normeperidine relies on renal excretion for elimination, meperidine is contraindicated in patients with renal dysfunction. It is also contraindicated in patients with seizure disorders and in patients taking monoamine oxidase inhibitors. Patients using meperidine PCA have been shown to be at particularly high risk for adverse drug reactions caused by overall cumulative dose and duration.[95]

Meperidine may not offer any better analgesic effect than that provided by morphine or hydromorphone, but it does carry significantly more risk.[96,97] When meperidine is used, patients may require up to 10 mg/kg or more per day for adequate analgesia. This high dosage requirement can lead to normeperidine accumulation with extended usage, even in patients without renal dysfunction. It has previously been suggested that a maximum dose of 10 mg/kg per day for a 3-day period can be considered to be safe.[94] Extreme caution should be exercised, especially when meperidine is used for longer durations. Because meperidine has no advantage over morphine or other opioids, its use is generally reserved as a last resort when all other mu-agonists have failed.[40,98]

Clinical Pearls

- Fentanyl's lipophilicity allows for fast onset and offset, but over prolonged periods of time there will be a marked increase in context-sensitive half-time.
- Fentanyl may have less nausea/vomiting, pruritus, urinary retention, and sedation compared to morphine and hydromorphone.
- Sufentanil has a fast onset with no increase in context-sensitive half-time.
- Remifentanil is useful in situations of severe, but brief pain, such as labor.
- Hydromorphone undergoes metabolism in the liver and can be considered to be a reasonable alternative to morphine in renal insufficiency.
- Morphine has active metabolites that may accumulate in kidney failure.
- Morphine releases histamine, which may produce flushing, tachycardia, hypotension, pruritus, and bronchospasm.
- Tramadol is a racemic mixture that works via opioid and nonopioid mechanisms; i.e., inhibition of serotonin and norepinephrine reuptake.

IV PCA IN THE OPIOID-TOLERANT PATIENT

Patients may become opioid tolerant from use of chronic opioid therapy for cancer pain or other chronic pain conditions or from illicit narcotic use, including heroin abuse or methadone maintenance.[99] Pain control with opioids can be challenging in such patients. Standard IV-PCA settings used for opioid-naïve patients will likely provide inadequate pain control in the opioid-tolerant patient[23] and lead to withdrawal symptoms as a result of physical dependence. On the other side of this spectrum, when conventional IV-PCA settings are used, these patients can develop high rates of adverse effects as opioid doses are escalated in an attempt to achieve pain control. This situation occurs because over time, patients develop tolerance to the analgesic effects of opioids but remain sensitive to the untoward effects, such as somnolence and respiratory depression. To further complicate the problem, opioid requirements and clinical responses may vary widely between patients.[100–102]

A baseline pain score should be assessed and the goals of pain management should be discussed with the patient and healthcare care team, ideally before the commencement of pain management. The patient and members of the acute pain service should actively participate in formulating a plan for pain management. Providing pain relief adequate for patient functionality (i.e., ambulation, use of an incentive spirometer, physical therapy exercises, and performing appropriate activities of daily living) is paramount to obtaining a pain score of zero. However, undertreatment of pain is a violation of a patient's rights and may lead to drug-seeking behavior known as pseudoaddiction.[99,103] Regardless of why a patient is opioid tolerant, it is important from both a patients' rights perspective and an ethical perspective to treat pain adequately.

Higher than normal opioid doses are often required to provide adequate pain relief in opioid-tolerant patients.[40] To achieve this goal, it may be necessary to allow increased opioid IV-PCA boluses and use a background opioid infusion.[23,104] However, the risk of developing respiratory depression also increases. To prevent withdrawal, the total 24-hour opioid dose should be maintained and may be given via background infusion over 24 hours with IV-PCA boluses for breakthrough pain. Although opioid IV PCA can be used safely and effectively in this population, it is also recommended that clinicians institute a multimodal approach to pain management, including nonopioid IV or oral adjuvants and regional anesthesia techniques, to avoid excessive use of opioids.[99] When patients become refractory to the analgesic effects of one opioid, switching to another opioid may be effective; however, the dose of opioid must be appropriately adjusted, owing to cross-tolerance. There have also been reports of switching IV- PCA medications from high-dose morphine to methadone in refractory cases.[87] Opioid agonists-antagonists may lead to acute withdrawal and, therefore, should be avoided in this patient population.[99,105,106]

Notably, high pain scores have been reported in opioid-tolerant patients.[23,100,107] To gain further insight into the adequacy of pain control, objective techniques such as behavioral pain assessment may be helpful. Behavioral scoring includes assessing for signs of discomfort, such as facial grimacing, increased muscle tone, groaning, crying, inconsolability, and restlessness. During this assessment, members of the healthcare team should also note signs of increasing sedation and respiratory depression.

Clinical Pearls

- Standard IV-PCA settings used for opioid-naïve patients will likely provide inadequate pain control in the opioid-tolerant patient and lead to withdrawal symptoms. It may be necessary to allow increased opioid IV-PCA boluses and use a background opioid infusion.
- Although opioid IV-PCA can be used safely and effectively in this population, it is also recommended that clinicians institute a multimodal approach to pain management, including nonopioid IV or oral adjuvants and regional anesthesia techniques, to avoid excessive use of opioids.
- To gain further insight into the adequacy of pain control, objective techniques such as behavioral pain assessment may be helpful.

IV PCA IN OBSTRUCTIVE SLEEP APNEA/OBESITY

Obstructive sleep apnea (OSA) affects up to 20% of the general population, and a significant number (75%) of those who could benefit from treatment remain undiagnosed.[32,108] OSA is defined as five or more episodes of apnea per hour.[109] Moderate to severe OSA varies from 15 to >30 apneic-hyponeic episodes per hour.[109]

The clinical suspicion for OSA should be raised in patients with risk factors for OSA. One study[110] revealed that preoperatively, anesthesiologists and surgeons failed to identify a significant number of patients with diagnosed OSA and symptomatic undiagnosed OSA. This study included 819 patients, of which 111 had preexisting OSA. Sixty-four (58%) of those were not diagnosed by the surgeons and 17 (15%) were not diagnosed by the anesthesia practitioners. Preoperatively, of the 267 patients with moderate to severe OSA, 245 (92%) and 159 (60%) were not diagnosed by the surgeons and anesthesiologists, respectively.

Obesity is frequently associated with OSA.[111] Patients with OSA commonly have a higher mean body mass index and a higher frequency of comorbidities than do patients without OSA.[112] In general, postoperative complications, most commonly oxygen desaturation, in OSA patients may be significant.[112] According to one study, the highest rate of postoperative complications was seen in patients who did not use a continuous positive airway pressure (CPAP) device preoperatively, but required one in the postoperative period.

Multimodal pain management is recommended in patients with OSA,[113] but depending on the clinical scenario, the use of IV PCA may be warranted. The concomitant use of sedatives or hypnotics should be avoided while patients are on IV PCA. The use of a background infusion with IV PCA increases the risk of respiratory depression, especially in patients with OSA. Progressive sedation, not a decrease in respiratory rate, is the best early clinical indicator of opioid-induced respiratory depression; use of respiratory rate is unreliable.[114–116] The progression from sedation to respiratory depression or cardiac arrest that is attributed to opioids administered by IV PCA is usually a gradual process. If sedation is noted at an early stage, the opioid can be discontinued and later implemented at a lower dose, when concern for sedation has abated.[108] In addition to receiving standard monitoring (pulse oximetry, respiratory rate), OSA patients on IV PCA should receive $EtCO_2$ monitoring with capnography. Providing adequate supplemental oxygen (e.g., O_2 face mask, CPAP) to OSA patients in the perioperative period is important. Oxygen therapy does not alter the number of apneic-hyponeic episodes, but it can reduce the occurrence of significant hypoxemia in these patients.[108,117,118]

There is no evidence that supports modifying the IV-PCA dose based on patient's weight in the adult population.2[3] In fact, morbid obesity is common in patients with OSA, and the same considerations in OSA patients should be made in patients with morbid obesity.[32,109]

Clinical Pearls

- Multimodal pain management is recommended in patients with OSA, and the concomitant use of sedatives or hypnotics should be avoided while patients are on IV PCA.

- Progressive sedation, not a decrease in respiratory rate, is the best early clinical indicator of opioid-induced respiratory depression; use of respiratory rate is unreliable.
- In addition to receiving standard monitoring (pulse oximetry, respiratory rate), OSA patients on IV PCA should receive $EtCO_2$ monitoring with capnography.

IV PCA IN THE ELDERLY

The elderly population (age >65) is vastly expanding and is projected to more than double between 2012 and 2060, from 43.1 million to 92.0 million according to the US Census Bureau. Therefore, knowledge of the interaction between elderly patients and pain management is important. Pain in the elderly may be overlooked and undermanaged[119] by healthcare workers for fear of untoward adverse effects of opioids.[120,121]

Elderly patients may have age-related decreases in physiologic reserves and should be assessed for comorbidities such as cardiac, pulmonary, hepatic, and renal dysfunction, which would affect the choice and dose of opioid used for IV PCA. For example, a patient with chronic kidney disease would not be given morphine IV PCA.[122] Because of comorbidities, elderly patients have a higher incidence of postoperative complications, especially in the presence of poor pain control. Polypharmacy is also common in this patient population[122,123] and may complicate the multimodal approach to pain management.

Pain perception can change with age. The elderly may have decreased pain perception, possibly from decreased Aδ-fiber and C-fiber function and delays in central sensitization.[124,125] In general, elderly patients exhibit increased tolerance to low-intensity and short noxious stimuli, but they may have increased perception of pain from high-intensity and persistent stimuli.[126,127] This phenomenon may involve a decrease in descending modulation subsequent to intense stimuli.[125,127] Over time, such alterations may contribute to the development of chronic pain in elderly patients.[125,127]

Because of an age-related decline in physiologic reserves and changes in pharmacokinetics, elderly patients are particularly sensitive to opioids. Diminished first-pass metabolism of opioids leads to increases in its bioavailability. In addition, analgesic requirements decrease with age. Opioids should be titrated slowly to produce the desired level of analgesia while limiting adverse effects. Although the incidence of pulmonary complications does not differ between PCA and conventional boluses,[121] the use of IV PCA will compensate for the wide interpatient Variability.[128,129]

Elderly patients are also prone to develop delirium and postoperative cognitive dysfunction, especially with poor pain control.[130–132] Patients with baseline cognitive dysfunction or delirium are generally not candidates for IV PCA. It may be challenging to assess pain score via visual analogue scales in this patient population owing to cognitive dysfunction, poor communication, debilitating depression, or cultural and social barriers.[133–136] Behavioral assessments[124] in conjunction with neurologic and pulmonary assessments play a vital role in this scenario.

IV PCA has been used effectively in elderly patients. It is associated with high patient satisfaction and provides better analgesia than conventional intermittent IV opioids.[121,128,137–139] However, because elderly patients are at risk for developing respiratory depression, a background infusion of opioid via PCA is not recommended. Supplemental oxygen may also be of benefit www.census.gov/newsroom/releases/archives/population/cb12-243.html.

Clinical Pearls

- Because of an age-related decline in physiologic reserves and changes in pharmacokinetics, elderly patients are particularly sensitive to opioids.
- In general, elderly patients exhibit increased tolerance to low-intensity and short noxious stimuli, but they may have increased perception of pain from high-intensity and persistent stimuli.
- Elderly patients are also prone to develop delirium and postoperative cognitive dysfunction, especially with poor pain control.

IV PCA IN OBSTETRIC ANALGESIA

IV PCA also has a place in providing labor analgesia. It is most commonly used when access to neuraxial anesthesia is not readily available. IV PCA may also be an option for labor analgesia in patients with contraindications to epidural analgesia.[140]

Miyakoshi et al.[141] compared the effects IV PCA and no analgesia on nulliparous women in labor. The study revealed that the women who received IV-PCA fentanyl had longer labor and a greater need for augmentation of labor with oxytocin than did nulliparous women without analgesia. Additionally, the rate of cesarean section was less frequent in the IV PCA group. Vacuum-assisted delivery rate and neonatal outcomes (i.e., Apgar score <7 at 1 or 5 minutes, umbilical artery pH <7.20) were comparable between groups, irrespective of mode of delivery. In a subset of women who were asked about their satisfaction, 72% (48/67) rated their satisfaction as "excellent" or "good" for IV PCA use.

Remifentanil IV PCA is considered for use in labor analgesia because it has an extremely fast onset of action (30–60 seconds) and peak analgesic effect (2.5 minutes),[142,143] its metabolism is independent of organ function, and it has rapid maternal and fetal clearance.[144–146] Tveit et al.[147] reported that remifentanil IV PCA provided adequate pain relief and high maternal satisfaction during the first and second stages of labor. However, moderate maternal sedation and respiratory depression occurred. Multiple studies have found that women in labor are at risk for sedation, especially during the time between uterine contractions.[72,144,148–150] Therefore, continuous monitoring is necessary. No serious neonatal side effects have been recorded.

Marwah et al.[146] compared the analgesic efficacy of remifentanil and fentanyl IV PCA during labor and their effects on neonatal outcomes. Both remifentanil and fentanyl IV PCA provided moderate labor analgesia. However, transient maternal oxygen desaturation occurred more commonly with remifentanil, and fentanyl was associated with increased need for neonatal resuscitation. The cumulative effects of fentanyl can be seen with continuous infusions, owing to redistribution from inactive tissue sites.[146,151,152] As a result, the context-sensitive halftime increases[146,152,153] in neonates, in whom the elimination half-life varies from 75 to 440 minutes.[153]

Douma et al.[70] compared IV PCA with remifentanil, fentanyl, and meperidine during labor. The pain scores differed during the first hour of labor, but subsequently they were comparable. Within 3 hours, pain scores returned to values that were similar to those reported before the implementation of IV PCA. There were no differences in neonatal outcomes,[70] and the drugs were apparently safe for use during labor analgesia, as reported in other studies.[66,69,72,73,144–146,148–150,154–160] However, there have been conflicting reports of fentanyl IV PCA causing neonatal respiratory depression.[146,153,161–165]

Clinical Pearls

- IV PCA for labor analgesia may be used when access to neuraxial anesthesia is not readily available or in patients with contraindications to neuraxial analgesia.
- IV PCA for labor analgesia may cause longer labor, a greater need for augmentation of labor with oxytocin, moderate maternal sedation, and respiratory depression. Therefore, continuous monitoring is necessary.
- Remifentanil IV PCA is considered for use in labor analgesia because it has an extremely fast onset of action (30–60 seconds) and peak analgesic effect (2.5 minutes), its metabolism is independent of organ function, and it has rapid maternal and fetal clearance.

CHAPTER 71

Continuous Peripheral Nerve Blocks

Amanda M. Monahan and Brian M. Ilfeld

INTRODUCTION

The maximum duration of a single-injection peripheral nerve block is approximately 8–24 hours.[1] Prolonging a peripheral nerve block may be desirable, and can be achieved with a continuous local anesthetic infusion via a perineural catheter. A continuous peripheral nerve block (CPNB) requires placement of a perineural catheter in the vicinity of a targeted peripheral nerve for the purpose of subsequently administering local anesthetic. Another term for this practice is *perineural local anesthetic infusion*. CPNBs are utilized for a wide variety of indications, most typically for anesthesia or analgesia in a peripheral nerve distribution. While not every application of CPNB has been exhaustively validated by randomized trials, continuous blocks have been reported for over 20 anatomic locations. The majority of described applications of CPNBs relate to the treatment of perioperative surgery-related pain.

HISTORY AND BACKGROUND OF CPNBS

The practice of continuous perineural analgesia has developed in parallel with technologic advances over nearly 70 years' time. Methods for identification of the catheter target have included anatomic landmarks, paresthesias, electrical stimulation, fluoroscopy, and ultrasound.[1] Continuous peripheral nerve blockade was described as early as 1946 by Ansbro.[2] A series of patients undergoing upper extremity surgeries as long as 4 hours in duration received a cork-stabilized needle at the supraclavicular level of the brachial plexus.[2] Other early reports include a similar practice in 1950 by Humphries.[3] In 1951, Sarnoff and colleagues reported placement of a polyethylene tube advanced through an insulated needle placed adjacent to a peripheral nerve using electrical stimulation.[4] By 1995, continuous perineural catheters were being inserted using multiple modalities. Pham-Dang and colleagues described fluoroscope-guided catheter placement adjacent to the brachial plexus within the axilla.[5] In that same year, Guzeldemir reported using ultrasound to place an axillary brachial plexus catheter.[6] By the late 1990s, ambulatory continuous peripheral nerve blocks gained popularity.[7,8] Relatively small, light, and inexpensive portable infusion pumps permitted outpatient infusion.[9]

Equipment providing a continuous infusion has evolved from a simple cork stabilizing a delivery needle,[2] to a catheter sheath advanced over a needle stylet,[5] to epidural-type catheters threaded through stimulating needles.[10–12] Stimulating catheters were introduced in an attempt to improve perineural location of the catheter tip,[13] although they are being reported far less frequently due to the evolution of ultrasound-guided (nonstimulating) catheter insertion techniques.[14] Whatever the technique or method of insertion, catheters are always placed within a tissue space that contains the plexus or nerve(s) of interest. (Figure 71–1) Patient selection for perineural catheters has also evolved from a solely hospital-based practice to inclusion of outpatient infusions.[15] While adhering to patient selection criteria, continuous techniques can be applied to pediatric, pregnant, and geriatric patients, as well as healthy ambulatory patients and the critically ill. Reported locations for continuous nerve blocks span a multitude of anatomic sites in the upper extremities, trunk, and lower extremities.

Klein and colleagues were some of the first investigators to objectively quantify the benefits of local anesthetic infusion in a randomized double-blind placebo-controlled manner.[16] Patients undergoing open shoulder surgery were randomized and underwent interscalene catheter placement using electrical stimulation. They received a postoperative infusion of either ropivacaine 0.2% or normal saline at 10 mL/hour via a disposable elastomeric pump for up to 23 hours. Pain scores were lower in the ropivacaine infusion group, averaging 1 (of 10) compared with 3 for subjects receiving perineural saline. These results suggested a significant benefit for continuous perineural infusion in the postoperative setting with the use of a portable pump. However, the possible advantages for use in the outpatient

FIGURE 71–1. An illustration depicting the general concept of catheter insertion. After successful needle placement into the tissue plane that contains the nerve, the catheter is inserted beyond the needle tip to provide access to the tissue plane for infusion and/or boluses of local anesthetic.

setting remained in question. A series of 70 outpatient catheter infusions was described by Rawal and colleagues in 1998.[9] Data from randomized, controlled studies involving CPNBs in the outpatient setting were subsequently published.[15]

Clinical Pearl

- The first continuous peripheral nerve block was described in 1946; and, the first ambulatory infusion was reported in 1998.

PATIENT SELECTION FOR CPNB

Indications

Most reports of CPNBs involve management of acute perioperative pain of greater than 12–24 hours' duration that is expected to be difficult to control by traditional methods such as systemic analgesics.[17] This is one of the few indications that has been evaluated with randomized controlled trials.[18] A catheter may also be advantageous in a patient who does not tolerate other analgesic regimens due to adverse effects.[19] Other reported indications include sympathectomy/vasodilation after vascular accidents or embolism,[20,21] digit replantation,[22,23] limb salvage,[24] and treatment of Raynaud phenomenon.[25] In the combat trauma setting, continuous perineural infusions have been utilized during transport to a treatment center.[26] Continuous infusions have also been described for chronic painful conditions such as phantom limb pain,[27,28] complex regional pain syndrome,[29] cancer pain,[30] preoperative pain control,[31] and trigeminal neuralgia.[32] Both pediatric and adult CPNBs have been described.[1,24,29,33–38]

Clinical Pearl

- Most perineural infusions are provided for postoperative analgesia, but other indications include avoiding opioids and opioid-related side effects, and treating chronic pain conditions such as complex regional pain syndrome and cancer pain.

Contraindications

While most contraindications to CPNB are relative in nature, commonly described absolute contraindications include infection at the catheter-insertion site,[39] allergy to local anesthetics,[40] and patient refusal/inability to cooperate. Many relative contraindications have been described, including coagulopathy/anticoagulation,[40] systemic infection/bacteremia, preexisting neuropathy, desire for postoperative neurovascular examinations, and elevated fall risk/inability to comply with activity restrictions.[1] For ambulatory infusions, inability to care for the infusion at home may also be a relative contraindication.[15] Additional relative contraindications are unique to the proposed catheter location. Certain infusions may affect ipsilateral phrenic nerve and diaphragm functions, such as interscalene, supraclavicular, or cervical paravertebral catheters. While the effects of ipsilateral diaphragmatic paralysis may be minimal in relatively healthy patients,[41] this may not hold true for those with significant pulmonary morbidity, such as chronic obstructive pulmonary disease or preexisting contralateral diaphragmatic paralysis.

Clinical Pearl

- Locations that may result in ipsilateral diaphragmatic paralysis include interscalene, supraclavicular, and cervical paravertebral catheters.

Catheter Insertion

Whatever the technique or method of insertion, catheters are always placed within a tissue space that contains the plexus or nerve(s) of interest (see Figure 71–1). Early catheters were inserted by inducing a paresthesia, seeking the tactile feedback of a tactile "pop" or "click," or using fluoroscopy.[1] From the time period of the 1970s to 1990s, most reported perineural catheters were inserted using electrical nerve stimulation.[1]

Ultrasound-guided catheter insertion has been compared to nerve stimulation techniques in multiple randomized controlled trials.[1] Insertion time and insertion discomfort are often reduced with ultrasound techniques, and the quality of analgesia is similar.[1] Ultrasound guidance can allow for catheter placement that would not otherwise be feasible with electrical stimulation techniques, such as patients with amputated limbs or those unable to elicit a muscle response.[42] Real-time

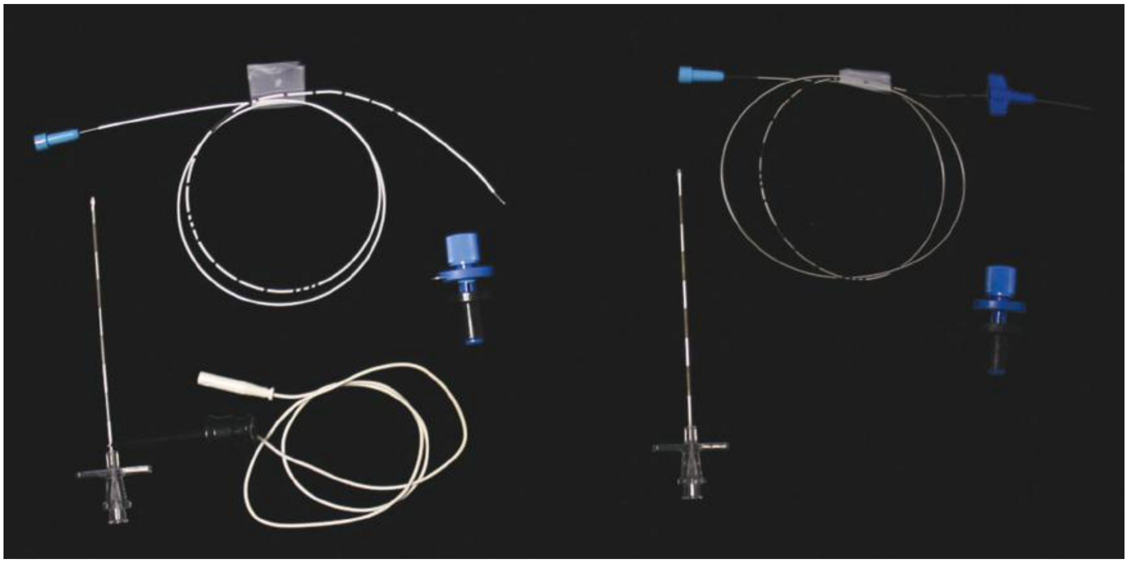

FIGURE 71–2. Examples of two perineural catheter designs: (**A**) an insulated needle and stimulating catheter (StimuCath, Teleflex/Arrow, Reading, PA); and, (**B**) an uninsulated needle and nonstimulating catheter (FlexBlock, Teleflex/Arrow, Reading, PA).

ultrasound allows for identification of vessels, which may make it an attractive modality when abnormal coagulation status is encountered.[43] Numerous methods for ultrasound-guided perineural catheter placement have been described.[14] Combining ultrasound and nerve stimulation has not demonstrated significant benefit—and it sometimes introduced new difficulties—in the majority of studies.[44–46]

Several types of catheters are available for perineural use. Some are specifically marketed for perineural infusions, and others are designed and approved for epidural infusions, and thus are used off-label when inserted adjacent to a peripheral nerve. Two broad design categories are stimulating and nonstimulating catheters (Figure 71–2). A stimulating catheter conducts electrical current to its distal end.[47] Elicited muscle movement is monitored as the catheter is advanced as an approximation of the distance between the catheter tip and target nerve. Nonstimulating catheters are typically advanced either "blindly" or under ultrasound visualization (unfortunately, the latter is technically challenging since flexible catheters do not remain within a two-dimensional plane).[14]

Optimal catheter insertion distance will allow for minimal dislodgements while also avoiding catheter knotting. Catheter knots have been reported with insertion greater than 5 cm.[48–50]

Clinical Pearl

- Optimal perineural catheter insertion distance will allow for minimal dislodgements while also avoiding catheter knotting; catheter knots have been reported with insertion greater than 5 cm.

Benefits

While case reports describe numerous potential benefits for continuous peripheral nerve blocks, available randomized controlled trials (RCTs) focus on benefits in the postoperative setting.[1] Postoperative pain relief is the primary benefit for performing a CPNB, and other benefits appear to derive from the improved analgesia.[18] Additional benefits demonstrated by RCTs include decreased opioid analgesic requirements and opioid-related adverse effects such as nausea/vomiting,[51,52] pruritus,[53,54] sedation, dizziness, and bowel dysfunction.[53,55] Non–opioid-related benefits include earlier achievement of physical therapy goals,[51,56] less sleep disturbance,[57] decreased pain upon coughing,[58] higher patient satisfaction scores,[52] and earlier readiness for and decreased time until hospital discharge.[53,59–61]

A small number of studies have explored the benefits of CPNB extending beyond the time of catheter removal. Currently, there are little data suggesting that a perioperative CPNB decreases subsequent chronic pain or disability following the perineural infusion.[1]

The location of the catheter and surgical site will influence the degree of benefit. Coverage of the entire surgical site within the sensory distribution of the target nerve typically provides the most complete analgesia. For this reason, shoulder (interscalene catheter) and foot procedures (sciatic catheter) are particularly amenable to regional anesthesia.[11,12,16,59,62,63] Infraclavicular catheters have also been validated by RCT.[10] However, to provide adequate analgesia often requires a relatively high dose of local anesthetic at this location, which may lead to an insensate arm or fingers.[64,65]

Surgical sites such as the knee or hip are innervated by multiple nerves, thus even with a functional CPNB, additional analgesics are typically required.[60,66] Femoral catheters have been studied extensively in the setting of knee arthroplasty, and continuous femoral infusions have been validated with multiple documented in-hospital benefits including improved analgesia and earlier attainment of range-of-motion. Short-term postinfusion benefits include continued improved knee range-of-motion at 1 month postoperatively.[67] One study reported improved physical therapy endpoints 6 weeks postoperatively in patients receiving a continuous femoral nerve block[68]; however, multiple other trials detected no such prolonged benefit.[69–72] The value of adding a sciatic perineural catheter in addition to the femoral catheter for total knee arthroplasty has also been evaluated by randomized controlled trials. Pain control until the second postoperative day is superior with combined catheters.[73] However, discharge readiness remains unaffected. In a review of four randomized and three observational trials, no benefit beyond 24 hours postoperatively was found by the addition of a sciatic single block or continuous block.[74] Efforts to minimize motor block while providing femoral nerve-distribution analgesia have led to placement of perineural catheters near the femoral nerve at the mid-thigh "adductor canal" region.[75,76] Decreased quadriceps weakness, relative to an inguinal-level block, has been demonstrated in a volunteer study.[77] While decreased opioid requirements and earlier ambulation have been demonstrated with adductor canal infusion versus placebo,[78] it remains unknown if this relatively new modality provides equivalent analgesia compared with continuous femoral nerve blocks.[75]

Popliteal-sciatic catheters provide significant improvements in analgesia, opioid consumption, sleep disturbance, patient satisfaction, and same-day hospital discharge following foot and ankle surgery.[11,61] Paravertebral catheters have been validated by RCTs to demonstrate the benefits of pain relief and tissue oxygenation. In one study when compared to intravenous (IV) opioids, a continuous thoracic paravertebral technique for breast reconstruction has been associated with improved analgesia as well as superior latissimus flap tissue oxygen tension.[79] Following open lung surgery, paravertebral catheters provide similar analgesia with superior cardiovascular stability as thoracic epidural infusion.[80] Case series suggest improved spirometry performance after paravertebral infusion for rib fractures.[81] RCTs documenting benefits are sparse for other locations, such as axillary,[82] supraclavicular,[83,84] transverus abdominis plane,[85,86] and intercostal catheters.[87]

Clinical Pearls

- The majority of Benefits are derived from decreasing pain, and include avoiding opioid-related adverse effects, earlier achievement of physical therapy goals, less sleep disturbance, higher patient satisfaction scores, and earlier readiness for and decreased time until hospital discharge.
- To provide adequate analgesia with an infraclavicular catheter often requires a relatively high dose of local anesthetic at this location, which may lead to an insensate arm or fingers.
- Surgical sites such as the knee or hip are innervated by multiple nerves, thus even with a functional CPNB, additional analgesics are typically required.
- There are little data suggesting significant benefits from catheters in the axillary, supraclavicular, transversus abdominis plane, and intercostal anatomic locations.

Risks

All medical procedures carry some degree of risk, which must be carefully balanced with the potential benefits. Known risks common to any regional anesthetic include bleeding, infection, or neurologic injury. When compared to single-injection blocks, continuous techniques appear to have a similar frequency of complications, most of which are relatively minor.[88]

Catheters may be unintentionally inserted into the intravascular, epidural,[89–91] intrathecal,[92–94] or intraneural spaces.[95] Infectious risks specific to perineural catheters have been investigated in multiple studies. A range of data has been reported; recent studies report up to 29%–58% catheter colonization, 3%–4% local inflammation, and 2%–3% clinically relevant infection rates.[96–98] Within these studies, 0.8%–0.9% of patients required incision and drainage. Neurologic complications are a rare but serious complication of any regional technique. It is difficult to attribute the contribution of the surgical procedure, patient positioning, the single-injection block, or the catheter/infusion. Despite these limitations, the incidence of transient neurologic symptoms after a continuous technique has been reported from 0%–1.4%.[1] Long-lasting (greater than 6 weeks) neurologic symptoms have been reported at a rate of 0.2% in one large study of 3500 catheters.[96] Catheters may unintentionally dislodge, occlude, break, or be retained.[1] A recent study in healthy volunteers reported that up to 25% of femoral catheters may dislodge from their original intended location.[97]

The third edition of the American Society of Regional Anesthesia and Pain Medicine guidelines regarding regional anesthesia in the patient receiving antithrombotic or thrombolytic therapy outlined a 26-patient case series of bleeding complications with plexus or peripheral blockade.[98] All patients with neurologic deficits experienced a resolution within 6–12 months. Serious blood loss appeared to be the most morbid complication associated with the bleeding.

In addition, site-specific risks have been identified. For example, the incidental phrenic or recurrent laryngeal nerve blockade with an interscalene catheter may not be tolerated in patients with limited pulmonary reserve or contralateral vocal cord lesion.[99] Falls are a concerning risk, especially with CPNBs of the lower extremity. A pooled analysis of several studies suggests an increased association of falls with continuous femoral/psoas compartment blocks after knee or hip arthrolasty.[100]

Clinical Pearls

Perineural infusions that affect the femoral nerve have been associated with an increased risk of falling.

- Adductor canal perineural infusion may provide similar analgesia to femoral infusions while decreasing induced quadriceps weakness; however, further research is required to draw conclusions.
- CPNB's risk of complications is relatively low, but includes infection, bleeding, and neurologic injury. When compared to single-injection blocks, continuous techniques appear to have a similar frequency of complications, most of which are relatively minor.

PART 12

SUMMARY

A CPNB, or perineural local anesthetic infusion, is a method to extend the effects of a single-injection technique by placement of a perineural catheter and subsequent local anesthetic infusion. Precatheter patient selection and counseling are crucial for both inpatient and ambulatory cases. Numerous techniques are used for accurate catheter tip placement. Multiple benefits have been documented by randomized controlled trials, most of which result from improving analgesia. Finally, most related adverse effects are minor and easily remedied; however, rare serious complications have also been reported.

CHAPTER 72

Organization of an Acute Pain Management Service Incorporating Regional Anesthesia Techniques

Amanda Lukof, Eugene R. Viscusi, Leslie Schechter, Suzanne Lenart, Kathleen Colfer, and Thomas Witkowski

INTRODUCTION

Acute pain management is constantly evolving, especially in recent years. In the past, acute pain management consisted primarily of opioids given intermittently by intramuscular injection. In addition to pain on injection, this led to undesirable "analgesic gaps," or periods of inadequate pain control between peak and trough opioid levels. Consequently, patients were often reluctant to request pain medications that were ordered "as needed."

To provide more consistent analgesia, intravenous patient-controlled analgesia (IV-PCA) was introduced in the 1980s, leading to the development of specialized pain management teams, most often under the direction of anesthesiologists. The additional advancement intrathecal opioids and epidural analgesia for postoperative pain management heralded the first pain service in the United States.[1] In Europe, Narinder Rawal promoted the role of nurses as valued members of the acute pain management team.[2] By the early 1990s, 40% of US hospitals had acute pain services.[3]

In recent years, regional anesthesia has gained popularity because if its contribution to postoperative pain management. Single-injection and continuous peripheral neural blockade are increasingly practiced in both the inpatient and outpatient settings. This provides another key component of multimodal therapy, in which pain is targeted with a variety of techniques and medication classes.[4] However, effective application of these techniques requires adequate expertise, surveillance, and organization.

A dedicated acute pain management team is the pivotal component in managing these procedures and techniques to optimize pain control. The primary goals of the team are to offer a wide variety of services, provide a high level of patient surveillance, and integrate these services into the overall hospital setting. Optimal analgesia requires judicious dose adjustments to maximize the benefits and minimize the side effects of therapy. This can only occur if the patient is adequately monitored.

The American Society of Anesthesiologists (ASA) Task Force first established practice guidelines for acute pain management in 1995.[5] The most recent revision was in 2012; please refer to this document for details.[6] The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) established standards (Table 72–1) for pain management in January 2001 that are still practiced today.[7] These standards provided an impetus for hospitals to have an institutionwide commitment for policies and procedures to support effective pain management. This effort promoted the concept of pain as the "fifth vital sign" and established the patient's right to pain management. It also became evident that an effective pain management program can only be achieved with a strong institutional commitment. The revised ASA guidelines of 2012 highlighted the importance of multidisciplinary collaboration among anesthesiologists, surgeons, nurses, pharmacists, and other members of the healthcare team.

The purpose of this chapter is to provide strategies for effective postoperative pain management while enhancing safety and facilitating delivery of services. An organizational model for

PART 12

TABLE 72–1. Key points from JCAHO pain management standards.

- Patient has a right to pain management.
- Pain must be assessed at regular intervals. Pain should be reassessed soon following an intervention to treat pain to ensure a response.
- Institutions are required to have policies and procedures for pain assessment and treatment.
- Patient education for pain management is mandated.
- Staff education concerning pain management is required.
- Pain assessments are required as a discharge criteria.

JCAHO, Joint Commission on Accreditation of Healthcare Organizations.

a nursing-based acute pain service is presented. Standard orders and protocols are also provided to facilitate implementation of the suggested principles and approaches. Finally, we provide many of the organizational tools and concepts we have found useful in the organizational design of our acute pain service.

ROLE IN PATIENT SAFETY

The acute pain management team should focus not only on effective pain management, but delivery in the safest way possible. Many advisory organizations have released guidelines on the safe use of opioids. In 2012, the Joint Commission released their Sentinel Event Alert #49: *Safe Use of Opioids in Hospitals*.[8] The Joint Commission's Sentinel Events are a review and recommendations on unexpected occurrences that result in death or serious injury in medical settings in the United States.

In the case of Sentinel Event #49, the unexpected occurrences were adverse events caused by opioid administration. In their review, 47% of these events were associated with the erroneous dose of opioid being administered; this can be from human error in ordering or dosing, or a lack of adequate knowledge regarding the medications. Interestingly, 29% were due to inadequate monitoring. There were a variety of suggestions made to reduce these events with the strongest focus on development of policies and procedures regarding use of opioids, and having a group of practitioners with appropriate training not only to use opioids safely, but troubleshoot when problems do arise. They also encourage use of nonnarcotics either with or even before opioids to decrease side effects. All of these recommendations can be met by the implementation of an acute pain management team.

Adverse events related to opioids often occur in a "high-risk" patient. Acute Pain Management Service (APMS) teams can identify these patients, particularly those who are opioid tolerant, and implement individualized strategies that go beyond dose escalation (see below section on opioid tolerance). Multimodal therapy can be used not only for patient comfort, but to increase safety as well.[9] Many of the recommendations are in widespread use already, such as the avoidance of arbitrary pain ratings in favor of standardized tools such as Posero Opioid-Induced Sedation Score (POSS) scoring (Table 72–2).[10]

TABLE 72–2. Pasero opioid-induced sedation score.

S = Sleeping, easy to arouse
Acceptable; no action necessary; may increase opioid dose if needed.

1 = Awake and alert
Acceptable; no action necessary; may increase opioid dose if needed.

2 = Slightly drowsy, easily aroused
Acceptable; no action necessary; may increase opioid dose if needed.

3 = Frequently drowsy, arousable, drifts off to sleep during conversation
Unacceptable; monitor respiratory status and sedation level closely until sedation level is stable at less than 3 and respiratory status is satisfactory; decrease opioid dose 25%–50% (1) or notify prescriber (2) or anesthesiologist for orders; consider administering a nonsedating, opioid-sparing nonopioid, such as acetaminophen or an NSAID, if not contraindicated.

4 = Somnolent, minimal or no response to verbal and physical stimulation
Unacceptable, stop opioid; consider administering naloxone[3,4]; notify prescriber or anesthesiologist; monitor respiratory status and sedation level closely until sedation level is stable at less than 3 and respiratory status is satisfactory.

NSAID, nonsteroidal anti-inflammatory drug.

INTRAVENOUS PATIENT-CONTROLLED ANALGESIA

IV-PCA is commonly used as part of a multimodal approach to postoperative pain control. Sechzer[11] and Forrest[12] popularized the concept of PCA. Patients self-administer small doses of intravenous opioid at predetermined intervals (lockout), to maintain a minimum effective analgesic concentration (MEAC). This titration of the opioid provides a more constant plasma level of analgesic[13] and more consistent analgesia.[14] Maintaining opioid plasma levels within a tight range improves analgesia while reducing unwanted side effects that can occur with larger boluses. PCA pumps can be programmed to deliver opioids either by intermittent patient-controlled bolus doses alone or with a continuous background (or basal) infusion. PCA pumps are programmed to set the demand dose, lockout interval, hourly total dose, and basal infusion. Importantly, before starting PCA, analgesia must be established with an initial loading dose of opioid.[15] Without front loading, MEAC is not achieved for at least three elimination half-lives.[16] PCA is intended to *maintain* a level of pain control, not to initiate satisfactory analgesia. Therefore, if the PCA process is interrupted by pump failure, a faulty intravenous line, or inadequate patient dosing, the patient will require bolus titration to achieve comfort before reinitiating PCA. PCA advantages over intermittent injections include fewer analgesic gaps, maintaining analgesia with less total opioid consumption (thus with fewer side effects), less use of nursing staff time, and improved patient satisfaction. Patients can anticipate and proactively manage their pain, particularly before moving or coughing. There is also a psychologic advantage because of the shortened interval between perception of pain and administration of medication.

Clinical Pearl

- PCA advantages over intermittent injections include fewer analgesic gaps, maintenance of analgesia with less total opioid comsumption, fewer side effects, less use of nursing time, and greater patient satisfaction.

In the opioid-naïve patient, the addition of a basal infusion to IV-PCA has been shown not to improve analgesia, but increases the risks of this technique.[17] Without a basal infusion, the risk of clinically significant respiratory depression is generally low. Patients maintain normal levels of arterial CO_2 in the early postoperative period while receiving PCA therapy. Postoperative respiratory functions (forced expiratory volume, functional residual capacity, and peak flow rates) are not significantly different from those in patients receiving intramuscular injections of opioids.[18,19] Basal infusions are not recommended except in a very limited subset of patients. Studies have demonstrated they have a higher risk of respiratory depression and may not provide any improvement in pain scores.[20] The most common problem associated with IV-PCA use is operator error, the most common cause of which is programming error and incorrect drug concentration.[21] When a medication error involves a PCA pump, the risk of patient harm increases 3.5 times.[22] The Food and Drug Administration's (FDA's) Manufacturer and User Facility Device Experience (MAUDE) Database for 2004 identified 21 deaths involving IV-PCA pumps; 16 deaths were related to large-volume infusion pumps (LVPs). Given that there are approximately 10 times as many LVPs as PCA pumps, it appears that the risk of a severe respiratory event from a PCA pump is at least 10 times greater than with an LVP.[23] To avoid these errors, the nursing staff must understand the basis for therapy and be knowledgeable about the operational aspects of PCA pumps. Patient-related PCA problems include failure to understand PCA therapy, intentional analgesic abuse, underutilization because of unwarranted fears of addiction, and PCA by proxy (operation by an individual other than the patient). Patients should be educated about PCA before surgery; the education should be frequently reinforced throughout treatment.

Clinical Pearl

- The addition of a basal infusion to PCA increases the risk of respiratory depression without the benefit of improving analgesia. Without a basal infusion, the risk of clinically significant respiratory depression is low.

Morphine is the most commonly used PCA opioid. Hydromorphone and fentanyl are also favored because of their favorable metabolite profile. Meperidine has little place as an analgesic because of its neurotoxic metabolite, normeperidine. Table 72–3 summarizes the commonly used IV-PCA equianalgesic opioid solutions.

When converting the equivalent dose of opioids, calculated dose should be considered as an approximation because of incomplete cross tolerance. Patient responses may vary when converting from one opioid to another. Similar rules apply when converting the IV opioid therapy to the oral opioid analgesic therapy. Clinicians must have a thorough understanding of equianalgesic opioid doses. However, they must also appreciate that these dose conversions are simply guidelines and can vary patient to patient. There should be room to titrate in safe conversions.

Clinical Pearl

- Before starting PCA, analgesia must be established with loading doses of opioid.

Safe and effective use of PCA requires institutionwide protocols and standard orders. These protocols allow primary floor nursing and medical staff to utilize these systems without constant direct supervision from the acute pain management team.

There are a number of nonintravenous PCA alternatives. An iontophoretic, transdermal drug-delivery system (ITS) has demonstrated the ability to provide needle-free patient-controlled delivery of fentanyl. This patient-controlled transdermal analgesia (PCTA) system is a preprogrammed and self-contained

TABLE 72–3. Common IV-PCA equianalgesic opioid solutions.

	Concentration (mg/mL)	Dose (mL)[a]	Lockout Interval (min)	Max Hourly Dose (mL)
Morphine sulfate	1	1–2	6	10–20
Hydromorphone (Dilaudid)	0.2	0.5–2	6–8	8–10
Fentanyl (Sublimaze)	0.01–0.02	1–2	6	10–20

[a]Intended for opioid-naïve patients.

device about the size of a credit card. Clinical trials have demonstrated analgesic efficacy similar to that from standard morphine IV-PCA.[24]

Another form of PCA currently under evaluation by the FDA is the Sufentanil NanoTab. This is a noninvasive, sublingual delivery of sufentanil using new PCA technology that may become an option in the United States in the future. Thus far, clinical trials have demonstrated safety and efficacy of this system.[25]

PERIPHERAL NERVE BLOCKS

Peripheral nerve blocks are useful in providing surgical anesthesia and postoperative analgesia[26] with an acceptable side-effect profile.[26,27] Single-injection techniques are limited in duration but can be extremely useful in the immediate postoperative period. Continuous catheter techniques can extend the duration of analgesia to the desired length of time. There are commercially available catheter insertion kits and drug-delivery systems that are small, portable, lightweight, and frequently disposable. There is a large variety of commercially available PCA pumps with different characteristics.[28] The introduction of these lightweight, portable infusion pumps has made home infusion possible, and it has been shown to be effective in randomized, double-blind, placebo-controlled studies.[29–31]

Numerous approaches have been described to the lumbar, sacral, and brachial plexuses and in the paravertebral space. The planned surgical procedure will determine the peripheral nerve block needed for postoperative analgesia. The reader should refer to the respective chapters on individual nerve block techniques for in-depth discussion on indications and technical aspects of their use. In general, the peripheral nerve block techniques are indicated in patients expected to have moderate-to-severe postoperative pain that is not easily controlled with opioids or when opioid side effects are problematic.

Possible modes of local anesthetic infusion through these catheters include intermittent bolus, continuous infusion, or continuous infusion with PCA boluses. Infusion mode is often a matter of clinician preference. Continuous infusions and continuous infusion with PCA have been shown to be superior to the intermittent bolus technique.[32] Successful use of infusions requires a solid infrastructure consisting of anesthesiologists with additional training in regional techniques who can provide coverage around the clock, supportive surgeons, pharmacists familiar with local anesthetic dosing, and specially trained nurses who can manage catheters and educate patients. There must also be an institutional commitment to provide these services and organizational tools to implement them including standardized procedure note, order sets, and documentation records. Recommendations for local anesthetic injection volume and catheter infusion rates are provided in the respective chapters. The reader should note that the suggested doses, volumes, concentrations, and infusion rates are only general guidelines and must be adjusted for individual patients. More in-depth discussion on these variables can be found in Chapters 10 (Local Anesthetic Solutions for Continuous Nerve Blocks) and 71 (Continuous Peripheral Nerve Blocks in Outpatients).

In an ambulatory setting, patient selection is critical when considering continuous infusion techniques. Only patients who are capable of accepting the additional responsibility of the catheter and infusion pump should be selected. Since some degree of cognitive dysfunction may occur in the early postoperative period, patients will benefit from a caregiver at home for the first 24–48 hours who can participate in patient care. To decrease the risk of local anesthetic toxicity, patients with hepatic or renal insufficiency should not be sent home with continuous catheters if they do not have a caregiver at home. Hence, patients without a caregiver, with baseline cognitive difficulties, with certain underlying medical problems, or patients living a distance from the medical facility may be poor candidates for ambulatory infusion techniques.

The successful use of peripheral catheters in the ambulatory setting requires patient education that should start in the preoperative area and extend into the postoperative period. Both patients and their caregivers must be involved. Instructions should be both verbal and written and include pager numbers and telephone numbers of responsible healthcare providers who will be available around the clock if problems occur. Although the surgeon is responsible for the overall care of the patient, the anesthesiologist providing the continuous regional technique must be responsible and available for catheter-related problems.

Key elements of patient instructions include:

- Protect the operative limb for the duration of the block.
- Keep the catheter site clean and dry.
- Do not operate machinery or drive a vehicle for the duration of the block.
- Approximate duration/resolution of the surgical block.
- Use of supplemental oral analgesics/opioids.
- Portable pump instructions.
- When and how to remove the catheter.
- Look for signs of catheter/local anesthetic infusion complications.
- Observe catheter site for swelling, tenderness, and drainage.

Clinical Pearl

- Successful use of peripheral catheters in the ambulatory setting requires thorough patient education, including written and verbal instructions.

Careful follow-up is necessary with any continuous catheter technique. Visiting nurses may be helpful. Patients may benefit from daily telephone contact with specific questions about quality of analgesia, local anesthetic side effects, and possible catheter site infection. Documentation of these patient contacts should be made. Patients may remove their peripheral infusion catheters at home, may return to the medical facility to have them removed, or a visiting nurse may remove the catheter. This may depend on the patients' abilities, the distance they must travel from the hospital, and their degree of mobility. In the ambulatory setting, disposable elastomeric pumps are utilized. With proper selection and education of patients, the incidence of injury to the blocked limb is very low.[33]

Complications of Continuous Catheter Techniques

1. Local anesthetic toxicity is a potential complication that can occur when large volumes or high concentrations of local anesthetics are used. Intravascular placement of catheters can be detected with epinephrine-containing local anesthetic test doses. Low concentrations of a long-acting local anesthetic with an acceptable safety profile are advisable. Ropivacaine, in 2 mg/mL concentration, infused in a continuous interscalene (brachial plexus) catheter at 6–9 mL/h has demonstrated safety.[34, 35]
2. Patients should be instructed to look for signs of local infection at the catheter site, local tenderness, redness, and fever. These should be immediately reported to the healthcare providers. Even though infection at catheter sites is uncommon, one study reported 57% of femoral catheters showed bacterial colonization at 48 h.[36]
3. Although a rare occurrence, catheter migration must always be considered. Catheter failure is the most common sign of migration. Since the actual location of the local anesthetic infusion cannot be determined, failed catheters should always be removed promptly. Catheters may migrate into the intravascular compartment. Patients should be provided with a list of signs of intravascular infusion of local anesthetics: tinnitus, metallic taste in the mouth, and anxiety. Intramuscular migration of the catheter will result in either a decrease or complete cessation of analgesia. The infusion should be stopped since there is a theoretic risk of myositis.[37]
4. Careful dressing of the catheter site and use of surgical tape can reduce catheter dislodgment. Clear dressings are advantageous since they permit visualization of the insertion site. Commercially available skin preparations (similar to ostomy site skin preparations) may increase adhesion while reducing skin breakdown. Adhesive surgical strips may be beneficial in regions that are difficult to secure. Catheters can also be secured by suturing or tunneling. This may be helpful for longer term placement.
5. Many varieties of infusion pumps are available for either continuous infusion or patient-controlled boluses. Use of LVPs (250–400 mL) will provide longer periods of analgesia. However, larger volumes of local anesthetic may increase the risk of systemic toxicity.

MULTIMODAL APPROACH TO ACUTE PAIN MANAGEMENT

Multimodal analgesia produces optimal pain relief by targeting pain at multiple pathways.[38] Combining analgesic techniques and drugs has a synergistic or additive effect and decreases the requirement for individual medication, thereby reducing the incidence of side effects.[39] One of the strongest recommendations from the revised 2012 ASA guidelines on acute pain was for providers to use at least two nonopioid therapies around the clock for baseline pain. Opioids should be employed as rescue therapy in this management plan.

Clinical Pearl

- All patients should be approached with a suitable multimodal analgesia regimen. Opioids should not be used as the sole agent.

The surgical stress response produces endocrine and metabolic responses in the body. These pathways can be targeted pharmacologically at specific levels by adopting a multimodal approach to pain control.[40] The focus of the multimodal approach to acute postoperative pain management is to facilitate the patient's rehabilitation. Multimodal approaches combined with accelerated recovery protocols can reduce length of hospital stay.[41] This has been shown to work when the surgical team, anesthesiologists, nurses, and patients work together within established clinical pathways.[42]

Chronic pain has been identified as a consequence of surgery and poorly controlled acute pain.[43] Multimodal techniques may reduce central sensitization, improve pain control, and ultimately reduce long-term sequelae. Local anesthetics and regional anesthesia techniques are critical components of multimodal analgesia. These methods reduce the need for systemic pain medications and allow patients to get out of bed sooner, which decreases hospital stay and hastens recovery.

Ketamine, an N-methyl-D-aspartate (NMDA) receptor antagonist, when used in small doses (0.5–0.15 mg/kg IV) has been shown to improve pain relief if administered with opioids intravenously or epidurally.[44,45] This is discussed in further detail later in the chapter in the section on opioid tolerance.

With appropriate patient selection, nonsteroidal anti-inflammatory drugs (NSAIDs) can be very effective in multimodal pain plans. However, in some patients and situations NSAIDs can exert an antiplatelet effect that can cause surgical bleeding. They may also cause renal dysfunction. NSAIDs have an opioid-sparing effect[46] and can be administered orally or parentally. Cyclooxygenase-2 (COX-2) inhibitors, such as celecoxib, do not have an antiplatelet effect, making them desirable for postoperative pain management. Concern for cardiovascular problems has led to the withdrawal of other COX-2 inhibitors from the market. However, this risk is associated with duration of use longer than is indicated for most acute pain situations.

Acetaminophen is also used commonly in the multimodal scheme. It is particularly effective in conjunction with opioids. Dosed appropriately, it is equally effective both orally and intravenously (both 1000 mg q6h) to improve pain scores and lessen opioid requirements.[47] IV acetaminophen is preferred when the patient is unable to take medications by mouth, as during the immediate preoperative or postoperative period. This was approved for use in the United States in 2010.

Neuropathic pain is often the most difficult pain to control, particularly since the drugs previously mentioned do not target this pain pathway as effectively. Gabapentin, a gamma-aminobutyric acid (GABA) analogue that was developed originally as an antiseizure medication, has been found to be effective to help treat this pain type. Pregabalin, another medication for this modality, has a higher bioavailability than gabapentin, making it more useful in the acute pain setting as patients can get an effect with lower doses. This helps keep side effects, most notably sedation, at a minimum. Both medications also can decrease narcotic use in the postoperative period.[48] These are the most commonly used antiepileptics for pain control, although others are available and may be used in certain patient populations.

CONTINUOUS EPIDURAL ANALGESIA

Use of continuous epidural infusions of local anesthetic with or without opioids has become a cornerstone of multimodal analgesia.[49] The use of dilute local anesthetic solutions has been shown to decrease the incidence of deep venous thrombosis in the postoperative period.[50] It is an effective weapon in attenuating the endocrine metabolic response to surgical stress and to provide dynamic pain relief.[51] The epidural catheter must be functional and cover the dermatomal distribution of the surgical incision to be effective. Epidural catheters are best inserted at the mid-dermatome of anticipated surgical trauma. Care must also be taken to advance between 3 and 5 cm of epidural catheter into the epidural space. A shallower insertion results in greater incidence of catheter dislodgement, whereas an excessive length of catheter reduces efficacy and increases risk of catheter knotting. The routinely used nylon epidural catheters are difficult to direct in the epidural space, regardless of the direction of the epidural needle bevel. Hence, it is best to target a short length of catheter at the precise spinal cord level to cover surgical pain.

Clinical Pearl

- Use of continuous epidural infusions of local anesthetic with or without opioids is a cornerstone of multimodal analgesia.

In a meta-analysis comparing epidural analgesia with parenteral opioids, epidural analgesia was found to provide more effective pain control.[52] Epidural opioids or local anesthetics either alone or in combination demonstrated superiority. Hence, when surgical pain is of high intensity and likely to last at least 48 hours, epidural analgesia deserves consideration. Side effects of epidural analgesia include motor block, nausea and vomiting, pruritus, urinary retention, sedation, and respiratory depression. Epidural catheters in the presence of anticoagulation may increase the risk of epidural hematoma. The American Society of Regional Anesthesia & Pain Medicine (ASRA) has established specific guidelines for neuraxial anesthetic techniques in the presence of anticoagulants that is important for all members of an acute pain team to know and understand.[53]

A number of other agents have demonstrated analgesic efficacy when administered by the epidural route either alone or in combination with other agents. These agents include anticholinergic agents, NMDA receptor antagonists (e.g., ketamine) and α_2-adrenergic agonists. Epidural epinephrine, clonidine,[54] and dexmedetomidine[55] have demonstrated analgesic efficacy. However, these agents are seldom used, perhaps due to varied side effects.

Clinical Pearls

- Check coagulation status before placement and removal of epidural catheters.
- Insert epidural needle at mid-dermatome of surgical trauma.
- Obtain an anesthetic level and ensure epidural is functioning BEFORE surgery.
- If breakthrough pain, always establish a level before dosing. This can be determined with ice (cold sensation).

A standard epidural order form and an epidural procedure note (both seen in Figures 72–1 and 72–2) enhance documentation and reduce medication errors. Commonly used solutions for epidural infusion and rates of administration are detailed in Tables 72–4 and 72–5.

Infiltration With Local Anesthetics

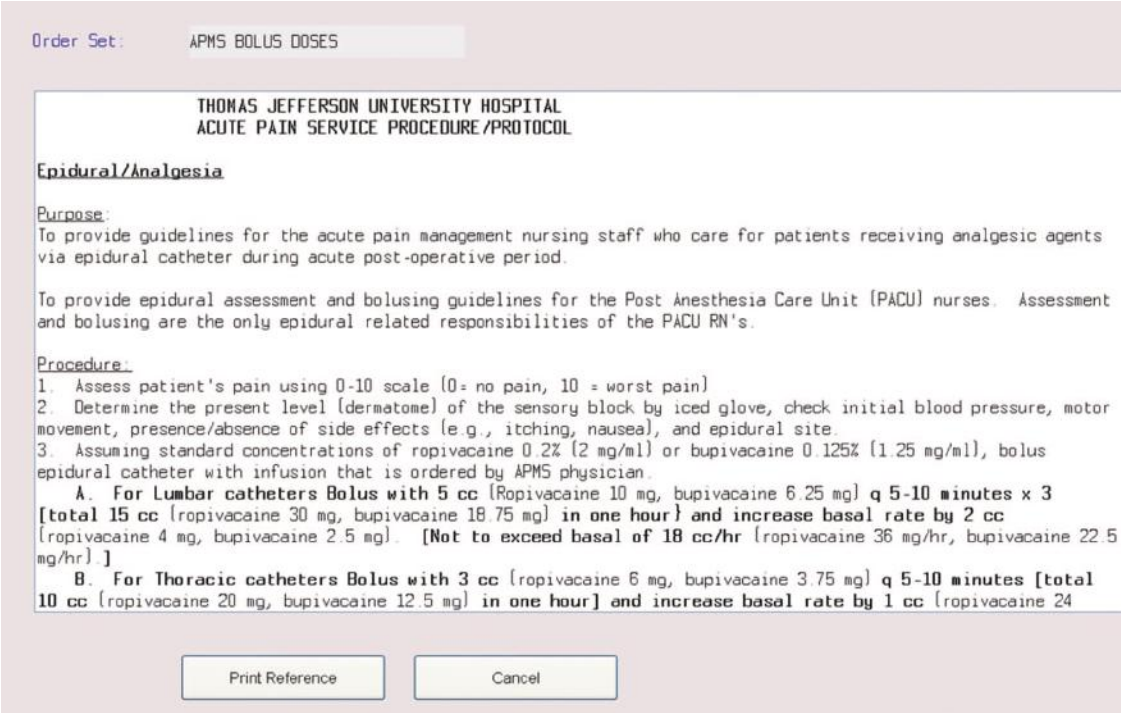
Infiltrating the operative site with local anesthetic is a simple way to enhance pain control.[56] Local anesthetics can be injected or infused into joint spaces, surgical wounds, or in the vicinity of nerves near the surgical site. Local anesthetics are relatively inexpensive and remain the most useful and safe component of multimodal analgesia. With introduction of delayed-release local anesthetic on the market, the utility of infiltration has substantially increased along with the increased duration of analgesic action.

Acute Pain in the Patient With Chronic Pain

Patients with chronic pain present special challenges in the perioperative period. Their pain is typically poorly controlled by the routine administration of opioids alone. It is critical that such patients are identified in the preoperative period and an analgesia plan established before surgery[57] to avoid unnecessary prolonged periods of severe uncontrolled postoperative pain. Evidence from the literature supports that the opioid requirement in these patients can be much higher than in opioid-naïve patients.[58] These patients may present with a history of chronic opioid use, often at high doses and perhaps in conjunction with a variety of other pain medications. Following identification, these patients require careful assessment in the preoperative phase to fully describe the nature of their chronic pain, to quantify opioid requirements, and to document all current medications. Then, an analgesic plan must be formulated with the patient as an active participant.[59] Table 72–6 details practical approach to postoperative pain management in the patient with history of chronic pain.

Opioid-Tolerant Patients

Opioid-tolerant patients may include patients with chronic pain,[60] active opioid abusers, or former addicts enrolled in



Order Set: APMS BOLUS DOSES

THOMAS JEFFERSON UNIVERSITY HOSPITAL
ACUTE PAIN SERVICE PROCEDURE/PROTOCOL

Epidural/Analgesia

Purpose:
To provide guidelines for the acute pain management nursing staff who care for patients receiving analgesic agents via epidural catheter during acute post-operative period.

To provide epidural assessment and bolusing guidelines for the Post Anesthesia Care Unit (PACU) nurses. Assessment and bolusing are the only epidural related responsibilities of the PACU RN's.

Procedure:
1. Assess patient's pain using 0-10 scale (0= no pain, 10 = worst pain)
2. Determine the present level (dermatome) of the sensory block by iced glove, check initial blood pressure, motor movement, presence/absence of side effects (e.g., itching, nausea), and epidural site.
3. Assuming standard concentrations of ropivacaine 0.2% (2 mg/ml) or bupivacaine 0.125% (1.25 mg/ml), bolus epidural catheter with infusion that is ordered by APMS physician.
   A. For Lumbar catheters Bolus with 5 cc (Ropivacaine 10 mg, bupivacaine 6.25 mg) **q 5-10 minutes x 3 [total 15 cc** (ropivacaine 30 mg, bupivacaine 18.75 mg) **in one hour} and increase basal rate by 2 cc** (ropivacaine 4 mg, bupivacaine 2.5 mg). **[Not to exceed basal of 18 cc/hr** (ropivacaine 36 mg/hr, bupivacaine 22.5 mg/hr).**]**
   B. For Thoracic catheters Bolus with 3 cc (ropivacaine 6 mg, bupivacaine 3.75 mg) **q 5-10 minutes [total 10 cc** (ropivacaine 20 mg, bupivacaine 12.5 mg) **in one hour] and increase basal rate by 1 cc** (ropivacaine 24

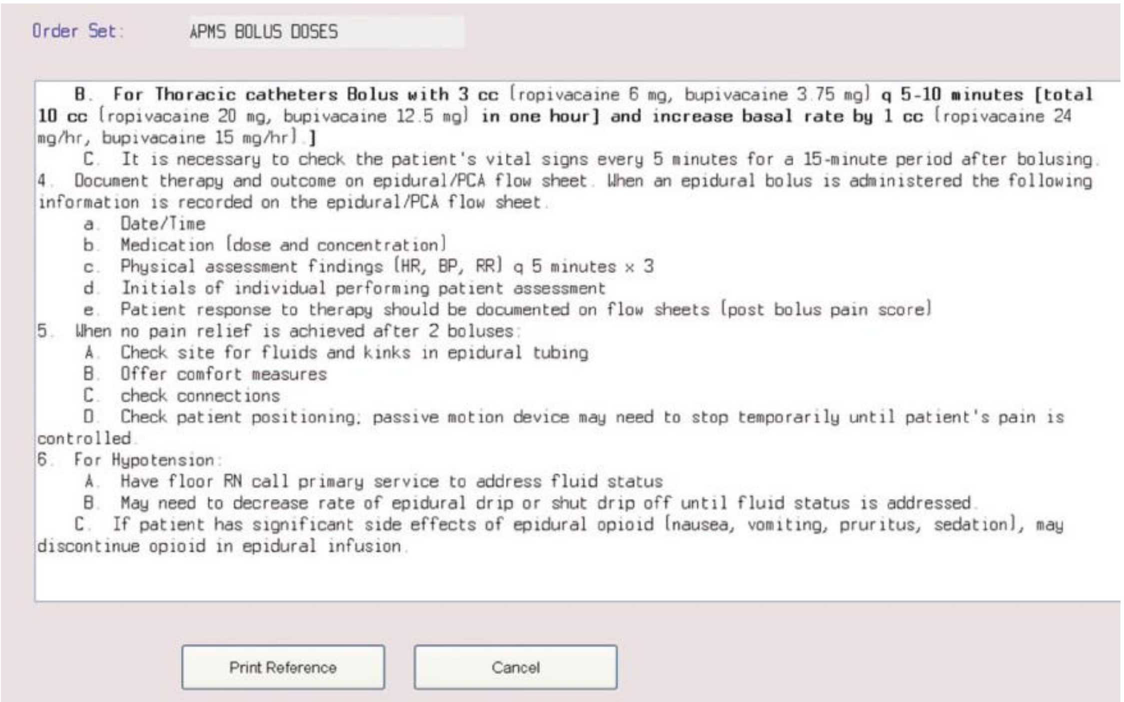
FIGURE 72–1. A standard epidural order form.

long-term methadone maintenance programs. All of these patients have a high tolerance to the antinociceptive effects of opioids,[61] are pain-intolerant,[62] and can have opioid-induced hyperalgesia.[63]

It is important to identify these patients in the preoperative period and establish a sound pain management strategy before surgery. In the postoperative period these patients will often require more than twice their stable opioid dose. This rapid increase in opioid requirement has been termed *acute tolerance.* Patients should receive their daily maintenance opioid dose on the morning of surgery. Even if regional anesthesia techniques are used, these patients must receive their minimum opioid requirement to prevent opioid withdrawal symptoms. In the immediate postoperative period, consider higher than routine



Order Set: APMS BOLUS DOSES

   B. For Thoracic catheters Bolus with 3 cc (ropivacaine 6 mg, bupivacaine 3.75 mg) **q 5-10 minutes [total 10 cc** (ropivacaine 20 mg, bupivacaine 12.5 mg) **in one hour] and increase basal rate by 1 cc** (ropivacaine 24 mg/hr, bupivacaine 15 mg/hr).**]**
      C. It is necessary to check the patient's vital signs every 5 minutes for a 15-minute period after bolusing.
4. Document therapy and outcome on epidural/PCA flow sheet. When an epidural bolus is administered the following information is recorded on the epidural/PCA flow sheet.
      a. Date/Time
      b. Medication (dose and concentration)
      c. Physical assessment findings (HR, BP, RR) q 5 minutes x 3
      d. Initials of individual performing patient assessment
      e. Patient response to therapy should be documented on flow sheets (post bolus pain score)
5. When no pain relief is achieved after 2 boluses:
      A. Check site for fluids and kinks in epidural tubing
      B. Offer comfort measures
      C. check connections
      D. Check patient positioning; passive motion device may need to stop temporarily until patient's pain is controlled.
6. For Hypotension:
      A. Have floor RN call primary service to address fluid status
      B. May need to decrease rate of epidural drip or shut drip off until fluid status is addressed.
   C. If patient has significant side effects of epidural opioid (nausea, vomiting, pruritus, sedation), may discontinue opioid in epidural infusion.

Print Reference | Cancel

FIGURE 72–2. An epidural procedure note.

TABLE 72–4. Common epidural analgesia LA solutions.

Lower extremity (Lumbar Catheters) - Ropivacaine 0.2%/morphine 0.025 mg/mL - Ropivacaine 0.15%/morphine 0.025 mg/mL - Ropivacaine 0.2% (plus patient-controlled analgesia)
Thoracic/Abdominal Surgery (Thoracic Catheters) - Bupivacaine 0.125%/morphine 0.05 mg/mL - Bupivacaine 0.125%/morphine 0.025 mg/mL
Labor and Delivery (Lumbar Catheters) - Bupivacaine 0.1%/fentanyl 1.5 mcg/mL

doses of IV-PCA with morphine or hydromorphone. Hydromorphone and sufentanil are regarded as higher efficacy opioids and may be more helpful in opioid-tolerant patients.

Regional analgesia with local anesthetic and systemic opioid is a more efficient way of providing pain control than parenteral opioids alone. Use of an opioids with high intrinsic efficacy, such as sufentanil, is more effective[64] in the setting of opioid receptor downregulation.[65] These patients may benefit from the regional anesthesia, epidural, or parenteral opioids for a longer period of time than opioid-naïve patients.

Clinical Pearls

- Regional anesthesia with local anesthetic and systemic opioid is a particularly efficient tool in opioid-tolerant patient.
- Opioid with high intrinsic efficacy, such as sufentanil, is more effective.
- Before and after hospital discharge, referral to a pain specialist can be helpful in optimizing management and facilitate dose tapering.

In the postoperative period, converting opioid-tolerant patients to oral opioids can be quite challenging. One approach is to calculate the patient's 24-hour opioid requirement from IV-PCA and give two thirds that amount in the form of a long-acting oral opioid and one third in the form of a short-acting oral opioid to be used as needed. Baseline opioid doses should be tapered slowly to prevent withdrawal. Addition of other adjuncts such as α_2-adrenergic receptor agonists like clonidine, dexmedetomidine, NMDA receptor antagonists, and COX-2 inhibitors all help to decrease opioid need and improve analgesia. Tricyclic antidepressants may help with neuropathic pain, although these agents usually require several weeks to achieve efficacy. Membrane-stabilizing agents (e.g., gabapentin) can be very helpful during the perioperative period in the presence of neurogenic or neuropathic pain. Routine doses of these agents should be continued.

Ketamine is being used more frequently in recent years to help treat opioid-tolerant patients both intraoperatively and postoperatively. Ketamine has been used for decades but fell out of favor for a time due to its psychotropic side effects. These include vivid dreams, hallucinations, confusion, and an

TABLE 72–5. Recommended epidural infusion rate.

Thoracic catheter: 3–6 mL/h
Lumbar catheter: 6–10 mL/h

TABLE 72–6. Management of acute pain in the patient with chronic pain.

Preoperative Phase
1. Identify the patient with chronic pain preoperatively.
2. Assure the patient that pain control is a priority.
3. Evaluate the location and character of chronic pain.
4. Accurately determine the preoperative opioid requirement and identify all other pain medications.
5. Formulate a multimodal analgesic plan (as part of the anesthetic plan) that incorporates the patient's preferences and cooperation.
6. Communicate this plan to the primary anesthesia team and surgeon.

Operative Phase
1. Ensure that patient has received morning doses of opioids and other pain medications and adequate preoperative sedation.
2. Communicate with members of the surgical team the specific considerations for this patient.
3. Incorporate a multimodal approach to the anesthetic (preoperative NSAID or COX-2 inhibitor, possible dose of membrane-stabilizing agents, local anesthetics wherever practical, adequate intraoperative doses of opioids).
4. Ensure that patient is reasonably comfortable before leaving the operating room.

Postoperative Phase
1. Inform recovery room nurse of plan and ensure that patient is comfortable prior to discharge from recovery room.
2. Inform floor staff nurse of plan and provide individual or service to contact for pain issues.
3. Maintain patient's routine pain medications throughout the perioperative period.
4. Consider acute pain plan as an "overlay" on the patient's chronic pain management.
5. Initiate oral therapy as soon as is practical.
6. Utilize extended-release oral opioids to reduce the analgesic "gap" between doses of short- acting opioids.
7. Evaluate patient daily and adjust plan as needed.
8. Pain medication requirements may change drastically during the weeks following discharge, so plan early for outpatient pain management.

Abbreviations: COX-2, cyclooxygenase-2; NSAID, nonsteroidal anti-inflammatory drug.

out-of-body sensation. At high doses, ketamine causes a dissociative anesthetic state. Lower doses (a continuous infusion of up to 1 mg/kg/min) can be used to effectively treat pain in the opioid -tolerant population. The side effects at these doses are minimal and can be improved with benzodiazepines. Where available (Europe), the racemic ketamine (S) can be used to minimize the psychotropic side-effects. Ketamine is effective both in the perioperative period and also in select groups of nonoperative patients, such as those with cancer or sickle-cell disease.[66,67] These nonoperative patients are often on very high doses of opioids and develop remarkable tolerance to those medications.

Many institutions, including our own, have restricted the titration and management of ketamine to the Acute Pain Management Service. Because this drug is an anesthetic, only trained anesthesia providers should manage it. This management should be driven by an APMS-developed protocol.

Regardless of the inpatient therapy selected, referral to a pain specialist can be very helpful in treating the opioid-dependent patient to help optimize pain management during rehabilitation and facilitate opioid dose tapering. Whenever possible, the pain specialist familiar with the patient's history should be involved in the postdischarge pain management. This is best accomplished when the visit occurs prior to surgery or hospitalization to formulate a clear plan. With patients chronically treated with opioids, patients may be better served by having a single opioid prescriber.

Clinical Pearl

- Converting opioid-tolerant patients to oral opioids can be challenging. One approach is to calculate the patients 24-hour requirement from IV-PCA and give two thirds that amount as long-acting medication and one third as short-acting medication as needed.

ACUTE PAIN MANAGEMENT FROM A NURSING PERSPECTIVE

Nurses are a key component of an acute pain service. The pain nursing team may be composed of acute pain management nurses, pain resource nurses, and floor nurses. Acute pain management nurses are dedicated to promoting and providing care for patients in pain. In most settings, acute pain nurses work in collaboration with the department of anesthesiology. Acute pain management nurses operate best within an established framework of hospital-approved protocols and guidelines and through decision trees. Guidelines and protocols are intended to establish the basic standard of care and provide consistency in management.[68] Protocols prescribe methods of care in a less flexible way then guidelines,[69] but neither is a substitute for personal knowledge. Thoughtful application is essential if guidelines and protocols are to be safe and effective.

A nurse-driven acute pain service consists of a physician director and the nursing team. The physician determines the appropriate analgesic technique. The care team, consisting of an attending physician, resident, and an acute pain nurse, assesses patients on morning rounds and develops a comprehensive management plan. A standard daily clinical note will facilitate documentation. The pain management plan is communicated and coordinated by the acute pain nurse to the other members of the patient care team. The pain resource nurse is a floor nurse with special training in the assessment of pain and technical expertise in the various infusion devices. Optimally, every nursing unit has a pain resource nurse to provide peer support to other floor nurses and provide basic troubleshooting and assessment. Standard documentation sheets for pain assessment, epidural, and PCA are helpful. The roles of the various team members are discribed in Table 72–7.

A very specific process is followed so that protocols can be considered, approved, and eventually become part of a standard order set. The proposed protocols are then reviewed by the pharmacy and therapeutics (P&T) committee that makes recommendations resulting from evidence-based practice. The P&T committee is a multidisciplinary group composed of physicians, pharmacists, administrators, and nurses. Standard order sets then typically require the approval of a medical executive committee. Where computer physician order entry is employed (CPOE), standard order sets must be configured to maintain all necessary order details of the protocol. Thus, physicians are able to order a protocol of decision trees that allow the acute pain nurses to follow a defined path in the management of specific pain management scenarios.

With a nurse-driven acute pain service, the pain nurse is the first to respond to calls for the patient's pain issues. Pain nurses must possess astute assessment and critical thinking skills. This requires a background in critical care or postanesthesia care. Utilizing decision trees and critical thinking, pain nurses are called on to manage pain and side effects of pain therapies, troubleshoot epidural and peripheral block catheters, titrating and bolusing as needed, and removing catheters when indicated. Pain nurses must be well trained at assessing hypotension, motor block, and excessive sedation. All actions and interventions of the pain nurse are entirely within the scope of institutional protocols.

Pain management is truly a specialty in nursing. It is recommended that pain nurses become board certified. Attaining certification confirms that the pain nurse has the necessary skills to practice safely and effectively.

Although pain management teams strive to provide an opioid-sparing multimodal pain management regimen, opioids are frequently the primary pharmacologic choice, often necessitated by the increasing numbers of opioid-tolerant patients being admitted to hospitals, as discussed above. In an effort to provide superior care, pain teams may institute plans of care that are quite complex, often including opioids in very high doses. It is for this reason that acute pain nurses must be clinically astute in their assessment and monitoring of sedation and respiratory depression in all patients who are receiving opioids.

Pain management nurses should be familiar with the American Society for Pain Management Nursing Guidelines on Monitoring for Opioid-Induced Sedation and Respiratory Depression.[70] This position paper offers recommendations

TABLE 72–7. Description of roles on an acute pain management service (APMS)[a].

Director	Clinical Nurse Specialist (Advanced Practice Nurse)
• Determines direction of service • Defines and coordinates clinical, educational, and research goals • Develops protocols and policies for pain assessment and treatment • Reviews quality assurance indicators	• Coordinator of services providing continuity of care to APMS patients • Designs and implements educational programs for the department of nursing and patient observation • Responsible for data collection and quality assurance activity • Assists director in development of goals, policies, protocols, and standards
Attending Staff • Conducts daily patient rounds • Performs and supervises regional anesthesia procedures • Performs and supervises consultations • Participates in education and research	**Acute Pain Nurse** • Holds service pager and responds to calls for pain-related problems • Conducts frequent proactive assessments of analgesia and its side effects • Adjusts pain therapy according to algorithms in coordination with residents and staff • Employs complementary techniques (i.e., relaxation, imaging, distraction) • Point-of-care peer support to staff nurses
Residents and Fellows • Daily patient rounds • Responds to APMS consults • Performs various regional anesthesia techniques both preoperatively and postoperatively • When "on-call": rounds with pain nurse late in the day to discuss management issues; available by pager for questions and/or consults throughout the night • Participates in research and education	

[a]All members work together by staying in communication regarding all issues. Frequent discussion about specific patients, especially where therapy is actively being modified.

for analgesic pharmacotherapy, education, and monitoring. It is often the acute pain management nurses who are responsible for disseminating these evidence- based guidelines throughout their facility. This task can be accomplished by establishing hospitalwide, policies and procedures, and educational programs.

In an effort to provide effective and safe pain management, it is imperative to have in place an easy and reliable as well as valid assessment tool for opioid-induced sedation, as opposed to sedation tools that assess purposeful, goal-directed, sedation for procedures or for ventilated critical care patients. In a descriptive survey-based study the POSS (see Table 72–2) scored highest in combined measures of ease of use, nursing confidence, and usefulness of information provided to make clinical decisions. The POSS has been considered to be a superior scale and is recommended for the assessment of sedation in adult patients during opioid administration for pain management in noncritical care settings.[71] In addition, the POSS scale includes directed nursing interventions when advancing sedation is present. Again, acute pain nurses can be instrumental in having this scale added to their facility's nursing assessment tools. The addition of this tool can only facilitate better assessment and, likely, better patient outcomes.

Clinical Pearl

- Pain should always be assessed using a validated pain assessment tool.

Pain nurses are the critical link in providing education and peer support to the various members of the nursing service. Nurse-driven acute pain services function proactively, closely monitoring and anticipating problems. The visible presence of pain nurses increases patient satisfaction, improves pain control and safety, and may improve patient outcome. Busy acute pain services utilizing aggressive regional anesthesia/analgesia techniques and opioid therapies may benefit from an organizational design that places nurses in key patient management positions. A nurse-driven acute pain service integrates the treatment of these patients into the overall hospital milieu, and helps facility institutional consistency in the management of all pain issues within the facility.

PHARMACIST CONSIDERATIONS IN ACUTE PAIN MANAGEMENT

A pharmacist offers a unique perspective when establishing or expanding an acute pain service using regional anesthesia/analgesia techniques. Pharmacists have extensive training in pharmacology, pharmacokinetics, and pharmacoeconomics. In addition to the traditional role of the pharmacist in compounding and dispensing medications, a pharmacist can be a valued team member who provides clinical services in the areas of safe, rationale, and cost-effective drug therapy. Pharmacists may provide patient education and instruction, drug information, and alternative therapy options. Pharmacists may also be included in quality assurance data collection, proper pump selection, proper medication labeling, safety considerations, and the development of policies and procedures. Pharmacists can also be involved in hospital formulary medication decisions and have an important role in evaluating new products for formulary addition.

Pharmacy Considerations With Epidural Delivery

When the technique of epidural and intrathecal administration was developed, it was standard practice to administer medication as a single bolus or multiple as-needed bolus injections. Anesthesiologists generally prepared and administered the doses. This technique, however, may result in periods of inadequate pain control and has been associated with a higher frequency of adverse effects resulting from temporary peak levels of medications creating unwanted side effects.[72] Development of protocols for initial bolus doses followed by continuous infusions with or without patient-controlled epidural analgesia (PCEA) has revolutionized pain management. Continuous infusions of epidural opioids or local anesthetics (or both) avoid the peaks and valleys of pain control and the need for multiple bolus injections.[72–74] Studies comparing continuous infusions and intermittent bolus administration have shown that continuous administration provides better analgesia with lower total doses administered.[73]

Pharmacists should be involved in the procurement and preparation of the epidural continuous infusion solutions. The preparation of epidural infusions must follow strict aseptic techniques outlined by the standard of practice for compounding sterile preparations, published in Chapter 797 in *The United States Pharmacopeia* (USP).[75] Epidural solutions are considered a "moderate risk level" for microbial contamination based on the fact that the solution contains no preservatives. Appropriate labeling of epidural solutions is detailed in Table 72–8.

Peripheral Nerve Blocks and Catheters

Peripheral anesthetic techniques have increased in popularity for the management of acute and chronic pain conditions. Studies have shown that patients who receive peripheral nerve blocks experience reduced postoperative pain and analgesia requirements and report more satisfaction with their pain management.[76] These techniques involve either bolus or intermittent doses, or continuous infusions of local anesthetics through a catheter near or around the nerve or nerve plexus that supplies the surgical area.[77,78]

A perineural placement of catheters for continuous local anesthetic is growing in popularity.[79–81] This technique of continuous peripheral nerve blocks or perineural local anesthetic infusions involves the percutaneous insertion of a catheter directly adjacent to the peripheral nerves or plexuses supplying an affected surgical site.[82] In the hospital setting, local anesthetic infusions can be prepared by the pharmacy, and the continuous infusion can be accomplished with an infusion pump. In recent years, smaller electronic infusion pumps, syringe pumps, elastomeric pumps, and spring-powered pumps have been designed for use in the ambulatory setting. Because of the inherent risks of sending a patient home with an infusion device, most published studies limit ambulatory use of the pumps to patients expected to have moderate to severe postoperative pain of a duration of more than 24 hours and who will have difficulty managing the pain with oral opioids.[82] In addition, special consideration must be given to the caregiver's capability for managing the pump or the need for home care or visiting nurses to monitor, regulate, or discontinue the infusion.

An alternative to continuous regional blocks is continuous infusion of local anesthetic directly into the wound site.[83] A pump is attached to a catheter inserted near an incision site. The pump infuses a continuous flow of local anesthetic and may include the capability for patient control. For wound instillation devices, the local anesthetic may be added to the device in the sterile environment of the operating room or added into the device by pharmacy personnel using aseptic technique.

With the capability of infusing local anesthetics epidurally, intrathecally, peripherally, and topically, guidelines must be established for all healthcare providers to be aware of the type and route of local anesthetic administration. Unintentional administration of local anesthetic via two different routes may increase the risk for systemic toxicity. To prevent double administration, all local anesthetic administration should be documented in the patient chart. If CPOE is available, all orders should be entered into the computer. A warning screen should appear if duplicate local anesthetic orders are entered for a patient.

With the evolution of multimodal therapy, anesthesiologists and surgeons must communicate regarding all pain management therapy. In addition, pharmacists must review medication profiles and be aware of all local anesthetics dispensed and administered to patients. Pharmacists play a crucial role in monitoring the overall pharmacologic management of the patient.

Infusion Devices

Pharmacist involvement in the selection of infusion devices will offer a unique perspective on the advantages and disadvantages of various pumps. Many factors must be considered to determine the optimal device for a given clinical situation. Infusion devices should be safe, accurate, reliable, easy to use, and compatible with the drug-delivery systems available.[74] For the management of acute pain, an external pump is standard. Several external devices are available on the market, including syringe pumps, peristaltic devices, and elastomeric reservoir pumps. When selecting a pump, several factors should be considered, including the acceptable infusion rate accuracy, PCA bolus capability, and total local anesthetic volume required.

Syringe pumps are used to deliver the contents of a syringe over a given period.[74] These devices can be programmed to deliver the contents of a syringe over several hours to several days. These pumps are commonly used for the delivery of opioids for IV-PCA. Prefilled morphine and meperidine syringes are commercially available. Pharmacy personnel or pharmacy outsourced compounding companies must compound other opioids or differing concentrations of commercially available products. Most of these devices must be locked to prevent patient manipulation and to prevent diversion of a controlled substance.

Peristaltic devices deliver a drug from a flexible reservoir via administration tubing that is mechanically squeezed.[74] These pumps are traditionally used to administer intravenous fluids. Some peristaltic devices have locked chambers to secure solutions. This would be of benefit for opioid infusions. Peristaltic pumps can accommodate larger volumes of solution. Flow rate capabilities range from 0.1 to 999 mL/h. Newer pumps have more sophisticated programming, allowing for minimum and maximum rates of any drug programmed into the device. Some programs also calculate infusion rates based on the patient's weight and the amount of drug to be administered per minute or hour. This new technology was developed to help prevent potential medication errors.

Elastomeric reservoir pumps force fluid through a flow regulator via elastomeric pressure of a balloon reservoir.[74] Depending on the brand, the reservoir volume varies, allowing for varying rates and length of therapy. This technology is used for continuous delivery of local anesthetics for continuous peripheral blocks or instillation directly into the wound.

Regardless of the type of infusion pump used, the maximum reservoir volume must be considered when establishing the use of epidural solutions or continuous nerve infiltrations. In addition, the range of administration rates is a critical factor in epidural delivery of medications. [74] Epidural infusion rates vary depending on the location of the epidural catheter and the drugs administered into the epidural space. Rates greater than 20 mL/h are generally not indicated.

When choosing an infusion device, consideration should be given to devices that allow for safe and secure administration of solutions while maximizing the time between refills or the interval between bag, syringe, or cassette changes. Smart infusion technology now allows for increasingly sophisticated programming features including close error reduction software, commonly known as drug libraries.[84] This technology allows infusion pumps to perform functions that assist healthcare providers with accurate programming. However, while smart pump technology helps reduce medication error, it is not intended to replace clinical judgment. The potential for pump misidentification or confusion is ever-present, leading to medication errors or error in route of deliver. From a systems standpoint, rigorous policies are needed to prevent medication errors. This may include special labeling, route-specific tubing, and dedicated pumps for specific techniques, color-coding of labels and tubing, and two practitioner pump set-up checks. Representatives from the departments of biomedical engineering, nursing, anesthesiology, and pharmacy should all be involved in pump selection.

Solution Preparation, Stability, and Sterility

As described previously, pharmacists offer many valuable services to all areas of patient care. In regard to regional anesthesia, the most important contributions include accurate preparation and assurance of sterility and stability for all solutions prepared.

Any drug administered into the epidural or intrathecal space must be free of neurotoxic preservatives.[73,85] Agents containing preservatives such as methylparaben, benzyl alcohol, methylhydroxybenzoate, propylhydroxybenzoate, phenol, and formaldehyde must be avoided.[73,85] Standard epidural preparations guidelines call for the use of preservative-free solutions.

Although infection of the epidural or intrathecal space is rare, it can be fatal, as evidenced by the outbreak of fungal meningitis from contaminated lots of methylprednisolone acetate compounded by the New England Compounding Center, Framingham, MA. As of May 6, 2013, 741 reported cases of fungal meningitis and other fungal infections had been reported with 55 deaths in 20 states attributed to the contaminated methylprednisolone product.[86] Preparation of all epidural solutions must be performed with strict adherence to sterile aseptic technique. As of January 1, 2004, the Joint Commission officially surveys accredited organizations for compliance with the USP general Chapter 797, Pharmaceutical compounding—sterile preparations.[75] USP Chapter 797 details the procedures and requirements for compounding sterile preparations and sets standards that are applicable to all practice settings in which sterile preparations are compounded. Based on these guidelines, because epidural solutions contain no preservatives, they are considered to be a medium risk for microbial contamination. Certified pharmacy personnel using a laminar flow hood should prepare epidural, intrathecal solutions as well as solutions for continuous peripheral neural blockade.

The stability of morphine, fentanyl, hydromorphone, and fentanyl mixed with various local anesthetics in a variety of syringes and reservoirs has been studied.[87–90] Solutions studied maintained potency for at least 12 days. However, the risk of microbial contamination in preservative-free solutions is problematic. Current guidelines from the Centers for Disease Control and Prevention (CDC) recommend that preservative-free infusion solutions be completely used or discarded within 24 hours of preparation when not refrigerated.[73,91,92] CDC guidelines also recommend that preservative-free solutions be stored under refrigeration for no more than 7 days.[91] Refrigeration must be continuous and occur immediately after mixing the solution. After the product is dispensed for patient use, a 24-hour expiration date must be applied. USP Chapter 797 gives a medium risk level to preparations 30 hours at room temperature and 7 days under refrigeration.[75] According to

USP Chapter 797, if the product is not made in a laminar flow hood, it will be considered high risk and should be used within 24 hours.[75] It would be prudent for institutions administering epidural, intrathecal, and continuous peripheral local anesthetic solutions to have the solutions prepared in accordance with USP Chapter 797.

Standardization of Regional Anesthesia Continuous Solutions

Standardizing epidural solution volumes, medications used, and drug concentrations is important consideration when establishing an epidural program. Consistency in prescribing and preparing epidural, intrathecal, and continuous peripheral local anesthetic solutions helps to reduce the potential for medication errors and simplifies the preparation process.[93–95] Having a limited number of concentrations for epidural solutions will prevent medication errors in prescribing, preparing, and administering epidurals. Pharmacists should work with anesthesiologists to determine dosing ranges for epidural drugs. Pharmacists should be familiar with the dosing ranges and should question orders that deviate from established guidelines. It would be beneficial to minimize the size of the solution bag for epidurals. If the rate of an epidural is mistakenly increased, a limited amount of epidural solution would be infused at the incorrect rate.

When initially establishing standard epidural solutions, physician preference and stability considerations should be assessed.[95] Decisions regarding standard epidural preparations must also take into consideration safety, cost, time, narcotic accountability, and reservoir volume of the infusion device.[93–95] When possible, using whole rather than partial ampules and vials and using available package sizes of the drugs will help to minimize waste.[95] This is beneficial in helping to keep narcotic inventories as simple as possible. Although standard epidural solutions are usually adequate for most patients, it should be noted that these standard preparations might not be suitable for every patient. There may be instances when a patient requires a specialized preparation. The patient may have an allergy to one of the standard epidural components, or the patient may have a history of opioid tolerance and will require higher concentrations. If a nonstandard epidural is ordered, highlighting the concentrations may help to prevent confusion and errors.

Standardization of epidural solutions may allow for batch preparation. Batch preparation helps to prevent a delay in starting an epidural. In addition, depending on the infusion rate, more than one infusion bag may be needed per day. If an infusion is running dry, having batched solutions available prevents the possibility of interrupting continuous pain therapy. Batching puts less stress on pharmacy personnel preparing solutions and on nurses in a need of a new solution bag. However, maintenance of continuous pain relief therapy for the patient is the most important benefit. To provide the maximum expiration dating, certified individuals should do batch preparation of epidural solutions without preservative under strict aseptic conditions. Storage should be in accordance with the CDC and USP Chapter 797.[75]

Compounding pharmacies offer a wide range of sterile pharmaceutical products, including epidural infusions, PCA syringes, and prefilled elastomeric pain devices in various volumes and drug concentrations. Currently, compounding pharmacies are not regulated by the FDA, although legislation has been proposed for federal regulation. If an institution purchases sterile compounded products from a compounding pharmacy, appropriate quality assurance measures must be ensured. Expiration dating is extended beyond 7 days based on USP Chapter 797 guidelines. Institutions handling a large number of surgical and obstetric cases may find this service of use because compounding large amounts of epidurals requires additional staffing, supplies, and time. Therefore, the cost of the compounded products should be weighed against pharmacy considerations associated with preparing the solutions.[95]

Safety Considerations

Medication errors related to the use of opioid infusions and epidurals are among the most frequently reported.[93] To help prevent medication errors, it is imperative that all epidural solutions be labeled in a clear, concise, consistent manner. Labels should be legible and permanently affixed to the infusion bag or syringe in a manner that makes it easily readable.[92] The patient's name, date of preparation, and solution expiration should be clearly stated. The medication contents should be distinctly labeled with the name of the drugs and volumes used to prepare the solution. In addition, the final concentration and total volume should be clearly marked on the bag in bold lettering. Last, a bright auxiliary label reading *For Epidural Use Only* should be affixed to the bag or syringe.

Drugs intended for intravenous administration have been accidentally administered into the epidural or intrathecal space.[73,93–94] An error in the route of administration could have catastrophic consequences. The route of administration must be clearly noted on all order forms. Drug concentrations vary dramatically between intravenous, continuous peripheral block, epidural, and intrathecal routes. If an intravenous solution of morphine 1 mg/mL is administered epidurally, respiratory depression and death may result. In addition to anesthesiologists and nurses, pharmacists should be familiar with dosing ranges and standard concentrations for epidural and intrathecal preparations.

Proper labeling of the epidural tubing is also imperative. It is recommended that the distal ends of epidural and intravenous lines be labeled to clearly differentiate them.[93] A line dedicated to the administration of epidurals with port-free tubing should always be used to prevent accidental epidural administration of drugs intended for intravenous use.[93–94] It is also helpful to use single-chamber pumps dedicated to epidural infusions. Infusion pumps should also be labeled *For Epidural Use Only.* If a multiple-chamber pump must be used for epidural administration, the other chambers should not be used for the infusion of any other medications. If an adjustment in rate or another medication is administered to the patient, nurses should always trace the tubing from the insertion site to a pump. If more than one pump is being used, placing the IV pump on the opposite side of the patient's bed from the epidural pump may help to prevent mistakes.[93]

   c. Uncontrolled pruritus
9. Instructions for whom to contact if problems occur
10. Date, time, and signature of prescribing anesthesiologist

Healthcare practitioners should be aware of the potential for error with handwritten orders. Only proper abbreviations should be accepted, and clarification of any order should be completed prior to processing. The use of preprinted order forms has helped to reduce these types of errors. The ASA Task Force on Pain Management has established guidelines for the use of preprinted order forms in acute pain management.[96] The key elements for epidural analgesia preprinted order forms are listed in Table 72–9.

Clinical Pearl

- The service or anesthesiologist managing the epidural should be the only service or anesthesiologist prescribing additional sedatives or opioids.

If a patient is receiving an epidural opioid, prescribing other sedative agents should be done with extreme caution. The service or anesthesiologist managing the epidural should be the only service or anesthesiologist prescribing other sedatives. If another service prescribes another sedative, the pharmacist should intervene and notify the service managing the opioid epidural. If CPOE is available, a warning screen should be displayed if a sedative is ordered. The pharmacist's role in regional anesthesia may include reviewing patients' drug therapy, optimizing medication selection, and developing policies and procedures. Pharmacists also supervise and evaluate solution preparation, stability, storage, and safety issues. Additionally, the pharmacist can provide information on the cost of different mediation modalities, offering suggestions for the most cost-effective choices.

CONSIDERATIONS FOR THE FUTURE: POLICIES IN THE UNITED STATES

A recent strategy in improving patient care has focused on patient satisfaction. In 2008, a new initiative, the Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS), was launched to measure how hospitals are meeting patient needs.[97] Hospitals self-administer questionnaires that address six main issues related to patient experience: Communication with Nurses, Communication with Doctors, Staff Responsiveness, Pain Management, Communication about Medicines, and Discharge Information, in addition to one composite that combines the hospital Cleanliness and Quietness survey items; and one Global item, Overall Score of hospital. It is designed to allow patients to "make 'apples to apples' comparisons to support consumer choice"[97] by having a standardized measurement tool. However, it is also being used by the Center for Medicare and Medicaid (CMS) to modulate payment to hospital and physician groups, starting in Fiscal Year 2013. The Hospital Value-Based Purchasing (Hospital VBP) program links a portion of hospital pay to performance on a set of quality measures with two parts, the Clinical Process of Care and the Patient Experience of Care; the latter part is based on HCAHPS. Put another way, patient experience will determine up to 30% of reimbursement for services the medical team provides.[98]

Anesthesiologists have a unique and important role in this new framework because of their input regarding inpatient pain control. Their interactions with patients can significantly alter patient experience, and downstream alter compensation. Studies have demonstrated that a high level of pain control is strongly correlated with overall satisfaction and higher HCAHPS scores.[99] Implementation of an APMS helps to facilitate this interaction by helping patients achieve improved pain scores, particularly in the population where standard treatments are not adequate. Having a team available with specialized expertise may make the difference in how a patient perceives their experience.

While patient satisfaction is obviously an important part of why patients choose a particular healthcare system, certain members of the medical community have started to question whether such strong focus on making patients happy is actually improving outcomes. An interesting study published in the *Archives of Internal Medicine* systematically addresses this question. A prospective cohort study was performed on a large population across the United States comparing patients' satisfaction scores with mortality and healthcare utilization measures over a 7-year period. The results of the study were surprising. Patients in the highest quartile of patient satisfaction scores had statistically significant increased mortality when adjusted for various socioeconomic and environmental factors.[100] As the practice of medicine evolves we must decide where is the line between patient happiness and good medicine? And when, or should, we have to sacrifice one to achieve the other? The answers to these questions are not simple, and it is not within the scope of this chapter to discuss them. However, these considerations are important for pain providers to bear in mind in striving to care for patients.

SUMMARY

Anesthesiologists, surgeons, pharmacists, and various members of the nursing team all have important roles when considering the organization of an acute pain service. Acute pain management requires a multimodal and multidisciplinary approach with a clear organizational framework. Regional anesthesia techniques for surgical anesthesia are a highly effective component of acute pain management. Maximizing the contributions of regional anesthesia to acute pain management requires integrating these techniques into the larger framework of patient care. This requires an organizational framework that includes all members of the healthcare team, standard order sets, assessment and documentation forms, and institutionwide policies and procedures for the management of aggressive pain techniques.

Clinicians comprising of acute pain team must regard their efforts as extending beyond the operating room and postanesthesia care unit. The team improves not only the experience of the patients they directly care for, but also the entire healthcare system by instituting protocols and safety measures that impact all patients. These specially trained clinicians are uniquely positioned to assist and lead efforts to make these broader changes, which are vital to optimizing patient experiences. Unwavering institutional commitment to these measures is imperative.

CHAPTER 73

Neurobiologic Mechanisms of Nociception

Qing Liu and Michael S. Gold

INTRODUCTION

Optimal postoperative pain management is a clinical priority because poorly managed pain may delay functional recovery from surgery and /or lead to chronic pain.[1] Nevertheless, despite considerable effort to improve postoperative pain management, one third of patients continue to suffer from moderate to severe pain.[2] The lack of consistently effective analgesics devoid of deleterious consequences remains one of the main causes of the inadequacy of postoperative pain management. Therefore, identification of novel therapeutic targets and more effective management strategies remain high priorities in pain research.

To provide a framework to facilitate understanding of the mechanisms underlying the efficacy of currently available pain management strategies, at least some of the reasons for the failure to achieve adequate pain relief, as well as identify viable targets for future interventions, this chapter covers fundamental neurobiologic mechanisms of the nociceptive system. Given space constraints, and the fact the functional alterations of the nociceptive system in the context of chronic pain are addressed in more detail in subsequent chapters, this issue will be not be discussed at length here.

NEUROBIOLOGIC MECHANISMS OF PAIN

Overview of Nociceptive/Pain Pathway

The simplest depiction of the neural circuit underlying the perception of pain in response to noxious or potentially tissue damaging stimulation of peripheral tissue involves three neurons. The first is a nociceptor, a specialized primary afferent neuron with a peripheral terminal innervating the site of stimulation, a cell body in a spinal or dorsal root ganglia or trigeminal ganglia, and a central terminal in the spinal cord or brainstem dorsal horn. The second is an "output," or projection, neuron in the spinal cord/trigeminal dorsal horn that receives input from the nociceptor and projects to the thalamus. And the third neuron projects from the thalamus to the sensory cortex. But as a sensory and emotional experience that is highly motivational (i.e., withdrawal/escape), pain necessarily involves far more than three neurons. This point is further underscored when one considers the heterogeneity of the pain experience which varies in intensity, quality, duration, location, emotional valence, whether it is evoked or ongoing, and so on.

The integration of nociceptive information in supraspinal regions leads to complex sensory, emotional, and motivational components that make up the perception of pain. Ascending sensory information reaches many cortical sites via parallel pathways. Along the way, however, this information also impinges upon subcortical and brainstem sites that underlie coordinated physiologic responses required for "fight or flight" as well as the modulation of the ascending nociceptive signal. Projections from the brainstem to the spinal cord are referred to as descending modulations. These sites may also be accessed via therapeutic interventions to block or attenuate pain (Figure 73–1, Table 73–1).

PERIPHERAL MECHANISMS

Nociceptors and Signal Transduction

In contrast to other afferent subtypes responsible for signaling low-threshold mechanical stimuli (touch, vibration, stretch), the peripheral terminals of nociceptors, sensory neurons that encode noxious, or potentially tissue-damaging stimuli, are not associated with a particular cell type or structure. Rather, they are said to terminate in "free" nerve endings. Consequently, while there is increasing evidence indicating that other cells in the periphery, such as the urothelial cells that line the bladder[3] or the keratinocytes that make up skin,[4] contribute to the afferent response to noxious stimuli, as predicted, there is also evidence the nociceptors express proteins that enable them to respond to noxious thermal (heat and cold), mechanical, and chemical stimuli.[5]

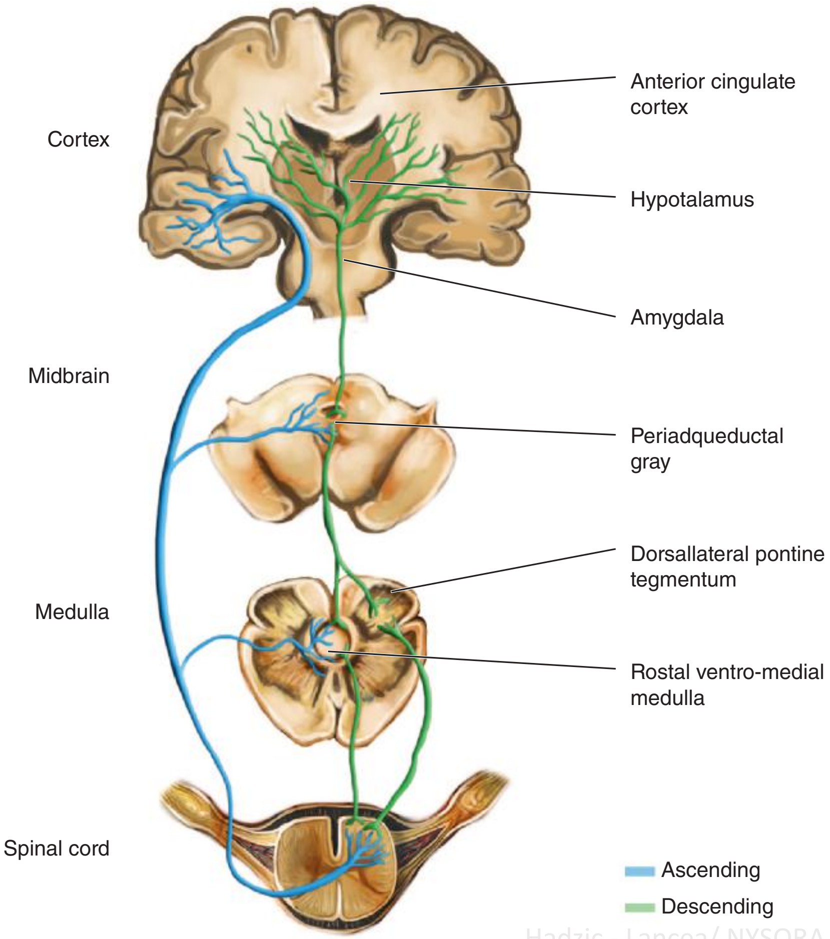

FIGURE 73–1. Overview of nociceptive pain pathway. Major structures in ascending and descending nociceptive pathway. Ascending: primary afferent fibers provide nociceptive input to the spinal cord, which projects to brainstem (spinomedullar tract) and thalamus (spinothalamic tract). The projections ultimately target the hypothalamus, amygdala, and somatosensory cortex to process the sensory, affective, and cognitive components of pain. Descending: Brain structures relevant for the affective and cognitive components of pain (Insulate cortex, amygdala, and hypothalamus) exert descending nociceptive control. The PAG and RVM are to integrate input from cerebral structures and relay processed information to the spinal dorsal horn. Nuclei at the dorsolateral pontine constitute a second most important structure projecting to the dorsal horn. PAG: periaqueductal gray; RVM: rostral ventromedial medulla.

Thus, nociception typically starts when noxious mechanical, thermal, and/or chemical stimuli act on these specialized proteins or receptors. To enable the energy of the noxious stimulus to be converted, or transduced, into an electrical signal, these receptors either contain an ion channel, or are coupled to an ion channel, such that receptor activation results in a change in membrane conductance and, consequently, membrane depolarization. Such a depolarization is referred to as a generator potential, which passively spreads through the peripheral terminal. If the generator potential is large enough and/or spreads far enough to drive activation of enough voltage-gated Na^+ channels, an action potential is generated. This process is referred to as transformation. The action potential is propagated along slowly conducting unmyelinated (C fibers), or more rapidly conducting thinly myelinated (A delta fibers) axons of the nociceptors to the central terminals in the superficial layers of the spinal cord dorsal horn. As the action potential invades the central terminals of nociceptive afferents, voltage-gated Ca^{2+} channels are activated, enabling Ca^{2+} influx necessary for transmitter release. While subpopulations of nociceptive afferents contain neuropeptides that can act within the dorsal horn, all nociceptive afferents use the excitatory amino acid, glutamate, as a transmitter for fast excitatory signaling via ionotropic glutamate receptors on postsynaptic neurons.

The majority of cell surface proteins studied in detail for the process of nociceptive signal transduction, transformation, propagation, and transmitter release fall into two major classes: ion channels and metabotropic receptors. The former are further subdivided into voltage-dependent or voltage-independent channels, Ca^{2+}–activated/modulated channels, and ligand-gated channels. The latter are subdivided into G protein–coupled receptors (GPCRs), and receptor tyrosine kinases and non–tyrosine kinase receptors. A detailed review of these proteins has been provided elsewhere.[5] The following is a brief description of the channels, at each phase of the process, that serve as targets for the currently available therapeutics.

Ion Channels

While many ion channels have been identified that are involved in signal transduction, transformation, and propagation, very

TABLE 73-1. Glossary.

- **Action potential,** electrical signal propagated along neuronal processes that enables communication to postsynaptic neurons in the pain pathway
- **Allodynia,** pain evoked by a normally innocuous stimulus
- **Central sensitization**, increased synaptic efficacy in central (spinal dorsal horn) neurons leading to increased pain perception
- Generator potential
- **Hyperalgesia**, increased pain perception elicited by a noxious stimulus; **primary hyperalgesia**, hyperalgesia in the area of injury or exposure to noxious stimulus; **secondary hyperalgesia**, hyperalgesia in the region surrounding the area exposed to a noxious stimulus. Reflecting a decrease in threshold and/or increase in suprathreshold response.
- **Inflammatory pain,** pain associated with tissue injury and inflammation
- **Nociception**, neural process of encoding the processing noxious stimuli
- **Nociceptors**, peripherally localized primary afferent nerve fibers capable of encoding noxious stimuli
- **Noxious stimuli,** damaging or potentially damaging stimuli (mechanical, thermal and chemical) that provoke and avoidance response
- **Plasticity,** a dynamic modulation of signaling
- **Sensitization**, increased excitability of nociceptors, which usually develops as a

few are currently targets for therapeutic interventions. These include several members of the transient receptor potential (TRP) family, voltage-gated Na^+ channels, and voltage-gated Ca^{2+} channels. However, because an antiepileptic compound approved for use in Europe targets a K^+ channels, we have included a brief discussion of this channel as well.

TRP Channels

Long before the discovery of the TRP vanilloid type 1 (TRPV1) as the receptor for capsaicin, the pungent compound in chili peppers, there was evidence that this compound had efficacy for the treatment of pain. Applied cutaneously via a variety of vehicles, this compound was shown to block pain by "desensitizing" cutaneous tissue to thermal, mechanical, and chemical stimulation. This appeared to be due Ca^{2+} influx and the subsequent retraction of afferent terminals from the sight of the capsaicin application.[6] This phenomena serves as the basis for the therapeutic efficacy of the various preparations of capsaicin currently in use today, which includes the capsaicin patch (Qutenza) for the topical treatment of pain for postherpetic neuralgia.[7] Most recently, in this regard, is the use of intrathecal administration of the ultrapotent TRPV1 agonist, resiniferatoxin, as a way to selectively "ablate" the central terminals of nociceptive afferents as an effective way of blocking pain from even deeper peripheral structures.[8]

The identification of TRPV1 as the target for capsaicin has proven to be a watershed in the pain field for the number of additional observations that have arisen from its discovery. First, it was shown that TRPV1 is not only a receptor for capsaicin, but functions as a "heat" receptor, playing a major role in the heat hypersensitivity observed in the presence of inflammation. It is also activated by a number of endogenous mediators associated with tissue injury and/or inflammation, such as protons, and a variety of lipids. And it serves as a common target for a variety of second-messenger cascades activated with tissue injury, resulting in the sensitization of the receptor (such that it is activated with lower intensities of stimulation), and increases in receptor density as a result of altered trafficking, translation, and expression. Consequently, a number of antagonists of TRPV1 have been developed, at least one of which made it into clinical trials.[9] Unfortunately, because this channel also functions in the neural circuits controlling core body temperature, hyperthermia was the side effect that stopped the further development of these compounds (although there is some evidence that it may be possible to avoid this side effect with a properly targeted compound.[10] Finally, because the TRPV1 channel dilates with prolonged activation, there is evidence that the channel can be used to enable a nociceptor-specific nerve block.[11]

Other members of theTRP family have also been studied. Most notable are the TRPM8 (sensing coldness and menthol) and TRPA1 (sensing noxious coldness, pungent chemicals, such as cinnamon and wasabi, and acrolein) receptors. Low concentrations of menthol (0.01%–1.0%) have been used in over-the-counter analgesics.[12]

Voltage-Gated Ion Channels

Voltage-gated Na^+ channels (NaVs) play an essential role in the initiation and propagation of action potentials. NaV channels are composed of α- and β-subunits. Nine isoforms of the α-subunit (NaV1.1 –1.9) have been identified, with three (NaV1.7, 1.8, and 1.9) preferentially expressed in nociceptors. Compelling lines of evidence have implicated each of these subunits in the pain and hypersensitivity of inflammation and/or nerve injury, and, consequently, all three subunits remain activity targets of drug development. However, because of the high homology between α-subunits in both the voltage sensor and pore domains of the channel, subtype-selective antagonists have remained elusive. Nevertheless, even nonselective Na^+ channel blockers, such as local anesthetics, antiepileptics, and even tricyclic antidepressants, have therapeutic efficacy for the treatment of pain. The most widely used of these, of course, are the local anesthetics, that have remained the mainstay of regional anesthetic techniques, and enable complete pain relief with an appropriately placed peripheral nerve block.

The high-voltage–activated (HVA) Ca^{2+} channels are essential for the transmitter release at the central terminal of the primary afferents.[13] Consequently, they are a primary mechanism underlying presynaptic inhibition via endogenous signaling mechanisms involving adrenergic, gababergic, and opioidergic receptors. Thus, HVA channels are a primary target for exogenous agonists of these receptors such as clonidine and

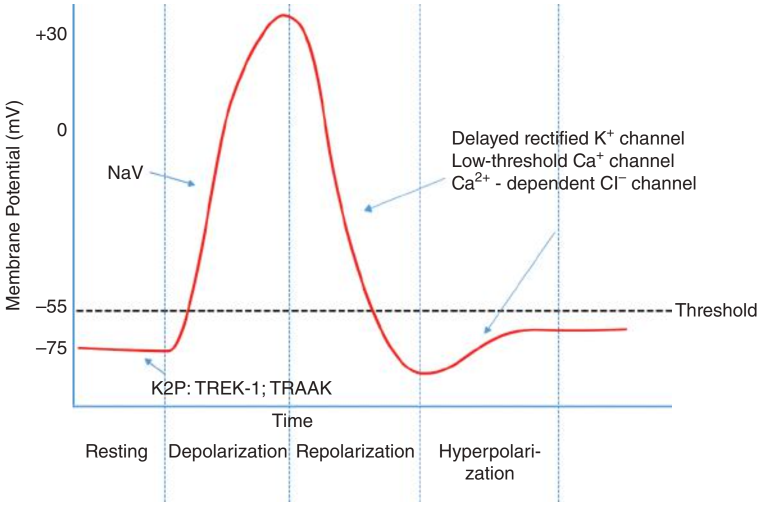

FIGURE 73–2. Schematic diagram of neuronal membrane and action potential showing typical ion channels for each of the phases (resting, depolarization, repolarization, and hyperpolarization). K2P: two-pore domain potassium channel; TREK1: TWIK-related potassium channel 1; TRAAK: TWIK-activated arachidonic acid potassium channel; NaV: voltage-gated sodium channel. Each of the ion channels could serve as a novel therapeutic target.

morphine. Direct inhibition of these channels is also useful for the treatment of pain, as has been demonstrated for ziconotide.[14] Furthermore, because tissue injury may result in the upregulation of the alpha2delta subunit, which is critical for trafficking HVA channels to the afferent terminals, and this subunit is the primary binding site for gabapentin and pregabalin, the available evidence suggests that the analgesic efficacy of these compounds is ultimately due to the inhibition of HVA channels.[15]

K^+ channels are crucial to maintain the membrane potential and the repolarization of the action potential. K^+ channel openers effectively decrease the membrane excitability, making them potentially powerful therapeutic targets. Consistent with this suggestion, retigabine, a K^+ channel opener, may hold a promise for the treatment of inflammatory pain[16] (Figure 73–2).

G Protein–Coupled Receptors

GPCRs are a large family of receptors that underlie both pronociceptive pathways, such as those associated with inflammatory mediators (CGRP [calcitonin gene–related peptides, bradykinin and prostaglandin), as well as antinociceptive pathways, such as opioids and adrenergic receptors. While many targets have been explored for therapeutic use, currently available analgesics appear to focus on the three major pathways: (1) the inhibition of HVA channels as noted above, (2) the activation of K^+ channels, most commonly G protein–gated inwardly rectifying K^+ (GIRK) channels,[17] and (3) the inhibition of pronociceptive second-messenger cascades via the inhibition of adenylate cyclase.[18] While the activation of GIRK channels is a common mechanism of inhibition in the central nervous system, there are only indirect lines of evidence suggesting that such a mechanism contributes to the GPCR-induced inhibition of nociceptor signaling. In contrast, the inhibition of adenylate cyclase appears to be particularly important for the antinociceptive actions of peripherally administered opioid agonists.[18] It is important to note that there are GPCRs that appear to be uniquely engaged, enabling the therapeutic specificity of triptans ($5\text{-}HT_1$ subtype–selective agonists); e.g., for the treatment of migraine.[19] More recently, a biologic approach has been developed to block pronociceptive GPCR signaling, with antibodies against CGRP or the CGRP receptor showing efficacy in initial trials for the treatment of migraine.[20] It is interesting in this regard as to why antagonists for the receptors of major proinflammatory mediators such as prostaglandin and bradykinin have not done better in clinical trials, but this may be a reflection of the parallel pathways activated in the presence of inflammation, as well as crosstalk between pathways. The extent of the crosstalk is illustrated by considering modulation of TRPV1 (Figure 73–3).

Neurotrophin Receptors

Neurotrophic factors are not only essential for survival and axon guidance during development, but are also important for maintaining afferent phenotype and, more relevantly, pain in adults. The best studied of these in the peripheral nervous system is nerve growth factor (NGF), which is dramatically upregulated in the presence of inflammation,[21] and has been shown both to acutely sensitize TRPV1 and NaV channels as well as drive longer term changes in gene expression that appear to contribute to the manifestation of inflammatory pain.[22] However, while preclinical data are all very promising, the phase 3 clinical trial of an NGF antibody for the treatment of osteoarthritis was stopped because of unexplained joint damage.[23] Another neurotrophic factor that also appears to contribute to inflammatory hypersensitivity is artemin, a member of the glial cell line–derived family of trophic factors. Artemin is also increased in the presence of inflammation and appears to act synergistically with NGF to prolong the sensitization of nociceptor afferents.[24] However, there is evidence that under certain conditions, artemin may also attenuate nociceptive signaling, particularly in the presence of nerve injury.[25] There are ongoing clinical trials with artemin, also called neublastin, for the treatment of neuropathic pain.

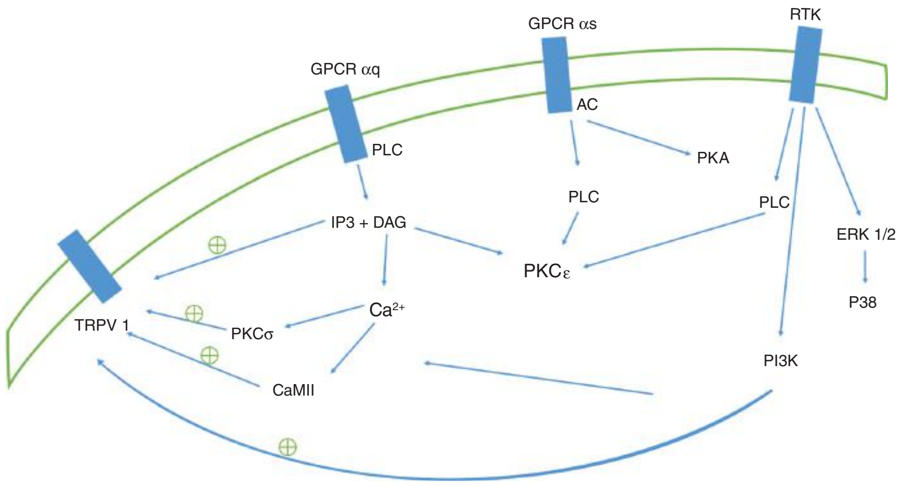

FIGURE 73–3. TRPV1 as a common target of multiple-second messenger signaling pathways after nociceptor activation. There are multiple other points of interaction between each pathway, including at the level of signaling molecules such as Ca^{2+}, and effector molecules such as PKCε. CaM: calmodulin; PLC: phospholipase C; DAG: diacyglycerol; IP3: inositol triphosphate; AC: adenylate cyclase; PI3K: phosphoinositide 3-kinase; ERK 1/2: extracellular signal-regulated kinases 1 and 2; RTK: receptor tyrosine kinase.

SPINAL MECHANISMS

While the nociceptive signal is subject to a considerable degree of modulation from the site of its initiation in the periphery, this modulation pales in comparison to the degree that it occurs in the spinal cord dorsal horn. Organized in cytoarchitecturally distinct parallel laminae, the major components of the spinal cord dorsal horn include the central terminals of primary afferents, the terminals of axons from neurons located at other segments, the brainstem or higher brain structures, interneurons, projection neurons, and glia. Nociceptive afferents terminate predominantly in the superficial layers of the spinal cord (lamina I and II), as well in lamina V, while nonnociceptive input largely terminates in laminae III and IV (Figure 73–4). While there is evidence of monosynaptic connections between nociceptive afferents and projection neurons, the majority of input and output from the dorsal horn is organized in microcircuits with both inhibitory and excitatory interneurons that serve to sculpt both the temporal and spatial features of the sensory input.[26] Emerging evidence suggests that this circuitry is also critical for defining the sensory features of the input, such as would be needed to distinguish itch from pain.[27] Importantly, these microcircuits appear to be the substrate upon which descending input from the supraspinal and intrasegmental sites acts to modulate sensory signals. Glutamate is the major neurotransmitter released by excitatory primary afferents and interneurons, which binds to ionotropic glutamatergic receptors, such as N-methyl-D-aspartate (NMDA) receptors. Gamma-aminobutyric acid (GABA) and glycine are the main neurotransmitters released by inhibitory interneurons and descending inputs (Figure 73–5).

Both tissue inflammation and nerve injury can result in abnormal pain sensations, including hyperalgesia, allodynia, and spontaneous pain. Several changes in the spinal cord that could underlie these phenomena have been reviewed.[28] They include intrinsic plasticity of dorsal horn neurons, changes in

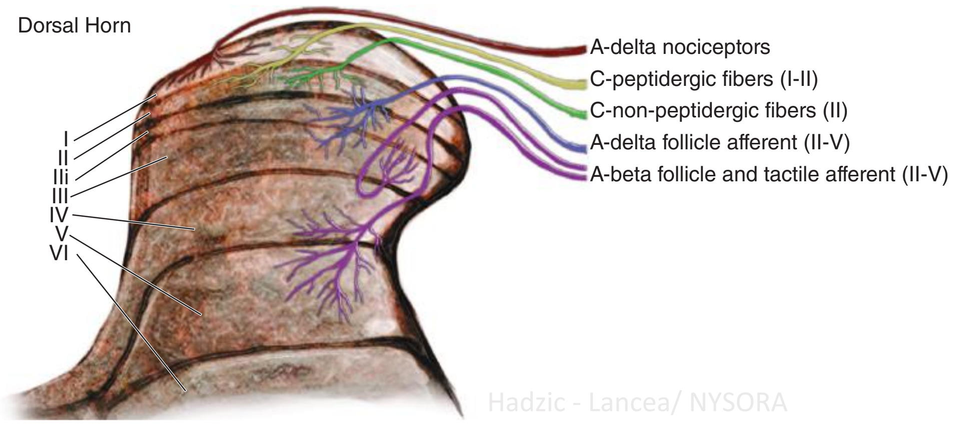

FIGURE 73–4. Schematic example of laminar organization (I–V) of spinal dorsal horn and the termination sites of primary afferents. Abeta tactile afferents mainly end in laminae II–V. A delta nociceptors predominately terminate in lamina I. C-peptidergic primary afferents end in lamina I and the outer portion of lamina II. C-nonpeptidergic afferents terminate in lamina II. (Modified with permission from Todd AJ: Neuronal circuitry for pain processing in the dorsal horn. *Nat Rev Neurosci.* 2010 Dec;11(12):823–836.)

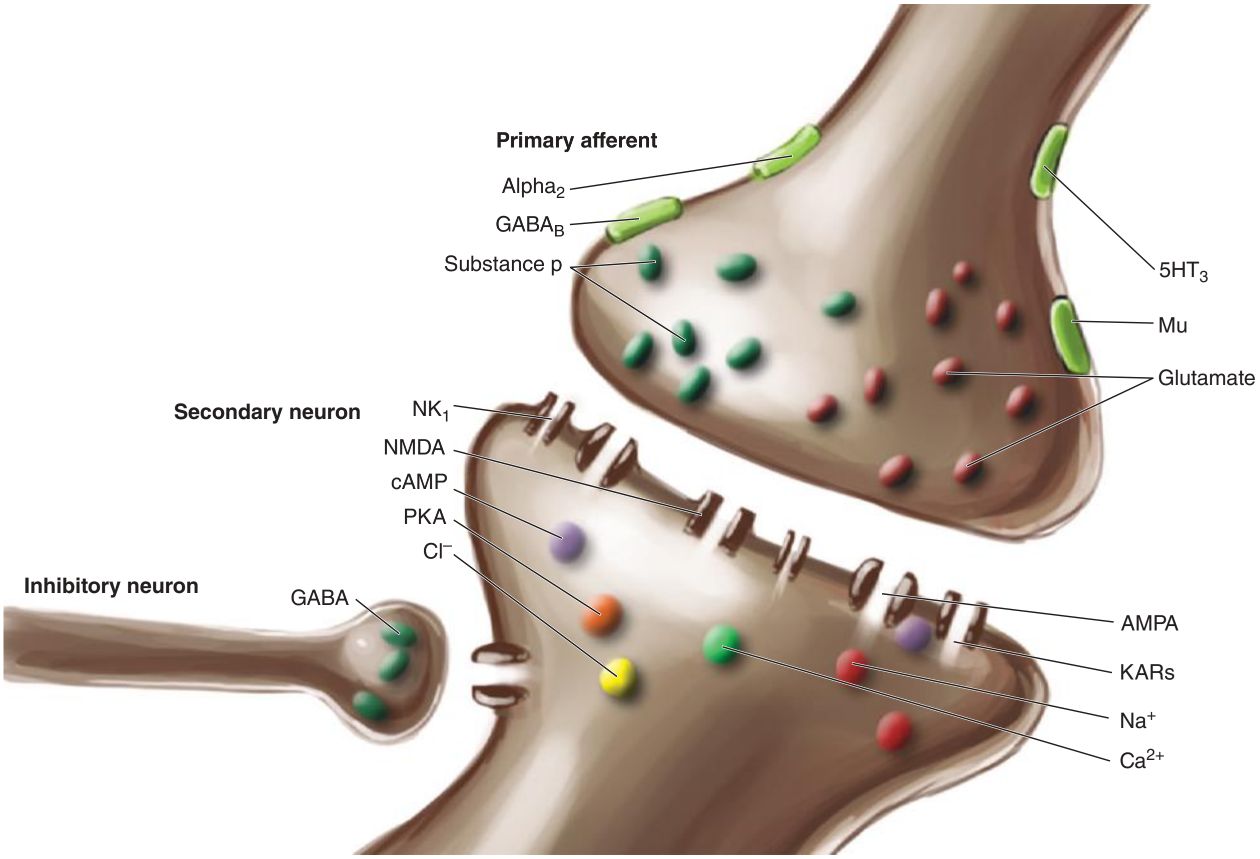

FIGURE 73–5. Schematic diagram of spinal dorsal horn synapse. The central terminal of the primary afferent contains neurotransmitters such as substance P and glutamate and neuromodulators such as BDNF. Release glutamate activates AMPA /kainate receptors leading to fast Na^+ influx and depolarization of the postsynaptic membrane. Sustained synaptic input can depolarize the postsynaptic membrane sufficiently to activate the voltage gated NMDA receptor leading to Ca^{2+} influx, underlying the hyperalgesic states. This process is modulated by activities of many presynaptic (e.g., 5-HT_3, α_2- adrenergic, opioid mu, $GABA_B$) and postsynaptic (e.g., $GABA_A$) receptor systems. For example, activation of postsynaptic NK1 receptors via substance P activates cAMP-PKA signaling pathway, which facilitates NMDA receptor activation, whereas release of presynaptic GABA enhances Cl^- influx, which hyperpolarizes postsynaptic membranes and inhibits activity. BDNF: brain-derived neurogenic factor; AMPA:; cAMP: cyclic adenosine monophosphate; GABA: gamma-aminobutyric acid; NK1: neurokinin; NMDA: N-methyl-D-aspartate; PKA: protein kinase A.

spinal microcircuits, changes in descending inputs, and changes in glial cells.

Intrinsic plasticity of dorsal horn neurons refers to the changes in the properties of the neurons themselves that influence excitability. This generally includes the same types of ion channels as those impacting excitability and transmitter release in nociceptive afferents. The net result is a change in the output (action potentials) of a dorsal horn neuron in response to a given input (synaptic transmission). There is, of course, synaptic plasticity (presynaptic or postsynaptic), that can underlie changes in the stimulus-response function of a dorsal horn neuron, where changes in receptor density and/or functional synapses have both been described. Mechanisms underlying changes in synaptic strength are analogous to the long-term potentiation and depression[29] described in the hippocampus in association with learning and memory, but do not appear to involve the mechanisms enabling the changes to persist indefinitely.

Importantly, it is the changes in spinal microcircuits that appear to underlie the emergence of the phenomena of mechanical allodynia, where low-threshold Abeta afferent activation can produce the sensation of pain.[30] While there is evidence to suggest several changes contribute to this phenomena, the most compelling evidence to date suggests that changes in microcircuits involving both a decrease in inhibitory interneuron signaling[31] and a change in excitatory interneuron signaling[32] enable the low-threshold input to deeper layers of the dorsal horn to gain access to nociceptive circuits in the superficial layers.[33] The role of NDMA receptors in the initiation and/or maintenance of these changes is thought to account for the therapeutic efficacy of NMDA receptor antagonists such as ketamine.[34,35]

Changes in descending inputs include a shift from inhibitory to facilitatory influences on the spinal processes in pronociceptive states associated with inflammation and injury.[36]

Finally, changes in glial cells (microglia and astrocytes) in response to nerve injury and inflammation include the release of inflammatory mediators (brain-derived neurogenic factor [BDNF], prostaglandin, interleukins IL-1β and IL-6, and tumor necrosis factor-α [TNF-α]) through the purinergic ($P2X_4$, $P2X_7$, $P2Y_{12}$) signaling mechanisms.[37,38]

Findings from these studies have provided many therapeutic targets for analgesia in yhe spinal cord in addition to the

NMDA receptor. For example, nonsteroidal anti-inflammatory drugs (NSAIDs) produce the analgesic effects by inhibiting the cyclooxygenase (COX) enzyme, consequently the generation of prostaglandins in the dorsal horn.[39] Since the loss of inhibition is an important mechanism underlying many spinal changes, research has recently focused on the restoration of the normal inhibition.[40,41] Drugs that modulate the glial cell activation have also been introduced to treat pain. For example, methotrexate has been shown to attenuate osteoarthritis pain.[42] However, the failure of propentofylline, a nonspecific glial inhibitor to treat postherpetic pain[43] highlights the need for further research.

SUPRASPINAL MECHANISMS

Neurons of spinal dorsal horn (laminae I and V) project along the spinothalamic and spinoreticulothalamic tracts to supraspinal sites (brainstem, thalamus, amygdale, and cortex), where pain signals are processed, integrated, and modulated. Neuroimaging studies have now identified several important supraspinal regions in humans that appear to play a critical role in the processing of ascending nociceptive signaling, including brainstem periaqueductal gray (PAG), hypothalamus, amygdala, the S1 and S2 cortices, the insular and anterior cingulate, and the prefrontal cortices (PFCs). The relatively large number of brain regions activated by noxious stimuli is often referred as the "pain matrix," which together appear to account for the sensory, emotional, and motivational aspects of pain.[44] It should be noted that none of the brain regions included in the pain matrix are exclusively activated by noxious stimuli, and, in fact, many of the same brain regions have been implicated in a variety of physiologic and pathophysiologic States.[45] More recently, researchers have attempted to understand how the pain is encoded in the brain by studying dynamic changes in brain function. This includes the assessment of how well activity in different brain areas is correlated, which used to infer "functional connectivity," where pain states are associated with changes in functional connectivity. Similarly, researchers have identified a pattern of activity when the brain is at "rest," referred to as the default mode network, where again the presence of pain has been shown to result in disruption in this network.[46] As with all brain imaging, distinguishing cause from effect remains an elusive goal. Even more elusive is the "signature" of the chronic pain brain, despite the fact that is it is now possible to determine not just whether an individual is experiencing acute pain but how much acute pain an individual may be experiencing.[47]

Descending Modulation Pathways

Structures at the midbrain, such as the PA, and the rostral ventromedial medulla (RVM) are the gateway through which cortical and subcortical sites can influence nociception. It is now well established that the PAG is a source of descending opioid-mediated inhibition of nociceptive inputs. This region receives inputs from cortical sites and has reciprocal connections with the amygdala[48] and receives ascending nociceptive inputs from the spinal dorsal horns by way of the parabrachial nuclei. The inputs from the rostral anterior cingulated nucleus (rACC) (rACC) to the PAG likely mediates the placebo analgesia.[49] The PAG influences descending pain modulation primarily through its reciprocal connections with the RVM, which in turn projects to superficial and deep laminae in the dorsal horn (see Figure 73–1). While both excitatory and inhibitory modulation can occur, the best-studied mechanism related to pain is descending inhibition, which involves the action of a number of endogenous neurotransmitters, such as opioids, serotonin, norepinephrine, cannabinoids, GABA and glycine. Many traditional pain-management strategies act at least partially via these inhibitory mechanisms.

Other brainstem sites appear to work in concert with the PAG and RVM and include the noradrenergic projection of the pontine locus coeruleus to the dorsal horn via the ventrolateral funiculus[50] and the subnucleus reticularis dorsalis (SRD) at the caudal medulla for the diffuse noxious inhibitory controls (DNIC).[51]

Descending pain modulation is the underlying mechanism for many surgical, psychologic, and pharmacologic interventions for pain treatment. The surgical interventions include deep brain and spinal cord stimulation.[52] The psychologic interventions include biofeedback, cognitive-behavioral therapy (CBT), and conditioned pain modulation (CPM).[53] The pharmacologic interventions include the traditional opioids, antidepressants, and anticonvulsants as well as newly developed strategies, such as intranasal oxytocin.[54]

Challenges for Analgesic Discovery

Pain is a complex process by which the specific mechanisms as well as the severity and duration can be influenced by many factors. These include (1) type of injury (inflammation vs nerve injury); (2) the site of injury; (3) timing, in terms of the trajectory of the response to injury, chronologic age, and previous history; (4) sex; and (5) genetic background. With respect to the type of injury, inflammatory and neuropathic pain may share some common mechanisms but are also fundamentally distinct, and as a result, they require different treatments.[55] Similarly, the neurons and circuits underlying pain arising from somatic structures (skin, muscle, joints, and bone) appear to be very different from each other as well as those underlying visceral and trigeminal structures. Time-dependent changes in the mechanisms underlying pain after injury have been well documented.[56] There are some pain syndromes such as migraine and temporomandibular disorder that are far more common in young adults, while others, such as trigeminal neuralgia and postherpetic neuropathy, are more common in the elderly.[57] Similarly, nerves with a preexisting injury (diabetic and/or chemotherapeutic neuropathies) are at much greater risk of a second, possibly subclinical, insult. This "double crush syndrome" highlights the impact of the history of injury on the choice of treatment.[58] Despite the relatively small sexual differences described in the laboratory in association with either pain or analgesia, it remains a fact that the incidence and severity of chronic pain is higher in women than in men.[59] Finally, it has now been well documented that genetic differences contribute to differences in pain susceptibility and in responses to analgesics.[60]

TABLE 73–2. Neurobiologic mechanisms for nociception.

Site of Actions	Mechanisms	Analgesics
Peripheral	Block signal transduction	Inflammatory factor release inhibition: NSAIDs
		TRPV1 agonist: capsaicin
		TRPV1 antagonist: resiniferotoxin
		TRPM8 agonist: menthol, peppermint oil
	Block action potential initiation/propagation	NaV blockers: local anesthetics, antiepileptics, TCAs
		HVA Ca^{2+} channel blockers: clonidine, opioids, gabapentin, ziconotide
		K^+ channel blocker: retigabine
		GPCR blocker: triptans, peripheral opioids
		NGF inhibitor: Fasinumab, Neublastin
Spinal	Prevent intrinsic plasticity	NMDA receptor antagonist: ketamine, dextromethorphan
	Block hypersensitivity	Inflammatory factor release inhibition: NSAIDs
	Restore normal inhibition	GABA receptor agonist: baclofen, benzodiazepine
	Glial cell modulation	Glial cell modulator: methotrexate, propentofylline
Supraspinal	Modulate descending pain pathways	Surgical: DBS/SCS
		Psychologic: biofeedback, CPM
		Pharmacologic: opioids, TCAs, oxytocin

Abbreviations: CPM: conditioned pain modulation; deep brain stimulation; GABA: gamma-aminobutyric acid; GPCR: G protein-coupled receptor; HVA: high voltage activated; NaV: voltage-gated Na^+ channel; NGF: nerve growth factor; NMDA: N-methyl-D-aspartate; NSAIDs: nonsteroidal anti-inflammatory drugs; SCS: spinal cord stimulation; TCAs: tricyclic antidepressants; TRPV: transient receptor potential cation channel.

SUMMARY

Both the existing and future therapeutic interventions for the treatment of pain are grounded in the neurobiologic mechanisms of nociception (Table 73–2). While it may not possible to identify the ultimate, "silver bullet" for pain treatment, with an increased understanding of the multitude of variables that influence both the development of pain and the response to interventions, the promise of personalized medicine with interventions tailored to the specific needs of the patient appears to be a possibility in foreseeable future. Given the specific needs of the patient in the perioperative setting, we may be even closer to providing optimal pain management for all patients with the tools and approaches already available.

CHAPTER 74

Pain: Epidemiology, Psychology, and Impact on Function

Trent Emerick and Steven L. Orebaugh

THE IMPACT OF PAIN

Some 30 million surgeries are performed annually in the United States, many resulting in significant acute postoperative pain. There also is an increasing trend toward utilization of oral opioids as the mainstay therapy.[1]

Although most available literature on the prevalence of pain and its effects on patients focuses on chronic, rather than acute, pain, these studies nonetheless provide important insights into the impact of pain on quality of life. The prevalence of chronic pain is estimated to be approximately 4.1% for extremity pain to 10.1% for low back pain, although there is considerable variability among reports.[2,3] The percentage of patients who experience severe pain after surgery is difficult to determine in the literature, although it has been approximated in the 20%-40% range.[4]

Osteoarthritis and rheumatoid arthritis remain two of the most common causes of chronic pain. Chronic pain affects many important aspects of a patient's life. These include sleep, exercise tolerance, activities of daily living, social activities, sexual function, and employment status.[5] In a European study of patients with chronic pain of various types, it was reported that patients with chronic pain lost a mean time of 7.8 days of work over a 6-month period due to their pain.[5] Approximately 60% of patients had visited a physician between two and nine times in the previous 6 months for pain-related issues. In this same study, 21% of respondents stated that they had been diagnosed with depression because of their pain.

Likewise, acute pain has many undesirable effects on patients beyond the unpleasantness of the sensory experience itself (Table 74–1). While the relationship between disturbed sleep and chronic pain remains somewhat difficult to discern, with evidence that either may exacerbate or facilitate the other,[6] it is reasonably clear that acute, postoperative pain disturbs the sleep cycle,[7] and that this may require time to revert toward normal, especially with regard to restoration of lost rapid-eye-movement sleep.[8] The use of opioids in the perioperative period may further distort normal sleep patterns.[9]

Research suggests that both deep and superficial pain stimuli in muscle increase sympathetic nervous system activity, with concomitant elevations of heart rate and blood pressure.[10] Such adrenergic excitation may predispose older patients with vascular occlusive disease to be at risk for adverse postoperative outcomes, since tachycardia is an independent risk factor for perioperative myocardial infarction.[11] Highly effective analgesic techniques, such as the use of regional anesthesia, have the potential to reduce such complications.[12]

It is difficult to separate the effects of surgical tissue trauma from the pain that invariably accompanies it; as such, the marked elevation of serum markers of stress and inflammation that accompany tissue injury may at least, in part, be related to nociception. Studies suggest that improvements in pain control through regional techniques can attenuate these rises in inflammatory biomolecules,[13] which may also have favorable effects on perioperative outcome.[12]

Poorly controlled acute pain has deleterious effects on activities that patients wish or need to return to after surgery. For instance, on the day of surgery, improved pain control with peripheral nerve blockade results in earlier eating, drinking, ambulation, and discharge from the hospital, among other potential benefit[14,15] (Table 74–2). Although single-shot blocks do not appear to translate into a long-term reduced pain burden once they have resolved,[16] peripheral nerve block (PNB) catheters,[17] various additives, such as dexamethasone,[18] or altered drug formulations, such as liposomal bupivacaine,[19] may extend the duration of single blocks. Preservation

of quadriceps muscle strength in association with adequate pain control allows improved function and participation in physical therapy in the acute phase of recovery after total knee arthroplasty.[20] Improved pain control in the early postoperative period may allow patients to return to work earlier as well.[21]

In one large prospective study, younger age, female gender, and preoperative history of chronic pain were all found to be risk factors for more intense postoperative pain independent of the type of surgery.[22] In a large, prospective study in ambulatory surgical patients, Chung et al, reported that younger male patients, American Society of Anesthesiologists (ASA) Physical Status I patients, and patients with a greater body mass index (BMI) had the highest incidence of severe postoperative pain.[23]

Gerbershagen et al,[4] evaluated the level of pain on the first postoperative day among 179 different surgical types, and found that 22 of the top 40 most painful procedures were orthopedic or trauma procedures on the extremities. This underscores the potential of regional anesthesia in decreasing the occurrence of severe postoperative pain. Interestingly, these practitioners also noted that common procedures such as laparoscopic/open appendectomy, open cholecystectomy, and tonsillectomy also ranked in the top 25 most painful procedures. Of note, these procedures ranked worse in pain tha open abdominal procedures with the use of neuraxial anesthesia.

Often, anesthesiologists care for acute pain in the recovery room, while surgeons continue to provide analgesia after patients leave the postanesthetic care unit (PACU) to return home or move to the ward, although continuous catheter techniques have resulted in a greater involvement in postoperative care. The current move toward a perioperative surgical home suggests that anesthesiologists will play a larger role in directing perioperative medical therapy and postoperative analgesia.[24]

TABLE 74–2. Benefits of improved perioperative pain control with regional techniques.

Improved patient satisfaction
Bypass of phase I recovery
Earlier discharge from hospital
Improved participation in physical therapy
Earlier return of concentratison
Fewer side effects of opioids
Earlier return of activities, including eating, drinking, ambulation

PAIN PSYCHOLOGY AND BEHAVIORAL EFFECTS OF PAIN

The connection between behavior, personality, and acute postoperative pain is an area of intense interest in pain research. For instance, some studies have shown that the act of catastrophizing (in which a patient treats minor issues as catastrophes) and a lower preoperative mental health score (as measured by a standardized mental health survey) result in worse scores on postoperative function and pain for total knee arthroplasty but not total hip arthroplasty.[25,26] In contrast, the preoperative level of anxiety, personality type, and fear of movement were psychologic symptoms that did not significantly affect the degree of postoperative pain or function.

Pain psychology is a component of a multidisciplinary approach to treatment of chronic pain.[27] Cognitive-behavioral therapy is one of the most commonly utilized approaches to treating a patient with chronic pain through behavioral modification. This therapy analyzes a patient's perception of pain as well as various psychologic variables such as anticipation, avoidance, and mood in an effort to alter how a patient ultimately responds to pain. One important finding of research in this area has been to elucidate that patients can actively process pain information, as opposed to being passive reactors, and that their thoughts can actively alter physiologic responses.[27]

Behavioral assessment is typically conducted through a personal interview with the patient, during which the examiner attempts to develop an understanding of the patient's experience with pain, elicit a detailed psychosocial history, and perform an evaluation of the patient's mood and coping mechanisms. Cognitive behavioral therapy can help patients develop coping skills such as relaxation, breathing exercises, and attention training whereby they concentrate their thinking on a nonpainful stimulus when their pain worsens.

In addition, there are a number of cognitive patterns that have been characterized in the pain psychology literature that are of direct importance to pain perception.[27,28] Examples of these patterns include the polarizing type (in which a patient characterizes a performance or feeling as either perfect or a failure), overgeneralization type (in which a patient assumes a single painful experiences translates into an overall poor outlook), and catastrophizing type.

ASSESSMENT OF PAIN

A myriad of pain-intensity scales have been developed to aid in the assessment and treatment of both acute and chronic pain. It is often noted that no single pain scale has been shown to be more efficacious than another, and these scales are not meant to compare one patient's pain levels to another patient's pain levels. Instead, pain scales should be utilized to compare a single patient's pain intensity at various time points. Many scales incorporate not only an assessment of the patient's pain but also how it impacts their mood and function.

The assessment of pain has become more thorough and complex over the last 20 years. In a speech to the American Pain Society in1995, Dr. James Campbell spoke on the idea of describing pain as the fifth vital sign in an attempt to bring about more effective pain management.[29] This idea was largely adopted by multiple national hospital oversight agencies including the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) and the Veterans Health Administration and is used in hospital quality measures.[30,31] Unfortunately, since the adoption of pain as a fifth vital sign, opioid use has nearly doubled and the incidence of serious side effects due to opioid treatment has substantially increased as well. Morone and Weiner point out that providers will ultimately fall short in the management of a patient's pain if the treatment plan only considers the sensory component; pain is instead an important quality measure because it can impact sensation, mood, function, and cognition.[30] These investigators also note that there is a distinction between acute pain and chronic pain within a context of the vital sign. Chronic pain should not be viewed as a vital sign because it is a simplistic view of a multidimensional problem that often has varying impacts on a patient's life.

The Visual Analog Scale (VAS) is a unidimensional scale that rates a patient's pain on a scale of 0–10. It is very widely used, and its validity has been assessed in numerous patient populations for numerous painful conditions.[32–34] The revised version of the short form of the McGill Pain Questionnaire is a multidimensional validated pain scale that assesses the quality of a patient's neuropathic and nonnociceptive pain through assessment of gnawing, throbbing, or shooting, a pain intensity scale, and labeling pain on a diagram of the body.[35] The Brief Pain Inventory (BPI) also includes a human body pain diagram and questions on mood, function, and psychologic effects of their pain. This scale is widely used for various types of cancer pain and noncancer pain to assess pain and how it impacts a patient's life.[36,37] Furthermore, there are also numerous facial expression scales for evaluating pain in the pediatric population, such as the Wong-Baker FACES Scale.[38] These scales are cited as the preferred method of reporting pain in the pediatric population.[39]

All pain scales, however, have some limitations. First, the patient should have access to their previously reported pain scores to accurately assess their current pain.[40] Interestingly, it has been shown that patients rate their pain differently on using a VAS depending on whether the scale is presented in a vertical or horizontal format.[41] It is also difficult to directly convert a score from one pain scale to a score on a different pain scale.[42] Likewise, the pain score may not directly correlate with patient satisfaction as the data in the emergency medicine literature suggest.[43]

While historically, quantifying pain has taken on increasing importance, scoring alone is not sufficient to direct appropriate therapy and guide future research. Newer scoring systems take into account the alteration in function or activity that a patient experiences, as well as affective responses to the pain, as noted above. The direction of research in postoperative acute pain management is now oriented toward more inclusive assessments, conducted at multiple time periods.[44,45] In 2013, Choi et al evaluated the acute pain literature related to total knee arthroplasty, and found the assessment of postoperative pain and function was seriously deficient, and they called for increased use of more comprehensive scoring systems as well as repeated assessments in the short, intermediate, and long term.[45]

PAIN PHENOTYPING

The future of acute and chronic pain management is evolving toward the ability to tailor a patient's pain regimen in a more individualized fashion. Janda et al recently reported that preoperative fibromyalgia survey scores can predict postoperative opioid consumption in patients having a hysterectomy.[46] The fibromyalgia survey score ranges from 0–31 and incorporates a number of painful body areas (score of 0–19) and associated symptoms such as fatigue and headaches among other factors (score of 0–12). In this study, each 1-point increase in the 31-point fibromyalgia scale equated with an adjusted increase of approximately 7 mg in total morphine dose in the acute inpatient postoperative period. Although only 8.2% of patients in the survey were considered "fibromyalgia positive" based on a total score of 13 or greater of 31, it is important to note that the associations between opioid use and fibromyalgia score could be seen across all scores. For instance, Brummet et al also showed that the fibromyalgia score was predictive of postoperative opioid consumption in the knee and hip arthroplasty population.[47]

Clinical Pearls

- Pain, whether acute or chronic, causes major life disruption for patients, and disturbs many activities of living, leading to significant psychologic consequences.
- Pain may be assessed and quantitated with a number of different scales. However, it is becoming increasingly important to assess not only the degree of discomfort experienced by a patient, but also the severity of functional and psychologic disruption.
- Pain phenotyping seeks to determine which patients may be predisposed to a greater degree of discomfort after a procedure, and this information can be utilized to more effectively plan an analgesic regimen.
- Opioids are useful and effective analgesics, but are limited by adverse effects. Multimodal analgesic techniques allow for a greater diversity of interventions with less reliance on opioids. In acute pain, regional techniques can be particularly effective.

Catastrophizing has been shown to be predictive of increased postoperative opioid requirements. This behavior could potentially be recognized during the preoperative assessment in order to aid in postoperative management.[46] It has been suggested that patients with higher fibromyalgia scores or other preoperative pain phenotyping scores may have intrinsic differences in the functioning of the intrinsic opioid system.[48] These scores could potentially be utilized by the anesthesiologist to customize an intraoperative and postoperative plan that minimizes the likelihood of severe pain.

Individual differences in a patient's endogenous opioid function may dictate a patient's response to exogenous opioids such as morphine. For example, patients with low endogenous opioid function and those with high endogenous opioid function were exposed in one study to two forms of acute evoked painful stimuli. The patients with lower levels of endogenous opioid function at baseline showed a greater response to morphine than those with higher degrees of function at baseline. This may have clinical applications in the future, and methods to test endogenous opioid function may be increasingly more often used.[49] Morphine appears to provide better relief in the treatment of chronic back pain in patients with lower endogenous opioid function as well.[50]

Limitations of Opioid-Based Analgesia

A multimodal treatment plan is of particular benefit to patients' perioperative pain, whether preexisting or not, given the inherent limitations of opioids. The World Health Organization (WHO) has produced an analgesic ladder (originally developed for cancer pain) that helps providers form an algorithm to treat pain in a balanced and multimodal approach—nonopioids for mild to moderate pain, mild opioids for moderate to severe pain, and strong opioids for severe pain.[51]

Common examples of frustrating side effects of opioids include constipation, nausea, pruritus, dysphoria, and urinary retention.[52,53] More serious adverse effects include the development of ileus, with attendant delays in oral intake, as well as oversedation and life-threatening hypoventilation[54] (Table 74–3). Opioids have been associated with numerous deaths during treatment of both acute and chronic pain.[55]

There is a considerable amount of literature that describes not only tolerance to opioids from chronic use but also rapid acute tolerance to perioperatively adminstered opioids.[56–59] Although there is a decreasing margin of efficacy with opioid medications over time due to opioid tolerance, the connection between chronic pain and addiction/opioid abuse deserves further clarification.[52] Finally, the concern for opioid-induced hyperalgesia both in the acute postoperative pain setting (as well as the chronic pain setting) should not be ignored.[60]

Just as the WHO ladder deemphasized opioids when possible to treat chronic pain, multimodal analgesia should be utilized in the acute setting to minimize perioperative pain. Multimodal analgesia incorporates various pharmacologic agents such as acetaminophen, nonsteriodal anti-inflammatories, gabapentinoids, and α_2 agonists,[61,62] as well as other analgesic techniques (Table 74–4). For example, both the preoperative use of beta blockers and α_2 agonists have been shown to have anesthesia-sparing and analgesia-sparing effects and reduce postoperative pain and improve cardiovascular stability.[63] In addition, steroids, local anesthetic infusions, and magnesium have all shown some promise in the management of acute pain.[62,64] In addition, there is some evidence that multimodal analgesia may reduce the incidence of chronic postsurgical pain.

Ketamine and dextromethorphan (N-methyl-D-aspartate antagonists)
Magnesium
Local anesthetic parenteral infusion
Gabapentinoids
Beta-blocking agents
Local anesthetic wound injection
Neuraxial local anesthetic infusion
Peripheral nerve blockade

Regional anesthesia should be an integral part of a multimodal treatment plan in order to minimize the side-effect burden of opioid medications. Peripheral nerve blockade and/or catheter placement is practical and effective in the perioperative setting for orthopedic and many other painful surgeries.[65,66] Liu et al reported in a meta-analysis that neuraxial and peripheral nerve blockades reduced postoperative pain scores and reduced PACU analgesic administration compared to general anesthesia.[67] Compared with general anesthesia, peripheral nerve blockade has also been shown to increase the ability to bypass PACU, decrease nausea, decrease the number of minutes of stay in PACU, and increased incidence of excellent patient satisfaction.[14,15] Continuous peripheral nerve catheters improve pain control for a longer period, and also favorably affect discharge times for both upper and lower extremity procedures.[68,69]

Considerable debate exists as to whether opioids can alleviate specific types of chronic pain such as neuropathic pain. Furlan et al,[52] as well as other investigators,[70] demonstrated that neuropathic and musculoskeletal pain intensity scores may be decreased by as much as 30% with potent opioids for chronic pain. Many studies evaluating the benefits of long-term opioid use have significant limitations, and further study is required to firmly address this question. Functional improvement is another endpoint which requires ongoing investigation for patients with chronic pain as well, as such benefits have been called into question.[1,70,71]

SUMMARY

Acute, postoperative pain is often inadequately controlled. This is also true for many surgeries that are not routinely thought of as being "painful." Pain, both acute and chronic, has significant effects on a patient's psychology, as well as measurable physiologic effects, including a biomolecular and adrenergic stress response. The impact of pain on patients' daily activities is profound, and serious life disruption is common. Psychologic profiles have given us insight into which patients may have an increased pain burden after surgery, as has pain phenotyping. Both aspects of pain assessment may allow for better and more individualized analgesic regimens in the future. Pain assessment scoring systems have increased in complexity and breadth in order to take into account the impact of pain on the individual, rather than simply allowing quantitative expressions of its severity at a moment in time. Multimodal analgesic techniques with integration of peripheral nerve blockade or other regional anesthesia techniques have the potential for the greatest effect on reducing both pain and its associated adverse outcomes, as well as the many undesirable side effects of high-dose opioids.

CHAPTER 75

Multimodal Analgesia: Pharmacologic Interventions and Prevention of Persistent Postoperative Pain

Adam C. Young and Asokumar Buvanendran

INTRODUCTION

Multimodal analgesia was popularized in 1993 by Kehlet and Dahl and described as "combined analgesic regimens" in order to achieve "sufficient analgesia due to additive or synergistic effects between different analgesics, with concomitant reduction of side effects."[1] Through the past 20 years, many patients have benefitted from practical implementation of this concept. By modulating multiple receptor-ligand systems involved in the transduction and sensation of pain, we have also appreciated the ability for certain agents to reduce acute postoperative pain and, therefore, reduce the incidence of persistent postsurgical pain. Several individual medications have been identified, although precise dosage, timing, and route of administration have yet to be completely understood. Additionally, there are techniques available, which if used in the perioperative phase, may prevent development of chronic pain after surgery.

MULTIMODAL ANALGESIA

Many analgesic combinations have been shown to demonstrate synergistic analgesia when used in combination, as opposed to the analgesic effects of those agents used individually. Examples include combinations of acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), N-methyl D-aspartate (NMDA)–receptor antagonists, anticonvulsants, and corticosteroids. Other mechanisms of analgesia include the use of regional anesthesia and local wound infiltration.

The sum of these efforts can result in a postoperative course that allows patients undergoing some of the more painful surgical procedures, even total knee arthroplasty, to meet discharge criteria and be discharged the same day as surgery.[2,3]

Surgical stimuli produce a multitude of mediators—leading to inflammation, sensitization, and pain.[4,5] The process begins with tissue damage and the production of prostaglandins (PGs), particularly PGE_2.[4] Other mediators include histamine, bradykinin,[5] substance P, and the excitatory neurotransmitters (glutamate and aspartate).[6] Nociceptors become sensitized as a result of the expression of the *c*-fos, nitric oxide (NO) synthase, and cyclooxygenase (COX) genes augmenting the sensation of pain and perhaps beginning the process of developing persistent postsurgical pain. By using a multimodal approach to treating acute surgical pain, the various mediators or their targets, optimal pain relief can be achieved both acutely and chronically.

Acetaminophen

Acetaminophen, (paracetamol), produces its analgesic effect by inhibiting central prostaglandin synthesis with minimal inhibition of peripheral prostaglandin synthesis.[7,8] Often labeled as an NSAID, the two substances have some important differences. This includes acetaminophen's weak anti-inflammatory effect[9] and its generally poor ability to inhibit COX in sites of inflammation.[10] Unlike NSAIDs, acetaminophen does not have an adverse effect on platelets[11] or the gastric mucosa.[10]

The use of acetaminophen in the perioperative setting had been limited until intravenous (IV) acetaminophen became available for use. The IV formulation has some benefits over enteral routes of administration; bioavailability is 100% and shorter time peak effect; the onset of 'meaningful' pain relief is less than 30 minutes after administration.[12] In addition, the IV formulation of acetaminophen has been used as the foundation for multimodal analgesia in Europe for years. Since its introduction in the United States, IV acetaminophen has gained praise in the surgical community, and its benefits have been reported in several randomized clinical trials and meta-analyses. The latest shows that IV acetaminophen reduced pain and also the opioid-related side effects.[13]

When used as a combination with NSAIDs, acetaminophen confers superior analgesia compared to either drug alone.[14] This synergism highlights the value of combined central and peripheral COX inhibition. The combination of NSAIDs and acetaminophen has also been proven to decrease pain scores, opioid consumption, sedation, and postoperative nausea and vomiting and improve patient satisfaction in the acute postoperative period.[14,15] Overall, IV acetaminophen has been well received by both patients and physicians and it has become the foundation for multimodal analgesia.

The total daily maximum dose of acetaminophen is 3000 mg to decrease the risk of hepatotoxicity. Prescribers need to take into account combination tablets containing acetaminophen (e.g., Norco, Percocet, or Excedrin) when making this calculation. Liver failure is an absolute contraindication to its administration; relative contraindications include hepatic insufficiency, alcohol abuse, and alcohol dependency.

NSAIDs

Nonselective NSAIDs (e.g., ibuprofen, naproxen, ketorolac) inhibit both the COX-1 and COX-2 isoforms. When cell membranes are damaged, arachadonic acid is liberated; these drugs decrease the conversion of arachadonic acid to prostaglandins and thromboxane. Peripherally, prostaglandin E_1 (PGE_1) and prostaglandin E_2 (PGE_2) sensitize nociceptive sensory nerve endings to histamine and bradykinin.[16,17] The same prostaglandins modulate nociceptors to respond to nonnociceptive stimuli.[18,19] By reducing PGE_1 and PGE_2, NSAIDs decrease inflammation and these processes that lead to sensing pain.

The risks of renal damage, gastrointestinal hemorrhage, and platelet dysfunction[20] have led some physicians to forego using nonspecific NSAIDs in the perioperative period. These effects are due to the inhibition of COX-1, an enzyme that is expressed constitutively. Conversely, the COX-2 isoform is upregulated in damaged tissue,[21] and the desired anti-inflammatory effects of NSAIDs in the periphery can be realized without these posed risks.

Nonspecific COX inhibitors, ibuprofen, and ketorolac have been used intravenously in the acute pain and perioperative setting. Ketorolac has an a COX-1:COX-2 specificity of approximately 330:1,[22] onset of action of 10 minutes, peak analgesic effect at 2–3 hours, and analgesic duration of 6–8 hours.[7] As a single 30-mg preoperative dose, ketorolac has been shown to decrease narcotic consumption and limit nausea. Ketorolac has been incorporated in multimodal pain regimens for total joint arthroplasty and reduced acute postoperative opioid consumption.[18–19] IV ibuprofen may be more attractive for perioperative pain management given its stronger affinity for the COX-2 isoform (COX-1:COX-2 ratio of 2.5:1).[24] Suggested dosing begins at 400 mg every 6 hours; however, greater analgesia is observed following doses of 800 mg every 6 hours.[23] The current literature includes three small studies that demonstrated IV ibuprofen improves acute pain at rest and with movement, promotes faster times to ambulation, and reduces opioid requirements following surgical procedures.[25,24]

There is only one selective COX-2 inhibitor available to the practitioner in the United States, celecoxib, and it is administered orally. Doses range from 100–200 mg and administration can be taken daily or twice daily. There is a suggestion that initiating a COX-2 inhibitor 2–3 days prior to surgery can lead to accumulation in the cerebrospinal fluid, providing benefit in the perioperative period.[25] Ideally, a COX-2 inhibitor should be continued for at least 2 weeks following surgery, as this coincides with the duration of the acute inflammatory process. Celecoxib has been incorporated in multimodal regimens and consistently demonstrates reduced opioid requirements and correlates with earlier physical activity.[26] In joint arthroplasty, incorporating celecoxib has been correlated with improved outcomes, such as range of motion.[27]

The use of NSAIDs to prevent the development of chronic pain remains controversial. The studies that have investigated NSAIDs have frequently employed ibuprofen or ketorolac in varying doses, and if not administered in a single dose, for short durations postoperatively. The results have favored single-dose ketorolac to reduce pain in the acute postoperative period,[28] although these have failed to demonstrate prevention of chronic pain.[29] With regard to celecoxib, one study did demonstrate a significant difference in pain at rest in patients 12 weeks postoperatively after knee arthroplasty; this difference was not maintained beyond 12 weeks.[29]

Contraindications to NSAIDs include allergy to aspirin as well as to sulfonamides. The dose should be reduced in the elderly or those with reduced renal function. Despite clear evidence, there is concern that NSAIDs in the perioperative period can lead to impaired bone healing.[30] Prior to prescribing an NSAID following a procedure in which bone was manipulated, we suggest consulting with the surgeon.

Anticonvulsants

The gamma-aminobutyric acid analogues, gabapentin and pregabalin, bind to the $\alpha_2\delta$-subunit of the voltage-dependent calcium channel. These drugs inhibit the opening of these channels and reduce the influx of calcium and consequently the release of excitatory neurotransmitters (substance P and calcitonin gene–related peptide). The evidence for incorporating anticonvulsants in multimodal analgesia has increased dramatically. Gabapentin and pregabalin are two of the most commonly used medications in this class; however, there are unique differences to each.

Gabapentin is an orally administered medication that is actively transported across the gastrointestinal mucosa. There are individual differences in the amount of transporters that an individual patient has, and as a consequence patients respond differently to similar doses of gabapentin. As an example, gabapentin 900 mg divided three times per day has an oral bioavailability of nearly 60%. Escalating the dose to 1200, 2400, or 3600 mg results in 47%, 34%, or 33% oral bioavailability, respectively.[31] This point demonstrates the ability of gabapentin to saturate the transporter system assigned to its absorption. Despite the challenges with titrating gabapentin, some studies have shown perioperative gabapentin can lead to improved functional recovery in knee arthroplasty, acutely reducing opioid consumption, and demonstrating fewer opioid-related side effects (nausea, vomiting, and pruritus).

Pregabalin has become popular in the perioperative period on account of its ≥90% oral bioavailability, longer half-life, increased lipid solubility (more readily crossing the blood-brain barrier), and fewer drug interactions.[32] Similar results of opioid-sparing and decreased opioid-related side effects have been seen with pregabalin administered perioperatively.

Voltage-dependent calcium channels may play an important role in developing chronic pain; these receptors are upregulated in the dorsal root ganglia following surgical trauma and are thought to lead to central sensitization.[10] This has been tested in animal models; administering pregabalin has been shown to reduce postoperative hyperalgesia in these studies.[33]

The ability of anticonvulsants to reduce chronic pain has been reviewed with the finding that both gabapentin and pregabalin can reduce the incidence of chronic pain.[34,35] In those reviews, anticonvulsants demonstrated this effect in patients undergoing thyroidectomy, cardiac surgery, abdominal hysterectomy, knee arthroplasty, inguinal hernia repair, or mastectomy. The investigators studying this meta-analysis indicated that pregabalin might have a greater ability to prevent chronic pain compared to gabapentin.

On an outpatient basis, titration of gabapentin is usually accomplished over several weeks to months to achieve satisfactory relief, likely corresponding with adequate serum levels of this drug. This limitation has been expressed in studies investigating single doses of perioperative gabapentin; anywhere from 300–1200 mg have had no impact on chronic postsurgical pain.[31] Even a titration to a median of 2100 mg/day did not have long-term effects in one study.[36] This limitation of gabapentin has been overcome by using pregabalin in the acute postoperative period. Pregabalin given preoperatively and repeated within 24 hours of surgery was effective in reducing chronic pain following discectomy and thyroidectomy.[37–38] Extended courses of pregabalin may prove additional benefit in surgical procedures notorious for inciting chronic postsurgical pain, such as total knee arthroplasty. A single preoperative dose of pregabalin 300 mg followed by a 14-day course of 300 mg divided twice daily reduced the incidence of persistent postsurgical pain to 0% at 6 months following total knee arthroplasty (compared to 5.2% in the placebo group).[39] Of note, the incidence of sedation was significantly higher in the treatment group.

Anticonvulsant use can be limited by side effects. These include dizziness, somnolence, ataxia, blurred vision, weight gain, and fatigue. The best method to minimize these effects is to use the lowest effective dose, titrating to the higher (clinically therapeutic) dosages as tolerated. A reduced dose is indicated in the elderly or patients with impaired renal function, as both gabapentin and pregabalin are excreted renally.

NMDA-Receptor Antagonists

Inhibition of the NMDA receptor is another means of improving pain by prolonging analgesia in the acute setting, potentially attenuating opioid-induced hyperalgesia (OIH), and reducing the incidence of chronic pain. NMDA-receptor antagonism is suspected to interfere with the development of OIH. OIH is a paradoxical effect of the administration of opioids that results in increased sensitivity to noxious stimuli. It has been suggested that OIH develops as a result of changes in both the antinociceptive and pronociceptive systems[40]; NMDA receptors have a role in modulating these processes. It is worth noting that patients with OIH experience postoperative pain that is often difficult to treat. This is of importance as poorly controlled acute pain is an independent risk factor for the development of chronic pain.[41]

Ketamine is a noncompetitive NMDA-receptor antagonist. The discovery of the NMDA receptor and its links to nociceptive pain transmission and central sensitization has renewed interest in ketamine. Ketamine has become the NMDA receptor of choice in the perioperative period. Outside of the operating room, administering ketamine can be difficult as oral preparations are not commonly on formulary and intravenous infusions present a challenge to all personnel involved in patient care.

Ketamine, as part of a multimodal regimen, has been shown to decrease opioid consumption and lower pain scores following spine and hip surgery.[42,43] This is merely part of a growing body of evidence that low-dose ketamine may play an important role when used as an adjunct to opioids, local anesthetics, and other analgesic agents.[44] In combination with IV or epidural opioids, ketamine also prolongs and improves analgesia.

Memantine is available as an oral formulation and could be useful in the acute postoperative period as it is a more potent NMDA-receptor antagonist with a longer half-life. Current studies have not supported perioperative memantine for reducing acute or chronic pain. One study indicated that following traumatic amputation memantine, in combination with regional anesthesia, decreased overall phantom pain intensity for up to 6 months. However, these effects were not maintained beyond 6 months; the treatment group had similar pain scores as the placebo group at 1 year postoperatively.[45]

Ketamine has been shown by prior investigators to reduce the incidence of persistent postsurgical pain in patients undergoing a variety of procedures. A single dose of ketamine 0–0.5 mg/kg followed by an intraoperative and postoperative infusion of 0.7–4.2 mcg/kg/min was able to demonstrate fewer cases of persistent postsurgical pain at 6 months.[44,46,47] A meta-analysis of these data supported not only a preincisional bolus and intraoperative infusion, but an infusion for up to 24 hours.[31] In a separate study, patients undergoing spine surgery received ketamine 0.5 mg/kg followed by an intraoperative ketamine infusion of 10 mcg/kg/min correlated with reduced pain scores compared to placebo at 6 weeks.[45] Although this does not meet the 3-month time mark (which is required to meet the definition of persistent postsurgical pain), this is an impressive finding as these patients were opioid dependent prior to their spine surgery.

Ketamine may have received a "bad rap" with regard to its side effects. It is known that high doses (>2 mg/kg) can cause psychomimetic effects including hallucinations, nightmares, cognitive dysfunction, or excessive sedation. Low-dose ketamine (<1 mg/kg) appears to be associated with less adverse effects and may allow physicians to harness the benefits of perioperative ketamine.

Steroids

Administration of steroids in the perioperative period serves to modulate peripheral inflammatory pathways. By reducing the flood of inflammatory mediators, postoperative pain can be attenuated by adding corticosteroids to a multimodal regimen. Timing of administration to obtain the anti-inflammatory benefits appears to be most effective if steroids are administered preoperatively. The optimal dosage has been debated. Some investigators have obtained a positive effect in reducing acute postoperative pain with dexamethasone 16 mg as part of a multimodal regimen.[48] Half the dose (dexamethasone 8 mg) has provided mixed results; some investigators obtained the same positive result[49] and others have not.[50]

Side effects of corticosteroids have produced some hesitance in investigators using them more widely. These effects include gastrointestinal complications, wound healing complications, hyperglycemia, and potential suppression of the hypothalamic-pituitary-adrenal axis. However, an extensive review concluded that short-term use of corticosteroids for acute postoperative analgesia in relatively healthy individuals is safe.[51]

With regard to the prevention of chronic pain, a recent meta-analysis concluded that high-dose dexamethasone (>0.2 mg/kg) reduces acute pain and demonstrates opioid- sparing effects.[52] Unfortunately, none of the studies included in that meta-analysis reported on pain scores beyond the acute pain phase. Of the few studies that have investigated the effect of perioperative steroids on chronic pain, one study concluded that hydrocortisone 100 mg before open heart surgery followed by a short IV infusion and taper demonstrated significantly reduced pain scores at 6 months.[53]

Opioids With Dual Action

The effects of mu (μ)–receptor agonism in concert with serotonin reuptake inhibition, norepinephrine reuptake inhibition, or NMDA-receptor antagonism have gained interest as these medications when used alone achieve analgesia through multiple mechanisms. The list of dual-action opioids includes tramadol, tapentadol, and methadone.

Tramadol, a weak agonist of the mu-receptor, also inhibits serotonin and norepinephrine reuptake. It has been used successfully to treat chronic neuropathic pain, and it has been suggested that it may be similarly effective in treating acute neuropathic pain. Following oral administration, tramadol must be metabolized to render both serotonin and norepinephrine reuptake inhibition. This is accomplished by the P450 2D6 enzyme; it has been reported that 5%–15% of the population have reduced function of this P450 enzyme, which may explain a variable response between patients. With regard to acute pain, tramadol has been incorporated in multimodal regimens for total knee arthroplasty[54] and rotator cuff repair[55] with positive results on reducing acute pain. When compared to other analgesics with singular mechanisms of action, tramadol can provide superior analgesia.[56]

Tapentadol has the mechanisms of both mu-receptor agonism and norepinephrine reuptake inhibition. Tapentadol has stronger opioid activity and does not require metabolism of the parent compound to exert its effects. By increasing norepinephrine levels, afferent pain signaling is attenuated leading to improved analgesia. It has been suggested to be as effective as traditional opioids in the acute postoperative setting.[57] Tapentadol holds promise for acute pain stemming from painful procedures, as 100 mg doses are equipotent to oxycodone 15 mg.

Precipitating serotonin syndrome is a potential consequence when starting patients on tramadol or tapentadol if they concomitantly take antidepressants that increase levels of serotonin. Other side effects include nausea, constipation, and sedation (although less sedation than pure mu-receptor agonists).

A substance with mu-receptor agonism and NMDA-receptor antagonism, methadone has historically been used to treat chronic pain. The titration of oral methadone can be complicated as the half-life is variable. However, methadone has been used in the perioperative period as a single dose given IV immediately following induction of anesthesia. Doses have ranged from 0.2[58,59]–0.25 mg/kg.[60] All studies determined single IV doses of methadone were superior to conventional intraoperative opioids. Acute pain scores and opioid consumption were lower in all studies without serious side effects. Potential adverse effects of methadone include those associated with any opioid: nausea, vomiting, constipation, pruritus, somnolence, respiratory depression, and death. A unique concern to chronic methadone use is the prolongation of the QT interval; this can lead to fatal ventricular dysrhythmias.

There are currently no studies investigating dual-action opioids in preventing chronic pain. As mentioned in a previous section, the NMDA receptor appears to be important in the transition from acute to chronic pain. Of the medications mentioned in this section, methadone likely has the largest promise in preventing chronic pain due to its ability to block the NMDA receptor.

Regional Anesthesia

Perioperative regional anesthesia has become popular for a number of reasons. Widespread use of ultrasound has allowed anesthesiologists to perform peripheral nerve blocks that were once impossible with ease. There is emerging evidence that regional anesthesia may be able to reduce not only acute pain, but also the incidence of hyperalgesia, central sensitization, and chronic pain.

A recent meta-analysis on this subject provided some much needed insight into this exciting concept.[61] Epidural anesthesia in 250 (pooled) patients undergoing thoracotomy was shown to have a strong correlation with reduced persistent postsurgical pain; the number needed to treat was 4. Epidural anesthesia also has been studied in abdominal surgery[62]; patients who received epidural anesthesia intraoperatively were pain free at 1 year compared to 28% who received no epidural infusion. Of note, these investigators did include an intraoperative ketamine infusion for patients in all study groups (control and epidural.) Other situations where neuraxial anesthesia has been compared to nonregional methods for pain control include prostatectomy,[63] gynecologic surgery,[64] and lower extremity amputation.[65] One of these studies indicated a positive effect of neuraxial anesthesia; however, the benefits were similar to a group in the study that received systemic opioids and general anesthesia.[68]

Single-shot paravertebral blocks have also been shown to reduce the incidence of persistent postsurgical pain at 4–5 months[66] and 1 year.[67] Both studies were performed on patients undergoing surgery for breast cancer, some including axillary lymph node dissections.

A continuous local wound infiltration at the site of iliac bone graft site for 48 hours after surgery improved pain 4 years postoperatively.[68] The study sample was small at follow-up (19 patients, 9 in the treatment group) but the effects were significant with none of the treatment group experiencing dysesthesias over the harvest site versus 70% of the control group.

Many of the studies investigating regional anesthesia to prevent chronic pain are overall small and provide significant variability in study design.[64] However, there are promising effects of neuraxial blocks, peripheral nerve blocks, and local infiltration to prevent persistent postsurgical pain.

SUMMARY

The concept of multimodal analgesia was described more than 2 decades ago and has gained much support with individual investigators experimenting and developing combinations of analgesics to enhance patient care in the perioperative period. This excitement has led to a variety of combinations tested, albeit with significant variability between studies. The evidence that exists suggests a diverse surgical population can benefit from these interventions.

Chronic pain is costly in terms of both costs to the health care system and to the gross domestic product (GDP) in terms of lost productivity. The 21st century began with a decade of pain research and innovation. Among the many things that came out of this time period was the attention to perioperative pain management. Greater appreciation for the transition from acute pain to chronic pain has led many investigators to investigate the molecular mechanisms responsible for secondary hyperalgesia, central sensitization, and the development of persistent postsurgical pain.

The future of perioperative pain management relies on refining the knowledge accumulated in the past 15 years. Further research is required to determine the maximally effective doses of the medications included in multimodal regimens, as well as the optimal dose to prevent chronic pain. Many of the medications discussed in this chapter have shown a dose-specific effect. Below a certain threshold, the short-term and long-term benefits of a medication could be missed. Large, randomized, prospective trials investigating single agents over appropriate time courses (at least 3 months) at varying doses will help fill this void in our knowledge base. Finally, use of regional anesthesia techniques (peripheral or neuraxial) has gained significant popularity for a number of reasons. Technology has allowed us to perform continuous blocks with peripheral nerve catheters and elastomeric pumps. What will be interesting is if longer acting local anesthetics will replace this technology and lead to a longer lasting block, and perhaps a longer lasting effect.

Clinical Pearls

- **Acetaminophen**
  - The daily limit of acetaminophen is 3000 mg per day.
- **NSAIDs**
  - Prostaglandins sensitize both nociceptive and nonnociceptive nerve endings, resulting in the two groups of transmitting pain signals regardless of the type of stimulus.
- **Anticonvulsants**
  - Pregabalin's bioavailability and ability to titrate quickly makes it an ideal agent to use in the perioperative phase.
- **NMDA-Receptor Antagonists**
  - Low-dose intraoperative ketamine infusions can have a significant effect on not only acute pain, but also on chronic pain.
- **Steroids**
  - Single doses of corticosteroids given intraoperatively appear to have a dose-effect relationship.
- **Dual-Action Opioids**
  - Norepinephrine reuptake inhibition adds a beneficial effect by reducing ascending nociceptive pathway transmission.
- **Regional Anesthesia**
  - Thoracic epidural anesthesia prevents chronic pain following thoracotomy.
  - Paravertebral blocks reduce chronic pain following breast cancer surgery.

CHAPTER 76

The Role of Nonopioid Analgesic Infusions in the Management of Postoperative Pain

Gildasio S. De Oliveira, Jr, Honorio T. Benzon, and Paul F. White

INTRODUCTION

Opioids are the most commonly used medications for perioperative pain control. However, opioid-related side effects such as constipation, nausea, vomiting, and respiratory depression often accompany the use opioids. Many studies have evaluated the efficacy of nonopioids such as ketamine, lidocaine, naloxone, and magnesium as perioperative infusions to decrease postoperative pain and minimize the use of opioids after surgery. Infusions of the short-acting beta-blocker esmolol and the α_2 agonist dexmedetomidine have also been investigated as adjuvants to reduce the postoperative opioid requirement. In this chapter, the results of the studies on infusions of ketamine, lidocaine, naloxone, esmolol, α_2 agonists, and magnesium will be summarized, and recommendations on their clinical applicability as part of perioperative pain management will be made.

INTRAVENOUS KETAMINE INFUSION

Ketamine is a noncompetitive N-methyl-D-aspartate glutamate (NMDA) receptor antagonist and a sodium channel blocker.[1] The drug is available as racemic ketamine which contains the S (+) and R (–) stereoisomers. The S (+) ketamine has four times greater affinity for the NMDA receptor than the R (–) ketamine. Ketamine has a half-life of 80–180 minutes. Its metabolite norketamine has a longer half-life life and is one third as potent as the parent compound.[2] Early studies showed ketamine to have analgesic properties at low doses.[3–7]

Ketamine has many qualities as an analgesic. It does not suppress cardiovascular function in the presence of an intact nervous system,[8] does not depress the laryngeal protective reflexes and causes less depression of ventilation compared to opioids,[9] and may even stimulate respiration.[10]

Ketamine has been used in subanesthetic doses as an analgesic.[6] The analgesic effects of ketamine occur at plasma concentrations of 100–150 ng.mL^{-1},[11] The undesirable characteristics of ketamine include postoperative malaise,[12] accumulation of metabolites,[13] development of tolerance,[14] cardiovascular excitation, and the occurrence of psychotomimetic side effects.[15,16] Psychotomimetic effects are the most common feared complication by clinical practitioners but few studies have formally evaluated these side effects.[4-7]

Randomized controlled clinical studies on perioperative IV ketamine showed some beneficial effect. In a study in patients who underwent cervical and lumbar spine surgery, ketamine (1–mg/kg bolus followed by 83 mcg/kg^{-1}/h^{-1}) resulted in lower pain scores, less analgesic requirements, and better satisfaction than patients who had saline infusions or those who had lower doses of ketamine infusions (same bolus but with an infusion rate of 42 mcg/kg^{-1}/h^{-1}).[17] The same salutary effects were seen in patients who had major abdominal surgery. Perioperative ketamine infusion (0.5–mg/kg bolus followed by 2 mcg/kg^{-1}/min^{-1}) for 48 hours after surgery resulted in lower morphine consumption than patients who had saline infusion or those who had the same infusion given intraoperatively.[18] The pain scores were noted to be lower in the ketamine group compared to the control group. To better evaluate the effect of a ketamine bolus on the infusion, Bilgin et al[19] compared ketamine bolus followed by an infusion with ketamine bolus alone given either before the surgical incision or at wound closure. In this study, the patients underwent gynecologic laparotomy. The investigators noted that the patients who had the ketamine bolus and infusion had lower pain scores and lower morphine consumption. Similarly, ketamine infusion reduced postoperative opioid consumption in patients who had spinal anesthesia for cesarean section.[20]

No beneficial effect of ketamine infusion was noted when the general anesthetic consisted of total intravenous anesthesia with remifentanil and propofol infusions.[21] The absence of beneficial effect may be related to the generous use of intraoperative opioids. A systematic review evaluating over 4700 patients demonstrated the efficacy of ketamine in reducing postoperative opioid consumption and pain, especially for thoracic, upper abdominal, and major orthopedic surgical procedures.[22] The investigators demonstrated that despite using less opioid, 25 of 32 treatment groups (78%) experienced less pain than the placebo groups at some point postoperatively when ketamine was efficacious. This finding suggested an improved quality of pain control in addition to decreased opioid consumption.

The effect of perioperative IV ketamine infusion in preventing postamputation pain has been also studied.[23] Ketamine 0.5 mg/kg^{-1} bolus followed by an infusion of 0.5 mg/kg^{-1}/h^{-1} for 72 hours was not effective in reducing morphine consumption or in decreasing the incidence of stump allodynia. At 6-month follow-up, the incidences of phantom pain and stump pain were 47% in the ketamine group compared to 71% and 35% in the control (saline) group. There was no statistical difference in the incidences, so the investigators concluded that IV ketamine did not significantly reduce acute central sensitization or the incidence and severity of postamputation pain.[23]

Ketamine infusion appears to have a beneficial effect on epidural analgesia. The addition of a ketamine infusion to an epidural analgesia in patients who underwent colorectal surgery resulted in less patient-controlled analgesia (PCA) morphine requirements and reduced the area of hyperalgesia.[24] Another group of investigators noted the salutary effect of adding low-dose IV ketamine (0.05 mg/kg^{-1}h^{-1}; approximately 3 mg/h) to epidural analgesia after thoracotomy.[25] In this study, the patients who had the ketamine infusion had less pain and took less analgesics at 3 months after the surgery. Unfortunately, this beneficial effect of ketamine in preventing chronic pain after surgery was not confirmed in other studies.[26,27] In one study, the ketamine infusion (1 mg/kg^{-1} at induction, 1 mg/kg^{-1}/h^{-1} during surgery, then 1 mg/kg^{-1} for 24 hours) in addition to intrapleural ropivacaine improved immediate postoperative pain compared to saline.[26] At 4 months after surgery, however, the analgesic intake and neuropathic pain scores were the same in both groups. In another study, the incidences of moderate and severe postthoracotomy pain syndrome at 3 and 6 months were similar in the ketamine and saline groups.[27]

The addition of ketamine infusion appears to be beneficial in opioid-tolerant patients. An earlier study by Loftus et al showed reduced opioid consumption in the first 48 hours after back surgery in patients who had ketamine bolus ([0.5 mg/kg]) and intraoperative infusion (10 mcg/kg [–1] min [–1]).[28] A more recent study showed that the addition of ketamine infusion (0.2 mg/kg/h) to hydromorphone IV PCA resulted in a statistically significant reduction of “average” pain scores in the opioid-dependent patients.[29] However, “least” and “worst” pain scores and postoperative opioid use did not differ between the ketamine and saline groups.

Most of the studies showed no increased side effects when low-dose ketamine infusions are used. Zakine et al[18] did not observe nightmares, delusions, sleep, or psychiatric disorders in their study. Sleep disturbance and psychomotor were similar between the ketamine infusion group and control group. In a quantitative systematic review, Laskowski and colleagues detected that hallucinations and nightmares were more common with ketamine but sedation was not.[22] They noted that when ketamine was efficacious for pain, postoperative nausea and vomiting were diminished.

Review articles on ketamine infusion noted the small number of patients in the studies, large variations in clinical settings, different ketamine regimens, and different routes of administration.[22,30–34] Most of the randomized controlled studies showed some beneficial effects of a low-dose ketamine infusion. Ketamine infusion appears to improve the efficacy of epidural analgesia. It does not seem to have any effect when the anesthetic technique is total intravenous anesthesia where moderate or substantial amounts of intraoperative opioid are used. IV ketamine may find its use as an adjunct in opioid-tolerant patients, or in patients with a higher incidence of chronic postsurgical pain such as thoracotomy, inguinal herniorraphies, or mastectomies.

Clinical Pearl

- Ketamine intraoperatively is beneficial adjunct in the control of perioperative pain in opioid-dependent patients.

INTRAVENOUS LIDOCAINE INFUSION

Lidocaine has peripheral and central properties that are suitable for pain relief. It decreases albumin extravasation in animal models of chemical peritonitis[35] and inhibits leukocyte migration and metabolic activation.[36] Lidocaine has been shown to modify the neuronal responses in the dorsal horn[37] and selectively suppress synaptic spinal transmission by decreasing C fiber–evoked activity in the spinal cord.[38] Clinically, local anesthetic infusions have been used in the treatment of neuropathic pain[39,40] and pain from burns.[41]

Several studies showed the beneficial effects of intravenous lidocaine in abdominal surgery. In a randomized, double-blind, placebo-controlled study, Cassuto et al[42] showed the analgesic efficacy of a low-dose lidocaine infusion in patients who underwent cholecystectomy. After an intravenous bolus of 100 mg of lidocaine, they infused lidocaine at 2 mg/min, starting at 30 minutes before the surgery, and continued for 24 hours after the surgery. Compared to the group who had saline infusions, the patients who had the lidocaine infusions had significantly lower pain scores during the first day of surgery and required significantly less meperidine during the first 2 postoperative days.[42] Other randomized controlled studies showed the technique to result in lower postoperative pain scores, less opioid consumption, faster return of bowel function, and reduced hospital stay.[43–45] Groudine et al[43] compared lidocaine with saline in patients who had radical retropubic prostatectomy. In the lidocaine group, the patients had 1.5– mg/kg bolus of lidocaine before induction, an intraoperative infusion of either 3 mg/min or 2 mg/min (for patients weighting <70 kg) that was continued until 1 hour postoperatively. Although the analgesic consumption between the patients in the two groups was the same, the patients who had the lidocaine infusion had lower pain scores, a shorter return of bowel movement (62 ± 13 hours vs 74 ± 16 hours) and a shorter hospital stay (4 vs 5 days). In patients who underwent major abdominal surgery, Koppert et al[44] gave a 1.5–mg/kg bolus over 10 minutes, followed by 1.5/mg/kg/h 30 minutes before surgical incision and continued up to 1 hour after the end of surgery. The control group had saline bolus followed by saline infusion. The lidocaine infusion group had lower pain scores, less morphine requirement (130 vs 159 mg) over a 72-hour period, and had bowel movements sooner.[44] The opioid-sparing effect was noted to be most pronounced on the third postoperative day, prompting the investigators to theorize that the lidocaine infusion may have a true preventive analgesic effect. In another study done in patients who had laparoscopic cholecystectomy,[45] the patients were given a lidocaine bolus injection of 1.5 mg/kg at the induction of anesthesia followed by a continuous infusion of 2 mg/kg/h intraoperatively and 1.33 mg/kg/h postoperatively for 24 hours. The control group had saline bolus injections followed by a saline infusion. The times to first flatus (17 vs 28 h), defecation (28 vs 51 h), and hospital discharge (2 vs 3 days) were significantly shorter in the patients who had the lidocaine infusion. In addition, the lidocaine infusion also significantly reduced opioid consumption and postoperative pain and fatigue scores.

Two studies not only looked at pain relief but also the effect of the lidocaine infusion on markers of inflammation and immune response. A randomized study in patients who underwent transabdominal surgery showed less severe postoperative pain in the first 8 hours after surgery, both at rest and during coughing.[46] However, there was no difference in pain scores for the 12–72 hours after surgery between the IV lidocaine and IV saline. The investigators noted less ex vivo production of interleukin-1ra (IL-1ra) and IL-6 and better maintenance of the lymphocyte proliferation response to phytohemagglutinin-M in the intravenous saline group, signifying the ability of lidocaine to reduce surgery-induced immune changes. Another study did not notice improved pain scores but showed other salutary effects when lidocaine infusion is employed in patients undergoing colorectal surgery. Herroeder et al[47] gave an IV bolus of lidocaine 1.5 mg/kg followed by a continuous infusion of 2 mg/min until 4 hours postoperatively. Although the pain ratings were the same compared to a saline control group, the return of bowel function was accelerated and the length of hospital stay was shortened by 1 day. The investigators also noted significant attenuation of the plasma levels of IL-6, IL-8, complement C3a, and IL-1ra as well as expression of CD11b, P-selectin, and platelet-leukocyte aggregates. The findings showed the ability of IV lidocaine to modify the anti-inflammatory activity, which modulates the surgery-induced response.

The salutary effects of IV lidocaine infusion were not duplicated in patients who had a total hip replacement or coronary artery bypass graft surgery. In a randomized, double-blind, placebo-controlled study, 1.5 mg/kg lidocaine bolus was given over 10 minutes at 30 minutes before surgical incision followed by an infusion of 1.5 mg/kg/h until 1 hour after the end of the surgery.[48] There was no difference between the lidocaine and saline groups in terms of postoperative pain scores and opioid consumption (17 vs 15 mg morphine over 24 hours) and no difference in hip flexion. Low-dose lidocaine infusion was also noted to be ineffective in reducing the supplemental fentanyl, midazolam, or propanolol postoperative requirements in patients who underwent coronary artery bypass.[49] In this study, the lidocaine infusion did not reduce the time to extubation, intensive care unit (ICU) stay, or hospital length of stay. It is not clear if lidocaine infusion has no beneficial effect in coronary artery bypass graft (CABG) or total hip surgery since there is only one study for each surgery. Additional studies are needed to determine if ketamine infusion is really ineffective in these surgical settings.

Initial studies on lidocaine infusion (1.5–mg/kg bolus followed by an infusion of 2 mg/kg^{-1}/h^{-1}) in patients undergoing ambulatory surgery noted that the infusion resulted in less intraoperative opioid use and less pain scores.[50] De Oliveira et al determined that perioperative lidocaine not only reduced postoperative pain and opioid consumption, but also improved overall quality of postsurgical recovery in patients undergoing outpatient laparoscopic gynecologic surgery. Patients who received lidocaine met discharge criteria faster than the group who received saline.[51]

Intravenous lidocaine infusion is not as effective as perioperative epidural analgesia. IV lidocaine was inferior to thoracic epidural analgesia in terms of pain relief and attenuation of cytokine "surge" in patients who underwent colonic surgery. In a nicely done randomized blinded study, Kuo et al[52] showed that thoracic epidural analgesia resulted in better pain relief, lower opioid consumption, earlier return of bowel function, and lesser production of cytokines than IV lidocaine during the 72-hour observation study period. The patients who had the IV lidocaine experienced better pain relief and less cytokine release than the control (saline) group.

A randomized but unblinded study compared IV lidocaine infusion with epidural analgesia in patients who had open colon resection.[53] The IV lidocaine group had infusions of 1–2 mg/min (1 mg/min in <70 kg patients and 2 mg/min in >70 kg patients), while the epidural analgesia group had 10 mL/h of 0.125% bupivacaine and hydromorphone 6 mcg/mL. The infusions were started within 1 hour of the end of surgery and continued until return of bowel function or by the fifth day. There were no statistical differences in the average pain scores (visual analog scale [VAS] of 2.2 in the epidural group vs 3.1 in the IV lidocaine group) and a trend toward greater opioid consumption in the IV lidocaine group. The return of bowel function or the length of hospital stay was not statistically different between the groups.[53] It is interesting to note that two chronic pain patients in the IV lidocaine group were excluded, and an epidural had to be subsequently placed in one of the patients for "further pain treatment."

Two meta-analysis articles showed beneficial effects of perioperative lidocaine infusion. An earlier meta-analysis of eight trials noted improved rehabilitation and shortened hospital stay when a lidocaine infusion is used.[54] The improved recovery was supported by decreased postoperative pain at 24 hours after

TABLE 76-1. Efficacy of perioperative ketamine and lidocaine intravenous infusions.

	Ketamine	Lidocaine
Bolus dose	0.5 –1.0 mg/kg	100 –1.5 mg/kg
Usual infusion dose	40 –100 mgkg^{-1}/h^{-1}	2 –3 mg/min (2 mg/min for patients <70 kg)
Infusion dose with epidural analgesia	0.05 (~3 mg/h)– 0.25 mg/kg^{-1}/h^{-1}	
Efficacy		
Abdominal surgery	Beneficial	Beneficial
Pelvic: gynecologic, urologic	Beneficial	Beneficial
Spine surgery	Beneficial	
Total hip replacement		Not beneficial
Coronary artery bypass surgery		Not beneficial
TIVA	No additional benefit	
Concomitant PCEA	Additional benefit	
Compared to PCEA		Blinded study showed less efficacy[52] while a randomized but unblinded study showed non-statistically significant pain scores and a trend towards greater opioid consumption in the IV lidocaine group.[53]

Source: Reproduced with permission from Benzon HT, Raja SN, Liu SS, et al: *Essentials of Pain Medicine and Regional Anesthesia*, 3rd ed. New York: Elsevier/Churchill Livingstone; 2011.

surgery, lower incidence of nausea and vomiting, and shorter duration of ileus. The ability of IV lidocaine to shorten the duration of ileus was shown clinically; e.g., first passage of gas and feces, and also through radiopaque markers and serial abdominal radiographs.[55] A meta-analysis evaluating over 1700 patients[56] showed that at 6 hours postoperatively, intravenous lidocaine infusion reduced pain at rest (weighted mean difference [WMD] –8.70, 95% confidence intervals [CI] –16.19 to –1.21), during cough (WMD –11.19, 95% CI –17.73 to –4.65), and during movement (WMD –9.56, 95% CI –17.31 to –1.80). Intravenous lidocaine infusion also reduced morphine requirement (WMD –8.44 mg, 95% CI –11.32 to –5.56), time to first flatus (WMD –7.62 hr, 95% CI –10.78 to –4.45), time to first feces (WMD –10.71 hr, 95% CI –16.14 to –5.28), nausea/vomiting (risk ratios = 0.71, 95% CI 0.57–0.90), and hospital length of stay (WMD –0.17 days, 95% CI –0.41 to –0.07). The investigators concluded that lidocaine infusions used for abdominal surgery was strongly associated with benefits.[56]

The beneficial effects of a perioperative lidocaine infusion in abdominal surgery may be related to its ability to suppress inflammatory processes from the surgery.[46,52] The ability of IV lidocaine to attenuate increased levels of proinflammatory cytokines prevents the development of peripheral and central nervous system sensitization which leads to clinical hyperalgesia.[57]

In terms of prevention of chronic postsurgical pain, systemic perioperative lidocaine has been shown to reduce the development of this postsurgical pain syndrome after mastectomies.[58] The effect was very large but the study sample size was small (36 subjects). Future larger randomized trials are needed to refute or confirm the role of lidocaine as an effective intervention to reduce chronic postsurgical pain.

The comparable efficacy of perioperative intravenous ketamine and lidocaine infusions is shown in Table 76–1. It can be seen that infusion of either drug is beneficial in abdominal surgery. Ketamine infusion is effective in spine surgery but showed no added benefit when the technique of general anesthesia is total intravenous anesthesia. Lidocaine infusion appears to have no benefit in patients who undergo total hip replacement or coronary artery bypass surgery. A randomized blinded study showed less efficacy of intravenous lidocaine infusion when compared to epidural analgesia.

Clinical Pearl

- Lidocaine infusion can be beneficial in abdominal surgeries but not in total hip surgery. It accelerates the postoperative return of bowel function.

INTRAVENOUS NALOXONE INFUSION

Naloxone is a pure mu-receptor antagonist. Naloxone infusion has been utilized to decrease the incidence of nausea, vomiting, respiratory depression, and urinary retention after epidural[59,60] and intrathecal opioids.[61,62] However, its use comes with the possibility of reversing the analgesia from the opioid.[63] Studies showed that a naloxone infusion at 10 mcg/kg^{-1}/h^{-1} reduced the duration and quality of analgesia from epidural morphine[59] or fentanyl.[60] In patients who had hip surgery under spinal analgesia with bupivacaine and morphine, naloxone infusion at <1 mcg/k^{-1}/h^{-1} was associated with inferior analgesia.[61] Another study showed that the infusion of naloxone at 1 mcgkg^{-1}h^{-1} attenuated the pain relief in the patients who had intrathecal morphine after lumbar laminectomy.[62] In patients who had radical prostatectomy who were given 0.8–1.7 mg intrathecal morphine, the IV infusion of naloxone at 5 mcg/kg/h provided excellent analgesia with infrequent and minor side effects.[64] Unfortunately, the study was retrospective and without a control group.

The efficacy of naloxone infusion in decreasing the incidence of side effects from neuraxial opioids led Gan et al to investigate the effect of naloxone infusion on PCA morphine.[65] In a randomized, double-blind study, 60 patients who underwent hysterectomy were assigned into three groups: (1) PCA morphine, 1 mg/mL, with saline infusion; (2) PCA morphine with low-dose naloxone infusion (0.25 mcg/kg^{-1}/h^{-1}); and (3) PCA morphine with high-dose naloxone infusion (1 mcg/kg^{-1}/h^{-1}).[65] They noted that both naloxone doses were equally effective in reducing the incidence of nausea and vomiting and pruritus compared with placebo. There was no difference in the pain scores between the three groups even though the cumulative morphine usage was significantly lower in the low-dose group (42.3 ± 1 24.1 mg) compared with the placebo (59.1 ± 27.4 mg) or the high-dose group (64.7 ± 33 mg). There was no respiratory depression and no difference in sedation scores, respiratory rate, hemodynamic parameters, or antiemetic use between the three groups.[65] Movafegh et al[66] examined the effect of a 24-hour low-dose naloxone infusion in 90 patients who had hysterectomies. They showed that naloxone significantly reduced morphine consumption over the first 24 postoperative hours compared with the control group (saline). Morphine consumption was also lower, 19.5 (standard deviation [SD] 3.4) mg versus 27.5 (SD 5.9) mg. In addition, the incidence and severity of nausea and vomiting was significantly reduced in the naloxone group, similar to what was observed by Gan et al.[65]

The ability of low doses of naloxone to improve postoperative analgesia is secondary to its dose-dependent effect on pain. Woolf noted that small doses of naloxone produced analgesia in rats while large doses resulted in hyperalgesia.[67] Levine et al also noted that naloxone initially produced analgesia in a dose-dependent manner and then caused hyperalgesia.[68] Other investigators noted this biphasic or dual modulatory effect of naloxone.[69–71] The mechanisms of analgesic effect of naloxone maybe related to the release of endorphins or displacement of endorphins from receptor sites not related to analgesia.[72] Augmentation of the activity of opioid receptors is another possibility, although this upregulation phenomenon has been demonstrated after prolonged naloxone infusion (7 days) and in animals.[73,74] At higher doses, naloxone blocks the action of the released or displaced endorphin at the postsynaptic receptor.

There is no added efficacy when naloxone is administered via IV PCA.[75–77] The different pharmacokinetics of the drug when given intermittently compared to when given as infusion may explain the lack of added benefit. Naloxone has an alpha half-life of 4 minutes and a beta half-life of 55–60 minutes[78,79]; a continuous infusion of the drug, therefore, results in constant plasma levels resulting in a more consistent effect.

The present indication for IV naloxone infusion is to control the side effects of neuraxial opioids. Few studies such as the one by Gan et al[65] and the one from Movafegh et al[66] showed the efficacy of a low-dose naloxone infusion in reducing opioid consumption. Its increased clinical use for postoperative analgesia should await additional controlled studies in different surgical procedures.

Clinical Pearl

- While low-dose naloxone infusion is effective in reducing postoperative opioid consumption, additional studies are needed its role in different surgical settings and whether the analgesic effect of concomitant opioid is diminished.

MAGNESIUM INFUSION

Magnesium is the second most common intracellular ion with a crucial role in maintaining the functions of organisms. Magnesium is an essential component for the function of enzymes, neurotransmission, and cell signaling.[80] Animal studies demonstrated that magnesium is an antagonist of N-methyl-D-aspartate (NMDA) receptors and minimizes the perception and duration of pain.[81] Since dietary intake is the main source of magnesium in humans, long periods of dietary restriction as well as unpredictable operating room schedules are important causes of hypomagnesemia during the perioperative period.[82] In addition, the perioperative administration of intravenous fluids may also contribute to the development of low levels of magnesium.

The effect of systemic magnesium on postoperative analgesia has been examined by different investigators in a large variety of surgical procedures. Two studies looked at the effect of intravenous magnesium to minimize postoperative pain in patients undergoing major abdominal surgery.[83,84] Both studies utilized an initial bolus of magnesium sulfate (50 mg/kg) followed by a postoperative infusion. The study of Jaoua et al examined only 40 patients, and the investigators were not able to detect an opioid-sparing effect of magnesium.[83] In contrast, the study of Amor et al examined 48 patients, and morphine consumption was significantly higher in the control group compared to the magnesium group on the first postoperative day (52 ± –4 mg vs 30 ± –3 mg).[84]

In patients undergoing total abdominal hysterectomy, lower postoperative pain scores and less cumulative postoperative analgesic consumption were noted in patients who received magnesium compared to placebo.[85] Spine surgery is another procedure where perioperative magnesium infusion has been confirmed to improve postoperative analgesia.[86] An area that remains to be investigated is the use of systemic magnesium to minimize postoperative pain in ambulatory surgical patients as there is only one study in this setting. Tramer et al[87] studied 200 patients undergoing ambulatory ilioinguinal hernia repair or varicose vein operation under general anesthesia and randomized them to receive magnesium sulfate 4 g IV or physiologic saline after anesthetic induction. There was no difference in postoperative opioid consumption or pain scores between the study groups. However, it is important to note that patients in the study received a concomitant multimodal analgesic regimen which consisted of diclofenac 100 mg rectally for the patients who underwent varicose vein surgery and a postoperative ilioinguinal-iliohypogastric nerve block for the patients who had hernia repair. Currently, it remains to be determined if perioperative magnesium infusion is a valuable adjunct in minimizing postoperative pain in ambulatory surgical procedures.

Recently, De Oliveira et al performed a meta-analysis to quantitatively assess the effect of perioperative magnesium infusions on postoperative pain outcomes.[88] They evaluated 20 randomized clinical trials, and over 1200 subjects were included in their final analysis. In most of the studies, 30– to 50–mg/kg boluses were initially given followed by an intraoperative infusion of 10–15 mg kg^{-1}/h^{-1}. The overall effect of magnesium on postoperative pain was small for early pain at rest –0.74 (99% CI –1.08 to –0.48) on a 0–10 numerical rating scale. The overall effect of magnesium compared to saline was also small for late pain (24 hours) at rest, –0.36 (99% CI –0.63 to –0.09). In contrast, the effect of magnesium on opioid sparing compared to saline was substantial, –10.52 (99% CI –13.50 to –7.54) mg morphine IV equivalents. After performing a subgroup analysis, the investigators concluded that the intraoperative and postoperative administration of magnesium had greater analgesic effect than a sole intraoperative administration. None of the studies included in the meta-analysis reported signs or symptoms of magnesium toxicity related to high levels of perioperative magnesium.

In summary, magnesium infusion seems to be a promising strategy to minimize postoperative opioid requirement. The lack of reported toxicity also makes it a safe option. However, more studies are still needed to confirm the analgesic effect of systemic magnesium for ambulatory surgical procedures.

Clinical Pearl

- Intraoperative and postoperative administration of magnesium may have an opioid-sparing effect, studies reported no signs of systemic toxicity.

ESMOLOL INFUSION

Esmolol is a cardioselective $beta_1$-receptor blocker commonly used in the anesthesia to treat intraoperative tachyarrhythmias or to blunt the adrenergic response caused by various stimuli during surgery such as in laryngoscopy, intubation, surgical stimulation, and tracheal extubation. The drug has a very rapid onset and short duration of action.[89] Esmolol is rapidly hydrolyzed by plasma esterases at the ester-methyl side chain, which is the basis for the drug's short duration of action. Esmolol's elimination half-life is about 9 minutes.[90]

The effect of esmolol infusions on postoperative pain outcomes has been examined by several investigators with most studies demonstrating a favorable analgesic effect. Esmolol was first used as an alternative to opioid analgesics in 1991 by White's group in ambulatory arthroscopic procedures.[91] The investigators compared esmolol to alfentanil when used to supplement propofol-N_2O-atracurium anesthesia according to a randomized, double-blind protocol, and they concluded that esmolol may be used in place of alfentanil to supplement anesthesia in outpatients undergoing arthroscopic procedures. They noted that avoiding alfentanil did not decrease the incidence of postoperative nausea and vomiting in this outpatient population.[91]

A study examined the influence of perioperative esmolol administration compared to saline on postoperative pain management among patients undergoing hysterectomy.[92] The investigators demonstrated that perioperative esmolol administration during anesthesia reduced the intraoperative use of inhalation anesthetic and fentanyl, decreased hemodynamic responses, and reduced morphine consumption (by 17 mg IV morphine equivalents) for the first 3 postoperative days. Another study compared esmolol with either intermittent fentanyl or continuous remifentanil on postoperative opioid sparing, side effects, and time of discharge in patients undergoing ambulatory cholecystectomy.[93] The investigators concluded that intraoperative IV infusion of esmolol contributes to a significant decrease in postoperative administration of fentanyl and ondansetron and facilitates earlier discharge. More recently, Lee and colleagues confirmed the analgesic properties of esmolol in patients undergoing laparoscopic appendectomy.[94]

The safety of perioperative esmolol infusions has been recently examined by a systematic review of 67 randomized controlled trials.[95] Esmolol infusions titrated to a hemodynamic endpoint was found to be safe and effective in low-risk patients. In contrast, safety data from studies in higher risk patients are needed to establish a perioperative safety and efficacy profile of esmolol.

In summary, esmolol infusions seem to be a valid strategy to ameliorate postoperative pain. The results of randomized studies are particularly encouraging in the ambulatory surgical population.

Clinical Pearl

- Esmolol infusion is a useful an adjuvant in reducing the anesthetic requirement and decreasing acute hemodynamic responses to noxious surgical stimuli. Esmolol can also reduce postoperative opioid requirements and can reduce side effects (e.g., PONV) in ambulatory surgery patients.

α_2 AGONISTS

The α_2 agonists are often used as anesthetic adjuncts due to its desirable properties including anxiolysis, sedation. and hypnosis.[96] In addition, α_2 agonists have also been found to have analgesic properties. Their analgesic effect is attributed to the stimulation of two adrenoreceptors located in the central nervous system and spinal cord. It also has been suggested that systemic α_2 agonists potentiate the analgesic effects of opioids.[97] Systemic clonidine is thought to have opioid-sparing and antiemetic properties, but its routine clinical use as an infusion has been limited by the presence of adverse effects such as hypotension and bradycardia.[98] Another α_2 agonist commonly used in the perioperative setting is dexmedetomidine. Intravenous infusion of dexmedetomidine is commonly initiated with a 1– mcg/kg loading dose, administered over 10 minutes, followed by a maintenance infusion of 0.2–1.0 mcg/kg/h.[99]

The first clinical trial to evaluate the effect of dexmedetomidine infusion on postsurgical pain was performed by Aho and colleagues on patients undergoing laparoscopic tubal ligation.[100] They concluded that intravenously dexmedetomidine relieves pain and reduces the opioid drug requirement but is attended by sedation and a high incidence of bradycardia. Arain et al also detected a beneficial opioid-sparing effect of dexmedetomidine after major inpatient surgery.[101] Another group evaluated dexmedetomidine infusion on pain outcomes in patients undergoing abdominal hysterectomy.[102] In this study, 50 women were randomly assigned to two groups. Group D (n = 25) received a loading dose of dexmedetomidine 1 mcg/kg (–1) IV during induction of anesthesia, followed by a continuous infusion at a rate of 0.5 mcg/kg (–1)/hr (–1) throughout the operation. The investigators demonstrated that continuous IV dexmedetomidine during abdominal surgery provides effective postoperative analgesia, and reduces postoperative morphine requirements without increasing the incidence of side effects.

More recently, Tramer's group performed a meta-analysis of randomized trials on 1792 patients and detected an opioid-sparing effect of dexmedetomidine compared to placebo of –4.1 mg IV morphine equivalents (95% CI –6.0 to –2.2 mg).[103] However, dexmedetomidine increased the risk of postoperative bradycardia (number needed to harm, 3).

In summary, dexmedetomidine appears to be a promising perioperative analgesic, decreasing opioid requirements after surgery. It does not increase side effects, although it can result in bradycardia.

SUMMARY

Several preoperative nonopioid infusions have been adequately studied and can be recommended as part of multimodal approach to post-operative pain management. Ketamine infusions are notable adjuncts in opioid-dependent patients, while lidocaine infusions not only decrease perioperative opioid requirements in abdominal surgeries, but also shorten bowel recovery recovery. Esmolol and dexmedetomidine infusions have well-documented opioid-sparing effects and offer potential advantages in patients with enhanced cardiovascular responses to surgical stimuli. Magnesium may be a viable alternative, but convincing evidence of improved patient outcomes is still lacking. The more widespread use of low-dose naloxone infusions also awaits further studies. The effect of these nonopioid infusions on chronic post-surgical pain awaits further elucidation in clinical trials.

Clinical Pearl

- Infusion of dexmetomidine can reduce both anesthetic and opioid requirements. However, it may result in bradycardia and sedation.

PART 13

EDUCATION IN REGIONAL ANESTHESIA

This page intentionally left blank

CHAPTER 77

Teaching Regional Anesthesia

Ahtsham U. Niazi and Joseph M. Neal

INTRODUCTION

Regional anesthesia enhances patient satisfaction and favorable outcomes, especially in obstetrics and acute pain management. Over the past 20 years, the importance of training anesthesiologists in regional anesthesia has become recognized worldwide, but the actual accomplishment of quality training remains a challenge for residents and fellows, as well as practicing anesthesiologists. Quality training in regional anesthesia is necessary to promote not only clinical competence, but also practitioner confidence in their ability to perform the skill proficiently and safely. Surveys of residency programs demonstrate narrowing variability in training, and recent consensus-based regional anesthesia and acute pain medicine fellowship guidelines may further improve training at all levels. Academic programs have employed conventional and unconventional methods to complement the exposure to regional anesthesia opportunities that residents and fellows receive in the operating room, obstetric suite, and pain clinic. In this chapter, such concepts will be discussed as well as future goals for improving regional anesthesia training for all anesthesiologists.

PAST AND CURRENT TRAINING EXPERIENCE

Evolution of Regional Anesthesia Training

As early as the 1920s, there were dedicated teachers of regional anesthesia. In the United States, both Gaston Labat and John S. Lundy offered 3-month courses to teach the basics to interested practitioners; such teaching influenced many renowned anesthesiologists, including Ralph Waters and Emery Rovenstine.[1] At that time, a few experts promoted regional anesthesia, including the members of the first American Society of Regional Anesthesia, which was founded by Dr. Labat. Yet, prior to the last quarter century, only a few residency programs had officially incorporated regional anesthesia as part of their educational curriculum.

In fact, it was not until 1996 that the Anesthesiology Residency Review Committee (RRC) of the Accreditation Council for Graduate Medical Education (ACGME) formally listed a minimal number of regional anesthetic blocks as a requirement of training in anesthesiology.[2] Prior to that time, there was wide variability in regional anesthesia training in residencies. A survey conducted in 1980 showed that regional anesthesia use ranged from 2.8%–55.7% among responding training programs, with approximately 21% of all cases using regional anesthesia.[3] Indeed, diplomates of well-respected programs could graduate having performed less than a handful of spinal anesthetic procedures. These numbers improved somewhat by 1990, but although regional anesthesia was utilized in more cases (29.8%), primarily reflecting increases in obstetric and pain management applications of regional techniques, the large discrepancy continued with regional techniques contributing 2.8%–58.5% of total caseload experience.[4] By the year 2000, the number of surgical cases with regional anesthetics did not significantly increase (30.2%), nor did the distribution of the types of anesthetics (Figures 77–1 and 77–2), but there was much less disparity in experience between training programs nationwide.[5]

Accreditation Agency Requirements

The current RRC program requirements state that residents must perform 50 epidural, 50 spinal, and 40 peripheral nerve blocks plus an additional 25 nerve blocks for pain management.[2] The most recent survey of residents' experience (2015) shows that over 70% of residents met the minimum for spinal anesthetics. Although all residents performed the minimum number of epidurals, that nearly 80% were from the lumbar approach suggests that most epidural training still occurs in the obstetric suite.[45] These data are encouraging, since studies of clinical competence show it takes between 60 and 90 epidural blocks to reach at least 80% success[6–8] (Figure 77–3).

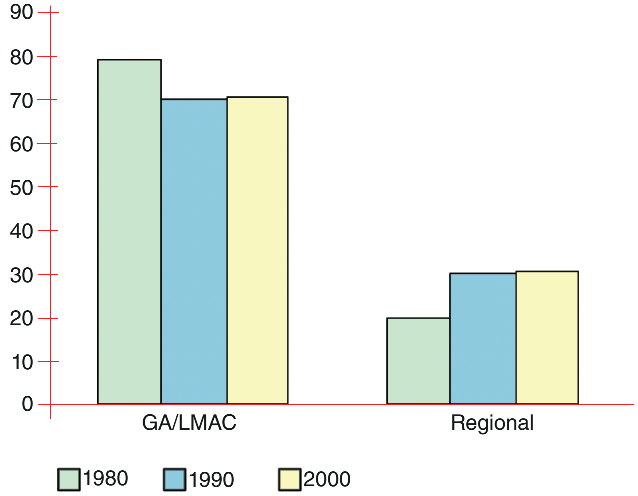

FIGURE 77–1. The use of regional anesthesia in residency training programs compared to general or local anesthesia for cases in 1980 (21.3%), 1990 (29.8%), and 2000 (30.2%).

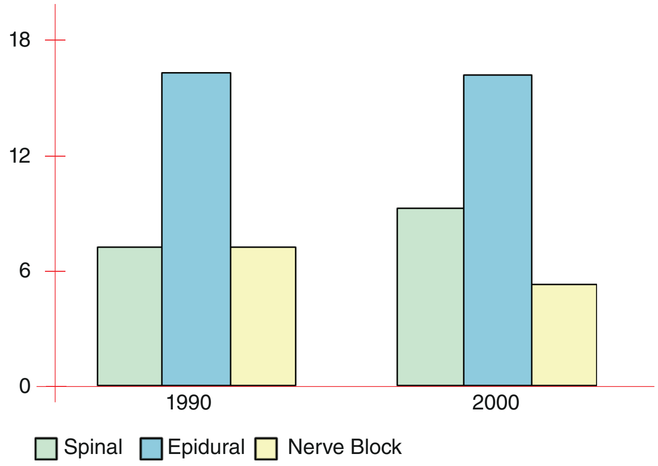

FIGURE 77–2. Distribution of types of regional anesthesia in residency training programs did not change significantly between 1990 and 2000 (*P* = .75).

Achieving a level of competency is reflected in resident confidence, as surveys of graduating residents showed more than 94% were very confident in their lumbar epidural skills.[8–10] Similar evidence exists for spinal blocks, with surveyed residents feeling very confident in their ability to perform spinal anesthesia.[9] Kopacz et al demonstrated that at least 45 spinal anesthetics needed to be performed before at least 90% success rate was attained,[7] a number much closer to the RRC requirement.

The data for peripheral nerve block are encouraging. In the year 2000, approximately 40% of residents reported inadequate experience with peripheral nerve blocks, which had both educational and safety implications.[5] Residents not adequately trained in a particular block are unlikely to use that block in practice[11]; or worse, they may try to use techniques without the proper skills.[9,12] Multiple older surveys have demonstrated that graduating residents did not feel confident in their peripheral nerve block skills[9] (Figure 77–4). This was especially true of lower extremity nerve blocks[12,13] (Figure 77–5). By the year 2015, nearly 90% of residents reported exceeding the suggested number of continuous and single-injection peripheral nerve blocks by a wide margin, including extensive experience with lower extremity blocks. Not surprisingly, ultrasound-guidance as a nerve localization tool now surpasses by a wide margin peripheral nerve stimulation. [Personal communication: Joseph M. Neal, MD].

Furthermore, the vagueness of "40 peripheral blocks" allows a discrepancy between block types to occur. Because no specific blocks have been named in the core curriculum, it is not possible to ensure that graduates from all resident programs will have comparable expertise in all nerve block procedures. Nearly 34 peripheral nerve block techniques have been suggested as regional anesthesia procedures.[14] If trainees were to perform an equal frequency of each block, they would still not be able to gain competency in any single block in the recommended

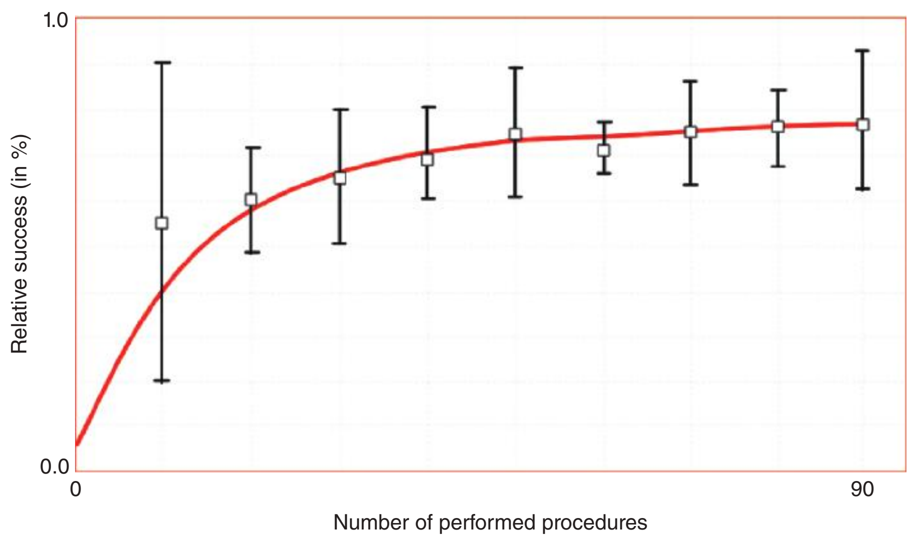

FIGURE 77–3. The learning curve for epidural anesthesia: demonstrating a minimum of 65 blocks to consistently reach 90% success rate.

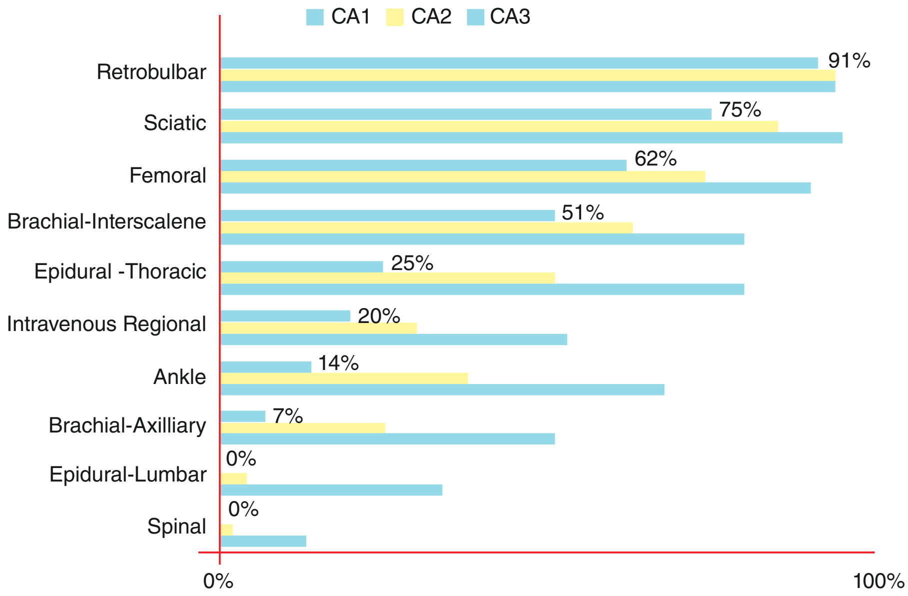

FIGURE 77–4. The percentage of residents, per training year, who categorized themselves as "not confident" in performing a particular block. Exact percentages are listed for the CA-3 resident class. Residents felt least confident with peripheral nerve blocks, and no CA-3 resident admitted to being "not confident" for spinal or lumbar epidural anesthesia.

40 peripheral nerve block performances. In addition, 40 performances of any *one* nerve block may not be suitable to attain competency. Konrad et al demonstrated that 70 axillary blocks are needed before an 85% success rate can be achieved[6] (Figure 77–6). Rosenblatt et al showed that more than 10 interscalene blocks are necessary before the resident attains at least 50% autonomy.[15] Therefore, it is likely that many residents are unable to develop the necessary proficiency because they are not performing enough peripheral nerve blocks. Furthermore, some teaching departments have fewer regional anesthesia teachers than they would prefer. A 2013 survey of department chairs noted that on average they would ideally hire one to three additional regional anesthesia specialists at their faculty.[16]

Clinical Pearl

- Anesthesiology residents trained in the United States are much more likely to fulfill accrediting agency requirements for spinal and epidural anesthesia than for peripheral nerve blocks.

ENRICHING THE EDUCATIONAL EXPERIENCE

Assessing Competency

In addition to a skilled faculty and a culture of using regional anesthesia for surgical cases, learning regional anesthesia

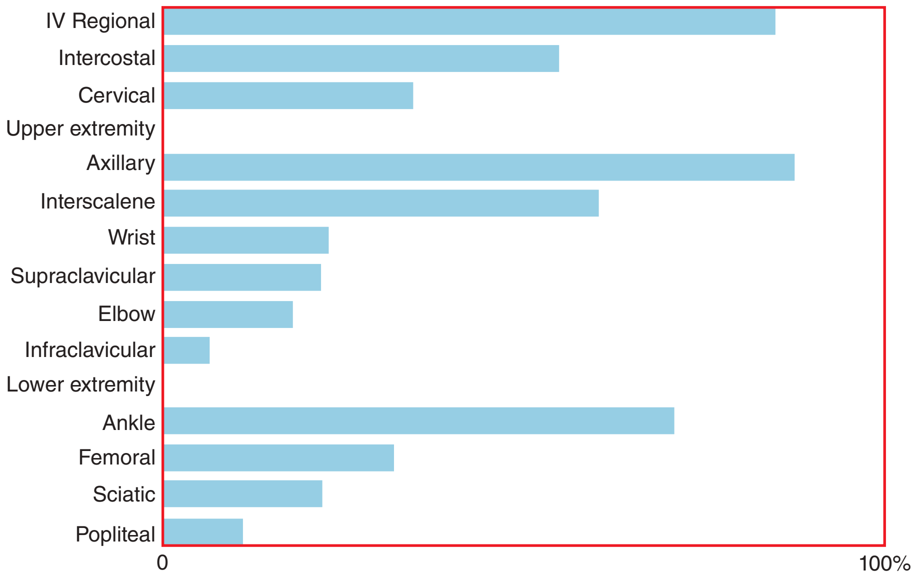

FIGURE 77–5. Percentage of peripheral nerve blocks performed in practice in the United States, as reported by practitioners. (Reproduced with permission from Hadzić A, Vloka JD, Kuroda MM, et al: The practice of peripheral nerve blocks in the United States: a national survey [p2e comments]. *Reg Anesth Pain Med*. 1998 May-Jun;23(3):241–246.)

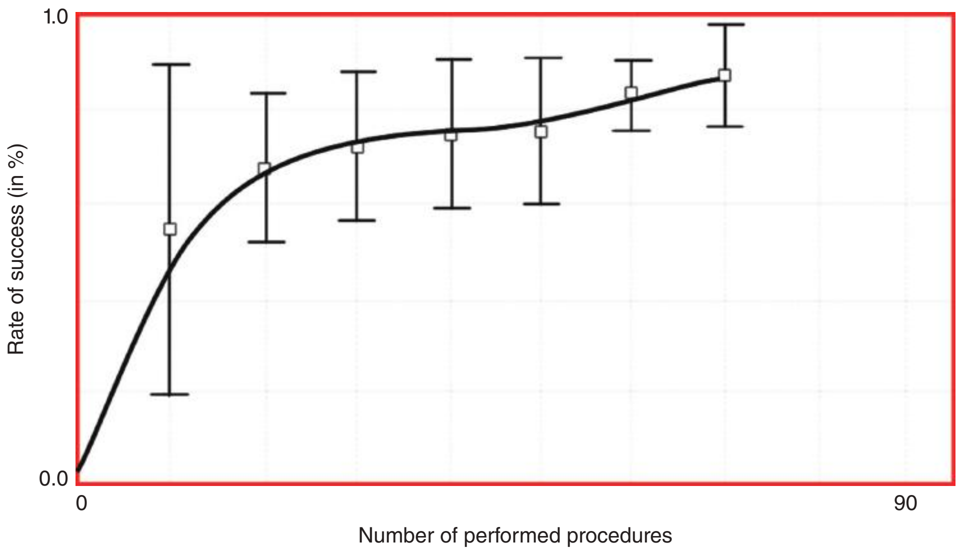

FIGURE 77–6. The learning curve for brachial plexus anesthesia: demonstrating a minimum of 70 blocks to reach 85% success rate.

procedures requires much more than mastering the technical aspects of directing a needle to the intended target. The current RRC focus on the number of blocks performed during training does little to assess actual technical competence, much less nontechnical proficiency. Resident or fellow confidence in the technical aspects of regional anesthesia may not be at all reflective of their overall competence. Indeed, inexperienced trainees may overestimate their technical skills, while at the same time be incompetent in the nontechnical aspects of regional anesthesia. The actual number of blocks performed says little about the trainee's mastery of the physiology and pharmacology of regional anesthesia, intraoperative sedation skills, awareness and management of complications, or overall judgment in selecting which patients should be offered regional techniques.[17] Expertise in regional anesthesia has been defined as not only an ability to have good technical skills but also to have good cognitive skills.[18] These include communicating with the patient, trying to anticipate and minimize their discomfort, and recognizing the limits of safe practice. While competence in cognitive knowledge and problem solving and adaptability can be assessed to some degree by written and oral certifying examinations, respectively, the teaching and assessment of technical and nontechnical aspects of regional anesthesia remain a challenge. Many checklists have been developed for assessment of technical skills for individual peripheral nerve blocks[19,20] and have been validated. However, a need for a single validated checklist for all peripheral nerve blocks remains. Recently, a global checklist has been developed by the Delphi method, which is suitable to assess all ultrasound-guided nerve blocks, and this has been validated in both patients and simulation models. A valid and reliable assessment tool for remote simulation-based ultrasound-guided regional anesthesia.[21] Unfortunately, only limited evidence exists for technical skill assessment in regional anesthesia, and examples have to be obtained from the surgical literature. In surgical training specific and global checklists have been used to grade performance on simulation models, and they have been proven to be valid, reliable, and cost and time effective.[22]

Alternatives to Bedside Teaching

Anesthesia teaching and learning has traditionally followed the apprenticeship model of "see one, do one, teach one." However, a new paradigm of teaching has emerged which focuses on "see one, practice one, and do one," and this has become an integral part of ultrasound-guided regional anesthesia training programs.[23] This is due to an emphasis on operating room efficiency and patient safety. Specific skills for regional anesthesia can be practiced and assessed on bench model simulators in a "pretraining"[24] period prior to exposure to patients. This provides the student with an unhurried environment that encourages deliberate practice, which is critical process of developing expertise. Deliberate practice calls for repeating a defined task to improve on particular aspects of performance.[25] It allows the teacher to provide immediate feedback and coaching to the trainee and convey their expectations. The use of bench models also allows the task to be broken down to its core components, which can be taught individually.

There is growing evidence that knowledge attained during practice on a simulation model does improve skills in the operating room.[26–28] Barsuk et al have demonstrated that simulation training of central venous catheterization can lead to higher success rates as well as reduce rates of infection in intensive care patients.[29]

Another important area of inquiry concerning simulators is whether high-fidelity simulation training has any advantage over low-fidelity simulation. Friedman et al have shown that low-fidelity and high-fidelity models have an equal impact on teaching of novices.[30] This is interesting as low-fidelity simulation models are cheaper than high- fidelity models and provide similar benefits in the early learning period. However, high-fidelity simulation models do provide some advantage in regional anesthesia. They provide the user with surface anatomy similar to that of real patients. In ultrasound- guided regional anesthesia these models allow the operator to position the transducer and insert the needle in relation to the normal contours of the body. These models also have sophisticated software that allows immediate feedback and also allows the teacher to objectively assess the learner.

Unconventional and inexpensive simulation models can be created with everyday household objects. For example, one model was created with a banana, some slices of bread, and a balloon. As the resident passes the needle through the banana using loss of resistance technique, the fruit mimics the feel of the subcutaneous tissues and ligamentum flavum, and if the resident should advance the needle too far through the bread (epidural space), the balloon (dura) will pop.[31] A foam-block model can be used to teach residents how minimally changing the angle of the needle at the skin greatly affects where the tip of the needle is ultimately placed.[7]

There are also a number of inexpensive simulation models developed from meat,[32] tofu,[33] and gelatin[34] for ultrasound-guided regional anesthesia. Meat models provide realistic tissue feedback, permit injection of local anesthetic and have low background echogenicity, allowing good needle visibility. The gelatin and tofu models provide low background echogenicity but do not reproduce tissue qualities.[35]

Other than simulation bench models, there is a growing trend of using cadavers and virtual reality for teaching skills relevant to regional anesthesia. Unembalmed cadavers are probably the closest phantom media to live human tissue.[35] Embalming of cadavers can change the characteristics of block performance, and it has been seen that Thiel embalmed cadavers provide more realistic simulation than fresh cadavers.[36] This embalming process provides a realistic feeling of passing through fascial planes and also nerve swelling on intraneural injection. Despite their advantages, cadavers are expensive, may provide an infection risk, and teaching has to take place in a remote setting from the operating room. Another disadvantage is that cadaver blood vessels are collapsed and this may impact on their use with ultrasound-guided regional anesthesia. Hocking and his group have described a novel technique to overcome this problem in which gelatin is injected into cadaver blood vessels to prevent them from collapsing.[37]

Virtual reality is another platform of pretraining that can be accessed at one's own time and is an interactive and dynamic form of simulation. A problem with virtual reality for regional anesthesia is that it is expensive and difficult to form an immersion model where the learners feel that they are in a virtual environment. Another problem is feedback from haptic cues. During our clinical practice we rely on touch and pressure feedback that is difficult to incorporate into virtual reality models. Kulcsar et al have developed a virtual reality–based simulator for teaching spinal anesthesia.[38] This model accurately replicates haptic sensations of skin, ligaments, and bone. When used in combination with didactic teaching, this model did not show any benefits to didactic teaching alone when performing spinal anesthesia on a patient. Interestingly, there was, however, a trend toward higher scores on a task-specific checklist and less stress while performing spinal anesthesia in a clinical setting with the group that had trained on the virtual reality simulation model. In ultrasound-guided regional anesthesia virtual reality is still at its preliminary stages. A virtual reality spine model has been developed to teach anatomy and sonoanatomy of the spine.[39] This simulation model allows the user to perform an interactive prepuncture scan on a simulated patient. Anesthesia residents, who had access to the complete module, when compared to those who had access to the anatomy module alone, achieved higher scores on a task-specific checklist while performing a prepuncture scan on live models. The students in the study group were able to identify more key structures such as the vertebral bodies, ligaments, and dura mater, which are important when identifying an ideal intravertebral space to perform neuraxial anesthesia.

Other methods of teaching away from the bedside include interactive graphics on CD-ROMs; a learning tool that is readily at hand (literally, as handheld devices can carry the software) and, therefore, is increasingly popular among residents. Outstanding DVDs are available that allow the student to learn the relevant anatomy and block placement in a three-dimensional mode.[40] Invaluable experience in the placement of continuous perineural catheters can be gained in anesthetized pigs and other animals. Some investigators have described using ultrasound as a visual aid to teach correct needle placement for obstetric lumbar epidural blocks, as such guidance has been shown to improve residents' learning curve.[41]

Residents can also learn from receiving regional anesthesia themselves. Residents participating in compensated volunteer studies learned aspects of regional anesthesia that cannot be taught. After the experience, residents acknowledge that they learned to be more sensitive to patient concerns and to be better communicators with their patients regarding regional anesthesia. Other common observations included the value of sedation, the concept of gentle versus rough touch, and the discomfort caused by local anesthesia infiltration, nerve stimulators, and paresthesias.[42]

Simulation can also be used to teach nontechnical skills. Smith et al have described expertise in regional anesthesia, and have shown that it extends beyond competence in technical skills.[18] To be a true expert one should be able to communicate with the patient, anticipate and minimize their discomfort, and recognize the limits of safe practice. Simulated patients or mannequins can give trainees the ability to practice patient interviews, explanation of regional anesthesia procedures, and crisis management in regional anesthesia. Neal et al have shown that a simulation laboratory scenario can be used to teach residents the use of a specific checklist for local anesthetic toxicity.[43] Hospitals where block rooms are available can perform simulations where team training can take place. This can improve communication and coordination skills between team members and reduce adverse events and improve patient outcome. Figures 77–7 and 77–8 demonstrate several models and simulations commonly used in teaching ultrasound- guided regional anesthesia courses.

Regional Anesthesia Fellowship Training

The ultimate means for a resident to become a highly skilled regional anesthesiologist is to enroll in a fellowship program.

FIGURE 77–7. A simulator for teaching hand–eye coordination during ultrasound-guided regional anesthesia introduced by Adhikary and colleagues.

In 2005, there were approximately 12 active fellowship programs in the United States and Canada.[16] That number has been considerably increased from the two or three training programs that were available prior to the mid- 1990s,[44] and by 2013, the number of regional anesthesiology and acute pain medicine programs had grown to 55.[45] Regional anesthesiology and acute pain medicine is likely to be the latest accredited fellowship by the ACGME (full approval expected fall 2016). The training experience and clinical focus of regional anesthesia / acute pain medicine fellows varies considerably from pain medicine fellowship training. Experience and clinical focus varies considerably among programs.[16,44] Until formal accreditation and program requirements are implemented, regional anesthesiology and acute pain medicine fellowship program directors have produced training guidelines periodically to ensure that fellows receive the quality and quantity of regional anesthesia experience they need to become true experts in the field.[44,46] At the time of this book publication, the fellowship in Regional Anesthesia and Acute Pain Medicine is likely to be recognized as ACGME approved and will result in a formal certification.

FIGURE 77–8. NYSORA ultrasound-guided nerve blocks and vascular access workshop. A number of nerve block and vascular models as well as tissue models of peripheral nerves are used to simulate the needle guidance under ultrasound and practice core skills in simulated, nonclinical environment.

Continuing Education Opportunities

A final challenge is how best to train postgraduate anesthesiologists in emerging regional techniques. The time-honored method of learning new techniques using patients is less than ideal. To a great extent, continuing medical education programs such as those offered by the American Society of Regional Anesthesia and Pain Medicine and NYSORA serve a valuable role in updating anesthesiologists on the nontechnical aspects of regional anesthesia and pain medicine advances. But technical training is incompletely accomplished in workshop settings. However, the increased availability of cadaver-based anatomy courses and workshops, animal laboratories, and computer-generated imaging technologies are encouraging as future generations of anesthesiologists strive to maintain their skills in an ever-changing subspecialty.

Clinical Pearls

- The numbers of blocks performed or consistently placing a needle near the target nerve are not entirely satisfactory measures of regional anesthesia competency.
- Skills for regional anesthesia should be practiced and assessed on bench model simulators in a "pretraining" period prior to exposure to patients.
- Further development is required to determine means of assessing technical and nontechnical skills required for regional anesthesia.
- Innovative teaching methods are needed not only for resident and fellow training, but also for the continuing education of postgraduate practitioners.

FUTURE DIRECTIONS

Training residents and postgraduates in regional anesthesia has improved remarkably over the past two decades, but many challenges remain. Current research in how regional techniques affect perioperative outcome, as well as the rapid development of continuous perineural catheters, extended-duration local anesthetic and opioid preparations, and ultrasound-assisted nerve localization all point to future anesthesiologists becoming more, not less, involved in regional anesthesia. Certainly, nonpatient training techniques such as bench model simulation, virtual reality, interactive learning programs, and animal laboratories will play an increasing role in the education of future residents and postgraduates alike. The Recommendations for Education and Training in Ultrasound Guided Regional Anesthesia[47] and the *Guidelines for Regional Anesthesia Fellowship Training*[46] should improve the overall quality of regional anesthesia training.

ACKNOWLEDGEMENT

The authors wish to recognize Susan B. McDonald, MD, for her contributions to the original version of this chapter, which appeared in the first edition of this textbook.

CHAPTER 78

Regional Anesthesia and Acute Pain Medicine Fellowship

Jinlei Li and Thomas M. Halaszynski

INTRODUCTION

Regional anesthesia was established early in the history of medicine, but became somewhat obsolete, if not abandoned following the introduction of modern and safer general anesthetics. Acute pain management has regained attention and popularity by anesthesiologists over the past few decades due to several factors, such as significant advances in regional anesthesia technology, patient parameters of a continuing search for improved safety and satisfaction criteria in medicine, and an enhanced accountable evaluation of healthcare system resource utilization. The demand for and acceptance of regional anesthesia practices from both surgeons and patients has also increased over the past few decades. Patients benefit with enhanced approval and outcome and surgeons receive increased patient referrals and decreased perioperative complications with better pain management.[1] Advancement of medical technologies, especially ease and availability of ultrasound developments, have reshaped regional anesthesia into a more accurate, effective, and efficient modality toward enhanced patient care. Trained and experienced anesthesiologists from regional anesthesia fellowship programs are now able to deliver fast, safe, consistent, and reliable regional techniques, especially peripheral nerve blocks, in contrast to the previous conventional (e.g., paresthesia) "hit or miss" methods of regional anesthesia. An enhanced emphasis on effective and adequate pain control, patient autonomy, and patient satisfaction (both surgical and pain management experiences) play a significant role in this continuing transition. Additional benefits of practicing regional anesthesia techniques by fellowship-trained physicians became appreciated by hospital administrators, other healthcare providers besides surgeons, such as earlier ambulation, shorter hospital stay(s), an improved proactive role in rehabilitation, and minimization of adverse side effects often associated with narcotic-based pain medications, to list a few of the clinically relevant advantages. In addition, economic pressure(s) to enhance cost-efficiency of surgical centers, shorten both operating room time and post-anesthesia care unit (PACU) stay, improve Hospital Consumer Assessment of Health Plans Survey (HCAHPS) scores (nationally standardized patient outcome survey), and advance perioperative pain control have all made regional anesthesia/analgesia more appealing as an readily available option toward both patient-specific and procedure-specific anesthesia care. Incorporating regional anesthesia can also provide an alternative for the aging population with complex comorbidities that continue to pose significant risks in healthcare management.

Regional anesthesia continues to play an ever-increasing role and is recognized as a vital component toward more effective patient pain medicine and complementary fulfillment of perioperative medical care. Regional anesthesia/acute pain medicine fellowships are positioned to further emphasize patient and healthcare system value-added when incorporating regional anesthesia/analgesia options into medical management of the surgical patient. The first documented regional anesthesia fellowships were founded at Brigham and Women's Hospital in Boston, Massachusetts (by Benjamin Covino) and at Virginia Mason Medical Center in Seattle, Washington (by Daniel Moore) in the 1980s.[2] The decades that followed were characterized as a continued developmental stage. As of 2007, a total of 11 American Society of Regional Anesthesia/Acute Pain Medicine (ASRA)–recognized regional anesthesia fellowship programs were documented followed by another 10 programs under consideration in the next few subsequent years. Most recently, there has been a continued increase in interest toward regional anesthesia fellowships with 60 programs in 2016 in the United States and 8 in Canada listed on the ASRA website[3] (Table 78–1).

HISTORY AND EVOLUTION OF REGIONAL ANESTHESIA AND REGIONAL ANESTHESIA FELLOWSHIPS

Following innovation of ether and commencement of general anesthesia in 1846, the discovery of local anesthetics marked the introduction of regional anesthesia into medicine and recognition of regional anesthetic techniques separate from general anesthesia.[4] In 1884, cocaine, an extract from coca leaves, made regional techniques possible prior to implementation of modern-day local anesthetics. Subsequent development of various amino ester and then amino amide compounds (with different pharmacodynamics and pharmacokinetics) provided anesthesiologists with additional options to diversify regional techniques.[5] Although spinal and epidural anesthesia has been used since 1899,[6] it was not until 1902 when the term *regional anesthesia* was coined by Harvey Cushing as he started to perform extremity peripheral nerve blockade procedures. A similar analogy (lagging behind in implementation of peripheral nerve blockade) in the history of modern anesthesia is reflective of what is occurring in anesthesiology residency training. Secondary to underutilization and lack of appreciation of peripheral nerve block techniques in clinical practice, regional anesthesia and acute pain medicine training for anesthesia residents largely comes from central neuraxial blockade experience.[1,7] Until relatively recently, most anesthesiology residency programs in the United States and outside of North America were not prepared, equipped, or motivated to provide residents with regional anesthetic technique training beyond constraints of remaining compliant with (ACGME) program requirements. Therefore, it was not until after additional postgraduate training in a regional anesthesia fellowship program that anesthesiology physicians were able to achieve the skill set(s) necessary to safely, effectively, and independently implement regional anesthetic/analgesic techniques.

To fulfill ACGME requirements, anesthesia residents need to perform 50 epidurals, 40 spinals, 40 peripheral nerve blocks (PNBs), and 25 block techniques for chronic pain management. In Germany, a minimum of 100 neuraxial and 50 PNBs are necessary during the training period. There have been many attempts, studies, and program surveys about minimum numbers of procedures for mastery and adeptness at spinal and epidural anesthesia during anesthesiology residency training. For example, Konrad showed that proficiency with spinal anesthesia requires 70 cases, and 90 cases were necessary to show competency with epidural techniques.[8] However, there is a limited number of studies to investigate and determine minimum numbers of PNBs required to demonstrate proficiency. Among the few available studies on PNBs, Rosenblatt showed that a minimum of 15 interscalene blocks were required to achieve a degree of competency[9] and Schuepfer showed that a minimum of 55 psoas compartment blocks were necessary to achieve a 70% success rate.[10] Clearly, the diversity of PNB procedures requiring different skill set levels makes this matter even more complex to assess and standardize. Nonetheless, it is clear that the ACGME does not yet recognize the need to emphasize proficiency in PNB training, as a total number of 40 PNBs during residency training remains insufficient. Anesthesia house-staff receive more training and emphasis with the more commonly performed neuraxial techniques, and this is not unique for North America. As an example, in a teaching hospital in Australia, first-year anesthesia residents (clinical anesthesia year 1; CA-1) perform on average 6.5 PNB procedures, second-year residents (CA-2) receive training with only 13.5 PNB techniques, CA-3 residents with 14.9 PNBs, CA-4s with an average of 19.1 PNB interventions, and regional fellows achieve higher numbers with an average of 144 PNB techniques.[7] Recently, both the American Society of Anesthesiologists (ASA) and ASRA have jointly launched an ultrasound-guided regional anesthesia (UGRA) education and training initiative for physicians interested in UGRA. In order to receive certification for this UGRA portfolio, a minimum of 10 hours of didactic lectures (knowledge base) is required followed by a written examination of 50 questions, 6 hours of regional anesthesia workshop demonstrating technical skills, and a case log performing 40 PNB techniques. This program is closely reflective of the basic structure and requirements of anesthesia residents in an ACGME-accredited anesthesia-training program.[11]

However, the ASRA membership/administration has not yet petitioned for formalization of recognition, and none of the ASRA regional anesthesia fellowship programs has received either ACGME accreditation or American Board of Medical Specialties (ABMS) certification.[3,12] As a result, regional fellowship programs have candidates performing varying degrees of clinical duties, research endeavors, and patient care responsibilities without receiving formalized certification following completion of their subspecialty training.[3] In addition, some fellowship participants are able to generate a range of revenue potential along with receiving a wide range of compensations during their training periods. This also translates into a variable degree of institutional duties with fellows responsible for minimum or no overnight in-house call to as much as 20%–50% of their training time engaged as junior faculty or clinical instructors. This variability across the regional anesthesia/pain medicine fellowship programs would change once the individual fellowship site would petition for ACGME accreditation. As an example, the duration of fellowship training could range from a mandatory single year to receive a diploma with up to a 2-year optional training period for a research track and the originally offered 3- to 6-month fellowship program would no longer be recognized as fulfillment for a certificate of completion. The proposals for a 2-year fellowship training option (1 research year) would mimic those from the recently developed pediatric anesthesia[13] and critical care medicine[14] anesthesia fellowships.[15]

Despite the variability of structure that exists in the present regional fellowship programs of North American, most of the fellowship candidates rotate through formalized didactics, perform clinical patient care rotations in hospitals and surgical centers, many have research opportunities and occasionally educational rotations to other outside institutions. Several fellowship programs offer clinical patient care incentives and provide support for research. For example, there are programs that offer up to 20% dedicated research time, continuing medical education travel time, and compensation for other academic endeavors. Most regional anesthesia fellowship program directors are collaborative decision data participants who meet several times a year to discuss and exchange current regional fellowship participant activities and concerns applicable to future fellowship candidates in order to maintain a minimum standard of convention and protocol formalization for those programs that wish to participate. This implies that participating programs voluntarily adhere to standards of Regional Anesthesiology and Acute Pain Medicine Fellowship Director Group's "Collaborative Decision Data Agreements" (such as pre and interim training examinations). For those institutions that have such an agreement, it is also stated that no fellowship applicant should be required to accept or decline a fellowship position offer from any participating fellowship program prior to a predetermined date (September) of the previous academic year.[3] The participating programs implemented this initiative in order to improve upon the application process for candidates. Currently (2016), all United States Regional Anesthesia Fellowship Programs collectively generate around 130 formal Regional Anesthesia/Acute Pain Medicine fellowship–trained anesthesiologists annually, and Canada has added another 17 fellowship-trained physicians with an expertise in regional anesthesia. Clearly, regional fellowship training in North American has become more diversified in terms of centers available for trainees and has significantly expanded the opportunities that these centers can provide which has visibly strengthened this subspecialty.[16]

Regional Anesthesia/Acute Pain Medicine Fellowship Curriculum

Following publication of the original version of *Regional Anesthesia Fellowship Training Guidelines* in 2005, regional fellowship program directors across the nation have agreed to grant a regional fellowship diploma to those who have not only finished basic anesthesia training in an ACGME-accredited residency program, but also have been trained for at least a 12-month period in a regional anesthesia fellowship program.[17] Further maturity of the core competencies from anesthesiology residency training remains a vital part of every regional fellow's daily learning and practice and should continue as basic desirable attributes of any regional fellowship program. Regional fellowship training and further perfection of the six core competencies continues beyond that from residency as each fellow is encouraged to apply and practice ALL six of the measures into regional anesthesia daily practices (Table 78–2). In addition, both ASRA and the European Society of Regional Anesthesia (ESRA) committees have developed and incorporated core competencies related to ultrasound-guided regional anesthesia and identified 10 common tasks to be accomplished during UGRA implementation. These 10 tasks summarized the basic procedural and troubleshooting steps in UGRA and emphasized the importance of familiarity with regional anatomy and its variations, direct visualization of needle movement, and local anesthetics distribution patterns as well as adequate patient monitoring.[18,19]

With an emphasis on providing best evidence-based practice, perioperative efficacy, ensuring patient safety, and reducing adverse events/patient complications, regional anesthesiology fellowship training programs have been formally structured with teaching methods in regional anesthesia/acute pain medicine that include, e.g., didactic sessions, cadaver workshops, practice training toward improving ultrasound guidance techniques, and reviewing ultrasound/computed tomography (CT)/magnetic resonance imaging (MRI) video clips.[1] Ultrasound imaging and three-dimentional video clip review has been shown to improve operator performance, and such published guidelines assist in setting the basis for structured fellowship training programs in regional anesthesia.[18,20] In addition, these structured protocols contain the necessary flexibility that permits each individual program to further capitalize and take into account the unique strengths of each academic institution along with considerations for each individual fellow's learning curve and desires in which to tailor pursuit of research endeavors. There are also several regional fellowship programs that incorporate simulation into the curriculum. Simulation in healthcare training has evolved from manual simulation to now include an ability also to focus on nontechnical skills of the trainee.[21] There is evidence supporting the notion that simulation can result in providing better patient care, improving objective measures in technical skill sets of the operator, and an overall enhancement of education for regional fellows.[21,22] Simulator experience has also been shown, e.g., to expedite the learning-skill process, to more effectively familiarize regional fellows with an understanding of applied clinical anatomy, and to allow one to become more efficacious with the necessary physics of ultrasound, sonographic views, and spacial orientation.[23]

PART 13

TABLE 78–2. Core competencies for training in ultrasound-guided regional anesthesia (UGRA).

Patient care	*Understand the indications and contraindications and use proper judgment in patient selection and exclusion. *Use appropriate monitoring during UGRA: ECG, BP, SPO_2. *Provide adequate/appropriate sedation during regional techniques. *Understand and become competent with nerve and nerve plexus localization techniques with and without assistance from other localization techniques. *Develop competent, safe, effective, and efficient peripheral and central neuraxial nerve block techniques.
Ultrasound knowledge	*Become familiar with basic of UGRA techniques. *Become familiar with the physics of ultrasound machines. *Understand key artifacts and pitfall errors associated with UGRA. *Understand benefits and limitations of UGRA techniques and use adjunct techniques as indicated. *Become familiar with in-plane and out-of-plane techniques and apply appropriately into clinical practice. *In depth knowledge of ultrasonographic anatomy of the major neurovascular structures of extremities and trunks.
Interpersonal/ communication skills	*Communicate sensitively and effectively with patients and families regarding risks and benefits and alternatives. *Explain UGRA and PNBs effectively to surgeons and other medical professionals not familiar with PNBs. *Develop leadership skills and executive expertise in establishing and managing a regional anesthesia service.
Professionalism	*Remain current with UGRA techniques and evidence-based literature. *Effective communication skills with patients to explain benefits from PNBs while identifying potential complications. *Develop effective interactions and engagement protocols with surgical teams and other support services.
System-based practice	*Recognize UGRA costs along with UGRA technology limitations. *Collaborate with other members of the healthcare team to ensure quality of perioperative patient care. *Use evidence-based, cost-conscious strategies in caring for patients (e.g., patient-specific and procedure-specific regional techniques).
Practice-based learning and improvement	*Identify, acknowledge, and remedy gaps in personal knowledge and skill-sets in the care of patients presenting for UGRA. *Use reference-based knowledge opportunities such as: textbook, journals, and computer-based resources to broaden the knowledge base of UGRA techniques. *Competence to perform electronic medical literature searches of articles that address medical issues surrounding UGRA. *Understand and critically evaluate outcome studies related to influences of UGRA on perioperative outcome. *Attend, participate, and direct departmental teaching conferences and supervise residents. *Develop time management skills to perform required tasks in a reasonable amount of time with consistent and satisfactory quality.

Abbreviations: BP: blood pressure; ECG: electrocardiogram; PNBs: peripheral nerve blocks; SPO_2: functional oxygen saturation pulse oximetry.

Another attribute of advanced regional fellowship training focuses upon the nontechnical skill sets that have been divided into two subgroups: cognitive or mental and social or interpersonal skills. Both technical and nontechnical skills are necessary and equally important for well-trained regional fellows to achieve levels of becoming a competent leader in any regional anesthesia practice.[21] The curriculum that synthesizes regional fellowship training with instruction and practice of nonprocedural aspects of the subspecialty also needs to be emphasized. Regional anesthesia and acute pain medicine fellowship programs will need to continue to focus on the many nontechnical skill training aspects such as research endeavors, career development, and leadership coaching, to name a few. Due to the lack of such training in these various fields during anesthesiology residency, regional anesthesia subspecialty programs are positioned to provide regional fellows with administrative, executive, infrastructural, as well as medicolegal expertise and skills in conflict solving. The above concept will also continue to challenge regional anesthesia program directors to design dynamic program curricula that expand beyond medical knowledge and technical skills with added emphasis on nontechnical domains in order to train regional fellows capable of advancing the subspecialty into the future and moving ahead with trained physicians capable of more than technical expertise.[1,24] Therefore, undertaking a specialized curriculum and providing experiences of advanced regional fellowship training will escalate and solidify a regional fellow's regional anesthesia/analgesia/acute pain-specific knowledge base, achieve a more solid proficiency with technical skills, improve upon the "whole-task" approach to patient care, offer an environment and opportunity toward training of a "balanced" clinician inclusive of nonprocedural skill sets, and provide a foundation recognized as "value-added" to perioperative anesthesia care.

Despite the many efforts made toward standardization in regional anesthesia fellowship training, there has not yet been a well-defined set number of individual PNB procedures or identification of most appropriate types of individual nerve or nerve plexus blockade modalities needed to establish regional fellow proficiency. Suggesting or determining some basic procedural numbers may serve to identify one objective measure of reference for regional fellowship training guidance, but these number specifications alone would not necessarily provide appropriate assessment of regional fellowship candidate qualifications. These predetermined requirements of minimum nerve and nerve plexus blockade techniques would rather simply assist with a degree of objective standardization(s) for regional fellowship training guidelines. Establishing minimum numbers of regional interventions could also serve as one of the many fundamentals that will move forward with regional anesthesia subspecialty recognition and the ACGME accreditation process. In addition, defining minimum numbers could assist as an objective measure assessing a regional fellow candidate's technical skill level. As an example, Chin et al studied regional anesthesia fellow's performance in their first month and then again in the last 3 months of training by measuring time to perform a nerve block procedure, examining ultrasound probe and hand movements, quantifying needle hand movements, and measuring time duration within both ultrasound scan and needling phases.[25] The above study was able to identify that a regional fellow's early performance showed no statistical difference when compared to anesthesia residents. However, these same regional fellow's demonstrated performance during their last 3 months of training revealed no statistically different measurements when compared with regional anesthesiologists with a minimum of 3 years clinical experience when performing an ultrasound-guided supraclavicular nerve blockade.

The current structure of the national ACGME accredited anesthesiology residency programs has traditionally focused on core competencies and evidence-based training of residents with little effort being directed toward research guidance.[26] According to the ACGME, there is no minimum time requirement for anesthesiology residents or fellows to conduct research endeavors, but each resident candidate has to complete an academic assignment. A survey of pediatric fellowship graduates suggested that more responders recommended formal research training during the fellowship period than the number of individuals who actually received such training.[13] As another example, the recently accredited ACGME Obstetric Anesthesia Fellowship requires candidates to take part in at least a 3-month equivalent of time actively engaged in an academic pursuit.[27] The same Obstetric Anesthesia Fellowship Program also requires that more than half of the faculty demonstrate active involvement in research in the format of peer-reviewed journal publication(s), conducting research activities, or developing educational programs.[27] The examples above suggest that regional anesthesiology fellowship programs (those with an aspiration to work toward ACGME accreditation) should focus on objective measures toward developing research initiatives and competencies that can identify quality measures of fellowship programs that have meet ACGME standards.

It may be premature at this stage of regional fellowship training development to make research endeavors mandatory, but those fellowship candidates enthusiastic about research should be carefully supported by the availability of research projects and research mentors. Regional fellowship programs providing such opportunities should be endorsed and encouraged to provide protected research time, along with continuing medical education (CME) time and subspecialty meeting support. There remains several obstacles for fellowship candidates to participate in research such as not enough faculty support and lack of appropriate funding to identify a few of the current hurdles. However, formalized training of regional fellows with both superior clinical skills along with research accomplishments will prove to serve well toward the future of the subspecialty. In addition, if some regional anesthesia fellowship programs could develop and offer an optional 2-year fellowship (with 1 year committed to research) as a way to gain recognition of the subspecialty could further elevate perception and acknowledgement of the specialty. As another example, some cardiac fellowship programs have interdepartmental partnerships (e.g., clinical pharmacology department) that contribute to potential candidate appeal and interest with an additional offer of a master's degree of science specifically designed for young investigators on statistical analysis and clinical trial design.[28]

The regional anesthesia guidelines, originally published in 2005, updated in 2010 and again in 2014, have provided the much needed general guidance for fellowship training[17,20] (Appendix I; pp. 1266-70). In addition, each regional training program recognized on the ASRA web site has identified how it has developed its own unique and comprehensive curriculum that typically incorporates basic and advanced regional techniques along with multi-modal pain management strategies. The individual curriculum and protocols developed by training programs provide guidance for fellows to acquire medical knowledge and cultivate a foundation for clinical and scientific research. With this diversity, some form of standardized examination system will be required to provide uniform direction of this postresidency educational process in order to ensure quality of training (similar to the national board of echocardiography in cardiothoracic anesthesia fellowship training).

CURRENT CHALLENGES AND FUTURE PROSPECTIVE FOR REGIONAL ANESTHESIA FELLOWSHIP TRAINING

Anesthesiology became a recognized medical specialty in the 1930s when anesthesiologists were awarded the first certificates for specialized training. The ABMS formally accepted anesthesiology as a specialty in 1941. The first recognized regional organization, the American Society of Regional Anesthesia, was founded in 1923. However, this early organization of regional anesthesia was practiced predominantly by surgeons and other nonanesthesia-trained physicians. Currently, there are many subspecialties in anesthesiology that offer fellowshiptraining opportunities as listed in Table 78–3. Prior to 2013, the ABMS offered certifications in the first five subspecialties in anesthesiology,[12] and the ACGME accredited four originally, including cardiac, critical care, chronic pain, and pediatric anesthesia. Then in 2013, obstetric anesthesiology became the fifth ACGME-recognized fellowship training program. As of July 2013, there are now nine obstetric anesthesia fellowship programs throughout the United States that have received formal accreditation. Through petition with the ACGME, securing evidence of meeting fellowship-training qualifications, being awarded endorsement as an approved fellowship program and providing continued evidence of compliance with certification- training mandates; these five anesthesiology subspecialties have the authority and obligation to offer subspecialty training certification by developing and implementing individual specialty specific board examination protocols. Subspecialization in any medical specialty creates an environment for the development of practice parameter expertise and making tremendous strides toward improving healthcare along with advancing patient safety and also providing opportunities for greater further achievements for medical professionals. Other non-ACGME–accredited subspecialty graduates (including regional anesthesia) receive diplomas, but these subspecialties are currently not recognized by the American Board of Anesthesiology (ABA) or the ABMS. Listed in Table 78–3 are the accreditation and certification status of clinical subspecialties in anesthesiology.[3,12,29,30]

At the present, expert training facilities with regional anesthesia pain medicine, as non-ACGME–accredited training programs, cannot compete with those accredited programs that provide ACGME certifications in seeking applicants wishing to receive fellowship opportunities. ACGME recognition, evaluation, approval, and accreditation (recognition from ABA) of regional anesthesia/acute pain medicine fellowship programs will elevate (medical community at large), formalize, and standardize regional subspecialty training. This formal process will also ensure that regional pain medicine fellowship candidates receive superior training that can offer all users (e.g., hospital administration, healthcare paraprofessionals, surgeons, patients) of the service with unique therapy alternatives and clinically relevant

TABLE 78–3. Accreditation and certification status of clinical subspecialties in anesthesiology.

Fellowship	ACGME Accreditation	ABMS Certification	ASA Recognition
Critical care	Yes	Yes	Yes
Pain medicine	Yes	Yes	Yes

treatment options. Therefore, how well regional pain medicine fellows are trained and the ultimate structure of fellowship program along with factors of development toward an ACGME fellowship program will determine what regional anesthesia/pain medicine as a subspecialty will look like in the future. This is exemplified using the example of cardiac anesthesiology fellowship. A survey of faculty from 30 randomly selected cardiac fellowship programs throughout the United States identified faculty from ACGME-accredited programs as producing more scholarly activities in the forms of increased peer-reviewed journal publications, citations, and higher H-indices when compared to those from non-ACGME–recognized programs.[31] However, there are advantages and concerns with ACGME accreditation. The positive aspects are viewed as consistency within the curriculum, potential for graduate medical education (GME) funding, rigorous review process implementation, subspecialty certification, and the potential for more effective fellowship candidate recruitment. Other less favorable aspects may be ACGME accreditation permits less curriculum flexibility, the possibility that Medicare may confer a teaching penalty(s), ACGME hour limitations secondary to program formatting, a faculty practice plan potentially experiencing ineligibility leading to loss of revenue, and lack of opportunities for fellowship candidates to pursue other facets of anesthesiology training. A similar analogy can be portrayed when seeking ABMS certification with advantages including increased clinical expertise, better job satisfaction, and more research opportunities. However, these gains from ABMS certification could result in a cost to collecting medical care dollars, will be associated with an increased duration of training, and risking the potential loss of general anesthesiology skills.[30]

Recent development and implementation of several evidence-based changes have reformed the regional anesthesia community, and has fundamentally reshaped experiences and exposures of candidates during their regional fellowship training. Undoubtedly, foremost of these changes was the embracing of adoption and acceptance of ultrasonography and tailored ultrasound technology implementation into regional anesthesia daily practice and fellowship training. This remains similar to those parameters of cardiothoracic anesthesia fellowship training, where echocardiography experience remains an integral part and plays a major role toward training and proficiency within such programs. Specifically in the situation of regional anesthesia fellowship programs, experiences with real-time ultrasound imaging should be considered an integral part of such fellowship training. Achievement toward goals of expertise and great proficiency with ultrasound utilization during the practice of regional anesthesia/analgesia would be an objective in order to strive toward an evolution of excellence in delivery of healthcare. Incorporation of ultrasound regional techniques into fellowship training will serve to maintain the “state of the art” and high level of development as a device, technique, and scientific field in regional anesthesia/acute pain medicine. In addition, a competent regional fellowship-trained anesthesiologist, with a solid foundation in medical knowledge and ultrasound training, would be prepared to take on, e.g., the challenges of newly developed innovations, nerve block techniques, and cutting-edge modernization, in the field of regional anesthesia.

Similar in scope to other fields of advanced medical education, the intensions of regional fellowship training would be for graduates to continue with a competency of self-education and self-training. In this context, regional trained anesthesia physicians would be better equipped to continue to lead the subspecialty, develop and advance teaching skills, become innovative and/or invent new techniques, tools, research opportunities, and renovate technology related to regional modalities as an added option in the treatment of the surgical patient. In addition, the practice of anesthesiology (especially the subspecialty of regional anesthesia) is currently and will remain into the near future a high-skill set–centered specialty. Both ASRA and ESRA recognize that there are different levels of difficulty for the various procedures and that the mission of and specialty of regional anesthesia fellowship training protocols can vary greatly between the multitude of programs. Therefore, standards and dynamic objective subspecialty regional training characteristics need to be developed and formally implemented that would be capable of addressing some of the numerous hurdles such as (1) deep PNBs (resulting in degradation of ultrasound and block needle tip imaging), (2) strategically addressing those blocks that have the potential to cause serious injury (e.g., pneumothorax, local anesthetic toxicity, unintentional neuraxial injection), (3) nerve blocks that involve smaller distal nerves (often difficult to image), (4) peripheral blocks that involve nerves lacking distinct ultrasonographic interfaces (can often result in difficulties distinguishing nerve structures from surrounding tissues), (5) patient-related factors (e.g., obesity, musculoskeletal disease), and (6) regional catheter-related techniques (e.g., requiring simultaneous transducer stabilization, needle manipulation, catheter threading) along with many other direct and indirect consequences associated with regional anesthesia/acute pain medicine training.

There has been tremendous progress made, e.g., in better understanding of surgical patient trauma, pathophysiologic bases of acute pain, and influence of patient comorbidities related to surgery and anesthesia, but there remains a continued need for clinicians to implement evidence-based procedure-specific multimodal analgesic protocols. Such an approach to patient care modified to meet the needs of individual patients, to enhance the quality of anesthesia services/perioperative pain management, and address clinically relevant patient needs will further complement the accomplishments of our anesthesiology specialty. In addition, there will continue to be a need for collaboration between the various healthcare providers, to integrate improved perioperative medicine with fast-track recovery paradigms; and an innovative approach to improve the quality of the surgical recovery process, reduce length of hospital stay(s) and postoperative morbidity, lead to shorter periods of convalescence, and yield improved patient experiences resulting in higher patient satisfaction.[32,33] Therefore, rather than simply performing systematic reviews and meta-analysis of the literature, an investigational and clinical role of regional anesthesia/acute pain medicine fellowship programs have been well positioned and structured to return to the hard work of performing, e.g., bench research, conducting prospective and randomized clinical trials on a procedure-specific basis, incorporating evidence-based regional anesthesia modalities as anesthetic/analgesic alternatives, and evaluating use of analgesic combinations as part of multimodal analgesic treatment regimens for the perioperative period.[34]

However, there still remains a disparity between the pathophysiologic data on the mechanisms responsible for, e.g., surgical and anesthesia trauma/stress, perioperative pain, and level and degree of medical intervention(s), and the subsequent translation of this evidence into clinically relevant and value-based practices.[35,36] Despite these hurdles, a way forward would be to design, investigate, and show scientific evidence for a necessity to begin to routinely implement procedure-specific, clinically meaningful anesthesia management and pain medicine protocols into the perioperative period by expertly trained physicians.[32,36] This concept provides further evidence as to how such a void could be bridged with regional anesthesia/acute pain medicine, and how well these procedure-specific analgesic care designs could be combined with a fast-track recovery strategy to obtain improvements in surgical and medical patient outcomes. This single important aspect lends further evidence as to how such regional fellowship training programs are positioned for success. In addition, this approach represents a logical next step despite the fact that existing concepts in the literature fail to support unanimous evidence that improvement in pain management automatically leads to enhanced recovery and reduced morbidity.[37] Therefore, it is becoming increasingly more evident that considering all aspects of a perioperative event should prove to yield improved outcomes along with escalated patient satisfaction that can be consistently achieved.[38,39] Once again, this provides additional evidence that subspecialty training with a regional anesthesia fellowship could led toward such an accomplishment and yield clinical results that are meaningful and relevant to the healthcare of surgical patients.

Identified in Table 78–4 are many additional parameters that provide further insight as to the impact that regional

TABLE 78–4. List of ongoing and future endeavors of formalized regional anesthesia/acute pain medicine fellowship programs.

1. Increase public awareness of existing deficiencies and possibilities for improving pain management.
2. Educating surgical patients and family members regarding steps they can take to improve quality of perioperative analgesia and facilitate recovery.
3. Provide evidence that immediate along with future solutions to improving the quality of pain management exists at organizational levels.
4. Generate further clinical research to better delineate the essential components of procedure-specific, multimodal, nonopioid analgesic regimens.
5. Conduct the necessary investigation to determine additional potential for evidence of clinical improvement in pain related outcomes by a peripheral approach (targeting pain at the site of origin before centrally mediated changes occur in the spinal cord/cerebral cortex).[40]
6. Study the effects/influences of local application of long-acting local analgesic formulations (e.g., depo-bupivacaine and extended-release bupivacaine,) and topical medications.
7. Design research that may provide evidence and clinical use of novel receptor populations on sensory nerve endings (transient receptor potential binding sites) which may prove to be useful targets for developing new analgesic adjuvants to add to opioid and nonopioid analgesic compounds.
8. Research findings that may led to discovery of other new classes of analgesic drugs and selective analgesic agonists.
9. An important area for future clinical research includes the need to develop a more in-depth understanding of the basis of the large interindividual variability in the pain response to similar noxious surgical stimuli.
10. Continue to show relevance to the concept that improving the quality of clinical outcome may in part require an individualized approach to acute pain management.
11. Is it possible to determine a patient's pain threshold before any surgical intervention?[41]
12. Areas of genetic research that may increase the ability to identify specific genotypes that may influence pharmacodynamics and pharmacokinetics of analgesic choices.[42]
13. Who in the future will be better prepared to investigate pharmacogenetics; an intriguing area for investigations aimed at improving pain management.
14. Study into perioperative pain management related to the influence of metabolic factors, aging, and gender on responses to anesthetic/analgesic interventions.
15. Population of the elderly age category continues to increase at a rapid rate. Therefore, clinical studies are needed to examine the effect of aging on responses to opioid and nonopioid analgesic medications/interventions.
16. Regional fellows are best positioned to continue to study the concept of "preemptive analgesia" and to examine, by randomized trials, any influence on the timing issue of initiating analgesia (medications and/or techniques) before vs after an invasive stimulus.
17. Information is needed regarding optimal duration of postdischarge therapy on a procedure-specific basis and how such treatment should be modified based on individual patient pain response factors.

anesthesia/acute pain medicine fellowship programs will have on the practice of medicine since it is no longer appreciated that implementation of evidenced-based guidelines for pain management protocols alone is sufficient to achieve the desired improvement(s) in patient outcomes. Implications from the several competencies included in Table 78–2, along with many others, and those cultivated from continuing research will advance the expertise and relevance that anesthesia services can provide real clinical value to and for patients receiving perioperative care, surgeons and other members of the healthcare team, hospital administrators, insurance companies, and other governmental regulatory bodies. A structure of this approach would continue to increase public awareness of the existing possibilities to improve anesthesia and surgical care and pain management along with reducing morbidity. It could also serve toward providing evidence to surgical patients and family members of the strides being made to improve the overall quality of anesthesia services and innovative advances to facilitate the recovery process.

SUMMARY

Following anesthesiology residency training, there are a multitude of options for graduating clinicians to consider as they venture forward into their careers as is listed in Table 78–3. A fellowship in regional anesthesia/acute pain medicine is an increasingly popular option that has been selected by anesthesiology fellowship candidates. Interest, enthusiasm, and attraction continues with this anesthesia subspecialty as more and more applicants continue to apply to a limited number a regional fellowship positions and as more academic facilities nationwide and in Canada are creating recognized regional fellowship programs within their institutions. The continued growth of this subspecialty comes partially from evidence-based directives that regional anesthesia/analgesia has become a valuable option for a wide variety of surgical and medical interventions. In addition, the ACGME has made an effort toward having anesthesiology residency programs graduate anesthesiologists with a proficiency in the basics of regional techniques.[43] Although the goals of this certifying organization have not yet been completely fulfilled, initiatives to accomplish ACGME efforts on a nationwide scale continue. Therefore, candidates who have completed an anesthesiology residency and wish to develop an expertise in regional anesthesia/analgesia have an option to pursue additional training in a regional fellowship program. Both professional interests from the medical/surgical community as well as an increasingly larger portion of the educated surgical patient population are making requests and demands for regional anesthesia options when amendable prior to surgical procedures, for postoperative pain management, and during invasive medical interventions. It is this growing enticement with regional anesthesia/analgesia alternatives brought about by public and professional entities that will continue to excite, expand, and inspire continued growth of regional anesthesia and regional anesthesia fellowships.

APPENDIX I. GUIDELINES FOR FELLOWSHIP TRAINING IN REGIONAL ANESTHESIOLOGY AND ACUTE PAIN MEDICINE (as adopted from the ASRA website)

Mission Statement

The purpose of this endeavor is to recommend the necessary components of subspecialty fellowship training in regional anesthesiology and acute pain medicine. Although an effort has been made to create a comprehensive set of goals and competency-based objectives, these recommendations may not apply to all programs, nor will they be used for any form of accreditation of fellowship programs. Participating fellowship program directors will ensure the ongoing development of regional anesthesiology and acute pain medicine as a defined subspecialty. Educational curricula, clinical care, and research activities are emphasized.

Programmatic Goals for Fellowship Training in Regional Anesthesiology and Acute Pain Medicine

Outline

I. Organization and Resources
   a. Scope and Duration of Training
   b. Institutional Organization
   c. Program Director and Faculty
   d. Facilities and Resources

II. Education Program
   a. Program Goals
   b. Medical Knowledge
   c. Patient Care
   d. Scholarly Activities/Practice-Based Learning
   e. Interpersonal and Communication Skills
   f. Professionalism
   g. Systems-Based Practice

III. Evaluation Process

I. Organization and Resources

a. Scope and Duration of Training

1. Scope of Training. Regional anesthesiology and acute pain medicine is a subspecialty focused on the perioperative management of patients receiving neuraxial or peripheral neural blockade for anesthesia and/or acute analgesia. Specifically, the setting of this training might include (a) intraoperative application (with or without general anesthesia), (b) postoperative application in inpatients and outpatients, and/or (c) acute pain management of nonsurgical patients. Fellowship training should be concerned with the development of expertise in the practice and theory of regional anesthesiology and acute pain medicine.
2. Duration of Training. The time required for subspecialty training in regional anesthesiology and acute pain medicine shall be 12 months. Program directors are granted flexibility to tailor the program to meet the individual needs of fellows. Specialized clinical rotations of less than 12 months may be made available to interested clinicians, but the minimum amount of training necessary to use "fellowship" in the diploma language shall be 1 year.

b. Institutional Organization

1. Relationship to a Core Program. Institutions with subspecialty training in regional anesthesiology and acute pain medicine must have a direct affiliation with an Accreditation Council for Graduate Medical Education (ACGME) accredited residency in anesthesiology (or similar; e.g., Royal College of Physicians and Surgeons of Canada or Royal College of Anaesthetists). If the institution at which the fellowship is based is other than the primary institution of an accredited residency, a written agreement linking the two is required. An evaluation

protocol consistent with ACGME (or equivalent)–approved standards for residency programs is also a prerequisite.

2. Institutional Policy and Resources. The fellowship should be recognized and approved by the core Department of Anesthesiology and the institution's Department/Division of Medical Education.
3. Institutional Oversight. The core program is encouraged to internally review the fellowship program at least every 5 years to ensure general compliance with these guidelines.

c. Program Director and Faculty

1. Program Director. The director of the fellowship training program must be an American Board of Anesthesiology—certified anesthesiologist (or equivalent) who has completed 1 year of fellowship training in regional anesthesiology and/or acute pain medicine, or is a dedicated and skilled practitioner of these disciplines. The program director must also have an academic and/or clinical affiliation with an ACGME (or equivalent)—accredited institution.
2. Faculty. The majority of the faculty in the training program must be board certified (or equivalent) in anesthesiology. A division of the faculty in the training program must also demonstrate an expertise in regional anesthesiology and/or acute pain medicine. The number of faculty in a program may vary based on the number of fellows in training; however, the program must have a minimum of two regional anesthesiology and/or acute pain medicine faculty.

d. Facilities and Resources

1. Equipment. Suitable equipment for the performance of a wide variety of regional anesthesia/analgesia techniques must be available. Such equipment must include nerve simulators, neuraxial and peripheral block supplies, catheter systems, ultrasound systems, and the basic requirements for conducting general anesthesia according to American Society of Anesthesiologists standards. Dedicated and acceptable on-call facilities must also be maintained, if applicable.
2. Support Services. Appropriate support services may include, but are not limited to, anesthesia technical support and pharmacy support systems.
3. Library. A departmental library, or a portion of the institutional library dedicated to anesthesiology, must be maintained with literature specific to the practice of regional anesthesiology and acute pain medicine.

II. Educational Program

a. Program Goals

Over the course of the 12-month fellowship, the fellow will enhance their cognitive, psychomotor, and affective skills to safely and effectively administer and teach regional anesthesiology and acute pain medicine as a consultant in anesthesiology. The fellow is responsible for decisions related to case and block selection to facilitate the smooth flow of the operating room (OR) cases and to enhance patient recovery. The fellow will be expected to develop and demonstrate the skills needed to establish regional anesthesiology and acute pain medicine as a primary component of their future practice.

b. Medical Knowledge

Upon completion of the program, the fellow should demonstrate knowledge in the following areas sufficient to:

1. Local Anesthetics

a. Describe the pharmacology of local anesthetics with respect to mechanism of action, physicochemical properties, comparative attributes, and appropriate dosing for site of single injection or continuous infusion.
b. Determine the selection and dose of local anesthetics as indicated for specific medical conditions.
c. Compare the dosing, advantages, and disadvantages of local anesthetic adjuncts.
d. Compare toxic risk of local anesthetics and signs, symptoms, and treatment of local anesthetic systemic toxicity or neurotoxicity.

2. Neuraxial and Systemic Opioids, Nonsteroidal Anti-Inflammatory Drugs, and Nonopioid Adjuncts or Analgesia

a. Neuraxial Opioids
   1. Describe indications/contraindications, mechanism of action, physicochemical properties, effective dosing, and duration of action of neuraxial opioids.
   2. Compare extended release epidural morphine with standard preservative-free opioids.
   3. Recognize complications and adverse effects, including related monitoring, prevention, and therapy.
   4. Differentiate intrathecal versus epidural administration relative to dose, effect, and adverse effects.

b. Systemic Opioids
   1. Discuss the pharmacokinetics of opioid analgesics: bioavailability, absorption, distribution, metabolism, and excretion.
   2. Discuss the site and mechanism of action of opioids.
   3. Discuss the differences of chemical structure of the various opioids.
   4. Describe challenges of postprocedure analgesic management in the patient with chronic pain and/or opioid induced hyperalgesia.

c. Nonopioid Analgesics
   1. Describe the concept of multimodal analgesia and its impact on functional restoration after surgery.
   2. Differentiate the pharmacology of nonsteroidal anti-inflammatory drugs (NSAIDs), cyclooxygenase-2 (COX-2) inhibitors, N-methyl-D-aspartic acid antagonists, α_2 agonists, gamma-aminobutyric acid, and pentanoid agents with respect to optimizing postoperative analgesia.

3. Nerve Localization Techniques

a. Explain principles, operation, advantages, and limitations of the peripheral nerve stimulator to localize and anesthetize peripheral nerves.
b. Explain principles, technique, and advantages and disadvantages of paresthesia-seeking, perivascular or transvascular approaches to nerve localization.
c. Explain principles, operation, advantages, and limitations of ultrasound to localize and anesthetize peripheral nerves.

4. Spinal Anesthesia

a. Describe the indications, contraindications, adverse effects, complications, and management of spinal anesthesia.
b. Recognize the cardiovascular and pulmonary physiologic effects of spinal anesthesia.
c. Compare local anesthetics for intrathecal use: agents, dosage, surgical and total duration of action, and adjuvants.
d. Explain the relative importance of factors affecting intensity, extent, and duration of block such as patient position, dose, volume, and baricity of injectate.
e. Define postdural puncture headache, and describe symptoms, etiology, risk factors, and treatment.
f. Differentiate advantages and disadvantages of continuous spinal anesthesia.

5. Epidural Anesthesia (Lumbar, Thoracic, Caudal)

a. Describe the indications, contraindications, adverse effects, complications, and management of epidural anesthesia.
b. Compare the local anesthetics available for epidural use agents, dosage, adjuncts, and duration of action.
c. Differentiate between spinal and epidural anesthesia with regard to reliability, latency, duration, and segmental limitations.
d. Explain the value and techniques of test dosing to minimize certain complications of epidural anesthesia.
e. Interpret the volume-segment relationship and the effect of patient age, pregnancy, position, and site of injection on resultant block.
f. Differentiate combined spinal epidural anesthesia from lumbar epidural anesthesia, including advantages/ disadvantages, dose requirements, complications, indications, and contraindications.
g. Categorize outcome benefits of thoracic epidural analgesia for thoracic and abdominal surgery and thoracic trauma.
h. Differentiate caudal epidural and thoracic epidural anesthesia from lumbar epidural anesthesia, including advantages/ disadvantages, dose requirements, complications, indications, and contraindications.
i. Explain the impact of antithrombotic and thrombolytic medications on neuraxial and peripheral anesthesia/ analgesia with specific reference to the American Society of Regional Anesthesia and Pain Medicine guidelines: *Regional Anesthesia in the Patient Receiving Antithrombotic or Thrombolytic Therapy.*

6. Upper-Extremity Nerve Block

a. Describe the anatomy and sonoanatomy of the brachial plexus in relation to sensory and motor innervation.
b. Compare local anesthetics for brachial plexus block: agents, dose, duration of action, and adjuvants.
c. Explain the value and techniques of intravascular test dosing to minimize local anesthetic systemic toxicity associated with peripheral nerve block.
d. Differentiate the various brachial plexus (or terminal nerve) block sites, including indications/contraindications, advantages/disadvantages, complications, and management specific to each.
e. Contrast the indications and technique for cervical plexus, suprascapular, or intercostobrachial block as unique blocks, or supplements to brachial plexus block.
f. Summarize the use and advantages/disadvantages specific to continuous brachial plexus anesthesia.

7. Lower-Extremity Nerve Block[9]

a. Describe anatomy and sonoanatomy of the lower extremity: sciatic, femoral, lateral femoral cutaneous, and obturator nerves (and their clinically important branches) in relation to sensory and motor innervation.
b. Compare local anesthetics for lower-extremity block: agents, dose, duration of action, and adjuvants.
c. Explain the value and techniques of intravascular test dosing to minimize local anesthetic systemic toxicity associated with peripheral nerve block.
d. Differentiate the various approaches to lower-extremity blockade, including indications/contraindications, adverse effects, complications, and management specific to each.
e. Summarize the advantages/disadvantages and indications for continuous lower-extremity neural blockade.

8. Truncal Blockade

a. Describe the relevant anatomy for intercostal, paravertebral, ilioinguinal-hypogastric, rectus sheath, and transverses abdominus plane blocks.
b. Compare local anesthetics for truncal blockade: agents, dose, and duration of action.
c. Summarize the indications, contraindications, adverse effects, complications, and management of truncal blockade.

9. Intravenous Regional Anesthesia

a. Review the mechanism of action, indications, contraindications, advantages and disadvantages, adverse effects, complications and management of intravenous regional anesthesia (IVRA).
b. Compare agents for IVRA: local anesthetic choice, dosage, and use of adjuvants.

Hadzic A, Vloka J, Koenigsamen J. Training requirements for peripheral nerve blocks. Curr Opin Anaesthesiol. 2002;15:669Y673.

10. Complications of Regional Anesthesia and Acute Pain Medicine

Discuss those complications specific to regional anesthesia and acute pain medicine practice. A partial list of these complications includes:

a. Hemorrhagic complications in the patient receiving antithrombotic or thrombolytic agents,
b. Infectious complications of neuraxial and peripheral blockade,
c. Neurological complications of regional anesthesia and acute pain medicine,
d. Local anesthetic systemic toxicity, and
e. Opioid-induced respiratory depression.

c. Patient Care

Upon completion of the program, the fellow should be able to:

1. Describe rational selection of regional anesthesia and/or postoperative analgesic techniques for specific clinical situations. Such techniques may involve nontechnical options, such as multimodal analgesia, opioid and nonopioid pharmacologic management, and so on.
2. Debate the advantages/disadvantages of regional versus general anesthesia for various procedures and patients in regard to patient recovery, patient outcome, or efficiency, and cost of care.
3. Recognize and intervene to manage inadequate operative regional anesthetic and postoperative analgesic techniques with supplemental blockade, alternative approaches, and/or pharmacologic intervention.
4. Demonstrate the knowledge and skills necessary to perform and to effectively teach a wide range of advanced practice block techniques, achieving a high success and low complication rate. Examples of blocks in this category, modified from Hadzic et al, include:

    1. Deep cervical plexus block
    2. Suprascapular nerve block
    3. Interscalene block
    4. Supraclavicular block
    5. Infraclavicular block
    6. Continuous interscalene block
    7. Continuous infraclavicular block
    8. Continuous axillary block
    9. Intercostal nerve block
    10. Thoracolumbar paravertebral block: single or continuous
    11. Rectus sheath block
    12. Transversus abdominis plane block
    13. Ilioinguinal-iliohypogastric block
    14. Sciatic nerve block: posterior approaches
    15. Sciatic nerve block: anterior approach
    16. Sciatic popliteal block
    17. Lumbar plexus block
    18. Femoral nerve block
    19. Lateral femoral cutaneous block
    20. Obturator nerve block
    21. Saphenous nerve block
    22. Continuous femoral nerve block
    23. Continuous sciatic nerve block
    24. Continuous popliteal sciatic block

5. Demonstrate an understanding of how the acute pain medicine service addresses (a) surgical regional anesthetic techniques (as placed by the operating room anesthesiologist), (b) the perioperative use of analgesic techniques by the acute pain medicine service, (c) the perioperative management of acute pain medicine interventions, (d) the provision of acute pain medicine services directed toward the chronic pain patient who is now experiencing acute pain, and (e) the provision of acute pain management to select nonsurgical patients, such as those with sickle cell anemia.
6. Demonstrate the ability to direct the acute pain medicine service with attending supervision. Patient management will include multimodal analgesic techniques such as neuraxial and peripheral nerve catheters, local anesthetic and narcotic infusions, and nonnarcotic analgesic adjuvants.

d. Scholarly Activities/Practice-Based Learning

1. Academic Activities

a. Fellows are encouraged to participate in research as a major activity of the year-long fellowship. To accomplish these objectives, the regional anesthesiology and acute pain medicine faculty will mentor the fellow in the production of research, coauthorship of papers as appropriate, and preparation of clinical research proposals with institutional review board approval prior to the start of the fellowship year.

2. Teaching Activities

a. Create and present a lecture during departmental or divisional grand rounds, or a local/regional/national meeting covering a topic or case relevant to regional anesthesia or acute pain medicine.
b. Prepare resident education lectures and journal reviews for regional anesthesiology and/or acute pain medicine subspecialty conference.
c. Participate and direct portions of cadaver anatomy laboratories if available.
d. Develop teaching techniques by instructing residents and/or medical students at the bedside under the supervision of faculty.
e. Review and enhance Web-based teaching resources such as resident teaching materials, curriculum documents, and self-study and testing materials.

3. Practice-Based Learning

a. Evaluate and apply evidence from scientific studies, expert guidelines, and practice pathways to their patients' medical conditions.
b. Apply information technology to obtain and record patient information, access institutional and national policies and guidelines, and participate in self-education.

c. Analyze their own practice with respect to patient outcomes (especially success and complications from regional blockade) and compare with available literature.

e. Interpersonal and Communication Skills

Upon completion of the program, the fellow should be able to:

1. Summarize information to the patient and family with respect to the options, alternatives, risks and benefits of regional anesthesia, and/or acute analgesic techniques in a manner that is clear, understandable, ethical, and appropriate.
2. Develop effective listening skills and answer questions appropriately in the process of obtaining informed consent.
3. Operate effectively in a team environment and communicating and cooperating with surgeons, residents, nurses, pharmacists, physical therapists, and other members of the perioperative team. This requires the fellow to:
   a. Recognize the roles of other members of the team.
   b. Communicate clearly in a collegial manner that facilitates the achievement of care goals.
   c. Help other members of the team to enhance the sharing of important information.
   d. Formulate care plans that utilize the multidisciplinary team skills, such as a plan for facilitated recovery.

f. Professionalism

Upon completion of the program, the fellow should be able to:

1. Continuously conduct the practice of medicine with integrity, honesty, and accountability.
2. Demonstrate a commitment to lifelong learning and excellence in practice.
3. Practice consistent subjugation of self-interest to the good of the patient and the healthcare needs of society.
4. Demonstrate a commitment to ethical principles in providing care, obtaining informed consent, and maintaining patient confidentiality.

g. Systems-Based Practice

Upon completion of the program, the fellow should be able to:

1. Effectively balance the need for operating room efficiency with high-quality patient care. The fellow will effectively choose surgeons, patients, techniques, and approaches to achieve the best balance possible to use regional anesthesia and/or analgesia to improve patient outcomes.
2. Understand the interaction of the acute pain medicine service with other elements of the healthcare system including primary surgical and medical teams and other consultant, nursing, pharmacy, and physical therapy services.
3. Demonstrate awareness of healthcare costs and resource allocation, and the impact of their choices on those costs and resources.
4. Advocate for the patient and their family within the healthcare system and assist them in understanding and negotiating complexities in that system.

III. Evaluation Process

A. Consistent with ACGME residency guidelines, the attending faculty will be evaluated by the fellows at least annually.
B. Written evaluations of fellows by all faculty with whom they have worked shall occur at least every 6 months. The results of these evaluations shall be recorded and reviewed with the fellows by the program director or faculty advisor no less often than every 6 months.
C. A review will be conducted at least twice annually to assess professional development.
D. A 360-degree assessment process will occur at least annually.

PART 14

STATISTICS AND PRINCIPLES OF RESEARCH DESIGN IN REGIONAL ANESTHESIA AND ACUTE PAIN MEDICINE

This page intentionally left blank

CHAPTER 79

Principles of Statistical Methods for Research in Regional Anesthesia

Maxine M. Kuroda

NECESSARY BASICS

Anesthesiologists treat thousands of patients in their busy clinical careers; they also save thousands of lives. However, anesthesiologists also have a place in research where their work is far reaching and can impact the lives of millions of people worldwide. This chapter is dedicated to those anesthesiologists who actively undertake research and who keep abreast of the research literature in order to better serve their patients.

The chapter begins with some very basic principles of statistics that form the foundation for those methods most frequently used in regional anesthesia research. These principles, albeit more theoretic and seemingly abstract, are included in the hopes of offering more than a cookbook approach to the statistical procedures. Several statistical packages are available "to crunch data," yet a minimal number of formulas and calculations are included to illustrate what happens to data when submitted to a statistical program. It is hoped that this chapter will foster more effective dialogue between anesthesiologist and statistician. By the end of the chapter, the reader should have a better understanding of what a statistician needs to know about studies and why this information is crucial to reaching valid research conclusions.

What Is Statistics?

Sir Ronald A. Fisher (1890–1962), the father of modern statistics, considered the science of statistics to be mathematics applied to observational data: "Statistics may be regarded as (i) the study of populations, (ii) as the study of variation, (iii) as the study of methods of the reduction of data."[1] His definition has three important implications for research:

1. Investigators would like to apply their research findings to vast populations, but it is seldom feasible to study an entire population, so they must study samples from it.
2. Each sample studied will be slightly different; i.e., there is variation among samples. Thus, there will be differences among samples even from studies that have used the same design and methods, and even among samples taken from the same population.
3. Investigators summarize and test the data from their study sample in order to reach reasonable conclusions about the parent population that they can communicate to colleagues, to journal editors, and to the public.

Types of Data

The types of data collected in a study determine the types of statistical analyses. Table 79–1 describes the three types of data, what they represent, their typical level of measurement, and their properties.[2]

Quantitative data are on a scale that has equal intervals. For instance, the difference between 35 and 45 years of age is the same as the difference between 60 and 70 years of age. When the scale has a true zero point, it is possible to look at the ratio of measurements; e.g., a patient who weighs 192 lb is twice as heavy as a patient who weighs 96 lb.

Ranked data indicate relative standing. For instance, the American Society of Anesthesiologists (ASA) physical status is assigned to each patient prior to surgery as an indicator of anesthetic risk. Although there is order, we can *not* say that an ASA physical status IV patient is twice as risky as an ASA physical status II patient.

Qualitative data indicate class membership. For instance, women delivering vaginally are in a different category from women delivering by cesarean section. It should be noted that with qualitative data, one category is no better than another. Thus, the vaginal and cesarean section categories merely reflect class membership; they do not reflect amount of risk that may accompany the delivery method.

TABLE 79–1. Properties of three types of data.

Type	Numbers Are	Typical Level of Measurement and Properties
Quantitative	Amount or count	Cardinal (interval-ratio)
		True zero
		Equal intervals
		Order
		Classification
		Frequency distribution
Ranked	Relative standing	Ordinal
		Order
		Classification
		Frequency distribution
Qualitative	Class membership	Nominal
		Classification
		Frequency distribution

Although seemingly elementary, it is often surprisingly difficult to determine what type or types of data variables represent. It is always a wise idea to keep a data dictionary. Table 79–2 illustrates the setup for such a data dictionary with examples of possible variables that might be included. A field for comments (an alphanumeric string variable) is quite useful for recording remarks on individual patients; e.g., "Intraoperative time lengthened because electrocautery device malfunctioned."

Basic Study Designs

Study design plays an important role in ensuring the validity of a study. Table 79–3 describes the four basic study designs.[3] The hallmark of the experimental design is that the investigator manipulates the exposure or treatment (independent variable) to assess its effect on disease or outcome (dependent variable). The cross-sectional, retrospective, case-control, and prospective cohort designs are primarily observational in that the investigator does not manipulate exposures or treatments. For instance, a researcher may want to know whether family infrastructure affects time to return to work following surgery. Since patients cannot be assigned to supportive or nonsupportive families, data must be obtained through interviews or other observational techniques.

There are many other study designs, most of which are variants of these basic ones, and many studies will include a combination of designs. Choice of design depends on the research question or hypothesis as well as feasibility and cost. Each design has its advantages and limitations. Even the experimental (clinical trial) design, considered to be the "gold standard," is not always ethical, and strictly speaking, results are only generalizable to patients like those who participated in the study. Moreover, no study is immune to bias; i.e., any systematic error that threatens the validity of research findings.[4] For instance, a study's recruitment methods may enroll predominantly employed, upper middle class participants. These subjects tend to be more health conscious, and may have better access to medical care where their health problems can be detected earlier when less severe. Therefore, depending on the particular exposure and outcome being studied, the research findings may be biased by the inclusion of numerous subjects with milder disease. There are endless ways in which a study can contain such systematic errors. Your past experience (or that of your colleagues) may allow you to anticipate certain features of a study that would make it vulnerable to bias. Incorporate this information into your study design because, once a study is biased, its data cannot be "fixed" through statistical wizardry.

Studies in regional anesthesia will often follow the protocols of the experiment or clinical trial. The investigator will typically begin by randomly assigning patients to the "arms" of the experiment. For instance, in order to compare the effectiveness of a new anesthetic with an established standard, an investigator would randomly assign patients to receive one *or* the other of these medications. Similarly, patients might be randomly assigned to receive a novel combination of anesthetics to see whether the new cocktail is more effective or has fewer side effects than standard combinations of the anesthetics.

Random assignment ensures that the overall likelihood of assignment is equivalent for the treatment arms. Because patients are not more likely to be assigned to one arm of the trial than another, the overall effect of random assignment is to reduce confounding by extraneous factors. However, random assignment can occasionally produce atypical groups; say, all male patients are assigned to one group and all female patients to another. If such groups occur following random assignment, subjects should not be reassigned by the investigator; rather, some regression techniques may be useful in adjusting for unbalanced groups. Fortunately, extreme groups are rare, and random assignment typically creates groups that are similar with respect to known (and even unrecognized) confounders.[5]

Random assignment is conducted in several ways. For simple randomization, a popular method is to use sealed envelopes. After consent to participate in the study has been given by the patient, the investigator or an assistant randomly picks an envelope that contains the group assignment for that patient. An equally valid method of random assignment involves the use of a printed table of random numbers (found in many statistics books) or computer-generated random numbers (an option in many statistical packages). A number in the table is pointed to with eyes closed. After this starting point is established by "blind stab," the numbers are consecutively followed in a prespecified direction (top to bottom, left to right, or even diagonally). Numbers are taken in groups of 2s, 3s, or 4s, depending on whether ≤99, 100–999, or 1000+ patients are to be included in the study. If even numbers have been prespecified as the placebo group and odd numbers as the treatment group, any

TABLE 79–2. Data dictionary.

Variable	Label	Definition	Type	Values	Comments
gender	Gender		N	0 = Female 1 = Male	
race	Race		N	1 = White 2 = Black 3 = Hispanic 8 = Other 9 = Unknown	Include "mixed" race in "other" category
dos	Date of surgery		D		Not date of preoperative visit
induct	Induction time (min)	Anesthesia start to anesthesia completed; e.g., spinal anesthetic injected	N		Missing for MAC patients
vas36h	VAS 36 h	VAS 36 hours after PACU discharge	N	1–100	Not available on patients who bypassed PACU
nrs2wk	NRS 2 wk	NRS 2 weeks after hospital discharge	N	1–10	Obtained by phone interview
laconc	LA concentration	Concentration of local anesthetic	N	Values entered as decimal (e.g., 0.0567, not 5.67×10^{-2})	Initial concentration administered
comments	Comments		S		Miscellaneous notes on patients

Abbreviations: D, date; MAC: monitored anesthesia care; N, numeric, PACU: postanesthesia care unit; S, string (alphanumeric); VAS, visual analogue scale; NRS, numeric rating scale.

patient who consents when the number is even is assigned to the placebo group. If the next number is odd, the next patient who consents is assigned to the treatment group; however, if the next number is even, that patient becomes the second individual assigned to the placebo group, and any patient who consents when the number is odd is assigned to the treatment group. The process continues until all consenting patients are assigned to a group, but may produce unequal numbers in the groups. Modifications to this scheme are incorporated depending on whether three or more groups are being studied. For example, numbers 01–33 could be assigned to the first group, 34–66 to the second group, and 67–99 to the third group.[5]

Other methods, such as blocked, stratified, weighted, or cluster randomization, may be useful[5] and will be mentioned briefly. Blocked randomization is used when the investigator wishes to keep the number of subjects in each group very similar, and is especially useful if a trial could be stopped early. Blocks are developed in which the treatment arms occur the same number of times but in different orders. For instance, because the A, B, and C treatment arms occur twice in the ABCABC and CBABAC blocks, each treatment arm will have the same number of subjects. Stratified randomization is used when there is prior knowledge that it is important to balance a particular characteristic among groups. For example, to study the effects of two different epidurals on laboring women, the researcher may want to assign women by parity status to ensure that similar numbers of

TABLE 79–3. Basic study designs.

1. Experimental (clinical trial)
   Exposure manipulated by the researcher
2. Cross-sectional
   Exposure and disease/outcome obtained at the same time or within a short period of time
3. Retrospective case-control
   Cases and controls selected and past exposures ascertained through interviews, medical records
4. Prospective cohort
   Exposed and unexposed individuals selected and followed to disease/outcome

primiparous and multiparous women are assigned to each of the two epidural groups. Here, the primiparous stratum may be assigned to epidural group 1 or 2 in the 1-2-2-1 order, and the multiparous stratum may be assigned to epidural group in the 2-1-1-2 order.

Weighted randomization is used when there is a reason to have unequal numbers of subjects in the groups (perhaps more subjects are needed in a particular group in order to obtain a precise estimate of a key variable). This is easily accomplished by adapting the methods of simple randomization; e.g., numbers 01–66 could be assigned to the first group and 67–99 to the second group. Finally, cluster randomization can be used to allocate treatment arms to geographic areas rather than to individual subjects. Multicenter clinical trials to evaluate the efficacy of local anesthetics might want to ensure that treatment arms are assigned equivalently among the centers when it is known that approaches to drug delivery and/or monitoring vary in different areas of the country.

Difference Between Descriptive and Inferential Statistics

There are two main subdivisions of statistics. *Descriptive statistics* portray features of the data that are of interest by organizing and summarizing the collection of observations.[6] How this is done depends on the type of data collected. For example, age of patient in years is a quantitative amount and would be presented as a mean and standard deviation of age for each of several peripheral nerve blocks (PNBs); however, gender of patient is a qualitative indicator of class membership and would be presented as a number and percentage for each PNB.

Inferential statistics uses information from study samples to test hypotheses about effects that are thought to be true in the population as a whole.[6] Inferential statistics can be used to answer such questions as whether length of stay in the postanesthesia care unit (PACU) is significantly longer for patients who received femoral or sham block for anterior cruciate ligament repair.

Both areas of statistics are important. The distributional characteristics (i.e., central tendency, spread, and shape) that constitute descriptive statistics are the very foundation of the more "glamorous" inferential statistics. Moreover, because descriptive statistics characterize key features of the data, it is an important tool for data cleaning. Are there missing values? If so, how much information is missing and why? Do the data make sense? Although an equal number of male and female patients may be expected to receive neuraxial anesthesia for lower extremity surgery, it would be an error to find a male receiving an epidural prior to delivering a baby. Are there outliers; if so, are they true outliers or simply typographic errors? Did the patient weigh 702 lb or was weight written sloppily and the patient actually weighed 202 lb? Finally, the assumptions that must be met in order to apply inferential statistics properly are based on the distributional characteristics of descriptive statistics. Thus, statisticians look at these characteristics to decide whether data need to be transformed before inferential statistics can be applied.

Measures of Central Tendency

The three most commonly used measures of central tendency are the mean, median, and mode.[6] The *mean* is the balance point of the distribution and is responsive to the exact position of each score in the distribution. It is an indicator of skewness (i.e., nonbell shapes) when used in conjunction with the median. However, because it is sensitive to each score in the distribution, the mean is more easily influenced by extreme scores than the median or the mode.

The *median* is the point that divides the upper and lower halves of a scale of ordered scores. Since it is not responsive to the exact value of the scores, it is less affected by extreme scores than the mean, and is often a better choice than the mean when describing central tendency for strongly skewed distributions. In fact, it is the only relatively stable measure for open-ended distributions.

The *mode* is simply the most frequently occurring score or the class interval that contains the largest number of subjects. The mode is easily "calculated," and is the only measure suitable for qualitative (class membership) data. Nonetheless, the mode is of little use beyond the descriptive level.

Measures of Spread

The three most commonly used measures of spread are the range, variance, and standard deviation.[6] The *range* is simply the distance spanned by the highest and lowest scores in an ordered distribution. Thus, it does not account for scores that fall between these two extremes. The range is easily "calculated" but is of little use beyond the descriptive level.

As noted by Fisher, *variance* is a key concept in statistics. Simply put, variance is the mean of squared deviations from the mean, $S^2 = [\Sigma(X - \bar{X})^2]/n$. Each score or observation in a sample is subtracted from the sample mean. These differences (deviations) are squared and summed, and the total is divided by the number of scores. Although vital to statistical inference, variance is of little use for descriptive purposes because people generally find it difficult to think in squared terms.

It is easier to think in terms of the *standard deviation*, which is merely the square root of the variance, $\sqrt{[\Sigma(X - \bar{X})^2]/n}$. The standard deviation is not only the most important measure to describe spread, but is of great use in inferential statistics. It is responsive to the exact position of each score in the distribution, but is quite resistant to variation among samples. It should also be noted that the standard deviation decreases as sample size increases.

Measures of Shape

Distributions come in many shapes; e.g., J-shaped, U-shaped, rectangular. Shape can be described in terms of skewness and kurtosis.[6] A distribution is positively *skewed* if its values appear to be pulled toward the higher end of the scale; conversely, it is negatively skewed if its values appear to be pulled toward the lower end of the scale (as shown in (E) and (F), respectively, in Figure 79–1). The visual analogue scale (VAS) scores that are used to record patient ratings of pain are often positively skewed immediately after surgery, indicating that

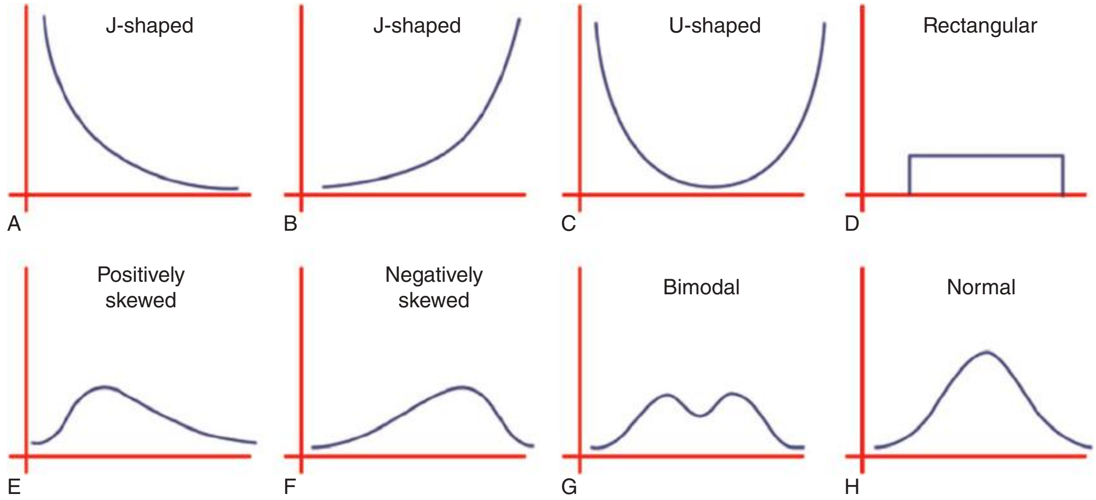

FIGURE 79–1. A few common distributional shapes.

most patients are comfortable right after surgery, and rate their pain at the low end of the distribution. Because the shape of the VAS distribution is not symmetric and bell shaped, it would be appropriate to consider categorizing pain levels into discrete, reasonable ranges; e.g., 0–3 none to mild pain, 4–7 moderate pain, and 8–10 excruciating pain. Nonparametric statistical procedures can be applied to test associations of interest with respect to these categories of pain.

Kurtosis describes peakedness. Leptokurtic distributions have many values in the center and fewer values in the tails of the distribution, giving them a peaked shape with "skinny" tails. In contrast, platykurtic distributions are less peaked, so more values reside in the tails of the distribution, giving them a flatter shape with "fatter" tails. Finally, the mesokurtic distribution is more bell shaped.

The Normal Curve

There is only one standard normal curve. This gaussian curve, named for Carl Friedrich Gauss, a German mathematician (1777–1855), has particular distributional characteristics that are important for inferential statistics. It is symmetric, bell shaped, and has a mean of 0 and a standard deviation of 1. As shown in Figure 79–2, its tails do not touch the horizontal axis because the distribution continues to infinity. Approximately 68% of the scores fall within ± 1 standard deviation of the mean, and roughly 95% of the scores fall within ± 2 standard deviations of the mean; hence, few drawings of the normal curve need to continue beyond ± 3 standard deviations. Figure 79–4 gives areas under the standard normal curve for values of z. In particular, note that z scores of ± 1.96 correspond to 2.5% in each tail of the curve.

The convenient distributional characteristics of the gaussian curve allow us to calculate standard, or z scores; i.e., $z = (X - \overline{X}) / S$. This simple calculation of score minus mean divided by standard deviation gives individual scores their "addresses" on the normal curve. As scores have been standardized to the same curve, we can compare performance on different measures. For example, a score of 95 on an English examination and a score of 75 on a math exam does not necessarily mean that the student performed better on the English exam than on the math exam. If the mean for the English exam was 100 with a standard deviation of 7.5, the student's score of 95 is two thirds of a standard deviation *below* the mean. If the mean for the math exam was 60 with a standard deviation of 10, the student's score of 75 is 1.5 standard deviations *above* the mean. Thus, this student actually performed better on the math exam than on the English exam.

Sampling Distribution of the Mean

Instead of individual scores, the sampling distribution of the mean consists of the *means* of all samples of a specified size taken from the entire population.[2] A particular sample mean's address is located on this distribution.

The hypothetic parent population at the top of Figure 79–3 consists of four scores. The means of every possible sample of size 2 are calculated and distributed into the sampling distribution of the mean at the bottom of the illustration. This allows us to determine the address of any sample mean (here, of size 2) that we might obtain. Thus, a sample mean of 4.5 can be shown to have an address 1.25 standard deviations above the mean on this sampling distribution.

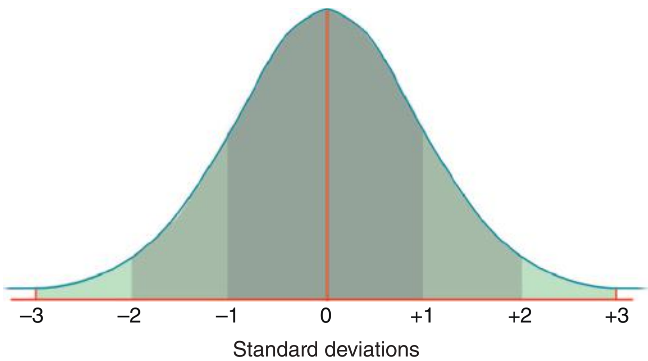

FIGURE 79–2. The gaussian (standard normal) curve.

TABLE 79–4. Type I and Type II errors.

		State of Nature	
		H_0 false	H_0 true
Decision	Retain H_0	Type II (β)[a]	Correct
	Reject H_0	Correct[b]	Type I (α)[c]

[a] "Missing the boat," or failing to convict a guilty person.

[b] "Power" or rejecting H_0 when H_0 is false $(1 - \beta)$.

[c] "False alarm" or convicting an innocent person.

Central Limit Theorem

In order for the concept of sampling distribution of the mean to be useful, we must also consider the third distributional characteristic, shape. Here, we are fortunate to have an ally known as the central limit theorem. It states that the shape of the sampling distribution of the mean approximates a normal curve if sample size is sufficiently large. So, the question becomes "what is sufficiently large"? This depends on the shape of the parent population. If the parent population is normal, any sample size is sufficiently large. Depending on the extent of

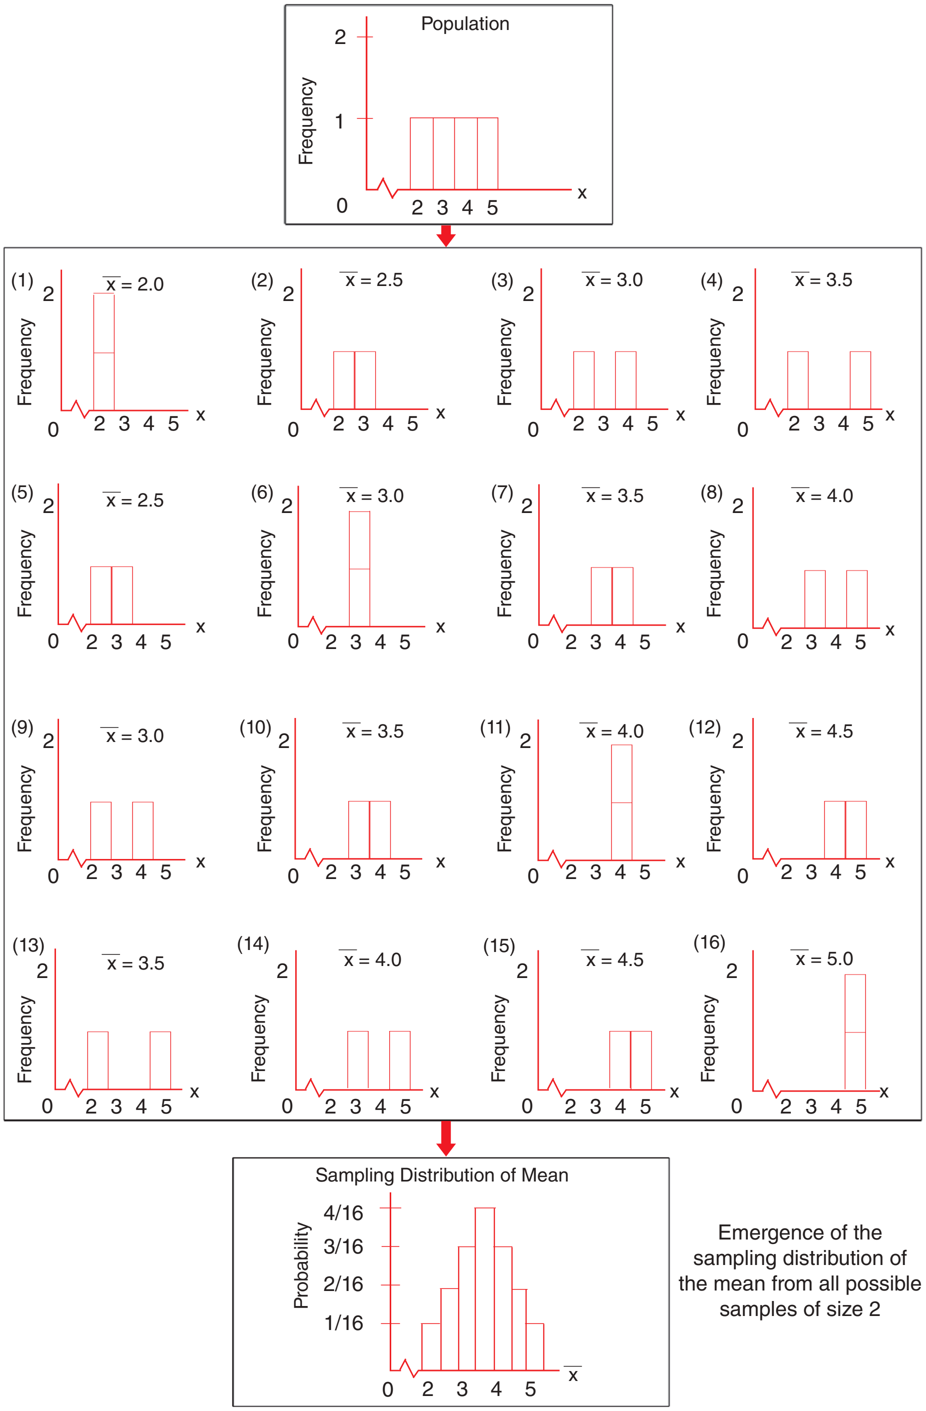

FIGURE 79–3. A sampling distribution of the mean.

abnormality in the parent population, sample sizes between 25 and 100 are typically large enough for the sampling distribution of the mean to have the symmetric bell shape and tapered tails on either side.

Null Hypothesis

The null hypothesis (denoted as H_0) is a statement that there is no effect (e.g., there is no difference in length of PACU stay between patients given regional anesthesia and patients given general anesthesia). H_0 is presumed true until proven false. We must decide whether to reject or retain H_0 based on samples of patients given regional or general anesthesia. Our decision depends on the address of the test statistic on its sampling distribution (Figure 79–4). We are more likely to reject H_0 when our test statistic has an address in the extreme tails of the distribution; conversely, we are more likely to retain H_0 when it has an address in the middle of the distribution. *P*-values indicate how extreme a test statistic is and are used as a guide to rejecting or retaining the null hypothesis.

Alternative Hypotheses

The null hypothesis always makes a claim about one specific value. For example, if we test that there is no difference in time to onset of two anesthetics, we are testing that the difference in onset time between the two anesthetics is literally 0.0000. The alternative, or research, hypothesis (denoted as H_1 or sometimes as H_A) generally complements the null hypothesis and makes a claim about a range of values. Since it is impossible to test infinitesimally every value in a range, we end up testing the specific value of the null hypothesis despite the fact that our real research interest lies in the alternative hypothesis.

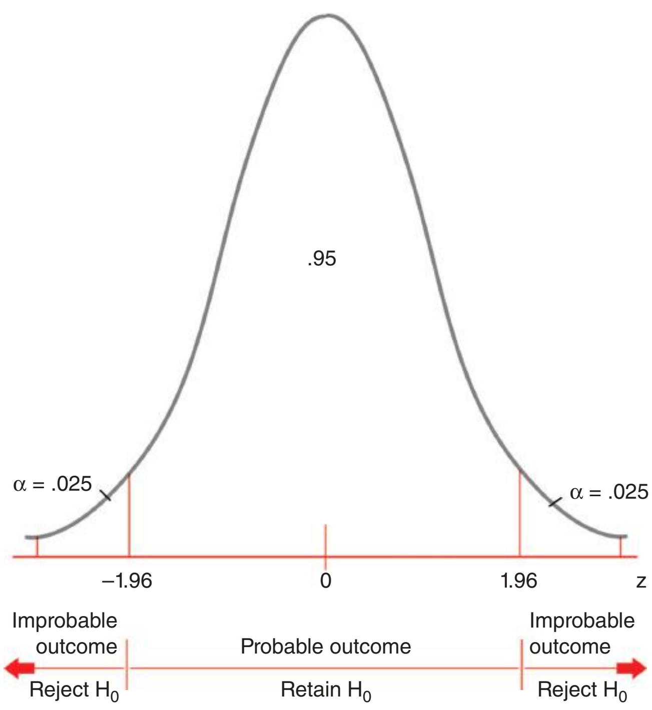

FIGURE 79–4. Hypothesized sampling distribution of *z*.

The alternative hypothesis comes in three forms: two-sided, one-sided with lower tail critical, one-sided with upper tail critical. If we state that the effect of a new anesthetic on intraoperative blood pressure is different from that of the more established anesthetic, we have not indicated directionality (the new anesthetic may either raise or lower intraoperative blood pressure), so the alternative hypothesis is two-sided. If we state that the effect of a new anesthetic is to lower or to raise intraoperative blood pressure, the alternative hypothesis is one-sided with lower tail critical or with upper tail critical, respectively. Choice of the one-sided alternative hypothesis should be stated when sole concern is about deviations in one direction. However, for most studies, the two-sided alternative hypothesis should be stated, and especially for studies of novel treatments and for early investigations into a new field.

The null hypothesis and *one* of these alternative hypotheses is stated for each research aim of a study. These hypotheses are not questions and should not be written as such. They should not be influenced by preliminary peeks at the data, and ideally should be stated before data are even collected. Once statements about H_0 and H_1 are made, they cannot be changed to accommodate the empirical findings of the study.

Type I and Type II Errors

The type I and type II errors are probabilities:

The type I error is the probability of rejecting H_0 when H_0 is, in fact, true (there actually is no effect). The type II error is the probability of accepting H_0 when H_0 is, in fact, false (there actually is an effect). Neither error can be avoided entirely, so investigators must decide how much error they can tolerate. Is it more important to avoid a type I error (perhaps concluding that a particular anesthetic provides excellent pain relief even at a low dose when it really does not, thus resulting in unnecessary pain for the patient), or is it more important to avoid a type II error (perhaps concluding that a particular anesthetic does not cause bradycardia when it really does, thus endangering the patient during surgery) (Table 79–4)?

After due consideration, the investigator sets the tolerable type I error by specifying α. Typically, this is 0.05, that is, the investigator is willing to take a 5% chance of committing the type I error. Things are a bit more complex with the type II error inasmuch as a number of factors can affect the size of the type II error. The factor over which the investigator has most control is sample size. Studying a larger sample lowers the probability of committing the type II error (Table 79–5).

Principles of Sample Size Estimation

Figure 79–5 shows the underlying sampling distribution of the population means under both the null and alternative hypotheses. For simplicity, only one curve (that for a one-sided lower tail critical test) is shown for the alternative hypothesis. If the researcher has decided to set the type I error at, say, 0.05, the critical value ("address"), denoted in the figure as $\mu_0 - z_0/\sqrt{n}$ is –1.64 for the *z* statistic. Test statistics with addresses to the right of this critical value would result in retention of the null hypothesis, and addresses to the left of the critical value would result in rejection of the null hypothesis.

TABLE 79–5. Factors affecting type II error (β).

Sample size: Larger sample size lowers β.
Discrepancy between what is hypothesized and what is true: Larger discrepancy lowers β.
Standard deviation of variable: Smaller σ lowers β.
Relation between samples: Dependent (paired or matched) samples can lower β.
Level of significance: Larger α lowers β.
Choice of H_1: β is smaller for a one-sided test than for a two-sided test.

Source: Data from Minium EW: *Statistical Reasoning in Psychology and Education*, 2nd ed. New York; Wiley & Sons; 1978.

Power (1 – β) is determined by the sampling distribution of the alternative hypothesis. As previously mentioned, increasing sample size decreases variability. Thus, if sample size is increased, both curves pull apart, resulting in less overlap of their tails. The probability of committing a type II error (β) is lessened as the two curves pull apart. However, with too many subjects, the overlap of the curves may be so slight that even a small, clinically unimportant difference can meet or exceed the criterion for statistical significance. Conversely, with too few subjects, the overlap of the curves may be so considerable that it may not be possible to detect any difference, even a sizable one. Therefore, sample size should be reasonable for any study, and grant proposals and manuscripts now require investigators to describe the factors on which the sample size for their study was based. These include criterion for significance (type I error probability, α), desired power (1-type II error probability, β), minimum expected difference with its estimated variability), interest in the one- or two-sided alternative hypothesis, and study design factors (independent *v* paired/matched subjects, number of treatment arms, continuous *v* proportional data collected). Factors that affect sample size are summarized in Table 79–6.

An article by Eng on sample size estimation includes useful suggestions for websites that can be used to estimate sample sizes for some parametric and nonparametric statistics as well as helpful hints on minimizing sample size.[7] However, for descriptive studies (or surveys and polls) in which there is no central hypothesis to test, sample size can be estimated based on an acceptable margin of error (E). This statistic reflects the amount of random sampling error in the results of a survey; hence investigators have more confidence in results with small E (more precision) and less confidence in results with large E (less precision). Several websites contain simple calculators for E; e.g., http://www.raosoft.com/samplesize.html.

Degrees of Freedom

As the name implies, degrees of freedom (df) are the number of values, within a given set of values, that are free to vary. It is a truth in mathematics that differences from a mean must sum to zero; that is, $\Sigma(X_i - \bar{X}) = 0$. So, given three scores (X_1, X_2, X_3) in the sample, the first deviation $(X_1 - \bar{X})$ might be +4, and the second deviation $(X_2 - \bar{X})$ might be –5. The third deviation $(X_3 - \bar{X})$ must, therefore, be +1. That is, the score X_3 is not free to vary; this sample has only 2 df.

In general, a degree of freedom is used whenever a parameter is estimated, when estimating each regression coefficient in multivariable modeling, and when estimating each treatment and interaction effect in multifactorial analyses of variance. But, importantly, df are also used when estimating error variance ("rubber in the yardstick"). It is little wonder that statisticians worry about having sufficiently large sample sizes to offset the df used during their statistical procedures.

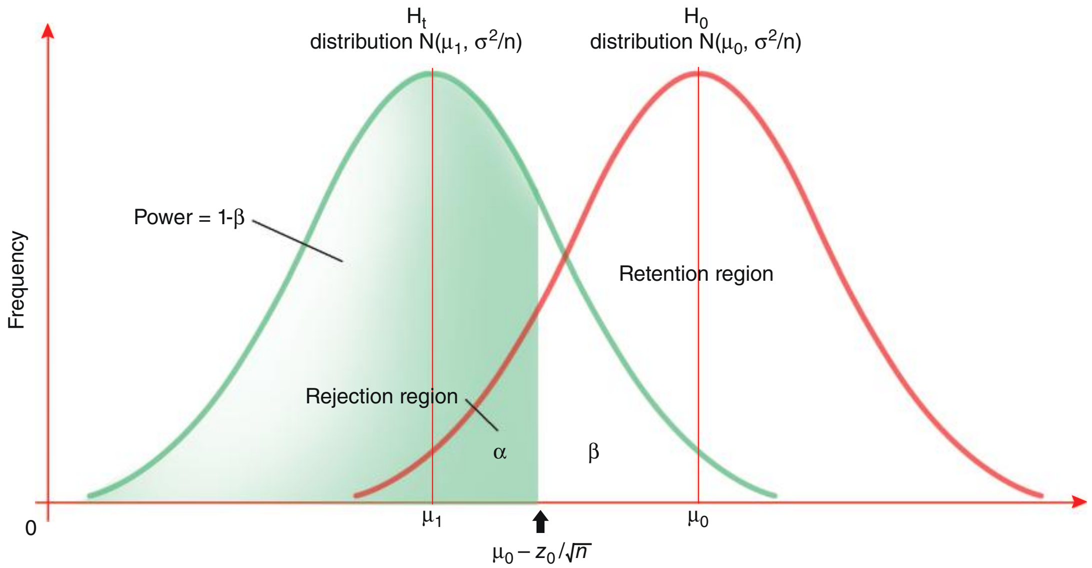

FIGURE 79–5. Sample size estimation.

TABLE 79–6. Factors affecting sample size (*n*).

n increases as variance (σ^2) increases.
n increases as the significance level is made smaller (i.e., as α decreases).
n increases as the required power is made larger (i.e., as $1 - \beta$ increases).
n decreases with larger absolute value of the distance between the null and alternative means (i.e., as $\lvert\mu_0 - \mu_1\rvert$ increases).
n is larger for two-sided than for one-sided tests.

P-Values

Thus far in this chapter, no formal statistical testing has been conducted; however, the concept of critical values has been described: A test statistic is computed and compared to a critical value (the "address" that delineates the retention and rejection regions of H_0). These regions typically contain 2.5% in each tail of the curve for the two-sided test or 5% in one tail for the one-sided test.[8] Although statisticians are not certain how Fisher chose the magical *P*-value of ".05," he may have felt that this is the size of type I error that most researchers could comfortably accept (Table 79–7).

So the *P*-value is the probability of obtaining a test statistic as extreme as or more extreme than the actual test statistic obtained given that H_0 is true. Most statistical software programs automatically provide *P*-values. The computer printout will contain notations attached to test statistics, such as $P = .036$, indicating that the probability of obtaining a test statistic at least as extreme as the one obtained is only 3.6%. And, as this is rather rare, H_0 would be rejected. Note that the *P*-value of .036 should not be interpreted as a 96.4% chance that H_0 is wrong. Put another way, *P*-values are calculated on the assumption that H_0 is true, *but they do not tell us whether that assumption is correct in the first place.*[9]

TABLE 79–7. Guidelines for judging the significance of a *P*-value.

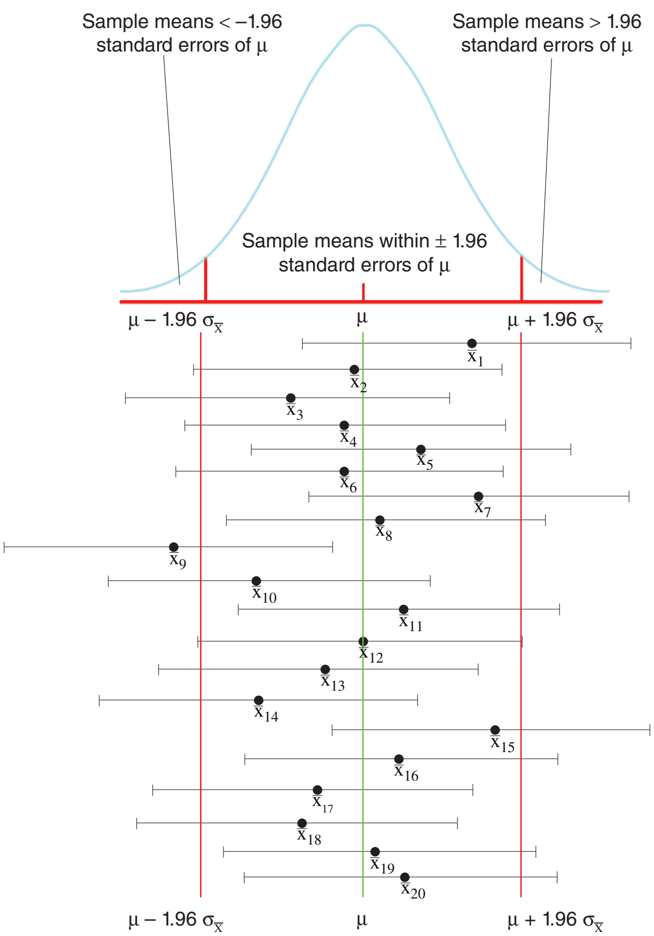
If 01 ≤ *P* < .05, then the results are *significant.*
If 001 ≤ *P* < .01, then the results are *highly significant.*
If *P* < .001, then the results are *very highly significant.*
If *P* > .05, then the results are considered *not significant* (sometimes denoted by NS).
However, if .05 ≤ *P* < .10, then a trend toward statistical significance is sometimes noted.

Source: Data from Rosner B: *Fundamental of Biostatistics*, 5th ed. Duxbury Press; 2000.

Confidence Intervals

Confidence intervals expand our view beyond *P*-values. Figure 79–6 illustrates that for samples of a given size, intervals can be constructed that may or may not include the population parameter under scrutiny (here, the population mean, μ). Over the collection of all 95% confidence intervals that could be constructed from repeated random samples of a given sample size, 95% of them will contain μ. In reality, you would not be able to construct this figure because you study only a single sample. Consequently, you would not know for certain whether the confidence interval from your particular sample actually does include the population value. You would know, however, that 95% of the intervals from studies such as yours will contain the population parameter. Thus, you will have an estimate of the population parameter with reasonable certainty.

Confidence intervals have several advantages. The *P*-value approach makes a statement about a derived statistic (usually the family of *F*, *r*, or chi-square statistics). This approach merely produces a yes or no answer about whether to reject or retain H_0 and could lead to confusion between statistical significance



*Although 95% confidence intervals have been constructed for the purpose of illustration, it is possible to construct intervals for any desired certainty (e.g., 90%, 99%).
**Confidence intervals can be constructed for population parameters other than the mean (e.g., for the population correlation coeficient, p (rho)).

FIGURE 79–6. Several 95% confidence intervals arising from the sampling distribution of the mean.

and clinical importance. Confidence intervals, on the other hand, make a statement about the actual parameter of interest. An estimate of the population parameter is produced along with an idea of the precision with which the estimate was made. If the confidence interval is narrow, the estimate was probably based on a sizable number of subjects and precision is good; conversely, if the confidence interval is wide, the estimate was probably based on fewer subjects and precision is not as good.

As noted earlier, the minimum expected difference (MED) that the investigator deems important to detect is a crucial factor in sample size estimation. A simple way of quantifying the MED is to divide it by the standard deviation of the population from which the different treatment groups were taken. This so-called "effect size" (also known as Cohen's d) follows the formula

$$\textit{Effect size} = \frac{(\textit{Mean of experimental group}) - (\textit{Mean of control group})}{\textit{Standard deviation}}$$

where the standard deviation may be estimated either from the control group or pooled from both the experimental and control groups using

$$\mathrm{SD}_{\text{pooled}} = \sqrt{\frac{(n_e - 1)SD_e^2 + (n_c - 1)SD_c^2}{n_e + n_c - 2}}$$

Effect sizes are standardized (divided by the standard deviation) and, therefore, unitless. An effect size of 0.96 indicates that the average score in the experimental group is nearly a full standard deviation above that of the average score in the control group. (Effect sizes can be negative as, e.g., if the control group provided higher scores than the experimental group in that study.) Cohen has described 0.2 as "small," 0.5 as "medium," and 0.8 as "large" effects.[10] Because they are standardized, effect sizes can be compared (carefully) among different studies such as in meta-analyses where they have been most frequently used. Nonetheless, they should be included in most reports as they help us appreciate the "significance" of significance tests. For example, the statement that "the effect of gender on reported pain scores was large, Cohen's d = 2.1, t(12) = 3.2, $P < .01$" tells us that the impact of gender was sizable despite the small sample size (here, total sample size was 14).

Parametric and Nonparametric Statistical Tests and When to Use Them

A parameter is a characteristic of a population. One of the parameters that we are often interested in is the population mean, μ. Parameters are usually denoted by Greek letters, whereas characteristics of samples are usually denoted by Roman letters (e.g., a sample mean is denoted as $\bar{X}$).

Parametric tests are used with quantitative data and require assumptions about the precise form of the population distribution, e.g., normality and equal variance (also known as homogeneity of variance). Nonparametric tests are used with quantitative, ranked, or qualitative data and require no assumptions about the precise form of the population distribution. These "distribution-free" tests *can be used* with quantitative data that have nonnormal distributions and when variances of the groups are not equal, however, they *must be used* with ranked or qualitative data.

When it is believed that the normality and homogeneity assumptions are met, parametric tests are more powerful than nonparametric tests. However, when sample size is small (say, less than 10), there is a very good possibility that the assumption of normality has been violated. Furthermore, when sample sizes are small *and* unequal, there is a very good possibility that the assumption of equal variance has been violated. Under these circumstances, the nonparametric tests should probably be used. We have already discussed an example of nonnormality with the VAS scores. It was suggested that perhaps the scores should be categorized into levels of pain and submitted to nonparametric tests (as discussed in the section on Nonparametric Tests).

Data Transformations

Raw data may need to be transformed in order to meet the assumptions of the parametric statistical tests. As described throughout this section, data must come from a population with normally distributed values. Thus data that are inconsistent with this assumption should be transformed prior to conducting a parametric statistical test. It is convenient that transforming to normality can reduce the influence of outliers (atypical values) on the analysis, and a nonparametric test may become unnecessary. Another assumption of many parametric tests is that the groups have the same variance; hence, violations to this assumption may require data transformation. A third assumption applies to linear regression (which is covered in the section on Parametric Tests). It states that the model must be a linear combination of variables; hence, transformation must be considered if regression coefficients or raw data suggest a nonlinear (curvilinear) model. It is indeed fortunate that the same transformation often helps to meet the first two assumptions (and sometimes even the third), rather than dealing with one assumption at the expense of the other two.

The only transformation that will be described here is the log transformation as it is by far the most frequently used. Simply, the logarithm of each raw value is computed and used in the inferential statistical analysis. However, results of the analysis are presented in the original scale of measurement. Other transformations require that the square root, reciprocal, square, or even the arcsin of the raw data be obtained prior to analysis.[11] Statistical advice is necessary when using transformations, as certain conditions apply. For instance, a statistician is likely to suggest the log transformation if s/he notes that variance increases as the mean of the groups increases (thereby producing a rather funnel-shaped scatter-plot). However, the statistician will also know that this transformation can only be used with outcome variables that take positive values.

PARAMETRIC TESTS

Our foray into inferential statistics begins with the *z* test for a single population mean, the most fundamental of the inferential tests. This test is accurate only when the population is normally distributed (or the sample size is large enough to satisfy the central limit theorem), and the population standard deviation, σ, is known. Unfortunately, in regional anesthesia and in other areas of medicine, we rarely know σ, so the z statistic cannot be used. We turn, instead, to the t test for a single sample:

$$z = \frac{(\text{normally distributed variable}) - (\text{constant})}{(\text{constant})}$$

$$= \frac{\bar{X} - \mu}{\sigma_{\bar{X}}} \quad \text{where } \sigma_{\bar{X}} = \frac{\sigma}{\sqrt{n}}$$

$$t = \frac{(\text{normally distributed variable}) - (\text{constant})}{(\text{variable})}$$

$$= \frac{\bar{X} - \mu}{s_{\bar{X}}} \quad \text{where } s_{\bar{X}} = \frac{s}{\sqrt{n}}$$

Not surprisingly, there is a whole family of t curves, one curve for each sample size. As shown in Figure 79–7, although each curve is bell shaped, the area in the tails increases as sample size decreases. Thus, the z score address on a curve with few df must be higher (in the upper tail) and lower (in the lower tail) than the address on a curve with many df. This is to accommodate the thickness of their tails. For the curves shown in the Figure 79–7, the z scores are ± 2.776 and ± 2.228 with 4 and 10 df, respectively, for 2.5% in each tail, as compared to ± 1.96 for the infinite df of the standard normal curve.

The difference between the t and standard normal distributions is greatest for small sample size (usually <30). As sample size increases, the curves converge to that of the standard normal curve because the sample variance (s^2) decreases, and s^2 is better able to approximate the population variance (σ^2).

For our example of the t test for a single sample, we wish to know whether the heart rate of patients undergoing interscalene brachial plexus block differs from the adult norm of 72. Heart rate is recorded on 18 patients (mean 75 beats per minute [bpm] ± 8.8). We calculate $t_{df=17} = (75-72)/(8.8/\sqrt{18}) = 1.45$, which is not significant (P >.05). Thus, heart rate in our sample of patients undergoing interscalene brachial plexus block does not differ from the adult norm of 72 bpm. Note that the test is with 17 df because one degree of freedom was used to estimate s.

Student's *t*

The *Student t* test compares two independent groups with respect to some continuous variable. The test was named for William S. Gosset, a British chemist and statistician (1876–1937), who worked out the mathematics for the family of t distributions and wrote under the penname of Student. The groups must be independent, so a patient cannot contribute more than one value to a group, nor can a patient contribute values to both groups. The formula to test is basically the same as that for the one sample case, in which the sample mean has been replaced by the sample mean difference, $(\bar{X}_1 - \bar{X}_2)$, the population mean by the population mean difference, $(\mu_1 - \mu_2)$, and the sample standard deviation by the standard error of the mean difference, $S_{\bar{X}1-\bar{X}2}$. It should be noted that $(\mu_1 - \mu_2)$ is regarded as 0 whenever the null hypothesis posits no difference between the groups. It should also be noted that the standard error is essentially a standard deviation; the term *error* is often used to describe variability of computed measures, such as variability in *mean* differences.

For our example, we wish to know whether postoperative heart rate measured in the recovery room differs between patients who receive general anesthesia and those who receive spinal anesthesia. Postoperative heart rate of 10 patients who received general anesthesia (87.7 ± 8.8) is compared with that of 10 patients who received spinal anesthesia (72.7 ± 7.1), $t_{df=18}$ = 4.2, P = .001. Thus, postoperative heart rate differs by anesthetic technique (it is higher in patients who receive general anesthesia). Note that df = $(n_1 - 1) + (n_2 - 1) = (10 - 1) + (10 - 1) = 18$, so two df were used estimating s_1 and s_2.

$$t = \frac{(\bar{X}_1 - \bar{X}_2) - (\mu_1 - \mu_2)}{s_{\bar{X}_1 - \bar{X}_2}}$$

$$\text{where } S^2_{\text{Pooled}} = \frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{(n_1 - 1)(n_2 - 1)}$$

$$s_{\bar{X}_1 - \bar{X}_2} = \sqrt{\frac{S^2_{\text{Pooled}}}{n_1}} + \sqrt{\frac{S^2_{\text{Pooled}}}{n_2}}, \text{ and}$$

$$\text{df} = (n_1 - 1) + (n_2 - 1)$$

Since,

$$s_p^2 = \frac{(10-1)(8.8^2) + (10-1)(7.1^2)}{(10-1)(10-1)} = 63.925 \text{ and}$$

$$s_{\bar{X}_1 - \bar{X}_2} = \sqrt{\frac{63.925}{10}} + \sqrt{\frac{63.925}{10}} = 3.576,$$

$$\therefore t = \frac{(87.7 - 72.7) - 0}{3.576} = 4.2\,(p = .001)$$

Note: The table of z values found in many statistical texts was not included in this chapter; neither were tables of the critical values for the t, F, chi-square (χ^2), and other tests. This is because P-values and confidence intervals for most statistics are included as standard output by the programs used to calculate them, and separate tables are generally not needed.

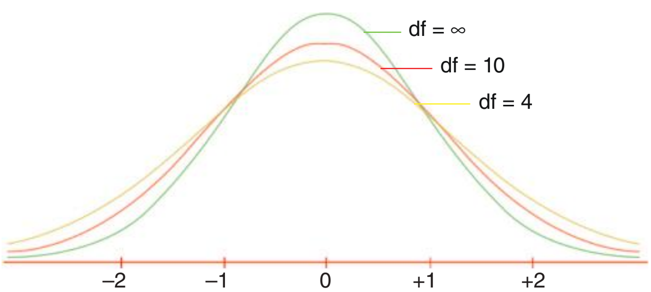


FIGURE 79–7. A couple of t distributions.

Dependent (Paired or Matched) *t*

Groups are not independent if subjects are matched on some variable or the same subjects are tested before and after some intervention, or a cohort of subjects is repeatedly evaluated over an interval of time. For our example, we wish to know whether heart rate differs in 10 patients who received epidural anesthesia at the T1 level before and after a bolus of 15 mL of 2% lidocaine. Heart rate before bolus (78.7 ± 7.4) is compared with heart rate after bolus administration (69.6 ± 6.7) in the same patients, $t_{df=9} = -10.4$, $P < .001$. Heart rate before bolus differs from heart rate after bolus (it is lower following bolus administration). Note the similarity with the *Student t* formula: The sample mean difference, $(\bar{X}_1 - \bar{X}_2)$ has been replaced by the mean difference between scores, $\bar{D}$, the population mean difference, $(\mu_1 - \mu_2)$, has been replaced by the population difference, μ_D and the standard error of the mean difference, $S_{\bar{X}_1 - \bar{X}_2}$, by $S_{\bar{D}}$. It should also be noted that μ_D is again regarded as 0 because the null hypothesis posits no difference in heart rate before and after boluses of lidocaine.

$$t = \frac{\bar{D} - \mu_D}{S_{\bar{D}}}, \text{ where } s_D = \sqrt{\frac{n(\sum D^2) - (\sum D^2)}{n(n-1)}},$$

$$s_{\bar{D}} = \frac{s_D}{\sqrt{n}}, \text{ and df} = (\text{pairs} - 1).$$

Given $\Sigma D = -91$, $\Sigma D^2 = 897$ (calculations not shown),

$$\bar{D} = \frac{-91}{10} = -9.1,\ s_D = \sqrt{\frac{10(897) - (-91)^2}{10(10-1)}} = 2.7669,$$

$$\text{and } s_{\bar{D}} = \frac{2.7669}{\sqrt{10}} = 0.87496$$

$$\therefore t = \frac{-9.1}{0.87496} = -10.4\,(p < .001)$$

One-Way Analysis of Variance

One-way analysis of variance (ANOVA) extends the *Student t* test of two population means to three (or more) population means. Whereas the difference in postoperative heart rate between patients randomly assigned to receive one of two different anesthetic techniques might be tested with the *Student t* test, differences in postoperative heart rate among patients randomly assigned to receive one of three (or more) different anesthetic techniques might be tested by one-way ANOVA. The assumptions in ANOVA are the same as those for *Student t*; i.e., all underlying populations are normally distributed with equal variance.

Deviations reflecting random error and the effect of treatment are calculated and compared as a ratio of two variances, known as the *F* ratio in honor of Fisher. When the null hypothesis is true and there is no treatment effect, both the numerator and denominator of the F ratio will reflect sums of squared deviations resulting from random error. As numerator and denominator tend to be similar, the *F* ratio will vary about a value of 1. Conversely, when the null hypothesis is false and there is a treatment effect, the sum of squared deviations that is due to treatment enlarges the numerator and the *F* ratio can become much greater than 1. The F ratio's address is located on the F distribution (a sampling distribution of variance ratios) in order to determine whether it has become large enough to meet statistical significance. Like the *t* distributions, there is a whole family of F distributions based on the df in the numerator and denominator of the F ratio. Fortunately, levels of significance for the F ratio are automatically provided in statistical output.

For our example, we wish to know whether postoperative heart rate differs among patients who received general or spinal anesthesia or PNB for knee arthroplasty surgery. Postoperative heart rate is studied in patients who are randomly assigned to receive one of the three anesthetic techniques (20 patients per group). We find from the ANOVA that postoperative heart rate differs significantly by anesthetic technique (the critical value for *F* with 2 and 57 df is approximately 5.0 for *P* = .01 and is exceeded by the obtained *F* ratio of 6.5). Subsequent pairwise comparisons reveal that postoperative heart rate is lower in patients given spinal anesthesia (72 bpm) than in those given general anesthesia (88 bpm) but does not differ from that of patients given PNB (78 bpm).

ANOVA Table

Source of Variation	df	Sum of Squares	Mean Square	*F*	*P*-Value
Treatment (anesthetic technique)	2	115.6	57.8	6.5	<.01
Error	57	507.4	8.9		
Total	59	623			

Abbreviations: *df*, degrees of freedom; *F*, where $df_{treatment}$ = (groups − 1) = (3 − 1) = 2, df_{error} = (subjects − groups - 1) = (60 − 2 − 1) = 57, and df_{total} = (subjects − 1) = (60 − 1) = 59.

Factorial ANOVA

Even though we studied three groups in the one-way ANOVA example and could have studied more, we nonetheless looked at a single independent variable (e.g., anesthetic technique). A researcher who wishes to look at more than one independent variable turns to factorial ANOVA. For instance, the researcher interested in the effects of three anesthetic techniques (general or spinal anesthesia or PNB) *and* intake of a beta-blocker (yes/no) on postoperative heart rate would use a 3 × 2 factorial ANOVA. The researcher would be able to look at the effects of anesthetic technique and intake of beta-blocker as well as any interaction between them. These analyses are possible using the same subjects, so factorial designs can be a statistical "best buy."

Factorial ANOVA has the same assumptions as one-way ANOVA. Whereas with one-way ANOVA, there is not much to fear about violating assumptions as long as the group sample sizes are equal and fairly large (>10 per group), factorial ANOVA is not as robust. Even small departures from equal sample sizes could cause extensive computational and interpretation problems. Thus, very complex factorial designs are typically discouraged. For instance, our 3 × 2 factorial could also be assessed by gender and repeated over five time points in a 3 × 2 × 2 × 5 (repeated) design. This and innumerable other complex factorials should be done with a statistician because some may not be as robust as others. Moreover, there will not be much confidence in results from factorials that are difficult to interpret.

Interaction

Interaction occurs when the measure of effect (between exposure and outcome) is modified by the presence of another variable. For our example, the interaction between anesthetic technique and intake of a beta-blocker is statistically significant.

ANOVA Table

Source of Variation	*df*	Sum of Mean Squares	Mean Square	*F*	*P*-Value
Treatment (anesthetic technique)	2	97	48.5	6.1	<.01
Beta-blocker (yes/no)	1	39.6	39.6	5.0	<.05
Interaction (technique × blocker)	2	114	57	7.2	<.01
Error	54	426.6	7.9		
Total	59	677.2			

Abbreviations: *df*, degree of freedom; F, where $df_{treatment}$ = (groups – 1) = (3-1) = 2, beta-blocker Y/N (2 - 1) = 1, interaction (2 x 1) = 2, and df_{error} = (subjects – groups – 1) = (60-2-1-2-1) = 54, and df_{total} = (subjects – 1) = (60-1) = 59.

Postoperative heart rate is low and fairly stable in patients who received beta-blockers, but is substantially increased in patients given spinal anesthesia or PNB (as illustrated in the left panel of Figure 79–8). Note that when interaction is found, it is the interaction that is of interest and thus described in the report. In our example, the main effects of anesthetic technique and intake of beta-blocker are also statistically significant, but they no longer have "center stage." On the other hand, if there had been *no* interaction (as illustrated by the parallel lines in the right panel of Figure 79–8), the main effects would have been reported separately, as both are statistically significant; e.g., postoperative heart rate differs by anesthetic technique and is decreased in patients who receive beta-blockers prior to surgery regardless of anesthetic technique.

Multiple Comparisons

We return to the one-way ANOVA example of the effects of three different anesthetic techniques on postoperative heart rate. If our *F* ratio is statistically significant, we know that the three sample means come from different populations; i.e., the anesthetic techniques differ in how they affect postoperative heart rate. However, a significant *F* ratio does not tell us which group or groups are different. Is postoperative heart rate in patients who receive general anesthesia different from that in patients who receive spinal anesthesia, but not different from that in patients who receive PNB? If specific interest in a comparison (say, between general and spinal anesthetic techniques) had been stated *before looking at the data*, the difference in postoperative heart rate between these two techniques could be followed by the *Student t* test. However, when such a priori comparisons have not been expressed, several comparisons among the groups must be conducted to determine where the significant difference(s) lie. These comparisons are considered post hoc because they involve data that have already been reviewed and analyzed (here, by the one-way ANOVA). But increasing the number of statistical tests increases the risk for committing a type I error (saying there is a difference when there really is none). This is because a null hypothesis rejected at $\alpha = 0.05$ on a *single* test confers a 5% chance of committing a type I error, but as more and more multiple comparison tests are made, the experiment-wise α rises, and it can rise very fast.

For α set at 0.05, the experiment-wise type I error rate (α_{EW}) rises to nearly 20% by the time four comparisons are made.

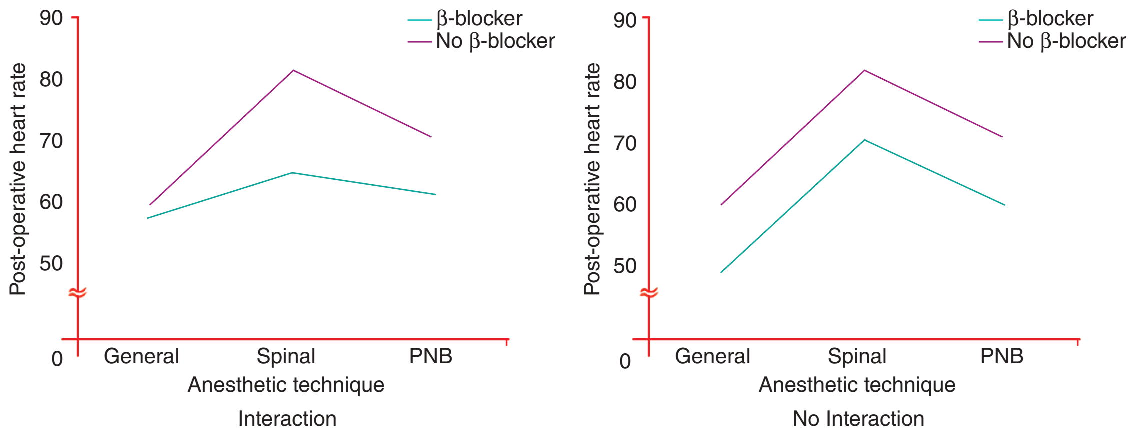

FIGURE 79–8. Interaction vs no interaction.

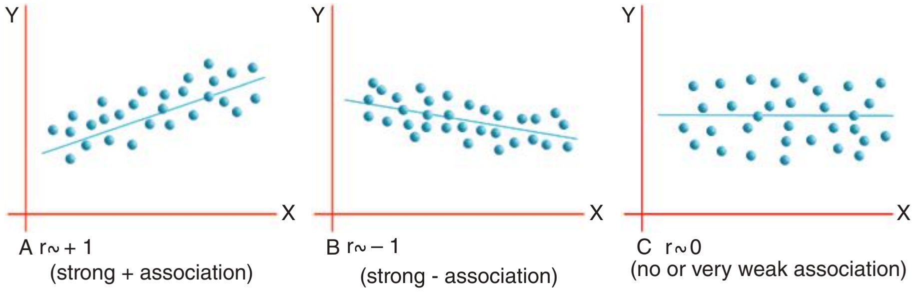

FIGURE 79–9. Pearson product moment correlation coefficient (*r*).

Most researchers would not be comfortable with a type I error probability this high:

$\alpha_{EW} = 1 - (1 - 0.05)^1 = 1 - 0.95^1 = 0.05$ for one comparison

$\alpha_{EW} = 1 - (1 - 0.05)^2 = 1 - 0.95^2 \approx 0.10$ for two comparisons

$\alpha_{EW} = 1 - (1 - 0.05)^3 = 1 - 0.95^3 \approx 0.14$ for three comparisons

$\alpha_{EW} = 1 - (1 - 0.05)^4 = 1 - 0.95^4 \approx 0.19$ for four comparisons

Fortunately, a number of tests are designed to help control the experiment-wise error. Three methods are commonly used when the investigator wishes to compare all pairs of means: the Bonferroni approach, the Tukey honestly significant difference test, and the Student-Newman-Keuls comparison test. In the Bonferroni approach, the α level is divided by the number of all possible *pairs* of groups to be compared. For three groups in the experiment (here, simply designated as A, B, and C), α would be divided by 3 (AB, AC, BC); for four groups (A, B, C, D), α would be divided by 6 (AB, AC, AD, BC, BD, CD). Group differences are tested by the *Student t* test using the pooled estimate of the variance (error mean square from the one-way ANOVA). The *t* statistic for each comparison must then exceed the more stringent α in order to be declared statistically significant. The Bonferroni approach tends to be conservative (less powerful) and should be used only when testing a few pairs of means (i.e., not more than five groups). The Tukey and Student-Newman-Keuls tests use range tests to identify homogeneous subsets of means that are not different from one another. They make all possible comparisons between groups and are more powerful when testing a large number of pairs of means. Other popular post hoc comparison methods include the Dunnett test, which is useful when the investigator is not interested in comparing groups among themselves, but instead wishes to compare one control group to each of the other treatment groups. The Scheffé method is useful if the investigator is interested in elaborate comparisons (known as contrasts); e.g., the mean of (A + B + C) vs D; however, it is more conservative than other post hoc tests. Clearly, statistical expertise should be sought when multiple comparison decisions need to be made.

Correlation — Pearson *r*

Numerous statistics can be calculated to assess the extent of association between variables; e.g., Φ coefficient, biserial, point biserial. However, the most well-known and frequently used is the Pearson product-moment correlation coefficient (simply denoted as *r*). The Pearson *r*, named for the British mathematician, Karl Pearson (1857–1936), is a measure of association between two continuous variables (Figure 79–9). Subjects contribute once to each variable; hence subjects are independent in that they do not make multiple contributions to each variable. The coefficient ranges from +1 (perfect positive association) to –1 (perfect negative association). Values around 0 indicate that the two variables are not associated. As *r* approaches +1, an individual with a high value for one variable is likely to have a high value for the other; an individual with a low value for one variable is likely to have a low value for the other. For instance, time to motor response is positively correlated with distance from nerve at which local anesthetic injection commences. As *r* approaches –1, an individual with a high value for one variable is likely to have a low value for the other; an individual with a low value for one variable is likely to have a high value for the other. For instance, extent of motor response is negatively correlated with distance from nerve at which the injection commences.

It is important to note, however, that the Pearson *r* does not measure several things:[11]

- *r* makes no statement about causality. Even though two variables are strongly associated (either positively or negatively), one did not *cause* the other.
- *r* is not a measure of the magnitude of the slope of the regression line (Figure 79–10). Both lines indicate perfect association; however, the slope is only impressive for the panel on the left.
- *r* is not a measure of the appropriateness of the straight-line model (Figure 79–11). Regardless of a high or low *r*,

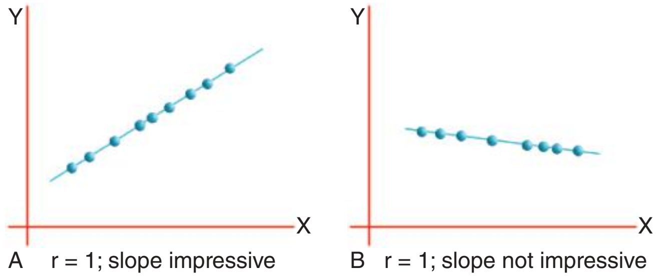

FIGURE 79–10. *r* Is not a measure of slope.

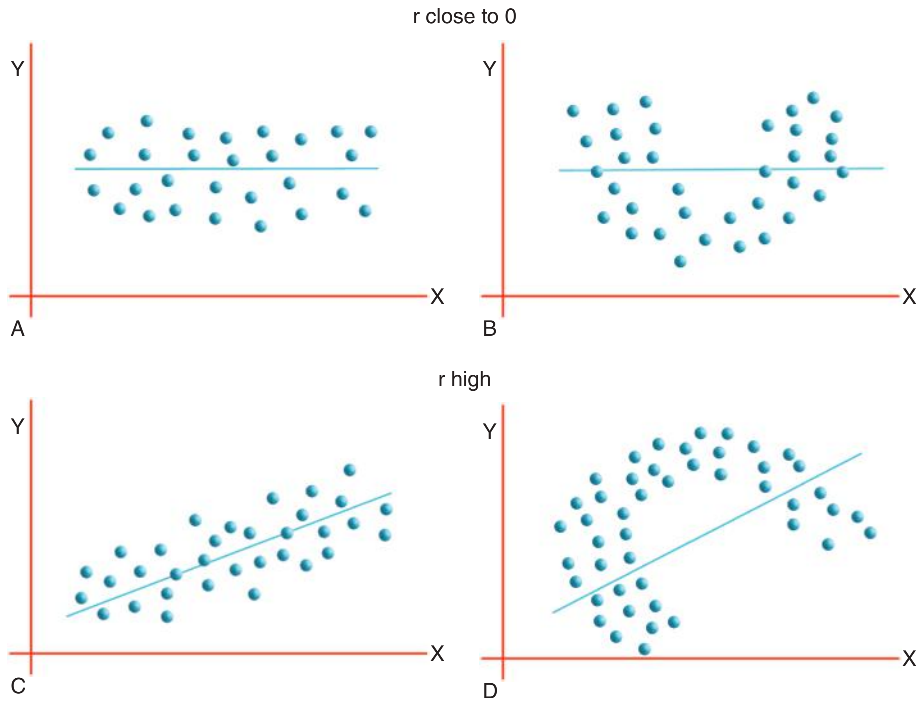

FIGURE 79–11. *r* Is not a measure of appropriateness of straight-line model.

there could be a nonlinear association in the data that is not reflected in the value of *r*. A picture is worth a 1000 words!

Also be aware that:

- r can be sensitive to outliers (i.e., it is easily influenced by them).
- r should not be calculated or should be carefully calculated.
  - Between the time 1 and time 2 measures of the same variable
  - Between two variables at various times (unless time trends have been removed)
  - Between two variables where one variable is included in the other (i.e., if X is part of Y, then r between X and XY should not be calculated)
  - Between a variable and the change in that variable over time (i.e., *r* between X_0 and $X_1 - X_0$ should not be calculated)
- *r* should not be calculated if the research focus is on agreement between two tests or devices as other statistical approaches are more appropriate.[12,13]
- Type I error may increase when many variables are correlated with each other in the same study.

We will not derive the level of significance associated with values of the Pearson *r*. Suffice it to say that *P*-values of Pearson *r* included in the bivariate correlation output derive from testing the null hypothesis that the population correlation (ρ) between the two variables is zero (i.e., H_0: ρ = 0). Researchers who wish to test whether ρ is some value other than zero based on past experience or theory (i.e., H_0: $\rho = \rho_0$ where $\rho_0 \neq 0$) should consult a statistician who will be able to test these hypotheses and construct the appropriate confidence intervals. Moreover, statistical expertise is advised if your research interest lies in testing the equality of two correlations from independent random samples (i.e., H_0: $\rho_1 = \rho_2$) or two correlations of different variables within the same sample (e.g., H_0: $\rho_{12} = \rho_{13}$).

Least Squares Regression

When the correlation coefficient is 0, we know that *x* is useless in predicting *y*. When the correlation coefficient is +1 or –1, we know that *x* is exactly correct in predicting *y*. However, the value of the correlation coefficient, in and of itself, does not tell us how to go about making the prediction. If the *x* and *y* variables have a linear relationship, a line could be drawn through the scatterplot of points, in which each dot represents the intersection of a subject's *x* and *y* values. The problem is that innumerable lines could be drawn through the scatterplot. Which is the "best fitting" one? Pearson determined this line in such a way that the sum of the squared differences (d_i's) between the line and each scatterplot dot is as small as possible (hence the term, *least squares regression*). That is, the sum of squared discrepancies shown in Figure 79–12 is at a minimum. No other line through that scatterplot has a lower sum of squares.

With bivariate (simple) linear regression, a continuous variable *y* is predicted from a continuous variable *x* based on the equation for a straight line, $y = \alpha + \beta x + \varepsilon$. Thus, the components that predict *y* are a constant that indicates the value of *y* when *x* is 0 (known as the intercept of the line, α), a coefficient that indicates the change in *y* for each 1-unit change in *x* (known as the slope, β), and an error term that indicates variability of the observed values from the regression line (ε). For our example, we wish to predict duration of femoral nerve

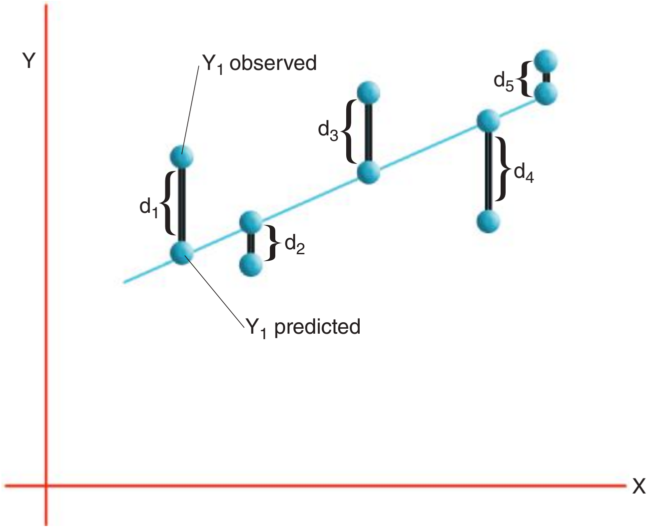

FIGURE 79–12. Least squares regression.

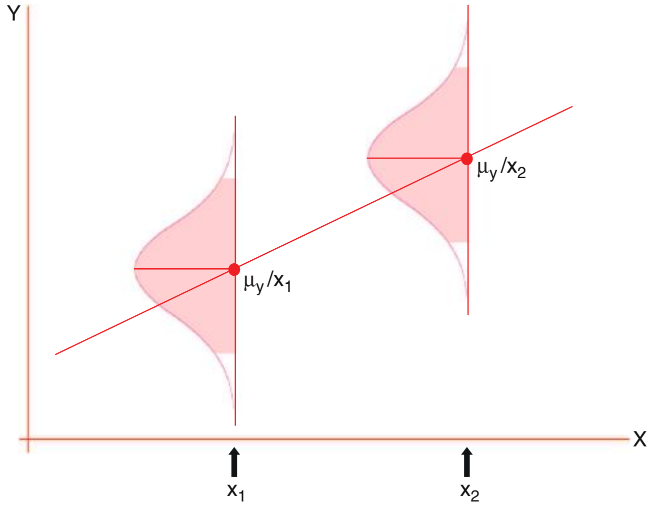

FIGURE 79–13. HEIL Gauss.

blockade from the concentration of 0.5% lidocaine administered. Duration of femoral nerve blockade (in minutes) is measured in 24 patients receiving 0.5%, 1.0%, 1.5%, or 2.0% lidocaine. The model produced is $y = -2.5 + 124\ x = -2.5 + 124(0.5) = 59.5$ (calculations not shown), indicating an increase of approximately 60 minutes in duration of femoral nerve blockade for every unit increase of 0.5% lidocaine.

With multiple linear regression, a continuous variable y is predicted from a continuous variable x, *while controlling or adjusting for the influence of one or more potentially confounding variables (i.e., other* x*'s in the model).* When mixed with the exposure and outcome, confounders can strengthen, weaken, or otherwise distort the true association between exposure and outcome.[14] As an example, we found from bivariate linear regression that lidocaine concentration is predictive of duration of femoral blockade. However, concentration of local anesthetic may predict a duration of femoral blockade that is substantially longer or shorter than 60 minutes when a variable reflecting presence or absence of preexisting neuropathy (e.g., diabetic neuropathy) is also included in the model. On the other hand, concentration of local anesthetic may *not* predict duration of femoral blockade when stimulating current at which motor response is observed is included in the model. To determine the relative influence of such potentially confounding covariates and to take a more undisturbed look at the $x - y$ relationship, we construct multiple linear regression models of the form

$$y = \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \ldots + \beta_i x_i + \varepsilon.$$

This would allow us to look at the effect of 0.5% lidocaine concentration on duration of femoral blockade after the effects of preexisting neuropathy and intensity of nerve-stimulating current are controlled.

Covariates can be continuous (e.g., age), ordinal (e.g., level of education), or nominal (e.g., gender). With multiple regression, quadratic terms can be added to model nonlinear relationships (e.g., x_1^2), and product terms can be added to model interactions (e.g., x_2x_3). If these nonlinear and interaction terms are included in the model, their respective component terms (x_1, x_2, x_3) should also be included in the model; e.g.,

$$y = \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_4 x_1^2 + \beta_5 x_2 x_3 + \varepsilon$$

Assumptions for the Straight-Line Model

Whether we construct a bivariate or multivariable regression model, five assumptions must be met. Students of statistics remember them by the acronym, HEIL Gauss (homoscedasticity, existence, independence, linearity, and normality), even though it seems more logical to describe these assumptions in a different order.[8] So, referring to Figure 79–13, let us begin with "existence." This assumption states that, at any given fixed value of the variable x, there exists a random variable y, and this random variable y has a probability distribution with finite mean and variance. The distribution of y for any fixed value of x has a normal (gaussian) distribution, the variance of y is the same for any of its distributions at x (homoscedasticity is just a fancy term for equal variance), and the mean value of y, i.e., $\mu_{y|x}$, is a straight-line function of x (linearity). Finally, "independence" assumes that patients are not matched on some variable and that the outcome variable is not measured over time on the same patients.

NONPARAMETRIC TESTS

Many of the parametric tests are quite "robust" even though their assumptions are violated, and they are especially robust when the sample size is moderate or large. However, if the violations are sizable and the sample size is small or, if the data are ordinal or qualitative, we turn to the nonparametric tests. The nonparametric tests are more appropriate and can even be more powerful under these circumstances.

Chi-Square

Arguably the most frequently used nonparametric test is the chi-square (χ^2) test. It requires that observations are

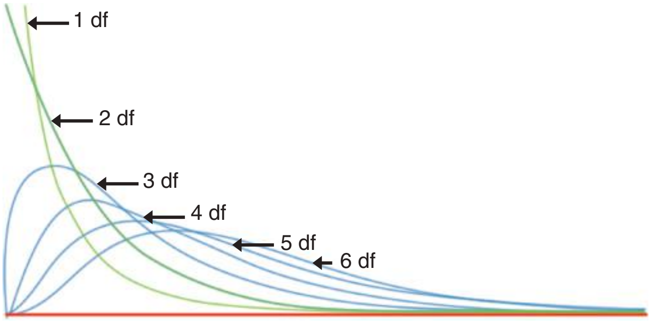

FIGURE 79–14. A family of χ^2 distributions.

independent; i.e., each subject is counted in one, and only one, cell of a contingency table. It also requires that expected frequencies are sufficiently large. So, how are expected frequencies obtained, and what is "sufficiently large"? An expected frequency for a given cell is obtained by multiplying the row and column marginals for that cell and dividing the product by n. Thus, in the 2 × 2 contingency table, the expected frequency for the upper left-hand cell with observed frequency a is $[(a + b)(a + c)]/n$. This process is repeated for each of the remaining three cells. An expected frequency of 5 typically suffices for the test (Figure 79-14A).

		Variable A		
		Level 1	Level 2	Total
Variable B	Level 1	a	b	a+b
	Level 2	c	d	c+d
	Total	a+c	b+d	N

$$\chi^2 = \Sigma \frac{(|f_O - f_E| - 0.5)^2}{f_E} \quad \text{where } f_O \text{ isobserved frequencyand } f_E \text{ isexpected frequency}$$

Note: The Yates' correction (0.5) is sometimes subtracted from the observed-expected differences before squaring because the continuous χ^2 distribution is used to test the discrete distribution of sample frequencies. Today, the correction is less frequently used as it may overadjust the χ^2 statistic, making its P-value too conservative. Moreover, the Yates' correction only makes a noticeable difference when cell counts are small, and computers can calculate "exact" P-values in these instances.

For each cell, the difference between observed and expected frequencies is squared and divided by the expected frequency; the squared quantities are then summed. Since the χ^2 statistic reflects the size of the discrepancies between observed and expected frequencies as a proportion of the expected frequency, large χ^2's indicate differences that are not likely to be due to chance; conversely, small χ^2's indicate differences that could be due to chance. As with the t distributions, there is a whole family of χ^2 distributions of different shapes (and, therefore, different areas in their tails) (Figure 79–15). Hence the critical values that delineate statistical significance are based on the χ^2 statistic's df (rows – 1)(columns – 1).

Our example evaluates the association between parity and requests for epidurals during labor; 70% of primiparous women opt for epidurals compared with 55% of multiparous women. Following the calculations just described, the χ^2 statistic has a value of approximately 9. Is this large enough to conclude that the sample did not produce a chance finding? The test statistic exceeds the = 0.05 and the 0.01 levels of significance (3.84 and 6.64, respectively); thus, requests for epidurals is associated with parity (requests are higher from primiparous women than from multiparous women).

$$X^2 = \sum \frac{(|f_O - f_E| - 0.5)^2}{f_E} = \frac{(|140 - 125| - 0.5)^2}{125} + \frac{(|60 - 75| - 0.5)^2}{75} + \frac{(|110 - 125| - 0.5)^2}{125} + \frac{(|90 - 75| - 0.5)^2}{75} = 8.97$$

where f_E = (200)(250)/400 = 125 for cells a and c, and (200)(150)/400 = 75 for cells b and d, and df = (rows – 1) (columns – 1) = (2 – 1)(2 – 1) = 1 (Figure 79-14B).

It should be noted that, although χ^2 is an excellent measure of the statistical *significance* of an association, it does not measure the *extent* of association.[15] Thus, it would be wrong to conclude that primiparous women are about nine times more likely to opt for epidurals than multiparous women. Rather, the odds ratio (a measure of "risk") can be calculated for this 2 × 2 table to estimate risk for epidural request: [(a)(d)]/[(b)(c)] = [(140)(90)]/[(60)(110)] = 1.9, indicating that epidural requests are approximately twofold among primiparous women compared to multiparous women.

		Epidural		
		Yes	No	Total
Parity	Primiparous	140	60	200(50%)
	Multiparous	110	90	200(50%)
	Total	250(62%)	150(38%)	N

$$\chi^2 = \Sigma \frac{(|f_O - f_E| - 0.5)^2}{f_E}$$

Chi-square tests can be done on larger tables, such as a 4 × 5 table, following the principles described above. However, if the overall χ^2 statistic is significant, you must conduct several comparisons to determine which cells are different from each other, and you would again be faced with the issue of multiple comparisons. In other instances, you may wish to test a variable that has an intrinsic order. For example, you may wish to examine the association of patient position (supine *vs* sitting) by level of spinal anesthesia, which has an intrinsic quantitative order (e.g., <L1, L1 ≤ T8, >T8). Or, you may wish to examine the association of nerve localization (e.g., nerve stimulator vs "blind") by PNB success, which has an intrinsic qualitative order (e.g., failed, incomplete, complete). A statistician will be able to conduct the χ^2 tests that are appropriate for these situations.

Fisher Exact Test

The "exact" test (more properly, the Fisher-Irwin exact test) applies when the expected value of at least one cell in a 2 × 2 table is <5. Recall that expected frequencies are based on marginal frequencies; but marginals that are small or uneven are less precise and may lead to an inaccurate chi-square test of significance. Thus, the Fisher exact test derives an exact probability (P_{obs}) that is associated with the observed cell frequencies. Exact probabilities are calculated for all other tables that can possibly be constructed using the same marginal frequencies as those in the observed table, and any probabilities that are less than or equal to P_{obs} are summed. This sum is the Fisher exact *P*-value. As is typical, Fisher exact *P*-values <.05 are considered to be statistically significant.

The test has been extended to give exact probabilities for tables greater than the 2 × 2. Calculators for such tests, known as the Freeman-Halton extensions of the Fisher exact test, are even available online; e.g., http://vassarstats.net/fisher2x3.html (for the 2 × 3 table) and http://vassarstats.net/fisher2x4.html (for the 2 × 4 table).

McNemar Chi-Square

As noted earlier, χ^2 tests require that subjects are independent; i.e., each is counted in one, and only one, cell. The McNemar χ^2 applies when subjects are matched or their before–after scores are tested. In the example depicted, we wish to know whether block success differs by type of catheter. Interscalene blocks are induced by boluses of local anesthetic through stimulating or nonstimulating catheters. The procedures are performed 2 weeks apart in the same (n = 20) volunteers. Intuitively, it can be appreciated that the concordant cells (*a* and *d*) do not give us any information about differences in block success by type of catheter. So we look to the discordant cells (*b* and *c*) for the test. The value of the McNemar χ^2 test statistic is a mere 0.2. The statistic is referred to the χ^2 critical value of 3.841 with 1 degree of freedom at α = 0.05 and is not significant. There is no association between type of catheter and interscalene block success (Figure 79-14C).

Non-stimulating catheter	Stimulating catheter: Time 1	Stimulating catheter: Time 2
Time 1	a = 3	b = 7
Time 2	c = 5	d = 5

$$X^2_{\text{McNemar}} = \frac{(|b-c|-0.5)^2}{b+c} = \frac{(|7-5|-0.5)^2}{7+5}$$

$$= 0.1875(\text{NS})$$

Spearman *r*

The Spearman correlation coefficient (sometimes denoted as r_s) was named for British psychologist Charles E. Spearman (1863–1945) and is the nonparametric counterpart to the Pearson *r*. It is used to examine the association between two variables when one or both are ordinal or has a very nonnormal shape. Spearman *r* quantifies the degree of linear association between the ranks of two variables, and varies between +1 and –1.

Since Spearman *r* is computed on the relative standing of scores within a set of observations (i.e., their ranks), it does not make full use of the quantified scores themselves and may underestimate the degree of association.

For our example, we wish to evaluate the association between pain and function. Patient-reported pain and function scores from 10 subjects are both ranked, and r_s is calculated to be 0.91 (calculations not shown). Its *P*-value of .02 indicates that the correlation was not likely due to chance and that pain and function are positively correlated.

Kendall Tau (τ)

It is important to note that, unlike the Pearson *r*, the Spearman *r* does not estimate a natural population parameter, here, the population correlation, ρ. Hence many statisticians prefer a lesser known correlation coefficient known as the Kendall τ (τ_a is computed when there are no ties in rank; τ_b when there are ties in rank). For our example, two attending physicians rank 12 anesthesia residents at their institution. Concordant and discordant pairs of ranks are computed for a Kendall τ of 0.82 (P < .001), indicating high correlation between the ranks of residents assigned by the two attending physicians (calculations not shown).

The Spearman *r* on the same data is 0.96, which is slightly larger than the Kendall τ. Nonetheless, τ has more accurate *P*-values and is not overly influenced by a few very discrepant rankings that can influence Spearman *r*. Importantly, however, Kendall τ does estimate the population variance (the probability of concordance minus the probability of discordance), and, therefore, has an intuitive link from sample to population that Spearman *r* does not have.

Some Other Nonparametric Tests Commonly Used in Regional Anesthesia Research

Mann-Whitney U (Wilcoxon Rank Sum)

The Student *t* test has several nonparametric counterparts. The most popular of these is the Mann-Whitney U, a test which is fundamentally equivalent to the Wilcoxon rank sum test. Like Student *t*, these tests assume that the groups are independent; however, they are immune to violations to normality and equal variance assumptions. The nonparametric tests consider entire population distributions (e.g., ranks throughout the samples) rather than differences among specific population parameters (e.g., difference between two population means). However, if the two population distributions are even moderately similar in shape and variability, the nonparametric tests are excellent tests of central tendency. And, since these tests are based on ranks, they are often interpreted as comparisons of medians.

For the Mann-Whitney U, observations from both groups are combined, and ranks are assigned in ascending order.

(Average rank is assigned whenever scores are tied; however, the number of ties should be small compared with the total number of observations.) The collective ranks for each group would be similar if there is no difference between the underlying populations; i.e., the samples come from the same or similar populations (H_0 is true). Conversely, the collective ranks for each group would be dissimilar if the underlying populations are different; i.e., the samples come from different populations (H_0 is not true). The statistic U is the *smaller of* U1 (the number of times a value in the first group precedes a value in the second group) and U2 (the number of times a value in the second group precedes a value in the first group). Thus, if sample sizes are n_1 and n_2, the quantity U/n_1n_2 is the estimated proportion or probability that a new observation sampled from the first population will be less than a new observation sampled from the second population. When the sample size of either group exceeds 20, U can be used to approximate a z ratio that has the standard normal distribution. Statistical significance is then estimated from the standard normal distribution. Thus, at the 0.05 level of significance, the null hypothesis is rejected if the observed z is more negative than or equal to –1.96 (two-sided test) or –1.645 (one-sided test); otherwise the null hypothesis is retained.

For our example, we wish to know whether the extent of reliable anesthesia for hand surgery differs by method of axillary block (single-injection *vs* multiple-injection) administered to 40 patients randomly assigned to either method (20 patients in each group). The Mann-Whitney U indicates that the mean percent of arm blocked by the single-injection method (85%) differs from that blocked by the multiple-injection method (95%) at $P <.05$ (calculations not shown).

When conducting the nonparametric statistical tests, consult a statistician if many ties occur in your data; complicated corrections should be applied when there are too many ties (say, as many as a third of all scores are tied). Moreover, computer packages should automatically adjust for tied ranks, but not all do. If your sample is small (<10), exact probabilities should be calculated. Beware that computer packages may use the large-sample normal approximation to calculate statistical significance even for small samples.

Sign

The sign test and Wilcoxon signed rank (Wilcoxon T) test are nonparametric counterparts to the dependent t test. They apply to studies in which subjects are matched on a potentially confounding variable (and then randomly assigned to treatment groups) or to studies in which the same subjects are assessed at two separate times (e.g., before and after treatment). Half of the subjects are expected to have positive differences and half are expected to have negative differences, so observed and expected frequencies are submitted to a χ^2 test with 1 degree of freedom (χ^2 value 3.841) to determine whether the difference is beyond chance fluctuation. This will be reasonably accurate for 10 or more pairs of scores; smaller numbers of pairs require a small-sample approach (the binomial test). The sign test responds only to the direction of the difference between pairs of scores and is likely to have little utility in regional anesthesia studies.

Wilcoxon Signed Rank (Wilcoxon T)

Unlike the sign test, the Wilcoxon T uses information about the size of the difference as well as directionality. For our example, we wish to know whether the extent of anesthesia for hand surgery differs by method of axillary block (single-injection *vs* multiple-injection) administered to 12 volunteers in randomized order 2 weeks apart. Thus, the same volunteers receive each of the injection methods.

Differences in sensory block by injection method are ranked, and the positive and negative ranks are summed separately. Wilcoxon T is the smaller of these sums, and is 1.5 for the *single*-injection method (calculations not shown). At df = number of pairs with nonzero absolute differences = 10, our Wilcoxon T is significant *at* $P < .01$; sensory block differs by injection method (sensory block is greater for the *multiple*-injection method).

The Wilcoxon T assumes that there are no ties in rank (even though the test is reasonably robust provided the number of ties is small) and that the *differences* between pairs of scores have a symmetric distribution. This last assumption makes the Wilcoxon T the only nonparametric method whose results can be affected by data transformations. In the case of the Wilcoxon, a transformation should be used only if it makes the distribution of the differences more symmetric. Thus, a statistician should be consulted to determine whether data transformations are appropriate for your data. If the number of nonzero differences is >15, the Wilcoxon can be used to approximate a z ratio that has the standard normal distribution. As described earlier, focus is on the smaller sum, so the value of the observed z will always be negative (or equal to zero). Thus, at the 0.05 level of significance, the null hypothesis is rejected if the observed z is more negative than or equal to –1.96 (two-sided test) or –1.645 (one-sided test); otherwise the null hypothesis is retained. Special small-sample methods are used if the number of nonzero differences is ≤15, and a statistician should again be consulted.

Kruskal-Wallis H

This nonparametric counterpart to one-way ANOVA tests whether three or more independent samples are from the same population. It is an extension of the Mann-Whitney U and assumes independence. Scores from all subgroups are combined and ranked in ascending order. Ties are assigned the mean rank of the scores that are tied. Once ranks have been assigned in the combined group, the subgroups are reconstructed, and the mean rank for each subgroup is compared with the mean rank for the combined group. If the subgroup samples come from identical populations, the subgroup ranks are similar to the overall mean rank. If the samples come from different populations, the subgroup ranks vary more widely from the overall mean rank. Kruskal-Wallis H compares the total magnitude of these discrepancies with what might be expected by chance. Exact probabilities have been worked out for tiny samples. However, in most cases (e.g., with three groups and four or more subjects in each), the χ^2 distribution may be used to evaluate the Kruskal-Wallis H with good approximate results. Like χ^2, Kruskal-Wallis H is nondirectional because it reflects the magnitude of the discrepancies without regard to their direction. So, like χ^2, the region of rejection appropriately lies in the upper tail of the distribution. Finally, it is possible to make multiple comparisons among the groups compared by the Kruskal-Wallis H (with proper cautions regarding inflation of the experiment-wise type I error).

For our example, we wish to know whether opening injection pressure (psi) differs in patients randomly assigned to receive interscalene block for shoulder surgery by three different approaches (n = 12 in each group). Variability is uneven among the three groups, so data are analyzed by the Kruskal-Wallis test. The Kruskal-Wallis H is calculated as 4.8 (calculations not shown) and compared to critical values from the chi square distribution with 2 df = (number of groups - 1) = (3 - 1) = 2. The Kruskal-Wallis is not significant (P >.05); psi does not differ by the three interscalene approachs studied for shoulder surgery.

A variant of the Kruskal-Wallis H, the Jonckheere trend test (or Jonckheere-Terpstra test) evaluates linear trend in the pattern of observations across three or more ordered groups. The test is more powerful than the Kruskal-Wallis test when there is a priori ordering of the groups. For example, a study may be interested in whether length of stay in the PACU differs by increasing ASA physical status (I–V). A one-tailed alternative hypothesis may state that length of stay *increases* with ASA physical status.

Logistic Regression

As discussed in the section on Parametric Tests above, multivariable linear regression models can contain a number of covariates (independent variables) that help to predict a continuous outcome (dependent variable). It is, however, often the case that the outcome of interest is a dichotomous variable; e.g., the presence or absence of a disease. Logistic regression applies in such instances. Why? If an outcome variable can only take numeric values of 0 or 1, then the mean of these values in a sample of patients is the proportion of patients with the disease (or equivalently, the probability that a patient has the disease of interest). Thus, instead of predicting a continuous outcome, the task of the logistic regression model is to predict the *proportion* of patients with the outcome given the explanatory variables in the model. Unfortunately, this approach can produce impossible probabilities outside the range of 0 to 1, so it is useful to work with a *transformation* of the proportion to be predicted. Logistic regression uses the logit transformation; i.e., the natural logarithm of the odds of the outcome, logit(p) = $\log_e(p/[1-p])$, where p is the proportion of patients with the outcome and always lies in the range 0 and 1.

Unlike least squares regression, the intercept and coefficients in a logistic regression model are obtained through an iterative process that results in a unique set of maximum likelihood estimates. Among all possible values that could describe the parent population from which the sample emerged, the maximum likelihood estimates are those values that most likely gave rise to the observed data. For our example, logistic regression is used to estimate the risk for severe hypotension (decrease in blood pressure >30% of baseline) *vs* no severe hypotension following neuraxial blockade. A single binary predictor (dry mucosa *vs* no dry mucosa) is included in the model. The analysis yields a maximum likelihood coefficient, $b_{\text{dry mucosa}} = 0.6931$, with standard $\text{error}_{\text{dry mucosa}} = 0.1119$. For binary predictors coded 0 or 1, the odds ratio (a widely used measure of risk) can be directly estimated by exponentiating the logistic regression coefficient; i.e., OR = e^b. Thus, if patients without dry mucosae are coded as 0 and patients with dry mucosae as 1, exponentiation of the coefficient, $e^{0.6931} = 2$, indicates a twofold risk for severe hypotension for patients with dry mucosae. Moreover, a confidence interval can be constructed, i.e., $e^{[b \pm (z_{\alpha/2})(s.e._b)]}$, which yields $e^{[0.6931-(1.96)(0.1119)]} = 1.6$ and $e^{[0.6931+(1.96)(0.1119)]} = 2.5$ as the lower and upper 95% confidence limits, respectively. Compared with patients without dry mucosae, risk for severe hypotension for patients with dry mucosae is likely to be increased approximately 0.6-fold but no greater than 2.5-fold.

Another expression for the estimated probability of disease, $p = 1/(1+e^{-\beta\alpha+{}_1x_1\beta\ldots+)_i x_i})$, can be rearranged in terms of the log odds of disease, i.e., logit(p) = $\alpha + \beta_1 x_1 + \ldots + \beta_i x_i$, which is reminiscent of the multiple linear regression model, but will always yield values of p that are between 0 and 1. The coefficients (b_i's) denote the amount of increase or decrease in the log odds of the outcome associated with a unit change in the predictor. For instance, a model for the probability of severe hypotension associated with neuraxial blockade might contain the following predictors and their coefficients (Table 79–8).

The log odds for severe hypotension in a 60-year-old hypovolemic patient with preoperative urine output >100 mL/h, preoperative heart rate of 82 bpm, and no dry mucosa is

$$\begin{aligned}\text{logit}(p) &= -4.5799 + (0.0296 \times 6) + (-0.6931 \times 0)\\ &\quad + (1.6094 \times 1) + (0.6900 \times 1) + (0.5878 \times 0)\\ &= -2.1029\end{aligned}$$

TABLE 79–8. Severe hypotension associated with neuraxial blockade: an example of a patient with specific clinical characteristics.

Predictor	Coefficient	Patient
Intercept	–4.5799	
Age (10-year increments)	0.0296	60 years old
Preoperative urine output (>100 mL/h = 0 vs ≤ 100 mL/h = 1)[a]	–0.6931	>100 mL/h
Hypovolemia (No = 0, Yes = 1)	1.6094	Yes
Preoperative heart rate (10 bpm increments over 72 bpm)	0.6900	82 bpm
Dry mucosa (No = 0, Yes = 1)	0.5878	No

[a] The coefficient for preoperative urine output is negative as the riskier condition (>100 mL/h) is coded as 0.

This patient's probability of severe hypotension is $1/[1 + e^{-(-2.1029)}]$, or about 11%.

It is also possible to compare the risk profiles of two patients using the coefficients in the model. For instance, logit(p_1) for a patient with dry mucosa can be compared with logit(p_2) for a patient without dry mucosa (all other predictive characteristics being the same between these patients). That is,

$$\text{logit}(p_1) - \text{logit}(p_2) = \log\left(\frac{p_1}{1-p_1}\right) - \log\left(\frac{p_2}{1-p_2}\right)$$

$$= \log\left[\frac{p_1(1-p_2)}{p_2(1-p_1)}\right]$$

For our example, the coefficients for the intercept, age, preoperative urine output, hypovolemia, and preoperative heart rate cancel out between these two patients as they are the same for both patients. This results in logit (p_1) = 0.5878 for the patient with dry mucosa and logit (p_2) = 0 for the patient without dry mucosa. When the difference, logit (p_1) – logit (p_2) = 0.5878, is exponentiated, $e^{0.5878} = 1.8$, we obtain the odds ratio (risk) for severe hypotension due to dry mucosa that has been *adjusted for* age, preoperative urine output, hypovolemia, and preoperative heart rate. The adjusted odds ratio of 1.8 is slightly lower than the unadjusted odds ratio of 2 calculated earlier.

Clinical Pearls

1. Know your data. Know the types of variables that you are measuring.
   - Keep a data dictionary.
2. Consult with your statistician at the planning stage of your research study.
   - Strive to use the least complex study design and statistical analyses that will answer your research questions.
3. Remember that bias typically cannot be corrected through statistical methods. So, think carefully and thoroughly about features of your study design that may lead to systematic errors, in particular with respect to (a) ascertainment and selection of your subjects, and (b) measurement of your exposure variables (e.g., vulnerability to recall or interviewer bias).
4. Think carefully about your specific aims and hypotheses. Null and alternative hypotheses are not questions, so write clear, declarative *statements* for your null and alternative hypotheses. Once on paper, they should not be changed to fit the research findings. The two-sided alternative hypothesis is generally more appropriate than the one-sided alternatives, especially so for new areas of research.
5. Have a reasonable idea of the type I and type II error probabilities that you would be willing to tolerate based on your area of research interest and clinical experience.
6. Have some idea of the difference that is clinically meaningful to detect. A literature review may help you estimate this difference and may provide an estimate of variability in the outcome of interest. (If not available, you may need to conduct a preliminary or pilot study to estimate these parameters.) Your statistician will use this information to calculate the sample size required to detect the desired difference at your specified probability of committing a type I error (α) and with sufficient power (1 – β).
7. Potential confounding variables must be included during the design phase of the study. Their choice and accuracy of measurement directly affects the extent to which confounding can be controlled by statistical procedures. During your background literature review, consider potential confounders that other investigators have included in their studies. Did they feel that these factors could have influenced their findings? Did they suspect other factors that were not included (or could not be included) in their studies but perhaps should have been?
8. With the help of your statistician, choose between parametric and nonparametric alternatives. You will usually perform one (not both) of these methods to test a given variable. For quantitative data, this will typically be a parametric method unless there are clear indications that the underlying assumptions of normality and equal variance are not met. If violations to these assumptions are noted, your statistician will offer advice with respect to data transformations that may be appropriate for your study prior to running a parametric test. For ranked or qualitative data, descriptive or nonparametric methods must be used.
9. Discuss multiple comparisons with your statistician. If numerous comparisons or contrasts are included in your study, what adjustments are necessary?
10. With the help of your statistician, plan the best ways to present your findings. You may want to feature selected findings in tables and figures.

OBSERVATIONS FROM REVIEWING MANUSCRIPTS SUBMITTED TO ANESTHESIOLOGY JOURNALS

This section describes several common errors found while reviewing manuscripts that have been submitted for publication in anesthesiology journals. Comments pertain to the research (nonclinical) perspective.

Clinical Relevance and Conceptualization

Research questions arise primarily from clinical need, but studies must still be sold to the anesthesiology community. For example, researchers embarking on a study of catheter shearing during removal would have to substantiate the importance of focusing on an occurrence that is exceedingly rare (and perhaps of little clinical interest). Moreover, these researchers must be careful to use catheter shearing forces that could actually be encountered in the clinical setting.

Authors often neglect to explain their choice of study parameters. For instance, if patients must be older than 50 years of age in order to be eligible for a study of cervical plexus block, the authors should provide the reason for this inclusion criterion. Is it because the surgeries for which cervical plexus block is appropriate are rarely performed in individuals younger than 50 years of age? Similarly, choice of drugs is universally explained, but the rationale for choosing specific doses to be studied is sometimes neglected.

Clinical relevance dictates conceptualization of a study in other, often subtle, ways. For instance, when studying ultrasound-guided PNB of the sciatic nerve using different landmarks, it is important to establish the level of experience of the anesthesiologists participating in the study. As their experience may be more extensive with the brachial plexus and femoral nerve blocks than with the sciatic nerve block, it is not sufficient to tell the readers that each anesthesiologist has completed more than 50 ultrasound-guided peripheral nerve blocks. The readers should also be told how much of this experience was specifically with the *sciatic nerve* block, as this is the focus of the study.

Methodology

The two most common problems in methodology are inadequate control for potential confounding variables and inaccuracies in measurement. For instance, a study comparing the length of postoperative analgesia between two local anesthetics administered by popliteal nerve block would have to control for physiologic attributes of the patient (e.g., age, presence of diabetic neuropathy) that could be associated with effectiveness of the drugs and postoperative analgesia. In regional anesthesia studies, this is typically accomplished by randomly assigning patients to receive one or the other of the two local anesthetics, but often the method of randomization and the team members who are blinded to patient assignment are not described. For follow-up, patients are often phoned at home and asked the time that they took their first analgesic medication and NRS scores at specific times following discharge. But even patients discharged with detailed, written directions could misunderstand or fail to record this information. Moreover, accuracy depends heavily on the interviewer's skill with neutral probing as the patient attempts to recall the requested information. Thus, it is necessary to work closely with the patients (providing them with easy-to-follow directions and questionnaires) and with well-trained research assistants in order to collect data as accurately as possible.

Statistics

A statistician may have conducted the statistical analyses, but may have little involvement in writing the manuscript. For instance, a paper may report differences in duration of surgery among three PNBs, but fail to mention the statistical tests used to assess these differences. If a nonparametric statistical procedure was performed instead of a parametric one, it is helpful to explain why the nonparametric counterpart was chosen. For instance, VAS scores may have been categorized and submitted to a χ^2 analysis because of nonnormality of the distribution.

Similarly, less frequently used statistical procedures that may be unfamiliar to the readership should be described with appropriate citation(s) to support their use in the analyses. Statistical packages should be identified with name, version number, and date.

As is frequently done, groups are compared at a series of time points (serial measurements). Because of time dependency in the outcome variable, these studies should consider methods other than *t* tests or one-way ANOVAs at each time point. A valid alternative approach that is likely to address the study's question(s) calculates a suitable summary response (over time) for each subject. The summary responses are then analyzed as raw data using standard statistical techniques.[16]

Finally, it is important to address data that are missing for any number of reasons, ranging from the subject who withdraws from a study to equipment failure and data entry omissions. Missing data can distort the inferential conclusions drawn in a study. A sample in which data are missing at random may still be representative of the population, whereas a sample in which data are systematically missing is likely to be biased and no longer representative of the population. Ideally, missing data should be avoided in the design phase of the study; e.g., research assistants should check forms for skipped questions before the subject leaves the research setting, and questionnaires can be carefully worded so that specific groups will not be offended and skip any of the items. Datasets containing <5% data missing at random can still be analyzed, but a statistician should be consulted to choose the imputation, interpolation, or deletion technique most appropriate for the analysis.

Presentation of Results

- Investigators should avoid being side-tracked by the *P*-value. Errors of presentation often revolve around the confusion between statistical significance and clinical importance. Writers mistakenly refer to a nonsignificant or insignificant effect as being "clinically unimportant" or as having "little clinical impact."
- Sometimes a test will reach statistical significance that was unanticipated. While it is appropriate to evaluate design, subject, and/or data factors that contributed to the result, the finding may, in fact, be a fluke and not reproducible in future studies. Thus, authors should consider carefully whether the clinical impact of the finding or changes to the direction of the study itself warrant space in the Discussion section of their paper. In any event, hypotheses cannot be changed post hoc to accommodate statistically significant yet surprising findings.
- Conversely, a result that has a *P*-value slightly higher than that required for statistical significance may not receive the attention it deserves. As an example: Investigators might compare quality of recovery between a combined regional anesthesia procedure and general anesthesia. Recovery scores may be higher for the former than for the latter up to postoperative day 6, but may not quite reach the traditional criterion for statistical significance on postoperative day 7 (say, $P = .08$). Given results in the

earlier postoperative period and perhaps information in the literature on the combined procedure that prompted the study in the first place, the *P*-value of .08 should not be dismissed so readily. It could be that recovery scores are, in fact, higher for the combined procedure than for general anesthesia *for the entire first postoperative week*.

Tables

- Tables are often "recited" in the text. As readers can read for themselves, short summaries of the table contents are more useful. For instance, if a table includes the information that in the United States, 35% of patients received general anesthesia and 65% received peripheral nerve blocks in 2004, it can be more informative to state, "Nearly twice as many patients received peripheral nerve blocks than general anesthesia in 2004, an increase of 15% from 2000."
- Often the converse is true, i.e., authors include too much verbiage that could be more clearly presented in a table. For instance, stating, "Surgical procedures included open-shoulder stabilization (n = 5), hemiarthroplasty (n = 10), rotator cuff surgery/decompressions (n = 5), other shoulder procedures (n = 5)" could be better appreciated as part of the patient demographic and clinical characteristics table. The readers can easily check that the total number of patients (here, n = 25) is accounted for.
- Tables often contain unnecessary information; e.g., both standard deviations and ranges when one of these measures of variability usually suffices. A column or row of zeroes to indicate that no block failures occurred may already be in the text and a series of zeroes just looks silly. N(%) for each gender may not be as useful as the male:female ratio. Moreover, if only ASA physical status I or II patients are eligible for a study, it is not entirely necessary to give the n(%) of patients in each of these two categories, especially if no comparisons between these categories are relevant to the study. The ASA physical status breakdown in the table becomes superfluous.
- Occasionally, variables that are not continuous measures are presented as though they are. For instance, T11.25 and T9.75 for thoracic positions in the longitudinal plane could be misleading if whole vertebrae were measured and not parts of them.
- Sometimes it is unclear what comparisons a *P*-value refers to in a table. For instance, a table may include measurements on several dorsal locations and several ventral locations. Yet, it is unclear that the *P*-value refers to a comparison of the *mean* measurements of all dorsal locations against the mean measurements of all ventral locations.
- Notations contained in the table may not be explained in the footnotes (and sometimes not even in the text). For instance, asterisks in the table indicate that a footnote applies, yet the footnote or legend may be missing from the table.

Figures

- Journal articles often include an excessive number of figures, many of which are simply unnecessary. The idea is not to present the same results in different ways. Moreover, a finding can often be described in a single sentence, and each sentence does not need a figure.
- The wrong type of graph may be used to portray the data. For instance, a bar graph (small spaces between bars) is appropriate for nominal categories (e.g., a series of different types of PNBs), whereas a histogram (flush bars) is appropriate for categories of a continuous variable (e.g., age groups, VAS scores that have been categorized).
- Figures are not always consistent with the text. For instance, the text may state that lidocaine kinetics was completed on 15 patients, but the figure may include values for only 10 patients.
- Error bars (typically denoting the 95% confidence interval) should be included with group means for continuous variables. The box and whiskers plots are especially useful when depicting median values. The median value is placed within a "box" where the interquartile range (IQR) (the 75th and 25th percentiles) defines the upper and lower borders of the box. Outliers are identified as values residing above the 75th percentile + (1.5 × IQR) or values residing below the 25th percentile – (1.5 × IQR).

Discussion and Conclusions

Overoptimism appears to be the bane of discussion and concluding statements. Not only do authors have a tendency to *re*state their findings, but they are often tempted to *over*state their findings. For instance, a statement to the effect that 0.5% ropivacaine *is superior to* 1% mepivacaine for a particular block may not be warranted if the study only looked at length of postoperative analgesia. Many other factors go into making one drug "superior" to another (e.g., speed of onset, success rate). The authors should simply state that 0.5% ropivacaine provided longer postoperative analgesia than 1% mepivacaine.

Authors are often tempted to overstep the boundaries of their study. For instance, the conclusion that "Dose of remifentanil for sedation during carotid endarterectomy under cervical plexus block should be reduced in patients older than 70 years of age" may not be warranted if the drug was not tested at lower doses in the study. Satisfactory block may not be achieved in patients older than 70 years of age if the drug is given at lower doses. Similarly, it could not be concluded that "The 12.5-mcg dose of fentanyl is optimal in terms of surgical anesthesia, hemodynamic stability, and reliability of block" if the 12.5-mcg dose was the highest dose tested. Higher doses may be even more "optimal."

Misleading statements are not easy to detect. For instance, stating that the tensile strength of 19- and 20-gauge Brand X epidural catheters differed at *varying* temperatures implies that the catheters were tested on a gradient of temperatures. If only two temperatures were studied, the statement should be revised to reflect that fact (e.g., the tensile strength of 19- and 20-gauge Brand X epidural catheters differed at the two temperatures studied). Similarly, stating that significantly more "technical failures" in nerve stimulation occurred in a specific group may be misleading if the so-called technical failures were only a portion of the total number of block failures that occurred. This is because the total number of block failures may be the primary outcome and may be similar among the groups, but the readers would be left with the impression that one group had more failures (overall) than the others. Finally, it would be misleading to omit some of the parameters tested in a study. For instance, when comparing two approaches to the sciatic nerve block in emergency situations, time to establish landmarks may be significantly shorter by approach A, yet time to perform the block may be shorter by approach B. It would be misleading to conclude that approach A is faster than approach B if time to establish landmarks can be offset by time to perform the block.

CHAPTER 80A

Cervical Plexus Block

Jerry D. Vloka, Ann-Sofie Smeets, Tony Tsai, and Cedric Bouts

INTRODUCTION

Cervical plexus anesthesia was developed early in the 20th century with two main approaches being used. In 1912, Kappis described a posterior approach to the cervical and brachial plexus, which attempted to block the nerves at their point of emergence from the vertebral column.[1] The posterior approach was advocated because the vertebral artery and vein lie anterior to the plexus.[2] However, the needle must pass through the extensor muscles of the neck which causes considerable discomfort, and the long path of the needle is more hazardous. Consequently, this technique is not recommended as a routine for cervical or brachial plexus block.

In 1914, Heidenhein described the lateral approach, which has formed the basis for subsequent techniques of anesthetizing the cervical plexus.[6] Victor Pauchet also described a lateral approach to blocking the cervical plexus in 1920 and recommended it over the posterior approach.[7] Winnie revisited the lateral approach to the cervical plexus block in 1975, and described a simplified, single-injection technique.[8] The lateral approach is currently the more commonly used approach and will be described in this chapter.

INDICATIONS AND CONTRAINDICATIONS

Deep and superficial cervical plexus blocks can be used in a variety of surgical procedures, including superficial surgery on the neck and shoulders and thyroid surgery. Its use is most common in carotid endarterectomy, in which an awake patient self-monitors to ensure adequate cerebral blood flow during cross-clamping of the carotid artery (Figure 80A–1).[9,10] Since the description of the first carotid endarterectomy in 1954 by Eastcott, the number of these operations has been growing annually.[11] Regional anesthesia is a viable anesthetic choice for carotid surgery, although debate continues whether it improves patient outcomes.[12–25] The largest randomized trial to date on this topic (GALA trial) showed no difference in 30-day stroke or mortality rates, a conclusion that has been supported by a recent meta-analysis.[26,27]

The superficial cervical plexus block can be used for many superficial surgeries in the neck area, including lymph node dissection, excision of thyroglossal or branchial cleft cysts, carotid endarterectomy, and vascular access surgery.[28]

Comparisons of superficial vs deep cervical plexus blocks for carotid endarterectomy have either shown equivalence or favored the superficial block due to the lower risk of complications.[29–31] Although both the deep and superficial cervical plexus blocks can be performed separately, they have been used by some also in combination for anesthesia and postoperative analgesia for head and neck surgery.[32–34]

Contraindications to performing a cervical plexus block include patient refusal, local infection, and previous surgery or radiation therapy to the neck. Likewise, due to the risk of

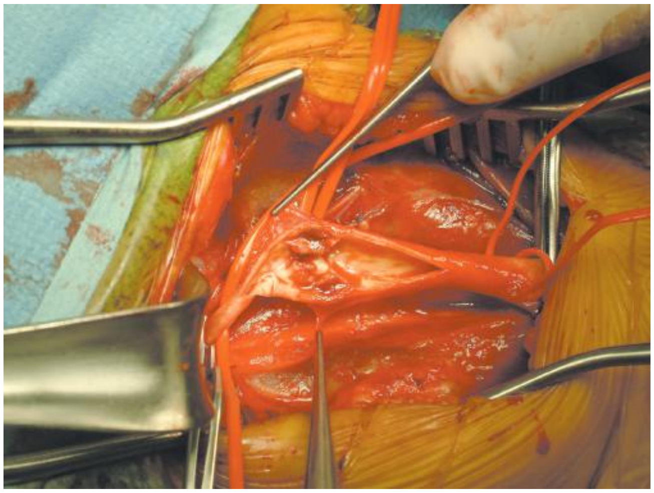

FIGURE 80A–1. Carotid endarterectomy. The image shows open, cross-clamped carotid artery and a plaque inside its wall.

phrenic nerve paresis, the deep cervical plexus block is relatively contraindicated in patients with contralateral phrenic nerve palsy and significant pulmonary compromise.

FUNCTIONAL ANATOMY OF DEEP CERVICAL PLEXUS BLOCKADE

The cervical plexus is formed by the anterior divisions of the four upper cervical nerves (Figure 80A–2). The plexus is situated on the anterior surface of the four upper cervical vertebrae, resting on the levator anguli scapulae and scalenus medius muscles, and is covered by the sternocleidomastoid muscle. The dorsal and ventral roots combine to form spinal nerves as they exit through the intervertebral foramen. The first cervical root is primarily a motor nerve and is of little interest for locoregional anesthesia. The anterior rami of the second through fourth cervical nerves form the cervical plexus. The branches of the superficial cervical plexus innervate the skin and superficial structures of the head, neck, and shoulder (Figure 80A–3). The branches of the deep cervical plexus innervate the deeper structures of the neck, including the muscles of the anterior neck and the diaphragm, which is innervated by the phrenic nerve. The third and fourth cervical nerves send a branch to the spinal accessory nerve, or directly into the deep surface of the trapezius to supply sensory fibers to this muscle. The fourth cervical nerve may send a branch downward to join the fifth cervical nerve and participate in the formation of the brachial plexus. The cutaneous innervation of both the deep and superficial cervical plexus blocks includes skin of the anterolateral neck and the anteauricular and retroauricular areas (Figure 80A–3).

Anatomic Landmarks

The following three landmarks for a deep cervical plexus block are identified and marked (Figure 80A–4):

1. Mastoid process
2. Chassaignac tubercle (transverse process of the sixth cervical vertebra)
3. Posterior border of the sternocleidomastoid muscle

To estimate the line of needle insertion that overlies the transverse processes, the mastoid process (MP) and the Chassaignac tubercle, which is the transverse process of the sixth cervical vertebra (C6), are identified and marked (Figure 80A–5). The transverse process of C6 is usually easily palpated behind the clavicular head of the sternocleidomastoid muscle at the level just below the cricoid cartilage (Figure 80A–6). Next, a line is drawn connecting the MP to the Chassaignac tubercle. Position the

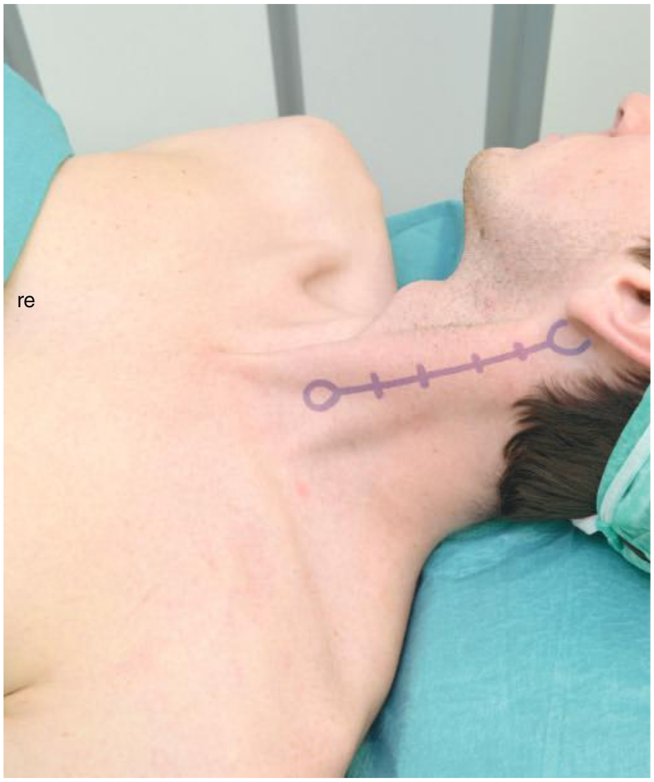

FIGURE 80A–4. Anatomic landmarks for the cervical plexus. Shown are estimates of the transverse processes C2-C3-C4-C5-C6.

FIGURE 80A–5. Palpation of the transverse process of C6.

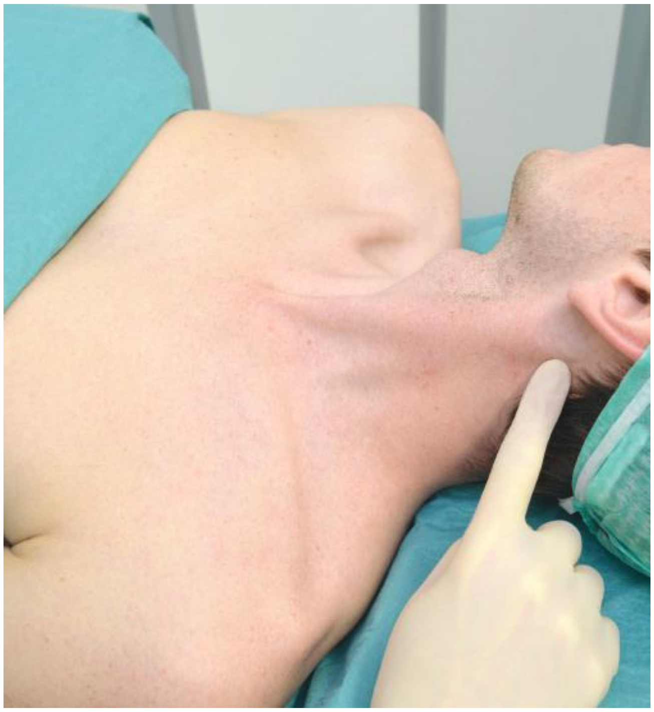

FIGURE 80A–6. Palpation of the mastoid process.

palpating hand just behind the posterior border of the sternocleidomastoid muscle. Once this line is drawn, label the insertion sites over the C2, C3, and C4, which are respectively located on the MP–C6 line 2 cm, 4 cm, and 6 cm, respectively, caudal to the mastoid process. It is also possible to perform a single injection at the C3 level, which is considered safe and effective.[35]

Clinical Pearls

- The distances specified for spacing along the transverse processes at various levels are estimates at best.
- Once two neighbouring transverse processes are identified, the spacing between the other transverse processes follows a similar pattern.

Choice of Local Anesthetic

A deep cervical plexus block requires 3–5 mL of local anesthetic per level to ensure reliable blockade. Except perhaps with patients with significant respiratory disease who rely on their phrenic nerve to adequately ventilate, most patients benefit from the use of a long-acting local anesthetic. Table 80A–1 shows commonly used local anesthetics with onset and duration of anesthesia and analgesia for deep cervical plexus blocks. Ropivacaine 0.5% provides good quality block of longer duration,[36] and it is one of most common choices for carotid endarterectomy surgery.[37]

Equipment

A standard regional anesthesia tray is prepared with the following equipment:

TABLE 80A–1. Commonly used local anesthetics for deep cervical plexus blocks.

	Onset (min)	Anesthesia (h)	Analgesia (h)
1.5% Mepivacaine (+ HCO_3^- + epinephrine)	10–15	2.0–2.5	3–6
2% Lidocaine (+ HCO_3^- + epinephrine)	10–15	2–3	3–6
0.5% Ropivacaine	10–20	3–4	4–10
0.25% Bupivacaine (+ epinephrine)	10–20	3–4	4–10

- Sterile towels and 4-in. × 4-in. gauze pads
- 20-mL syringe(s) with local anesthetic
- Sterile gloves and marking pen
- One 1.5 -in., 25-gauge needle for skin infiltration
- A 1.5 -in.-long, 22-gauge, short-beveled needle

Technique

After cleaning the skin with an antiseptic solution, local anesthetic is infiltrated subcutaneously along the line estimating the position of the transverse processes. The needle should contact the posterior tubercle of the transverse process where the spinal nerves at the individual levels are located just in front of the transverse process.

The block needle is connected to a syringe with local anesthetic via flexible tubing. The block needle is inserted between the palpating fingers and advanced at an angle perpendicular to the skin. A slight caudal orientation of the needle prevents the inadvertent insertion of the needle toward the cervical spinal cord. The needle should never be oriented cephalad. The needle is advanced slowly until the transverse process is contacted (Figure 80A–7). At this point, the needle is withdrawn 1–2 mm and stabilized for injection of 4 mL of local anesthetic per level after a negative aspiration for blood. The block needle is then removed, and the procedure is repeated at the consecutive levels.

Clinical Pearls

- The transverse process is typically contacted at a depth of 1–2 cm in most patients.
- Never advance the needle beyond 2.5 cm due to the risk of spinal cord injury.
- Paresthesia is often elicited in proximity to the transverse process but should not be relied on as the successful needle placement because of its nonspecific radiating pattern.

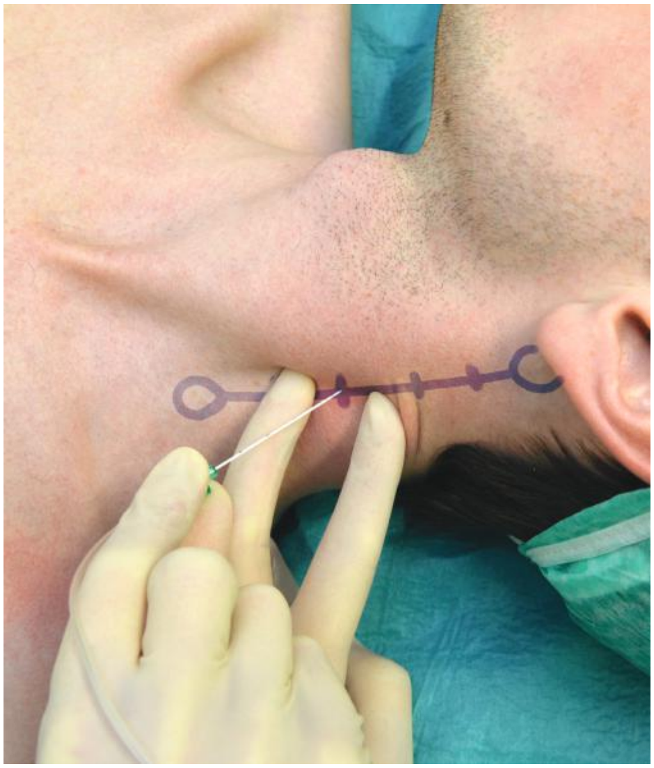

FIGURE 80A–7. Needle insertion to block a single cervical level during deep cervical blockade.

Block Dynamics and Perioperative Management

Although the placement of deep cervical block may be uncomfortable for the patient, excessive sedation should be avoided. During surgery, airway management may be difficult due to the close proximity of the surgical field. Surgeries like carotid endarterectomy require that the patient be cooperative for intraoperative neurologic assessment.[13] Excessive sedation and the consequent lack of patient cooperation can lead to restlessness and patient movement intraoperatively.

The onset time for this block is 10–15 min. The first sign of onset is decreased sensation in the distribution of the respective components of the cervical plexus. It should be noted that due to the complex arrangement of the neuronal coverage of the various layers in the neck area as well as cross coverage from the contralateral side, the anesthesia achieved with cervical plexus block is often incomplete, and its use often requires a knowledgeable surgeon who is skilled in supplementing the block with local anesthetic as necessary.

Clinical Pearl

- Carotid surgery also requires blockade of the glossopharyngeal nerve branches, which is easily accomplished intraoperatively by injecting the local anesthetic inside the carotid artery sheath.

FUNCTIONAL ANATOMY OF SUPERFICIAL CERVICAL PLEXUS BLOCKADE

The superficial cervical plexus innervates the skin of the anterolateral neck (see Figure 80A–3). The terminal branches emerge as four distinct nerves from the posterior border of the sternocleidomastoid muscle. The lesser occipital nerve is usually a direct branch from the main stem of the second cervical nerve. The larger remaining part of this stem then unites with a part of the third cervical nerve to form a trunk that gives rise to the greater auricular and transverse cervical nerves. Another part of the third cervical nerve runs downward to unite with a major part of the fourth cervical nerve to form a supraclavicular trunk, which then divides into the three groups of supraclavicular nerves.

Anatomic Landmarks

A line extending from the mastoid process to C6 is drawn as described above (Figure 80A–8). The site of needle insertion is marked at the midpoint of this line. This is where the branches of the superficial cervical plexus emerge from behind the posterior border of the sternocleidomastoid muscle.

Choice of Local Anesthetic

Superficial cervical plexus block requires 10–15 mL of local anesthetic (3–5 mL per each redirection/injection). Since motor block is not sought with this technique a lower concentration of long-acting local anesthetic is most often used (e.g.,, 0.2–0.5% ropivacaine or 0.25% bupivacaine). Higher concentration, however, may result in both a greater success rate and a longer duration of blockade.[33]

Table 80A–1 shows choices of local anesthesia, with onset time and duration of anesthesia and analgesia.

Equipment

A standard regional anesthesia tray is prepared with the following equipment:

- Sterile towels and 4-in. × 4-in. gauze pads
- 20-mL syringe with local anesthetic
- Sterile gloves, marking pen
- A 1.5-in., 25-gauge needle for block infiltration

Technique

Anatomic landmarks and the needle insertion point are marked as described above. After cleansing the skin with an antiseptic solution, a skin wheal is raised at the site of needle insertion using a 25-gauge needle. Using a "fan" technique with superior–inferior needle redirections, the local anesthetic is injected alongside the posterior border of the sternocleidomastoid muscle 2–3 cm below and then above the needle insertion site. The goal is to achieve blockade of all four major branches of the superficial cervical plexus.

The goal of the injection is to infiltrate the local anesthetic subcutaneously and behind the sternocleidomastoid muscle. Deep needle insertion should be avoided (e.g., >1–2 cm).

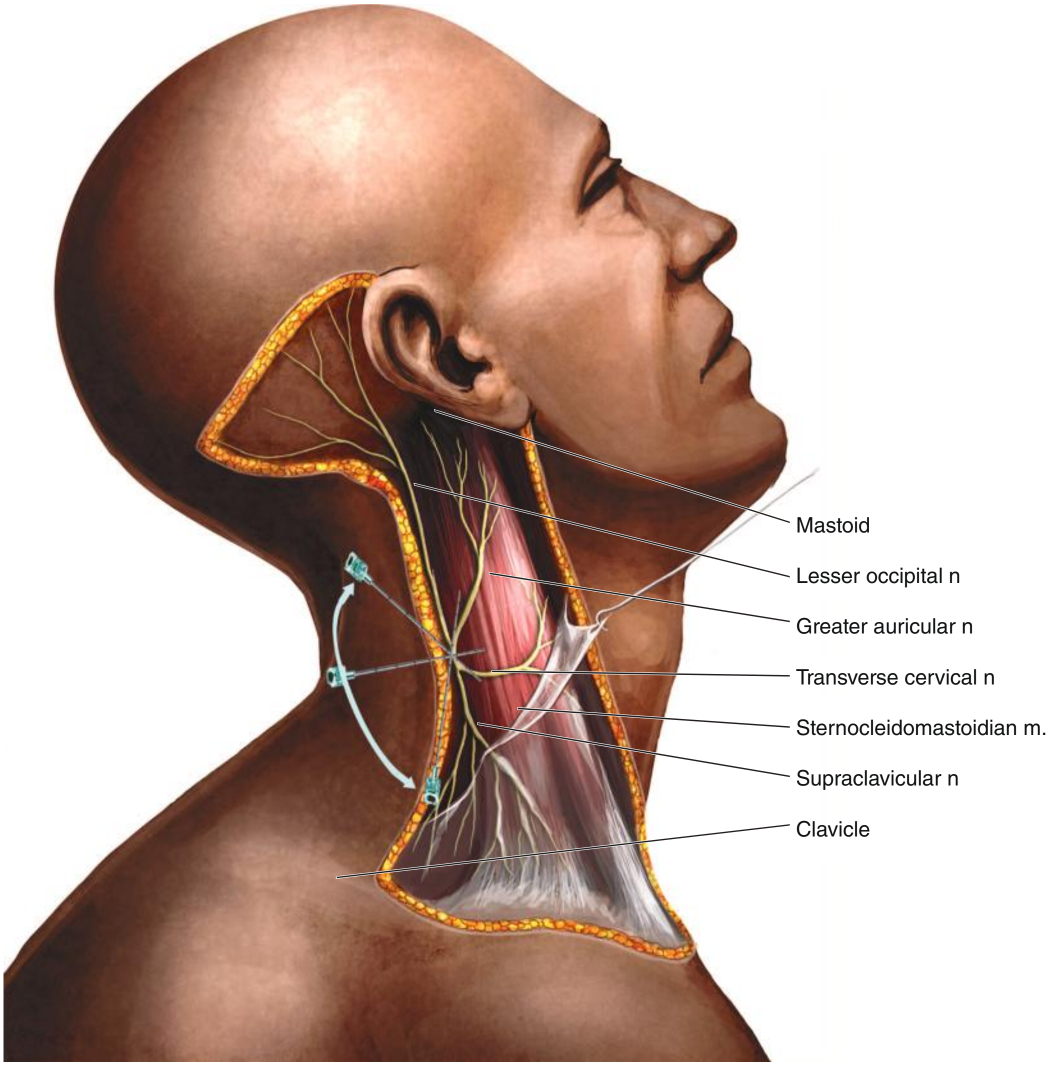

FIGURE 80A–8. Supraclavicular nerve block. An initial injection of 3 mL local anesthetic is deposited at the midpoint of the sternocleidomastoid muscle, followed by 7 mL injected subcutaneously in a caudad and cephalad direction along the posterior border of the muscle.

Block Dynamics and Perioperative Management

The superficial cervical plexus block is associated with minor patient discomfort, so little or no sedation should be required.

Similar to deep cervical plexus blockade, the sensory coverage of the neck is complex and a degree of cross coverage from the cervical plexus branches from the opposite side of the neck should be expected. The onset time for this block is 10–15 minutes; the first sign of the blockade is decreased sensation in the distribution of the superficial cervical plexus.

Ultrasound guidance can also be used when performing the superficial cervical plexus block, although a studies to date have not demonstrated an advantage over a landmark-based technique.[38,39]

Clinical Pearls

- A subcutaneous midline injection of the local anesthetic extending from the thyroid cartilage distally to the suprasternal notch will also block the branches crossing from the opposite side.
- Superficial cervical plexus can be considered as a "field" block and is very useful for preventing pain from surgical skin retractors on the medial aspect of the neck.

COMPLICATIONS AND HOW TO AVOID THEM

Complications can occur with both deep and superficial cervical plexus blocks (Table 80A–2). Infection, hematoma formation, phrenic nerve block, local anesthetic toxicity, nerve injury, and inadvertent subarachnoid or epidural anesthesia can all occur when performing these blocks.[40–44] In a large prospective study of 1000 blocks for carotid artery surgery, Davies and colleagues reported only 6 blocks (0.6%) showing evidence of intravascular injection.[13] Other possible complications include transient

TABLE 80A–2. Complications of cervical plexus block and means to avoid them.

Infection	• Low risk • A strict aseptic technique is used
Hematoma	• Avoid multiple needle insertions, particularly in anticoagulated patients • Keep 5 minutes of steady pressure on the site if the carotid artery is inadvertently punctured
Phrenic nerve blockade	• Phrenic nerve blockade (diaphragmatic paresis) invariably occurs with a deep cervical plexus block • A deep cervical block should be carefully considered in patients with significant respiratory disease • Bilateral deep cervical block in such patients may be contraindicated • Blockade of the phrenic nerve does not occur after superficial cervical plexus block
Local anesthetic toxicity	• Central nervous system toxicity is the most serious consequence of the cervical plexus block • This complication occurs because of the rich vascularity of the neck, including vertebral and carotid artery vessels and is usually caused by an inadvertent intravascular injection of local anesthetic rather than absorption • Careful and frequent aspiration should be performed during the injection
Nerve injury	• Local anesthetic should never be injected against resistance or when the patient complains of severe pain on injection
Spinal anesthesia	• This complication may occur with injection of a larger volume of local anesthetic inside the dural sleeve that accompanies the nerves of the cervical plexus • It should be noted that a negative aspiration test for CSF does not rule out the possibility of intrathecal spread of local anesthetic • Avoidance of high volume and excessive pressure during injection are the best measures to avoid this complication

Abbreviation: CSF, cerebrospinal fluid.

ischemic attacks either during surgery or in the postoperative period and recurrent laryngeal nerve blockade.[45–47] As with other nerve blocks, the risk of complications can be decreased by meticulous technique and attention to detail.[48–51]

SUMMARY

In summary, cervical plexus blocks have been in clinical use for nearly a century. Although modifications have been made to the approaches first described, the most common approach remains the lateral approach to deep cervical plexus block.

CHAPTER 80B

Interscalene Brachial Plexus Block

Alain Borgeat, Matthew Levine, Malikah Latmore, Sam Van Boxstael, and Stephan Blumenthal

INTRODUCTION

The first brachial plexus blocks were performed by William Stewart Halsted, in 1885, at the Roosevelt Hospital in New York City. In 1902, George Washington Crile described an "open approach" to expose the (axillary) plexus facilitating direct application of cocaine. The need for surgical exposure of the brachial plexus led to limited clinical utility of this technique. This changed in the early 1900s when percutaneous access to the brachial plexus was first described. In 1925, July Etienne[1] reported the successful blockade of the brachial plexus by inserting a needle halfway between the lateral border of the sternocleidomastoid muscle and the anterior border of the trapezius muscle at the level of the cricothyroid membrane, making a single injection in the area around the scalene muscles. This approach was most likely the first clinically useful interscalene block technique. In 1970, Alon Winnie[2] described the first consistently effective and technically suitable percutaneous approach to the brachial plexus block. The technique involved palpating the interscalene groove at the level of the cricoid cartilage and injecting local anesthetic between the anterior and middle scalene muscles. Winnie's approach was modified over the years to include slight variations to the technique such as perineural catheter placement.[3] However, the success of this approach and the widespread adoption of the interscalene brachial plexus block as the "unilateral spinal anesthesia for the upper extremity," should be credited solely to Alon Winnie.

More recently, the introduction of ultrasound-guided techniques has allowed for additional refinements and improved block consistency with reduced local anesthetic volumes (see Chapter 32B).[4–6]

Indications

The interscalene block is indicated for procedures on the shoulder and proximal humerus as well as the lateral two thirds of the clavicle. The interscalene block can also be utilized for surgery of the arm or forearm; however, the higher incidence of incomplete blockade of the inferior trunk with this technique may provide inadequate analgesia in the ulnar distribution. The patient's positioning and comfort, the surgeon's preferences, and the duration of surgery may necessitate coadministration of a general anesthetic. An interscalene catheter may be inserted for prolonged postoperative analgesia (Table 80B-1).

Clinical Pearls

- Up to 70% of patients report severe pain on movement after open major shoulder surgery, which is more than after hysterectomy (60%), gastrectomy, or thoracotomy (60%).[7]
- Major shoulder surgery entails massive nociceptive input from the richly innervated joint and periarticular tissues, which produce continuous deep somatic pain and bouts of reflex spasm of muscles.
- Periarticular structures exhibit not only C afferents, but also A alpha and A delta afferents, the latter being poorly blocked by opioids, which explains the relative inefficacy of opioids to control this type of postoperative pain.

Contraindications

Absolute contraindications include patient's refusal, local infection, active bleeding in an anticoagulated patient, and proven allergy to local anesthetic. Relative contraindications include chronic obstructive airway disease, contralateral paresis of the phrenic or recurrent laryngeal nerves, and previous neurologic deficit of the involved arm. The risks and benefits of the chosen anesthetic technique should be discussed with the patient and the surgeon.

PART 15

TABLE 80B–1. Single-injection vs the choice of technique: interscalene catheter according to surgery.

Type of Surgery	Type of Block Single-Injection	Catheter
Open Surgery		
Arthroplasty	+	+
Rotator cuff repair	+	+
Arthrolysis	+	+
Acromioplasty	+	+
Bankart's repair	+	+
Latarjet	+	+
Proximal humerus osteosynthesis	+	±
Acromioclavicular resection	+	–
Shoulder luxation	+	–
Clavicle osteosynthesis	+ (± superficial cervical block)	–
Arthroscopic Surgery		
Rotator cuff repair	+	+
Arthrolysis	+	+
Bankart's repair	+	±
Acromioplasty	+	±

Skin infiltration of the posterior arthroscopic port site with local anesthetic is often necessary despite a successful interscalene block.

Clinical Pearl

- Skin infiltration of the posterior arthroscopic port site with local anesthetic is often necessary for arthroscopic shoulder surgery in addition to interscalene block.

Anatomy

The plexus is formed by the ventral rami of the fifth to eighth cervical nerves and the greater part of the ventral ramus of the first thoracic nerve (Figure 80B–1). In addition, small contributions may be made by the fourth cervical and the second thoracic nerves. There are multiple complex interconnections between the neural elements of brachial plexus as they course from the interscalene groove to their endpoints in terminal nerves. However, most of what happens to these roots on their way to becoming peripheral nerves is not clinically essential information for the practitioner. However, spatial arrangement of the trunks (superior, middle, and inferior) and interpretation of the motor response with nerve stimulation can be of importance. (Table 80B–2).The brachial plexus supplies all the motor and most of the sensory functions of the shoulder except the cephalad cutaneous parts of the shoulder. These are innervated by the supraclavicular nerves originating from the lower part of the superficial cervical plexus (C3–4) (Figure 80B–2) which supply sensation to the shoulder above the clavicle, the first two intercostal spaces anteriorly, the posterior cervical triangle and the upper thorax in this area as well as to the tip of the shoulder.[9]

Only three nerves of the brachial plexus innervate the shoulder. The most proximal of these is the upper lateral brachial cutaneous nerve, a branch of the axillary nerve that innervates the lateral side of the shoulder and the skin overlying the deltoid muscle. The upper medial side of the arm is innervated by both the medial brachial cutaneous and the intercostobrachial cutaneous nerves. In the anterior portion of the arm over the biceps muscle, the skin is innervated by the medial antebrachial cutaneous nerve.[9]

Apart from the cutaneous nerve supply to the shoulder, the innervation of the joint deserves special consideration. In general, a nerve crossing a joint gives branches that innervate that joint. Therefore, the nerves supplying the ligaments, capsule, and synovial membrane of the shoulder derive from the axillary, suprascapular, subscapular, and musculocutaneous nerves.[10,11] The relative contributions of these nerves are not constant, and the supply from the musculocutaneus nerve may be very small or completely absent. Anteriorly, the axillary nerve and suprascapular nerve provide most of the nerve supply to the capsule and glenohumeral joint (Figure 80B–3). In some instances, the musculocutaneous nerve may innervate the anterosuperior portion of the joint. In addition, the anterior capsule may be supplied by either the subscapular nerves or the posterior cord of the brachial plexus after piercing the subscapularis muscle. Superiorly, the primary contribution is from two branches of the suprascapular nerve, one branch supplying the acromioclavicular joint and proceeding anteriorly as far as the coracoid process and coracoacromial ligament and the other branch reaching the posterior aspect of the joint. Other nerves contributing to this region of the joint are the axillary nerve and musculocutaneous nerve. Posteriorly, the main nerves are the suprascapular nerve in the upper region and the axillary nerve in the lower region (Figure 80B–4).

Inferiorly, the anterior portion is primarily supplied by the axillary nerve, and the posterior portion is supplied by a combination of the axillary nerve and lower ramifications of the suprascapular nerve.

Clinical Pearls

- **Arthroscopic shoulder surgery:** Nerves of importance to anesthesia: supraclavicular, suprascapular, and axillary (radial) nerves.
- **Open shoulder surgery:** Knowledge of the surgical approach is important because surgery may also involve the territories of the median cutaneous, intercostobrachial, and the median antebrachial cutaneous nerves.

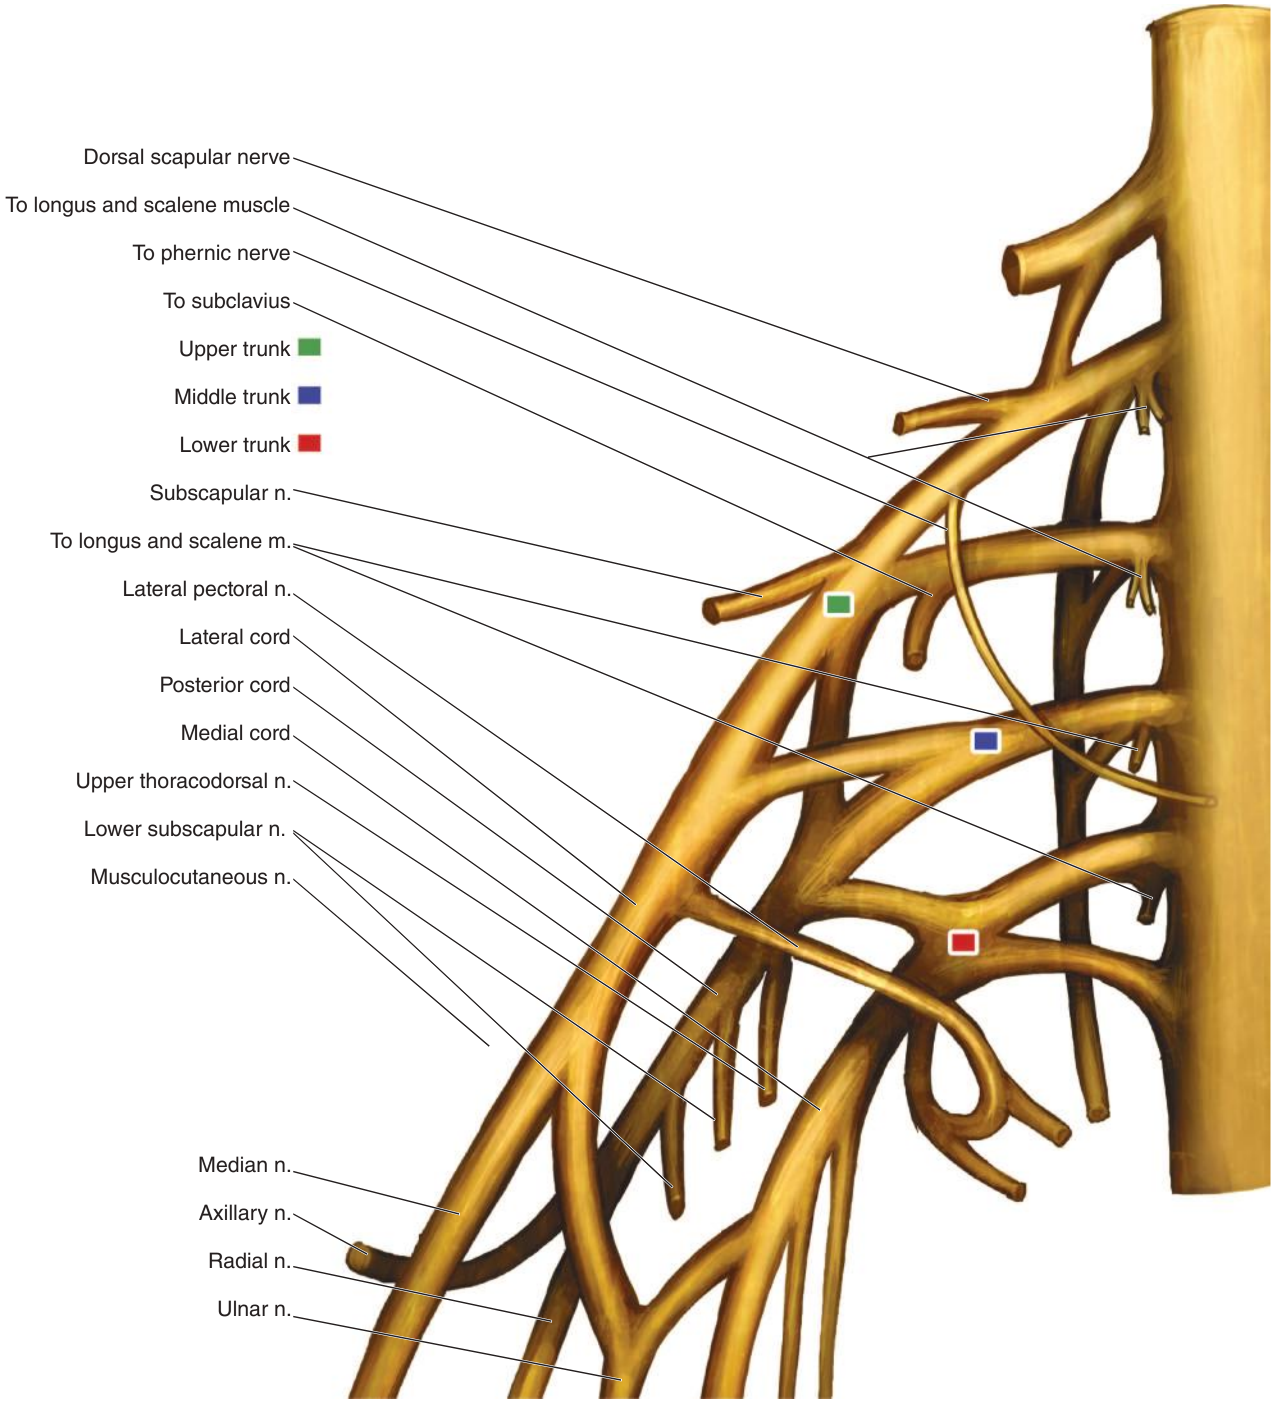

FIGURE 80B–1. Organization of the brachial plexus.

Landmarks

The following surface anatomy landmarks are important in identifying the interscalene space:

1. Sternal head of the sternocleidomastoid muscle
2. Clavicular head of the sternocleidomastoid muscle
3. Upper border of the cricoid cartilage
4. Clavicle (Figure 80B–5)

Equipment for Single-Injection Technique

Standard regional anesthesia equipment for a single-shot block consists of the following items (Figure 80B–6):

Marking pen, ruler
Sterile gloves
Peripheral nerve stimulator, surface electrode

TABLE 80B–2. Distribution of the brachial plexus.

Nerve(s)	Spinal Segment(s)	Distribution
Subclavius nerve	C4 through C6	Subclavius muscle
Dorsal scapular nerve	C4–C5	Rhomboid muscles and levator scapulae muscle
Long thoracic nerve	C5 through C7	Serratus anterior muscle
Suprascapular nerve	C4, C5, C6	Supraspinatus and infraspinatus muscles
Pectoralis nerves (medial and lateral)	C5 through T1	Pectoralis muscles
Subscapular nerves	C5, C6	Subscapular and teres major muscles
Thoracodorsal nerve	C6 through C8	Latissimus dorsi muscle
Axillary nerve	C5 and C6	Deltoid and teres minor muscles; skin of shoulder
Radial nerve	C5 through T1	Extensor muscles of the arm and forearm (triceps brachii, extensor carpi radialis, extensor carpi ulnaris) and brachioradialis muscle; digital extension and abductor pollicis muscle; skin over posterolateral surface of the arm
Musculocutaneous nerve	C5 through C7	Flexor muscles of the arm (biceps brachii, brachialis, coracobrachialis); skin over lateral surface of the forearm
Median nerve	C6 through T1	Flexor muscles of the forearm (flexor carpi radialis, palmaris longus); pronator quadratus, and pronator teres muscles; digital flexors (through the palmar interosseous nerve); skin over anterolateral surface of the hand
Ulnar nerve	C8, T1	Flexor carpi ulnaris muscle, adductor pollicis muscle, and small digital muscles, skin over medial surface of the hand

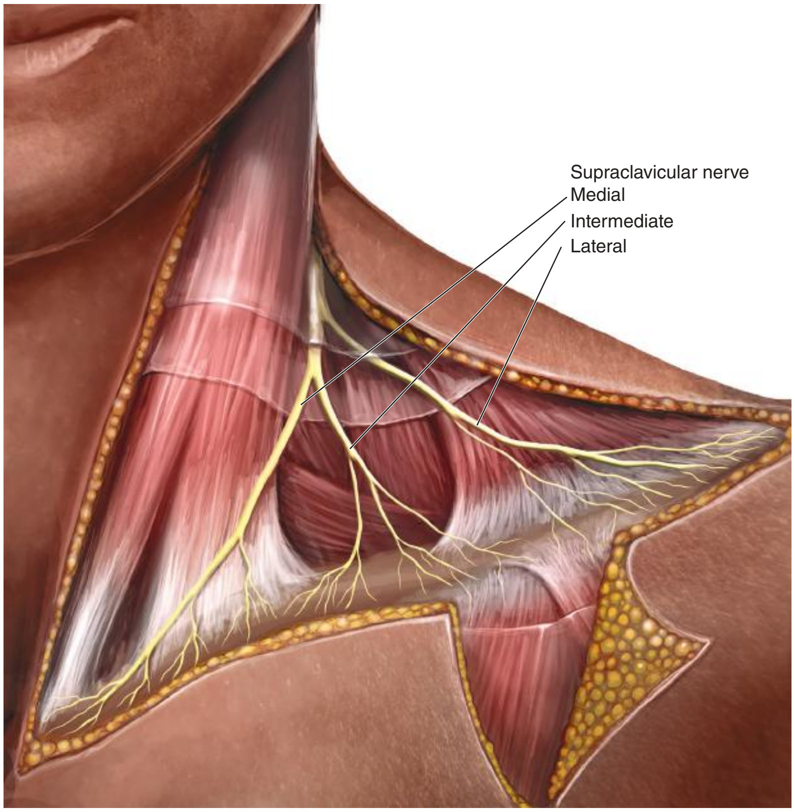

FIGURE 80B–2. The innervation of the skin over the shoulder and clavice.

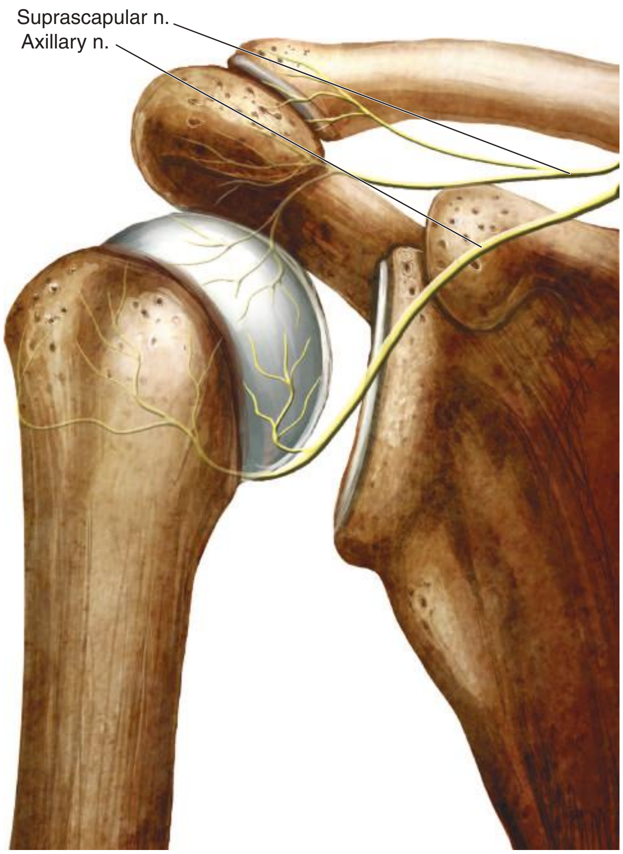

FIGURE 80B–3. The innervation of the anterior portion of the shoulder. The axillary and suprascapular nerves form most of the nerve supply to the capsule and the glenohumeral joint.

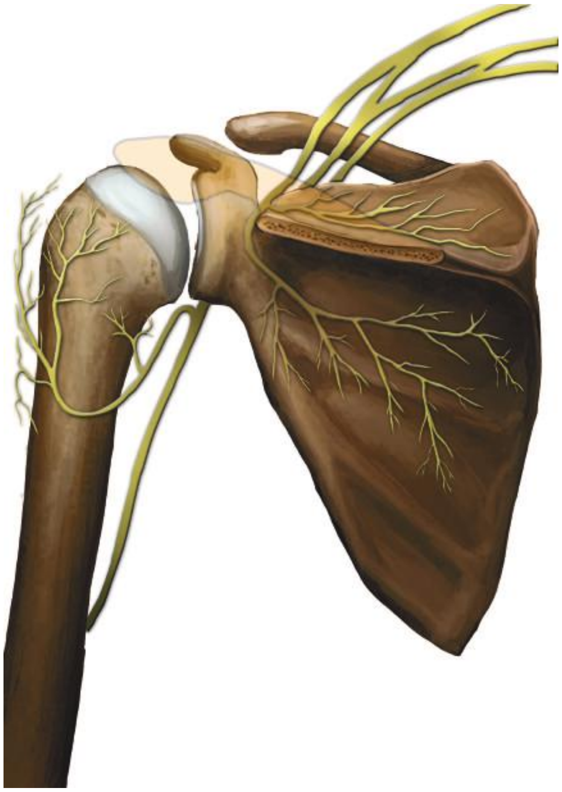

FIGURE 80B–4. The posterior innervation of the shoulder joint. The primary nerves are the suprascapular and the axillary.

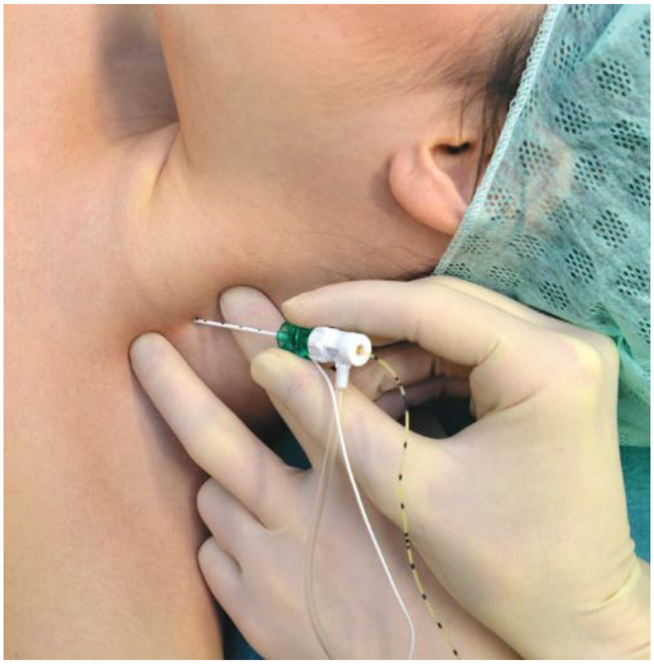

FIGURE 80B–5. Continuous interscalene brachial plexus block. The needle is inserted between anterior and middle scalene muscles in the pictured direction. The needle should not be placed deeper than 2-3 cm in most patients.

Disinfection solution and sterile gauze packs
2- to 5-cm, short-bevel, 22-gauge insulated stimulating needle
Syringes with local anesthetic
Injection pressure monitor

Equipment for Continuous Technique

Standard regional anesthesia equipment for a continuous nerve block consists of the following items (Figure 80B–7).

Marking pen, ruler
Peripheral nerve stimulator, surface electrode
Disinfection solution, sterile gauze packs
Sterile transparent drapes
Syringes with local anesthetic for skin infiltration and block injection
25-mm, 25-gauge needle for skin infiltration at puncture point and for tunneling
A set with stimulating needle for continuous nerve block and catheter
Adhesive material for securing the catheter

APPROACHES TO AND TECHNIQUES FOR BRACHIAL PLEXUS BLOCK AT THE LEVEL OF THE NECK

Several approaches to the interscalene brachial plexus block have been described with the use of a nerve stimulator. In this chapter, we describe the, classic (Winnie) technique and common modifications, including the low interscalene approach. The posterior (paravertebral) approach and its modifications

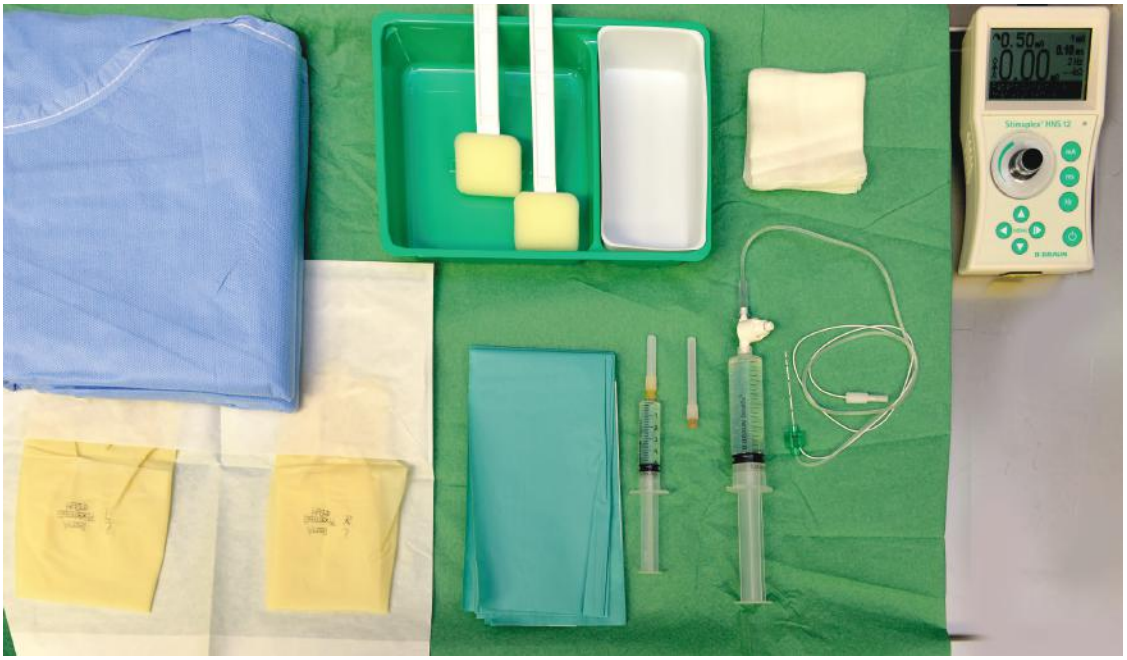

FIGURE 80B–6. Equipment for single-injection interscalene block.

have been largely abandoned for safety reasons and will be omitted from this volume.[16-19]

Classic Technique (Winnie)

The classic approach of Winnie[2] is performed at the level of the sixth cervical vertebra. Winnie originally used a paresthesia technique; however, most practitioners eventually adopted nerve stimulation.

1. The patient is placed in a semisitting or supine position with the head turned away from the side to be blocked.
2. The patient is asked to elevate the head slightly to bring the clavicular head of the sternocleidomastoid muscle into prominence.
3. The index and middle fingers of the nondominant hand are placed immediately behind the lateral edge of the sternocleidomastoid muscle. The patient is instructed to relax so that the palpating fingers can be moved medially

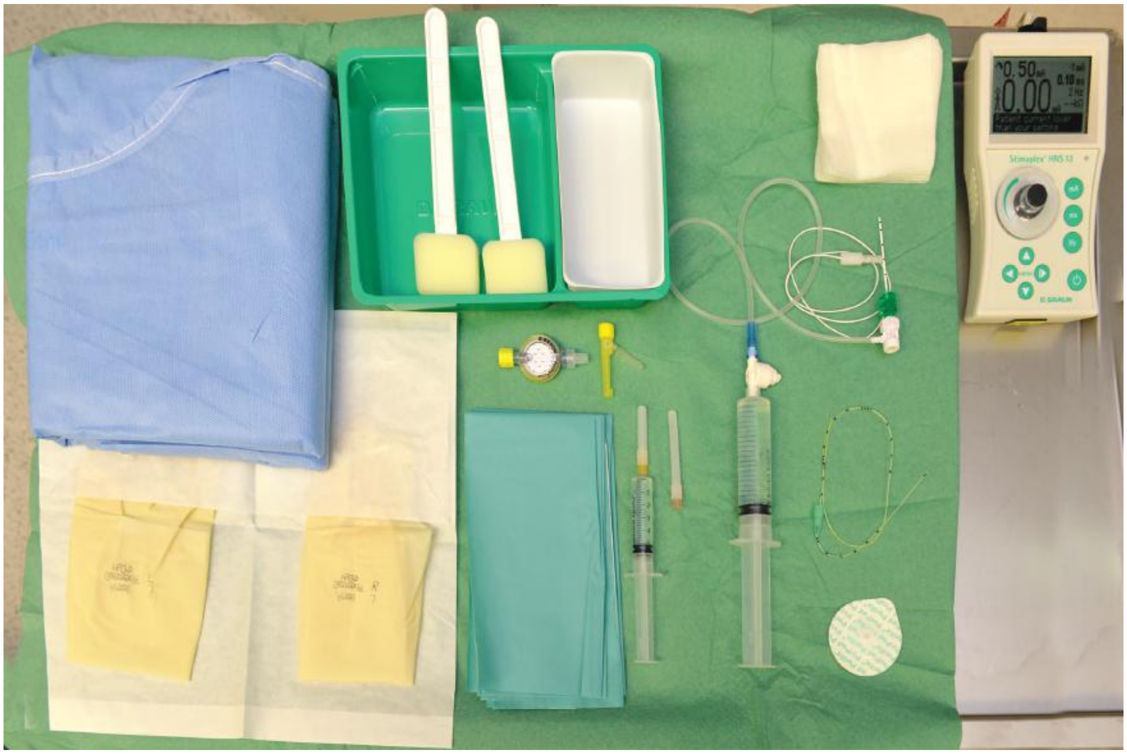

FIGURE 80B–7. Equipment for continuous interscalene block.

behind this muscle and finally lie on the belly of the anterior scalene muscle.

4. The palpating fingers are then rolled laterally across the belly of the anterior scalene muscle until they fall into the interscalene groove (formed by scalene anterior and posterior muscles).
5. With both fingers in the interscalene groove, a 1.5-in., 22- gauge, short-bevel needle is inserted between the fingers at the level of C6 in a direction that is perpendicular to the skin in every plane.
6. After a motor response is obtained, aspiration is carried out to rule out intravascular or intrathecal placement. While the patient is monitored closely for signs of local anaesthetic toxicity or inadvertent subarachnoid injection, 15–20 mL of local anesthetic is slowly injected.

Clinical Pearls

- In Winnie's original description, the needle is advanced slowly until a paresthesia is elicited or until the transverse process is encountered.
- Paresthesia below the level of the shoulder is sought because a paresthesia to the shoulder could result from stimulation of the suprascapular nerve inside or outside the interscalene space.
- If bone is contacted without producing a paresthesia, this is likely the transverse process and the needle should be gently "walked off " anteriorly millimeter by millimeter until a paresthesia or motor response is evoked.

Reported complications with this technique are total spinal anesthesia,[12,13] epidural anesthesia,[14] cervical spinal cord injection with resultant paraplegia, as well as injections into the vertebral artery.[15] These complications are more likely to occur with the classic technique than its modifications because the needle is directed perpendicularly towards the spinal cord. Although an infrequent complication, pneumothorax can also occur. This technique is not well suited for the placement of an interscalene catheter because of the perpendicular approach to the trunks.

Low Interscalene Brachial Plexus Block

The low interscalene technique of brachial plexus block[21] differs in three important aspects from the classic approach and its modifications (Figure 80B-5).[32]

1. Insertion of the needle is significantly lower than with the classic approach, which should reduce the risk of the needle entering the cervical cord or vertebral artery.
2. The brachial plexus is very superficial at this location; the skin to brachial plexus block distance is often less than 1 cm and rarely deeper than 2 cm.
3. The block can be considered a cross between a classic interscalene block (the plexus is approached in the distal interscalene groove) and a supraclavicular block (the needle insertion is slightly above the clavicle).

In contrast to the other approaches, the low interscalene approach provides reliable anesthesia for shoulder, elbow, and forearm surgeries alike.[22]

Landmarks

The landmarks for the low interscalene approach are as follows (Figure 80B–8):

- Clavicle
- Posterior border of the clavicular head of the sternocleidomastoid muscle
- External jugular vein

The landmarks for the low interscalene approach are accentuated by the following maneuvers, which should be routinely performed:

1. Ask the patient to face slightly away from the side to be blocked. This tenses the sternocleidomastoid muscle.
2. Ask the patient to reach the ipsilateral knee on the side to be blocked or pull the patient's wrist toward their knee. This flattens the skin of the neck and helps to identify both the scalene muscles and the external jugular vein.
3. Ask the patient to lift the head off the table while facing away. This tenses the sternocleidomastoid muscle and helps to identify the posterior border of the clavicular head.

Technique

The fingers of the palpating hand should be gently pressed between the anterior and middle scalene muscles to reduce the distance between the skin and brachial plexus (Figure 80B–9). The palpating hand should not be moved during the entire procedure to allow for precise redirections of the needle. A needle connected to a nerve stimulator is inserted between the palpating fingers and advanced at an angle almost perpendicular to the skin and in a slight caudad direction (Figure 80B–10). The nerve stimulator should be initially set to deliver 1 mA (2 Hz, 100 μsec). The needle is advanced slowly. Once any motor response of the brachial plexus is elicited, 15–20 mL of local anesthetic is injected slowly, with intermittent aspiration.

Some common responses to nerve stimulation and the course of action to obtain the proper response are shown in Table 80B–3. The following motor responses can all be accepted as successful localization of the brachial plexus with a similar success rate:

- Pectoralis muscle
- Deltoid muscle
- Triceps muscles
- Any twitch of the hand or forearm
- Biceps muscle

Continuous Interscalene Brachial Plexus Block

The continuous interscalene brachial plexus block is an advanced technique. Paradoxically, although the single-shot interscalene block is one of the easiest intermediate techniques

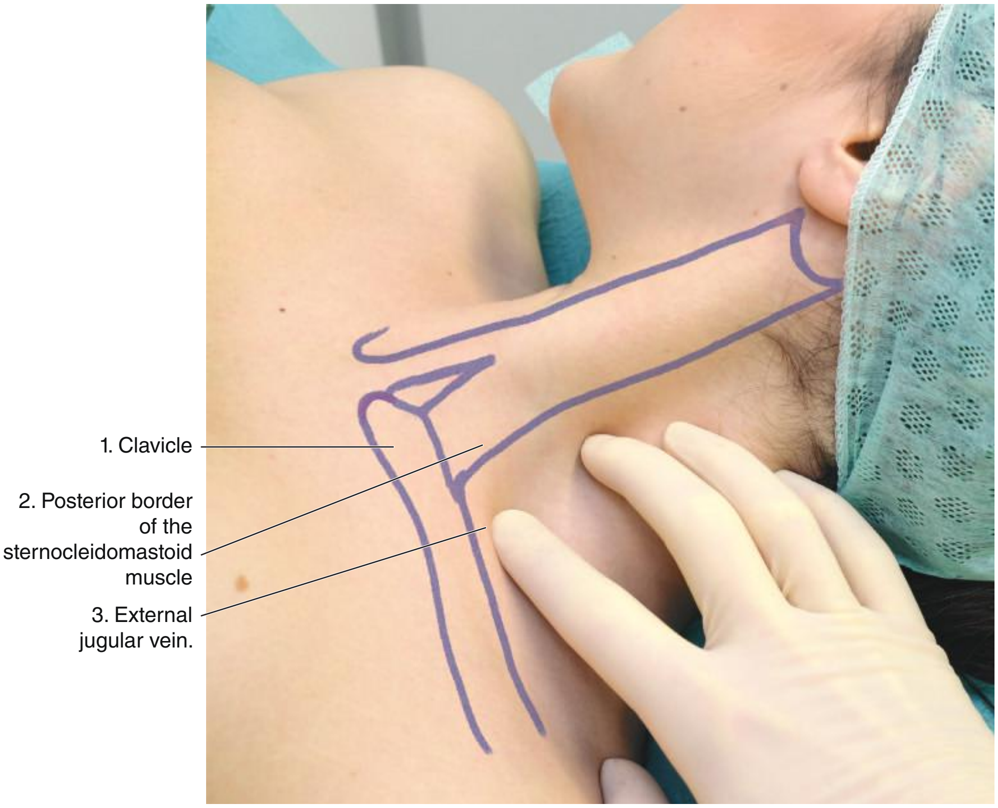

FIGURE 80B–8. Landmarks for low interscalene approach to brachial plexus block: (1) Clavicle. (2) Posterior border of the sternocleidomastoid muscle. (3) External jugular vein. The palpating fingers are positioned in the scalene "groove" between anterior and middle scalene muscles.

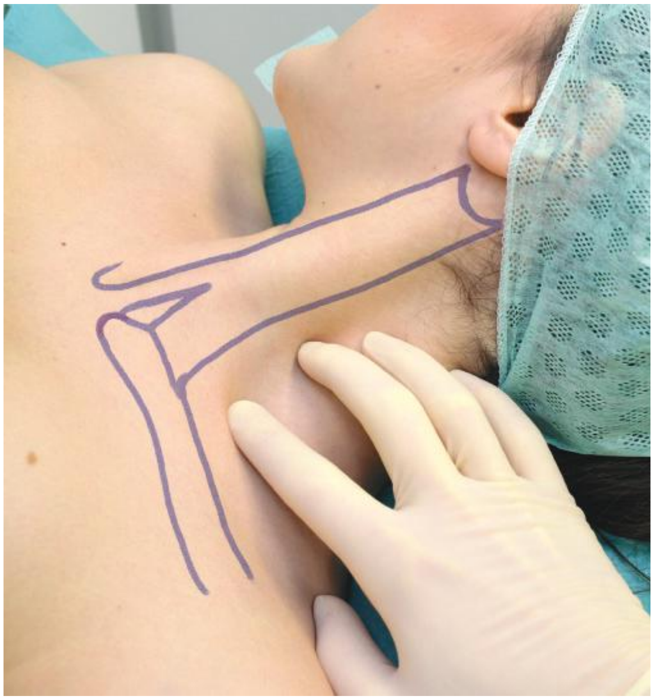

FIGURE 80B–9. Fingers of the palpating hand are positioned in front of the external jugular vein and in the interscalene groove made up of anterior and middle scalene muscles. Interscalene groove is the widest and easiest to palpate in this position.

FIGURE 80B–10. Low interscalene block. Proper angle of the needle direction is medial with a slight caudad angulation.

TABLE 80B–3. Guide to troubleshooting interscalene block.

Response Obtained	Interpretation	Problem	Action
Local twitch of the neck muscles	Direct stimulation of the anterior scalene or sternocleidomastoid muscles	Needle pass is in the wrong plane; usually anterior and medial to the plexus	Withdraw the needle to the skin and reinsert 15 degrees posterior
Needle contacts bone at 1–2 cm depth; no twitches seen	The needle is stopped by the transverse process	The needle is inserted too posterior; the needle contacts anterior tubercles of the transverse process	Withdraw the needle to the skin and reinsert 15 degrees anterior
Twitches of the diaphragm	The result of stimulation of the phrenic nerve	The needle is inserted too anterior and medial	Withdraw the needle and reinsert 15 degrees posterior and lateral
Arterial blood noticed in the tubing	Puncture of the carotid artery (most likely)	The needle insertion and angulation are too anterior	Withdraw the needle and apply pressure for 5 min; reinsert 1–2 cm posterior
Pectoralis muscle twitch	Brachial plexus stimulation (C4–C5)		Accept and inject local anesthetic
Twitch of the scapula	Twitch of the serratus anterior muscle; stimulation of the thoracodorsal nerve	Needle position is posterior/deep to the brachial plexus	Withdraw the needle to the skin, and reinsert the needle anterior
Trapezius muscle twitches	Accessory nerve stimulation	Needle posterior to the brachial plexus	Withdraw the needle and insert more anteriorly
Twitch of pectorals, deltoid, triceps, biceps, forearm, and hand muscles	Stimulation of the brachial plexus	None	Accept and inject local anesthetic

to perform and master, placement of the catheter in the interscalene groove is much more challenging. This is partially due to the shallow position of the brachial plexus and difficulties in stabilizing the needle during catheter advancement. This technique provides excellent analgesia in patients after shoulder, arm, and elbow surgery.[33]

Technique

The patient is positioned in the same position as in the single-injection technique. After local anesthesia, a 5-cm long needle attached to a nerve stimulator (1.0 mA) is inserted at a slightly caudal angle and advanced until the brachial plexus twitch is elicited at 0.2–0.5 mA (Figure 80B–11). While paying meticulous attention to the position of the needle, the catheter is inserted some 3 cm beyond the tip of the needle and secured to the skin.

The catheter must be carefully checked for intravascular placement before administering large volumes or an infusion of local anesthetics. Before initiating the infusion of local anesthetic, the catheter is first checked for patency, and intravascular placement is ruled out by administering a small volume (2–3 mL of 1% lidocaine with epinephrine 1:300,000). The management of the continuous infusion of local anesthetic is discussed in the section about intraoperative management below.

FIGURE 80B-11. Continuous interscalene block. Note the low angle of needle insertion, which is necessary to facilitate insertion of the catheter.

Clinical Pearl

- The following maneuvers help to localize the interscalene groove:
  1. Ask the patient to turn the head away from the side to be blocked and then to lift the head off the table. This maneuver tenses the sternocleidomastoid muscle and helps to identify the lateral border of the clavicular head of the sternocleidomastoid muscle.
  2. In some patients, the clavicular head of the sternocleidomastoid and anterior scalene muscles are packed together. The practitioner can ask the to sniff as the practitioner places the fingers firmly on the muscles. The anterior and middle scalene muscles contract during this maneuver, making their palpation and recognition of the scalene space easier.

INTRAOPERATIVE MANAGEMENT OF AN INTERSCALENE BLOCK DURING SHOULDER SURGERY

Sedation is almost always useful to improve patient comfort and satisfaction. This is in keeping with the preference of most surgeons for their patients to be 'asleep' during surgery, as is also the preference of most patients.

Drugs most commonly used to accomplish this are propofol, midazolam, and an intravenous opioid. A face mask with oxygen (4–6 L/min) should be routinely applied. Patients should be kept warm by using forced air or warm blankets. The onset of shivering can turn a successful regional anesthetic into a significant intraoperative challenge.

Intraoperative use of pneumatic equipment close to the patient's ear can result in noise levels over 100 dB. A significant amount of sedation is needed to mask this noise.[23] The use of earplugs, headphones with or without music, or blankets to protect the patient's ears can make a substantial difference in their comfort, and reduce the amount of sedative drugs required. Hyperhydration should be avoided because the patients are typically not given a urinary catheter, and the sensation of a full bladder can cause considerable discomfort for the patient. It is a good idea to ask patients to empty their bladder before administering any drugs.

Choice of Local Anesthetic

For single-shot techniques, a variety of local anesthetics can be used (Table 80B–4), depending on the desired duration and density of blockade. The typical volume of local anesthetic used for interscalene blocks is 15–20 mL of ropivacaine 0.5% or 0.75%.[25,26,27] Clonidine,[28] but not opioids,[29,30] can prolong the duration of both anesthesia and analgesia with intermediate-acting local anesthetics.[28] The addition of epinephrine also prolongs the duration of action of most local anesthetics.[31]

Continuous infusion of local anesthetics through an interscalene catheter compared with traditional patient-controlled analgesia (PCA) with opioids provides significantly better control of pain, with a lower incidence of side effects and greater patient satisfaction.[34,35] Catheters are typically left in place for 2–3 days. A typical regimen for continuous infusion would be the use of ropivacaine 0.2% at a rate of 5 mL/h with a 5 mL q60min patient controlled bolus.[36-39]

TABLE 80B–4. Local anesthetic mixtures used for single-injection techniques.

	Onset (min)	Anesthesia (h)	Analgesia (h)
3% 2-Chloroprocaine (+ HCO_3 + epinephine)	5–10	1.5	2
1.5% Mepivacaine (+ HCO_3)	10–20	2–3	2–4
1.5% Mepivacaine (+ HCO_3 + epinephrine)	5–15	2.5–4	3–6
2% Lidocaine (+ HCO_3)	10–20	2.5–3	2–5
2% Lidocaine (+ HCO_3 + epinephrine)	5–15	3–6	5–8
0.5% Ropivacaine	15–20	6–8	8–12
0.75% Ropivacaine	5–15	8–10	12–18
0.5% Bupivacaine (+ epinephrine)	20–30	8–10	16–18

SIDE EFFECTS AND COMPLICATIONS AND HOW TO AVOID THEM

Complications associated with the different techniques of interscalene block are summarized in (Table 80B–5). The most common side effects encountered after interscalene block

TABLE 80B–5. Complications of interscalene block according to approach.

	Winnie	Posterior	Modified Lateral
Spinal injection	++	++	–
Epidural injection	++	++	–
Vertebral artery injection	+	(+)	–
Intravenous injection	+	+	+
Pneumothorax	+	+	+
Discomfort	(+)	++	(+)
Conditions for catheter placement	–	+	++

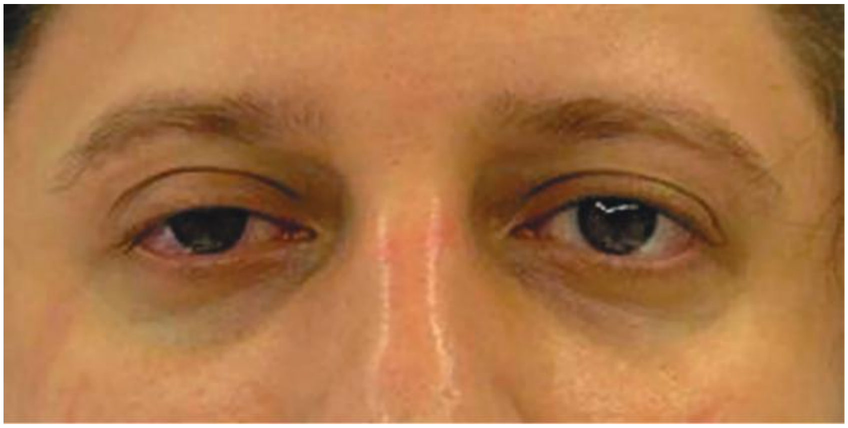

FIGURE 80B-12. Horner syndrome is common after interscalene block and consists of ptosis, myosis, and enophthalmia.

are hoarseness (10%–20%) due to the blockade of the recurrent laryngeal nerve, which occurs more frequently on the right side. Horner syndrome is characterized by ptosis, myosis, and enopthalmia due to the diffusion of the local anesthetic solution on the sympathetic cervical ganglion chain (including the stellatum ganglion) (Figure 80B–12). The reason for this complication is the spread of the local anesthetic around the anterior scalene muscle behind the carotid artery and internal jugular vein toward the longus colli muscle (Figure 80B–13). This results in blockade of the cervical ganglion (Horner syndrome) and phrenic nerve, which are located in this area. In addition, the superior laryngeal nerve (Figure 80B–14) can be affected. It occurs in 40%–60% of patients and resolves with resolution of the block; patient reassurance is all that is needed for management. Ipsilateral hemidiaphragmatic paresis is a common finding and may be present in nearly 100% of patients[40] (Figure 80B–15). However, this rarely presents a problem clinically, and most patients are not aware of it. The paradoxical Bezold-Jarisch reflex (occurrence of bradycardia and hypotension; incidence 15%–30%), can occur when the patient is placed in the sitting position for shoulder surgery and can be prevented by avoiding hypovolemia. It is easily treated by atropine and ephedrine administration.

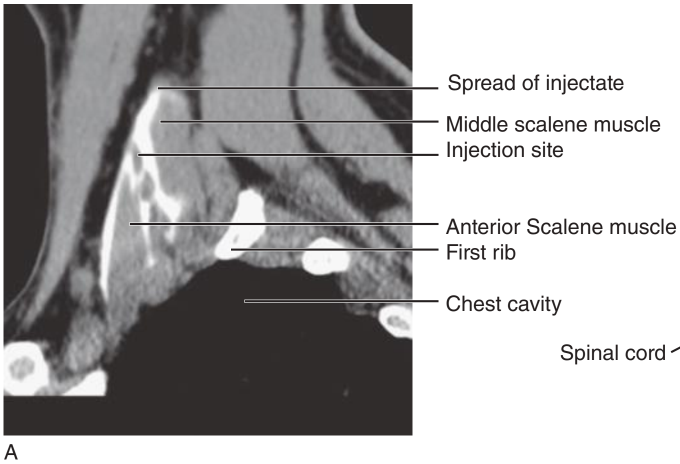
Early complications (soon after block administration), such as epidural, spinal, or intravascular injection are primarily related to the approach chosen (see Table 80A–5). Late complications include neuropathy, mechanical plexus injury, and infection.

Nerve injuries are a well-recognized complication of anesthesia, although nerve injury directly attributable to interscalene block is extremely rare.[41,42]

Factors related to patient position, such as the use of shoulder braces and the head position, malposition of the arms, and sustained neck extension may increase the risk of injury.[42] Little data are available on the rate of complications related to the use of the continuous interscalene catheters.[43,44] Table 80B–6 lists reported complications of interscalene blocks and suggestions on how to avoid them.

SUMMARY

Interscalene nerve block is one of the most clinically applicable nerve block techniques. With proper training, equipment, and monitoring precautions the technique results in a predictable success rate, excellent anesthesia, and superb postoperative analgesia.



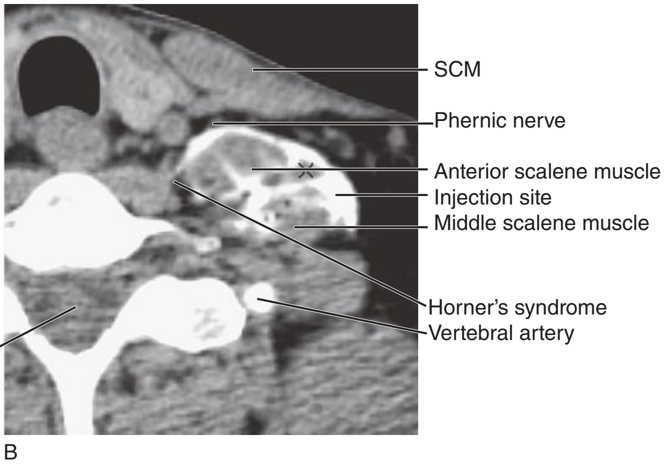


FIGURE 80B–13. Spread of the solution after injection into interscalane space. The contrast is seen in the scalene space around brachial plexus as well as dispersing underneath cervical fascia over anterior and middle scalene muscles. This spread helps explain the common occurrence of phrenic block and Horner's syndrome after ISBPB.

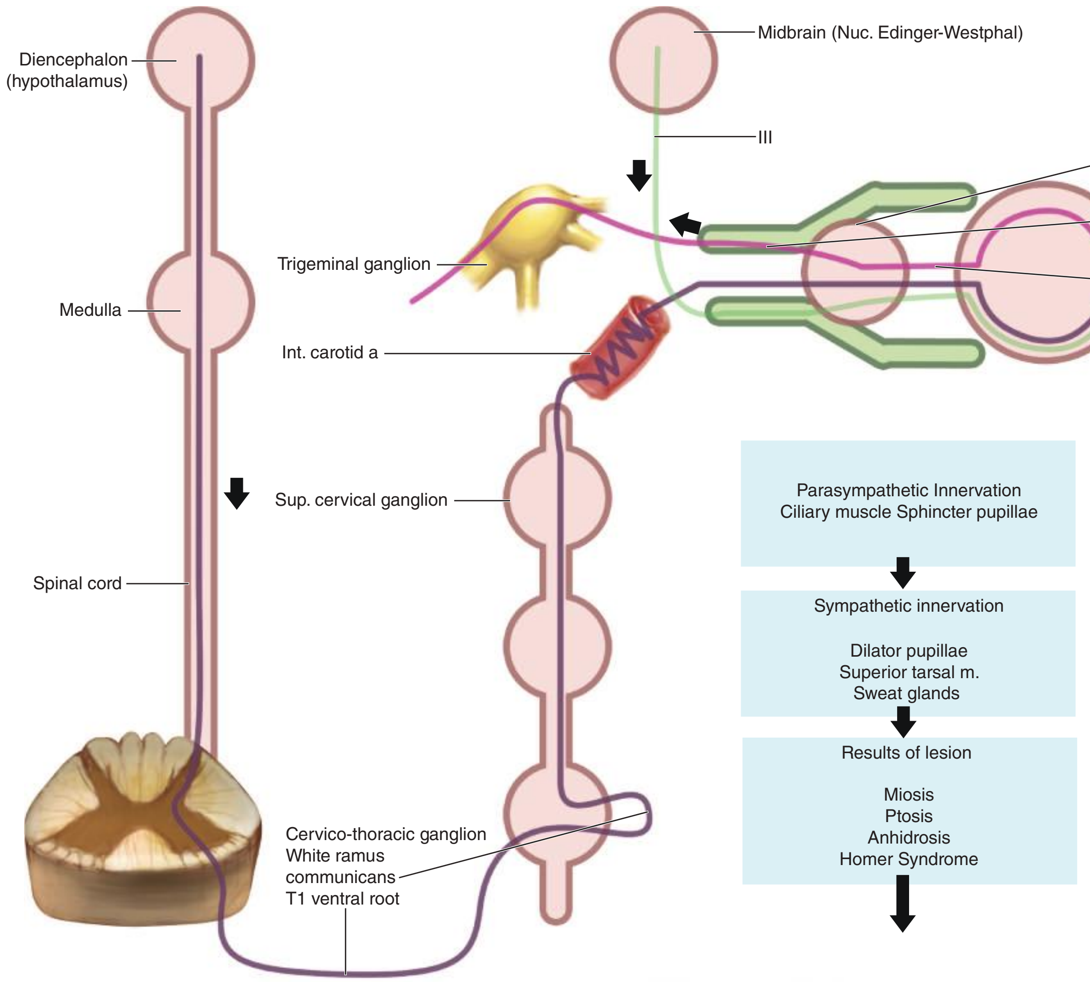

FIGURE 80B–14. Horner syndrome results from interruption of the sympathetic pathway anywhere from the hypothalamus (diencephalon) to the eye.

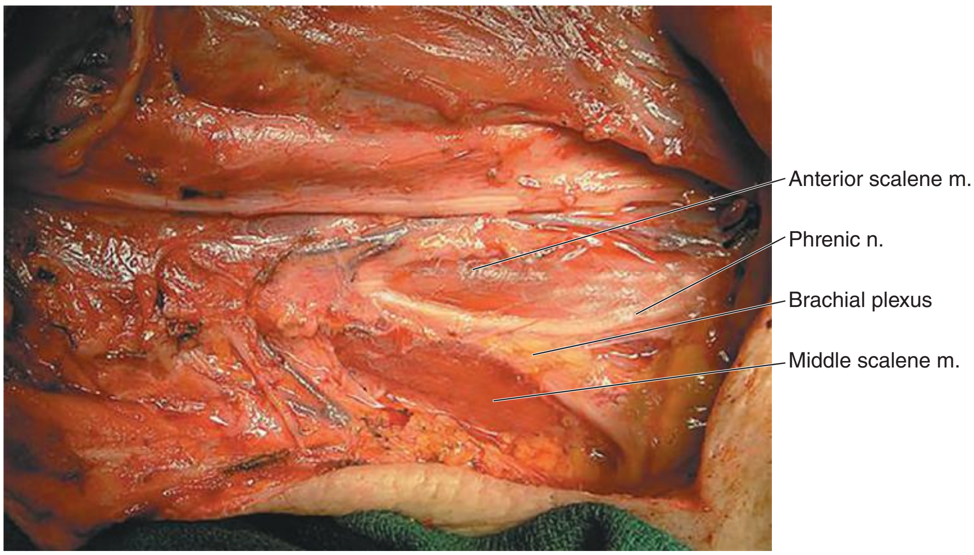

FIGURE 80B–15. Neck dissection reveals the relationship of the phrenic nerve, which leaves the brachial plexus anteriorly, and the rest of the brachial plexus, which remains sandwiched between the anterior and middle scalene muscles.

TABLE 80B–6. Complications and how to avoid them.

Infection	• A strict aseptic technique is used
Hematoma	• Avoid multiple needle insertions, particularly in anticoagulated patients • Apply steady pressure for 5 min when carotid artery is inadvertently punctured • Use a smaller gauge needle to localize the brachial plexus in patients with difficult anatomy • In the absence of spontaneous bleeding, the use of anticoagulant therapy should not be regarded as a contraindication for this block
Vascular puncture	• Vascular puncture is not common with this technique • Apply steady pressure for 5 min when the carotid artery is punctured
Local anesthetic toxicity	• Systemic toxicity due to absorption of local anesthetic after interscalene block is rare • Systemic toxicity most commonly occurs during or shortly after injection of local anesthetic; this is most commonly caused by an inadvertent intravascular injection or channeling of forcefully injected local anesthetic into small veins or lymphatic channels cut during needle manipulation • Large volumes of long-acting anesthetic should be reconsidered in older and frail patients. • Careful and frequent aspiration should be performed during the injection • Avoid forceful, fast injection of local anesthetic
Nerve injury	• Never inject local anesthetic when abnormal pressure on injection is encountered (opening pressure >15 psi) • Local anesthetic should never be injected when patient complains of severe pain or exhibits a withdrawal reaction on injection
Total spinal anesthesia	• When stimulation is obtained with current intensity of <0.2 mA, the needle should be pulled back to obtain the same response with current >0.2 mA before injecting local anesthetic to avoid injection into the dural sleeves and the consequent epidural or spinal spread • Never inject local anesthetic when abnormal pressure on injection is encountered
Horner syndrome	• Occurrence of ipsilateral ptosis, hyperemia of the conjunctiva, and nasal congestion is common, and it is dependent on the site of injection (less common with the low interscalene approach) and total volume of local anesthetic injected; patients should be instructed on the occurrence of this syndrome and reassured about its benign nature
Diaphragmatic paralysis	• Commonly present; avoid interscalene blockade or a large volume of local anesthetic in patients

CHAPTER 80C

Supraclavicular Brachial Plexus Block

Carlo D. Franco, Bram Byloos, and Ilvana Hasanbegovic

INTRODUCTION

The supraclavicular block is one of several techniques used to anesthetize the brachial plexus. The block is performed at the level of the brachial plexus trunks where almost the entire sensory, motor, and sympathetic innervation of the upper extremity is carried in just three nerve structures confined to a very small surface area. Consequently, this technique typically provides a predictable, dense block with rapid onset.[1–3] In 1911, Georg Hirschel described a surgical approach to the brachial plexus in the axilla. A few months later, Diedrich Kulenkampff, in Germany, performed the first percutaneous supraclavicular approach, reportedly on himself. The technique was published in 1928 by Kulenkampff and Persky.[4] As they described it, the technique was performed with the patient in the sitting position ("a regular chair will suffice") or in the supine position with a pillow between the shoulders. The operator sat on a stool at the side of the patient. The needle was inserted above the midpoint of the clavicle where the pulse of the subclavian artery could be felt and was directed medially toward the spinous process of T2 or T3. Kulenkampff 's familiarity with brachial plexus anatomy allowed him to recognize that "the best way to reach the trunks was in the neighborhood of the subclavian artery over the first rib." His technique was also simple: "all the branches of the plexus could be anesthetized through one injection." These two assertions are still valid today. Unfortunately. his advice on needle direction carried an inherently high risk of pneumothorax. The popularity of the supraclavicular block remained unrivaled during the entire first half of the 20th century until well after World War II. During this time the technique underwent several modifications, most of them intended to reduce the risk of pneumothorax.[1,5–8]

The introduction of axillary techniques by Accardo and Adriani[9] in 1949 and by Burnham[10] in 1958 marked the beginning of the decline in enthusiasm for the supraclavicular block. The axillary block was particularly popularized after a publication in the journal *Anesthesiology* by Rudolph De Jong in 1961[11] The paper was based on cadaver dissections and included the now well-known calculation of 42 mL as the volume needed to fill a cylinder 6 cm long (axillary sheath); according to De Jong, this dose "should be sufficient to completely bathe all branches of the brachial plexus." The article was also critical of the supraclavicular approach. Coincidentally, the same journal published a paper by Brand and Papper,[12] who compared axillary and supraclavicular techniques and warned of the 6.1% rate of pneumothorax frequently quoted for supraclavicular block.

More modern modifications of supraclavicular block include Alon Winnie and Vincent Collins's subclavian perivascular technique[13] and the "plumb-bob" technique of Brown and collaborators.[14] The former is more a concept than a radically different technique, stating that plexus anesthesia is performed around a main vessel (perivascular) and within the confines of a sheath. Otherwise, their technique is similar to Murphey's,[7] who in 1944, described a single-injection technique performed just lateral to the anterior scalene muscle directing the needle caudad. The plumb-bob technique, published in 1993, is based on cadaver dissections and magnetic resonance imaging performed on volunteers. In this technique, the needle is introduced above the clavicle, just lateral to the sternocleidomastoid (SCM) muscle and advanced perpendicularly to the plexus in an anteroposterior direction. If the needle misses the plexus, the pleural dome could be penetrated.

Many investigators appear to perceive the supraclavicular block as being complex and associated with a significant risk of pneumothorax. However, its rapid onset, dense and predictable anesthesia, and high success rate make it a very useful approach, which, according to Brown and collaborators,[14] is "unrivaled" by other techniques. Indeed, in our practice, the supraclavicular approach is the cornerstone of distal upper extremity regional anesthesia, and we use it extensively with a very low rate of complications.[15]

INDICATIONS

The supraclavicular block provides anesthesia and analgesia to the upper extremity below the shoulder. It is an excellent choice for elbow and hand surgery.

CONTRAINDICATIONS

General contraindications to the use of this technique are those that apply to any regional block, such as local infection, significant coagulation abnormalities, and inability to cooperate during block placement or surgery. Like interscalene block, supraclavicular block is not used bilaterally or in patients with respiratory compromise because of the potential risk of pneumothorax or phrenic nerve block.

ANATOMY OF THE BRACHIAL PLEXUS ABOVE THE CLAVICLE

The brachial plexus is formed by five roots originating from the ventral divisions of C5 through T1. The roots lie between the anterior and middle scalene muscles (Figure 80C–1). The anterior scalene muscle originates from the anterior tubercles of the transverse processes of C3 through C6 and inserts on the scalene tubercle of the upper surface of the first rib. The middle scalene muscle originates in the posterior tubercles of the transverse processes of C2 through C7 and inserts on the upper surface of the first rib behind the subclavian groove. The five roots converge toward one another to form three trunks—upper, middle, and lower—which are stacked one on top of the other as they traverse the triangular interscalene groove, formed between the anterior and middle scalene muscles.

This space becomes wider in the anteroposterior plane as the muscles approach their insertion on the first rib. The subclavian artery accompanies the brachial plexus in the interscalene groove anterior to the lower trunk. Although the roots of the plexus are long, the trunks are almost as short as they are wide, soon giving rise to anterior and posterior divisions as they reach the clavicle. Figure 81C–1 shows the clinical anatomy of the brachial plexus and surrounding structures in the supraclavicular area.

The pleura can potentially be injured in two places during a supraclavicular block; the pleural dome and the first intercostal space. The pleural dome is the apex of the parietal pleura, circumscribed by the first rib. The first rib is a short, broad, and flattened bone shaped like the letter C. It's medial border forms the outer boundary of the pleural dome. The anterior scalene, by inserting in this border of the first rib, comes in contact medially with the pleural dome. There is no pleural dome lateral to the anterior scalene muscle. The first intercostal space on the other hand, is for the most part infraclavicular (see Figure 81C–1) and consequently should not be reached when a supraclavicular block is properly performed.

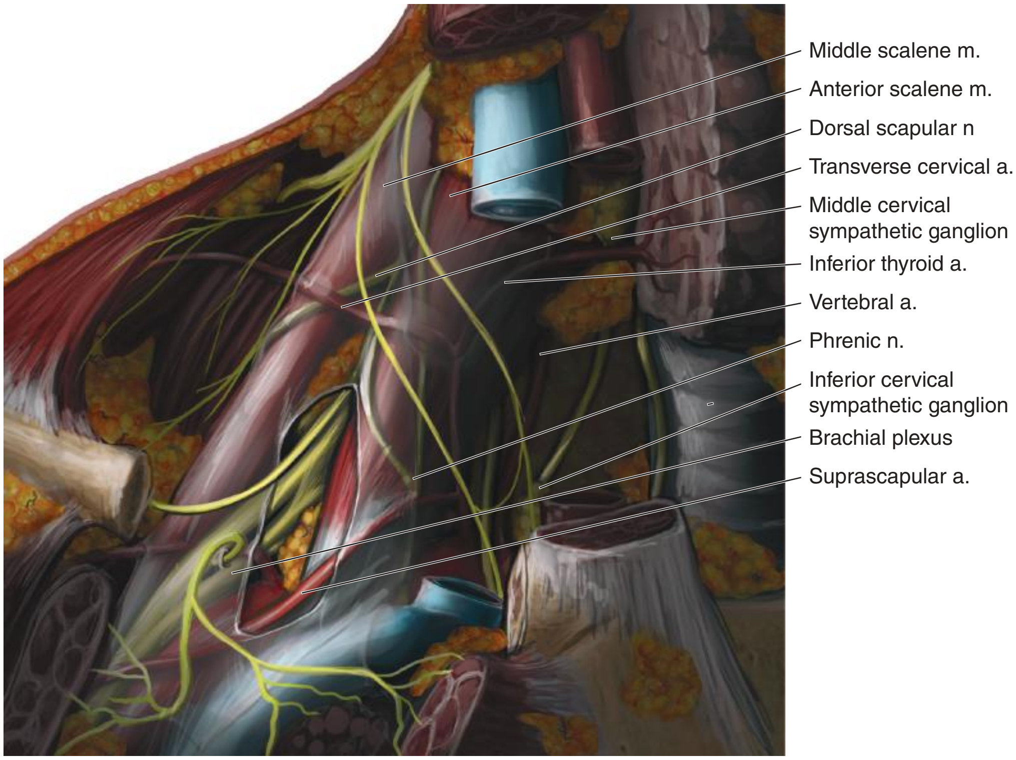

FIGURE 80C–1. Anatomy of the brachial plexus at the low interscalene space and supraclavicular area.

Clinical Pearls

- With the shoulder pulled down, the three trunks of the brachial plexus are located above the clavicle; therefore, the block needle should never need to reach below the clavicle during a supraclavicular block.
- The first intercostal space is located below the clavicle, thus its penetration is unlikely during a properly performed supraclavicular block.
- The needle should never cross the parasagittal plane medial to the anterior scalene muscle because of the risk of pneumothorax.
- The SCM muscle inserts on the medial third of the clavicle, and the trapezius muscle on the lateral third of it, leaving the middle third for the neurovascular bundle. These proportions are maintained regardless of patient's size.
- Because the brachial plexus moves from medial to lateral as it descends, the higher in the supraclavicular area the more medial (closer to the SCM) the plexus is located.

LANDMARKS

The technique described in this chapter combines the simplicity of the original single-injection Kulenkampff technique with important anatomic principles, which should make the technique safer than the original description. The main landmarks for this block are the lateral insertion of the SCM muscle in the clavicle, the clavicle itself, and the patient's midline. These three landmarks are easily identifiable in the majority of patients.

EQUIPMENT

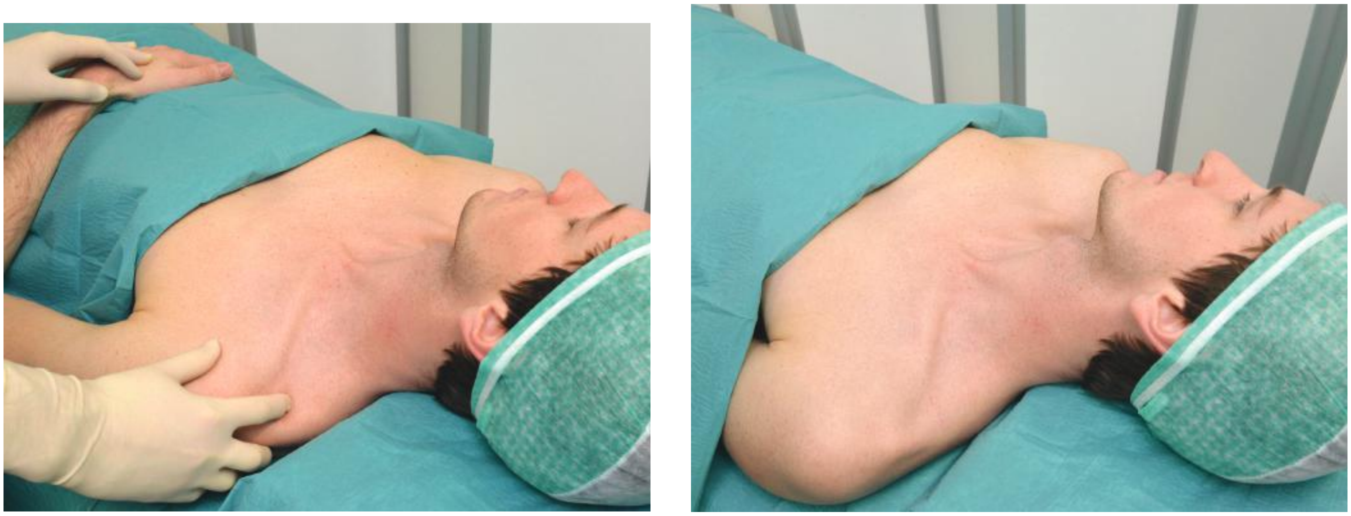
- Gloves
- Antiseptic solution for skin disinfection
- Marking pen
- Sterile gauze
- Two 20-mL syringes for local anesthetic solution
- One 1-mL syringe with a 25-gauge needle for skin wheal
- One 5-cm, short-beveled, 22-gauge insulated needle
- Surface electrode
- Nerve stimulator
- Injection pressure monitor

TECHNIQUE

Ideally, the block is performed in a room dedicated to regional anesthesia with American Society of Anesthesiologists (ASA) standard monitors, an oxygen source, suctioning, and resuscitation equipment and drugs including lipid emulsion. A contingency plan for emergencies must be in place to deal safely and expeditiously with any emergency that might arise.

If not contraindicated, this block is best performed after premedication (e.g., midazolam 1 mg plus fentanyl 50 mcg IV for the average adult). In young and healthy patients, this dose can be repeated as necessary. The patient is best kept sedated but cooperative and able to relate pain or any undue discomfort.

The block is performed with the patient in a semisitting position with the head rotated to the opposite side as shown in Figure 80C–2A. The semisitting position is more comfortable than the supine position both for the patient and the operator. Because patient positioning is very important in regional anesthesia, the operator should not try to recognize any landmarks until the patient has adopted the desired position. The patient is asked to lower the shoulder and flex the elbow, so the forearm rests on the lap. The wrist is supinated so the palm of the hand faces the patient's face, as shown in Figure 80C–2B. This maneuver allows for detection of any subtle finger movement produced by nerve stimulation. If the patient cannot supinate their wrist, a roll is placed under it so the fingers are free to move.



A B

FIGURE 80C–2. A: Patient positioning. The patient lies in a semisitting or supine position with the head turned away from the side to be blocked. **B**: The shoulder is down, the elbow is flexed, and the palm of the hand rests on the patient's lap while it is turned toward his face.

The operator usually stands on the side to be blocked, so for a left-side block, the palpation is done with the left hand and the needle is manipulated with the right (see Figure 80C–2B).

For a right-side block, the operator manipulates the needle with the left hand and palpates with the right. However, the operator may choose to manipulate the needle with their preferred hand regardless of the block side.

Point of Needle Entrance

With the patient in the described semisitting position and the shoulder down, the lateral (posterior) border of the SCM muscle is identified and followed distally to the point where it meets the clavicle. This particular point is marked on the skin over the clavicle, as shown in Figure 80C–3. The lateral border of the SCM is usually clearly visible at the level where the external jugular vein crosses it. From this level, the border can be traced caudally to the point where it meets the clavicle. A parasagittal line (parallel to the midline) is drawn at this level to recognize an area medial to it that is at risk for pneumothorax. The point of needle entrance is found lateral to this parasagittal plane, separated by a distance we call "margin of safety." This distance is about 1 in. (2.5 cm) lateral to the insertion of the SCM on the clavicle, as shown in Figure 80C–4. The margin of safety can be alternatively established using a distance equal to the width of the clavicular head of the SCM at its insertion on the clavicle.[16]

The palpating index finger is placed at this site as shown in Figure 80C–5. We customarily draw two arrows at this location pointing to each other. The proximal arrow, above the finger, is used to localize the needle entrance point, the distal one shows the direction of the needle path.

The needle is inserted immediately cephalad to the palpating finger and advanced first perpendicularly to the skin for 2–5 mm (depending on the amount of the patient's subcutaneous tissue) and then turned caudally under the palpating finger to advance it in a direction that is parallel to the midline, as shown in Figure 80C–5.

FIGURE 80C–4. Margin of safety. A distance of approximately 1 in. (2.5 cm) is measured laterally from the SCM, to assure the needle placement away from the pleural dome.

The block should take place above the clavicle, under the palpating finger. As a goal we like to elicit an isolated muscle twitch in all fingers either in flexion or extension to confirm needle proximity to the lower trunks of the plexus. Any other response carries a significantly lower success rate.[17]

If repositioning of the needle is necessary, the needle is withdrawn and the angle is adjusted in the anteroposterior plane, but always parallel to the midline and never directed medially.

Nerve Stimulator Settings

The nerve stimulator is initially set to a current intensity of around 0.8 mA and a pulse width of 100 μs. Once the desired response is obtained (i.e., a muscle twitch of the fingers) injection is initiated without reducing the nerve stimulator current.

FIGURE 80C–3. Landmarks. The lateral insertion of the SCM to the clavicle is shown underneath the palpating finger.

FIGURE 80C–5. Point of needle entrance and direction. The point of needle entrance is located just cephalad to the palpating finger and one fingerbreadth above the clavicle. The needle is first introduced perpendicular to the skin and is then turned and advanced parallel to the midline.

This is a unique characteristic of the supraclavicular block. One study has shown that the onset, duration, and success rate with a supraclavicular block is unaffected by reducing the nerve stimulator to 0.9 mA or less.[18] Supraclavicular and lumbar plexus blocks are the only peripheral nerve blocks in which injecting at a higher current than 0.5 mA is recommended.

Clinical Pearls

- The lateral border of the SCM muscle follows a straight line from the mastoid to the clavicle.
- The needle is inserted in a direction that is parallel to the midline.
- Depending on the patient's weight, the palpating finger needs to exert different amounts of pressure on the deeper tissues. This maneuver helps bring the plexus closer to the skin and makes the trajectory of the needle shorter.
- The needle should never be inserted deeper than 1 in. (2.5 cm) if a twitch from the brachial plexus is not present.
- Because the trunks are contiguous, elicited twitches from one trunk follow the other without interruption. If the twitches instead disappear before reaching the lower trunk, the needle is withdrawn to the point of the previous twitch and advanced with a slight change in the anteroposterior angle of insertion.
- The margin of safety of about 1 in. (2.5 cm) lateral to the insertion of the SCM on the clavicle provides a safe distance lateral to the outer boundary of the pleural dome for the needle to travel. Because of the steep downward direction of the trunks, increasing this distance laterally may prevent the needle from contacting the plexus above the clavicle or miss the short trunks altogether.
- In the supraclavicular block, an initial nerve stimulator current of 0.8 mA is high enough to produce guidance into the plexus, but low enough to assure sufficient proximity for successful blockade.
- The risk of intraneural injection is minimized by using low injection pressures and meticulous technique.
- The injection is performed slowly with frequent aspirations while carefully observing the patient.
- If pain or abnormal pressure is felt at any point during injection, the needle should be withdrawn 1–2 mm, after which a new assessment is made.

CONTINUOUS TECHNIQUE

Traditionally, the supraclavicular technique has not been considered to be an optimal choice for placement of catheters. The great mobility of the neck at this location carries a risk for catheter dislodgement. Tunneling the catheter to the infraclavicular level could help to make the catheter more stable; however; little data are currently available on this topic.

LOCAL ANESTHETIC CHOICES FOR SINGLE-SHOT AND CATHETER TECHNIQUES

Most of upper extremity surgeries performed under regional anesthesia last 1–3 hours. Consequently, we most commonly use 30 mL of 1.5% mepivacaine with 1:200,000 epinephrine, which provides about 3–4 hours of anesthesia. The same anesthetic solution without epinephrine provides about 2–3 hours of anesthesia. To speed block onset, 2 mL of 8.4% sodium bicarbonate may be added to every 20 mL of mepivacaine solution. Solutions of levobupivacaine, ropivacaine, or bupivacaine provide longer acting anesthesia (5–7 hours) when required. Recent studies have suggested that the use of ultrasound guidance may reduce the volume needed for a successful block.[19] For continuous techniques, a bolus dose of about 10–15 mL of local anesthetic solution can be given, followed by an infusion rate of 8–10 mL/h. A solution of 0.2% ropivacaine can be used for this purpose. A patient-controlled bolus of 3–5 Ll every 30–60 minutes can be added, with the basal infusion decreased to around 5 mL/h. Breakthrough pain must be treated with a bolus of local anesthetic because simply increasing the rate of infusion could take several hours to have an effect.

PERIOPERATIVE MANAGEMENT

The patient that receives single-shot blocks can undergo surgery under intravenous sedation titrated to the patient's comfort. The sedation requirements vary from patient to patient and range from small intermittent boluses of midazolam or fentanyl, to a propofol infusion at 25–50 mcg/kg/min, to light general anesthesia.

COMPLICATIONS

Common side effects associated with this technique include phrenic nerve block with diaphragmatic paralysis and sympathetic nerve block with development of Horner syndrome. These are typically self-limiting and do not require intervention. Phrenic nerve block reportedly occurs about 50% of the time, although this may be reduced by the use of ultrasound guidance.[20,21]

Intravascular injection with systemic local anesthetic toxicity and hematoma formation can also occur. To reduce the risk, high level of vigilance is needed due to the risch vascularity of the supraclavicular region.[22] In the case of the supraclavicular block, this can be due to puncture of the subclavian, transverse cervical or dorsal scapular arteries, all of which are located near the plexus at this level.

Pneumothorax occurs as often as 6.1%, which was an incidence reported in 1961 that compared 230 consecutive supraclavicular blocks with 246 consecutive axillary blocks.[12] However, the comparison was neither blinded nor randomized, and the study used several different techniques.[7] In contrast, this complication is rare in the modern literature.[15]

It is frequently mentioned that the pneumothorax complicating a supraclavicular block has a delayed onset.[23,24] Although such cases have been published in the literature, most of the pneumothoraces reported have been diagnosed within a few hours of the procedure and before the patient's discharge.[1,25] Based on the available literature, the pneumothorax associated with supraclavicular block is uncommon, typically small, and it presents within a few hours following the procedure. In some instances its presentation can be delayed up to 12 hours.

SUMMARY

Supraclavicular block is a reliable, rapid-onset approach to brachial plexus anesthesia. The anatomy of the brachial plexus, with its three trunks confined to a much-reduced surface area, affords a high success rate for achieving anesthesia in the upper extremity below the shoulder. A combination of good anatomic knowledge, simple landmarks, and meticulous technique are paramount for consistent success rate and limiting its potential for complications.

CHAPTER 80D

Infraclavicular Brachial Plexus Block

Laura Clark

INTRODUCTION

The infraclavicular block provides a block of the arm below the shoulder. Unlike the axillary approach, it can be performed without abduction of the arm, making it useful for patients with limited shoulder mobility. It is amenable to continuous catheter placement by being more accessible and more comfortable for a catheter than the axilla.

Georg Hirschel, in 1911, is considered to have carried out the first percutaneous axillary block because he approached the plexus from the axilla.[1] His goal was to place the local anesthetic on top of the first rib via the axilla. He discovered after his own dissections of the plexus the reason for incompleteness of the axillary block, and was the first to describe that the axillary and musculocutaneous nerves separated from the plexus much higher than in the axilla. However, the needles in the early 1900s were not long enough to reach this area to block those nerves.[2] To remedy this problem in 1911, Diedrich Kulenkampff's supraclavicular description was soon to follow.[2] He felt his technique was safer and more accurate than Hirschel's, but after initial success, the reports of complications of pneumothorax ensued.

In 1914, Bazy[3] described injecting below the clavicle just medial to the coracoid process along a line connecting with the Chassaignac tubercle. The needle trajectory was pointed away from the axilla, close to the clavicle, and was felt to present little chance of pleural damage. Several modifications occurred in the ensuing 8 years. Babitszky said that "to discuss the anatomical relationship and the technique more fully would be superfluous, as it is customary to familiarize oneself with the anatomy of the field in question on the cadaver any time one tends to use an unfamiliar technique."[2] Gaston Labat, in 1922, essentially redescribed Bazy's technique in his textbook, *Regional Anesthesia*,[5] as did Achille Dogliotti[6] in 1939. However, the technique seemed to fade into obscurity. For instance, infraclavicular block was not included in Daniel Moore's *Regional Block*[7] in 1981 or Michael Cousins and Phillip Bridenbaugh's Neural Blockade in Clinical Anesthesia and Pain Management.[8]

Prithvi Raj[9] is credited with reintroducing the approach in 1973 with modification from the earlier descriptions. He described the initial entry point at the midpoint of the clavicle and directed the needle laterally toward the axilla using a nerve stimulator. His data suggested a virtual absence of risk of pneumothorax with the technique. and a more complete block of musculocutaneous and the ulnar nerves.[9] However, these results were not reproducible in other practitioner's clinical practice.

Kurt Whiffler, in 1981, described what is commonly referred to today as the coracoid block. The injection site was very close to that detailed by Sims,[10] but Whiffler felt that the shoulder should be depressed with the head turned to the opposite side and the arm abducted 45 degrees from the chest wall to make the plexus closer to the coracoid process. To estimate the depth of the plexus one identifies two points. One is the point past the midpoint of the clavicle where the subclavian pulse disappears. The second point is found by determining the highest pulse of the artery in the axilla and placing the thumb of the same hand on the anterior surface of the chest wall that corresponds to that point. Those points are connected, and the needle is then inserted inferior and medial to the coracoid process on that line to the depth that the plexus has been estimated. Whiffler did not use a nerve stimulator because he felt "this simpler approach does not require a nerve stimulator." Incremental injections were used to a total volume of 40 mL, withdrawing the needle 1 cm one to two times.[11]

In 1983, Alon Winnie's book, *Plexus Anesthesia*, describes several infraclavicular approaches including the techniques of Raj (1973), Sims (1977), and Whiffler (1981), although it does not devote a section to infraclavicular block. He states that "none of the infraclavicular techniques appears to offer significant advantages over the more established perivascular techniques …," and documents once again that the sheath can be entered at any level.[12]

The Infraclavicular block gained popularity in the 1990s along with the upsurge of regional anesthesia.

Oivind Klaastad, in 1999, performed a magnetic resonance imaging (MRI) study and determined that if followed exactly as described, the needle was not in close proximity to the cords. In a significant number of cases the cords were caudad and posterior to the target. Furthermore, the needle trajectory's shortest distance to the pleura was only 10 mm, and in one case hit the pleura. Klaastad concluded that a more lateral approach would make it more precise and reduce the risk of complications. This was actually what Raj had found clinically and was suggesting in lectures, but had not published. He had changed the point of needle insertion to be on a line between the pulsation of the subclavian and brachial artery and 2.5 cm from this line, crossing with the inferior border of the clavicle. This is what is commonly referred to as the modified Raj approach.[13]

Four approaches will be described in this chapter: (1) vertical infraclavicular block as described by Kilka and colleagues,[14] (2) the coracoid approach described by Whiffler[11] and modified by Wilson and coworkers,[15] (3) the modified Raj approach,[9] and (4) the lateral and sagittal approach described by Klaastad and associates often used for ultrasound.

INDICATIONS AND CONTRAINDICATIONS

Clinical Pearls

- Distribution of anesthesia consists of the hand, wrist, forearm, elbow, and most of the upper arm.
- Indications are similar to those for axillary block; hand, forearm, elbow, and arteriovenous fistula surgery.
- This approach affords greater applicability due to greater coverage and obviates the need for special arm positioning (abduction).

Indications for infraclavicular block are the same as for axillary blockade but complete anesthesia of the arm is obtained from the lower shoulder to the hand, making it applicable for any surgery up to but not including the shoulder. A tourniquet is well tolerated without supplementation of the intercostobrachial nerve. Bilateral blocks can be carried out without fear of blocking the phrenic nerve. The coracoid process and clavicle landmarks are easily palpable even in obese patients. The technique is also conducive to continuous catheter placement and long-term infusion.

Other than the obligatory contraindications of infection at or near the site or existing coagulopathy, there are no block-specific contraindications to infraclavicular block. Coagulopathy is a relative contraindication and based on the risk-vs-benefit ratio.

FUNCTIONAL ANATOMY

Clinical Pearls

- Block occurs at the level of the cords of the brachial plexus below the clavicle.
- Three cords surround the axillary artery.
- The anatomy of the brachial plexus is complex in this area and variability exists.
- The lateral cord is the most superficial, the posterior cord is encountered next, the medial cord is the deepest and is below the axillary artery.
- The lateral cord and the medial cord each contain half of the median nerve.
- The posterior cord contains all of the radial nerve.
- The musculocutaneous nerve is often outside but very close to the lateral cord.

The pertinent anatomy is illustrated in Figure 80D-1. Divisions exist as the brachial plexus crosses the first rib into the infraclavicular area. They originate from the trunks and divide into anterior and posterior divisions, thus, the origin of the name division. The anterior divisions usually supply flexor muscles (which are most often positioned anterior) and posterior divisions usually supply extensor muscles (which are generally posterior).

The brachial plexus makes most of its major changes in the infraclavicular area in just a few centimeters as it twists and turns from a parallel course in the neck to circumferentially surround the axillary artery in the infraclavicular area and progresses into the axilla as terminal nerves. Mixing of the nerves occurs, and its organization can be quite complex.

Figure 80D–2 shows the course of the brachial plexus from the interscalene to the infraclavicular area. The anatomic terms for the cords are based with the body in anatomic position and relative to its center; this is not how the brachial plexus is encountered clinically. Many textbooks feature two-dimensional rather than three-dimensional diagrams of the plexus in this area, which contributes to the confusion. However, a solid understanding of the three-dimensional organization of the plexus is perhaps the most important factor in its successful blockade.

Divisions, Branches, Cords, and Terminal Nerves

The anterior divisions of the upper (C5 and C6) and middle trunk (C7) unite to form the lateral cord, which lies lateral to the axillary artery and most superficial to the anterior chest. The anterior divisions of the lower trunk (C8 and T1) form the medial cord. It lies medial to the axillary artery and is the deepest from the chest wall. The posterior cord is formed from all of the posterior divisions (C5 through T1) and lies posterior to the artery just under the lateral cord. The cords end in terminal branches that are mixed nerves, which contain both sensory and motor components. They are the musculocutaneous, ulnar, median, axillary, and radial branches.

Other branches also exit the plexus prior to the formation of the terminal nerves. They are not mixed and are unique in that they are either sensory or motor nerves. These nerves are often not addressed but are important because the motor branches can be stimulated during performance of a block and knowing where they originate will help determine where to locate the tip of the needle. Tables 80D–1 and 80D–2 list the branches of the brachial plexus and their innervation.

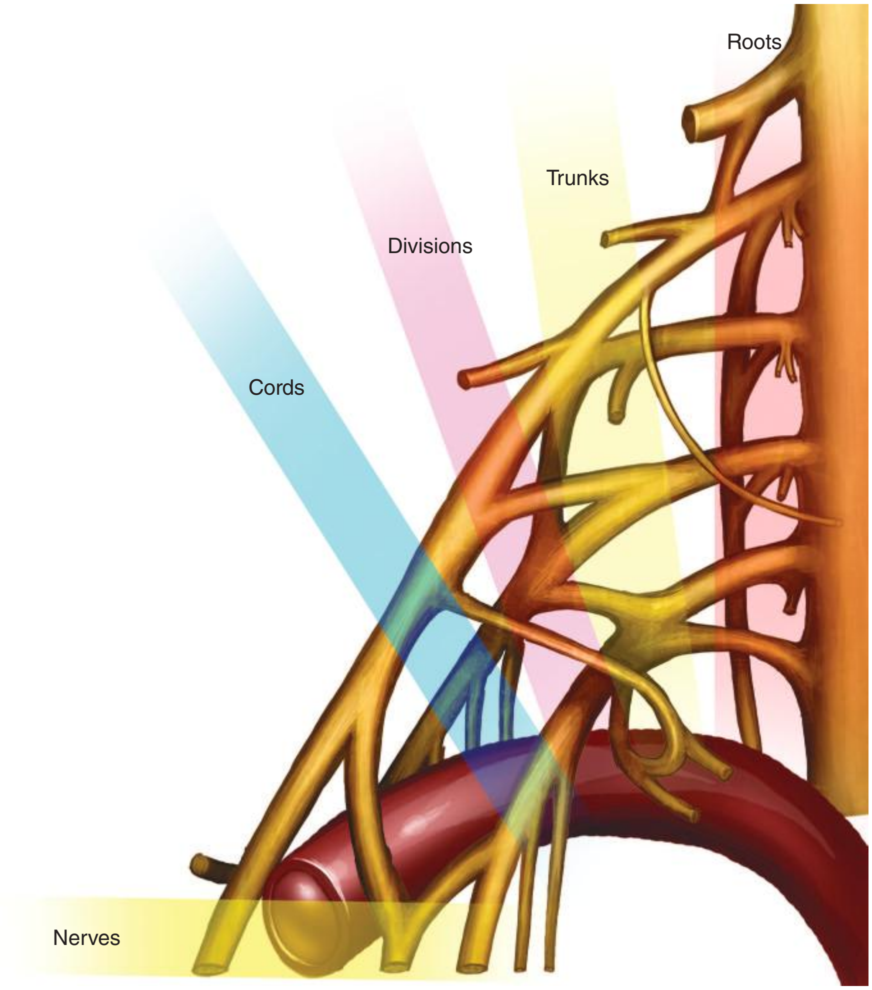

FIGURE 80D–1. Organization of the brachial plexus.

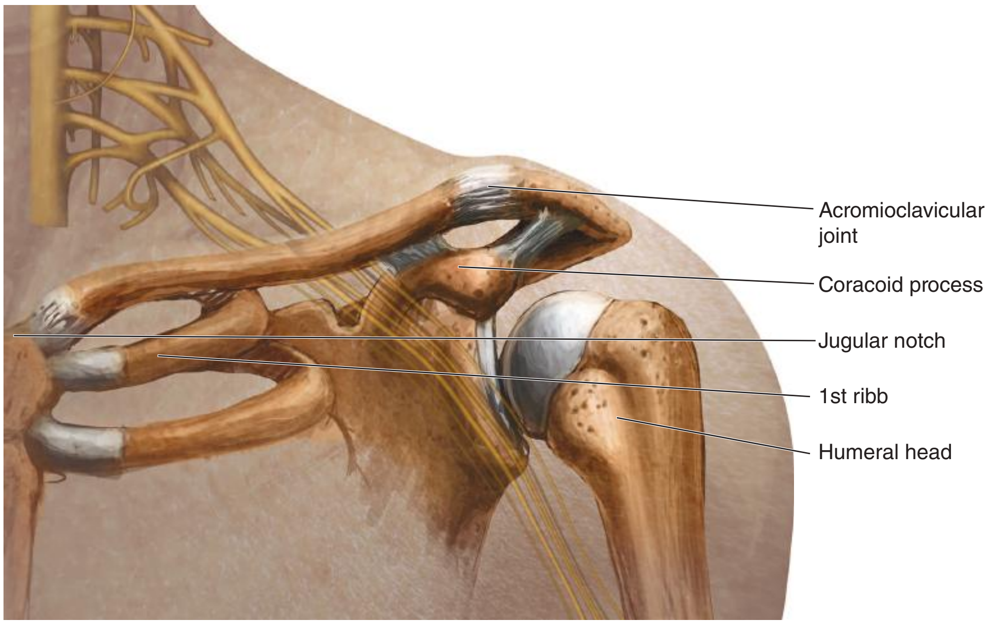

FIGURE 80D–2. Relationship of the brachial plexus, clavicle, and coracoid process.

TABLE 80D– 1. Branches of brachial plexus.

	Motor Innervation	Motion Observed	Sensory Innervation
Lateral			
Lateral pectoral nerve	Pectoralis major	Contraction of pectoralis	
Dorsal scapular nerve	Rhomboid major and minor; levator scapulae	Adducts and rotates shoulder, raises scapula	
Posterior			
Upper subscapular	Subscapularis (superomedial part)	Medial rotation or arm	
Thoracodorsal	Latissimus dorsi	Abduction of arm	
Lower subscapular	Subscapularis (lateral part), teres major	Internal rotation, adduction of shoulder	
Axillary	Deltoid, teres minor	Elevation of upper arm	Skin of upper lateral arm
Medial			
Medial pectoral	Pectoralis minor and major	Contraction of pectoralis	
Medial cutaneous nerve of arm			Skin of medial side or arm
Medial cutaneous nerve of forearm			Skin of medial side or forearm

TABLE 80D–2. Terminal nerves of brachial plexus.

	Motor Innervation	Motion Observed	Sensory Innervation
Lateral			
Musculocutaneous	Coracobrachialis, biceps brachii, brachialis	Flexion of elbow	Skin of lateral side of forearm
Median	Flexor digitorum superficialis—all, pronator teres, flexor carpi radialis palmaris longus	Flexion of first fingers, opposition of thumb	Skin of radial half of palm and palmer side of radial three and a half digits
Posterior			
Radial	Brachioradialis, abductor pollicis longus, extensor muscles of the wrist and fingers	Abduction of thumb, extension of wrist and fingers	Skin of posterior arm, forearm and hand
Medial			
Ulnar	Abductor pollicis interossei intrinsic muscles of the hand	Contraction of the 4th and 5th fingers and thumb abduction	Skin of medial side of wrist and hand and ulner one and a half digits
Median	Flexor digitorum superficialis—all, pronator leres, flexor carpi radialis palmaris longus	Flexion of first $3^1/_2$ fingers, opposition of thumb	Skin of radial half of palm and palmer side of radial three and a half digits

Note: *All branches from the medial cord carry C8 and T1 fibers, and that of the higher spinal segments in the brachial plexus (C5 through C6) tend to innnervate muscles more proximal on the upper extremity, whereas the lower segments (C8, T1) tend to innervate more distal muscles, such as those in the hand (T1). Anatomic variation and the comingling of fibers from both lateral and medial cords makes it impossible to tell with certainty which cord is being stimulated with distal median nerve response.*

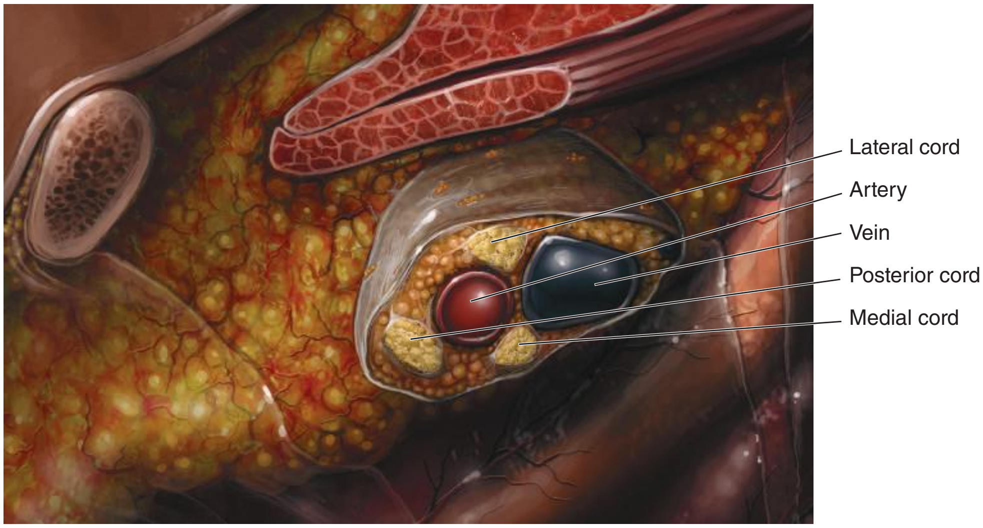

FIGURE 80D–3. Close-up view of the relationship of the cords of the brachial plexus at the level of infraclavicular blockade to the subclavian/axillary artery.

CLINICAL ANATOMY

A simplified schematic diagram of the plexus is shown in Figure 80D–1. This diagram depicts the plexus as it actually exists and a more clinical representation of how it is encountered when performing infraclavicular block. As shown, the posterior cord is not actually the most posterior cord but instead lies between the lateral and medial cords. The most helpful anatomic picture is in the sagittal plane, as shown in Figure 80D–3. This figure illustrates the brachial plexus at the level of infraclavicular blockade to show this relationship. The relationship shown in Figure 80D–3 is helpful for guiding needle placement while performing this block. The sagittal view shown here illustrates the cords in a close-up view surrounding the artery. Once this relationship is learned, the ability to change the needle directions for correct positioning is based on anatomy, and the need for subsequent passes to achieve successful placement lessens.

The cord that is most often encountered first when performing the infraclavicular block is the lateral cord because it is the most superficial. Just beyond the lateral cord is the posterior cord, which is in close proximity but just a bit deeper than the lateral cord. The medial cord is actually caudal or below the axillary artery, as can be seen in the sagittal view in Figure 80D–3. The schematic diagram of the cord shown in Figure 80D–4 demonstrates the 90-degree angle of needle insertion for the lateral and posterior cord. This figure also illustrates the proximity of the artery and the risk of puncturing the artery when attempting to encounter the medial cord. The anatomy of the plexus varies widely among individuals. The MRI study of Sauter revealed that the cords are found within 2 cm from the center of the artery, approximately within two thirds of a circle Figure 80D–5.

The Lateral Cord

The lateral cord supplies the lateral half of the median nerve and the musculocutaneous and the pectoral nerve branches (see Tables 80D–1 and 80D–2). This lateral portion of the median nerve is the motor innervation to the flexor muscles in the forearm, flexor carpi radialis, pronator teres (pronation of the forearm), and the thenar muscle of the thumb. It provides sensory innervation for the thumb to the lateral half of the fourth finger including the dorsal tips. The most distal motor response would be flexion of the fingers or flexion and opposition of the thumb.

The thumb has motor innervation from the ulnar nerve as well, which may be confusing if trying to interpret isolated thumb twitch. The ulnar nerve supplies the adductor pollicis, flexor pollicis brevis, and the first dorsal interosseous muscle. These muscles radially adduct the thumb. The flexor pollicis brevis assists in opposition of the thumb. The median nerve's innervation of the flexor pollicis longus, abductor pollicis brevis, and the opponens pollicis are the major flexors for opposition of the thumb.

The musculocutaneous nerve has only muscular branches above the elbow and is purely sensory below the elbow as it becomes the lateral antebrachial cutaneous nerve. The motor response is flexion of the elbow by contraction of the biceps and sensation to the middle to median part of the forearm.

The anatomic relationship of the musculocutaneous nerve to the cords and the coracoid process is pertinent to infraclavicular block. It could be considered a branch because it exits early, but it is more like a terminal nerve because it has sensory and motor innervations. Variations in brachial plexus anatomy are common. Because the musculocutaneous nerve most often exits the lateral cord quite early, the stimulation of this nerve is felt to be an unreliable indicator of stimulation of the lateral cord.[16] It often overlies the lateral cord, which will be stimulated with deeper advancement of the needle as it passes the point of musculocutaneous nerve stimulation. Figure 80D–6 depicts the lateral cord with its stimulated hand motor response.

The Posterior Cord

The posterior cord is just deep or inferior to the lateral cord. The axillary, the thoracodorsal, and upper and lower

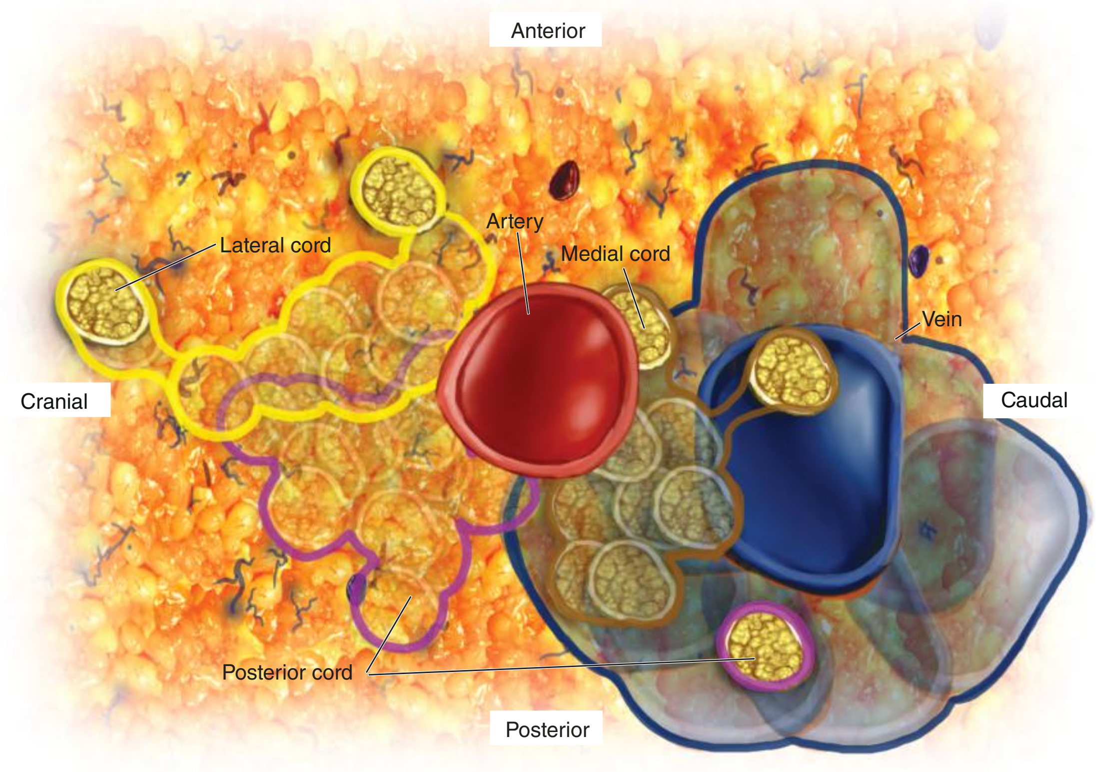

FIGURE 80D–4. Schematic of the relationship of the cords of the brachial plexus to the subclavian/axillary artery.

subscapular nerves are the branches from the posterior cord. They are involved in upper arm movement and shoulder movement and rotation as well as adduction of the shoulder and abduction of the arm. The branch most often encountered is the axillary nerve because it often has separated from the cord prior to the coracoid process. The axillary nerve to the deltoid elevates the upper arm. In addition to its branches, the posterior cord is responsible for the complete radial nerve. The distal responses from stimulation are abduction of the thumb and extension of the wrist and fingers (Figure 80D–7). The brachioradialis muscle is innervated by the radial nerve and is classified as an extensor. Its stimulation should be characterized because it may be confused as a median nerve response because it actually flexes the elbow joint. Elbow flexion with radial

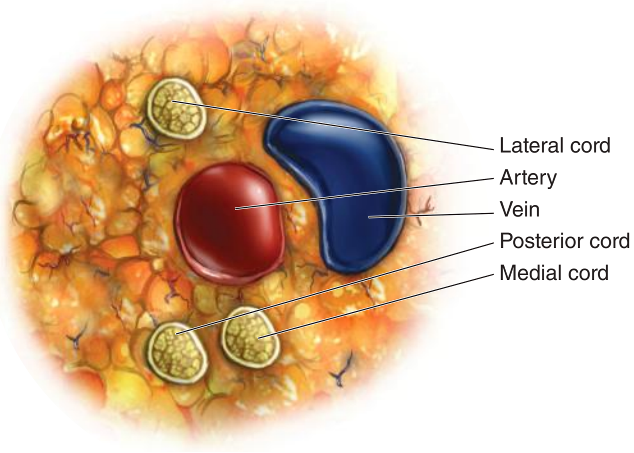

FIGURE 80D–5. Anatomic variations of the infraclavicular brachial plexus among individuals.

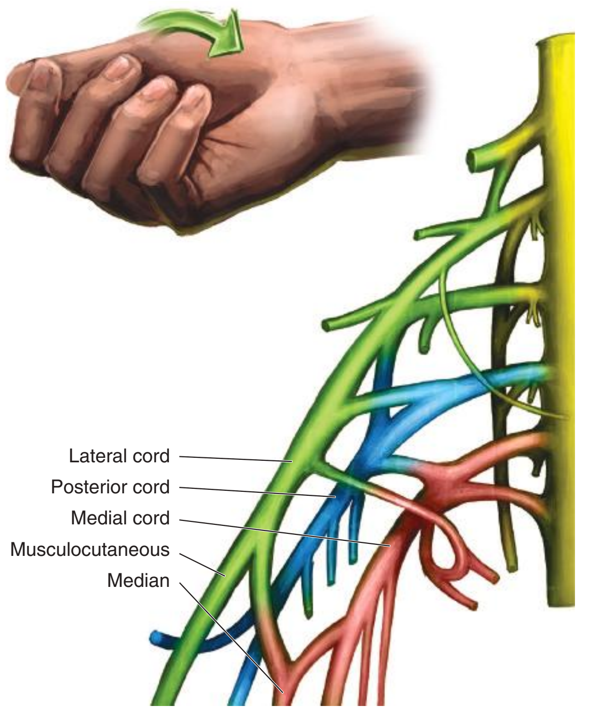

FIGURE 80D–6. Organization and motor response of the lateral cord.

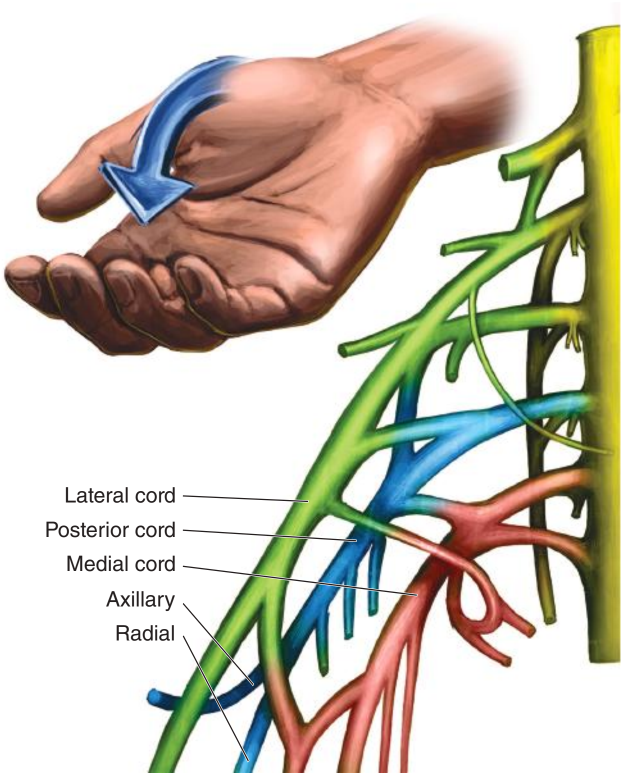

FIGURE 80D–7. Organization and motor response of the posterior cord.

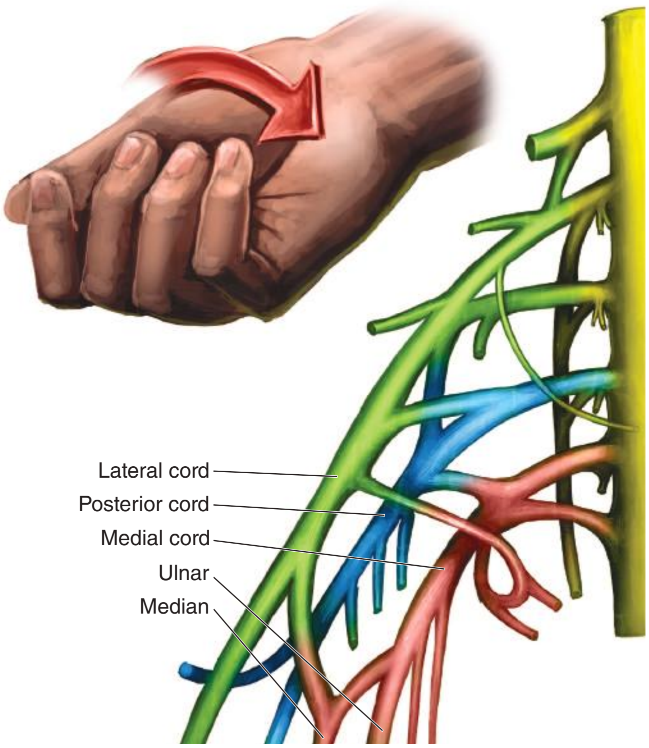

FIGURE 80D–8. Organization and motor response of the medial cord.

deviation of the wrist represents stimulation of the brachioradialis muscle and a posterior cord response. The needle should be readjusted to obtain a more distal response of the radial nerve.

The Medial Cord

The medial cord branches into the ulnar nerve and the medial half of the median nerve. Branches include the medial pectoral, medial brachial cutaneous, and the medial antebrachial cutaneous nerves. These branches innervate the skin of the anterior and medial surfaces of the forearm to the wrist. The ulnar nerve innervates half of the fourth and the fifth fingers, the adductor pollicis, and all interossei, which results in contraction of the fourth and fifth fingers and thumb adduction. Median nerve stimulation results in flexion and sensation of the first three and one half fingers, opposition of the thumb, and sensation of the palm (Figure 80D–8).

Unlike the axillary block, responses to stimulation of the median nerve during infraclavicular block could conceivably arise from either the lateral or medial cord. Classic studies of fiber topography of the median nerve by Sunderland identified pronator teres fibers and flexor carpi radialis in the lateral root, along with nerves to the flexor digitorum profundus, flexor pollicis longus, and intrinsic thenar muscles in the medial root.[17]

Nerve injury studies also suggest that median fibers to the finger flexors are most likely found in the medial cord and medial root of the median nerve.[16] With the most commonly occurring plexus anatomy, finger flexion most likely identifies medial cord (or root) stimulation, but wrist flexion may result from either median or lateral cord (or root) stimulation.[18]

Tables 80D–1 and 80D–2 summarize the cords, branches, terminal nerves, and their motor stimulus response. Because of anatomic variability and the mixing of the median nerve between the medial and lateral cords, the same responses are listed for both nerves. Except in rare variants, the ulnar nerve is carried within the medial cord.

LANDMARKS AND TECHNIQUE

General Guidelines

The bony landmarks used in most approaches are the clavicle, the jugular fossa or notch, the acromioclavicular joint, and the coracoid process, depicted in Figure 80D–9.

MODIFIED RAJ APPROACH

A small amount, approximately 5 mL or less, of local anesthetic is needed for the skin and subcutaneous tissue. Care must be taken to avoid the pleura by never directing the needle in a medial direction. If the plexus is not encountered, the needle should be withdrawn and redirected sequentially by a factor of 10 degrees in either a cephalad or caudad direction. If those maneuvers are not successful, the landmarks should be reassessed before attempting another pass. Initial settings on the nerve stimulator are 1.5 mA, with an acceptable response occurring at less than 0.5 mA. Distal motor responses (below the elbow) are preferable. The infraclavicular block is a large-volume block, and 30 mL of local anesthetic is necessary to block the entire brachial plexus. Some commonly used local anesthetic solutions are listed in Tables 80D–3.

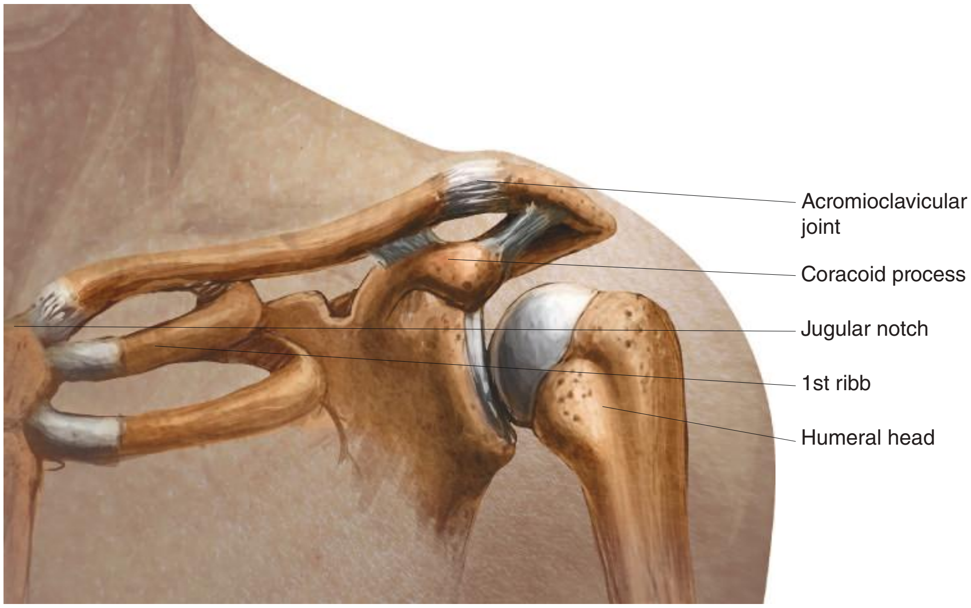

FIGURE 80D–9. Relationship of the jugular (sternal) notch, clavicle and coracoid process.

The patient is in the recumbent position with the head turned away. The subclavian artery is palpated where it crosses the clavicle, or the midpoint of the clavicle is marked. The brachial artery is palpated and marked at the lateral border of the pectoralis muscle. A line joining these two points is made with needle insertion 2.5–3.0 cm below the midpoint of the clavicle at a 45- to 65-degree angle toward the axillary artery (Figure 80D–10).

The operator stands on the opposite side to the site of block placement. The skin is infiltrated with local anesthetic into the skin and pectoralis muscle. The first two fingers of the palpating hand anchor the skin at the point of insertion, and the needle is advanced at a 45- to 65-degree angle toward the point of brachial pulsation or parallel to a line connecting the medial clavicular head with the coracoid process if pulsation cannot be felt (Figure 80D–11).

If the plexus is not encountered, the needle should be withdrawn and redirected 10 degrees cephalad or caudad, depending on the originating angle of insertion. At no time should the needle be pointed medially or posteriorly toward the lung.

TABLE 80D–3. Local anesthetic solutions for infraclavicular block.

Duration	Anesthetic	
Short (1.5–3.0 h)	3% chloroprocaine	
	1.5% lidocaine	
	1.0%–1.5% mepivacaine	
Intermediate (4–5 h)	2% lidocaine + epinephrine	
	1.0%–1.5% mepivacaine	
Long-Lasting (10–14 h)	0.25%–0.50% bupivacaine	(0.0625%–0.1% for infusion)
	0.50% ropivacaine	0.1%–0.2% for infusion)

VERTICAL INFRACLAVICULAR BLOCK

The vertical infraclavicular block was described by Kilka and coworkers in 1995.[14] The landmarks are the midpoint of a line from the middle of the jugular notch and the ventral process of the acromion (Figure 80D–12). The patient is lying in a supine position with the forearm relaxed on the chest with the head turned slightly to the side.

- Needle insertion is at the midpoint of the line from the jugular fossa to the acromioclavicular joint.
- Insertion is just under the clavicle.
- Needle assumes a 90-degree needle angle.
- A 50-mm needle is used.

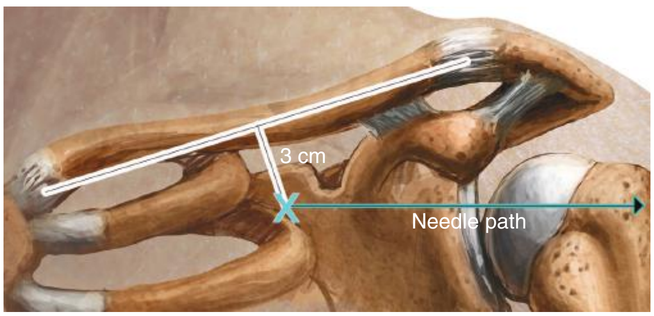

FIGURE 80D–10. Raj approach: Landmarks and needle insertion plane.

FIGURE 80D–11. Raj approach: Needle insertion and orientation.

A 50-mm needle is inserted close to the clavicle at an angle of 90 degrees (see Figure 80D–12). Local anesthetic is injected after a distal stimulus is obtained at or below 0.5 mA. If on first pass the needle does not encounter the plexus, only the angle is changed while keeping the same plane by 10 degrees caudad or cephalad. The needle is never directed in a medial fashion.

Clinical Pearls

The three most common errors that increase the risk of pneumothorax are[19]:

- Too medial insertion of the needle
- Depth of needle insertion >6 cm
- Medial direction of needle

Adams described an improved success rate by moving the puncture site 1 cm laterally. The rate of unsuccessful block (defined as need for additional analgesic or sedation) was reduced to 8.3%, although this may depend on patient size. Using ultrasonographic assessment, Greher and colleagues demonstrated topographic anatomy in volunteers and compared the classic approach to a puncture site determined by high-resolution ultrasound location of the plexus. A clear trend was found to a more lateral puncture site, especially in women. They found that when the line from jugular fossa to acromion measured 22.0-22.5 cm the puncture site was exactly at the center of this line. However, for every 1 cm decrease in the length of this line the puncture site moved 2 mm laterally from the center and for every 1 cm increase the puncture site moved 2mm medially.[20]

CORACOID TECHNIQUE (BLOCK)

The coracoid block as described by Whiffler[11] in 1981 used a needle entry site that is most often inferior and medial to the coracoid process. In 1998, Wilson reviewed MRIs and located a point 2 cm medial to the coracoid process and 2 cm caudad. At this skin entry site, direct posterior insertion of the needle makes contact with the cords at a mean range of 4.24 cm ± 1.49 (2.25–7.75 cm) in men and 4.01 ± 1.29 cm (2.25–6.5 cm) in women.[15] As shown in Figure 80D–13, the lateral tip of the coracoid process (not the medial edge) is palpated. Kapral,[19] in 1999, described a lateral approach with the patient in the same position. The point of needle insertion is lateral to the lateral point of the coracoid process. After identifying the coracoid process by touching the bone, the 7-cm needle is withdrawn 2–3 mm and redirected underneath the coracoid process 2–3 cm until the brachial plexus is reached. The usual distance was 5.5–6.5 cm. Rodriguez described his series of coracoid blocks as closer to the coracoid process by making his puncture site 1 cm inferior and 1 cm medial to the coracoid process. He reported a similar success rate.[21,22]

THE LATERAL AND SAGITTAL TECHNIQUE LANDMARKS

In 2004, Klaastad and coworkers described this technique and tested it in an MRI model.[23] The point of needle insertion is the intersection between the clavicle and the coracoid process (see Figure 80D–2). The needle is advanced 15 degrees posteriorly, always strictly in the sagittal plane next to the coracoid process

A B

FIGURE 80D–12. A AND B. Vertical approach: Needle insertion and orientation.

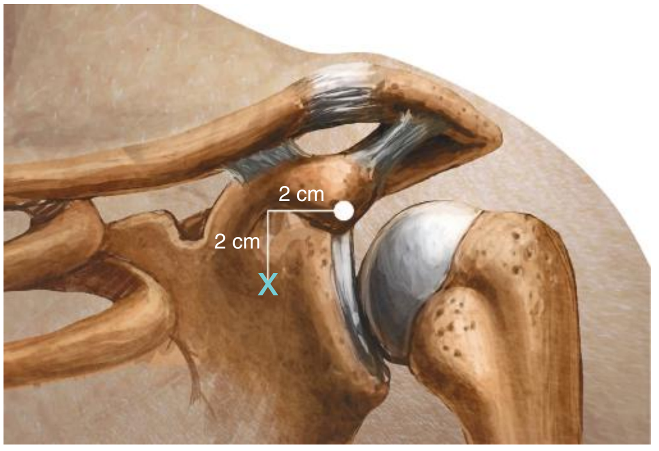

FIGURE 80D–13. Coracoid approach: Landmarks.

while abutting the anteroinferior edge of the clavicle. All needle directions in this method adhere strictly to the sagittal plane through this coracoid prominence. The posterior cord and medial cord were more often reached than the lateral cord. Insertion depth should be no greater than 6.5 cm. Although the cords are usually reached before the axillary artery and vein, puncture of these vessels as well as the cephalic vein is always a possibility.[24] Klaastad and coworkers reported occasionally needing to insert the needle more than 6.5 cm (their estimated maximal safe depth) to obtain satisfactory nerve contact and has not had a case of pneumothorax. The needle can encounter a vessel.[25]

Although initially used with a nerve stimulator, this technique has become the preferred method for use with ultrasound localization of the brachial plexus cords.[14] The cords are superior and posterior to the axillary artery, most commonly at a depth of 4–6 cm. Although it is always possible to puncture the artery, the trajectory of this approach appears to avoid puncture of the axillary vessels because the cords are encountered cephalad to the artery and 2–3 cm cephalad to the pleural cavity. The use of ultrasound may improve block success and decrease morbidity compared with nerve stimulator alone.[26]

SINGLE INJECTION VS MULTIPLE INJECTION AND CONTINUOUS TECHNIQUE

Single stimulation has been reported to have success rates from 82% to 100%.[19,24,27,28] Gaertner and colleagues compared single stimulation to stimulation of all three cords. Multistimulation took slightly longer (9.0 vs 7.5 min); however, 2 of the 40 patients in the multistimulation group were excluded because three cords could not be localized within 15 minutes.[24]

A distal response in the hand or wrist was considered adequate with 10 mL of local anesthetic injected at each site. In the single-stimulation group, 30 mL of local anesthetic was injected after identifying a single response from any cord, (Figure 80D–14). Although their overall success rate was low for both techniques (40.0% for single stimulation and 72.5% for multiple stimulation), Gaertner and colleagues reported that multiple stimulation was significantly more successful than single. The amount of local anesthetic, 30 mL, could have contributed to the overall decreased success rate. However, these researchers attributed the bulk of the difference in overall success to the varying definition of success in the literature. Hand surgery constitutes a large part of the surgeries in these studies. Most hand surgery can be performed with two or three of the nerves to the hand blocked if they are in the correct distribution of the surgery. Gaertner and colleagues felt more stringent criteria should be used. A complete

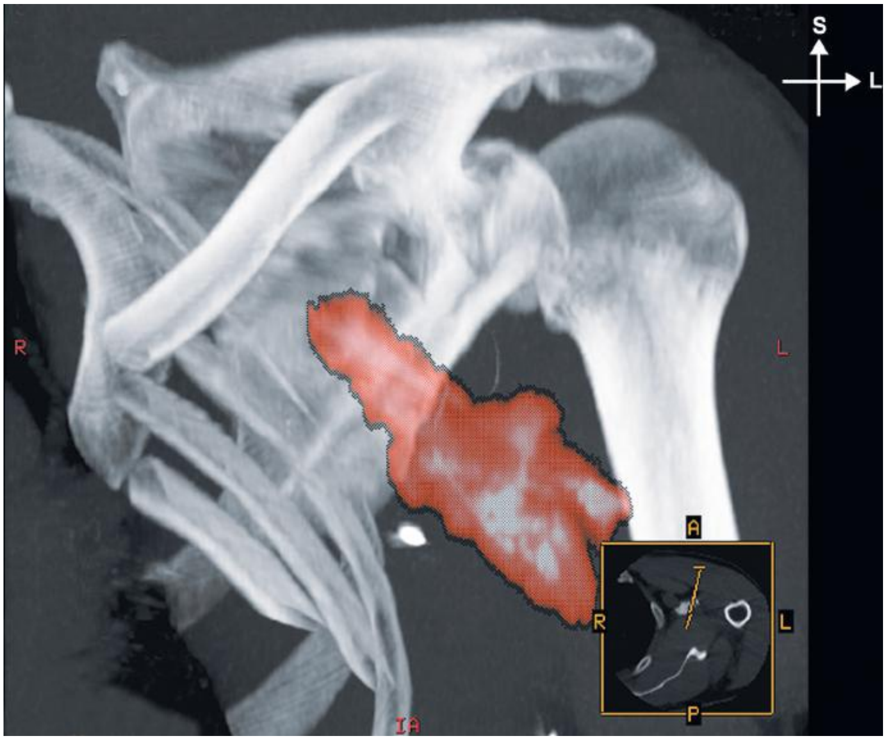

FIGURE 80D–14. Distribution of the local anesthetic after injection through an indwelling catheter.

motor and sensory block of all nerves was necessary for their criteria of success as compared with success defined as completing the procedure without supplementation or the need for general anesthesia.

An example of this criterion is demonstrated by Rodriguez and collaborators[21] in a random controlled trial comparing injection of 42 mL of mepivacaine using a single-, dual-, or triple-injection technique. A significantly less complete motor blockade was found with single injection versus the dual or triple injection. No significant difference was found in the dual- or triple-injection groups. In another study,[22] comparing single and dual stimulation, 22% of the single stimulation group had a musculocutaneous or axillary response. The investigators state that the recommendations for not accepting these responses is based on a published anecdotal report[29] on a noncoracoid approach. Dual injection was suggested as the best balance between efficacy and comfort for patients and resulted in shorter block performance times and decreased vascular puncture rates compared with that for triple-stimulation injection.[30]

Deluze and coworkers found a similar effective rate when comparing single stimulation to triple stimulation by using 40 mL of 0.75% ropivacaine.[31]

Continuous Technique

The infraclavicular block is well suited for continuous nerve block. Patient comfort and catheter securing are easier accomplished with an infraclavicular catheter rather than a dressing in the axillary area. If the distribution of the pain is in the axillary nerve or musculocutaneous areas, the chance of constant sensory blockade of those areas and pain relief are greater.

All approaches have been utilized successfully with a continuous technique, and there is no overwhelming evidence that favors a particular approach.[19,25,32,33]

Clinical Pearl

- The coracoid process can easily be found even in obese patients. The middle finger is placed just below the clavicle and the hand is moved laterally toward the shoulder. The first bony prominence that is felt by the index finger is the coracoid process. The patient's head should be turned to the opposite side.

SUMMARY

The infraclavicular block provides a useful alternative to axillary block for surgery of the arm. The block is reliable for surgery and amenable to ultrasound technique and can be used for continuous as well as single-shot techniques.

CHAPTER 80E

Axillary Brachial Plexus Block

Zbigniew J. Koscielniak-Nielsen and Monika Golebiewski

INTRODUCTION

Brachial plexus block at the level of the axilla is typically chosen for anesthesia of the distal upper limb. Axillary block is one of the most common approaches to brachial plexus blockade. Easy landmarks and simplicity make this block suitable for a wide range of surgical procedures.

HISTORY

The surgical technique of this block was first described by William Hallstead[1] in New York City (Roosevelt Hospital, also the clinical affiliation for NYSORA 1995-2014) in 1884, whereas the percutaneous technique was described by Georg Hirschel[2] in 1911. In 1958, Preston Burnham[3] recognized that filling the neurovascular "sheath" with local anesthetic could simplify the axillary block. He also described the characteristic fascial "click" felt upon needle entry into the axillary sheath. In 1961, while using the formula for a cylinder volume, Rudolph De Jong[4] calculated that in an average adult, 42 mL of local anesthetic (LA) was necessary to fill the fascial compartment to the level of the cords and block all terminal nerves to the arm. A year later, Ejnar Eriksson and Skarby,[5] in an effort to promote the proximal spread of LA, advocated wrapping a rubber tourniquet around the arm, distal to the needle. In 1979, Alon Winnie and coworkers[6] found the tourniquet ineffective and painful and recommended firm distal digital pressure on the neurovascular sheath instead. In addition, they also recommended arm adduction after LA injection, thinking that the head of the abducted humerus com pressed the neurovascular sheath. Both maneuvers were later proved to be clinically ineffective.[7–9] Gale Thompson and Duane Rorie,[10] in 1983, studied brachial plexus using computed tomograms and suggested that the median, ulnar, and radial nerves lie in separate fascial compartments within the neurovascular sheath; this hypothesis provided a rational explanation for incomplete blocks. However, anatomic studies by Lassale and Ang[11] in 1984 and Vester-Andersen and coworkers[12] in 1986 did not confirm the existence of a true neurovascular sheath. The interfascial space they found contained the median and the ulnar nerves, infrequently the musculocutaneous, and occasionally the radial nerves. Moreover, the space was suggested to communicate proximally only with the medial cord of the plexus. In 1987, Partridge and coworkers[13] found the interneural septa, which were easily broken by injection of dyed latex. In 2002, Oivind Klaastad and coworkers[14] were the first to investigate the spread of the LA through the axillary catheter in studies using magnetic resonance imaging (MRI) scanning. They found that in most patients the spread of LA was uneven and the clinical effect inadequate.

Until the 1960s, the prevalent block techniques were double or multiple axillary injections. After the concept of the neurovascular sheath had been established by De Jong[4] in 1961, the single-injection technique, being the simplest, became standard. However, Vester-Andersen and coworkers[15,16] demonstrated in 1983 and 1984 that despite high volumes of LA, analgesia was often inconsistent ("patchy"). In the early 1990s, the double-injection, transarterial technique was popularized by Urban and Urquhart[17] and Stan and coworkers.[18] More recently, however, development of peripheral nerve stimulators and insulated atraumatic needles has allowed electrolocation and separate blockade (multistimulation technique) of the individual terminal nerves (median, musculocutaneous, ulnar, and radial). This is known as the multiple-nerve stimulation technique. Baranowski and Pither[19] (in 1990), Lavoie and coworkers[20] (in 1992), Koscielniak-Nielsen and coworkers[21,22] (in 1997 and 1998), and Sia and coworkers[23,24] (in 2001 and 2002) independently showed that multiple-nerve stimulation was superior, both to the single- and the double-injection methods by increasing the success rate and shortening the block onset. A recent Cochrane review by Handoll and coworkers[25] validated these findings.

INDICATIONS AND CONTRAINDICATIONS

The most common indications for axillary block include surgery of the forearm, wrist, or hand of moderate to long duration, with or without an arm tourniquet. Relative contraindications to the use of this block are skin infection at the block site, axillary lymphadenopathy, and severe coagulopathy. In addition, this block is best avoided in patients with preexisting neurologic disease of the upper extremity because sensory assessments may be difficult.

PERTINENT ANATOMY

In the apex of the axilla, the three plexus cords (lateral, medial, and posterior) form the main terminal nerves of the upper extremity (axillary, musculocutaneous, median, ulnar, and radial). However, only the last three nerves accompany the blood vessels through the axilla where the blocks are performed (Figure 80E–1), while the axillary and the musculocutaneous nerves leave the plexus approximately at the level of the coracoid process. The axillary nerve departs at a wider angle from the posterior cord, laterally and dorsally, and the musculocutaneous nerve, which originates from the lateral cord, runs obliquely laterally into the coracobrachial is muscle and continues downward. The medial antebrachial cutaneous and brachial cutaneous nerves run subcutaneously parallel to the axillary vessels, although the medial antebrachial cutaneous nerve often follows the median nerve within the neurovascular sheath. In the axilla, the median and musculocutaneous nerves lie superior to the artery, whereas the ulnar and radial nerves lie inferior to it. The depths at which the nerves are found vary. Typically, the median nerve is more superficial than the musculocutaneous, and the ulnar nerve is more superficial than the radial. Occasionally, the radial or the musculocutaneous nerves (or both) are found behind the artery. These two nerves progressively diverge from the neurovascular sheath, continuing down the upper arm, the musculocutaneous above (anterior) and the radial below (posterior) to the humerus, where they can be approached using the mid-humeral approach.[26]

Landmarks

Surface landmarks for the axillary brachial plexus block include (Figure 80E–2):

1. Pulse of the axillary artery
2. Coracobrachialis muscle
3. Pectoralis major muscle
4. Biceps muscle
5. Triceps muscle

EQUIPMENT

- Sterile towels and 4-in. × 4-in. gauze packs
- Sterile gloves, marking pen, and a skin electrode
- 1-in., 25-gauge needle for skin infiltration
- 1- to 1.5-in. atraumatic, insulated stimulating needle
- 20-mL syringes containing LA of choice
- Peripheral nerve stimulator
- Means of assessing opening injection pressure

INJECTION TECHNIQUES

Arm Position for the Block

The arm to be operated on is abducted approximately 90 degrees (see Figure 80E–2). The elbow is flexed and the forearm rests comfortably, supported by a pillow. The arterial pulse is palpated at the level of the major pectoral muscle, and the subcutaneous tissue overlying the artery is infiltrated with 4–5 mL of LA (to block the intercostobrachial and medial cutaneous nerves of the arm). Several techniques and approaches to the brachial plexus block at the level about the axilla have been described; we will describe only some of the well-studied techniques.

A triple-injection axillary block is probably the most efficient technique for axillary brachial plexus blockade.

NERVE STIMULATION TECHNIQUES

Single-Injection (Stimulation) Technique

1. The nerve stimulator is set to deliver 0.5–1.0 mA (2 Hz, 0.1 msec); electrical connections with the needle and the neutral electrode are checked.
2. Depending on the surgical site (palmar and medial or dorsal and lateral aspects of the hand/forearm), the stimulating needle is inserted above the arterial pulse (toward the median nerve) or below the arterial pulse (toward the radial nerve), respectively (Figures 80E–3).
3. As the superficial fascia is penetrated, a characteristic "click" is often felt, and the current amplitude is slowly increased (e.g., at 1-mA increments) until the desired

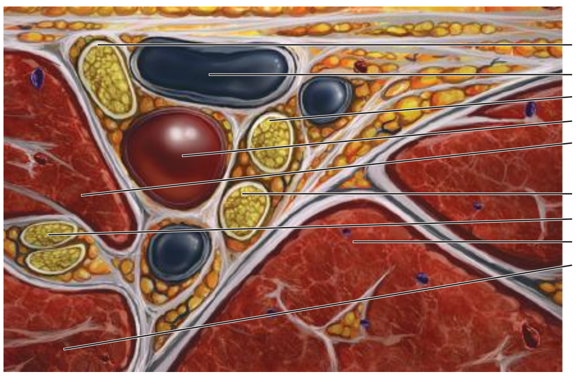

FIGURE 80E–1. Anatomy of the brachial plexus at axilla and at the midhumeral level.

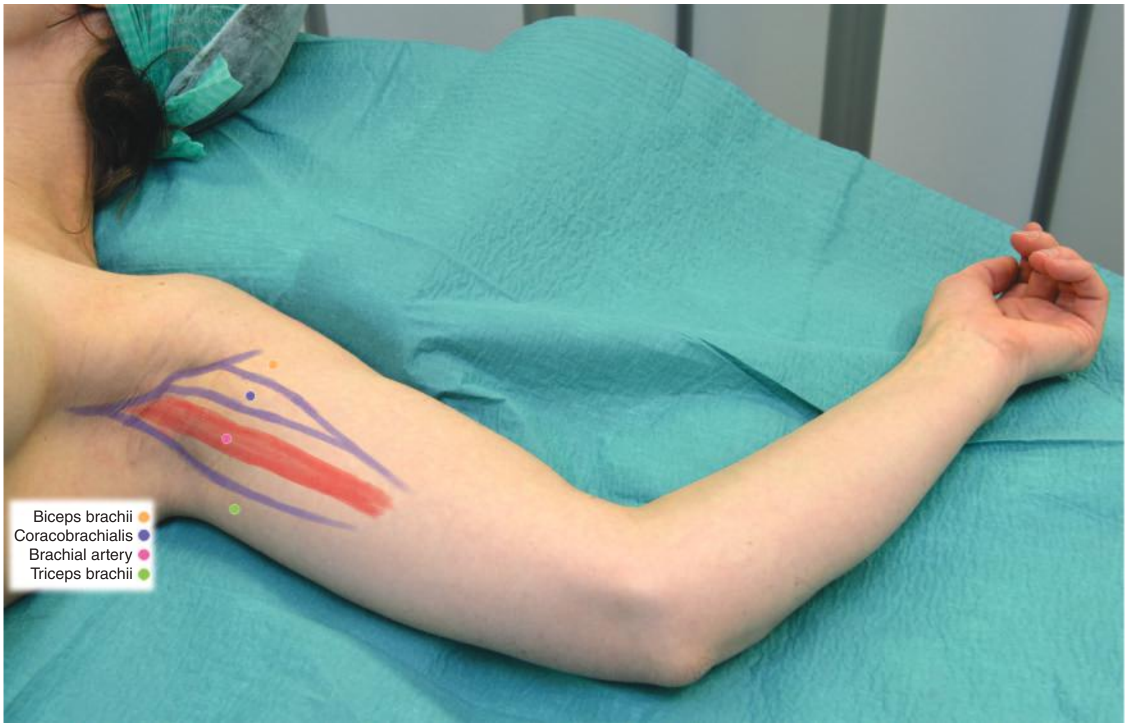

FIGURE 80E–2. Landmarks for the axillary brachial plexus block.

twitch (flexion or extension of the wrist and fingers) is obtained. This helps avoid painful electrical paresthesia when the elastic fascia suddenly "gives in" and the needle enters the neurovascular sheath.[27]

4. After the initial motor response is obtained, the needle is slowly advanced toward the stimulated nerve while reducing the amplitude.
5. Once the stimulation is obtained using a current intensity of 0.3–0.5 mA, the entire volume of LA is injected slowly, while intermittently aspirating to reduce the risk of accidental intravascular injection. This results in substantial spread of the LA within the tissue layers encompassing the brachial plexus (Figure 80E–5).

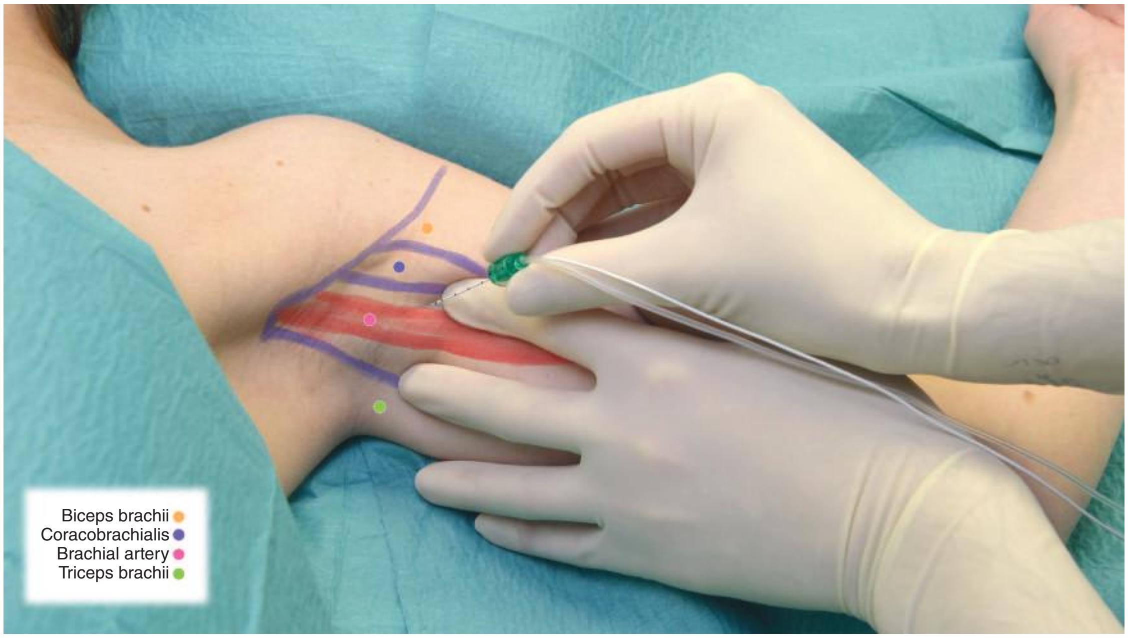

FIGURE 80E–3. Radial nerve block: The needle is inserted above the pulse of the axillary (brachial) artery. CB = coracobrachialis.

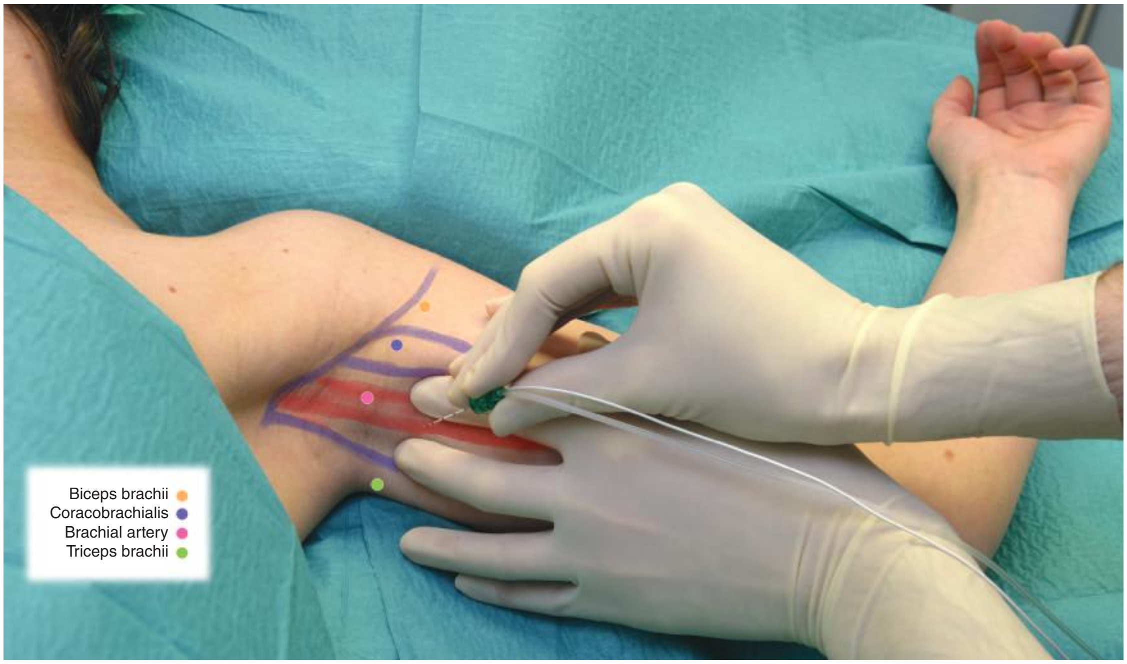

FIGURE 80E–4. Median nerve block: The needle is inserted below the pulse of the axillary (brachial) artery. CB = coracobrachialis.

Clinical Pearls

- Arterial pulse palpation may prove challenging in some patients. In these patients, the initial motor response can be used to guide needle redirection to achieve the desired response.
- Elbow flexion (stimulation of the coracobrachialis muscle or the musculocutaneous nerve) indicates that the needle is outside the neurovascular sheath; the needle should be redirected downward and more superficially.
- Extension of the wrist and hand (radial nerve) indicates that the needle is below the artery; the median and ulnar nerves are above the artery.
- The more difficult differentiation is between the median and the ulnar nerves, which both result in wrist/finger flexion. In this scenario, the following method can be used to differentiate between the two nerves:
- When flexion is accompanied by forearm pronation, the stimulated nerve is the median (the needle is positioned above the artery).
- Another way to differentiate between these two nerves is by palpation of the flexor tendons at the wrist. Median nerve stimulation produces movements of the palmaris longus and the flexor carpi radialis tendons, which lie in the middle of the wrist, whereas ulnar nerve stimulation produces movement of the flexor carpi ulnaris tendon, which lies medially.
- Decreasing the intensity of the output current of the nerve stimulator helps facilitate differentiation between median and ulnar nerve stimulation.

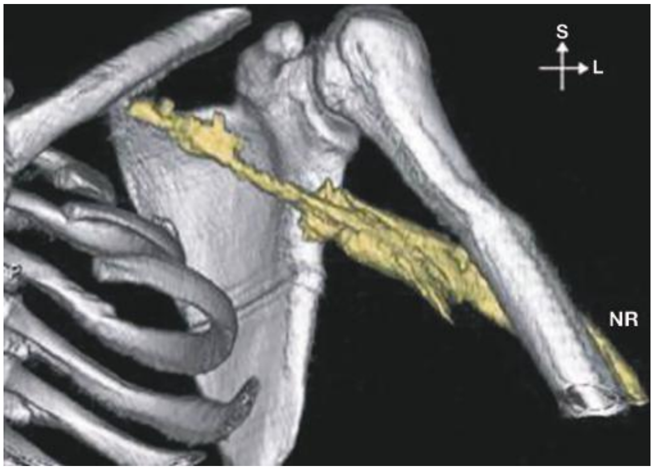

FIGURE 80E–5. Distribution of local anesthetic injected during axillary brachial plexus blockade. NR = nervus radialis.

Double-Injection Technique

1. The stimulating needle is first inserted above the artery, below the coracobrachialis muscle (see Figure 80E–3). After penetrating the fascia, the amplitude is increased until synchronous wrist flexion/pronation and flexion of the first three fingers are obtained (median nerve stimulation). The needle is advanced slowly toward this nerve while reducing the amplitude to 0.3 to 0.5 mA. At this point, half of the planned volume of LA is slowly injected with intermittent aspiration to rule out intravascular injection.
2. The needle is then withdrawn and inserted below the artery and above the triceps muscle (see Figure 80E–4). The fascia is again penetrated and the amplitude slowly increased. The

first response is usually either arm extension (muscular branches to the triceps) or thumb adduction and flexion of the last two fingers (ulnar nerve). However, these responses are ignored, and the needle is advanced deeper, often slightly upward, behind the artery (Figure 80E–6) until wrist and finger extension is obtained (radial nerve). After stimulation is obtained using a current intensity lower than 0.5 mA, the remaining volume of LA is slowly injected with intermittent aspiration.

Clinical Pearl

- With ultrasound-guided nerve blocks motor stimulation below 0.5 mA is avoided to decrease the risk of needle–nerve contact or intraneural injection. With nerve stimulator–guided blocks, however, motor response is sought at 0.3—0.5 mA as evoked motor response is the only means of nerve localization, and nerve stimulation does not allow visualization of the tissue spaces or spread of the local anesthetic which is possible with ultrasound guidance.

Multiple-Injection Technique

Needle insertion sites are identical to those for the double-injection technique.

1. After electrolocation of the median nerve, 5–10 mL of the LA volume is injected (see Figure 80E–3).
2. The needle is withdrawn subcutaneously and redirected obliquely, above and into the coracobrachialis muscle. After obtaining stimulation-synchronous biceps flexion, the amplitude is reduced to 0.3–0.5 mA and another 5–10 mL of LA is injected to block the musculocutaneous nerve.
3. The needle is removed and inserted below the artery (see Figure 80E–4). The first stimulated nerve is usually the ulnar nerve, into which 5–10 mL of LA is injected.
4. The needle is advanced deeper until the radial nerve is found (see Double-Injection Technique, p. 1345.).

Clinical Pearls

- Two studies by Sia and colleagues[23,28] suggest that two separate injections below the artery do not improve success rates, and therefore only one such injection is needed. This injection is made close to the radial nerve and should contain half of the planned LA volume.
- Electrolocation of multiple nerves may occasionally take some time. Because the first injection of the LA injection in the vicinity of the median nerve may partially block the ulnar nerve, the search for the nerves should be made expeditiously to minimize the risk of needle-nerve contact or intraneural injection into an anesthetized nerve.
- For these reasons, this technique could be considered an advanced regional anesthesia technique. Careful assessment of resistance to injection by an experienced practitioner or objective monitoring of injection pressure should be used with each injection.

Transarterial Technique

This relatively simple technique does not rely on a nerve stimulator; instead, placement of the needle within the neurovascular sheath is identified by relying on the axillary artery:

- The axillary artery is palpated and stabilized using a two-finger palpation technique.
- As the needle is advanced toward the pulse of the axillary artery, bright red arterial blood is aspirated. A thin, long-beveled needle (typically 1.5-in., 25-gauge) is used to minimize the risk of axillary hematoma.

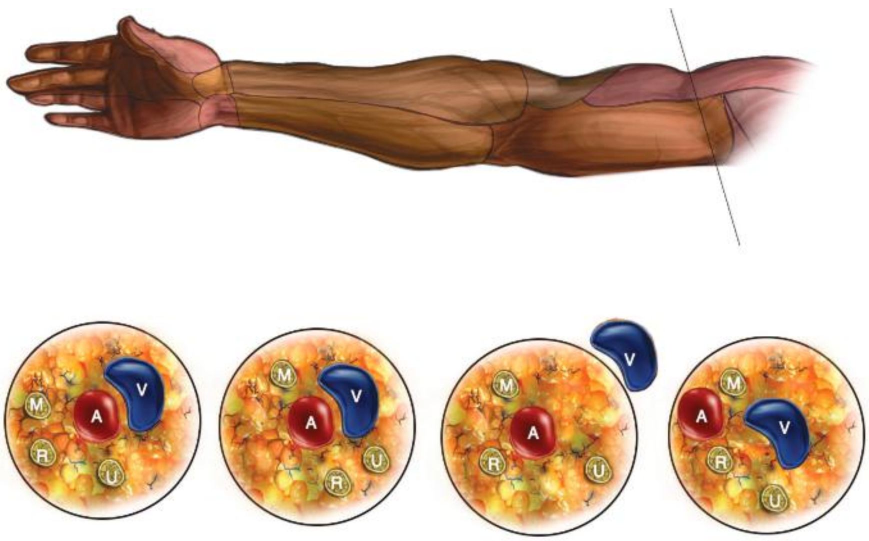

FIGURE 80E–6. Spatial arrangement of the terminal nerves of the brachial plexus in the axilla. M = median nerve, A = artery, V = vein, R = radial nerve, U = ulnar nerve.

- The needle is advanced deeper until blood cannot be aspirated (the tip of the needle has exited the artery) and half of the volume of the LA is injected behind the posterior wall. This should block the radial nerve.
- The needle is slowly withdrawn while aspirating. As the needle enters the axillary artery, bright red blood is again aspirated.
- The withdrawal of the needle is continued until blood cannot be aspirated (the needle exits the artery and its tip is positioned superficial [media] to the artery inside the neurovascular sheath).
- The remaining volume of LA is injected superficial to the anterior wall to block the median and the ulnar nerves.
- A transarterial injection is made as high up in the axilla as possible, and the needle should traverse the artery at an oblique angle. This reduces the risk of making the injection behind the artery intramuscularly and improves the spread of the LA to the plexus cords to block the musculocutaneous nerve.

MIDHUMERAL APPROACH (HUMERAL CANAL BLOCK)

The difference between the multiinjection axillary and the midhumeral (humeral canal) approaches is that in the latter, two terminal nerves, the musculocutaneous and the radial, are blocked separately, above and below the humeral bone, respectively (Figures 80E–1 and 80E-7). With any multistimulation technique, there is always a risk that an intraneural injection may be made into the already anesthetized nerves. Although the four-injection midhumeral block has been found to be more effective than the double-injection axillary technique,[30] either block results in a very high success rate when four injection techniques are used.[24] An advantage of the axillary approach is that incomplete axillary blocks can be supplemented with a midhumeral block.[31] The opposite is not possible, nor is it recommended because electrostimulation may be precluded by blockade distal to the site of nerve localization. An incomplete midhumeral block, on the other hand, can be supplemented at the elbow or the wrist.

Technique

The injection technique for the midhumeral block is similar to the four-injection axillary technique, except the injections are made more distally. In addition, the musculocutaneous and the radial nerves are sought at a deeper location than in the axillary approach (see Figure 80E–7). Figure 80E–8 demonstrates the spread of the injected local anesthetic in the midhumeral technique.

- The nondominant hand grips the biceps muscle while searching for the musculocutaneous nerve, and the stimulating needle is inserted below the muscle (to avoid direct stimulation).
- When the bone is contacted before eliciting the twitches, the needle is redirected upward, toward the belly of the biceps muscle.
- The triceps muscle is stabilized similarly while attempting stimulation of the radial nerve. It should be kept in mind that the radial nerve winds around the humeral shaft on its way downward, which makes electrolocation of this nerve challenging with distal approaches.

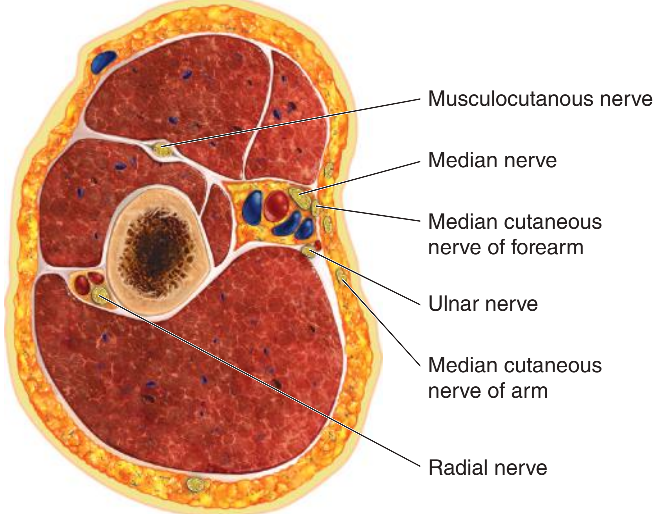

FIGURE 80E–7. Spatial arrangement of the terminal nerves of the brachial plexus at the midhumerus.

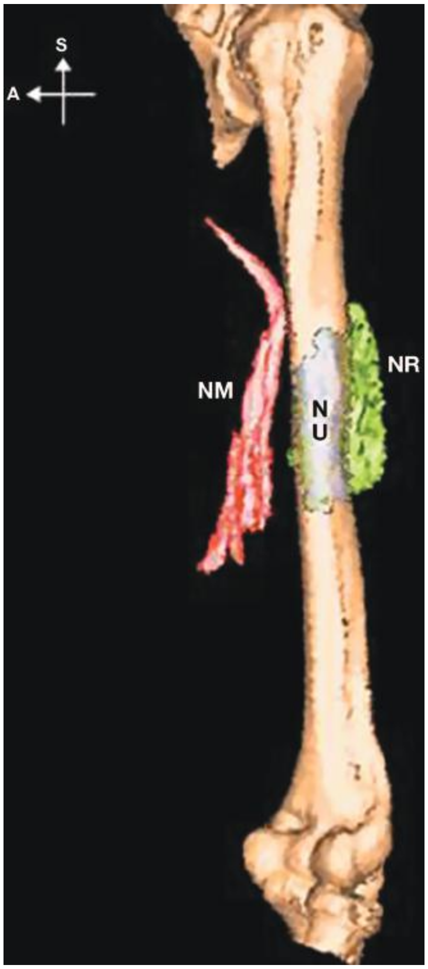

FIGURE 80E–8. Distribution of injectates after midhumeral blockade. NM = nervus medialis, NU = nervus ulnaris, NR = nervus radialis.

CHOICE OF LOCAL ANESTHETIC

The choice of LA depends on the length of surgery and the desired density and duration of blockade. For single-injection blocks, short- and medium-acting LAs (prilocaine, 2-chloroprocaine, lidocaine, or mepivacaine) in concentrations of 1.5%–2% (3% for 2-chloroprocaine), with or without epinephrine or sodium bicarbonate, will provide reliable sensory and motor block of rapid onset (10–20 min) and sufficient duration (3–4 h; 1.5–2 h for 2-chloroprocaine) for most acute and subacute procedures (e.g., wound debridement; closed fracture repositions; ligament-, tendon-, or nerve sutures; finger amputations). For elective procedures of longer duration (e.g., arthrodeses, arthroplasties, osteosyntheses, extensive palmar fasciectomies) ropivacaine 0.5%–0.75% or bupivacaine 0.375%–0.5%, with or without epinephrine, will provide analgesia of slightly slower onset (15–20 min) and longer duration (6–16 h). For specialized hand surgery that may last several hours—for example, multiple joint replacements or reimplantations of severed extremities—a continuous ropivacaine (0.2%–0.375%) infusion via an axillary catheter is probably the best technique. Clonidine (0.5 mcg/kg) may be added to intermediate-acting LAs to prolong analgesia after single-shot blocks.[32]

PERIOPERATIVE MANAGEMENT

The multiple-nerve stimulation technique is uncomfortable for patients[27,33] and should be preceded by adequate premedication (e.g., midazolam + sufentanil).[34] Adequate sedation and analgesia not only improve patients' acceptance of the block but also help relax the arm muscles. This makes precise needle manipulation as well as eliciting and interpreting the motor responses to nerve stimulation significantly easier for the practitioner and more acceptable to patients.

Clinical Pearls

- The first sign of a successful block is weakness of the upper arm muscles, which can be tested immediately after needle withdrawal. This can be done by asking the patient to place the hand on the abdomen or touch the practitioner's finger.
- Loss of coordination signifies that the mantle fascicles of the musculocutaneous and radial nerves, which supply flexors and extensors, are being blocked. Very often patients report an early loss of the position sense in the blocked extremity.

The onset and distribution of analgesia can be tested every 5 or 10 minutes after block administration in the sensory areas of the seven terminal nerves (Figure 80E–9). Thirty minutes after block insertion, the unblocked nerves can be supplemented distal to the initial block site (e.g., elbow blocks).

Clinical Pearls

- Most hand surgery (e.g., palmar fasciectomies and nerve or tendon repair) is performed on the volar aspect and theoretically can be performed with partial blocks (i.e., without the radial or musculocutaneous nerves).
- For elbow surgery, an infraclavicular approach is a better choice then the axillary block.
- Tourniquet analgesia may be more related to the total injected dose of LA rather than to successful block of the medial cutaneous brachial nerves. Most of the injected LA is absorbed into the surrounding muscles, which are the main source of ischemic pain.[35]

CONTINUOUS AXILLARY BLOCK

The indications for continuous axillary block include control of acute postoperative pain, management of chronic pain, and treatment of vascular disease, (e.g., Raynaud syndrome).

Technique

The axillary fossa is shaved and disinfected. After subcutaneous LA infiltration, the specific muscle twitch from the nerve of greatest interest is elicited by a needle or stimulating introducer cannula (see Single-Injection Technique, p. 1343). The intensity of the stimulating current is progressively reduced to 0.5 mA or less, while making fine adjustments to the needle position. A catheter is inserted (under sterile conditions) 5–8 cm cephalad into the neurovascular sheath and either sutured to the skin or tunneled. This helps maintain the catheter in place because the nerves are superficial and the arm sweat makes maintenance of an occlusive dressing difficult.

Clinical Pearl

- Difficulty with catheter insertion usually indicates placement of the needle outside the neurovascular sheath.

Maintenance

Diluted solutions of long-acting LAs (eg, 0.125% bupivacaine or 0.2% ropivacaine) are most often used for continuous infusions. A common infusion regimen includes intermittent bolus of LA (5-10 mL Q 4-6 hrs) of the dilute mixture of LA with or without continuous infusion of 5 mL/h.

Clinical Pearl

- A typical infusion regimen for 0.2% ropivacaine is a basal rate of, for example, 0.1 mL/kg bodyweight per hour (minimum, 5 mL; maximum, 10 mL) and a 5 mL patient-controlled bolus with a lock-out time of 30 minutes.

Complications

Vascular Puncture Vascular puncture can occur with axillary block but it usually can be detected. However, venous puncture may be undetected if aspiration or palpation pressure collapses the venous lumen.

Intravascular LA Injection Intravascular LA injection manifests itself as lightheadedness and or tachycardia (ropivacaine- or epinephrine-containing solutions). Note that intra-arterial injection produces hand paresthesia during injection accompanied by sudden paleness. Slow injection with repeated needle aspirations is mandatory.

Hematoma Hematoma may occur after arterial puncture. If the artery is punctured, firm, steady pressure should be applied over the puncture site for 5–10 minutes. For the transarterial technique, needles of smaller gauge should be used to minimize the risk of hematoma.

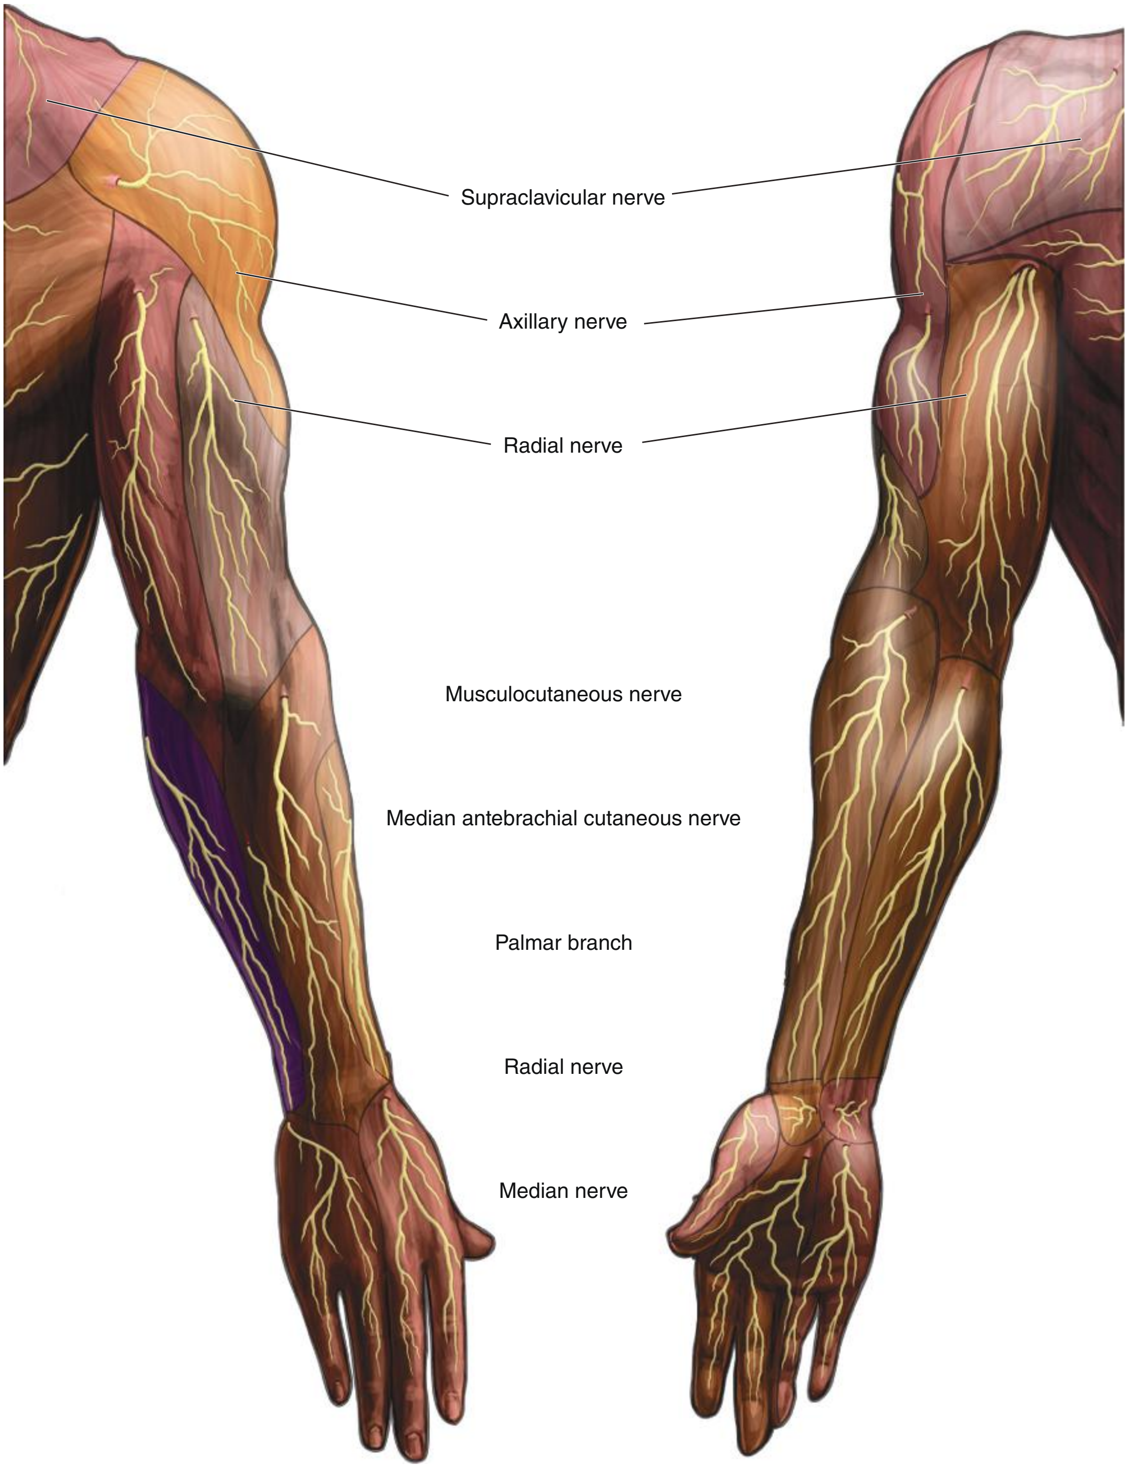

FIGURE 80E–9. Sensory innervation of the upper extremity.

Toxicity Due to Absorption of LA Toxicity due to absorption of LA (in contrast to the accidental intravascular injection, which becomes symptomatic during or immediately after the injection) usually becomes symptomatic 5–20 minutes after injection. The symptoms include lightheadedness, dizziness, tunnel vision, circumoral paresthesia, bradycardia or tachycardia, anxiousness (eventually progressing to unconsciousness), and seizures. Oxygen, a sedative/hypnotic in titrated doses, and airway support if necessary should be immediately administered.

Nerve Injury Nerve injury may be caused by the advancing needle, intraneural injection, application of a tourniquet, or a combination of these. Intraneural injections are characterized by pain, extremity withdrawal, and resistance to injection. Needle and injection injuries typically manifest as neurologic deficit in the distribution of the affected nerve. However, ischemic damage caused by prolonged application of the tourniquet more commonly results in a diffuse injury, affects several nerves, and is usually accompanied by soreness of the upper arm. Symptoms of nerve damage (sensory loss and persistent paresthesia) usually appear within a day or two after recovery from the block. Most nerve injuries are neurapraxia (functional damage), which carry a good prognosis and heal within a few weeks.

Clinical Pearls

- When the motor response to nerve stimulation is seen with currents <0.2 mA, the tip of the needle should be slightly withdrawn or repositioned to maintain the twitch with 02–0.5 mA.
- LA should never be injected when abnormal resistance (high opening pressure) to injection is encountered. When this occurs, the needle should be pulled back slightly and the injection reattempted. If the resistance persists, the needle should be completely withdrawn and cleared; it should never be assumed that the cause of the resistance is related only to needle obstruction.

SUMMARY

For axillary brachial plexus block, a triple-injection nerve stimulator technique with electrolocation of median, musculocutaneous, and radial nerves is preferred.[36,37] A double- injection technique is the next best and may be used with or without a nerve stimulator. The midhumeral (a four-injection technique) is probably best suited for supplementing incomplete axillary blocks, although it can be used as a primary technique. For continuous blocks, the catheter should be placed close to the main nerve innervating the surgical site (e.g., the median nerve for surgery of medial and volar surfaces; the radial nerve for surgery of lateral and dorsal surfaces). For more extensive surgery involving the entire circumference of the arm (e.g., major trauma/amputation), an approach higher in the axilla or infraclavicular block may be better suited. An optimal perineural infusion technique is a basal infusion plus patient-controlled boluses; the suggested LA for this application is ropivacaine 0.2%. An accidental intravascular injection is the most common complication of axillary block. The risk of systemic toxicity of LA can be decreased by avoiding fast, forceful injection and using frequent aspiration to rule out intravascular injection. Pain, paresthesia, extremity withdrawal, or high injection pressure may indicate intraneural needle placement; occurrence of any of these signs and symptoms should prompt immediate cessation of the injection and reevaluation.

CHAPTER 80F

Wrist Block

Paul Hobeika, Tessy Castermans, Joris Duerinckx, and Sam van Boxstael

INTRODUCTION

The wrist block involves anesthesia of the median, ulnar, and radial nerves, including the dorsal sensory branch of the ulnar nerve. The wrist block is simple to perform, essentially devoid of systemic complications, and highly effective for a variety of procedures on the hand and fingers. Wrist blocks can be used in the office or operating room setting. As such, skill in performing a wrist block should be in the armamentarium of every practitioner.[1–9] A study comparing intra-articular and portal infiltration versus wrist block for analgesia after arthroscopy of the wrist has shown that wrist block provides better and more reliable analgesia in patients undergoing arthroscopy of the wrist without exposing patients to the risk of chondrotoxicity.[10]

INDICATIONS & CONTRAINDICATIONS

A wrist block is most commonly used for hand and finger surgery.[11,12] The most common hand surgery in the United States is carpal tunnel release. Sir James Paget described carpal tunnel syndrome in 1853.[1,13] Although Sir James Learmonth reported release of the carpal tunnel at the wrist in 1933, it was not until the 1950s that the surgery became popular through the efforts of George Phalen.[14–16] Because of the ease of performing a wrist block, wrist blocks are used in a variety of settings including the emergency room, outpatient surgery centers, and office-based anesthesia practices. Hand surgeons rely on the wrist block to perform minor procedures in their offices. A wrist block can be used in a patient with a full stomach requiring emergency surgery, thereby obviating the need for general anesthesia and reducing the risk of aspiration.

Although only there are only a few contraindication to wrist blocks, local infection at the site of needle insertion and allergy to local anesthetic are the most cited. Patients are usually able to tolerate a tourniquet on the arm without anesthesia for 20 minutes; a wrist tourniquet can be tolerated for about 120 minutes.

FUNCTIONAL ANATOMY OF WRIST BLOCK

Innervation of the hand is shared by the ulnar, median, and radial nerves (Figure 80F–1). The ulnar nerve innervates more intrinsic muscles than the median nerve, and supplies digital branches to the skin of the medial one and a half digits (Figure 80F–2). A corresponding area of the palm is innervated by palmar branches that arise from the ulnar nerve in the forearm. The deep branch of the ulnar nerve accompanies the deep palmar arch and supplies innervation to the three hypothenar muscles, the medial two lumbrical muscles, all the interossei, and the adductor pollicis. The ulnar nerve also innervates the palmaris brevis muscle.

The median nerve traverses the carpal tunnel and terminates as digital and recurrent branches. The digital branches innervate the skin of the lateral three and a half digits and, usually, the lateral two lumbrical muscles. A corresponding area of the palm is innervated by palmar branches that arise from the median nerve in the forearm. The recurrent branch of the median nerve supplies the three thenar muscles. In the palm, the digital branches of the ulnar and median nerves lie deep in the superficial palmar arch, but in the fingers, they lie anterior to the digital arteries that arise from the superficial arch. Although the innervation of the ring and middle fingers may vary, the skin on the anterior surface of the thumb is always supplied by the median nerve and that of the little finger by the ulnar nerve. The palmar digital branches of the median and ulnar nerves also innervate the nail beds of their respective digits.

The radial nerve passes along the front of the radial side of the forearm. It arises first from the lateral side of the radial

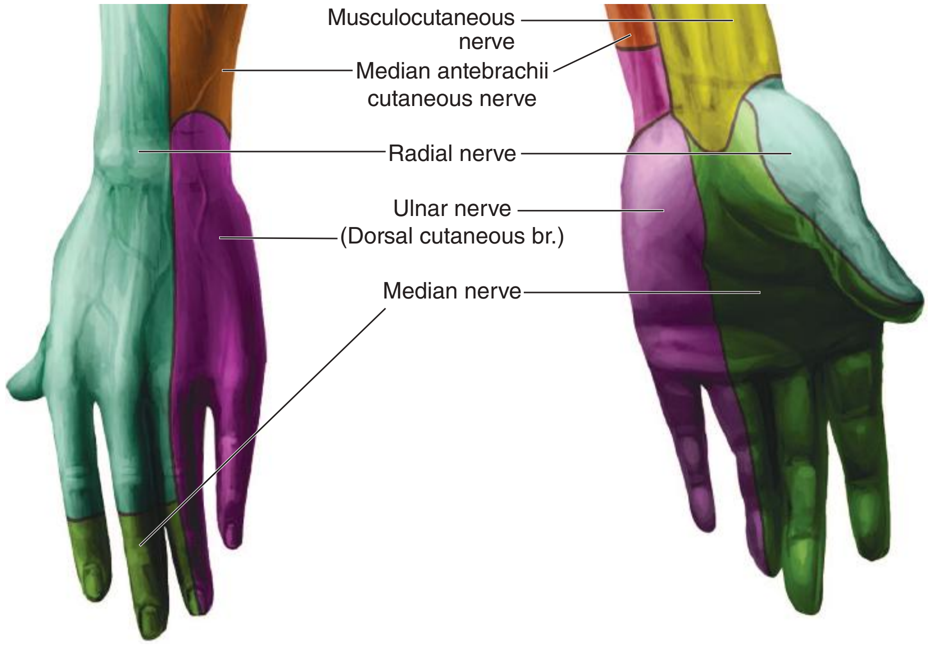

FIGURE 80F–1. Innervation of the hand.

artery and beneath the supinator muscle. About 3 in. above the wrist, it leaves the artery, pierces the deep fascia, and divides into two branches (Figure 80F–3). The superficial branch, the smaller of the two branches, supplies the skin of the radial side and base of the thumb, and joins the anterior branch of the musculocutaneous nerve. The deep branch of the radial nerve communicates with the posterior branch of the musculocutaneous nerve. On the dorsum of the hand, the deep branch of the radial nerve forms an arch with the dorsal cutaneous branch of the ulnar nerve.

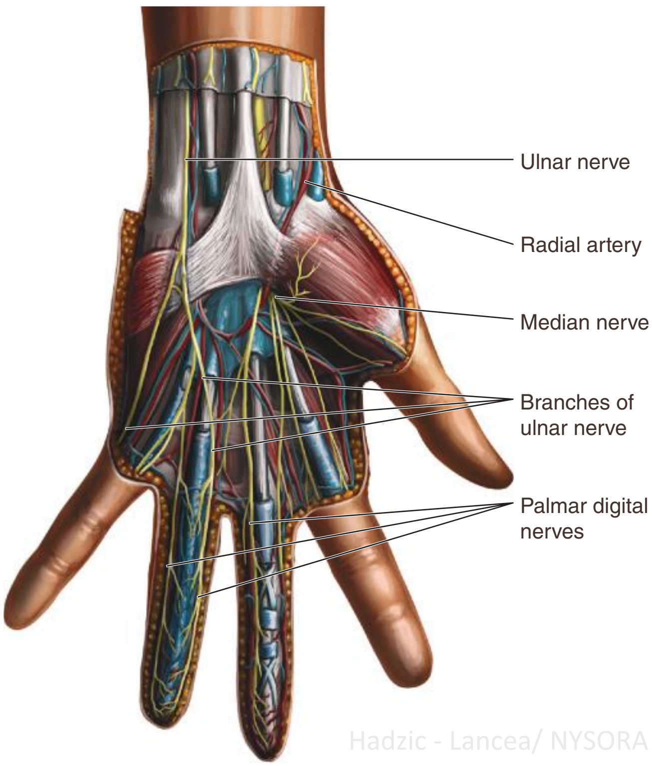

FIGURE 80F–2. Innervation of the hand: The course of the terminal nerves.

ANATOMIC LANDMARKS

The superficial branch of the radial nerve runs along the medial aspect of the brachioradialis muscle (see Figure 80F–3). It then passes between the tendon of the brachioradialis and radius to pierce the fascia on the dorsal aspect. Just above the styloid process of the radius, it gives off digital branches for the dorsal skin of the thumb, index finger, and lateral half of the middle finger. Several of its branches pass superficially over the anatomic "snuff box."

The median nerve is located between the tendons of the palmaris longus and the flexor carpi radialis (Figures 80F–4; see 80F–2). The palmaris longus tendon is usually the more prominent of the two tendons, and the median nerve passes just lateral to it.

The ulnar nerve passes between the ulnar artery and tendon of the flexor carpi ulnaris (see Figures 80F–2 and 80F–4). The tendon of the flexor carpi ulnaris is superficial to the ulnar nerve.

EQUIPMENT

A standard regional anesthesia tray is prepared with the following equipment:

- Sterile towels and 4-in. × 4-in. gauze pads
- 10-mL syringes with local anesthetic (LA)
- One 1.5 -in., 25-gauge needle

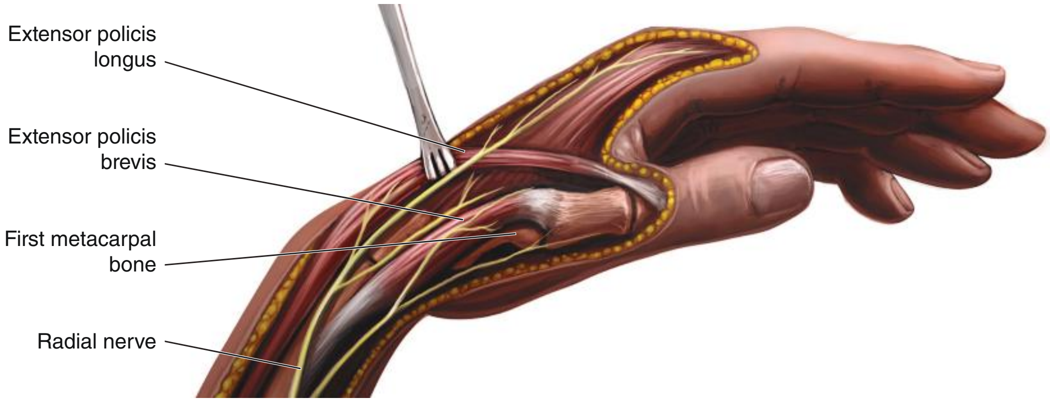

FIGURE 80F–3. Position and course of the radial nerve at the wrist.

TECHNIQUE

The patient is in the supine position with the arm abducted. The wrist should be kept in a slight dorsiflexion.

Block of the Radial Nerve

The radial nerve block is essentially a "field block" and requires a more extensive infiltration because of its less predictable anatomic location and division into multiple, smaller cutaneous branches. Five milliliters of LA is injected subcutaneously just above the radial styloid while advancing the needle medially (Figure 80F–5). The infiltration is then extended laterally, using an additional 5 mL of LA.

Block of the Dorsal Sensory Branch of the Radial Nerve

The dorsal sensory branch of the radial nerve is blocked by inserting the needle 1 cm proximal to the radial styloid, which is radial to the radial artery (Figure 80F–6). This branch of the radial nerve exits from between the brachioradialis and extensor carpi radialis longus 5–8 cm proximal to the radial styloid. The needle is advanced to the Lister tubercle, and if there are no paresthesias, 5 mL of LA is injected subcutaneously throughout this area.

Block of the Ulnar Nerve

The ulnar nerve is anesthetized by inserting the needle under the tendon of the flexor carpi ulnaris muscle close to its

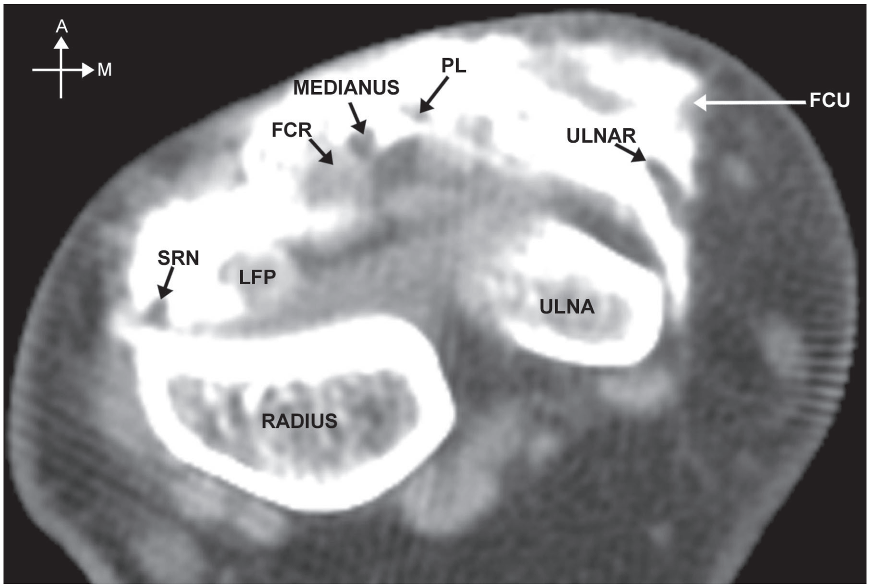

FIGURE 80F–4. Cross-sectional anatomy of the wrist as shown on an MRI scan just above the carpal tunnel. A = anterior, M = medial, SRN = superficial radial nerve, LFP = tendon of the flexor palmaris longus, FCR = flexor carpi radialis, PL = tendon of the palmaris longus, FCU = tendon of the flexor carpi radialis.

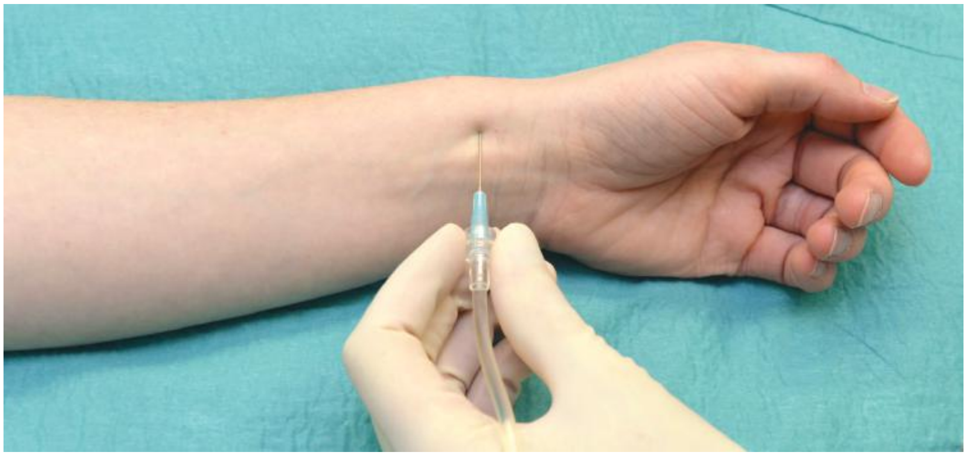

FIGURE 80F–5. Block of the radial nerve above the head of the radius.

distal attachment just above the styloid process of the ulna (Figures 80F–7 and 80F–8; see Figure 80F–4). The needle is advanced 5–10 mm to just past the tendon of the flexor carpi ulnaris. Three to 5 mL of LA solution is injected. A subcutaneous injection of 2–3 mL of local anesthesia just above the tendon of the flexor carpi ulnaris is also advisable in blocking the cutaneous branches of the ulnar nerve, which often extend to the hypothenar area.

Block of the Dorsal Sensory Branch of the Ulnar Nerve

The dorsal sensory branch of the ulnar nerve is blocked by inserting the needle at the level of the ulnar styloid because it travels from palmar to dorsal in the area of the ulnar styloid (Figure 80F–9). Start the injection at the flexor carpi ulnaris and extend subcutaneously dorsally toward the distal radioulnar joint. Five milliliters of LA is injected subcutaneously throughout the area.

Block of the Median Nerve

The median nerve is anesthetized by inserting the needle between the tendons of the palmaris longus and flexor carpi radialis (Figures 80F–10 and 80F–11; see Figure 80F–8). The needle is inserted until it pierces the deep fascia. Three to 5 milliliters of LA is injected. Although the piercing of the deep fascia has been described to result in a fascial "click," it is more reliable to simply insert the needle until it contacts the bone. At that point, the needle is withdrawn 2–3 mm and the LA is injected. Figure 80F–12 demonstrates the spread of the LA after injection of 5 mL using the described technique.

Clinical Pearls

- A "fan" technique is recommended to increase the success rate of the median nerve block.

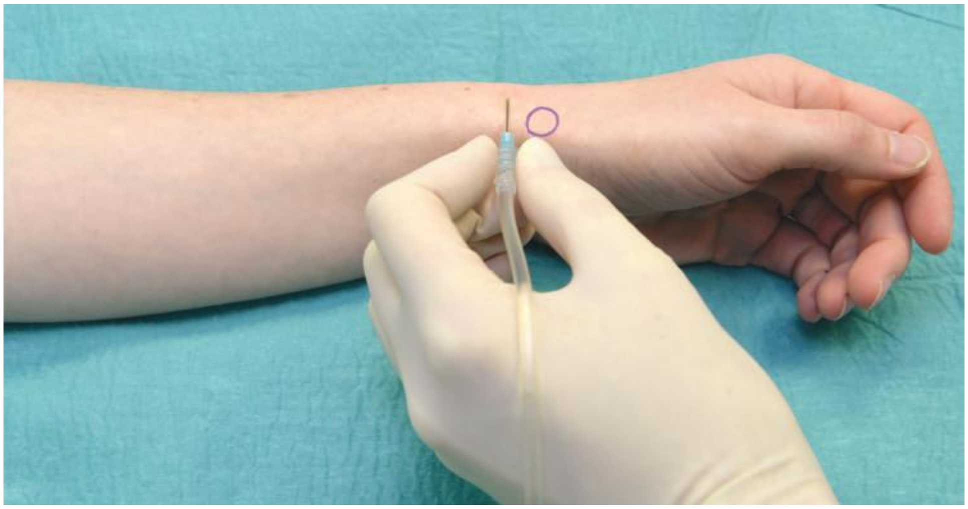

FIGURE 80F–6. Block of the superficial radial nerve

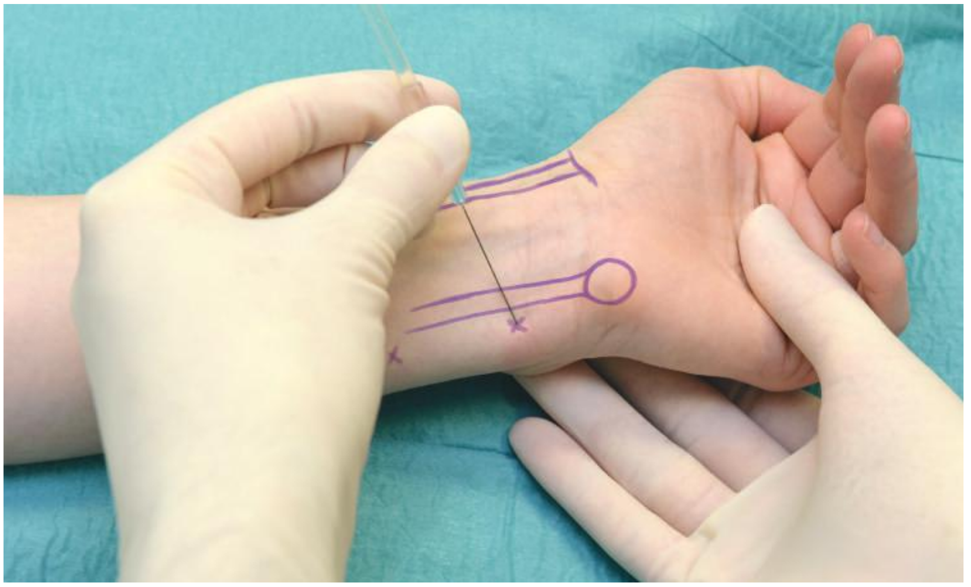

FIGURE 80F–7. Block of the ulnar nerve–the needle is shown inserted just medial to the flexor carpi ulnaris

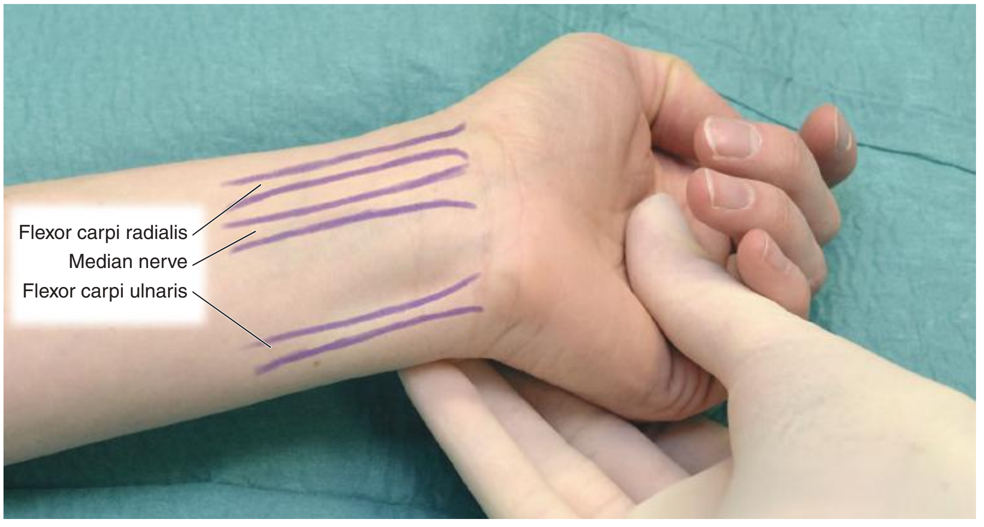

FIGURE 80F–8. Tendons of the wrist flexors and position of the medianus nerve in relationship to the flexor tendons.

FIGURE 80F–9. Block of the superficial branch of the ulnar nerve.

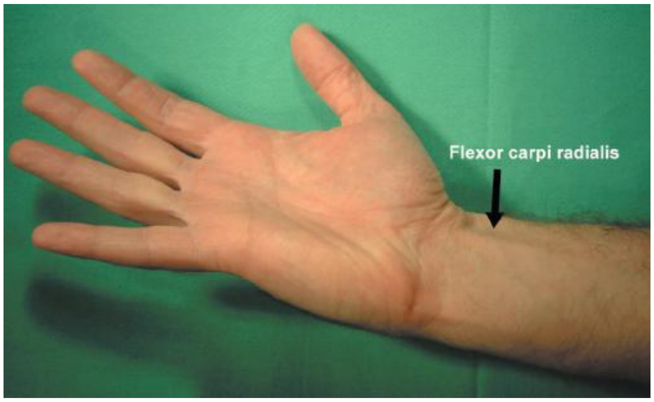

FIGURE 80F–10. A maneuver to accentuate the tendon of the flexor carpi radialis.

- After the initial injection, the needle is withdrawn back to the skin level, redirected 30 degrees laterally, and advanced again to contact the bone.
- After pulling back 1–2 mm off the bone, an additional 2 mL of LA is injected.
- A similar procedure is repeated with a medial redirection of the needle.

Nerve Stimulation Technique

Median and ulnar nerve can also be blocked at the wrist using a nerve stimulator. These blocks may be used for finger flexor tendon repairs, when the surgeon wishes to test their function intraoperatively (function of the forearm muscles is not affected). The median nerve is found in the carpal tunnel between the palmaris longus and the flexor carpi radialis tendons, and the ulnar nerve is found between the flexor carpi ulnaris and the ulnar artery. Twitches are similar to elbow blocks except for the forearm pronation, which is missing. Two to 3 mL of LA is sufficient to block either nerve.

CHOICE OF LOCAL ANESTHETIC

The choice of the type and concentration of LA for wrist blockade is based on the desired duration. Lidocaine is the most used anesthetic for wrist block, but bupivacaine can be used safely, also.[16] Table 80F–1 provides onset times and duration for some commonly used LAs. Clean the entire wrist area with a disinfectant solution. Aspirate prior to injection of LA to avoid intravascular injection.

BLOCK DYNAMICS AND PERIOPERATIVE MANAGEMENT

This technique is associated with moderate patient discomfort because multiple insertions and subcutaneous injections are required. Appropriate sedation and analgesia, midazolam (2–4 mg) and alfentanil (250–500 mcg), are required to ensure the patient's comfort. A typical onset time for a wrist block is 10–15 minutes, depending primarily on the concentration of LA used. Sensory anesthesia of the skin develops faster than the motor block. Placement of an Esmarch latex-free bandage or a tourniquet at the level of the wrist is well tolerated and does not require additional blockade.

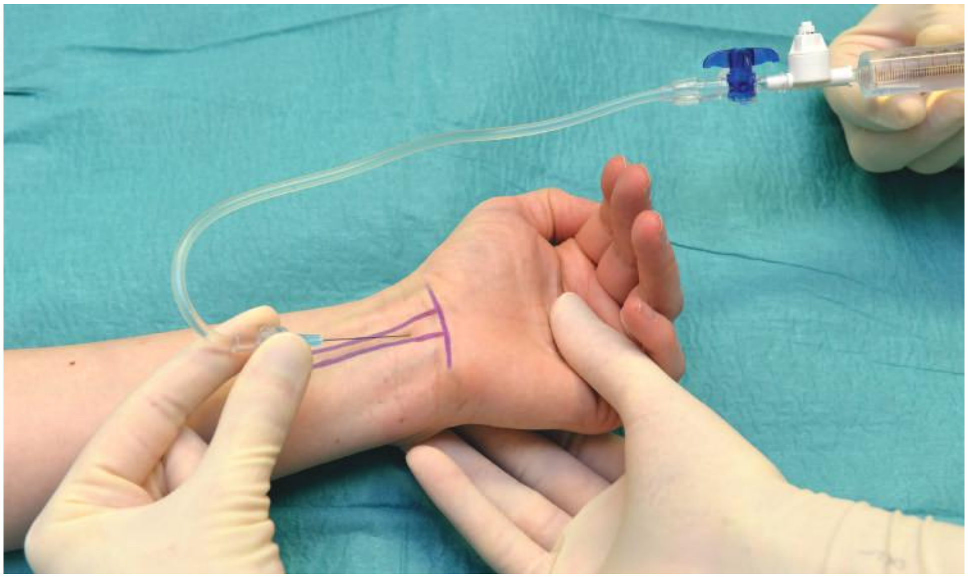

FIGURE 80F–11. Block of the median nerve at the wrist. The needle is shown inserted just medial to the flexor carpi radialis.

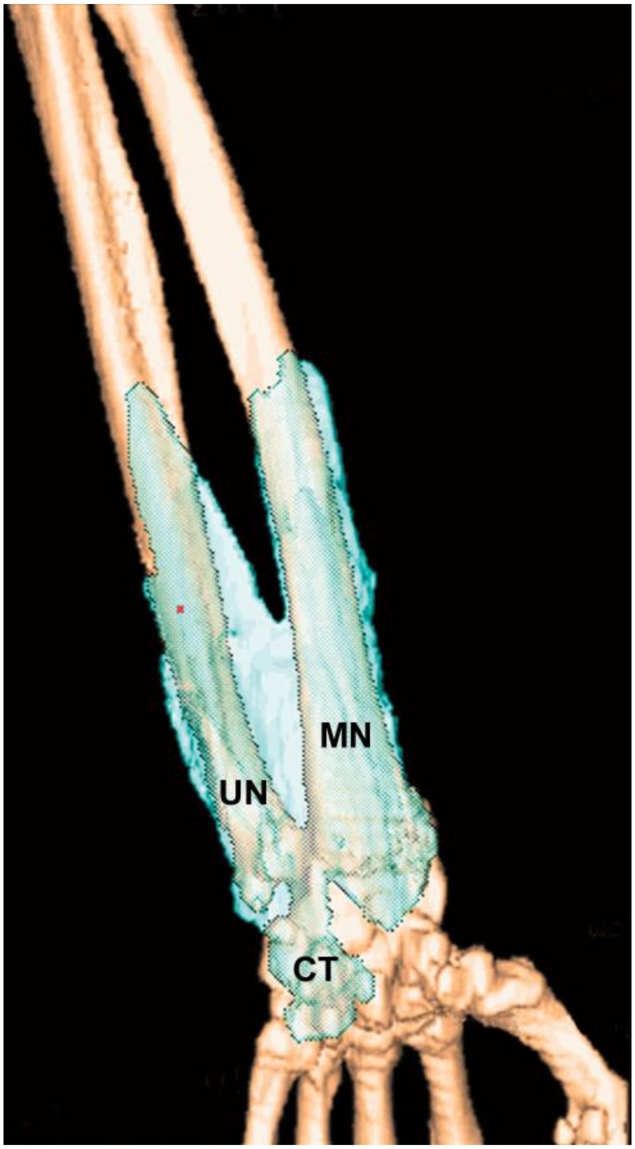

FIGURE 80F–12. Distribution of the dye after wrist block. MN = median nerve, UN = ulnar nerve, CT = carpal tunnel.

TABLE 80F–1. Onset times and duration for commonly used local anesthetic mixtures.

	Onset (min)	Anesthesia (h)	Analgesia (h)
1.5% Mepivacaine (+ HCO_3^-)	15–20	2–3	3–5
2% Lidocaine (+ HCO_3^-)	10–20	2–5	3–8
0.5% Ropivacaine	15–30	4–8	5–12
0.75% Ropivacaine	10–15	5–10	6–24
0.5% Bupivacaine (or L-bupivacaine)	15–30	5–15	6–30

TABLE 80F–2. Complications from wrist block.

Infection	This should be very rare with the use of an aseptic technique.
Hematoma	Avoid multiple needle insertions for superficial blocks. Most superficial blocks can be accomplished with one or two needle insertions. Use 25-gauge needle and avoid puncturing superficial veins.
Vascular complications	Do not use epinephrine with wrist and finger blocks.
Nerve injury	Do not inject when the patient complains of pain or high pressure on injection is detected. Do not reinject the median and ulnar nerves.
Other	Instruct the patient on the care of the insensate extremity.

Clinical Pearl

- Both nerves lie quite superficially in tight compartments and cannot move away from the needle. Extra caution should therefore be used when advancing the needle and injecting LA.

COMPLICATIONS AND HOW TO AVOID THEM

Most common complications after wrist block are residual paresthesias due to an inadvertent intraneural injection. Systemic toxicity is rare because of the distal location of the blockade (Table 80F–2).

CHAPTER 80G

Digital Block

Sam Van Boxstael, Ann-Sofie Smeets, and Jerry D. Vloka

INTRODUCTION

Strauss[1] provided the first description of the digital block in 1889 for the condition of an ingrown toenail, using 20% cocaine at the base and under the nail. In 1905, Heinrich Braun reported the synergistic advantage of adding epinephrine to local anesthetics.[2,3] However, the use of epinephrine in digital block anesthesia has been avoided due to the theoretical risk of ischemia and possible gangrene. However, Bradon Wilhelmi and colleagues[4] demonstrated the safety and efficacy of epinephrine-containing local anesthetic for digital block. Digital block is one of the most common nerve block techniques. It is frequently used in the emergency department and primary care settings for various procedures such as lacerations of the finger or toe, nail removal, nail bed repair, paronychia drainage, removal of foreign bodies, and any other painful procedures on digits.

In 1990, almost a century after the first publication regarding traditional digital block, David Chiu[5] described a technique of digital block that produced complete finger anesthesia with a single injection into the flexor tendon sheath at the level of the distal palmar crease. In anatomic investigations he showed that after injection of methylene blue into the flexor tendon sheath there was "complete staining of the entire flexor tendon sheath and centrifugal diffusion of the blue dye circumscribing the entire circumference of the proximal phalanx" (see Transthecal Digital Block). The advantages of this technique are (1) rapid onset of action, (2) only a small volume of anesthetic solution is required, (3) only a single injection is required, and (4) absence of risk of direct trauma to the neurovascular bundles.[6–8] Although Chevaleraud and coworkers[9] did not find anesthesia of the dorsum of the finger in all cases, some investigators consider the transthecal method to be as effective as a traditional digital nerve block.[10] Others have found that it results in anesthesia comparable to the newer single-injection subcutaneous digital blocks,[11] both in experimental and clinical situations.[12,13]

Transthecal anesthesia appears to be safe and effective without causing any long-term damage to the tendon sheath.

Several different techniques of digital block and their modifications are available: In this chapter, we describe the two that are most commonly used in our institution.

REGIONAL ANESTHESIA ANATOMY

The common digital nerves are derived from the median and ulnar nerves and divide in the distal palm into the volar aspect, tip, and nail bed area (Figure 80G–1). The main digital nerves, accompanied by digital vessels, run on the ventro-lateral aspect of the finger immediately lateral to the flexor tendon sheath (Figure 80G–2). Small dorsal digital nerves run on the dorsolateral aspect of the finger and supply innervation to the back of the fingers as far as the proximal joint.

EQUIPMENT

A standard regional anesthesia tray is prepared with the following equipment:

- Sterile towels and 4-in. × 4-in. gauze pads
- A controlled, 10-mL syringe with local anesthetic
- One 1.5 -in., 25-gauge needle

TECHNIQUE

Block of Volar and Dorsal Digital Nerves at the Base of the Finger

A 25-gauge, 1.5 -in. needle is inserted at a point on the dorsolateral aspect of the base of the finger, and a small skin wheal is raised. The needle is then directed anteriorly toward

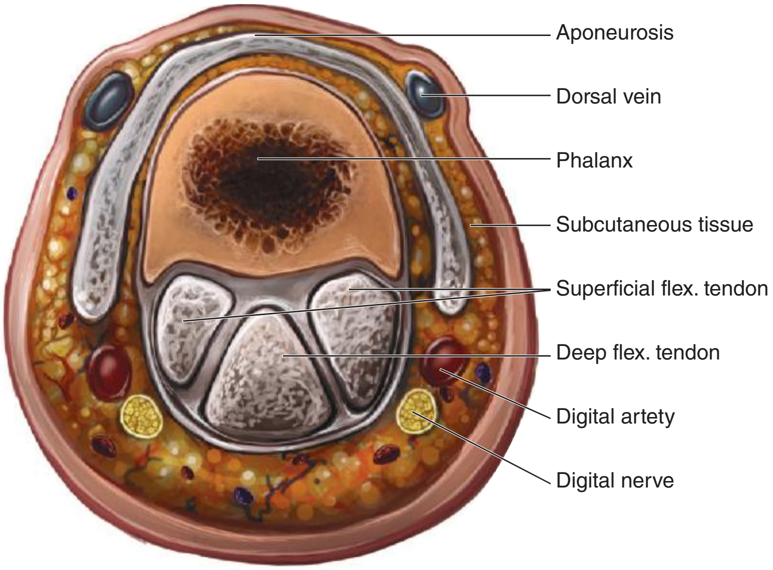

FIGURE 80G–1. The origin and distribution of the digital nerves.

the base of the phalanx (Figures 80G–3 and 80G–4 A and B). The needle is advanced until it contacts the phalanx, while the anesthesiologist observes for any protrusion from the palmar dermis directly opposite the needle path (Figure 80G–5). One milliliter of solution is injected as the needle is withdrawn 1–2 mm from the bone contact. An additional 1 mL is injected continuously as the needle is withdrawn back to the skin. The same procedure is repeated on each side of the base of the finger to achieve anesthesia of the entire finger (Figure 80G–6 A and B).

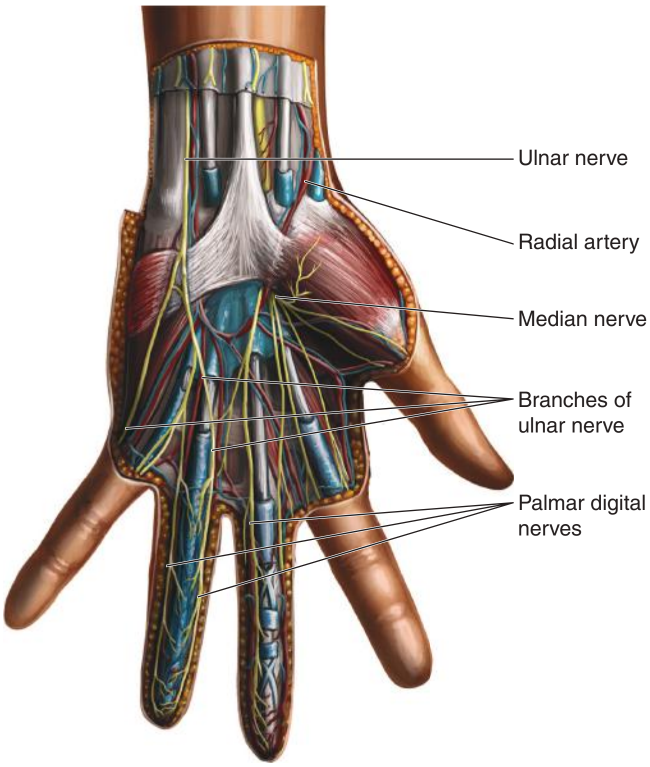

FIGURE 80G–2. Cross-sectional view of the anatomy of the phalanx.

Transthecal Digital Block

The transthecal digital block is placed by using the flexor tendon sheath for local anesthetic injection. In this technique, the patient's hand is supinated and the flexor tendon is located. Using a 25- to 27-gauge, 1-in. needle, 2 mL of local anesthetic is injected into the flexor tendon sheath at the level of the distal palmar crease (Figures 80G-3 and 80G-7). The needle should puncture the skin at a 45-degree angle. Resistance to the injection suggests that the needle tip is against the flexor tendon. Careful withdrawal of the needle results in the free flow of medication as the potential space between tendon and sheath is entered. Proximal pressure is then applied to the volar surface for the duration of the injection for the diffusion of the medication throughout the synovial sheath.

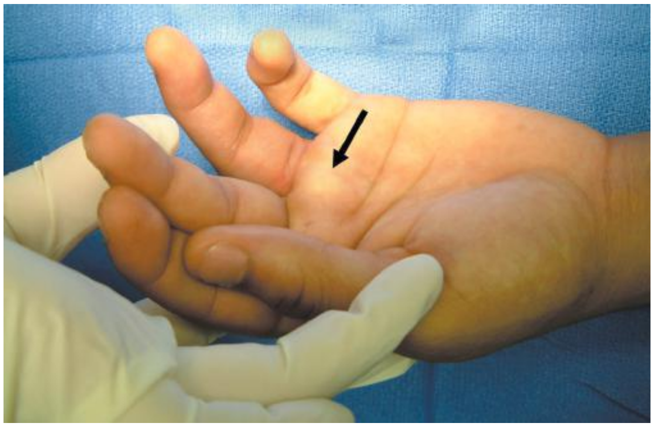

FIGURE 80G–3. Angle of needle insertion for transthecal digital block.

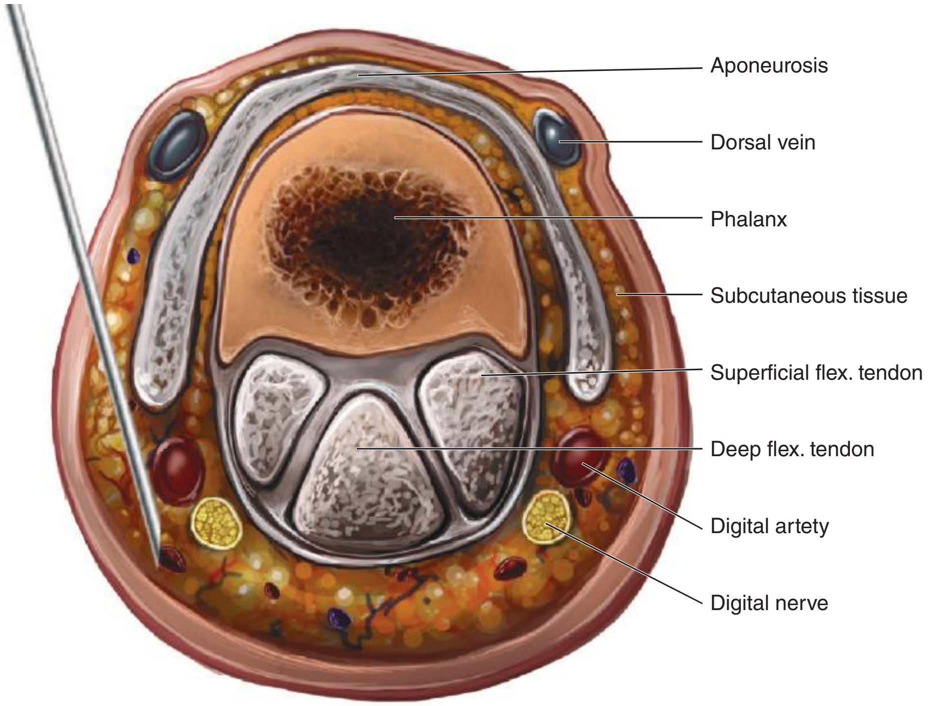

FIGURE 80G–4. The needle is shown inserted at the base of the proximal phalanx to block the medial digital nerve.

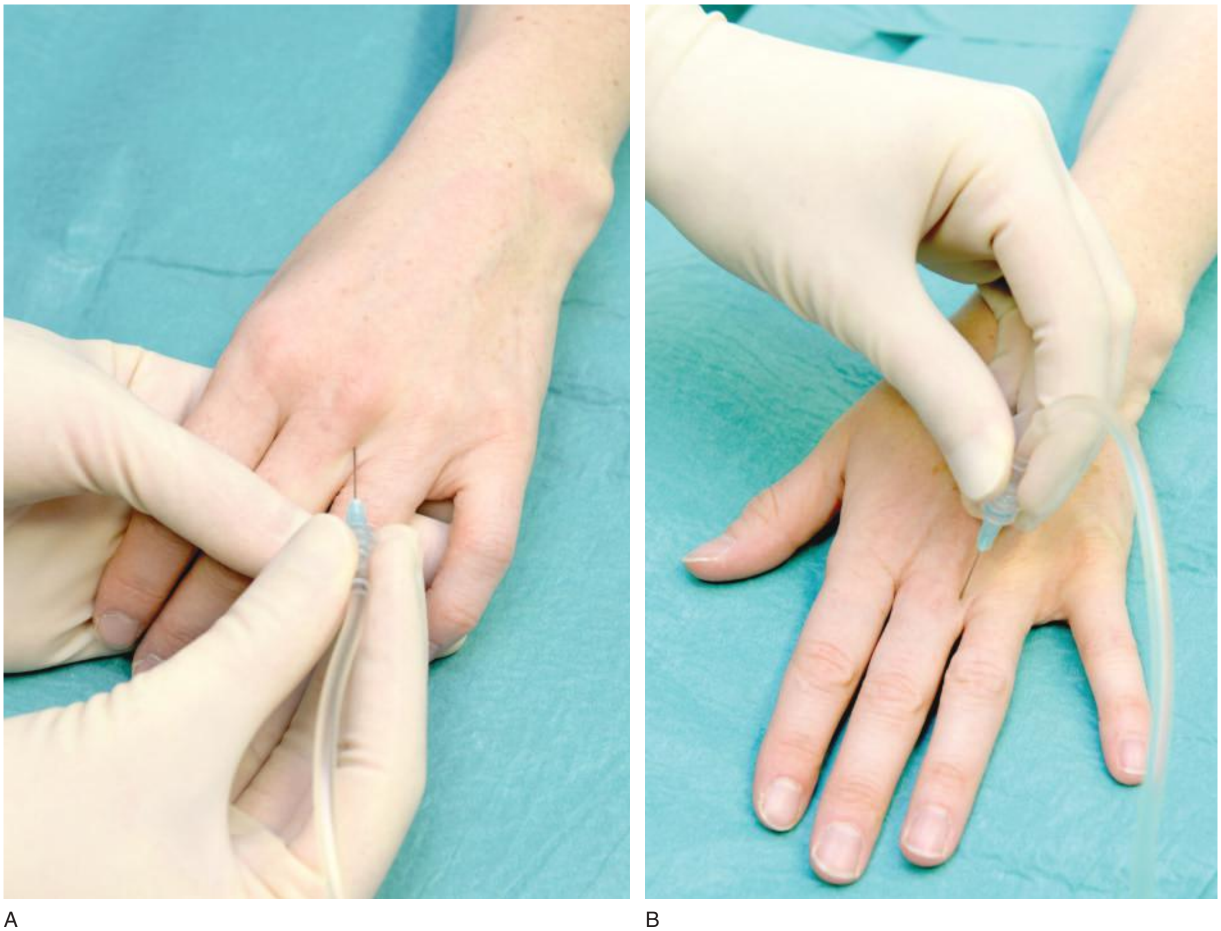

FIGURE 80G–5. As the needle is inserted and injection is being made, the operator observes the palmar area to stop the advancement of the needle should a protrusion from the palmar dermis opposite the nerve tip be seen.

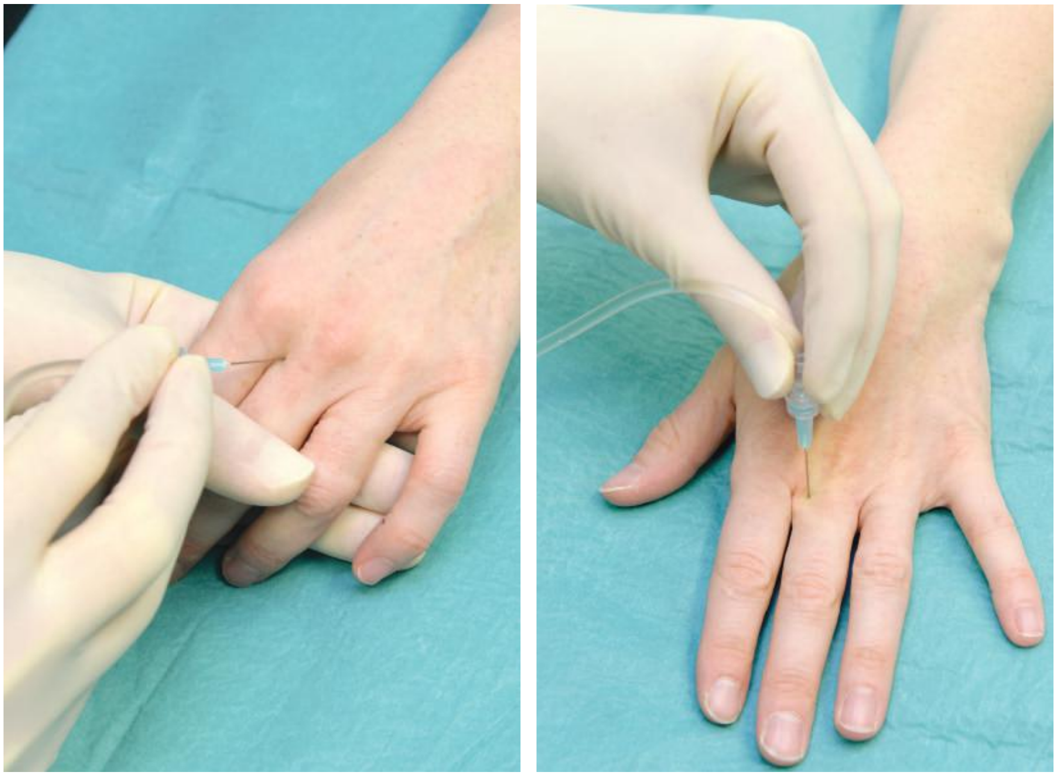

FIGURE 80G–6. A and B: The identical procedure is repeated on the radial side of the proximal phalanx to block the radial branch of the digital nerve.

Clinical Pearls

- The advantage of this approach is the provision of anesthesia to the entire digit with a single injection and a reportedly higher success rate.
- For more extensive surgery on the finger, it may be advantageous to combine both approaches discussed in this chapter for a greater success rate and more extensive distribution of anesthesia.

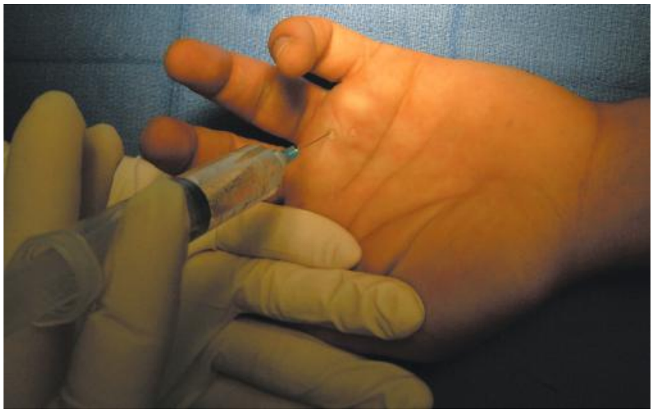

FIGURE 80G–7. Transthecal digital block. The needle is placed into the flexor tendon sheath. To confirm the correct needle placement in the tendon sheath, the needle can be placed without the syringe, in which case the operator flexes and deflexes the finger. This should result in a free and substantial swinging of the needle.

BLOCK DYNAMICS AND PERIOPERATIVE MANAGEMENT

A skin wheal at the point of needle insertion significantly reduces the discomfort during the placement of the block. A digital block requires a small dose of a sedative or a narcotic during placement. Typical onset time for this block is 10–20 min, depending on the concentration and volume of local anesthetic used.

CHOICE OF LOCAL ANESTHETIC

The choice of the type and concentration of local anesthetic for a digital block is based on the desired duration of blockade (Table 80G–1).[14]

TABLE 80G–1. Onset times and duration of anesthesia for some commonly used local anesthetics mixtures.

	Onset (min)	Anesthesia (h)	Analgesia (h)
1.5% Mepivacaine (+ HCO_3^-)	15–20	2–3	3–5
2% Lidocame (+ HCO_3^-)	10–20	2–5	3–8
0.5% Ropivacaine	15–30	4–8	5–12
0.75% Ropivacaine	10–15	5–10	6–24
0.5% Bupivacaine (or L-bupivacaine)	15–30	5–15	6–30

TABLE 80G–2. Complications of digital blocks.

Infection	This should be very rare with use of an aseptic technique.
Hematoma	Avoid multiple needle insertions. Use 25-gauge needle (or smaller) and avoid puncturing superficial veins.
Other	Instruct the patient on the care of the insensate finger.
Gangrene of the digit(s)	The use of epinephrine-containing solutions for this block is avoided by many; the safety of its use is controversial. Limit the injection volume to 3 mL on each side. The mechanical pressure effects of injecting solution into a potentially confined space should always be borne in mind, particularly in blocks at the base of the digit. In patients with small-vessel disease, perhaps an alternative method should be sought in addition to avoidance of digital tourniquet.
Nerve injury	Residual paresthesias are rare and may be due to an inadvertent intraneuronal injection. Systemic toxicity is rare because of the distal location of the blockade and small dose of local anaesthetic used. Do not inject when the patient complains of pain or when high resistance to injection is encountered.

COMPLICATIONS AND HOW TO AVOID THEM

One specific complication of digital blocks is vascular insufficiency and gangrene.[15] This catastrophe is a result of digital artery occlusion together with collateral circulation insufficiency. A series of causative factors is often involved to produce this rare, but serious complication (Table 80G–2).

CHAPTER 80H

Cutaneous Blocks for the Upper Extremity

Joseph M. Neal and Yavuz Gurkan

INTRODUCTION

Although most upper extremity regional anesthesia is accomplished by means of various approaches to the brachial plexus, there are occasions when individual terminal nerves or their branches are blocked selectively. There are generally three instances in which the anesthesiologist desires to perform these selective nerve blocks. First, some surgical sites are partially innervated by sensory nerves that are not part of the brachial plexus or not consistently anesthetized with plexus blocks. This chapter describes how and when to anesthetize the most common of these nerves—the supraclavicular, the suprascapular, and the intercostobrachial. The second indication is when the block of the entire brachial plexus block is not necessary for the planned procedure. In this case, selective upper extremity cutaneous anesthesia or analgesia may involve blocking terminal nerves (radial, median, or ulnar nerves) or their branches (lateral and medial antebrachial cutaneous nerves) distally at the elbow. A final and controversial indication for selective upper extremity nerve blocks is their use as a supplement to an incomplete brachial plexus block.

When considering the application of these various blocks, the reader is reminded that innervation of the upper extremity is often variable and overlapping.[1] Therefore, when faced with the choice of performing a single nerve block versus blocking several adjacent nerves, it is advisable to err on the side of multiple blocks, particularly in those adjacent cutaneous areas that represent potential crossover innervation (Figures 80H–1 and 80H–2). The relevant anatomy will be covered with specific nerve block description.

Local Anesthetic and Adjuvant Selection

Local anesthetics for individual upper extremity nerve blocks are selected for their desired duration of anesthesia and/or analgesia. If intermediate-acting local anesthetics are selected (lidocaine or mepivacaine), duration can be increased with either adjuvant epinephrine (2.5 mcg/mL). Neither adjuvant significantly increases duration if a long-acting local anesthetic such as bupivacaine or ropivacaine is chosen.[1]

SUPRACLAVICULAR NERVE BLOCK INDICATIONS

The supraclavicular nerve provides sensory innervation to the "cape" of the shoulder (Figure 80H–3). Commonly anesthetized as a component of cervical plexus block for carotid surgery, the supraclavicular nerve may also require blockade for surgery involving the shoulder or supraclavicular area. Local anesthetic spread in an interscalene plexus block often blocks the cervical plexus and therefore it is adequate to block the supraclavicular nerve, but the nerve is frequently not anesthetized with a supraclavicular brachial plexus block.

Anatomy

The supraclavicular nerve is derived from the ventral rami of the third and fourth cervical nerve roots (C3–C4); it is thus separate from the brachial plexus. The nerve becomes superficial as it penetrates the midbelly of the sternocleidomastoid muscle, thereafter forming three branches (Figure 80H–3). These branches provide sensory innervation to the cape area, which spans from the midline to the deltoids, and from the second rib anteriorly to the top of the scapula posteriorly.

Technique

Blockade of the supraclavicular nerve is accomplished with 5–10 mL of an intermediate- or long-acting local anesthetic, depending on analgesic requirements. Three milliliters is deposited with a 22- to 25-gauge sharp needle into the midbelly of the sternocleidomastoid. The remaining local anesthetic is then injected subcutaneously in a cephalad and caudad direction along the posterior border of the sternocleidomastoid

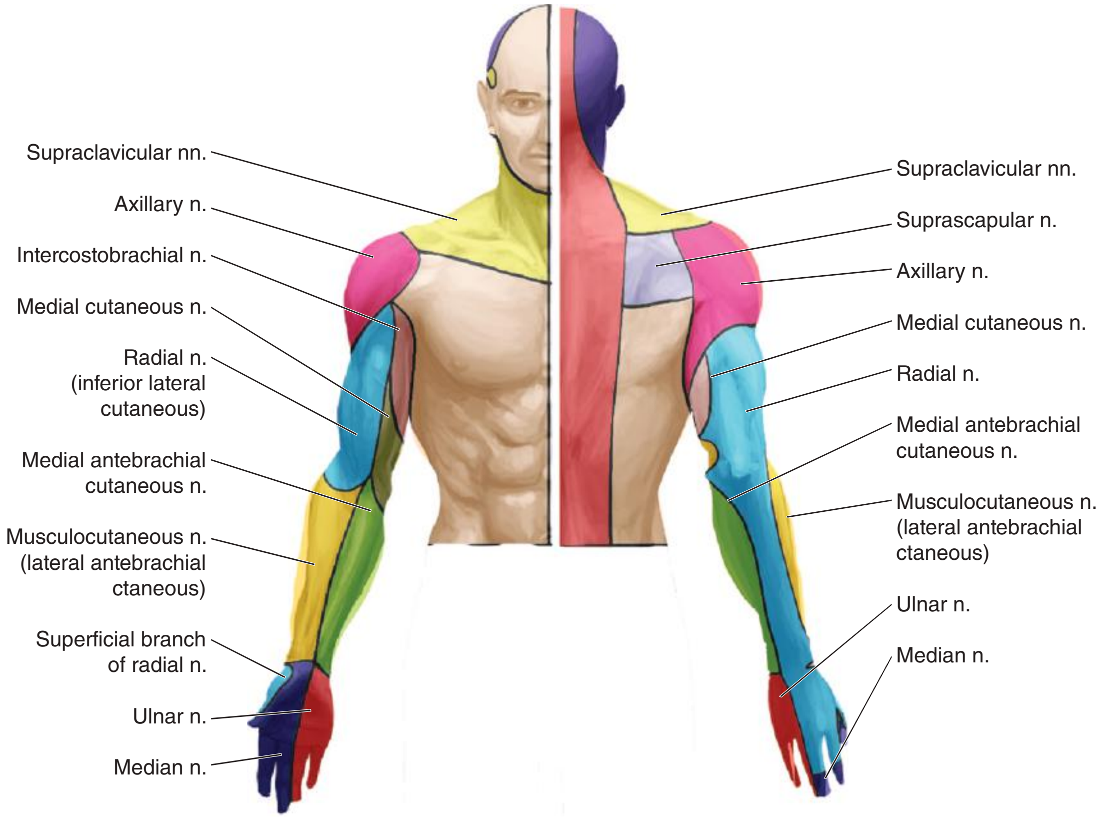

FIGURE 80H–1. Cutaneous innervation of the upper extremity. Actual patients demonstrate large variation in the depicted pattern of innervation and significant crossover between nerves.

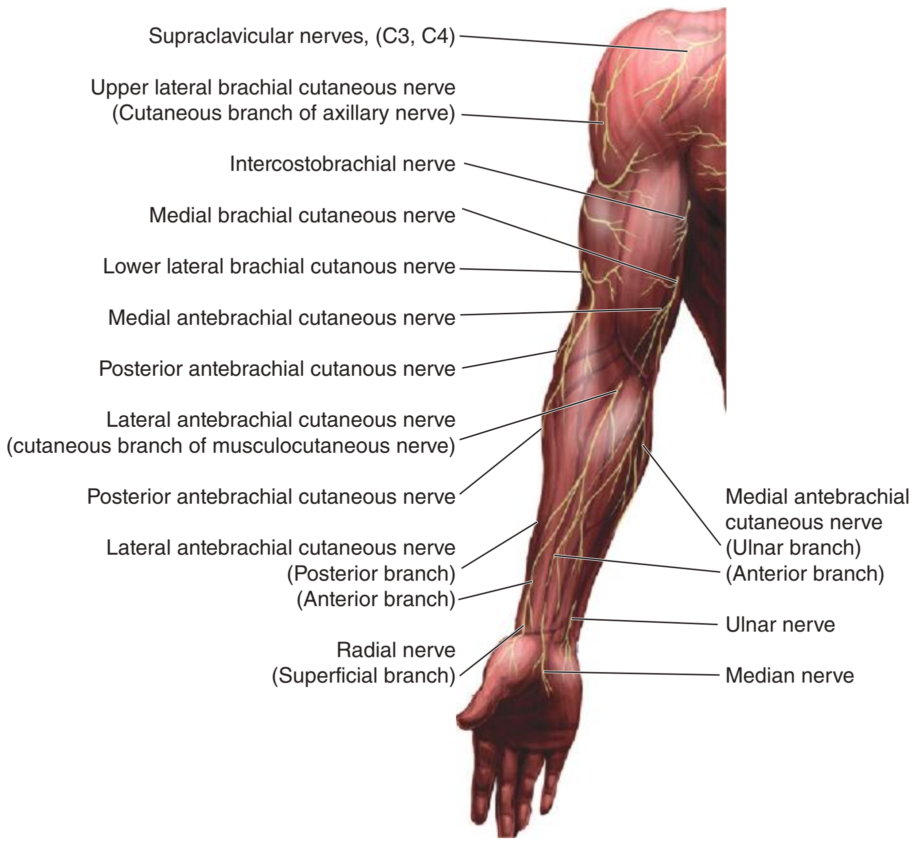

FIGURE 80H–2. Idealized distribution of the cutaneous innervation of the upper arm and forearm.

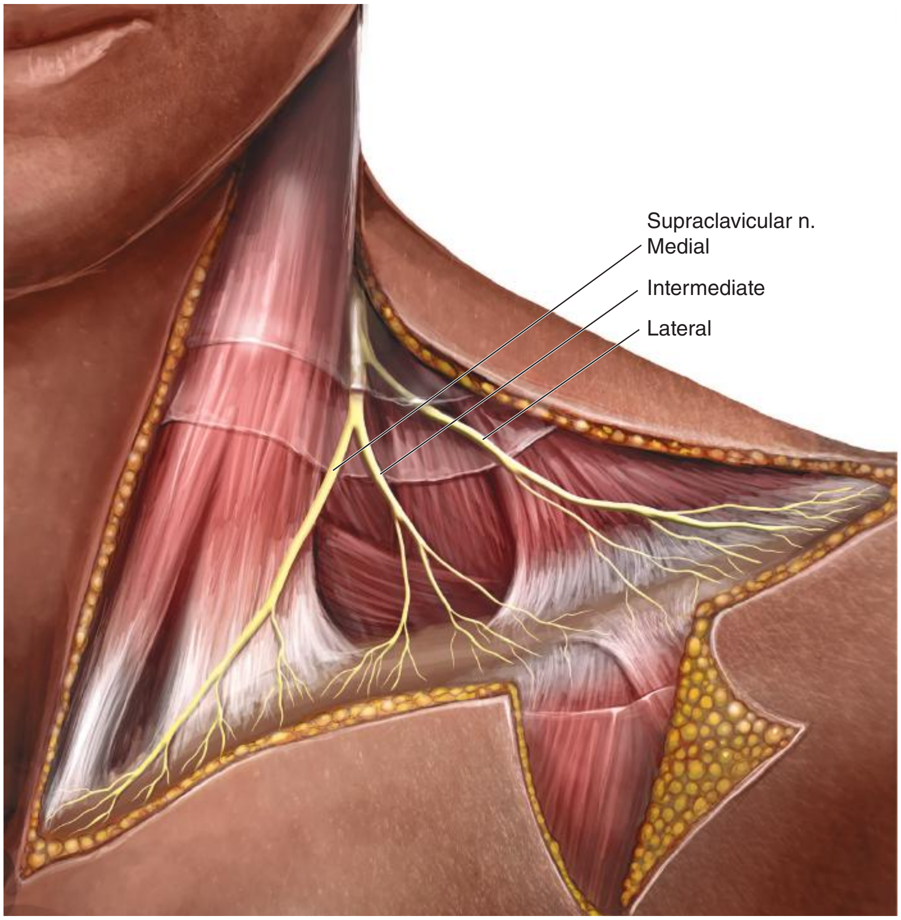

FIGURE 80H–3. Supraclavicular nerves, derived from C3–C4 nerve roots, is not part of the brachial plexus, and provides sensory innervation of the shoulder "cape."

Complications

Complications of the supraclavicular nerve block are uncommon. The external jugular vein should be avoided to prevent hematoma.

SUPRASCAPULAR NERVE BLOCK

Indications

Suprascapular nerve block (SSNB) can be used as an adjunct to arthroscopic shoulder surgery and total shoulder arthroplasty. When combined with general anesthesia for shoulder arthroscopy, SSNB improves analgesia, reduces opioid-related side effects, and hastens hospital discharge,[2] although SSNB is not superior to interscalene block in this setting.[3]

For anterior open shoulder surgery, supplemental SSNB does not affect outcome when combined with interscalene block.[4]

Anatomy

The suprascapular nerve (C4–C5) branches from the superior trunk of the brachial plexus and, therefore, it is usually anesthetized by an interscalene block. It traverses the suprascapular notch and continues laterally along the superior border of the scapular spine (Figure 80H–5). The supraclavicular nerve provides sensory innervation to 70% of the posterior-superior shoulder joint, the acromioclavicular joint, and a portion of the anterior axilla in up to 10% of patients.[1]

The suprascapular nerve provides motor innervation to the supraspinatus and infraspinatus muscles, but minimal if any cutaneous innervation over the scapula or posterior shoulder.

Technique

Surface landmarks are identified by drawing one line along the superior border of the scapular spine and then bisecting it with a second line drawn parallel with the vertebral spine. From where these two lines cross, the suprascapular notch underlies a point approximately 2–3 cm toward the middle of the upper/outer quadrant (see Figure 80H–5). A 1.5-in. 22-gauge needle is placed at this entry mark and directed caudad in the sagittal plane until it contacts the scapular spine, followed by injection of 10 mL of a long-acting local anesthetic. If a peripheral nerve stimulator is used, the suprascapular nerve is identified by the motor response of external shoulder rotation.

Complications

Pneumothorax can result from a needle that passes through the suprascapular notch and enters the pleural space. This

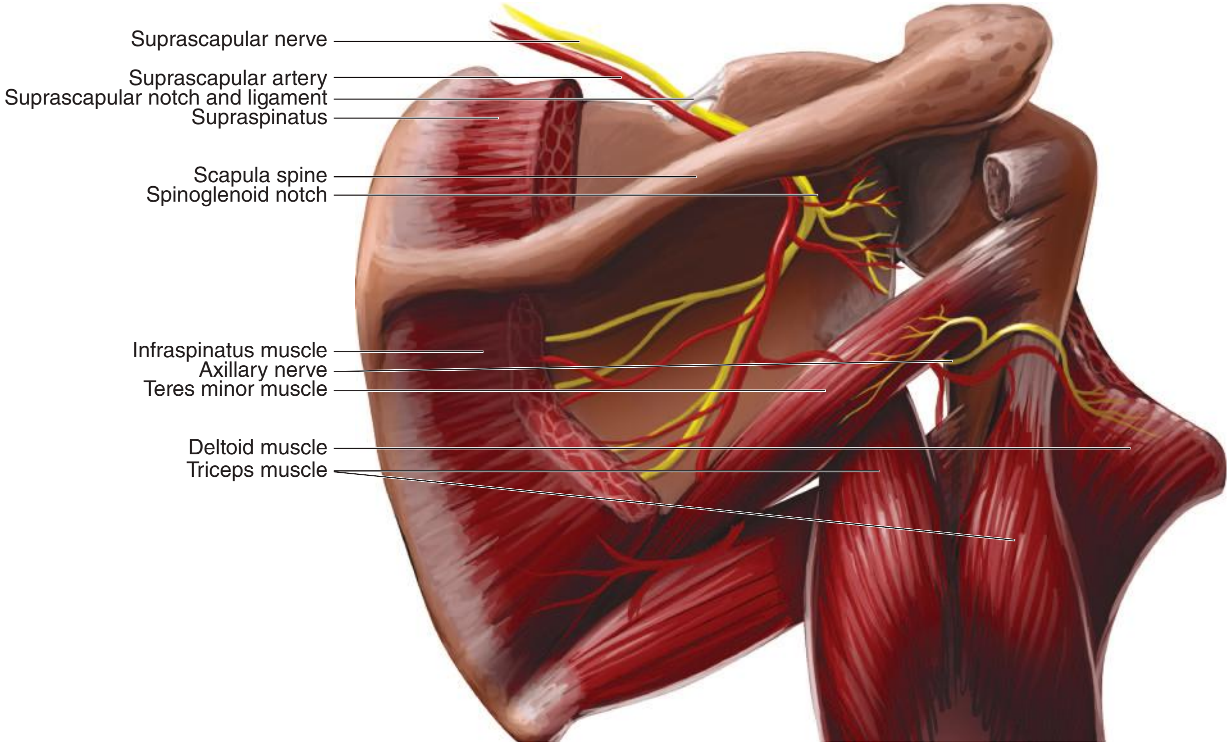

FIGURE 80H–4. Suprascapular nerve block is accomplished by injecting local anesthetic in the suprascapular notch.

complication is largely avoidable by directing the needle in a caudad, rather than anterior, direction.

Clinical Pearls

- Suprascapular nerve block is a valuable analgesic adjunct for shoulder arthroscopy performed with the patient under general anesthesia.
- Suprascapular nerve block does not add value to open shoulder procedures in which an interscalene block is the primary anesthetic.
- Suprascapular nerve block is probably a valuable supplement to interscalene block during total shoulder arthroplasty or in the occasional patient who experiences pain at the anterior arthroscopic port site.

INTERCOSTOBRACHIAL NERVE BLOCK

Indications

The intercostobrachial nerve block is indicated for surgery involving the medial/posterior upper arm and/or for anterior arthroscopic port placement. A secondary indication is to alleviate the sensation resulting from a pneumatic tourniquet applied to the upper arm. Despite commonly held misperception, the intercostobrachial nerve block does not block the ischemic, compressive components that cause tourniquet pain; this is accomplished by brachial plexus block with supplemental intraoperative sedation—additional cutaneous anesthesia is not necessary.

Anatomy

The intercostobrachial nerve arises from the second thoracic (T2 and occasionally T1) nerve root (see Figure 80H–2). As such, it is not a component of the brachial plexus and is, therefore, not anesthetized by any brachial plexus approach. Along with the medial cutaneous nerve of the arm (an intermediary branch of the medial cord), the intercostobrachial nerve provides cutaneous sensation to the upper half of the medial/posterior arm. It also innervates a portion of the anterior axilla (see Figures 80H–1 and 80H–2).

Technique

The intercostobrachial is anesthetized by depositing 5 mL of local anesthetic subcutaneously superiorly and inferiorly along the axillary crease via a 1.5-in. 25-gauge needle (Figure 80H–6).

Complications

Because of its superficial placement, complications of the intercostobrachial nerve block are virtually nonexistent.

Clinical Pearl

- The intercostobrachial nerve block is a useful supplement to any brachial plexus block when surgery involves the upper medial/posterior arm, a pneumatic tourniquet, and/or an anterior arthroscopic port.

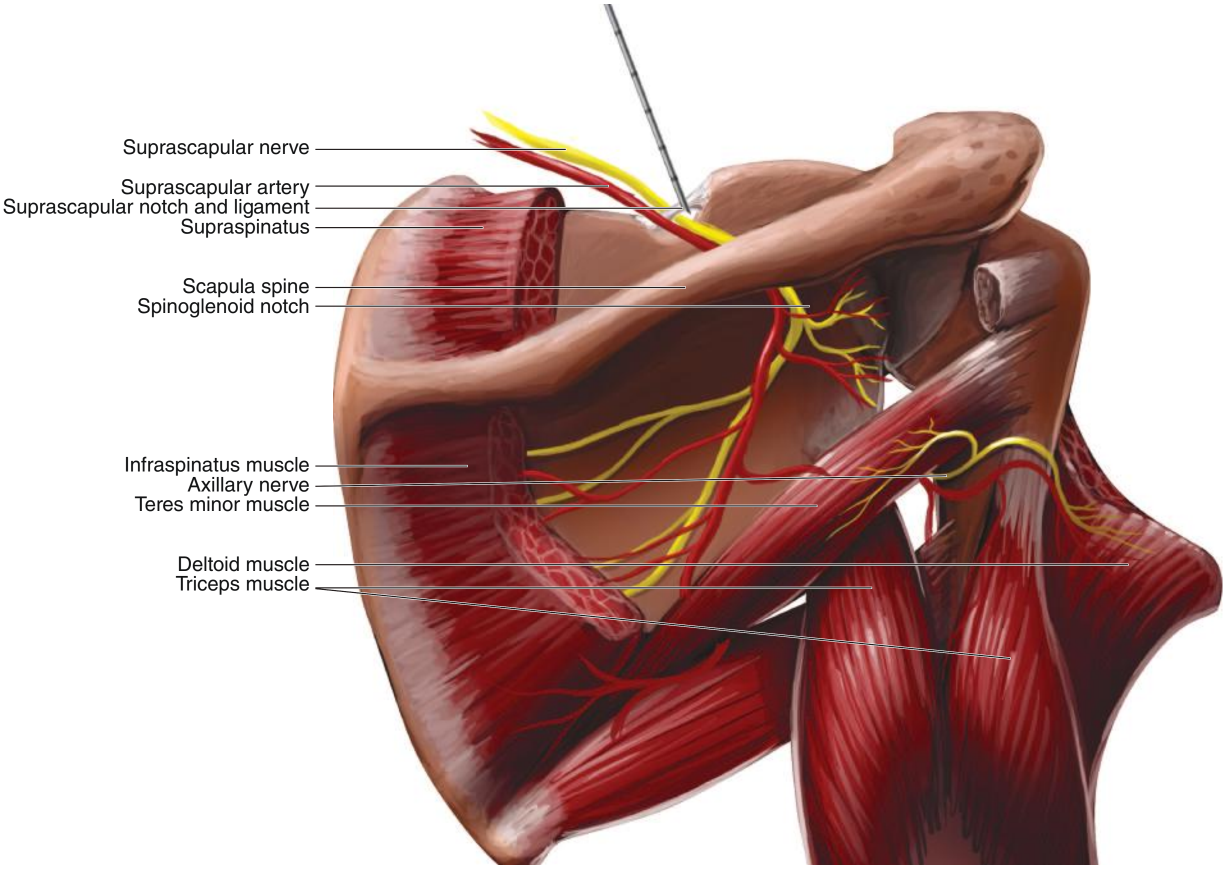

FIGURE 80H–5. Suprascapular nerve block. The suprascapular nerve is blocked as it emerges from the suprascapular notch. Directing the needle caudally substantially reduces the risk of pneumothorax.

LATERAL AND MEDIAL ANTEBRACHIAL CUTANEOUS NERVE BLOCK

Indications

Local anesthetic blockade of the lateral and medial antebrachial cutaneous nerves is indicated for superficial surgery of the forearm, such as arteriovenous fistula surgery, or as a supplement to incomplete brachial plexus block.

Anatomy

The lateral antebrachial cutaneous nerve of the forearm (LAC) is the primary cutaneous branch of the musculocutaneous nerve. It provides cutaneous innervation to the lateral (radial) half of the volar forearm. The medial antebrachial cutaneous nerve of the forearm (MAC) is an intermediary branch of the medial cord. It provides cutaneous innervation to the medial (ulnar) half of the volar forearm, an area commonly misperceived as innervated by the ulnar nerve (see Figures 80H–1 and 80H–2).

Technique

Considering the unpredictable overlap of forearm cutaneous innervation, it is advisable to perform both LAC and MAC nerve blocks when forearm anesthesia is desired. Blocking the LAC is accomplished with two local anesthetic injections placed along the intercondylar line. The first 5 mL of local anesthetic is injected just deep to the lateral margin of the biceps tendon; the second 5 mL area injected subcutaneously and lateral from the first injection site, along the elbow crease (Figure 80H–7). The MAC is blocked by injecting a half-ring of 5–7 mL local anesthetic about a quarter of the arm's length above the medial elbow

FIGURE 80H–6. Intercostobrachial nerve block. The intercostobrachial nerve is anesthetized by subcutaneous injection of 3–5 mL local anesthetic along the axillary crease.

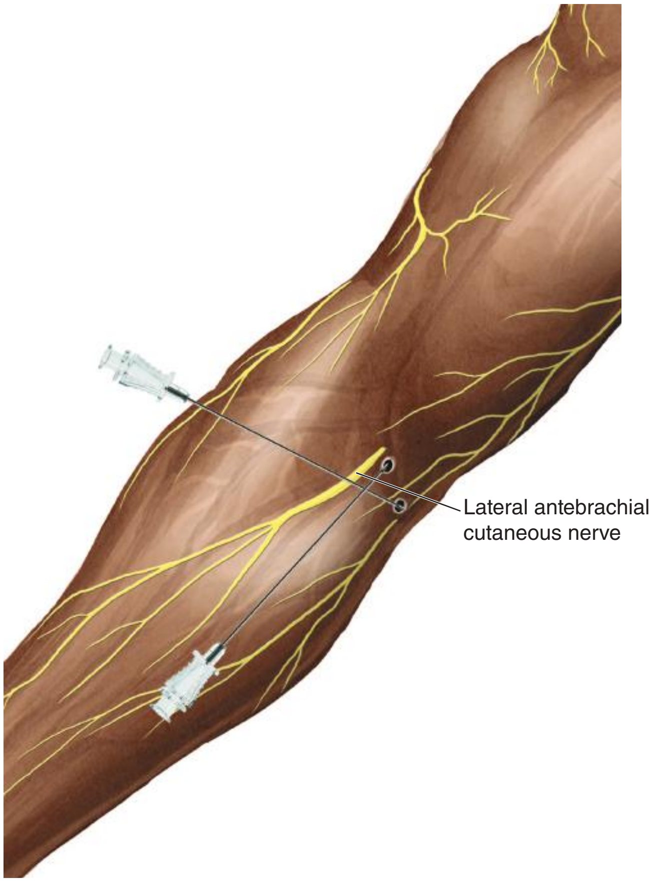

FIGURE 80H–7. Blocks of the lateral and medial antebrachial cutaneous nerve. Anesthesia for lateral antebrachial cutaneous nerve requires two injections. The first deposits 5 mL local anesthetic just lateral to the border of the biceps tendon. A second 5 mL is then injected subcutaneously and lateral from the first injection site.

(Figure 80H–7). When LAC and/or MAC nerve blocks are supplemental to a previous incomplete brachial plexus block, the additional 15–20 mL of local anesthetic should be well tolerated by patients if injected 20–30 minutes after the primary block.[5]

Complications

Techniques for anesthetizing the LAC and MAC nerves involve only superficial injection of local anesthetic; thus the risk of nerve injury is very low. For this reason, these blocks may be preferable to selective elbow or wrist blocks as a supplement to incomplete brachial plexus anesthesia involving volar forearm cutaneous distribution.

Clinical Pearls

- Medial and lateral antebrachial cutaneous nerve blocks are useful techniques for superficial volar forearm procedures, such as arteriovenous fistula creation.
- The nerve blocks also represent a reasonable alternative for supplementation when proximal brachial plexus block is incomplete.

SELECTIVE NERVE BLOCKS AT THE ELBOW

Indications

Proximal techniques of brachial plexus block are often superior to selective nerve block at the elbow because the latter are more difficult to perform, are more time-consuming and uncomfortable, and potentially carry a greater risk of complications. For instance, the practitioner may rather choose the midhumeral brachial plexus block, where selective application of clonidine[6] or low concentration of long-acting local anesthetics[7] to the median and ulnar nerves prolongs analgesia without concomitant prolongation of motor block. Another reason to avoid selective elbow blocks is the commonly misunderstood cutaneous innervation of the forearm. For example, block of the musculocutaneous nerve must be performed in the axilla to render motor block of the biceps and brachioradialis muscles. But anesthetizing the cutaneous distribution of the musculocutaneous nerve is best accomplished with a LAC nerve block. Anesthetizing the skin of the medial forearm requires blockade of the MAC nerve, not the ulnar nerve at the elbow. A third issue is to avoid elbow blocks to supplement incomplete brachial plexus blocks because this practice theoretically increases the risk of anesthesia-related nerve injury. Indeed, the only indication for elbow approaches is to block forearm flexor and extensor muscles when the surgeon desires immobility of the fingers. Selective nerve blocks can sometimes be used also for pain treatment of minor trauma or surgery. Some authors have even reported selective catheterization to avoid unnecessary motor block or numbness of the uninvolved parts of the upper extremity.[8,9]

Radial Nerve block

Anatomy

The radial nerve supplies sensation to the dorsum of the forearm and hand (see Figures 80H–1 and 80H–2); it also innervates the musculature of the dorsal forearm. The radial nerve descends the posterior arm, traversing from the medial to the lateral side. At the epicondyles, the radial nerve lies relatively deep between the brachialis and brachioradialis muscles (Figure 80H–8).

Technique

The patient is positioned supine for radial nerve block with the arm supinated and abducted. Selective block of the radial nerve is accomplished by placing a needle approximately 1.5 cm lateral to the biceps tendon at the level of the epicondyles (see Figure 80H–8). Three to 5 mL of local anesthetic is injected when a paresthesia to the hand is elicited. If using a peripheral nerve stimulator, one seeks the motor response of wrist extension.

Median Nerve Block

Anatomy

The median nerve provides sensation to the radial palm, the proximal fingers from the thumb to the long finger, and motor control to the forearm flexors (see Figures 80H–1 and 80H–2).

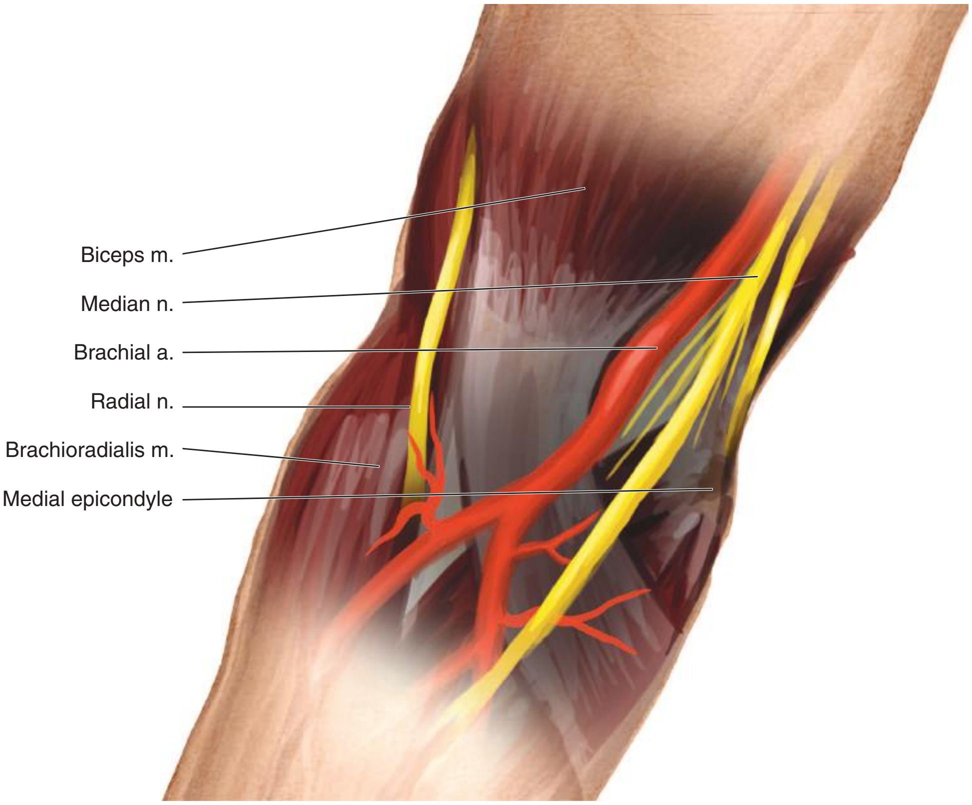

FIGURE 80H–8. Radial and median nerves are approached at the level of the epicondyles. The radial nerve is found approximately 1.5 cm lateral to the biceps tendon. The median nerve is more superficial and identified by a needle placed just medial to the brachial artery.

It passes the elbow joint just medial to the brachial artery and in front of the brachialis muscle.

Technique

Median nerve block at the elbow is accomplished with a 1.5-in. needle that is placed just medial to the brachial artery at the level of the epicondyles (see Figure 80H–8). Either a motor response that consists of wrist flexion and/or thumb opposition or a paresthesia to the thumb or index finger is sought before injecting 3–5 mL of local anesthetic.

Ulnar Nerve Block

Anatomy

The ulnar nerve at the elbow is located superficially in the ulnar groove (Figure 80H–9). At this level, blockade of the ulnar nerve results in anesthesia of the little finger and motor block of the intrinsic muscles of the hand.

Technique

The patient is placed supine for ulnar nerve block, and the forearm is flexed at the elbow (see Figure 80H–9). After identification of the ulnar groove, a short needle is placed approximately 1 cm proximal to the epicondyles and directed distally. The desired endpoint is paresthesia to the little finger or a motor response consisting of finger flexion, thumb adduction, and/or ulnar deviation of the wrist. It is suggested that only 2–3 mL of local anesthetic be injected to avoid excessive pressure within the tight fascial space of the ulnar groove and thereby lessen the possibility of compromising neural blood flow.

Complications

Selective nerve blocks at the elbow may cause hematoma if brachial artery is punctured during procedure.

Clinical Pearls

- Selective nerve blocks at the elbow can be recommended for hand surgery when forearm motor block is desired and motor block of the proximal brachial plexus block is not desired.
- Selective nerve blocks at the elbow to supplement incomplete proximal brachial plexus should be practiced with caution.

PERIOPERATIVE MANAGEMENT

Because cutaneous nerve blocks of the upper extremity require only small amounts of local anesthetic, which are typically injected subcutaneously and not close to major vessels, they can be placed with standard American Society of Anesthesiologists (ASA) monitoring. Patients should be informed to protect their insensate limb from external pressure or temperature extremes.

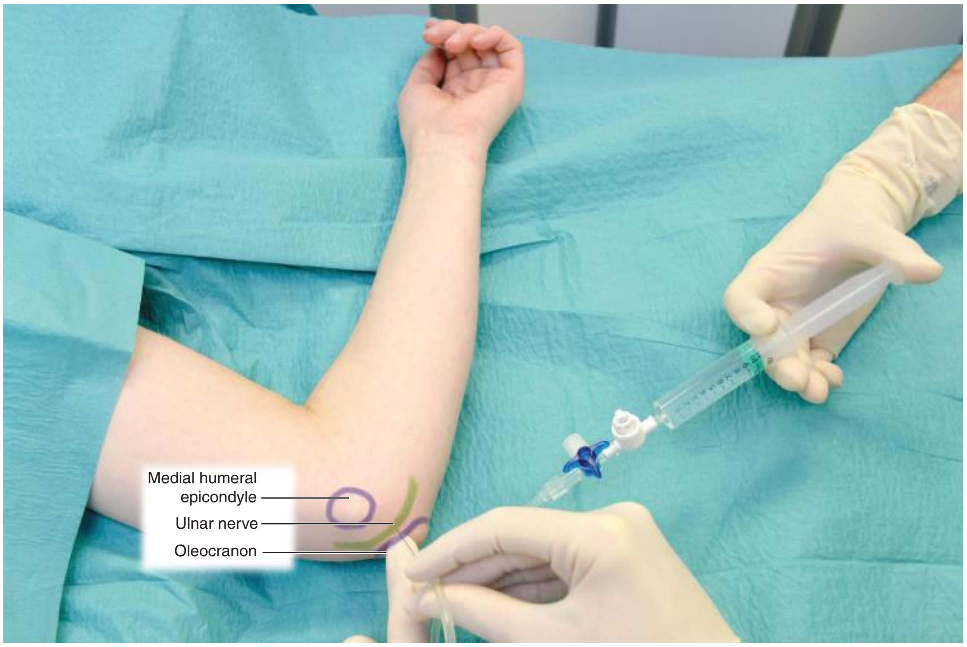

FIGURE 80H–9. Ulnar nerve block at the elbow. The forearm is flexed, the ulnar groove identified, and a needle is placed 1 cm proximal to the epicondyles and directed distally.

Finally, the advent of ultrasound-guidance has substantially facilitated performance of cutaneous blocks.[10]

SUMMARY

Selective upper extremity nerve blocks can be useful supplements to brachial plexus blocks. Supraclavicular, suprascapular, and intercostobrachial nerve blocks are valuable adjuncts to the anesthesia and/or analgesia primarily provided by a plexus block or general anesthesia. The LAC and MAC nerve blocks can provide either primary anesthesia for superficial forearm operations or supplement an incomplete plexus block. Selective elbow blocks are inferior alternatives to brachial plexus blocks. Their use as a supplement to incomplete plexus blockade should be carefully considered.

SECTION 2 Truncal Blocks

CHAPTER 81A

Thoracic & Lumbar Paravertebral Block

Manoj K. Karmakar, Roy A. Greengrass, Malikah Latmore, and Matthew Levin

THORACIC PARAVERTEBRAL BLOCK

Thoracic paravertebral block (TPVB) is the technique of injecting local anesthetic alongside the thoracic vertebra close to where the spinal nerves emerge from the intervertebral foramen.[1,2] This produces unilateral, segmental, somatic, and sympathetic nerve blockade,[3] which is effective for anesthesia and in treating acute and chronic pain of unilateral origin from the chest and abdomen.[1] Hugo Sellheim of Leipzig (1871–1936) is believed to have pioneered TPVB in 1905.[1,2] Kappis, in 1919, developed the technique of paravertebral injection, which is comparable to the one in present day use.

Although paravertebral block (PVB) was fairly popular in the early 1900s, it seemed to have fallen into disfavor during the later part of the century; the reason for which is not known. In 1979, Eason and Wyatt re popularized the technique after describing paravertebral catheter placement.[4] Our understanding of the safety and efficacy of TPVB has improved significantly in the last 25 years, with renewal of interest in this technique. Currently, it is used not only for analgesia but also for surgical anesthesia,[5–7] and its application has been extended to children.[8–10] Introduction of ultrasound to the practice of regional anesthesia led to the renewed efforts to increase safety and consistency of PVBs.

Anatomy

The thoracic paravertebral space (TPVS) is a wedge-shaped space located on either side of the vertebral column (Figure 81A–1). The parietal pleura forms the anterolateral boundary. The base is formed by the vertebral body, intervertebral disc, and the intervertebral foramen with its contents.

The transverse process and the superior costotransverse ligament form the posterior boundary. Lying in between the parietal pleura anteriorly and the superior costotransverse ligament posteriorly is a fibroelastic structure, the endothoracic fascia, which is the deep fascia of the thorax (Figures 81A–1 through 81A–3).[1,11–15] Medially, the endothoracic fascia is attached to the periosteum of the vertebral body. A layer of loose areolar connective tissue, the subserous fascia, lies between the parietal pleura and the endothoracic fascia.

Therefore, there are two potential fascial compartments in the TPVS: the anterior extrapleural paravertebral compartment and the posterior subendothoracic paravertebral compartment (see Figures 81A–1 and 81A–2). The TPVS contains adipose tissue within which lie the intercostal (spinal) nerve, the dorsal ramus, intercostal vessels, and rami communicantes and anteriorly the sympathetic chain. The spinal nerves are segmented into small bundles and lie freely in the adipose tissue of the TPVS, which make them accessible to local anesthetic solutions injected in the TPVS.[16] The TPVS communicates with the epidural space medially[17,18] and with the intercostal space laterally. The TPVSs on either side of the thoracic vertebra also communicate with each other through the epidural and prevertebral space.[1,12,15] The cranial extension of the TPVS is challenging to define and may significantly vary; however, there is direct paravertebral spread of radiopaque contrast medium from the thoracic to the cervical paravertebral space, indicating anatomic continuity. The TPVS also communicates caudally through the medial and lateral arcuate ligaments with the retroperitoneal

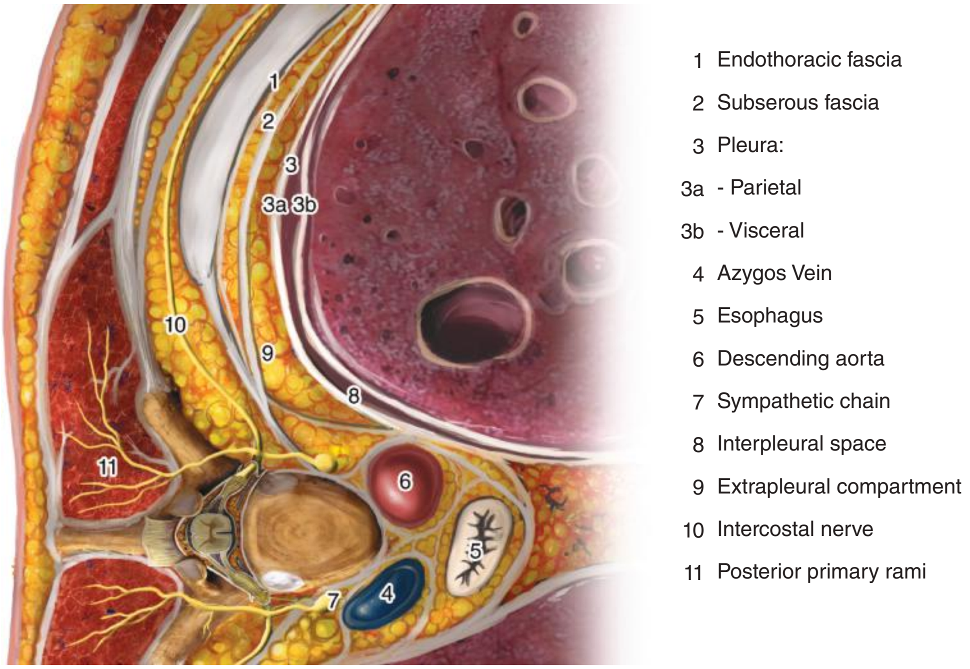

FIGURE 81A–1. Anatomy of the thoracic paravertebral space, chest cavity and intercostal nerves.

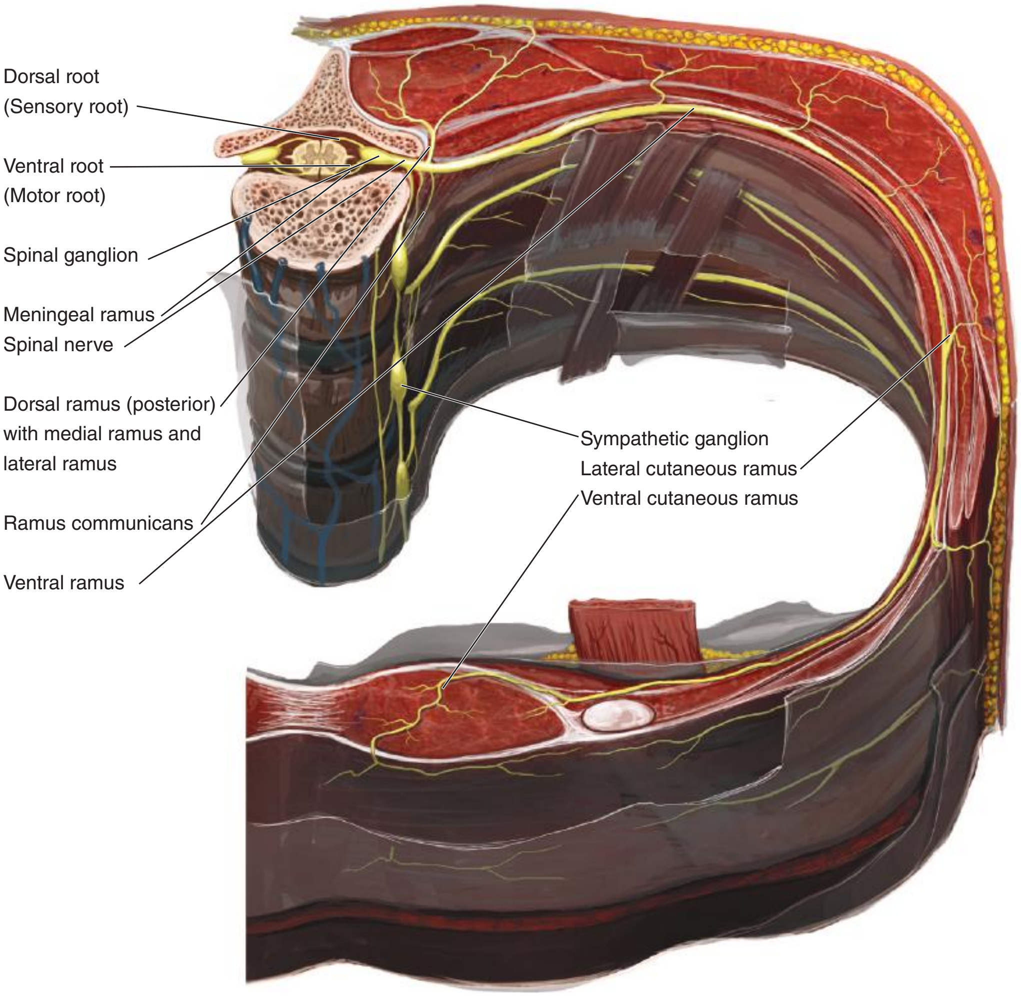

FIGURE 81A–2. Crossectional anatomy of the vertebra and chest wall demonstrating relationship of paraveretbral space, sympathetic ganglia, spinal and intercostal nerves.

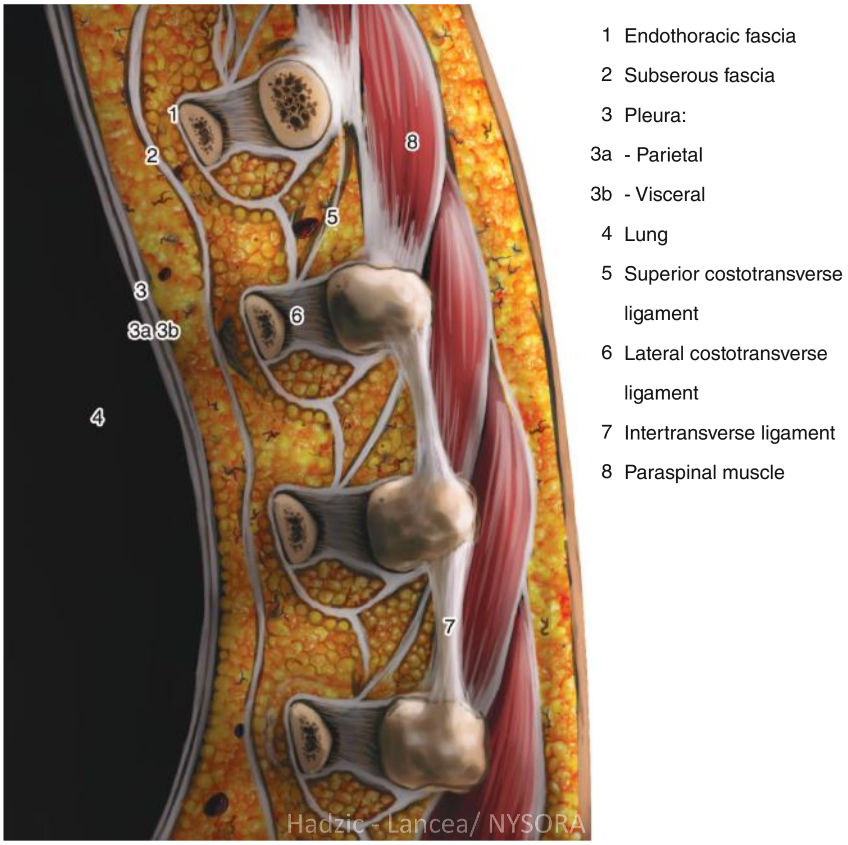

FIGURE 81A–3. Sagittal section through the thoracic paravertebral space.

space behind the fascia transversalis, where the lumbar spinal nerves are located.[13,19–21]

Mechanism of Block & Distribution of Anesthesia

TPVB produces ipsilateral somatic and sympathetic nerve blockade (Figure 81A–4) due to a direct effect of the local anesthetic on the somatic and sympathetic nerves in the TPVS, extension into the intercostal space laterally, and the epidural space medially. The overall contribution of epidural spread to the dermatomal distribution of anesthesia following a TPVB is not well defined. However, some degree of ipsilateral spread of local anesthetic toward the epidural space probably occurs in the majority of the patients, resulting in a greater distribution of anesthesia than occurs with paravertebral spread alone.[18] The dermatomal distribution of anesthesia following a single injection of a large volume varies and is often unpredictable, but the injected solutions routinely spread both cephalad and caudad to the site of injection to some extent (Figure 81A–5).[1,3,22] Nevertheless, the multiple injection technique, where small volumes (3–4 mL) of local anesthetic are injected at several contiguous thoracic levels, is preferable over single, large-volume injection. This is particularly important when reliable anesthesia over several ipsilateral thoracic dermatomes is desired, such as when TPVB is used for anesthesia during breast surgery. Segmental contralateral anesthesia, adjacent to the site of injection, occurs in approximately 10% of patients after single-injection TPVB and may be due to epidural or prevertebral spread.

Bilateral symmetric anesthesia due to extensive epidural spread or unintentional intrathecal injection into a dural sleeve may occur, particularly when the needle is directed medially or when a larger volume of local anesthetic (>25 mL) is used. For this reason, patients should be monitored using the same vigilance and methods as those employed for injection using the large-volume, single-injection epidural technique. The ipsilateral ilioinguinal and iliohypogastric nerves may also occasionally be involved after lower thoracic paravertebral injections. This is either due to epidural spread or extended subendothoracic fascial spread to the retroperitoneal space where the lumbar spinal nerves are located. The effect of gravity on the dermatomal spread of anesthesia after TPVB is unknown, but there may be a tendency for preferential pooling of injected solution toward the dependent levels.[3,23,24]

Technique

It is preferable to perform TPVB with the patient in the sitting position because the surface anatomy is better visualized and patients are often more comfortable. However, when this is not possible or practical, TPVB can also be performed with the patient in the lateral, or prone position. The number and levels of injections are selected according to the desired spread of local anesthesia. In this example, description of the TPVB for breast surgery is described. Surface landmarks are identified and marked with a skin marker before block placement (Figure 81A–6). Skin markings are also made 2.5 cm lateral to the midline at the thoracic levels that are to be blocked.

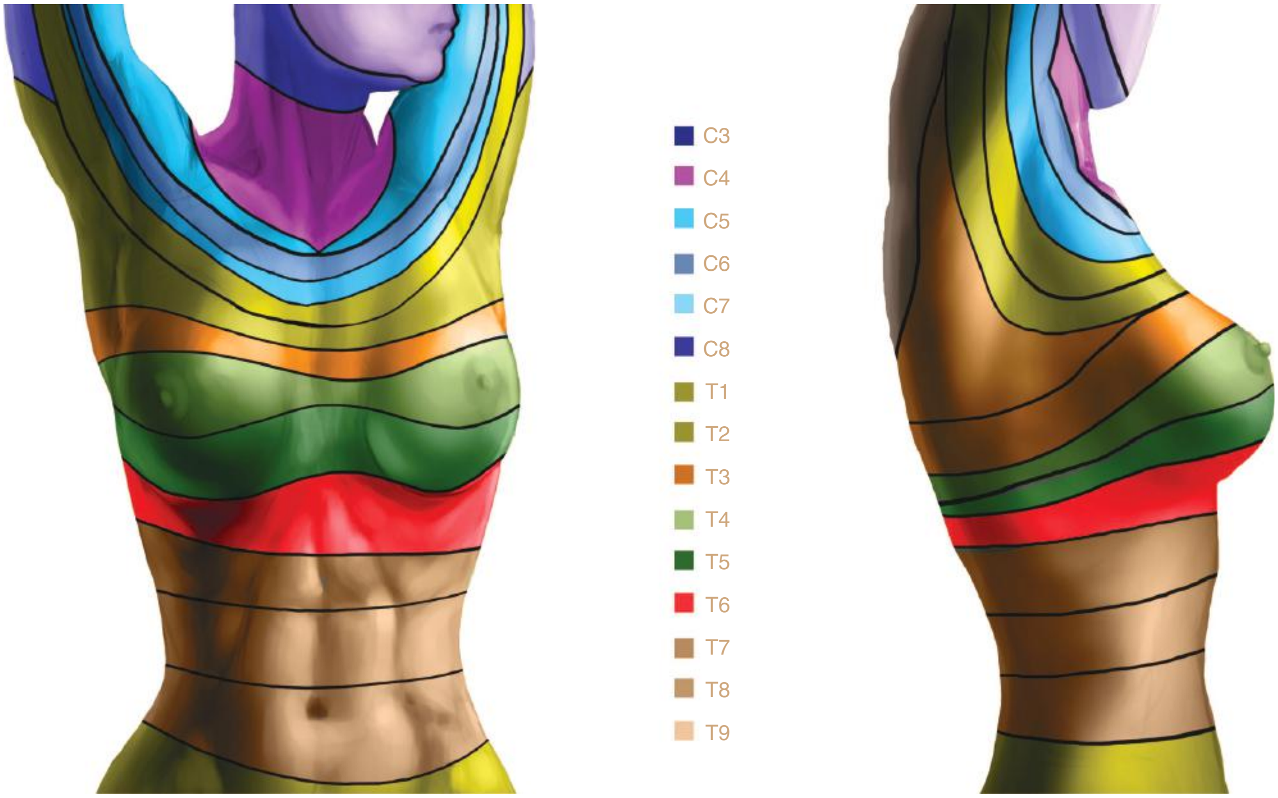

FIGURE 81A–4. Segmental thoracic anesthesia achieved with paravertebral blocks.

These markings indicate the needle insertion sites and should lie over the transverse process of the vertebra (Figure 81A–7). A standard regional anesthesia tray is prepared, and strict asepsis should be maintained during block placement.

A 22-gauge Tuohy needle is recommended for TPVB (Figure 81A–8). Ideally, the needle should have depth markings on its shaft. Alternatively, a depth guard (see Figure 81A–8) is recommended. An epidural set is used if insertion of a catheter

into the TPVS is planned. TPVB requires proper premedication to ensure patient acceptance and comfort during block placement.

Loss-of-Resistance Technique

There are several different techniques of TPVB. The classic technique involves eliciting loss of resistance. The skin and underlying tissue is infiltrated with lidocaine 1%, and the block needle is inserted perpendicular to the skin in all planes to contact the transverse process of the vertebra. Note that due to the acute angulation of the thoracic spines in the midthoracic region, the transverse process that is contacted is the one from the lower vertebra (Figures 81A–9 and 81A–10).

The depth at which the transverse process is contacted varies (3–4 cm) and depends on the build of the individual and the level at which the needle is inserted. The depth is deeper at the cervical and lumbar spine level and shallower at the thoracic levels. During needle insertion it is possible to miss the transverse process and inadvertently puncture the pleura. Therefore, it is imperative to search and make contact with the transverse process before advancing the needle too deep and risking pleural puncture. To minimize this complication, the block needle should initially be inserted only to a maximum depth of 4 cm at thoracic and 5 cm at cervical and lumbar levels. If bone is not

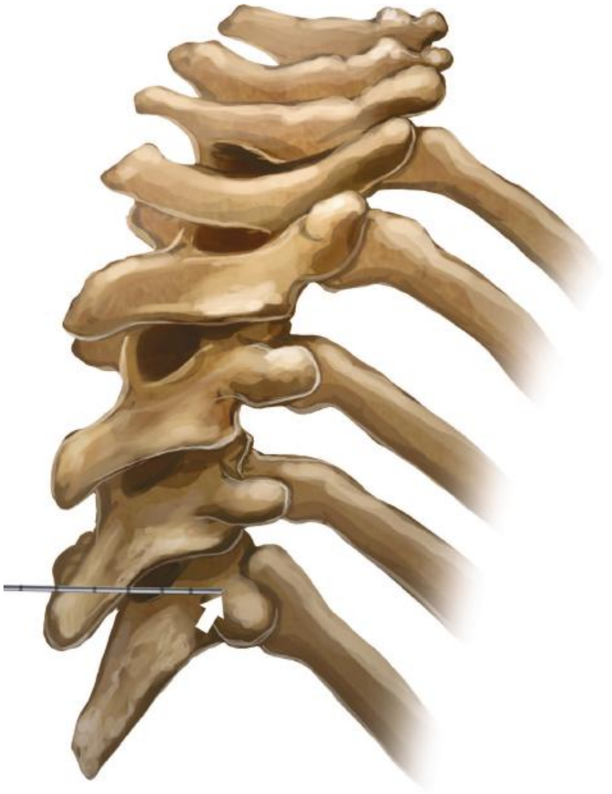

FIGURE 81A–9. Relationship between the spinous and transverse processes at the thoracic level. Due to the steep downward angulation of the spinous processes at the thoracic levels, the needle inserted at the level of the spinous process contacts the transverse process that belongs to the vertebra below it.

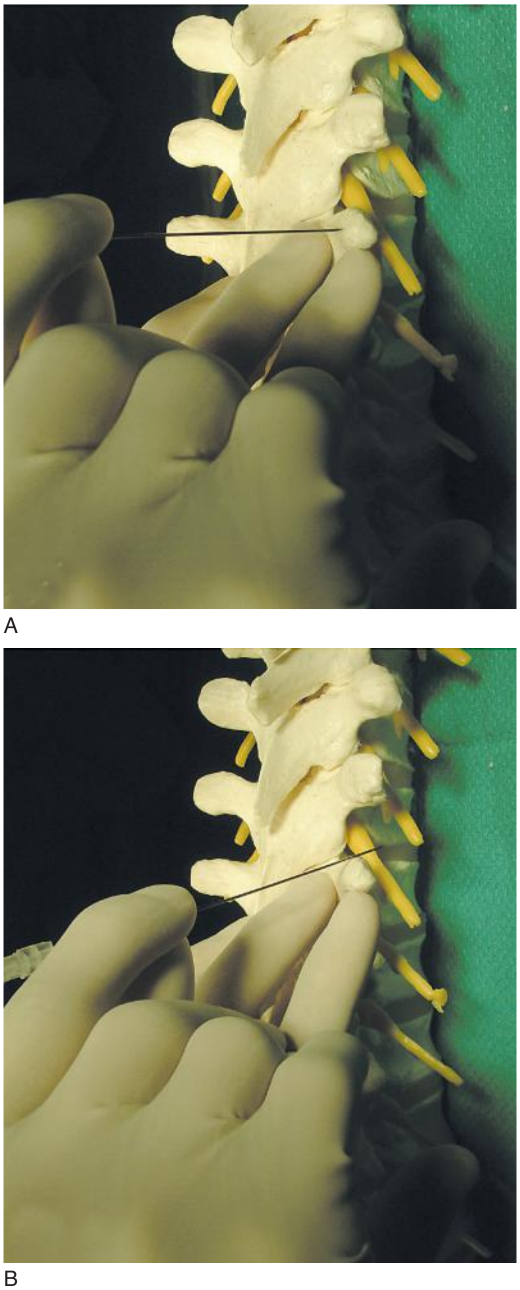

FIGURE 81A–10. Technique of "walking off" the transverse process. **A**: The needle is shown contacting the transverse process. **B**: The needle is shown walking off the superior aspect of the transverse process. Walking off the inferiorly may be safer at thoracic level.

contacted, it should be assumed that the needle is in between two adjacent transverse processes. The needle should be withdrawn to the subcutaneous tissue and reinserted with a cephalad or caudad direction to the same depth (4 cm) until bone is contacted. If bone is still not encountered, the needle is advanced a further centimeter and the above procedure repeated until the transverse process is identified. The needle is then walked above or bellow (safer) the transverse process and gradually advanced until a loss of resistance is elicited as the needle traverses the superior costotransverse ligament into the TPVS (Figures 81A–11; see Figure 81A–3).

Clinical Pearls

- "Walking" off the lower aspect of the transverse process is recommended in case the needle has contacted the rib rather than transverse process. When this happens, walking off the rib cephalad may result in pneumothorax.
- This usually occurs within 1.0–1.5 cm from the superior edge of the transverse process (see Figure 81A–3). Although a subtle "pop" or "give" may be appreciated as the needle traverses the superior costotransverse process, this should not be entirely relied on. Instead, the depth of the needle placement should be guided by the initial bone contact (skin-transverse process + 1.0–1.5 cm).

Predetermined Distance Technique

TPVB can also be performed by advancing the needle by a fixed predetermined distance (1 cm) once the needle is walked off the transverse process, without eliciting loss of resistance (Figure 81A–12A and B).[5–7,23] Proponents of this technique have used it very successfully with low risk of pneumothorax. The use of a depth marker is recommended to avoid inadvertent pleural or pulmonary puncture.

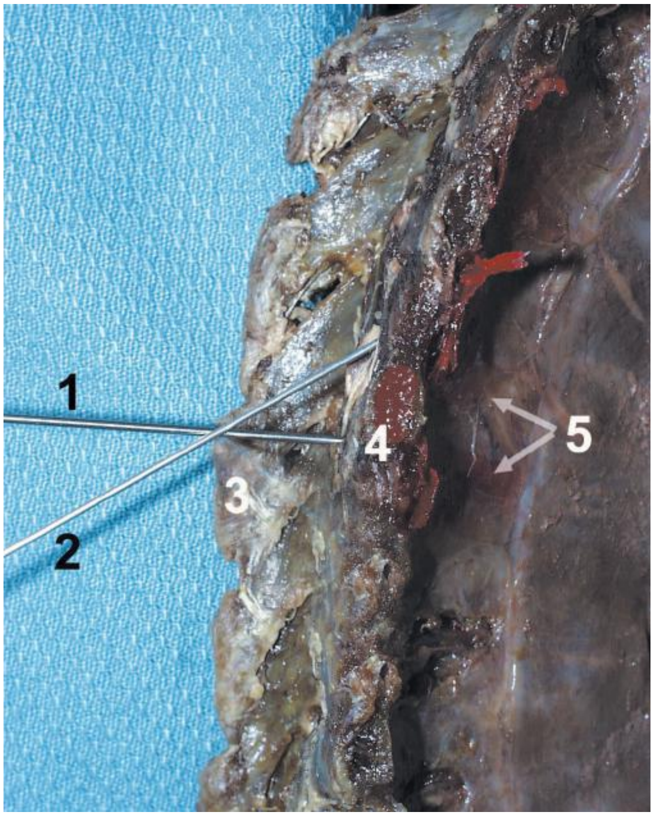

FIGURE 81A–11. Paravertebral block technique. The needle (1) is first advanced to contact the transverse process (4), then redirected cephalad (2) or caudad to walk off the transverse process and enter the paravertebral space. Other structures shown are spinous process (3) and the dispersion of the dye in the paravertebral space and intercostal sulcus.

Clinical Pearls

- Perform TPVB with the patient in the sitting position.
- Surface landmarks should always be identified and marked with a skin marker.
- Use needles with depth markings to facilitate estimation of the depth of insertion.
- It is imperative to search and make contact with the transverse process before advancing the needle any farther.
- The depth at which the transverse process is contacted varies in the same patient at different thoracic levels. It is deepest in the cervical, upper and lower thoracic, and shallowest in the midthoracic region.
- The needle should not be advanced more than 1.5 cm beyond the contact with the transverse process.
- Avoid directing the needle medially to prevent inadvertent epidural or intrathecal needle misadventure.

Placement of Thoracic Paravertebral Catheter

If a continuous TPVB (CTPVB) is planned, a catheter is inserted through a Tuohy needle into the TPVS.[4,22] Unlike epidural catheterization, certain resistance is commonly encountered during insertion of the paravertebral catheter. This can be facilitated by injecting 5–10 mL of saline to create a space before catheter insertion. An unusually seamless passage of catheter should arouse the suspicion of interpleural placement. Perhaps the safest and simplest method of placing a catheter into the TPVS is to place it under direct vision from within the open chest cavity.[8,25] Obviously, this requires an open thorax and is, therefore, done exclusively in patients undergoing a thoracotomy. This technique involves reflecting the parietal pleura from the posterior wound margin onto the vertebral bodies over several thoracic segments, thereby creating an extrapleural paravertebral pocket (Figure 81A–13) into which a percutaneously inserted catheter is placed against the angles of the exposed ribs. The pleura is reapposed to the chest wall, and the thorax is closed. This method can be combined very effectively with a preincisional, single-shot, percutaneous thoracic paravertebral injection to provide perioperative analgesia during thoracic surgery.[26]

Clinical Pearls

- Injecting saline or the bolus dose of the local anesthetic before catheter insertion makes it easier to insert a catheter.
- Very easy passage of catheter (>6 cm) should raise the suspicion of intrapleural placement.
  - Catheter should not be inserted >3 cm to prevent their migration toward epidural space.

Indications

TPVB is indicated for anesthesia and analgesia for unilateral surgical procedures in the chest and abdomen. Commonly reported indications are listed in Table 81A–1. The use of bilateral TPVB has also been reported.

Contraindications

Contraindications for TPVB include infection at the site of injection, allergy to local anesthetic drug, empyema, and a neoplastic mass occupying the paravertebral space. Coagulopathy, bleeding disorders, or patients receiving anticoagulant drugs are relative contraindication for TPVB. One must exercise caution in patients with kyphoscoliosis or deformed spines and those who have had previous thoracic surgery. The chest deformity in the former may predispose to inadvertent thecal or pleural puncture, and the altered paravertebral anatomy due to fibrotic obliteration of the paravertebral space or adhesions of the lung to the chest wall in the latter may predispose to pulmonary puncture.

Choice of Local Anesthetic

Since TPVB does not result in motor weakness of the extremities, long-lasting analgesia is nearly always desirable with TPVB. Consequently, long-acting local anesthetic drugs are typically used. These include bupivacaine or levobupivacaine

A

B

FIGURE 81A–12. Needle angle to contact the transverse process (**A**) and to walk off the transverse process inferiorly (**B**). Once the transverse process is contacted, the needle is walked off and inserted 1.5 cm deeper while paying attention to the depth marks or using a rubber stopper (Figure 81A-8).

0.5% and ropivacaine 0.5%. For single-injection TPVB, 20–25 mL of local anesthetic is injected in aliquots, whereas for multiple-injection TPVB, 4–5 mL of local anesthetic is injected at each level planned.

The maximum dose of local anesthetic must be adjusted in the elderly, poorly nourished, and frail patients. The TPVS is well vascularized, leading to relatively rapid absorption of local anesthetic into the systemic circulation. Consequently, peak plasma concentration of the local anesthetic agent is attained quickly. Epinephrine (2.5–5.0 mcg/mL) containing local anesthetic solutions may be used during the initial injection because it reduces systemic absorption and thereby reduces the potential for toxicity. Epinephrine also helps in increasing the maximum allowable dose of local anesthetic.

The duration of anesthesia after TPVB ranges from 3–4 h, but analgesia often lasts much longer (8–18 h). If a continuous TPVB (CTPVB) is planned, e.g., for postoperative analgesia after thoracotomy or continuous pain relief for multiple fractured ribs, then an infusion of bupivacaine or levobupivacaine 0.25% or ropivacaine 0.2% at 0.1–0.2 mL/kg/h is started after the initial bolus injection and continued for 3–4 days or as indicated. It is our experience that using a higher concentration of local anesthetic (e.g., bupivacaine 0.5% instead of 0.25%) for the CTPVB does not result in better quality of analgesia, and it may increase the potential for local anesthetic toxicity.

Clinical Pearls

- Consider using lidocaine or chloroprocaine for skin and subcutaneous infiltration to reduce the total dose of the more toxic long- acting local anesthetic.
- Use an epinephrine-containing (e.g., 1:200 000 or 1:400 000) long-acting local anesthetic because it reduces systemic absorption and, therefore, the potential for systemic toxicity.
- Local anesthetic dose should be adjusted in the elderly and those with impairment of hepatic and renal function.

FIGURE 81A–13. **A**: Extrapleural paravertebral catheter placement under direct vision in an infant. Figure shows a curved artery forceps that has been inserted into the extrapleural paravertebral pocket that was created by reflecting the parietal pleura from the posterior wound margin on to the vertebral bodies over several thoracic dermatomes. **B**: Extrapleural paravertebral catheter placement under direct vision in an infant. Figure shows a Tuohy needle that has been inserted from the lower intercostal space into the thoracic paravertebral space; .i.e, the extrapleural paravertebral pocket previously created. A catheter is then inserted through the Tuohy needle and secured in place against the angles of the exposed ribs, after which the pleura is reapposed and the chest is closed.

- Catheter dislodgement is not uncommon and must be excluded whenever a patients complain of breakthrough pain that is not easily controlled.
- Exclude local anesthetic toxicity whenever a patient becomes confused while receiving a continuous thoracic paravertebral infusion.

Practical Management of Thoracic Paravertebral Block

Breast Surgery

Thoracic paravertebral injection of local anesthetic at multiple levels (C7 through T6) in conjunction with intravenous sedation is effective for surgical anesthesia during major breast surgery (Figure 81A–14).[5,6,27] The C7 spinous process is the most prominent cervical spinous process; the inferior border of the scapula corresponds to T7. Compared with patients who receive only general anesthesia (GA), patients who receive a multiple-injection TPVB for major breast surgery have less postoperative pain, require fewer analgesics, and have less nausea and vomiting after surgery. However, to effectively use the multiple-injection TPVB technique for anesthesia during breast surgery, one must understand the complex innervation of the breast. The anterior and lateral chest wall receives sensory innervation from the anterior and lateral cutaneous branches of the intercostal nerves (T2 through T6), the axilla (T1–T2), the infraclavicular region from the supraclavicular nerves (C4–C5), and the pectoral muscles from the lateral (C5–C6) and medial (C7–C8) pectoral nerves. There also may be overlapping sensory innervation from the contralateral side of the chest. This complex innervation of the breast from the C4–T6 spinal segments explains why TPVB may not provide complete anesthesia for dissection over the pectoral muscle or the infraclavicular region. However, this can be overcome with proper sedation during surgery as well as by injections of local anesthetic by the surgeon intraoperatively into the sensitive areas. Injection of a local anesthetic subcutaneously along the inferior border of the

clavicle or to perform ipsilateral superficial cervical plexus block in order to anaesthetize the supraclavicular nerves (C4–C5) will minimize discomfort and sedative and analgesic requirements during surgery. A combination of midazolam, or propofol infusion, or IV opioid can be used to provide comfort to the patients intraoperatively. Dexmedetomidine, a highly selective α_2-adrenoceptor agonist, with its sedative, analgesic, and minimal or no respiratory depression properties, is a useful alternative for sedation during breast surgery under TPVB.

When combined with general anesthesia, a single injection TPVB with ropivacaine (2 mg/kg diluted to 20 mL with 0.9% saline) with 1:200 000 epinephrine, performed prior to the induction of GA can be used. This provides excellent postoperative analgesia, reduces postoperative analgesic requirement, reduces postoperative vomiting, facilitates the earlier resumption of oral fluid intake, reduces the postoperative decline in respiratory function, and augments the recovery of postoperative respiratory mechanics.

Postthoracotomy Pain Relief

CTPVB is an effective method of providing analgesia after thoracotomy (Figure 81A–15). Ideally, TPVB should be established before the thoracotomy incision, via a catheter that is inserted percutaneously, and continued for 4–5 days after surgery. However, if an extrapleural paravertebral catheter is being placed under direct vision from within the chest during surgery, then a single-injection TPVB can be performed at the level of the thoracotomy incision before the surgical incision, and a continuous infusion of local anesthetic is commenced after the catheter placement.[26] Analgesia achieved by CTPVB is comparable to epidural analgesia but with less hypotension, urinary retention, and the side effects commonly seen with epidural opioid administration.[1,26,28,29] The opioid requirement with such an approach is significantly reduced by the CTPVB, and analgesia is superior to IVPCA alone.[1,30]

Multiple Fractured Ribs

TPVB is an effective method of providing pain relief in patients with unilateral multiple fractured ribs.[1,22,23] A single thoracic paravertebral injection of 25 mL of bupivacaine 0.5% produces pain relief for a mean duration of 10 h and improves respiratory function and arterial blood gases.[1,23] To avoid recurrence of pain and deterioration in respiratory function, a thoracic paravertebral

A B

catheter can be inserted midway between the highest and the lowest fractured rib, and a CTPVB can be commenced after administration of the initial bolus injection. CTPVB in combination with an NSAID provides continuous pain relief and produces a sustained improvement in respiratory parameters and arterial oxygenation.[22] Since TPVB does not cause urinary retention or affect lower limb motor function, it is useful in patients with multiple fractured ribs who also have concomitant lumbar spinal trauma since it also allows continuous neurologic assessment for signs of spinal cord compression.[31]

Pharmacokinetic Considerations

Relatively large doses of local anesthetics are commonly used during CTPVB. Therefore, there is the potential for local anesthetic toxicity, and patients should be closely monitored during CTPVB and the infusion stopped if signs develop. During a prolonged thoracic paravertebral infusion there is progressive accumulation of local anesthetic in the plasma, and the plasma concentration of the drug may exceed the threshold for central nervous system toxicity (e.g,, 2.0–4.5 mcg/mL for bupivacaine). Despite the systemic accumulation, local anesthetic toxicity is rare. This may be the case because, although the total plasma concentration of the local anesthetic increases postoperatively, the free fraction of the drug remains unchanged[32] and may be due to the postoperative increase in α_1-acid glycoprotein concentration,[32] the protein that binds to local anesthetic drugs. There is also a greater increase in the S-bupivacaine enantiomer,[33,34] which is associated with lower toxicity, than the R-enantiomer. Due to concerns of systemic accumulation and local anesthetic toxicity with prolonged paravertebral infusion, it is preferable to use a local anesthetic with lower potential for toxicity, such as ropivacaine. One must also exercise caution in the elderly and frail patients as well as in patients with impaired hepatic and renal function.

Complications and How to Avoid Them

Based on published data the incidence of complications after TPVB is relatively low and varies from 2.6%–5%.[1,5,35,36] These include vascular puncture (3.8%), hypotension (4.6%), pleural puncture (1.1%), and pneumothorax (0.5%).[35] Unlike with thoracic epidural anesthesia, hypotension is rare in normovolemic patients after TPVB because the sympathetic blockade is unilateral. However, TPVB may unmask hypovolemia and result in hypotension. Therefore, TPVB should be used with caution in patients who are hypovolemic or hemodynamically labile. Nevertheless, hypotension is rare even after bilateral TPVB, probably owing to the segmental nature of the bilateral sympathetic blockade.

Pleural puncture and pneumothorax are two complications that often dissuade anesthesiologists from performing a TPVB. Inadvertent pleural puncture is uncommon after TPVB and may not result in a pneumothorax, which is usually minor and can be managed conservatively. Clues that suggest pleural puncture during a TPVB pronounced loss of resistance as the needle enters chest cavity, cough, onset of sharp chest or shoulder pain, or sudden hyperventilation. Contrary to the common belief, air cannot be aspirated through the needle unless the lung is also inadvertently punctured or air that may have entered the pleural cavity during removal of the stylet is aspirated. Such patients should be closely monitored for the possible development of a pneumothorax. It should be kept in mind that pneumothorax may be delayed in onset and a chest radiograph taken too early to exclude a pneumothorax may not be conclusive. Even a radiologic contrast study using a chest radiograph may be difficult to interpret because the intrapleural contrast disperses rapidly, does not define any specific anatomic plane, and tends to spread to the diaphragmatic angles or horizontal fissure. Systemic local anesthetic toxicity can occur due to inadvertent intravascular injection or from using an excessive dose of local anesthetic. The local anesthetic solution must be injected in aliquots, and the dosage must be adjusted in the elderly and frail patient. An epinephrine-containing local anesthetic solution is suggested to enable the recognition of the intravascular injection and reduce the absorption of the local anesthetic in the systemic circulation. Inadvertent epidural, subdural, or intrathecal injection and spinal anesthesia can also occur. Published data suggest that these complications are more frequent when the needle is directed medially but may also occur with a normally positioned needle due to the close proximity of the needle to the dural cuff and intervertebral foramen. Therefore, the needle must never be directed medially, and care must be taken to exclude intrathecal injection by routinely performing an aspiration test before injection. Transient ipsilateral Horner syndrome can occasionally develop after TPVB. This is due to cephalad spread of the local anesthetic to the stellate ganglion or to the preganglionic fibers of the first few segments of the thoracic spinal cord. Bilateral Horner syndrome has also been reported and may be due to epidural spread or prevertebral spread to the contralateral stellate ganglion. Sensory changes in the arm and lower extremity may also occur after a TPVB. The former is due to spread of local anesthetic to the lower components of the ipsilateral brachial plexus (C8 and T1), and the latter is due to extended subendothoracic fascial spread to the ipsilateral retroperitoneal space where the lumbar spinal nerves are located (discussed earlier), but epidural spread as a cause cannot be excluded. Motor blockade or bilateral symmetric anesthesia involving the lower extremity is rare. It generally suggests significant epidural spread and may be more common if large volumes of local anesthetic (>25–30 mL) are injected at a single level. Therefore, if a wide segmental spread of anesthesia is desired, it is preferable to perform the multiple-injection technique or inject a smaller volume of local anesthetic at several levels a few dermatomes apart.

LUMBAR PARAVERTEBRAL BLOCK

Lumbar paravertebral block (LPVB) is technically similar to a TPVB but due to differences in anatomy between the thoracic and lumbar paravertebral spaces the two paravertebral techniques are described separately. LPVB is used most commonly in combination with a TPVB, as a thoracolumbar paravertebral block, for surgical anesthesia during inguinal herniorrhaphy.

Anatomy

The lumbar paravertebral space (LPVS) is limited anterolaterally by the psoas major muscle; medially by the vertebral bodies, the intervertebral discs, and the intervertebral foramen with its contents; and posteriorly by the transverse process and the ligaments that are interposed between the adjoining transverse processes. Unlike the TPVS, which contains adipose tissue, the LPVS is occupied primarily by the psoas major muscle. The psoas major muscle is made up of a fleshy anterior part that forms the main bulk of the muscle, and a thin accessory posterior part.[37] The main bulk originates from the anterolateral surface of the vertebral bodies and the accessory part originates from the anterior surface of the transverse process.[37] The two parts fuse to form the psoas major muscle except near the vertebral bodies where the two parts are separated by a thin fascia within which lie the lumbar spinal nerve roots and the ascending lumbar veins.[37] The ventral rami of the lumbar spinal nerve roots extend laterally in this intramuscular plane formed by the two parts of the psoas major muscle and form the lumbar plexus within the substance of the psoas major muscle.[37] The psoas muscle is enveloped by a fibrous sheath, "the psoas sheath," which continues laterally as the fascia covering the quadratus lumborum muscle. During a LPVB the local anesthetic is injected anterior to the transverse process into a triangular space between the two parts of the psoas major muscle containing the lumbar spinal nerve root.

The LPVS communicates medially with the epidural space. A series of tendinous arches extends across the constricted parts of the lumbar vertebral bodies, which are traversed by the lumbar arteries and veins and sympathetic fibers. These tendinous arches may provide a pathway for the spread of local anesthetic from the LPVS to the anterolateral surface of the vertebral body, the prevertebral space, and the contralateral side and may be the pathway through which the ipsilateral lumbar sympathetic chain may occasionally be involved.

Mechanism of Block and Distribution of Anesthesia

A lumbar paravertebral injection produces ipsilateral dermatomal anesthesia (Figure 81A–16) by a direct effect of the local anesthetic on the lumbar spinal nerves and by medial extension into the epidural space via the intervertebral foramen. The contribution of epidural spread to the overall distribution of anesthesia after a LPVB is unknown but probably occurs in the

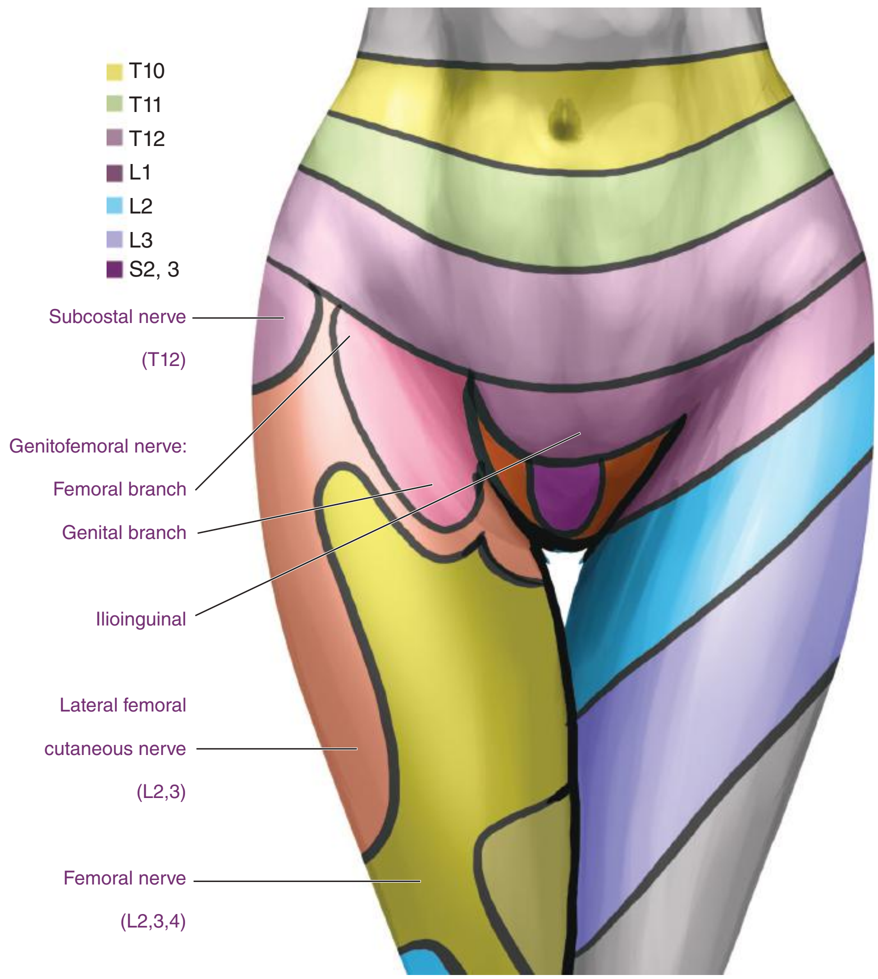

FIGURE 81A–16. Segmental distribution of anesthesia with lumbar paravertebral levels.

majority of patients and depends on the volume of local anesthetic injected at a given level. Ipsilateral sympathetic blockade may also occur due to epidural spread or spread of local anesthetic anteriorly via the tendinous arches to the rami communicantes or the lumbar sympathetic chain.

Technique

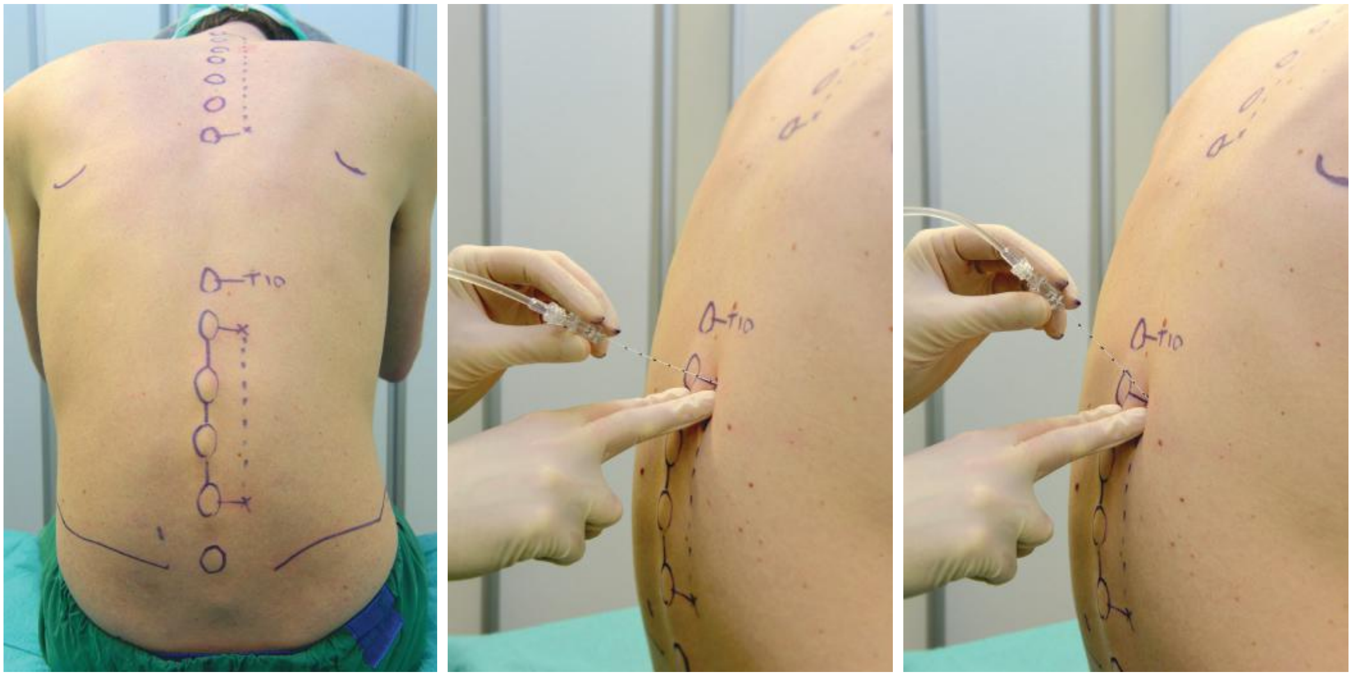
Lumbar paravertebral block can be performed with the patient in the sitting, lateral, or prone position. Surface landmarks must be identified and marked with a skin marker before block placement. The spinous process of the vertebra at the levels to be blocked represents the midline, the iliac crest corresponds to the L3-L4 interspace, and the tip of scapula corresponds to the T7 spinous process. Skin markings are also made 2.5 cm lateral to the midline at the levels that are to be blocked (Figure 81A–17A) or one can draw a line 2.5 cm lateral to the midline and perform the injections along this line (Figure 81A–17B and C). A standard regional anesthesia tray is prepared; strict asepsis should be maintained during block placement. An 8-cm, 22-gauge, Tuohy tip needle (see Figure 81–1–8) is used for LPVB. Similarly to the recommendations for TPVB, the use of needles with depth markings on the shaft of the needle or a guard indicating the depth (see Figure 81–1–8) is recommended. Advancing the needle by a fixed predetermined distance (1.5–2.0 cm) beyond the transverse process, without eliciting paresthesia, is the method most commonly used to perform LPVB. The block needle is inserted perpendicular to the skin until the transverse process is contacted. The depth at which the transverse process is contacted is variable (4–6 cm) and depends on the build of the patient. Once the transverse process is identified, the marking on the needle is noted or the depth marker is adjusted so that it is 1.5–2.0 cm beyond the skin–transverse process depth. The needle is then withdrawn to the subcutaneous tissue and reinserted at a 10- to 15-degree superior or inferior angle so that it slides off the superior or inferior edge of the transverse process, similarly to the technique in thoracic paravertebral block (see Figure 81A–11). The needle is advanced by a further 1.5–2.0 cm beyond the contact with the transverse process or until the depth marker is reached. After negative aspiration for blood or cerebrospinal fluid (CSF), the local anesthetic is injected. Since spread of local anesthetic after a single large-volume lumbar paravertebral injection is unpredictable, the multiple-injection technique in which 4–5 mL of local anesthetic is injected at each level is more commonly used.

Choice of Local Anesthetic

As for TPVB, long-acting local anesthetic agents such as bupivacaine 0.5%, ropivacaine 0.5%, or levobupivacaine 0.5% are commonly used for LPVB. During a multiple injection LPVB, 4–5 mL of the local anesthetic is injected at each level. Anesthesia develops in about 15–30 minutes and lasts for 3–6 h. Analgesia is also long-lasting (12–18 h) and generally outlasts the duration of anesthesia. There are no data on the pharmacokinetics of local anesthetic after LPVB. Nevertheless, the addition of epinephrine (2.5–5.0 mcg/mL) to the local anesthetic may reduce systemic absorption and reduce the potential for toxicity.

Indications and Contraindications

LPVB is commonly used in combination with TPVB (T10 through L2) for surgical anesthesia during inguinal herniorrhaphy. It can be also effective for rescue in patients with severe pain after total hip replacement. It can also be used for



A B C

FIGURE 81A–17. A: Surface landmarks and needle insertion sites for lumbar paravertebral block. **B** and **C:** Needle insertion.

diagnostic purpose during evaluation of groin or genital pain, such as that following nerve entrapment syndrome after inguinal herniorrhaphy. Contraindications for LPVB are similar to TPVB, but caution should be exercised in patients who are anticoagulated or are receiving prophylactic anticoagulants since psoas hematoma with lumbar plexopathy has been reported.

Complications and How to Avoid Them

Published data suggest that complication is rare after LPVB.[38,39] Nevertheless, it is possible to inadvertently inject local anesthetic into the intravascular, epidural, or intrathecal spaces during LPVB, and this may be more common if the needle is directed medially. Therefore, the direction of the block needle should be maintained perpendicular to the skin during insertion, and medial angulation should be avoided. Intraperitoneal injection or visceral injury (renal) may also occur, although this can occur only as a result of gross technical error. Motor weakness involving the ipsilateral quadriceps muscle may result if the L2 spinal nerve is blocked (femoral nerve L2–L4).

SUMMARY

Proper training is necessary to acquire stereotactic techniques required to ensure a high success rate. Thoracic paravertebral block produces unilateral somatic and sympathetic nerve blockade that is adequate for surgical anesthesia during breast surgery and for analgesia when pain is of unilateral origin from the chest or abdomen. It has been also described as a rescue analgesic therapy in patients with rib fractures and respiratory compromise.[40] Lumbar paravertebral block is less commonly used in clinical practice. As a thoracolumbar paravertebral block, it is effective for surgical anesthesia during inguinal herniorrhaphy. Hemodynamic stability is usually maintained after a paravertebral block due to the unilateral nature of sympathetic blockade. Bladder and lower limb motor function is also preserved, and no additional nursing vigilance is required during the postoperative period. Successful clinical applications of bilateral paravertebral block have also been reported.

CHAPTER 81B

Intercostal Nerve Block

Anthony M.-H. Ho, Robbert Buck, Malikah Latmore, Matthew Levine, and Manoj K. Karmakar

INTRODUCTION

The intercostal nerves (ICNs) innervate the major parts of the skin and musculature of the chest and abdominal wall. The block of these nerves was first described by Braun in 1907 in the textbook *Die Lokalanastesie*.[1] In the 1940s, clinicians noticed that intercostal nerve blocks (ICNBs) can reduce pulmonary complications and in opioid requirements after upper abdominal surgery.[1] In 1981, continuous ICNB was introduced to overcome the problems associated with repeated multiple injections.[1] Today, ICNB is used in a variety of acute and chronic pain conditions affecting the thorax and upper abdomen, including breast and chest wall surgery. Introduction of ultrasound guidance to the practice of regional anesthesia further facilitates its practice. The disadvantages of intercostal block, however, include the requirement for technical expertise, risks of pneumothorax, and local anesthetic toxicity with multiple levels of blockade.

INDICATIONS

ICNB provides excellent analgesia in patients with rib fractures[2,3] and for postsurgical pain after chest and upper abdominal surgery such as thoracotomy, thoracostomy, mastectomy, gastrostomy, and cholecystectomy.[4] Respiratory parameters typically show impressive improvements on relief of pain.[2,3] Blockade of the two dermatomes above and the two below the level of surgical incision is required. ICNB does not block visceral abdominal pain, for which a celiac plexus block is required. Neurolytic ICNB is used to manage chronic pain conditions such as postmastectomy pain (T2) and postthoracotomy pain.

CONTRAINDICATIONS

1. Disorders of coagulation, although this is not an absolute contraindication
2. Local infection, lack of expertise and resuscitating equipment

FUNCTIONAL ANATOMY

As thoracic nerves T1 to T12 emerge from their respective intervertebral foramina, they divide into the following rami (Figure 81B–1):

1. The paired gray and white anterior rami communicantes, which pass anteriorly to the sympathetic ganglion and chain.
2. The posterior cutaneous ramus, supplying skin and muscle in the paravertebral region.
3. The ventral ramus (ICN, the main focus of this chapter).

T1 and T2 send nerve fibers to the upper limbs and the upper thorax, T3 through T6 supply the thorax, T7 through T11 supply the lower thorax and abdomen, and T12 innervates the abdominal wall and the skin of the front part of the gluteal region (Figure 81B–2). Carrying both sensory and motor fibers, the ICN pierces the posterior intercostal membrane about 3 cm (in adults) distal to the intervertebral foramen to enter the subcostal grove where it, for the most part, continues to run parallel to the rib, although branches may often be found anywhere between adjacent ribs. Its course within the thorax is sandwiched between the parietal pleura and innermost intercostal (intercostalis intimus) muscles and the external and internal intercostal muscles (Figures 81B–3 and 81B–4). Just anterior to the midaxillary line, it gives off the lateral cutaneous branch. As the ICN approaches the midline, it turns anteriorly and pierces the overlying muscles and skin to terminate as the anterior cutaneous branch.

However, there are many anatomic variations. The first thoracic nerve (T1) has no anterior cutaneous branch, usually has no lateral cutaneous branch, and most of its fibers leave the intercostal space by crossing the neck of the first rib to join those from C8, while a smaller bundle continues on a genuine intercostal course to supply the muscles of the intercostal space. Some fibers of T2 and T3 give rise to the intercostobrachial

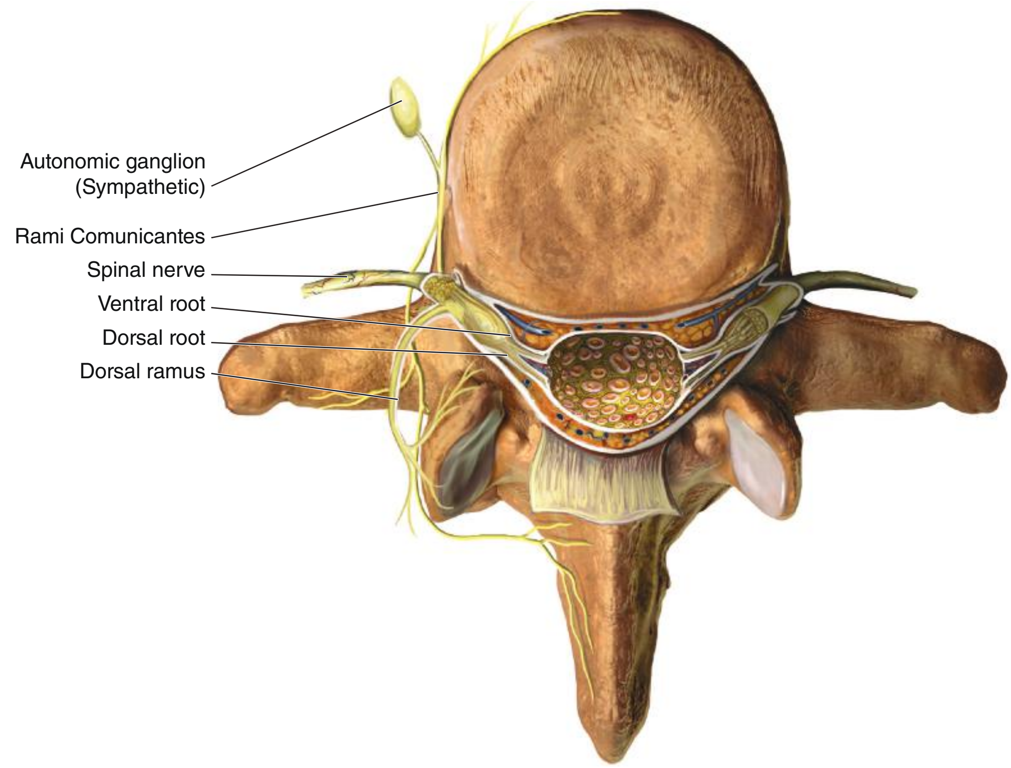

FIGURE 81B–1. Anatomy of the spinal nerve.

nerve, which innervates the axilla and the skin of the medial aspect of the upper arm as far distal as the elbow. In addition, the ventral ramus of T12 is similar to the other ICNs but is called a subcostal nerve because it is not positioned between two ribs.

Lateral Cutaneous Branch

The lateral cutaneous branches of T2 through T11 pierce the internal and external intercostal muscles obliquely before dividing into the anterior and posterior branches (see Figure 81B–4). These branches supply the muscles and skin of the lateral torso. The anterior branches supply of T7–T11 innervate the skin as far forward as the lateral edge of the rectus abdominis. The posterior branches of T7–T11 supply the skin overlying the latissimus dorsi. The lateral cutaneous branch of T12 does not divide. Most of the ventral ramus of T12 joins that of L1 to form the iliohypogastric, ilioinguinal, and genitofemoral nerves; the rest pierces the transverse abdominal muscle (TAM) to travel between TAM and the internal oblique muscle.

Anterior Cutaneous Branch

The anterior cutaneous branches of T2 through T6 pierce the external intercostals and pectoralis major muscles to enter the superficial fascia near the lateral border of the sternum to supply the skin of the anterior part of the thorax near the midline and slightly beyond (see Figure 81B–4). Smaller branches (T1 through T6) exist to supply the intercostal muscles and parietal

Distribution of the dye after injection into the intracostal sulcus.

pleura, and these branches may cross to adjoining intercostal spaces. The anterior cutaneous branches of T7 through T12 pierce the posterior rectus sheath to supply motor nerves to the rectus muscle and sensory fibers to the skin of the anterior abdominal wall. Some final branches of T7 through T12 continue anteriorly and, together with L1, innervate the parietal peritoneum of the abdominal wall. Their anterior course continues and becomes superficial near the linea alba to provide cutaneous innervation to the midline of the abdomen and a couple of centimeters beyond.

MECHANISM OF BLOCK AND DISTRIBUTION OF ANESTHESIA

ICNB blocks the ipsilateral sensory and motor fibers of the ICNs. Local anesthetic solution injected into the subcostal groove spreads both distally and proximally; some of the injectate may enter paravertebral space as well. (see Figure 81B–3).

TECHNIQUE

An intravenous line should be established, and resuscitation drugs should be readily available. Sedation and analgesia are always used judiciously. ICNB may be performed in an anesthetized patient, although spinal anesthesia has been reported in patients when ICNB was performed under general anesthesia,[4] and there is a concern that the risk of pneumothorax may be increased in a patient under positive pressure ventilation. After the block, the patient should be monitored for potential complications, particularly delayed pneumothorax, local anesthetic toxicity, hematoma, and occurrence of spinal anesthesia (rare).

The ICN can be blocked anywhere proximal to the midaxillary line, where the lateral cutaneous branch takes off. In children, the block is commonly carried out at the posterior axillary line or, alternatively, just lateral to the paraspinal muscles, at the angle of the rib. In adults, the most common site for ICNB is at the angle of the rib (6–8 cm from the spinous processes; Figure 81B–5). At the angle of the rib, the rib is relatively superficial and easy to palpate, and the subcostal groove is the widest. The nerve is inferior to the posterior intercostal artery, which is inferior to the intercostal vein (Figure 81B–6) (mnemonic: VAN [vein/artery/nerve]). VAN are surrounded by adipose tissue and are sandwiched between the internal intercostal and the interior intercostal (intercostalis intimus) muscles. The nerve often runs as three or four separate bundles, without an enclosing endoneural sheath, making it easily accessible to blockade. Blocking intercostal nerves medial to the angle of the rib is not recommended because the nerves lies deep to the posterior intercostal membrane with very little tissue between it and the parietal pleura, and the overlying sacrospinalis muscle makes rib palpation difficult. On the other hand, block distal to the anterior axillary line is more difficult because the nerve has left the subcostal groove and reentered the intercostal space and lies in the substance of the internal intercostal muscle.

ICNB can be performed with the patient in the prone, sitting, or lateral position (block side up). In prone position, a pillow should be placed under the patient's upper abdomen, and the arms are allowed to hang off the sides. The sitting patient should lean slightly forward holding a pillow and be supported. The arms should be forward. The position of the arm in either position is to pull the scapulae laterally and facilitate access to the posterior rib angles above T7 (see Figure 81B–5). Under aseptic conditions, the block sites are identified.

Clinical Pearls

- Ribs can be counted starting from the twelfth rib, or from the seventh rib (inferior tip of the scapula).
- The inferior edges of the ribs to be blocked are marked just lateral to the lateral border of the sacrospinalis (paraspinous) muscle group (usually 6–8 cm from the midline at the lower ribs and 4–7 cm from the midline at the upper ribs), corresponding to the angles of the ribs.

Inferior borders of the ribs to be blocked are palpated and marked (see Figure 81B–5). The needle entry sites are infiltrated with lidocaine 1%–2%. A site of entry is well placed

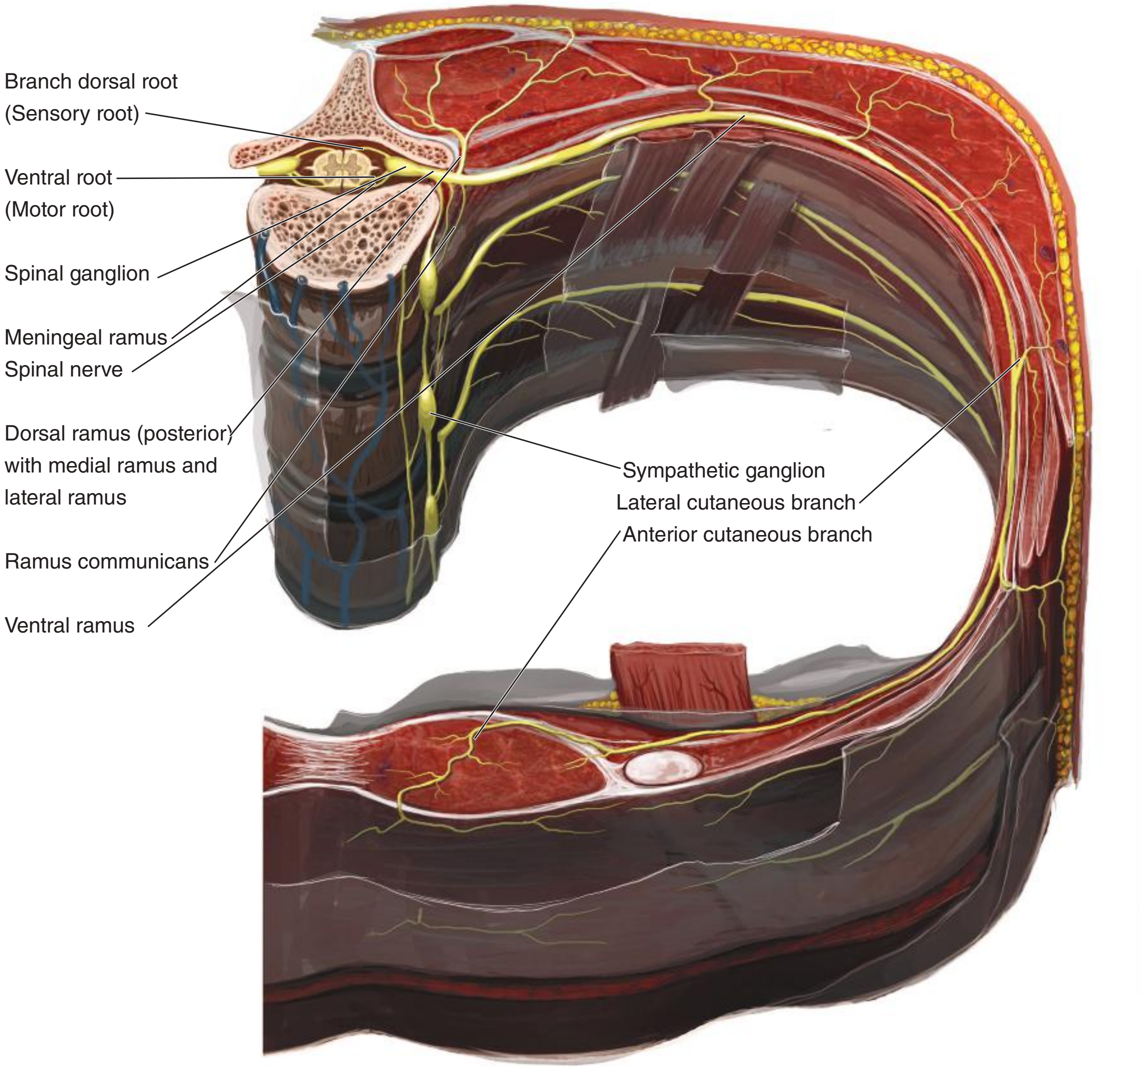

FIGURE 81B–4. Anatomy of the intercostal nerve.

when a needle introduced through it at 20 degrees cephalad (sagittal plane; see Figure 81B–6) scrapes underneath the inferior border of the rib and reaches the subcostal groove. The skin is first drawn cephalad with the palpating hand by about 1 cm, and a 4- to 5-cm, 22- to 24-gauge (for single-shot injection) needle is introduced through the chosen entry site at a 20-degree cephalad angle with the bevel facing cephalad. The needle is advanced until it contacts the rib at a depth of less than 1 cm in most patients. A small amount of local anesthetic may be injected to anesthetize the periosteum. With the palpating hand holding the needle firmly and resting securely on the patient's back, the injecting hand gently "walks" the needle caudally while the skin is allowed to move back over the rib (Figure 81B–7).

The needle is now advanced farther a few mm, while maintaining the 20-degree tilt angle cephalad (even a slight caudad-pointing angle by the needle greatly reduces the chance of success). A subtle "give" or "pop" of the fascia of the internal intercostal muscle may be felt, especially if a short-beveled needle is used. As the average distance from the posterior aspect of the rib to the pleura averages 8 mm, advancement of the needle much beyond a few mm increases the risk of pneumothorax.[5] Paresthesia, although not actively sought, occasionally occurs as an additional confirmation of the correct needle placement. Radiologic guidance is advised for neurolytic blocks. At this point, on negative aspiration for blood, 3–5 mL of local anesthetic is injected. For a single ICNB, it is desirable to block at least one ICN cephalad and one caudad because some degree of overlapping innervation from adjacent ICNs is common. To ensure that the tip of the needle remains in the optimal location, unaffected by hand and chest movements, some clinicians prefer to connect extension tubing between the needle and the syringe and have an assistant perform the aspiration and injection.

Blockade of T1 through T7 is technically more challenging because of the scapulae and the rhomboid muscles. For this reason, we prefer to perform a thoracic paravertebral block or an epidural blocks when high thoracic blockade is required.

FIGURE 81B–5. The sitting patient should lean slightly forward and be supported. The arms should pull the scapulae laterally to facilitate access to the posterior rib angles above T7. The inferior edges of the ribs to be blocked are marked just lateral to the lateral border of the sacrospinalis (paraspinous) muscle group, corresponding to the angles of the ribs. Points of needle entry are marked at 6–8 cm from the midline in most adults.

EQUIPMENT

Needle: Single shot: 20- to 22-gauge 4- to 5-cm needle (adults)
Catheter placement: 18- to 20-gauge Tuohy needle (adults)
Syringe and needle for local infiltration
Syringe with extension tubing
Sterilizing and resuscitation equipment and drugs, drapes, marking pen, pillow, portable fluoroscope (for neurolytic blocks)

CHOICE OF LOCAL ANESTHETIC

The choice of local anesthetic for single-shot ICNB includes bupivacaine 0.25%–0.5%, lidocaine 1%–2% with epinephrine 1/200,000–1/400,000, and ropivacaine 0.5%. Three to 5 mL of local anesthetic is injected at each level during a multiple-injection ICNB. The duration of action is usually 12 ± 6 h. Addition of epinephrine to bupivacaine or ropivacaine does not significantly prolong the duration of block, but may slow the systemic absorption and increase the maximum allowable dose with a single shot by 30%.[4] Maximum bupivacaine dose is 2 (for plain solution) to 3 (with epinephrine) mg/kg/injection (total at one time)[7] and 7–10 mg/kg/day. Maximum lidocaine dose is up to 5–7 (with epinephrine) mg/kg/injection[7] and 20 mg/kg/day. Volunteers reportedly may tolerate 30% more ropivacaine than bupivacaine before neurologic symptoms

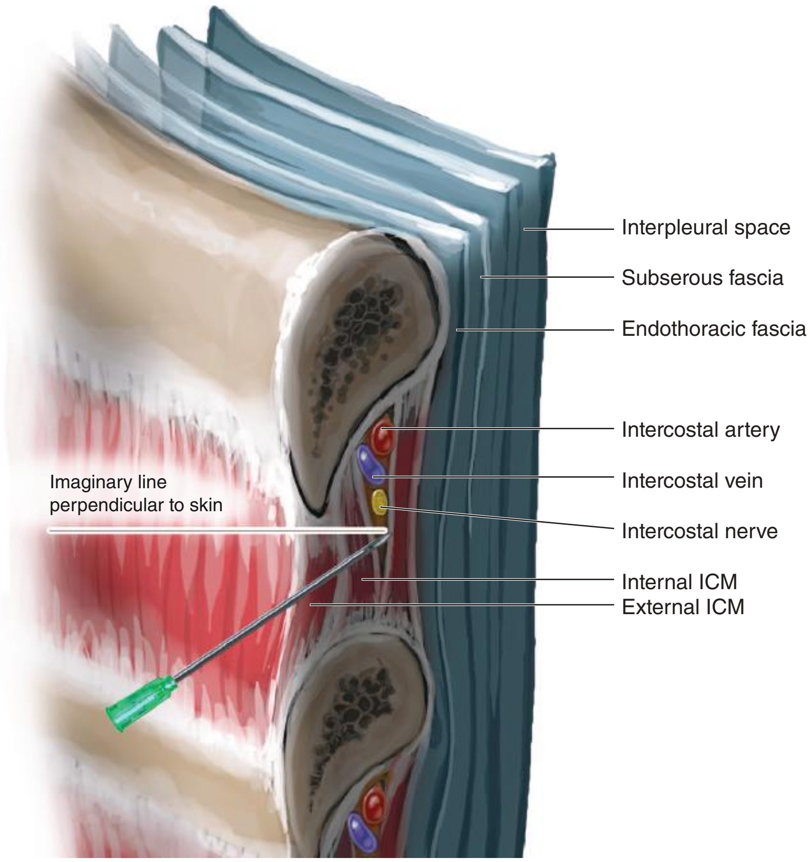

FIGURE 81B–6. Needle angle required to enter intercostal sulcus. Note the relationship of the intercostal vessels to the nerve.

FIGURE 81B–7. With the palpating hand holding the needle firmly and resting securely on the patient's back to control the needle advancement, the injecting hand gently "walks" the needle caudally while the skin is allowed to move back over the rib.

develop.[8] The maximum single injection dose for ropivacaine is 2.5 mg/kg and 4 mg/kg with epinephrine,[7] whereas the maximum daily dose is 9–12 mg/kg/24 h. The maximum single injection of epinephrine as an additive is 4 mcg/kg. Vascular sites favor more rapid local anesthetic absorption, and the blood levels of local anesthetics after ICNB are higher than for most other regional anesthetic procedure. As such, it is advisable to leave a safety margin between the doses given and the maximum recommended dosages, especially in young children; the elderly; debilitated patients; and those with underlying cardiac, hepatic, or renal impairment. For continuous infusion, patients can usually tolerate a gradual build-up of the plasma local anesthetic level better than acute rises. One recommended regimen is a loading dose of 0.3 mL/kg followed by an infusion of 0.1 mL/kg/h of either bupivacaine 0.25% or lidocaine 1%.[5]

Clinical Pearls

- Best needle insertion site for ICNB is the angle of the rib, about 7 cm lateral to midline in adults.
- The ideal angle of entry into the subcostal groove is about 20 degrees cephalad.
- Epidural analgesia may be better suited alternative to bilateral ICNBs because of the risk of bilateral pneumothorax and the potential for local anesthetic toxicity due the large dose of local anesthetic required.
- ICNB above T7 may be difficult because of the scapulae; an alternative technique such as paravertebral or epidural block should be considered.

COMPLICATIONS

The foremost concern is pneumothorax, which may occur in about 1%. Tension pneumothorax and the subsequent need for tube thoracostomy, however, is rare. If an asymptomatic pneumothorax is detected, the best management is observation, reassurance, and, if necessary, supplemental oxygen. The peritoneum and abdominal viscera are at risk of penetration when lower ICNs are blocked. Absorption of local anesthetic from the intercostal space is rapid; arterial plasma concentration peaks in 5-10 minutes, and venous plasma concentration peaks several minutes later.

SUMMARY

ICNB is a useful regional anesthesia technique; which is very effective in the controlling pain involving the thorax and upper abdomen. Although there is the risk of pneumothorax and local anesthetic toxicity, these can be reduced with proper technique and consideration given to the maximum allowable drug dose. The proper use of ICNB includes balancing its advantages and disadvantages against those of alternative techniques such as epidural and paravertebral block. With expertise and proper indications, intercostal nerve block may provide a uniquely suitable anesthetic option in patients in whom general or other regional anesthesia choices may be limited.[9]

CHAPTER 82A

Lumbar Plexus Block

Jerry D. Vloka, Tony Tsai, and Admir Hadzic

INTRODUCTION

Lumbar plexus is an advanced regional anesthesia technique, practiced by relatively few, experienced regional anesthesiologists. This is because these techniques have been challenging to master and resulted in frequent failure.[1–3] Dogliotti[4] pointed out, "the nerve trunks of the lumbar plexus which run into the inferior extremity are at a great distance from each other, so much so that in order to produce anesthesia, multiple procedures are necessary with separate injections, for each nerve trunk." Hence, anesthesiologists preferred the more time-efficient, simpler and reliable techniques of spinal or epidural anesthesia. Several variations of the original technique have been proposed, the main differences in these various approaches being in the level of blockade and the distance from the midline for the needle insertion.[4–6] However, given the deep location of the lumbar plexus, various approaches often represent minuscule technical variations rather than clinically relevant modifications. For instance, Chayen's approach is thought to result in too high incidence of epidural blockade,[7] but another proposed technique also resulted in a 15% incidence of epidural blockade.[8] Although ultrasound guidance may allow visualization of the lumbar plexus, the ultrasound guided technique still requires expertise and is technically challenging; refer Chapter 38.[9-11] Regardless of which technique is followed, certain safety precautions must be used for successful and safe use of this technique.

Indications

Lumbar plexus block has been used for a number of lower extremity procedures. It has been shown to be particularly useful for femoral shaft and neck fractures, knee procedures, and procedures involving the anterior thigh.[1,12–14] However, lumbar plexus block alone cannot provide adequate anesthesia for major surgery of the lower extremity because of the contributing innervation by the sciatic nerve. In one report, even when combined lumbar plexus–sciatic blocks are used for anesthesia in patients undergoing total knee arthroplasty, 22% of patients still required general anesthesia.[15]

Regional Anesthesia Anatomy and Management

The lumbar plexus consists of five nerves on each side, the first of which emerges between the first and second lumbar vertebrae and the last between the last lumbar vertebra and the base of the sacrum. As the L2, L3, and L4 roots of the lumbar plexus split off their spinal nerves and emerge from the intervertebral foramina, they enter the psoas major muscle[16] (Figure 82A–1). Within the muscle, these roots then split into anterior and posterior divisions, which reunite to form the individual branches (nerves) of the plexus.[17] The major branches of the lumbar plexus are the genitofemoral nerve, lateral femoral cutaneous nerve, femoral nerve, and obturator nerve (Figure 82A–2). Within the psoas major muscle, the lateral femoral cutaneous and femoral nerves are separated from the obturator nerve by a muscular fold in more than 50% of patients; anatomic variations are also common.[17,18] The femoral nerve is formed by the posterior divisions of L2–L4 and descends from the plexus lateral to the psoas muscle. The anterior divisions of the same roots unite to form the other major branch of the lumbar plexus, the obturator nerve. The reader is referred to Chapter 39 for more in-depth discussions of anatomy.

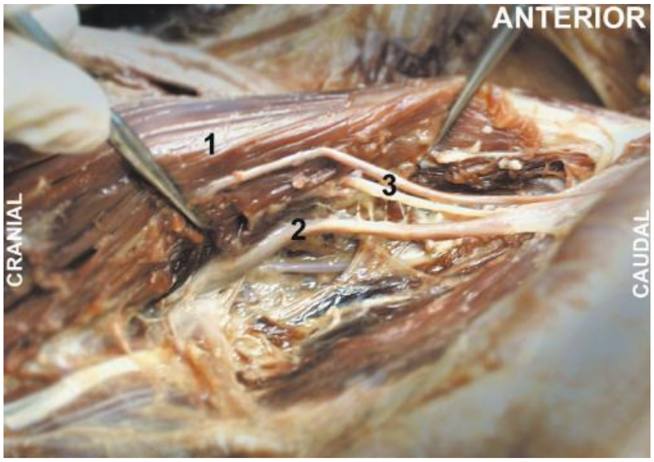

FIGURE 82A–1. Psoas muscle (*1*) is shown exposed from within abdominal cavity with lumbar plexus branches (*2*, *3*).

Distribution of Anesthesia

Injection of local anesthetic during lumbar plexus block most commonly results in spread of the injectate within the body of the psoas muscle around the lumbar branches (L2–L4), with cephalad spread to the lumbar nerve roots.[19]

The femoral nerve supplies motor fibers to the quadriceps muscle (knee extension), the skin of the anteromedial thigh, and the medial aspect of the leg below the knee and foot. The obturator nerve sends motor branches to the adductors of the hip and a highly variable cutaneous area on the medial thigh or knee joint. The lateral femoral cutaneous and genitofemoral nerves are purely cutaneous nerves. Figure 82A–3 illustrates the cutaneous innervation of the lumbar plexus.

FIGURE 82A–2. Lumbar plexus branches.

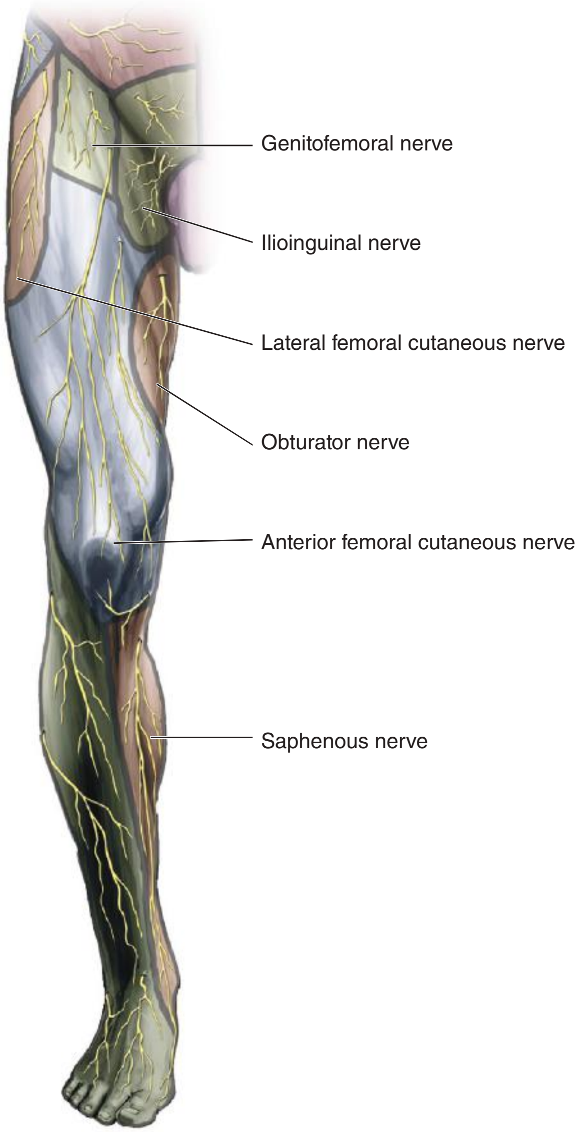

FIGURE 82A–3. Distribution of anesthesia and analgesia after a successful lumbar plexus block.

Choice of Local Anesthetic

Lumbar plexus blockade requires a relatively large volume of local anesthetic. The choice of the type and concentration of local anesthetic should be based on whether the block is planned for surgical anesthesia or pain management. Because of the vascular nature of the area and the potential for inadvertent intravascular injection, rapid absorption from the deep muscle beds, and epidural spread, then rapid, forceful injections should be avoided.[20] Epinephrine is almost routinely used as a vascular marker. The most commonly used local anesthetic for this block in our institution for short procedures is alkalinized 2-chloroprocaine 3% with 1:300,000 epinephrine in patients having knee arthroscopy.[21,22] Some common choices of local anesthetics for this block are listed in Table 82A–1.

PART 15

TABLE 82A–1. Local anesthetic choices for lumbar plexus block.

	Onset (min)	Anesthesia (h)	Analgesia (h)
3% 2-Chloroprocaine (+ HCO_3; + epinephrine)	10–15	1.5	2.0
1.5% Mepivacaine (+ HCO_3)	10–15	2	2–4
1.5% Mepivacaine (+ HCO_3; + epinephrine)	10–15	2.5–3	2–5
2% Lidocaine (+ HCO_3)	10–20	2.5–3	2–5
2% Lidocaine (+ HCO_3 + epinephrine)	10–20	5–6	5–8
0.5% Ropivacaine	15–20	4–6	6–10

Technique

The patient is in the lateral decubitus position with a slight forward tilt (Figure 82A–4). The foot on the side to be blocked should be positioned over the dependent leg so that twitches of the quadriceps muscle and/or patella can be seen easily.

A standard regional anesthesia tray is prepared with the following equipment:

- Sterile towels and 4-in. × 4-in. gauze packs
- 20-mL syringes with local anesthetic
- Sterile gloves, marking pen, and surface electrode
- One 1.5-in., 25-gauge needle for skin infiltration
- A 10-cm long, short-bevel, insulated stimulating needle
- Peripheral nerve stimulator
- Injection pressure monitor

Landmarks for the lumbar plexus block include (Figure 82A–5):

1. Midline (spinous processes)
2. Iliac crest
3. Needle insertion labeled 4-cm lateral to the intersection of landmarks 1 and 2

After cleaning with antiseptic solution, the skin is anesthetized by infiltrating local anesthetic subcutaneously. The fingers of the palpating hand are pressed against the paravertebral muscles to stabilize the landmark and decrease the skin–nerve distance. The needle is inserted at a perpendicular angle to the skin (Figure 82A–6A and B). The nerve stimulator should be initially set to deliver current intensity of 1.5 mA. As the needle is advanced, local twitches of the paravertebral muscles are obtained first at a depth of a few centimeters. The needle is then advanced further until twitches of the quadriceps muscle are obtained (usually at the depth of 6–8 cm). After the twitches are obtained, the current should be lowered to obtain stimulation between 0.5 and 1.0 mA.

At this point, 25–35 mL of local anesthetic is slowly injected with frequent aspiration to rule out inadvertent intravascular placement of the needle. Of note, while ultrasound guidance allowed for reduction of the volume and dose of local anesthetics for most nerve block procedures, this is not the case in the lumbar plexus block.[10]

Clinical Pearls

- Successful lumbar plexus blockade depends on the disposition of the local anesthetic in the fascial plane (psoas muscle) where the roots of the plexus are situated. Nerve stimulation is used to identify this plane by eliciting stimulation of one of the roots.

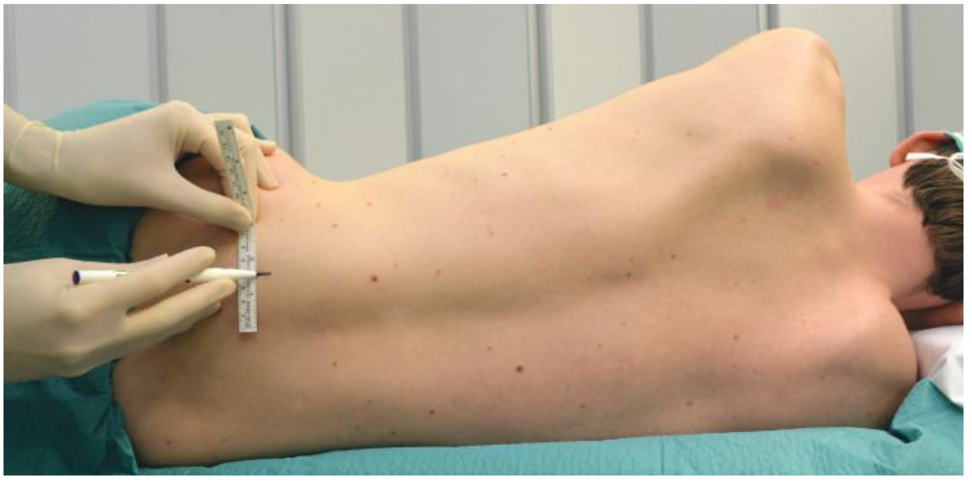

FIGURE 82A–4. Patient position for lumbar plexus block.

TABLE 82A–2. Troubleshooting procedures during lumbar plexus blocks.

Response Obtained	Interpretation	Problem	Action
Local twitch of the paraspinal muscles	Direct stimulation of the paraspinal muscles	Too shallow placement of the needle	Continue advancing the needle
Needle contacts bone at 4–6 cm depth; no twitches are seen	The needle advancement is stopped by the transverse process	Indicates proper needle placement, but requires redirection of the needle	Withdraw the needle to the skin level, and redirect 5 degrees cranially or caudally
Twitches of hamstrings muscles are seen; needle inserted 6–8 cm	Result of stimulation of the roots of the sciatic plexus (sciatic nerve)	Needle inserted too caudally	Withdraw the needle and reinsert 3–5 cm cranially
Flexion of thigh at the depth of > 6–8 cm	This subtle and often missed response is caused by direct stimulation of the psoas muscle	Needle inserted too deep (missed the lumbar plexus roots); further advancement may place the needle intraperitoneally	Stop advancing the needle; withdraw the needle and reinsert using the protocol outlined in the technique description
Needle is placed deep (10 cm), but twitches were not elicited and bone is not contacted	Needle missed the transverse process and roots of the lumbar plexus	Needle placement too lateral	Withdraw the needle and reinsert with a slight medial angulation (5–10 degrees)

- Stimulation at currents less than 0.5 mA should not be sought because stimulation with a low current may indicate placement of the needle inside a dural sleeve. An injection inside this sheath can result in spread of the local anesthetic toward the epidural or subarachnoid space.

When insertion of the needle does not result in quadriceps muscle stimulation, the maneuvers outlined in Table 82A–2 should be followed.

Block Dynamics and Perioperative Management

A lumbar plexus block is uncomfortable for patients owing to the needle passage through multiple muscle planes and adequate premedication is necessary. Typically, we use midazolam 2-4 mg after the patient is positioned and alfentanil 500–750 mcg just before needle insertion. A typical onset time for this block is 15–25 minutes, depending on the type, concentration, and volume of local anesthetic and the level at which the needle is placed.

For example, although an almost immediate onset of anesthesia in the anterior thigh and knee can be achieved with an injection at the L3 level, additional time is required for local anesthetic to block the lateral thigh (L1) or obturator nerve (L5). The first sign of the onset of blockade is usually the loss of sensation in the saphenous nerve territory (medial skin below the knee).

CONTINUOUS LUMBAR PLEXUS BLOCK

Continuous lumbar plexus blockade is an advanced regional anesthesia technique, and adequate experience with the single-shot technique is a prerequisite to ensure its efficacy and safety. Otherwise, the technique is similar to the single-shot injection except that the Tuohy-style tip needle is preferable. The needle opening should be directed cephalad to facilitate threading of the catheter. This technique can be used for postoperative pain management in patients undergoing hip, femur, and knee surgery.[23] However, because a large volume of local anesthetic is required to accomplish analgesia, continuous infusion requires intermittent boluses for success. Consequently, some feel that its advantages over femoral block for postoperative analgesia are questionable at best, and that continuous lumbar plexus block should not be in routine use for postoperative analgesia.[24]

Equipment

A standard regional anesthesia tray is prepared with the following equipment:

- Sterile towels and 4-in. × 4-in. gauze packs
- 20-mL syringe with local anesthetic
- Sterile gloves, marking pen, and surface electrode
- One 1.5-in. 25-gauge needle for skin infiltration
- A 10-cm long, insulated stimulating needle (preferably Tuohy-style tip)
- Catheter
- Peripheral nerve stimulator

Technique

The skin and subcutaneous tissues are anesthetized with local anesthetic. The needle is attached to the nerve stimulator (1.5 mA, 2 Hz, 100 μsec) and to a syringe with local anesthetic. The palpating hand should be firmly pressed and anchored against the paraspinal muscles to facilitate the needle insertion and redirection of the needle when necessary. A 10-cm, Tuohy-style tip, continuous block needle is inserted at a perpendicular angle and advanced until the quadriceps twitch response is obtained at 0.5–1.0 mA current. At this point, the initial volume of local anesthetic is injected (e.g., 15–25 mL), and the catheter is inserted approximately 8–10 cm beyond the needle tip. The needle is then withdrawn back to the skin level, while the catheter is simultaneously advanced. This method prevents inadvertent removal of the catheter and intravascular and intrathecal placement by negative aspiration test.

Clinical Pearl

- The skin in the lumbar area can be mobile; thus insertion of the catheter to a depth of 5–6 cm is necessary to help prevent its removal during patient repositioning.

Continuous Infusion

Continuous infusion is initiated after an initial bolus of dilute local anesthetic through the catheter. For this purpose, we routinely use ropivacaine 0.2% (15–20 mL). The infusion is maintained at 10 mL/h or 5 mL/h when a patient-controlled analgesia (PCA) dose is planned (5 mL/q60min). Figures 82A–7 and 82A–8 show the dispersion of 20 mL of a contrast solution within the psoas sheath.

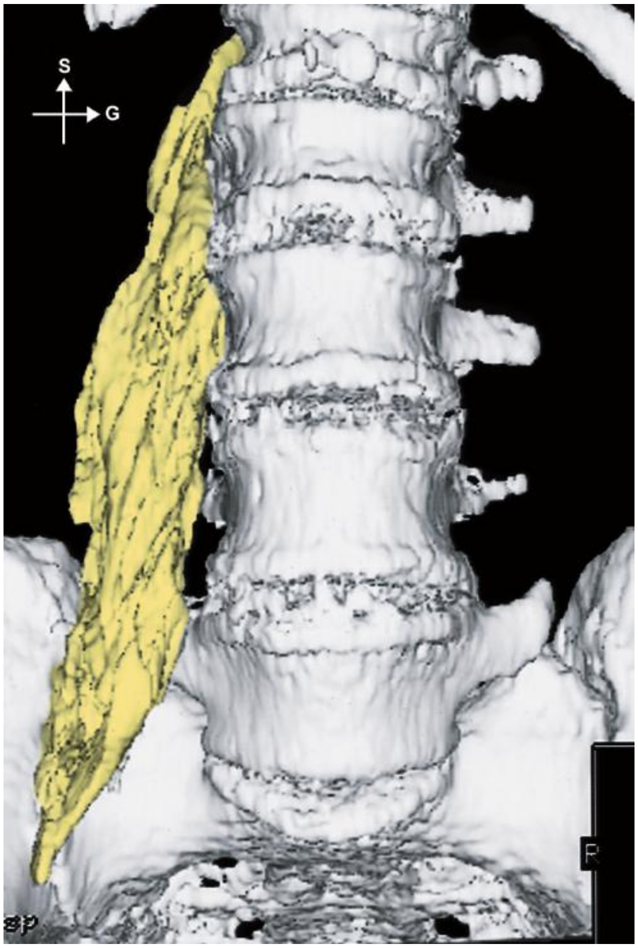

FIGURE 82A–7. Distribution of 20 mL of injectate after lumbar plexus block. A typical fusiform distribution within the psoas muscle is seen.

COMPLICATIONS AND HOW TO AVOID THEM

The lumbar plexus block is an advanced technique with a potential for serious complications. The most common complications reported with lumbar plexus block are epidural spread with a risk of high neuraxial anesthesia,[20,25–28] hypotension, local anesthetic toxicity,[29–31] spinal anesthesia[32] or iliopsoas or renal hematoma.[33–36] Although the plasma concentrations of local anesthetics are not significantly higher after lumbar plexus block compared with other peripheral nerve blocks, there is the potential for rapid absorption and intravascular channeling owing to the large volumes required for this block and intramuscular location of the needle.[37] In addition, this block is best avoided in anticoagulated patients due to the risk of haematoma.[35] Table 82A–3 provides some general and specific instructions on possible complications and methods to avoid.

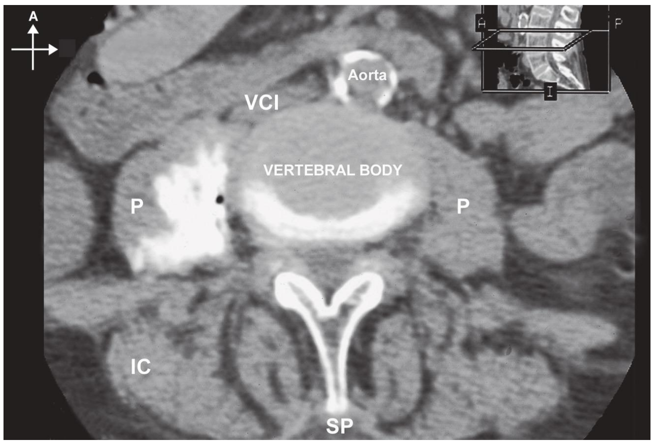

FIGURE 82A–8. An MRI image demonstrating distribution of local anesthetic after lumbar plexus block. (A, anterior; I, inferior; IC, iliac crest; P, psoas muscle; SP, spinous process; VCI, vena cava inferior.)

TABLE 82A–3. Strategies to decrease the risk of complications.

Complication	Instruction
Infection	• A strict aseptic technique is used
Hematoma	• Avoid multiple needle insertions, particularly in anticoagulated patients • Avoid continuous lumbar plexus blocks in anticoagulated patients • Antiplatelet therapy is not a contraindication for lumbar plexus block in the absence of spontaneous bleeding
Vascular puncture	• Deep needle insertion should be avoided (vena cava, aorta)
Local anesthetic toxicity	• Large volumes of long-acting anesthetic should be reconsidered in older and frail patients • Careful and frequent aspiration should be performed during the injection • Avoid forceful, fast injection of local anesthetic
Nerve injury	• Risk after lumbar plexus block is low • Local anesthetic should never be injected when the patient complains of pain or when abnormally high pressure on injection is noted • When stimulation is obtained with current intensity of <0.5 mA, the needle should be pulled back to obtain the same response with a current of 0.5 mA before injecting local anesthetic to avoid injection into the dural sleeves and the consequent epidural or spinal spread
Hemodynamic consequences	• Lumbar plexus blockade results in unilateral sympathectomy • Spread of the local anesthetic to the epidural space may result in significant hypotension and occurs in up to 15% of patients • Patients receiving a lumbar plexus block should be monitored to the same extent as patients receiving epidural anesthesia

CHAPTER 82B

Obturator Nerve Block

Herve Bouaziz

INTRODUCTION

Selective obturator nerve block was first described by Gaston Labat in 1922.[1] More interest in obturator nerve block emerged a few years later when Victor Pauchet, Sourdat, and Gaston Labat stated, "obturator nerve block combined with blocks of the sciatic and femoral nerves, anesthetized the entire lower limb." However, a lack of clear anatomic landmarks, the block complexity, and inconsistent results were the reasons why this block had been used infrequently. Historically, Labat's classic technique remained forgotten until 1967, when it was modified by Parks.[2] In 1993, the interadductor approach was described by Wassef,[3] which was further modified by Pinnock in 1996.[4] In 1973, Alon Winnie introduced the concept of the "3-in-1 block," an anterior approach to the lumbar plexus using a simple paravascular inguinal injection to anesthetize the femoral, lateral cutaneous and obturator nerves.[5] Since its description however, many studies have refuted the ability of the 3-in-1 block to reliably block the obturator nerve with this technique. With the introduction of modern nerve stimulators, and particularly ultrasound guidance selective blockade of the obturator nerve has become more reliable.

Indications

Obturator nerve block is used to treat hip joint pain and is also used in the relief of adductor muscle spasm associated with hemiplegia or paraplegia. Muscle spasticity is a relatively common problem among patients suffering from central neurologic problems, such as cerebrovascular pathology, medullar injuries, multiple sclerosis, and cerebral palsy. Spasticity of the adductor muscle induced via the obturator nerve plays a major role in associated pain problems and makes patient hygiene and mobilization very difficult. Tenotomies, cryotherapy, botulinum toxin infiltration, surgical neurolysis, and muscle interpositions have been suggested to remedy this problem.[6–9] Common clinical practice is to combine a sciatic nerve block with the femoral nerve block for surgical procedures distal to the proximal third of the thigh. When deemed necessary, addition of a selective obturator nerve block may reduce intraoperative discomfort, improve tourniquet tolerance, and improve the quality of postoperative analgesia in these cases.

Obturator nerve block is also occasionally used in urologic surgery to suppress the obturator reflex during transurethral resection of the lateral bladder wall. Direct stimulation of the obturator nerve by the resector as it passes in close proximity to the bladder wall results in a sudden, violent adductor muscle spasm. This is not only distracting to the surgeon, but may increase the risk of complications such as bladder wall perforation, vessel laceration, incomplete tumor resection, and obturator hematomas.[10,11] Prevention strategies include muscle relaxation, reduction in the intensity of the resector, the use of laser resectors, shifting to saline irrigation, periprostate infiltrations, and/or endoscopic transparietal blocks.[12–16] A selective obturator nerve block remains an effective remedy to this problem.[17–22]

Clinical Pearl

- The obturator reflex is not abolished by spinal anesthesia. It can be suppressed only by a selective obturator nerve block.

Neurolytic blocks with alcohol or phenol, performed with the help of a nerve stimulator and/or fluoroscopy, result in a cost-effective and effective reduction of muscle spasms.[3,9,23–26] The main drawback to neurolytic blockade is its temporary duration and the need to repeat the block when the previous block wears off. Selective obturator nerve block has also been used in the diagnosis and treatment of chronic pain states secondary to knee arthrosis or pelvic tumors resistant to conventional analgesic approaches.[27–31]

Contraindications

Patient refusal, inguinal lymphadenopathy, perineal infection, or hematoma at the needle insertion site all are contraindications to obturator nerve blockade. Preexisting obturator neuropathy, clinically manifested by groin pain, pain of the posteromedial aspect at the thigh, and occasionally paresis of the adductor group of muscles, are relative contraindications to this block. Obturator nerve blocks should be avoided in the presence of a coagulopathy.

Anatomy

The obturator nerve is a mixed nerve, which, in most cases, provides motor function to the adductor muscles and cutaneous sensation to a small area behind the knee. It is derived from the anterior primary rami of L2, L3, and L4 (Figure 82B–1). On its initial course, it runs within the psoas major muscle. Taking a vertical course, it emerges from the inner border of the psoas, staying medial and posterior at the pelvis until it crosses at the level of the sacroiliac joint (L5) under the common iliac artery and vein and runs anterior/lateral to the ureter (Figure 82B–2). At this level, it courses close to the wall of the bladder on its inferior/lateral portion and then it takes place anterior to the obturator vessels within the superior part of the obturator foramen, exiting the pelvis below the pubic superior branch. In its intrapelvic course, the obturator nerve is separated from the femoral nerve by the iliopsoas muscle and iliac fascia. It innervates the parietal peritoneum on the lateral pelvic wall and contributes collateral branches to the obturator externus muscle and the hip joint. It leaves the pelvis by passing through the obturator canal before entering the adductor region of the thigh (Figure 82B–3). Here, 2.5–3.5 cm after leaving the obturator foramen, the obturator nerve divides into its two terminal branches, anterior and posterior, providing innervation to the hip adductor compartment (Figure 82B–3).[32]

The anterior branch descends behind the pectineus and adductor longus and in front of the obturator externus and adductor brevis. It gives muscular branches to the adductor longus, adductor brevis, gracilis, and occasionally the pectineus, and it terminates as a small nerve that innervates the femoral artery (Figure 82B–4). In 20% of subjects, it contributes a branch, which anastomoses with branches of the femoral nerve and forms the subsartorial plexus, from which sensory branches emerge to supply sensation to posteromedial aspect of the inferior third of the thigh. The anterior branch contributes articular branches to anteromedial aspect of the hip joint capsule (Figure 82B–5) but does not innervate the knee joint. Under ultrasound guidance, selective block of the anterior or posterior branches can be performed. Block of the anterior branch alone may be adequate for preventing the adductor reflex during bladder surgery."[33–35]

The posterior branch descends between the adductor brevis in front and the adductor magnus behind. It terminates by passing through the adductor hiatus to enter the popliteal fossa, supplying the posterior aspect of the knee joint and the popliteal

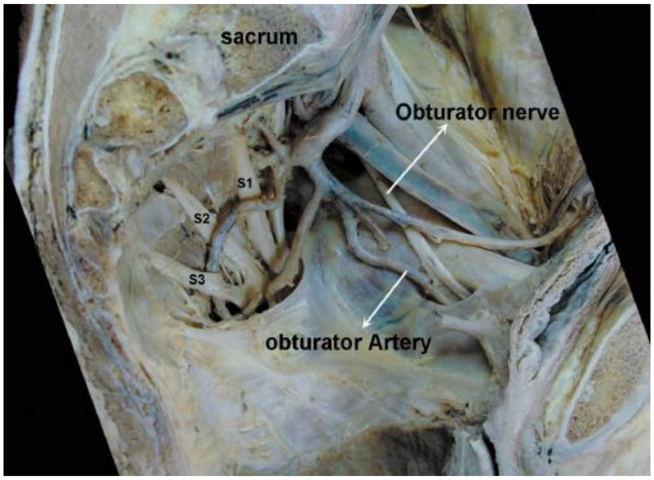

FIGURE 82B–2. Intrapelvic trajectory of the obturator nerve. After crossing under the iliac vessels, the obturator nerve travels toward the obturator foramen via the lateral pelvic wall. During this course, the obturator artery and vein join the nerve, forming the obturator neurovascular bundle.

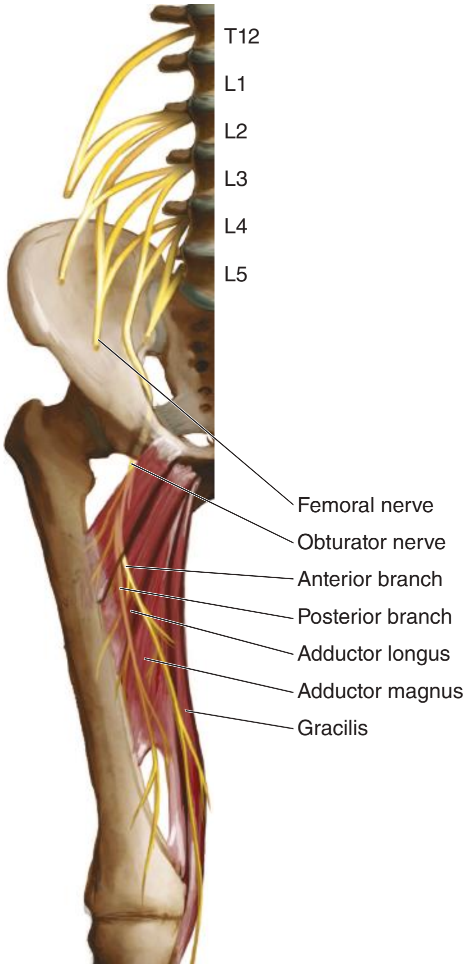

FIGURE 82B–1. Anatomy of the obturator nerve.

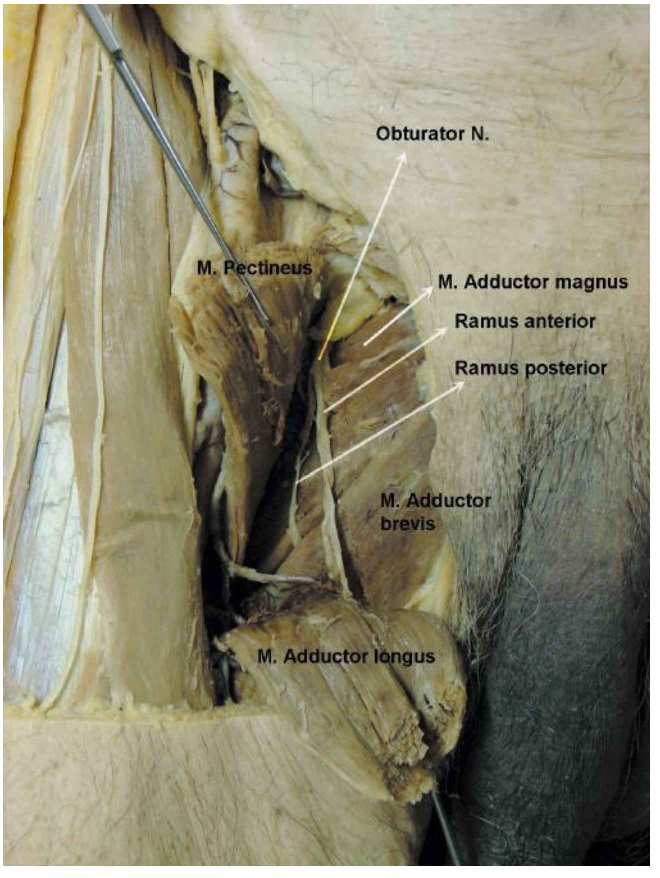

FIGURE 82B–3. Distribution of the anterior and posterior divisions of the obturator nerve after exiting the obturator foramen.

artery. During its course, the posterior branch sends muscular branches to the obturator externus, the adductor magnus, and occasionally the adductor brevis muscles (see Figure 82B–4).

Cutaneous innervation by the obturator nerve varies according to the investigators and is illustrated in Figure 82B–6.

The functions of the muscles innervated by the obturator nerve are adduction of the thigh and assistance with hip flexion. The gracilis muscle assists knee flexion, and the obturator externus aids the lateral rotation of the thigh. To request an active adduction of the thigh, therefore, tests the function of the obturator nerve. The patient should be supine with knees extended. The leg is then adducted against resistance while the examiner supports the contralateral leg. The paralysis (or block) of the nerve is characterized by a severe weakening of the adduction, although it is not completely lost as the adductor magnus (the most powerful adductor muscle) receives fibers from the sciatic nerve and eventually from the femoral nerve.

Anatomic Variants

Numerous variations to the formation, course, and distribution of the obturator nerve can have clinical implications. For instance, in 75% of cases, the obturator nerve divides into its two terminal branches as it passes through the obturator canal. In 10% of cases, this division occurs before the nerve reaches the obturator canal; in the remaining 15% of cases, after entering the thigh.

Occasionally, the anterior and posterior branches descend through the thigh behind the adductor brevis. Note that the sensory cutaneous branch of the obturator nerve is often absent.

Up to 20% of subjects possess an accessory obturator nerve that can be formed from variable combinations of the anterior rami L2–L4 or emanate directly from the trunk of the obturator nerve.[36] It accompanies the obturator nerve as it emerges from the medial border of the psoas, but unlike the obturator, passes in front of the superior pubic ramus to supply a muscular branch, the pectineus. It contributes articular branches to the hip joint and terminates by anastomosing with the obturator nerve itself.

Equipment

To perform a block, the following equipment is required:

- Nerve stimulator
- Insulated stimulating needle (5–8 cm, depending on the approach chosen)
- Local anesthetic: 1% mepivacaine (onset of motor block 15 min, duration 3–4 h) or 0.75% ropivacaine (on-set of motor block 25 min, block duration 8–10 h)
- Sterile fenestrated drape
- Marking pen
- Ruler
- A 10-mL syringe
- Disinfectant
- Sterile gloves

Landmarks

Anatomic landmarks vary depending on the chosen approach. However, it is useful to identify and outline the following landmarks regardless of the approach chosen (Figure 82B–7):

Bony landmarks: Anterior and superior iliac spine and pubic tubercle, inguinal ligament

Vascular landmarks: Femoral artery, femoral crease

Muscular landmarks: Tendon of the adductor longus muscle

Techniques

Several methods can accomplish block of the obturator nerve. These approaches can be grouped into plexus block techniques where the obturator nerve is blocked along with other components of the lumbosacral plexus and specific single-nerve block techniques for the obturator nerve.

3-in-1 Block Technique

Based on the theoretic existence of a suprainguinal compartment, in 1973 Winnie described the lumbar plexus block by an anterior approach or the "3 in 1 block".[5] According to the 3-in-1 concept, a large volume of local anesthetics is injected over the femoral nerve to spread underneath the fascia iliaca. When combined with distal compression, the local anesthetic spreads proximally reaching the lumbar plexus. Unfortunately, studies have repeatedly failed to demonstrate the reliability of

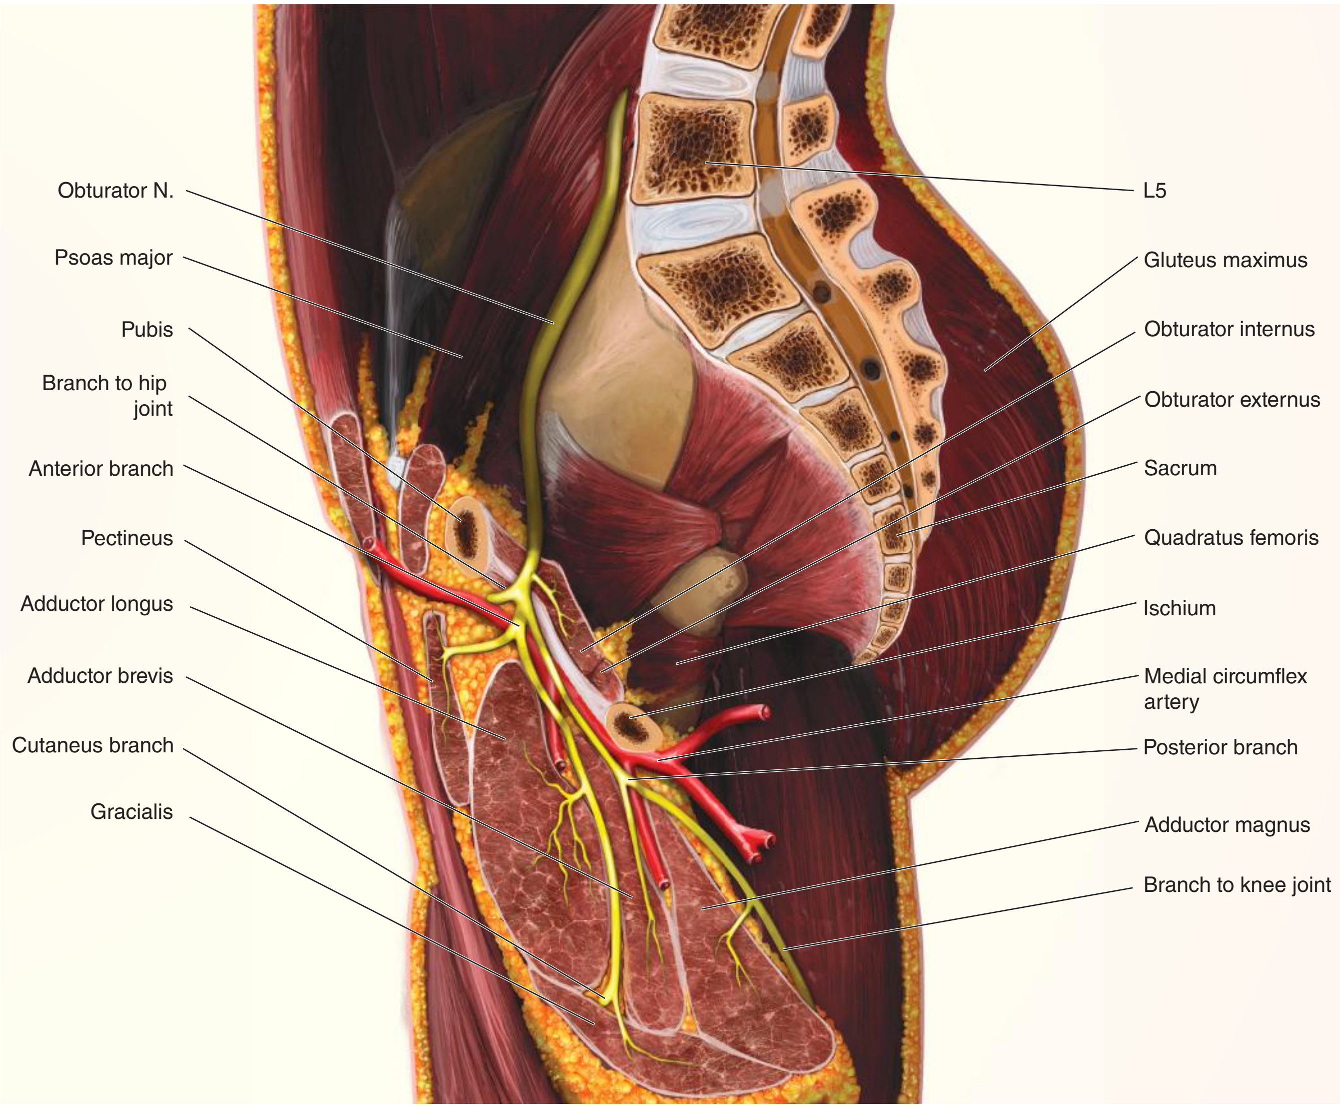

FIGURE 82B–4. Sagittal section demonstrating the relationship of the obturator nerve to the adductor muscles.

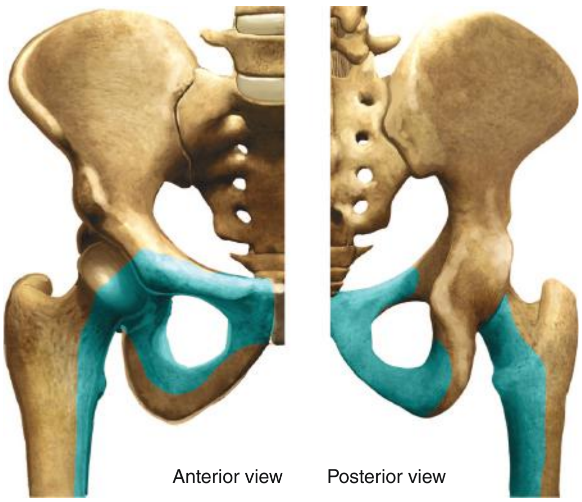

FIGURE 82B–5. The role of the obturator nerve in the sensory innervation of the hip.

this technique to obtain a block of the lumbar plexus or the obturator nerve.[5,37–39] In addition, studies in human cadavers have documented the absence of a fluid-conducting compartment that would allow such an extensive proximal spread of the local anesthetic.[40]

Of note, increasing the volume of injectate does not increase the spread toward the lumbar plexus; no differences were found when local anesthetic injection volumes of 20 or 40 mL were compared.[41]

Theoretically, catheters inserted by an inguinal approach can ascend toward the psoas compartment, however, only a minor percentage (23%) of catheters can be adequately placed in the therapeutic position.[42.43]

Iliofascial Block Technique

Dalens first described this approach in 1989 for use in pediatric patients.[44] Following Winnie's reasoning for the 3-in-1 block,

FIGURE 82B–6. Skin innervation by obturator nerve according to different investigators.

he took a more lateral approach and reported a 100% success rate for femoral and femoral cutaneous nerve blockade and 88% success rate for the obturator nerve. However, follow-up studies in adults did not confirm these results.[42,45]

In adults, the iliofascial approach allows more successful blockade of the lateral femoral cutaneous nerve when compared with the 3-in-1 technique. However, the obturator nerve remains spared.[45,46]

Psoas Compartment Block

Since Winnie's description of the posterior approach to the lumbar plexus in 1974 (psoas compartment block), numerous modifications of the technique have been described.[46–50]

The obvious advantage is the ability to obtain a complete lumbar plexus block with a single injection. Indeed, studies have demonstrated femoral nerve block close to 100% plexus block with this technique, whereas femorocutaneous and obturator nerve blocks are anesthetized 88%–93% of the time.[51,52]

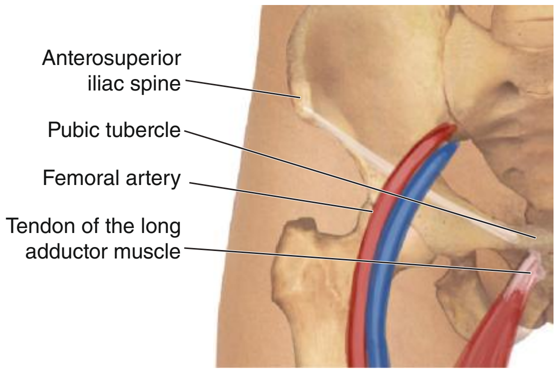

FIGURE 82B–7. Anatomic landmarks for blockade of the obturator nerve.

Parasacral Sciatic Block

Mansour initially described this technique in 1993 with the objective of achieving a more complete sciatic nerve block.[53,54] Since this technique is a plexus block, it provides more consistent anesthesia of all branches of the sciatic nerve. It successfully blocks the posterior cutaneous nerve of the thigh, the gluteal superior and inferior nerves, and the pudendal nerve. In addition, the splanchnic nerves, the inferior hypogastric plexus, the proximal portion of sympathetic trunks, and the obturator nerve are located close to the point of injection. Thus, a blockade of all these nervous structures would be theoretically achievable with a single injection. However, recent anatomic and clinical studies suggest that the parietal peritoneum and the pelvic fascia surrounding the sacral plexus are anatomically separated from the obturator nerve that runs along the medial border of the psoas. Consequently, although the parasacral approach to sciatic nerve block should result in a complete block of the sacral plexus, it is not reliable for obturator nerve block.[55]

Selective Block Techniques

Labat's Classic Technique

Labat's classic approach was a common technique before the development of newer approaches that are easier to perform and less uncomfortable to patients. Originally described as a paresthesia method, the advent of nerve stimulation has increased the effectiveness and reduced patient

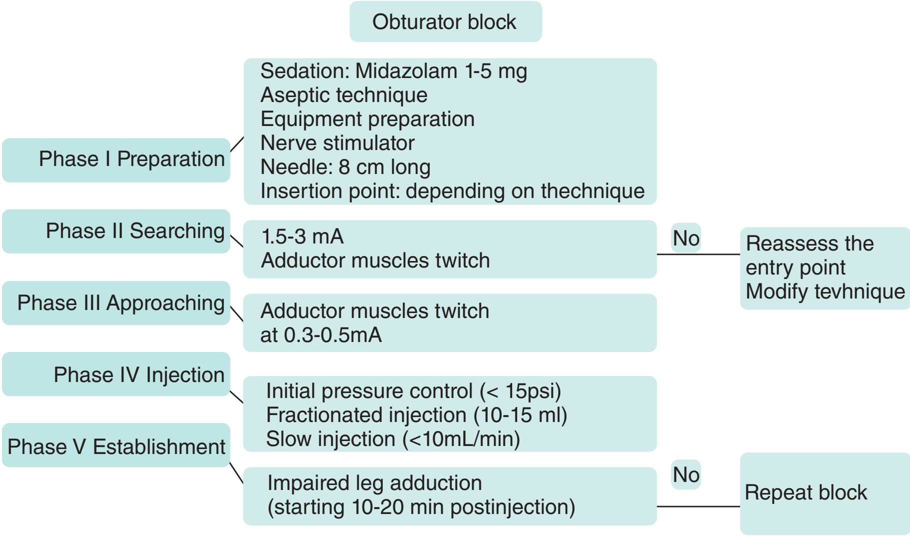

FIGURE 82B–8. A practical algorithm to obturator nerve block.

discomfort, complications, and number of needle insertions. The procedure sequence consists of five phases, depicted in Figure 82B–8.

Nerve stimulation is begun using a current intensity of 2–3 mA (2 Hz, 0.1–0.3 msec) and reduced to 0.3–0.5 mA before injection of local anesthetic. The patient lies supine, with the limb to be blocked at 30 degrees abduction. The pubic tubercle is identified by palpation, and a 1.5-cm long line is drawn laterally and caudally; the injection insertion site is labeled at the tip of the end of the caudal line (Figure 82B–9). The classic approach consists of carrying out three consecutive movements of the needle until the tip of the needle is placed over the top of the obturator foramen, where the nerve runs before splitting into its two terminal branches. With a 22-gauge, 8-cm long needle, the skin is penetrated perpendicularly and the needle is advanced until it makes contact with the inferior border of the superior pubic branch at a depth of 2–4 cm. During the second phase, the needle is slightly withdrawn and then slipped along the anterior pubic wall (another 2–4 cm). After this, it is redirected anteriorly/posteriorly. Finally, the needle is withdrawn again and slightly redirected (cephalad and laterally) at an angle of 45 degrees for another 2–3 cm until contractions of the thigh adductor muscles are observed.

This technique can be simplified by eliminating the second movement of the needle. Hence, after making contact with the pubic branch, the needle can be redirected 45 degrees laterally to the obturator foramen (see Figure 82B–9).

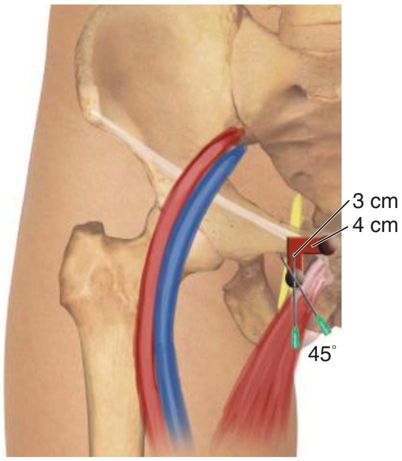

FIGURE 82B–9. Obturator nerve block. Simplified Labat classic technique.

Paravascular Selective Inguinal Block

This technique consists of a selective block of the two branches of the obturator nerve (anterior and posterior), performed at the inguinal level and slightly more caudad than the previously described techniques.[56] The femoral artery and the tendon of the adductor longus muscle at the pubic tubercle are identified. For tendon identification, extreme leg abduction is required (Figure 82B–10). A line is drawn over the inguinal fold from the pulse of the femoral artery to the tendon of the long adductor muscle. The needle is inserted at the midpoint of this line at an angle of 30 degrees anteriorly/posteriorly and cephalad (Figure 82B–11). By following the needle a few centimeters in depth via the adductor longus muscle, twitches of the adductor longus and gracilis muscles are easily detectable on the posterior and medial aspect of the thigh. Subsequently, the needle is inserted deeper (0.5–1.5 cm) and slightly laterally over the adductor brevis muscle until a response from the adductor magnus muscle is obtained and can be visualized on the posterior-medial aspect of the thigh. After needle insertion, infiltration of 5–7 mL local anesthetic is recommended. Occasionally, a more caudal division of the obturator nerve is found; the two branches are located within the same location at the inguinal fold, and two different motor responses may be observed with a single injection.

FIGURE 82B–10. Leg abduction.

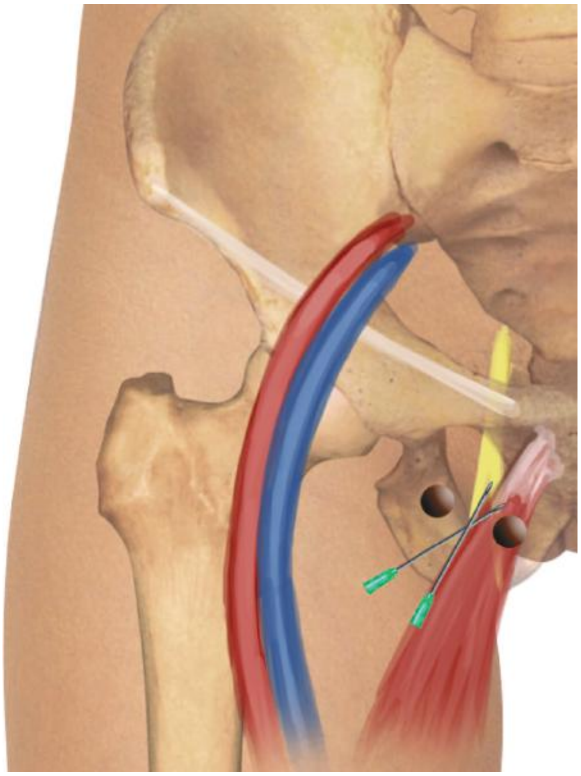

FIGURE 82B–11. Paravascular selective inguinal approach to oobturator nerve. Needle insertion and redirection.

Clinical Pearls

- The inguinal approach to the obturator nerve is easier to perform and more comfortable to the patient.
- The needle insertion site with this approach is away from intrapelvic contents, resulting in a lower risk of complications.
- Articular branches to the hip joint are not blocked with this approach.

Choice of Local Anesthetic

Ten milliliters of local anesthetic is adequate. The type and concentration of the local anesthetic depend on the indication for the block. For diagnostic–therapeutic blockades, highly concentrated neurolytic solutions are used to achieve long-lasting blocks. In the literature, combinations of phenol, ethanol, bupivacaine, levobupivacaine, and/or steroids are well reported.[3,9,23–26]

For lower limb surgeries, the recommended anesthetic technique consists of the administration of medium- to long-lasting local anesthetics that are associated with adequate postoperative analgesia, such as bupivacaine 0.25%–0.5%; ropivacaine 0.25%, and levobupivacaine 0.25%–0.5%. To avoid adductor muscle spasms during transurethral surgery, the use of medium- to long-acting local anesthetics is not required because the surgery does not last more than 2 hours. Therefore, mepivacaine 1%–2% or lidocaine 1%–2% should be adequate for this purpose.[17,57]

BLOCK EVALUATION

The onset of motor blockade is seen approximately 15 minutes after administration of 1% mepivacaine and 25 minutes after injection of 0.5% ropivacaine. Evaluation of an obturator block by sensory testing is unreliable due to the variability in its sensory distribution (see Figure 82B–10). In some cases, the obturator nerve may not contain any sensory branches that can be clinically tested for adequacy of the blockade. In addition, even when a sensory branch is present, there is considerable overlap of cutaneous innervation from the obturator, femoral, and sciatic nerves. It is often erroneously thought that the skin of the medial aspect of the thigh is innervated by the obturator nerve; in fact, sensory branches of the femoral nerve contribute sensory innervation to this region.

Clinical Pearls

- Evaluation of an obturator block by sensory testing can be challenging because of the variability in its sensory distribution.
- The most common sensory innervation of the obturator nerve is the skin in a small region located on the posteromedial aspect of the knee.

- A considerable overlap of cutaneous innervation exists among the obturator, femoral, and sciatic nerves.
- Reduction in adduction strength is the most reliable means of demonstrating successful obturator nerve blockade.

The area of skin most commonly regarded as having exclusive obturator nerve supply is a small region located on the posteromedial aspect of the knee. Also, the strength of the lower limb adductors relies 70% on the obturator nerve. Consequently, reduction in the strength of the adductors of the thigh is the most reliable sign of successful obturator nerve blockade (Figure 82B-10). Adductor muscle strength can be objectively evaluated by comparing the maximal pressure exerted by the patient squeezing a sphygmomanometer that has been preinflated to 40 mm Hg and placed between the legs before and after block performance. Failure to demonstrate a reduction in adductor muscle strength from baseline is synonymous with block failure.

PERIOPERATIVE MANAGEMENT

Patients must be warned that ambulation may be impaired because of the blockade of the thigh adductors.

COMPLICATIONS

There are no reports of complications associated with obturator nerve block. The lack of reported complications, however, is more likely due to the infrequent use of this block rather than to its inherent safety. Needle orientation for the classic pubic approach of Labat is toward the pelvic cavity. Therefore, if advanced too far in a cephalad direction, the needle can pass over the superior pubic ramus and penetrate the pelvic cavity, perforating the bladder, rectum, and spermatic cord. Accidental puncture of the obturator vessels could result in unintentional intravascular injection and hematoma formation. A retropubic anastamosis between the external iliac and obturator arteries (corona Mortis) is present in up to10% of patients: bleeding secondary to puncture of the corona Mortis can be difficult to control. Obturator neuropathy, secondary to needle trauma, intraneural injection, nerve ischemia, or local anesthetic toxicity are also possible, as with other peripheral nerve block techniques.

CHAPTER 82C

Femoral Nerve Block

Jerry D. Vloka, Admir Hadzic, and Philippe Gautier

INTRODUCTION

The femoral nerve block is one of the most clinically applicable nerve block techniques that it is relatively simple to perform, carries a low risk of complications, and results in a high success rate.

Indications

Single-Injection Technique

Femoral nerve block is well suited for surgery on the anterior aspect of the thigh and for superficial surgery on the medial aspect of the leg below the knee. Some examples include repair of the quadriceps tendon or quadriceps muscle biopsy, long saphenous vein stripping, and postoperative pain management after femur and knee surgery. A perineural catheter can be placed to provide prolonged analgesia for patients with fractures on the femoral neck or shaft. Femoral nerve block provides effective analgesia following total knee arthroplasty. Femoral nerve block can also be used to supplement a sciatic or popliteal block to provide complete anesthesia of the lower leg and ankle.[1–4]

Continuous Technique

The primary indication of continuous femoral nerve block is pain management after major femur or knee surgery.[5–21]

In addition, when compared with a single-dose technique or placebo, continuous femoral nerve block significantly reduces postoperative morphine consumption in patients having total hip replacement.[22,23]

Continuous femoral nerve block provides excellent analgesia in patients with femoral shaft or femoral neck fractures.[13,14,20,24] Its relative simplicity makes it uniquely suitable for use to provide analgesia in the emergency room and facilitate physical and radiologic examinations as well as manipulations of the fractured femur or hip.

After major knee surgery, continuous femoral nerve block provides better pain relief than parenteral administration of opioids (IV PCA, intramuscular)[6,11,15,16,19] or intra-articular analgesia.[17,25] For knee surgery, continuous femoral block is as effective as continuous lumbar plexus block[26] or continuous epidural analgesia,[11,19] but causes fewer complications.[27]

Contraindications

Relative contraindications for femoral nerve block include previous ilioinguinal surgery (femoral vascular graft, kidney transplantation), large inguinal lymph nodes or tumor, local infection, peritoneal infection, and preexisting femoral neuropathy.

Anatomy

The femoral nerve is the largest branch of the lumbar plexus. It is formed by the dorsal divisions of the anterior rami of the L2, L3, and L4 spinal nerves. It emerges from the lateral border of the psoas muscle, approximately at the junction of the middle and lower thirds of that muscle. Along its course to the thigh, it remains deep to the fascia iliaca. It enters the thigh posterior to the inguinal ligament, where it is positioned immediately lateral and slightly posterior to the femoral artery (Figure 82C–1). At this level, it is situated deep to both fascia lata and fascia iliaca (Figure 82C–2). As the nerve passes into the thigh, it divides into anterior and posterior branches (Figure 82C–3). Located above the fascia iliaca, the anterior branches innervate the sartorius and pectineus muscles (Figure 82C–4) and the skin of the anterior and medial aspects of the thigh.

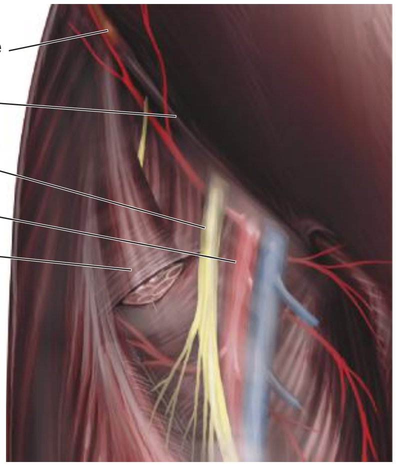

FIGURE 82C–1. Anatomic relationship in the femoral triangle.

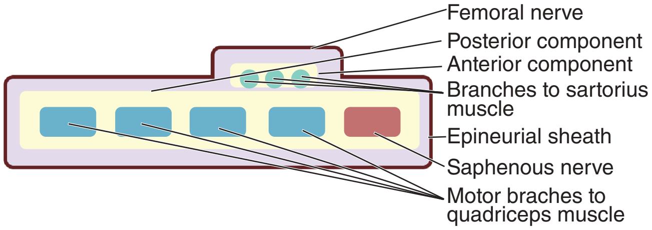

FIGURE 82C–3. Composition of the femoral nerve at the level of blockade.

Clinical Pearl

- In obese patients, the identification of the inguinal crease can be facilitated by asking an assistant to retract the lower abdomen laterally (see Figure 82C–7).

Equipment

A standard regional anesthesia tray is prepared with the following equipment:

- Sterile towels and gauze packs
- 20-mL syringe with local anesthetic
- Sterile gloves, marking pen
- One 25-gauge, 1.5-in. needle for skin infiltration
- A 5-cm long, short-bevel, insulated stimulating needle
- A peripheral nerve stimulator and a surface electrode
- Injection pressure monitor

BLOCK TECHNIQUE

Patient position. The patient lies in the supine position. The ipsilateral extremity is abducted 10–20 degrees and slightly externally rotated with the lateral side of the foot resting on the table.

Site of needle insertion. The site of needle insertion (Figure 82C–6) is located at the femoral crease but below the inguinal crease and immediately lateral (1 cm) to the pulse of the femoral artery.

Located under the fascia iliaca, the posterior branches innervate the quadriceps muscle and the knee joint and give off the saphenous nerve. The saphenous nerve supplies the skin of the medial aspect of the leg below the knee (Figure 82C–5).

Landmarks

The following landmarks are used to determine the site of needle insertion: inguinal ligament, inguinal crease, femoral artery (see Figure 82C–6).

Clinical Pearls

- It is useful to think of the mnemonic VAN (vein, artery, nerve) going from medial to lateral when recalling the relationship of the femoral nerve to vessels at the inguinal crease.

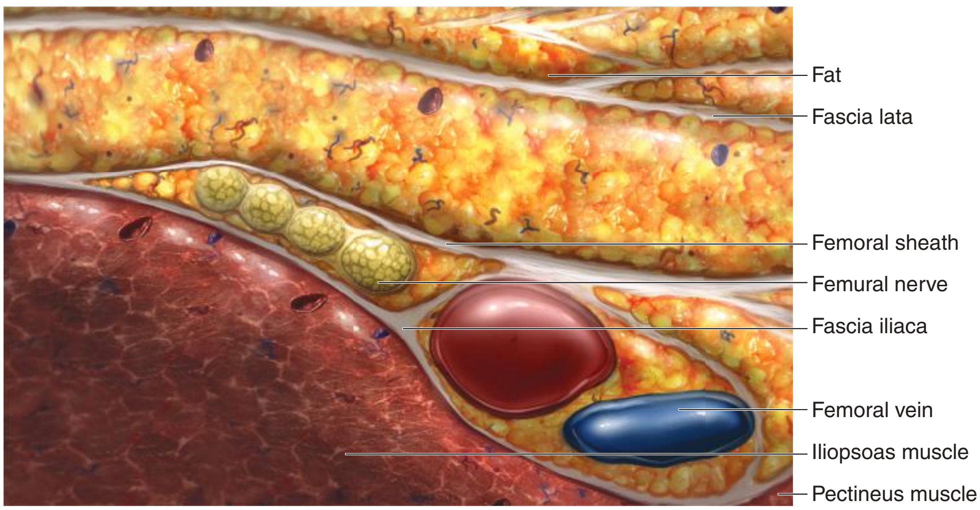

FIGURE 82C–2. Tissue sheaths and femoral nerve, artery and vein relationships.

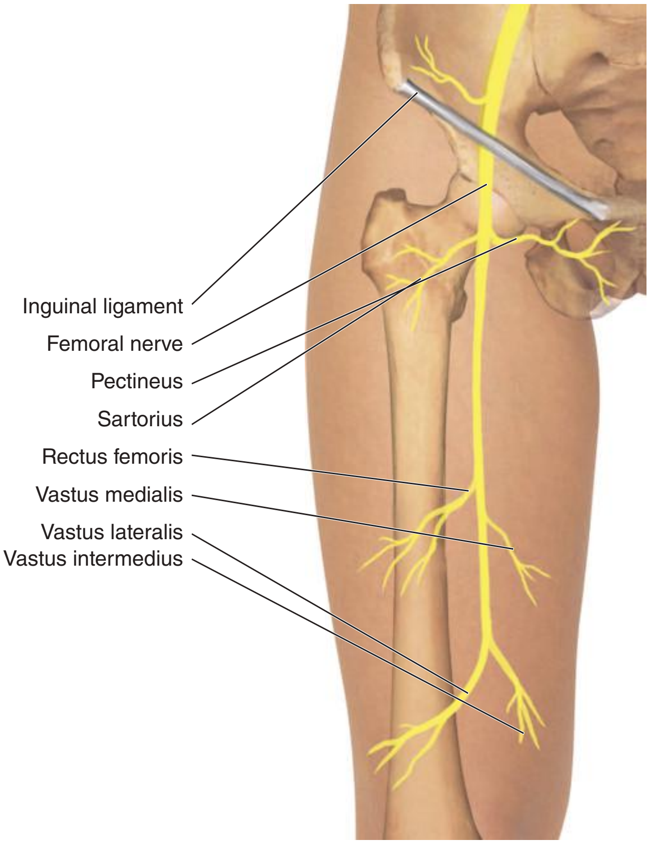

FIGURE 82C–4. Motor branches of the femoral nerve.

- The femoral nerve is approached at the femoral crease, rather than at the inguinal ligament.

Single-Injection Technique

In obese patients, the lower abdomen is retracted laterally to allow access to the inguinal area (Figure 82C–7). The needle is connected to a nerve stimulator set at a current intensity of 1 mA (0.1 msec/2 Hz) and introduced at a 30- to 45-degree angle to the skin in a cephalad direction (Figure 82C–8). The needle is advanced through the fascia lata and iliaca, often associated with a certain feeling of a "pop" as the needle pierces the fasciae.

As the quadriceps muscle contractions (i.e., patellar twitch) are obtained, the current is gradually decreased while the needle is advanced. The position of the needle is adequate when patellar twitches are elicited with current output between 0.3 and 0.5 mA. After negative aspiration; 15–20 mL of local anesthetic is injected. Some common responses to nerve stimulation and appropriate action to troubleshoot are featured in Table 82C–1.

Multiple injection techniques have also been described, where vastus lateralis, intermedius, and medialis twitches are individually identified and separate injections of local anesthetic made at each nerve branch.[30,31] When compared with a single injection, the total volume of local anesthetic required and the block onset time were significantly reduced. However, 14% of patients reported paresthesia, and 28% reported discomfort during block performance.[32] Consequently, this technique has been largely abandoned as being unnecessary.

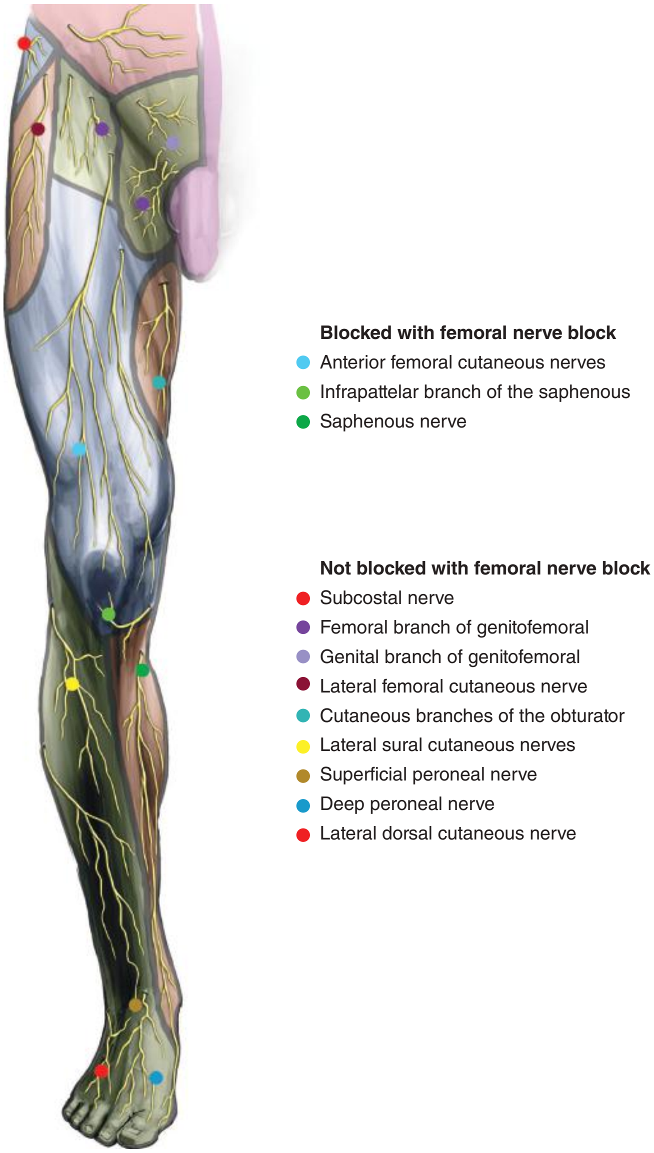

FIGURE 82C–5. Sensory innervation of the femoral nerve and distribution of anesthesia with femoral nerve block.

Clinical Pearls

- The needle tip must be positioned below fascia iliaca to obtain a complete femoral nerve block.
- Larger volume than 15-20 mL is not necessary because it is not associated with a better success rate.[33]

Continuous Femoral Nerve Block

The continuous technique is similar to the single-injection technique. After passage through both fascia lata and iliaca, the needle is advanced to elicit a patellar twitch using a current output between 0.3 and 0.5 mA (0.1 msec) (Figure 82C–9).

FIGURE 82C–6. Anatomic landmarks for femoral nerve block. The needle insertion site (*X*) is located just below the inguinal crease, 1–2 cm lateral to the pulse of the femoral artery.

The catheter is then inserted 5 cm beyond the tip of the needle and secured in place. After a negative aspiration test for blood, a bolus dose of 10 mL of local anesthetic is injected and followed by a continuous infusion of dilute local anesthetic and/or intermittent boluses of 5 ml hourly. (Figure 82C–10).

- Catheter insertion under the fascia iliaca should be without resistance. When this is not the case, the needle is probably not under the fascia iliaca. The needle should be withdrawn to the skin and reinserted.

Block Assessment

Sensory blockade is assessed by cold or pin prick test on the anterior and medial aspect of the thigh (femoral nerve) and on the medial aspect of the lower leg (saphenous nerve). Motor blockade is evaluated by asking the patient to extend the knee (e.g., to elevate the foot from the table).

CHOICE OF LOCAL ANESTHETIC

Single-Injection Technique

For surgical anesthesia, mepivacaine or lidocaine 1.5–2.0% or ropivacaine 0.5%–0.75% are frequently used, depending on the expected duration of surgery. For postoperative analgesia alone, a more dilute concentration of long acting local anesthetic (eg ropivacaine or bupivacaine 0.2%–0.25%) is appropriate. Onset times and mean duration of both anesthesia and analgesia with different types and concentrations of local anesthetic solution are presented in Table 82C–2.

Continuous Technique

The initial bolus of 10–15 mL is followed by an infusion of dilute concentration (e.g., ropivacaine 0.2%). A typical infusion regimen is 5 mL/h basal infusion with a 5 mL/q60min patient-controlled bolus.

FIGURE 82C–7. The abdomen is retracted laterally to facilitate exposure of the anatomy during femoral nerve blockade.

FIGURE 82C–8. The needle is connected to a nerve stimulator set at 1 mA current intensity and introduced at a 30- to 45-degree angle to the skin in a cephalad direction.

TABLE 82C–1. Common responses to nerve stimulation and action to obtain femoral nerve twitch.

Response Obtained	Interpretation	Problem	Action
No response	The needle is inserted either too medially or to laterally	Femoral artery not properly localized	Follow the systematic lateral angulation and reinsertion of the needle as described in the technique
Bone contact	The needle contacts hip or superior ramus of the pubic bone	The needle is inserted too deep	Withdraw to the level of the skin and reinsert in another direction
Local twitch	Direct stimulation of the illiopsoas or pectineus muscle	Too deep insertion	Withdraw to the level of the skin and re-insert in another direction
Twitch of the sartorius muscle	Sartorius muscle twitch	The needle tip is slightly anterior and medial to the main trunk of the femoral nerve	Redirect the needle laterally and advance deeper 1–3 mm
Vascular puncture	Needle placement into the femoral or femoral circumflex artery, less commonly - femoral vein	Too medial needle placement	Withdraw and reinsert laterally 1 cm
Patella twitch	Stimulation of the main trunk of the femoral nerve	None	Accept and inject local anesthetic

PERIOPERATIVE MANAGEMENT OF FEMORAL NERVE BLOCKS

The performance of femoral nerve block is associated with minor patient discomfort because the needle passes only through the skin and adipose of the inguinal region. Femoral nerve block is associated with weakness of the quadriceps muscle, leading to the decrease in its use in some practices, particularly where ultrasound is available for adductor canal blocks. This is because knee extension and weight bearing on the blocked side are impaired with femoral nerve block, which must be clearly explained to the patient to reduce the risk of falls. The use of a knee immobilizer for ambulation following femoral nerve block has been shown to reduce the risk of falls, particularly following total knee arthroplasty.[34,35]

Complications and How to Avoid Them

Complications of femoral nerve block include[13] vascular puncture,[33] femoral nerve compression by a hematoma,[36] diffusion of

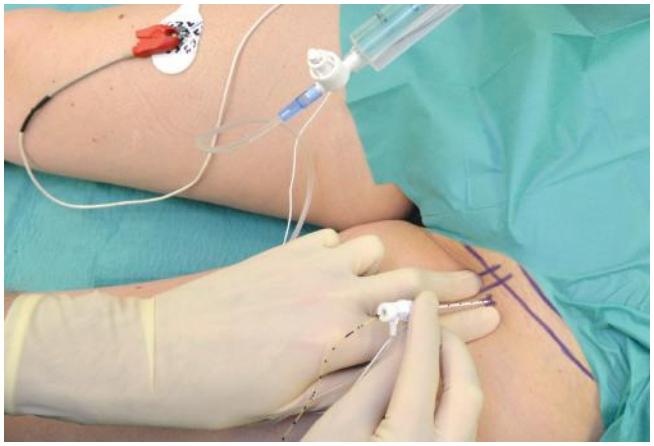

FIGURE 82C–9. Continuous femoral nerve block: Needle insertion.

TABLE 82C–2. Onset and duration of 20 ml of local anesthetic in femoral block.

	Onset (min)	Anesthesia (h)	Analgesia (h)
3% 2-Chloroprocaine	10–15	1	2
3% 2-Chloroprocaine (+ HCO_3 + epi)	10–15	1.5–2	2–3
1.5% Mepivacaine	15–20	2–3	3–5
1.5% Mepivacaine (+ HCO_3 + epi)	15–20	2–5	3–8
2% Lidocaine	10–20	2–5	3–8
0.5% Ropivacaine	15–30	4–8	5–12
0.75% Ropivacaine	10–15	5–10	6–24
0.5 Bupivacaine	15–30	5–15	8–30

TABLE 82C–3. Femoral nerve block: complications.

Hematoma	• When the femoral artery or vein is punctured, the procedure should be stopped and pressure applied over the puncture site for 2–3 min.
Vascular puncture	• Maintain a palpating finger on the femoral pulse and insert the needle just lateral and parallel to the pulse. • The needle should never be directed medially.
Nerve injury	• Use a nerve stimulator avoid injection when motor response is present at <0.3 mA (0.1 msec). • Do not seek paresthesia as method of localization of FN because paresthesia is rarely elicited with femoral nerve block and should not be sought or relied on to indicate an intraneural injection. However, should severe pain on injection be reported, abort the injection. • Do not inject when high pressures on injection are encountered. • Use the minimal efficient volume and concentration of local anesthetic (15-20 mL).
Catheter infection	• Use strict aseptic technique during catheter insertion. • Sterile drapes should be used with continuous techniques. • Remove the catheter after 48–72 h (risk of infection increases with time).
Prevention of Falls	• Instruct patient on the inability to bear weight on the blocked extremity.

the local anesthetic solution into the epidural space with resultant epidural block,[37] catheter shearing,[38] and femoral nerve injury (incidence of 0.25%).[12,39,40] With regard to continuous catheters, bacterial contamination of the catheters commonly occurs after 48 hours.[32,39,40] However, local or systemic infection remains rare, with the estimated risk of 0.13%[41], Table 82C-3.

SUMMARY

Femoral nerve block is easy to perform and associated with a low risk of complications. It is suitable for catheter insertion. When used alone, it is effective for surgery on the anterior thigh and for postoperative pain management after femur and knee surgery. When combined with sciatic and/or obturator nerve blocks, anesthesia of almost the entire lower limb from the midthigh level can be achieved.

CHAPTER 82D

Sciatic Nerve Block

Elizabeth Gartner, Elisabeth Fouché, Olivier Choquet, Admir Hadzic, and Jerry D. Vloka

INTRODUCTION

Victor Pauchet, a French surgeon, first described the sciatic nerve block in *L'Anesthesie Regionale* in 1920: "the site of needle insertion for blocking the sciatic nerve at the level of hip: 3 cm along the perpendicular that bisects a line drawn between the greater trochanter and the posterior superior iliac spine."[1] This technique has since been referred to as "The classic approach of Labat," possibly because it was first described in the English language literature in 1923 by Gaston Labat, a student of Pauchet, in his book *Regional Anesthesia: Its Technic and Clinical Application*.[2] Labat's book went through several reprints of the first edition of one of the first English-language textbooks of regional anesthesia. Curiously, this book was very similar to *L'Anesthesie Regionale*.[3] In the same year, Labat founded the American Society of Regional Anesthesia (ASRA). Anecdotally, Labat intended to name the new group "The Labat Society" in his own honor, but the name ASRA remains today as we know it.

Alon Winnie eventually modified the Labat approach in 1975.[4] Alternatives, such as the anterior approach described by George Beck in 1963 and the lithotomy approach described by Prithvi Raj in 1975, were devised to allow the sciatic nerve to be blocked in the supine patient.[5,6] A number of other approaches have been proposed, most of which include minor modifications. The most useful of these newer techniques are likely the subgluteal and parasacral approach introduced by Pia di Benedetto and Philippe Cuvillon, respectively.[7,8] In this chapter, we focus on the classic approach to sciatic nerve block, parasacral and subgluteal modifications, and the anterior approach.

Indications and Contraindications

Indications for sciatic nerve block include lower-limb surgery, combined with a femoral or psoas compartment block.[9] For distal surgery of the lower extremity, however, more distal approaches such as ankle block or popliteal sciatic nerve block are preferable whenever feasible. Note that the sciatic nerve block often needs to be combined with additional blocks, such as lumbar plexus (femoral or saphenous nerve) when anesthesia of the entire lower extremity is desired.

Contraindications to sciatic nerve block may include include local infection and bed sores at the site of insertion, coagulopathy, preexisting central or peripheral nervous systems disorders, and allergy to local anesthesia.

Functional Anatomy

The union of the lumbosacral trunk with the first three sacral nerves forms the sacral plexus (Figure 82D–1). The lumbosacral trunk originates from the anastomosis of the last two lumbar nerves with the anterior branch of the first sacral nerve. This structure receives the anterior branches of the second and third sacral nerves, forming the sacral plexus. The sacral plexus is shaped like a triangle pointing toward the sciatic notch, with its base spanning across the anterior sacral foramina. It rests on the anterior aspect of the piriformis muscle and is covered by the pelvic fascia, which separates it from the hypogastric vessels and pelvic organs. Seven nerves stem from the sacral plexus: six collateral branches and one terminal branch—the sciatic nerve, the largest nerve of the plexus (Figure 82D–2).

The sciatic nerve is the largest peripheral nerve in the body and measures more than 1 cm in width at its origin. It exits the pelvis through the greater sciatic notch below the piriformis muscle, then descends between the greater trochanter of the femur and the ischial tuberosity. The nerve then runs along the posterior thigh to the lower third of the femur, where it diverges into two large branches, the tibial and common peroneal nerves. This division may occur at any level proximal to the lower third of the femur.[10,11] The common peroneal and tibial nerves are separated from their onset at the sacral plexus (15%); in this case, the common peroneal nerve typically pierces the piriformis muscle. The course of the sciatic nerve can be

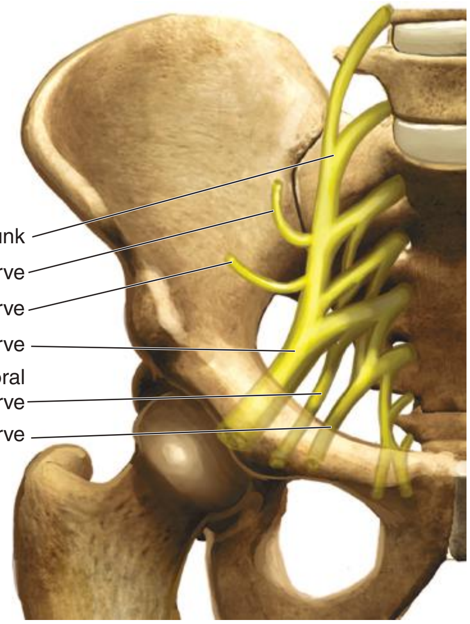

FIGURE 82D–1. Formation of the sacral plexus.

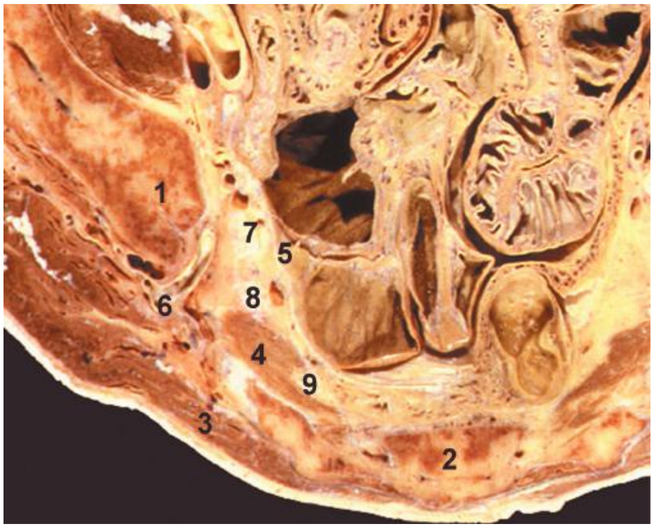

FIGURE 82D–3. Parasacral area. Transversal section at the S3 level. *1*, Iliac bone; *2*, sacrum; *3*, gluteal muscle; *4*, piriformis muscle; *5*, pelvic aponeurosis; *6*, inferior gluteal plexus; *7*, lumbosacral trunk; *8*, first sacral root; *9*, second sacral root.

estimated by drawing a line on the back of the thigh beginning from the apex of the popliteal fossa to the midpoint of the line joining the ischial tuberosity to the apex of the greater trochanter. From its onset, the sciatic nerve also gives off numerous articular (hip, knee) and muscular branches.

In the upper part of its course, the sciatic nerve lies deep in the gluteus maximus muscle and rests on the posterior surface of the ischium (Figures 82D–3 and 82D–4). The sciatic

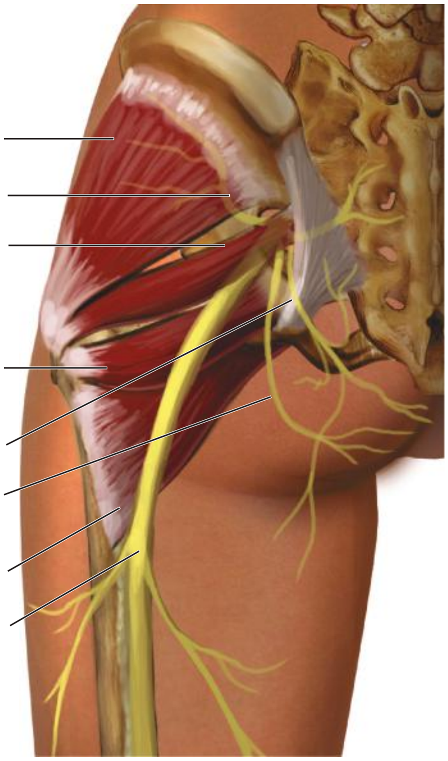

FIGURE 82D–2. Course of the sciatic nerve at the exit from the pelvis.

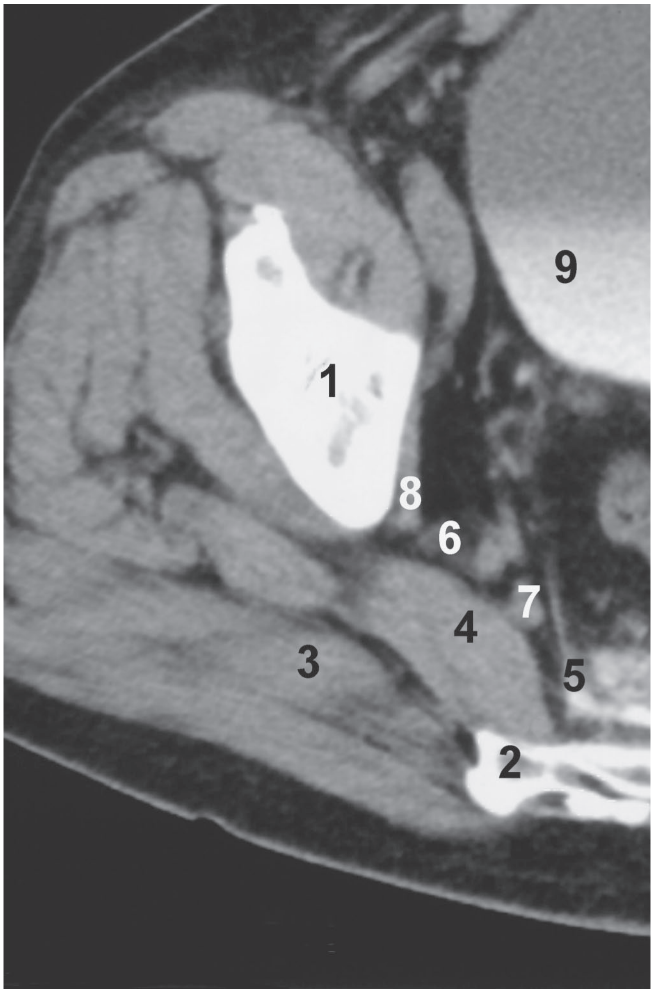

FIGURE 82D–4. Computed tomographic (CT) scan of the parasacral area, at the S3 level. *1*, Iliac bone; *2*, sacrum; *3*, gluteal muscle; *4*, piriformis muscle; *5*, pelvic aponeurosis; *6*, inferior gluteal plexus; *7*, lumbosacral trunk; *8*, first sacral root; *9*, bladder.

nerve crosses the external rotators, obturator internus, and gemelli muscles, then passes on to the quadratus femoris. The quadratus femoris separates the sciatic nerve from the obturator externus and the hip joint. Medially, the posterior cutaneous nerve of the thigh and the inferior gluteal plexus accompany the sciatic nerve, whereas more distally the sciatic nerve lies on the adductor magnus. The long head of the biceps femoris crosses the sciatic nerve obliquely. The articular branches of the sciatic nerve arise from the upper part of the nerve and supply the hip joint by perforating the posterior part of its capsule. However, the articular branches are sometimes derived directly from the sacral plexus. The muscular branches of the sciatic nerve innervate the gluteus, the biceps femoris, the ischial head of the adductor magnus, the semitendinosus, and the semimembranosus muscles (Figure 82D–5; Table 82D–1). The branches for the ischial head of the adductor magnus and semimembranosus muscles arise from a common trunk. The nerve to the short head of the biceps femoris comes from the common peroneal division, whereas the other muscular branches arise from the tibial division of the sciatic nerve.

The parasacral area is delineated by the ventral aponeurosis of the piriformis muscle dorsally, by the pelvic aponeurosis medially, and by the aponeurosis of the obturator internis muscle laterally.[8] The common peroneal component passes through the piriformis muscle or above it, and only the tibial component passes below the muscle.

The tibial and common peroneal elements of the sciatic nerve each have their own outer layer of epineurium. Both components are further enclosed by a dense layer of connective tissue, which runs from the origin of the sciatic nerve to its bifurcation. This layer has been given several names over the years, but lately it is commonly referred to as the "paraneural sheath" of the sciatic nerve. Injection of local anesthetic deep to this sheath (but outside the epineurium of the tibial or common peroneal nerves) has been shown to spread a considerable distance proximally and distally, and result in a rapid onset, dense block. This is not considered an "intraneural" injection as the injection occurs outside of the epineurium.[12–14]

TABLE 82D–1. Branches, source, and motor innervation of the sacral plexus.

Nerve	Source	Muscular Innervation
Nerve to obturator internus muscle	Lumbosacral trunk and S1	Obturator internus
Superior gluteal nerve	Lumbosacral trunk and S1	Gluteus medius
		Gluteus minimus
		Tensor fasciae lata
Nerve to piriformis muscle	S2	Piriformis
Nerve to biceps femoris superior	Anterior portion of plexus	Biceps femoris superior
Nerve to biceps femoris inferior and quadratus femoris	Anterior portion of plexus	Biceps femoris inferior
		Quadratus femoris
		Branch to coxofemoral articulation
Posterior femoral cutaneous nerve (lesser sciatic nerve)	Lumbosacral trunk, S1, S2	Inferior gluteal n. to gluteus maximus muscle
		Sensory branch to buttock, thigh, popliteal fossa, and lateral aspect of knee

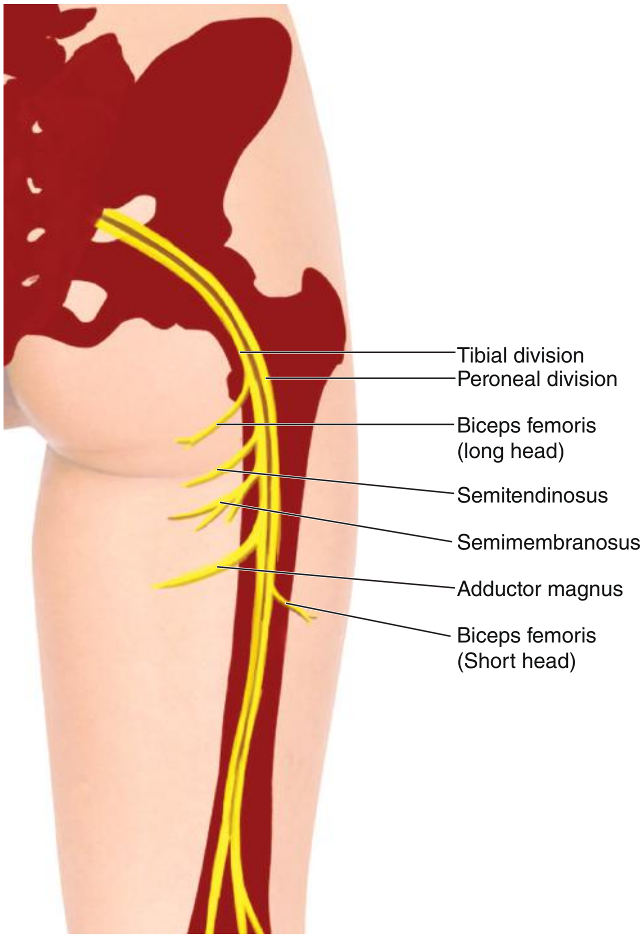

FIGURE 82D–5. Sciatic nerve. Downward course and motor branches to the hamstrings muscles.

TABLE 82D–2. Local anesthetic choices for sciatic nerve block: duration of anesthesia and analgesia.

	Onset (min)	Anesthesia (h)	Analgesia (h)
3% 2-Chloroprocaine	10–15	2	2.5
1.5% Mepivacaine	10–15	4–5	5–8
2% Lidocaine	10–20	5–6	5–8
0.5% Ropivacaine	15–20	6–12	6–24
0.75% Ropivacaine	10–15	8–12	8–24
0.5% Bupivacaine	15–30	8–16	10–48

Choice of Local Anesthetic

Despite its large size, sciatic block requires a relatively low volume of local anesthetic to achieve anesthesia of the entire trunk of the nerve.[15] Generally, 20–25 mL of local anesthetic is sufficient. The choice of the type and concentration of local anesthetic should be based on whether the block is planned for surgical anesthesia or pain management[16] (Table 82D–2). When seeking prolonged pain relief, longer-acting local anesthetic may be more appropriate.[17,18] Addition of epinephrine may be justified in patients undergoing above the knee amputation, in whom prolonged analgesia is desired.

Equipment

As with all regional anesthesia techniques, the heart rate, blood pressure, and pulse oximetry are routinely monitored before performing the block. Resuscitation equipment and emergency medications must be immediately available and ready to use. Supplemental oxygen via face mask is routinely used before giving sedation. A standard regional anesthesia tray is prepared with the following equipment:

- Sterile towels and 4-in. × 4-in. gauze packs
- 20-mL syringe with local anesthetic
- Sterile gloves, marking pen, and surface electrode
- One 1.5 -in., 25-gauge needle for skin infiltration
- A 10-cm long, short-bevel, insulated stimulating needle (15 cm for anterior approach)
- Peripheral nerve stimulator
- Injection pressure monitor

Interpreting Responses to Nerve Stimulation

Twitches of the hamstrings, calf, foot, or toes at 0.3–0.5 mA current all can be used as signs of successful localization of the sciatic plexus (nerve). Table 82D–3 presents common responses to nerve stimulation and the course of action to take to obtain the proper response.[19]

BLOCK DYNAMICS AND PERIOPERATIVE MANAGEMENT

Sciatic nerve block may cause patient discomfort because the needle passes through the gluteus muscles. Adequate sedation and analgesia are important to ensure patient comfort. Midazolam 2–4 mg can be given for patient positioning, and

TABLE 82D–3. Common responses to nerve stimulation and action to take.

Response Obtained	Interpretation	Problem	Action
Local twitch of the gluteus muscle	Direct stimulation of the gluteus muscle	Too shallow (superficial) placement of the needle	Continue advancing the needle
Needle contacts bone but local twitch of the gluteus muscle not elicited	Needle inserted close to the caudal aspect of the iliac bone or the lateral aspect of the sacrum	Too superior or too medial needle insertion	Slightly laterally and caudally redirect the needle
Needle encounters bone and sciatic twitches elicited	Needle missed the plane of the sciatic nerve and is stopped by the hip joint or ischial bone	Needle inserted too laterally (hip joint) or medially (ischial bone)	Withdraw the needle and redirect slightly medially or laterally (5–10 degrees)
Hamstring twitch	Stimulation of the main trunk of the sciatic nerve	None. These branches are within the sciatic nerve sheath at this level	Accept and inject local anesthetic
The needle placed deep (10 cm) but no twitches elicited and no bone contact	Needle has passed through the sciatic notch	Too inferior needle placement	Withdraw and redirect the needle slightly laterally, or cephalad
Paresthesia of the genital organs	Needle is stimulating the inferior roots of the sacral plexus (pudendal nerve)	Too inferior and too medial needle placement	Withdraw and redirect the needle slightly cephalad and laterally

alfentanil 500–750 mcg is given just before needle insertion. A typical onset time for this block is 10–25 minutes, depending on the type, concentration, and volume of local anesthetic used. The first signs of block onset are usually reported by the patient as a feeling that the foot is "different" or that they cannot wiggle their toes.

Clinical Pearl

- Inadequate skin anesthesia despite an apparent timely onset of the blockade can occur. Local infiltration at the site of the incision by the surgeon is often all that is needed to allow the surgery to proceed.

POSTERIOR APPROACHES TO SCIATIC NERVE BLOCK

General Considerations

The posterior approach to sciatic block has wide clinical applicability for surgery and pain management of the lower extremity. The block require expertise with more basic nerve blocks for successful and safe practice.[20,21] It is particularly well suited for surgery on the knee, calf, Achilles tendon, ankle, and foot. It provides complete anesthesia of the leg below the knee with the exception of the medial strip of skin, which is innervated by the saphenous nerve (Figure 82D–6). When combined with a femoral nerve or lumbar plexus block, anesthesia of almost the entire leg can be achieved.

FIGURE 82D–6. Sciatic nerve. Cutaneous innervation.

Distribution of Anesthesia

Sciatic nerve block results in anesthesia of the skin of the posterior aspect of the thigh, hamstrings, and biceps muscles, part of the hip and knee joints, and the entire leg below the knee, with the exception of the skin of the medial aspect of the lower leg (see Figure 82D–6). Depending on the level of surgery, the addition of a saphenous or femoral nerve block may be required.

Classic Posterior Approach

Anatomic Landmarks

Landmarks for the posterior approach to sciatic blockade are easily identified in most patients (Figure 82D–7A, B). Proper palpation technique is of utmost importance because the adipose tissue over the gluteal area may obscure these bony prominences. The landmarks are outlined by a marking pen:

1. Greater trochanter
2. Posterior superior iliac spine
3. Needle insertion site 4 cm distal to the midpoint between the two landmarks

Technique

The patient is in the lateral decubitus position with a slight forward tilt–this prevents the "sag" of the soft tissues in the gluteal area and significantly facilitates block placement. The foot on the side to be blocked should be positioned over the dependent leg so that twitches of the foot or toes can be easily noted. After cleaning with an antiseptic solution, local anesthetic is infiltrated subcutaneously at the determined needle insertion site.

Clinical Pearl

- Raise the height of the bed enough and assume an ergonomic position to allow a comfortable and stable position for the patient during block placement and for observation of the motor responses to nerve stimulation.

The fingers of the palpating hand should be firmly pressed on the gluteus muscle to decrease the skin–nerve distance (Figure 82D–8). The palpating hand should not be moved during block placement; even small movements of the palpating hand can substantially change the position of the needle insertion site because the skin and soft tissues in the gluteal region are highly mobile. The needle is introduced at an angle perpendicular to the spherical skin plane (Figure 82D–8A and B). The nerve stimulator should be initially set to deliver 1.0–1.5 mA current (2 Hz, 100 μsec) to allow detection of twitches of the gluteal muscles and stimulation of the sciatic nerve.

As the needle is advanced, the first twitches observed are from the gluteal muscles. These twitches merely indicate that the needle position is still too shallow. The goal is to achieve

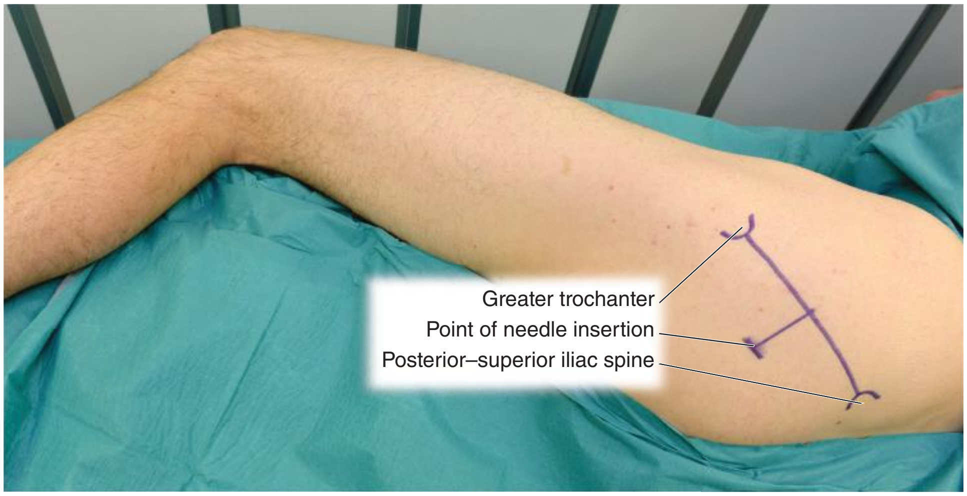

FIGURE 82D–7. Sciatic nerve block, posterior approach.

visible or palpable twitches of the hamstrings, calf muscles, foot, or toes at 0.3–0.5 mA current. Twitches of the hamstrings are equally acceptable because this approach blocks the nerve proximal to the separation of the neuronal branches to the hamstrings muscle. Once the gluteal twitches disappear, brisk response of the sciatic nerve to stimulation is observed (hamstrings, calf, foot, or toe twitches). After the initial stimulation of the sciatic nerve is obtained, the stimulating current is gradually decreased until twitches are still seen or felt at 0.3–0.5 mA current. This typically occurs at a depth of 5–8 cm.

After negative aspiration for blood, 15–25 mL of local anesthetic is injected (Figure 82D–9). Any resistance to the injection of local anesthetic should prompt needle withdrawal by 1 mm. The injection is then reattempted. Persistent resistance to injections should prompt complete needle withdrawal and ensuring needle patency before reintroduction.

Clinical Pearls

- Since the level of the blockade with this approach is above the departure of the branches for hamstring muscles, twitch of any of the hamstring muscles can be accepted as a reliable sign of localization of the sciatic nerve without deliberately seeking foot response.
- When the first needle pass does not result in nerve localization, do not regard it as a failure. Instead, use a systematic approach to troubleshooting:
- Ascertain the nerve stimulator is functional, properly connected, and set to deliver the desired current.
- Mentally visualize the plane of the initial needle insertion, and redirect the needle in a slightly caudal direction (5–10 degrees) to the initial insertion plane.
- If the above maneuver fails, withdraw the needle to the skin and redirect it slightly cephalad (5–10 degrees) to the initial insertion plane.
- Failure to obtain hamstrings or foot response to nerve stimulation should prompt a reassessment of the landmarks and patient position.

Continuous Block

The continuous sciatic nerve block is an advanced regional anesthesia technique, and experience with the single-shot technique is recommended to ensure its efficacy and safety. Continuous sciatic nerve block was described by Gross in 1956.[22] The current technique used is similar to the single-shot injection; however, slight angulation of the needle in the caudal direction is necessary to facilitate threading of the catheter. Securing and maintenance of the catheter are easy and convenient. This technique can be used for surgery and postoperative pain management in patients undergoing a wide variety of lower leg, foot, and ankle surgeries. Perhaps the single most important indication for use of this block is for amputation of the lower extremity.

Technique

Patient positioning, marking of landmarks, skin preparation and local anesthetic infiltration are performed as described above. An 8–10 cm long, insulated stimulating needle (preferably Tuohy-style tip) is inserted in the same manner as for the single-injection technique. The opening of the needle should face distally (pointing toward the patient's foot) to facilitate catheter insertion.

Clinical Pearls

- When insertion of the catheter proves difficult, lowering the angle of the needle can be helpful.
- It is useful to inject some local anesthetic intramuscularly to prevent pain on advancement of larger gauge and blunt-tipped needles typically used for this block.

After obtaining the motor response at a current of 0.3–0.5 mA, a 20-mL bolus of local anesthetic is injected. This is followed by insertion of the catheter 5 cm beyond the needle tip (Figure 82D–10). The catheter is then aspirated to check for inadvertent intravascular placement.

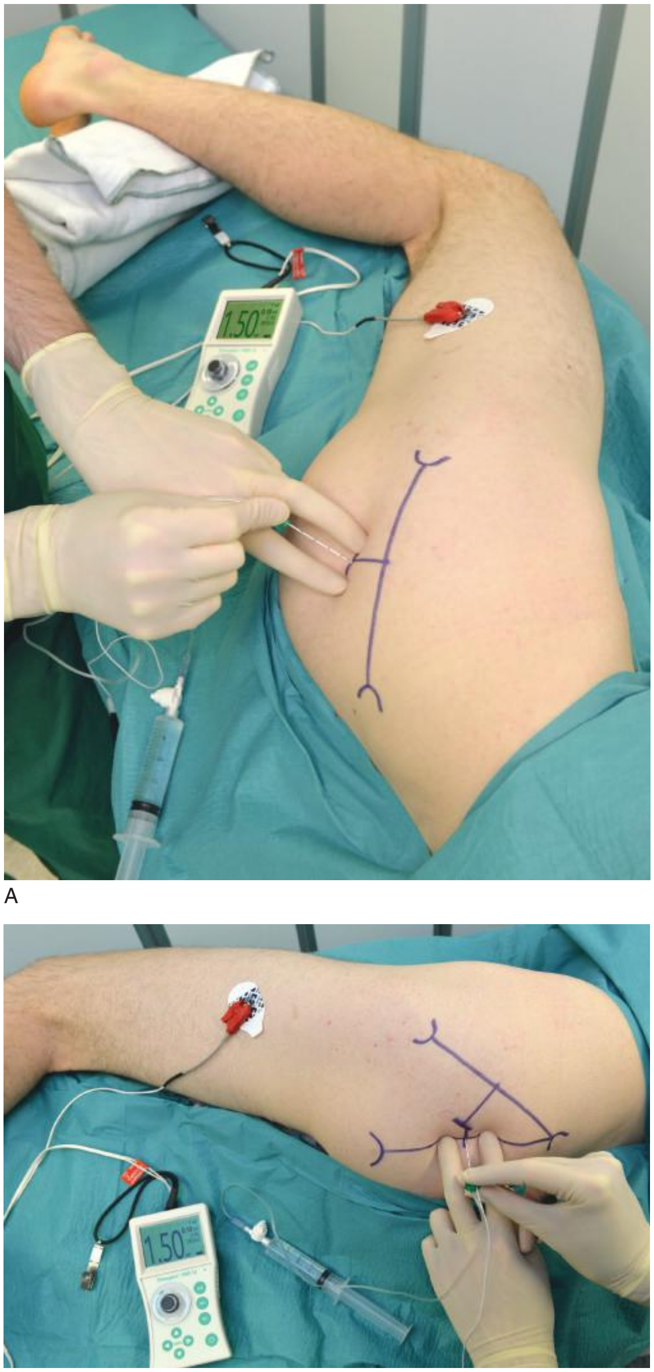

FIGURE 82D–8. A and B. Sciatic nerve block, posterior approach. Needle insertion is in the perpendicular plane; the palpating hand is firmly pressed to decrease the skin–nerve distance and stabilize the anatomy.

A number of techniques to secure the catheter to the skin have been proposed. A benzoin skin preparation followed by application of a clear dressing and a cloth tape is one such simple and efficacious method. The infusion port should be clearly marked as "continuous sciatic block."

Continuous Infusion

Continuous infusion is always initiated after an initial bolus of dilute local anesthetic through the catheter. Ropivacaine 0.2%

FIGURE 82D–9. Sciatic nerve block, posterior approach. Dispersion of the local anesthetic after injection.

is commonly used for this purpose (15–20 mL). Diluted solutions of bupivacaine or L-bupivacaine are also suitable, but can result in undesirably greater motor blockade. The infusion is initiated at 10 mL/h or 5 mL/h when a patient-controlled analgesia (PCA) dose is planned (5 mL).[23,24]

Parasacral Approach

Described by Mansour in 1993, the parasacral sciatic nerve block is well suited for continuous infusion of local anesthetic.[9,25–30] In addition, this block has characteristics of a

FIGURE 82D–10. Continuous sciatic nerve block, posterior approach. Shown is the course of the catheter (*1*) and the fusiform-shaped contrast area indicating the spread of the local anesthetic in the sheath of the sciatic nerve (*2*). In this example, a mere 2 mL of the local anesthetic is injected.

plexus block and yields anesthesia of the entire sacral plexus, and obturator nerve.[26,2731] Ripart[25] reported a 94% success rate in his series of 400 parasacral sciatic nerve block cases.

The parasacral approach to sciatic blockade has a wide clinical applicability for surgery and pain management of the lower extremity, particularly when combined with a femoral or psoas compartment block.[26,31] This technique is associated with a high success rate and is particularly well suited for surgery on the popliteal fossa and the knee.[32]

Distribution of Anesthesia

Parasacral sciatic nerve blockade results in anesthesia of the skin of the posterior thigh, hamstrings, and biceps femoris muscles; part of the hip and knee joint; and the entire leg below the knee except the medial cutaneous skin of the lower leg (see Figure 82D–6). Morris[26] demonstrated extension of anesthesia to the obturator nerve after sciatic nerve block, as tested by the presence of adductor muscle weakness on a numeric scale. Jochum however,[32] suggested that the obturator nerve is sporadically affected by the parasacral sciatic nerve block.

Anatomic Landmarks

Landmarks for the parasacral approach to sciatic blockade are easily identified in most patients (Figure 82D–11). Careful palpation technique is important because the adipose tissue over the gluteal area may obscure these bony prominences (Figures 82D–12 and 82D–13). The following landmarks are outlined by a marking pen:

- Posterior–superior iliac spine (PSIS)
- Ischial tuberosity (IT)
- A line between the PSIS and the IT is drawn. The needle insertion point lies 6 cm caudad to the PSIS on this line. The insulated needle is inserted at this point and advanced in a sagittal plane.

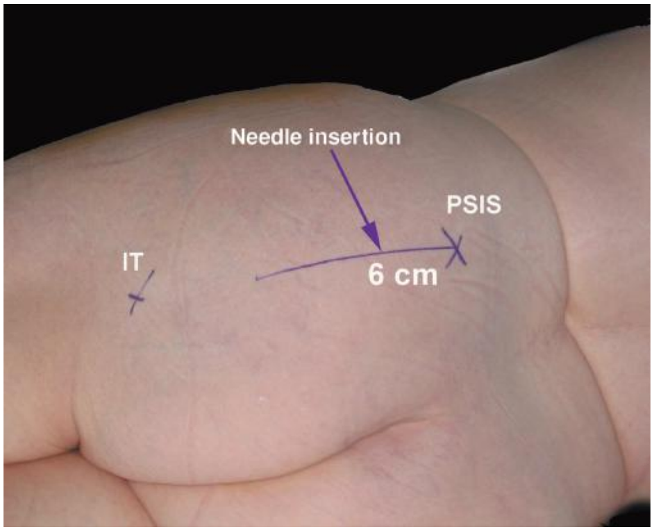

FIGURE 82D–11. Parasacral approach to sciatic nerve block. Shown are the posterior superior iliac spine (PSIS) and the ischial tuberosity (IT). The needle insertion site is marked as 6 cm caudad to the PSIS on the line connecting PSIS with IT.

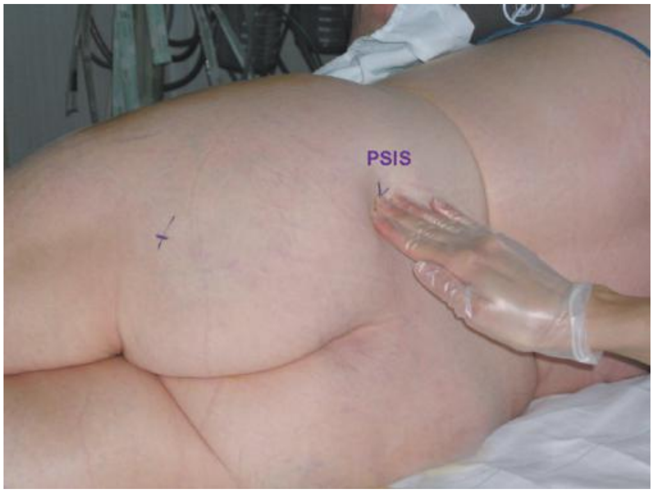

FIGURE 82D–12. Parasacral sciatic nerve block. Palpation technique to identify posterior superior iliac spine (PSIS).

Technique

The patient is positioned in a lateral decubitus position, similar to the position required for the classic posterior approach to sciatic block (Figure 82D–13). The dependent limb is kept straight while the limb to be blocked is flexed at both the hip and knee. Appropriate sedation and analgesia are mandatory to ensure the patient's comfort throughout the procedure. After cleaning with an antiseptic solution, local anesthetic is infiltrated subcutaneously at the determined needle insertion site.

- Contact with the bone usually indicates the needle contact with the wings of the sacrum or the iliac bone, superior to and near the greater sciatic notch.
- In this case, the needle is withdrawn and redirected slightly caudally and laterally.
- Contact with the bone can be used as a depth test. The needle depth is noted; the needle should not be advanced

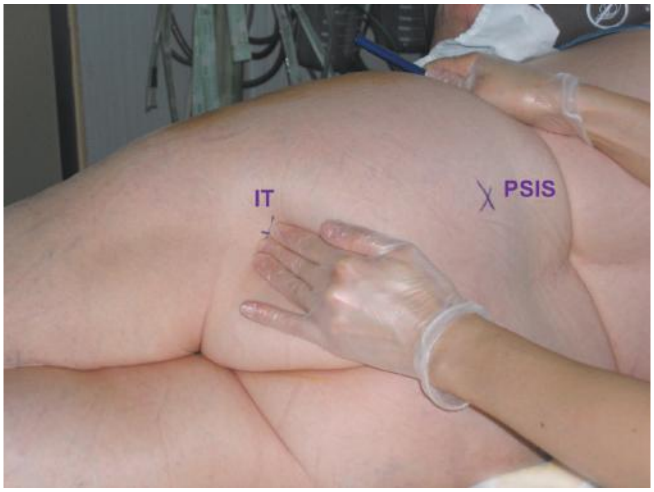

FIGURE 82D–13. Parasacral sciatic nerve block. Proper palpation technique to identify the ischial tuberosity. (IT, ischial tuberosity; PSIS, posterior superior iliac spine.)

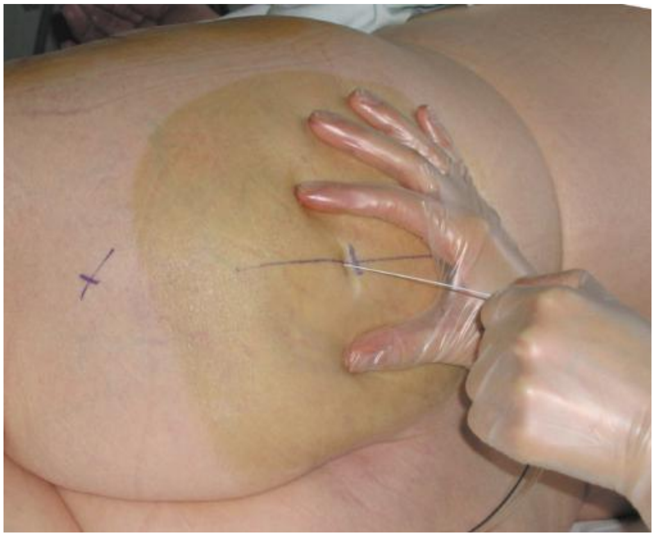

FIGURE 82D–14. Parasacral sciatic nerve block. Needle insertion is perpendicular to the horizontal plane.

more than 2 cm beyond this depth. At this site, the sciatic nerve is approached at the top of the greater sciatic foramen while leaving the pelvis. Advancing the needle deeper may expose pelvic viscera and vessels to risk of injury.

The needle is inserted perpendicular to the skin and advanced slowly (Figure 82D–14). The motor response of the sciatic plexus is usually obtained at a depth between 6 and 8 cm. The goal is to achieve visible or palpable twitches of the hamstrings, calf muscles, foot, or toes at the current intensity of 0.3–0.5 mA. The distal motor response may be either a tibial or a peroneal response—it is not necessary to stimulate both components (Figure 82D–15).[33,34] Twitches of the hamstrings are equally acceptable because this approach blocks the sciatic nerve proximal to the separation of the neuronal branches to the hamstring muscles.

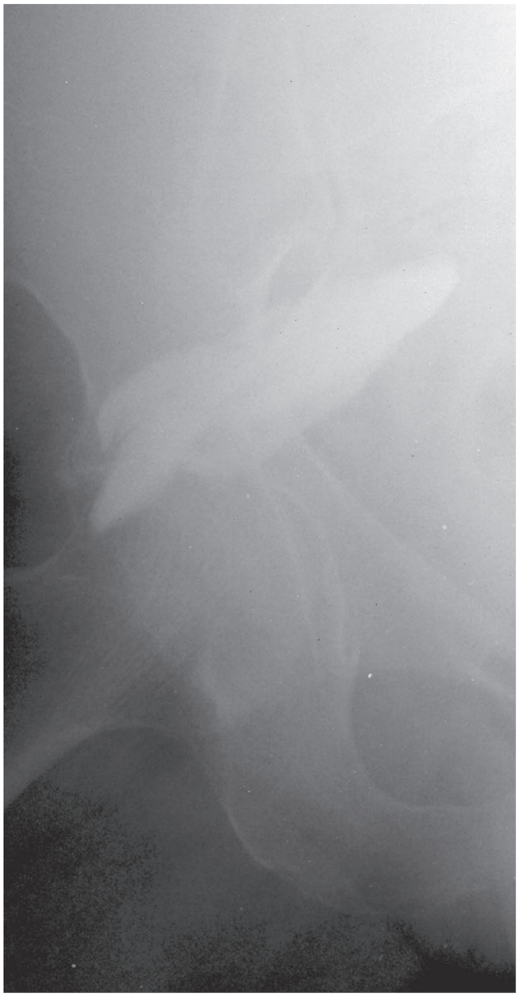

FIGURE 82D–16. Parasacral nerve block: dispersion of the contrast after injection, the "negative" contrast sign, and a typical fusiform distribution of the injectate.

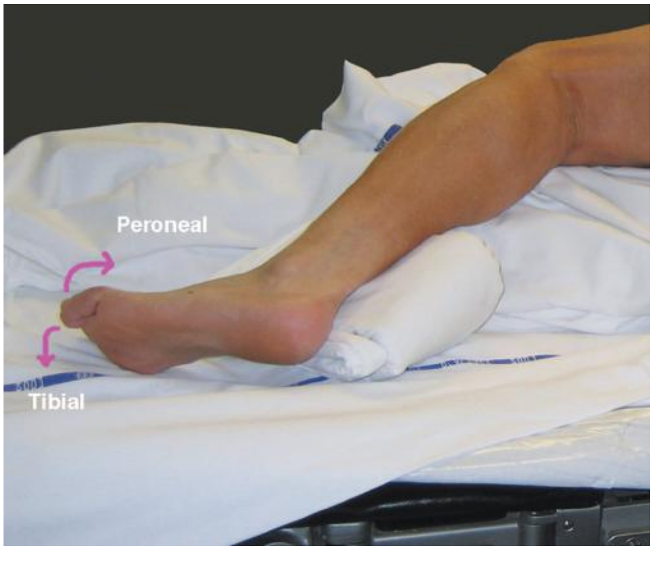

FIGURE 82D–15. Sciatic nerve stimulation: motor response of the common peroneal and tibial nerves indicate proper localization of the sciatic nerve.

Once an appropriate response is obtained, 20-25 mL of local anesthetic is injected slowly with intermittent aspiration (Figure 82D–16).

Cuvillon et al.[8] compared the parasacral sciatic nerve block with Winnie's approach with one or two stimulations. Winnie's approach using the double-injection technique required more time to perform the block compared with Winnie's single-injection technique and the parasacral method. Although the onset of sensory and motor blocks were significantly faster with the double- injection method, the additional time needed to perform the double-injection block eliminated the advantage of the faster onset.

Continuous Parasacral Sciatic Nerve Block

The continuous parasacral sciatic nerve block is similar to the single-shot injection; however, slight caudal angulation of the needle is necessary to facilitate threading of the catheter. Securing and maintenance of the catheter are easy and convenient.[36] This technique can be used for surgery and postoperative pain

FIGURE 82D–17. Equipment for continuous sciatic block.

FIGURE 82D–18. Parasacral sciatic block: shown is the course of the catheter and visualization of the injectate around the sciatic nerve.

management in patients undergoing a wide variety of knee, lower leg, foot, and ankle surgeries.

The technique is identical to the single injection technique, except a continuous-block needle is used (Figure 82D–17). The opening of the needle should face distally to facilitate catheter insertion.[37] The initial intensity of the stimulating current should be 1.0–1.5 mA.

Clinical Pearl

- It is useful to inject some local anesthetic intramuscularly to decrease pain during placement of the continuous nerve block needle.

After obtaining the motor response at 0.3–0.5 mA, a 20 mL bolus of local anesthetic is injected and the catheter inserted 3-5 cm beyond the needle tip. If confirmation of catheter placement is desired, contrast media can be injected through the catheter and radiographic images can be studied.[31] The presence of a spindle 2–3 cm in length with an oblique orientation crossing the sciatic notch on the anteroposterior radiograph and/or shadowing of the sacral roots are considered to indicate injection into the correct plane and adequate placement of the catheter (see Figure 82D–18). After securing the catheter, an infusion (e.g., ropivacaine 0.2% at 5 mL/hr with 5 mL/q60min patient-controlled bolus) is initiated.

ALTERNATIVE POSTERIOR APPROACHES

Di Benedetto[38] described a subgluteal approach to the sciatic nerve block in 2002. This technique is a good alternative to the more proximal approaches to the sciatic nerve, with the potential for reducing the discomfort experienced by the patient during block placement. The landmarks with the subgluteal approach are the greater trochanter of the femur, the ischial tuberosity, and a line between the two with the midpoint marked. From the midpoint, another line is drawn perpendicularly and extended 4 cm in the caudal direction to identify the needle insertion point. A 20-gauge, 10-cm needle and nerve stimulator are used for this approach, and 20 mL of local anesthetic is injected when twitches of the sciatic nerve are obtained at ≤0.5 mA current.

Of note, ultrasound-guided subgluteal approach to sciatic block has become one of the most common sciatic nerve block techniques in modern regional anesthesia. Traditional approaches to the sciatic nerve at the pelvic level require identification of pelvic bone structures. Although the size of the buttocks is variable among different individuals and in the same individual over time, the relation of the sciatic nerve to the pelvis is constant throughout life. Using this premise, Franco has suggested a more simplified approach to the sciatic nerve block that does not require palpation of deep bony structures. The landmarks with this approach are the midline of the intergluteal sulcus, and a point 10 cm lateral to the midline of the intergluteal sulcus where the block needle will be inserted. The curvature of the buttocks is disregarded when locating the needle insertion point. Care must be taken not to stretch the soft tissues when marking the needle insertion site as subsequent recoil of the tissues will occur, causing the distance to the nerve to be underestimated. The patient is either in the prone or lateral position and the needle is inserted parallel to the midline.[39]

Complications in Posterior Approaches and How to Avoid Them

Table 82D–4 lists instructions on possible complications of sciatic nerve blockade and methods to decrease the risk.

TABLE 82D–4. Complications and how to avoid them.

Infection	Use strict aseptic technique
Hematoma	Avoid multiple needle insertions, particularly in anticoagulated patients
Vascular puncture	Avoid deep needle insertion (pelvic vessels)
Local anesthetic toxicity	Avoid using large volumes and doses of local anesthetic owing to the proximity of the large vessels and the potential for rapid absorption
	Injection of local anesthetic should be carried out slowly and with frequent aspiration to rule out intravascular injection
Nerve injury	Sciatic nerve has a unique predisposition for mechanical and pressure injury
	Use nerve stimulation and slow needle advancement
	Never inject local anesthesia when the patient complains of pain or when abnormally high pressure on injection is noted
	Never assume that the needle is obstructed with tissue debris when resistance to injection is met
	When stimulation is obtained with a current intensity of <0.2 mA, withdraw the needle slightly to obtain the same response with a current intensity of >0.2 mA before injecting local anesthetic
Nerve injury	Advance the needle slowly when twitches of the gluteus muscle cease to avoid impaling the sciatic nerve on a rapidly advancing needle
Other	Instruct the patient and nursing staff on the care of the insensate extremity
	Explain the need for frequent body repositioning to avoid stretching and prolonged ischemia (sitting) on the anesthetized sciatic nerve
	Advise heel padding during prolonged bed rest or sleep to prevent pressure sores from developing
Perforation of pelvic organs	Directing the needle medially should be exercised with this complication in mind
Anesthesia of the pudendal nerve	The pudendal nerve, a branch of the sacral plexus, may be anesthetized by the parasacral nerve block owing to diffusion of the injected local anesthesia
	Inform patients that this problem is transient
Tourniquet	Injection of the local anesthetic within the sciatic nerve sheath, epinephrine, and a tourniquet over the site of injection all can combine to cause ischemia of the sciatic nerve

ANTERIOR APPROACH

General Considerations

The anterior approach to a sciatic block is an advanced nerve block technique. The block is suited for surgery on the leg below the knee, particularly on the ankle and foot. It provides complete anesthesia of the leg below the knee with the exception of the medial strip of skin innervated by the saphenous nerve (Figure 82D–19). When combined with a femoral nerve block, anesthesia of the entire knee and lower leg is achieved.[40] The anterior approach is much less clinically applicable than posterior approaches because the distribution of anesthesia is more limited and a higher level of skill is required. In addition, this technique is not suitable for catheter insertion because of the deep location and perpendicular angle of needle insertion required to reach the sciatic nerve. Consequently, this block is best reserved for patients who cannot easily be moved to the lateral position needed for the posterior approach; e.g., patients with spinal injuries or under general anesthesia.[41,42]

Since the original description by Beck[5] several clinicians have attempted to devise more reliable landmarks and technique for this block. However, all described approaches derive the needle insertion site at nearly identical points regardless of whether they use bony prominences, soft tissue, or femoral artery as landmarks.[40,43–47] In addition, even if these different approaches varied slightly in the site of needle insertion, the long path by the needle required to reach the sciatic nerve (8–12 cm) and the tendency of long, blunt-tipped needles to bend on insertion through the tissues make any such differences meaningless when it comes to increasing the precision of the technique.

Equipment

A standard regional anesthesia tray is prepared with the following equipment:

- Sterile towels and 4-in.× 4-in. gauze packs
- 20-mL syringes with local anesthetic

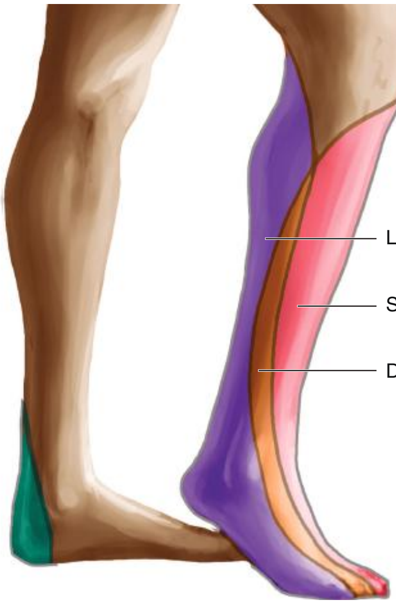

FIGURE 82D–19. Distribution of anesthesia with anterior approach to sciatic nerve block.

- Sterile gloves, marking pen, and surface electrode
- One 1.5-in., 25-gauge needle for skin infiltration
- A 15-cm long, short-bevel, insulated stimulating needle
- Peripheral nerve stimulator

Anatomic Landmarks

The following landmarks should routinely be outlined using a marking pen (Figure 82D–20):

1. Femoral crease
2. Femoral artery pulse
3. Needle insertion point marked 4–5 cm distally on the line passing through the pulse of the femoral artery and perpendicular to the femoral crease

Technique

The leg is fully extended on the table with the patient in the supine position. After cleaning the area with an antiseptic solution, local anesthetic is infiltrated subcutaneously at the needle insertion site. The fingers of the palpating hand should be firmly pressed against the quadriceps muscle to decrease the skin–nerve distance. The block needle (connected to a nerve stimulator set to deliver a current of 1.5 mA) is introduced at a perpendicular angle to the skin plane (Figure 82D–21). Motor response of the sciatic nerve is typically obtained at a depth of 8–12 cm. Acceptable responses are visible or palpable twitches of the calf muscles, foot, or toes at a current of 0.3–0.5 mA. After negative aspiration for blood, 20 mL of local anesthetic is slowly injected. If high injection pressure is detected, the needle should be withdrawn by 1 mm and injection attempted again. If high injection pressure persists, the needle should be withdrawn and flushed prior to further attempts.

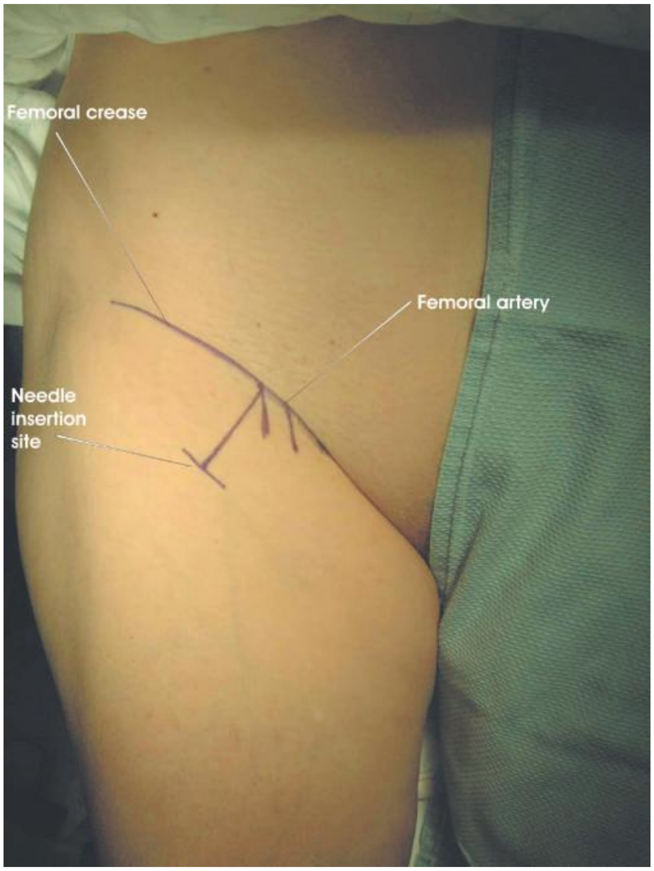

FIGURE 82D–20. Sciatic nerve block through the anterior approach.

Clinical Pearls

- Local twitches of the quadriceps muscle are often elicited during needle advancement. The needle should be advanced past these twitches.
- Although there is a concern of femoral nerve injury with further needle advancement, at this level, the femoral nerve is divided into smaller terminal branches that are movable and unlikely to be penetrated by a slowly advancing, blunt-tipped needle.
- Resting the patient's heel on the bed surface may prevent the foot from twitching even when the sciatic nerve is stimulated. This can be prevented by placing the ankle on a footrest or by having an assistant continuously palpate the calf or Achilles tendon.
- Because branches to the hamstring muscle may depart the main trunk of the sciatic nerve at the level of needle insertion, twitches of the hamstrings should not be accepted as a reliable sign of sciatic nerve localization.

Bone contact is frequently encountered during needle advancement. This indicates that the needle has contacted the femur (usually lesser trochanter). In this case, the foot is first rotated laterally, which should swing the lesser trochanter out of the path of the needle and allow deeper advancement of the

FIGURE 82D–21. Sciatic nerve block through the anterior approach. Needle insertion.

TABLE 82D–5. Interpreting responses to nerve stimulation.

Response Obtained	Interpretation	Problem	Action
Twitch of the quadriceps muscle (patella twitch)	Common; stimulation of the branches of the femoral nerve	Too shallow (superficial) placement of needle	Continue advancing the needle
Local twitch at the femoral crease area	Direct stimulation of the iliopsoas or pectineus muscles	Too superior insertion of needle	Stop the procedure and reassess the landmarks
Hamstring twitch	Needle may be stimulating branch(es) of the sciatic nerve to the hamstring muscle; direct stimulation of the hamstrings with higher current is also possible	Unreliable-difficult to determine whether the needle is in the proximity of the sciatic nerve	Withdraw the needle and redirect slightly medially or laterally (5–10 degrees)
The needle is placed deep (12–15 cm) but twitches were not elicited and bone is not contacted	The needle is likely too medial		Withdraw and redirect slightly laterally
Twitches of the calf, foot, or toes	Stimulation of the sciatic nerve	None	Accept and inject local anesthetic

needle and nerve localization. If this maneuver fails, the needle is redirected slightly medially or reinserted more medially. Table 82D–5 lists some common responses to nerve stimulation and the course of action to take to obtain the proper response.

SUMMARY

Although the sciatic nerve block was described in 1920, many practitioners avoided this block because of its perceived complexity. Sciatic nerve block is an important technique for the regional anesthesiologist to master because the combination of this block and a femoral nerve block or lumbar plexus block can anesthetize almost the entire leg. Although the posterior sciatic nerve block has an intermediate level of difficulty, with practice and knowledge of anatomy, high success rates can be achieved. Many approaches have been proposed; the most relevant have been presented in this chapter. Finally, nearly all described approaches are similar in clinical efficacy; therefore, learning one single approach well is recommended as this would suffice for most clinical indications.

CHAPTER 82E

Block of the Sciatic Nerve in the Popliteal Fossa

Jerry D. Vloka and Admir Hadzic

INTRODUCTION

Distal sciatic nerve block (popliteal fossa block) is a very clinically valuable technique that results in anesthesia of the calf, tibia, fibula, ankle, and foot.[1–3] The sciatic nerve can be approached from either the posterior approach, described by Duane Keith Rorie,[3] or the lateral approach, described by Jerry Vloka.[1] Both approaches provide equivalent anesthesia and are suitable for catheter placement. Overall, however, the posterior approach is easier for trainees to learn.[1,2]

Popliteal fossa block performed with long-acting local anesthetics such as ropivacaine can provide 12–24 hours of analgesia after foot surgery.[3,4]

When used as a sole technique popliteal fossa block provides excellent anesthesia and postoperative analgesia, allows use of a calf tourniquet, and avoids the disadvantages of neuraxial blockade.[5]

Analgesia with popliteal fossa blocks lasts significantly longer than with ankle blocks. For instance, David H. McLeod found that lateral popliteal fossa block with 0.5% bupivacaine lasted 18 hours when compared with ankle block, which lasted only 6.2 hours.[6] Popliteal fossa block has also been used as an effective analgesic technique in children.[7] In a study of the efficacy of the popliteal sciatic nerve blockade (0.75 mL/kg of ropivacaine 0.2%) after foot and ankle surgery, 19 of 20 children required no analgesic agents during the first 8–12 hours postoperatively.

Indications and Contraindications

The popliteal block is one of the most commonly used techniques in regional anesthesia practice. Some common indications include corrective foot surgery, foot debridement, short saphenous vein stripping, repair of the Achilles tendon, and others.[8] As opposed to the more proximal block of the sciatic nerve, popliteal fossa block anesthetizes the leg distal to the hamstring muscles, allowing patients to retain knee flexion.[9,10]

Functional Anatomy

The sciatic nerve consists of two separate nerve trunks: the tibial and common peroneal nerves. A common paraneural sheath envelops these two nerves from their origin in the pelvis, which is distinctly separate from the epineurium of each nerve.[11] Studies utilizing ultrasound imaging have shown that injecting local anesthetic within this sheath consistently gives a rapid onset, safe, and effective block.[12] This is not considered to be an intraneural injection as long as the epineurium of the individual nerves is not breached.[13,14] As the sciatic nerve descends toward the knee, the two components eventually diverge just proximal to the popliteal fossa, giving rise to the tibial and common peroneal nerves (Figure 82E–1). This division of the sciatic nerve usually occurs between 50 and 120 mm proximal to the popliteal fossa crease.[15,16] Following its divergence from the sciatic nerve, the common peroneal nerve continues its path laterally and descends along the head and neck of the fibula. Its major branches in this region are branches to the knee joint and cutaneous branches that form the sural nerve. Its terminal branches are the superficial and deep peroneal nerves. The tibial nerve is the larger of the two divisions of the sciatic nerve and continues its path vertically through the popliteal fossa. Its terminal branches are the medial and lateral plantar nerves. Its collateral branches give rise to the cutaneous sural nerves, muscular branches to the muscles to the calf, and articular branches to the ankle joint. The tibial nerve is enveloped by a well-defined paraneural sheath; consequently, a single injection of a large volume of local anesthetic into the sheath of the tibial nerve may carry a higher success rate than an injection into the sheath of the common peroneal nerve.[11] Note that in contrast to the

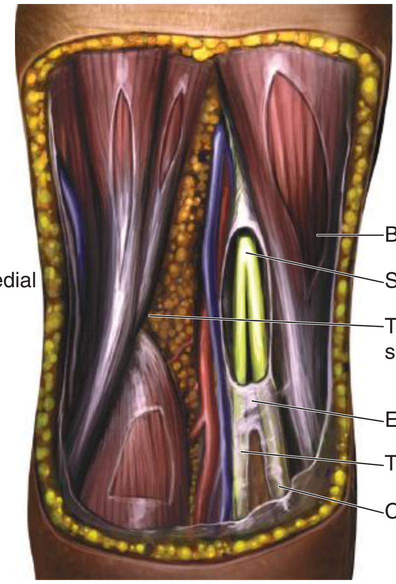

FIGURE 82E–1. Anatomy of the distal sciatic nerve. The sciatic nerve descends between the hamstring muscles and diverges as tibial and common peroneal nerves approximately at or below 7–8 cm above the popliteal fossa crease. A common epineural sheath that serves as a conduit for injected local anesthetic is shown dissected.

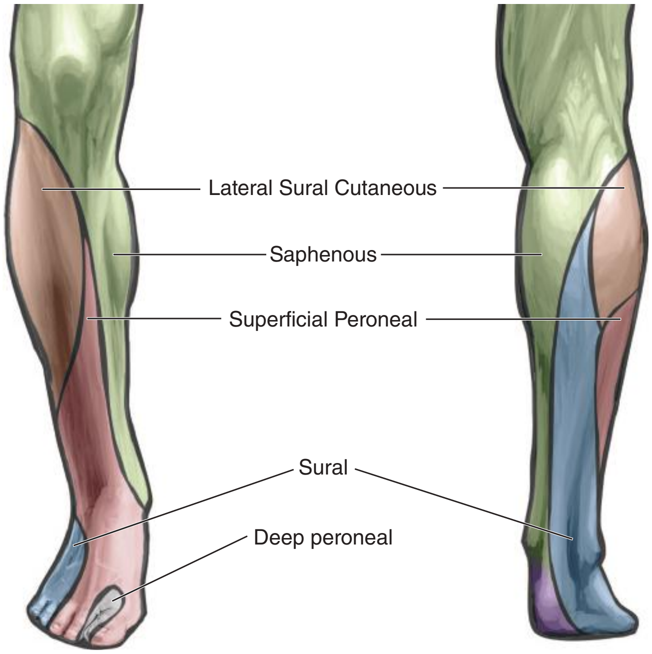

FIGURE 82E–2. Sensory distribution of anesthesia after popliteal blockade. Popliteal block results in anesthesia of all shaded areas except that of the saphenous nerve (femoral).

common assumption, the sciatic nerve is not enveloped by the same tissue sheath as are the popliteal vessels; consequently, the concept of the neurovascular sheath is not applicable to this block.[11] Instead, in the popliteal fossa, the sciatic nerve components are lateral and superficial to the popliteal artery and vein. This anatomic characteristic is important in understanding why vascular punctures and systemic toxicity are so rare after popliteal blockade.

Distribution of Anesthesia

Popliteal block results in anesthesia of the entire distal two thirds of the lower extremity, with the exception of the medial aspect of the leg[17] (Figure 82E–2). Cutaneous innervation of the medial leg below the knee is provided by the saphenous nerve, a superficial terminal extension of the femoral nerve. Depending on the location of surgery, the addition of a saphenous nerve block may be required. Saphenous nerve block is not generally required for patients to tolerate tourniquet pain below the knee because this pain is the result of pressure and ischemia of the deep muscle beds.

Choice of Local Anesthetic

Popliteal blockade requires a larger volume of local anesthetic (20 mL) to achieve anesthesia of both divisions of the nerve.[5] The choice of type, volume, and concentration of local anesthetic should be based on the patient's size and general condition and whether the block is planned for surgical anesthesia or pain management. The type and concentration of local anesthetics and the choice of additives to local anesthetic influence the onset and, particularly, the duration of the blockade (Table 82E–1).

TECHNIQUES

Intertendinous (Posterior) Approach

The patient is in the prone position.[18] The foot on the side to be blocked should be positioned so that even the slightest movement of the foot or toes can be easily observed. This is best achieved by allowing the foot to protrude off the edge of the bed.

Equipment

A standard regional anesthesia tray is prepared with the following equipment:

TABLE 82E–1. Local anesthetics choice for popliteal block.

	Onset (min)	Anesthesia (h)	Analgesia (h)
3% 2-Chloroprocaine	10–15	1	2
1.5% Mepivacaine	15–20	2–3	3–5
1.5% Mepivacaine epinephrine	15–20	2–5	3–8
2% Lidocaine epinephrine	10–20	2–5	3–8
0.5% Ropivacaine	15–30	4–8	5–12
0.75% Ropivacaine	10–15	5–10	6–24
0.5 (L) Bupivacaine	15–30	5–15	6–30

- Sterile towels and 4-in. × 4-in. gauze packs
- One 20-mL syringes with local anesthetic
- Sterile gloves, marking pen, and surface electrode
- One 1.5-in., 25-gauge needle for skin infiltration
- A 5-cm long, short-bevel, insulated stimulating needle
- Peripheral nerve stimulator
- Injection pressure monitor

Anatomic Landmarks

Landmarks for this approach are easily identified, even in obese patients (Figure 82E–3). The landmarks should be routinely outlined by a marking pen: (1) popliteal fossa crease, (2) tendon of biceps femoris (laterally), and (3) tendons of semitendinosus and semimembranosus (medially).

The needle insertion point is marked at 7 cm above the popliteal fossa crease at the midpoint between the tendons. This point is just above the sciatic nerve in the popliteal fossa in nearly two thirds of patients (Figure 82E–4).

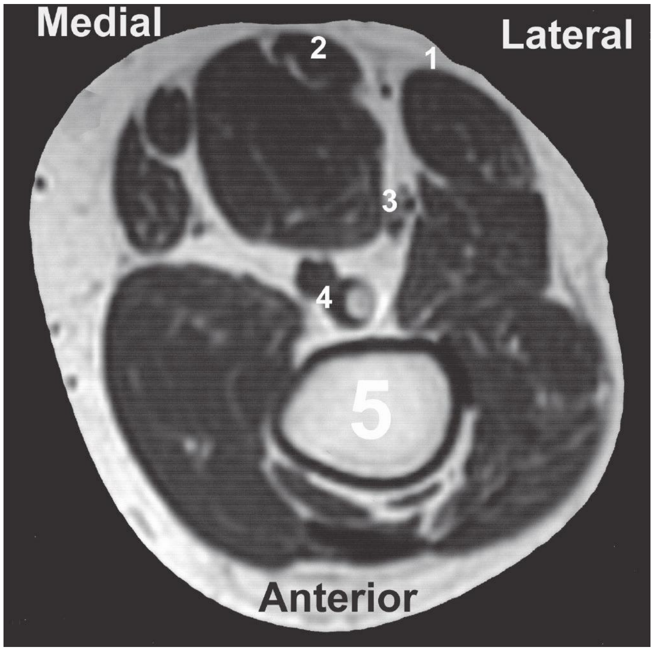

FIGURE 82E–4. Magnetic resonance image (MRI) of the popliteal fossa 7 cm above the popliteal fossa crease. *1*, Tendon of the biceps femoris muscle; *2*, tendon of the semitendinosus muscle; *3*, sciatic nerve in the popliteal fossa (shown are both components: the tibial nerve is positioned more anteriorly and medially, whereas the common peroneal nerve is more posterior and lateral); *4*, popliteal artery and vein; *5*, femur.

Clinical Pearls

- Relying on tendons (rather than on subjective interpretation of the "popliteal fossa triangle" as described elsewhere) gives a much more precise and consistent localization of the popliteal nerve.
- The landmarks can be accentuated by asking the patient to flex the knee joint (Figure 82E–5). This maneuver tightens the hamstring muscles and facilitates more accurate palpation of the tendons.

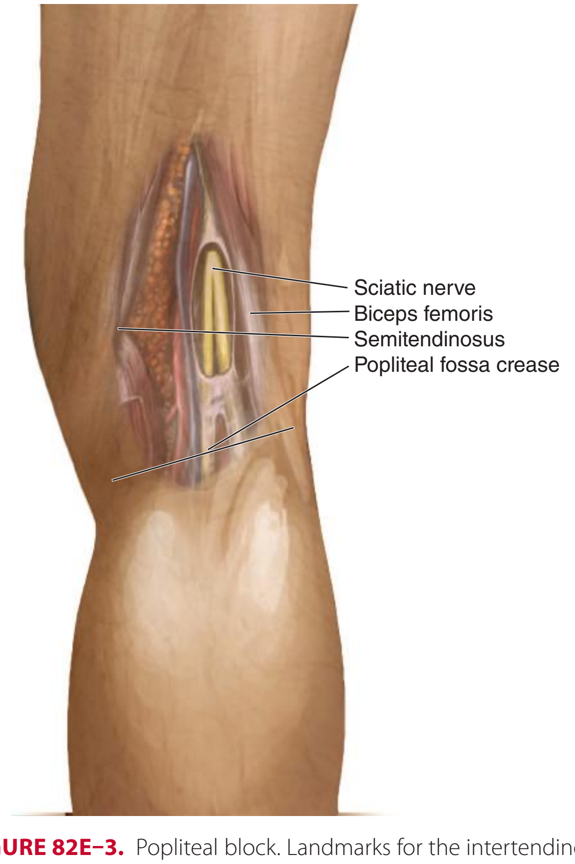

FIGURE 82E–3. Popliteal block. Landmarks for the intertendinous approach.

Technique

The practitioner is best positioned on the side of the patient with the palpating hand on the biceps femoris muscle while observing the motor response of the foot and toes

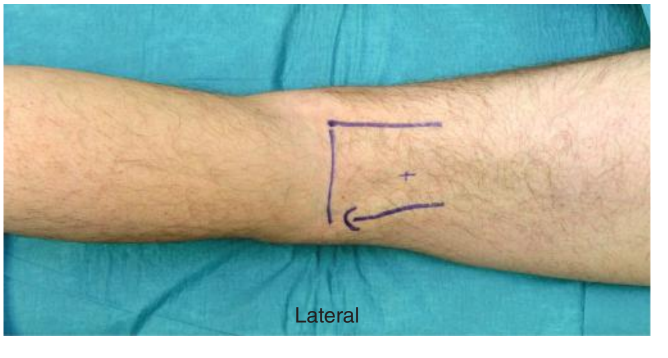

FIGURE 82E–5. Landmarks for the popliteal block, intertendinous approach. The landmarks can be accentuated by asking the patient to flex the leg. The arrow indicates attachment of the biceps femoris tendon; + sign indicates site of needle placement.

(Figure 82E–6A–C). The needle is introduced at the midpoint between the tendons. The nerve stimulator should be initially set to deliver 1.5 mA current (2 Hz, 100 μsec). When the needle is inserted in the correct plane, advancement of the needle should not result in any local muscular twitches; the first response to nerve stimulation is typically that of the sciatic nerve (foot twitch). The stimulating current is gradually decreased and the needle repositioned until twitches are still seen or felt at 0.2–0.5 mA. This typically occurs at a depth of 3–5 cm from the skin. After negative aspiration for blood, 20 mL of local anesthetic is slowly injected.

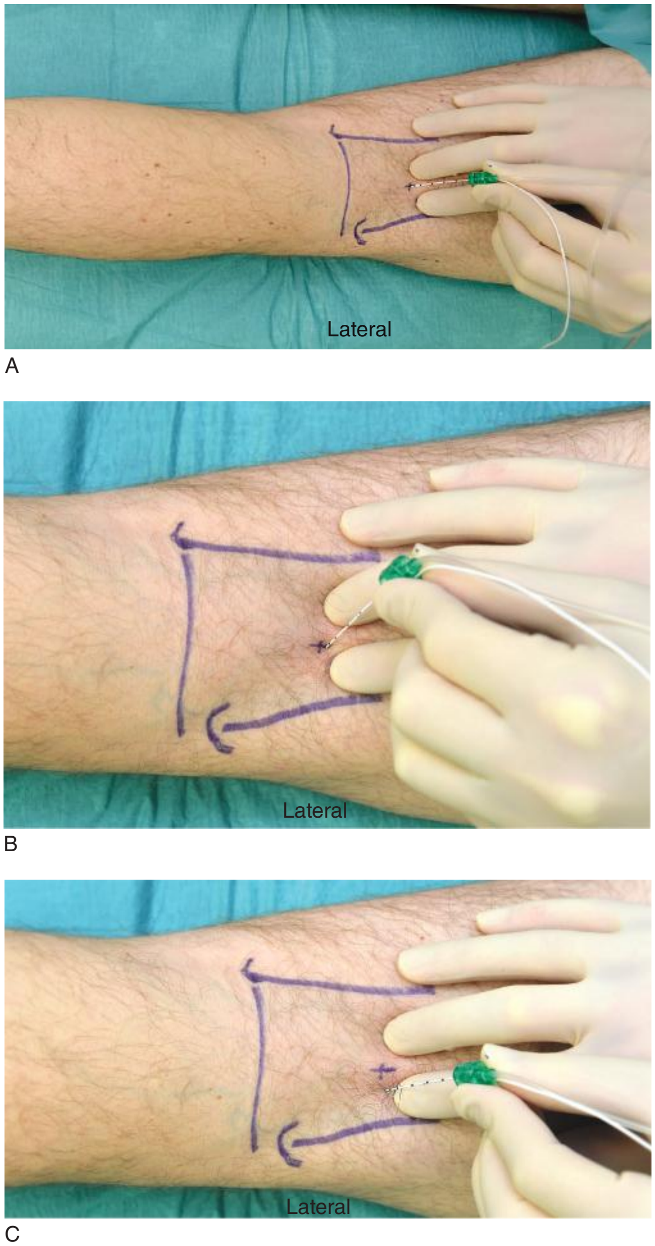

FIGURE 82E–6. **A.** Popliteal block, intertendinous approach. The needle is inserted perpendicularly between tendons of the biceps femoris and semitendinosus muscles. **B.** In case no foot or toe twitch can be elicited, withdraw and redirect 15 degrees laterally. **C.** In case no foot or toe twitch can be elicited after redirection, withdraw needle completely, reinsert 1 cm laterally, and repeat the procedure starting with perpendicular needle insertion.

Clinical Pearls

- In patients with long- standing diabetes mellitus, peripheral neuropathy, sepsis, or severe peripheral vascular disease. Stimulating currents up to 1 mA can be accepted.
- When a rather small change in the needle position (e.g.,1 mm) results in a change of the motor response from that of the popliteal nerve (plantar flexion of the foot) to that of the common peroneal nerve (dorsiflexion of the foot), the needle tip is above the divergence of the sciatic into tibial and common peroneal nerves.
  - Entrance of the needle into the sciatic sheath is almost always associated with a "fascial click." The skilled practitioner should use this sign as a valuable clue in conjunction with the nerve stimulation information to ascertain proper needle position.
  - Absence of high opening injection pressure is essential to assure extrafascicular needle placement as motor response may be absent after injection.

There are two types of motor responses that can be elicited with sciatic nerve stimulation at the level of the popliteal fossa. Common peroneal nerve stimulation results in dorsiflexion and eversion of the foot, whereas stimulation of the tibial nerve results in plantar flexion and inversion (Figure 82E–7). As the

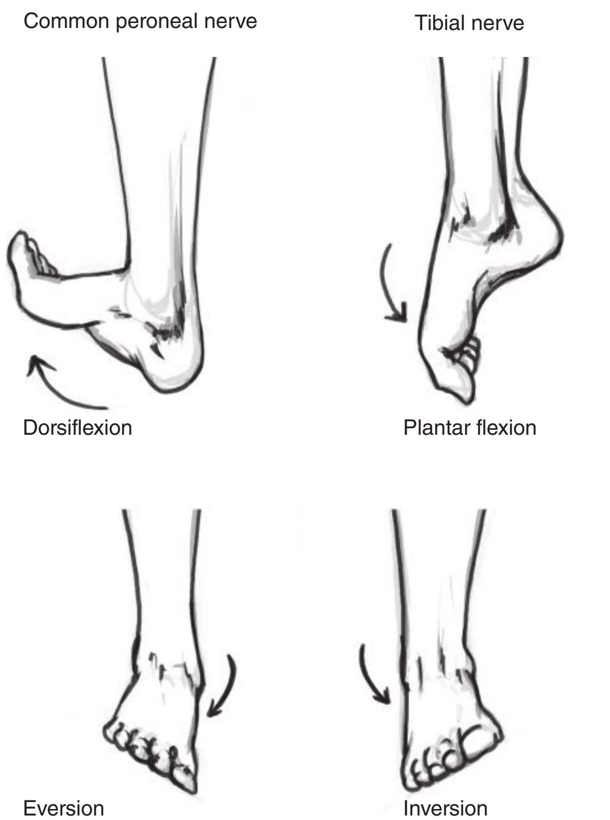

FIGURE 82E–7. Motor responses obtained on stimulation of the sciatic nerve in the popliteal fossa.

TABLE 82E–2. Intertendinous popliteal block: troubleshooting.

Response Obtained	Interpretation	Problem	Corrective Action
Local twitch of the biceps muscle	Direct stimulation of the biceps femoris muscle	Too lateral placement of the needle	Withdraw the needle and redirect slightly medially (5–10 degrees)
Local twitch of the semitendinosus/ membranosus muscles	Direct stimulation of the semitendinosus/ membranosus muscles	Too medial placement of the needle	Withdraw the needle and redirect slightly laterally (5–10 degrees)
Twitch of the calf muscles without foot or toe movement	Stimulation of the muscular branches of the sciatic nerve	These small branches are often outside the sciatic sheath	Disregard and continue advancing the needle until the foot/toes twitches are obtained
Vascular puncture	Blood in the syringe most commonly indicates placement into the popliteal artery or vein	Too medial or too deep needle placement	Withdraw and redirect laterally
Bone contact	The needle encounters the femur	Too deep needle insertion—either the nerve was missed or motor response was not appreciated	Withdraw the needle slowly and look for the foot twitch; if twitches are not seen, reinsert in another direction

stimulating current is being decreased, the twitch of the great toe often remains the only motor response seen with currents of <0.5 mA. Either response is adequate when the response is still present with current intensity of 0.2–0.4 mA (0.1 msec) as long as a large volume of local anesthetic is used. Some common responses to nerve stimulation and the course of action to obtain the proper response are shown in Table 82E–2.[19]

Block Dynamics and Perioperative Management

The intertendinous approach to the popliteal block is associated with relatively minor patient discomfort because the needle passes only through the adipose tissue of the popliteal fossa. Regardless, adequate sedation and analgesia are always important to ensure a still and tranquil patient. Midazolam 1–2 mg after the patient is positioned and alfentanil 250–500 mcg or 5 mg ketamine just before block placement suffices for most patients. A typical onset time for this block is 10–25 minutes, depending on the type, concentration, and volume of local anesthetic used. The first signs of block onset are usually that the patient reports that the foot "feels different" or that they are unable to wiggle the toes. Sensory anesthesia of the skin with this block is often the last to develop. Inadequate skin anesthesia despite the apparent timely onset of the blockade is common because it may take up to 30 minutes for full blockade to develop. However, local infiltration at the site of the incision is often all that is needed to allow the surgery to proceed.

Continuous Popliteal Block

Continuous popliteal block is an advanced regional anesthesia technique, and adequate experience with the single-shot technique is necessary to ensure its efficacy. The technique is similar to the single-shot injection; however, slight angulation of the needle cephalad is necessary to facilitate insertion of the catheter. This technique can be used for surgery and postoperative pain management in patients undergoing a wide variety of lower leg, foot, and ankle surgeries.

Ilfeld[9] reported excellent postoperative analgesia using a continuous catheter in the popliteal fossa and a portable infusion pump for outpatients having moderately painful, lower extremity orthopedic surgery. The patients who received ropivacaine experienced a significant decrease in sleep disturbances, oral opioid use, and opioid-related adverse effects, and had a high rate of satisfaction with the technique.[20]

Klein et al.[21] examined the efficacy and complications of long-acting popliteal nerve block after discharge home. This prospective study included 1791 patients who had received an upper- or lower-extremity nerve block with 0.5% ropivacaine and were discharged on the day of surgery. The results showed that long-acting popliteal nerve block may be used in the ambulatory setting with a high degree of efficacy, safety, and satisfaction.

Chelly et al.[22] documented the benefits of a continuous lateral popliteal sciatic nerve block infusion technique for postoperative analgesia in patients who had undergone open reduction and internal fixation of the ankle. Continuous infusion of ropivacaine 0.2% was associated with a significant reduction of morphine consumption by 29% and 62% during postoperative days 1 and 2, respectively.

Technique

After insertion, the block needle is advanced slowly with a slight cranial direction while seeking a motor response. After

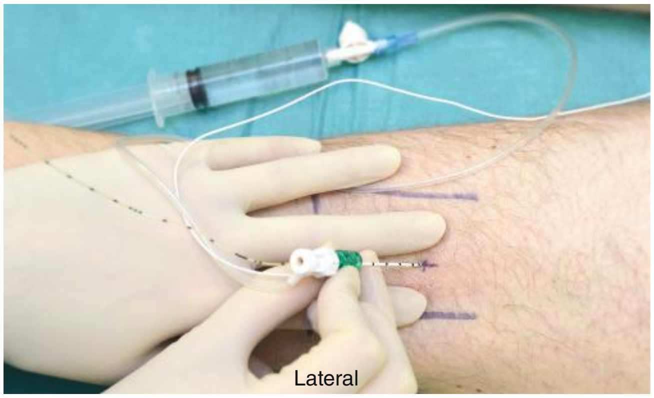

FIGURE 82E–8. Image depicts a non-sterile catheter field. Popliteal block, intertendinous approach. Catheter insertion.

obtaining an appropriate motor response at a current of 0.5 mA, a bolus of local anesthetic is injected (10-15 ml) and the catheter advanced 5 cm beyond the needle tip (Figure 82E–8). The catheter is aspirated to check for inadvertent intravascular placement, then an infusion can be started. A typical infusion regimen is ropivacaine 0.2% at 5 mL/h with a 5 mL/q60min patient-controlled bolus.

Clinical Pearls

- Breakthrough pain in patients on continuous infusion is always managed by administering a bolus of local anesthetic. Increasing only the rate of infusion is never adequate.
- Patients receiving continuous nerve block infusion should also be prescribed an alternative oral or intravenous (e.g., intravenous patient-controlled analgesia [IV PCA]) pain management protocol because incomplete analgesia and catheter dislodgement can occur leaving the patient without a back-up option.

Popliteal (Lateral) Approach

The main advantage of the lateral approach, described by Jerry Vloka is that the patient does not need to be positioned in the prone position.[6,1923]

Regional Anesthesia Anatomy

The sciatic nerve is located between the biceps and semitendinosus muscles (see Figure 82E–4). During block performance, stimulation of the common peroneal nerve is usually obtained first (65%) because this nerve is positioned more lateral and superficial than the tibial nerve.

Patient Positioning

The patient is in the supine position. The foot on the side to be blocked should be positioned so that even the slightest movement of the foot or toes can be easily observed. This is best achieved by placing the foot on a footrest.

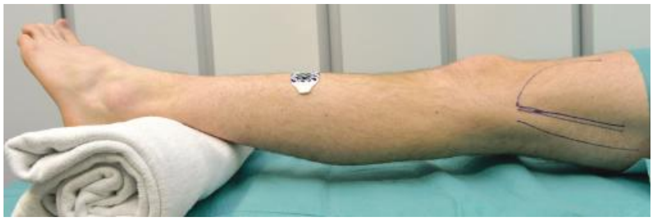

FIGURE 82E–9. Popliteal block, lateral approach. Landmarks for this technique include vastus lateralis (VL), biceps femoris (BF), and popliteal fossa crease. The needle insertion site is marked 8 cm above the popliteal fossa crease (*thick vertical line*).

Equipment

The equipment is identical to that for the posterior intertendinous approach except that a 10-cm stimulating needle is used.

Anatomic Landmarks

Landmarks for the lateral approach to popliteal block include the popliteal fossa crease, vastus lateralis muscle, and biceps femoris muscle (Figure 82E–9). The needle insertion site is marked in the groove between the vastus lateralis and biceps femoris muscles, 8 cm proximal to the popliteal crease (Figure 82E–10).

Technique

The operator should be seated, facing the side to be blocked. The height of the patient's bed is adjusted to allow for an ergonomic position and greater precision during block placement. This position also allows the operator to simultaneously monitor both the patient and the responses to nerve stimulation. The site of needle insertion is cleaned with an antiseptic solution and infiltrated with local anesthetic.

A 10-cm, 22-gauge needle is connected to a nerve stimulator inserted in a horizontal plane between the vastus lateralis and biceps femoris muscles, and advanced to contact the femur (see Figure 82E–10). The contact with the femur is important because it provides information on the depth of the nerve (typically 1–2 cm beyond the skin–femur distance) as well as on the angle at which the needle will need to be redirected

FIGURE 82E–10. Popliteal block, lateral approach. The needle is inserted between vastus lateralis (VL) and biceps femoris in the horizontal plane to contact the femur.

FIGURE 82E–11. After the femur is contacted, the needle is redirected 30 degrees posterior to the plane in which the femur was contacted. VL, vastus.

posterior to stimulate the nerve. The current intensity is initially set at 1.5 mA. Keeping the fingers of the palpating hands firmly pressed and immobile in the groove, the needle is then withdrawn to the skin, redirected 30 degrees posterior to the angle at which the femur was contacted, and advanced toward the nerve (Figure 82E–11).

When the sciatic nerve is not localized on the first needle pass, the needle is withdrawn to the skin level and the following procedure is followed:

Clinical Pearls

- Assure that the nerve stimulator is functional and properly connected to the patient and to the needle and that it is set to deliver current of desired intensity.
- Assure that the leg is not externally rotated at the hip joint and that the foot forms a 90-degree angle to the horizontal plane of the table. Any deviation from this angle changes the relationship of the sciatic nerve to the femur and biceps femoris muscle.
- Mentally visualize the plane of the initial needle insertion and redirect the needle in a slightly posterior direction (5–10 degrees posterior angulation).
- If the above maneuver fails, withdraw the needle and reinsert with an additional 5–10 degrees posterior redirection.
- If the above maneuvers fail, withdraw the needle to the skin and reinsert 1 cm inferior to the initial insertion site; then repeat the above steps.
- Failure to obtain foot response to nerve stimulation should prompt reassessment of the landmarks and leg position. In addition, the stimulating current should be increased to 2 mA.

After the initial stimulation of the sciatic nerve is obtained, the stimulating current is gradually decreased until motor response of the foot or toes is still seen or felt at 0.5 mA. This typically occurs at a depth of 5–7 cm. Entrance of the needle into the sheath with a Touhy-style tip needle is often accompanied by a perceptible "click." At this point, the needle should be stabilized, and after negative aspiration for blood, 20 mL of local anesthetic is slowly injected. The hands should be kept as immobile as possible to prevent injection outside the sheath of the sciatic nerve.

Continuous Popliteal Block Through the Lateral Approach

The continuous popliteal block technique through the lateral approach is similar to the single-injection technique, except that a10-cm Tuohy-style tip needle is used. When the needle is directed towards the sciatic nerve, a slight cranial angulation should be taken to facilitate catheter insertion (Figure 82E–12).

After obtaining appropriate twitches at 0.2–0.5 mA, a bolus of local anesthetic is injected and the catheter advanced 5–7 cm beyond the tip of the needle. The management of the catheter is similar to that of the intertendinous technique.

Clinical Pearls

- In some patients, the biceps muscle may be atrophic and the iliotibial aponeurosis may be more prominent. In such cases, the needle insertion site is labeled in the groove between the vastus lateralis and the iliotibial tract.
- Flexing the patient's leg in the knee helps with identification of the popliteal fossa crease and the biceps and vastus lateralis muscles (Figure 82E–13).

Some common responses during block placement using a nerve stimulator and the course of proper action to obtain twitches of the foot (Table 82E–3).

FIGURE 82E–12. Popliteal block, lateral approach. Continuous technique is similar to the single-injection method except that a larger needle is used. The needle opening should be directed cephalad, and a slight cephalad needle angulation is used after localization of the sciatic nerve; these maneuvers facilitate insertion of the catheter.

FIGURE 82E–13. Popliteal block, lateral approach. Asking the patient to flex the leg in the knee joint facilitates identification of the landmarks (popliteal fossa crease, vastus lateralis, and biceps femoris).

TABLE 82E–3. Lateral popliteal block: troubleshooting.

Response Obtained	Interpretation	Problem	Corrective Action
Local twitch of the biceps muscle	Direct stimulation of the biceps femoris muscle	Too shallow placement of the needle	Advance the needle deeper
Local twitch of the vastus lateralis muscle	Direct stimulation of the vastus lateralis muscles	Too anterior placement of the needle	Withdraw the needle and reinsert posterior
Twitch of the calf muscles without foot or toe movement	Stimulation of the muscular branches of the sciatic nerve	These small branches are often outside the sciatic sheath	Disregard and continue advancing the needle until the foot/toes twitches are obtained
Vascular puncture	Blood in the syringe most commonly indicates placement into the popliteal artery or vein	Too deep and anterior placement of the needle placement	Withdraw and redirect laterally
Twitches of the foot or toes	Stimulation of the sciatic nerve	None	Accept and inject local anesthetic

TABLE 82–4. Complications of popliteal block and measures to prevent them.

Infection	• Use strict aseptic technique
Hematoma	• Avoid multiple needle passes with a continuous block needle; the larger needle diameter and/or Tuohy design may result in a hematoma of the biceps femoris or vastus lateralis muscles
Vascular puncture	• Avoid too deep insertion of needle because the vascular sheath is positioned medially and deeper to the sciatic nerve • When the nerve is not localized within 2 cm after the local twitches of the biceps muscle cease, the needle should be withdrawn and reinserted at a different angle, rather than advanced deeper
Nerve injury	• Use nerve stimulation and slow needle advancement; do not inject when patient complains of pain or high pressures on injection are met; do not inject when stimulation is obtained at <0.2 mA current (100 μsec)
Pressure necrosis of the heel	• Instruct patient on the care of the insensate extremity • Use heel padding and frequent repositioning

COMPLICATIONS AND HOW TO AVOID THEM

A retrospective review of 400 continuous popliteal catheters revealed one case of infection (abscess formation requiring surgical drainage) and two cases of nerve injury resulting in paresthesias.[24]. Table 82E–4 provides specific instructions on possible complications and how to avoid them. Special attention should be paid when common peroneal response is elicited as most neurologic injuries occur to this nerve, probably because of its composition where there is often one or two large fascicles that present a greater risk for an intrafascicular needle placement.

SUMMARY

Popliteal sciatic block is useful technique to accomplish anesthesia and analgesia for ankle and foot surgery. Posterior and lateral approaches are both highly effective and applicable in numerous clinical scenarios.

CHAPTER 82F

Ankle Block

Joseph Kay, Rick Delmonte, and Paul M. Greenberg

INTRODUCTION

Anesthesia of the foot can be accomplished by blocking the five peripheral nerves that innervate the area at the level of the ankle.[1–5] This technique relies on anatomic landmarks that are easily identified. It does not require special equipment, paresthesia elicitation, nerve stimulation, special positioning, or patient cooperation.[1–5] The ankle block can be used for all types of foot surgery and is safe and reliable, and has a high success rate.[2,3,5–9]

Ankle block impairs ambulation on the affected leg, but to a lesser degree than sciatic or popliteal block, and patients can be discharged home before the block wears off.[4] Long-acting local anesthetics with ankle block can provide excellent postoperative analgesia.[6,9]

Indications and Contraindications

All types of foot surgeries can be carried out with ankle block, including bunionectomy, forefoot reconstruction, arthroplasty, osteotomy, and amputation.[1–10] Ankle block can also provide analgesia for fracture and soft tissue injuries[11] and or gout arthritis.[12] Moreover, it can be used for diagnostic and therapeutic purposes with spastic equinovarus[13] and sympathetically mediated pain.[14] Because motor block of the proximal leg and calf is avoided, ankle block may be preferable to sciatic/femoral (saphenous) nerve block for outpatient forefoot surgery.[15]

Ankle block should be avoided in patients with local infection, infection, edema, burn, soft tissue trauma, or distorted anatomy with scarring in the area of block placement.

Clinical Pearls

- Ankle block is well suited for ambulatory foot surgery.
- Ankle block can be life saving by avoiding the risks of general anesthesia in very ill patients having foot surgery (e.g. toes amputation, debridment).

Clinical Anatomy

The foot is innervated by five nerves (Figures 82F–1 and 82F–2). The medial aspect is innervated by the saphenous nerve, a terminal branch of the femoral nerve (Figure 82F–3). The rest of the foot is innervated by branches of the sciatic nerve:

- The lateral aspect is innervated by the sural nerve arising from the tibial and communicating superficial peroneal branches (Figure 82F–4).
- The deep ventral structures, muscles, and sole of the foot are innervated by the posterior tibial nerve, arising from the tibial branch (Figure 82F–5).
- The dorsum of the foot is innervated by the superficial peroneal nerve, arising from the common peroneal branch (Figure 82F–6).
- The deep dorsal structures and web space between the first and second toes are innervated by the deep peroneal nerve (see Figure 82F–2).[16,17]

At the level of the malleoli, the saphenous, superficial peroneal, and sural nerves are relatively superficial and subcutaneous. The posterior tibial and deep peroneal nerves are deep to the flexor and extensor retinaculi, respectively, and are more difficult to locate.

The posterior tibial nerve passes with the artery posterior to the medial malleolus deep to the flexor retinaculum, giving off a medial calcaneal branch to supply the lower and posterior surface of the heel.[18] The nerve and artery then become superficial and more accessible as they curve behind and underneath the sustentaculum tali, a bony ridge on the calcaneus about 2–3 cm below the medial malleolus. The nerve then divides into medial and lateral plantar nerves.[2]

The deep peroneal nerve passes lateral to the anterior tibial artery, extensor hallucis longus, and tibialis anterior tendons, and medial to the extensor digitorum longus tendon, deep to the extensor retinaculum. It becomes more superficial to travel

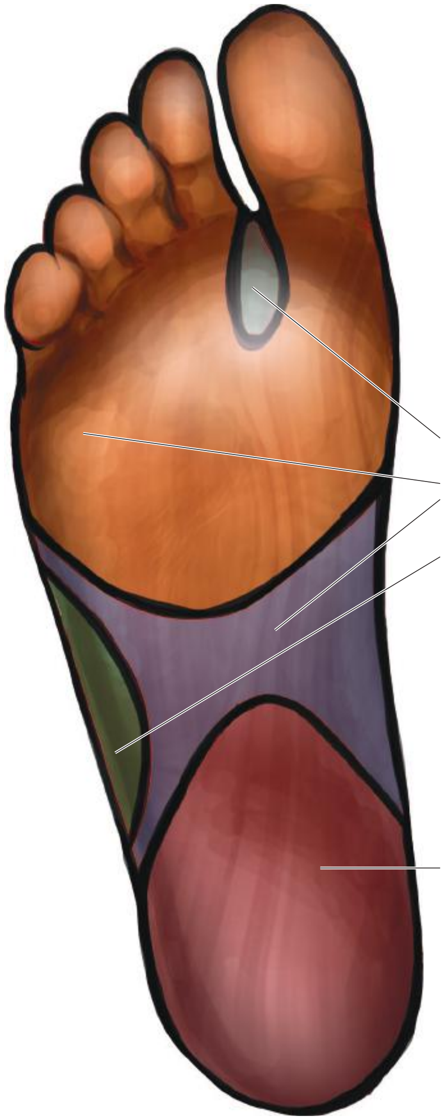

FIGURE 82F–1. Sensory innervation of the sole of the foot.

with the dorsalis pedis artery on the dorsum of the foot, where it is easily accessible.

Sensory innervation of the foot is highly variable. For example, in a study of 100 patients, 40% had the sural nerve extend medially to involve the fourth toe, and 10% had the saphenous nerve extend distally to involve the first metatarsophalangeal joint and occasionally the great toe.[18]

Because the deep structures of the foot are supplied by the deep peroneal and posterior tibial nerves and because cutaneous innervation is variable, it has been suggested that all five nerves should be blocked for any foot surgery, especially if a tourniquet is used.[19] The one exception would be purely cutaneous surgery without tourniquet in the distribution of the sural, saphenous, or superficial peroneal nerves.[20] Selective versus complete ankle block for forefoot surgery under ankle tourniquet demonstrated that 43% versus 89% of patients were pain free during surgery, suggesting that complete ankle block is preferable under these conditions.[12] In contrast, another study has demonstrated that saphenous nerve block is not necessary for bunion surgery in 97% of patients).[21]

FIGURE 82F–3. Saphenous nerve at the level of the ankle (*white arrow*).

Landmarks

The landmarks for ankle block are the medial and lateral malleoli, the Achilles tendon, extensor hallucis longus tendon (identified by having the patient extend the great toe) (Figure 82F–7), the posterior tibial and dorsalis pedis arteries, and the

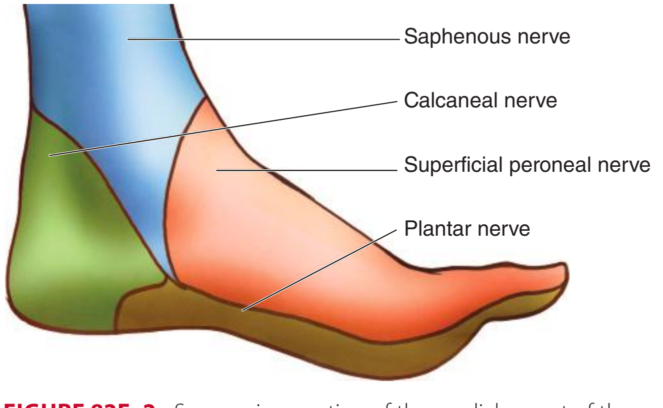

FIGURE 82F–2. Sensory innervation of the medial aspect of the foot.

FIGURE 82F–4. Sural nerve at the level of the ankle.

FIGURE 82F–5. Posterior tibial nerve at the level of the medial malleolus.

sustenaculum tali (a bony medial calcaneal ridge 2–3 cm below the malleolus).

For blockade at the level of the malleoli, the saphenous, sural, and superficial peroneal nerves are blocked with a circumferential subcutaneous injection of 10–15 mL of local anesthetic along a line just proximal to the malleoli and anterior from the Achilles tendon medially to laterally (Figures 82F–8 through 82F–10). The deep peroneal nerve is blocked by injection of 5 mL of local anesthetic just lateral to the extensor hallucis longus tendon deep to the retinaculum along the same circumferential line (Figure 82F–11). The posterior tibial nerve is blocked by injection of the same volume of local anesthetic just posterior to the posterior tibial artery if palpable, or midway between the Achilles tendon and medial malleolus deep to the retinaculum (Figure 82F–12).

For block at the midtarsal level, the saphenous, sural, and superficial peroneal nerves are blocked with a circumferential

FIGURE 82F–6. Superficial peroneal nerve. Shown is the emergence of the superficial nerve and its distribution on the dorsum of the foot. *1*, Superficial peroneal nerve; *2*, sural nerve.

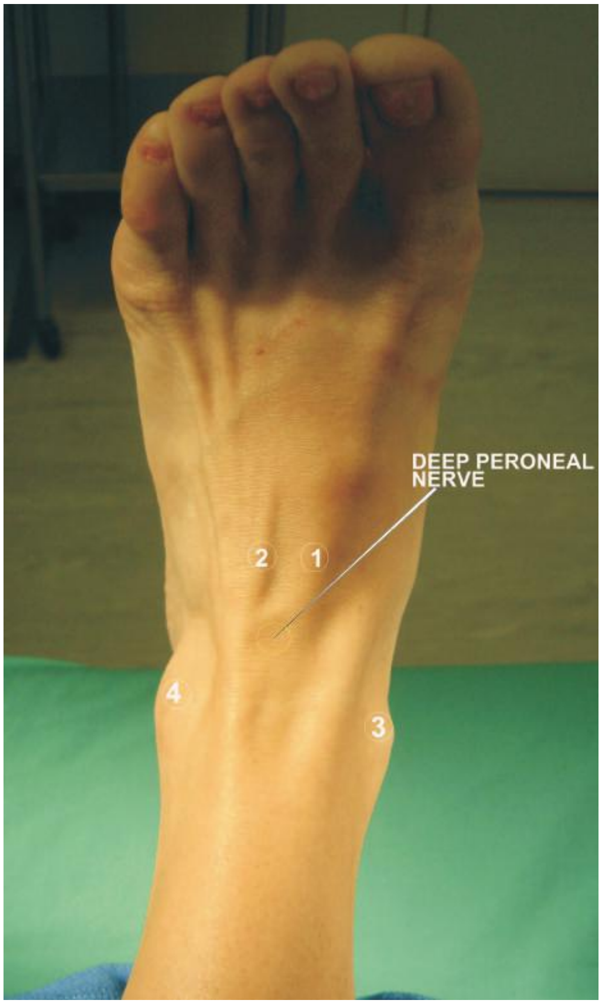

FIGURE 82F–7. Maneuver to accentuate the landmarks for the deep peroneal nerve block. *1*, Extensor hallucis longus; *2*, extensor digitorum longus; *3*, medial malleolus; *4*, lateral malleolus.

FIGURE 82F–8. Saphenous nerve block is accomplished by injection of 5 mL of local anesthetic subcutaneously at the level of the medial melleolus.

FIGURE 82F–10. Block of the sural nerve.

subcutaneous injection of 10–15 mL of local anesthetic along a line distal to the malleoli from the Achilles tendon medially to laterally. The deep peroneal nerve is blocked just lateral to the extensor hallucis longus tendon and medial to the dorsalis pedis artery. The posterior tibial nerve is blocked on either side of the posterior tibial artery (if palpable).

Equipment

No special equipment other than disinfectant, gauze, and 10-mL syringes with 1.5-in., 25-gauge needles is required for ankle block. Although nerve stimulation is not necessary for distal approaches, it has been described for the proximal approach to the posterior tibial nerve.[22]

If a tourniquet is required for surgery, a pneumatic ankle tourniquet should be used rather than an Esmarch bandage, because pressures with the latter are variable, are unknown, and may be extremely high, up to 380 mm Hg.[23,24]

Tourniquet pressures just above the malleoli between 200 and 250 mm Hg should ensure a bloodless field and maximize safety.[25,26] Ankle tourniquets are tolerated better than those placed at the midcalf or thigh, with less pain and no increase in neurologic complications.[27–30] An audit of 1000 cases of ankle block revealed that with proper tourniquet application and the option of sedation, only 3.1% of patients complained of tourniquet pain. Risk factors for tourniquet pain were age over 70 and tourniquet times greater than 30 minutes.[30]

FIGURE 82F–9. Superficial peroneal block.

FIGURE 82F–11. Block of the deep peroneal nerve.

FIGURE 82F–12. Block of the posterior tibial nerve.

Clinical Pearl

- Always ensure that when a tourniquet is required, a padded ankle tourniquet is used to maximize patient comfort, minimize sedation, and prevent general anesthesia.

Technique

There are several techniques for performing ankle block; they can be classified as *perimalleolar* or *midtarsal* (inframalleolar) blocks. The location of the block determines the procedures that can be done; forefoot surgery is easily accomplished under a midtarsal block, but midfoot and more proximal foot surgery require a perimalleolar block. Success rates are higher with the midtarsal technique because the deep peroneal and posterior tibial nerves are more superficial, so this technique is preferable for forefoot surgery.[2,3]

For all approaches, the patient can be supine, with a pillow under the calf to facilitate access.

Saphenous, Superficial Peroneal, and Sural Nerve Blocks

The saphenous, superficial peroneal, and sural nerves are already subcutaneous just proximal to the malleoli, and all can be blocked by a subcutaneous ring of local anesthetic at this location from just anterior to the Achilles tendon medially to laterally (see Figures 82F–8 through 82F–10). The advantage of blocking these nerves here is that the area under an ankle tourniquet will be anesthetized and tourniquet pain is less likely. By injecting slowly and continuously advancing a 1.5 -in., 25-gauge needle into the previously injected area, the number of injections and discomfort from them can be minimized. This subcutaneous ring of local anesthetic can also be performed distal to the malleoli for a midtarsal block.

Deep Peroneal Nerve Block

For the perimalleolar approach, the patient is asked to extend the great toe, which will tense and identify the extensor hallucis tendon (see Figure 82F–7). A 1.5-in., 25-gauge needle is inserted immediately lateral to the tendon, perpendicular to the tibia, and is advanced until it contacts bone (see Figure 82F–11). The needle is then withdrawn a few millimeters, and after negative aspiration, 5 mL of local anesthetic is injected.

For the midtarsal approach, the extensor hallucis tendon is identified as mentioned above, but more distally, and the pulse of the dorsalis pedis artery is identified on the top of the foot as well. A 1.5-in., 25-gauge needle is inserted immediately lateral to the tendon and medial to the artery, and after negative aspiration, 5 mL of local anesthetic is injected.

Posterior Tibial Nerve Block

For the perimalleolar approach, a 1.5-in., 25-gauge needle is inserted just posterior to the pulse of the posterior tibial artery behind the medial malleolus, or if it cannot be palpated, midway between the Achilles tendon and the posterior aspect of the medial malleolus (see Figure 82F–12). The needle is directed toward the tibia at a 45-degree angle to contact bone. The needle is then withdrawn a few millimeters, and after negative aspiration, 5 mL of local anesthetic is injected.

For the midtarsal approach, there are two approaches. Either the posterior tibial artery is identified below and distal to the medial malleolus on the calcaneus, or the sustentaculum tali is identified. The needle is directed toward the calcaneus, slightly under the bony shelf of the sustentaculum tali, or on either side of the tibial artery. After contact with bone, the needle is withdrawn 2 mm, and 5 mL of local anesthetic is injected.

Clinical Pearl

- Because the posterior tibial artery is not palpable in all individuals, the sustentaculum tali is a more consistent, easily palpable landmark for posterior tibial nerve block.

MAYO BLOCK

Clinical Anatomy

The Mayo block is a combination of the nerve block and a field block that involves the infiltration of local anesthesia through the tissues proximal to a surgical site in a ring shape around the first metatarsal (most commonly) or a lesser metatarsal base.[30] When the Mayo block is used around the first metatarsal base, the nerves that are anesthetized include the medial dorsal cutaneous nerve and the deep peroneal nerve on the dorsal aspect. The first and second branches of the common plantar digital nerves, which are superficial branches of the medial plantar nerve, provide sensation to the plantar aspect of the first metatarsal.

Indications

The Mayo block is commonly used in podiatric office surgery to anesthetize the area before performing bunion or hallux surgery. The injection can be used with or without epinephrine.

Technique

The Mayo block consists of three or four separate injections. The block is performed by raising a wheal of local anesthetic proximally and dorsally in the first intermetatarsal space and advancing the needle in the plantar direction while injecting 3–5 mL of local anesthetic (Figure 82F–13). The needle is then withdrawn partially and redirected medially, raising a subcutaneous wheal along its course (3–5 mL) (Figure 82F–14). The needle is then removed and reentered and directed laterally to raise a subcutaneous wheal along the course (3–5 mL) (Figure 82F–15). Finally, the needle is removed and directed plantar-medially to the metatarsal and injected from medial to lateral underneath the metatarsal bone (3–5 mL) (Figure 82F–16). The block encircles the entire metatarsal bone.

Choice of Local Anesthetic

The decision regarding which local anesthetic solution to use depends on the anticipated duration of surgery and the degree of postoperative pain. Commonly used solutions include lidocaine 2% for shorter, less painful procedures and ropivacaine 0.5% for longer or more painful procedures.

FIGURE 82F–13. Mayo block, step 2. After a wheal of local anesthesia is raised at the level of the first intermetatarsal space, the needle is advanced in the plantar direction and 3–5 mL of local anesthetic is injected. (Arrow, First metatarsal bone; X, first metatarsal space.)

FIGURE 82F–14. Mayo block, step 1. The needle is entered subcutaneously dorsomedially raising a wheal along the course. (Arrow, First metatarsal bone; X, first metarsal space.)

Blood levels of plain local anesthetic are well below toxic levels, even when large amounts are used. Bilateral midtarsal blocks performed with up to 30 mL of plain 0.75% bupivacaine resulted in peak venous blood levels of 0.5 mcg/mL^{-1}, whereas 13 mL of 2% lidocaine for unilateral block resulted in 1.1 mcg/mL.[−19] No adverse local anesthetic effects were reported in a series of 66 patients receiving bilateral ankle blocks with mixtures of plain lidocaine and ropivacaine 0.75%, ropivacaine 0.75% or ropivacaine 0.75% with clonidine 1 mcg/kg.[−16] The addition of epinephrine with ankle block remains controversial. The preponderance of the literature suggests that epinephrine should not be used in distal extremity local anesthesia.[31,33] However, low concentrations of epinephrine in local anesthetic solutions have been used with remarkable safety.[33] The overall incidence of severe vascular complications after injection of epinephrine-containing local anesthetics has been estimated to be 1 per 132,000 injections.

FIGURE 82F–15. Mayo block, step 3. The needle is directed medial to lateral subcutaneously and 3–5 mL is injected. (Arrow, First metatarsal bone; X, first metarsal space.)

FIGURE 82F–16. Mayo block, step 4. The needle is directed medial to lateral and plantar underneath the metatarsal bone while injecting 3–5 mL of local anesthetic. (Arrow, First metatarsal bone; X, first metarsal space.)

Note that the use of 1:100,000 solutions of epinephrine has a 2.5 greater risk of complications compared with 1:200,000, suggesting that when epinephrine is indicated, it should be used only as dilute concentrations (i.e., 1:300,000 or less). Regardless, epinephrine is probably best avoided altogether in patients with peripheral vascular disease or compromised circulation.

The high-efficacy, prolonged postoperative analgesia and safety of plain bupivacaine and ropivacaine suggest that these drugs should be the choice for surgery in which postoperative pain is expected. However, blocks should be performed 30 minutes before surgery (minimum of 20 minutes) when using bupivacaine or ropivacaine to maximize success rate. In a prospective analysis of 1000 patients, the failure rate was significantly lower after waiting 20 minutes after the injection, with the lowest failure rates occurring after 50 minutes.[7]

Clinical Pearl

- When using ropivacaine or bupivacaine, perform the block at least 30 minutes before surgery to allow adequate time for block onset.

PERIOPERATIVE MANAGEMENT

Because performing an ankle block requires more than one injection and requires subcutaneous infiltration, it can cause more discomfort than single-injection blocks. In addition to gentle, slow injection, patients usually benefit from anxiolysis and analgesia with midazolam 1–4 mg and fentanyl 25–100 mcg. Before starting surgery, the block should be checked in all five nerve distributions, and supplemental local anesthetic can be injected if necessary.

Tourniquets should have a soft lining or padding and should be placed just above the malleoli. Ankle tourniquets are tolerated better than those placed at the midcalf or thigh, with less pain and no increase in neurologic complications.[27–30] An audit of 1000 cases of ankle block revealed that with proper tourniquet application and the option of sedation, only 3.1% of patients complained of tourniquet pain.[30]

Supplementation by the surgeon intraoperatively may rescue an incomplete block.

Postoperatively, acetaminophen and a nonsteroidal anti-inflammatory drug (NSAID) can be continued routinely. Depending on the extent and type of surgery, small doses of a long-acting opioid such as controlled-release oxycodone may provide a smooth transition from block to postoperative analgesia and may facilitate rehabilitation.[34] Ambulation with crutches is possible right after surgery. Elevation of the leg, when not ambulating, may further decrease postoperative pain.

COMPLICATIONS AND HOW TO AVOID THEM

Because most surgery is done under tourniquet, it is difficult to differentiate the cause of neurologic complications. In a retrospective study of 3027 patients with pneumatic ankle tourniquet at relatively high pressures of 325 mm Hg, there were three cases (0.1%) of posttourniquet syndrome.[29] Ankle tourniquets have been used routinely with as little as 200 mm Hg pressure,[5] although a bloodless surgical field may require 218.6 ± 34.6 mm Hg, with younger normotensive patients requiring only 203.9 ± 22.3 mm Hg.[26] Thus, no more than 250 mm Hg pressure is necessary, and more pressure may be harmful.

The incidence of complications after ankle block is low and is usually in the form of transient paresthesias, which almost always resolve. The incidence is usually less than 1%, although it ranges from 0%–10%, depending on the source of the data. Complications may occur from injection or from application of the tourniquet. In a prospective survey of 284 patients with posterior tibial, sural, and saphenous blocks at the ankle and common peroneal block at the knee, no patient developed postanesthetic neuralgia or other complications. In three other studies with a total of 120 patients who received ankle blocks, no patients developed complications.[2,5,10] After midtarsal ankle block in 71 of 100 patients available for follow-up, 1 patient developed transient posterior tibial paresthesias, which resolved in 4 weeks.[3] In another study of 40 patients, 1 developed paresthesias lasting 6 weeks, which resolved.[1] In a retrospective study of 1373 patients who received ankle block followed by a posterior tibial nerve catheter for postoperative analgesia, 5 patients had transient paresthesias, with 1 patient developing neurolysis (probably related to the catheter insertion) but with complete recovery.[22] In a prospective randomized trial of 32 patients (40 total feet) undergoing forefoot surgery under ankle tourniquet (inflation pressure 100 mm Hg over systolic) under complete or selective ankle block of which 26 patients (33 total feet) were available for follow-up to injection or tourniquet, 1 had ankle pain, and 1 had cold toes.[8]

Local anesthetic systemic toxicity would be expected to be rare, given the low blood levels after injection. In the retrospective series of 1373 patients previously mentioned, 1 patient had a convulsion, thought to be secondary to an intravascular injection.[22] In another series of 1295 patients who received standard and modified ankle blocks as well as digital nerve blocks, 3 patients had vasovagal reactions and 1 had an episode of hypotension and supraventricular tachycardia, thought by the investigators to be from lidocaine toxicity. No other complications were seen in this series.[4]

There are single case reports of injection-related complications such as an Achilles tendon avulsion from tibial nerve block in a patient with spastic talipes equinovarus,[13] and acute compartment syndrome from ankle block in a patient with previous scarring from forefoot arthroplasty.[32]

Both of these patients had an altered anatomy, which may have predisposed them to the complication.

Clinical Pearls

- Ensure that the patient's anatomy is normal before injection and avoid injecting in scarred or swollen areas.
- Avoid injection of large volumes; most ankle blocks can be performed with less than 30 mL of local anesthetic.
- There should be no resistance to injection at any time. If there is, stop the injection and reposition the needle.

CHAPTER 82G

Cutaneous Nerve Blocks of the Lower Extremity

Jerry D. Vloka and Luc Van Keer

INTRODUCTION

Blocks of the lateral femoral cutaneous, posterior femoral cutaneous, saphenous, sural, and superficial peroneal nerves are useful anesthetic techniques for a variety of superficial surgical procedures and carry a low risk of complications.[1,2]

Indications and Contraindications

The lateral femoral cutaneous nerve block has been used to provide anesthesia for pediatric patients undergoing muscle biopsy[3] and to provide analgesia after femoral neck surgery in older patients.[4,5] The posterior femoral cutaneous nerve block is used for any surgical procedure performed on the posterior aspect of the thigh.[6] The saphenous, sural, and superficial peroneal nerve blocks can be used as part of an ankle block to provide complete anesthesia to the foot and ankle, or they can be used separately to provide anesthesia to specific portions of the foot and ankle.

The contraindications to performing cutaneous nerve blocks of the lower extremity are few, but include local infection at the sites of needle insertion, and allergy to local anesthetic.

Functional Anatomy

The cutaneous nerves of the extremities are blocked by injection of local anesthetic in the subcutaneous layers above the muscle fascia. The subcutaneous tissue contains a variable amount of fat, superficial nerves, and vessels. Deep to this area lies a tough membranous layer, deep fascia of the lower extremity enclosing muscles of the leg. This deep fascia is penetrated by numerous superficial nerves and vessels.

The cutaneous innervation of the lower extremity is accomplished by nerves that are part of the lumbar and sciatic plexuses (Figures 82G–1 and 82G–2). A more detailed review of the relevant anatomy is provided with a description of the individual block procedures in Chapter 3.

Choice of Local Anesthetic

Any local anesthetic can be used for cutaneous blocks of the lower extremity; the choice is based primarily on the desired duration of blockade. Because these blocks do not result in motor block, longer-cting local anesthetics are most commonly chosen (e.g., 0.2%–0.5% ropivacaine or 0.25%-0.5% bupivacaine). When performing blocks in the ankle area, it is always prudent to avoid using epinephrine owing to the risk of decreasing blood flow to the toes. Onset time for the block depends on the local anesthetic used[7] (Table 82G–1).

LATERAL FEMORAL CUTANEOUS NERVE BLOCK

General Considerations

This block can be used to provide complete anesthesia in patients undergoing skin graft on the lateral aspect of the thigh, or it can be combined with femoral block[8–10] or sciatic block. Its use has also been reported as a diagnostic tool for meralgia paresthetica, neuralgia of the lateral femoral cutaneous nerve of the thigh.

Distribution of Anesthesia

The lateral femoral cutaneous nerve provides sensation to the anterolateral aspect of the thigh (see Figure 82G–1). In some patients however, the nerve can provide surprisingly large innervation territory of the anterior thigh as well.

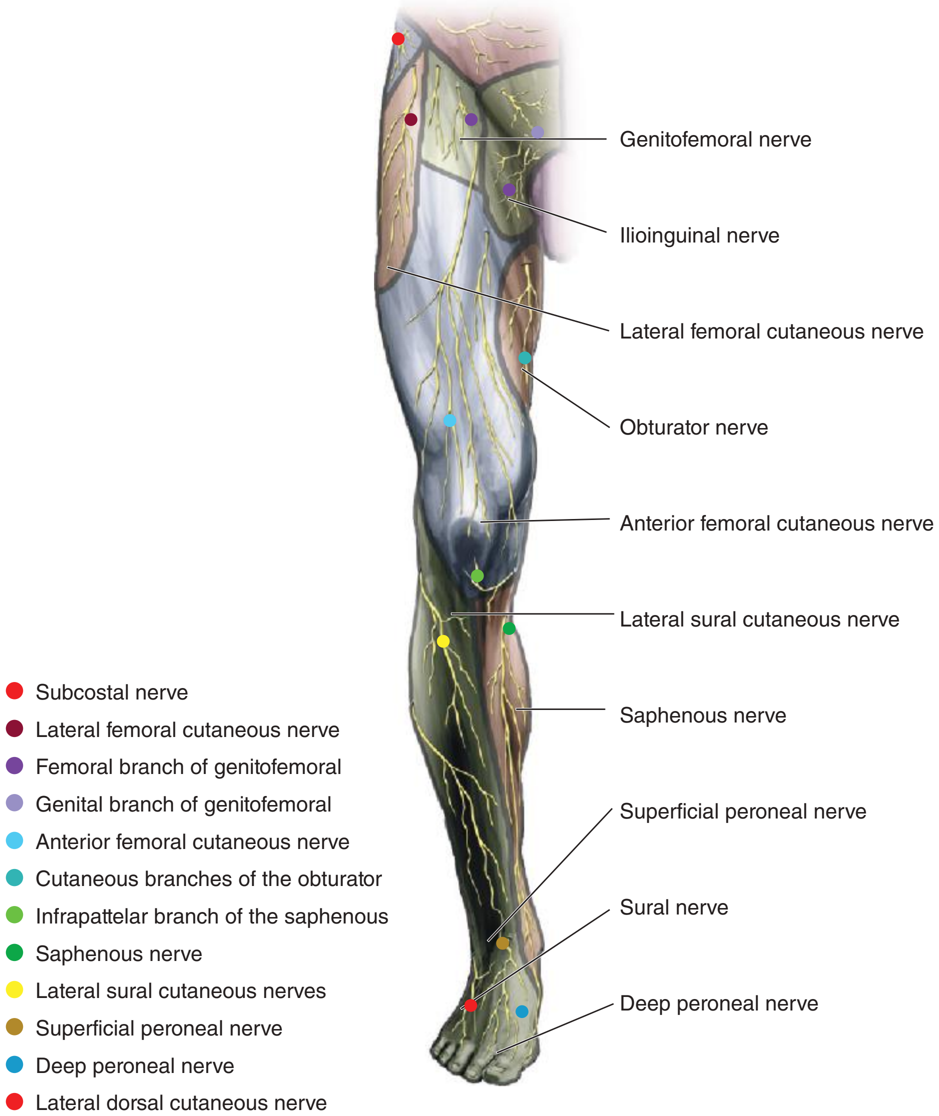

FIGURE 82G–1. Cutaneous innervation of the lower extremity, anterior view.

Patient Positioning

The patient is in a supine position and the anterior superior iliac spine is palpated and marked.

Anatomic Landmarks

The main landmark for lateral femoral cutaneous nerve blockade is the anterior superior iliac spine. The lateral femoral cutaneous nerve emerges from the lateral border of the psoas major muscle and crosses the iliacus muscle obliquely toward the anterior superior iliac spine, where it supplies the parietal peritoneum of the iliac fossa. The nerve then passes into the thigh behind or through the inguinal ligament, variably medial to the anterior iliac spine (typically about 1 cm) or through the tendinous origin of the sartorius muscle, dividing into anterior and posterior branches.

The anterior branch becomes superficial about 10 cm distal to the anterior superior iliac spine supplying innervation to the skin of the anterior and lateral thigh as far as the knee. It connects terminally with the cutaneous branches of the anterior division of the femoral nerve and the infrapatellar branch of the saphenous nerve, forming the patellar plexus. The posterior branch pierces the fascia lata higher than the anterior, dividing to supply the skin on the lateral surface from the greater trochanter to about the middle of the thigh and occasionally also supplying the gluteal skin.

Technique

A 22-25 gauge needle is inserted 2 cm medial and 2 cm distal to the anterior superior iliac spine (Figure 82G–3). The needle is advanced until a loss of resistance or a “pop” is felt as the needle passes through the fascia lata. Because this fascia “give” is not consistent and its perception may vary among practioners, local anesthetic is injected in a fanwise fashion both above and below the fascia lata from medial to lateral. A volume of 10 mL of local anesthetic is injected for this block. Although the lateral femoral cutaneous nerve is a sensory nerve, relatively higher

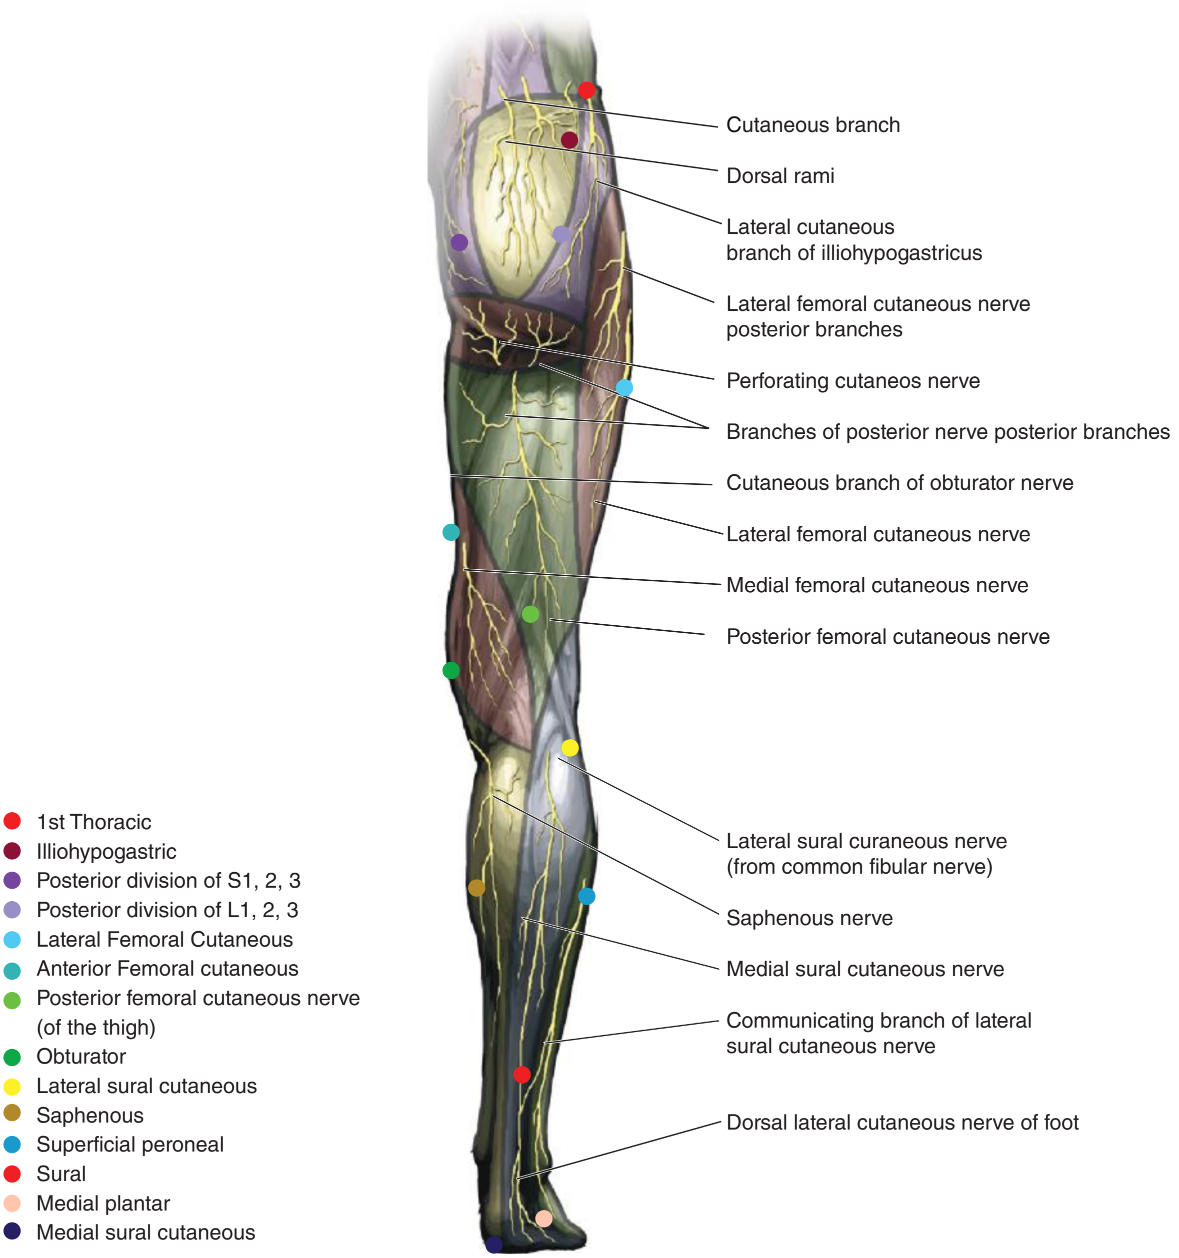

FIGURE 82G–2. Cutaneous innervation of the lower extremity, posterior view.

TABLE 80G–1. Choice of anesthetic for cutaneous nerve block of the lower extremity.

	Onset (min)	Anesthesia (h)	Analgesia (h)
1.5% Mepivacaine	15–20	2–3	3–5
2% Lidocaine	10–20	2–5	3–8
0.5% Ropivacaine	15–30	4–8	5–12
0.75% Ropivacaine	10–15	5–10	6–24
0.5% (L) Bupivacaine	15–30	5–15	6–30

concentrations of long-acting local anesthetic are useful to increase the success rate (0.5% ropivacaine or bupivacaine) because this is essentially a "blind" technique. Alternatively, nerve stimulator (2 mA, 1msec) can be used to elicit paresthesia sensation in the typical distribution of the nerve to assure its location.

When used to provide anesthesia for a skin graft harvest site on the lateral thigh, the peripheral innervation of the lateral femoral cutaneous nerve in specific patients is outlined before beginning skin harvesting.

Because no larger vascular structures or other organs are nearby, blockade of the lateral femoral cutaneous nerve carries a minimal risk of complications.

FIGURE 82G–3. Lateral femoral cutaneous nerve block. The landmark for this block is the anterior superior iliac spine.

POSTERIOR CUTANEOUS NERVE OF THE THIGH BLOCK

General Considerations

This block has been used in burn patients with donor skin for grafting taken from the posterior thigh or as part of a popliteal/posterior femoral cutaneous nerve block in short saphenous vein stripping.[11]

Distribution of Anesthesia

The posterior cutaneous nerve of the thigh innervates the skin over the posterior thigh between the lateral femoral cutaneous and anterior femoral cutaneous nerves (see Figure 82G–2).

Patient Positioning

The patient can be positioned prone, in the lateral decubitus position (shown in Figures 82G–4 and 82G–5), or supine with the leg elevated 90 degrees.

Anatomic Landmarks

The posterior femoral cutaneous nerve originates from the dorsal branches of the first and second sacral rami and from the ventral branches of the second and third sacral rami.

FIGURE 82G–4. Posterior cutaneous nerve of the thigh block, subgluteal approach.

It runs through the greater sciatic foramen below the piriformis and descends under the gluteus maximus muscle with the inferior gluteal vessels, posterior or medial to the sciatic nerve. The nerve then descends in the back of the thigh deep to the

FIGURE 82G–5. Posterior cutaneous nerve of the thigh block, midthigh approach.

fascia lata. Its branches are all cutaneous and are distributed to the gluteal region, the perineum, and the flexor aspect of the thigh and leg.

Technique

The gluteal fold is identified and 10 mL of local anesthetic is injected subcutaneously to raise a skin wheal (see Figure 82G–4). In addition, at the midpoint of the gluteal crease, 5 mL of local anesthetic is injected at a deeper level, using a fan technique to reach the nerve that has not emerged through the deep fascia.

To block the posterior cutaneous nerve of the thigh above the knee level, as for short saphenous vein stripping (as a complement to popliteal block),[11] 10 mL of local anesthetic is injected subcutaneously along a line 5 cm above and parallel with the popliteal crease (see Figure 82G–5).

SAPHENOUS NERVE BLOCK

General Considerations

The saphenous nerve block is most commonly used in combination with a sciatic nerve block or popliteal block to complement anesthesia of the lower leg for various vascular, orthopedic, and podiatric procedures. The saphenous nerve is a terminal cutaneous branch of the femoral nerve. Its course is in the subcutaneous tissue of the skin on the medial aspect of the ankle and foot. All cutaneous nerves of the foot should be thought of as a neuronal network rather than well defined innervation territories of specific nerves.

Distribution of Anesthesia

The saphenous nerve innervates the skin over the medial, anteromedial, and posteromedial aspects of the lower leg from above the knee (part of the patellar plexus) to as low as the first metatarsophalangeal joint in some instances (Figures 80G–1 and 80G–7).

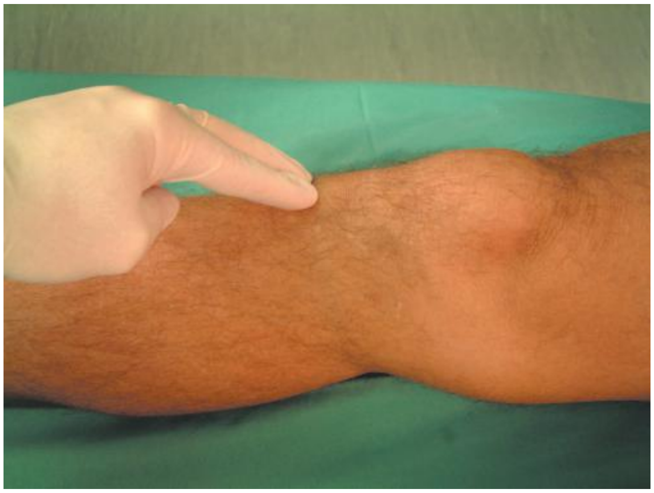

FIGURE 82G–6. Tibial tuberosity. Palpation of the landmark for the saphenous nerve block.

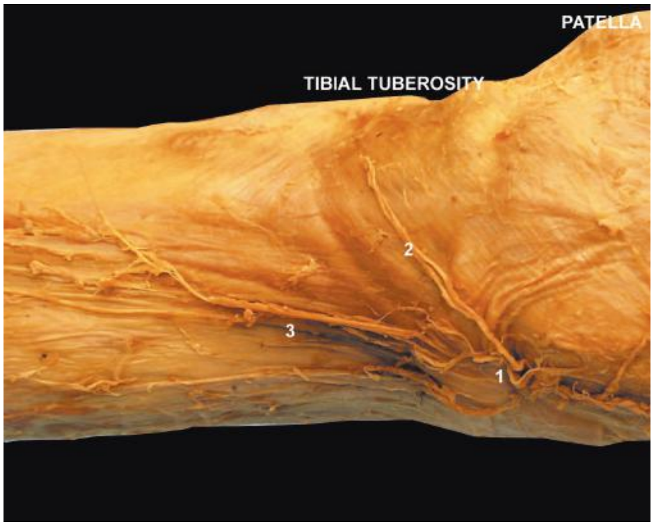

FIGURE 82G–7. Saphenous nerve anatomy. Saphenous nerve pierces through the sartorius muscle (1), subpatellar branch (2), saphenous nerve in its descent on the medial aspect of the thigh (3).

Patient Positioning

The patient is placed supine with the leg to be blocked supported by a footrest.

Anatomic Landmarks

The main landmark for this block is the tibial tuberosity, an easily recognizable and palpable bony prominence on the anterior aspect of the tibia, a few centimeters distal from the patella (Figure 82G–6). The saphenous nerve is the largest cutaneous branch of the femoral nerve. It descends lateral to the femoral artery into the adductor canal, where it crosses anteriorly to become medial to the artery. It proceeds vertically along the medial side of the knee behind the sartorius, pierces the fascia lata between the tendons of the sartorius and gracilis, and then becomes subcutaneous. From here, it descends on the medial side of the leg with the long saphenous vein. Note that the saphenous nerve divides into numerous small branches as it enters the subcutaneous space, and, as such, it is often difficult to achieve block of the entire extensive saphenous nerve network.

Techniques

The below-knee field block is performed with the patient in thesupine position. Five to 10 mL of local anesthetic is injected as a ring deeply subcutaneously, starting at the medial surface of the tibial condyle and ending at the dorsomedial aspect of the upper calf (Figure 82G–8).

A perivenous technique has also been described, which is based on the close relation of the saphenous vein and nerve, to achieve a higher success rate. First, the saphenous vein is identified using a tourniquet around the leg in dependent position. The technique involves injection of 5 mL of local anesthetic in a fanlike fashion around the vein on the medial side of the leg just distal from the patella.[12] This technique, however, carries a small risk of creating a hematoma if the saphenous vein is punctured.

FIGURE 82G–8. Saphenous nerve block. Shown is a subcutaneous injection of 10 mL of local anesthetic in a circumferential fashion on the medial aspect of the leg at the level of the tibial tuberosity.

In the transsartorial approach, with the patient in the supine position, a skin wheal is raised over the sartorius muscle belly. The sartorius muscle can be palpated just above the knee with the leg extended and actively elevated. The needle is inserted at 1 finger-width above the patella slightly posterior to the coronal plane and slightly caudad through the muscle belly of the sartorius until a loss of resistance identifies the subsartorial adipose tissue. The depth of insertion is typically between 1.5 and 3.0 cm. After negative aspiration for blood, 10 mL of local anesthetic is injected.

For surgery on the foot, the saphenous nerve is best blocked just above the medial malleolus, similar to the technique in ankle block (Figure 82G–9). Using a 1.5-in. needle, 6–8 mL of local anesthetic is injected subcutaneously immediately above the medial malleolus in a ring-like fashion. The most commonly reported complication of this block is a hematoma of the saphenous vein at the injection site.

The saphenous nerve can also be blocked by using a nerve stimulator technique and performing a low-volume femoral nerve block (see Chapter 82C). Injection of 10 mL of local anesthetic after obtaining either a medial muscle response, signified by contraction of the vastus medialis muscle, or an anterior muscle response, signified by contraction of the rectus femoris muscle and elevation of the patella, results in a high rate of block success.[13,14] Neurostimulation of the medial compartment of the femoral nerve requires even less volume of local anesthetic, compared with that of a standard femoral block.[15]

FIGURE 82G–9. Saphenous nerve block, distal approach above the medial malleolus.

Clinical Pearls

- The most effective method of blocking the saphenous nerve is a low-volume femoral nerve block.
- Injection of 10 mL of local anesthetic upon obtaining twitches of the patella or vastus medialis muscle results in a high success rate.

In a comparison of the different approaches to saphenous nerve block, the transsartorial approach resulted in 100% sensory blockade of the medial aspect of the leg, whereas the perifemoral and the below-knee field block were successful only in 70%. The medial femoral condyle block resulted in 40% of the patients having sensory blockade of the medial aspect of the leg with only 25% having complete anesthesia at the medial malleolus.[16] This supported the findings of a previous study in which 94% of patients had complete anesthesia of the medial malleolus after a transsartorial saphenous nerve block.[17] However, saphenous nerve often does not reach the level of the medial malleolus.[18] The introduction of ultrasound-guided techniques and several studies supporting its use as an alternative to femoral block for total knee arthroplasty have greatly increased the interest in the transsartorial (or "adductor canal") approach to the saphenous nerve.[19,20]

SURAL NERVE BLOCK

General Considerations

The sural nerve block is used for superficial surgery on the lateral aspect of the ankle and foot and in conjunction with ankle block for foot and toe surgery.

Distribution of Anesthesia

The sural nerve innervates the posterior and lateral skin of the distal third of the leg along the lateral side of the foot and little toe (see Figure 82G–1).

Patient Positioning

For the block procedure, the patient can be positioned prone or supine with the ankle supported by a footrest.

Anatomic Landmarks

The sural nerve, a branch of the tibial nerve, pierces the deep fascia proximally in the leg and is joined by a branch of the common peroneal nerve. It descends near the lesser saphenous vein and between the lateral malleolus and the calcaneus.

Technique

Using a 1.5-in., 25-gauge needle, a skin wheal is raised lateral to the Achilles tendon and just above the lateral malleolus (Figure 82G–10). The needle is then inserted through the wheal and advanced toward the fibula while injecting 6–8 mL of local anesthetic.

FIGURE 82G–10. Sural nerve block.

SUPERFICIAL PERONEAL BLOCK

General Considerations

A superficial peroneal block is used alone or in combination with other blocks for foot surgery or ascending venography.[21,22]

Distribution of Anesthesia

The superficial peroneal branches supply innervation to the dorsal skin of all the toes except that of the lateral side of the fifth and adjoining sides of the first and second toes (see Figures 82G–1 and 82G–2).

FIGURE 82G–11. Superficial peroneal block.

Anatomic Landmarks

The superficial peroneal nerve begins at the common peroneal bifurcation. It pierces the deep fascia in the distal third of the leg. It descends the leg adjacent to the extensor digitorum longus muscle, where it divides into terminal branches above the ankle.

Patient Positioning

For the block procedure, the patient can be positioned supine with the ankle supported by a footrest.

Technique

The superficial peroneal nerve is blocked immediately above and medial to the lateral malleolus. 5–10 mL of local anesthetic is injected to form a subcutaneous wheal from the extensor hallucis longus tendon to the anterior surface of the lateral malleolus (Figure 82G–11).

COMPLICATIONS

Few complications result from performing cutaneous nerve blocks of the lower extremity. Possible complications and suggestions for how to avoid them are outlined in Table 82G–2.

SUMMARY

There are many uses for cutaneous nerve blocks of the lower extremity in everyday clinical practice. These blocks are easy to perform and are nearly devoid of complications.

TABLE 80G–2. Possible complications from cutaneous nerve blocks of the lower extremity.

Systemic toxicity of local anesthetic	• Risk is small and may be of concern only when higher volumes are used in conjunction with other high-volume major conduction blocks
Hematoma	• Avoid multiple needle insertions and insertion of the needle through superficial veins
Nerve injury	• Usually manifested as transient paresthesias or dysesthesias • Avoid injecting when high pressures on injection are felt or when the patient reports pain in the distribution of the nerve

European Recommendations for Use of Regional Anesthesia in the Setting of Anticoagulation

Luc Van Keer, Dimitri Dylst, and Ine Leunen

Abbreviations Table 1A and B:

ACT: Activated clotting time
ACS: Acute coronary syndrome
Afib: Atrial fibrillation
Anesth.: Anesthesia
aPTT : Activated partial thromboplastin time
ASA: Acetylsalicylic acid
ATE: Arterial thromboembolism
BMS: Bare metal stent
COX: cyclooxygenase
CrCl : Creatinine clearance
CV: CHA_2DS_2-VASc
CVA: Cerebral vascular accident
CYP3A4: Cytochrome P450 3A4
DES: Drug eluting stent
DVT: Deep venous thrombosis
GP IIb-IIIa: glycoprotein IIb-IIIa
HB: HAS-BLED score
ICD: implantable cardioverter defibrillator
INR: International normalized ratio
IV: Intravenous
LMWH: Low molecular weight heparin
NOACs: New oral anticoagulants
OBR: Intra operative bleeding risk
Prim.: primary
PCI: Percutaneous coronary intervention
PE: Pulmonary embolism
P-gp: P-glycoprotein
PT: Prothrombin time
Prev.: prevention
PO: Per Os
RA: Regional anaesthesia
SC: Subcutaneous
Sec.: secondary
TER: Thrombo embolic risk
TIA: Transient ischemic attack
UFH: Unfractionated heparin
VKA: Vitamin K antagonist
VTE: Venous thromboembolism

⊗ time interval between drug stop and procedure
⊙ time interval to restart the drug after procedure

TABLE 1–1A. Overview of antiplatelet agents and anticoagulants with clinically useful information about dosage and perioperative management of patients using this type of drug. The overview was composed from a perspective of medical practice in western europe (Belgium).

Product (T½ in Hours)	Brand Name	Normal Dose	⊗	⊙	Bridging	Comments Concerning RA
COX inhibitors (ASA) PO					Don't bridge with LMWH	
Aspirin (3)	Asaflow®	Prim. prevention: 80 mg 1x/d	5 d	24 h		**Spinal anesthesia: OK**

TABLE 1–1B. Risk stratification and guide to management of patients undergoing surgical or diagnostic procedures in the presence of antiplatelet agents or new oral anticoagulants. The overview was composed from a perspective of medical practice in western europe (Belgium).

Intraoperative Bleeding Risk (OBR)

Low
- Minor dental procedures
- Superficial dermatologic procedures
- Cataract and glaucoma under topical anesth
- Diagnostic gastroscopy
- Diagnostic bronchoscopy without biopsies
- Coronarography or PCI by radial artery
- Replacement pacemaker or ICD

Standard
- Endoscopy with biopsies
- Bladder biopsy
- Phlebologic procedures
- Angiography
- Implantation pacemaker or ICD
- Coronarography or PCI by femoral artery
- Electrophysiologic examination ± ablation

High
- Neuraxial anesthesia, lumbar puncture
- Cardiac surgery
- Intracranial and spinal surgery (1)
- Thoracic and major abdominal surgery
- Peripheral and other major vascular surgery
- Hip and knee arthroplasty, cruciate ligament reconstruction
- Reconstructive and plastic surgery
- Major oncologic surgery
- Prostate and bladder surgery (2)
- Endoscopic resection of colon polyps
- Prostate, kidney, and liver biopsy
- Endoscopic sphincterotomy

Thrombophilia

Severe	Antitrombine deficiency, ≥ 2 mild thrombophilia factors, homozygous factor V Leiden or protrombine gene variant *G20210A*, antifosfolipid syndrome
Mild	Protein C or S deficiency, high factor VIII, heterozygous factor V Leiden or protrombine gene variant *G20210A*

Thrombo Embolic Risk (TER)

	Heart Valve Prosthesis	Atrial Fibrillation	Venous Thrombo Embolism
High ATE > 10%/y VTE > 10%/y	Mitral valve prosthesis, old aortic valve prosthesis (monoleaflet or ball prosthesis)	CV > 5; CVA/TIA (< 6 m) Rheumatic valve disease	DVT/PE < 3 mths Severe thrombophilia
Moderate ATE 5-10%/y VTE < 10%/y	Bileaflet aortic valve prosthesis	CV = 4 - 5 CVA/TIA > 6 m	DVT/PE 3 - 12 mths Recurrent DVT/PE Active Oncology Mild thrombophilia
Low ATE 2-5%/Y VTE < 2%/Y		CV ≤ 3 **and** no CVA/TIA	DVT/PE once > 12 mths **and** no thrombophilia

NOACs Interruption of therapy for elective surgery

If OBR = low: do not interrupt NOACs. Perform procedure 12 – 16 h after last intake. Normal dosage will be taken in the evening after surgery. NOACs should always be taken in the evening.

APPENDIX 2

Disposition of Injectate with Common Regional Anesthesia Techniques

Philippe Gautier

The outcome of regional anesthesia technique is ultimately dependent on the distribution of the local anesthetic in the relevant tissue space that contains the nerve(s) of interest. Prior to the introduction of ultrasound in regional anesthesia, our understanding of the disposition of the local anesthetic had been limited due to the lack of technology that could allow such monitoring. This addendum features studies of computed tomographic (CT) images that we painstakingly acquired by the author over a period of nearly 2 decades in attempt to elucidate the disposition of local anesthetic injections with nerve block injections and their relationship to the outcome of regional anesthesia. The maldistribution of local anesthetic associated with block failures and/or complications due to the spillage of local anesthetic to the undesired places, such as, for example, the phrenic nerv and neuraxial space are also demonstrated. A uniquely educational aspect of these images is the relationship of the volume of the injectate and its physical spread in the tissue spaces.

The all original material presented in this appendix is organized in clusters of images of distribution of local anesthetic containing radiopaque solution. In addition to images of the expected, desired distribution, the images of the maldistribution of local anesthetic are also included as well. Wherever available, images of desired distribution and maldistribution are presented in several imaging planes, as well as in three-dimensional (3D) reconstruction. Importantly, the distribution patterns presented in the images cannot be fully or reliably studied by ultrasonography; hence their relevance in the era of ultrasound-guided regional anesthesia.

CERVICAL PLEXUS BLOCK

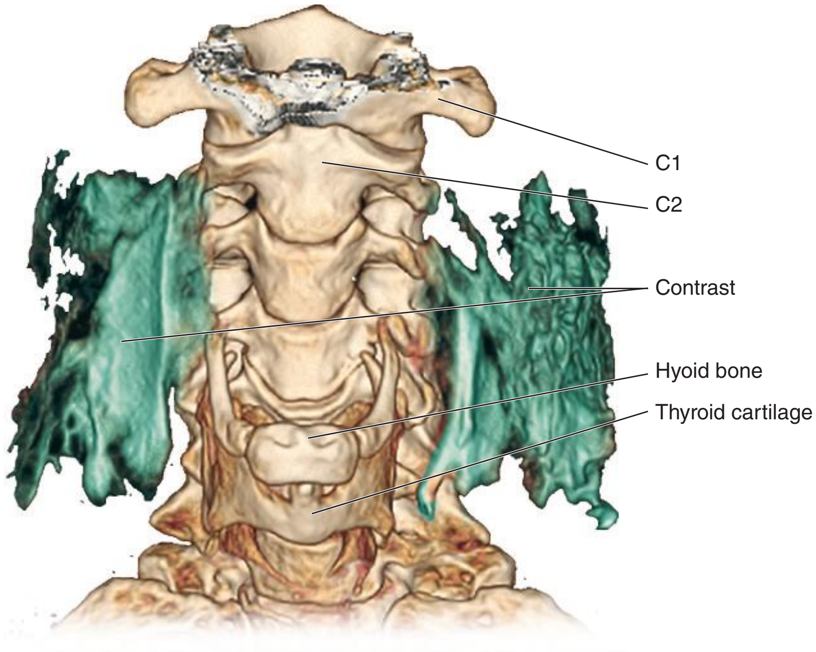

FIGURE 2–1. Five milliliers of local anesthetic solution containing radiopaque contrast was injected after insertion of the needle at the level of C4, behind the posterior aspect of the sternocleidomastoid muscle. An additional 10 mL was injected behind the sternocleidomastoid muscle. The 3D CT imaging shows bilateral distribution of the injectate from C2–C5 levels.

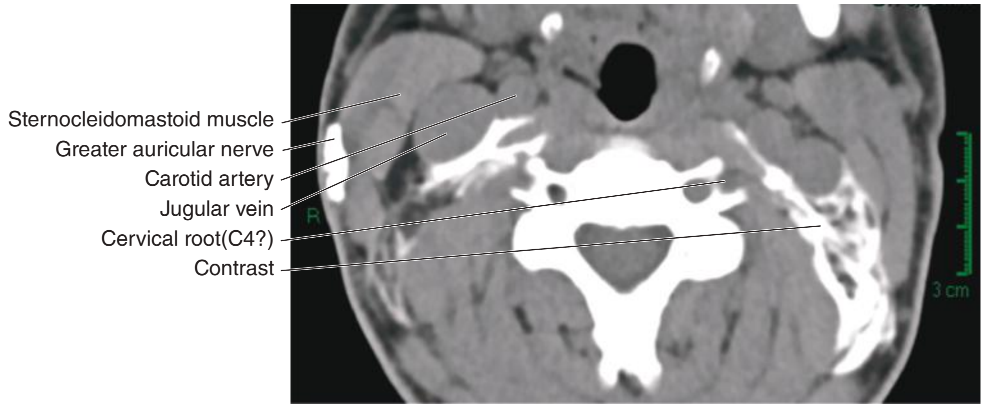

FIGURE 2–2. Injection of 15 mL of local anesthetic solution containing radi-opaque contrast behind the sternocleidomastoid muscle demonstrates substantial distribution of injectate in deeper tissue planes, resulting is contrast contacting cervical roots.

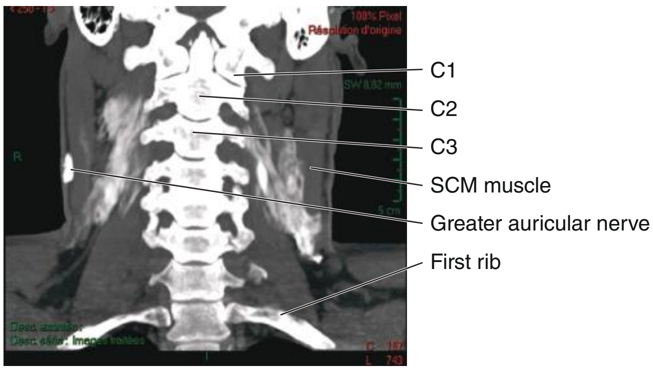

FIGURE 2–3. The same injection—frontal view. Injection of 15 mL of local anesthetic solution containing radiopaque contrast behind the sternocleidomastoid muscle demonstrates substantial distribution of injectate in deeper tissue planes, resulting is contrast contacting cervical roots.

INTERSCALENE BRACHIAL PLEXUS BLOCK

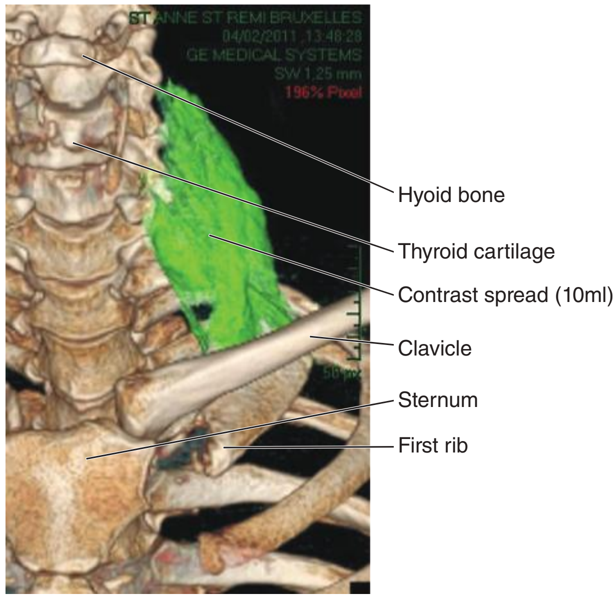

FIGURE 2–4. The image demonstrates typical contrast spread after injection of 10 mL of the solution in interscalene space for brachial plexus block. The contrast is seen spreading from C5 to the clavicle.

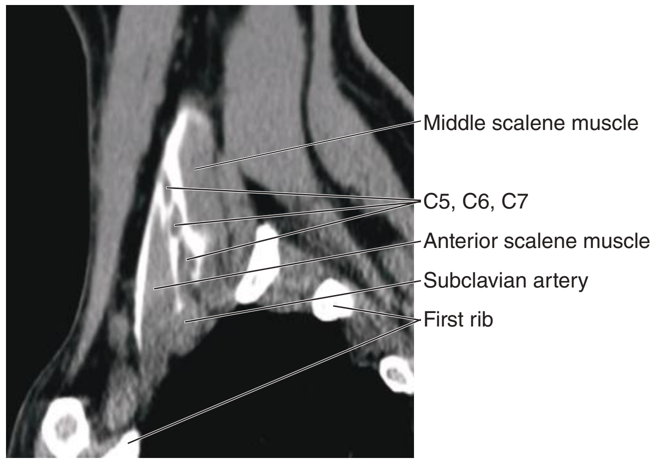

FIGURE 2–6. CT image—sagittal view of expected contrast spread after injection of 10 mL of the solution in interscalene space for brachial plexus block. The contrast is in the scalene space in contact with three roots of the brachial plexus (C5–C6). Also, the contrast is seen underneath fascia of the middle and anterior scalene muscles encountering phrenic nerve.

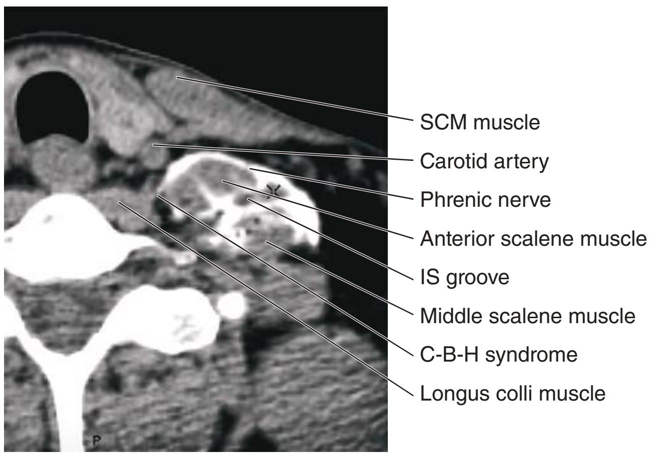

FIGURE 2–5. An axial CT image of expected contrast spread after injection of 10 mL of the solution in interscalene space for brachial plexus block. The contrast is in the scalene space in contact with three roots of the brachial plexus. Also, the contrast is seen underneath fascia of the middle and anterior scalene muscles encountering phrenic nerve. Claude-Bernard-Horner syndrome results from the block of the sympathetic fibers (C-B-H).

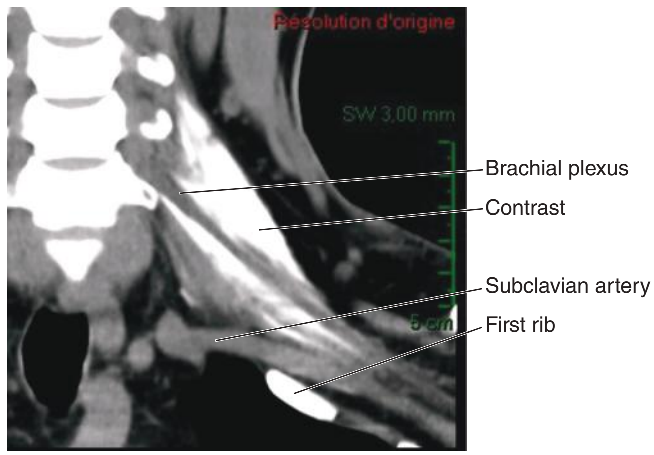

FIGURE 2–7. CT—frontal view of adequate spread of the contrast after injection of 10 mL of the solution in interscalene space for brachial plexus block. The contrast is in the scalene space in contact with all relevant roots of the brachial plexus. The roots are (brachial plexus) seen as negative contrast image. Distal spread toward the supraclavicular and infraclavicular spaces is seen as well, (see spread over the first rib) demonstrating the anatomical continuity of the brachial plexus sheath.

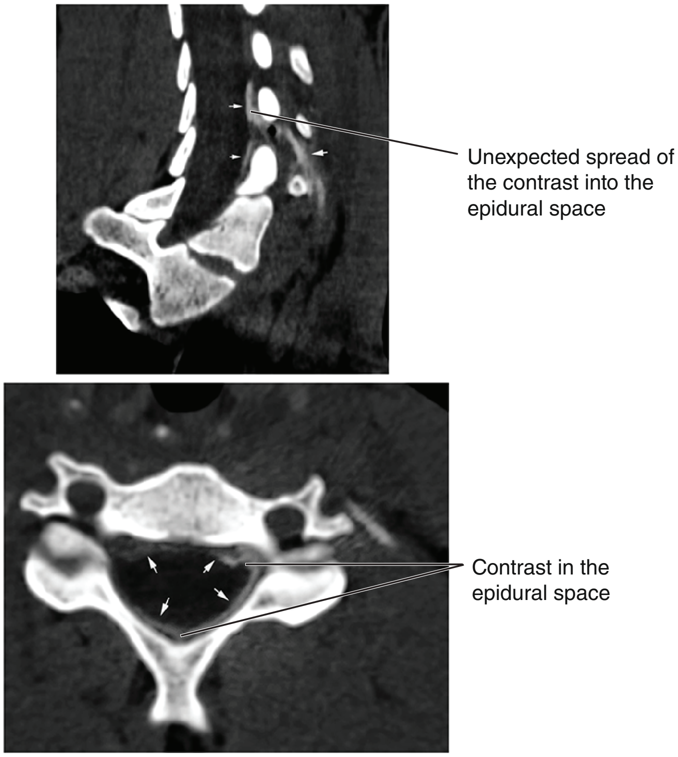

FIGURE 2–8. Epidural spread of the contrast after high-pressure (>25 psi) injection into the scalene brachial plexus. These images may explain the mechanism of the high neuraxial block that occasionally occurs after an interscalene brachial plexus injection.

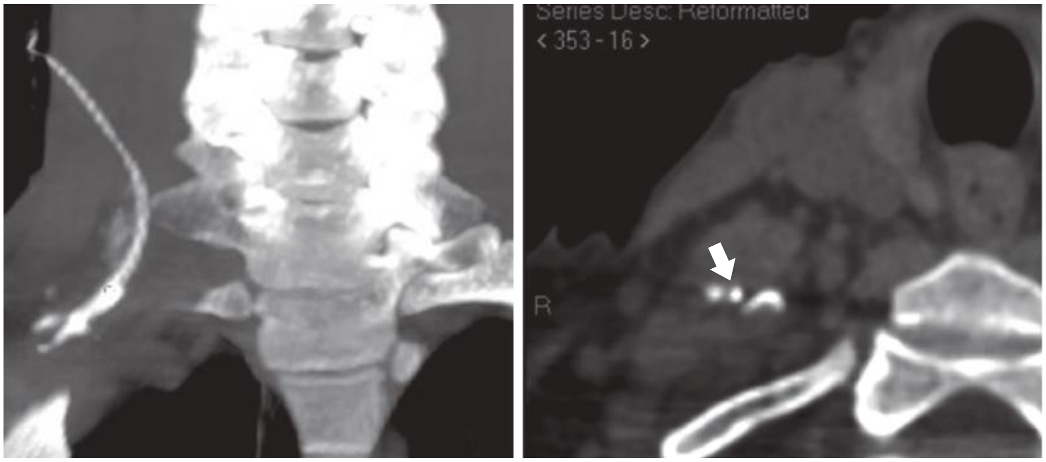

FIGURE 2–9. Course of the interscalene brachial plexus catheter . The catheter is seen curving and properly positioned in the scalene space 2–3 cm (*arrow*). The tip of the catheter is properly located between anterior and middle scalene muscles. Shown is opacification after injection of 0.15 mL of the contrast.

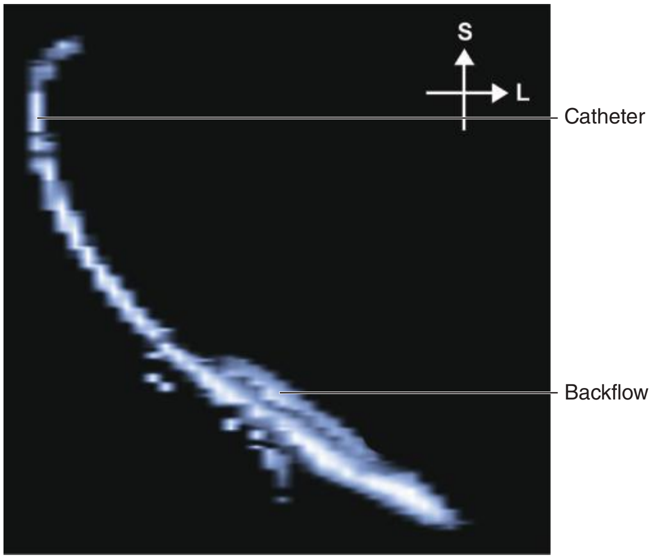

FIGURE 2–10. Course of the catheter inserted in an out of plane approach. After an injection of 0.2 mL of the contrast, the solution is seen inside the catheter, as well as backtracking alongside the catheter insertion track. This helps explain the mechanism of local anesthetic leakage around the catheter insertion site.

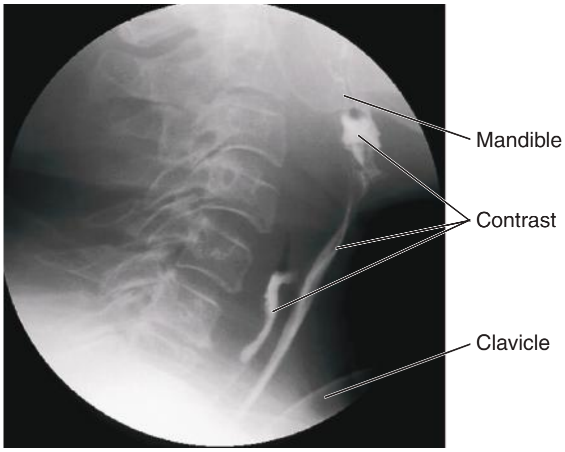

FIGURE 2–13. Catheter misadventure: The wire- reinforced catheter was intended to be placed into the interscalene space. However, the catheter was advanced too far, resulting in a distribution of the contrast in the paraesophageal space.

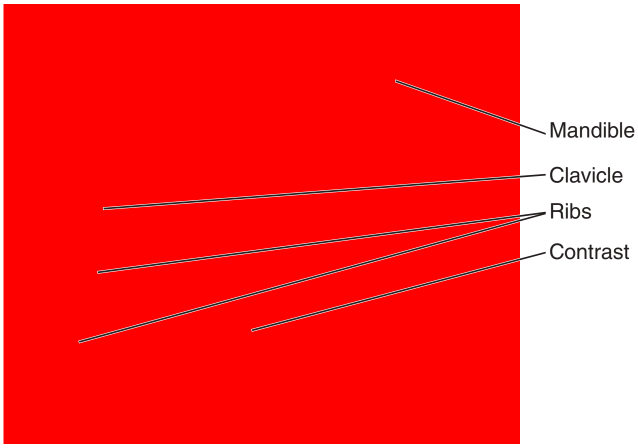

FIGURE 2–11. Maldistribution of the contrast injected through the catheter (20 mL) after the wire-reinforced catheter was advanced too far into the scalene space. The patient developed horse voice. The CT images shows contrast disposition paratracheally.

FIGURE 2–12. Maldistribution of the contrast in the same patient as in Figure 2–11, in oblique-frontal view. The catheter is seen passing through the scalene space into the paratracheal space. The dark areas represent lungs, trachea, and carina.

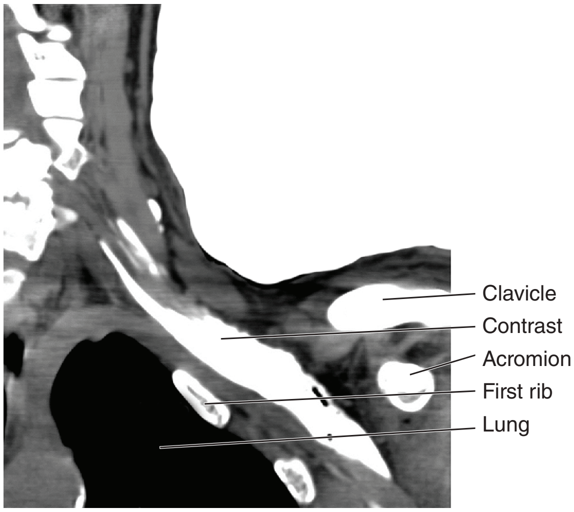

FIGURE 2–14. Too distal spread of the injectate into the infraclavicular and axillary brachial plexus sheath. The catheter was placed into the interscalene space, advancement of the catheter resulted in absence of the spread in the scalene space. These images demonstrate that the position of the tip of the catheter or distribution of the injectate should be checked by ultrasound to assure catheter functionality.

SUPRACLAVICULAR BLOCK

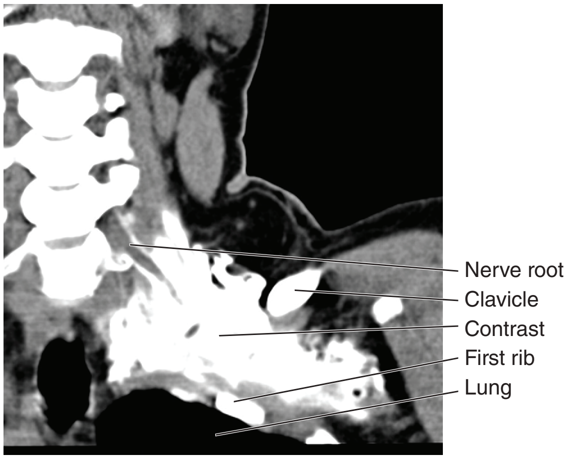

FIGURE 2–15. Twenty milliliters of injectate containing radiopaque contrast was injected into the supraclavicular brachial plexus sheath. The contrast is seen throughout the sheath, along with the negative contrast of one C7 root.

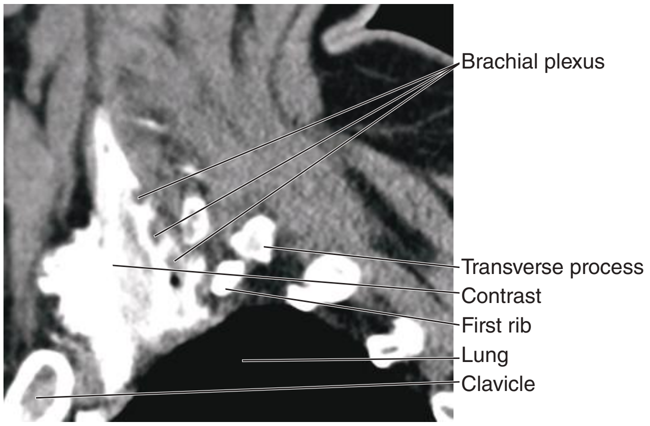

FIGURE 2–16. CT image in a parasagittal view of an injection of 20 mL of the contrast for the supraclavicular brachial plexus resulted in the expected spread within the supraclavicular brachial plexus sheath. In addition, the injection also resulted in a significant spread proximally alongside the brachial plexus sheath, into the lower interscalene space and bathing the C5-C7 nerve roots. This finding demonstrates that (a) brachial plexus sheath is continuous and (b) supraclavicular and low interscalene brachial plexus blocks share common clinical features as the injection of larger volume into either may result in both blocks simultaneously.

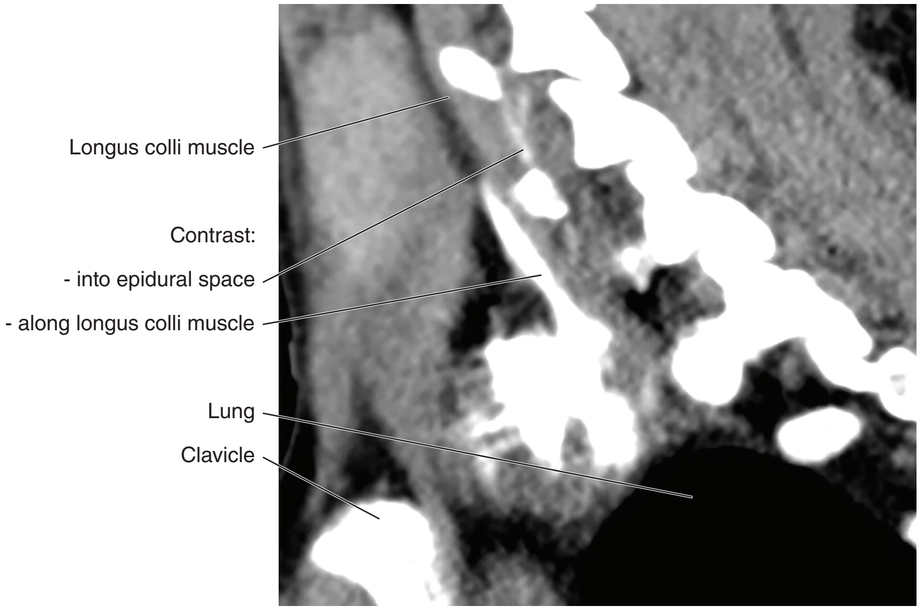

FIGURE 2–17. Supraclavicular block injection with a spread of the local anesthetic (sagittal view) alongside the longus coli muscle and even into the epidural space. This unexpected finding is rather common as large volumes of local anesthetic tend to continue to travel alongside tissue planes. Disposition of the injectate alongside the longus coli muscle contributes to the sympathectomy often obtained with supraclavicular blockade.

INFRACLAVICULAR BLOCK

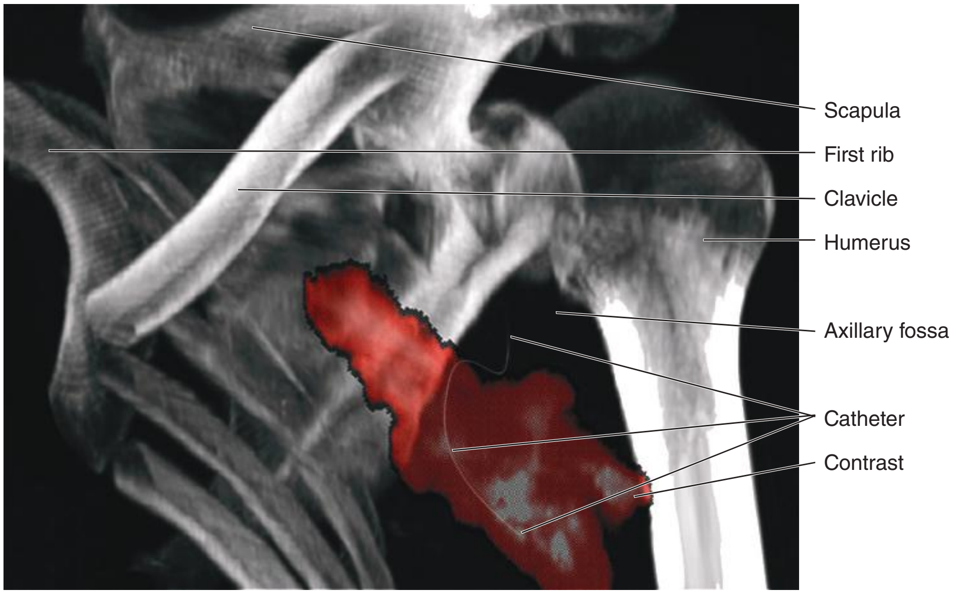

FIGURE 2–18. Spread of 20 mL of contrast around the subclavian artery, underneath the pectoralis minor muscle and within the infraclavicular brachial plexus space.

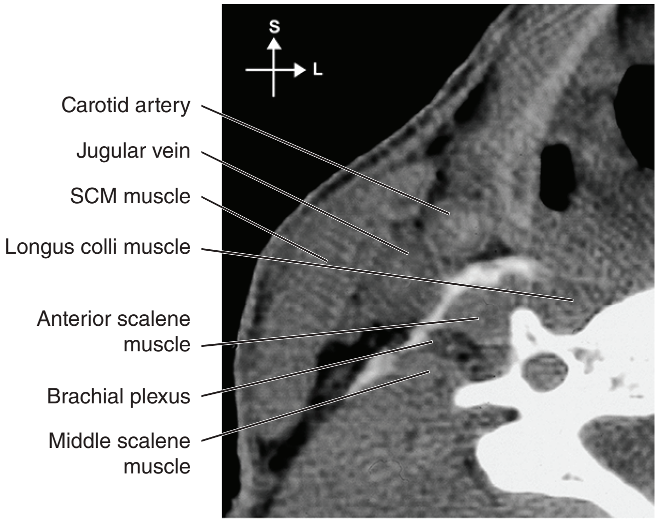

FIGURE 2–19. The spread of 20 mL of contrast around the subclavian artery, underneath the pectoralis minor muscle and within the infraclavicular brachial plexus space.

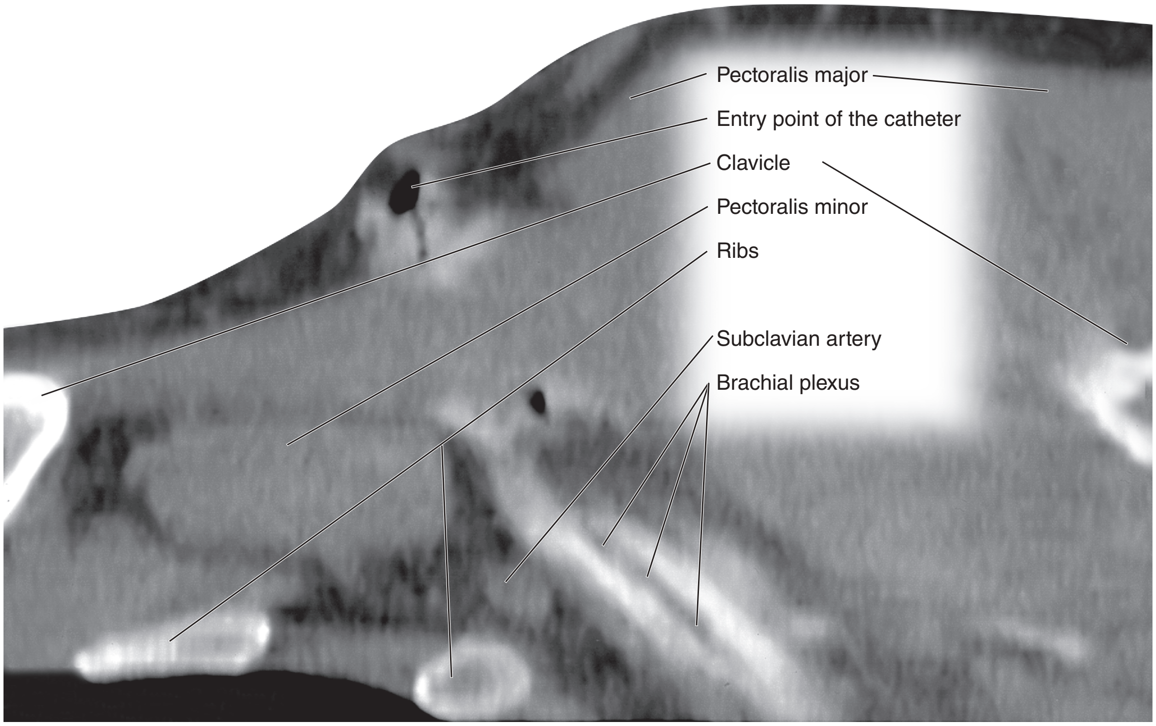

FIGURE 2–20. Anatomic distribution of 20 mL of contrast through the catheter placed in the infraclavicular space. Catheter insertion site is also seen in the image.

AXILLARY BLOCK MIDHUMERAL APPROACH

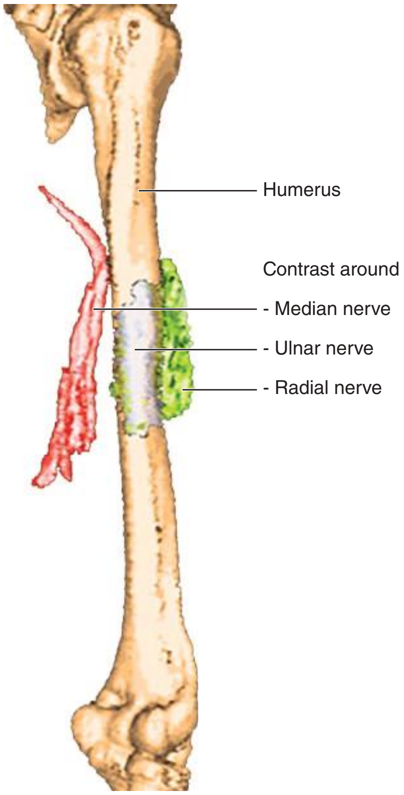

FIGURE 2–21. Distribution of the contrast alongside the medial, ulnar and radial nerves is demonstrated in this 3D CT image.

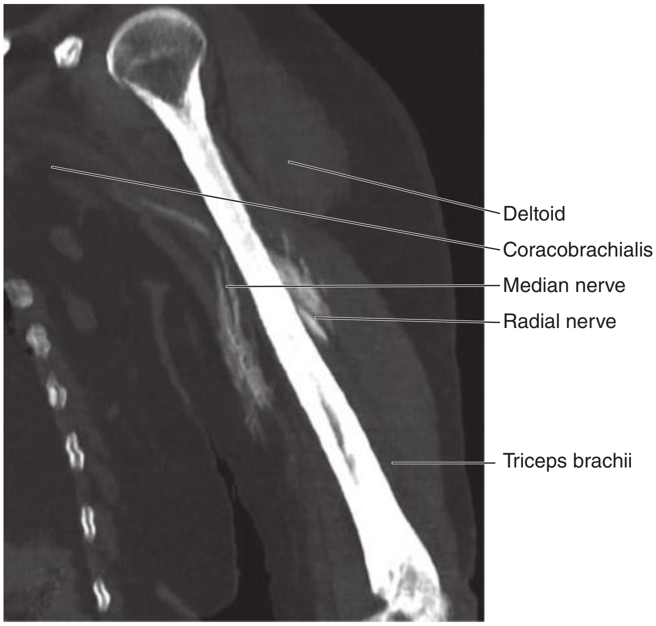

FIGURE 2–22. Negative radiocontrast image in the same patient demonstrating the distribution of 5 mL of radiocontrast after injections for radial and median nerves. Negative cotrast imprint is seen highlighting both nerves.

ELBOW BLOCK

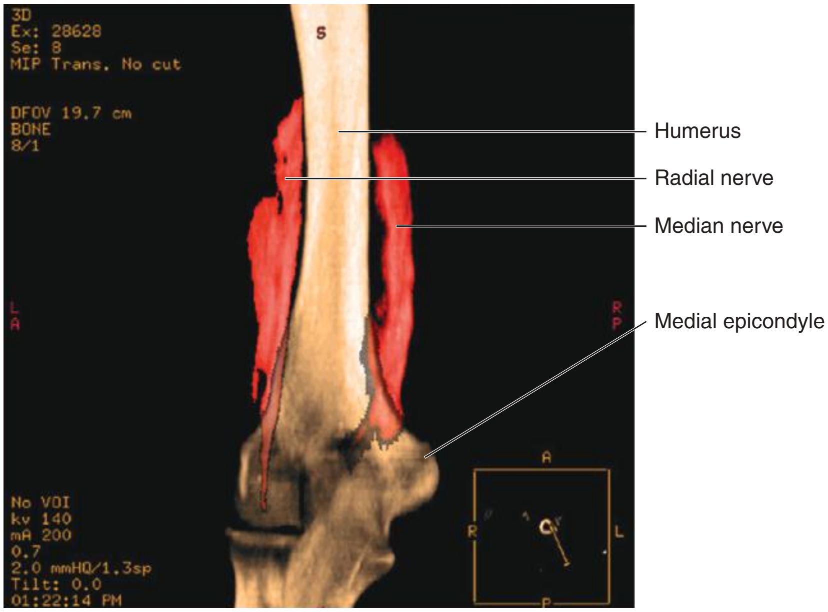

FIGURE 2–23. 3D CT image demonstrating spread of the injectate after radial and median nerve blocks (10 mL each) at the level of the elbow.

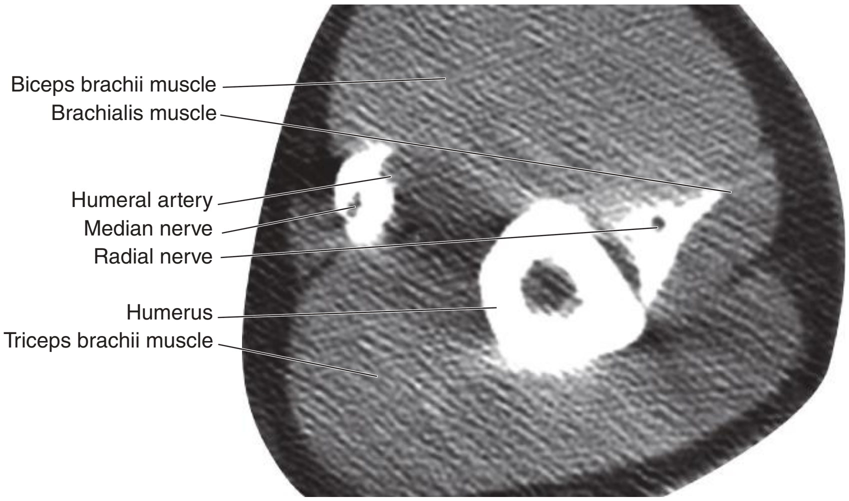

FIGURE 2–24. Axial view of the same patient as in Figure 2–23. The image demonstrates spread of the injectate after radial and median nerve blocks (10 mL each) at the level of the elbow.

PARAVERTEBRAL BLOCK

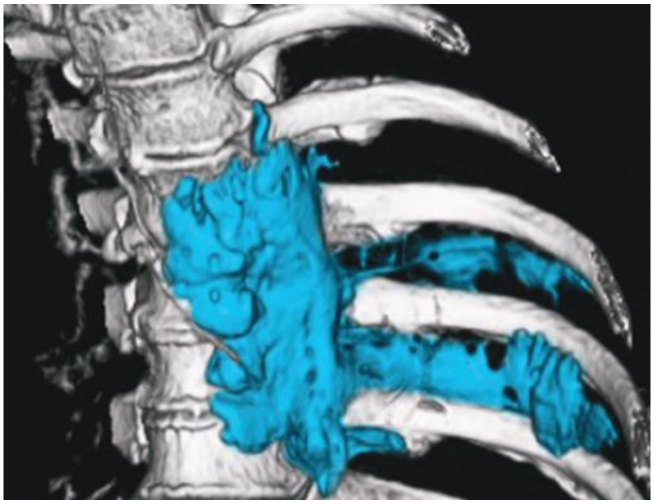

FIGURE 2–25. 3D CT image of 10 mL of the contrast demonstrating four levels of the blockade of the sympathetic chain and spread of the injectate out of the paravertebral space into two intercostal spaces.

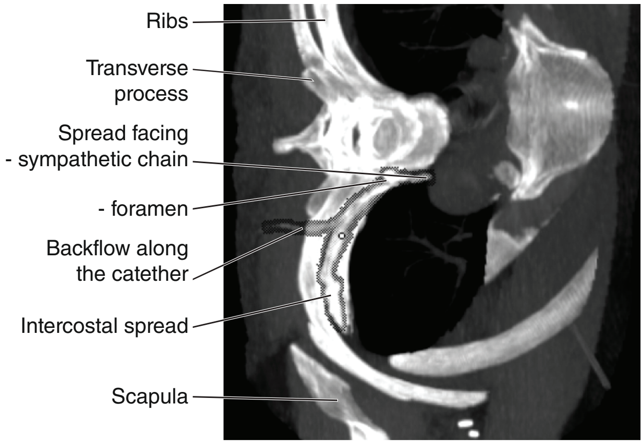

FIGURE 2–27. An axial CT images demonstrating the catheter tip position and the distribution of the injectate toward the sympathetic chain and paravertebral and intercostal spaces, explaining the mechanism of action of the paravertebral block. The backflow alongside the catheter insertion path is also seen.

FIGURE 2–26. Catheter placed in the paravertebral space. The entry point is at 4 cm from the midline, the Tuohy needle is advanced toward the articular process, walked off the process, and advanced an additional 1 cm. The catheter is then inserted 3–4 cm. In this case, the catheter tip is seen in the vicinity of the anterior aspect of the foramen.

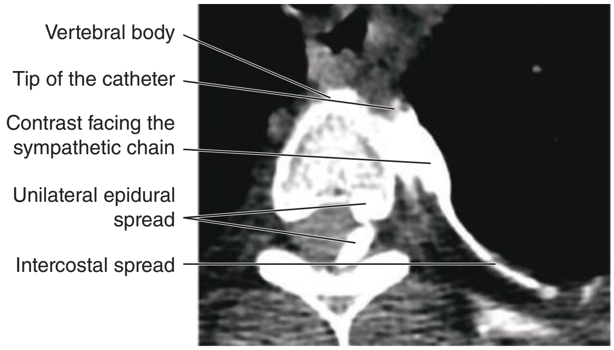

FIGURE 2–28. An axial image demonstrating the disposition of the injectate at the thoracic (T4) paravertebral space. Of note, spread to the epidural space, as seen in this image, is a common occurrence.

FIGURE 2–29. Malposition of the thoracic paravertebral catheter. The catheter is shown in the mediastinum. This image suggests the importance of avoiding insertion of the catheter too deeply too deeply (>4 cm).

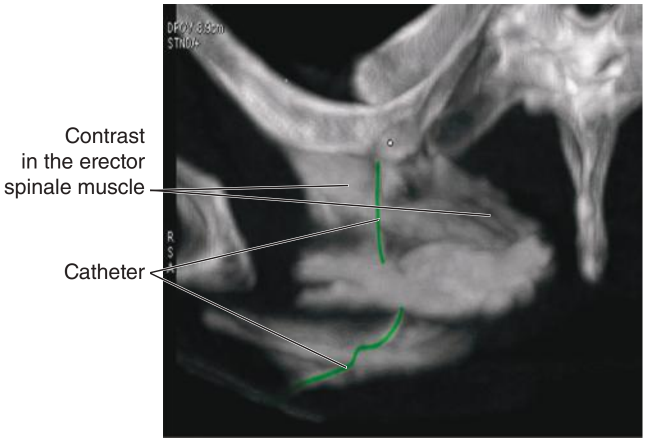

FIGURE 2–30. Malposition of the thoracic paravertebral catheter. In this case, the catheter was advanced only 2 cm beyond the tip of the needle, resulting in catheter migration out of the paravertebral space into the erector spinae muscle. Paravertebral skin and muscles are highly mobile, and sufficient depth of the catheter placement is necessary to prevent dislodgement outside of the paravertebral space.

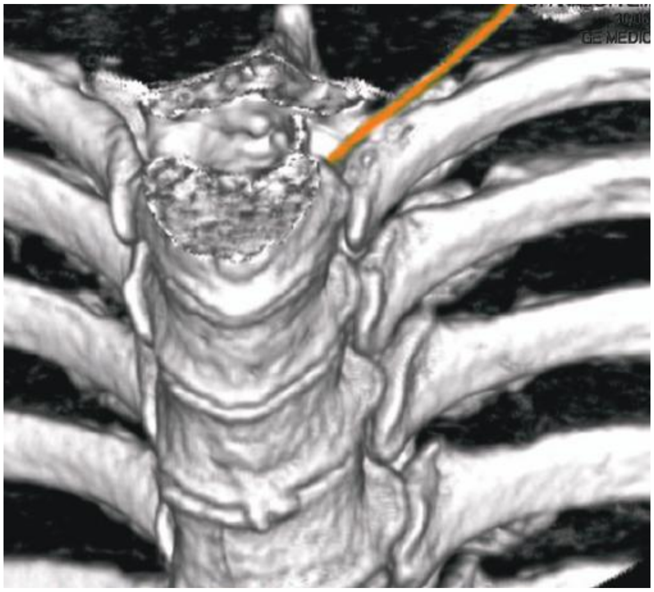

FIGURE 2–32. Reconstruction of the needle path in the Shibata-Renes approach. This 3D CT reconstruction illustrates the importance of avoiding needle advancement beyond the transverse process as this path may lead to the needle entry toward central neuraxis.

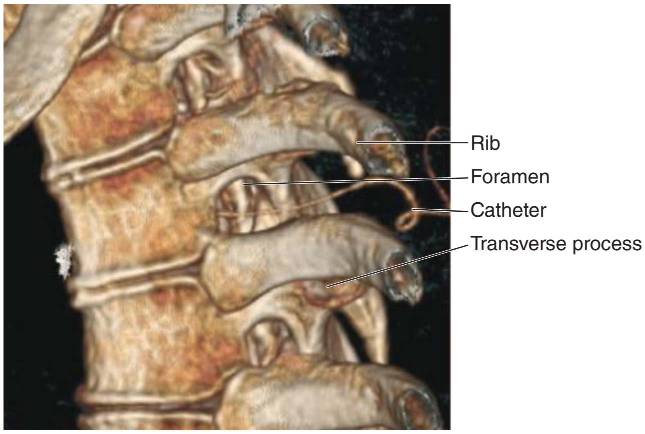

FIGURE 2–31. Malposition of the thoracic paravertebral catheter in the epidural space through the intervertebral foramen.

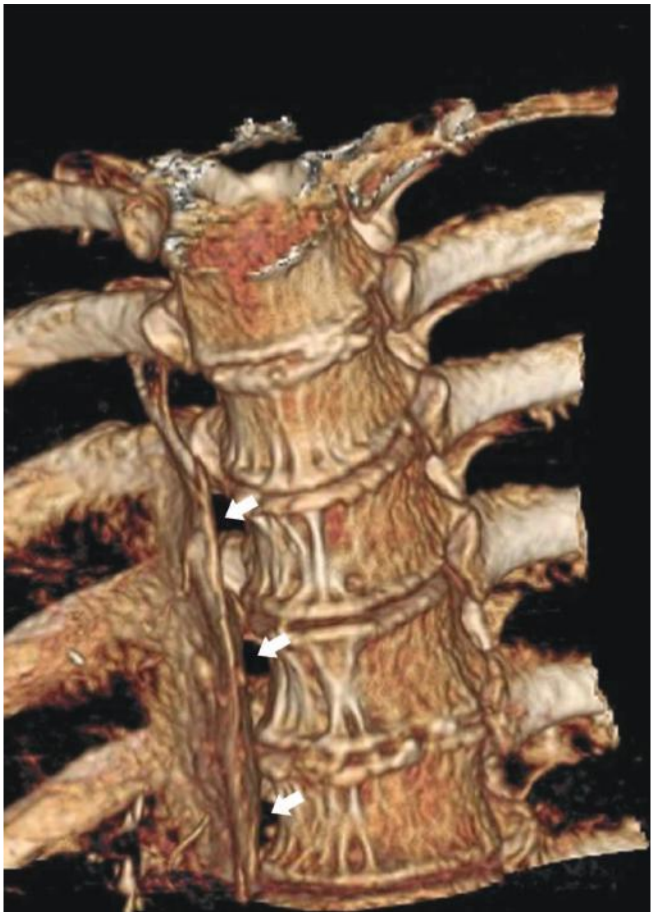

FIGURE 2–33. Malposition of the thoracic paravertebral catheter. The image demonstrate an intrapleural catheter placement (*arrows*), probably caused by too lateral needle insertion.

LUMBAR PLEXUS BLOCK

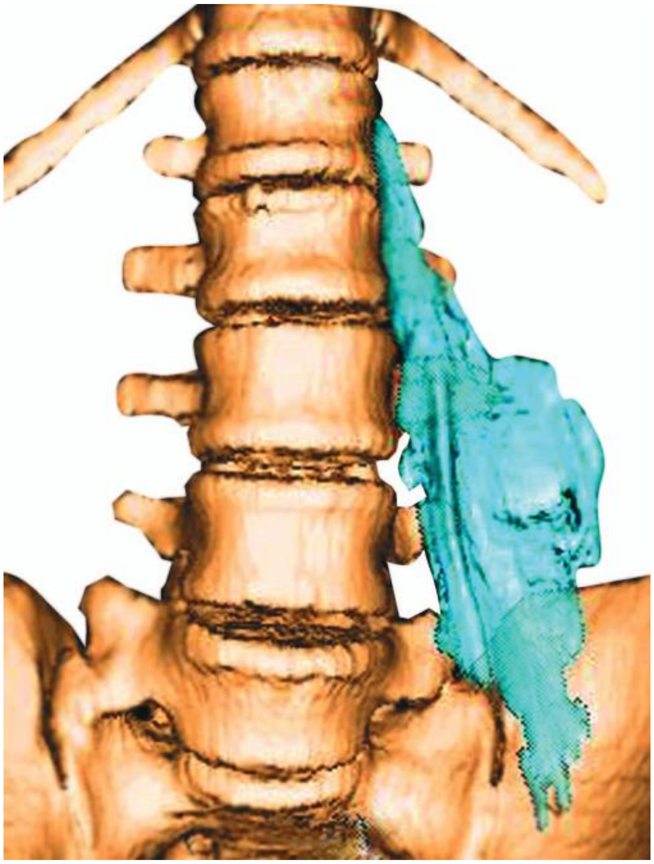

FIGURE 2–34. A typical fusiform injectate distribution from L1 to sacroiliac joint within lumbar plexus sheath.

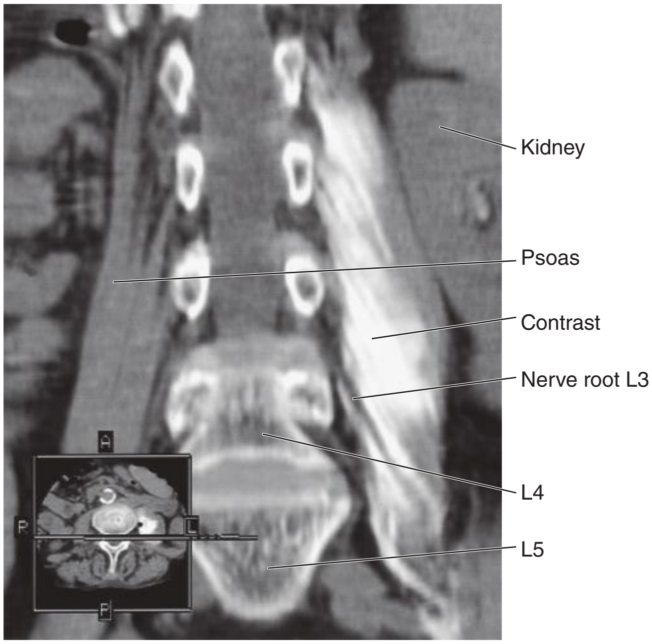

FIGURE 2–35. A desirable disposition of the injectate within the psoas sheath. Negative imprint of the L3 root is seen as well as a substantial spread of the injectate in the fusiform fashion, necessary for successful blockade of the lumbar plexus.

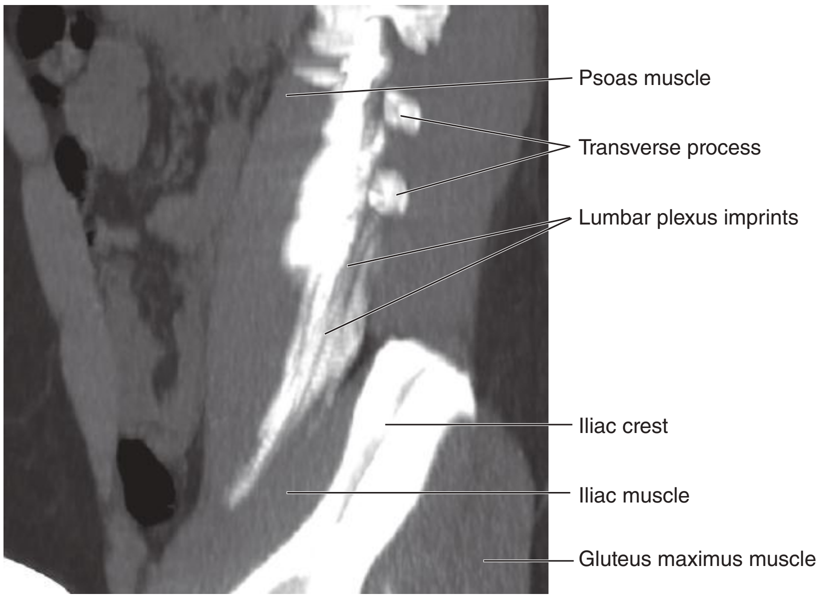

FIGURE 2–36. Proper disposition of the injectate within the psoas sheath,—sagittal view. Negative imprint of the lumbar roots is seen, as well as spread of the injectate in the fusiform fashion within the posterior aspects of the psoas sheath.

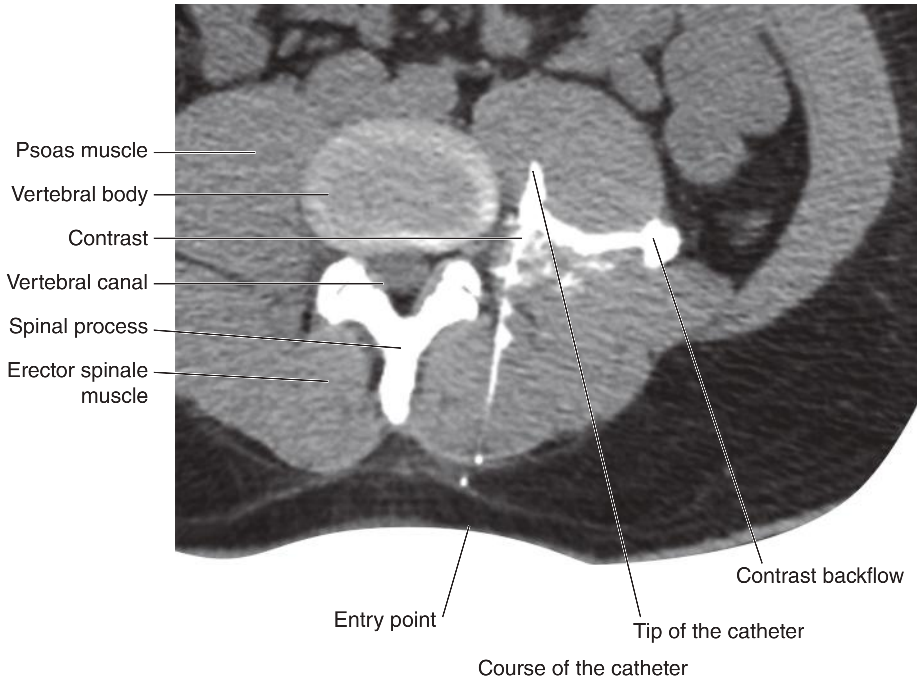

FIGURE 2–37. A proper position of the catheter for lumbar plexus block. The needle was inserted to the level of the nerve. The consequent insertion of the catheter brought the catheter tip in the posteromedial aspect of the psoas muscle. The spread of the contrast is seen in the vicinity of the neural foramen and outlining the outer surface of the psoas muscle underneath its posterolateral fascia.

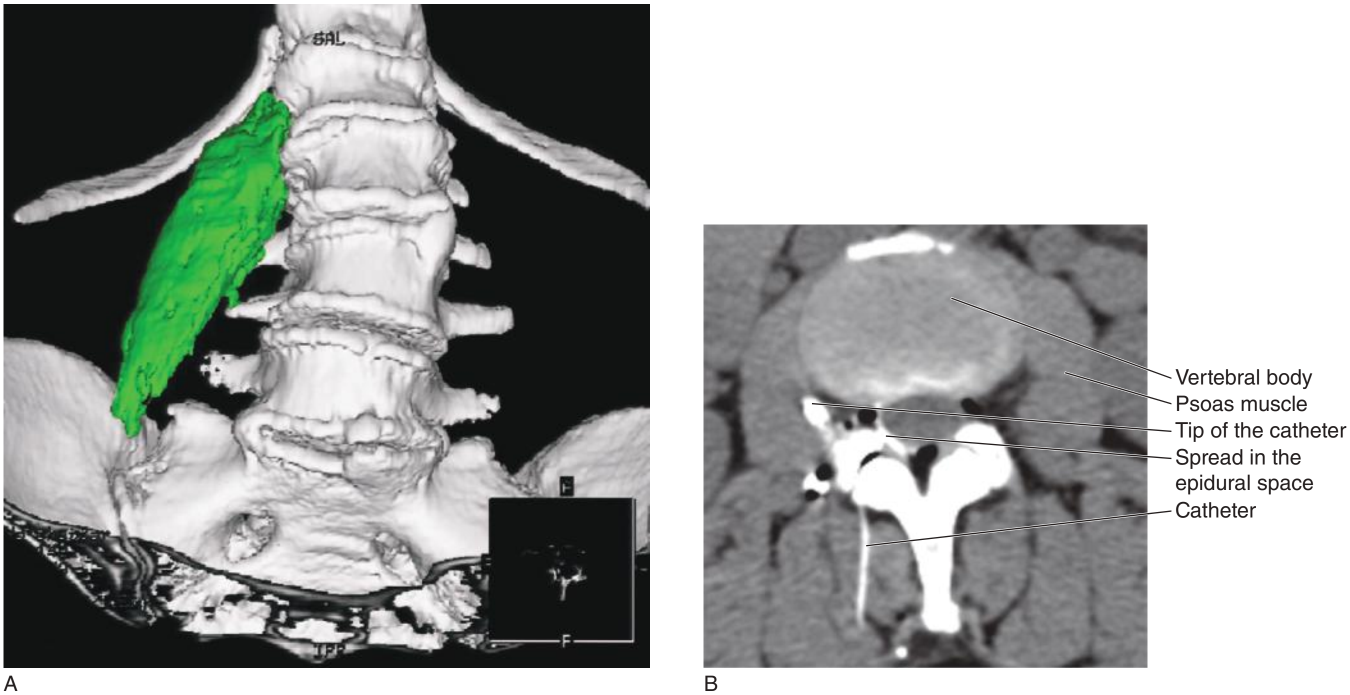

FIGURE 2–38A AND B. Maldistribution of the lumbar plexus block injection. The injectate is seen in the anterolateral aspect of the muscle underneath fascia, leading to block failure.

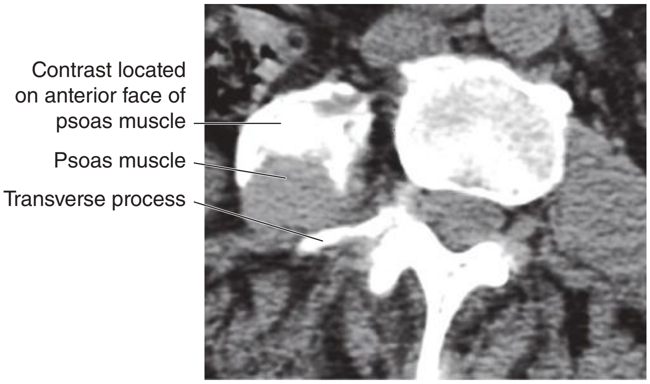

FIGURE 2–39. Same patient as in Figure 2–39 but with an axial image demonstrating maldistribution of the injectate in the anterolateral aspect of the muscle underneath fascia, resulting in block failure.

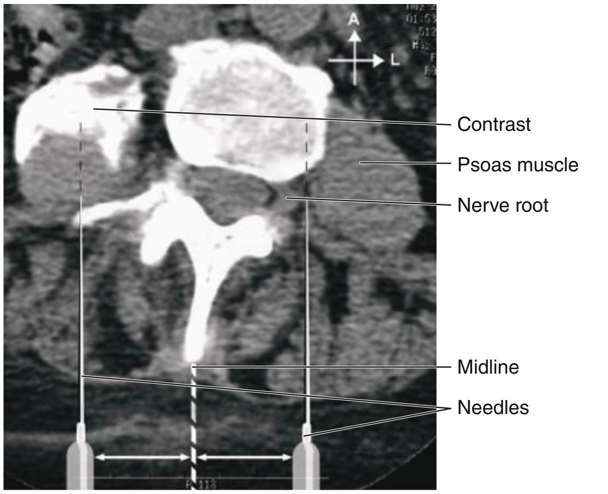

FIGURE 2–41. Simulation of the lumbar plexus block in a patient with scoliosis. Shown is estimated needle reach using customary landmark in a patient with scoliosis. Left: the contrast is seen in the anterolateral aspect of the muscle (failure), whereas on the right the needle is nearly entering the foramen. Since patients with a relatively minor scoliosis are common in daily practice, this possibility should be kept in mind when practicing lumbar plexus block.

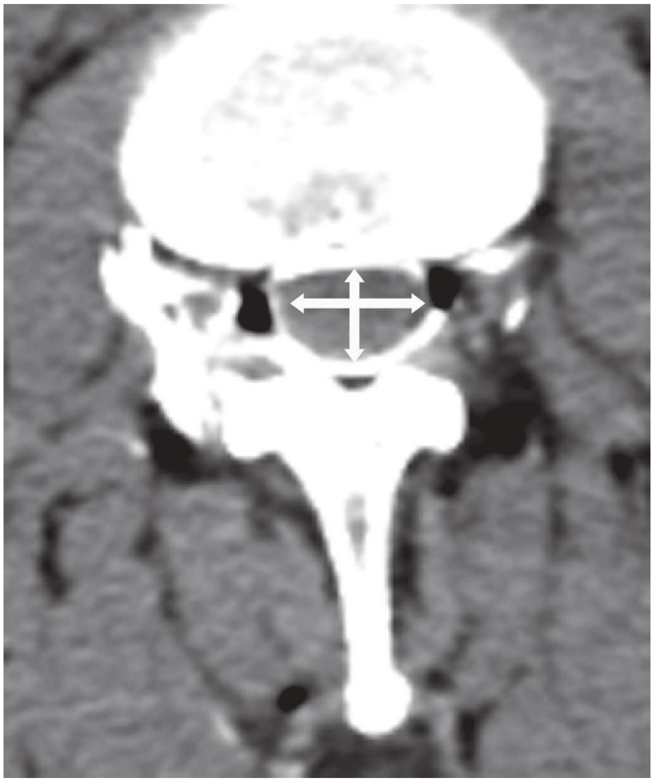

FIGURE 2–40. In this example, the spread of the local anesthetic injection through the catheter is seen in the epidural space. This observation is probably common and, in fact, may be contributory to the mechanism of action of lumbar plexus. High epidural spread may occur with high injection pressure injections.

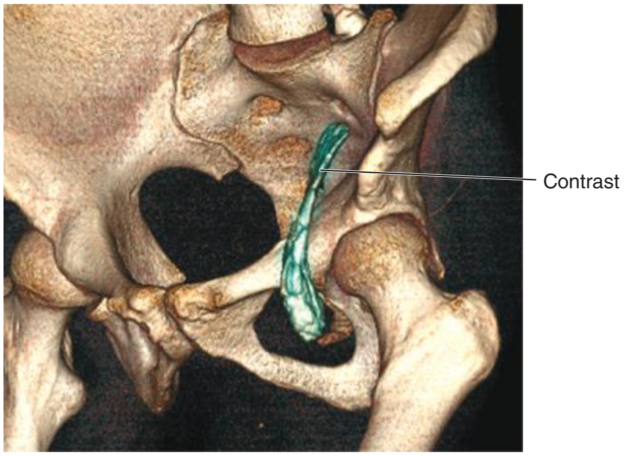

FIGURE 2–42. Spread of the injectate after femoral nerve block. The contrast is seen tracking proximally along the femoral nerve.

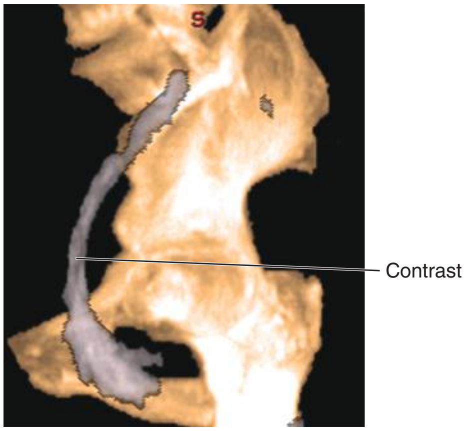

FIGURE 2–43. Femoral nerve block. The contrast (10 mL) is seen underneath iliacus fascia following femoral nerve nearly to L5 vertebra.

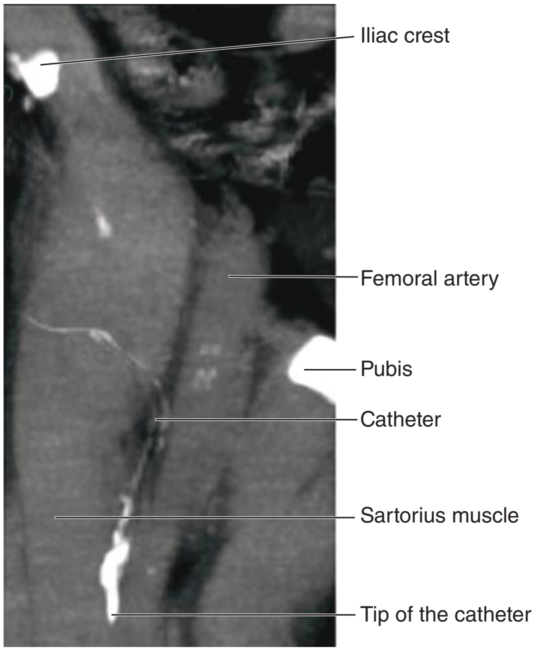

FIGURE 2–44. Femoral nerve catheter. The catheter is seen coursing alongside the femoral nerve. The iliopectineal ligament prevents the course of the catheter too medially; therefore, insertion of the femoral catheter 3–5 cm to prevent catheter withdrawal is desirable in this location.

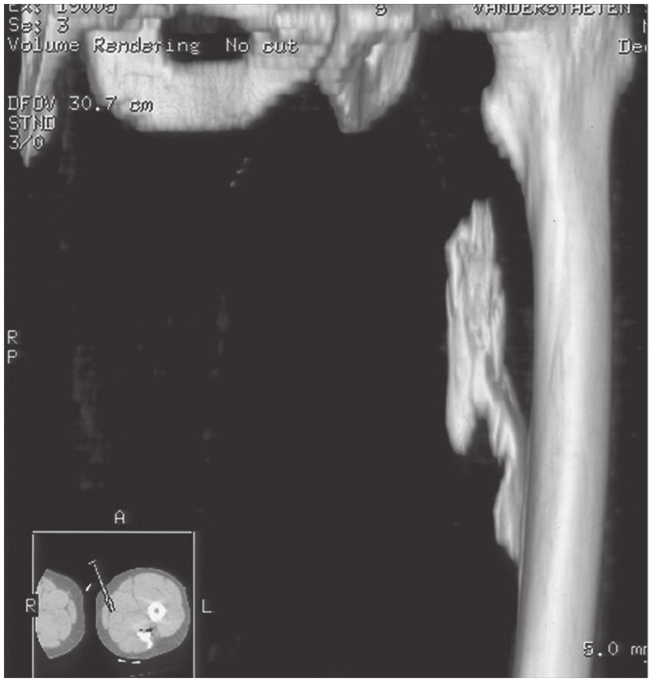

FIGURE 2–46. Subgluteal block —the contrast is seen in the frontal view with a typical distribution in the intermuscular canal, forming the sciatic nerve sheath. Twenty milliliters of the contrast-containing local anesthetic was injected

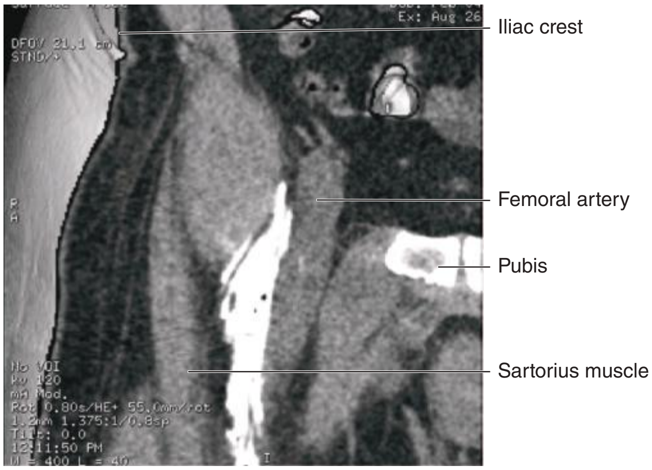

FIGURE 2–45. The same patient and catheter as in Figure 2–45, in frontal view. The distribution of the contrast (20 mL) is in the space between sartorius muscle and femoral artery.

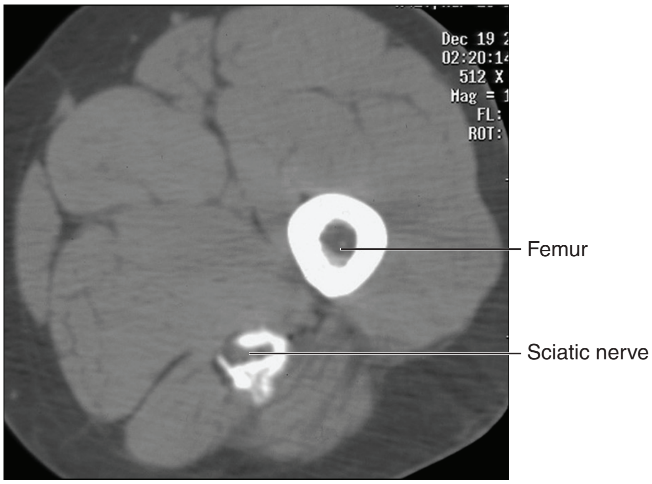

FIGURE 2–47. The same patient as in Figure 2–11 in a cross-sectional view. The contrast is seen surrounding the sciatic nerve in its intermuscular sheath.

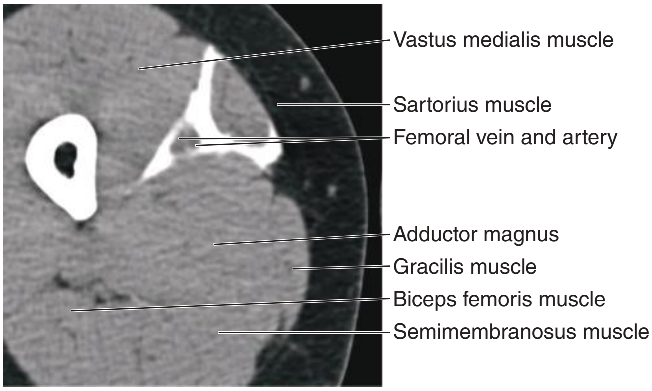

FIGURE 2–48. Adductor canal block. An injection of 20 mL of contrast injected the lower hiatus spreads extensively in the canal underneath the sartorius muscle and around the femoral artery in the canal.

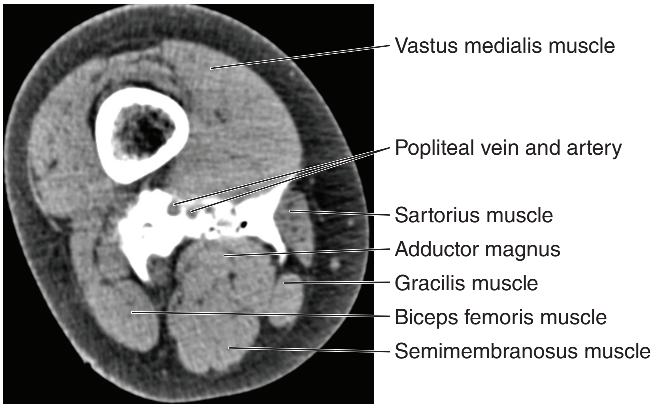

FIGURE 2–49. Adductor canal block. After injection of 20 mL of the contrast, the spread of the injectate is seen also reaching the popliteal fossa. This extensive spread alongside the tissue sheaths and into the fossa may help explain additional analgesic benefits of the adductor canal block, beyond the block of the saphenous nerve as the contrast reached the sciatic nerve.

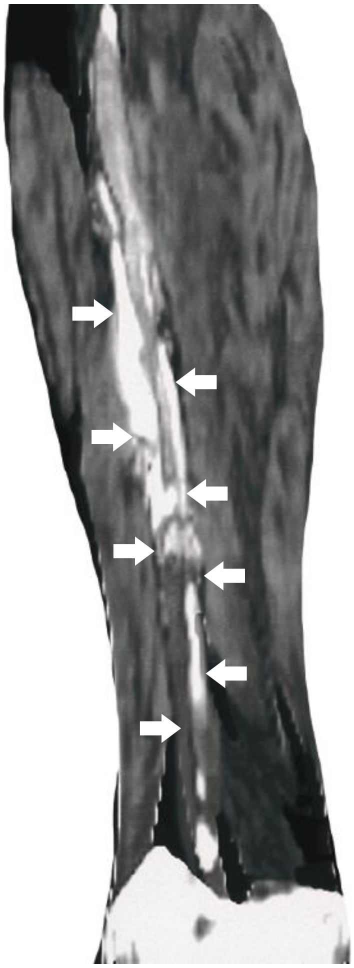

FIGURE 2–50. Popliteal block. Extensive spread of 20 mL of contrast injected into the sheath of the sciatic nerve resulted in a spiral spread around the sciatic nerve.

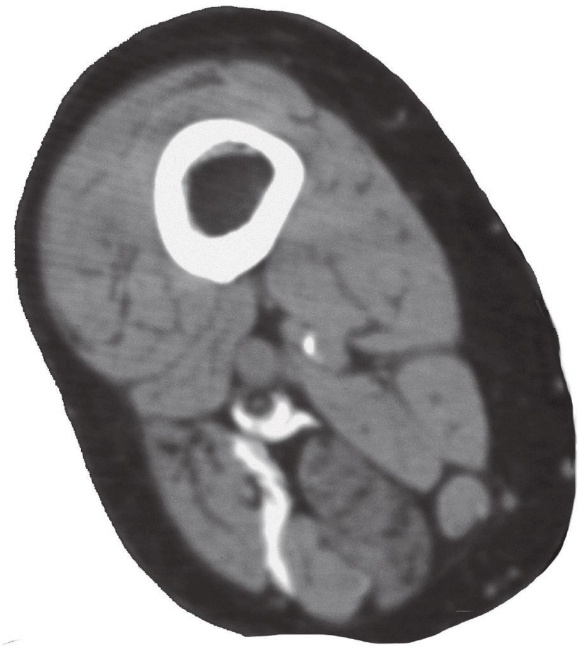

FIGURE 2–51. The same patient as in Figure 2–47 in axial view. Shown is the catheter path alongside with a backflow of the contrast. The circumferential spread of the contrast is seen within the sciatic nerve sheath.

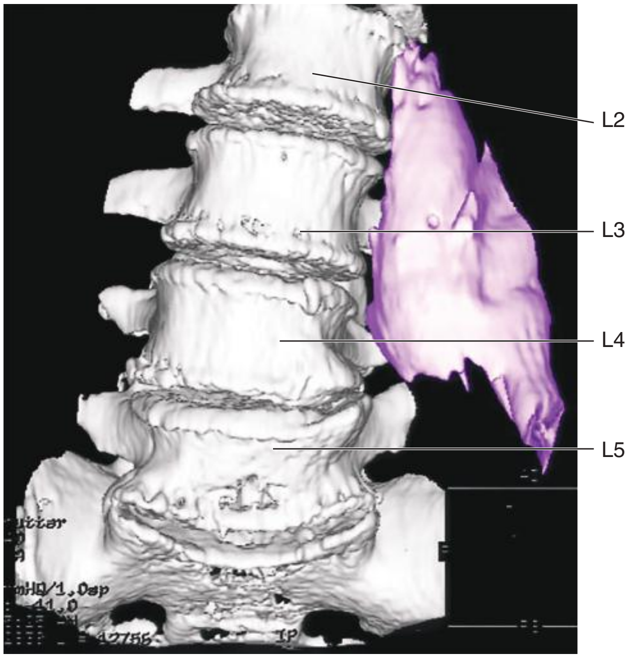

FIGURE 2–52. Tibial nerve: Injection of 10 mL of the contrast for tibial nerve block. The contrast is seen within the sheath of the tibial nerve, formed by the intermuscular canal.

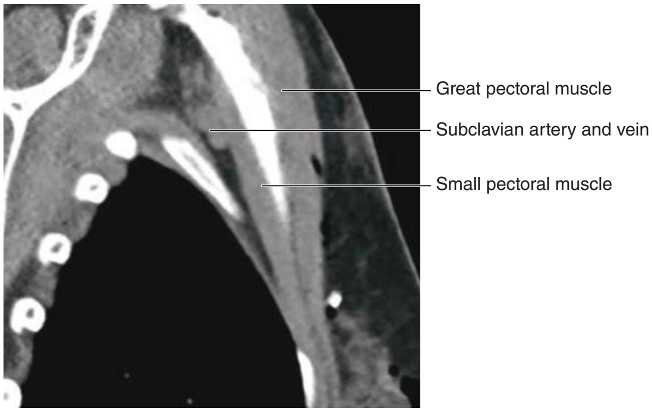

FIGURE 2–54. The same patient as in Figure 2–54, in a sagittal view. The contrast is seen spreading between pectoralis major and minor muscles.

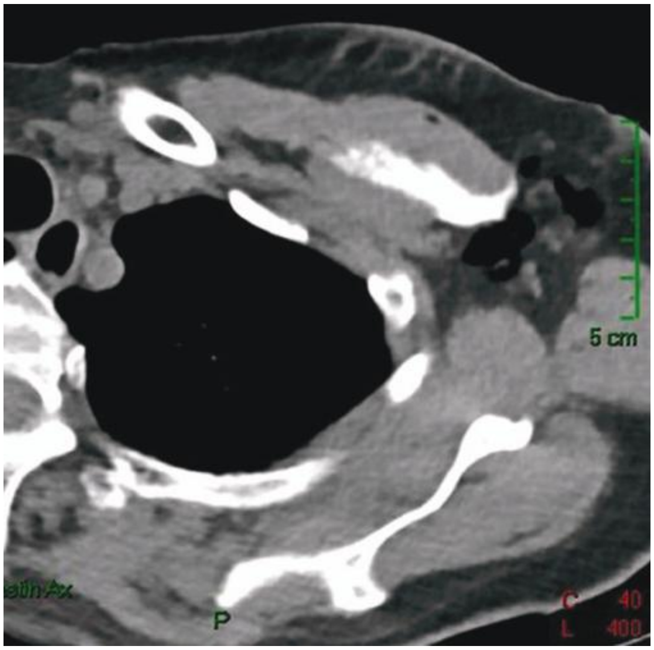

FIGURE 2–53. Pectoralis block (PEC I)—10 mL of the contrast was injected between pectoralis major and pectoralis minor muscles. Of note, the contrast did not spread toward the axillary fossa, possibly because of the barrier formed by the ligament of Gerdy (suspensory ligament of the axilla).

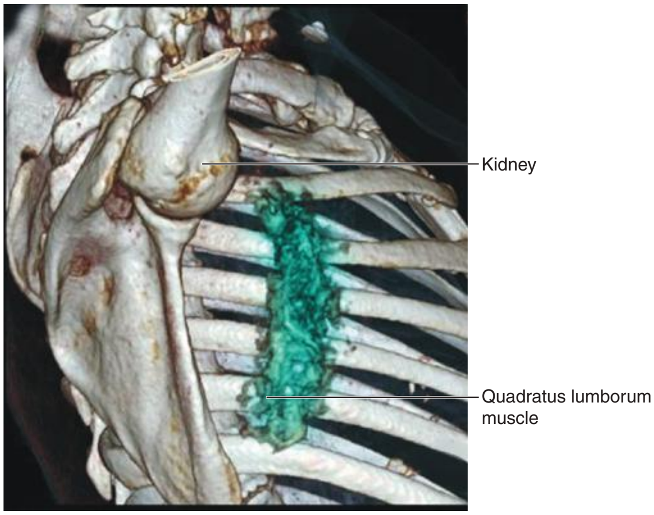

FIGURE 2–55. 3D image of pectoralis muscle block (PEC II). Injection occurred below the pectoralis minor muscle at the level of the 3rd rib in the anterior axillary line. Thirty milliliters of the contrast-containing local anesthetic was injected and resulted in the spread between third to seventh ribs.

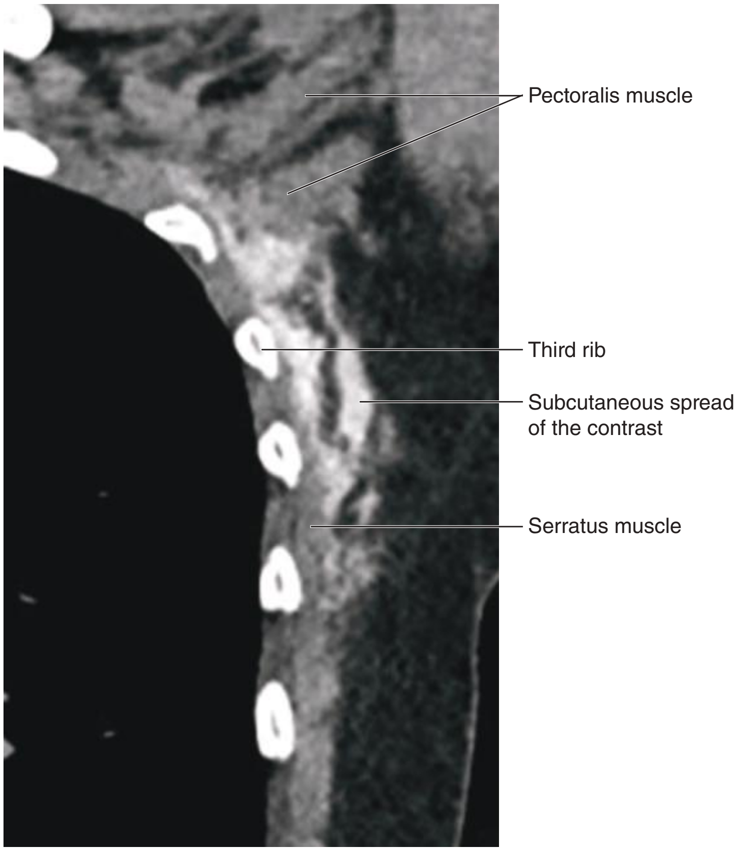
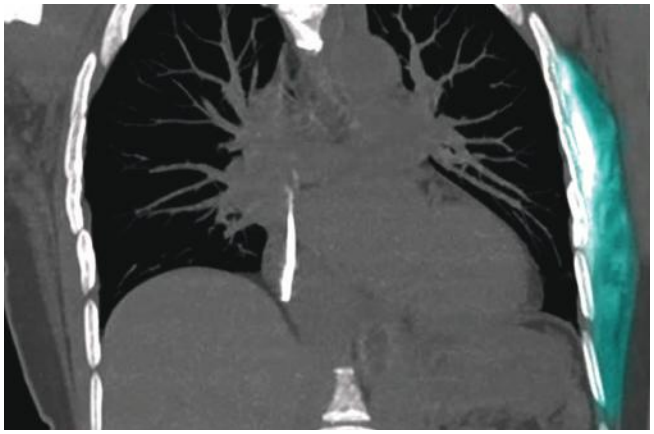


FIGGURE 2–56. The same patient as in Figure 2–56 but in a frontal view. Insertion of the pectoralis minor is seen as well as the spread of the contrast subcutaneously, superficial to the serratus muscles.



FIGGURE 2–57. Serratus block. Thirty milliliters of the contrast-containing local anesthetic was injected at the level of the forth and fifth ribs, between the ribs and the serratus muscle. The contrast is seen spreading distally to the seventh rib in the plane between the ribs and serratus muscle.

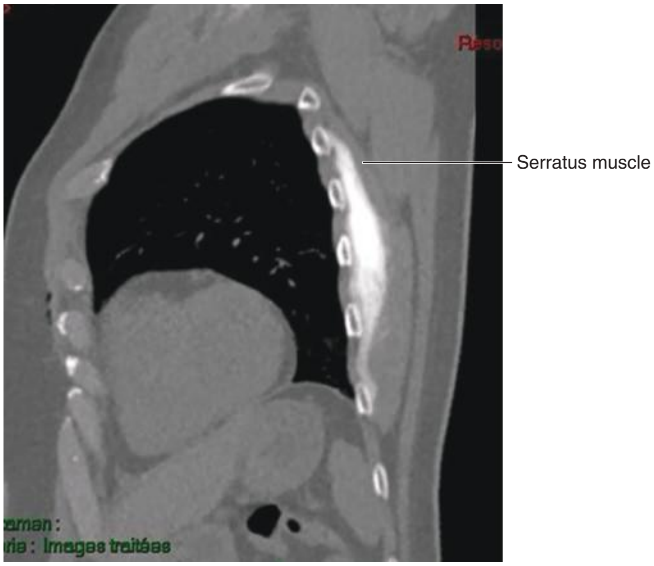


FIGURE 2–58. Serratus block, same patient as in Figure 2–58, but a sagittal view. The spread of 30 mL of contrast is shown deep to the serratus muscles and in the plane between the serratus muscles and the ribs.

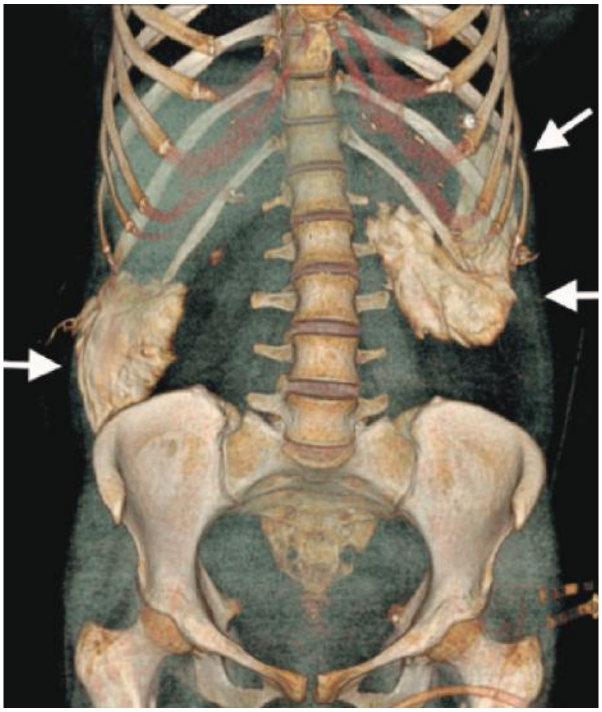

FIGURE 2–59. Quadratus lumborum space (QL1) injection.

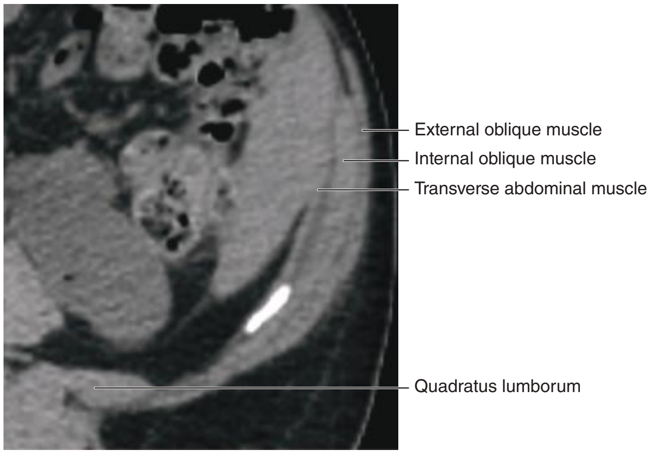

FIGURE 2–61. Transversus abdominis plane (TAP) block, axial view. An injection of 1 mL of radiocontrast is seen spreading in the plane between transversus abdominis and internal oblique muscles.

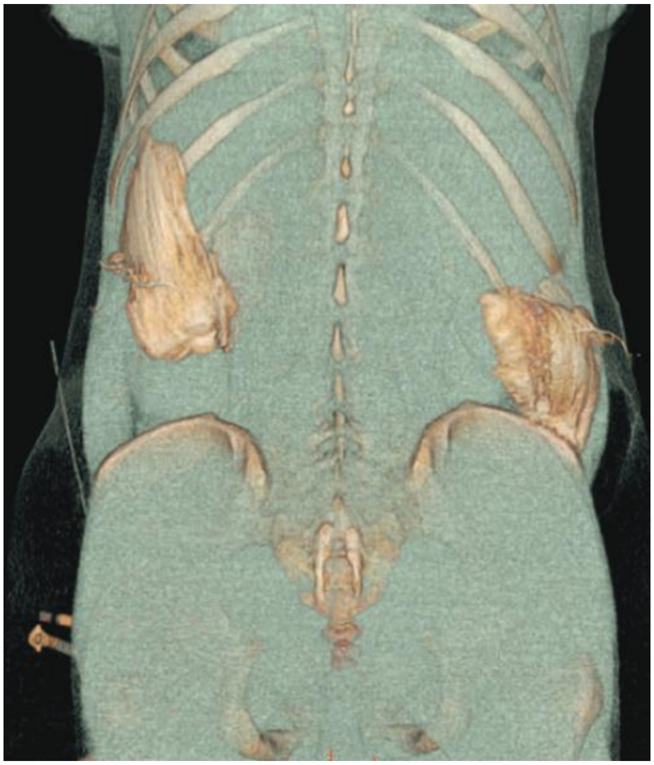

FIGURE 2–60. Transversus abdominis plane (TAP) block. The spread of the 20 mL of radiocontrast is injected bilaterally. The spread of the contrast on the patient's right side is after injection in the traditional TAP plane. The contrast spread on the patient's left side is after quadratus lumborum injection.

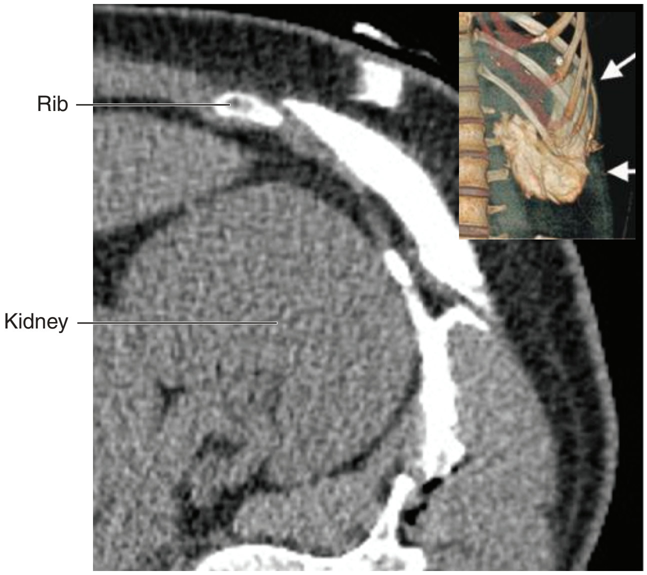

FIGURE 2–62. Quadratus lumborum block QL1. The contrast solution was injected at the lateral edge of the QL muscle at the L2 level, spreading to the posterior aspect of the QL muscle and medially toward the transverse process (see the 3D CT insert in the right upper corner). The dye solution spreads medially from the quadratus-lumborum space, cranially into the the thoraco-lumbar fascia up to the the 12th and 11th ribs.

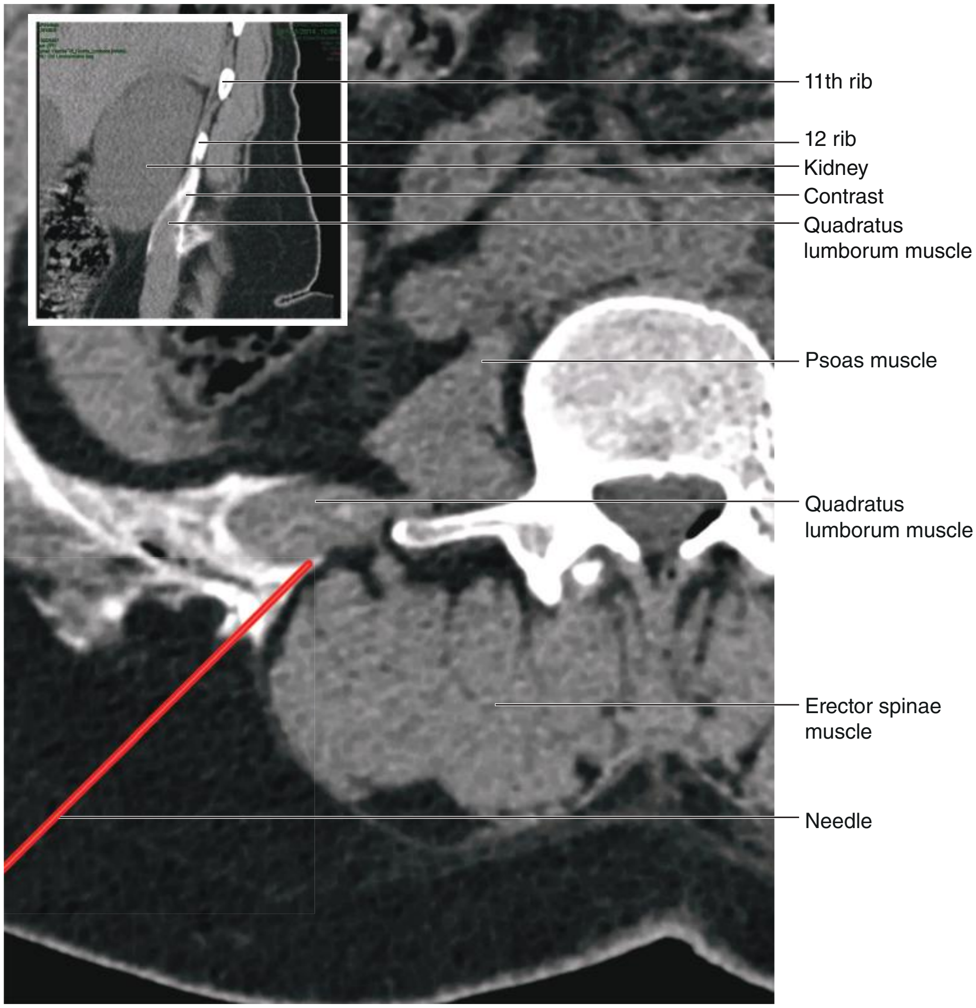

FIGURE 2–63. Quadratus Lumborum block QL2. Axial view of the distribution of 20 mL contrast after QL2 block. The injection was performed at the posterior aspect of the QL muscle. The contrast is seen on the anterolateral aspect of the quadratus muscle and laterally into the transversus abdominis plane. The insert (3D CT) in the left upper corner of the image shows the proximal extent of the injectate around QL muscle in the same patient.

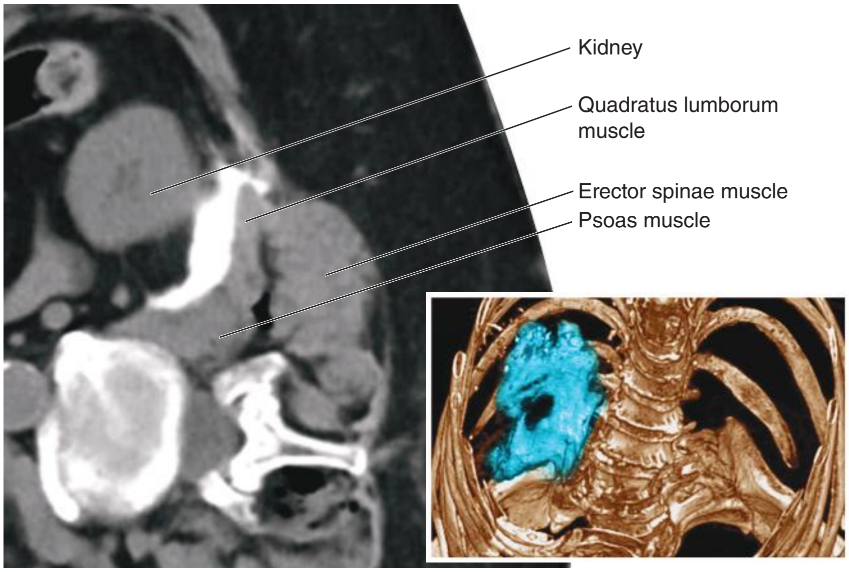

FIGURE 2–64. Quadratus lumborum block QL3. Twenty milliliters of contrast was injected between QL and psoas major muscles ("Shamrock" techniques). The injectate is seen between the QL and psoas major muscles and alongside the anterior aspect of the QL muscle without spread toward the paravertebral space is seen. The insert in the right lower corner of the image shows the proximal extent of the injectate in the same patient on a 3D CT.
